By selecting a significance level of 95%, the threshold was determined based on the chi-squared distribution, represented by the dashed line. Observations with a Mahalanobis distance exceeding this value were identified as outliers and subsequently removed. After that, it was performed standardization to ensure that all features have a consistent scale. In the final stage of the preprocessing data workflow, PCA was applied to reduce complexity while preserving as much variability as possible. Figure 2 shows the percentage of the dataset variance that is cumulatively explained by each PC.

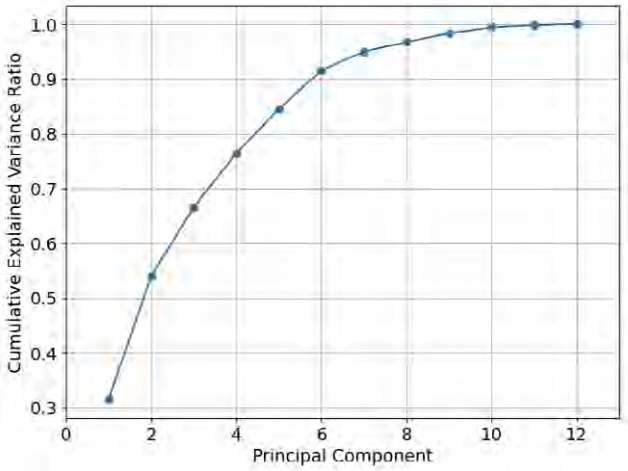

**Figure 2:** Cumulative variance ratio explained by the number of principal components.

From Figure 2, it was observed that the first PC explains around 30 % of the dataset variance. To explain 90 % of this variance, at least 6 PC are required, making 6 the chosen number of PC in this work.

Furthermore, the mRMR algorithm was applied to select the features relevant to the model: cells concentration, culture volume, irradiance, time duration for new addition of nutrients, and carotenoids concentration.

## Model development and evaluation

After preprocessing the data, the KS algorithm was applied to split the observations into training (80 %) and test (20 %) sets. Then, five-fold CV was applied in combination with GridSearch to find the optimal values of hyperparameter for each ML model. In this work, four ML algorithms were employed to predict the target variable: ridge regressor (RR), random forest (RF), artificial neural network (ANN) and support vector regressor (SVR).

Although RR and RF are easier to interpret, they are better suited for linear or moderately complex relationships and struggle with highly nonlinear patterns. On the other hand, ANN and SVR excel at capturing nonlinear relationships, however they are more challenging to interpret and require careful tuning and computational resources, particularly for large datasets [1,10].

Table 1 shows the hyperparameter values optimized in each one of the ML models in this work.

**Table 1:** Optimal hyperparameter values obtained for each ML model.

| Model | Hyperparameter | Optimal value |
|---|---|---|
| RR | Alpha | 25 |
| | Maximum number of iterations | 1000 |
| RF | Number of estimators | 100 |
| | Maximum depth | 5 |
| ANN | Number of hidden neurons | 1st layer: 4<br>2nd layer: 2 |
| | Activation function for the hidden layer | Hyperbolic tangent |
| | Alpha | 0.1 |
| SVR | C | 1 |
| | Kernel function | Radial basis |
| | Gamma | 0.5 |

In Table 1, it was observed that ANN and SVR have a larger number of hyperparameters to optimize compared to RR and RF. In this case, a more detailed tuning process is necessary for achieving optimal performance.

After optimizing the hyperparameter values, scatter plots were created for each ML model. These plots visually represent the relationship between predicted and actual values, providing a clear evaluation of model performance. In addition, the coefficient of determination ($R^2$) was calculated for each model, quantifying how well the predictions aligned with the observed data. The results, summarized in Figure 3, show the effectiveness of each ML model in predicting the nutrient requirements, in arbitrary units (A. U.), for each observation in the analysed dataset.

According to Figure 3, RF and SVR models displayed signs of overfitting, highlighted by the difference between the $R^2$ values for the training and test sets. Overfitting occurs when the ML model learns not only the underlying patterns but also the noise in the training data, leading to an overly complex model that cannot predict new data accurately. In such cases, the $R^2$ for the training set is typically very high, indicating a well-fitted model, while the $R^2$ for the test set is much lower, revealing poor generalization to unseen data. Overfitting arises due to several causes, such as insufficient regularization, model complexity due to hyperparameter values, or excessive training iterations that allow the ML model to memorize noise instead of only learning meaningful patterns [1,9].

In the scatter plot of RR model (see Figure 3 (a)), some observations are relatively dispersed around the

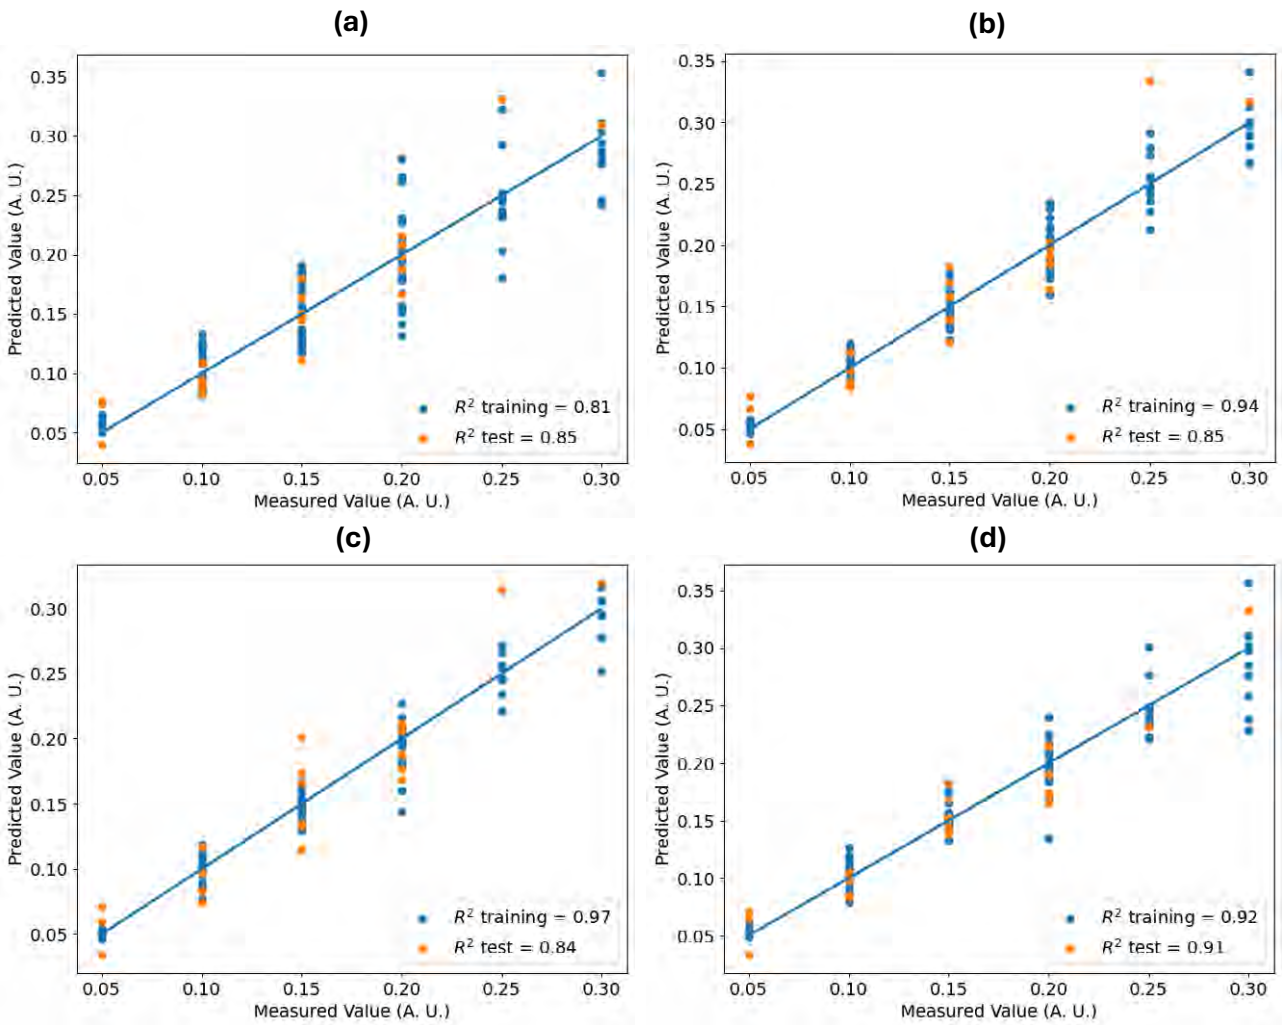

**Figure 3:** Scatter plots for each ML model considered in this work: (a) RR, (b) RF, (c) SVR, and (d) ANN. The coefficient of determination ($R^2$) is displayed for each plot, providing a quantitative measure of model performance.

diagonal line of perfect prediction, indicating moderate alignment between predictions and true values. In contrast, the scatter plot for ANN (see Figure 3 (d)) displays less observations dispersed along the diagonal, achieving superior $R^2$ values for both training and test sets. Superior RMSE values were also found for ANN. These results indicate that ANN generalizes better than RR, making it the preferred ML model for nutrient requirements.

Stacking process was also applied to the dataset by choosing as estimators the four ML models. In this case, the outputs of these ML models were considered in the stacking process, and ANN was chosen as the ML model that combines all the outputs, i.e., the meta-model. The scatter plot of the stacking model is shown in Figure 4.

In Figure 4, the scatter plot of the stacking model presents a good model fit, however when compared to the ANN model, its outputs exhibit more dispersion, reflecting a less accurate prediction. This is consistent with the fact that the $R^2$ values for both the training and test sets are higher in the ANN model compared to the stacking model, suggesting that the ANN model captures the underlying patterns in the data more effectively.

Several factors could contribute to the stacking model presenting a worse performance compared to the ANN model. One possibility is that the estimators used in the stacking process may not have provided complementary information, leading to limited improvement. In addition, the meta-model might not have been well-optimized, resulting in poor generalization on unseen data. Furthermore, the complexity added by the stacking method might have introduced more variance without offering significant predictive gains, especially if the estimators were not sufficiently diverse.

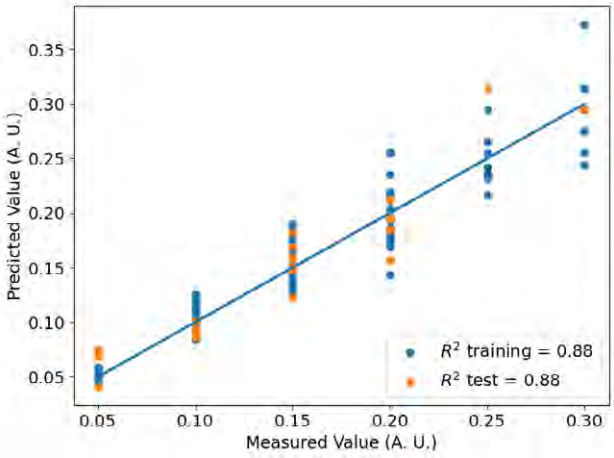

**Figure 4:** Scatter plot of the ML model generated through the stacking process.

## CONCLUSION

This study demonstrates the potential of ML models to predict the nutrient requirements of *Dunaliella* microalgae during the carotenogenic phase in a FP-PBR system. The performance of four ML models was compared alongside a stacking model that combined the outputs of these models. Among all the ML models evaluated, the ANN model presented the best evaluation metrics, indicating its ability to capture complex relationships in the dataset and to provide accurate predictions. In addition, a key factor contributing to the good performance of these ML models was the implementation of a robust DM process, which included a detailed preprocessing stage. Finally, this study highlights the value of applying well-structured DM processes and systematically evaluating ML methods to identify the most suitable models for process modeling.

## ABSTRACT

Precision modeling and forecasting of soil moisture are essential for implementing smart irrigation systems and mitigating agricultural drought. Most agro-hydrological models are based on the standard Richards equation, a highly nonlinear, degenerate elliptic-parabolic partial differential equation (PDE) with first order time derivative. However, research has shown that standard Richards equation is unable to model preferential flow in soil with fractal structure. In such a scenario, the soil exhibits anomalous non-Boltzmann scaling behavior. Incorporating the anomalous non-Boltzmann scaling behavior into the Richards equation leads to a generalized, time-fractional Richards equation based on fractional time derivatives. As expected, solving the time-fractional Richards equation for accurate modeling of water flow dynamics in soil faces extensive computational challenges. To target these challenges, we propose a novel numerical method that integrates finite volume method (FVM), adaptive fixed point iteration scheme, and neural network to solve the time-fractional Richards equation. Specifically, we develop an adaptive fixed point iteration scheme to solve the FVM-discretized equation iteratively, which avoids the stability issues when directly solving a stiff and sparse matrix equation. To improve the solution quality which is influenced by numerical errors and computational constraints during actual implementation, we propose to use neural networks that resemble an encoder-decoder architecture to map soil moisture profiles into a latent space and reconstruct them back. Through 1-D examples, we illustrate the accuracy and computational efficiency of our proposed physics-based, data-driven numerical method. Finally, we present a Markov chain Monte Carlo (MCMC) approach to solve the inverse problem to obtain soil-specific parameters given soil moisture solutions.

## INTRODUCTION

With increasing demand for food and the resulting food-energy-water nexus challenges from the growing population, there is an increasing interest among process systems engineering (PSE) researchers to design the next-generation food and agricultural systems that are sustainable, resource-efficient, and resilient. Along this line, by leveraging real-time soil monitoring technologies, sensor-based digital agriculture for sustainable and efficient use of water is essential for improving agricultural production and crop productivity and reducing agricultural droughts. To simulate the root-zone (top 1m of soil) soil moisture content, agro-hydrological models, which describe irrigation, precipitation, evapotranspiration, runoff, and drainage dynamics inside the soil, are widely used. Most existing agro-hydrological models are based on the standard Richards equation [1], which is a highly nonlinear, degenerate elliptic-parabolic partial differential equation (PDE) with first order time derivative with the form:

$$\partial_t \theta(\psi) + \nabla \cdot \boldsymbol{q} = 0, \tag{1}$$

$$\boldsymbol{q} = -(C(\theta)\nabla\theta + K(\theta)\nabla z), \tag{2}$$

where $\theta$ denotes the soil moisture content (in, e.g., $\mathrm{m}^3/\mathrm{m}^3$), $\boldsymbol{q}$ represents the water flux (in, e.g., $\mathrm{m}^3/\mathrm{m}^2 \cdot \mathrm{s}$), $K(\theta)$ is unsaturated hydraulic water conductivity (in, e.g., $\mathrm{m}/\mathrm{s}$), $C(\theta)$ is soil moisture diffusivity (in, e.g., $\mathrm{m}^2/\mathrm{s}$), $t \in [0, t_{total}]$ denotes the time (in, e.g., $\mathrm{s}$), and $\mathrm{z}$ corresponds

to the vertical depth (in, e.g., m). For this study, without loss of generality of our proposed numerical framework, we ignore the sink term in Equation (1) associated with root water uptake. The Richards equation is a nonlinear convection-diffusion equation, where the convection term is due to gravity and the diffusion term is originated from Darcy's law. For unsaturated flow, both $C$ and $K$ are highly nonlinear functions of soil moisture content and soil parameters, thereby posing significant computational challenges for solving the standard Richards equation itself [2]. The integral form of the standard Richards equation is simply given by:

$$\theta(t,\cdot) - \theta(0,\cdot) = \int_0^t \nabla \cdot (C(\theta)\nabla\theta + K(\theta)\nabla z)\mathrm{d}t, \qquad (3)$$

Besides being computationally difficult to solve, standard Richards equation is also limited when it comes to modeling realistic soil systems. For example, it has been experimentally shown that the anomalous non-Boltzmann scaling behavior is exhibited in porous media with fractal structure [3,4]. For soils exhibiting non-Boltzmann scaling behavior, the soil moisture content is a function of $\frac{\boldsymbol{x}}{t^{\frac{\alpha}{2}}}$, where $\boldsymbol{x}$ is the position vector, and $\alpha$ is a soil-dependent parameter indicating subdiffusion ($0 < \alpha < 1$) or superdiffusion ($1 < \alpha < 2$) [5]. Incorporating this anomalous flow behavior into the Richards equation leads to a generalized, time-fractional Richards equation:

$$\partial_t^\alpha \theta + \nabla \cdot \boldsymbol{q} = 0, \qquad (4)$$

which is even more computationally challenging due to the presence of time-fractional derivative $\partial_t^\alpha \theta$. Naïve implementations for solving Equation (4) typically involves discretizing the time-fractional Richards equation using finite difference method (FDM). However, this often causes numerical stability issues [6]. To ensure numerical stability in solving time-fractional PDEs, recent work features using a hybrid method, in which the FDM and finite element method (FEM) will be used to discretize the time and spatial domains, respectively [7]. Nevertheless, this approach was only used to solve the time-fractional fourth-order reaction-diffusion equation, where the only nonlinearity originates from the sink term. For solving the time-fractional Richards equation, a finite point method (FPM) was recently proposed to improve stability and accuracy [8]. However, this approach relies on solving the FPM scheme in matrix form, whose matrix is often stiff and sparse and hence can be difficult to solve.

To address the limitations of prevailing research, in this work, we propose a novel physics-based, data-driven numerical framework to solve time-fractional Richards equation. This framework discretizes Equation (4) using finite volume method (FVM), which inherently enforces mass conservation at the discretized level. To solve the FVM-discretized fractional Richards equation, instead of converting the discretized equations into a matrix equation, we adopt methods such as fixed point iteration scheme to convert the discretized equation system into an explicit scheme which can be solved iteratively. To enhance solution accuracy and stability, we introduce an adaptive fixed point iteration scheme that automatically selects a proper linearization constant for every iteration, time step, and discretized cell for time-fractional Richards equation based on our recent work [2]. Finally, this numerical scheme is synergistically integrated with an encoder-decoder-type architecture using simple neural networks, and the resulting data-driven, physics-embedded numerical framework achieves higher solution accuracy. This data-driven approach serves two major purposes that common numerical solvers often overlook. First, by training the neural networks using solutions obtained from solvers employing static fixed point iteration scheme under different settings (e.g., number of iterations), the encoder-decoder architecture can systematically capture and account for the numerical errors associated with realistic computational constraints (e.g., not being able to run for an infinite amount of time on a perfect computer) during actual implementation of the numerical scheme, thereby improving solution accuracy and robustness. Second, the use of data-driven approach is attractive also because it provides new opportunities for integrating physics-based modeling with online in situ soil moisture measurements for sensor-driven soil monitoring and precision agriculture applications. Commercial soil moisture sensors are not perfect and instrumental errors will always be present in their measurements. Furthermore, environmental factors (e.g., wind, temperature, evapotranspiration) and imperfect installation and maintenance will bring additional uncertainties to online soil sensing data. Thus, the data-driven approach in our numerical framework makes it amenable to leverage uncertainty-embedded dataset produced by in situ soil sensors in field environment for predictive modeling of root-zone soil moisture profiles.

Lastly, accurate estimation of soil parameters (e.g., $\alpha$ and $C$) from direct sensor measurements, also known as the inverse problem of physics-based models, is generally ill-posed due to insufficient and inaccurate measurements. Deterministic methods, which solve the inverse problem as a nonlinear optimization problem, tend to be trapped in local optima and are sensitive to data noise. Therefore, in this work, we present a probabilistic method based on Markov chain Monte Carlo (MCMC) [9] for identifying the optimal soil parameters $\alpha$ and $C$ in time-fractional Richards equation given soil moisture content information as a preliminary study. Through a 1-D case study, we illustrate the effectiveness of our proposed approaches.

## THE DATA-DRIVEN NUMERICAL FRAMEWORK

## Approximation of time-fractional derivatives

When it comes to representing time-fractional derivatives in Equation (4), there are several options, such as Riemann-Liouville fractional integral [10,11], Caputo fractional derivative [12], fractal derivative [13], and so on. In this work, we would like to adopt the Riemann-Liouville fractional integral of the following form:

$$\mathrm{I}_{0^+}^{\alpha}\mathrm{f}(t) = \frac{1}{\Gamma(\alpha)}\int_0^t (t-u)^{\alpha-1}\mathrm{f}(u)\,\mathrm{d}u, \tag{5}$$

where $\Gamma(\cdot)$ is the gamma function. With this, the integral form of time-fractional Richards equation can be expressed as:

$$\theta(t,\cdot) - \theta(0,\cdot) = \mathrm{I}_{0^+}^{\alpha}[\nabla\cdot(C(\theta)\nabla\theta + K(\theta)\nabla z)], \tag{6}$$

where $\alpha > 0$. Note that the integral form of the standard Richards equation, Equation (3), is just a special case of Equation (6) by setting $\alpha = 1$.

## FVM Discretization

First, we adopt an implicit Euler scheme to discretize Equation (6) in the spatial domain:

$$\theta(t_{m+1},\cdot) - \theta(t_m,\cdot) = \mathrm{I}_{0^+}^{\alpha}\big[\nabla\cdot\big(C\nabla\theta(t_{m+1},\cdot) + K\big(\theta(t_{m+1},\cdot)\big)\nabla z\big)\big] - \mathrm{I}_{0^+}^{\alpha}\big[\nabla\cdot\big(C\nabla\theta(t_m,\cdot) + K\big(\theta(t_m,\cdot)\big)\nabla z\big)\big], \tag{7}$$

where time step $m = 1,\cdots,\left\lfloor\frac{t_{total}}{\Delta t}\right\rfloor$. Next, in order to discretize Equation (6), one needs to accurately approximate Equation (5). Here, we adopt the trapezoidal quadrature formula [14] and express $\mathrm{I}_{0^+}^{\alpha}\mathrm{f}(t_{m+1})$ as:

$$\mathrm{I}_{0^+}^{\alpha}\mathrm{f}(t_{m+1}) \approx \frac{(\Delta t)^{\alpha}}{\alpha(\alpha+1)\Gamma(\alpha)}\sum_{k=0}^{m+1} a_{k,m+1}\mathrm{f}(t_{m+1}), \tag{8}$$

where the coefficient $a_{k,m+1}$ follows:

$$a_{k,m+1} = \begin{cases} m^{\alpha+1} - (m-\alpha)(m+1)^{\alpha}, & \text{if } k = 0 \\ (m-k+2)^{\alpha+1} + (m-k)^{\alpha+1} - 2(m-k+1)^{\alpha+1}, & \text{if } 1 \le k \le m \\ 1, & \text{if } k = m+1 \end{cases} \tag{9}$$

To adopt FVM, we first integrate both sides of Equation (7) over the control volume $V$:

$$\int_V \theta(t_{m+1},\cdot) - \theta(t_m,\cdot)\,\mathrm{d}V = \mathrm{I}_{0^+}^{\alpha}\Big\{\int_V[\nabla\cdot(C(\theta)\nabla\theta(t_{m+1},\cdot) + K(\theta)\nabla z)]\,\mathrm{d}V\Big\} - \mathrm{I}_{0^+}^{\alpha}\Big\{\int_V[\nabla\cdot(C(\theta)\nabla\theta(t_m,\cdot) + K(\theta)\nabla z)]\,\mathrm{d}V\Big\}. \tag{10}$$

Then, one can apply divergence theorem on the RHS of Equation (10), followed by discretizing the control volume $V$ into cells $V_i$, where $i = 1,2,\cdots,N_i$. Each $V_i$ is associated with surfaces $\omega_{i,j}$ for $j = 1,2,\cdots,N_{\omega_i}$, whose surface area is given by $A_{\omega_{i,j}}$. This would lead to the following FVM-discretized version of Equation (10):

$$\big(\theta_i^{m+1} - \theta_i^m\big)\mathrm{vol}(V_i) = \mathrm{I}_{0^+}^{\alpha}\Big[\sum_{j=1}^{N_{\omega_i}}(C(\theta)\nabla\theta + K(\theta)\nabla z)\big|_{\omega_{i,j}}^{m+1}\cdot\hat{n}_{\omega_{i,j}}A_{\omega_{i,j}}\Big] - \mathrm{I}_{0^+}^{\alpha}\Big[\sum_{j=1}^{N_{\omega_i}}(C(\theta)\nabla\theta + K(\theta)\nabla z)\big|_{\omega_{i,j}}^{m}\cdot\hat{n}_{\omega_{i,j}}A_{\omega_{i,j}}\Big], \tag{11}$$

where $\theta_i^m$ is a shorthand notation for the soil moisture at cell $i$ and time step $m$, $|_{\omega_{i,j}}^m$ operates on surface $\omega_{i,j}$ and time step $m$, and $\hat{n}_{\omega_{i,j}}$denotes the outward pointing unit normal vector associated with surface $\omega_{i,j}$. Equation (8) will be used to evaluate $\mathrm{I}_{0^+}^{\alpha}[\cdot]$ in Equation (11).

## Adaptive fixed point iteration scheme

In fixed point iteration scheme, for every cell $i$ and time step $m+1$, one would multiply the fixed linearization parameter $\gamma$ to Equation (11) and then add the term $\theta_i^{m+1,s+1} - \theta_i^{m+1,s}$ to either side of Equation (11), so that the Richards equation can be solved in an iterative manner to obtain the soil moisture solution upon convergence. Since $\gamma$ is a static constant, a trial-and-error procedure is typically required to obtain an appropriate $\gamma$ value that avoids convergence issues. Not only is this search procedure tedious to implement, the solutions obtained are also less accurate most of the time (to be shown in the case study) as the ground truth solutions are not known to us a priori. Thus, inspired by previous works [15], we introduce a novel adaptive fixed point iteration scheme that replaces the static fixed linearization parameter $\gamma$ with $\gamma_i^{m+1,s}$, which adjusts itself for each specific discretized cell, time step, and iteration count s. Specifically, we introduce the term $\theta_i^{m+1,s+1} - \theta_i^{m+1,s}$ to the LHS of Equation (11). When the scheme converges for sufficiently large s, this term vanishes, which preserves the equality of Equation (11). In our previous work focusing on solving standard Richards equation [2,17], we developed a systematic procedure for choosing $\gamma_i^{m+1,s}$ that would guarantee convergence and stability of the numerical scheme. In this work, we follow the same procedure for choosing the appropriate $\gamma_i^{m+1,s}$.

## Encoder-decoder-type data-driven framework

Once our adaptive linearization scheme of the FVM-discretized time-fractional Richards equation is established, we will obtain soil moisture solutions $\theta_i^{m+1,s}$ for every cell, time step, and iteration. Through the encode-decoder-type architecture, these solutions will first be mapped to their corresponding variables denoted as $\mu_i^{m+1,s}$ in a latent space via a trained neural network $\mathrm{f}_{\mathrm{NN}}$ (i.e., $\mathrm{f}_{\mathrm{NN}}$: $\theta_i^{m+1,s} \to \mu_i^{m+1,s}$), followed by applying inverse mapping from the latent space back to the soil moisture solutions $\hat{\theta}_i^{m+1,s}$ (which are expected to be more accurate than $\theta_i^{m+1,s}$ ) via another trained neural network $\mathrm{f}_{\mathrm{NN}}^{-1}$: $\mu_i^{m+1,s} \to \hat{\theta}_i^{m+1,s}$.

The dataset used to train the two neural networks

will come from two different sources/solvers. For example, during neural network training, $\theta$ solutions could be soil moisture solutions obtained from fixed point iteration scheme under different choices of linearization parameters and total iteration counts that cover their ranges expected during the actual solution process, whereas the $\mu$ solutions may come from direct sensor measurements or a simple finite difference based solver. Furthermore, we apply data augmentation to these "reference solutions" by adding zero-mean Gaussian noise with different variances [4]. After data augmentation, the resulting expanded set of reference solutions will be used for neural network training. This data augmentation step not only increases the size of the training dataset without having to actually solve the numerical schemes (thereby saving significant computational time), but also reflects the characteristics of actual soil sensing data, which are subject to various measurement uncertainties due to instrumental error, environmental uncertainties, and imperfect installation and maintenance. It turns out that introducing Gaussian noise can greatly reduce the biases of reference solutions and enhance generalization performance, thereby significantly improving the accuracy of numerical solutions.

Our data-driven adaptive fixed point iteration scheme works as follows. For a given time step $\mathrm{m}$ and iteration count $\mathrm{s}$, $\mathrm{f_{NN}}$ first maps the $\theta_i^{m+1,s}$ to a latent space where $\mu_i^{m+1,s} = \mathrm{f_{NN}}(\theta_i^{m+1,s})$ lies upon. The resulting adaptive linearization scheme of FVM-discretized time-fractional Richards equation in terms of $\mu_i^{m+1,s}$ is given by:

$$\mu_i^{m+1,s+1} - \mu_i^{m+1,s} = \frac{1}{\gamma_i^{m+1,s}}\left\{\mathrm{I}_{0^+}^{\alpha}\left[\sum_{j=1}^{N_{\omega_i}}(C\nabla\mu)_{\omega_{i,j}}^{m+1}\cdot \hat{n}_{\omega_{i,j}}A_{\omega_{i,j}}\right] - \mathrm{I}_{0^+}^{\alpha}\left[\sum_{j=1}^{N_{\omega_i}}(C\nabla\mu)_{\omega_{i,j}}^{m}\cdot \hat{n}_{\omega_{i,j}}A_{\omega_{i,j}}\right]\right\} + \frac{1}{\gamma_i^{m+1,s}}\mathrm{f_{NN}}(J), \tag{12}$$

where the quantity J is given by:

$$J = (\theta_i^m - \theta_i^{m+1,s})\mathrm{vol}(V_i) + \mathrm{I}_{0^+}^{\alpha}\left[\sum_{j=1}^{N_{\omega_i}}(K(\theta)\nabla z)_{\omega_{i,j}}^{m+1}\cdot \hat{n}_{\omega_{i,j}}A_{\omega_{i,j}}\right] - \mathrm{I}_{0^+}^{\alpha}\left[\sum_{j=1}^{N_{\omega_i}}(K(\theta)\nabla z)_{\omega_{i,j}}^{m}\cdot \hat{n}_{\omega_{i,j}}A_{\omega_{i,j}}\right].$$

Once $\mu_i^{m+1,s+1}$ is obtained by solving Equation (12) (which is an explicit scheme) provided $\mu_i^{m+1,s}$, we will apply the inverse mapping $\mathrm{f_{NN}^{-1}}$ to transform $\mu_i^{m+1,s+1}$ from the latent space back to its original space $\hat{\theta}_i^{m+1,s+1} = \mathrm{f_{NN}^{-1}}(\mu_i^{m+1,s+1})$. And the entire solution process iterates itself until a stopping criterion is reached. A commonly used stopping criterion is the relative error, which is estimated as $\varepsilon = \max_{\mathrm{i}} \frac{|\mathrm{f_{NN}^{-1}}(\mu_i^{m+1,s+1}) - \mathrm{f_{NN}^{-1}}(\mu_i^{m+1,s})|}{|\mathrm{f_{NN}^{-1}}(\mu_i^{m+1,s+1})|}$. Or, one can specify the total number of iterations needed for each time step and cell (which is what we use for the case study).

We remark that, the two neural networks $\mathrm{f_{NN}}$ and $\mathrm{f_{NN}^{-1}}$ can be treated as encoder and decoder, respectively, and Equation (12) essentially employs the "message passing" idea [16] via our numerical scheme.

## Solving inverse problem using MCMC approach

To solve the inverse problem of identifying soil parameters, we adopt a simple MCMC approach with Metropolis-Hasting (M-H) algorithm [9]. The algorithm begins by selecting an initial set of parameters $\alpha_0$. For each iteration, a candidate $y$ is drawn from the proposal density $q(\cdot|\alpha_t)$. The acceptance probability $h(\alpha_t|y)$ is then computed. If a randomly drawn value $r$ from the uniform distribution $\mathcal{U}([0,1])$ is less than $h(\alpha_t|y)$, the candidate $y$ is accepted, and $\alpha_{t+1}$ is updated to $y$. Otherwise, the current parameter $\alpha_t$is retained, setting $\alpha_{t+1} = \alpha_t$. This process continues iteratively to explore the parameter space.

# AN ILLUSTRATIVE EXAMPLE

In this section, we test and validate our proposed numerical framework on 1-D benchmark problem presented in [11], which features both classical and anomalous diffusion, by comparing our numerical solution with the analytical solution as well as solution obtained using fixed point iteration scheme.

## 1-D Classical Diffusion

For the classical diffusion problem, the parameter $\alpha$ is set to be 1. A constant soil moisture diffusivity $C = 24\times10^{-5}\ \mathrm{cm^2 min^{-1}}$ is used. The boundary condition is given by $\theta(0,t) = 0.5$ and $\theta(\infty,t) < \infty$. The initial condition is given by $\theta(z,0) = \begin{cases}0.5, \text{if } z = 0\\ 0.1, \text{if } z > 0\end{cases}$. The analytical solution for this problem is $\theta(z,t) = 0.4\cdot\mathrm{erfc}\left(\sqrt{\frac{z^2}{4Ct}}\right) + 0.1$.

Overall, we generate an augmented training dataset containing 84,480 pairs of noise-added solutions from solvers employing fixed point iteration scheme and our previously developed solver [2]. Two neural networks $\mathrm{f_{NN}}$ and $\mathrm{f_{NN}^{-1}}$, each adopting 5 layers with 32, 64, 128, 64, 32 neurons per layer and (leaky) ReLU activation function, are trained for 10000 epochs by Adam optimizer with a learning rate of 0.001.

From the results in Figure 1 and Table 1, one can make several observations. First, solution accuracy highly depends on the choice of linearization parameters, and without the prior knowledge about where the ground truth solution lies, it will be challenging for fixed point iteration scheme to correctly identify the optimal linearization parameter to use by itself. Second, for this specific problem, since the solution quality of fixed point iteration scheme changes as $\frac{1}{\gamma}$ varies from 1 to 500, a trial-and-error process, which is both tedious and computationally expensive, will be required for identifying the optimal linearization parameter. Our proposed framework, on the

other hand, does not require such trial-and-error procedure. Third, our proposed numerical framework closely matches with the analytical solution quite well, thanks to the adoption of adaptive fixed point iteration scheme and the integrated data-driven approach.

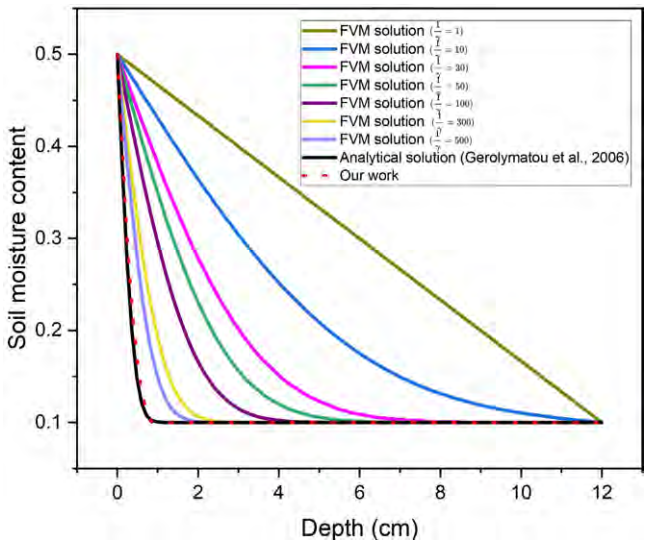

**Figure 1.** Numerical solutions obtained from fixed point iteration scheme and our numerical framework by setting 2,000 iterations as the stopping criterion for each time step and cell. In this example, we study the soil moisture profile across a 12-cm deep soil when $t_{total} = 200$ min.

**Table 1.** Mean Squared Error (MSE) measuring the discrepancy between numerical solutions and the analytical solution.

| Method | $\frac{1}{\gamma}$ value | MSE |
|---|---|---|
| FVM with a static fixed linearization parameter | 1 | 0.0487 |
| | 10 | 0.0239 |
| | 30 | 0.0121 |
| | 50 | 0.0085 |
| | 100 | 0.0050 |
| | 300 | 0.0017 |
| | 500 | 0.0009 |
| Our work | N/A | $2.4731 \times 10^{-5}$ |

## 1-D Anomalous Diffusion

We consider the case of subdiffusion ($0 < \alpha < 1$) for anomalous diffusion problem. Again, a constant soil moisture diffusivity $C = 24 \times 10^{-5}\ \mathrm{cm^2 min^{-\alpha}}$ is used. Other the boundary and initial conditions are the same as in classical diffusion problem. The analytical solution for this problem is given by $\theta(z,t) = 0.4 \cdot \mathrm{H}_{1,1}^{1,0}\left(\sqrt{\frac{z^2}{4Ct^\alpha}}\middle| \begin{matrix}(1,\alpha/2)\\(0,1)\end{matrix}\right) + 0.1$, where $\mathrm{H}_{1,1}^{1,0}(\cdot)$ is the Fox function (see [11] for more details).

First, we solve the forward problem by considering $\alpha = 0.6$. We are mainly interested in the top 1.2 cm of soil, where the soil moisture changes significantly. From Figure 2, it is clear that, compared to the asymptote solution presented in [11], our numerical framework achieves remarkable accuracy even when simulating the region where soil moisture changes the most. Second, we investigate the performance of numerical framework in solving inverse problem when it is integrated with MCMC approach. Without informing our solver, we set the soil parameters as $\alpha = 0.13$ and $C = 24 \times 10^{-5}\ \mathrm{cm^2 min^{-\alpha}}$. We examine two scenarios, one at $t_{total} = 3$ min and the other at $t_{total} = 300$ min. Due to the ill-posedness of this inverse problem, we impose upper and lower bounds for the two parameters $0 < \alpha < 1$ and $0 < C < 30 \times 10^{-5}\ \mathrm{cm^2 min^{-\alpha}}$. The results in Figure 3 shows that the MCMC approach can estimate the soil parameters reasonably well (<20% and <1% relative discrepancy for $\alpha$ and $C$, respectively). Furthermore, it provides an error bar for the parameters being estimated, which provides basis for uncertainty quantification.

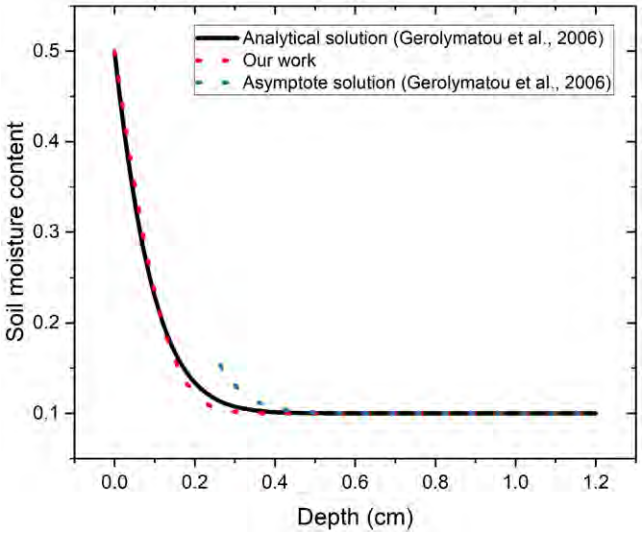

**Figure 2.** Solutions obtained from our numerical framework (stopping criterion: 2,000 iterations for each time step and cell) comparing to asymptote solution and analytical solution [11]. In this example, we examine the soil moisture profile across a 1.2-cm deep soil when $t_{total} = 200$ min. Here, $\alpha = 0.6$. Note that the MSE between numerical solutions from our numerical framework and analytical solution is $3.9130 \times 10^{-6}$, while that of asymptote solution is $6.7163 \times 10^{-5}$.

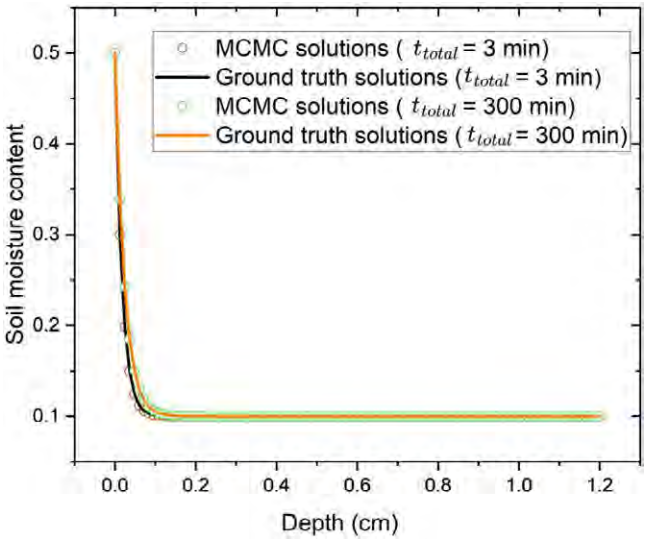

**Figure 3.** Numerical solutions obtained using the parameters identified by MCMC approach. Here, we conduct 1000 samplings. The resulting parameters are $\alpha = 0.13071 \pm 3.7310 \times 10^{-5}$ and $C = 23.808 \times 10^{-5} \pm 3.232 \times 10^{-12} \mathrm{cm}^2 \mathrm{min}^{-\alpha}$. Note that the MSE between numerical solutions and desired solutions are $2.8096 \times 10^{-8}$ and $7.6698 \times 10^{-9}$ for $t_{total} = 3\ \mathrm{min}$ and $t_{total} = 300\ \mathrm{min}$, respectively.

## CONCLUSION

In this work, we develop a novel physics-based, data-driven numerical framework for simulating anomalous diffusion of water in porous media such as soil, which is characterized by the highly nonlinear time-fractional Richards equation. To address the computational challenges associated with existing solvers, we integrate neural networks and adaptive fixed point iteration scheme in a FVM discretization framework. These innovative approaches not only improves solution accuracy and robustness, but also open opportunities for integrating physics-based models with in situ soil moisture sensing technologies for precision agriculture applications. We also briefly introduce a systematic approach to solve the inverse problem using MCMC. Preliminary results obtained on a 1-D benchmark problem indicate that our proposed forward and inverse problem solvers can be highly accurate and useful. Nevertheless, we notice that one limitation of the MCMC approach for solving the inverse problem is that its accuracy highly depends on the selection of parameter bounds. In our future work, we plan to investigate other probabilistic methods that are more scalable and robust for solving inverse problems (i.e., model parameter estimation and uncertainty quantification given in situ soil moisture measurements). Overall, it is expected that this numerical framework would be integrated in an irrigation control mechanism to provide farmers with quantitative insights and recommendations regarding when to irrigate, where to irrigate, and how much to irrigate [18].

## ABSTRACT

Miniaturised stirred bioreactors are crucial in high-throughput bioprocesses for their simplicity and cost-effectiveness. To accelerate process optimisation in chemical and bioprocess industries, models that integrate CFD-predicted flow fields with (bio)reaction kinetics are needed. However, conventional two-step coupling methods, which freeze flow fields after solving hydrodynamics and then address (bio)reaction transport, face numerical challenges in miniaturised systems due to unsteady radial flows, recirculation zones, and secondary vortices. These flow fluctuations prevent steady-state hydrodynamic convergence. This study addresses these challenges by time-averaging the RANS solutions of the transitional SST model to achieve statistical hydrodynamic convergence. This method is particularly effective for internal flow problems at low to midrange Reynolds numbers (<10,000), typical of transitional regimes. Following this, photo-bioreaction transport models were solved using these converged fields, considering the bioreactor's directional illumination and curvature. Applied to a 0.7 L Schott bottle photobioreactor mechanically mixed by a magnetic stirrer (100-500 rpm), the model predictions were thoroughly validated against tracer dye experiments and *Rhodopseudomonas palustris* biomass growth data. It accurately predicted swirly vortex fields at 500 rpm with a 7% error margin and the biomass growth profiles align to literature datasets. However, parallel computing efficiency did not scale linearly from 16 to 32 processor cores (4G of RAM/core), making time-averaging computationally expensive for simulating scale-up bioreactors. Improved bioreactor mixing influenced cell light/dark cycles and enhanced biomass productivity but stirring speeds above 300 rpm required increased light intensity (>100 W/m²) due to light limitation. This model provides a framework for optimising stirring speeds and refining operational parameters, aiding in the scale-up and scale-down of bioprocesses.

**Keywords**: Miniaturised stirred bioreactors, CFD modelling, Photobioreactor, Light attenuation and transport, Bioreaction kinetics.

## INTRODUCTION

As the global population grows, the demand for sustainable bioproducts intensifies, necessitating efficient large-scale production infrastructure such as bioreactors [1]. These bioreactors facilitate microbial conversion of substrates into valuable products like biofuels and biochemicals. Among factors influencing bioreactor performance, mixing plays a pivotal role and is achieved through mechanical, pneumatic, or natural circulation techniques[1]. Mechanical methods, including stirred tanks, magnetic stirrers, and orbital shakers, dominate process development due to their ability to meet critical scale-up criteria like power per unit volume and mixing time. Pneumatic mixing often complements these systems with pumps and spargers to facilitate oxygen

transfer rates, further enhancing process efficiency. In contrast, natural circulation, which relies on temperature-induced density differences for buoyancy-driven motion [1,2], is less commonly used in industrial applications.

To accelerate bioreactor design and optimisation across different configurations, Computational Fluid Dynamics (CFD) serves as a critical tool, simulating fluid flow and reaction transport across scales. However, challenges arise when simulating transitional flow regimes, especially in small-scale stirred bioreactors such as magnetic stirrer-driven systems, widely used for microbial strain screening and process optimisation [1,3]. In these systems, unsteady radial flows and secondary vortices prevent steady-state hydrodynamic convergence, complicating CFD-biokinetics coupling via the two-step approach: i.e., solving hydrodynamic to convergence in step one and freezing flow fields in step one to solve for bioreaction transport in step two [1,4–6], thus hindering scale-up. While time-averaging techniques address oscillating flow variables in other contexts [7–9], their application to transitional regime bioreactors remains largely unexplored for CFD-biokinetics coupling. High computational cost likely contributes to this gab, alongside the limitations of existing light transport models for photobioreactors, which are often limited to simplified geometries [6,10]. These challenges are further compounded when extending to 3D cylindrical systems. This underscores an urgent need for more efficient coupling approaches and advanced algorithms that seamlessly integrate fluid dynamics with (bio)reaction kinetics, enabling higher accuracy and reproducibility across scales, facilitating scalable and cost-effective bioreactor designs for industrial applications.

Therefore, this study develops a 3D CFD model for a cylindrical bioreactor mixed by a magnetic stirrer, operating under transitional flow regimes simulated with SST turbulence models. A case study involving a Schott bottle photobioreactor demonstrates the integration of light transport and photo-bioreaction kinetics. Experimental validation, including dye tracing and biomass photoproduction by *Rhodopseudomonas palustris*, confirms the model's accuracy. This work advances the coupling of CFD-predicted hydrodynamics and biokinetics, addressing a critical gap in bioreactor design for high-throughput and scalable production systems.

## METHODOLOGY

### Experimental setup, tracer conductivity measurements and photobioreaction model

The Schott bottle photobioreactor, previously described in detail [1,2], is a cylindrical glass vessel optimised for light transmission and minimal near-wall dead zones. It features autoclavable GL45 polypropylene lids and stainless-steel sampling tubes, with temperature controlled by a water bath. For this study, the overhead section and water bath were excluded to reduce the computational domain. The experimental setup, shown in Fig. 1 a), includes two conductivity probes placed at 62.5 mm and 47.5 mm from the bioreactor top to monitor tracer (NaCl) concentrations. Deionised water was filled to a height of 92 mm (680 mL working volume), and stirring speeds ranged from 100–500 rpm, generating transitional to early turbulent flow regimes. At $t$ = 0, 1 mL of 0.2 M NaCl was added, and normalised tracer data was collected and analysis for validations of CFD predicted hydrodynamic fields.

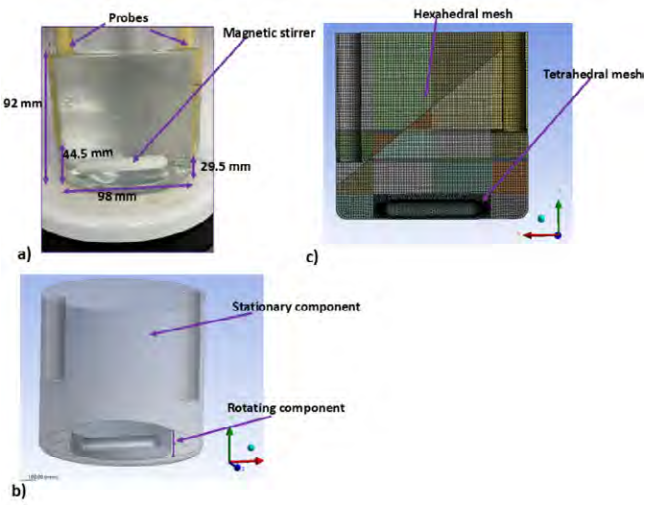

**Fig 1.** Experimental and numerical setup: a) Schott bottle bioreactor, mixed using a magnetic stirrer, illustrating the bioreactor dimensions and probe insertion points. b) 3D CFD geometry designed for a multi-reference simulation approach, incorporating an inner rotating component for the magnetic stirrer and an outer stationary component representing the remaining bioreactor structure. c) hybrid computational mesh, combining hexahedral and tetrahedral elements, was employed to discretize the computational domain efficiently.

Bioreaction simulations modelled *R. palustris* biomass growth, focusing on light/dark cycles driven by magnetic stirring dynamics. Shortened cycles at higher rpms improve photosynthetic efficiency by optimising protein oxidation-reduction balance, enhancing microbial growth [5]. The mechanistic growth model, along with parameter estimates retrieved from our previous work [3] is expressed as Eq. (1):

$$\frac{dX}{dt} = \mu_B \cdot X = \left[A' \cdot \exp\left(-\frac{E_a}{RT}\right) \approx 0.189\ hr^{-1}\right] \cdot \left(\frac{\frac{I_0}{(\tau \cdot X) \cdot L} \cdot \left(1 - e^{-(\tau \cdot X) \cdot l}\right)}{k_s + \left(\frac{I_0}{(\tau \cdot X) \cdot L} \cdot \left(1 - e^{-(\tau \cdot X) \cdot l}\right)\right)}\right) \cdot X \quad (1)$$

Here, key parameters include the specific growth rate ($\mu_B$), biomass concentration ($X$), incident light intensity ($I_o$), light absorption coefficient ($\tau$), light path length ($l$), light saturation coefficient ($k_s$) and temperature ($T$=*308.15* K), among others reported in [3] and thus not repeated here.

## CFD modelling

### Hydrodynamic model setup

The simulation employed the Volume of Fluid (VOF) method [1,11,12] to accurately model the two distinct phases: the liquid bio-suspension and the gaseous headspace, within the computational domain depicted in Fig. 1 b) and c). The chaotic fluid motion induced by magnetic stirring forces (Coriolis and centrifugal) was captured using the four-equation transitional SST (γ-Reθ) turbulence model [1,13]. This model seamlessly blends the k-ε and k-ω turbulence frameworks to simulate laminar, transitional, and turbulent flow regimes, ensuring precise representation of flow dynamics across a range of rotational speeds (100–500 rpm). The detailed mathematical formulation of the VOF model and the blending methodology of the k-ε and k-ω models within the transitional SST framework has been thoroughly described in prior studies [1,13] and is therefore not repeated here.

### Coupling of CFD hydrodynamic and photobioreaction models

This study employed a two-step approach [1,5,6], achieving hydrodynamic convergence before coupling bioreaction kinetics. Time-averaged flow variables, such as velocities, ($\bar{u}_{stats}$) and turbulent diffusivity ($\overline{\mu_{K,Turb}}_{stat}$), were calculate and implemented into the biomass transport equation (Eq. (2)) using User Defined Functions (UDFs) written in C programming language, with solutions being stored in User Defined Memories within ANSYS Fluent 2024 R1.

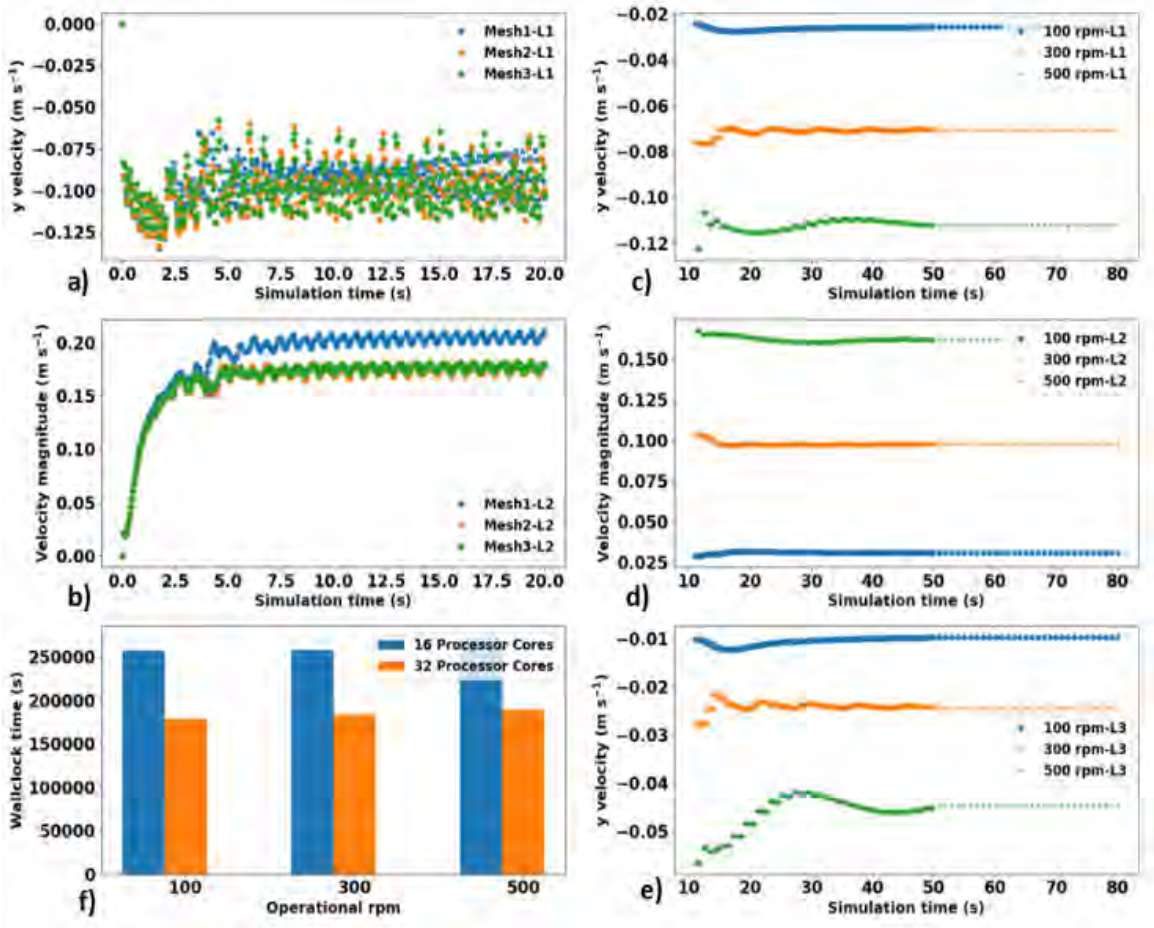

**Fig 2.** CFD hydrodynamic RANS solutions are presented for varying mesh element counts at vertical heights: a) 0.023 m and b) 0.046 m. Time-averaged RANS solutions are shown at vertical heights of c) 0.023 m, d) 0.046 m, and e) 0.069 m, under different operational stirrer rotational speeds. Furthermore, f) depicts the effect of increasing processor core counts on simulation costs during the time-averaging process.

$$\frac{\partial}{\partial t}(X) + \nabla \cdot (\bar{u}_{stats}\, X) = \nabla \cdot \left( \left( \mu_{k,Lam} + \frac{\overline{\mu_{K,Turb}}_{stat}}{Sc_t} \right) \cdot \nabla X \right) + \left[ \mu_B \cdot X = A' \cdot \exp^{\left(-\frac{E_a}{R \cdot T}\right)} \cdot \frac{I_0 \cdot \exp^{(-\tau \cdot X \cdot l)}}{I_0 \cdot \exp^{(-\tau \cdot X \cdot l)} + k_s} \cdot X \right] \quad (2)$$

From left to the right, the terms of Eq. (2) represent the accumulation, convection, diffusion, and biomass growth. Laminar diffusivity ($\mu_{k,Lam}$= 5.5×10-10 m2 s-1) and Schmidt number ($Sc_t$ 0.7) were obtained from literature [1,5]. Light attenuation effects were incorporated via the Beer-Lambert law [1], accounting for L/D cycles and photobioreactor curvature, using polar and Cartesian coordinates [1]. This iteratively methodology was executed with UDFs, ensuring high accuracy in simulating the photobioreaction.

### Solver settings and solution strategy

In stage one, hydrodynamic simulations used a 0.001 s time step, 40 iterations per step, and ran for 50 s. Convergence was achieved when residuals fell below $10^{-6}$, and velocity changes became negligible. Time averaging started after 10 s, yielding a 40 s averaged solution. In stage two, scalar transport was coupled to hydrodynamics with a 0.01 s time step, totalling 150 s for tracer simulations and 6,000 s for biomass transport. Biomass growth kinetics were accelerated by $1.152\times10^3$ to match an 8-day photo-fermentation period [1]. Simulations used parallel computing on 16–32 processors via The University of Manchester's HPC cluster.

## RESULTS AND DISCUSSION

### Grid sensitivity analysis, time averaging and computational cost analysis

To assess mesh independence, three meshes (Mesh1: 406,667 elements, Mesh2: 267,460, Mesh3: 151,291) were tested. Simulations were monitored at three heights (23.0 mm, 46.0 mm, 69.0 mm) in the bioreactor. Increasing mesh density prolonged simulation times from 4.35 hrs (Mesh3) to 32.71 hrs (Mesh1). Despite fluctuations in vertical velocities as depicted in Fig. 2 a) and b) due to the bioreactor's magnetic stirrer, all mesh results were aligned with the literature range of 0.0 m $s^{-1} \leq |\boldsymbol{u}| \leq$ 0.42 m $s^{-1}$ [7], validating their reliability. Mesh2 offered a balance between accuracy and cost and was therefore selected for all subsequent simulations. Time-averaging stabilised flow fields as seen in Fig. 2 c) to e), enabling bioreaction coupling. However, computational costs did not scale linearly with increasing processor cores (16 to 32) as seen in Fig. 2 f), suggesting that simulating larger bioreactors may require cost saving strategies. Techniques like compartment modelling [1,8], which bypass solving momentum balances and continuity equations at every element, could accelerate industrial-scale bioreactor simulations. Nevertheless, the highly fluctuating flow variables may necessitate a numerous compartment, potentially undermining the intended cost savings.

### CFD hydrodynamic: insights, validations and influences on biomass growth and light transport

To validate the CFD model's predictions against experimental results, qualitative and quantitative approaches were used. Qualitatively, visual inspection identified distinct liquid (water) and air zones in the bioreactor, confirming the VOF method's accuracy in representing multiphysics, as shown in Fig. 3 a) to d). Radial recirculation zones, indicated by arrowheads in Fig. 3 c) and d), aligned with literature [1,11,12], with more pronounced swirling at higher stirrer speeds, forming a tornado-like vortex at 500 rpm. This swirling effect's influence on biomass growth remains largely unexplored.

Quantitatively, normalised conductivity probe measurements were compared to CFD predictions. Fig. 3 e) demonstrates strong agreement, with deviations within 6.3%, aligning with literature-acceptable thresholds of 10% [1,2]. Deviations were most pronounced during the first 16 seconds, likely due to limitations in the model's representation of tracer diffusivity upon introduction. Beyond 20 seconds, the model accurately matched equilibrium values, validating its reliability. Lower rpm (100) exhibited the largest overshoots, suggesting reduced mixing velocity delayed tracer detection, a limitation of probe-based techniques [1]. For such fluctuating dynamics at low rpm, non-intrusive validation techniques, such as Laser Doppler Anemometry (LDA), are recommended.

With validated stage one hydrodynamics, stage two coupling to bioreaction simulations assessed hydrodynamic effects on biomass growth. Biomass growth profiles in Fig. 3 f) closely mimic those of purely mechanistic models in the literature [3], verifying the robustness of the coupling of strategy. Increasing stirrer speeds from 100–500 rpm enhanced biomass productivity by 88.16%, although the increase from 300 rpm to 500 rpm was marginal at 1.4% as reported in Table 1. This trend is attributed to improved culture mixing, particularly radial mixing which facilitates more frequent light/dark cycles, enabling microbial cells to absorb light energy for photosynthesis [1,5]. Analysis of the stirrer-induced mixing volume-averaged velocities in Table 1, shows a linear increase from 100 rpm to 500 rpm, corroborating other literature reports for both baffled [1,12] and unbaffled bioreactors [1,11].

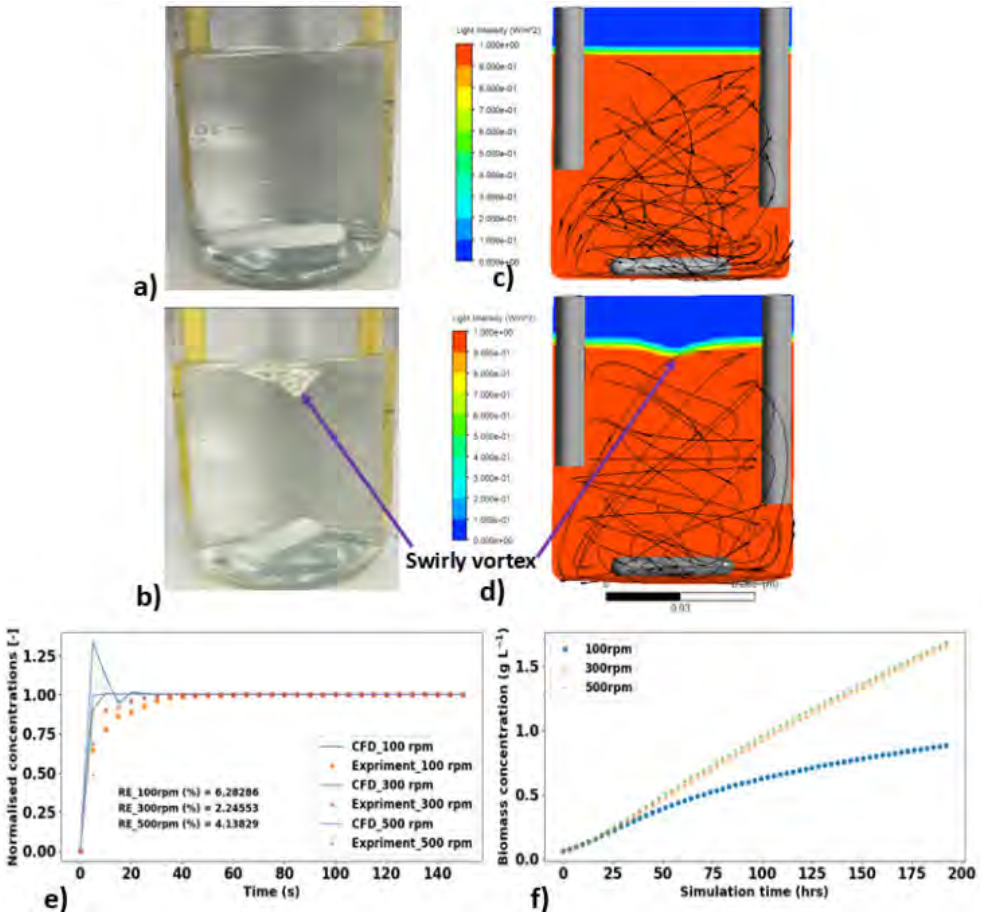

**Fig 3.** Flow visualisation images of the physical bioreactor operating at a) 100 rpm and b) 500 rpm are compared to CFD-predicted flow fields at c) 100 rpm and d) 500 rpm. The presence of swirling vortices in b) and d) confirms qualitative validation of the model. Quantitative validation is shown in e), highlighting the percentage relative error (RE) across different stirrer rotational speeds. Additionally, f) illustrates temporal changes in biomass concentration over time.

However, beyond 300 rpm, the linear increase in mixing velocity did not significantly enhance biomass productivity. This phenomenon can be attributed to excessively rapid light/dark (L/D) cycles, which shorten the relaxation time of excited photosystems, thereby limiting the efficient utilisation of absorbed energy for growth [1,5]. In such cases, microbial cells are effectively exposed to almost continuous light. Similar effects of overly rapid L/D cycles have been reported in the literature under purely turbulent regimes [1,5]. This interpretation is further substantiated by the Reynolds number data in Table 1, which indicates a value of 14,481.6 at 500 rpm—nearly double the 8,469.2 observed at 300 rpm. While prior studies [11,12], including our own [3], have successfully operated these bioreactors at 200 rpm, speeds beyond this benchmark remain largely unexplored.

Interestingly, light attenuation intensified with increasing rpm, becoming severe beyond 300 rpm. At these speeds, cells were exposed to insufficient light, as shown in Fig. 4, where average light intensities dropped to 7.2 W/m² at 300 rpm and 6.9 W/m² at 500 rpm by 112 hours (quantitative data not shown). Such low light levels explain why increasing rpm beyond 300 had negligible effects on biomass productivity (see Table 1). Conversely, augmenting the incident light intensity above 100 W/m² could provide more photoenergy, enhancing productivity at higher rpms. This aligns with findings across various photobioreactor designs in the literature [1,8,14].

**Table 1:** Relationships between biomass changes and the bioreactor's operating parameters.

| Operational rpm | Predicted velocity (m s$^{-1}$) | Calculated Reynolds Number | Final biomass concentration (g L$^{-1}$) |
|---|---|---|---|
| 100 | $2.48 \cdot 10^{-2}$ | 2,423.2 | 0.88 |
| 200 | $5.61 \cdot 10^{-2}$ | 5,488.7 | 1.53 |
| 300 | $8.66 \cdot 10^{-2}$ | 8,469.2 | 1.66 |
| 500 | $1.48 \cdot 10^{-1}$ | 14,481.6 | 1.68 |

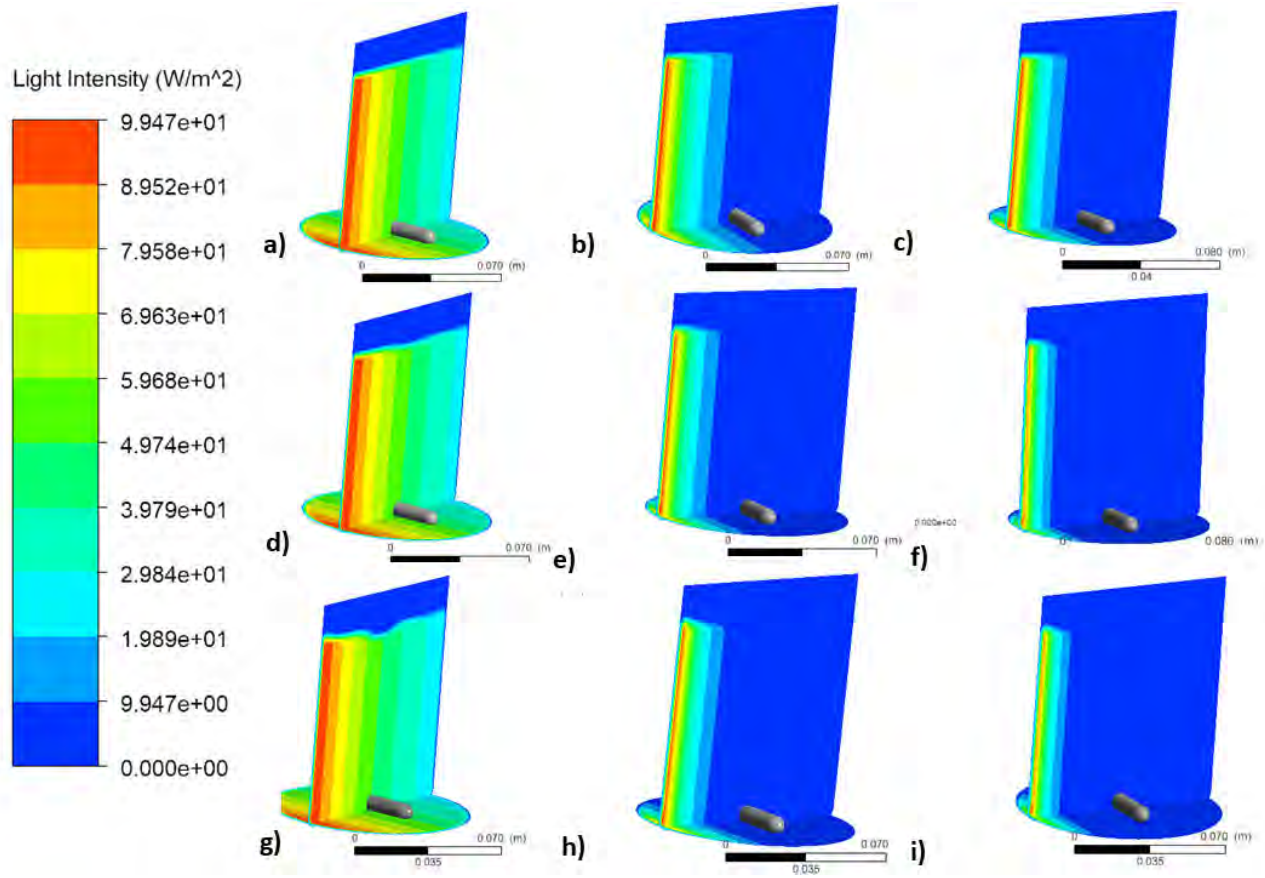

**Fig 4:** CFD qualitative predictions of light transport dynamics in the photobioreactor are shown for various stirrer speeds: 100 rpm (a–c), 300 rpm (d–f), and 500 rpm (g–i). Results were sampled at three-time intervals: 16 hours (a, d, g), 112 hours (b, e, h), and 192 hours (c, f, i). Severe light attenuation at higher operating speeds correlates with increased biomass growth, highlighting the trade-off between light availability and productivity under elevated stirrer speeds.

## Potential applicability of the proposed CFD model

The previous paragraph highlights the potentials of investigating untested bioreactor rotational speeds. However, further exploration of increased incident light intensities is necessary, as prior research with the same microbial strain tested up to 200 W/m² without inducing photoinhibition. A critical limitation of the current mechanistic model is the omission of biomass decay rates, which may result in overestimated growth predictions. This exclusion neglects the impact of shear stresses from high rotational speeds and light-induced stress. Moreover, the lack of a decay term produces unrealistic growth trends. To enhance accuracy, future studies must incorporate decay rates to optimise rotational speeds and light intensities effectively.

## CONCLUSION

This study investigated the challenges of coupling hydrodynamics with bioreaction transport in CFD simulations using a two-step approach, complicated by fluctuating hydrodynamic fields. To address this, hydrodynamic convergence was achieved by time-averaging instantaneous RANS solutions over extended periods, ensuring statistical reliability. These time-averaged fields were then used to simulate bioreaction transport via User Defined Functions (UDFs), which replaced instantaneous RANS fields in the CFD solver. Validation was conducted using a Schott bottle photobioreactor with fluctuating radial velocities, achieving experimental deviations within 7%. The time-averaging approach proved computationally demanding, with non-linear scaling as processor counts increased. Model predictions for light and biomass transport were validated at stirrer speeds below 200 rpm. While higher stirrer speeds enhanced biomass productivity, severe light attenuation above 200 rpm indicated the need for augmented incident light intensities. These findings underscore the necessity of future

optimisations to balance hydrodynamic efficiency and light availability.

# Parameter Estimation and Model Comparison for Mixed Substrate Biomass Fermentation

**Tom Vinestock[a], Miao Guo[a]***

[a] King's College London, Department of Engineering, London, United Kingdom
* Corresponding Author: miao.guo@kcl.ac.uk

## ABSTRACT

Most industrial fermentations in food and drink use a single, high purity sugar as a substrate. These pure substrates are more expensive and less sustainable than mixed substrates, that can be derived from agricultural byproducts such as straw. However, use of mixed substrates in fermentation leads to challenging modelling and parameter estimation problems, particularly when much academic research, intended to inform industrial applications, uses batch fermentations, while large-scale fermentation is usually continuous, thanks to its cost and productivity advantages. Our findings highlight key challenges in using batch-derived experimental data to inform models of the continuous fermentation processes used at industrial scale. Extrapolating from data obtained in batch to continuous fermentation is risky, as models with near-equivalent data-fit and predictions in a batch context give very different predictions for continuous culture. For continuous fermentations to switch to mixed substrates, we need to improve understanding of dual substrate growth in continuous fermentation, to allow for optimised process design and operation.

## BACKGROUND

### Single Cell Protein & Agricultural Residues

Currently, animal agriculture accounts for at least 16.5% of global greenhouse gas emissions [1]. Given Net Zero targets, this highlights the need for sustainable alternatives to livestock for dietary protein production. Single cell protein (SCP) fermentation is one such alternative, offering an effective means of transforming carbohydrate-rich substrates into high-protein foodstuffs, and is significantly more sustainable than conventional animal-based protein production, with lower greenhouse gas emissions, water use and land use [2-4]. Therefore, there is a strong environmental interest in increasing consumption and production of SCP to reduce dependence on animal-derived proteins [5].

However, whereas cows and other ruminants can be fed agricultural residues, such as corn stover, wheat and rice straw, SCP fermentations generally depend on high-purity single-substrate feedstocks [6], which are expensive, and directly compete for food crops. This raises the question of how to adapt SCP fermentations to more sustainable feedstocks derived from cheap residues of agriculture and forestry.

Globally, 11 100 megatons of these residues are produced annually [7], which if used as a feedstock for SCP fermentation would be more than enough to provide for all human dietary protein needs [7]. These residues are mainly composed of lignocellulose, a mixture of fibrous lignin and the carbohydrates cellulose and hemicellulose. While hydrolysis can be used to break down this mixture into simpler components, yielding 360g fermentable sugar per kg lignocellulose [7], only about 60% of the resulting fermentable sugar is glucose, the favoured 6-carbon sugar, with the other 40% coming from xylose, a 5-carbon sugar, along with trace sugars such as mannose [7].

### Batch & Continuous Fermentation

Modelling biomass growth on such a mixture of glucose and xylose is complicated and is one of the barriers to widespread adoption of lignocellulosic feedstock in SCP fermentation [8]. To design and operate a large-scale SCP fermentation using a lignocellulosic feedstock, accurate growth models that allow the growth behaviour

on mixed substrates and the resulting yields to be understood are needed. However, academic work to obtain these models often uses batch fermentation experiments [8,9], with all the nutrients available to the system added at the start, while industrial scale SCP production is usually operated as a continuous process, with biomass constantly harvested, and substrate added as it is consumed, as this affords a much higher biomass productivity for a given reactor volume [10].

### Structured & Unstructured Kinetic Models

In bioprocess kinetic modelling, a distinction is made between structured and unstructured approaches. Structured approaches incorporate detailed information about metabolic pathways, and so are useful for metabolic engineering [11] but this complexity can lead to challenges in parameter and state estimation, impeding practical applications [9]. Unstructured approaches, such as the Monod model, use simpler mathematical formulations based on empirical data [9]. The benefit of these models is their greater ease of use, with many fewer state variables and parameters to estimate. As this work focuses on bioprocesses modelling for process optimisation and control, the unstructured approach is adopted.

## RESEARCH OBJECTIVES

This work has two main aims. The first is to compare different unstructured models for dual substrate growth, using previously published batch fermentation data. The second aim is to evaluate these models' ability to predict continuous fermentation dynamics using parameters estimated from batch fermentation data.

The study focuses on the filamentous fungi strain *Fusarium Venenatum* A3/5, which is commercially significant as the most widely used SCP strain for food-grade protein production [12]. Unlike previous research that often examines a single model in the batch context [8,9], this study evaluates five different dual substrate growth models and extends the analysis to continuous fermentation systems. The findings are expected to enhance modelling of lignocellulose-derived mixed substrate fermentations, and illuminate the differences between batch and continuous fermentation in this context.

## METHODOLOGY

### Experimental Data

The data used in this work is from Banks *et al*"s [8] recent publication, in which a microplate reader and high-performance liquid chromatography were combined to measure biomass and (extracellular) glucose and xylose concentrations at regular intervals over a 120-hour batch fermentation on two glucose-xylose mixtures (15 $gL^{-1}$ glucose: 15 $gL^{-1}$ xylose and 20 $gL^{-1}$ glucose:10 $gL^{-1}$ xylose). 3 biological replicates were used, resulting in 3 sets of measurements for each timepoint. 5 different versions of each dataset were generated using leave-one-out validation, to give an indication of the uncertainty of each model's outputs.

### Parameter Estimation

Optimal parameters for each model were found using SciPy's differential evolution (DE) function for parameter optimisation in combination with ODEInt, a SciPy wrapper for LSODA, for numerical integration of the dynamical batch fermentation models defined below for each set of parameters [13, 14]**.** Stochastic methods such as DE can better identify global minima in non-convex problems such as parameter estimation than traditional gradient methods [8]. 50 generations were used for the DE, with initial populations generated using Latin hypercube sampling. At the end of this process the best population member was 'polished' using L-BFGS, a gradient descent method [15]. Default values were used for all the other algorithmic parameters. Mean absolute error (MAE) was used as the cost function, as shown in Equation 1.0. As in Banks *et al.* [8], the feedstock with equal concentrations of glucose and xylose was used as a calibration dataset, while validation was conducted using the 20 $gL^{-1}$ glucose:10 $gL^{-1}$ xylose data.

$$MAE = \frac{1}{3N}\sum_{k=0}^{N-1}\sum_{r=1}^{3}|X_{Pred}[k,r] - X_{Meas}[k,r]| + \left|S_{1,Pred}[k,r] - S_{1,Meas}[k,r]\right| + \left|S_{2,Pred}[k,r] - S_{2,Meas}[k,r]\right| \quad (1.0)$$

In the validation dataset, unmeasurable initial states, such as initial biomass, and where applicable, initial enzyme concentrations/intensities were back-calculated from measured values, using the DE approach described previously.

Each model, parameterised based on the calibration dataset, was then used to predict steady-state continuous fermentation behaviour, assuming a single, mixed feed containing 15 $gL^{-1}$ glucose and 15 $gL^{-1}$ xylose. Optimal dilution rates, defined as the dilution rates leading to the maximum steady-state biomass output rate, were found using exhaustive search for each model, with ODEInt used to numerically integrate the continuous fermentation models. Substrate efficiencies were then calculated based on this operating point.

### Growth Models

Five growth models are compared. Their parameters and states variables are detailed in Tables 1-3.

#### Single Substrate Growth Models

While there are many single substrate growth models, the Monod and Contois models are particularly widely used. The Monod model (EQ 1.1) [16] assumes that

the growth rate depends only on the substrate concentration, approaching a maximum rate of $\mu_{max}$ when the substrate concentration is much higher than the fixed threshold concentration given by $K_s$. The Contois model (EQ 1.2) [17] is similar to the Monod model but assumes that the substrate threshold concentration increases linearly with the biomass concentration.

$$\mu = \mu_{max}\frac{S}{S+K_s}, \qquad \mu = \mu_{max}\frac{S}{S+K_{SX}X} \qquad (1.1, 1.2)$$

## Multi-Substrate Growth Models

In the multi-substrate case, the specific biomass growth rate ($\frac{\dot{X}}{X}$) can be considered the sum of the growth rates ($\mu_i$) on each substrate, which may in general depend on the substrate concentration itself ($S_i$), as well as the concentrations of other substrates ($S_j$), and key enzymes required for the metabolism of the substrate itself ($Z_i$) and other substrates($Z_j$), with each growth rate's upper limit given by a substrate-specific parameter ($\mu_{mi}$).

$$\frac{\dot{X}}{X} = \sum_{i\in\{1,..N\}, j\in\{1,...,N\}, j\neq i} \mu_i\left(S_i, S_j, Z_i, Z_j\right) \qquad (1.3)$$

$$\mu_i \in [0, \mu_{m,i}]$$

As in [8,9], the consumption rate of each substrate ($\dot{S}_i$) is assumed to be specified by:

$$\dot{S}_i = \frac{-\mu_i}{Y_{xi}}X \qquad (1.4)$$

**Table 1:** Parameters common to all growth models considered.

| Symbol | Name | Description | Unit |
|---|---|---|---|
| $\mu_{m,i}$ | Maximum growth rate on substate *i* | Fixed parameter | $h^{-1}$ |
| $Y_{x,i}$ | Yield coefficient | Mass of biomass per mass of substrate *i* consumed | $g_{biomass}$ $g_{substrate}^{-1}$ |
| $\mu_i$ | Current growth rate of substrate *i* | Function depending on substrate and enzyme concentrations. | $h^{-1}$ |

In a continuous system with a dilution rate of $D$ per hour, we have, in the simpler case of two substrates:

$$\frac{\dot{X}}{X} = -D + (\mu_1 + \mu_2) \qquad (1.5)$$

$$\dot{S}_1 = \frac{-\mu_1}{Y_{x1}}X + D(S_{in1} - S_1) \qquad (1.6)$$

$$\dot{S}_2 = \frac{-\mu_2}{Y_{x2}}X + D(S_{in2} - S_2) \qquad (1.7)$$

$$\dot{y} = D * X \qquad (1.8)$$

In a batch system, $D = 0$, resulting in a further simplified system. We consider five different possible functions for $\mu_i$. We assume this function can be split into two parts: the first dealing with single substrate dynamics, the second dealing with interaction between substrates.

**Table 2:** State variables employed in the dual substrate growth models

| Symbol | Name | Applicability | Unit |
|---|---|---|---|
| $X$ | Biomass Concentration | All models | $gL^{-1}$ |
| $S_i$ | Concentration of Substrate *i* | All models | $gL^{-1}$ |
| $y$ | Cumulative Biomass Output | Continuous Models | g |
| $Z$ | Concentration of key enzyme required for growth on xylose | Enzyme Inhibition Model | $gL^{-1}$ |
| $z_i$ | Relative intensity of key enzyme required for growth on substrate *i* | Optimised Enzyme Production Model | % |

## Inhibition Models

When more than one substrate is present, there may be an interaction between the substrates. Usually, the growth rate on a mixture of substrates is less than or equal to the maximum of the single substrate maximum growth rates, because of substrate cross-inhibition [18].

## Direct Inhibition Model

Vega-Ramon *et al.* [9] introduce a direct inhibition model, with an inhibition term of the form:

$$\mu_i = \mu_i' * \frac{1}{1+\frac{S_j}{K_{ij}}} \; for \; i,j \in \{1,2\}, i \neq j, \qquad (2.1)$$

where $\mu_i'$ is the growth rate on substrate *i* in the absence of substrate *j*. Banks *et al.* [8] applied this model to the fermentation of *F. Venenatum* A3/5 on a glucose-xylose mixture, with Contois growth. Glucose growth was assumed to be unaffected by xylose, giving the following equations, with glucose as the preferred substrate ($S_1$) and xylose the less-favoured substrate ($S_2$).

$$\mu_1 = \mu_{m1}\frac{S_1}{S_1 + K_{X1}X}, \qquad (2.2)$$

$$\mu_2 = \mu_{m2}\frac{S_2}{S_2 + K_{X2}X}\frac{1}{1+\frac{S_1}{K_I}} \qquad (2.3)$$

## Enzyme Inhibition Model

**Table 3:** Model Specific Parameters

| Symbol | Name | Description | Model(s) | Unit |
|---|---|---|---|---|
| $K_s$ | Monod Half-Saturation | Substrate Concentration at which growth rate is half full single substrate rate. | Monod | gL-1 |
| $K_{SX}$ | Contois Half-Saturation | Ratio of substrate to biomass concentration giving a growth rate that is half the full rate. | Contois | $g_{substrate}$ $g_{biomass}^{-1}$ |
| $K_I$ | Inhibition Constant | Value of $S_1$ at which growth rate on $S_2$ is halved relative to the growth rate on $S_2$ in the absence of $S_1$. | Direct Inhibition | gL-1 |
| $K_{Z_S}$ | Enzyme Half Saturation | Enzyme concentration at which growth rate on $S_2$ is halved relative to case of excess enzyme. | Enzyme Inhibition | % |
| $K_{Z_d}$ | Enzyme Degradation Rate | | Enzyme Inhibition, Optimal Enzyme Production | h-1 |
| $K_{Z_c}$ | Enzyme Creation Rate | | Enzyme Inhibition, Optimal Enzyme Production | % |

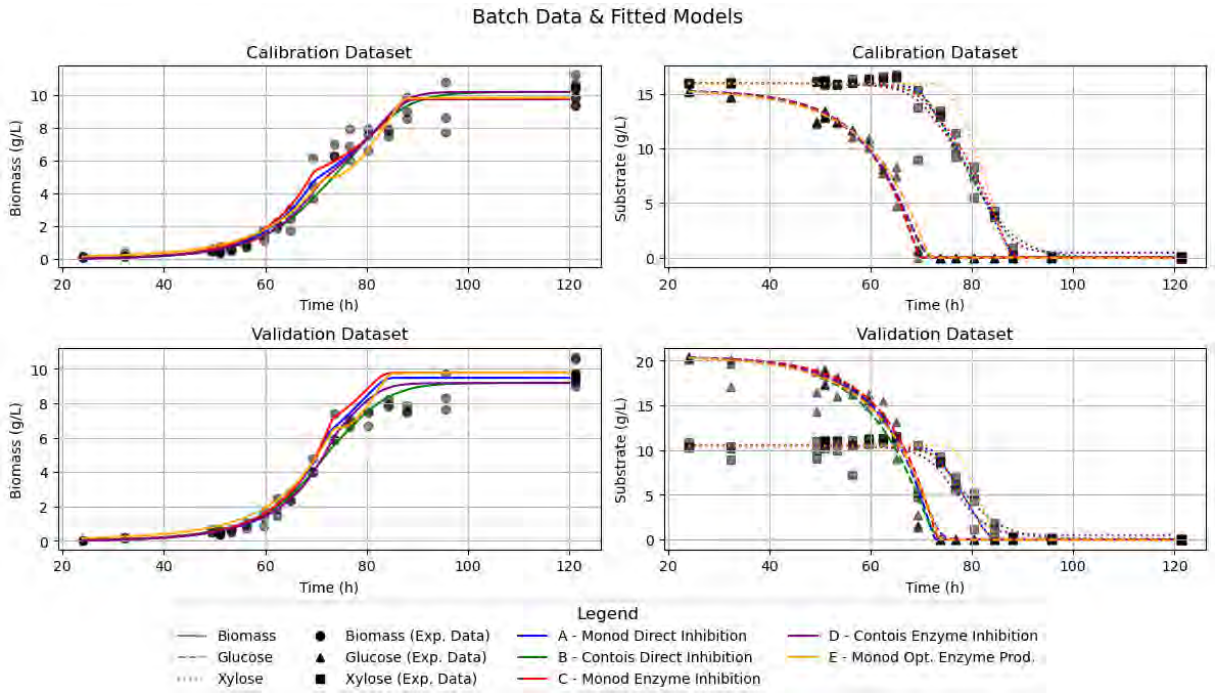

**Figure 1:** Fitted models, and the batch fermentation data from [8] used to fit the models.

Considering potential mechanisms for substrate cross-inhibition, instead of $S_1$ inhibiting $S_2$ growth directly, it can be modelled as reducing the production rate of an enzyme $Z$ that is key for $S_2$ growth and is assumed to be rate limiting at low concentrations. The Monod-type term with a constant $K_{Z_S}$ reflects that at a sufficient value of Z, it is no longer meaningfully rate limiting.

$$\mu_i = \mu_i * \frac{Z}{Z + K_{Z_S}} \tag{3.1}$$

$$\dot{Z} = -(K_{Z_d} + D) * Z + (K_{Z_c} * \mu * X * \frac{S_i}{S_i + K_{Si}} \frac{1}{1 + \frac{S_i}{K_{Z_{Si}}}}) \tag{3.2}$$

This model is a simplification of one proposed by Nakamura *et al.* [19]. Using the Monod model, and assuming as previously that glucose ($S_1$) growth is unaffected by xylose ($S_2$) gives the following:

$$\mu_1 = \mu_{m1} \frac{S_1}{S_1 + K_{S1}}, \quad \mu_2 = \mu_{m2} \frac{S_2}{S_2 + K_{S2}} \frac{Z}{Z + K_{Z_S}} \tag{3.3, 3.4}$$

## Optimal Enzyme Production Model

A third option is to model the concentration of the key enzymes for both $S_1$ and $S_2$ separately. This requires some modelling of cellular decision-making. In Kompala *et al.* [18], it is argued that cells optimise the allocation of resources to maximise growth rate. This leads to:

$$r_i = \mu_{mi} * z_i * S_i \tag{4.1}$$

$$v_i = \frac{r_i}{\max_j(r_j)}, \quad u_i = \frac{r_i}{\sum_j r_j} \tag{4.2, 4.3}$$

$$r_{Z_i} = K_{Z_c} * \frac{S_i}{K_{si} + S_i}, \quad \mu_i = r_i * v_i \qquad (4.4, 4.5)$$

$$Z_i = r_{Z_i} * u_i - K_{Z_d} * z_i - \sum_j \frac{\mu_j}{X} * z_i \qquad (4.6)$$

Here, $z_i$ is a relative enzyme intensity, defined as the enzyme mass per unit biomass, normalised by the maximum possible enzyme intensity.

## RESULTS & DISCUSSION

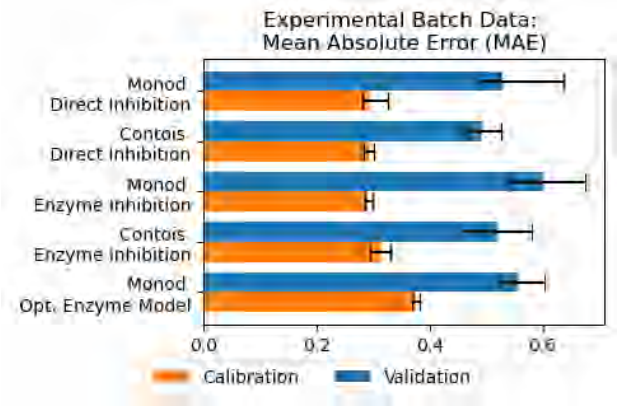

**Figure 2:** MAE in model predictions for calibration and validation batch data. Error bars show minimum and maximum MAE from 5 variant datasets created using leave-one-out method; the main bar shows the mean.

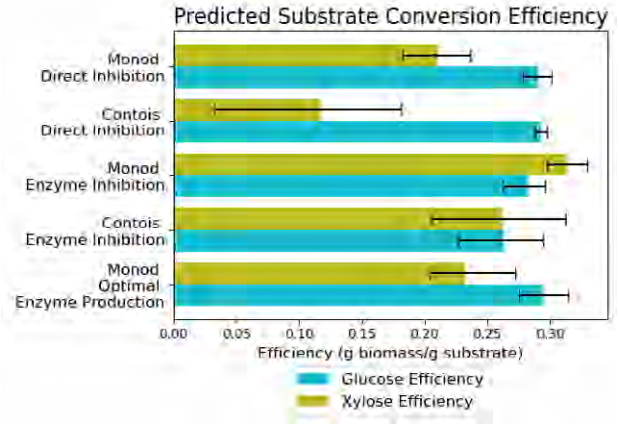

**Figure 3:** Predicted substrate conversion efficiency in continuous fermentation for glucose and xylose for each of the 5 dual substrate models evaluated.

Figure 1 shows that all 5 models give highly similar fits to the both the calibration and validation datasets (for legibility, only a single fit for each model is shown). This can also be seen from Figure 2, which shows the different models have similar errors. The similar values for validation error between the models suggests that the more complex models aren't overfitting.

One interpretation of the results presented in Figures 1-2 would be that the different models aren't meaningfully different. However, applying these models to continuous fermentation challenges this. Looking at Figures 3 and 4, the models make significantly different predictions for substrate yields, biomass production rates and optimal dilution rates in continuous fermentation.

Figure 3 shows the two Direct Inhibition Models predict much lower substrate yields for xylose compared to glucose, whereas the enzyme-based models predict more similar yields for the two substrates. This corresponds to the Direct Inhibition Models predicting that the glucose preference results in xylose being washed through the system in the continuous case, as glucose concentrations don't drop low enough to encourage the switch to xylose when it is diluted at the rate that maximises biomass output. The difficulty in discerning whether co-utilisation of glucose and xylose occurs in batch is the cause of much of the uncertainty in xylose efficiency, production rate and optimal dilution rate in Figures 3-4.

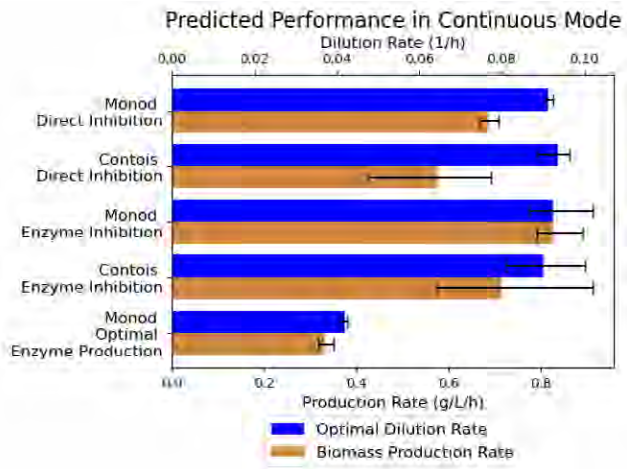

**Figure 4:** Maximum biomass production rates and the corresponding optimal dilution rates calculated for each model, based on the batch data parameterisations.

Figure 4 shows that the different models also predict very different biomass production rates and optimal dilution rates, although the biomass production rates and the optimal dilution rate are closely related, suggesting the steady-state biomass concentration is similar in all cases. There is a factor of about two between the largest predicted production rate, for Monod Enzyme Inhibition, and the smallest, for Monod Optimal Enzyme Production, which demonstrates the difficulty of extrapolating to continuous culture from batch fermentation results.

Additionally, differences, or uncertainties, between models exists alongside the parametric uncertainty within a model. For biomass production rate, optimal dilution rate and xylose efficiency, the inter-model uncertainty, characterised by the difference between model

mean values, exceeded the intra-model uncertainty, characterised by the range of values for one model, by factors of 3.2, 5.6 and 2.4, respectively.

### Limitations

While this work focuses on the uncertainty introduced from extrapolating from batch fermentation data to continuous fermentation performance, the change in reactor volume, and the consequent effects on mixing and gas-transfer, are another major source of uncertainty in the transition from lab scale to industry scale [20]. Additionally, the higher shear stresses from the more vigorous mixing required in large reactor can reduce cell viability and growth [21]. These effects are not addressed in this work, and the uncertainties they introduce would be in addition to the model uncertainty discussed here.

## CONCLUSIONS & FUTURE WORK

This research demonstrates the significant uncertainty generated by using batch fermentation data to assess and parameterise models intended for application to large-scale continuous fermentations. As a result, it suggests a need for greater focus on continuous fermentation within academia, in order to support industrial adoption of lignocellulosic feedstocks. It is relevant to academics and professionals working on design and optimisation of continuous fermentation, as it shows the risks of extrapolating from batch to continuous fermentation.

## ABSTRACT

Global biomanufacturing is projected to expand rapidly in the coming decade due to advancements in DNA sequencing and manipulation. However, the complexity of cellular behaviour introduces difficulty in modelling and optimizing biomanufacturing processes. Phenomenological models that represent the physics of the system in empirical equations suffer from poor robustness, while their machine learning (ML) counterparts suffer from poor extrapolative capability. On the other hand, hybrid models allow us to leverage both physical constraints and the flexibility of ML. This work describes a new approach for hybrid modeling that integrates the time-variant parameter estimation and ML model training into a singular step. We implement this approach on a proposed scheme for the cell-mediated conversion of a lignin derivative into a bioplastic precursor and show that our integrated hybrid model outperforms the traditional two-step hybrid, phenomenological, and ML model counterparts. Lastly, we demonstrate how to execute an interpretability analysis on the ML component of the integrated hybrid model to reveal new physical insights that are then used to further improve model performance.

## Motivation & Background

Growing need and sustainability concerns are increasing the strain on the traditional manufacturing pipelines for chemicals, drugs, and materials [1]. This has prompted increased interest on bio-centric manufacturing, as bioprocesses leverage the capability of microbial, plant, and animal cells to produce complex commercially relevant chemicals while enjoying a reduced carbon footprint, moderate reactor conditions, and high stereoselectivity [1]. Previously inaccessible renewable feedstocks can now be converted into bulk chemicals with the aid of metabolic strain engineering. Of particular interest is the soil bacterium *Pseudomonas putida*, which can valorize lignocellulosic biomass (Figure 1). Studies have demonstrated that *P. putida* can convert lignin into cis,cis-muconic acid (MA) [2]. MA can then be utilized to create polymers like Nylon and PET [2]. While the bacterial conversion of lignin into MA is documented, the kinetics is not well understood.

Cells are extremely complex systems with numerous reaction pathways, intermediates and products. Factoring in inter and intra-cellular relationships, it becomes intractable to simulate each cell and track metabolic dynamics [2]. This problem is countered using phenomenological models based on biological intuition that neglect information regarding biomass heterogeneity and metabolite influences on empirical parameters [3]. On the other hand, purely machine learning (ML) models have been shown to capture the nonlinear complexity of bioprocesses but have poor extrapolation and interpretability [3]. Additionally, experimental datasets are often sparse and noisy, resulting in poor model development and calibration, especially for ML models.

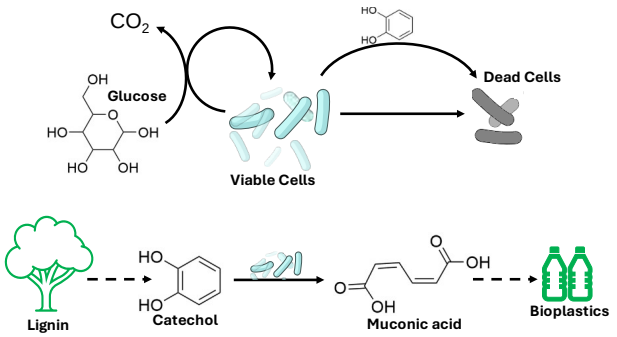

**Figure 1.** Conversion of lignocellulosic biomass into bioplastics by *P. putida*.

Hybrid models have been proposed to leverage the physical constraints of phenomenological models and the flexibility of ML ones [3]. This work explores an embedded hybrid model wherein ML models are utilized to capture the complexity of certain parameters "embedded" within the overarching ODE structure [4]. The hybrid modelling approach aids in capturing the complex relationships between external metabolites and bacteria physiology. Moreover, the embedded approach lends a better framework for interpretability.

To test our hybrid model, we outline a ground truth model that simulates the dynamics of the conversion of catechol, a lignin derivative, to MA by P. putida. The ground truth model also includes glucose as the representative carbon source for bacterial growth and the cell toxicity of catechol. A sparse and noisy dataset is then generated which mimics traditional experimental datasets.

This work will explore two scenarios for constructing hybrid models: A sequential method and an integrated method, which differ on how the parameters of the models are determined. Furthermore, we compare the extrapolative performance of the hybrid model to its phenomenological and ML counterparts. Finally, an interpretability study is performed on the ML components of the hybrid model to gain physical insight. Utilizing Captum python package, an Integrated gradients (IG) analysis is performed which gives insight into how changes in the input affect changes in output for the ML component [5].

## Methods

### Ground truth model

A system of ODEs is constructed to model the dynamics of *P. putida* consuming glucose and converting catechol to MA in a batch process. The system is constructed based on biological principles and previous characterization of *P. putida* [2] The following assumptions are made: (i) the growth rate of viable cells $(X_v)$ follows a logistic-Monod equations aimed at better recapitulating the lag phase of batch cultures (Eq. 1 and 2); (ii) glucose $(C_g)$ promotes cell division while catechol $(C_c)$ inhibits it (Eq. 2); (iii) the cell death rate is composed of a zero-order, catechol-independent component and a catechol-dependent component represented with a Monod-style rate equations (Eq. 2); (iv) dead cells $(X_d)$ are not degraded and accumulate in the culture and contribute to the total biomass $(X_t)$ (Eq. 4 and 5); (v) glucose is consumed for cell growth and to neutralize the toxic effect of catechol (Eq. 6); (vi) the generation of MA $(C_m)$ from catechol has non-growth associated and growth associated components (Eq. 7); and (vii) all the catechol consumed is directly converted to MA by the viable cells and no byproducts are formed (Eq. 8). Note that the following equation can be modified for batch and semi-batch by changing the spike glucose input $\left(C_g^{IN}\right)$, spike catechol input $(C_c^{IN})$ and spike time-period $(\tau)$.

$$\frac{dX_v}{dt} = (\mu_{gr} - \mu_{dt})X_v \quad (1)$$

$$\mu_{gr} = \left(1 - \frac{X_v}{Y_{xg}C_g^0}\right)\left(\frac{\mu_g C_g}{C_g + K_g}\right) \quad (2)$$

$$\mu_{dt} = k_d + \left(\frac{\mu_c C_c}{C_c + K_c}\right) \quad (3)$$

$$\frac{dX_d}{dt} = \mu_{dt}X_v \quad (4)$$

$$X_t = X_v + X_d \quad (5)$$

$$\frac{dC_g}{dt} = -\left(\frac{\mu_{gr}}{\mathrm{Y_{xg}}} + \frac{m_k C_c}{C_c + k_{cm}}\right)X_v + C_g^{IN} f(t) \quad (6)$$

$$\frac{dC_m}{dt} = Y_{mx}(\mu_{gr} + \beta)X_v \frac{C_c}{C_c + k_cr} \quad (7)$$

$$\frac{dC_c}{dt} = -\frac{dC_m}{dt} + C_c^{IN} f(t) \quad (8)$$

$$f(t) = \sum_{k=0}^{Z} \delta(t - \tau k) \quad (9)$$

Training data is generated by assuming batch operation. A 72-hour batch process is simulated with a 10-point discretization. To better reflect limitations in data acquisition commonly experienced in biomanufacturing, only data on the total biomass, glucose, catechol and MA concentrations are used for training (Fig. 2). For instance, only total biomass is easily measured during culturing (e.g., by measuring changes on optical density) while distinguishing viable and dead cells is more challenging. Glucose, catechol and MA are generally quantified with either chromatographic or biochemistry analyzers, which are expensive and time consuming to operate thereby limiting the amount of data collected.

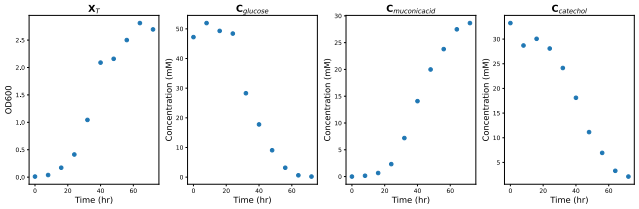

**Figure 2.** Ground truth model of the batch MA production bioprocess.

### Phenomenological model construction

This model reflects the traditional reactor kinetics style system of ODEs that are generally constructed to capture bioprocess dynamics. The data acquisition limitations highlighted in the previous section along with relevant literature informed the model construction. Combining dynamic observations of (Fig. 2) and literature studies [2], the following ODEs for the phenomenological model are created: (i) The total biomass growth is tied positively to glucose and inhibited by catechol via Monod kinetics (Eq.11); (ii) The MA production is observed to

occur in both the growth and stationary phases (Eq. 13); (iii) The MA concentration increased at the same rate as the catechol one decreased (Eq. 14)

$$\frac{dX_t}{dt} = \mu_{gr} X_t \tag{10}$$

$$\mu_{PM} = \left(\frac{\mu_g C_g}{C_g + K_g}\right) - \left(\frac{\mu_c C_c}{C_c + K_c}\right) \tag{11}$$

$$\frac{dC_g}{dt} = -\left(\frac{\mu_{gr}}{Y_{xg}}\right) X_t + C_g^{IN} f(t) \tag{12}$$

$$\frac{dC_m}{dt} = Y_{mx}(\mu_{gr} + \beta) X_t \frac{C_c}{C_c + k_cr} \tag{13}$$

$$\frac{dC_c}{dt} = -\frac{dC_m}{dt} + C_c^{IN} f(t) \tag{14}$$

$$f(t) = \sum_{k=0}^{Z} \delta(t - \tau k) \tag{15}$$

The spike input of glucose and catechol are set to zero for the training data. Note how the growth of the biomass in the phenomenological model closely mirrors the ground truth model.

## Hybrid model structure – Sequential vs Integrated

The construction of the hybrid model entrails the following steps: (a) time-variant parameter estimations (TVPE), (b) ML model parameter regression and (c) ODE-ML model integration. The integrated method differs from the sequential one as it performs steps (a) and (b) together. The equations shown here reflect the hybrid construction methodology. The observations outlined in the previous section are used to inform the overarching ODE structure. An assumption is made that the growth rate did not have a straightforward relationship between glucose and catechol. An artificial neural network (ANN) is used to model the growth rate which used glucose, catechol, MA and total biomass as inputs. Equations (16-19) highlight the hybrid model structure.

$$\frac{dX_t}{dt} = \mu_{ML} X_t \tag{16}$$

$$\mu_{ML} = ANN(X_t, C_g, C_c, C_m) \tag{17}$$

$$\frac{dC_g}{dt} = -\left(\frac{\mu_{ML}}{Y_{xg}}\right) X_t + C_g^{IN} f(t) \tag{18}$$

$$\frac{dC_m}{dt} = Y_{mx}(\mu_{ML} + \beta) X_t \frac{C_c}{C_c + k_cr} \tag{19}$$

Equations 14, 15 are included in the hybrid model to track the dynamics of catechol and the spike input frequency. The sequential hybrid modelling structure initially calculates the TVPE and then trains a ML model outside. Notice that within the initial optimization framework the TVPE is calculated as a discrete value at different time steps. A multi-objective optimization problem is formulated with a state space MSE and a smoothing index (sum of second derivatives) for the time variant parameters. The formulation shown below shows the sequential hybrid model's TVPE.

$$\min_{\theta^{TV}, \theta_{TIV}} \; w_M MSE + w_s SM \tag{20}$$

$$\boldsymbol{s.t.} \frac{dC_{si}}{dt} = f_{ODE}(C_{xi}, \theta_{TIV}, \theta_i^{TV}), \forall\, x = [0, S] \forall\, i = [0, N] \tag{21}$$

$$MSE = \frac{1}{NtS} \sum_{i=1}^{N} \sum_{j=0}^{t} \sum_{s=0}^{S} \left(C_{sji}^{pred} - C_{sji}^{act}\right)^2 \tag{22}$$

$$SM = \frac{1}{Nt} \sum_{i}^{N} \sum_{j}^{t-2} \left(\theta_{ij+1}^{TV} - 2\theta_{ij}^{TV} + \theta_{ij-1}^{TV}\right)^2 \tag{23}$$

$$\theta_{it}^{TV}, \; \theta_{TIV} \geq 0 \tag{24}$$

$N$ represents the number of experimental datasets, $t$ is the number of time points in each dataset and $S$ is the number of dynamic species. $f_{ODE}$ represent the hybrid system of ODE captured by Eqs (14-19). $\theta_{TIV}$ are the time invariant parameters in Eqs (14-19) while $\theta^{TV}$ represents time variant parameters. The integrated hybrid modelling structure simultaneously estimates the growth parameter while also training the ANN model to capture the parameter behavior. The optimization formulation shown below details how the ML model is trained and the TVPE is performed.

$$\min_{W, b, \theta_{TIV}} \frac{1}{NtS} \sum_{i=1}^{N} \sum_{j=0}^{t} \sum_{s=0}^{S} \left(C_{sji}^{pred} - C_{sji}^{act}\right)^2 \tag{25}$$

$$\boldsymbol{s.t.} \frac{dC_{si}}{dt} = f_{ODE}(C_{xi}, \theta_{TIV}, \theta_i^{TV}), \forall\, x = [0, S] \forall\, i = [0, N] \tag{26}$$

$$\theta_i^{TV} = f_{ML}(W, b, C_{xi}) \; \forall\, i = 0 \; to \; N \tag{27}$$

$$\theta_{TIV} \geq 0, \; W, b \subset [-1, 1] \tag{28}$$

$f_{ML}$ represents the ANN whose weights and biases ($W$ & $b$) are used to model the physics of the $\theta^{TV}$. The sequential hybrid modelling structure ignores the second equality constrain shown in Eq. (27) which captures the relationship between the time variant parameter and the ML model. Note that both the integrated and sequential method has hyperparameters which need to be tuned. For the phenomenological, integrated and sequential scenarios, the IPOPT multistart solver with fifty different initializations is used to solve the Pyomo DAE formulation [5].

## Black box model construction

The black box model is constructed using an ANN surrogate. The model inputs are the initial condition and time. A preprocessing step is performed where the inputs and outputs are scaled using a Z-score normalization. A rigours 5-fold cross validation and grid search is performed for tuning the hyperparameters of the system. The activation function, the number of hidden layers, the number of nodes, and the strength of the L2 regularization are all varied.

$$\left(X_t^t, C_g^t, C_m^t, C_c^t\right) = ANN\left(X_t^0, C_g^0, C_m^0, C_c^0, t\right) \tag{29}$$

## Extrapolative performance comparison

The initial data is generated by performing a Latin hypercube sampling of three initial conditions in the following ranges of initial glucose and catechol concentration: [50 mM, 70 mM] and [25 mM, 35 mM] with a constant total biomass concentration of 0.01 OD600. The performance of all models is evaluated utilizing an initial condition extrapolation for a fed-batch bioprocess. Note how in the training data the spike inputs are set to zero, however for the performance testing the spike inputs are respectively set to 10 mM and 3 mM for glucose and catechol with a time-period of 25 hrs. In the extrapolative scenarios, the glucose and catechol initial concentrations are varied from [20 mM, 100 mM] and [5 mM, 55 mM], respectively. Heatmaps and distribution curves of $R^2$ values are generated to compare the performance of different models and highlight performance in edge-cases.

### Interpretability analysis

Utilizing the Captum software, the ANN growth rate in Eq. 17 is analyzed and some of the model behaviours are explained [6]. A primary attribution analysis called Integrated gradients (IG) analysis is performed which tells the contribution of each input to the output of the model. The higher the attribution scores the more the input contributes to the model output [6]. Positive attribution means the output increase with the increase of the input and vice versa [6]. The attribution is calculated utilizing an integrated gradients technique.

### Improved hybrid model

Based on some insight from the ML interpretability analysis, new physical insights are integrated into the hybrid model to improve its overall performance. The physical insight added to the hybrid model is the Monod-kinetics relationship between biomass growth and glucose. The following ODE equations shown details the improved hybrid model. The improved hybrid model utilizes an ANN to model the fraction of viable biomass in the reactor. Equations 14, 15 are included in the improved hybrid model to track the dynamics of catechol and the spike input frequency.

$$\frac{dX_t}{dt} = \mu f_v X_t \tag{30}$$

$$f_v = ANN(X_t, C_g, C_c, C_m) \tag{31}$$

$$\mu = \left(\frac{\mu_g C_g}{C_g + k_g}\right) \tag{32}$$

$$\frac{dC_g}{dt} = -\left(\frac{\mu}{Y_{xg}}\right) f_v X_t + C_g^{IN} f(t) \tag{33}$$

$$\frac{dC_m}{dt} = Y_{mx}(\mu + \beta) f_v X_t \frac{C_c}{C_c + k_cr} \tag{34}$$

## Results and Discussion

### Sequential vs Integrated hybrid modeling

The hyperparameter tuning for the integrated model is a 3-fold cross validation to determine the ANN architecture. The hyperparameter tuning for the sequential model consist of two-steps: (i) a 3-fold cross validation to determine the smoothing weight ($w_s$) and (ii) a 5-fold cross validation to determine the ANN architecture. To simplify the hyperparameter search, the MSE weight ($w_M$) is set to a constant of unity. The performance of the sequential model is highest at a smoothing weight of 10. Following this, a grid search is done to determine the ANN architecture by varying the activation function, number of layers and nodes and L2 regularization weight.

The integrated model outperforms the sequential one across all points of extrapolation despite negligible computational cost differences (Figure 3). The heatmap can be divided into three broad regions: (I) high glucose, (II) low-glucose and low-catechol, and (III) low-glucose and high-catechol. The integrated models performs better than the sequential model in region (I) and (III) but suffers in region (II). In fact, the integrated model performs its best predictive performance in region (I) given the strong effect of high glucose concentrations on the growth rate. However, in region (II) the low glucose compounded with low catechol concentrations decreases the fraction of viable biomass which decreases growth rate. The integrated model overestimates the growth rate in this region. These results agree with our ground truth model which has a stunted growth rate at low glucose and low catechol concentrations, thereby negatively affecting the biomass accumulation. The CPU seconds of the integrated and sequential models showed marginal differences, 1.53 s and 0.95 s, respectively. Overall, while the integrated approach has advantages in performance, its cost will increase as the size of the ANN increases.

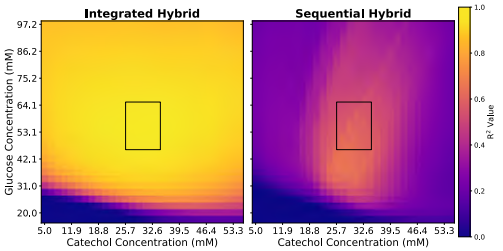

**Figure 3.** Extrapolative performance heatmap comparing the integrated and squential models.

### Hybrid model extrapolative performance

The previous section shows the performance of the integrated hybrid model to be better than the sequential hybrid one. Thus, the following sections will exclusively utilize the integrated hybrid model for comparison with the phenomenological and black box models.

On average, the hybrid model outperforms both the phenomenological and back box models in extrapolation

(Figure 4). The black box model had extremely poor extrapolative performance; while it captured the intricacies of the training data, it struggled to extrapolate the behaviour. The hybrid model outperforms the phenomeno-logical model in regions (I & III). However, it is extrapolative performance suffers slightly in regions (II) compared to its phenomenological counterpart, given that the latter has the physical insight which allows it to anticipate the contribution of catechol in low glucose environments.

Next, we sought to test versatility of the hybrid model. The glucose consumption in the ground truth model (Eq. 6) has two contributing terms: biomass growth and maintenance. The maintenance is tied to concentration of the catechol concentration. The hybrid model and the phenomenological model are formulated with the assumption that the maintenance term is not a huge contributor to glucose consumption. The versatility of the hybrid modelling structure is tested by increasing the contribution of the glucose consumption to match the growth-related glucose consumption. Despite the change in the physics of the ground truth model, Eq. 10-19 are not changed. The hybrid model still outperforms both the phenomenological and black box model in all the regions (Figure 5), showing that the versatility of the embedded ANN can capture the intricacies of the growth rate while also accounting for the additional strain of maintenance. The hybrid model's performance suffers in region (III); however, a trend observed to occur in the phenomenological model as well. The higher impact of catechol reduces the fraction of viable cells thereby overestimating the metabolic activity of the biomass to convert catechol into MA. This analysis demonstrates the flexibility of the integrated hybrid modelling structure to adapt to changes in the underlying physics of the system.

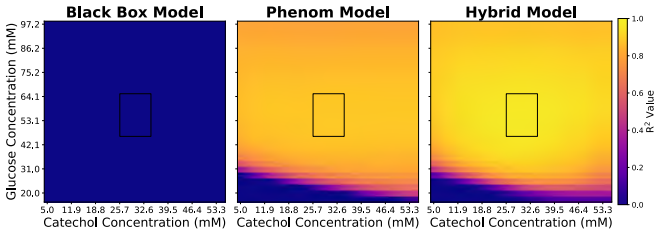

**Figure 4.** Extrapolative performance heatmap comparing the ML, phenomenological and hybrid models

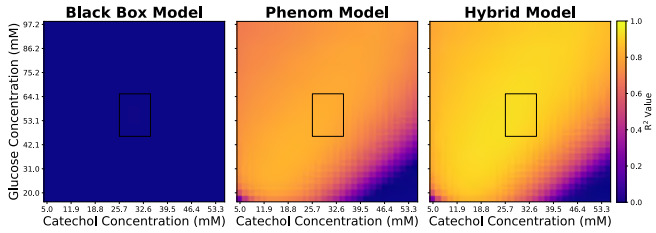

**Figure 5.** Extrapolative performance boxplot comparing the ML, phenomenological and hybrid models for greater contribution of maintenance coefficient effect on glucose

## Hybrid model interpretability

The hybrid model still has an embedded ANN piece within its structure and understanding the physics that is captured by the ANN component could aid in model refinement and experimental design. The bar graph shows the attribution score for the ANN component of the hybrid model. Note, the primary contributor to the model's predictive performance is the glucose and catechol concentrations. The glucose has a positive effect while catechol has a negative effect. This aligns with the physics that is present in the ground truth model. When we further analyze the attribution score of glucose as the concentration changes, further biophysical insights are caught. Fig. 6 looks at the glucose attribution score as the normalized glucose and catechol concentration changes. An important trend is how the attribution versus glucose plot mirrors the relationship between growth rate and substrate for Monod-style growth kinetics. Similarly note that catechol attribution score increases in magnitude as the concentration increases.

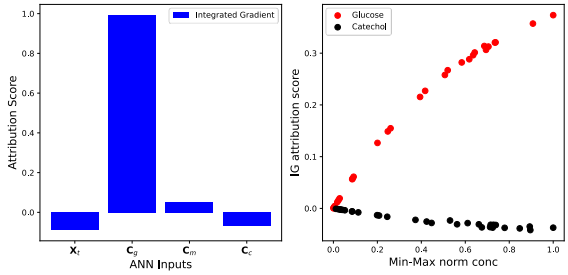

**Figure 6.** Primary attribution scores for the ML model in the hybrid ODE for training data. Model attribution score for changes in glucose and catechol concentration

The attribution score analysis presented above can function as first step in constructing more accurate empirical models to capture unexplained phenomenological behaviour. With the aid of the ML model interpretability, we could implement a build-train-improve cycle to incorporate and improve the physics captured by the hybrid model. We expect such an approach to be successful when the physics captured by the ANN is dominated by a single input. However, ANNs with multiple equally contributing inputs and multiple outputs might present difficulties to the interpretability analysis.

## Improved hybrid models with increased physics embedding

Based on the interpretability analysis, a Monod style relationship between glucose and growth rate is determined and incorporated into the improved hybrid model (Eq. 28-32). The improved hybrid model utilizes the ANN flexibility to capture the fraction of viable biomass in the system, which is the only entity metabolizing both glucose and catechol. Consequently, the aim of the

improved hybrid is capturing this fact even though only total biomass (viable plus dead cells) is used for training. As seen on the performance distributions plots below, the improved hybrid models outperformed the original hybrid model due to an increased accuracy in low-glucose high-catechol environments. The improved model performs better in regions where the original hybrid one struggles. Note the thinner and taller distribution peak of the improved model in high R2 value range. Since some burden is alleviated from the ANN component by incorporating learned physics insight, the black-box part of the improved hybrid model has less impact on the generalizability of the overall prediction. This two-step approach to hybrid modeling highlights how the black-box components, coupled by quantitative interpretability analysis could expedite model development. If important dynamics are not capture neither in the partial physics nor the data, the analysis might not lead to an improved hybrid model.

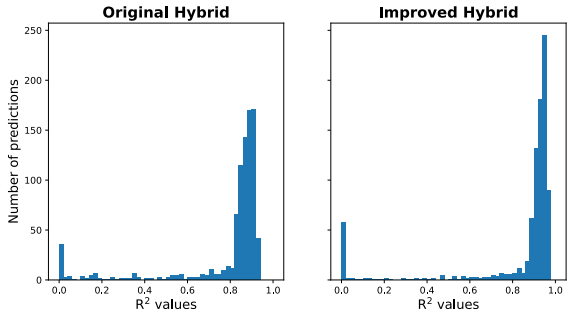

**Figure 7.** Extrapolative performance distributions for original hybrid and improved hybrid models.

## Conclusion

Here we outline the implementation of a hybrid modelling strategy to capture the dynamics of the bioconversion of catechol into MA, a bioplastics precursor. The biomass growth in the hybrid model is captured utilizing an ANN. A new hybrid model construction strategy is introduced which integrated the TVPE and the ML model training into a single step. The versatility, extrapolative capability, and sensitivity to initial conditions of the hybrid model is assessed by increasing the influence of various physical phenomena in the ground truth model. Our results show that the integrated hybrid model outperforms its sequential counterpart as well as commonly used phenomenological and ML models. An attribution analysis is performed to lend interpretability to the ANN piece of the hybrid model, revealing buried ground truth behaviour, which is then used to guide a model improvement cycle. The ultimate improved hybrid model reduced the computational load of the ANN by incorporating previously discovered biophysical insights.

## ABSTRACT

The use of metabolic networks is extremely valuable for design and optimisation of bioprocesses as they provide great insight into cellular metabolism. Within bioprocess optimisation, they have enabled better (economic) objective performance through more accurate network-based models. However, one of the drawbacks of using metabolic networks is their underdeterminacy, leading to non-unique flux distributions. Flux Balance Analysis (FBA) reduces this issue by making assumptions on the behaviour of the cell. However, for metabolic networks of higher complexity, can still struggle with underdeterminacy. Metabolic network reduction can remove or greatly reduce this effect but can be difficult, especially when data is limited. Structural analysis of the metabolic network through Elementary Flux Modes (EFM) or Extreme Pathways (EP) can help locate the relevant information within the network. This work presents a metabolic network reduction approach based on the EPs that best explain a small set of available measurements. Many of the reactions will not be active during the process and a significantly smaller network can therefore be constructed. A case study of oxygen-limited *Escherichia coli* is presented which showcases this approach, enabling accurate prediction of the process with much smaller network-based models. This leads to much lower complexity bioprocess models while keeping the necessary information on cellular metabolism for the given process.

## INTRODUCTION

Model-based optimisation of bioprocesses has already shown great potential, enabling higher return on economic objectives for a given process. In many optimisation studies, a macroscopic model is used which relies on kinetic expressions such as Haldane or Monod to quantify the dynamic evolution of (by-)product and substrate concentrations within the reactor. However, these types of models do not consider the complex interactions on the intracellular level, which has been shown to lead to poor predictive performance in a dynamic context [1].

The incorporation of intracellular information is possible through metabolic networks, which has led to significant improvements in objectives such as yield, productivity, and final concentration of product [2]. However, these studies rely on smaller, less complex metabolic networks as they require a high computational effort for the optimization study. Currently, many strains used for bioproduction have a genome-scale metabolic network (GEM) available, easily surpassing 1000 reactions. These GEMs are not suitable for the existing optimisation approaches, highlighting the need for reducing the complexity of the metabolic network, while ensuring minimal loss of key information regarding the bioprocess.

### Constraint-based modelling

The metabolic network can be represented through its stoichiometric matrix $\boldsymbol{S} \in \mathbb{R}^{m \times r}$, which links metabolites $m$ to the reactions $r$ they take part in. Analysis of metabolic networks usually relies on the constraint defined by the Pseudo-Steady-State-Assumption (PSSA):

$$\boldsymbol{S} \cdot \boldsymbol{v} = \boldsymbol{0} \tag{1}$$

This implies that there is no accumulation of metabolites within the network. The reaction rates or fluxes are then captured in vector $\boldsymbol{v}$. Constraint-based modelling techniques such as Flux Balance Analysis (FBA) are built

on this assumption. As $\boldsymbol{S}$ is not a full column rank, there is more than one possible solution for the network, making it an underdetermined system. Moreover, the solution space of the PSSA is usually high-dimensional, especially for large networks. Even with measurements to further constrain the solution space, many possible solutions will exist. This issue of underdeterminacy can be dealt with in many ways [3]. Ideally, the underdeterminacy should be eliminated or reduced significantly.

One way of dealing with the underdeterminacy is by assuming that the cell follows a specific metabolic target (e.g., maximising growth). Flux Balance Analysis or FBA solves an optimsation problem with the assumed objective. In many cases, this leads to good prediction of metabolic behaviour, but can still lead to non-unique solutions. Lexicographic optimization can ensure a unique solution but needs a priority list of metabolic objectives [4].

Metabolic Flux Analysis or MFA aims to estimate the fluxes based on only measurement data. For a dynamic MFA-based model, kinetic equations are used to describe some of the key fluxes. Nimmegeers et al. [5] used the concept of free fluxes, which are directly related to the degrees of freedom of the PSSA. For large metabolic networks, this leads to too many parameters to be estimated, especially when data is limited. Reducing the degrees of freedom while keeping the relevant information of the network is therefore key in this approach.

## Metabolic network reduction

Many metabolic network reduction approaches exist in literature, mainly focusing on retaining as much information as possible. Most of them can be described as a top-down or bottom-up approach. With top-down approaches [6,7], the full network is the starting point. With techniques such as Mixed-Integer Linear Programming (MILP), reactions are then iteratively removed. With bottom-up approaches [8], smaller subnetworks are the starting point, which are recombined to mimic the behaviour of the original network while maintaining a certain limit on the size of the network.

Alternatively, small macroscopic models can be constructed based on vectors characterising the solution space such as EPs and EFMs. Maton et al. [9] enumerated EFMs for a medium-scale metabolic network and selected the most informative ones. This leads to good reproduction of the experimental data and therefore a promising approach to analyse and model certain aspects of the metabolic network. Moreover, by selecting an upper bound on the number of EFMs, the degrees of freedom or free (macro-)fluxes can be directly controlled.

In this work, the potential of using characterising vectors is further investigated, evaluating how they can help reduce and extract relevant information from large metabolic networks. A relevant case study showcases the applicability of this method to model bioprocesses.

# MATERIALS AND METHODS

## Case study

A dFBA-based multi-scale model is used to simulate the oxygen-limited growth of *E. coli* on glucose in a batch reactor. The e_coli_core model [10] was used to estimate the fluxes in CobraPy throughout the process, applying bounds on the uptake fluxes through kinetic expressions. The dynamic model will consider 6 metabolites of interest: biomass, glucose, oxygen, acetate, formate, and ethanol. A term for the oxygen transfer from the gas phase to the liquid is incorporated, using a mass transfer coefficient of $k_L a = 7.5\ hr^{-1}$ [11]. The model can then be described as:

$$\frac{dC_X}{dt} = v_X \cdot X \tag{2}$$

$$\frac{dC_{glc}}{dt} = v_{glc} \cdot X \tag{3}$$

$$\frac{dC_{O_2}}{dt} = v_{O_2} \cdot X + k_L a(0.21 - C_{O_2}) \tag{4}$$

$$\frac{dC_{ac}}{dt} = v_{ac} \cdot X \tag{5}$$

$$\frac{dC_{for}}{dt} = v_{for} \cdot X \tag{6}$$

$$\frac{dC_{eth}}{dt} = v_{eth} \cdot X \tag{7}$$

The extracellular fluxes corresponding to the metabolites of interest are obtained from FBA at each timestep. The bound on the glucose uptake rate $v_{glc}$ was defined by Monod kinetics based on the glucose concentration $C_{glc}$ as follows [12]:

$$0 \geq v_{glc} \geq -10\frac{C_{glc}}{\mathbf{5.55}+C_{glc}} \tag{8}$$

The system of ODEs is then passed to SciPy's solve_ivp function, together with the initial conditions $\boldsymbol{C}_0 = [0.01\frac{g}{L}, \frac{20}{180}mM,\ 0.21\ mM, 0.4\ mM, 0\ mM, 0\ mM]$. Simulation was done on a virtual machine with a Intel(R) Core(TM) i5-1235U processor and 8GB of RAM available. The dFBA simulation ran in 133 seconds. For the e_coli_core [10] network, all the EPs are enumerated using an accelerated version of Canonical Basis Approach [13] developed in Mores et al. [14].

## Selection procedure

Given that the number of EPs is usually quite large, efficient procedures have to be developed to select the most informative EPs for the process. In this work, a two-step approach is presented. First, a preselection step based on yield is carried out to get a more manageable number of EPs. This is followed by an iterative routine based on optimization problems to find the final set of EPs to be used to create smaller biological models.

### Preselection based on yield analysis

Since not all EPs carry relevant information regarding the case study, a preselection is carried out to reduce the large number of EPs to a more manageable size. With yield analysis [15], the EPs are projected into yield space. The metabolites are split into products and substrates, which is used to define the yields of each EP. From the metabolites of interest in the case study, glucose and oxygen are the only substrates. As specified in Ramkrishna, a reference substrate is chosen (glucose) and the other substrates are given a minus sign. Within this yield space, a convex hull is constructed for the set of EPs. The points that define this convex hull encompass and therefore be able to describe the experimental data.

### Final EP set selection

After a significant reduction of candidate EPs through yield analysis preselection, different optimization problems will be defined to aid in selection the most informative EPs regarding a dataset. These optimization problems are based on minimization of error to the measurement, defined as follows [9]:

$$SSE = \sum_{k=1}^{met_i} (\boldsymbol{EP}_k \cdot \varphi - \boldsymbol{v}_{obs,k}) \boldsymbol{W}^{-1} (\boldsymbol{EP}_k \cdot \varphi - \boldsymbol{v}_{obs,k})^T, \quad (9)$$

where $\varphi$ corresponds to the macro flux vector of the extreme pathways, $\boldsymbol{v}_{obs}$ corresponds to the measured extracellular flux, and $\boldsymbol{W}$ corresponds to a diagonal matrix of weights defined by $(v_{obs,k})^2$, the maximum flux for each measured exchange reaction.

First, an initial sweep is done over the set of EPs where one EP is has its macro flux set to zero. If disabling an EP this way leads to an insignificant change to the $SSE$ resulting from the optimization, the EP is considered to not carry relevant information regarding the process and therefore is removed. Important to note is that the order of this initial sweep does have an influence on the result. Here we sweep stochastically.

To get the final selection of EPs, the worst performing EP will be removed iteratively until a desired set size is achieved. Every iteration, each remaining EP is set to inactive separately and the $SSE$ is re-evaluated. The EP whose inactivation leads to the best score is then selected for removal as it is the current worst performer.

## Model reduction approaches

To reduce the network-based model, two approaches will be used. Based on the results from EP selection, models are created by either considering the EPs separately or by reconstructing a network based on the active reactions in the selected EPs.

### Reduced network model

Since the EPs selected are the most informative pathways for the given process, they contain the most valuable, informative reactions. By reconstructing a network based on the reactions active in the set of EPs, a small network is created which focuses on relevant aspects of the metabolism. Direction of the reactions in the EPs is also considered, making reversible reactions with only one relevant direction irreversible. One of the benefits of using EPs here is that the pathways remain feasible since the EPs are minimal steady-state solutions of the system. This means that the reduced network still allows for techniques such as FBA to be performed.

### Macro-reaction model

Alternatively, the EPs themselves can be used as a model substituting for the metabolic network. This approach is similar to Maton et al. [9], where the macro-fluxes for the most informative EPs is used to model the process. Simulating with this model is done by maximization of the biomass output, similar to FBA. However, here the macro-fluxes are manipulated to achieve the objective instead of the individual fluxes of each reaction.

## RESULTS

Using the model described by Equations 2-8, a dataset is obtained for oxygen-limited *E. coli*. The dataset consists of 74 datapoints over a 15 hour time period. To account for ATP when selecting EPs, the minimal ATP requirement is added to each timepoint as an additional state. From this concentration data, the fluxes per individual cell were isolated by dividing the concentrations by the biomass.

### Extreme Pathway generation

Based on the e_coli_core network, the full set of EPs is generated using the CBA method as described previously. The final set consists of 100,235 EPs, which is too large to start applying the LP-based selection. Hence, a preselection step is done based on yield analysis. Afterwards, LP-based selection is done to try and reduce the EP set below the number of measured metabolites [9], in this case less than 7 since ATP is included as an additional metabolite.

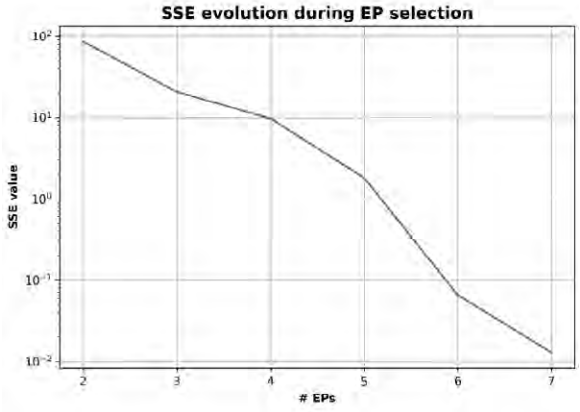

**Figure 1.** SSE scores during the final selection procedure

## Preselection

Preselection of EPs is done based on yield analysis, with glucose selected as the reference substrate for the process and all other metabolites from the process model as the products. In the yield space, a convex hull is then constructed, whose points should be able to fully represent the dataset generated from FBA. The EPs kept after preselection are then those who correspond to the vertices of the convex hull in yield space. This leads to a significant reduction of EPs, with only 113 EPs remaining.

## LP-based selection

A first sweep aims to eliminate the least informative EPs. The order of EPs is first randomized as the order does influence the selection results to try and reduce the bias towards some EPs. The threshold for significance is set at an SSE difference of 0.001. When an EP's removal leads to this level of decline in the SSE score, it is kept. This first sweep reduces the EP set to just 8 significant EPs. However, the goal is to have less than 7 EPs. Therefore, EPs are iteratively removed based on the worst-performer as described previously. SSE values are shown throughout this iterative reduction of EPs in Figure 1. Based on the trade-off between complexity and accuracy, a decision then has to be made on how many EPs to keep. In this work, 5 EPs are selected as it is below the threshold of 7 while keeping relatively good SSE values.

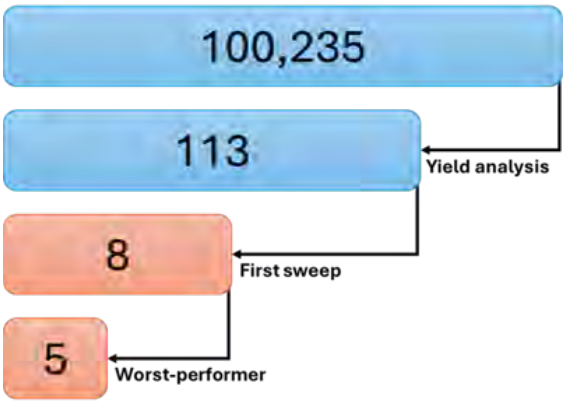

**Figure 2.** Evolution of EP set sizes with each reduction step. Blue indicates the yield analysis method, red indicates the LP-based reduction.

## Reduced Network Model

Important reactions for the process can be found by analysing the remaining EPs. Each reaction that does not take part in any of the remaining EPs is not needed to reproduce the observed metabolic behaviour. Therefore, these reactions can be seen as less important and can be removed from the network. This already reduces the complexity of the network significantly, but considering reversibility enhances this even more. If only one direction of a reversible reaction is present in the EPs, it can be converted within the network-based model to an irreversible reaction in the relevant direction for the process.

When this principle is applied to the remaining EPs, the network is reduced from 95 reactions to 60. From these remaining reactions, 25 are converted from reversible to irreversible in the relevant direction. When purely considering the number of reactions, this does not seem like a significant reduction. However, as discussed previously, the target for the reduction in this work is more aimed towards a reduction in free fluxes. The complexity of this reduced network is significantly smaller, needing only 6 free fluxes to be estimated instead of the original 28.

To validate if this reduced network is still capable of representing the same metabolic behaviour as the full network, dFBA is also applied to the reduced network with the same initial conditions. Even though the complexity of the network is reduced significantly, dFBA on the reduced network lead to a perfect reconstruction of the original dataset. This highlights the potential of this targeted network reduction approach with limited process information requirements, which can help reduce computational effort and data requirements for estimation of a network-based bioprocess model.

## Macro-reaction model

By using the EPs remaining as macro-reactions, another type of reduced model can be derived. Since there are 5 EPs as was selected, 5 macro-fluxes have to be estimated. The complexity of this network is thus even smaller than the reduced network approach since only 5 macro-fluxes must estimated instead of the previously discussed 6 free fluxes.

By using the same principle of biomass maximization using the 5 EPs as individual macro-reactions with the available uptakes of glucose and oxygen, metabolic behaviour can be approximated. Using the same initial conditions and kinetic equations as the original dataset, very similar metabolic behaviour can be observed throughout the process. Only very minor differences can be observed between the results of the macro-reaction model and the original network-based model as can be seen in Figure 3. Compared to the network-based models, the simulation time is reduced significantly, from 133 seconds to just 16 seconds.

# CONCLUSION

In this work, new approaches were developed to reduce metabolic networks when a limited amount of information is available. Using extracellular measurements, relevant aspects of the network can be identified and kept in the reduced network by employing static analysis of the network through Extreme Pathways. A relevant case study was defined, where extracellular measure-

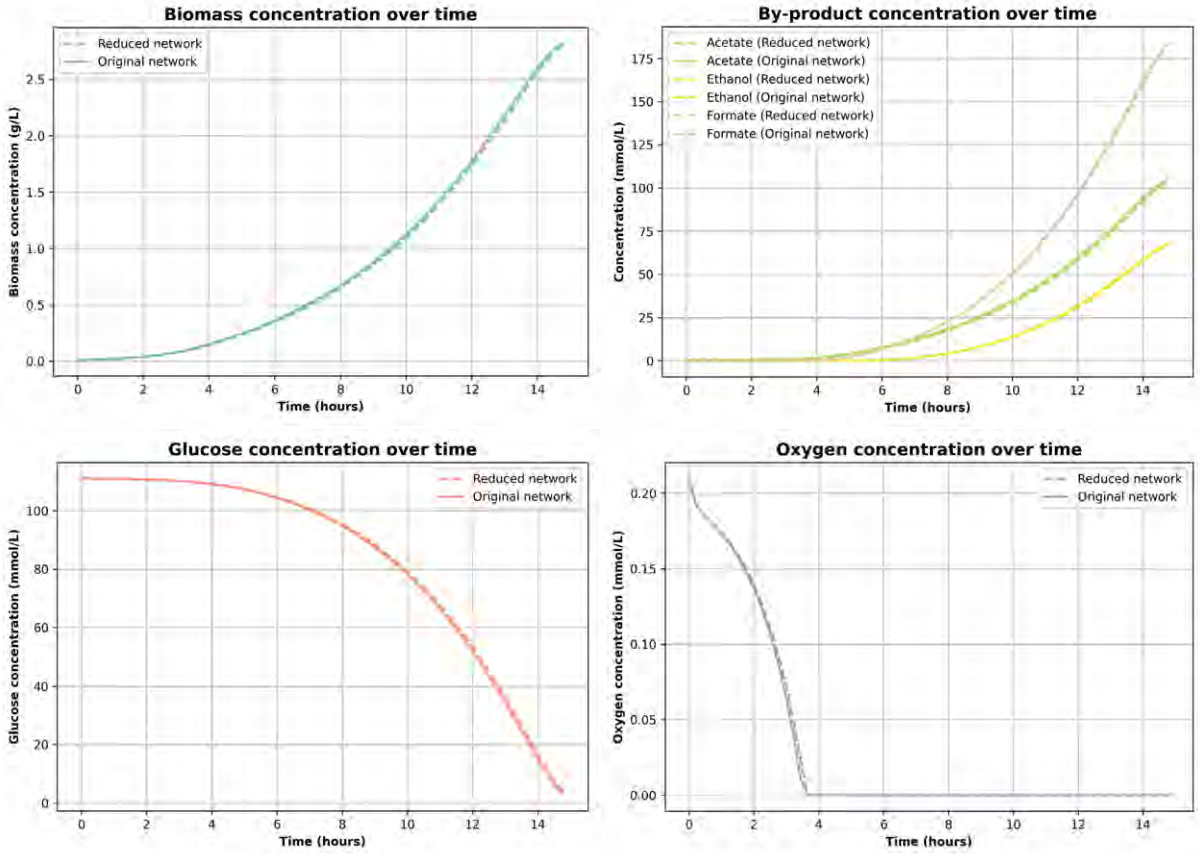

**Figure 3:** Reactor concentration profiles over the duration of the process. Solid lines are obtained using the full network-based model in CobraPy, dashed lines are obtained by finding the optimal macro-fluxes for the selected EPs every timestep.

ments were substituted through simulation based on a metabolic network of *E. coli.* Even though the network used is relatively small, it still suffers from the effects of underdeterminacy. In total, 26 free fluxes have to be estimated either through measurements or by making assumptions such as FBA objective functions. Many previous studies have focused on reducing the network to a minimal number of reactions, but free fluxes or degrees of freedom give a better idea of the complexity of the network. Analysis of the metabolic network is done through EPs, which are valid pathways through the network and adhere to the Pseudo-Steady-State-Assumption. The total EP set is very large, necessitating a preselection step based on the concept of yield analysis [15]. The remaining 113 EPs are then evaluated based on their ability to reproduce the measured metabolic behaviour of oxygen-limited *E. coli* and the 5 most informative EPs are finally selected to be used for model reduction.

Two model reduction approaches are defined and implemented for the case study. The first one reconstructs a network based on the active reactions in the 5 selected EPs. If a reversible reaction is only active in a single direction, it is transformed into an irreversible reaction in the relevant direction. This leads to a much less complex metabolic network, reducing the free fluxes from 28 to just 6 while keeping identical behaviour in the case study.

A second approach substitutes the network by the 5 EPs as macro-reactions themselves. Instead of estimating all intracellular fluxes, only 5 macro-fluxes then have to be estimated instead of the 28 free fluxes. Using this approach, only a small difference is found within the case study between the full network and the macro-reaction model while complexity is reduced significantly.

The results in this work indicate that analysis of metabolic networks through extreme rays such as EPs aids significantly in understanding and finding the relevant aspects of metabolism in a network given a limited amount of information on the process. Significantly reduced models can be created successfully using the most relevant EPs while keeping accurate metabolic behaviour. This leads to a much less complex estimation of the fluxes, potentially requiring much less data to get quality bioprocess models.

## ABSTRACT

Renewable energy and energy efficiency are increasingly recognised as crucial for creating new economic opportunities and mitigating environmental impacts. Anaerobic digestion (AD) transforms organic materials into a clean, renewable energy source. Co-digestion of various organic wastes and energy crops addresses the disadvantages of single-substrate digestion, increasing production flexibility yet adding process complexity and sensitivity. This study employs a two-pronged approach to optimise biogas production while considering global warming potential: a nonlinear programming (NLP) model for dynamic system economic optimisation with a model predictive control (MPC) strategy for precise temperature regulation within the digester. The NLP model integrates a combined heat and power (CHP) system to leverage dynamic electricity, heat, and gas prices, accounting for physical and economic parameters such as biomethane potential, chemical oxygen demand, and substrate density. A cardinal temperature and pH model ensures accurate depiction of substrate degradation and gas production rates under varying conditions. The MPC scheme, formulated as a system of differential-algebraic equations, offers fine-grained temperature control, capturing real-world complexities like heating/cooling delays, ambient conditions, and multiple feed components with different optimal digestion temperatures. Results demonstrate that this integrated model optimises the interaction between electricity production, biogas generation, and CHP operation for real-time multi-objective optimisation of profit, global warming potential and temperature control. A case study validates the model's capability for guiding decision-making in biogas facilities, emphasising strategic feedstock management and precise temperature control. Overall, this integrated approach advances the modelling and control of anaerobic co-digestion systems, enhancing both efficiency and profitability in biogas production.

## INTRODUCTION

In addition to reducing carbon emissions, renewable energy sources lessen dependency on fossil fuels[1]. Anaerobic digestion (AD) is a well-established and reliable method to convert organic feedstocks into clean energy. However, single-substrate digestion often limits operational flexibility and productivity [2]. Co-digestion—processing multiple substrates, such as organic waste and energy crops, simultaneously can significantly enhance biogas yields by leveraging the complementary characteristics of diverse feedstocks [3]. Despite these advantages, co-digestion introduces greater process complexity, increasing sensitivity to variables such as substrate composition, retention times, temperature control, and microbial balance [4]. These interdependent factors influence microbial growth, digestion kinetics, and, ultimately, system efficiency.

Optimising co-digestion processes therefore requires innovative solutions that integrate both the physical and economic dimensions of AD systems. A range of control strategies has been developed for AD; however, few of these strategies are deployed in industry due to the variability in waste characteristics and operating conditions [5]. Classical PID controllers, fuzzy logic expert systems, and neural networks are among the most common approaches, targeting controlled variables such as methane flow rate, pH, and chemical oxygen demand (COD). Moreover, several researchers have explored using model predictive control (MPC) in AD[6], motivated by its capability to handle multivariable processes with constraints. Despite this progress, predictive control in AD remains challenging due to the nonlinear, and the uncertain nature of the biochemical processes, which involve numerous microbial populations. These complexities are amplified in co-digestion systems because of the diverse range of substrates being processed simultaneously[7].

Recognising temperature as a crucial operational factor, particularly for mesophilic AD, this study applies MPC to regulate digester temperature, while simultaneously considering optimal feeding and gas processing strategy. Temperature exerts a direct influence on microbial activity and reaction rates, making its precise control pivotal for stable and efficient biogas production. While earlier work has addressed MPC for single-substrate AD, to the best of our knowledge, this is the first application of predictive control in an agricultural co-digestion context. By addressing both the inherent process complexity and the added challenges introduced by multiple substrates, MPC offers a promising avenue to improve the robustness and performance of AD systems under real-world operating conditions. In parallel with the challenges of process control, fluctuating energy prices underscore the need for strategic operational decisions in AD. Currently, studies often focus on isolated variables—such as temperature regulation—without capturing the interplay between feedstock availability, and market conditions. Without predictive insights into market trends, operators risk missing opportunities to maximise profitability and reduce operational risks [8].

Accordingly, this study proposes an integrated framework that combines dynamic optimisation, precise temperature management, and advanced price forecasting to enhance co-digestion-based AD systems. First, a nonlinear programming (NLP) model is formulated to optimise resource allocation and operational decisions, considering factors such as feedstock mix, digester capacity, and cost constraints. Second, a model predictive control (MPC) scheme ensures tight temperature management, accounting for real-world dynamics and uncertainties. Third, the Facebook Prophet model is used to forecast energy prices over time, enabling informed, data-driven decisions about biogas injection and energy generation. This model was selected due to its proven effectiveness in tackling complex market-related time-series forecasting challenges [9]. By synchronising these components, the framework aims to maximise production flexibility, profitability, and sustainability, addressing the growing demand for efficient, low environmental impact renewable energy solutions.

## METHODOLOGY

This study presents an integrated framework that combines dynamic real-time process optimisation, MPC, and energy price forecasting to enhance both the sustainability and economic viability of biogas production in AD systems. Figure 1 outlines the principal components of this approach: feedstock management, AD, energy generation, and product utilisation. Feedstock (e.g., maize and manure) is collected from harvesting sites and farms, where it can either be stored for later use or fed directly into the digester. The produced biogas follows two possible pathways: (1) injection into the gas grid following $CO_2$ removal, or (2) utilisation as a fuel source for CHP units. The residual digestate is employed as an organic fertilizer, further closing the loop on waste management.

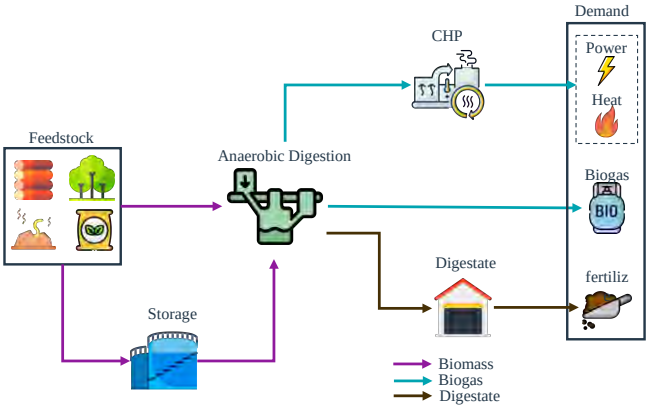

**Figure 1.** Superstructure of proposed model

To optimise resource utilisation and operational efficiency, an NLP model is formulated with a multi-objective function:

$$Max[Z] = \omega_1 Profit - \omega_2 GWP - \omega_3 Penalty_{MPC}\,, \sum \omega_i = 1 \quad (1)$$

Here, $Profit$ presents total profit of the AD process over the prediction horizon including profit of selling biogas and electricity and production costs; $GWP$ is the overall global warming potential (GWP) of the process that is calculated by summation of the greenhouse gas emissions from cultivation, transport, CHP operation and, biogas leakage [10]; and $Penalty_{MPC}$ penalises temperature deviations from the optimal range. The weighting

factors $\omega_i$ allow for customising the balance between maximising biogas output, minimising costs, and maintaining stable operating conditions. Physical and economic constraints, such as biomethane potential, chemical oxygen demand, and substrate density, ensure robust substrate utilisation and system performance.

A key innovation of this work is the incorporation of an advanced MPC scheme to regulate the digester temperature. By predicting future disturbances over a defined time horizon, the MPC dynamically adjusts heating ($Q_{heating}$) and cooling ($Q_{cooling}$) inputs to maintain optimal microbial activity. The thermal balance is captured by the following equation, which includes heating, direct thermal losses, cooling, and feed-related heat terms without delay for $Q_{loss}$ and $Q_{feed}$:

$$M_{digester}.\frac{C_p dT_{digester}}{dt} = Q_{heating}^{delayed} - Q_{loss} - Q_{cooling}^{delayed} + Q_{feed,}, \quad (2)$$

where $M_{digester}$ and $C_p$ are mass of the digester contents and specific heat capacity, respectively. To account for realistic response times, the control inputs for heating and cooling are represented by delayed states. These delays are modeled dynamically using first-order delay equations $\frac{dQ^{delayed}}{dt} = \frac{Q - Q^{delayed}}{\tau_{delay}}$. The parameter $\tau_{delay}$ represents the characteristic time constant for the delay associated with each process. Physically, it accounts for the lag in system responses due to the time required for heating elements, cooling mechanisms, or fluid dynamics to affect the digester temperature. By incorporating $\tau_{delay}$, the model ensures that control actions better reflect real-world system dynamics, improving the accuracy and robustness of the MPC.

The digester mass balance is expressed as: $\frac{dM}{dt} = f_{in} - f_{out}$, subject to a capacity constraint $M \leq \rho V_{dg}$. Here $f_{in}$, $f_{out}$, $\rho$, and $V_{dg}$ are the flows of input and output, density of feedstock and volume of digester, respectively. The inflow rate is determined by summing mass contributions of substrate and water content, whereas the outflow depends on a smooth step function governed by hydraulic retention time. This combination of material and energy balance constraints enables the MPC to maintain the digester temperature near an ideal setpoint, thus preserving optimal microbial activity and stabilising biogas output.

To accurately model microbial activity and biogas production over time, the study incorporates a cardinal temperature model (CTM) model [11]. This involves defining constraints for the specific growth rate for substrate *j* at time *t* ($\mu_{j,t}^{T}$) and biogas production:

$$\mu_{j,t}^{T} = \frac{\mu_j^{opt}(T_t - T_{max,j})(T_t - T_{min,j})^2}{(T_{opt,j} - T_{min,j})[(T_{opt,j} - T_{min,j})(T_t - T_{opt,j}) - (T_t - T_{opt,j})(T_{opt,j} + T_{min,j} - 2T_t)]} \quad (3)$$

where $\mu_j^{opt}$ is the optimal growth rate, $T_t$ is the digester temperature, $T_{min,j}$, $T_{max,j}$, and $T_{opt,j}$ are the minimum, maximum, and optimal temperatures for each substrate, and $\mu_j^{opt}$ is the optimal growth rate. By using $\mu_{j,t}^{T}$, the superimposed first order model [12] was used to predict the maximum biomethane production in time (, $P_t$):

$$BP_t = \left(\sum_{j,\tau} \frac{AV_{t,j}}{\sum_j AV_{t,j}}\right) BMP_j e^{1-\mu_{j,t}^{T}(t-\tau)}, \quad (4)$$

where $AV_{t,j}$ is the available substrate for species *j* at time *t*, and $BMP_j$ is the biomethane potential of species *j*. Here, $\tau$ is the time when substrate *j* is added, and ($t-\tau$) is the elapsed degradation time since its introduction into the digester. In addition to temperature constraints, other factors such as the carbon-to-nitrogen (C/N) ratio and total solids (TS) content are integrated into the model as constraints to maintain feasible operation within industrially relevant bands. These parameters also affect microbial activity and are thus accounted for in calculating overall biogas production, ensuring a more comprehensive and accurate representation of the AD process.

Future energy price forecasting is integral to optimising operational decisions, particularly concerning the timing of biogas injection into the grid versus CHP utilisation for electricity production. In this study, the Prophet model is used to predict electricity prices based on historical data, seasonal factors, and longer-term trends. Formally, Facebook Prophet can be represented as [13]:

$$y(t) = g(t) + s(t) + h(t) + \epsilon_t, \quad (3)$$

where $g(t)$ captures the piecewise linear or logistic trend, $s(t)$ represents seasonality, $h(t)$ accounts for holiday or special event effects, and $\epsilon_t$ is an error term. To refine forecasting accuracy, Bayesian optimisation is conducted over key hyperparameters—such as the changepoint prior scale, seasonality prior scale, and changepoint range—using a rolling-window cross-validation approach. The root mean square error (RMSE) is used to evaluate each parameter set; if no improvement is observed after multiple iterations, the search terminates early.

Once the optimal hyperparameters are identified, the final Prophet model is retrained on a rolling basis to produce accurate forecasts for the upcoming months. These forecasts guide strategic decisions, enabling operators to schedule biogas injection or CHP production during periods of favourable energy prices. By aligning operational activities with real-time market signals, the proposed methodology maximises revenues, promotes energy self-sufficiency, and supports environmental sustainability within biogas-based systems.

## Case Study

To demonstrate the performance of the model, we selected as case study a farm-scale AD plant with a digester capacity of 7,000 m³, designed to process energy crop maize and manures. The feeding rate is constrained

by a solid retention time (SRT) of 90 days, with the maximum total solids content of the digester feed limited to 35 %. All specified capacities and feed information are adapted from real site data provided by industrial partners with some changes to feed costs. The estimated parameters in equation (3) is presented in Table 1 [14], [15]:

**Table 2.** Cardinal temperature model parameters

| | $T_{min}$ (C) | $T_{opt}$ (C) | $T_{max}$ (C) | $\mu^{opt}$ (1/d) |
|---|---|---|---|---|
| Maize | -1.27 | 37.26 | 45.12 | 2.63 |
| Manure | 3.60 | 41.10 | 45.06 | 1.29 |

In an hourly timestep with a nine-day prediction horizon, electricity and gas price data were obtained from the Office for National Statistics of the United Kingdom [16], [17]. The results in Figure 2 illustrate that the Prophet model captures key price trends for both electricity and gas, while uncertainty bands (shaded in blue) reflect forecast confidence. The forecasted prices (blue lines) track the observed values (black dots) reasonably well, indicating satisfactory predictive performance. Using a shorter horizon helps reduce computational complexity while still providing actionable price estimates for operational decision-making.

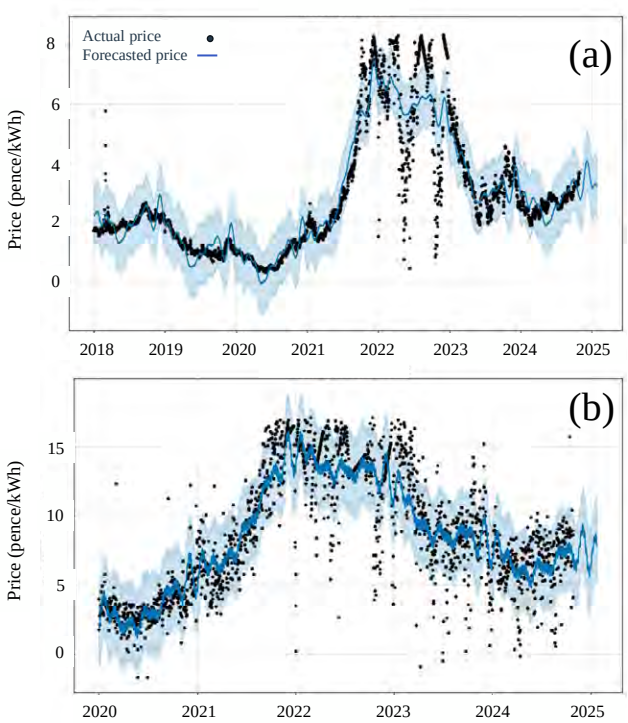

**Figure 2.** Historical data and forecasting performance for (a) gas price and (b) electricity prices.

## RESULTS AND DISCUSSION

The solutions of the case study were computed by implementing the proposed model in Pyomo — comprising 6,941 constraints (1,735 nonlinear) and 7,148 variables — and using the IPOPT solver, which effectively handles the non-linearities present in both the digester dynamics and the market-driven optimisation. The model was solved in 700 CPUs, demonstrating efficient computational performance given the problem's scale and complexity.

As depicted in Figure 3, the digester temperature tracks the ideal temperature setpoint with a small offset. Initially, the system demands a rapid increase in heating power (up to a maximum of 9000 W) to bring the digester from ambient conditions to near-optimal temperature, while significant heat losses occur due to the temperature gradient between the digester contents and the external environment. Given the higher cost of cooling, the maximum cooling power is limited to 900 W. Notably, an ambient temperature difference of about 20 °C was used to test the model's robustness under a challenging scenario. Once the system stabilises, the MPC strategy finely tunes both heating ($Q_{heating}^{delyaed}$) and cooling ($Q_{cooling}^{delyaed}$), ensuring close setpoint tracking. These observations affirm the efficacy of the delayed control action in sustaining microbial activity and preventing temperature overshoot. However, it is seen that the model does not always prioritise temperature control due to its weighting in the objective function being relatively low, leading to trade-offs in how the system balances temperature regulation against other operational goals.

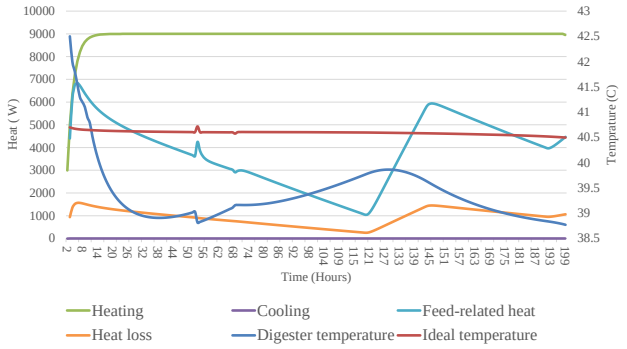

**Figure 3.** Performance of the proposed MPC.

As Figure 4 shows, electricity generation (blue bars) is presented alongside biogas sold to the grid (red line). The fluctuations in biogas sales are a result of real-time optimisation of feed rates and substrate compositions, driven by both technical constraints and market opportunities. During periods of higher electricity prices, the optimised solution diverts a greater proportion of biogas to the CHP unit, thereby maximising on-site power output for export. Conversely, when injecting gas into the grid proves more profitable, surplus biogas is channelled away from the CHP, underscoring the value of coupling accurate price forecasting with flexible production pathways.

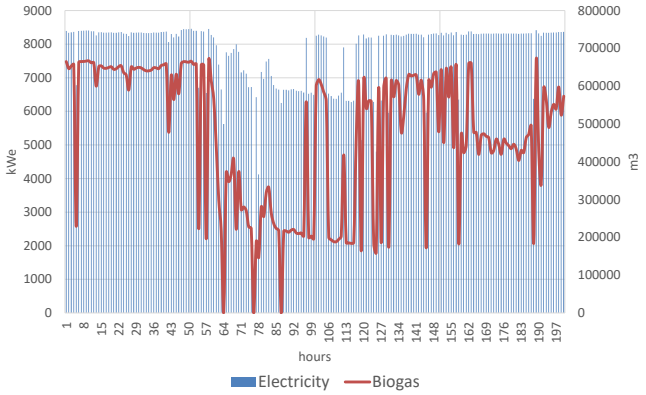

**Figure 4**. Optimal energy distribution by the process.

Figure 5 displays the co-digestion ratio shifts over time, with maize shown in blue and manure in red. By dynamically balancing these two substrates, the system exploits maize's higher biomethane potential while benefitting from manure's stabilizing influence on nutrient levels. Sudden changes in the substrate ratio frequently correlate with fluctuations in biogas yield, highlighting the intricate relationship between feedstock composition, microbial performance, and shifts in up- and down-stream pricing and feed availability. Overall, these results confirm that adaptively managing feed composition, temperature control, and energy allocation in response to real-time conditions can significantly enhance biogas production, ensure process stability, and optimise economic returns.

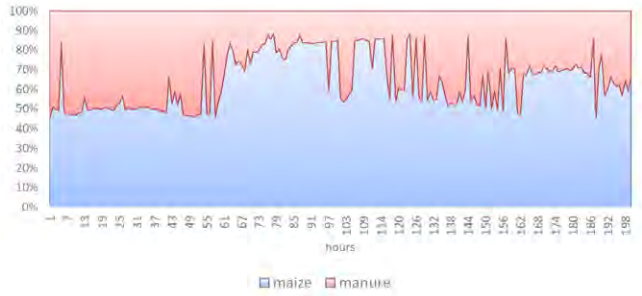

**Figure 5**. substrate co-digestion ratios in the process

Figure 6 shows four distinct contributions to GWP: substrate cultivation, transportation, CHP operation, and biogas leakage. Leakage, assumed to be 2% of biogas production[18], emerges as the predominant driver of GWP, highlighting the importance of robust sealing and monitoring to minimise fugitive methane emissions. The other three GWP components remain relatively modest, indicating that carefully managed process heating and CHP usage do not substantially elevate the plant's carbon footprint. Notably, periods with reduced gas leakage coincide with improved gas-tight integrity or targeted operational adjustments.

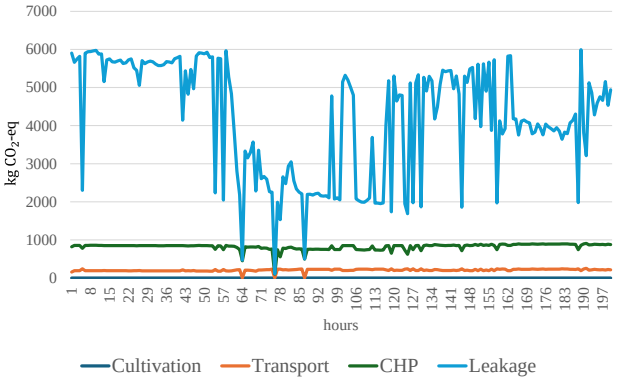

**Figure 6**. Global warming potential related to the process.

## CONCLUSION

This study demonstrates a comprehensive and synergistic approach to optimising anaerobic co-digestion systems by integrating an NLP model, temperature control via MPC, and advanced energy price forecasting. By leveraging the CHP unit and dynamic co-digestion strategies, the framework effectively adapts to varying substrate compositions, operational constraints, and fluctuating market conditions. The proposed delayed control scheme ensures tight temperature regulation, sustaining microbial activity near optimal levels and minimising the risk of thermal shocks. Additionally, the energy price forecasting component, based on the Prophet model, allows for strategic decisions on whether to allocate biogas to onsite electricity generation or injection into the grid, thereby maximising revenue streams.

Results indicate that co-digestion of maize and manure significantly enhances biogas yields while maintaining nutrient balance but also underscores the critical need to minimise methane leakage—the principal contributor to global warming potential. By identifying and mitigating fugitive emissions, operators can substantially reduce the environmental footprint of biogas production. Despite these advances, there remain avenues for improvement. Future work will focus on refining the biogas production model to capture higher fidelity microbial and kinetic responses with more accurate substrate interactions. In addition, efforts to decrease computational time—such as implementing advanced solution techniques or simplifying the problem structure—would make this framework more practical for larger-scale or real-time applications. Finally, exploring methods to remove certain nonlinear parameters could strengthen the model's scalability and facilitate adoption in a broader range of biogas facilities. By pursuing these improvements, the integrated approach stands to further enhance operational efficiency, profitability, and environmental sustainability in anaerobic co-digestion systems.

## ABSTRACT

The global reliance on fossil-based solvents has driven the search for sustainable alternatives. This study employs the IBSS® CAMD tool to evaluate building blocks derived, directly or indirectly, from agricultural residues - specifically orange and coffee wastes-, to replace toluene in furfural extraction. A three-stage methodology was implemented: (1) identification of potential building blocks from residues, (2) multi-objective optimization using genetic algorithms and group contribution models for properties calculation, and (3) analysis of the resulting candidates based on performance indicators. A total of 13 families were evaluated, generating millions of candidates. Target properties included minimization of Hansen Solubility Parameters (HSP) distance, boiling point above 250°C, melting point below 10°C, flash point above 61°C, and octanol-water partition coefficient (log(kow)) below 3. The most promising candidates were derivatives of glycerol (performance: 0.9986), limonene (0.9937), and furfural (0.9931), which exhibited low bioaccumulation potential, non-flammability, and liquid phases at typical usage temperatures. Notably, all the top-performing molecules derived from these building blocks outperformed toluene (performance: 0.6724) in terms of the selected properties. The findings highlight the dual benefits of addressing agricultural waste management challenges while advancing sustainable industrial practices. Further studies are required to confirm their stability and scalability for industrial applications.

## INTRODUCTION

Brazil has an outstanding agricultural production that reaches 94 million ha [1], which represents 11% of the nation's total territory. The country stands as the world's leading producer of several key commodities, including coffee and oranges. However, alongside such intensive production comes an increasing concern about the sustainable management of the vast amounts of agricultural waste generated throughout the supply chain [2].

In 2023, Brazil's coffee production reached 3.5 million metric tons [3], primarily through the dry processing method, where coffee cherries are dried immediately after harvest [4]. Notably, 90–99% of the fruit mass is classified as waste [5]. Also, in 2023, Brazil produced 18 million metric tons of orange, of which 72% [6] was destinated for orange juice production. During this process, 50–60% of the fruit mass becomes waste, primarily composed of seeds and peel [7].

Agricultural wastes from coffee and orange production are typically disposed in fields, repurposed as animal feed or incinerated [7]. These practices contribute to environmental impacts and these approaches overlook the significant potential of these residues. Rich in bioactive compounds, such as antioxidants and fibers, coffee and orange byproducts offer untapped opportunities for sustainable valorization [2].

The residues contain building blocks that can be extracted or produced from them and one that stands out is furfural. Furfural is produced via the dehydration of xylose, a sugar present in the hemicellulose fraction of

lignocellulosic biomass. It has a wide range of industrial applications, including the production of plastics, pharmaceuticals, agrochemical products, non-petroleum-derived chemicals and it is a precursor for various furan-based chemicals and feedstocks [8].

Although the synthesis of furfural dates to 1921, the process still faces challenges, including low efficiency (~50%) and high energy demands, especially when distillation is employed as a purification method. Therefore, liquid liquid extraction (LLE) appears as a possible purification method and the main solvent used is toluene, a fossil-based toxic solvent [9].

The procedure for solvent selection plays a crucial role in determining the efficiency and viability of the proposed new solvent. In this study, Computer Aided Molecular Design (CAMD) was chosen as an effective early-stage tool for discovering new molecules, which leverages the simplicity of semi-empirical quantitative structure-property relationships (QSPRs) in conjunction with genetic optimization algorithms [10].

An in-house CAMD tool called IBSS® was employed. This tool was developed in compliance with a model driven software engineering approach, and it is based on different analysis models (UML and BPMN) and object-oriented implementation models dedicated to Microsoft.NET framework (C# and VB.NET) [11]. IBSS® has been successfully applied in various contexts, such as identifying solvents for the perfume industry [12], developing greener solvents for photovoltaic panel production [13], and substituting hexane in metabolite extraction from biomass feedstock [14].

The objective of this work was to evaluate solvents derived from coffee and orange residues, to extract furfural from an aqueous solution with methanol and acetic acid, in substitution to toluene.

## METHODOLOGY AND PROBLEM FORMULATION

To accomplish the goal of finding a suitable bio-based solvent to replace toluene for furfural extraction, a three-stage methodology, depicted in Figure 1, was proposed based on the work of Heintz *et al.* [15].

### Molecular Fragments Literature Review

The first stage entailed a literature review to identify potential building blocks derived, directly or indirectly, from coffee and orange residues. From an initial pool of 46 building block families, 13 were selected for further evaluation: furoate, geranyl, glucaric acid, glutamic acid, hydroxymethylfurfural, hydroxypropionic acid, levulinic acid, limonene, 5-methylfurfural, oleic acid, succinic acid, glycerol, and furfural itself. Considering the derivatives from the abovementioned building block families, 103 different fixed fragments were analyzed.

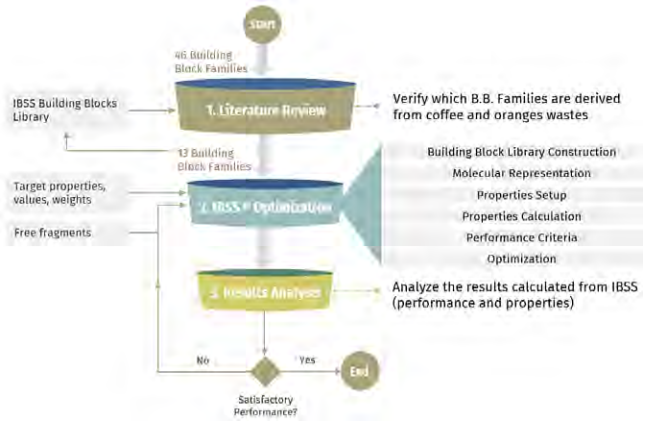

**Figure 1:** Methodology for solvent selection using IBSS® tool.

### IBSS® Optimization

The second stage corresponded to the IBSS® optimization, which involves essentially six key components: (1) building block library construction, (2) molecular representation, (3) properties setup, (4) properties calculation, (5) performance criteria for molecule evaluation, and (6) optimization [15]. The output consisted of a .txt file generated for the 200th generation of each fixed fragment studied, containing the calculated properties, performance metrics, and molecular graph structures of the individuals, ranked based on their performance.

#### Building block library construction

After the literature review, a preliminary verification was conducted to determine whether the molecules selected were already present in the IBSS® library. For those not included, new entries were created by assigning an ID, constructing the molecular graph, and defining functionalization points.

The newly fixed building blocks were drawn, and their SMILES representation were determined, which was entered in “evaluation mode” in the tool, to determine the molecular graph.

This process resulted in the creation of 7 new families of building blocks, comprising a total of 39 new fixed building blocks molecules.

#### Molecular representation

The selected molecular representation model is the molecular graph. In this representation, the diagonal elements represent non-hydrogen atoms, and the off-diagonal elements represent chemical connections. One of the implemented molecules is represented in Figure 2 as an example.

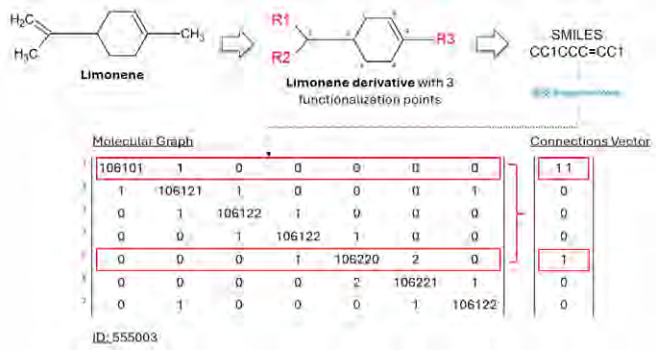

**Figure 2:** Molecular representation of Limonene.

## Properties set up

IBSS® tool allows users to specify the properties desired to calculate the performance, assigning their weights, target values, tolerances, and value of performance in the tolerance value.

The target properties chosen, detailed in Table 1, were defined based on the recommendations of Heintz *et al.* [15]. And the tolerance value reflects the confidence in the model prediction value, which can be assessed with help of the model accuracy and/or the property measurement standard deviation [16]. There were also included the standard deviation for the predictions.

The most critical property is the Hansen Solubility Parameter (HSP) distance, which accounts for three key interaction forces: D (London dispersion forces), P (dipole-dipole polarity interactions), and H (hydrogen bonding). The strategy was to minimize the HSP distance of the candidate molecules from furfural. To reflect practical considerations, the HSP distance between toluene and furfural (13.9) was set as the tolerance value, given that toluene is a viable solvent for furfural extraction.

For each configuration of fixed-building blocks and kmax (maximum number of fragments added in the fixed building block structure, varied from 4 to 8), a different input XML file was created. These files included the target properties (Table 1) and the variable fragments (-CH2-, -CH--, --C--, CH2=, -CH=, --C=, CH=-, -C=-, NH2-, -NH-, -N--, NH=, N=-, OH-, -O-, O=).

## Properties calculation

Using group contribution methods for property estimation, the tool is able to predict the melting point, boiling point and log(kow) with models developed by Hukkerikar *et al.* [16]; HSP distance with molecular breaking by Hiroshi Yamamoto [17] and flash point with a model created by Catoire, Paulmier and Naudet [18].

## Performance criteria for molecule evaluation

The performance of each candidate molecule is calculated from a performance function (Eq. 1), and it considers deviation of the predicted property values from their target values (Eq. 2).

$$Perf\ (MG_i) = \frac{\sum_{p=1}^{np} w_p.F_p.(MG_i)}{\sum_{p=1}^{np} w_p} \quad (1)$$

$$F_p(MG_i) = exp.\left[\ln(val).\left(\frac{P-x}{Tol}\right)^2\right] \quad (2)$$

In the equations, $Mg_i$ is the molecular graph, $Perf$ is the calculated performance, $n_p$ is the number of target properties, $F_p$ is the performance function, $w_p$ is the weight of property $p$, $Tol$ is the tolerance set, $x$ is the target value for property and $P$ is the property value.

## Optimization

The problem solved by IBSS® is a multi-objective optimization since multiple properties are considered in the performance equation. A genetic algorithm is used, which modifies the molecular graphs through mutation, crossover, deletion, and insertion. Newly generated molecules have their performance calculated and are ranked accordingly. The molecules with the best performance are selected for the next generation. The parameters of the genetic algorithm, presented in Table 2, were used in this study.

## Results Analysis

**Table 1:** Target properties setup.

| Property | Weight | Unit | Target | Tolerance | Cor. Perf.[1] | Justification | SD[2] | Ref. |
|---|---|---|---|---|---|---|---|---|
| HSP Distance | 3 | $MPa^{1/2}$ | 0 | 13.9 | 0.9 | Good solubility | - | [17] |
| Melting Point | 1 | °C | < 10 | 10 | 0.8 | Liquid at usage temperature | 21,45 K | [16] |
| Boiling Point | 1 | °C | >250 | 3 | 0.8 | Liquid at usage temperature | 7,67 K | [16] |
| Flash Point | 1 | °C | >61 | 3 | 0.8 | Non flammable | - | [18] |
| Log (Kow) | 1 | - | <3 | 0.8 | 0.8 | Low potential of bioaccumulation | 0,61 | [16] |

[1]Cor. Perf. = Corresponding Performance; [2]SD = Standard Deviation

The third stage involved an evaluation of the results to identify the most promising candidates. A total of 16 thousand molecules were generated in the final generations and more than 3 million properties were calculated throughout the study. The main results are presented below.

**Table 2:** Parameters of the genetic algorithm.

| Property | Value |
|---|---|
| Elitism | 5 |
| Population size | 100 |
| Number of generations | 200 |
| Crossover probability | 65% |
| Mutation probability | 15% |
| Insertion probability | 10% |
| Deletion probability | 10% |

## RESULTS

The computational exploration conducted using the IBSS® CAMD tool enabled the evaluation of millions of potential molecules, leading to the identification of promising alternatives to toluene for LLE of furfural. The best molecules for each fixed building block derived from orange and coffee wastes were ranked based on their performance and the outcome is presented in Table 3.

A set of alternative methods was tested for predicting properties: log(KoW), melting point and boiling points were predicted using a method by Marrero&Gani [19]; and HSP Distance was calculated using a method by Hukkerikar *et al.* [16]. The average variation in the calculated performances was 13%. This highlights the robustness of the property predictions, despite the inherent limitations of group contribution methods. Further analysis could explore how these variations impact the selection of candidate molecules in practical applications.

The results indicate that derivatives of glycerol, limonene, and furfural performed best. Nevertheless, 13 configurations exhibited high performances (above 0.9800), a promising outcome that suggests multiple alternative solvents worth exploring.

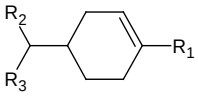
Toluene was evaluated in IBSS®, in evaluation mode, applying the same target properties outlined in Table 1. The calculated performance was 0.6724, lower than the performance of the generated molecules presented in Table 3. This low value is primally driven by the low flash point (8°C), low boiling point (116°C) and high HSP distance (13.9 $MPa^{1/2}$), indicating that the bio-based molecules generated have strong potential to serve as superior solvents for furfural extraction.

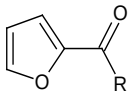
Analyzing the results in Table 3, it is not possible to establish a direct connection between number of radicals and performance, but it is noticed that for limonene, hydroxypropionic and glutamic acid, an increase in the number of functionalization points was positive to the performance and the opposite behavior was identified for glycerol, hydroxymethylfurfural, methylfurfural, geranyl and succinic acid.

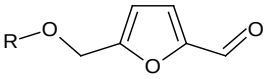
Also, it is observed that the biggest molecules, in general, did not score high performances. The average of non-hydrogen atoms for the molecules with performances greater than 0,9 was 14, while for the molecules with performances less than 0,9, it was 26.

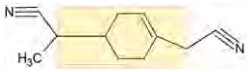
Three of the best 26 molecules presented in Table 3 were selected and their properties are detailed in Table 4. The values of the properties are highlighted in green if they meet the target value, or in blue if they don't meet the exact target but fall within the acceptable range defined by the target plus the tolerance.

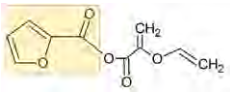
**Table 3:** Best molecules generated for each building block.

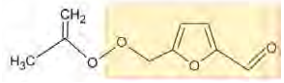












| Fixed Building Block (FP[2], Kmax) | B. P.[1] | Fixed Building Block (FP[2], Kmax) | B.P. |
|---|---|---|---|
| Glycerol (1, 8) | 0.9986 | Geranyl (2, 4) | 0.9817 |
| Glycerol (2, 4) | 0.9955 | Methylfurfural (2, 4) | 0.9810 |
| Limonene (3, 4) | 0.9937 | Glycerol (5, 6) | 0.8571 |
| Furfural (1, 8) | 0.9931 | Glutamic Acid (2, 5) | 0.8571 |
| Furoate (1, 7) | 0.9931 | HMF[4] (3, 5) | 0.8571 |
| Limonene (2, 4) | 0.9930 | Glutamic Acid (1, 7) | 0.8568 |
| HP[3] (3, 4) | 0.9925 | Succinic Acid (1, 8) | 0.8568 |
| HMF[4] (1, 4) | 0.9922 | Glycerol (3, 7) | 0.8567 |
| Levulinic Acid (1, 5) | 0.9914 | Succinic Acid (3, 5) | 0.8561 |
| HP[3] (2, 4) | 0.9913 | Glucaric Acid (6, 7) | 0.8552 |
| Succinic Acid (2, 6) | 0.9904 | Oleic Acid (2, 6) | 0.8550 |
| Glutamic Acid (4, 4) | 0.9883 | Glycerol (6, 6) | 0.8548 |
| Limonene (1, 7) | 0.9876 | Succinic Acid (4, 7) | 0.8541 |
| Methylfurfural (1, 5) | 0.9870 | Oleic Acid (1, 7) | 0.8510 |
| HMF[4] (2, 4) | 0.9848 | HP[3] (1, 7) | 0.8496 |
| Geranyl (1, 8) | 0.9843 | - | - |

[1]BP = best performance
[2]FP = functionalization points
[3]HP = hydroxypropionic
[4]HMF = hydroxymethylfurfural

In all three cases, the Hansen Solubility Parameter (HSP) distances were significantly smaller than the toluene-furfural distance of 13.9. Additionally, their melting and boiling points suggest that these solvents would remain liquid under ambient conditions and based on their flash point they are classified as non-flammable. Furthermore, their low log(Kow) values indicate minimal bioaccumulation concerns, supporting their suitability as sustainable solvent alternatives.

As shown in Figure 3, the maximum performance of the best molecule, derived from glycerol with one functionalization point, improved as generations progressed. This trend demonstrates the effectiveness of the genetic algorithm in identifying better-performing individuals across the tested generations. Furthermore, the results reveal that as kmax increases, the maximum

**Table 4:** Comparative analysis of molecules derived from limonene, furfural and hydroxymethylfurfural.

| Property | Limonene Derivative | Furfural Derivative | Hydroxymethylfurfural Derivative |
|---|---|---|---|
| Fixed building block structure |  |  |  |
| New molecule structure |  |  |  |
| Fixed building block | Limonene | Furfural | Hydroxymethylfurfural |
| Number of FP* | 3 | 1 | 1 |
| Kmax** | 4 | 8 | 4 |
| Performance | 0.9937 | 0.9931 | 0.9922 |
| Melting point (°C) | 11.95 | 10.09 | 10.06 |
| Boiling point (°C) | 304.99 | 286.48 | 264.69 |
| Flash point (°C) | 152.96 | 148.42 | 126.33 |

| Log (kow) | 1.92 | 0.66 | 1.06 |

*FP: functionalization point
**Kmax: maximum number of fragments allowed to be added in the fixed building block

performance also improves in this case, highlighting the algorithm's enhanced flexibility to create diverse molecular structures with higher potential.

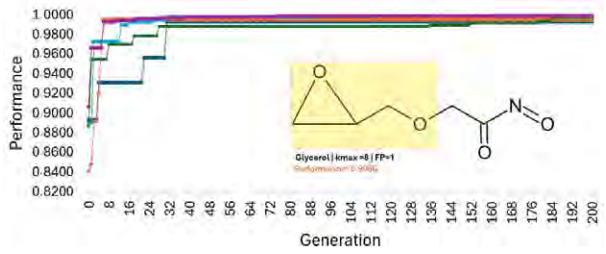

**Figure 3:** Performance evolution across generations for glycerol derivative with 1 functionalization point and representation of the best molecule generated.

From the list in Table 3, some molecules were selected and drawn based on the molecular graph provided as an output of IBSS®. These molecules are depicted in Figure 4. The chemical structures are diverse, and it is important to emphasize that further investigations are needed into process design, stability, and the viability of the proposed molecules. Nevertheless, this study highlights the potential of utilizing residues from high-demand fruits to design environmentally friendly solvents with superior performance characteristics.

## CONCLUSION AND NEXT STEPS

The results demonstrate that the IBSS® CAMD tool is an effective approach for designing bio-based solvents with specific properties to replace toluene in LLE of furfural from aqueous solutions. Through multi-objective optimization, alternative solvents were efficiently ranked based on a global performance value. For all the building blocks studied, molecules with enhanced desired properties compared to toluene were obtained, highlighting the derivatives of glycerol, limonene, and furfural itself. While this early-stage methodology shows significant promise, further studies are required to assess the stability and feasibility of synthesizing these molecules.

Nonetheless, those findings demonstrate a valuable pathway for developing alternative solvents derived from orange and coffee waste, offering a sustainable solution to reduce reliance on fossil-based solvents.

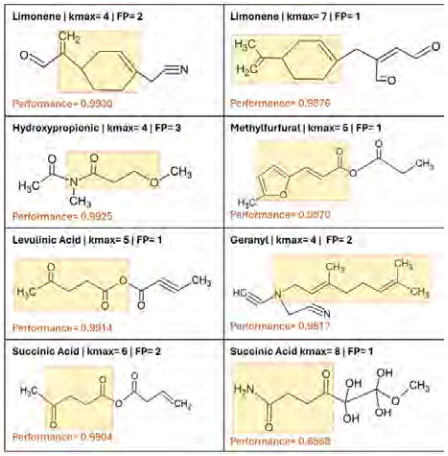

**Figure 4:** Molecular representation of molecules generated by IBSS®.

## ABSTRACT

Soybean is a highly valuable global commodity due to its versatility and numerous derivative products. During harvest, all non-seed materials become "straw". Currently, this waste is primarily used for low-value purposes such as animal feed, landfilling, and incineration. To address this, the present work proposes a conceptual biorefinery aimed at converting soybean straw into higher-value products. The study began with data collection to identify potential conversion routes. Based on this information, a superstructure was developed, comprising seven conversion routes: four thermochemical routes (pyrolysis, combustion, hydrothermal gasification, and liquefaction), two biological routes (fermentation and anaerobic fermentation), and one chemical route (alkaline extraction). Each process was evaluated based on product yields, conversion times, and associated capital and operating costs. Using this data, an MILP (Mixed-Integer Linear Programming) optimization model was built in Pyomo using CPLEX as the solver. The variables in this problem were the amounts of biomass processed by each conversion process. The objective function was to maximize the Net Present Value (NPV). The optimization considered a maximum raw material supply of 232,500 metric tons per year. As a result, pyrolysis was identified as the most profitable route, yielding US$447 million, producing biochar, bio-oil and gas as products. It was observed that only if the price of the optimum product was 46% lower would the optimum conversion process change. In conclusion, soybean straw offers significant potential for value-added applications in a biorefinery context, with pyrolysis emerging as the most profitable route.

**Keywords**: Optimization, Pyomo, Biomass, Soybean, Biorefinery

## INTRODUCTION

Since the Industrial Revolution, petroleum, coal and natural gas have been the primary energy sources. Technical achievements have come with the use of these energy sources, *e.g.*, developing steam engines, chemical products and fuels. However, oil has a depletion time of less than 270 years and takes approximately about 280 million years to regenerate [1]. Moreover, the exploitation of fossil fuels has a significant impact on the environment, including soil and water contamination and the release of harmful gases that intensify global warming [2]. Given this context, it is necessary to find different sources that have less environmental and social impacts.

Lignocellulosic biomass is one of the most promising alternatives to fossil fuels due to its large availability. In addition, its structure is complex, consisting of four different organic compounds (cellulose, hemicellulose, lignin and extractives) and one inorganic component (ash), which can produce a substantial number of different value-added products with high energy potential. The renewable nature of lignocellulosic biomass stems from the fact that the $CO_2$ produced when burning biomass is reabsorbed by plants during their development, maintaining a carbon-neutral cycle [3]. Various processes that modify biomass structure and generate new products have been studied over the years.

To develop sustainable and profitable production systems, large amounts of data are necessary, which can sometimes become intractable to analyze. From a process systems engineering (PSE) perspective, computation tools are recommended because analyzing vast

amounts of data from different sources manually is challenging [4]. Techno-economic optimization can reduce costs in the initial stages, particularly in process systems with significant uncertainties, such as biorefineries

Biorefinery is an integrated industrial process that incorporates individual units that convert biomass into power, biofuels and value-added chemicals. The conversion process used in biorefineries can be divided into four principal groups: mechanical processes (size reduction, separation and concentration of substances); thermochemical processes, (pyrolysis, gasification, liquefaction and combustion); biological processes (fermentation and anerobic fermentation); and chemical processes, which use chemicals to change the structure of the input material [5].

**Table 1** – Production of soybean by country/region in 2022/23 [6]

| | Production (MMT) | World Share (%)[1] |
|---|---|---|
| Brazil | 162 | 42,9% |
| United States | 116 | 30.7% |
| Europe | 2.61 | 0.69% |
| World | 378 | 100% |

[1] Country/Region production as a percentage of world production

Brazil is the largest producer of Soybean (*Glycine max)*, followed by the United States, collectively, they represent over 70% of global production (Table 1). With all this crop, a lot of waste is generated, the principal one is soybean straw, composed of leaves, steams and pods with lignocellulosic composition of 35% of cellulose, 22% of lignin, 17% of hemicellulose and 1% of ashes [7]. It is estimated that the ratio of straw to soybeans varies from 1.2 to 1.5 [8], which represented, in 2023, 194.4-243 million metric tons of waste. Most of the straw is used as landfill, livestock feed, incineration or dumping [7, 8].

Considering those known destinations, soybean straw does not have nutritional value compared to other crops residues *e.g.*, sorghum or corn, to be used as animal feed. However, it is necessary to keep part of the straw in the land to protect the soil from runoff, infiltration and soil loss. The Brazilian Agricultural Research Corporation (EMBRAPA) [9] estimated that it is necessary to keep 2.205 metric ton per ha to protect the soil, so almost 50% of all soybean straws needs to be used for landfill, in the context of Brazilian scenario.

Given the lack of current uses, the large availability and its lignocellulosic composition, soybean straw has a lot of potential to produce chemical products and fuels. The objective of this work was to develop a superstructure of a conceptual soybean straw biorefinery and solve it using an MILP (Mixed Integer Linear Programming) optimization, with Net Present Value (NPV) as the objective function.

# METHODOLOGY

The methodology was based on three steps. The first one was a literature review, which was necessary to find conversion processes and products that can be obtained from soybean straw. The second one was data treatment, to standardize the data, making it possible to use it in a generic framework. The final step was the development and solution of an MILP optimization model.

## Literature Review

All chosen products and their respective process routes for soybean straw valorization were gathered from academic literature.

Process costing was performed using similar routes reported in literature. There were two types of cost considered: a capital cost (CAPEX), which considers equipment, installation and instrumentation cost; and an operating cost (OPEX), which covers the reactants' price, labor charges and other administrations costs. For all the selected products, a revenue price was determined. While some have a known market price, others had to be estimated.

## Data Treatment

The basic premises considered were: 350 days a year as operating time; 2023 as the reference year; the biomass availability as all soybeans straw waste in the city of Itapeva, São Paulo State, in 2023 (232,500 metric ton) [10]; 10 years of plant lifetime operation; no cost associated with the feedstock; and a discount rate of 12.25% per year.

The yield of each product was adjusted to be per gram of biomass. Because it was used an annual biomass availability, it was necessary to find an annual yield of each product, so, the conversion time of each process was considered.

In Eq. 1, CAPEX was adjusted by capacity and time using a power-law expression [11], where A is the capacity of this biorefinery (27.68 MT $h^{-1}$); $CAPEX_{ref}$, $CEPCI_{ref}$ and $A_{ref}$ are the CAPEX, Chemical Engineering Plant Cost Index and plant capacity, in t $h^{-1}$, found in the articles for each route, respectively [21-28].

$$CAPEX = CAPEX_{ref} \cdot \left(\frac{CEPCI_{2023}}{CEPCI_{ref}}\right) \cdot \left(\frac{A}{A_{ref}}\right)^{0.67} \quad (1)$$

OPEX was adjusted, as well, using Eq. 2.

$$OPEX = OPEX_{ref} \cdot \left(\frac{CEPCI_{2023}}{CEPCI_{ref}}\right) \cdot \left(\frac{A}{A_{ref}}\right) \quad (2)$$

It was not possible to find the market price for some products. In such cases, two approaches were used to determine the price: comparing the function of the product (*i.e.*, the price of biochar produced in a pyrolysis route was estimated using coal as reference, using the low heating value as comparison parameter), or similarity

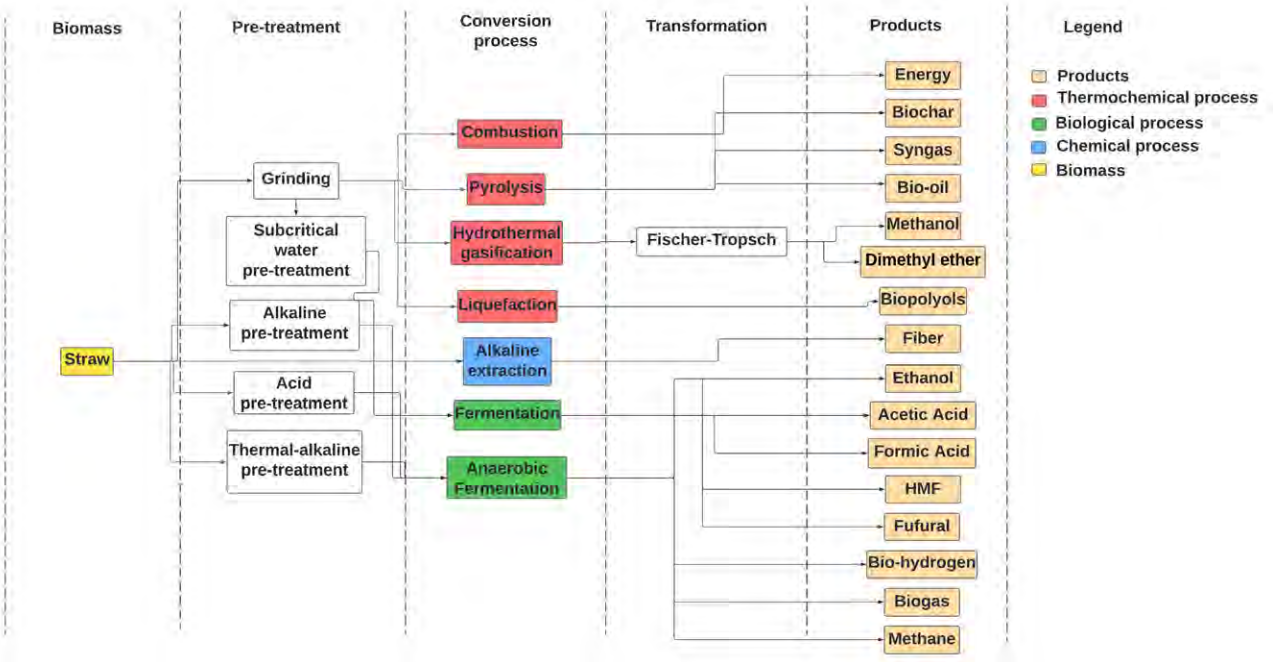

**Figure 1:** Superstructure for soybean straw valorization

with products commercially available (*i.e.,* the price of pulp and polyurethane was used as the price of fiber and biopolyols produced from soybean straw, respectively).

## MILP Optimization

For the MILP optimization, the capital letters represent the parameters and the small ones, the variables. The objective function (Eq. 3) was the maximization of the Net Present Value (NPV), where R represents the discount rate; *i* , *j* and *t* are the sets for processes, products and lifetime, respectively; $N_{i,j}$ represents the yield of each product *j* in the process *i*; $P_j$ is the price of the product *j*; $d_i$ is the non-negative variable, representing the amount of soybean straw used in the conversion process *i* ; $C_i$ and $O_i$ represents the CAPEX and OPEX for the process *i,* respectively, and $y_i$ is the binary variable to decide what process *i* will be selected.

$$\max NPV = \sum_{t=0}^{10} \frac{\sum_i \sum_j N_{i,j}.P_j.d_i - \sum_i O_i.y_i}{(1+R)^t} - \sum_i C_i.y_i \qquad (3)$$

The constraints used were:

A big-M constraint to represent the upper bound of the variable $d_i$ and the activation of the binary variable $y_i$(Eq. 4);

$$d_i \leq y_i.D \qquad (4)$$

The total biomass used in all processes is equal to the total available biomass (*D* ) (Eq. 5);

$$\sum_i d_i = D \qquad (5)$$

An anaerobic fermentation route includes two distinct pre-treatments; therefore, an additional constraint (Eq. 6) was required to prevent them from being selected simultaneously. The subindexes (6.1, 6.2) follow the numbering adopted in Table 2 for the conversion processes.

$$y_{6.1} + y_{6.2} \leq 1 \qquad (6)$$

The model was solved using Pyomo (a Python-based, open-source optimization modeling language). The solver used was CPLEX, which uses the "branch and bound" or "branch and cut" methods [12].

## Sensitivity Analysis

A sensitivity analysis was conducted to evaluate the impact of various uncertainties. Specifically, the market prices of the products associated with the optimal route were varied within a range of -60% to 30%. This analysis aimed to assess how the objective function and the decision variables are affected by these changes.

# RESULTS AND DISCUSSIONS

## Literature Review

Four thermochemical processes (pyrolysis [13], liquefaction [14], combustion [15], and hydrothermal gasification [16]), two biological processes (fermentation [17] and anaerobic fermentation [18, 19]), and one chemical (alkaline extraction [20]) were selected. Thus, the superstructure covers the main types of conversion routes.

Figure 1 represents the superstructure created. There were sixteen products found (biochar, bio-oil,

**Table 2:** Reference and calculated capital and operated costs per conversion process

| | Conversion process | $Capacity_{ref}$ (MT $h^{-1}$) | $CAPEX_{ref}$ (M US$) | $CAPEX_{calc}$ (M US$) | $OPEX_{ref}$ (M US$ $yr^{-1}$) | $OPEX_{calc}$ (M US$ $yr^{-1}$) | Ref. |

| 6.1 | Bio-hydrogen | 3.14 mL |
| | Ethanol | 0.006 g |
| | Acetic Acid | 0.019 g |
| 6.2 | Bio-hydrogen | 47.7 mL |
| | Ethanol | 0.001 g |
| | Acetic Acid | 0.019 g |
| 7 | Energy | 0.005 kWh |
| 8 | Methanol | 0.071 g |
| | Dimethyl ether | 0.051 g |

## Data Treatment

Table 2 has all the associated costs for each process. It is possible to observe, when CAPEX and OPEX were adjusted for the capacity of the biorefinery studied, thermochemical processes had lower costs when compared to biological and chemical processes, especially because almost no auxiliar materials (such as chemicals) are used.

Table 3 shows the yield of products for different conversion processes. It is possible to conclude that for the same route a change in the pre-treatment can significantly impact on the yield of some products (*e.g.,* biohydrogen). Moreover, when using aerobic microorganisms, a larger amount of ethanol is produced than when using anaerobic ones. In biorefinery context, even if inhibitors are produced (HMF and furfural) in a fermentation route, revenue is still obtained, and sometimes, this product can be transformed and have a higher market price than the main product. Furfural, for instance, is a chemical platform from which a lot of other chemicals can be derived from.

## MILP Optimization

For the MILP model, nine decision variables were considered with ten constraints. The objective function resulted in an NPV of US$447 million, selecting the pyrolysis route as the optimum route, producing biochar, bio-oil and gas.

Figure 2 illustrates the NPV of each process route evaluated. Three of the evaluated thermochemical routes were the most profitable, and only the thermochemical routes led to positive values for the objective function. This could be explained by the biomass chemical composition, as identified in the studies by Eason and Cremaschi [29], lignocellulosic waste (*e.g.*, switchgrass) is most efficiently utilized through thermochemical processes. In contrast, certain grains or seeds, which contain significant amounts of oil and starch, are better suited for valorization through transesterification or fermentation.

The NPV of the most profitable route, pyrolysis, is twice as high as that of the second most profitable route (*i.e.* combustion). It is known that pyrolysis process has a low TRL (Technology Readiness Level) compared with other thermochemical routes, mostly because of the high

complexity kinetics of this process creating some uncertainties. Alternatively, combustion is a well-developed process, which could be an interesting alternative for the pyrolysis process for this case.

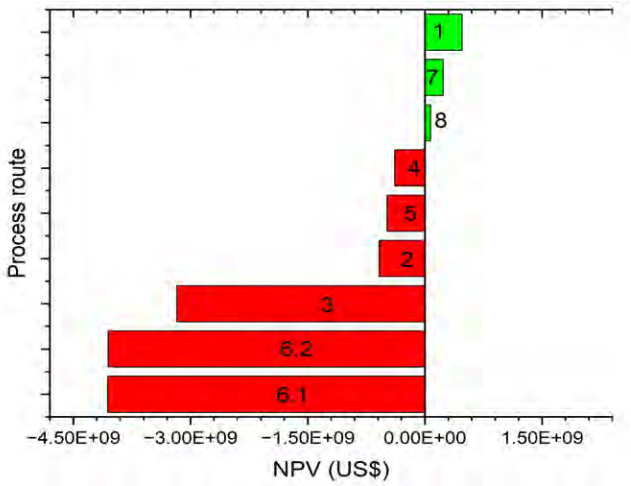

**Figure 2:** NPV value for each process route

## Sensitivity Analysis

The profitability of pyrolysis remains robust despite price fluctuations. In Figure 3, it was observed that it is necessary a 46% decrease in these products' price for the pyrolysis route to be substituted by the combustion as the best route. These two thermochemical routes have very profitable products and lower costs, which justify these optimum results.

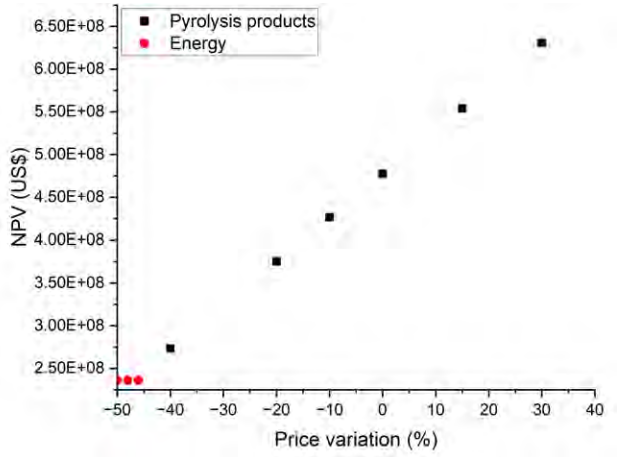

**Figure 3:** Effect of optimal product price variation on the objetive function

Fischer-Tropsch products are frequently cited as playing an important role in future biorefineries. To produce methanol and dimethyl ether in this biorefinery and keep almost the same profit as the optimum one, it will be necessary that the price of these products increases 6.5 times. This analysis shows that it is unlikely that Fischer-Tropsch chemicals could be profitable at least in the short term in a soybean straw biorefinery.

## CONCLUSION AND NEXT STEPS

A conceptual biorefinery using soybean straw as feedstock can be profitable. Pyrolysis emerged as the optimum route, generating biochar, bio-oil and syngas as products. The second-best route for soybean straw valorization was combustion. The optimum products demonstrated a resilient price market, although the technology has a significant associated uncertainty. Evaluating this biorefinery could foster sustainable industrial development by valorizing agricultural waste, serving as an initial study to further evaluate different supply combinations, operational conditions, or end-product prices.

Future research will focus on calculating equipment sizes to refine CAPEX and OPEX estimates. Moreover, the influence of other parameters (*e.g.*, feedstock cost variations, discount rate changes, and OPEX fluctuations) will be investigated to better understand the behavior of the decision variables. A multi-objective and multi-feedstock approach will also be considered to assess the environmental and supply chain aspects.

## DIGITAL SUPPLEMENTARY MATERIAL

A supplementary material is available in LAPSE:2025.0034 with the data extracted, from the literature review, and treated to model the optimization.

## ABSTRACT

This study provides standardized models for the chemical characterization of complex streams, ensuring the necessary adaptations while considering the differences in biomass types and forms. Several datasets are compiled and examined to establish a valid representation of the mixture, according to industry accepted standards and laboratory protocols. For reliable property estimation, correlations of key biomass properties are obtained from both computational models and experimental measurements. Existing data are used to create datasets for the biomass and the biocrude streams. This model builds upon existing knowledge and data technologies with emphasis on hydrothermal liquefaction (HTL). The proposed approach shows potential as a starting point for the design and modelling of more biorefinery-associated technologies. Sludge and pine wood are used as case studies for biomass feedstocks. Two biocrude samples are employed for biocrude characterization. The performance of the developed optimization model is compared favorably with results obtained using previous works. To ensure a variety of possible and valid solutions, integer cuts are implemented producing solution pools for the analysed streams.

## INTRODUCTION

Global emissions have increased rapidly over the last half-century, driving climate change [1]. Fossil fuels are by far the largest contributor, accounting for over 75% of global greenhouse gas emissions and nearly 90% of all $CO_2$ emissions [2]. Bioenergy offers a sustainable alternative, potentially supplying a quarter to a third of global primary energy by 2050 and replacing fossil fuels across energy markets [3]. Second-generation biorefinery processes convert a range of organic feedstocks into biocrude, which can be upgraded into liquid hydrocarbon fuels [4].

Among these, hydrothermal liquefaction (HTL) is a promising technology for converting biomass into biocrude and valuable chemicals under high temperature and pressure conditions [5]. The process offers advantages such as wet biomass processing and reduced tar formation [6] and is easily adaptable to various types of biomass feedstocks [7]. The reaction mechanisms involve depolymerization of biomass components, with proteins, lipids, and carbohydrates following distinct pathways [8]. Some HTL fuels can reduce Global Warming Potential by approximately 70% compared to conventional jet fuel [9].

Mechanistic kinetic models have been developed for HTL, to predict product yields and composition for different feedstocks [10]. Characterization of the biomass and biocrude streams is crucial for modeling the complexity of HTL reaction mechanisms and upgrading the process [11]. Various analytical methods can be employed, including conventional analytical methods like GC, FTIR, and NMR, or advanced 2D- GC, LC, NMR and HRMS techniques [12]. Conventional methods face limitations in comprehensively characterizing the complex composition of these streams, requiring advanced techniques to produce comprehensive results [13].

Stream characterization can also be done using computational techniques (in the form of optimization or Machine Learning models) using experimental datasets

containing information relevant to each studied system [14-16]. A common limitation across all methods mentioned is the inadequacy of available data, tools and flow sheeting techniques for accurately representing different biomass types.

Park et al. (2023) employed HPLC derived data to develop predictive equations correlating biochemical content with elemental composition in biomass characterization [17]. Ahmed et al. (2019) relied on machine learning techniques to estimate moisture content and compositional analysis based on data derived from NIR spectroscopy [18]. Taghipour et al. (2021) characterized biocrude streams through multi-objective optimization with the NSGA-II algorithm, by integrating distillation data [19]. Aslanoglou et al. (2024) proposed a model that utilizes both stochastic and deterministic algorithms to simulate the input and output streams associated with hydrothermal liquefaction (HTL) of sewage sludge [20].

This work builds on existing models and data to develop a robust generalized optimization model, to capture the composition diversity and characterize biomass and biofuel streams. The following sections present the proposed methodology and the material datasets utilized here, compare the model performance to previous works, and illustrate the use of integer cuts to deliver portfolios of solutions.

## METHODOLOGY

This section describes the mathematical model developed here for the characterization and analysis of biomass and biocrude streams and its implementation.

The objective function $F$ is formulated as follows:

$$min\{F\} = \sum_{m=1}^{M}\left(1 - f_m/\hat{f}_m\right)^2 + \sum_{k=1}^{K}\left(1 - f_k/\hat{f}_k\right)^2 \quad (1)$$

where $\hat{f}$ and $f$ denote experimental and first principle based data for each property $k \in \{1, \dots, K\}$ and $m \in \{1, \dots, M\}$, respectively.

The following sets of properties are considered:

- Elemental composition of $m$={Carbon, Hydrogen, Oxygen, Nitrogen, Sulfur,..} where $Nm_{m,j}$ denotes the number of elements in every compound and $Ar_m$ the element atomic number.

$$f_m = \frac{\sum_j x_j \cdot Nm_{m,j} \cdot Ar_m}{\sum_{m=1}^{M}\sum_j x_j \cdot Nm_{m,j} \cdot Ar_m} \quad (2)$$

- Biochemical composition $k$={Protein, Carbohydrate, Lignin, Lipid, etc.} where $B_{k,j}$ denotes the biochemical identification in every compound.

$$f_k = \sum_j x_j \cdot B_{k,j} \quad (3)$$

where $x_j$ denotes the composition of compound $j$.

- The model can also incorporate constraints on the stream property values, to ensure that they match experimental characterization data. These properties may include Higher Heating Values (HHV), densities and Boiling Point Temperature (TBP) profiles (only for biocrude mixtures).

Feasibility constraints are also applied:

$$\begin{pmatrix} I & -L_x I \\ -I & U_x I \end{pmatrix} \begin{pmatrix} x_j \\ y_j \end{pmatrix} \leq \begin{pmatrix} 0 \\ 0 \end{pmatrix}, \quad (4)$$

where $y_j$ is a binary variable indicating the presence of a compound in the mixture; $L_j$ and $U_j$ are the lower and upper bound of the continuous variable $x_j$.

$$\sum_j x_j = a, \quad a \leq 1 \quad (5)$$

$$\sum_j y_j \leq N \quad (6)$$

where $a$ is the total dry and ash-free composition.

The above are implemented in GAMS as a mixed-integer nonlinear programming (MINLP) problem solved using the BARON solver. The model inputs are the feedstock and biocrude properties. The model outputs are estimates of the unknown feedstock composition.

The model is solved iteratively to produce multiple solutions through integer cuts, resulting in alternate populations that match optimization requirements. We also apply integer cuts to generate a set of alternative stream compositions and investigate governing stream characteristics [21]. Algorithm 1 shows a pseudocode of the algorithm to solve the MINLP problem of Equations 1-6, including the integer cuts.

**Algorithm 1**: Implementation of the optimization model

```

## DATASETS

Two distinct datasets are used for stream characterization for biocrude (Table 1) and biomass (Table 2). Data on selected chemicals are collected from published works providing experimental (e.g. HPLC) and simulation data (e.g. Optimization) for biomass [20, 22-30] and biocrude [19, 20, 31, 32] characterization.

**Table 1**: Biocrude dataset description (144 compounds)

| |
|---|
| Saturated hydrocarbons; aromatic compounds etc. |
| Molecular weight ranges: 60-410 g/mol |
| TBP ranges: 50-550$^{O}$C |
| Properties (molecular weight, TBP, SMILES etc). |

**Table 2**: Biomass dataset description (111 compounds)

| |
|---|
| 18% amino acids |
| 23% carbohydrates |
| 31% lipids |
| 28% lignin compounds |
| Molecular weight ranges: 70-600 g/mol |
| Density ranges: 0.8-1.7 g/cm3 |
| Properties (chemical formula, density, SMILES etc). |

# CASE STUDIES

## Biomass characterization

We showcase the versatility and wide applicability of the proposed MINLP model by examining three sludge and pine wood feedstocks, which exhibit significant differences in protein and lignin content. In all three cases, we consider the biomass dataset of Table 2. When the compositions don't add up to 100% the model is adjusted to consider normalized values.

*Case F1*: Table 3 shows the obtained deviations between experimental and calculated values for the sewage sludge. The MINLP results are tested against those of Aslanoglou et al. (2024) who compared two evolutionary (firefly algorithm (FA) and particle swarm optimization (PSO)) and two deterministic algorithms (sequential quadratic programming (SQP) and least squares optimization (LS)). SQP had the best performance using a dataset tailored to sludge streams [20]. The current model outperforms significantly their best model (SQP) in fitting to the experimental values. We finally observe that the overall objective function value is reduced here by 93%.

**Table 3**: Comparison of biomass results in case F1

| | Exp. Data | SQP | | MINLP | |
|---|---|---|---|---|---|
| Carbon | 54.20 | 52.36 | 3.40% | 54.47 | 0.49% |
| Hydrogen | 7.30 | 7.43 | 1.77% | 7.30 | 0.00% |
| Oxygen | 34.20 | 36.85 | 7.73% | 34.63 | 1.26% |
| Nitrogen | 3.60 | 3.25 | 9.78% | 3.60 | 0.00% |
| proteins | 15.77 | 17.42 | 10.44% | 15.39 | 2.42% |
| H/C | 40.58 | 42.66 | 5.13% | 41.47 | 2.20% |
| lipids | 13.06 | 13.45 | 3.00% | 12.67 | 2.95% |
| Lignin | 25.10 | 26.47 | 5.46% | 24.97 | 0.51% |
| HHV | 24.51 | 23.71 | 3.24% | 24.62 | 0.47% |
| SSRD | | | 3.55E-02 | | 2.17E-03 |

*Case F2*: This case considers a pine wood sample from Obeid et al. (2021) (Type: Sawdust) [33]. Table 4 reports an excellent fit to the experimental values. In this case we did not have information on the mixture HHV.

*Case F3*: Table 5 reports the MINP model results for a sludge stream from Snowden-Swan et al. (2022) (Type: WW09 50/50 CCSD, DAF) [34]. In this case we also demonstrate the use of integer cuts. Table 5 reports the overall results statistics for 50 solutions of the MINLP model. Here we obtain a distribution of values for the elementary and the biochemical compositions, so we report the average and the standard deviations of SSRD.

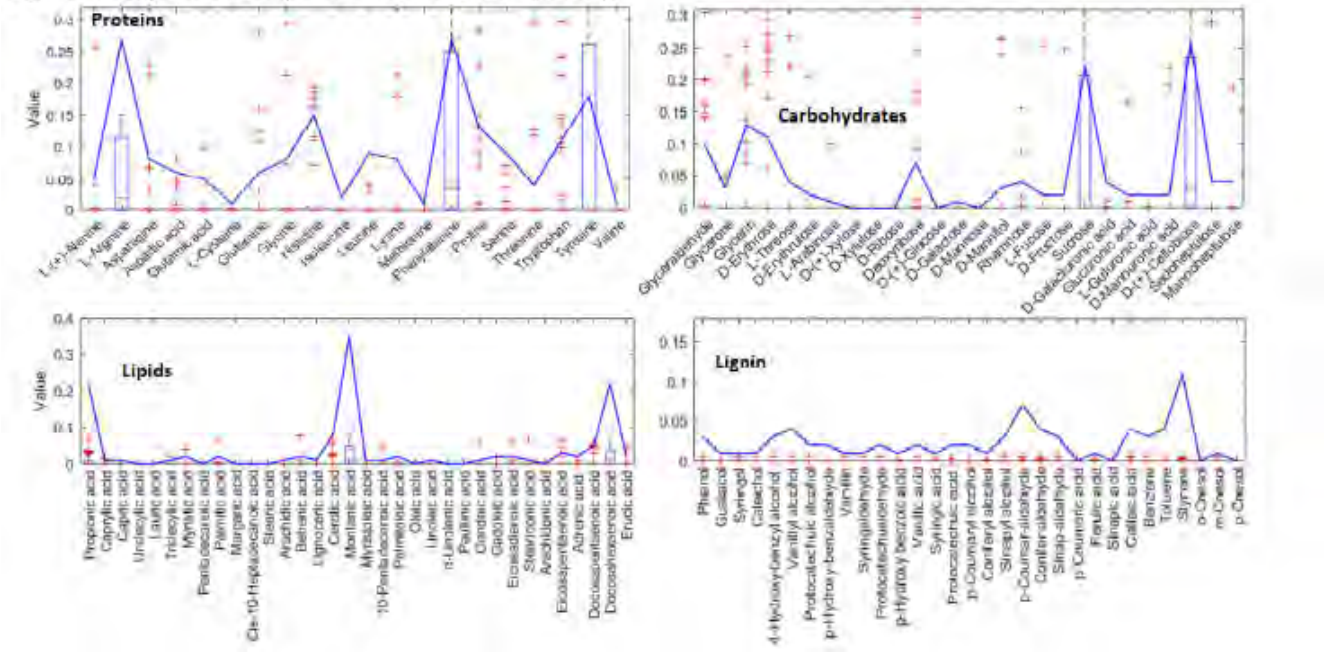
**Table 4**: Results for the pine wood stream F2

| | Exp. Data | MINLP | |
|---|---|---|---|
| Carbon | 44.68 | 43.69 | 2.21% |
| Hydrogen | 6.15 | 6.13 | 0.30% |
| Oxygen | 51.43 | 50.12 | 2.55% |
| Nitrogen | 0.06 | 0.06 | 0.00% |
| proteins | 0.50 | 0.50 | 0.10% |
| H/C | 66.90 | 76.38 | 14.17% |
| lipids | 2.80 | 2.82 | 0.59% |
| Lignin | 19.50 | 20.31 | 4.13% |
| SSRD | | | 2.30E-02 |

**Table 5**: Results for the sludge stream F3

| | Exp. Data | MINLP (average & st.dev.) | |
|---|---|---|---|
| Carbon | 51.10 | 51.50 | 0.009 |
| Hydrogen | 7.40 | 7.41 | 0.004 |
| Oxygen | 35.60 | 35.79 | 0.009 |
| Nitrogen | 5.30 | 5.31 | 0.003 |
| proteins | 45.40 | 45.42 | 0.031 |
| H/C | 46.10 | 46.08 | 0.030 |
| lipids | 8.00 | 8.00 | 0.005 |
| Lignin | 0.50 | 0.50 | 0.000 |
| SSRD | | 7.93E-05 | 5.41E-06 |

Figure 1 shows the boxplots of the compound concentrations (wt/wt) in the obtained results, which also show the frequency of compound appearance. Note that, we hide the compounds which are not present in any of the 50 solutions. It is observed that, among the lipids, Lignoceric acid and Docosahexanoic acid are the compounds with the highest concentrations (average 3% and 2% respectively). Among the carbohydrates, Cellobiose and Sucrose were found with the highest concentration with an average of 11% and 7% respectively. The most common amino acids found were Phenylalanine and Tyrosine with average values of 12% and 10%.



## Biocrude characterization

*Cases B1 & B2*: This case considers Aslanoglou et al. [20]. Table 6 reports an excellent fit to the experimental values. We observe 96% and 78% reductions of the objective function value compared to previous works on biocrude and upgraded biocrude, respectively.

# DISCUSSION

The performance of the model developed here is demonstrated on 3 different feedstocks, showing significantly lower deviations compared to previous works. Though we have a limited pool of results, the model seems to perform slightly better in sludge samples, compared to pine wood. This could be attributed to the higher lignin content in wood and woody biomass mixtures, which is more

**Figure 1**: Boxplots of compound concentrations (wt/wt).

challenging to model effectively, especially considering the structural randomness of its branched topology, as well as its diverse chemical behaviour [35].

**Table 6**: Results for the biocrude streams B1 and B2

| | | Exp. Data | LS | | MINLP | |
|---|---|---|---|---|---|---|
| Biocrude | Carbon | 74.67 | 75.38 | 0.95% | 75.68 | 1.35% |
| | Hydrogen | 10.30 | 10.70 | 3.88% | 10.28 | 0.16% |
| | Oxygen | 11.30 | 11.30 | 0.00% | 11.28 | 0.17% |
| | Nitrogen | 2.76 | 2.99 | 8.44% | 2.76 | 0.04% |
| | HHV | 33.20 | 33.49 | 0.87% | 33.63 | 1.30% |
| | SSRD | | | 8.80E-03 | | 3.57E-04 |

| | | Exp. Data | SQP | | MINLP | |
|---|---|---|---|---|---|---|
| Upgraded biocrude | Carbon | 86.20 | 85.41 | 0.92% | 85.22 | 1.13% |
| | Hydrogen | 13.00 | 13.56 | 4.31% | 13.96 | 7.41% |
| | Oxygen | 0.70 | 0.78 | 11.00% | 0.71 | 1.64% |
| | Nitrogen | 0.10 | 0.11 | 11.00% | 0.10 | 0.40% |
| | HHV | 38.06 | 37.71 | 0.92% | 37.62 | 1.16% |
| | SSRD | | | 2.62E-02 | | 6.04E-03 |

Integer cuts would provide (i) multiple feasible solution points that could establish key chemical components (ii) broader potential for data manipulation and machine learning implementation (iii) increased flexibility in choosing appropriate biomass profiles based on fuel or process requirements. Producing alternate populations of components, rather than single options, enhances the comprehensive understanding of complex streams, allowing complementary information to form holistic knowledge in the optimization and design of sophisticated chemical dynamics. The MINLP model was also tested in two biocrude samples.

The proposed MINLP model efficiently produces the chemical profiles of different biomass types and product streams, allowing for a more generalized approach in biorefinery understanding. This model can be adapted for various non-conventional mixtures by incorporating diverse substrate properties, allowing for a broader physiochemical representation. Thus, allowing its applicability across a wide range of biorefinery technologies.

## CONCLUSIONS AND FUTURE WORK

Efficient modelling of non-conventional streams requires a comprehensive analysis of first principle models along with experimental data, in accordance with industry accepted standards and laboratory protocols. The purpose is to match the experimental properties of the input or output stream to a mixture of appropriate chemical compounds and functional groups.

This work proposes a new MINLP formulation for the characterization and analysis of biomass and biocrude steams in HTL. Our analysis capitalizes on a combination of peer-reviewed references, experimental, simulation data and relevant databases to acquire specification parameters such as experimental measurements (e.g. moisture content), stoichiometric composition showcasing elemental ratios within samples, as well as thermodynamic properties associated with bioconversion technologies. Classifying biomass feedstocks, requires the chemical compounds to be divided into four biochemical categories, such as proteins, sugars, lipids and lignin.

Accurate representation of complex mixtures in all stages of the biomass conversion process would facilitate decision-making while also providing insight in reaction pathways, which signifies an industrial milestone for

biorefinery commercialization.

Decomposition of feedstock streams into chemical compounds allows the modularization of the chemical profile which can be used to redefine information into digital forms, while also creating collective databases of different material mixtures. In essence, digital passports to simplify biomass and biocrude classification.

Ongoing work also considers the incorporation of additional properties to improve accuracy, and also include TBP data to enable fitting to the experimental TBP curve for biocrude streams.

## ACKNOWLEDGEMENTS

The project is implemented within the framework of the National Recovery and Resilience Plan "Greece 2.0" and has been financed by the European Union (NextGeneration EU).

## ABSTRACT

Polyhydroxyalkanoates (PHAs) are microbial bioplastics that are fully biodegradable, biocompatible and can be produced by renewable feedstocks through fermentation. These are all desirable attributes for the replacement of current fossil-based plastics. Strong mathematical models describing bioprocesses are invaluable tools that can be used for enhancing bioprocess understanding as well as optimization. In this study, polyhydroxybutyrate (PHB), by *Cupriavidus necator* DSM 545 was produced using glycerol and ammonium sulphate (AS) as the sole carbon and nitrogen sources, respectively. In addition, a kinetic bioprocess model was developed. The kinetic parameters of the model were calibrated with five fermentation experiments with different initial conditions (e.g. variable glycerol and AS concentrations) in order to properly establish the inhibition regions and provide a generalized model as much as possible. The model was successfully validated by three independent experiments, two with extreme and one with moderate initial conditions. In addition, the analysis of the data provided valuable metabolic insights for this bioprocess. It was shown that the PHB storage capacity of cells strongly correlates with the initial nitrogen concentration in the medium, meaning that efforts for maximizing biomass production in a two-stage bioprocess strategy should be carefully designed so that the nitrogen concentration does not irreversibly compromise the maximum PHB accumulation potential. Furthermore, a preliminary kinetic analysis of the biodegradation of solvent casted PHB films was performed.

**Keywords**: Fermentation, Genetic Algorithm, Modelling, Modelling and Simulations, PHB, *C. necator* DSM 545

## 1. INTRODUCTION

Some 80% of all plastics globally produced have accumulated in or leaked to the environment [1]. Over 99.5% of plastics are currently being derived from petroleum-based resources [2]. A promising alternative to conventional fossil-based plastics is polyhydroxyalkanoates (PHA), microbial bioplastics synthesized through fermentation of renewable feedstocks, with poly(3-hydroxybutyrate) (PHB) being the most extensively studied variant [2]. The primary contributors to the high cost of PHA production are feedstock costs, which account for up to 50% of total production costs [3], alongside low PHA yields [4]. Crude glycerol, the primary byproduct of biodiesel production, representing about 10% w/w of the produced biodiesel, could be further valorised to PHB as the fermentation's main carbon source [5]. *Cupriavidus necator* DSM 545, is a well-studied microorganism able to consume glycerol as sole carbon substrate for the production of PHB[6–9], with productivities as high as 1.4 g/L/h[8]. *C. necator* DSM 545 along with *Zobellella denitrificans* MW1 are the only two reported microorganisms able to produce PHB on glycerol with productivities higher than 1 g/L/h[10]. Mathematical models are invaluable tools for the optimization and design of bioprocess and few studies have attempted to describe and/or optimize the production of PHB on glycerol by *C. necator* DSM 545 using such models[6–8,11].

In this work, a detailed macroscopic kinetic model was developed based on experimental observations to describe the batch fermentation of *Cupriavidus necator* DSM 545 under controlled pH (6.8) and DO (30% of saturation) conditions on a chemically defined mineral medium with glycerol and ammonium sulphate (AS) as the

carbon and nitrogen sources, respectively. The model was tuned on experimental data from batch fermentations. Sensitivity analysis was also performed. Batch was the preferred mode of operation to identify inhibition regions with respect to carbon and nitrogen sources, and to gain insight into the behavior and metabolic state of the microorganism for fermentations conducted with different initial conditions. Finally, the model was validated using experiments with initial conditions that were not used in the parameter tuning process.

## 2. MATERIALS AND METHODS

### 2.1 Microorganism and culture conditions

*Cupriavidus necator* DSM 545 was used as the microorganism for all fermentations. The master stock has been extensively adapted to glycerol previously in our research group and stored in cryovials at -80°C during their mid-exponential phase [7]. The fermentation medium was adapted from Kim et al[12]. The cultivation process has been described elsewhere [6,7]. Bioreactor fermentations were carried out in 0.5 L or 3 L Applikon bioreactors (Getinge, NE) under the following controlled conditions: 30°C, pH 6.8, dissolved oxygen at 30% saturation (achieved by automatic control of agitation speed and air flow rate, max 2vvm), and 10% mid-exponential phase inoculum. The pH of the medium was adjusted automatically using a 2M KOH solution. For fermentation follow up, 5 mL samples were taken in duplicate from each bioreactor at different time points for further analysis. All procedures were carried out aseptically where appropriate.

### 2.2 Biodegradation experiments

Compost was sourced from the Firs botanical grounds (University of Manchester, UK) as the biological environment to isolate an efficient PHB degrading microorganism. This 6-month-old compost was produced from garden waste and local kitchen food waste and sieved on-site (mesh size < 10 mm). A small amount of compost sample was spread on mineral PHB agar plate incubated at 37 °C for 48 h [13]. The microorganisms capable of growing on the plates were further isolated on the same plate recipe until a single colony type was achieved. The colonies were identified via sequencing of the 16S or 18S/28S RNA gene (for bacteria or fungi, respectively). Amplification was performed via colony PCR using GoTaqGreen® master mix (Promega, UK). Thereafter, the amplified gene was separated via gel electrophoresis and the Monarch® DNA gel extraction kit (New England Biolabs®, UK). The NCBI BLAST tool (NCBI) was used on the obtained sequence to annotate the taxonomy of the microorganisms. The PHB obtained from one of the fermentation experiments (biodegradation substrate) was casted on a petri dish using chloroform or hexafluoroisopropanol (HFIP) as solvent in $\frac{1g\ PHB}{25\ mL\ solvent}$ ratio. The isolated microorganism was thereafter inoculated (10% w/w) in 5 mL of appropriate medium and culture conditions, together with PHB films, in glass test tubes.

### 2.3 Analytical procedures

Cell dry weight (CDW) was measured gravimetrically as described previously[7]. The absorbance of each sample was measured at 600 nm using a UV spectrophotometer (UV-1280, Shimadzu®) to monitor microbial growth, particularly during the initial hours of fermentation. A correlation between cell dry weight (CDW) and optical density (OD) was established ($R^2$=0.9687) to account for potential inaccuracies in CDW measurements. PHB was quantified via Gas chromatography coupled with a Flame Ionization Detector (GC-FID, Agilent) using the method optimized by Lanham et al.[14]. Analysis was performed in an HP-5 column (Agilent J&W GC columns) with helium as the carrier gas and a split ratio of 1:10. Oven temperature was initially set to 80°C for 5 minutes, then ramped up to 280°C at 20°C/min, with a 2-minute hold. Calibration was performed using commercial methylated 3-HB (Sigma-Aldrich) in chloroform. Glycerol in sample supernatant was monitored via High-Performance Liquid Chromatography (HPLC) [7]. Total nitrogen concentration in sample supernatant was quantified via a total nitrogen analyser (TOC/TN multi N/C 3100, Analytik Jena). For this, 100 µL of the filtered supernatant was injected. After catalytic combustion, nitrogen oxide reacts with ozone to form excited states, emitting light upon returning to the ground state. This light, measured by a chemiluminescence detector, is proportional to the nitrogen content. Ammonium sulphate solutions in distilled water served as calibration standards. Scanning Electron Microscopy (SEM) of the PHB films were acquired by Zeiss Ultra 55 microscope. The samples were sputter coated with 80:20 Ad:Pd. Atomic Force Microscopy (AFM, Bruker) with probes of 4 N/m force constant was used.

### 2.4 Parameter tuning and sensitivity analysis

The kinetic constants of the model were tuned by minimizing the normalized mean squared error between experimental and predicted data (equation 1).

$$\min G(kk) = \sum_h^{n_h} \sum_j^{n_j} \sum_i^{n_i} \left( \frac{Z_{h,j,i}^{Exp}(kk) - Z_{h,j,i}^{Pred}(kk)}{\max\left(Z_{h,j,i}^{Exp}(kk)\right)} \right)^2 \qquad (1)$$

Here G is the objective function, Z represents experimental and predicted data sets, and kk the parameter set. Indices $n_i$, $n_j$, and $n_h$ correspond to the number of independent variables, data points, and training data sets, respectively. The minimization problem was solved using Matlab genetic algorithm (ga) to avoid local minima, followed by the deterministic function fmincon to refine solutions. Thereafter, sensitivity analysis was performed to assess the most sensitive parameters. For this purpose,

a normalized sensitivity parameter was used [15]:

$$S_{y/p} = \frac{dy_i}{dp_i} \cdot \frac{p_{0,i}}{y_{0,i}} \quad (2)$$

Here $\frac{dy_i}{dp_i}$ is the change of the model output $y_i$ in response to a change in a model parameter pi (5% perturbation was chosen) and $y_{0,i}$ is the model output when the parameter $p_{0,i}$ is set to its original value $p_{0,i}$. A positive sensitivity value translates into an increased model response when a parameter increases, whereas negative sensitivity values signify the opposite behaviour[15].

## 3. RESULTS AND DISCUSSION

### 3.1 Model development

Five state variables were considered for the model: residual biomass (xR), total nitrogen (N), Glycerol ($S_1$), PHB (P), and citric acid ($S_2$) concentrations. These variables were correlated by kinetic equations (equations 3-7) using their corresponding rate terms.

$$\frac{dx}{dt} = r_{xR}x \quad (3)$$

$$\frac{dN}{dt} = (q_{N,S_1} + q_{N,S_2})x \quad (4)$$

$$\frac{dS_1}{dt} = q_{S_1}x \quad (5)$$

$$\frac{dS_2}{dt} = q_{S_2}x \quad (6)$$

$$\frac{dP}{dt} = q_P x \quad (7)$$

#### 3.1.1 Biomass formation

Literature and experimental observations confirm that too high or too low of glycerol or AS negatively affects cell growth [6–9]. It has been reported that 30 g/L glycerol (as sole carbon source) and 2 g/L of AS (as sole nitrogen source) are the thresholds above which significant cell growth inhibition occurs for *C. necator* DSM 545 [16,6,7]. Nonetheless, these studies have evaluated the nitrogen inhibition ranges in shake flask experiments, which might be different than bioreactor fermentations where the pH of the media and oxygen levels are strictly controlled. To establish the nitrogen inhibition region for the model, five fermentations were carried out with 30 g/L of glycerol and varying initial AS concentrations ranging from 0.8-7.4 g/L. Figure 1 shows that the maximum residual biomass (xR) concentrations increase with AS across the entire range, although the increase rate gradually diminishes. Hence, 2 g/L of AS was not the growth inhibition threshold for the bioprocess in bioreactor fermentations. On the other hand, PHB concentration decreases significantly above 3.4 g/L AS. To account for glycerol and nitrogen inhibition effects on growth, Monod kinetics with Haldane inhibition terms[17] were applied on AS and glycerol as the limiting substrates (equation 8). Moreover, it was realized that the initial citric acid (CA) present in the medium formulation was first consumed as the preferred carbon substrate for growth before the cells began to metabolise any glycerol, having a boosting effect and eliminating the growth lag phase normally observed on glycerol. Therefore, the rate of biomass formation should be composed of two segments: biomass production on CA or biomass production on glycerol, starting only after CA depletion. The inhibition of CA on glycerol consumption was modelled via Hill kinetics [18]. Growth on citric acid was inhibited at high nitrogen concentrations (data not shown) hence it was necessary to consider Haldane inhibition kinetics for nitrogen also.

$$r_{xR} = \mu_{S_1} + \mu_{S_2} = \mu_1 \frac{S_1}{\frac{S_1^2}{K_{iS_1}} + S_1 + K_{S_1}} \cdot \frac{N}{\frac{N^2}{K_{iN}} + N + K_N} \cdot \frac{1}{1 + k_{S_2}(S_2)^{n_{S_2}}} + \mu_2 \frac{S_2}{S_2 + K_{S_2}} \frac{N}{\frac{N^2}{K_{iN,S_2}} + N + K_{N,S_2}} \quad (8)$$

Here $\mu_1$ and $\mu_2$ are specific growth rates [$h^{-1}$]; and $K_{S_1}$, $K_N$ and $K_{S2}$, $K_{N,S_2}$ pairs are the saturation constants for glycerol and CA, respectively [g/L]; $K_{iS_1}$, $K_{iN}$ and $K_{iN,S_2}$ are the inhibition constants [$(g/L)^2$] for glycerol and CA, respectively; $n_{S_2}$ is a Hill coefficient.

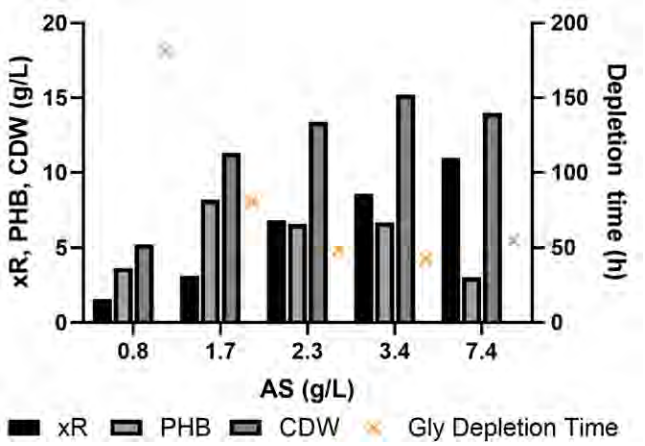

**Figure 1.** Cell dry weight (CDW), residual biomass (xR), PHB end values and glycerol depletion time vs. different initial AS concentrations (30 g/L glycerol).

Another interesting observation is that the glycerol depletion time heavily relied on the initial AS concentrations, e.g. ~2.3-3.4 g/L of AS resulted in lower depletion time and higher biomass growth, but was detrimental to the PHB concentrations.

#### 3.1.2 PHB production

The maximum PHB titer profile against initial AS concentrations in Figure 1 matches expectations, as it is well-known that the presence of nitrogen inhibits PHB production, and that PHB production favours high C/N ratios unlike biomass growth where lower C/N values are preferred[6,7]. PHB accumulation is predominantly induced by nitrogen limitation[7]. However, PHB synthase is a constitutive enzyme in *C. necator* [19], justifying partially growth-associated PHB production [9,20]. Hence, the

Luedeking-Piret model[21] was chosen to describe PHB production (equations 9-11). Throughout the nitrogen limited phase, it is expected that the carbon source should be mostly directed towards PHB production[22,23]. It has been reported however, that PHB production could halt prior to carbon source depletion[22]. This could be due to the fact that the size and number of PHB granules are theoretically capped by a regulatory system involving phasin proteins[22,24], or due to the fact that prolonged nitrogen starvation impairs the activity of PHB synthase. In order to account for such an effect, some studies have introduced powered inhibition functions in the PHB production rate equation[8,22]. However, it was realized in this study that no matter how much of the initial carbon source was allocated to biomass production, no more PHB was produced up to a certain extent even if glycerol was present after reaching the biomass stationary phase. According to Figure 2 the maximum PHB accumulation capacity of cells could be correlated to the initial total nitrogen concentration through the Haldane inhibition model (equation 6).

$$q_P = \alpha r_{xR} + \beta \times \left(1 - \left(\frac{f}{f_{max}}\right)^m\right) \quad (9)$$

$$\beta = \frac{\mu_P S_1}{S_1 + K_{S,P} + S_1^2/K_{iS,P}} \cdot \frac{1}{1 + k_{N,P} + N^{n_P}} \quad (10)$$

$$f_{max} = \frac{c(N_0 - h)}{\frac{(N_0 - h)^2}{d} + (N_0 - \mathrm{h}) + e} \quad (11)$$

$\alpha$ is the growth-associated constant for PHB, and $\beta$ the non-growth associated parameter; $f\ (\frac{PHB}{CDW})$ and $f_{max}$ are the PHB accumulation extent term, and its maximum, respectively; $N_0$ is the initial total nitrogen concentration in the broth [g/L]; c, d, and e are constants (c=3.3854 $h^{-1}$, d=0.2302 g/L, e=0.2771 g/L, h=0.1323 g/L).

### 3.1.3 Substrate and nutrient uptake

CA, glycerol and nitrogen uptake rates were necessary to compute new kinetic constants for the nitrogen uptake rate with nitrogen self-inhibition effect on growth utilising Haldane inhibition kinetics (equation 15).

$$q_{S_2} = \frac{1}{Y_{\frac{xR}{S_2}}} \mu_{S_2} \quad (12)$$

$$q_{S_1} = \frac{1}{Y_{\frac{xR}{S_1}}} \mu_{S_1} \quad (13)$$

$$q_{N,S_2} = \frac{1}{Y_{\frac{xR}{N}}} \mu_{S_2} \quad (14)$$

$$q_{N,S_1} = \frac{\mu_N S_1}{S_1 + K_{N,S_1}} \cdot \frac{N}{\frac{N^2}{K_{iN,N}} + N + K_{N,N}} \quad (15)$$

$Y_{\mathrm{xR}/S_2}$, $Y_{\mathrm{xR}/S_1}$ and $Y_{\mathrm{xR/N}}$ are CA, glycerol and nitrogen to biomass yields, respectively. $\mu_N$ is the specific nitrogen consumption rate ($h^{-1}$), $K_{N,S_1}$, $K_{N,N}$ and $K_{iS,N}$ are saturation and inhibition constants (g/L), respectively.

### 3.1.4 Model performance

Based on a 5% perturbation of the 36 kinetic constants, a range of average sensitivity values from $2.5 \times 10^{-8}$ to 12.5 was produced. It was decided to consider a sensitivity value threshold of ≥0.1, resulting in 13 sensitive parameters (final values in Table 1). The calibration data (figure 3, I-V) cover glycerol and nitrogen concentrations 13-43 g/L and 0.29-1.56 g/L, respectively. The independent validation data (figure 3, i-iv) was able to predict the state variables dynamics at extreme initial glycerol and nitrogen concentrations, 55 g/L and 2.53 g/L respectively, among milder conditions within the region of the values of the calibration data.

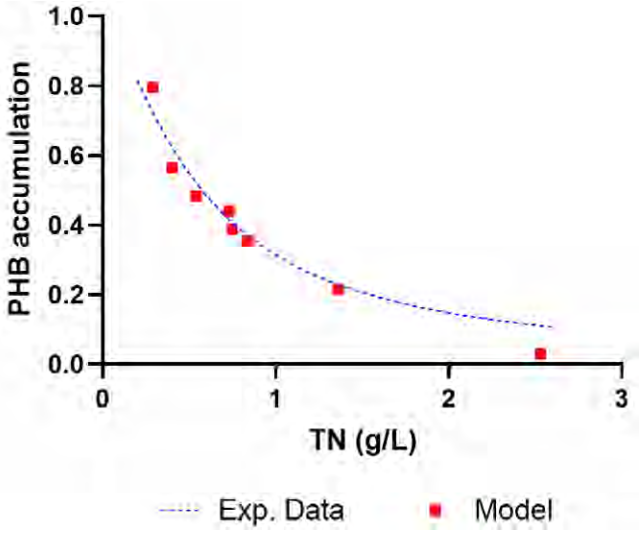

**Figure 2.** Emperical relationship between maximum PHB accumulation and initial nitrogen concnentration in the medium ($R^2$=0.9347).

**Table 1:** Values of the most sensitive model parameters.

| Parameter | Value | Unit |
|---|---|---|
| $k_{N,P}$ | 141 | g/L |
| $Y_{\frac{xR}{N}}$ | 3.15 | g/g |
| $\mu_2$ | 0.9079 | $h^{-1}$ |
| $K_{iS,P}$ | 25.8064 | g/L |
| $K_N$ | 0.3851 | g/L |
| $Y_{\frac{xR}{S_2}}$ | 0.8792 | g/g |
| $n_P$ | 1.49 | - |
| $K_{S_2}$ | 0.2872 | g/L |
| $k_{S_2}$ | 74.30 | g/L |
| m | 7.98 | - |
| $K_{N,N}$ | 2.2483 | g/L |
| $Y_{\frac{xR}{S_1}}$ | 0.3876 | g/g |
| $\mu_P$ | 0.8437 | $h^{-1}$ |

## 3.2 Biodegradation experiments

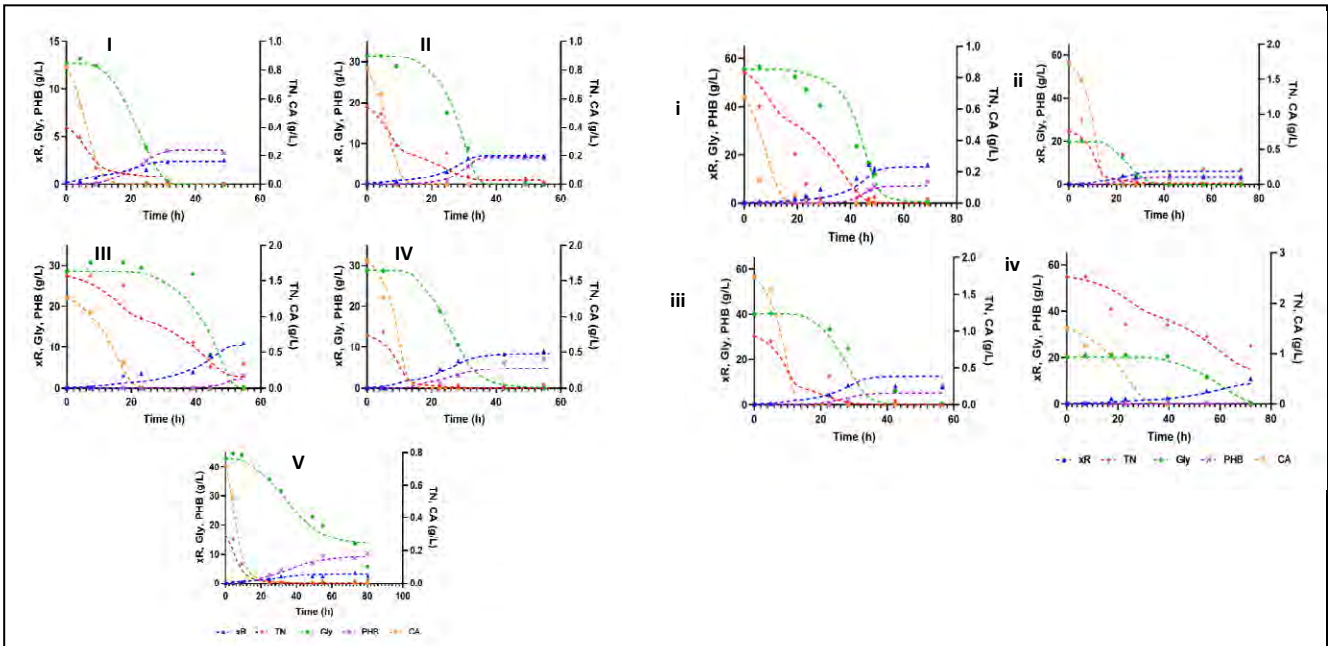

**Figure 3: Kinetic model** calibration (I-V) and validation (i-iv) runs. Dotted lines represent model predictions; data points are from fermentation experimetns. The state variables are: residual biomass (xR), total nitrogen (TN), glycerol (Gly), PHB and citric acid (CA).

A fungus able to grow on PHB mineral agar plate at 37℃ was successfully isolated from compost, its 28S RNA gene was amplified and sequenced. Based on NCBI BLAST, *Aspergillus fumigatus* produced significant alignment with the sequence, with a 99.11% identity score. The optimal culture conditions were extracted from the the literature[25]; The isolated fungi was cultured in liquid Busshnell-Haas medium (BHM) supplemented with 0.1% w/w PHB, at 45℃, and pH 7 for the biodegradation experiments to be ready for accelerated biodegradation of PHB films. It was desired to assess the biodegradation kinetics of PHB films with different casting solvents. The average initial inoculum was $26 \pm 9$ ($\times 10^4 \frac{spores}{ml}$). It can be seen from Figure 4 that the casting solvent altered the biodegradation kinetics of the films. The biodegradation behaviour could be modelled through first order kinetics ($-r_{PHB} = km_{PHB}$) giving rise to kinetic constants of 0.3453 and 0.3363 $h^{-1}$ for $CHCl_3$ and HFIP casted films, respectively. HFIP films had a lag phase of ~1 day unlike the $CHCl_3$ casted films. This could be explained through the different morphologies that the solvents produce affecting biodegradation kinetics as it is well-known that the biodegradation of PHB commences through microbial surface erosion. HFIP produced a film with much less surface features and fewer pore sizes but with pores orders of magnitude larger than the $CHCl_3$ casted films (Figure 5). Based on the AFM images, the spherulites of the HFIP casted films were very smooth, separated with rather deep depletion zones, whereas the $CHCl_3$ casted films exhibit many inhomogeneous surface features in the entire imaged area.

## CONCLUSIONS

The proposed generalized and improved kinetic model for the production of PHB by *C. necator* DSM 545 on glycerol and AS as carbon and nitrogen sources, respectively, provides valuable metabolic insights regarding PHB accumulation capacity of this microorganism. Moreover, it was found that biodegradation kinetics of solvent-casted PHB films depend on the type of solvent probably because it directly affected film morphology.

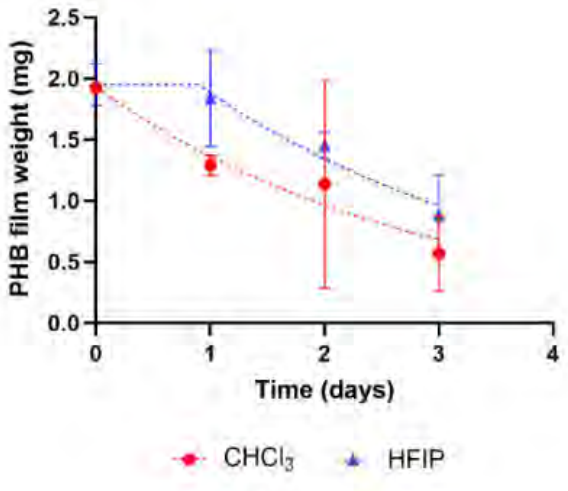

**Figure 4.** Mass loss of PHB films casted with $CHCl_3$ or HFIP. Dotted lines: first order kinetic model.

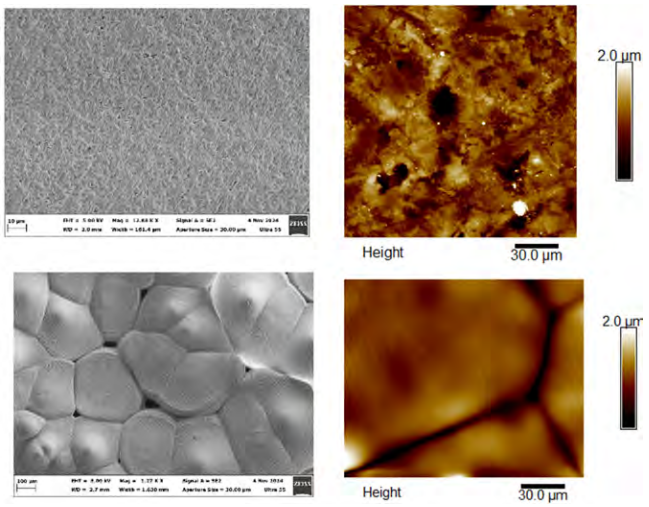

**Figure 5.** SEM and AFM images for PHB casted with $CHCl_3$ (top) and HFIP (bottom).

## ABSTRACT

The Fourth Industrial Revolution (Industry 4.0) brings a new chapter at dairy sector. Dairy 4.0 technologies are based on Big Data Analysis, Internet of Things, Robotics and Machine Learning. The usage of smart technologies to processing and analyzing complicated massive data has a significant impact in automation, optimization, functional costs and innovation. Artificial Intelligence tools are applied from dairy farms and production lines – including packaging- to supply chain. The aim of this paper is to demonstrate the most used applications of Machine Learning in dairy production so as to enhance the sustainability and the quality of dairy products. The most significant Machine Learning applications integrate machine vision, smart environmental sensors, activity collars, thermal imaging cameras, and digitized supply chain systems to facilitate inventory management. Challenges like milk adulteration, animal diseases, mastitis, traceability and supply chain losses are also addressed since they increase safety and quality standards in the dairy sector.

**Keywords**: Artificial Intelligence, Machine Learning, Algorithms, Dairy Production, Milk, Artificial Neural Network

## INTRODUCTION

The increasing demand for dairy products necessitates larger and faster production to enable the industry to meet consumers' nutritional needs. A particularly valuable subfield of Machine Learning (ML) is Deep Learning, which involves the use of Artificial Neural Networks based on mathematical functions. As illustrated in Figure 1, there are three levels: beginning with the input level, followed by the analysis and quantification of data, and the output layer utilized to generate probabilistic prediction outcomes, where the result is generated based on the specific task the algorithm is programmed to perform [1].

In recent times, Artificial Intelligence is evolving rapidly, finding applications in many fields of agriculture and food science and agriculture. ML, as a category of Artificial Intelligence, has a great potential to change the traditional methods in milk industry. ML is based on algorithms that are not entirely programmed. There are three categories of ML, supervised, unsupervised and reinforcement, which differ in the way of data processing. There are algorithms that are commonly used in industry for recognizing patterns, identifying data, making decisions and predictions that humans are unable to perform. Some algorithms that are used are: Support Vector Machine (SVM), Logistic Regression, K-nearest Neighbors, K-means, Decision Tree and Random Forest [2]. The Internet of Things (IoT) allows real time monitoring and data collection from the manufacturing stages. The Internet of Things is a system that consists of smart devices –smartphones, PCs, sensors, thermal cameras- which allow data transfer via wi-fi. These smart tools can be incorporated from dairy farms and raw material processing to final distribution. The main benefits of AI modeling are resource savings, high level productivity, operational efficiency, animal welfare and enhanced traceability. The necessity for integration in the dairy industry is based on the reduction of manual inspections, which pose potential risks, and the application of statistical and mathematical models to analyze large volumes of data that would be challenging and time-consuming for a scientist to resolve [3]. Moreover, it represents a model that contributes to sustainability

and enhances the industry's standards. The logistics system is improved, human errors and time-intensive manual tasks are minimized, and there is comprehensive control and coordination of production stages in compliance with quality and safety standards. Simultaneously, demand forecasting tools, aligned with consumer trends and preferences, aim to support informed decision-making, foster innovation, and drive the development of new products.

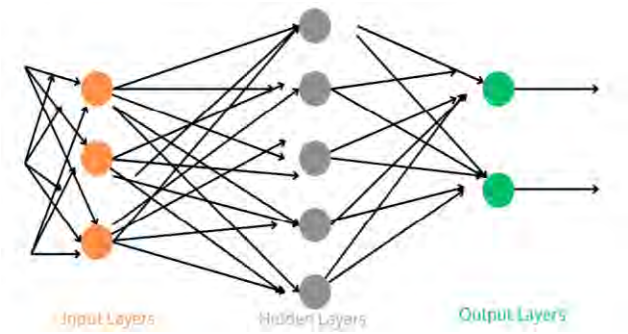

**Figure 1.** An example structure of ANN

## PRECISION LIVESTOCK FARMING

As mentioned before, the new technological advancements, begin at the farm level, enhancing the efficiency of animal management and living conditions. With the installation of intelligent environmental sensors, farmers can receive real-time updates on weather conditions, ambient temperature, humidity, and gas emissions. For optimal milk production, it is crucial to systematically monitor animals' health. Real-time health tracking is achieved through audio recordings, collars with integrated heart rate monitors, pedometers, and sensors that record animal behavior, productivity, body temperature, mobility, location, weight, and blood composition. Commonly used sensors in Precision Livestock Farming (PLF) include accelerometers, gyroscopes, temperature sensors, and biosensors. During data collection, ML analyzes these measurements to detect and prevent contagious diseases that could harm the herd. These PLF technologies further support farmers in making informed decisions, streamlining daily operations, and improving the overall supervision of their livestock [4].

## ROBOTIC MILKING SYSTEMS

It is crucial during milking that animals are not subjected to stress and that no damage or irritation is caused to their udders, as this could affect both their mental and physical health as well as the composition of the milk. To this end, automated milking systems have been developed to ensure the precise, efficient, and careful collection of milk from the animals' udders. These systems are equipped with durable sensors and high-resolution cameras in both two-dimensional (2-D) and three-dimensional (3-D) formats, enabling the monitoring of respiration, behavior, temperature, and thermal stress levels during the milking process [5]. Moreover, this system enables the calculation of milk yield, the percentage of milk protein, fat content, and somatic cell count. Additionally, parameters such as the lactation period, the animals' weight, and the frequency of milking per day are equally significant for monitoring the animals' health [6].

## AUTOMATIC FEEDING SYSTEMS

Another valuable addition to farm management is the use of automatic feeding systems, which represent a significant investment for livestock farmers, enhancing the efficiency of farm operations. There are two types of feeding systems: mobile systems and stationary systems, which are installed at specific locations. For mobile feeding systems, prior mapping of the area is required so that the machine can recognize the feeding points as well as any obstacles within the farm. The farmer adds various types of feed according to the animals' needs and schedules the feeding times for each day. In this way, the physical presence of the farmer at the farm is no longer required, granting them the flexibility to focus on other tasks. With the integration of sensors on the animals and automatic feeding systems, a comprehensive overview of the animals' health, the amount of feed consumed, and the precise calculation of the feed required for production needs is available. Research has shown that this approach reduces stress levels in animals and improves their feeding behaviour [7]. As a result, productivity and the quality of the milk produced are increased, while significant labour time and valuable financial resources are saved. Lastly, the algorithms used to analyze the aforementioned data provide more accurate results for farm management, reducing errors caused by human judgment. At the same time, the farmer can access the databases at any moment to stay informed about the herd's behaviour [8].

## MILK ADULTERATION

Milk and its derivative products are widely favored by consumers due to their highly nutritious composition, containing high-quality proteins, minerals, and vitamins that positively contribute to human health. The growing demand for these goods has brought forth incidents of adulteration that degrade product quality and mislead consumers. Potential adulterants include starch, water dilution, pseudo-proteins, mixing of different types of milk, addition of whey, or skimmed milk. The most sig-

nificant scandal in the history of the dairy industry involved the addition of melamine, a substance not approved for consumption, which was illegally added to milk products to falsify protein content. Beyond traditional methods of adulteration detection—which typically identify one or two components, such as the ELISA method—advanced models such as Support Vector Machines (SVM) have been developed. These models are non-destructive and outperform traditional methods in terms of specificity, sensitivity, and correlation, while enabling real-time data analysis. [2]. These models leverage multispectral sensors with the capabilities of AI and neural networks. Once data are collected, they are transmitted via Wi-Fi to a computer for processing. Using neural networks, the system identifies adulterants, displaying results as "adulterated" or "non-adulterated," and classifies the type of adulterant. This method is both cost-effective and highly efficient in data analysis [9]. Table 1 lists the algorithms with the highest accuracy in detecting milk adulteration.

Furthermore, at Table 2 the results of a study that examined the accuracy of milk quality classification using a milk dataset, comparing the Nearest Neighbors and Alpha-Beta algorithms are showed. [10]

**Table 1.** Accuracy Performance of Machine Learning Algorithms

| | Skimmed Milk | Full Cream Milk | Toned Milk | Double Toned Milk | Standardized Milk | Buffalo Milk | Average Accuracy |
|---|---|---|---|---|---|---|---|
| **Support Vector Machine** | 90% | 90.1% | 90.3% | 89,9% | 90% | 89.9% | 90% |
| **Decision Tree** | 91% | 91,9% | 92% | 91.5% | 91.8% | 92% | 91.7% |
| **Neural Network without hyperparameter** | 92.4% | 93% | 93.2% | 92.1% | 92.7% | 92.8% | 92.7% |
| **Neural Network with hyperparameter** | 100% | 100% | 100% | 100% | 100% | 100% | 100% |

**Table 2.** Milk quality assessment

| DATA SET | ALGORITHMS | METRICS | HIGHEST CLASSIFICATION ACCURACY | NOTES |
|---|---|---|---|---|
| Milk Data SET | 1. NN<br>2. AB | Accuracy<br>Precision<br>Recall<br>F1-Score | 95.4%<br>99.9% | Classification of milk quality by pH and temperature values |

## MACHINE VISION

Another change that can reduce errors and increase efficiency is the implementation of machine vision systems during the production and packaging of dairy products. Their operation is divided into two stages: the acquisition and processing of images captured from production points. Using cameras with two-dimensional and three-dimensional imaging capabilities, hyperspectral imaging—a combination of machine vision and spectroscopic techniques—ultrasound, X-rays, and sensors, real-time data are collected related to object recognition, cracks, foreign materials, the size of the product and its packaging, weight, shape, and color. These data are stored in databases for analysis to identify potential anomalies and deviations from standards. Particularly for dairy products, which are highly perishable, a defective package can compromise their quality and dissatisfy consumers [11].

## PASTEURIZATION MONITORING

One of the most critical processes in the production line of milk and dairy products is thermal processing, as it significantly affects both the quality and safety of the final products. Artificial Intelligence, and more specifically Machine Learning, in conjunction with the Internet of Things (IoT), plays a pivotal role in real-time monitoring of milk pasteurization. The intelligent software developed for this purpose can be seamlessly integrated into both older machinery and more advanced equipment. This system enhances the production line by incorporating sensors that measure pasteurization temperature, processing time, and moisture levels. These values are recorded and stored in databases at 10-second intervals. In the event of deviations from the desired values, corrective actions are automatically triggered through real-time activation of sensors to rectify errors promptly. By employing algorithms such as Random Forest, XGBoost, and Gradient Platform, the system can accurately predict the quality of the final food products based on the data collected from each batch. Additionally, it provides timely alerts for potential mechanical failures that could disrupt production. This automated model not only enhances product quality but also contributes to sustainable production by reducing and preventing errors that would otherwise lead to unnecessary energy consumption and resource waste [12].

## BLOCKCHAIN AND RFID TAGS IN DAIRY PRODUCTS

In modern times, consumers have developed a heightened interest in the origins of the food they consume, the living conditions of animals, the quality of animal feed, and the processing of these foods along the production line. By utilizing Blockchain technology and incorporating RFID (Radio Frequency Identification) tags, real-time data is collected from the farm to the

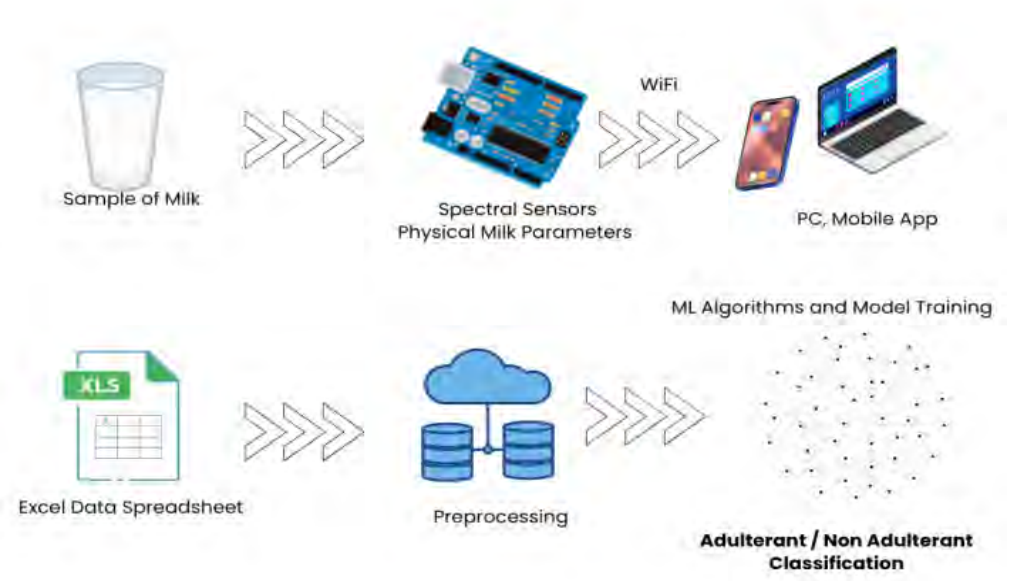

**Figure 2.** Graphical sceme of AI Enabled Multispectral Sensor System.

distribution points of the products. Through scanning the QR code on the product packaging, consumers can access a network of information regarding sustainability levels, factory greenhouse gas emissions, the quality of life of the animals from which the milk was sourced, the thermal processing undergone, and the records of temperature and humidity levels during storage and distribution. This model enhances both product traceability and identification. Any deviation from required conditions can be immediately detected, enabling the recall of an individual product rather than the entire batch, as is typically practiced today. Moreover, it is an intelligent method to ensure the authenticity of raw material origins and reduce incidents of product adulteration or unfair practices. Finally, the Blockchain system upgrades logistics management by providing real-time insights into inventory levels, the location of each batch in storage refrigerators, and the distribution routes of suppliers. This allows for more effective monitoring of production quantities and speeds, ultimately improving the efficiency of the supply chain [13-14].

## CUSTOMER CHURN PREDICTION MODELS

Machine Learning algorithms are also applied in the development of innovative products by collecting data on consumer preferences and market trends. Predictive algorithms are continuously trained using information circulating on the internet, social media platforms, and product reviews. After processing, categorizing, and evaluating the data, the system can propose ideas for new recipes and predict consumer audience responses. Algorithms such as Logistic Regression and Bayesian algorithms are used to predict the likelihood of customer attrition. Additionally, they can suggest improvements to existing recipes by modifying, for example, texture, proportions, or ingredients. With this software, scientists can conduct targeted trials for the development of new dairy products that meet market demands. Moreover, by considering specific dietary restrictions such as celiac disease, lactose intolerance, vegan, or vegetarian diets, it is possible to launch new products tailored to these groups, enriching their daily nutrition with innovative options. This model not only promotes sustainability but also helps the production company differentiate itself with products designed in alignment with contemporary trends [15-16].

## CHALLENGES

Artificial Intelligence, and more specifically Machine Learning, which is the focus of this study, provides a wide range of possibilities in the dairy production chain. It offers solutions to flow-related problems, reduces human error, and acts preventively to avoid costly damages. To integrate this new operating model, Dairy 4.0, targeted actions are required to maximize the potential benefits it offers. Naturally, with the introduction of new technologies, certain challenges arise in the early stages of implementation, which demand continuous attention and training regarding the new mechanisms. In particular, livestock farmers need to develop digital skills to understand the interactions within the Internet of Things (IoT). Furthermore, for a traditional farm to operate according to the principles of Dairy 4.0, the issue of digital

infrastructure and connectivity in rural areas must be addressed—an endeavor that requires both time and significant financial resources. At the same time, within the factory environment, where older-generation machinery lacking connectivity may still be in use, substantial investment will be necessary to replace such equipment. Consequently, this situation gives a competitive advantage to larger and more powerful dairy production companies over smaller producers, who will face greater difficulty and delays in adopting Machine Learning tools. Equally important is the need to provide systematic training to staff on the new systems, enabling them to leverage these tools to their full potential. This creates a challenge for companies in recruiting more specialized personnel, thereby hindering the rapid expansion of production. Training is also crucial for the timely handling of issues related to data breaches and threats to large datasets. Cybersecurity requires the installation of software that monitors the network and cloud security, providing early warnings of malicious attacks. [17] This approach ensures the reliability and integrity of the data.

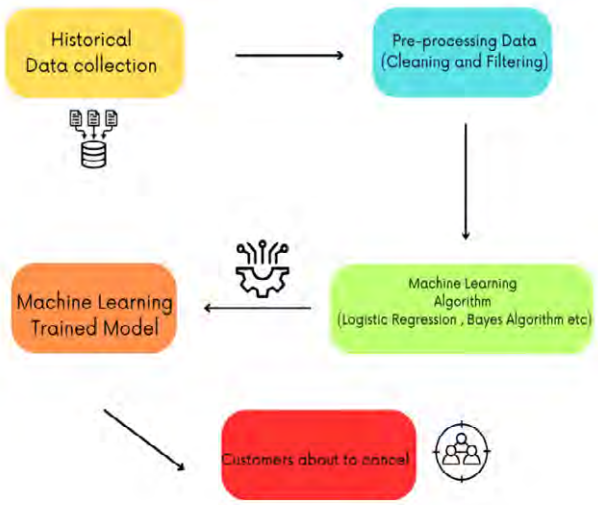

**Figure 3.** Customer Churn Prediction Model

## CONCLUSIONS

Machine Learning has the potential to transform the dairy industry into a modern, automated sector, enhancing both speed and efficiency. The Internet of Things (IoT), big data, and algorithms facilitate the digitization of processes and the continuous monitoring of production. However, transitioning from traditional operations to more advanced infrastructure requires time and capital, both for equipment and for software systems. Machine Learning models increase accuracy, enhance sustainability, and optimize the management of gas emissions. In the dairy industry, where safety and quality standards are exceptionally high, it is crucial to anticipate errors that could compromise the raw material and, subsequently, the final product. The solution lies in algorithm-based systems that are continuously trained through data recording, enabling rapid classification, data grouping, and the categorization of critical values—thereby improving production stages.

## ABSTRACT

The scale-up of processes with complex fluid flow presents significant challenges in process engineering, particularly in fermentation. Computational fluid dynamics (CFD) is a crucial tool for accurately modelling the hydrodynamic environment in bioreactors and understanding the effects of scale-up. This study utilizes Higher Order SVD (HOSVD), which is the multidimensional extension of Singular Value Decomposition (SVD), to identify the dominant structures (modes) of fluid flow in CFD data of fermentation process simulations. Similarly to Proper Orthogonal Decomposition (POD), also based on SVD, this method can be used to identify the dominant structures of fluid flow, and additionally explore the scale parameter space. As a first test case, we examined five scales of a reciprocally shaken flask bioreactor, from 125 mL to 10 L, specified using basic empirical scale-up rules. Results indicate a common set of spatial modes across all scales, thus confirming that the scale-up method assures some dynamic similarity. However, the relative importance of these common spatial modes changes sensibly across process scales. The main spatial mode that represents the large recirculating flow in the flask can account for 19.8% of the data variability for the 125 mL scale but only 11.7% for the 10 L scale case. In this larger scale, one needs a larger number of modes to capture flow dynamics, thus showing an increase in flow complexity. These findings illustrate the impact of scale on fluid dynamics in a particular bioreactor flow but also provide a proof of concept for this methodology.

**Keywords**: HOSVD, CFD, Scale-up, Fermentation

## INTRODUCTION

Scaling up fermentation processes is a primary focus in bioprocess engineering. Like other areas in chemical and process engineering, moving fermentation operations from bench-scale to pilot-scale, and ultimately to commercial-scale, exacerbates mixing inefficiencies, which are then responsible for spatial gradients in species concentration and mechanical stimuli. The biomass experiences these gradients as oscillatory stimuli, which can affect cell phenotype. Such effects can alter metabolic activity, resulting in hard to predict outcomes and decreased productivity [1].

The effects of scale arise from the interaction of the biological system with the hydrodynamics of the reactor [1]. Therefore, Computational Fluid Dynamics (CFD) is one important tool to clarify how transfer phenomena change with scale. Due to the difficulty of analysing the 3D scalar and vector fields resulting from a multiphase CFD simulation, the need for a solid method to do fluid flow feature extraction arises.

One of the most well-established methods for flow feature extraction is Proper Orthogonal Decomposition (POD). Its primary applications in Fluid dynamics have been to study, analyse and model turbulent coherent structures both from experimental as well as simulated data [2]. POD allows for the identification of the set of spatial modes (basis vectors) that represent most of the kinetic energy of the system and their temporal coefficients. The linear combination of the main modes allows

for a reconstruction of the data. The analysis of the modes and temporal coefficients can clarify the main coherent structures in a fluid flow.

POD has been demonstrated to be equivalent to Principal Components Analysis (PCA), Karhunen–Loève decomposition and Singular Value Decomposition (SVD), with the nomenclature used depending mostly on the area of application. POD, as well as PCA and SVD, are in general terms methods to reduce a large number of correlated variables into a smaller number of uncorrelated variables, finding a few ordered basis vectors able to optimally express (mean squared error wise) the initial large data set [2]. These basis vectors are often denoted in the context of CFD data as “modes”.

As a tool for identifying coherent structures and their dynamics, POD can enhance the understanding of scale-up effects in aerated fermentation and thus improve process design. Notable works applied to CFD include studies on stirred tanks by Mayorga et al. for a single-phase case [4]. Multiphase cases, as the one treated in this work, present greater complexity due to the interphase interactions in a turbulent flow, and are rarer in the literature. One such example is our previous work on CFD data of an aerated stirred tank bioreactor [5].

POD is only defined for a rank 2 tensor, that is a matrix, and as such it is not possible to directly apply it to a problem with additional parameters. To study the effect of scale on the main flow features, process scale can be defined as a parameter of interest and POD applied to each set of data corresponding to a particular process scale. However, the data will not be decomposed into the same basis vectors, that is the same modes, and thus a quantitative analysis of the impact of scale on the relative importance of the different modes is not possible.

To apply a similar methodology to a parametric case it is necessary to use tensor decomposition. Multiple methods for tensor decomposition exist, the most common being canonical polyadic decomposition (CP) and variations of Tucker decomposition such as Higher Order Single Value Decomposition (HOSVD) [6].

Canonical polyadic decomposition decomposes a tensor into a sum of rank one tensor (vector) products. Each rank one tensor can be seen as a mode in each parametric space, which then results in an equal number of modes in the decomposition for each parameter. Due to the nature of CFD data, in almost all cases there are many more points in space (number of finite volumes in the CFD mesh) than in time. Also, due to the cost of CFD simulations, the number of simulations made varying a particular parameter, such as the process scale, will be much lower than the number of finite volumes. This imbalance in the data makes CP a worse option for CFD data.

Tucker decomposition follows a different approach: it decomposes the original data into one smaller core tensor of the same rank, and one factor matrix for each parameter in study. The core tensor encapsulates the level of interaction between the parameters while the factor matrices can be seen as analogous to the modes found by POD or CP. With some data manipulation, the resulting tensor and matrices can be easily interpreted. Due to its greater flexibility and better fitting, we choose Tucker decomposition to proceed with our work despite the greater computational cost to perform the decomposition. In particular, we used the Higher Order Single Value Decomposition (HOSVD) implementation of Tucker decomposition [7].

Tensor decomposition has been used in various machine learning applications such as signal or image processing for tensor completion, principal component analysis, regression and classification, but tensor decomposition is less commonly applied to CFD data [8]. Applications of HOSVD to CFD data include parametric wind speed models, parametric models for flow over an aerofoil and flow feature identification on channel flows [9][10][11]. While much of the relevant literature highlights the potential of HOSVD in parametric model development, some studies recognise its use in flow feature identification. Despite this, in our review of the literature no instances were found where parametric modelling and feature identification are combined. We propose one such application of HOSVD focusing on flow feature identification while conducting a parametric study of the effects of process scale. This introduces innovation both methodologically and in the application to scale-up of bioreactors.

The approach here proposed enables us to identify the main coherent structures (modes) that emerge at various scales of fermentation and quantify the contribution of each one of the modes to the total energy of the system. Our methodology includes CFD simulations of the fermentation process at multiple scales, with the operating parameters determined by traditional scale-up criteria. The main challenge we found was the construction of the data tensor which requires all data to be referring to equivalent points in space. Through interpolation, we aligned the different CFD meshes and constructed a snapshots tensor of the CFD results across all process scales, standardized on the same spatial reference grid. This systematic approach bridges a gap in the literature, combining parametric modelling with flow feature identification to provide new insights into scale-up effects in fermentation. By helping to uncover the phenomenological roots of the scale-up problem, our methodology could inform new protocols, making the process of fermentation scale-up more expedient and efficient.

## METHODS

As a case study to illustrate tensor decomposition of CFD data modelling chemical and biochemical process scale-up we modelled a set of non-baffled Erlenmeyer flasks commonly used in small scale laboratory fermentation, at different process scales. We opted for this bioreactor due to its geometrical simplicity making it simpler to model. The geometry of the flasks was reproduced from commercially available models and is represented in Figure 1. We modelled flasks of scales 125 mL, 250 mL, 500 mL, 1 L and 10 L, maintaining geometrical similarity. The 10 L process scale is hypothetical but we expected it to provide enough scale contrast to illustrate the changes found with changing process scale. Mixing in these bioreactors is induced by a shaking motion [12], and in particular we have chosen reciprocal shaking, which is a periodic motion in one dimension. This isn't the most common shaking mode, but it was preferred due to its greater simplicity and suitability for 2D CFD simulations, with lower computational cost.

Although not fully representative we preferred 2D simulations, which should be good enough to illustrate our methods, and highlight the effect of process scale on the governing flow modes. All flasks were simulated with 20% of the capacity filled, consistent with common practice. The amplitude of the movement is known to have minor impact on mixing performance, so an arbitrary value of 1.5 cm was used for the smaller scale and then scaled accordingly for the larger scales [13]. The frequency of the movement was adjusted for each scale by keeping the power per unit volume of liquid (P/V) constant.

$$N_p = \frac{P}{\rho n^3 d^4 V^{1/3}} \approx 70Re^{-1} + 25Re^{-0.6} + 1.5Re^{-0.2} \quad (1)$$

The power number ($N_p$) was estimated using the correlation of Klöckner and Büchs as seen in eq. 1 [14]. The 10 L flask falls outside the scope of the experimental data fitted by this correlation, which is a common limitation in solving scale-up problems solely based on nondimensional numbers and other empirical rules (such as P/V constant). Table 1 summarizes the process scales under analysis and corresponding values of $d_{max}$ (maximum flask diameter) and n (frequency of agitation).

**Table 1:** Volume, maximum diameter and agitation frequency of each flask.

| **Scale (mL)** | 125 | 250 | 500 | 1000 | 10000 |
|---|---|---|---|---|---|
| **$d_{max}$ (mm)** | 66 | 83 | 101 | 128 | 271 |
| **n ($s^{-1}$)** | 2.00 | 1.81 | 1.71 | 1.52 | 1.07 |

To model the fluid dynamics, we used the Volume of fluid (VOF) model implemented in the interFoam solver of the OpenFOAM v2206 finite volume opensource library. The interFOAM solver has been validated to model shake flask flows [15]. In eq. 2-4 we present the VOF RANS equations with k-epsilon closure equations not presented for brevity, the closure equation parameters used are the standard OpenFOAM values.

$$\nabla U = 0 \quad (2)$$

$$\frac{\partial}{\partial t}\rho U + \nabla(\rho U \cdot U) = -\nabla p + \nabla(\tau + \tau_t) + \rho g + F_\sigma \quad (3)$$

$$\frac{\partial \alpha}{\partial t} + (U \cdot \nabla \alpha) = 0 \quad (4)$$

To model the shaking motion, we used an oscillatingLinearMotion dynamic mesh. The CFD meshes are 2D axial cuts of the geometry and were constructed with the OpenFOAM meshing tools. The meshes are hexahedral-dominant with from 25k to 210k finite volumes. To construct a coherent data tensor the mesh of the 125 mL flask was chosen as a basis and velocity fields from all larger geometries were interpolated onto that basis using OpenFOAM's transformPoints (scaling) and mapFields (interpolation) functions, one additional advantage of this is the effective down sampling making the tensor smaller

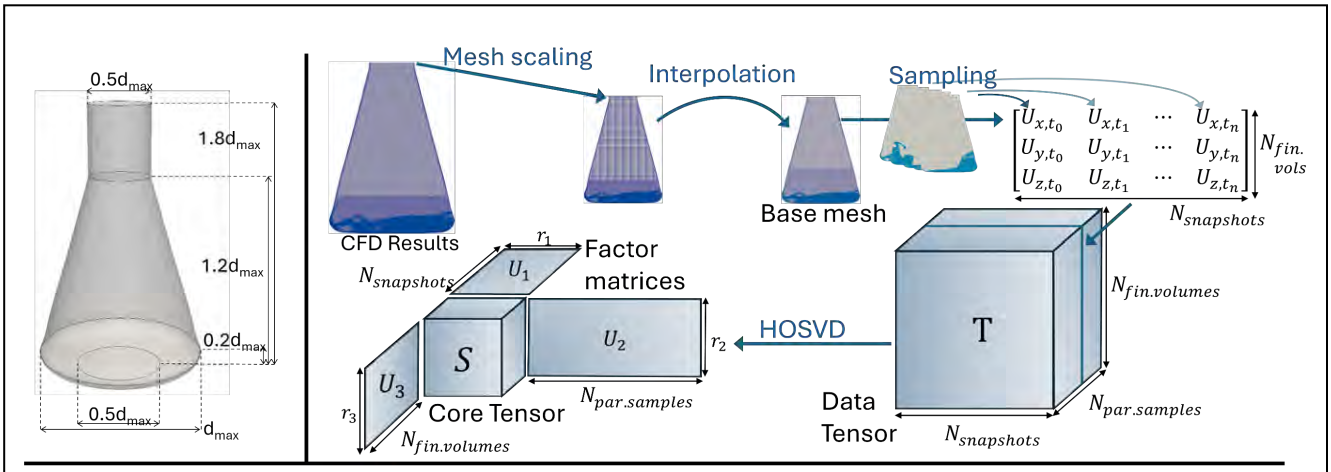

**Figure 1.** Schematic representation of the flask geometry and framework of the methods for data treatment.

and tensor decomposition computations lighter.

The snapshot matrix was constructed from velocity fields by arranging each velocity component per finite volume into columns, with each column representing a temporal snapshot. To ensure comparability across process scales, sampling was performed at 51 equally spaced times relative to the reciprocating movement's period, forming one full cycle. Snapshot matrices (shaped $N_{snapshots} \times 3N_{finite_volumes}$) for five scales were concatenated into a data tensor ($N_{snapshots} \times 3N_{finite_volumes} \times N_{scales}$).

The tensor was decomposed via truncated HOSVD using TensorLy a python library, with decomposition ranks of 20 (time), 5 (scale), and 50 (space). This decomposes the tensor into a core tensor (S), encoding parameter interactions (space, time, scale), and factor matrices ($U_1$, $U_2$ e $U_3$), analogous to POD modes (Eq. 5) in space, time, and scale, respectively.

$$T \approx S \times_1 U_1 \times_2 U_2 \times_3 U_3 \quad (5)$$

The method used here was proposed by Tucker and solves an eigenvalue problem to compute the leading left singular vectors of each matrix forming the data tensor. It then finds the core tensor by tensor multiplication of these vectors (transposed) with the data tensor. The number of left singular vectors corresponds to the rank of the decomposition in that parameter space. For the sake of brevity, we do not develop this methodology further, but further discussions on tensor decomposition and HOSVD can be found on the extensive review by Kolda and Bader [6]. The data tensor in this work includes ~$2 \times 10^7$ elements, it takes 60 seconds to construct the tensor and only 4 seconds to perform the decomposition, using an in-house modest workstation.

## RESULTS AND DISCUSSION

Figure 2 illustrates a set of snapshots of the volumetric fraction of water (α) for various scales taken at the same phase-matched times relative to the period of each movement (π). We present the α field as it is the most intuitive way to show the free-surface dynamics. Analysis of the snapshots reveals high dynamic similarity between the 125 mL and 1L scales. Particularly at the extremes of the flask's movement (at the relative times 2/5π and π) a similar wetted height of the flask wall is predicted and, the wave crests exhibit similar shapes. However, only at 2/5π are liquid ejections similarly predicted for both scales. At the 1/5π and 3/5π times, a similar wave pattern is predicted, but with greater amplitude for the smaller scale. For the 10 L scale less dynamic similarity is found. These differences illustrate the expected failure of the empirical scale-up correlation for the 10 L scale.

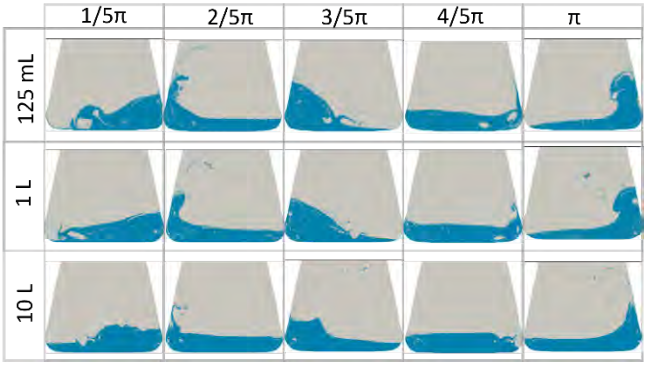

**Figure 2**. CFD results for different flask sizes, with the regions of water volumetric fraction greater than 0.95 painted in blue.

Following the preliminary qualitative analysis of the alpha fields, we propose tensor decomposition as a method to quantify the dynamic similarity of the fluid flow across process scales. The columns of the spatial factor matrix can be seen as spatial modes analogous to POD modes. Individual modes or combinations of modes are well-established to represent one or more correlated flow features. By quantifying the importance of each mode for each process scale, we can compare the fluid flow patterns at different scales. Applying tensor multiplication to the spatial factor matrix and the original data tensor provides a projection of the CFD data into the space spanned by the spatial modes. By taking the norm of the results of this operation over the temporal domain, we obtain the energy of each spatial mode for each process scale. The energy in this context means the amount of variability in the original data that is explained by each mode. Figure 3 presents these results, normalized by the sum of the energy of all modes for each process scale.

In Figure 3 we observe that the main two modes are the same across all process scales. But for less important modes the order of importance can change between process scales. Further, the combined importance of the two main modes decreases as the scale increases, from a combined normalized energy of 28.5% for 125 mL to 17.8% at 10 L scale. This loss of importance of the two top modes could be accompanied by an increase in the number of modes (ie. more relevant flow features), but we do not observe this. Depending on scale 43 or 44 modes are required to achieve 95% of the total energy represented in the decomposition. The top 30 modes represent a similar cumulative relative energy across all scales and the top 10 modes for each process scale represent 54%, 57%, 50%, 52% and 48% in ascending

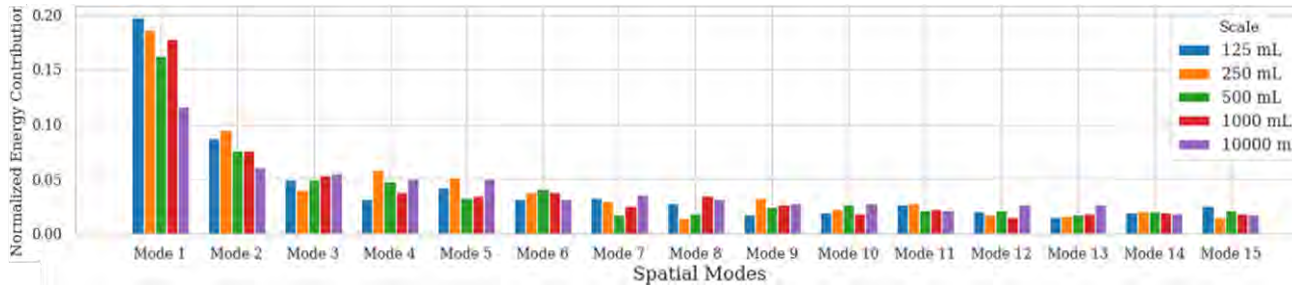

**Figure 3:** Relative normalized energy contribution (explained variability) of the 15 main spatial modes

process scale order. From these results we conclude that the relevant spatial modes are generally conserved across process scales, but their energy becomes more distributed and less concentrated on the top modes as scale increases. This redistribution of energy suggests a complexification of the velocity field with the increase of scale, likely due to enhanced turbulent effects for the larger scales.

To explore the connection between fluid flow features and spatial modes, we graphically analysed the spatial distribution of the modes and their temporal distribution. In Figure 4 the first five modes are presented and their normalized temporal coefficients for each process scale. The main modes exhibit a clear periodic oscillation in the normalized temporal coefficient curve, while the remaining modes appear to have a periodic nature with increased noise. Analysis of the Lissajous figures for each combination of the temporal coefficients (not presented for brevity) reveals that the two main modes have the same frequency and are π/2 out of phase for all process scales. Based on their spatial and temporal distribution mode 1 represents the rise of the fluid as the flask slows before reverting direction and mode 2 is the waving liquid transport during the movement of the flask. Mode 3 is π/4 out of phase and has twice the frequency of mode 1. It is then likely connected to the formation of wave crests at the extremes of the flask's movement.

Modes 4 and 5 exhibit interesting interactions with each other and with the two main modes. For the 125 mL and 250 mL scales, modes 2 and 4 are π/2 out of phase, as are modes 2 and 5. Modes 1 and 4 are 3π/4 out phase, while modes 1 and 5 are π/4 out of phase. This indicates that for these scales modes 1, 2, 4 and 5 represent coherent structures that peak sequentially at π/4 phase intervals. Modes 4 and 5 likely represent vortical structures related to the liquid jump at the extremes of the flask's movement. For the 500 mL scale a similar arrangement is found but with mode 6 (not pictured) showing similar dynamics to mode 4 as before, and mode 4 becoming an harmonic of mode 1. The results for 1 L and 10 L scales align with the results for 500 mL scale. These results indicate that the fluid flow during the travelling parts of the flasks movement represented by modes 1 and 2 is conserved with scale, at least for the adopted scale-up protocol. However, the phenomena at the extremes of the flask's movement show important changes with scale. Unexpectedly, an apparent discontinuity appears between the 250 mL and 500 mL scales, which seems to indicate that there is a particular loss of effectiveness in this scale-up protocol between these two scales.

Our findings demonstrate that as process scale increases, the main modes connected with dominant free-surface phenomena (e.g., wave formation, surface renewal) lose prominence relative to turbulence-driven dissipation within the bulk fluid phases (air and water). This redistribution of power dissipation highlights a decoupling of power dissipation and interfacial phenomena. The interfacial phenomena being the driving factor for oxygen mass transfer. From our analysis of this case we reach a central conclusion: scale-up strategies that neglect the evolving balance between surface and bulk dissipation mechanisms in free-surface aeration may fail to preserve mass transfer efficiency, despite achieving target power consumption metrics.

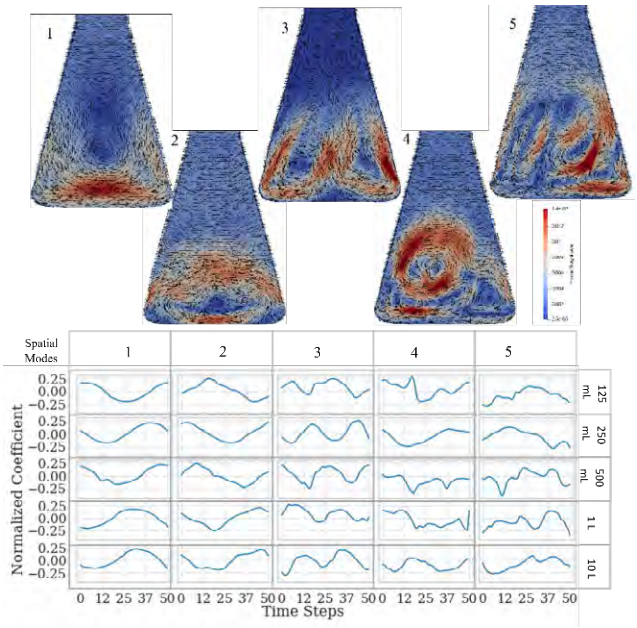

**Figure 4:** Spatial modes for the 5 main modes and normalized time coefficient curve for each mode/scale.

## CONCLUSION

In this work we introduced a new methodology to study the effects of scale-up of fermentation processes, demonstrated with the scale-up of a shake flask bioreactor fermentation. Our findings reveal the impact of scale on fluid dynamics in a particular bioreactor flow and provide a proof of concept for this methodology, which can give insights for a more rational approach to bioreactor scale-up and optimization. We believe there is wide future application for bioreactor types, where geometric similarity is maintained. While new methods are required for future applications where geometrical similarity is broken. The application of this method can be extended to other scale-up rules and beyond scale-up, to the construction of parametric reduced models of multiple processes including reaction and mass-transfer models.

## ABSTRACT

Extended Dynamic Mode Decomposition (EDMD) and its variant, the pqEDMD, which uses a p-q-quasi norm reduction of polynomial basis functions, are attractive tools to derive linear operators approximating the dynamic behavior of nonlinear systems. This study highlights how this methodology can be applied to data-driven modeling and control of bioprocesses by discussing the selection of several ingredients of the method, such as the polynomial basis, order, data sampling, and preparation for training and testing, and ultimately, the exploitation of the model in linear model predictive control.

**Keywords**: System Identification, Dynamic Modelling, Model Predictive Control, Process Control, Numerical Methods

## INTRODUCTION

Digital twins are increasingly popular as part of the Industry 4.0 revolution but are generally understood as digital representations of the industrial processes obtained through machine learning techniques and, in particular, the use of neural networks (NN). Although NNs are versatile and have proven their utility in many applications, there exist less popular yet appealing alternatives offered by the stream of research that revolves around the Koopman operator approximation [1–3], and the different decomposition methods to get an approximation of the Koopman operator [4]. In particular, the Extended Dynamic Mode Decomposition (EDMD) provides the possibility to derive a linear representation of a nonlinear system in a so-called “function space” of nonlinear basis functions (denoted “observables”) [5].

The objective of this study is to show the potential of EDMD [5,6] and one of its extensions, pqEDMD, developed by the present authors in [7] for modeling arbitrary systems, including bioprocesses. The main advantage of providing a linear representation is that standard linear estimation and control techniques can be further exploited, particularly linear model predictive control (MPC), whereas NNs require more complex nonlinear methods [8]. The prominent feature of pqEDMD is that it systematizes the definition of the dictionary of observable functions by resorting to orthogonal polynomials and selecting the approximation order by sweeping through two parameters, denoted p and q.

This paper explains how the approximation can be constructed, discusses practical aspects such as the selection of training and testing data, and shows how the resulting models can be exploited in linear MPC as applied to a simple yet representative bioreactor case study.

## MODELING AND CONTROL USING PQEDMD

This study considers a data-driven modeling strategy called the p-q-quasi-norm extended dynamic mode decomposition (pqEDMD) that takes its origins in the EDMD formulation from Williams, et al., [5]. This method applies a p-q-quasi norm reduction to the set of observables, limiting the maximum order of the orthogonal polynomials that compose the basis for the approximation. Following the approach for incorporating the system inputs in the EDMD decomposition [3], the overall approach is to approximate the original nonlinear dynamics with a linear operator and to apply linear control methods.

### pqEDMD Model Derivation

Consider an autonomous nonlinear system in

discrete-time, with state variables $x(k) \in \mathbb{R}^n$, discrete-time $k \in \mathbb{Z}_0^+$, and forcing signal $u(k) \in \mathbb{R}^m$, described by the following difference equation:

$$x(k+1) = T\big(x(k)\big) + Bu(k) \tag{1}$$

where $T: \mathbb{R}^n \to \mathbb{R}^n$ is the differentiable vector-valued evolution map, i.e., the nonlinear state transition rule, and $B \in \mathbb{R}^{n\times m}$ is the input matrix, defining the system as input affine. Note that the output of the system is the full state. An orbit of the system is the sequence of states $\{x_i\}_{i=0}^{k}$ that comes from the solution of (1). The sequence is the successive application of the non-linear mapping $T$ from an initial condition $x_0 \in \mathbb{R}^n$ at $k = 0$ and a specific sequence of forcing signals $u \triangleq \{u_i\}_{i=0}^{k-1}$. It is possible to group each orbit in a set of tuples $\{(x_i, y_i, u_i)\}$, where $y_i = T(x_i) + Bu_i$. Then, organize these tuples into the data matrices,

$$X = [x_1 \quad \dots \quad x_N],\ Y = [y_1 \quad \dots \quad y_N],\ U = [u_1 \quad \dots \quad u_N]. \tag{2}$$

The rationale behind the approach is to get linear predictors of a function space of observables $\Psi(x) = [\psi_1(x), \cdots, \psi_d(x)]^\top: \mathbb{R}^n \to \mathbb{C}^d$, where the elements of the function space come from a family of orthogonal polynomials, and the use of q-quasi norms with a maximum order p to reduce the maximum order and quantity of elements in the observables [7]. The condition that these observables must satisfy is:

$$\Psi(y) = A\Psi(x) + Bu + r(x,u) \tag{3}$$

where $r(x,u) \in \mathcal{F}$ is the residual term to minimize in order to find matrices $A$ and $B$. This leads to the least squares problem,

$$\|r(x,u)\|^2 = \frac{1}{N}\sum_{i=1}^{N}\frac{1}{2}\|\Psi(y_i) - A\Psi(x_i) - Bu\|_2^2.$$

The evaluation of the data matrices (2) with the set of observables produces the observed data matrices $\Psi(\{X,Y\}) \in \mathrm{R}^{d\times N}$. Then, from the singular value decomposition of the observed state $\Psi(X)^T = \mathcal{U}\mathcal{S}\mathcal{V}^T$, it is possible to determine the effective rank of $\Psi(X)$ using the singular values $\sigma_1, \sigma_2, \cdots, \sigma_d = \mathrm{diag}(\mathcal{S})$. The effective rank or $\epsilon$-rank $r_\epsilon = \min\{r: \sigma_r \le \epsilon N \sigma_1\}$, where $\epsilon << 1$, an arbitrarily small number, e.g., eps in Matlab.

From the effective rank, $\mathcal{U}_r = \mathcal{U}_{:,1:r_\epsilon}$, $\mathcal{S}_r = \mathcal{S}_{1:r_\epsilon,1:r_\epsilon}$ and $\mathcal{V}_r = \mathcal{V}_{:,1:r_\epsilon}$, and the solution becomes:

$$\begin{aligned} D_r &= \mathcal{S}_r \backslash \mathcal{U}_r^T \Psi(Y)^T \\ [A \quad B]^T &= \mathcal{V}_r D_r. \end{aligned} \tag{4}$$

Notice that the solution for the transition matrix $A$, i.e., equation (4), cannot guarantee the convergence of the function space into a stable attractor, i.e., $A$ may not be Hurwitz (all the magnitudes of its eigenvalues less or equal to one). Then, some solutions for some p-q parametrization give trajectories of observables that diverge to infinity. This guarantee is an open problem and highlights the importance of testing many combinations of p-q parameters on a particular dataset.

As the purpose of linear predictors, as in (3), is the synthesis of controllers, it is necessary to recover the state from the observables. Usually, the recovery of the state requires the solution of an additional least squares problem. Instead, we exploit the structure of the order-one polynomials in the set of observables and recover the state analytically. The order-one polynomials are linear functions of the individual states. Therefore, the $C$ matrix comes from converting the inverse of the order-one polynomials into a matrix form.

$$C = \Big[c_p \quad ; \quad \mathrm{diag}\{\psi_i^{-1}(x)\}_{i=1}^{n}; \quad 0_{(n,d-n-1)}\Big] \tag{5}$$

where $c_p \in \mathbb{R}^n$ is a vector where every element is the constant term of the order-one polynomials. This vector is concatenated with a diagonal matrix of the transformation into matrix form of the function inverse of the non-constant term of the order-one observables. The remaining entries for the higher-order polynomials are zero. The result is a linear operator $A$ acting on a function space $\Psi$ and an input matrix $B$. The linear time-evolution of the functions $\psi(x) \in \Psi(x)$ is related to the nonlinear time-evolution of the state $x$. Matrix $C$ achieves the transformation back to the original state space. Hence, the original nonlinear system (1) becomes:

$$\begin{aligned} \Psi\big(x(k+1)\big) &= A\Psi\big(x(k)\big) + Bu(k) \\ x(k) &= C\Psi\big(x(k)\big), \end{aligned} \tag{6}$$

## pqEDMD for MPC

For driving the system into a desired state, consider a model predictive control algorithm adapted from [9], and an MPC formulation in a function space similar to the developments by Korda et al. [3]. The objective is to find a sequence of inputs $u_k$ starting at the $k^{\text{th}}$ output measurement time-instant that spans a control horizon $N_c$, the sequence of inputs, drives the system to a desired output by minimizing a cost function over a prediction horizon $N_p$ while satisfying some input/output inequality constraints. The MPC formulation over the function space is

$$\begin{aligned} \min_u J(x,u) = &\sum_{i=0}^{N_p-1}\Big(\Psi_{\text{dev}}\big(x(i)\big)^T Q_\psi \Psi_{\text{dev}}\big(x(i)\big)\Big) \\ &+ \sum_{i=0}^{N_c-1}\big(u(i)^T Q_u u(i)\big) \\ &+ \Psi_{\text{dev}}\Big(x(N_p)\Big)^T F_\psi \Psi_{\text{dev}}\Big(x(N_p)\Big) \end{aligned} \tag{7}$$

subject to

$$u_{\min} \le u^i \le u_{\max}$$

where $\Psi_{\text{dev}}\big(x(i)\big) = \Psi\big(x(i)\big) - \Psi\big(x_{\text{ref}}(i)\big)$, the difference of the function space with its reference. The symmetric matrices $Q_\psi, F_\psi \in \mathbb{R}^{d\times d}$ are the weight matrices for the state sequence, and the terminal state and the symmetric matrix $Q_u \in \mathbb{R}^{m\times m}$ is the weighting matrix for the control inputs. The weighting matrix $F_\psi$ of the terminal state accounts for different prediction and control horizons and imposes a suitable terminal constraint to ensure stability. In contrast with the traditional MPC formulation, equation (7) is an objective function in the function space and

not the state space of a traditional linear system. It is necessary to transform the formulation (7) into a quadratic program in the function space, i.e., a quadratic objective function $\Delta u^T H \Delta u + h^T \Delta u$ with linear constraints $L\Delta u < b$, that has a solution using a standard solver.

The first step is to derive the observable weighting matrices $Q_\psi$ and $F_\psi$ from selected output weighting matrices $Q_y$ and $F_y$. The first method is to exploit the output matrix $C$ from the pqEDMD solution, i.e.,

$$Q_\psi = C^T Q_y C, \tag{8}$$

This formulation restricts the MPC optimization to the convergence of the order-one polynomials to their reference values, neglecting the fact that the remaining elements in the observables also depend on the outputs. Even if that is the case, formulating $Q_\psi$ this way gives good results and fast convergence. The second method uses the observables to transform the matrix,

$$Q_\psi = \text{diag}\left(\Psi\left(\text{diag}(Q_y)\right)\right) \tag{9}$$

This method weighs all the observables in the basis and should produce more accurate solutions. Performance-wise, the convergence of this solution is slower, and it may break the feasibility of the quadratic problem. These methods also apply to calculating $F_\psi$.

Continuing with the translation of the problem into a quadratic program, consider the solution of the identified dynamics in the function space $\Psi(x)$, a solution of (6) from an initial condition $x(0)$, and a sequence of inputs $\{u_i\}_{i=0}^{k-1}$ up to an arbitrary time $k$,

$$\Psi\big(x(k)\big) = A^k \Psi\big(x(0)\big) + \sum_{j=0}^{k-1} A^{k-1-j} B u(j), \tag{10}$$

Stacking up the state and the input sequences in column vectors and applying the solution of the pqEDMD (10) from a time-step $k$ and up to a prediction horizon $N_p$ gives

$$\underbrace{\begin{bmatrix} \Psi\big(x(k+1)\big) \\ \Psi\big(x(k+2)\big) \\ \vdots \\ \Psi\left(x(k+N_p)\right) \end{bmatrix}}_{\Psi_X} = \hat{A}\Psi\big(x(k)\big) + \hat{B} \underbrace{\begin{bmatrix} u(k) \\ u(k+1) \\ \vdots \\ u(k+N_c) \end{bmatrix}}_{\hat{U}} \tag{11}$$

where $\hat{A}$ and $\hat{B}$ are the block matrices that relate the initial evaluation of the observables $\Psi\big(x(k)\big)$ and the sequence of inputs $U$ to the sequence of observables $\Psi_X$,

$$\hat{A} = \begin{bmatrix} A \\ A^2 \\ \vdots \\ A^{N_p} \end{bmatrix}, \; \hat{B} = \begin{bmatrix} B & 0 & \cdots & 0 \\ AB & B & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ A^{N_p-1}B & A^{N_p-2}B & \cdots & B \end{bmatrix}, \tag{12}$$

where the number of block columns in $\hat{B}$ depends on the control horizon. In addition to the compact form of the sequence of observables (11), the compact form of the objective function (7) is,

$$J(x,u) = \; (\Psi_X - \Psi_{\text{ref}})^T Q_\Psi (\Psi_X - \Psi_{\text{ref}}) + U^T Q_U U, \tag{13}$$

where $Q_\Psi$ is a block diagonal matrix with the observable matrix repeated $N_p$ times along the diagonal and with $F_\psi$ as the final element, and $Q_U$ is a block diagonal matrix with the weighting matrix for the control input repeated $N_c$ times along the diagonal,

$$\begin{aligned} Q_\Psi &= \; \text{diag}\left(\{Q_\psi\}_{i=1}^{N_p}, F_\psi\right), \\ Q_U &= \; \text{diag}\left(\{Q_u\}_{i=1}^{N_c}\right). \end{aligned} \tag{14}$$

With the definition of the sequence of observables and the objective function in compact form, replacing solution (11) into (13) and expanding produce a quadratic element and a linear element in $U$, among other terms that do not depend on $U$, i.e.,

$$\begin{aligned} J(x,u) = \; & U^T \hat{B}^T Q_X \hat{B} U + U^T Q_U U \\ & + 2\left(\hat{A}\Psi\big(x(k)\big) - \Psi_{\text{ref}}\right)^T Q_\Psi \hat{B} U + r(x) \end{aligned} \tag{15}$$

where $r(x)$ are the terms that do not depend on $U$. Then, from (15) the Hessian is

$$H = \hat{B}^T Q_\Psi \hat{B} + Q_U, \tag{16}$$

and from the linear term of the compact cost function (15), the linear term of the quadratic program becomes

$$h^T = 2\left(\hat{A}\Psi\big(x(k)\big) - \Psi_{\text{ref}}\right)^T Q_\Psi \hat{B}, \tag{17}$$

that satisfies the objective of having the problem as a quadratic program, meaning that it is possible to calculate the optimal sequence of inputs via a standard solver, e.g., quadprog() in Matlab.

## BIOPROCESS APPLICATION

Consider a continuously stirred tank reactor (CSTR), where an arbitrary biological species grows on a substrate.

Assuming that both substrate and biomass concentrations are measurable, it is possible to get a description of their dynamics by applying a mass balance, resulting in the following differential equations:

$$\begin{aligned} \dot{x_1} &= x_1(\mu(x_2) - D), \\ \dot{x_2} &= D\big(x_{2,f} - x_2\big) - \frac{\mu(x_2) x_1}{\eta}, \end{aligned} \tag{18}$$

where $x_1$ is the first state, representing the biomass concentration $x_2$ is the second state, representing the substrate concentration, and $x_{2,f}$ is substrate inlet concentration, and a Haldane kinetics law represents the growth rate:

$$\mu(x_2) = \frac{\mu_{\max} x_2}{k_m + x_2 + k_1 x_2^2}, \tag{19}$$

where the parameter $\mu_{\max}$ is the maximum specific growth rate, $k_m$ is the activation constant, and $k_1$ is the inhibition constant. Finally, $\eta$ is the process yield and $D = F/V$ $[h^{-1}]$ the dilution rate. The following assumes that the bioreactor operates in chemostat mode (continuous feeding with constant volume). Table 1 reports the

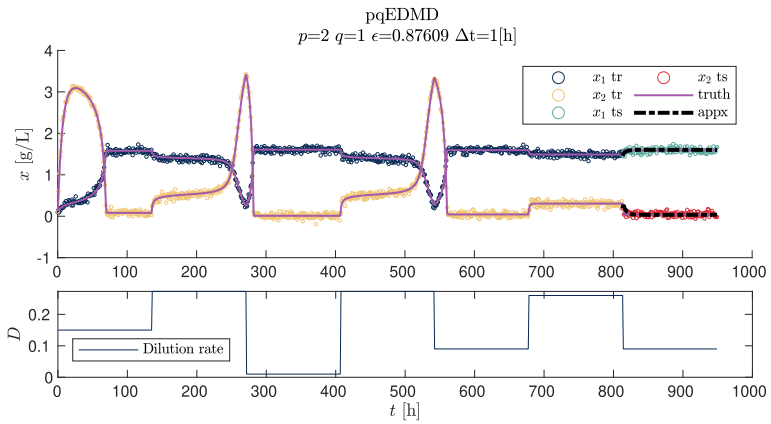

**Figure 1:** pqEDMD identification with fast sampling and high level of noise.

process parameter values.

**Table 1:** Reactor Parameters.

| Symbol | Value | Units |
|---|---|---|
| $\mu_{max}$ | 0.4 | [h$^{-1}$] |
| $k_m$ | 0.12 | [g/L] |
| $k_1$ | 0.4545 | [g/L]$^{-1}$ |
| $\eta$ | 0.4 | [-] |

# NUMERICAL RESULTS

## Model Training and Testing

To have a rich enough dataset for identification, it is necessary to select the time evolution of the dilution rate and the duration of the experiment. Two additional parameters determine the algorithm's performance: the sampling rate and the standard deviation of the measurement noise. For the time evolution of the dilution rate, the choice is a sequence of inputs that switch the convergence of the trajectories between the two asymptotically stable points. For the sampling and noise, we will consider three different scenarios that cover different values of the parameters: a scenario with fast sampling and low levels of noise, a second case, where we increase the uncertainty in the measurement, and a third, where we decrease the sampling rate. Table 2 shows the exact values of these parameters in the description of each scenario. For illustration, Figure 1 shows the second case, where there is fast sampling and high levels of noise.

In each scenario, the data set is made of a single experiment that starts from low values of biomass and substrate and is subject to 7 different steps of dilution rate, where each step has the same duration. With fast sampling, the data sets contain 951 points. The first 6 steps correspond to the training (814 points), while the rest (137 points) constitute the testing set. With slow sampling, there are 191 points in total, 162 for training, and 29 for testing.

It is possible to apply pqEDMD with a variety of orthogonal polynomials. In this application, their choice is not critical, and the following algorithm implementation uses Legendre polynomials. For some other applications, the choice of polynomials may be important. Also, for applications where the order of magnitude of the different measurements is not the same, normalizing the data may improve the numerical conditioning of the methods. This aspect is also not influential in the present application.

Each element of the observables comes from the product of univariate polynomials with a particular order $\alpha_j$ for each state variable $x_j$ being *observed /evaluated*. Therefore, it is possible to define each observable via a nonnegative vector $\alpha \in \mathbb{N}_+^n$ containing the set of integers corresponding to the orders of the univariate polynomials. A particular element of the set of observables is

$$\psi = \prod_{j=1}^{n} \pi^{\alpha_j}(x_j), \tag{20}$$

where $\pi^{\alpha_j}(x_j)$ is a univariate element from a family of orthogonal polynomials of order $\alpha_j$. It is possible to apply a selection criterion to each vector of integers $\alpha$ based on a q-quasi norm, which imposes a maximum order $p$,

$$\alpha = \{\alpha \in \mathbb{N}_+^n : \|\alpha\|_q \leq p\}, \tag{21}$$

where $\|\alpha\|$ is the q-quasi norm of the set of orders, and $p \in \mathbb{N}$ is a positive integer that determines the maximum order of the multivariate polynomial function $\psi$. The definition of a q-quasi norm of a vector $\alpha$ is

$$\|\alpha\|_q = \left(\sum_{i=1}^{n} \alpha_i^q\right)^{\frac{1}{q}}, \tag{22}$$

where $q \in \mathbb{R}$ defines the quasi norm, and the cardinality of the vector is $n$ because each element represents the order of a univariate polynomial for each of the $n$ states in the original system. In general, it is not a norm because $q$ can take noninteger values (for those cases, equation (22) does not satisfy the triangle inequality).

**Table 2:** Empirical error p-q parameters and basis size for the best performing and worst performing sets of observables from the p-q sweep.

| | Scenario | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | (1) $\Delta t = 1$ [h], $\sigma = .005$ [g/L]$^2$ | | | | (2) $\Delta t = 1$ [h], $\sigma = .05$ [g/L]$^2$ | | | | (3) $\Delta t = 4$ [h], $\sigma = .05$ [g/L]$^2$ | | | |
| $p$ | 4 | 5 | 5 | 4 | 2 | 2 | 5 | 5 | 2 | 2 | 3 | 3 |
| $q$ | 2.5 | 1.5 | 0.5 | 2.0 | 1.0 | 0.5 | 0.5 | 1.5 | 0.5 | 1.0 | 0.5 | 1.0 |
| $d$ | 18 | 24 | 12 | 17 | 6 | 5 | 12 | 24 | 5 | 6 | 7 | 10 |
| $\epsilon$ | 0.17 | 0.18 | 0.21 | 0.22 | 0.84 | 0.87 | 1.12 | 1.14 | 0.91 | 0.96 | 1.32 | 1.33 |

By applying a p-q norm reduction to the polynomial orders, we can significantly reduce the number of observables and their maximum order. This, in turn, enhances the algorithm's numerical accuracy and reduces computational time.

The answer to the question of the optimal p-q parameters to use for a particular dataset is still open. Large values of p-q pairs produce higher order polynomials, which increase the computational complexity of the algorithm without a guarantee of a more accurate approximation. The same effect applies to the uncertainties in the measurements, high-order polynomials tend to amplify the noise leading to unfeasible solutions. Therefore, the method to find the best combination is to perform a sweep over a set of candidate values. For each scenario, the candidate values are $p = [2\ 3\ 4\ 5]$ and $q = [0.5\ 1\ 1.5\ 2\ 2.5]$, giving 13 sets of unique observables to test (some combinations of p-q parameters give redundant sets of observables). Table 2 shows a summary of the results for the three scenarios, where $\epsilon$ is the empirical error of the test set that comes from the solution of (6) from the initial conditions of the test set and the application of the last step of the dilution rate. The definition of the empirical error is

$$\epsilon = \frac{1}{N}\sum_{i=1}^{N}\frac{|\hat{y}_i - y_i|}{|y_i|}, \tag{23}$$

where $\hat{y}$ is the approximation of the output and $y$ is the output from the dataset.

The results from Table 2 show that for the same underlying dynamics, there is no unique pair of p-q parameters that fit the data. In a deterministic case (no noise), with a very fast sampling time $\Delta t = 0.001$ [h] the *optimal* p-q pair is the same as the best approximation for the scenario with fast sampling and low levels of noise, but it is different from the other two scenarios. If the experimental setup involves a slow sampling, like the third scenario, the best p-q pair for the deterministic case produces a pqEDMD solution that diverges, highlighting the importance of a p-q sweep.

The experiments vary the dilution rate between low and high values. The high value of the dilution rate $D = 0.273$ gives the wash-out point a big region of attraction. Then, the value of the biomass starts to slowly decay until a change in the dilution rate brings the state back to the desired attractor (i.e., operating point). These changes in the concentrations of biomass and substrate give the pqEDMD the necessary information to characterize the system. Otherwise, without this dynamic spectrum, it would be necessary to perform more experiments with varying initial conditions.

In conclusion, it is possible to identify the dynamics of the nonlinear CSTR reactor via the pqEDMD algorithm when there is enough information on the system dynamics in an experimental dataset. The choice of orthogonal polynomials under a p-q-quasi norm reduction makes the algorithm versatile enough to identify the dynamics accurately. The advantage of having a linear representation of a dynamical system in a function space is the interpretability of the system, from the spectrum of the $A$ matrix to the analysis via theoretical concepts like the Koopman operator (restricted to the case where the pqEDMD converges to the operator).

## Linear Model Predictive Control

Figure 2 shows the application of the MPC control adapted to work in a function space instead of a state space for the three scenarios. Table 3 lists the controller parameters, which are the same across all scenarios.

**Table 3:** MPC parameters.

| Symbol | Value | Units |
|---|---|---|
| $N_p$ | 10 | [-] |
| $N_c$ | 7 | [-] |
| $Q_y$ | $\begin{bmatrix}1 & 0\\ 0 & 0\end{bmatrix}$ | [-] |
| $Q_u$ | 0.5 | [-] |
| $F_y$ | $\begin{bmatrix}1 & 0\\ 0 & 0\end{bmatrix}$ | [-] |
| $u_{\min}$ | 0.01 | [h$^{-1}$] |
| $u_{\max}$ | 2 | [h$^{-1}$] |

The choice of output weighting matrices $Q_y$ and $F_y$ only penalizes the biomass. The prediction and control horizons are obtained by trial and error. The convergence of the controller is influenced by the choice of transformation matrix $Q_y$ into $Q_\psi$, either using equation (8) or (9). For datasets with low noise (the first scenario), the algorithm performs better if the transformation comes from the first option. The second option achieves better

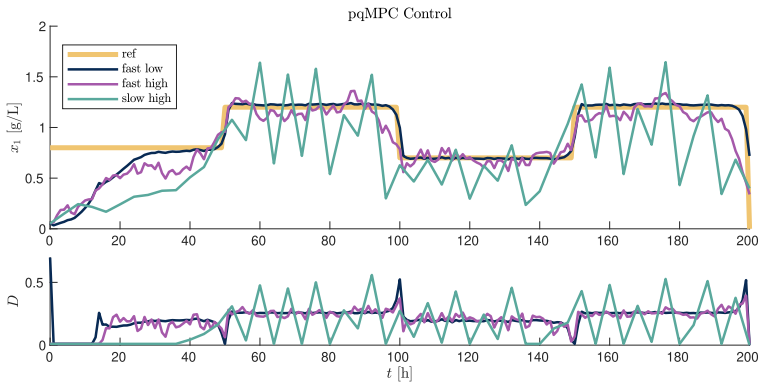

**Figure 2:** Linear Model Predictive Control for the three scenarios.

results for the experiment with a high noise level.

We observe a deviation from the setpoint in the scenario with a high noise level (notice the performance of the tests with high noise levels in Figure 2). This error is caused by the noise because, at every optimization step, it is necessary to know the evaluation of the function space, i.e., $\Psi(x(k))$ in (17). To obtain this value, it is required to *lift* the previous output with the set of observables, an output that has been corrupted with noise. Therefore, the next step in improving the algorithm is to develop a state observer to work in the function space and update the value of the function space at each optimization step.

## CONCLUSIONS

This paper implements a complete data-driven workflow for controlling a simple bioprocess. It uses the pqEDMD algorithm to model the dynamics and a traditional MPC controller adapted to work on the pqEDMD's function space. The main methodological developments are the application of a singular value decomposition to the regression matrix to get the effective rank and improve the approximation of the ordinary least squares. This study also shows how to adapt the traditional model predictive control formulation to work with the particularities of the function space of the pqEDMD. This study shows that EDMD approximations can be interesting alternatives to neural networks, as they provide a linear system representation in a function space where linear estimators and controllers can be developed. The conditions to satisfy for a successful implementation are the convergence of the pqEDMD to a stable solution and the feasibility of the MPC solutions, which depend on the information content of the training data and the selection of tuning parameters in the pqEDMD algorithm and the MPC.

## ABSTRACT

Large quantities of used cooking oil (UCO) are produced globally, primarily in densely populated urban centers. Although UCO is highly heterogeneous due to degradation during cooking, it still contains a significant fraction of triacylglycerols (TG) that could be used as raw materials in oleochemical biorefineries. A major challenge in reintegrating this residue into productive cycles is the presence of free fatty acids (FFA), which can affect subsequent catalytic or enzymatic transformations. Conventional processes for FFA removal are energy-intensive, require alkaline feedstocks, and generate problematic residues. To overcome these issues, alcoholic extraction of FFA is considered a promising pretreatment for UCO, enabling the extraction of FFA for subsequent esterification. In this regard, liquid-liquid film contactors (LLFC) have shown potential to intensify FFA extraction because they operate under mild conditions and at laminar flow regime, reducing energy consumption and enhancing productivity. This work presents the modeling and validation of a FFA extraction process suitable for deacidifying UCO using a LLFC with ethanol as a solvent. Experimental data were used to fit model parameters, which were optimized using a genetic algorithm. The validated LLFC model revealed that increasing the UCO mass flow rate and the ethanol-to-UCO ratio enhanced FFA mass transfer. Furthermore, a cascade configuration of three LLFCs was able to reduce the FFA content in UCO to 0.9 wt.%. It is anticipated that this technology will enable the pretreatment of UCO for further transformation into value-added oleochemicals and facilitate the exploitation of recovered FFA via subsequent ethanolic esterification.

**Keywords**: Liquid-liquid film contactor, used cooking oil, free fatty acids, mathematical modeling, genetic algorithm, liquid extraction.

## INTRODUCTION

Economic growth and lifestyle improvement of modern society have caused negative environmental impacts. Food waste generation is one such impacts, thus becoming a major challenge for sustainable development. Among the different types of food waste, post-consumption waste lipids are particularly problematic residues because they are produced in large volumes and present significant management challenges for densely populated urban areas. These residues include used cooking oil (UCO), lipids extracted from high-fat-content food waste (e.g. fried foods, sauces, dressings, dairy products), grease leached from cooking meats, grease from traps, oils from expired food (e.g mayonnaise, tuna cans), among others [1]. The generation of such residues is continually increasing due to the growing consumption of fast and industrialized food products [2], [3].

Among the different waste lipids, UCO is of major interest because they are inevitably produced when using vegetable oils and fats for food preparation. Edible vegetable oils (EVO), primarily composed of triacylglycerols (TG), undergo several chemical and physical changes that affect their quality. During cooking at high temperatures (≥150 ºC) and in the presence of air and moisture, EVO degrades generating changes in color, odor and producing harmful compounds potentially dangerous for human health. As a result, usable lifespan of

EVO is limited, and it must be discarded as UCO after certain time. The main decomposition reactions during frying include oxidation, hydrolysis, dehydration, cracking and polymerization. These reactions produce compounds such as aldehydes, alcohols, epoxides, oxidated sterols, free fatty acids (FFA), monoacylglycerols, diacylglycerols, cyclic monomers and nonpolar oligomers. However, main fraction of UCO (>90 wt.%) remains as mono-, di-, and triacylglycerols, making this residue a potential feedstock for oleochemical industry [4], [5].

Despite the reuse potential, a high FFA content in UCO can significantly affect the transformation of TG into high-value-added chemicals. Conventional treatments for reducing acidity are classified as either chemical or physical refining, depending how FFA are separated from UCO. In chemical refining FFA are neutralized with alkaline solutions, while in physical refining they are stripped from the oil using steam at high temperatures and low pressures. Despite their effectiveness, both methods have drawbacks. Chemical refining requires high water consumption to remove the formed soaps, generating large amounts of aqueous effluents and causing significant losses of neutral oil. In contrast, physical refining is highly energy-intensive, requiring high pressure steam, vacuum conditions and elevated temperatures, which further degrade TG [6].

To address these challenges, solvent deacidification has been extensively studied as an alternative since it can be performed at mild conditions, reducing energy consumption and avoiding the formation of toxic compounds. This process can be carried out using liquid-liquid film contactors (LLFC), originally developed for sulfur removal in fossil fuels [6]. These devices maximize the contact area between two fluid phases by employing a semi-structured packing system, preventing one phase from dispersing into the other. The co-current ethanolic extraction of FFA from UCO has been studied using this equipment, and the separation efficiency was assessed with respect to oil mass flow rate, oil-to-ethanol flow ratio and contactor's length [4]. Results indicate that the process is feasible and its scale-up must be further explored. Similarly, it has been reported that the acidity of refined, deodorized and bleached palm oil could be reduced by 51% when a single-stage LLFC is used, and that multiple-stage contactors would be necessary to reduce the FFA content to meet the specifications required by the international vegetable oil and UCO markets [6].

In this context, modeling of FFA ethanolic extraction from UCO using a LLFC is essential for defining suitable configurations and processing conditions for further scaling up. In this regard, a mathematical model based on mass transfer correlations was assessed to describe FFA extraction from UCO using a LLFC. This model was adapted from a previous study [6], and it assumed that the rate-controlling step in the process is the mass transfer of FFA from the bulk oil phase to oil-solvent interface. Based upon reported experimental data [4], this work is focused on adjusting a new set of model parameters to effectively describe deacidification of UCO via ethanolic extraction using a LLFC. The model is intended to be used in scale up and further feasibility assessments.

## METHODOLOGY

### Liquid-liquid film contactor configuration

The LLFC is part of a system that enables the continuous deacidification of UCO. This system consists of two tanks used to store UCO and ethanol, which are placed on their respective scales (Mettler Toledo GmbH, Schwerzenbach, Swizerland). This enabled to calculate operating mass flow rates by measuring the change in mass over time. Each tank was connected to an HMS EXT 2001 metering pump (EMEC Srl, Vazia, Italy) that transported the fluids throughout the unit. Prior to entering the LLFC, the fluids were heated independently using silicon shielded electric resistors equipped with temperature controllers (SHIMADEN SR 91, Japan). After heating, each fluid was fed to the LLFC at the specified operating temperature and put in contact to facilitate FFA mass transfer. The effluent of the LLFC went into a decanter, where both phases separated. Figure 1 presents a simplified schematic of this process unit.

The LLFC consisted of an SS304 column (ID = 0.023 m) packed with 3400 metallic threads (OD = 2.5 x $10^{-4}$ m). The packing provided high interfacial area between phases and enhanced FFA extraction from UCO. Additionally, the contactor was equipped with a jacket to enable the use of a heating service, allowing the extraction to be conducted at a constant temperature. The oil phase was fed into the top of the contactor and flowed downward forming a film around each thread inside the column. On the other hand, the alcoholic phase was fed into the contactor 20 cm below the oil phase nozzle to ensure the formation of a film over the oil phase. Then, FFA were transferred from the inner oil film to the outer alcoholic film due to the different chemical potentials in both phases. This configuration is shown in Figure 2b.

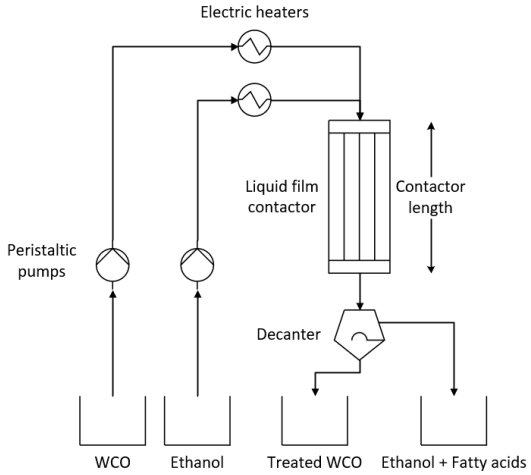

**Figure 1.** Diagram of the process unit.

## Mathematical model of LLFC

In systems with strong mass transfer resistance the rate-controlling step is the transport of the components from the bulk phase to the interface. FFA are transferred from the oil phase to the alcohol phase, passing through the interface. Since the viscosity of the oil phase is significantly higher than that of the alcoholic phase, the transfer of FFA from oil to the interface is considered the rate-controlling step in this extraction process [6]. The general equation for mass transfer within the contactor is presented in Equation (1), where $F_i$ is the mass flow rate of component i, Z is the position inside the contactor, $A_T$ is the area available for mass transfer, $k_i$ is the global mass transfer coefficient, $C_i^I$ is the concentration of component i in the bulk oil phase and $C_i^{I,EQ}$ is the equilibrium concentration of component i at the interface.

$$\frac{dF_i^I}{dZ} = A_T k_i (C_i^I - C_i^{I,EQ}) \quad (1)$$

Equation (1) can be applied to triacylglycerol (TG), free fatty acids (FFA), and ethanol (ET). Additionally, the mass transfer area can be expressed in terms of the number of threads inside the contactor ($n_{pack}$).

$$\frac{dF_{TG}^I}{dZ} = -\pi D_{pack} n_{pack} k_{TG}^I \rho_{Mix} (w_{TG}^I - w_{TG}^{I,EQ}) \quad (2)$$

$$\frac{dF_{FFA}^I}{dZ} = -\pi D_{pack} n_{pack} k_{FFA}^I \rho_{Mix} (w_{FA}^I - w_{FA}^{I,EQ}) \quad (3)$$

$$\frac{dF_{ET}^I}{dZ} = -\pi D_{pack} n_{pack} k_{ET}^I \rho_{Mix} (w_{ET}^I - w_{ET}^{I,EQ}) \quad (4)$$

$$\frac{dF_{TG}^{II}}{dZ} = -\frac{dF_{TG}^I}{dZ} \quad (5)$$

$$\frac{dF_{FFA}^{II}}{dZ} = -\frac{dF_{FFA}^I}{dZ} \quad (6)$$

$$\frac{dF_{ET}^{II}}{dZ} = -\frac{dF_{ET}^I}{dZ} \quad (7)$$

To solve the mass transfer equations throughout the contactor, it is necessary to calculate the global mass transfer coefficients along the contactor. The following expressions were used for this purpose [6]:

$$k_{TG}^I(Z) = C_1 Sc_I^{C4} Re_I^{C5} \left(\frac{D_{TG-MixI}}{\delta_I}\right) \quad (8)$$

$$k_{FFA}^I(Z) = C_2 Sc_I^{C4} Re_I^{C5} \left(\frac{D_{FA-MixI}}{\delta_I}\right) \quad (9)$$

$$k_{ET}^I(Z) = C_3 Sc_I^{C4} Re_I^{C5} \left(\frac{D_{ET-MixI}}{\delta_I}\right) \quad (10)$$

The parameters $C_1$, $C_2$, $C_3$, $C_4$ and $C_5$ can be obtained by regression through comparison of the model with experimental data [4]. To determine the diffusivities required in Equations (8) to (10), Equation (11) was used [7], where x is the associating factor of the solvent, M is the molar weight of the solvent, T is the system temperature, $\eta$ is the dynamic viscosity of the solvent, and V is the solute molal volume.

$$D = 7.4x10^{-8} \frac{(xM)^{\frac{1}{2}} T}{\eta V^{0.6}} \quad (11)$$

Another required variable in Equations (8) to (10) is $\delta_I$, the film thickness of the oil phase around a thread. This quantity is calculated from a momentum balance applied to a differential volume of a thread as presented in Figure 2a. In that Figure, the red arrows represent the direction of momentum flow. Since a no-slip condition is assumed at the thread surface, the velocity at this point is zero, while the fastest fluid layer is the farthest from the thread surface. In this scenario, momentum flows from the outer region toward the inner region. Applying a momentum balance to this volume yields the following equations, which are solved simultaneously to determine $a$ and $b$, which are dimensionless factors related to the oil and ethanol film thickness, respectively.

$$2a^2 - a^4 - a + 2\beta a^2 \left(2\ln(a) - 1 + \frac{1}{a^2}\right) - \psi_1 = 0 \quad (12)$$

$$2\lambda\left(\left(\frac{b}{a}\right)^2 - 1\right) - \left(\left(\frac{b}{a}\right)^4 - 1\right) + 2b^2\left(\left(\frac{b}{a}\right)^2\left(2\ln\left(\frac{b}{a}\right) - 1\right) + 1\right) - \psi_2 = 0 \quad (13)$$

$$\psi_1 = \frac{8\mu_I Q_{pack}^I}{\pi \rho_I g R_{pack}^4} \quad (14)$$

$$\psi_2 = \frac{8\mu_{II} Q_{pack}^2}{\pi \rho_{II} g R_{pack}^4} \quad (15)$$

$$\beta = \left(b^2 \frac{\rho_{II}}{\rho_I} + a^2\left(1 - \frac{\rho_{II}}{\rho_I}\right)\right) \quad (16)$$

$$\lambda = \left(a^2 + \frac{\rho_I \mu_{II}}{\rho_{II} \mu_I}(1 - a^2 + 2\beta\ln(a))\right) \quad (17)$$

## Implementation of the mathematical model of LLFC

The mathematical model of the LLFC was programmed in Python, and Euler's method was used to solve the differential mass balance equations (2) to (7). This numerical integration required the definition of a small step in the integration variable to ensure stability and good performance. In this case, the integration variable was the contactor's length, and the number of steps was set to 1000 to maintain stability during the solution process.

The initial conditions for solving the LLFC model included the mass flow rates of UCO and ethanol, the mass concentration of each component in both phases, the operating temperature and the total contactor's length to be integrated. The components considered were triacylglycerol, oleic acid (representing the free fatty acids in UCO), ethanol and water; however, the mass transfer of water was not included to simplify the model and to avoid the regression of an additional parameter. This assumption is supported by experimental results indicating that the extracted UCO moisture content was lower than 1.3 wt.% [4].

The next step involved determining the liquid-liquid equilibrium (LLE) of the system using validated models available in Aspen Plus. The UNIFAC-LL thermodynamic model was applied, and its binary interaction parameters values were updated to better fit the experimental LLE data [8]. The corresponding equilibrium calculation obtained in Aspen Plus were imported into Python and used in Equations (2) to (4) at each integration step.

Subsequently, determining the thickness and velocity of each film required the density and viscosity values of both fluids. The density of the liquid mixture of each phase was calculated using the molar volumes of the pure components and their molar fractions. The pure liquid molar volumes of the components were obtained from the Rackett model [9]. Meanwhile, the liquid mixture viscosity was estimated using the modified Andrade equation [10].

Next, Equations (8) to (11) were used to estimate the global mass transfer coefficients, followed by applying Euler's method to numerically solve the mass balance equations. The iterative process continued until the step position reached or exceeded the total contactor's length, at which point the iteration stopped, and the final component concentrations were obtained. A simplified scheme of the computation algorithm is presented in Figure 3.

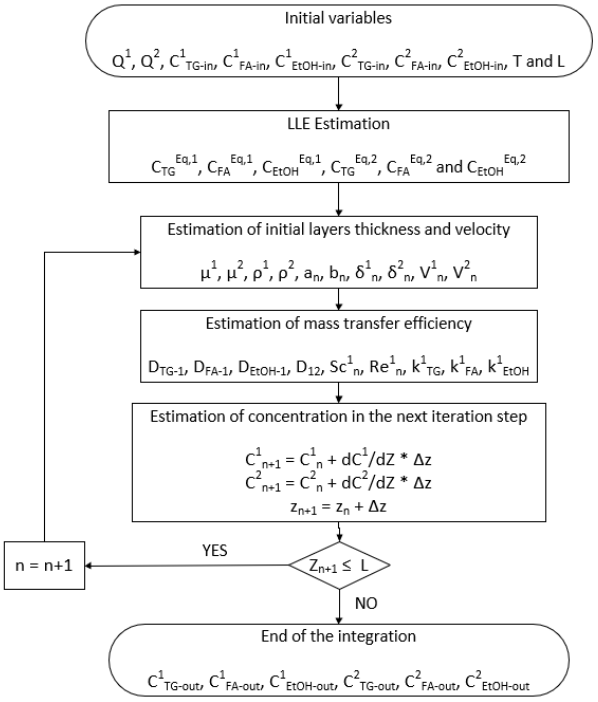

**Figure 3.** Solution algorithm of LLFC model.

The dimensionless parameters $C_1$ to $C_5$ were determined through regression using a genetic algorithm implemented in Python with the PyGAD library. This optimization procedure minimized the differences between the calculated and experimental mass fractions, as described in Equation (18), where E represents the number of experiments, P the number of phases and C the number of considered components. The total error was normalized by the number of measured concentrations to calculate an average relative error.

$$\min\left(\sum_k^E \sum_j^P \sum_i^C \frac{\left|w_{ijk}^{calc} - w_{ijk}^{exp}\right|}{w_{ijk}^{exp}}\right) \quad (18)$$

The genetic algorithm was executed with 10 generations, each containing 1000 chromosomes. Each chromosome consisted of five genes representing the set of dimensionless parameters. The 100 chromosomes with the lowest average relative error were selected as parents to generate the next generation. The steady-state

selection method was employed, and mutation was applied randomly at a rate of 15%. Furthermore, the search space for the dimensionless parameters was constrained within the ranges presented in Table 1. The optimization method was executed 80 times, with each starting population of chromosomes randomly generated within the defined search space.

**Table 1.** Search space for the dimensionless parameters $C_1$ to $C_5$

| Parameter | Lower bound | Upper bound |
|---|---|---|
| $C_1$ | $1.0x10^{-10}$ | $1.0x10^{-8}$ |
| $C_2$ | $1.0x10^{-9}$ | $4.0x10^{-8}$ |
| $C_3$ | $1.0x10^{-9}$ | $4.0x10^{-7}$ |
| $C_4$ | 0.0 | 2.0 |
| $C_5$ | 0.0 | 2.0 |

## RESULTS

After executing the optimization algorithm to fit the parameters of the model the values reported in Table 2 were obtained. these are presented with their corresponding lower and upper bounds of the confidence intervals. The objective function value for this parameters set was 507.6, corresponding to an average relative error of 8.46%. As observed, all values felt within 95% confidence intervals with a normal distribution for the computation based on the evaluation of 0.8 million different parameter sets. The average relative deviation of the reported parameters from their lower and upper bounds were 6.77%. This indicates that the obtained set of parameters is unique within the selected search space. moreover, these parameters were similar to those previously obtained in the modeling of a LLFC process for ethanolic deacidification of refined, deodorized and bleached palm oil.

**Table 2.** Mass transfer dimensionless parameters for the FFA extraction of UCO and their confidence intervals using ethanol as solvent in a LLFC

| | $C_1$ | $C_2$ | $C_3$ | $C_4$ | $C_5$ |
|---|---|---|---|---|---|
| Value | 1.23x10$^{-9}$ | 8.30x10$^{-9}$ | 3.99x10$^{-7}$ | 1.92 | 1.54 |
| Lower bound | 6.00x10$^{-10}$ | 7.70x10$^{-9}$ | 3.78x10$^{-7}$ | 1.91 | 1.53 |
| Upper bound | 1.24x10$^{-9}$ | 8.40x10$^{-9}$ | 4.00x10$^{-7}$ | 1.93 | 1.55 |

Figure 4 presents the parity plot between calculated and experimental mass fractions of components in the oil phase. Although the mass fractions appear to be closely aligned with the 45° line in Figure 4, the regression coefficient ($R^2$) for triacylglycerol, oleic acid, and ethanol were 0.224, 0.559 and 0.390, respectively. These low regression coefficients may result from experimental data uncertainty. It was reported that the 15 experiments used to correlate the parameters, comprising 45 mass concentration measurements, exhibited an average uncertainty of 7.7%. Additionally, some experiments used in the regression process yielded similar final FFA contents under significantly different operating conditions (i.e., UCO flow rate, ethanol-to-oil mass flow ratio and contactor length). Considering these factors, the regressed model is deemed suitable for describing the FFA extraction from UCO in the LLFC. Hereinafter, the model can be employed to study the effects of UCO flow rate, mass flow ratio between fluids and contactor's length, as well as to facilitate process scale up.

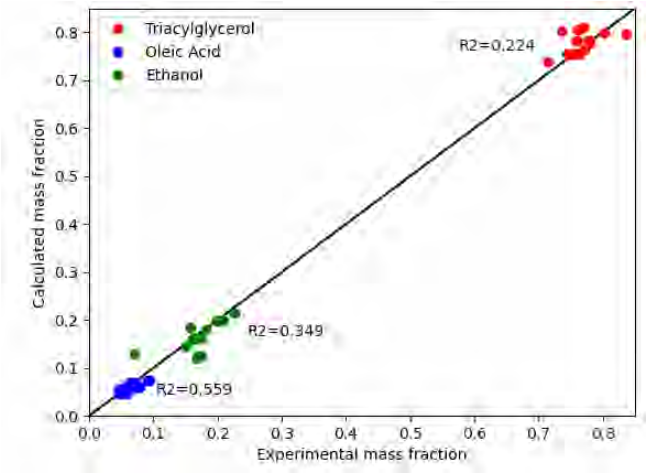

**Figure 4.** Parity plot of components mass fractions in oil phase.

Figure 5 illustrates the effect of the ethanol-to-oil mass flow ratio on FFA removal from UCO. Increasing this ratio enhances FFA extraction, as a higher ethanol content shifts the global mixture point deeper inside the LLE envelope. Consequently, the mixture lies on a larger tie line, increasing the concentration gradient between the bulk phases and interface. According to Equation (3), a larger concentration gradient improves FFA extraction from UCO.

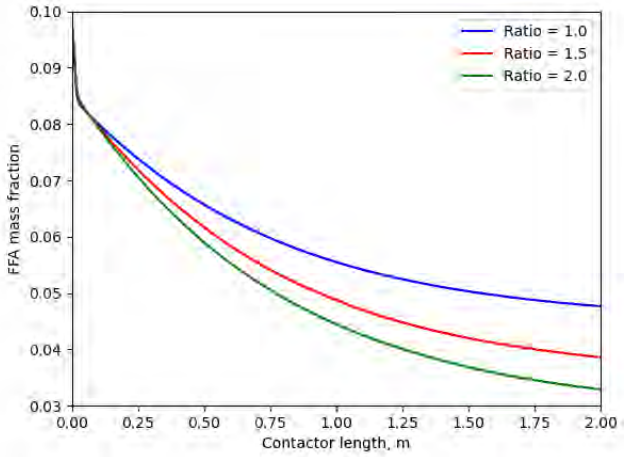

**Figure 5.** Ethanol to UCO mass flow ratio effect on FFA extraction. UCO mass flow rate: 1 kg/h; Temperature: 70°C; FFA in UCO at inlet: 9.7 wt%.

On the other hand, the effect of UCO flow rate on FFA removal is shown in Figure 6. The results indicate that FFA mass transfer is proportional to UCO mass flow rate within the range of reported experimental data. This occurs because a higher UCO mass flow rate increases the volumetric flow per thread, velocity, film thickness and Reynolds number. As shown in Equation (9) and table 2, the global mass transfer coefficient is proportional to the Reynolds number up to 1.54. Comparing the operating conditions of 1.0 kg/h and 0.5 kg/h of UCO, the Reynolds number decreases by 50%, leading to an approximate 65% reduction in the global mass transfer coefficient. This decrease in mass transfer coefficient results in lower FFA extraction from UCO. Despite the influence of the UCO mass flow rate, three cases presented in Figure 6 appear to be limited by LLE, as the outlet FFA mass fractions remain relatively unchanged.

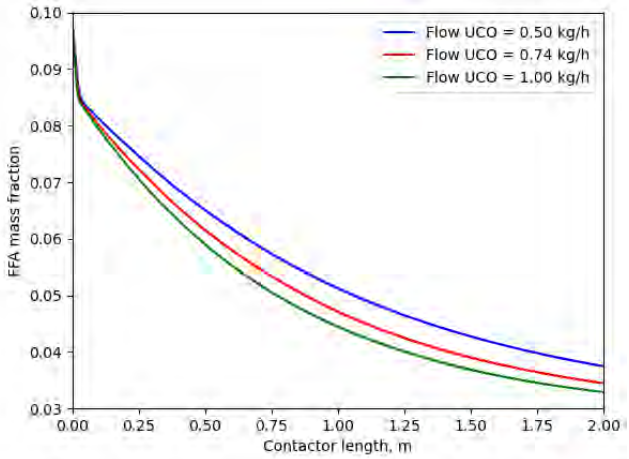

**Figure 6.** UCO flowrate effect on FFA extraction. Ethanol-to-UCO mass flow ratio: 2; Temperature: 70°C; FFA in fed UCO: 9.7 wt%.

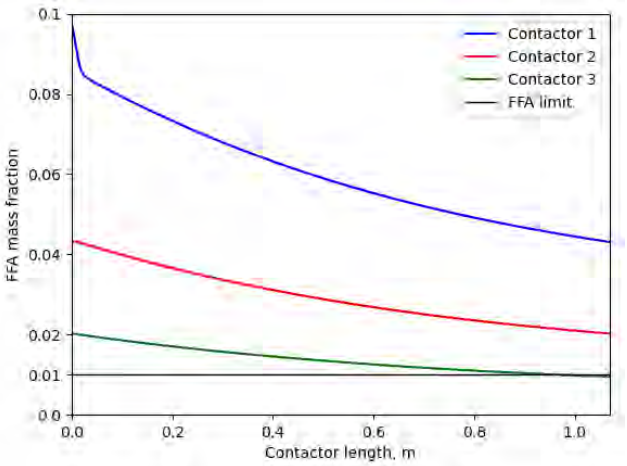

**Figure 7.** FFA extraction from UCO using three 1.07 m LLFCs operating in cascade configuration. The operating conditions for each LLFC are 70°C, an ethanol-to-UCO mass flow ratio of 2:1 and an initial FFA content of 9.7 wt% in UCO.

The recommended FFA content in treated UCO depends on its intended use as a raw material. If UCO is to be used as feedstock in feed industry, its FFA content must not exceed 0.05 wt.% (expressed as oleic acid) [11]. For biodiesel production, the allowable FFA content ranges between 0.5 wt.% and 1 wt.% [12], [13]. Then, using the developed model, it was possible to determine the number of contactors required to achieve a FFA content in UCO for a specific oleochemical application. For instance, Figure 7 presents the results obtained for a cascade configuration consisting of three 1.07 m contactors. The UCO feed flow rate was set to 1 kg/h, with an initial FFA concentration of 9.7 wt.%, operating at an ethanol-to-oil mass flow ratio of 2 and a temperature of 70°C. Under these conditions, the system produced a treated UCO with a FFA content of 0.9 wt.%. This arrangement was obtained after evaluation of different distributions of a 6 kg/h ethanol feed among three LLFCs operating in series.

## CONCLUSIONS

This study focused on developing a model of a liquid-liquid falling film contactor to assess the deacidification of UCO using ethanol as solvent, to obtain a treated stream suitable for further exploitation as oleochemical feedstock. The model incorporated mass transfer effects and it was assessed with respect to UCO mass flow rate, ethanol-to-oil ratio and contactor´s length. The effect of these variables was assessed with respect to FFA extraction from UCO. The results indicated that increasing the ethanol-to-oil mass flow ratio and UCO mass flow rate enhances FFA extraction. A higher ethanol content increased the concentration gradient between the bulk

phase and equilibrium FFA concentration throughout LLFC, while a greater UCO feed rate increases Reynolds number within the system. Both factors contribute to a higher global mass transfer coefficient for FFA. However, an increased Reynolds number resulting from a high UCO feed rate may alter the flow regime, leading to phase mixing at certain points inside the LLFC. Additionally, a higher UCO feed rate reduces the available space for ethanol and decreases the residence time of both fluids. These operating conditions could impact phase separation in the decanter and reduce the FFA extraction efficiency. Further investigation of these factors, along with model refinement, should be pursued in future studies. Regarding regressed parameters, all values felt within their respective 95% confidence intervals, and the average deviation from their lower and upper bounds were 6.77%, based on the evaluation of 0.8 million different sets. This indicates that the reported set of model parameters was unique within the selected search space. Furthermore, these parameters were like those previously obtained for deacidification of refined, deodorized and bleached palm oil. Finally, using the developed mathematical model, an arrangement of three LLFCs in series was simulated with different distributions of a 6 kg/h ethanol feed among the contactors. Results indicate that this configuration operates most efficiently when 2 kg/h of ethanol is fed into each LLFC. Under these conditions, the system can reduce the FFA content of a 1 kg/h UCO feed from 9.7 wt.% to 0.9 wt.% while operating at 70êC. It is expected that the developed mathematical model could be used for scaling up this intensified process and to assess potential industrial deployment.

## ABSTRACT

This study addresses the challenge of predicting final properties in batch processes with highly uneven durations, using the ibuprofen production process as a case study. Novel methodologies are proposed and compared against traditional regression algorithms, which rely on batch trajectory synchronization as a pre-processing step. The performance of each method is evaluated using established metrics. The data for this study were generated using Aspen Plus V12 simulation software, focused on batch reactors. To handle the unequal-length trajectories in batch processes, this research constructs a dual-transformer deep neural network with multi-head attention and layer normalization mechanism to extract shared information from the high-dimensional, uneven-length manipulated variable profiles into latent space, generating equal-dimensional latent codes. As an alternative strategy for representation learning, a dual-autoencoder framework is also employed to achieve equal-dimensional representations. The representation vectors are then used as inputs for downstream deep learning models to predict the target variables, achieving an accuracy with an $R^2$ score exceeding 0.9.

**Keywords**: Uneven durations, Batch process, Transformer, Autoencoder, Representation learning

## INTRODUCTION

In the chemical industry, batch processing is a commonly used production method [1]. Throughout an batch process, the quality of the final product is a key indicator of interest to both industry and academia. However, variations between batches often lead to unequal processing times across different batches. Due to the requirement for consistent input in building a soft sensor model for quality prediction, there are traditionally two methods for handling unequal-length batch trajectories: truncation and time-series alignment [2]. However, these two methods often come with certain issues. For the truncation methods, cutting off process-related operational trajectories can result in the loss of important information, which may affect the accuracy of subsequent soft sensor modeling. As for the time warping methods, significant differences in time lengths can cause trajectory distortion, and compression in certain segments may introduce noise. This situation can also lead to wrong models.

In this research, novel methodologies are proposed and compared against traditional regression algorithms [3], which rely on batch trajectory synchronization as a pre-processing step. In batch processes, handling three-dimensional data containing batch, time, and process variables is typically done using batch-wise unfolding, which transforms the data into a two-dimensional matrix. Due to the multivariate nature of chemical plant systems, Partial Least Squares (PLS) regression is commonly employed for modelling. This framework is referred to as Multiway Partial Least Squares (MPLS) [4]. Even though MPLS is a well-established method for handling batch process modelling, combining time warping with batch-wise unfolding can still result in the curse of dimensionality and model instability, especially when the data sampling size is too small, leading to overfitting [5].

This study aims to address the issue of excessively unequal production times between batches in quality prediction by employing a strategy based on Transformer and Autoencoder neural network architectures. Additionally, a case study on the batch production of Ibuprofen was conducted to demonstrate the approach. Ibuprofen is a pain reliever and anti-inflammatory drug commonly

used for headaches, toothaches, and minor pain. The data for this study were generated using Aspen Plus V12 simulation software [6], focused on batch reactors. To maintain process stability, it is important to prevent significant changes in the trajectories of operational variables within a given time unit. We implemented a statistical sampling approach, employing Latin Hypercube Sampling (LHS) to select samples within acceptable process boundaries [7]. The completion of each batch was determined based on the final isobutylbenzene conversion rate. A total of 1,000 simulation runs were performed, and the generated data were utilized to build a neural network model. The target variables for prediction are: (1) the isobutylbenzene conversion rate, and (2) the accumulated mass of ibuprofen.

The entire model architecture proposed in this study is built on a dual-transformer framework [8], integrating multi-head attention and layer normalization mechanisms. This approach captures shared information from the high-dimensional, uneven-length manipulated variable profiles, mapping them into latent space to produce latent codes of equal dimensions. An alternative feature extraction strategy involves utilizing a dual-autoencoder framework [9], which is also employed to obtain equal-dimensional representations. The downstream network structure consists of two fully connected neural networks, each designed to predict one of the two target variables. Additionally, the Neural Network Scalable Vector Graphics (NNSVG) tool is employed for visualizing the model structure [10].

## PRELIMINARIES

### Autoencoder

Autoencoder is a neural network framework based on an encoder and decoder. Through dimensional transformations in the intermediate layers of the neural network, the goal is to reconstruct data that is identical to the input. The reconstruction error, which serves as the loss function, can be expressed as follows:

$$L(x, x') = \| \mathrm{x} - \mathrm{x}' \|^2 \quad (1)$$

Similar to Principal Component Analysis, Autoencoder provides the capability for dimensional reduction of high-dimensional data. The difference lies in that the activation function in an autoencoder can provide nonlinear treatment to extract latent data. For latent vectors, the target is often to have the low-dimensional data represent the original high-dimensional data through the shared information extracted by the Autoencoder. Reducing the dimensionality can improve the computational efficiency of subsequent model development and help avoid the curse of dimensionality. Furthermore, the low-dimensional representation of data, regarded as important information, can also serve a filtering function to do the denoise.

### Transformer

The Transformer architecture utilizes attention mechanisms and layer normalization, eliminating the need for convolution or recurrence. There are various methods for data normalization. The advantage of using layer normalization in Transformers lies in its ability to handle three-dimension input data often associated with variable-length sequences, such as in translation tasks. When the length of sequences varies significantly, applying layer normalization to individual samples ensures that the mean and variance remain relatively stable. On the other hand, if batch normalization were used for mini-batch tasks, the insufficient padding part could affect the mean and variance, leading to fluctuations. When dealing with overly long new input sequences, the global mean and variance recorded by Batch Normalization may significantly affect the normalization of this unseen input.

In the Transformer model, multi-head attention is used, which involves multiple linear layers that project into lower-dimensional spaces. By utilizing multiple instances of scaled dot-product attention, the model learns projection parameters to identify different patterns in the sequence input. In scaled dot-product attention, the query and key undergo dot product and scaling, followed by the soft-max function to produce weight values between 0 and 1. Attention, in fact, can be regarded as a function, where the output is a weighted sum of the values. The weights are determined by the query's search over the keys corresponding to different values through the compatibility function, which can be viewed as a measure of similarity.

### Latin Hypercube Sampling

There are numerous approaches to statistical sampling, such as the memoryless Monte Carlo sampling. In this study, Latin Hypercube Sampling (LHS), a memory-based method, was chosen. The goal of using this approach is to capture the population data distribution of the original process variables with the least amount of sampling. Additionally, over time, LHS data can help avoid excessive fluctuations in the process variables of the chemical plant during simulation outputs.

With a limited sample size, random or Monte Carlo sampling may result in sample clustering. In contrast, LHS employs stratified sampling, ensuring a well-distributed sample by dividing the range into equal intervals and selecting points within each.

## DATASET AND SOFTWARE

This study used the batch production of ibuprofen as a case study to demonstrate that using feature extrac-

tion with latent codes of equal dimensions through Autoencoder and Transformer, expressed as feature learning for representing the original trajectories of chemical plant processes, combined with a neural network predictor, performs better than the approach of dynamic time warping combined with MPLS.

The dataset was generated from the Aspen Plus V12 simulation software, with the main reactor being a batch reactor, based on two feed streams and a final product outlet stream. The reactants include isobutylbenzene, acetic anhydride, hydrogen, and carbon monoxide for synthesis, with the primary product being ibuprofen. The side reaction produces acetic acid, and the chemical reaction is as follows,

$$\boldsymbol{C_{10}H_{14}} + \boldsymbol{C_4H_6O_3} + \boldsymbol{H_2} + \boldsymbol{CO} \rightarrow \boldsymbol{CH_3COOH} + \boldsymbol{C_{13}H_{18}O_2} \quad (2)$$

The kinetic information for the chemical reaction involved in Ibuprofen production indicates that the consumption of isobutylbenzene follows a second-order reaction, while the other reactants exhibit first-order consumption kinetics. The formation of the products also follows a first-order reaction.

To accurately model phase equilibrium behavior in the system, we employed the Wilson thermodynamic model, which is expressed as:

$$\ln \gamma_i = 1 - \ln\left(\sum_j A_{ij} x_j\right) - \sum_j \frac{A_{ij} x_j}{\sum_k A_{jk} x_k} \quad (3)$$

where $lnA_{ij} = a_{ij} + \frac{b_{ij}}{T} + c_{ij} lnT + d_{ij} T + e_{ij}/T^2$ .

The binary parameters $(a_{ij}, b_{ij}, c_{ij}, d_{ij}, e_{ij})$ were regressed using vapor-liquid equilibrium data from the Dortmund Databank, implemented via Aspen V12 software. In the pharmaceutical and chemical industries, the Wilson model is particularly advantageous due to its asymmetric interaction parameters, which enhance flexibility in capturing liquid-phase non-ideality, improving the accuracy of phase equilibrium predictions.

We used the conversion rate of isobutylbenzene as the stop criterion for each independent batch process. Due to different stop values and dynamic process operation profiles, the varying cycle times across batches were influenced. In this study, our goal was to do the regression two target variables: 1) the accumulated mass of ibuprofen and 2) the conversion rate of isobutylbenzene.

Using Python to drive Aspen software, we adjusted the two manipulated variables, temperature and pressure. The model training was based on Python 3.8.8, with the GPU being an NVIDIA GeForce RTX 2080 Ti. At each time step, the temperature and pressure points needed to obey with the range defined by LHS sampling while also avoiding large fluctuations in the variables, which was undesirable in chemical plant operations.

After data generation, we began by visualizing the issue of unequal lengths in batch data. As shown in Figure 1, we needed an effective solution for modeling with varying sequence lengths modeling. In 1,000 simulation experiments, the batch processing times varied significantly, with a maximum of 6158 seconds, a minimum of 2693 seconds, and a median of 3790 seconds. The subsequent comparison with the conventional methods employed the median as the representative template batch.

This study adjusted the dynamic process operations in the early stages of all batches, while the later stages reached a steady state following the Latin Hypercube Sampling method to generate data. We also visualize the variation of the two target variables across 1,000 independent batch simulations, shown in Figures 2 and 3.>

## METHODOLOGY AND RESULT DISCUSSIONS

This study employs two strategies to specifically address variations in process trajectories related to the manipulated variables of temperature and pressure, which could be extended to higher-dimensional systems with multiple process variables. The first strategy used in this study is the Autoencoder strategy, with the overall model architecture illustrated in the Figure 4. This model comprises a dual-autoencoder neural network, with two downstream predictors responsible for predicting the target variables: Ibuprofen accumulated mass and isobutylbenzene conversion rate, respectively. The overall loss function is a custom-defined loss function optimized through the Adam optimizer, which performs gradient descent to find the optimal weights. The total loss comprises the reconstruction loss of the two manipulated variables and the prediction loss of the two target variables.

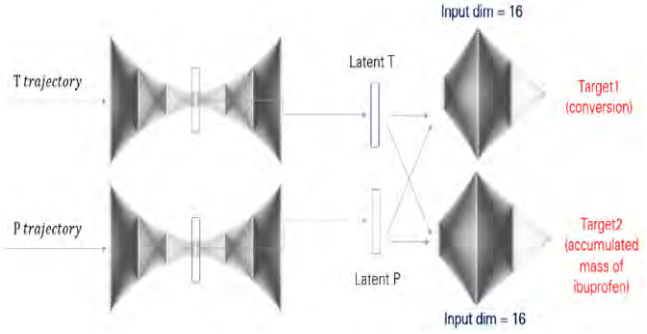

**Figure 4.** Framework of autoencoder strategy

The second strategy is the Transformer strategy, as shown in the model architecture Figure 5. Instead of using traditional recurrent neural networks to capture sequential relationships within the chemical engineering system, we utilize a multi-head attention mechanism. This mechanism applies multiple scaled dot-product attention layers and linear projections to identify trajectory similarities. To prevent the disproportionate influence of excessive padding on the global trajectory's mean and variance, layer normalization is applied. Furthermore, its scalability allows for adjusting the number of front-end Transformers to accommodate different chemical systems and corresponding manipulated variables.

The input layer for each autoencoder or Transformer basis consists of 62 parameters, where each corresponds to a single manipulated variable. The number 62 represents the sampling points for each manipulated variable in the longest production batch across all batches, with a time frequency of 100 seconds. For batches with fewer than 62 sampling points, padding is applied before entering the masking layer to ensure that these padded values are excluded from the loss function. Ultimately, the input data is compressed into an 8-dimensional latent space, and the two latent codes are merged into a 16-dimensional representation, which is then processed by the downstream predictor.

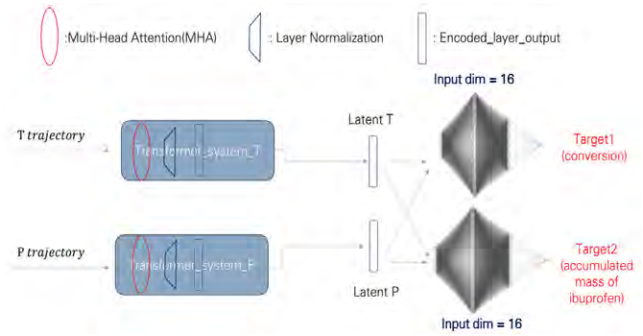

**Figure 5.**Transformer Method framework.

The conventional methods for comparison rely on using the golden batch as a template to align all candidate batches, followed by using dimensionality reduction machine learning algorithms (including MPLS and multi-way principal component regression (MPCR)) to predict the terminal properties of the process. The following Table 1 and Table 2 present performance comparisons.

**Table 1:** Ibuprofen accumulated mass prediction results

| **Ibuprofen accumulated mass performance metrics** | | | |
|---|---|---|---|
| **Subset** | **Train** | **Validation** | **Test** |
| **Method** | $R^2/RMSE$ | $R^2/RMSE$ | $R^2/RMSE$ |
| Autoencoder | 0.99/7.6 | 0.99/7.6 | 0.99/7.5 |
| Transformer | 0.99/11.3 | 0.99/10.6 | 0.99/10.4 |
| DTW+MPLS | 0.02/167 | - | -0.03/171 |
| DTW+MPCR | 0.01/167 | - | -0.03/171 |

**Table 2:** Isobutylbenzene conversion rate prediction results

| **Isobutylbenzene conversion rate performance metrics** | | | |
|---|---|---|---|
| **Subset** | **Train** | **Validation** | **Test** |
| **Method** | $R^2/RMSE$ | $R^2/RMSE$ | $R^2/RMSE$ |
| Autoencoder | 0.99/0.01 | 0.99/0.01 | 0.99/0.01 |
| Transformer | 0.99/0.01 | 0.99/0.01 | 0.99/0.01 |
| DTW+MPLS | 0.02/0.11 | - | -0.03/0.1 |
| DTW+MPCR | 0.02/0.11 | - | -0.03/0.1 |

The prediction results of the four methods on the test set, applied to the accumulated mass of Ibuprofen, are visualized in Figures 6 through 9. Among them, Figures 6 and 7 demonstrate that the proposed method in this study exhibits excellent predictive capability in addressing this a highly uneven-length batch production property prediction task.

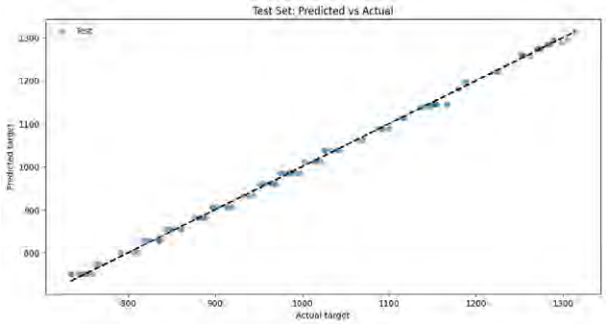

**Figure 6.** Ibuprofen accumulated mass (Autoencoder prediction results on the test set)

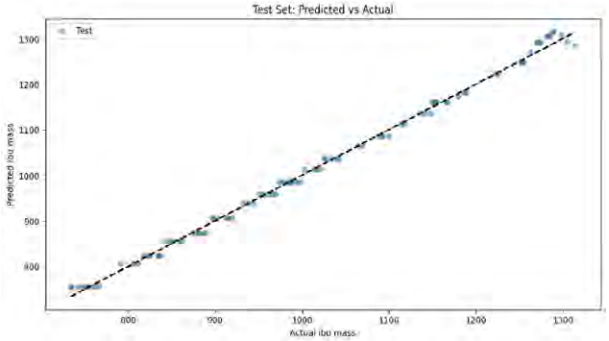

**Figure 7**. Ibuprofen accumulated mass (Transformer prediction results on the test set)

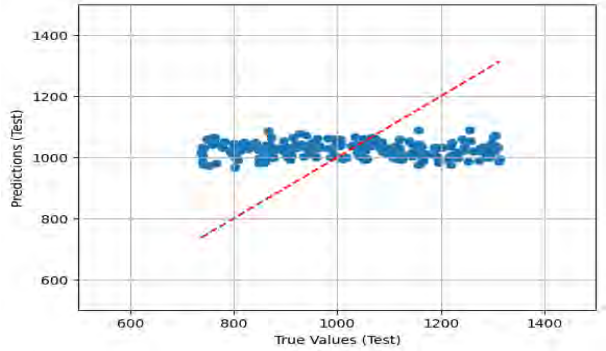

**Figure 8.** Ibuprofen accumulated mass (DTW+MPLS prediction results on the test set)

The prediction results of the four methods in test set can also be visualized in terms of the Isobutylbenzene conversion rate, as shown in the Figure 10 to Figure 13. The two strategies proposed in this study demonstrate better predictive performance compared to traditional trajectory synchronization and latent space dimensionality reduction machine learning methods. In the scatter plot, the prediction points are well-aligned near the ideal line, with $R^2$ for both target variables exceeding 0.9. This improvement is attributed to several factors: our neural network processes effectively handle the dynamics of trajectories with highly unequal lengths, avoiding the trajectory compression and introduction of error information that often result from warping. Additionally, both the autoencoder and transformer strategies incorporate activation functions, allowing for the handling of non-linear aspects of the system, which state-of-the-art methods lack in terms of non-linear learning capabilities.

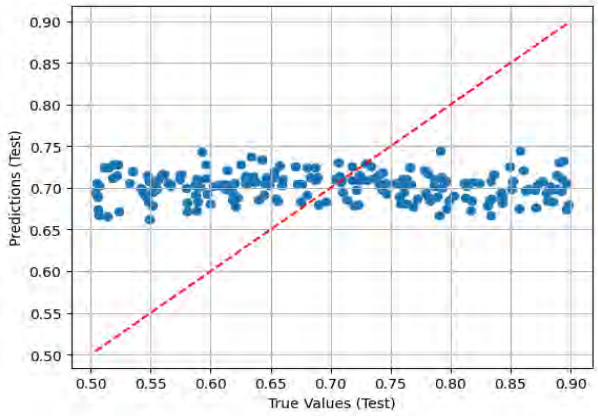

**Figure 12.** Isobutylbenzene conversion rate (DTW+MPLS prediction results on the test set)

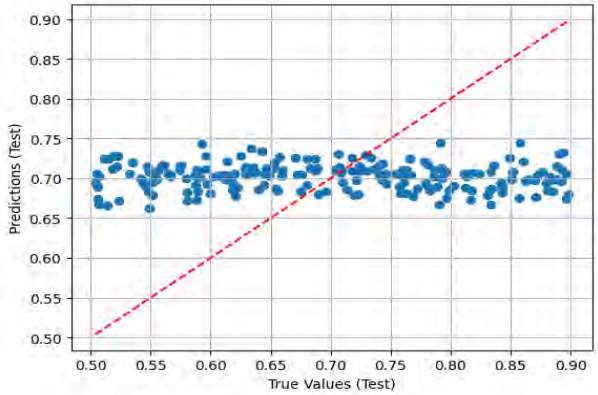

**Figure 13**. Isobutylbenzene conversion rate (DTW+MPCR prediction results on the test set)

## CONCLUSIONS

This study proposes two innovative approaches to address the prediction problem of terminal properties in chemical processes with unequal batch lengths. The research contains two strategies, the dual-Transformer and dual-Autoencoder strategies. The neural network modules are determined by several process variables to extract latent space vectors from process trajectory data and input them into the downstream of the overall architecture for quality predictor modeling. In the case study of batch ibuprofen production, the R-squared values for both target variables exceed 0.9. This shows a significant difference compared to using only DTW combined with MPLS or MPCR.

## ABSTRACT

Maintaining sufficient amounts of dissolved oxygen throughout a microbial cultivation is a classic control task in bioprocess engineering to avoid negative effects onto cell physiology and productivity. But traditional PID-based algorithms struggle when faced with pulsed substrate additions and the resulting sudden surge of oxygen uptake. In this work a nonlinear MPC is employed and compared to a PID setup for the cultivation of an *E. coli* strain exposed to intermittent feeding. Both controllers are tuned for a fast pulse response combined with efficient and robust control action. Their performance was tested *in-silico* with isolated feed pulses, as well as throughout a full cultivation run. Further, the effects of parameter uncertainty were investigated to assess the impact of a model-plant mismatch. The results showed that the predictive nature of the MPC is well suited for maintaining the dissolved oxygen levels above a threshold and outperforms the PID in almost all investigated simulation scenarios.

## INTRODUCTION

Dissolved oxygen concentration is an important process variable for cultivation-based bioprocesses. Together with the availability of a substrate source it facilitates the growth and energy production of aerobic cells. Limitations in available oxygen often cause the formation of unwanted by-products such as Acetate or Ethanol. This metabolic shift and additional stress can lead to reduced physiological health and ultimately loss of productivity, especially when the product is a complex molecule such as a recombinant protein [1].

Therefore, industrial processes are typically equipped with a feedback-control system to maintain the DO level above a certain threshold by acting on the stirring speed and the supplied airflow to the reactor. The standard implementation uses two separate PID controllers for each variable that are connected in a hierarchical cascaded logic that prioritizes changing the agitation rate over the airflow rate. More advanced strategies involve gain scheduling or feedback linearization to account for the plant non-linearities [2].

Nevertheless, these control strategies struggle when faced with fast changes in oxygen demand, which lead to prolonged affixation periods for the cells. These conditions can occur because of abrupt changes in nutrient availability or changes in the prioritized metabolic activity due to the addition of an induction agent. The first is often observed in high-throughput small scale multi-reactor systems since the only viable feeding strategy is through intermittent feed shots [3].

Model predictive control emerges as a promising alternative to tackle these highly dynamic but repetitive conditions. The predictive nature of the algorithm can take advantage of the known feed profile to reduce the oxygen limitation periods through proactive control action compared to the purely reactive nature of common PID controllers. Similar work has been done for optimizing the feed pulse volume by employing an MPC to ensure sufficient oxygen availability during the cultivation at each bolus shot [4].

This study sets out to setup a nonlinear MPC that maintains the dissolved oxygen (DO) level above a defined threshold by manipulating the stirrer speed and the airflow. It further compares the performance to an adequately tuned PID controller setup in a typical hierarchical cascaded mode regarding minimal time spent underneath the threshold and minimal control input needed.

# MATERIAL & METHODS

## Process model

A kinetic state-space model is setup and parameterized with experimental data to describe the growth of a strain of the bacteria *Escherichia coli (E. coli)*. The state vector is $x = [c_{O_2}, c_X, c_S, V_R]^T$, consisting of the concentrations for the dissolved oxygen $c_{O_2}$, biomass $c_X$, and substrate $c_S$ in $g/L$, as well as the reactor volume $V_R$ in $L$.

$$\frac{d}{dt}\begin{bmatrix} c_{O_2} \\ c_X \\ c_S \\ V_R \end{bmatrix} = \begin{bmatrix} k_L a \cdot (c_{O_2,eq} - c_{O_2}) - q_S \cdot c_X \cdot Y_{O/S} \\ \left((q_S - q_m) \cdot Y_{X/S} - \frac{F_{in}}{V_R}\right) \cdot c_X \\ (c_{S,in} - c_S) \cdot \frac{F_{in}}{V_R} - q_S \cdot c_X \\ F_{in} \end{bmatrix} \quad (1)$$

$$y = \mathrm{DO} = \frac{c_{O_2}}{c_{O_2,eq}} \cdot 100\,\% \quad (2)$$

The mass balances in the state evolution equation, eq. 1, are supplemented with the kinetic expressions for the specific substrate uptake $q_S$ and a model for the Oxygen Transfer Rate $OTR$ in the reactor. Eq. 2. Describes the conversion of the state $c_{O_2}$ into a DO signal, which was measured during the process. $q_S$ is modeled with an expanded Monod-type equation that considers the co-limitation by $c_S$ and $c_{O_2}$ in eq. 3.

$$q_S = q_{S,max} \cdot \frac{c_S}{c_S + K_S} \cdot \frac{c_{O_2}}{c_{O_2} + K_{O_2}} \quad (3)$$

The $OTR$ is modeled by the $k_L a$ equation in eq. 4, suggested by Van't Riet et al. [5] and describes the influence of the manipulated variables stirring speed $n_{stirr}$ and airflow $F_{air}$ onto the oxygen transfer.

$$k_L a = k_{k_L a} \cdot \left(\frac{N_p \cdot \rho \cdot {n_{stirr}}^3 \cdot D^5}{V}\right)^{\alpha} \cdot \left(\frac{F_{air}}{A}\right)^{\beta} \quad (4)$$

## Model parameterization & simulation base case

The model was parameterized in two steps. First the $k_L a$ values were obtained from water runs using the gas-degas method [5] from a full grid design of experiment analysis using 100 experiments.

Then the physiological parameters such as yield and kinetic parameters were obtained from four experimental runs using a $3\ L$ lab-scale bioreactor. An optimization algorithm obtained the parameter set by minimizing the normalized root mean squared error (NRMSE) between the simulated and measured values for $c_X$, $c_S$ and $DO$ (data not shown). The resulting parameter values are shown in Table 1.

The simulated process used to assess the controller performance is set to start with a batch phase and followed by an intermittent fed-batch phase until a final biomass of $25\ g/L$ is reached. For the tuning efforts a representative process state was chosen, assuming the bioreactor being substrate limited ($c_S = 0\ g/L$) at a biomass concentration halfway towards the target of the process with $c_X = 15\ g/L$ at $V_R = 2\ L$. The DO state is either at $100\,\%$ for the closed-loop pulse response or at $30\,\%$ for the steady-state open-loop step response. The technical limits for the two manipulated variables are $400 - 1200\ rpm$ for $n_{stirr}$ and $0.5 - 5\ L/min$ for $F_{air}$. Furthermore, the experimental data showed that the maximum rates of change are $63\ rpm/s$ and $0.21\ L/min/s$ respectively.

**Table 1:** Process model parameters.

| Parameter | Symbol | Value | Unit |
|---|---|---|---|
| *Physiological parameters* | | | |
| Max specific substrate uptake rate | $q_{S,max}$ | 1.140 | g/g/h |
| Monod constant substrate | $K_S$ | $8.135 \cdot 10^{-2}$ | g/L |
| Monod constant oxygen | $K_{O_2}$ | $10^{-5}$ | g/L |
| Specific maintenance coefficient | $q_m$ | $8.365 \cdot 10^{-3}$ | g/g/h |
| Biomass/substrate yield | $Y_{X/S}$ | 0.3581 | g/g |
| Oxygen/substrate yield | $Y_{O/S}$ | 0.1908 | g/g |
| *OTR parameters* | | | |
| $k_L a$ constant | $k_{k_L a}$ | 4.002 | - |
| Exponent 1 | $\alpha_1$ | 0.3842 | - |
| Exponent 2 | $\beta$ | 0.2556 | - |

## Controller design

Two different controllers are designed, tuned and evaluated in this simulation study, a variation of a PID controller and a non-linear Model Predictive Controller (MPC). For both strategies the same state-space model is used to tune the parameters, while for the performance evaluation the model parameters are varied to investigate their robustness.

Regarding the manipulated variables, the stirrer speed is the preferred input since it also ensures smaller bubble sizes for better gas-liquid transfer and more uniform mixing throughout the reactor. High airflows on the other side come with a number of downsides for the process such as enhanced stripping of volatile components, increased risk of foaming or higher energy demands [6].

The controlled variable is the DO state which is overlayed with a white noise corresponding to the observed measurement variance of the DO sensor of the experimental setup, found to be $\sigma_{DO} = 0.56\,\%\text{-}pts$. Further a measurement delay of $1\ s$ and a control action delay of $2\ s$ was identified and included in the closed-loop process simulation. The influence of the measurement noise on the closed-loop behaviour was reduced by implementing a low-pass filter for the DO signal. An exponential moving average filter (EMA) with a window size of $15\ s$ was chosen.

## PID controller setup & tuning

The PID controller is designed as a hierarchical

cascaded controller, that keeps the DO level above a defined threshold of $30\,\%$ of the maximum DO in the cultivation broth. First, a PID controller acts on the stirring speed $n_{stirr}$ until it is saturated at the technical limit. When this becomes insufficient a second PID controller increases the airflow $F_{air}$, while $n_{stir}$is kept at the maximum value. Both PID loops are setup up with different tuning parameters. For anti-windup the setpoint error was not added to the integral error when the actuators were both at the minimum and maximum values.

For tuning the PID values of each manipulated variable a multi-step approach was chosen. The model open-loop step response was analyzed to obtain the process time constant $\tau$, the dead time $\theta$ and the process gain. The deadtime was identified as the time delay until an increase of the DO signal $> 3 \cdot \sigma_{DO}$ was identified. These parameters were then used to calculate the proportional gain $K_p$ and integral gain $K_I$ to design a PI controller using the lambda method [7]. The method relies on choosing a closed-loop time constant $\tau_{CL}$ that determines the aggressiveness of the resulting controller.

The derivative gain $K_D$ was manually adjusted by analysing the closed-loop response of the system after a feed pulse. Starting from 0, $K_D$ was stepwise increased to tune the response speed of the input variable further, while introducing only moderate noise amplification. This procedure was done for both input variables separately.

## MPC setup & tuning

The MPC was setup with the same process model and parameters as the simulation model. For this work the python package do-mpc [8] and the software framework CasADi [9] were used to implement a non-linear MPC controlling the DO-level through adjusting the stirring speed $n_{stirr}$ and airflow $F_{air}$ simultaneously. The optimal input trajectory is calculated by minimizing the stage cost ($lterm$) and the terminal cost ($mterm$), described in eq. 5 and eq 6. In both cases the variables are scaled with their respective maximum values.

$$mterm = Q_1 \cdot \left(\frac{DO - DO_{th}}{DO_{th}}\right)^2 \tag{5}$$

$$lterm = mterm + R_1 \cdot \left(\frac{u_1}{u_{1,max}}\right)^2 + R_2 \cdot \left(\frac{u_2}{u_{2,max}}\right)^2 \tag{6}$$

The MPC is tuned by adjusting the weighting parameters $Q_1$, $R_1$ and $R_2$ until a satisfying closed-loop behaviour is achieved. Additionally, the rate of change for the input variables was penalized as well through the weights $\Delta R_1$ and $\Delta R_2$ to achieve a smoother control action. The optimisation results and computation time are influenced by the chosen prediction horizon of $1\,min$ and the step size of $1\,s$. First the noise-free model response was used to tune the weights for the inputs and outputs. Then the influence of the measurement noise was investigated and the weights were adjusted.

## Performance quantification

The subsequently designed controllers will be compared by evaluating the time spent underneath the threshold of $30\,\%$ DO $t_{<30}$ and the used system inputs, stirring speed $n_{stirr}$ and airflow $F_{air}$. The $k_La$ equation in eq. 4 was used to calculate the power input $P_{stirr}$ from the stirring speed with eq. 7. By integrating both input variables over the process time, the general resource demand, stirrer energy input $E_{stirr}$ and pressurized air input $V_{air}$, can be estimated and compared between the designed controllers.

$$P_{stirr} = N_p \cdot \rho \cdot {n_{stirr}}^3 \cdot D^5 \tag{7}$$

# RESULTS & DISCUSSION

The goal of this simulation study was to investigate the control of the DO-level during an *E. coli* cultivation with special emphasis on disturbances deriving from the feed addition Hereby the controller should act as fast as possible to avoid oxygen limitations after a feed shot.

## PID tuning

As a starting point the step-response from a designed state was analyzed. To achieve an unbiased response, the system was continuously excited, and the formed biomass and volume increase neglected to result in a steady state at $30\,\%$ DO. A step increase of the input variable was performed and the open-loop system response in Figure 1 was analyzed.

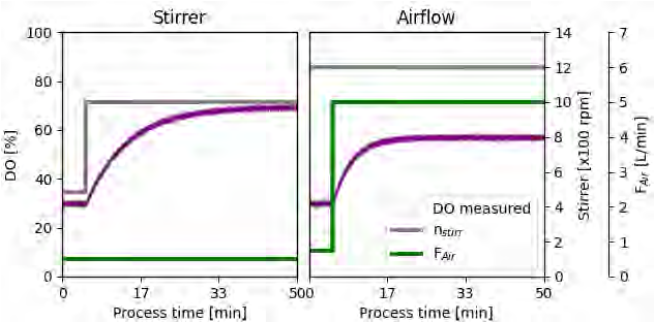

**Figure 1.** Open loop step responses of the noisy process model for the two hierarchically cascaded PID controller.

From the resulting changes in the DO signal, it is seen that in both cases the response follows only very little delay compared to the relatively long settling time to a new steady state. From this the process time $\tau$ and dead time $\theta$ were derived. Using the lambda method, the closed-loop time constant $\tau_{CL}$ was chosen as $2\,min$ for the stirring speed to achieve an aggressive tuning that reacts fast to the sudden increase of oxygen demand upon the feed shot. For the airflow a softer tuning was implemented with a $\tau_{CL}$ value of $4\,min$ to avoid oscillations, given also the smaller process time constant $\tau$.

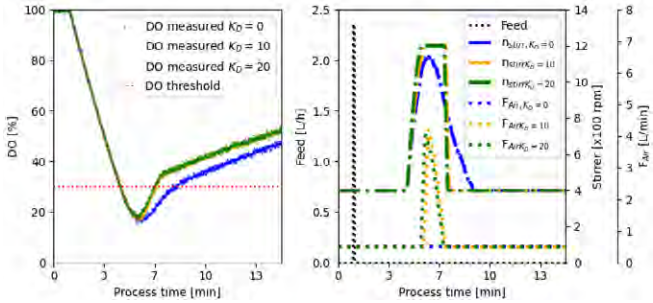

**Figure 2.** Feed pulse response with different $K_D$ tuning values for stirrer and airflow.

In the next step the derivative gain $K_D$ was adjusted manually by observing the closed-loop response to a feed pulse. Figure 2 shows the response for 3 different $K_D$ tunings for $n_{stirr}$. A significant difference in response time can be seen from raising $K_D$ up to 10, while increasing it further did not introduce any additional benefits. Higher $K_D$ values for the airflow did not improve the performance significantly, therefore it was set to zero to ensure smoother control action. The final tuning parameters are listed in Table 2.

**Table 2:** PID tuning parameters and time constants.

| PID parameters | Symbol | Stirrer | Airflow |
|---|---|---|---|
| process time constant | $\tau$ | 513.0 $s$ | 232.0 $s$ |
| Dead-time | $\theta$ | 10.0 $s$ | 7.0 $s$ |
| Closed-loop time constant | $\tau_{CL}$ | 2 $min$ | 4 $min$ |
| Proportional gain | $K_p$ | 51.61 | 0.29 |
| Integrative gain | $K_I$ | 0.10061 | 0.00124 |
| Derivative gain | $K_D$ | 10 | 0 |

## MPC tuning

Since the variables are scaled in the $lterm$ and $mterm$ cost equations by their maximum values, the weights were all initialized with 1 and then iteratively changed to achieve good setpoint tracking with minimal controller input. The tuning result can be seen in Figure 3 and the final parameters are listed in Table 3. Although the variables were scaled directly in the model equation, the tuning resulted in weights differing in several magnitudes. Especially the parameters connected with $n_{stirr}$ are low, which reflects the goal for the controller to act on the stirrer first before resorting to the airflow.

After finding acceptable values the MPC was tested with overlaying the DO measurement with the same white noise as done for the PID tuning. The MPC response showed almost identical control action and system responses. Nevertheless, the airflow was fluctuating due to the measurement uncertainties, therefore the penalty on the rate of control input changes $\Delta R_1$ and $\Delta R_2$ were adjusted towards heavier penalties. A further improvement to neglect measurement uncertainty induced fluctuations was the application of the low-pass filter as done for the PID controller. This resulted in the DO signal following the perfect model simulation closely.

**Table 3:** MPC tuning parameters.

| MPC parameters | Symbol | Value |
|---|---|---|
| DO state weight | $Q_1$ | $2 \cdot 10^4$ |
| Stirrer speed weight | $R_1$ | 1 |
| Airflow weight | $R_2$ | $10^3$ |
| Stirrer changes weight | $\Delta R_1$ | $10^{-1}$ |
| Airflow changes weight | $\Delta R_2$ | $10^2$ |

## Pulse response performance with perfect model

The final tunings for the two different control algorithms were compared with the previously set feed pulse response. The result can be seen in Figure 3 and Table 4. The advantage of the predictive optimisation for the MPC is evident when looking at the response times of the manipulated variables. This results in a better DO signal dynamic regarding the time spent underneath the threshold and a more efficient use of the input variables. The stirrer power consumption is lower while also the amount of sparged pressurized air is less.

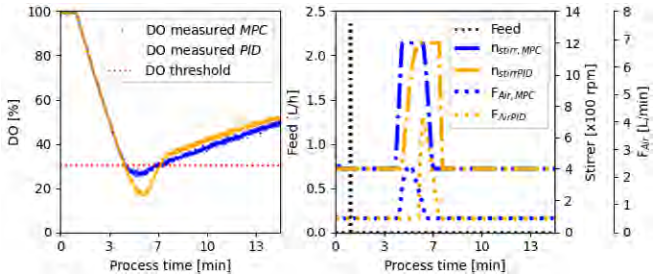

**Figure 3.** Feed pulse response for the final tunings of the MPC (blue) and PID (orange) algorithm.

**Table 4:** Performance for single feed pulse response.

| Controller | $t_{<30\%}$ $[min]$ | $E_{stirr}$ $[kJ]$ | $V_{air}$ $[L]$ |
|---|---|---|---|
| PID | 2.10 | 1.888 | 10.35 |
| MPC | 1.38 | 1.756 | 9.65 |

## Cultivation performance

To assess the controllers over the whole application range the defined cultivation process was simulated. It starts with a batch phase followed by pulsed feeding. The intervals are set to 5 $s$ of 3 $L/h$ pulses every 30 $min$, using a glucose feed concentration of 600 $g/L$ which results in a rapid addition of 2.5 $g$ of glucose to the cultivation. This causes fast and dynamic changes in oxygen demand, where the controllers act to keep the DO signal above 30 %. The process length and number of pulses is calculated to reach a final biomass concentration of

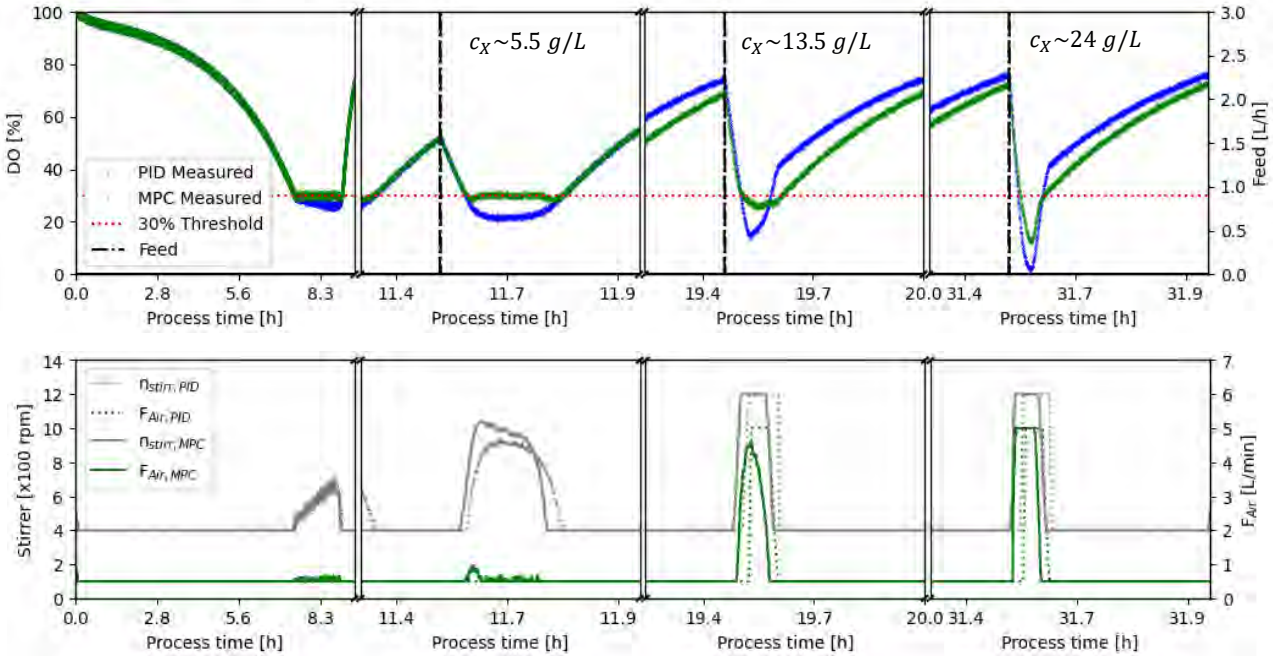

**Figure 4:** Controller performance for a complete cultivation, zooming in on the batch phase performance and 3 pulses – start, middle and end of process to show the response at progressing biomass concentrations.

$c_{X,final} = 25\ g/L$. The difference in performance assuming perfect model match between simulation and MPC is shown in Figure 4.

The results show that the MPC performs better throughout all phases of the process. The PID controllers perform equally well during the batch phase but struggle during the pulsed feed additions. First, they manage to maintain DO levels slightly below the threshold but remain there for a considerable amount of time. The MPC on the other hand avoids going below 30 % DO almost entirely in that phase. Later the increasing amount of biomass results in the $OUR$ being higher and the DO dips are getting more extreme. The MPC results in less deep DO signal dives and less time spent underneath the threshold, due to the predictive nature of the algorithm. The model implementation allows the controller to act before the setpoint deviation occurs that triggers the PID controllers. The total differences of the performance indicators are shown in Table 5. Here it shows that the MPC manages to minimize the time below the setpoint with almost identical control action.

**Table 5:** Performance for complete cultivation simulation.

| Controller | $t_{<30\%}\ [h]$ | $E_{stirr}\ [kJ]$ | $V_{air}\ [m^3]$ |
|---|---|---|---|
| PID | 5.30 | 204.3 | 1.471 |
| MPC | 2.15 | 208.7 | 1.463 |

## Pulse response performance with model-plant mismatch

The PID controllers and the MPC were tuned with the model response of a bacterial cultivation process. The MPC additionally bases its control action calculations on an internal model, which was assumed to be identical with the simulation model. Model identification and parameterization is generally regarded as challenging for bioprocesses and result in uncertainties regarding the parameter values [10]. To investigate the robustness of the developed controllers, a number of parameter values are varied to see the impact of a model-plant mismatch for the feed pulse responses. The results for a variation of $\pm 25$ % for $Y_{O/S}$ and $k_{k_La}$, as well as a mismatch between the state-space values for biomass in the process and the MPC simulator were investigated. The differences in performance values are listed in Table 6.

The parameter variations affected the controllers differently. The PID is less affected than the MPC since it only uses the incorrect model for the initial tuning. But no general trend can be observed. For the MPC the performance differs stronger, where overall parameter variation resulting in less OUR or more OTR lead to better results than the base case and vice versa. Nevertheless, the MPC outperformed the PID in all cases.

The influence of the biomass yield $Y_{X/S}$ uncertainty can not be observed at a single feed-pulse, since the biomass increase is minimal. But over the progress of a cultivation process it can lead to significant differences between the estimated and the actual biomass concentration, similar to the case of variations in $c_{X,0}$.

**Table 6:** Performance for model parameter variations.

| Simulation | $t_{<30\%}\ [min]$ | $E_{stirr}[J]$ | $V_{air}[L]$ |
|---|---|---|---|
| Base case MPC | 1.38 | 1755.8 | 9.65 |
| $c_{X,0}$ +25 % MPC | 1.43 | 1876.0 | 11.39 |
| $c_{X,0}$ -25 % MPC | 2.30 | 1415.2 | 8.51 |
| $Y_{O_2/S}$ +25 % MPC | 2.88 | 2642.8 | 16.02 |
| $Y_{O_2/S}$ -25 % MPC | 0.00 | 418.8 | 7.50 |
| $k_{k_La}$ +25 % MPC | 0.18 | 1492.7 | 8.66 |
| $k_{k_La}$-25 % MPC | 2.23 | 2166.3 | 11.47 |
| base case PID | 2.10 | 1888.4 | 10.35 |
| $c_{X,0}$ +25 % PID | 1.97 | 1875.7 | 11.40 |
| $c_{X,0}$ -25 % PID | 3.27 | 1325.9 | 7.50 |
| $Y_{O_2/S}$ +25 % PID | 3.03 | 2716.5 | 17.01 |
| $Y_{O_2/S}$ -25 % PID | 0.00 | 416.7 | 7.50 |
| $k_{k_La}$+25 % PID | 2.45 | 1208.5 | 7.50 |
| $k_{k_La}$-25 % PID | 2.50 | 2377.3 | 13.51 |

## CONCLUSION

A hierarchical cascaded PID controller and a non-linear MPC were designed for a threshold control problem to keep the dissolved oxygen signal above 30 % in an intermittent fed-batch cultivation of *Escherichia coli*. Both controllers were assisted with a low-pass filter for the measurement signal. A kinetic state-space model with additional white noise at the DO signal was used to simulate the plant response. The controller parameters were tuned to achieve minimal time underneath the threshold, while also considering efficient control input.

The results showed that the MPC outperforms the PID regarding the response time in all analyzed cases, while also being more economical for most of them. The impact of model and state vector to plant mismatch were investigated and proofed the MPC superior in the conducted simulations, although the manipulated variables input exceeded the optimal in some cases.

Finally, a defined bioreactor run was simulated and showed the cumulative benefits the MPC gives over the commonly used PID approach for intermittent fed-batches. With a reasonable tuning it keeps the DO signal above a defined threshold more effectively and resource efficiently. Pairing the controller with a filter algorithm results in a robust control scheme for the given task that is also resistant to some parameter and state uncertainty. Nevertheless, the additional implementation effort, computational demands and more complex tuning compared to traditional controller designs must be considered.

## ABSTRACT

This work presents a hybrid-modeling approach to monoclonal antibody (mAb) production processes design using automated bioreactor equipment. Experimental data covering a reasonable yet broad range of cultivation conditions was collected by the equipment. Using the data, a model applicable to a wide range of cultivation conditions was developed. In the modeling, a data-driven model was applied to describe complicated/unknown phenomena that could not be captured by previously proposed mechanistic models. In the hybrid model, while maintaining the mass balance of the mechanistic model, coefficients of the equations were estimated with random forest regression. Overall, the model could describe the dynamic concentration profiles of product mAb and quality-relevant impurities depending on the media/glucose feeding conditions. The model was then applied to determine an optimal condition that maximized product mAb concentration and satisfied the impurity constraints. The work can further support model-based design of cell cultivation processes with considering multi-input & multi-output nature.

**Keywords**: Process Design, Dynamic Modelling, Biosystems

## INTRODUCTION

Monoclonal antibody (mAb) drugs offer advantages such as higher affinity and specificity as compared to conventional drugs for the treatment of critical diseases. Such advantages have led to a rapid growth of the mAb market, along which new technologies have been developed including host cel lines such as a high-yield CHO-MK cell line [1]. In the cultivation step, not only the final product, mAb, but also impurities such as host cell proteins (HCP), DNA, and charge variants are produced. These impurities have a significant impact on quality in the time- and resource-intensive cultivation step, making this step a major factor influencing the overall cost, time, and quality [2]. Since these impurities and mAb are affected by many cultivation conditions, such as agitation speed, dissolved oxygen (DO), feed rate, and cultivation time [3], it is essential to select conditions appropriately. Therefore, mathematical models that describe the target process based on cultivation conditions and can reduce experimental burdens are useful in the design of this critical cultivation step [4].

In modeling the cultivation step involving many complex biological phenomena, it is challenging to describe all the phenomena with a mechanistic model, making hybrid models useful. Various hybrid models for the cultivation step have been developed using different methods and for different purposes. A hybrid model of a CHO-K1 perfusion process was developed to optimize media exchange rates [5]. Hybrid models using different machine learning algorithms were compared and utilized to predict viable cells and titer [6]. A hybrid model was developed to predict critical quality attributes such as mAb and glycan profiles [7]. A hybrid model for fed-batch process with Adaptive Moment Estimation Method was developed [8]. Different hybrid models were compared

by introducing the concept of the degree of hybridization [9]. A hybrid modeling approach was proposed incorporating a data-driven model to improve the predictions of lactate which is important for predicting impurities [2]. However, hybrid models in previous studies were developed for limited cultivation conditions (for example, agitation rate and DO were constant in a previous study [8]). This limitation made it challenging to describe the relationships between various conditions and impurities as well as mAb, posing a significant obstacle to comprehensive multi-input, multi-output process design.

This work presents a hybrid-modeling approach to CHO cell cultivation process design. Experimental data covering a reasonable yet broad range of cultivation conditions was collected by the equipment. Using this data, a hybrid model applicable to a wide range of cultivation conditions was developed. The hybrid model combines mass balance equations (mechanistic component) with coefficients of the equations being estimated with random forest regression (data-driven component). Overall, the developed model could describe the concentrations of product mAb and quality-relevant impurities such as charge variants, HCP and DNA depending on the media/glucose feeding conditions. The model was then applied to determine an optimal condition that maximized product mAb concentration and met the impurity constraints considering 3,840 alternatives.

## EXPERIMENTAL METHODS

Figure 1 represents an overview of the experimental methods. In the experiments, a newly developed CHO-MK cell line [1], known for exhibiting extremely complex metabolic phenomena, was used. Cells were extracted from a frozen stock, thawed, and cultured in flasks for one week to increase cell density. Subsequently, cultivation was carried out with automated bioreactor equipment (Ambr® 250) which contained twelve bioreactors, each with a 250 mL volume. Initial solution volume $V_0$ was set to 170 mL in all experiments. Three cycles of fed-batch cultivation were performed by varying agitation speed $agitation$, DO $DO$, normal feed (referred to as feed hereinafter) rate $F_{\mathrm{in}}$, glucose feed rate $F_{\mathrm{in,glc}}$, feed start timing $t_{\mathrm{in}}$, and glucose feed start timing $t_{\mathrm{in,glc}}$. Table 1 shows the minimum and maximum values of each cultivation condition. Experiments were conducted once under 20 different conditions, and each condition was determined to cover a reasonable yet broad range to extend the interpolation range of the model. During the experiments, feed and glucose feed were supplied at a constant rate. Items such as DO and agitation speed were measured online every few seconds. In addition, multiple items including viable cells, cell viability, mAb, metabolites, and impurities were measured offline as time series data once or twice per day.

**Table 1:** Minimum and maximum values of each cultivation condition.

| Process parameters | Minimum | Maximum |
|---|---|---|
| $t_{\mathrm{in}}$ [h] | 24 | 42 |
| $t_{\mathrm{in,glc}}$ [h] | 42 | 42 |
| $F_{\mathrm{in}}$ [$V_0$ day$^{-1}$] | 0.08 | 0.1 |
| $F_{\mathrm{in,glc}}$ [g L$^{-1}$ day$^{-1}$] | 4.8 | 18.8 |
| $agitation$ [rpm] | 700 | 1400 |
| $DO$ [%] | 20 | 50 |

## MODEL DEVELOPMENT

### Mechanistic model equations

First, mechanistic model equations were formulated based on model equations proposed in previous studies [10,11]. To develop a model applicable to a wide range of cultivation conditions, the equations were simplified as much as possible. The components included density/concentrations of viable cell, dead cell, glucose, lactate, mAb, main/acidic charge variant, HCP, and DNA as shown in Eqs. (1)–(9) in Table 2. In the equations, $V$ [L], $X_{\mathrm{v}}$ [cells L$^{-1}$] , $X_{\mathrm{d}}$ [cells L$^{-1}$], [GLC] [mmol L$^{-1}$], [LAC] [mmol L$^{-1}$], $P$ [g L$^{-1}$], [Main] [g L$^{-1}$], [Acid] [g L$^{-1}$], [HCP] [g L$^{-1}$], [DNA] [g L$^{-1}$] are the solution volume, density/concentrations of the viable/dead cells, glucose, lactate, mAb, main/acidic charge variant, HCP, and DNA. $F_{\mathrm{in}}/F_{\mathrm{in,glc}}$ [L h$^{-1}$] and $c_{\mathrm{in_glc}}/c_{\mathrm{in,glc}}$ [mmol L$^{-1}$] are normal/glucose feed flow rate and glucose concentration of feed/glucose feed, respectively. $\mu$ [h$^{-1}$] and $\mu_{\mathrm{d}}$ [h$^{-1}$] are specific cell growth and death rates, respectively. $Q_{\mathrm{p}}$ [g cell$^{-1}$ h$^{-1}$] and $Q_{\mathrm{lac}}$ [mmol

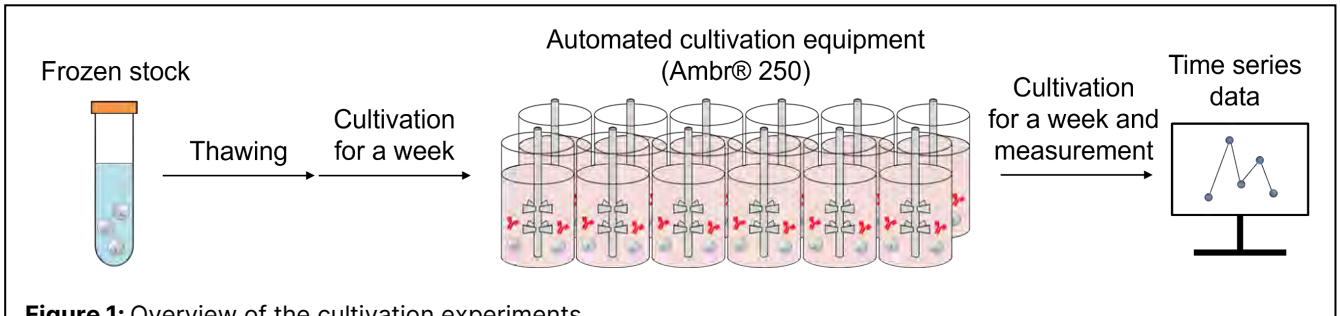

**Figure 1:** Overview of the cultivation experiments.

**Table 2:** Mechanistic model equations.

$$\frac{d(VX_\mathrm{v})}{dt} = (\mu - \mu_\mathrm{d})VX_\mathrm{v} \quad (1)$$

$$\frac{d(VX_\mathrm{d})}{dt} = \mu_\mathrm{d}VX_\mathrm{v} - k_{X_\mathrm{d},\mathrm{lysis}}VX_\mathrm{d} \quad (2)$$

$$\frac{d(V[\mathrm{GLC}])}{dt} = -\left(\frac{\mu-\mu_\mathrm{d}}{Y_{X_\mathrm{v}/\mathrm{glc}}} + m_\mathrm{glc}\right)VX_\mathrm{v} + F_\mathrm{in}c_{\mathrm{in_glc}} + F_{\mathrm{in,glc}}c_{\mathrm{in,glc}} \quad (3)$$

$$\frac{d(V[\mathrm{LAC}])}{dt} = Q_\mathrm{lac}VX_\mathrm{v} \quad (4)$$

$$\frac{d(VP)}{dt} = \begin{cases} Q_{\mathrm{p,a}}VX_\mathrm{v}|_{[\mathrm{GLC}]\geq[\mathrm{GLC}]_\mathrm{threshold}} \\ Q_{\mathrm{p,b}}VX_\mathrm{v}|_{[\mathrm{GLC}]<[\mathrm{GLC}]_\mathrm{threshold}} \end{cases} \quad (5)$$

$$\frac{d(V[\mathrm{Main}])}{dt} = \frac{d(VP)}{dt} - (k_\mathrm{acid} + k_\mathrm{base})V[\mathrm{Main}] \quad (6)$$

$$\frac{d(V[\mathrm{Acid}])}{dt} = k_\mathrm{acid}V[\mathrm{Main}] \quad (7)$$

$$\frac{d(V[\mathrm{DNA}])}{dt} = Y_{\mathrm{dna}/X_\mathrm{d}}k_{X_\mathrm{d},\mathrm{lysis}}VX_\mathrm{d} - k_{\mathrm{dna,lysis}}V[\mathrm{DNA}] \quad (8)$$

$$\frac{d(V[\mathrm{HCP}])}{dt} = Y_{\mathrm{hcp}/X_\mathrm{v}}VX_\mathrm{v} + Y_{\mathrm{hcp}/X_\mathrm{d}}k_{X_\mathrm{d},\mathrm{lysis}}VX_\mathrm{d} - k_{\mathrm{hcp,lysis}}(V[\mathrm{HCP}])^\mathrm{n} \quad (9)$$

cell$^{-1}$ h$^{-1}$] are specific production rates of mAb and lactate, respectively, with $Q_\mathrm{p}$ being classified based on whether glucose is depleted or not. $Y_{X_\mathrm{v}/\mathrm{glc}}$ [cells mmol$^{-1}$] and $m_\mathrm{glc}$ [mmol cell$^{-1}$ h$^{-1}$] are specific glucose consumption for cell growth and cell maintenance, respectively. $k_{i,\mathrm{lysis}}$ is the rate constant of the dead cell lyses and the impurity dissolution, where $i$ includes dead cell, HCP, and DNA. $k_\mathrm{acid}$ and $k_\mathrm{base}$ are the rate constants for changes of main charge variants into acidic and basic charge variants. $Y_{i/X_\mathrm{v},X_\mathrm{d}}$ [mg cell$^{-1}$] is the mass of impurity $i$ released from a viable cell and a lysed dead cell, where $i$ includes HCP and DNA.

## Parameter estimation of the mechanistic model

Time series data from 20 experiments across three cycles were used for parameter estimation, and a part of the results are shown in Figure 2. The experimental data indicated that lactate repeated cycles of production and consumption, and viable cell density saturated in the later stages. However, due to the constant $Q_\mathrm{lac}$ previously addressed for improvement [2], and the exponential form of the viable cell density equation, the mechanistic model could not capture the behavior of lactate and viable cell density.

## Hybrid modeling

To address the issues mentioned above, a hybrid model was developed. Utilizing a hybrid model can contribute to overcoming the challenge of fully elucidating the biological phenomena causing lactate shifts and cell growth saturation, and to avoid increasing the number of estimated parameters. The hybrid model, whose overview is shown in Figure 3, maintained the mass balance of the mechanistic model while estimating the coefficients $\mu - \mu_\mathrm{d}$ and $Q_\mathrm{lac}$ with a data-driven model as shown in Eq. (10).

$$Coef = f\left(t, V, t_\mathrm{in}, t_{\mathrm{in,glc}}, F_\mathrm{in}, F_{\mathrm{in,glc}}, agitation, DO\right) \quad (10)$$

where $Coef$ represents $\mu - \mu_\mathrm{d}$ and $Q_\mathrm{lac}$. Since the values of $Q_\mathrm{lac}$ and $\mu - \mu_\mathrm{d}$ change dynamically, the model inputs included not only constant experimental conditions (agitation speed, DO, feed/glucose feed rate, and feed/glucose feed start timing), but also dynamically changing

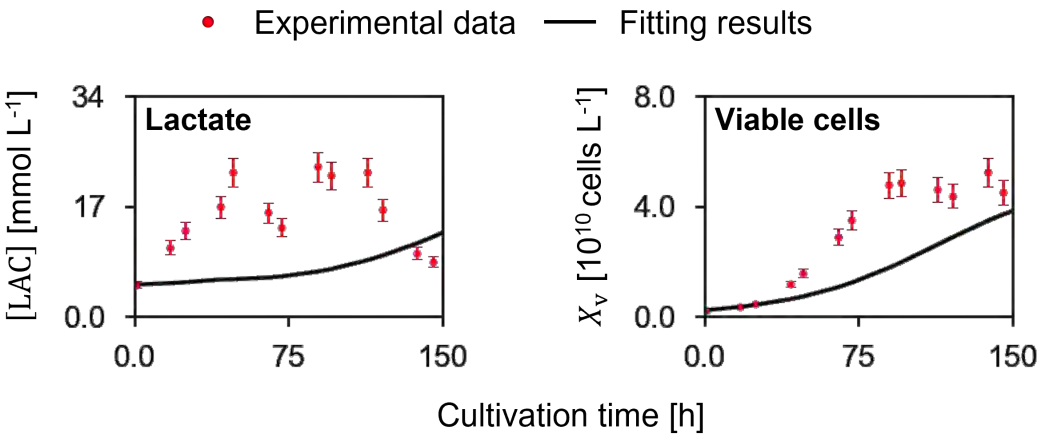

**Figure 2:** A part of the modeling results based on the mechanistic model.

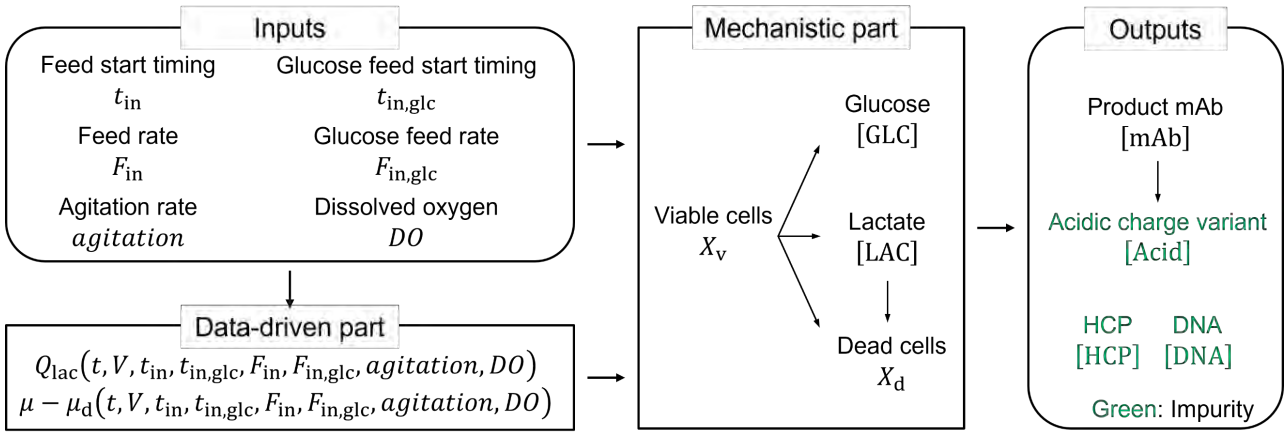

**Figure 3:** Overview of the developed hybrid model.

cultivation time and solution volume. Random forest regression was selected as a method for the data-driven model due to its high accuracy. In model development, experimental data were interpolated to compensate for the limited amount of data, and the values of $\mu - \mu_d$ and $Q_{lac}$ were calculated based on the interpolated values using Eqs. (1) and (4), respectively. To avoid overfitting, a portion of the calculated values was extracted, and the model was developed based on the values. Time series data from 20 experiments across three cycles were used for parameter estimation, and a part of the results are shown in Figure 4. Table 3 presents the average values

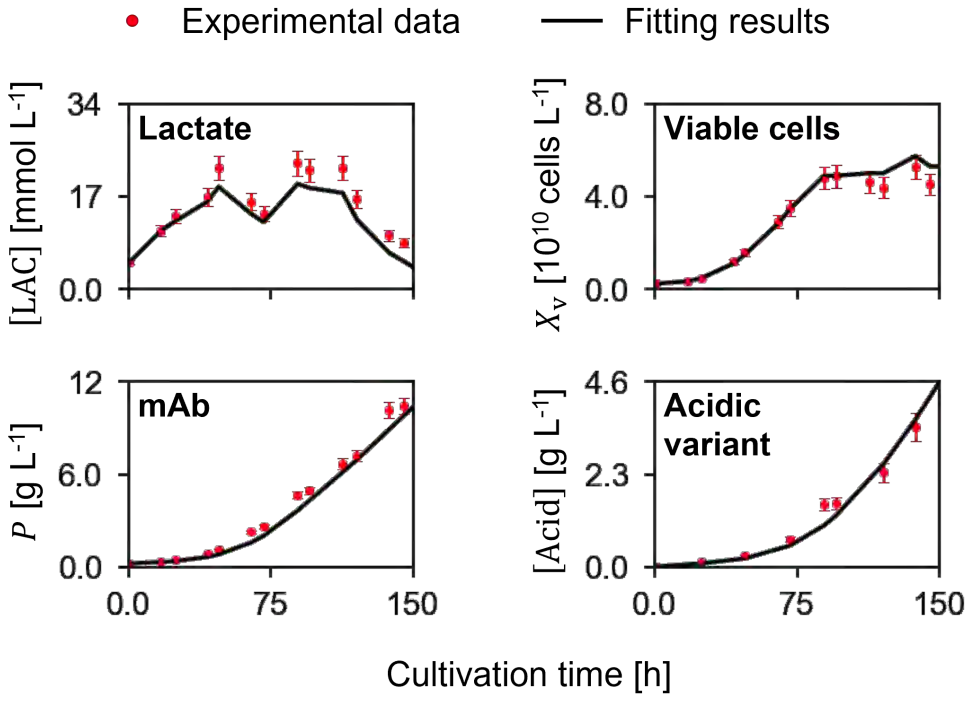

**Figure 4:** A part of the modeling results based on the hybrid model.

**Table 3:** Average values of $R^2$ and NRMSE for each component.

| | $X_v$ | $X_d$ | [GLC] | [LAC] | $P$ | [Main] | [Acid] | [HCP] | [DNA] |
|---|---|---|---|---|---|---|---|---|---|
| $R^2$ | 0.99 | 0.70 | 0.85 | 0.86 | 0.95 | 0.92 | 0.92 | 0.68 | 0.69 |
| NRMSE | 0.035 | 0.16 | 0.10 | 0.10 | 0.078 | 0.099 | 0.091 | 0.19 | 0.18 |

of $R^2$ and NRMSE for all training datasets used in the estimation for each component. The results indicated that high $R^2$ values and low NRMSE values were obtained for all components, showing that the model could capture not only the behavior of mAb but also impurities across a wide range of cultivation conditions.

## MODEL APPLICATION

A model-based assessment of cultivation conditions was conducted by using the developed hybrid model. In the assessment, a design problem was formulated to maximize mAb while keeping impurity levels low as shown in the following equation:

$$\max\ [\mathrm{mAb}]\left(t, t_{\mathrm{in}}, t_{\mathrm{in,glc}}, F_{\mathrm{in}}, F_{\mathrm{in,glc}}, agitation, DO\right) \quad (11)$$

subject to

$$\begin{aligned}
t\ [\mathrm{h}] &\leq 145\\
[\mathrm{HCP}]\ [\mathrm{g\ L^{-1}}] &\leq 2.2\\
[\mathrm{DNA}]\ [\mathrm{g\ L^{-1}}] &\leq 0.42\\
[\mathrm{Acid}]/P\ [\%] &\leq 40\\
t_{\mathrm{in}}\ [\mathrm{h}] &\in \{42, 48\}\\
t_{\mathrm{in,glc}}\ [\mathrm{h}] &\in \{42, 48\}\\
F_{\mathrm{in}}\ [V_0\ \mathrm{day^{-1}}] &\in \{0.08, 0.1\}\\
F_{\mathrm{in,glc}}\ [\mathrm{g\ L^{-1}\ day^{-1}}] &\in \{5, 6, \ldots, 17, 18, 18.8\}\\
Agitation\ [\mathrm{rpm}] &\in \{700, 800, \ldots, 1300, 1400\}\\
DO\ [\%] &\in \{20, 30, 40, 50\}
\end{aligned}$$

where $t$ [h] represents cultivation time. In the design problem, impurity values in the constraint were set according to expert opinions. Based on the design problem, 3,840 cultivation conditions were explored, with results evaluated at each one-hour interval of cultivation time. Table 4 shows the top three conditions with the highest mAb values satisfying the constraints, along with the corresponding cultivation time.

Figure 5 shows the simulation results for the top three conditions. In the simulations, glucose levels remained low but non-depleted until the later stages of the cultivation and only became depleted at the end of the cultivation. Glucose is widely recognized as a critical factor for both cell growth and mAb production; however, glucose levels are proportional to osmolarity, and high osmolarity is known to have a negative impact on cell growth [12]. Therefore, it was found that setting conditions to maintain appropriate glucose levels was important. Furthermore, the simulation results revealed that both mAb and impurities increased over time, indicating that setting an appropriate cultivation duration was crucial to obtaining more mAb while keeping impurity levels low.

**Table 4:** Top three conditions with the highest mAb values satisfying the constraints.

| Rank | $t_{\mathrm{in}}$ | $t_{\mathrm{in,glc}}$ | $F_{\mathrm{in}}$ | $F_{\mathrm{in,glc}}$ | $Agitation$ | $DO$ | $t$ |
|---|---|---|---|---|---|---|---|
| 1 | 48 | 42 | 0.1 | 15 | 700 | 40 | 135 |
| 2 | 48 | 42 | 0.1 | 15 | 1000 | 50 | 135 |
| 3 | 42 | 48 | 0.1 | 14 | 700 | 40 | 136 |

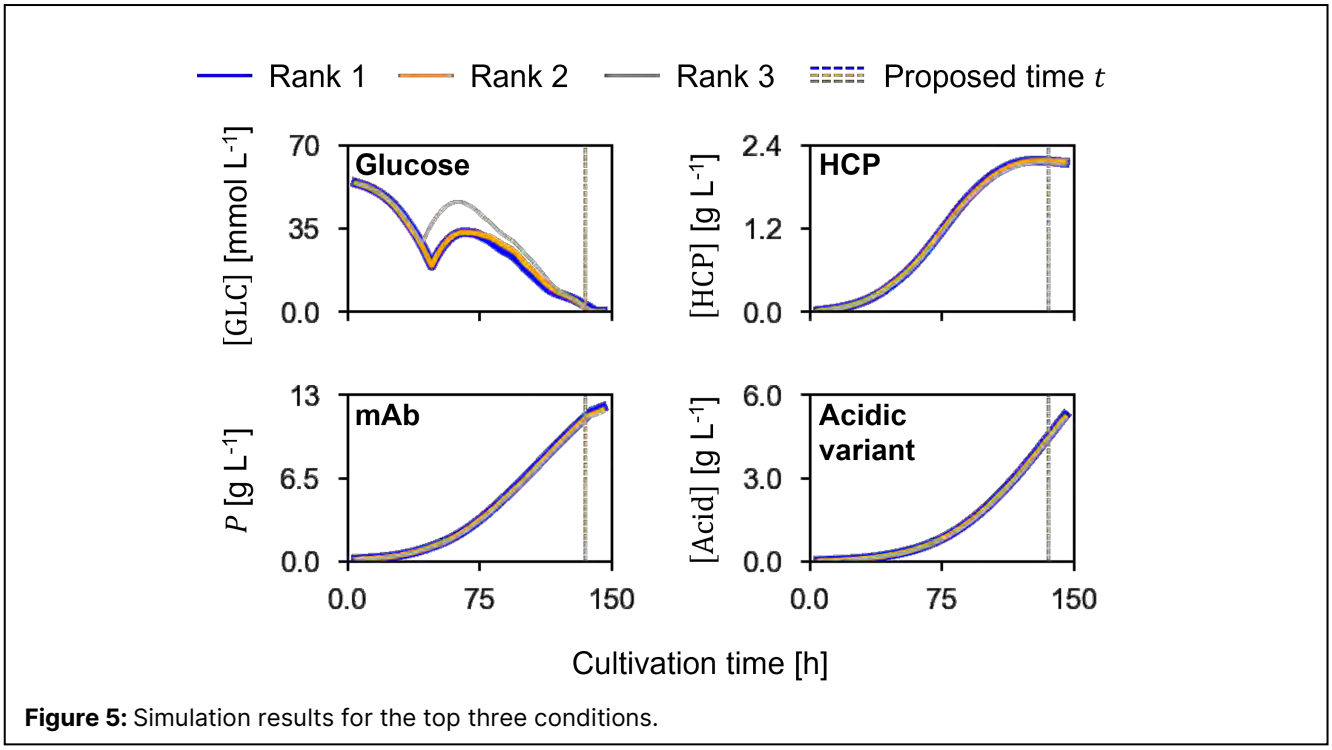

**Figure 5:** Simulation results for the top three conditions.

## CONCLUSIONS AND OUTLOOK

This work presented a hybrid-modeling approach to mAb production process design. Using automated bioreactor equipment enabled the acquisition of experimental data that covers a reasonable yet broad range. Using this data, a model applicable to a wide range of cultivation conditions was developed. In the hybrid model, the coefficients of the mechanistic model were estimated with a data-driven model, while maintaining the mass balance of the systems components. In the case study, the model enabled determination of a cultivation condition that maximized the product mAb concentration with meeting the impurity constraints out of 3,840 candidates. This work supports model-based design of cell cultivation processes with considering the multi-input & multi-output nature of the process. The future work includes expansion to dynamic optimization, operation support, and integration with purification processes.

## ABSTRACT

This work presents a kinetic model of drug substance synthesis considering slug flow characteristics in Stevens oxidation. The developed model is also applied to determine the feasible range of the process parameters. Flow experiments were conducted to obtain kinetic data, varying the inner diameter, temperature, and residence time. A kinetic model was developed for the change in concentrations of the starting material, products, and catalysis. In the kinetic model, slug flow was considered by including a volumetric mass transfer coefficient during this flow. In the initial experiments, early-stage kinetic data were insufficient, conducting additional experiments at shorter residence times. Furthermore, the initial model could not reproduce the residual of the starting material, introducing the oxidant consumption that inhibits the starting material consumption and improving the initial model. The improved model could reproduce experimental results and demonstrated that, as the inner diameter increases, the efficiency of mass transfer in slug flow decreases with slowing down the reaction. Moreover, the improved model was considered applicable to different scales. The developed model was used to simulate the yields of the desired product, and the dimer, and the process mass intensity, thereby determining the feasible range. As a result, it was shown that when methanol and oxidant concentration was either too high or too low, operating conditions fell outside the feasible range. This kinetic model with flow characteristics will be useful for the process design of drug substance synthesis using liquid-liquid reactions.

## INTRODUCTION

Recently, in the production of drug substances (or active pharmaceutical ingredients), flow synthesis has attracted attention as an effective method. Flow synthesis is increasingly being introduced due to its various advantages, such as high surface volume ratio and small system size compared to conventional batch synthesis [1,2]. One of the promising applications that leverages the advantages of flow synthesis is liquid-liquid reactions [3,4]. By performing these reactions in flow synthesis, the interfacial contact between immiscible liquids could be increased, which is expected to enhance process efficiency.

When two immiscible liquids enter together in a flow reactor, unique flow patterns, especially like slug flow, are formed [5]. Slug flow is a phenomenon where the liquids flow in alternating enclosed segments, making a dynamic interface. Flow patterns like slug flow are determined by the liquid properties (e.g., viscosity and density) and the reactor specifications and have a significant impact on the mass transfer. Previous studies have investigated the effect of slug flow on mass transfer in liquid-liquid reactions using computational fluid dynamics [6,7] and explored flow pattern changes in solvents and reactor specifications and improvements in mass transfer [8,9]. These studies provide valuable insights into the influence of flow characteristics on reaction. However, there is a lack of modeling approaches that simultaneously account for flow characteristics and reaction kinetics. The absence of such models prevents understanding the interaction between flow characteristics and reaction

kinetics, potentially resulting in suboptimal process design and diminishing yields in practical application.

In this study, we developed a kinetic model of drug substance synthesis by incorporating slug flow characteristics in a liquid-liquid reaction, with the aim to determine a feasible range of the process parameters. The target reaction was Stevens oxidation, which is a novel liquid-liquid reaction of organic and aqueous phases, producing the ester via a shorter pathway than the conventional route [10]. In this reaction, a catalyst which moves between organic and aqueous phases was used, and slug flow formation was necessary to enhance mass transfer efficiency. A model can consider slug flow characteristics. In pharmaceutical industry, models are effective in reducing the number of experiments. By using models, it becomes possible to identify a feasible range of the process parameters that satisfies quality. Therefore, the developed model was utilized to define the feasible range.

## MATERIALS AND METHODS

### Target Reaction and Flow Experiments

Figure 1 shows the target Stevens oxidation and the flow experiment overview. In this reaction, (4-nitrophenyl) methanol (SM, starting material) undergoes a reaction with methanol (MeOH), and oxidant (NaOCl). Tetrabutylammonium bromide (TBAB) is the catalyst which moves between the organic and aqueous phases. The ester methyl 4-nitrobenzoate (DP, desired product), the impurity 4-nitrobenzyl 4-nitrobenzoate (Dimer), 4-nitrobenzoic acid (CA, carboxylic acid), 4-nitrobenzaldehyde (Ald, aldehyde) are produced.

In the flow experiments, the inner diameter, temperature, and residence time were varied in different runs. Experimental conditions were adjusted to form slug flow to promote the catalyst's mass transfer. High-performance liquid chromatography (HPLC) was used to quantify the concentrations of SM, DP, Dimer, CA, and Ald in the samples.

### Model Development

Figure 2 shows a calculation flow on the developed model. The inputs were defined as the equivalent concentration of MeOH, $C_{\mathrm{MeOH}}$ [equivalent], and the equivalent concentration of NaOCl, $C_{\mathrm{NaOCl}}$ [equivalent]. The outputs were defined as the yield of the desired product, $y_{\mathrm{DP}}$ [%], the yield of the dimer, $y_{\mathrm{Dimer}}$ [%], and the process mass intensity, PMI, which are evaluation indicators, respectively.

#### Kinetic model

The kinetic model was developed for the changes in concentration of SM, DP, Dimer, CA, Ald, and the catalyst.

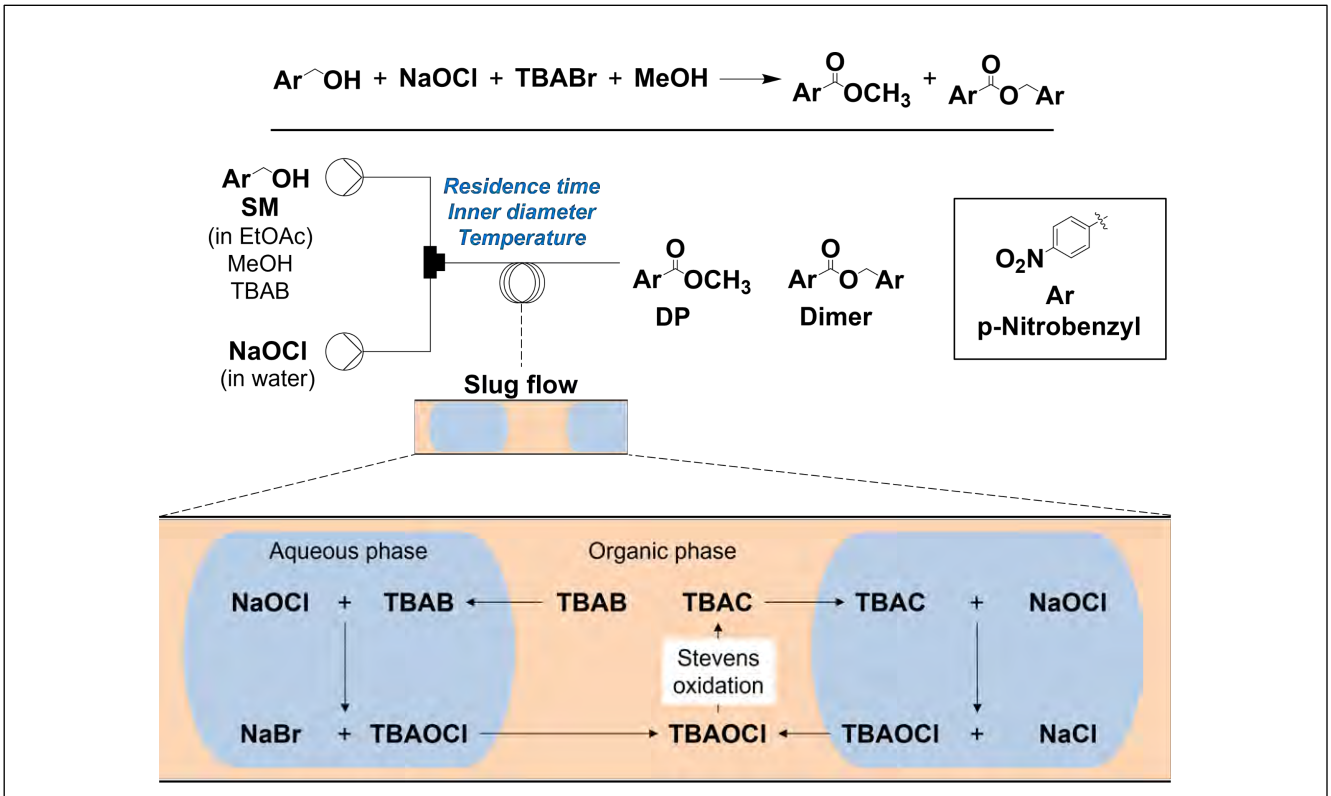

**Figure 1.** Target Stevens oxidation and the flow experiment overview. The blue text indicates the conditions varied in the experiments. TBAB moves from the organic phase to the aqueous phase, becoming the active form TBAOCl. TBAOCl then moves to the organic phase, reacting with the starting material to produce various products.

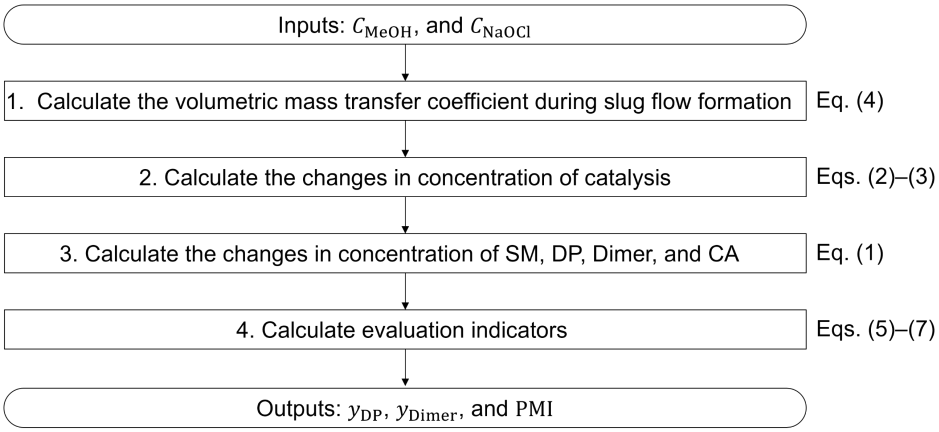

**Figure 2.** Calculation flow using the developed model. In the 1st step, the overall volumetric mass transfer coefficient during slug flow formation is calculated using Eq. (4). In the 2nd step, the changes in concentration of catalysis are calculated using Eqs. (2)–(3). In the 3rd step, the changes in concentration of SM and products are calculated using Eq. (1). Finally, in the 4th step, the evaluation indicators are calculated using Eqs.(5)–(7).

In the changes in the catalyst concentration model, slug flow was considered using the overall volumetric mass transfer coefficient during this flow formation. The changes in concentration were modelled as follows:

$$\frac{dC_i}{dt} = -r \quad (1)$$

$$\frac{dC_{j,\mathrm{org}}}{dt} = -Ka_{\mathrm{org}}\left(\frac{1}{m}C_{j,\mathrm{org}} - C_{j,\mathrm{aqu}}\right) - r \quad (2)$$

$$\frac{dC_{j,\mathrm{aqu}}}{dt} = -Ka_{\mathrm{aqu}}\left(mC_{j,\mathrm{aqu}} - C_{j,\mathrm{org}}\right) - r \quad (3)$$

Here, $C_i$ [mol m$^{-3}$] is the concentrations of $i$ (SM, DP, Dimer, CA, and Ald), $C_{j,\mathrm{org}}$ and $C_{j,\mathrm{aqu}}$ [mol m$^{-3}$] is the concentrations of $j$ (TBAB, TBAOCl, and TBAC) in the organic and aqueous phases, $r$ [mol m$^{-3}$ s$^{-1}$] is the reaction rate, $m$ [–] is the partition coefficient, $Ka$ [s$^{-1}$] is the overall volumetric mass transfer coefficients in the organic and aqueous phases, and it was defined as follows [11]:

$$Ka_p\frac{L}{u_p} = \alpha Ca^{\beta}Re^{\gamma}\left(\frac{d}{L}\right)^{\delta}\left(\frac{L_p}{d}\right)^{\varepsilon} \quad (4)$$

Here, $p$ is the phase (organic or aqueous), $L$ [m] is the reactor length, $u$ [m s$^{-1}$] is the flow velocity, $Ca$ [–] is the mean capillary number of two phase, $Re$ [–] is the mean Reynolds number of two phase, $d$ [m] is the inner diameter, $L_p$ [m] is the slug phase length in the organic and aqueous phases, and $\alpha, \beta, \gamma, \delta$, and $\varepsilon$ are estimated parameters.

## Evaluation model

To determine a feasible range of the process parameters, three evaluation indicators were determined in this study, namely, the yield of the desired product ($y_{\mathrm{DP}}$) [%], the yield of the dimer ($y_{\mathrm{Dimer}}$) [%], the process mass intensity (PMI) as follows:

$$y_{\mathrm{DP}} = \frac{C_{\mathrm{DP}}(L)}{C_{\mathrm{SM}}(0)} \times 100 \quad (5)$$

$$y_{\mathrm{Dimer}} = \frac{C_{\mathrm{Dimer}}(L)}{C_{\mathrm{SM}}(0)} \times 100 \quad (6)$$

$$\mathrm{PMI} = \frac{mass_{\mathrm{SM}}(0)+mass_{\mathrm{MeOH}}(0)+mass_{\mathrm{NaOCl}}(0)+mass_{\mathrm{TBAB}}(0)}{mass_{\mathrm{DP}}(L)} \quad (7)$$

Here, $y_{\mathrm{DP}}$ and $y_{\mathrm{Diemr}}$ [–] are the yields of DP and Dimer, PMI [–] is the process mass intensity,$C_{\mathrm{SM}}(0)$ [mol m$^{-3}$] is the initial concentration of SM at the inlet, $C_{\mathrm{DP}}(L)$ and $C_{\mathrm{Dimer}}(L)$ [mol m$^{-3}$] are the concentrations of DP and Dimer at the outlet, $mass_i(0)$ [kg] is the mass of $i$ (SM, MeOH, NaOCl, or TBAB) at the inlet, and $mass_{\mathrm{DP}}(L)$ [kg] and $mass_{\mathrm{Dimer}}(L)$ [kg] is the mass of DP and Dimer at the outlet.

## Condition settings for feasible range

The feasible range was formulated as follows:

$$FR = \{(C_{\mathrm{MeOH}}, C_{\mathrm{NaOCl}}) : z(\boldsymbol{Y}) = 1\} \quad (8)$$

Subject to

$$z(\boldsymbol{Y}) = \begin{cases} 0\ (\boldsymbol{Y} \notin S) \\ 1\ (\boldsymbol{Y} \in S) \end{cases}$$

$$\boldsymbol{Y} = f(C_{\mathrm{MeOH}}, C_{\mathrm{NaOCl}}, T, L, d, Q)$$

$$S = \{(y_{\mathrm{DP}}, y_{\mathrm{Dimer}}, PMI) : y_{\mathrm{DP}} \geq 88, y_{\mathrm{Dimer}} \leq 5, \mathrm{PMI} \leq 15\}$$

$$C_{\mathrm{MeOH}} \in \{10, 20, \ldots, 70, 80\}$$

$$C_{\mathrm{NaOCl}} \in \{3.0, 4.0, \ldots, 7.0, 8.0\}$$

Here, $FR$ is the feasible range, $z$ takes the value of 1 if all evaluation indicators are satisfied and 0 if at least one evaluation indicator is not satisfied, $S$ is a set of evaluation indicator constraints, and $\boldsymbol{Y}$ is the prediction results. In addition, $T$ is temperature [K] and $Q$ is the volume flow rate [mL m$^{-1}$].

## RESULTS AND DISCUSSION

### Kinetic analysis

Fitting results of the initial model are shown in Figure 3(a). In the experimental conditions of $(T, d) = (323, 0.5)$, minimal changes in concentration were observed, and it was believed that the reaction had completed within the measurement residence time. Consequently, additional experiments were performed at shorter residence times of $d = 0.5$ mm to obtain kinetic data during the early-stage reaction (Figure 3(b)). The initial model was unable to reproduce the results that included additional experiments. And then, residual SM was observed in the experiments, whereas the model predictions indicated its complete consumption. To address this discrepancy, the following hypothesis was proposed: SM undergoes with oxidant but competes with a mechanism in which oxidant is

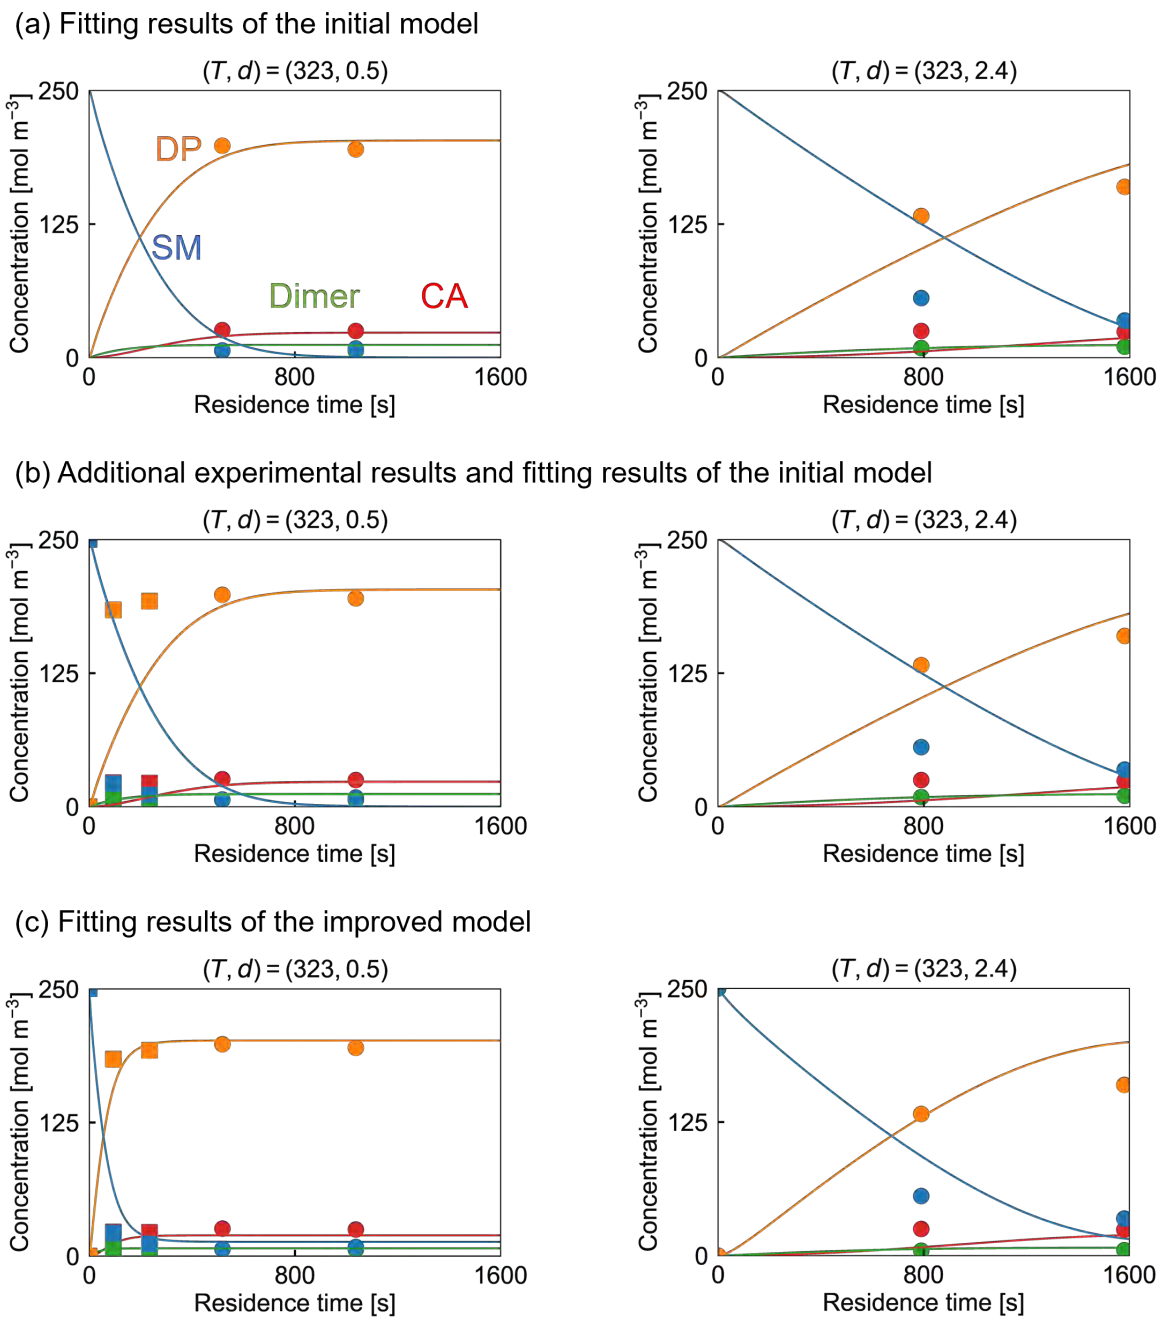

**Figure 3.** Fitting results, (a) of the initial model, (b) of the initial model only to the initial experimental results, and (b) of the improved model to all experimental results. Circules represent the initial experimental results, and squares represent the additional experimental results

consumed through a different pathway, thereby limiting the consumption of SM. Based on the hypothesis, the methanol oxidation mechanism was added as an alternative pathway for the consumption of oxidant, and the model was improved accordingly. The improved model was used to conduct kinetic analysis again.

Fitting results of the improved model are shown in Figure 3(c). The average value of determination coefficients ($R^2$) of SM, DP, Dimer, and CA for all experimental conditions was 0.96, which means the model could reasonably reproduce experimental results. In this way, analyzing the discrepancies of the simulation results and the experimental results made it possible to select effective experimental conditions for the model development. The experimental results indicated that the reaction is slower under conditions with a larger inner diameter compared to those with a smaller inner diameter. This is believed to be due to the reduced mass transfer enhancement effect of slug flow as the inner diameter increases, resulting in a longer time required for catalyst movement. Indeed, it has been reported that larger inner diameters lead to slower mass transfer rates [12]. The model predicted that, as the inner diameter increased, the efficiency of mass transfer in slug flow decreased with slowing the reaction, which is a similar trend of experiments. Therefore, we judged that the developed model could consider the slug flow characteristics and adopt to different scales and provide sufficient performance for determining the feasible range.

## Feasible range determination and analysis

To determine a feasible range of the process parameters, the developed model was used to simulate the three evaluation indicators. The simulations were conducted within the range of the equivalent concentration of MeOH and NaOCl, as defined in Eq. (8). Figure 4 presents the results of (a) the yield of the desired product, (b) the yield of the dimer, (c) the PMI, and (d) feasible range. According to the simulation results, the high equivalent concentration of MeOH and NaOCl enhanced the yield of the desired product, and the high equivalent concentration of MeOH diminished the yield of the dimer. In contrast, as depicted in Figure 4(c), increasing the equivalent concentrations of MeOH and NaOCl caused to escalate the process mass intensity. High quality, meaning a large amount of DP and a small amount of Dimer,

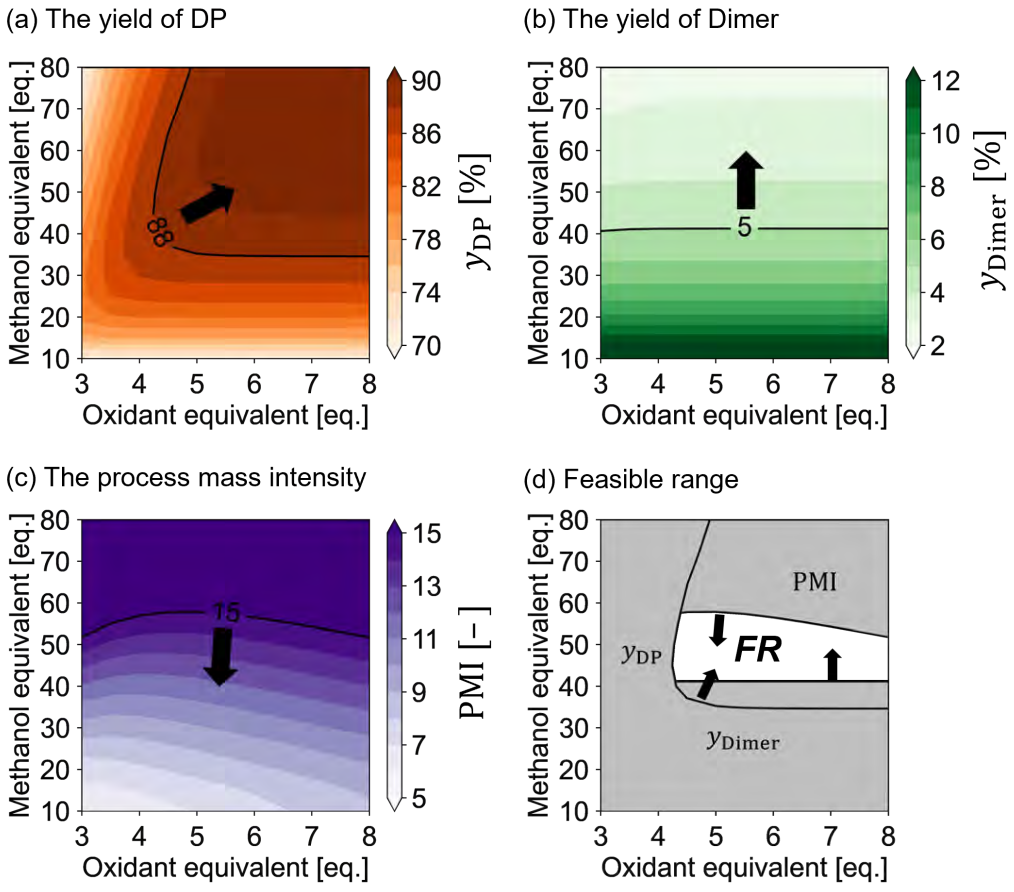

**Figure 4.** Simulation results for the individual evaluation indicators: (a) $y_{DP}$ (b) $y_{Dimer}$ (c) PMI, and (d) the determied feasible range using the developed model.

was achieved with the high equivalent concentrations ($C_{\mathrm{MeOH}}$ and $C_{\mathrm{NaOCl}}$). Conversely, low waste was attained at the low equivalent concentrations, indicating a trade-off in regent quantity. Figure 4(d) shows the feasible range which satisfies the predefined constraints in Eq. (8) ($y_{\mathrm{DP}} \geq 88, y_{\mathrm{Dimer}} \leq 5, \mathrm{PMI} \leq 15$), indicated by the white area. Within the range of the lower equivalent concentration of MeOH, the process did not meet the yield of the dimer. When the equivalent concentrations were too high, operating conditions fell outside the feasible range due to not satisfying the process mass intensity constraints. This feasible range could facilitate the identification of the process parameters that satisfied the constraints. Additionally, the feasible range could consider uncertainty and measurement noise by introducing stochastic approach such as Monte Carlo simulation.

## CONCLUSIONS AND OUTLOOK

We presented the kinetic model of drug substance synthesis by incorporating slug flow characteristics and demonstrated the feasible range in Stevens oxidation. Flow experiments were conducted to obtain kinetic data, and a kinetic model considering flow characteristics was developed. For feasible range determination, the evaluation indicators developed, the yields and the process mass intensity. Utilizing the determined indicators, the feasible range was discussed, which could help in determining operating conditions. The kinetic model with slug flow characteristics would be useful for the process design of drug substance synthesis using liquid-liquid reactions. Future work includes conducting validation of the feasible range and presenting the scale-up strategy based on the simulation results using the developed model.

## ABSTRACT

Biomacromolecules have intricate crystallisation behaviour due to their size and many interactions in solution and can often only crystallise in narrow ranges of experimental conditions. High solute concentrations are needed for crystal nucleation and growth, exceeding those eluted upstream and therefore preventing the adoption of crystallisation in downstream separation steps. By promoting molecular aggregation and nucleation via a lowered energy barrier, heterogeneous surfaces or templates can relax the supersaturation requirements and widen the crystallisation operating space. Though templates are promising candidates for process optimisation, their experimental testing has generally been limited to small-volume experiments, and quantification of their impact on process intensification and quality metrics at higher volumes remains unexplored. To address the knowledge gap, a model-based investigation of template-induced protein crystallisation systems through evaluation of key metrics is presented. Porous silica nano-particles with three chemical functionalisations (hydroxyl, carboxyl and butyl) are added to batch lysozyme crystallisation experiments at 40ml. Crystallisation population balance models are parametrised with an experimentally-validated parameter estimation methodology and further experiments are simulated. The templates appear to lower the estimated interfacial energy compared to the homogeneous case, leading to nucleation rate profiles which are less dependent on supersaturation. For this reason, the templates can crystallize quicker than the homogeneous system, particularly at lower initial concentrations. The simulation results highlight the ability of heteronucleants to alter nucleation rate profiles, and their potential to be used as process optimisation and intensification tools for biomacromolecule purification.

## INTRODUCTION

Advanced therapeutic proteins, such as monoclonal antibodies and immunoglobins are effective at treating many chronic medical conditions [1]. Their increased demand and improvements in their upstream manufacturing have indicated the need for intensified and cost-effective downstream protein purification [2, 3]. Chromatographic units, currently able to separate the therapeutic proteins at very high purity, remain expensive, difficult to scale-up and have a significant environmental footprint [4]. It is therefore critical to identify alternative and more efficient purification methods that reduce costs and improve consumer access to the novel therapies being released on the market.

The majority of small-molecule active pharmaceutical ingredients (APIs) are purified through crystallisation, a first-order phase transition in which a highly pure, thermodynamically stable and easily filterable solid is formed in solution [5]. Crystalline formulations offer improved stability, purity, handling and storage compared to chromatography separation alternatives [6]. Due to the protein's size, structural flexibility and many sources of chemical interaction, the macromolecules often only

crystallise in narrow ranges of conditions, which are firstly difficult to identify and secondly restrict the crystalliser's operational flexibility [7]. High energetic barriers are associated with crystal nucleation since the proteins must rotate and fold to rearrange themselves into the ordered crystal lattice, requiring strong thermodynamic driving forces and high supersaturations. It is important to highlight that the minimum solute concentrations needed for crystallisation exceed those eluted by upstream processes prior to any purification steps [8]. Therefore, processes designed to produce solid formulations of advanced therapeutics require concentrating chromatographic purification steps before crystallisation becomes thermodynamically possible. If, however, minimum concentration requirements for crystallisation can be relaxed and low-supersaturation nucleation is facilitated, chromatographic units can be avoided to improve scale-up, costs and the environmental footprint of the processes.

Template-induced nucleation involves the use of additives in the crystallisation solution to favour molecular rearrangement into a nucleus through three methods: functional group matching, epitaxy, and topographic features [9]. Soft templates are dissolved additives, such as amino acids [10], which disrupt the protein's hydration layer and enhance favourable protein-protein interactions. Hard templates instead are un-dissolved, heterogeneous surfaces which, particularly through complementary surface chemistries and porous structures, promote protein aggregation and concentrate the protein to induce higher local supersaturations. Many template types have been shown to act as nucleation enhancers to lower concentration requirements for nucleation, as well as preferentially crystallising specific polymorphs [10–15]. However, template-induced nucleation investigations have generally been limited to small-volume studies to obtain diffraction-quality protein crystals [2], and there is a lack of reliable, quantitative information describing both how templates affect crystallisation kinetics and the extent to which template addition can drive process intensification. To the authors' knowledge, no comprehensive studies on the effect of templates on kinetic parameters and the crystallisation operating space have been published, and their impact on crystallisation process design remains uncertain. Fully-experimental characterisation of crystallisation kinetics requires time consuming and costly experiments, and solution volumes must be reduced to prevent excessive API use [16]. Population-balance models (PBMs) can be used to support the experimental campaign and accelerate process development with fewer, larger-scale experiments [17, 18]. Once the PBMs are parametrised, aspects of the crystallisation process such as nucleation rate, yield and crystal size profiles, which might be experimentally unavailable or costly to measure at scale, can be quickly queried through model simulations. By probing the PBMs for multiple crystalliser conditions, operating spaces of template-induced nucleation systems can be identified and assessed to support template adoption for pharmaceutical manufacturing. While previous studies on template-assisted protein crystallisation have studied templated-nucleation probabilities [8, 19], to the author's knowledge this is the first investigation of template-assisted nucleation that integrates PBMs to assess how the surfaces affect the operating spaces and support scale-up by aiding the selection of optimal initial conditions and residence times.

To this end, a model-based evaluation of template-induced protein crystallisation operating spaces is presented in this work. Lysozyme is crystallised homogeneously and in the presence of functionalised porous silica nano-particles (SNPs) at 40ml. PBMs are parametrised and used for high-throughput *in-silico* experimentation. The regressed models indicate that particularly at lower initial concentrations, template-induced nucleation is quicker and less dependent on supersaturation compared to the homogeneous system.

## METHODOLOGY

### Experimental protocol for lysozyme crystallisation

Lysozyme anti-solvent crystallisation experiments are performed at 40ml in a stirred batch crystalliser ($T = 20℃$, 0.1M sodium acetate buffer, pH $= 4.2$, [NaCl] $=$ $50$ mg/ml, 75 rpm stirring). Lysozyme is first dissolved and filtered through a 0.22$\mu$m filter to obtain buffered solutions of different lysozyme concentrations. NaCl is dissolved at $100$ mg/ml concentration in the sodium acetate buffer to prepare the anti-solvent solution. Crystallisation starts by mixing equal volumes of the protein and precipitant solution. Lysozyme concentration is monitored at regular time intervals using a Thermo Fisher NanoDrop One UV-Vis spectrophotometer unit by drawing approximately 0.1ml from the broth and filtering with a 0.22$\mu$m filter to prevent the solids from affecting UV absorbance. At batch termination, the solution is filtered and dried. The collected crystals are suspended in isopropyl alcohol for laser-diffraction particle size measurements with an Anton Paar PSA 1190 unit.

### Computational methodology

One-dimensional crystallisation PBMs are formulated and parametrised against the measured concentration profiles and crystal sizes to predict the crystallisation operating space. Firstly, aggregation and breakage are neglected in the population balance, a common and valid assumption for lysozyme crystallisation modelling [17, 20] (Eq. 1). Due to the balance's hyperbolic partial differential structure, the balance is solved transformed via the

Method of Moments [21], and the resulting 6 differential equations are solved in Julia, with access of model gradients though forward-mode automatic differentiation. A mass balance is included to model solute consumption (Eq. 3). Classical nucleation theory, power-law growth and negligible aggregation and breakage kinetics are assumed (Eq. 4,5). The nucleation and growth equations each require two kinetic parameters to be regressed. Parameter estimation and uncertainty quantification is carried out using a Markov Chain Monte Carlo No-U-Turn Sampler [22]. Uniform priors are used for candidate parameter sampling, and the negative log likelihood, an indicator of model mispredictions of the experimental measurements, is used to identify parameter posterior distributions. Each model was parametrised with experiments using at least two different initial conditions, and each experiment was repeated three times. Given that templates are assumed to only affect nucleation kinetics, growth parameters are estimated from template-free measurements and their posterior is fixed before template-induced nucleation parameters are estimated from their respective measurements. High-throughput *in-silico* experimentation is carried out by simulating each model for a range of initial concentrations and residence times and calculating process metrics of interest.

## RESULTS

Each of the parameter estimation routines appear to be successful, with good agreement to the experimental measurements. The model predictions of lysozyme crystallisation with carboxyl-functionalised silica templates are shown in Figure 1. The predicted concentration trajectories accurately capture the experimentally measured trends. Both the measured and predicted trajectories appear to have low uncertainty, suggesting the models can be used to predict each system's concentration and fractional yield for a wide range of initial conditions.

The measured average particle sizes have higher uncertainty. Average particle size prediction of Measurement 1 ($C_0 = 20$ mg/ml) appears to be accurate, with overlapping uncertainty ranges (Meas. $= 5.13 \pm 1.28$ µm, Pred. $= 6.69 \pm 0.98$ µm). The model fit to Measurement 2 ($C_0 = 16$ mg/ml) instead leads to poorer prediction of the measured particle size (Meas. $= 20.17 \pm 5.04$ µm, Pred. $= 7.23 \pm 1.3$ µm). The same assessment of the model parametrisations can be made for the predictions of hydroxyl- and butyl-functionalised templated systems, whereby concentration predictions have good agreement with the measured points, and the predicted average particle size is less accurate. Although the mispredictions may be caused by inaccurate assumptions in the model formulation and parametrisation (such as restriction of growth kinetic parameters for the templated systems), the models are nonetheless valuable to assess the templates' impact on crystallisation process design, and poor understanding of template-assisted crystallisation currently prevents further investigations of more appropriate model assumptions.

**Figure 1**: Comparison between experimental data of

crystallisation with carboxyl-functionalised silica templates and fitted model.

The regressed nucleation parameters of each tested system are reported in Table 1. The pre-exponential nucleation constant $A_j$ is interpreted as a function of the rate of molecular attachment to the critical nucleus, and is related to the protein's molecular mobility in solution; high $A_j$ values indicate high attachment frequencies and the presence of many nucleation sites [23]. The surface energy $\gamma$ refers to the energy of the crystal-solution interface; lower $\gamma$ is associated with critical nuclei of fewer molecules [23, 24]. While CNT models have simplifying assumptions, they are nonetheless valuable tools to mechanistically interpret differences between unseeded and template-assisted nucleation through parametric comparison. Compared to the homogeneous system, lower pre-exponential constants are regressed for the templated systems, suggesting molecular attachment is less frequent or fewer nucleation sites are available.

Lower surface energy is also predicted for each templated system, suggesting that while templates slow the growth of the critical nucleus, it however has a

reduced energetic barrier, has fewer molecules and its' state transition is more thermodynamically favoured. Nucleation enhancements can be explained by the lysozyme-SNP affinity; since lysozyme has been reported to have non-specific adsorption onto hydrophobic and hydrophilic surfaces, each surface chemistry has chemical affinity to lysozyme and can induce higher local lysozyme concentrations [25]. Additionally, computational studies have shown transport into porous structures also induces higher supersaturations [26], another contributing factor towards easier lysozyme nucleation.

**Table 1**: Regressed nucleation and growth parameters of the unseeded and templated systems

| System | $A_j$ $[\log(\#\,m^{-3}s^{-1})s]$ | $\gamma$ $[mJ\,m^{-2}]$ |
|---|---|---|
| Unseeded | 39.8 ± 2.0 | 0.68 ± 0.022 |
| Hydroxyl | 29.9 ± 2.2 | 0.49 ± 0.05 |
| Butyl | 22.7 ± 0.55 | 0.14 ± 0.07 |
| Carboxyl | 27.4 ± 2.45 | 0.32 ± 0.05 |
| **Growth param.** | $A_g$ $[nm\,min^{-1}]$ | $g$ $[-]$ |
| | 0.37 ± 0.08 | 3.30 ± 0.14 |

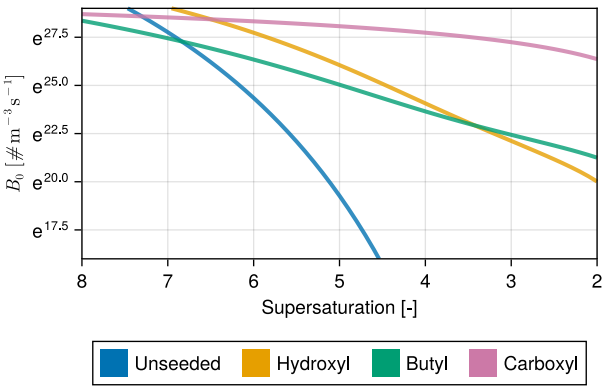

**Figure 2:** Calculated nucleation rate profiles for a range of supersaturations

The calculated nucleation rate profiles for a range of supersaturations (Figure 2) indicate template-induced nucleation is sustained across a wide range of supersaturations, remaining high even at $S < 4$ when homogeneous nucleation has reduced considerably. Secondly, the rates are flatter and less-dependent on supersaturation, possibly due to saturation of the templates' nucleation-enhancing effects if the templates' surface and pores are completely covered and filled with dissolved lysozyme.

After parameter estimation, simulations from each PBM are used to assess how templates alter the crystallisation operating space, with key trajectories of interest shown in Figure 3. While each system's fractional yield trajectories at intermediate and high initial concentrations ($C_0 = 17,20$ g/L) overlap, discernible differences are calculated for systems with lower initial concentrations ($C_0 = 14$ g/L) whereby templates, and in particular the carboxylic- and butyl- functionalised SNPs, generate crystalline mass quicker than the unseeded system. Further performance metrics for this initial condition are collected in Table 2; each template reduces the time to reach 60% fractional yield, halving it in the case of butyl and carboxyl templates, and templates at-least-double the predicted crystalline mass in solution at equal residence times.

**Table 2:** Process metrics of each tested system with $C_0 = 14$ g/L

| System | Avg. Time for 60% Frac. Yield [min] | Avg. Frac. Yield at 300 min |
|---|---|---|
| Unseeded | 884 | 0.18 |
| Hydroxyl | 528 **↓-40%** | 0.38 **↑+111%** |
| Butyl | 528 **↓-40%** | 0.39 **↑+116%** |
| Carboxyl | 310**↓-65%** | 0.59 **↑+228%** |

The collected fractional yield and average particle size trajectories in Figure 3 show a widened crystallisation operating space towards lower initial concentrations due to the addition of templates to the crystalliser, as the templates enable low-supersaturation nucleation. The average particle size however is not solely determined by nucleation enhancements, but rather is also affected by the crystalliser's operation and the amount of solute available for crystal growth. In the case of the unseeded system, a decreasing particle size with increasing initial concentration is predicted. Since homogeneous nucleation slows considerably at lower supersaturations, systems which already start at low supersaturations have more solute mass and time for each crystal to grow, while higher initial supersaturations lead to more solute competition between nucleated crystals. An opposite trend can be observed in the case of the templated systems, caused by the sustained nucleation rate profiles, whereby the predicted average particle size slightly increases with increasing initial concentration. Since similar numbers of crystals are nucleated with each initial condition, higher initial concentrations reduce solute competition for growth by having more API mass available in solution, and lead to minor increases in the average particle size. The unseeded particle size is more sensitive to changes in initial conditions than the templated systems, highlighting templates' ability to mitigate upstream disturbances and act as crystallisation rate-limiters and controllers.

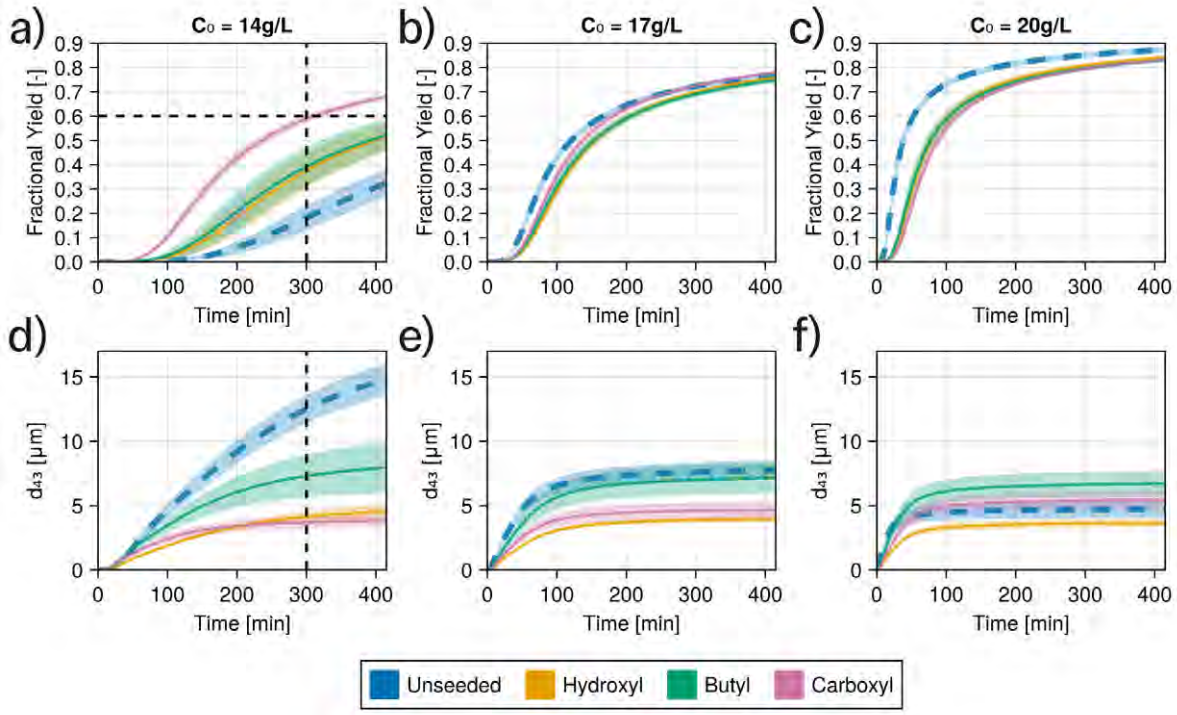

**Figure 3:** Fractional yield vs. residence time (a-c) and volume-weighted average particle size vs residence time (d-f) plots for three different initial concentrations

## CONCLUSIONS

The adoption of crystallisation for protein purification of therapeutic manufacturing is challenged by the tight conditions in which proteins crystallise. If a solid formulation is targeted and designed for, additional purification units upstream of the crystalliser are needed which lead to increased manufacturing costs and environmental impacts.

The work presented shows that templates can be introduced to scaled-up crystallisation processes to widen the crystallisation operating space by providing a higher and more-controlled nucleation rate than the template-free system. The effect is more pronounced when the crystalliser is operated at lower initial concentrations since templates sustain nucleation at conditions where homogeneous nucleation has reduced considerably. Operating the crystalliser at lower solute concentrations is useful to facilitate control and avoid excessive nucleation or precipitation of the amorphous solute. As such, by enhancing nucleation through the addition of templates, the crystalliser's robustness can be improved to more-easily mitigate upstream disturbances, while also delivering intensified downstream purification.

## ABSTRACT

Choosing suitable solvents for crystallisation processes can be a challenging task when developing new pharmaceuticals, given the vast number of candidates available. To streamline this task, however, process modelling tools can be used to systematically probe the behaviour of different crystallisation setups entirely in-silico. In fact, it is possible to couple thermodynamic models with basic solid-liquid equilibria (SLE) principles to determine the impact of key process variables (e.g., temperature and solvent choice) on process performance, prior to conducting lab-scale experiments. In light of this, in this study we have used thermodynamic computational modelling tools (implemented within MATLAB®) to evaluate the cost and environmental impact of different batch crystallisation processes that may be used to manufacture flurbiprofen – a non-steroidal anti-inflammatory drug (NSAID) that can be used to treat various forms of arthritis. To complete this work, we have used the Apelblat equation to study the solubility of flurbiprofen in four (4) common solvents (n-octane, methyl tert-butyl ether, n-propanol, and isopropyl acetate) over a wide temperature range (283.15-323.15 K). Further to this, we have used green metrics (i.e., E-factor) and established costing methodologies to compare each process candidate; before evaluating their Scope 1 and 2 $CO_2e$ emissions by considering their electricity usage and incineration activities.

**Keywords**: Non-Steroidal Anti-Inflammatory Drugs (NSAID), flurbiprofen, crystalliser, design, solvent selection

## 1. INTRODUCTION

In 2024, the global market for non-steroidal anti-inflammatory drugs (NSAIDs) reached 21.56 billion USD, and it is projected to grow at a Compound Annual Growth Rate (CAGR) of 5% over the next 8 years [1]. Consequently, cost-effective manufacturing processes must be developed for NSAIDs if we hope to satisfy future demand [2-3]. In light of this, we have used computational modelling to study the impact of solvent choice and process temperature on the batch cooling crystallisation of flurbiprofen – a generic NSAID (with global sales of 100 million USD per year [4]) which is used to treat rheumatoid arthritis, migraines and osteoarthritis [5]. To do this, we have used a purely thermodynamic approach, whereby the Apelblat equation is used to assess the solubility of flurbiprofen (Fig. 1) in four (4) pharmaceutical solvents (n-octane, methyl tert-butyl ether, n-propanol, and isopropyl acetate) [5] at different temperatures ($T$).

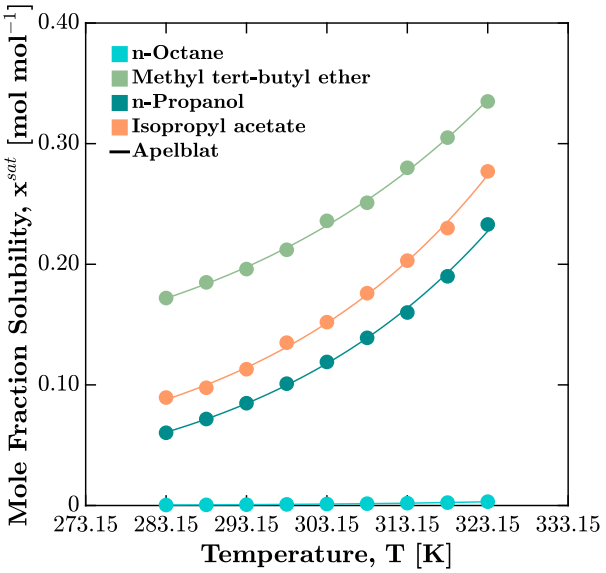

**Figure 1.** Flurbiprofen solubility in four solvents. Data [5].

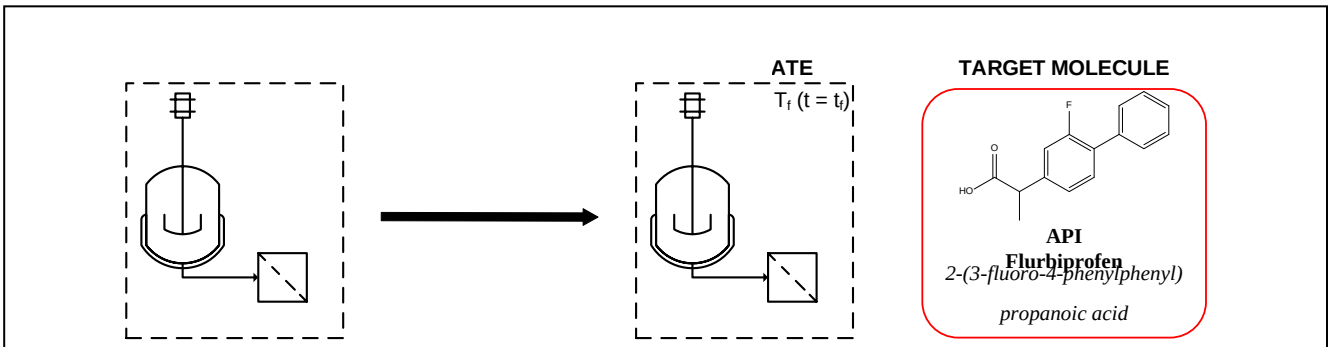

**Figure 2:** Batch cooling crystallisation using thermodynamic considerations alone.

Established green metrics and cost-estimation methods have then been used to identify the solvent and process conditions which afford the lowest cost solution whilst maintaining a reasonable carbon footprint.

## 2. PROCESS DESIGN & SIMULATION

As has been demonstrated by several authors [3, 6], it is possible to design crystallisers using thermodynamic principles alone (Fig. 2). The main benefit of this approach being that it allows promising solvent candidates to be identified prior to establishing their crystallisation kinetics; thereby reducing the number of experimental trials required to develop new processes.

In light of these observations, we have used the Apelblat equation (Eq. 1) alongside solid-liquid equilibrium (SLE) principles (Eqs. 2-5) to calculate the mass of flurbiprofen produced by each crystallisation batch cycle ($m_{BC}$) as we vary the initial and final temperatures ($T_0$, $T_f$) used. Meanwhile, we have used Eqs. 6-10 to determine any process volumes, operating times and production strategies required by each system; whilst Eqs. 11-12 have been used to determine product recoveries and cooling requirements.

Fig. 3 depicts the calculation sequence used to carry out this work, where basic physical properties (e.g., molecular weights, melting ($T_{mp}$) and boiling ($T_{bp}$) points) have been taken from the literature wherever possible [5, 7]. It is important to note, however, that the density and specific heat capacity of each solvent has been estimated using temperature-dependent empirical correlations when performing these calculations [8]. Meanwhile, only crystallisers of standard-size (1000, 2000, 5000, 10000, 20000 L) have been considered (70 v/v % fill capacity); whilst parallel production lines ($N_{PT}$) have been permitted whenever production targets could not be met using a single production line.

$$\ln x^{sat} = A + \frac{B}{T} + C\ ln(T) \quad (1)$$

$$n_{prod,0} = x_{prod,0}^{sat} n_S \quad (2)$$

$$n_{prod} = x_{prod}^{sat} n_S \quad (3)$$

$$n_{prod}^{cryst} = n_{prod,0} - n_{prod} \quad (4)$$

$$m_{prod}^{cryst} = M_{prod} n_{prod}^{cryst} \quad (5)$$

$$V_{cryst} = \frac{m_{prod}^{cryst}}{\rho_{prod}} \quad (6)$$

$$V_{liq} = \frac{M_S n_S}{\rho_S} \quad (7)$$

$$V_{sys} = V_{liq} + V_{cryst} \quad (8)$$

$$t_{BC} = t_{cryst} + t_{CIP} \quad (9)$$

$$m_{annual} = m_{BC} N_{BC} N_{PT} \quad (10)$$

$$r_T^{cryst} = \left(\frac{n_{prod,0} - n_{prod}}{n_{prod,0}}\right) \quad (11)$$

$$Q = \Delta T C_{P_S} n_S \quad (12)$$

$$\{T_0, T_f\} \geq \max \begin{Bmatrix} T_{min,Apel} \\ T_{mp_{solv}} + T_{os_1} \\ T_{min,phys} \end{Bmatrix} \quad (13)$$

$$\{T_0, T_f\} \leq \min \begin{Bmatrix} T_{max,Apel} \\ T_{bp_{solv}} - T_{os_2} \\ T_{max,phys} \end{Bmatrix} \quad (14)$$

In addition to this, we have also stipulated that the initial state of a crystalliser must have a temperature greater than that of the final state; all the while abiding by the constraints defined in Eqs. 13-14 ($T_{OS,1} = 5; T_{OS,2} = 10\ K$) so as to prevent any solvent phase changes from occurring during crystallisation [3, 6] (Fig. 3). Likewise, we have specified that each process must use a minimum of 4 mL of solvent per gram of solute so as to avoid high shear forces during mixing [3].

Using this approach, material balances have been constructed across each process by assuming that: (i) 100 metric tonnes of API are produced per year ($m_{annual}$); (ii) each process operates for a maximum of 6000 h annually ($t_{op}$); (iii) all mixtures are well-mixed, fully suspended and have uniform temperature and concentration profiles; (iv) vessel clean-in-place times ($t_{CIP}$) are 30 minutes between batches; and (v) each crystallisation batch takes 12 hours ($t_{cryst}$) [2]. It is important to note, however, that several unit operations are likely to precede the crystallisation steps studied in this work. Thus, each production line should only be allowed to complete

one full-process batch cycle per day – irrespective of an individual crystallisation unit's batch cycle time ($t_{BC}$). Otherwise, unrealistic manufacturing processes could be developed which demand infeasibly large numbers of batches to be produced each day.

Eqs. 1-14 introduce terms $n_S$, $n_{prod,0}$ and $n_{prod}$ to represent the molar amount of solvent used in each process, as well as the initial and final amounts of drug product dissolved in this solvent (mol). Terms $x_{prod,0}^{sat}$, $x_{prod}^{sat}$ and $x^{sat}$ are also used to denote the mole fraction of dissolved product for a given process state (mol mol$^{-1}$). Meanwhile, $A$ (–), $B$ (K) and $C$ (–) are used to denote Apelblat correlation coefficients. $n_{prod}^{cryst}$ (mol) and $m_{prod}^{cryst}$ (kg) are then used to describe the molar and mass amounts of product produced; whilst $r_T^{cryst}$ (–) and $Q$ (kJ) give the API recovery and heating requirements. $M_{prod}$ and $M_S$ are used to represent the molar mass (g mol$^{-1}$) of the drug-product and solvents, respectively; whilst $\rho_{prod}$ and $\rho_S$ denote their densities (kg m$^{-3}$). Terms $V_{cryst}$, $V_{liq}$ and $V_{sys}$ are then left to represent crystal, liquid (mother-liquor) and total system volumes (L) for each batch in a process; whilst $C_{P_S}$ (J mol$^{-1}$ K$^{-1}$) represents the specific heat capacity of a solvent and $T_{min,Apel}$, $T_{max,Apel}$, $T_{min,phys}$, $T_{max,phys}$ (K) denote the minimum and maximum temperatures for which the Apelblat and physical property correlations are applicable. $N_{BC}$ gives the number of batch cycles per production line for a given throughput.

## 3. ENVIRONMENTAL IMPACT

Environmental ($E_{factor}$) and emission factors (i.e., the amount of $CO_2$e produced per kilogram of product, $PCE$) have been used to assess the environmental impact of each process (Eqs. 15-16). Consequently, any Scope 1 and 2 emissions expected to arise from each process (due to material and energy consumption) have been calculated assuming that: (i) 0.20705 kg $CO_2$e are produced per kWh of electricity used [9]; (ii) any emissions produced during waste incineration activities only occur due to the complete combustion of waste material; and (iii) on-site scrubbing and catalytic reduction facilities are available to completely abate any $NO_x$ and $SO_x$ gases which arise during these incineration activities (allowing their potential generation to be ignored).

$$E_{factor} = \frac{m_{total\ input} - m_{total\ prod}}{m_{total\ prod}} \quad (15)$$

$$PCE = \frac{m_{total\ CO_2e}}{m_{total\ prod}} \quad (16)$$

Eqs. 15-16 introduce terms $m_{total\ input}$, $m_{total\ prod}$ and $m_{total\ CO_2e}$ to represent total process material requirements, API production, and $CO_2$e emissions (kg).

## 4. ECONOMIC ANALYSIS

An established costing methodology [2, 10] has been used to assess the viability of each process. As part of this, the capital costs ($CapEx$) associated with each process have been calculated in USD by taking the sum of any fixed ($FCC$) and working ($WCC$) capital costs (Eq. 17). Consequently, any $FCC$ costs have been calculated

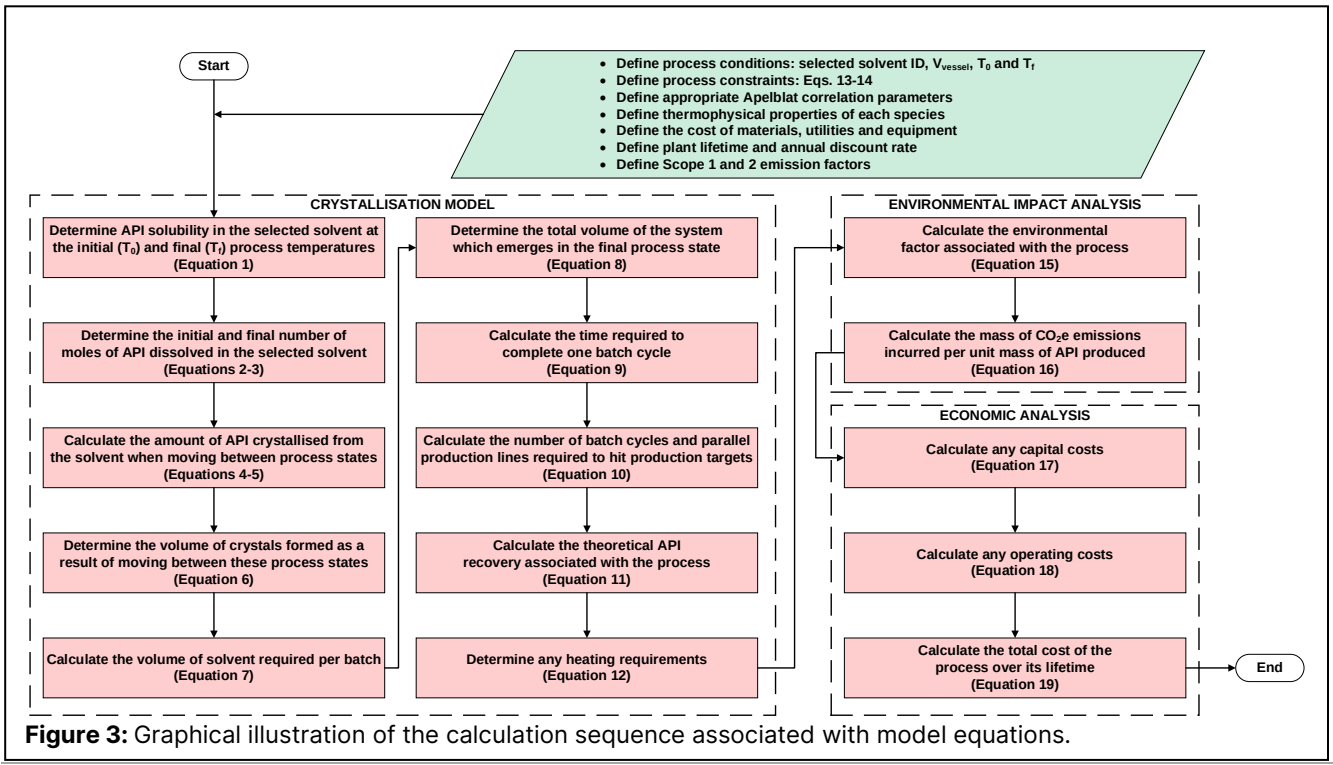

**Figure 3:** Graphical illustration of the calculation sequence associated with model equations.

as sum of the inside battery limits, outside battery limits, engineering and contingency costs (using Chemical Engineering Plant Cost Indices and Lang factors to account for the effects of inflation and equipment installation); whilst any $WCC$ costs have been assumed equal to 15 % of the $FCC$ costs. Likewise, any operating costs have been simply calculated as the sum of the fixed ($FCOP$) and variable ($VCOP$) costs of production (Eq. 18). Where, any $VCOP$ costs have been calculated as the sum of any raw material, waste disposal, and utility costs; whilst any $FCOP$ costs have been broken down into: (i) supervision and management costs; (ii) maintenance costs; (iii) renting of land/buildings; (iv) insurance premiums/property taxes; (v) direct salary overheads; and (vi) labour costs.

$$CapEx = FCC + WCC \tag{17}$$

$$OpEx = FCOP + VCOP \tag{18}$$

The total cost of each process ($TPC$) has then been determined via Eq. 19 – assuming all $CapEx$ occurs in year zero, whilst any $OpEx$ is incurred from year one onwards.

$$TPC = CapEx + \sum_{n=1}^{t_{LTP}} \frac{OpEx}{(1+I_{dr})^n} \tag{19}$$

Bulk prices used to calculate material costs have been calculated by averaging values published by known vendors and market research firms (i.e., the IMARC group) in the last year (2023-2024) wherever possible. However, import and export reports published for major markets have been used if this information was unavailable. Similarly, waste disposal costs have been estimated in-line with recommendations made by Jolliffe and Gerogiorgis (2017) [11] and the World Health Organization (1999) [12]. Meanwhile, a plant lifetime ($t_{LTP}$) of 20 years has been assumed, with an annual discount rate ($I_{dr}$) of 5.5 % [11]. An efficiency of 40 % has been assumed when converting electrical energy to crystalliser cooling duties.

## 5. RESULTS & DISCUSSION

Using the modelling framework presented in Sections 2-4, we have visualised the design space associated with each crystallisation process. From this, we observed that (regardless of the solvent used) it is wise to use the largest crystalliser available (20000 L) since this will reduce process costs, whilst also minimising the number of batches and parallel production lines required to achieve a given throughput (Fig. 4a). Alongside this, however, we also observed that it is also best to maximise the temperature difference between the initial and final states of a given process if we wish to minimise its production costs whilst maximising drug recovery. Fig. 4b provides findings from these investigations for two of the solvents studied in this work: n-octane (low API solubility) and n-propanol (moderate API solubility). Consequently, we could safely set the volume and temperature difference of each system to their maximum allowable values before studying the impact of solvent choice on: (i) process cost (Fig. 5a); (ii) material usage (Fig. 5b); (iii) $CO_2$e emissions (Fig. 5c); and (iv) API recovery (Fig. 5d).

Interestingly, however, from studying these trends, we found that simply choosing the solvent with the highest expected API solubility (i.e., methyl tert-butyl ether herein) will not necessarily result in a cost-optimal (Fig. 5a) or environmentally friendly (Figs. 5b-c) manufacturing process. Rather, we must take into account the cost of purchasing and disposing of any materials (as well as

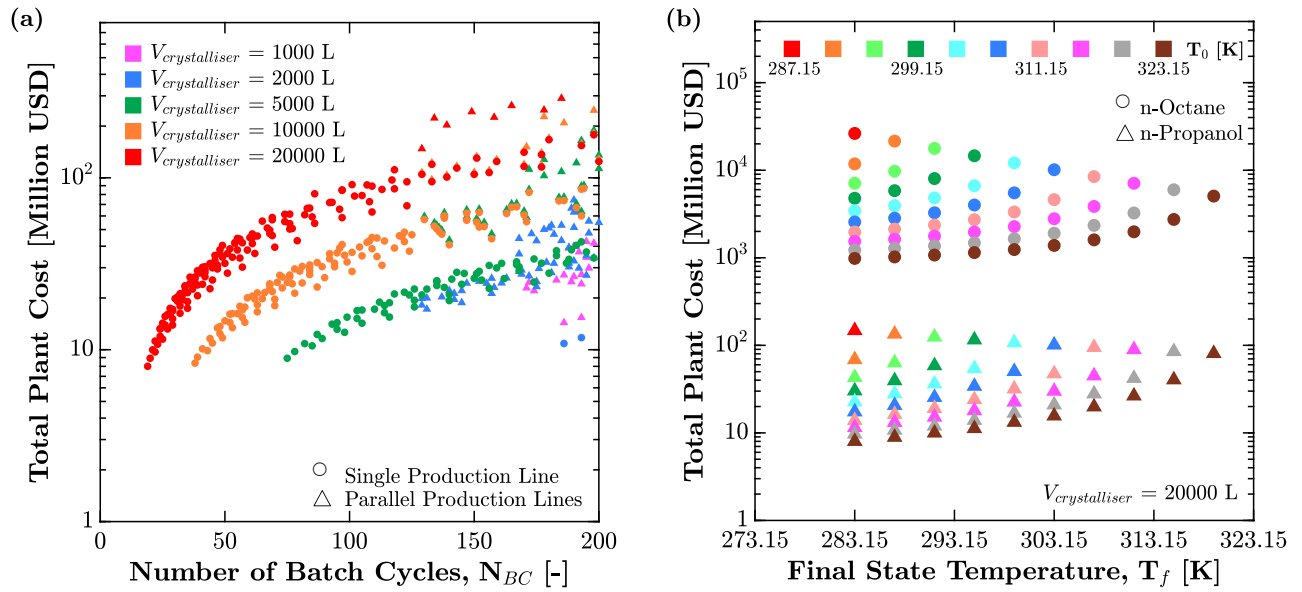

**Figure 4:** Impact of: (a) crystalliser volume (for all solvents, at various process conditions); and (b) process temperature ($T_0$, $T_f$) on process cost.

the volatility of any solvents used) if we wish to identify cost-optimal processes; since these variables can have a significant impact on the overall viability of a process. Consequently, in this work, n-propanol was identified as the best solvent available for flurbiprofen crystallisation ahead of methyl tert-butyl ether (Figs. 1 and 5); with the final optimised process exhibiting a total cost of 8.00 million USD, an API recovery of 73.31 w/w % and $CO_2$e emissions of only 4.23 $kg_{CO_2e}/kg_{API}$.

In light of these findings, it was worth examining the cost breakdown associated with this process to understand what aspects of process design influence the cost of batch crystallisation processes most. From this, it was found that an initial investment ($CapEx$) of only 0.10 million USD ($FCC$: 86.96 %; $WCC$ 13.04 %) would be required to design and build the optimised n-propanol process; yet, it would cost around 0.66 million USD annually ($FCOP$: 4.95 %; $VCOP$: 95.05 %) to operate ($OpEx$). It is, therefore, abundantly clear that batch cooling crystallisation processes such as those studied in this work are dominated by operating costs rather than capital investment (with material acquisition, utility usage, and waste disposal costs making up 9.50, 37.76 and 52.74 % of any $VCOP$ costs incurred in this case).

In addition to these findings, however, it was also observed that simply targeting maximum product recoveries (or crystal yields) can be hazardous when optimising a new process. Especially, since doing so can result

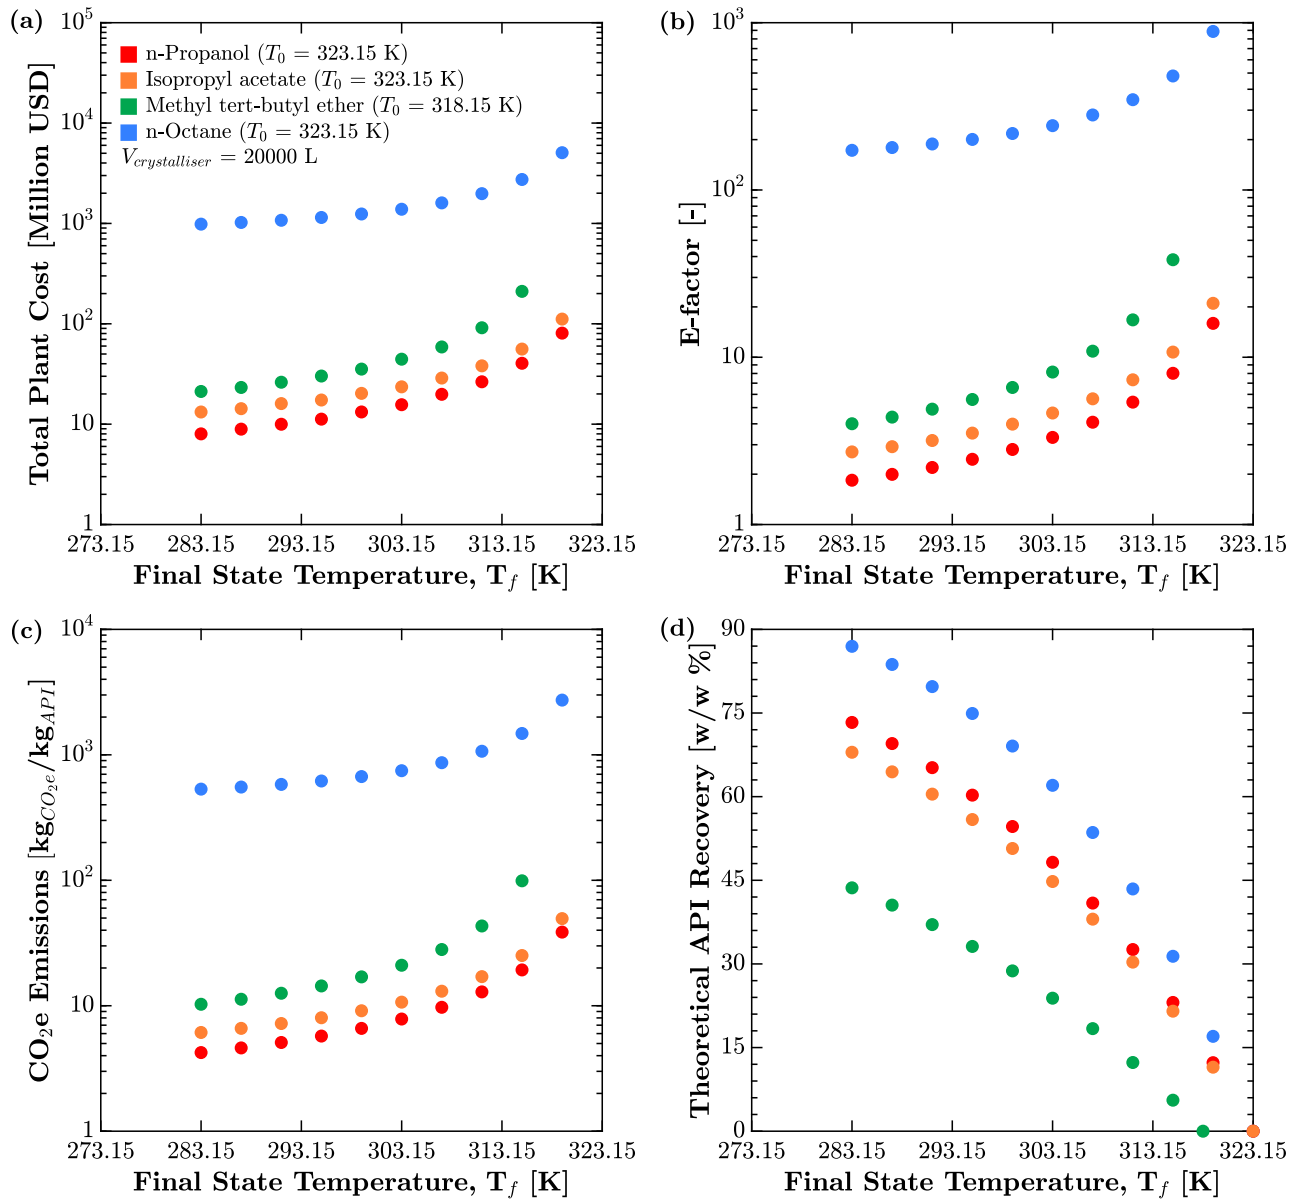

**Figure 5:** Impact of solvent choice on: (a) process cost; (b) E-factor; (c) $CO_2$e emissions; and (d) API recovery. $T_0$ set to maximum allowable value for each solvent.

in the selection of solvents which have extremely low drug solubilities (Fig. 1) even though this raises process costs on account of the larger volumes of solvent required in such scenarios (Fig. 5d). Hence, it is safer to evaluate processes in terms of their process costs and environmental impact, as has been done in this work.

## 6. CONCLUSIONS

In this work, we have presented a practical modelling framework for the visualisation and optimisation of design spaces associated with batch cooling crystallisation processes. Further to this, we have demonstrated how this framework can be used to identify cost-optimal process conditions for flurbiprofen production, whilst minimising carbon emissions. As part of this, we have successfully identified n-propanol as the most suitable solvent (of those tested) for the batch cooling crystallisation of flurbiprofen ($V_{crystalliser}$ = 20000 L; $T_0$ = 323.15 K; $T_f$ = 283.15 K). Consequently, the systematic methods presented in this paper can also be used to explore the design space associated with a whole host of other small molecule APIs, since around 80% of all small molecule pharmaceuticals produced today require crystallisation at some point(s) during the manufacturing process [3].

# Active Pharmaceutical Ingredients from Unused Solid Drugs

**Shrivatsa Korde[a], Aishwarya Menon[b], Gintaras V. Reklaitis[a] and Zoltan K. Nagy[a]***

## ABSTRACT

The increased use of pharmaceuticals globally over the past two decades has contributed to an increase in unused pharmaceuticals and a corresponding surge in pharmaceutical waste. Thus, there is an impetus for the development of processes for the recovery of the active pharmaceutical ingredients (APIs) from these unused drugs. This study introduces a decision framework for solvent selection to enable the recovery of APIs using a general separation train where cooling crystallization is the final step. The framework is designed to base solvent selection not just on the solubilities of the formulation contents but also considers the overall recovery that can be achieved in the process. In addition, the environmental sustainability of the framework is analyzed using the process mass intensity metric (PMI). The effectiveness of this framework is demonstrated by using paracetamol (PA) as a model API in a formulation consisting of five of the excipients commonly found in PA formulations. The results show that selecting a solvent based on the dissolution of pharmaceutical tablets may not be the best possible approach, whereas choosing a solvent that maximizes the theoretical recovery is preferred.

**Keywords**: API recovery, Solvent Selection, Sustainability, Process Design

## INTRODUCTION

The rapid population growth and escalating use of medicines to treat human diseases have caused a concurrent rise in pharmaceutical waste, necessitating proper management strategies to address this challenge effectively. Unused pharmaceutical products are often disposed of as household trash or flushed down the toilet. Incineration and land disposal are the two common ways to get rid of unused drugs collected as trash, resulting in an inherent environmental impact [1]. Even though incineration (involving heating at temperatures over 1000°C) is effective, it is highly energy-intensive and releases harmful gases such as $CO_2$, $SO_2$, $NO_x$, etc. Drugs that are disposed of in landfills or flushed down the toilets eventually appear in the water system, causing harm to the flora and fauna, if not people. Another source of waste drugs is batches that fail final quality control during manufacturing, which are then incinerated. Expired drugs which are discarded at any point in the supply chain are another source of unused drugs.

Research has shown that many expired drugs retain a substantial portion of their potency[2] and thus, whether in landfill or wastewater, constitutes a hazard. One of the effective ways to treat the disposal of expired drugs is to have an infrastructure that facilitates their return at collection centers and recovery of the active pharmaceutical ingredient (API) from the unused drug formulation. The API is the most valuable component of a drug product; recovering it in its pure form enables its reformulation and conversion into new drug products. Among various drug administration methods, oral administration via tablets and capsules is the primary route for delivering APIs to patients [3]. When recycling APIs, it is crucial to ensure that the recovered APIs possess the desired critical quality attributes (CQAs), such as purity, drug shelf life, and bioavailability, while adhering to strict FDA regulations.

Crystallization is the process of converting a chemical from a liquid or solution into a solid crystalline state, where the atoms or molecules are arranged in a definite geometric pattern or lattice. Crystallization serves both

as a separation process and a particle control strategy to target specific CQAs such as yield, polymorph selection, and crystal size distribution (CSD). Over 90 % of active pharmaceutical ingredients (APIs) are synthesized as crystalline products. Proof-of-concept studies demonstrating API recovery have been carried out in the past [4]. However, these processes suffer from low overall recovery and lack sufficient solvent selection guidelines for the final separation stage via crystallization.

To address these gaps, this study aims to develop a solvent selection framework to enable a higher overall recovery of the API present in the unused formulation. The remainder of the paper is organized as follows: first, the solvent selection framework for optimal solvent selection is presented. Subsequently, the devised framework is applied in a case study consisting of a formulation of paracetamol with five of the common excipients, and preferred solvents are narrowed down from an existing ten solvents commonly used in cooling crystallization.

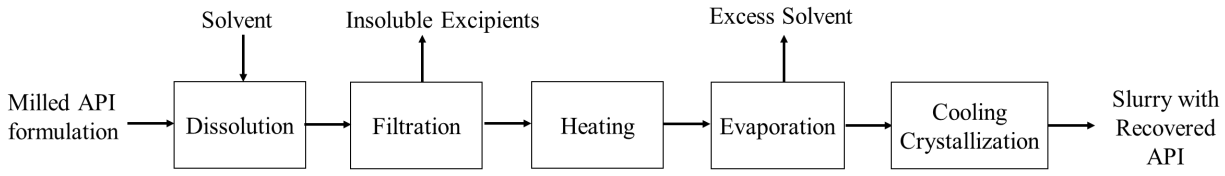

**Figure 1:** Generic separation train considered for the API recovery process.

## Proposed Methodology

A general separation train for recovering API, as depicted in Figure 1, comprises a few general processing steps: (i) dissolution, (ii) filtration, (iii) heating, (iv) evaporation, and (v) crystallization. Initially, the tablets are milled, and the resulting powder is dissolved in the selected solvent at a specified temperature. After dissolution, the mixture is filtered, separating the insoluble excipients. A 5% solvent loss is considered to account for filtration losses. After filtration, the solution is heated to saturation to evaporate excess solvent, a critical step to facilitate nucleation when the temperature is subsequently lowered. Each step involves operating decisions that impact the performance of the given flowsheet. The entire process is conducted in a batch mode. In the process, the operating temperatures for each operation are important to ensure minimal energy consumption while ensuring a high yield in the batch crystallization.

The solvent selection framework is based on three important considerations. The first is selecting the solvent right at the dissolution stage, which was adopted in an earlier study [4], in a preliminary form, where a solvent was classified as a 'good solvent' if it dissolved the API in more than a specified quantity However, our approach seeks to maximize the relative difference between the API ($m_{API}^{d}$) and the excipients ($m_{Ei}^{d}$) dissolved at a given dissolution temperature $T_D$.

$$\begin{aligned} &\max_{\boldsymbol{x},\boldsymbol{y}} f \\ &s.t.\ g_i(\boldsymbol{x}) \le 0\ \forall\, i \in I, \\ &h_j(\boldsymbol{y}) \le 0\ \forall\, j \in I \\ &\boldsymbol{x_{lb}} \le \boldsymbol{x} \le \boldsymbol{x_{ub}} \\ &\boldsymbol{y} \in \{0,1\} \end{aligned} \tag{1}$$

Equation 1 shows that the mathematical formulation of the solvent selection framework can be posed as an optimization problem in which an objective function is maximized given a set of constraints and variable bounds. The objective function selected depends on the criteria for solvent selection. The second metric consists of selecting a solvent based on the overall recovery of the process, thus giving a more comprehensive picture. The third metric consists of selecting a more sustainable solvent, i.e., a minimal requirement for solvent for API recovery.

## Solvent Selection Criteria

Table 1 shows the two different methods for solvent selection. In the dissolution-based approach, the solvent that dissolves the API selectively but not the excipients is considered a good solvent.

**Table 1:** Description of the dissolution and recovery-based solvent selection methodologies.

| Description | Dissolution Based | Recovery Based |
|---|---|---|
| Objective Function | $S_j\left(m_{API}^{d} - \sum_{i=1}^{n} m_{Ei}^{d}\right)$ | $S_j\left(\frac{100}{1-X_2}\left(1-\frac{X_2}{X_1}\right)\right)$ |
| Decision Variable(s) | $T_D, S_j$ | $T_1, T_2$ |
| Constraint(s) | $\sum_{j=1}^{m} S_j = 1$ | $X_{solids} \le 0.2$<br>$\sum_{j=1}^{m} S_j = 1$ |
| Variable bounds | $T_{LB} \le T_D \le T_{UB}$<br>$S_j \in \{0,1\}$ | $T_{LB} \le T_1 \le T_{UB}$<br>$T_{LB} \le T_2 \le T_{UB}$ |

This approach can provide the optimal solvent for the given objective and determine the optimal dissolution temperature that facilitates selective API dissolution.

Multiplying this relative difference with a binary variable ($S_j$) that indicates if a solvent is selected results in an MINLP formulation. On the other hand, the recovery-based approach focuses on increasing the yield obtained during the final stage, i.e., crystallization.

The objective, given in Table 1 for this approach consists of the percentage recovery under cooling crystallization [5] where $X_1$ and $X_2$ are the API's initial and final mass fractions before and after cooling at temperatures $T_1$ and $T_2$. It is important to note that while in cooling crystallization, as the solids begin to crystallize, there is an increasing possibility of fouling in the transfer line. Thus, a constraint to restrict the amount of solids crystallized is imposed. Finally, the bounds on the dissolution temperature are imposed. The initial and final temperatures vary from the maximal of the freezing point of a solvent and the lowest possible temperature that may be achieved by the heat exchanger and the smaller of the API degradation temperature and the boiling point of the solvent for the upper bound.

For the third metric of process sustainability, the process mass intensity (PMI) is used in this study. This metric was chosen over the E-factor metric as it is the ratio of the total mass in the process and the amount of API recovered, thus providing a fuller picture of the process's inputs and not just the waste. Equation 2 shows how PMI is calculated.

$$PMI = \frac{Total\ Mass\ [kg]}{API\ recovered\ [kg]} \quad (2)$$

## FRAMEWORK APPLICATION

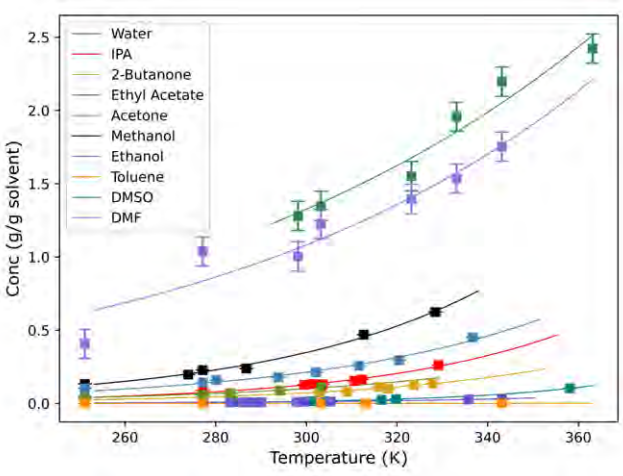

**Figure 2**: Solubility of API in all the chosen solvents.

The above-described solvent selection approach is applied to a formulation of paracetamol. The formulations for any specific API differ slightly from manufacturer to manufacturer; however, the set of excipients employed does not vary significantly. Hence, with this API, five common excipients are chosen to constitute a representative formulation. The details of this formulation can be seen in Table 2. The developed solvent selection framework applies to selecting solvents from an existing set. Hence, a list of ten common solvents for crystallization is proposed for selecting the appropriate solvents, as shown in Table 3, is proposed from which the most appropriate solvent will be selected. Most of the solvents belong to class 3, which are solvents of low toxicity, and two of them belong to class 2, which are solvents of limited use according to the guidelines of the International Council of Harmonization of Technical Requirements for Pharmaceuticals for Human Use (ICH) [6].

**Table 2:** Selected paracetamol formulation adapted from [7].

| Label | Name | Quantity (mg/tablet) |
|---|---|---|
| API | Paracetamol | 500.00 |
| E1 | Starch | 44.00 |
| E2 | Microcrystalline Cellulose (MCC) | 30.00 |
| E3 | PVP-K-30 | 18.00 |
| E4 | Magnesium Stearate | 2.00 |
| E5 | Silica | 2.00 |

**Table 3:** Common solvents used in crystallization studies.

| Label | Solvent Name | Solvent Class |
|---|---|---|
| S1 | Water | 3 |
| S2 | Methanol | 3 |
| S3 | Ethanol | 3 |
| S4 | Toluene | 2 |
| S5 | 2-Propanol (IPA) | 3 |
| S6 | Dimethylformamide (DMF) | 2 |
| S7 | Acetone | 3 |
| S8 | Ethyl acetate | 3 |
| S9 | 2-Butanone | 3 |
| S10 | Dimethyl sulfoxide (DMSO) | 3 |

Having selected the candidate solvents, the solubility of the API is determined experimentally using the Technobis Crystalline equipment apparatus [8], which measures the transmissivity of solutions during heating and cooling cycles. The clear point of a sample is defined as the temperature at which transmissivity reaches 100% during heating, indicating full transparency. In contrast, the cloud point is the temperature at which transmissivity drops to zero during cooling, indicating turbidity. For measurements, solutions of the API with known

**Table 4:** Summary of excipients solubilities in chosen solvents; Y: soluble, N: insoluble.

| Solvent Names | MCC | MgSt | PVP-K-30 | Silica | Starch |
|---|---|---|---|---|---|
| Water | N | N | Y | N | N |
| Methanol | N | N | Y | N | N |
| Ethanol | N | N | Y | N | N |
| Toluene | N | N | N | N | N |
| 2-propanol | N | N | Y | N | N |
| N,N-Dimethylformamide | N | N | Y | N | N |
| Acetone | N | N | Y | N | N |
| Ethylacetate | N | N | N | Y | N |
| 2-butanone | N | N | Y | Y | N |
| Dimethyl sulfoxide | N | N | Y | Y | N |

concentrations were prepared in 5 ml vials for the selected solvents. The obtained experimental data is then fitted to a two-parameter modified Apelblat equation (Equation 3), where C is the concentration of API in g/g-solvent at temperature T, and the constants A and B are obtained.

$$\ln C = A + BT \tag{3}$$

The solubilities of the excipients were determined using the gravimetric method. The reason is that most excipients are sparingly soluble in the candidate solvents, making the transmissivity measurements difficult.

Replicate solutions in sets of three to minimize error containing excess excipient were prepared in 20 ml scintillation vials, which were stirred for 24 hours. The temperature was kept within ± 0.1°C of the desired temperature and was checked with a Pt-100 resistance thermometer. After equilibration, the excess excipient was allowed to settle for 24 hours without agitation. A sample of clear saturated solution (approximately 10 ml) was transferred into a previously weighed petri dish ($m_d$) after filtering with the filter of pore size 0.2 µm and weighed again ($m_s$). Subsequently, the filtered samples were left in the oven at 45°C for the solvent to evaporate for 3 days. The dishes were weighed each day to account for changes in mass. After the mass of dishes did not change by more than 5 mg, the mass of dry residue ($m_r$) was recorded. The solubility was calculated as shown in Equation 4.

$$C = \left(\frac{m_r - m_d}{m_s - m_r}\right)\frac{g\ solute}{g\ solvent} \tag{4}$$

The excipients were then simply classified as soluble or not in a specific solvent, as summarized in Table 4. Consequently, the solvent required to dissolve the API completely becomes crucial. Also, post-filtration, the solution is saturated with the active ingredient by evaporating the excess solvent. Since paracetamol is sparingly soluble in toluene, the most solvent is required if toluene is used. By contrast, DMF and DMSO are required in lesser quantities due to their high solubility of the API. The next step involved applying the solvent selection framework for a formulation of PA (Table 5) to execute the flowsheet described in Section 2. A basis of 1000 g (1 kg) of API was chosen for evaluating the associated process flowsheet. The optimal solvent for dissolution

**Table 5:** Summary of preferred solvents for each method and the process parameters required to achieve the desired recovery.

| Metric | Preferred Solvents | Process Parameters | | | | Recovery |
|---|---|---|---|---|---|---|
| | | $T_D$ (K) | $T_1$ (K) | $T_2$ (K) | Solvent Required (kg) | (%) |
| Recovery | Water | 298.2 | 353.2 | 273.2 | 75.7 | 94.7 |
| | 2-Butanone | 298.2 | 253.2 | 352.8 | 17.7 | 92.0 |
| | Ethyl Acetate | 298.2 | 350.3 | 253.2 | 105.0 | 90.5 |
| Sustainability | DMF | 353.2 | 353.2 | 253.2 | 0.6 | 30.7 |
| | DMSO | 353.2 | 353.2 | 292.2 | 0.6 | 30.9 |
| | Methanol | 337.9 | 337.9 | 253.2 | 1.3 | 47.0 |
| Solubility | Ethyl Acetate | 298.2 | 350.3 | 253.2 | 105.5 | 92.0 |
| | Toluene | 298.2 | 353.2 | 253.2 | 2942.2 | 83.3 |

depends on the solution of the solubility metric described in Table 1.

An enumeration-based approach was used to solve the problem formulated in Equation 1 for both dissolution and recovery-based methods. Thus, the objective functions for both approaches were evaluated for all the solvents at the respective temperature bound of the solvent.

Interestingly, for the chosen formulation, four out of the five excipients were insoluble in the solvents initially considered for screening. This meant that the relative difference in the amount of API and the excipient dissolved reduced to the difference in the quantity of PA and PVP-K-30 dissolved. Solvents ethyl acetate and toluene are preferable when selecting a solvent based on dissolution, as none of the excipients are soluble in them. All the remaining solvents are equally favorable as the difference in the API and excipients dissolved is constant.

For the recovery-based solvent selection, Figure 3 shows the maximum possible recoveries that can be obtained using the ten solvents. Water has the highest recovery, followed by 2-butanone and ethyl acetate. Due to the constraint on the solids fraction in the crystallization stage not being more than 20%, the actual recovery is lower than the predicted theoretical recovery, limiting the extent to which the feed can be cooled. Hence, the recoveries for solvents DMF and DMSO are significantly lower, even though PA is highly soluble in these solvents.

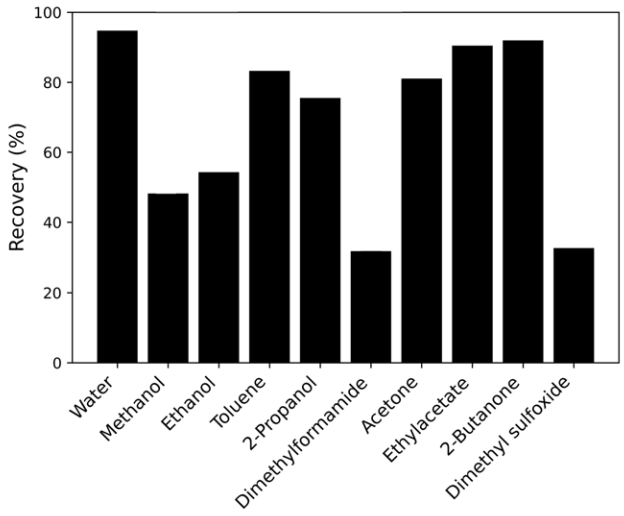

**Figure 3:** Recovery of PA from the chosen formulation for the chosen solvents.

Figure 4 summarizes the amount of solvent required to achieve the recoveries described in Figure 3 and the respective PMI. Solvents with high solubility of API naturally are required in lesser quantities and, therefore, have a low PMI. On the contrary, despite a relatively high theoretical recovery, the PMI is the highest in the case of toluene due to its tendency to dissolve a very small quantity of PA. Thus, there is a trade-off when it comes to selecting a solvent with a high recovery and a sustainable solvent. Targeting high recovery while maintaining a relatively low PMI was observed in the cases of water and 2-butanone. These solvents were notable because the mass fraction of crystallized solids did not exceed the 20% threshold, ensuring that the flowability constraint was not violated. This allows the maximal recovery to be the same without considering the flowability constraint.

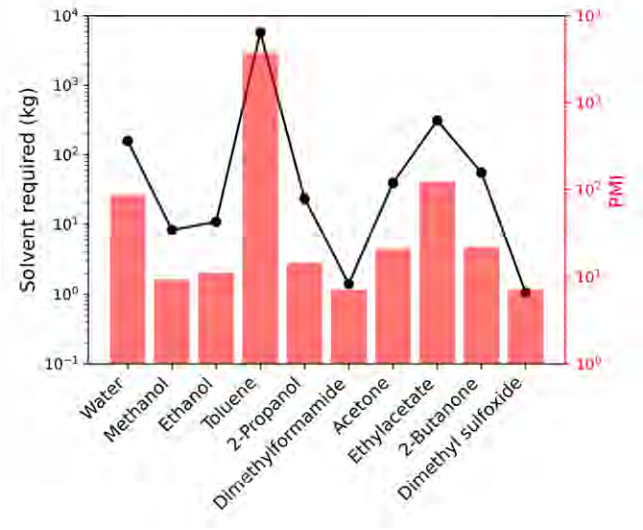

**Figure 4:** Amount of solvent required and the respective PMI for a basis of 1 kg of PA in the formulation.

The specific metrics of interest should guide the selection of solvents. Although 2-butanone and ethyl acetate exhibit a lower PMI than water, this is accompanied by a trade-off in recovery. Table 5 summarizes this solvent screening approach, which allows for the prioritization of specific metrics, facilitates informed decisions regarding solvent selection based on objectives, and enables subsequent process modeling. As can be seen, the values of the objective function of each metric (such as recovery and the amount of solids dissolved) change as the temperatures $T_1$, $T_2$, and $T_d$ vary with changes in these temperatures (< 1°C). The sensitivity of this change is related to the solubility of the API and the excipients at those temperatures, which depend on the constants A and B obtained from experiments. However, with small changes in temperatures, the overall ranking of the solvents is not impacted significantly.

However, a formulation with excipients that show different behaviors, such as gel formation, will need more attention when applying this methodology. Either imposing different bounds on the process temperature or eliminating the solvents where these different behaviors are observed will be necessary. Overall, the developed solvent selection approach provides a systematic

framework for enabling API recovery with maximal recovery and ensuring the key process constraints are met.

## CONCLUSION

In this study, a solvent selection framework was developed for a sustainable recovery of API. The framework was applied effectively in a case involving a paracetamol formulation, wherein solvents are selected according to each desired approach. It can be shown that this framework can be extended to different APIs that have variable solubility with temperature, thus enabling separation via cooling crystallization with a high recovery. Analyzing the solvents by ranking them provided valuable insights into the trade-offs of choosing a solvent with high recovery and a more sustainable solvent. This solvent selection framework constitutes an important step towards the development of a generalized framework for sustainable API recovery processes.

After obtaining the API from cooling crystallization by selecting the most appropriate solvent, further processing is necessary to recover the API. While this will depend on the API that is being recovered, a general trend involves washing and filtering the crystallized slurry and subsequently drying the mixture.

## ABSTRACT

Emerging sectors within the biopharmaceutical industry are undergoing rapid scale-up due to the market boom of gene therapies and vaccine platform technologies. Manufacturers are pressured to orchestrate resources and plan investments under future demand uncertainty and, critically, an early-stage process uncertainty for platforms still under development. In this work, a multi-product multi-stage stochastic optimization problem integrating demand uncertainty is presented and augmented with a worst-case optimization approach with respect to process uncertainty. Results focus on a comparison between fixed equipment facilities and modular technologies, highlighting an inherent flexibility of the latter option due to shorter recourse actions for capacity scale-out. The impact of process uncertainty integration is quantified. With more conservative decisions taken in first-stages of the time horizon, expected costs result lower for modular single-use equipment. This suggests that capacity adjustments also help adapt to varying process performance and reduce the propagation conservative design decisions.

## INTRODUCTION

Pharmaceutical capacity planning is crucial to meet product demands from clinical to commercial stages. In recent years, the market boom of gene therapies and demand for vaccines in pandemic contexts has highlighted a need to improve responsiveness of supply chains to demand fluctuations and unforeseen events. To this end, the industry has seen an uptake of single-use equipment (SU) to substitute more inflexible stainless-steel multi-use (MU) facilities, allowing for rapid scale-up and scale-out of manufacturing capacity. In this space, investment planning is challenged by a need to make scale-up decisions before processes are fully intensified and process capabilities known for certain[1]. Furthermore, process uncertainty in early stages of planning is combined with an uncertainty in future demands. In this context, an overestimation of attainable production targets and sub-optimal demand forecasting can result in shortages and exacerbate costs[2].

The complexity of investment planning problem under demand uncertainty can be represented as a stochastic optimization embedding a multi-stage scenario tree for demand outcomes. The PSE literature presents a number of decision support tools based on stochastic programming finding a direct application in capacity planning in pharmaceutical contexts. First stage variables include initial capacity investments, product selection and initial allocation of manufacturing resources to products. Second stage recourse decisions consist in additional capacity investment or sale of capacity, re-allocation of products to resources. Extensive research in PSE has focused problems of capacity planning using stochastic programming[3,4]. Alternatively, simulation-based approaches[5,6] and rolling horizon strategies[7,8] have been proposed to decision-making based on simulated demand outcomes.

This work focuses on investigating whether early-stage process uncertainty which characterizes advanced biopharmaceutical products undergoing rapid scale up is

worth integrating in capacity planning optimization problems. The proposed approach accounts for the different time scales of uncertainty and differentiates the flexibility of MU-based and SU-based equipment, which thus far has not been considered explicitly in the context of biopharmaceutical planning under uncertainty. The presented planning tool integrates process uncertainty using a worst-case approach, using previously quantified process uncertainty[9] and cost-related inputs obtained via techno-economic models, and demand uncertainty using stochastic programming and uses. Comparative analyses for SU and MU cases discuss the impact of process uncertainty integration compared to a deterministic-process counterpart and focus on network responsiveness to demand uncertainty.

# METHODOLOGY

## Problem statement

The capacity planning problem considered in this study is aimed at minimizing total supply chain capital and operating cost and determine a set of demand scenario independent design decisions and scenario-dependent decisions. These differ based on whether equipment is multi-use (MU) or single-use (SU).
The optimization considers:

- A set $T$ of time periods $t$;
- A set $I$ of products $i$;
- A set $N$ of nodes $n$;
- A set $T$ of time periods $t$;
- A set $A$ of process scales $a$;
- A set $S$ of process section $s$;
- A set $L$ of process lines $l$;
- A set $DS$ of demand scenarios $y$;

In the MU case, the partition of first-stage and second-stage scenario-dependent decisions results as follows:

1. Network structure and links between nodes;
2. Investment in manufacturing facilities;
3. Scales of manufacturing and number or parallel lines;
4. *Scenario-dependent* manufacturing levels,
5. *Scenario-dependent* transportation flows;
6. *Scenario-dependent* supply flows at each demand node.

In the SU case, the optimization considers the selection of scales and parallel lines as *scenario-dependent*, hence treating it as a recourse action or second-stage decision.

The optimization requires information on costs of technologies at different manufacturing scales $a$, for different process sections $s$ for the different products considered $i$ and specific to MU-based equipment vs SU-based equipment. This is obtained via techno-economic modelling of the processes of interest. Furthermore, it requires input data with respect to storage and transport cost per unit (Sarkis et al.[10] – SI) and target demands for each product $i$, realizing over time and differing by scenario $y$.

Whilst demand realizes in stages, process uncertainty is mainly present in early stages of scale-up. Before process capabilities are known, decision-makers may consider adopting a *risk-averse* approach. Once process uncertainty realizes, true capabilities are known and optimization decisions can adapt accordingly. This concept is integrated through a two-stage worst-case optimization approach. Ultimately, by combining expected demand outcomes and this process uncertainty mitigation strategy, decision-makers can obtain *here-and-now* investment plans which minimize expected costs and mitigate early-stage shortage risks. Depending on underlying equipment-related recourse actions, the resulting planning solutions may differ.

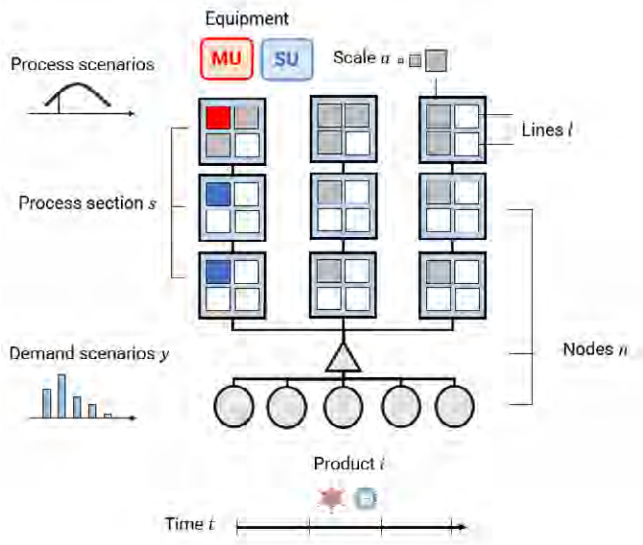

**Figure 1.** Optimization superstructure for multi-product supply chain case study.

## Techno-economic performance quantification

Techno-economic models of the manufacturing technologies of interest are developed using SuperPro Designer (Intelligen). In this work, the focus is the quantification of techno-economic performance of MU-based and SU-based manufacturing at scale $a \in A = \{50,200,1000,2000\}$ and for products $i \in I = \{LV, AdV\}$.

Details regarding the development of underlying models is included in Sarkis et al.[9] (SI). Here, equipment has been modified to fully SU or MU accordingly. Techno-economic KPIs for each platform include batch size $\chi$, cycle time $\tau$, end-to-end process time $\alpha$, and capital and operating costs $c$. Costs are assumed to be deterministic and dependent on equipment type, product $i$ and scale $a$. Instead, throughput related uncertainty as quantified in Sarkis et al.[9] is considered, yielding ranges of performance for batch size $\chi \in [\chi^{min}, \chi^{max}]$, cycle time $\tau \in [\tau^{min}, \tau^{max}]$ and process time $\alpha \in [\alpha^{min}, \alpha^{max}]$ for each product- and scale-specific process.

## Optimization formulation

The optimization considers a multi-period multi-product planning problem where $T = \{T_1, T_2, T_3, T_4\}$ and $I = \{LV, AdV\}$, where LV is a lentivirus-based product for gene therapy applications and AdV is an adenovirus-based product for vaccine applications. As mentioned, throughput related parameters are considered uncertain, whereas cost-related parameters are held at the deterministic value quantified via techno-economic modelling. On the demand side, a set of demand scenarios $y$ is considered $DS = \{DS_1, DS_2 \ldots DS_N\}$, which result from combinations of individual product demands in a multi-stage stochastic scenario tree. The optimization formulation is summarized in Table 1.

As shown in Eq.1, the objective function $z$ corresponds to the total expected supply chain cost, which a summation of capital and operating costs of manufacturing, storage costs and transport costs. These are scenario-dependent quantities and normalized by scenario probability $\Pi_y$. Manufacturing capital costs $TC^{CAPj}$ embed equipment installation costs $C^{EQj}$ for each node $n \in N^J$ and time $t$ (Eq. 2.), which are a function of equipment installation cost coefficients $c^{EQjl}$ and equipment installation binaries $H$, with respect to time $t$, node $n \in N^J$, scale $a$, line $l$, section $s$ and scenario $y$ (Eq. 3).

Manufacturing operating costs $TC^{OPj}$ include labour related costs $C^{LABj}$, variable costs $C^{VARj}$ and facility-dependent costs $C^{FACj}$ (Eq. 4), which are respectively function of cost coefficients $c^{LABj}$, $c^{VARj}$, $c^{FACj}$ for each scale $a$, section $s$ and product $i$ multiplied by either the number of batches $B$ (Eq. 5-6), and product-specific equipment installation $M$ (Eq. 7). Hence, the benefit of economies of scale on cost effectiveness is captured within the optimization, with a balance between costs that scale with production levels and fixed costs. Storage related costs $TC^{OPk}$ are computed as multiplication of a handling coefficient $c^{OPk}$, which depends on scale $a$ and product $i$ and the sum of transport flows $Q$ passing through all storage nodes at time $t$ and in scenario $y$ (Eq. 8). Transport costs $TC^T$ consider a cost coefficient per km travelled and batch delivered $c^T$ multiplied by distance $\rho$ between nodes $n$ and $m$ and transport flows $Q$.

33 $V_{tnay} = V_{tnay\prime} \quad \forall t, n \in N^J, a, y$

34 $Z_{tnasly} = Z_{tnasly\prime} \quad \forall t, n \in N^J, a, s, l, y$

35 $M_{tnasliy} = M_{tnasliy\prime} \quad \forall t, n \in N^J, a, s, l, i, y$

Sourcing constraints impose that a link $X$ at time $t$ between nodes $n$ and $m$ is established only if the upstream node exists through the activation of binary $Y$ (Eq. 10). Furthermore, all downstream nodes $m$ must be sourced by at least one link with an upstream node $n$ (Eq. 11-12). The equipment allocation constraint in Eq. 13 constrains the activation of scale $a$ in node $n \in N^J$ at time $t$ and scenario $y$ to nodes which are active ($Y = 1$) and allows the selection of at most one scale at a time, as the sum on the L.H.S. cannot exceed 1. A line $l$ of scale $a$ within process section $s$ can be installed through the $Z = 1$, if the respective scale is active within the node $n$, at time $t$ and in scenario $y$ (Eq. 14). Similarly, product-specific equipment installation through $M$ is allowed if the respective line $Z$ is active (Eq. 15). Product allocation occurs when $W = 1$, within manufacturing lines where equipment suitable for manufacturing of product $i$ is installed (Eq. 16). A change-over occurs ($N = 1$) when both products $i$ are manufactured within the same equipment, whereby the R.H.S. of Eq. 17 takes the value of 1. Product-specific change-over ($C = 1$) within the same time period $t$ is counted only once with respect to the LV product switching to AdV (Eq. 18), whilst the AdV to LV switch is always 0 (Eq. 19). An equipment manufacturing line can exist ($Z = 1$) at time period $t$ if investment has occurred through $H = 1$ or if it existed in the previous time period (Eq. 20). Noting the inequality sign which allows equipment to be deinstalled in the SU case, this becomes an equality constraint for the MU case (Eq. 20').

Production constraints in Eq. 21 bound the time allocated to manufacturing $T$ of product $i$, as well as the total utilisation time $U$ per year (Eq. 22-23). The number of batches $B$ is a function of time allocated to production

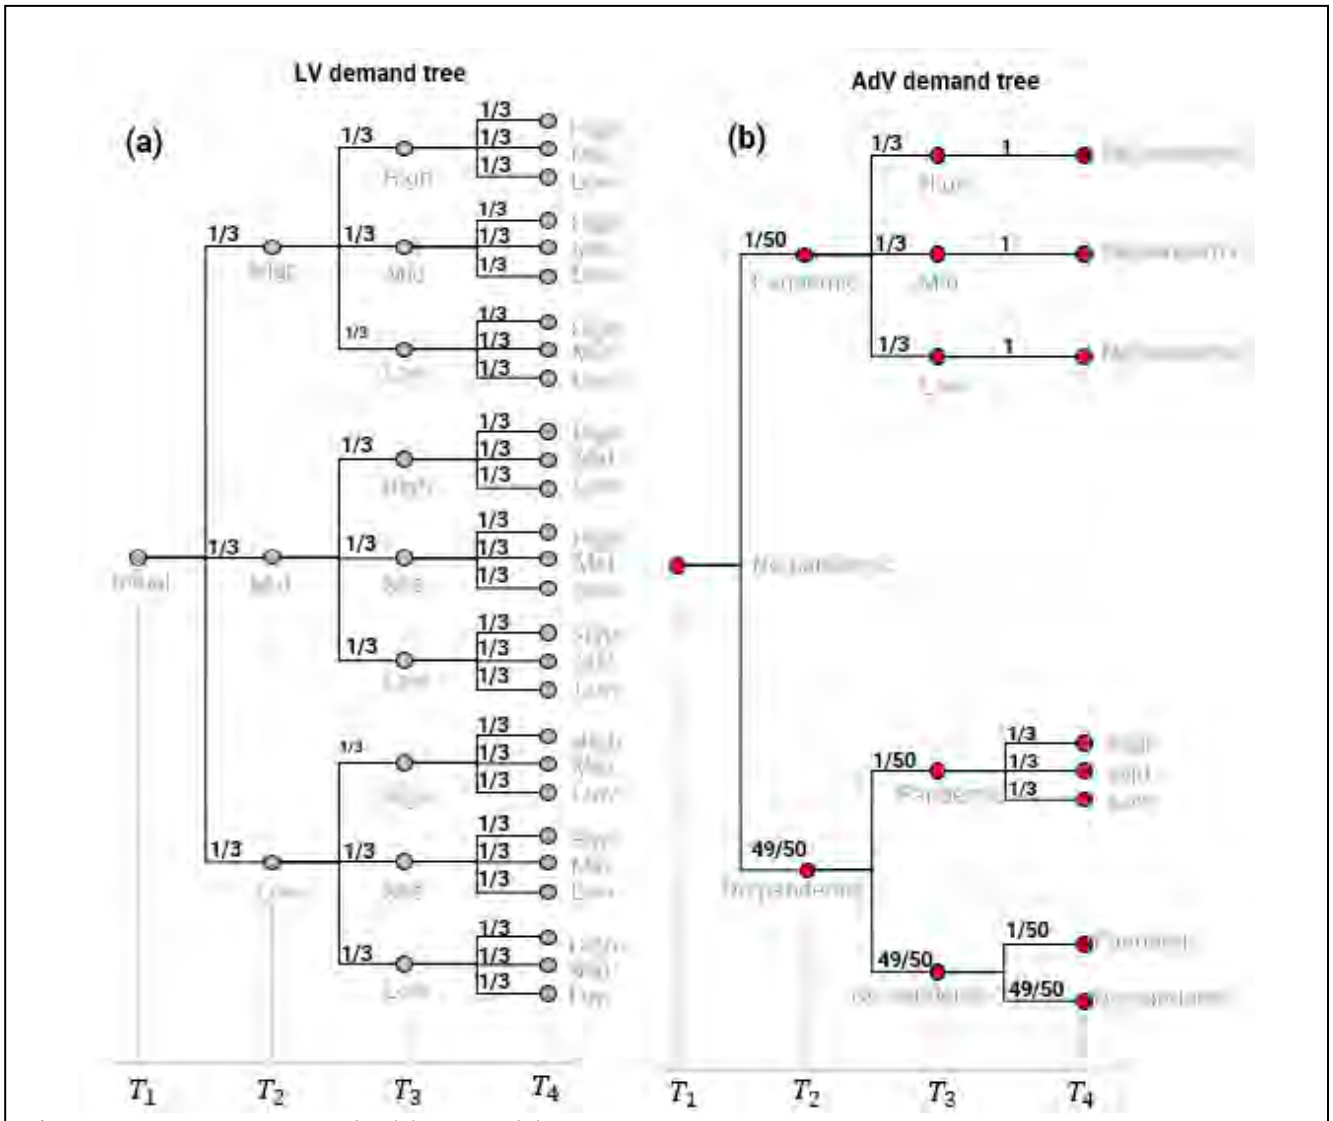

**Figure 2:** Demand scenarios for (a) LV and (b) AdV.

and process-specific throughput parameters, including the bottleneck time $\tau$, the process time $\alpha$ and changeover time $\kappa$, accounting for the time required to process the first batch within the campaign and the subsequent ones in shorter intervals (Eq. 24). In Eq. 25 the number of batches processes within each section $s$ is regulated by a material balance. Furthermore, network balances (Eq. 26-29) regulate the accumulation of inventory within the manufacturing nodes and the shipment of products so that the sales demand constraint is met (Eq. 29) for each product $i$, demand zone $n \in N^Z$ in each time period $t$ and demand scenario $y$. The location-specific product demands $D$ are a function of the total demand in each scenario $D^T$, which is an input within the optimization (Figure 2). Transport flows $Q$ are also regulated by upper bounds and lower bounds (Eq. 31). Non-anticipativity constraints are included in the formulation to ensure that scenarios remain indistinguishable until realization (Eq. 32), enforcing that all scenario-dependent variables are equal across the set of indistinguishable scenario pairs $\Delta$ at each stage $t$ .

Finally, the MU case requires additional constraints based on the assumption that the installation of additional capacity is not considered a recourse action, hence scenario-dependent. In Eq. 33-35, equipment installation binaries are forced to be equal across scenario and made *first-stage* decisions.

## Demand scenarios

A total of 216 scenarios $y \in D^S$ each with a probability of $\Pi_y$ is obtained by combining LV and AdV scenario trees. As can be seen in Figure 2a, LV scenarios consider that at a first stage demand corresponds to a nominal value (10,000 doses per year). As time progresses, demand may realize to be *high* (20,000 doses per year), *mid* (10,000 doses per year), *low* (5,000 doses per year), with equal probabilities 1/3 each year, capturing irregular demands for cancer therapies. Mariani et al.[11] estimate probability of a pandemic outbreak per year of 1/50, hence the AdV scenario tree (Figure 2b), captures *non-pandemic* and *pandemic* yearly outcomes. In the former case, the tree branches into pandemic/non-pandemic scenarios at $T_2$ . In the latter case, the demand for vaccines is *high* (400 million doses per year), *mid* (200 million doses per year), or *low* (100 million doses per year), due to market competition and/or issues with side-effects post commercialization. The pandemic is assumed to resolve within 2 years, hence demand is 0.

## Process uncertainty integration

Early-stage process uncertainty is integrated within the problem via a two-stage worst-case optimization approach (WO). This is compared to a deterministic-process approach (DET), whereby process uncertainty is not integrated. In WO, risk-averse decision-making is assumed, in order to avoid early-stage shortages. Process uncertainty is present at $t \in T_1$, whilst a deterministic realization at a median value (Sarkis et al.[10]) is assumed in subsequent time period, as knowledge is acquired in later time periods. To this end, the throughput related uncertainty quantified in Sarkis et al. is assumed to be described by *box uncertainty* sets for each parameter. Therefore:

$$u = \begin{Bmatrix} \chi_{ait}^{MIN} \le \chi_{ait} \le \chi_{ait}^{MAX}, \forall a,i,t \in T_1 \\ \tau_{st}^{MIN} \le \tau_{st} \le \tau_{st}^{MAX}, \forall s,t \in T_1 \\ \alpha_{st}^{MIN} \le \alpha_{st} \le \alpha_{st}^{MAX}, \forall s,t \in T_1 \end{Bmatrix},$$

where $\chi^{MIN}, \chi^{MAX}$ are bounds for process yield $\chi$ at scale $a$, for product $i$ and the first time period, $\tau^{MIN}, \tau^{MAX}$ are bounds for process time within section $s$, and $\alpha^{MIN}, \alpha^{MAX}$ are bounds for bottleneck time in section $s$. To formulate the worst-case deterministic optimization problem requires the following modifications for Eq. 24 and Eq. 29 within the first stage $T_1$, as follows:

**Eq. 24':** $B_{tnasliy} = W_{tnasliy} + \tau_{st}^{MAX}\left(T_{tnasliy} - \alpha_{st}^{MAX} W_{tnasliy} - \kappa C_{tnasiy}\right) \quad \forall t \in T_1, n \in N^J, a,s,l,i,y$

**Eq. 29':** $\sum_{a \in A} S_{tnaiy}\, \chi_{ait}^{MIN} \ge D_{tniy}\ \forall t \in T_1, n \in N^Z, i,y$

## Computational statistics

The MU multi-stage formulation involves a smaller problem size compared to SU because it involves less scenario-dependent decisions (Table 2). The model is implemented in PYOMO, solved with GUROBI v11 via high-throughput computing (1 node, 48nCPUs, RAM:100GB). The optimality gap threshold is set to 10% to obtain a solution to compare within 48h. Strategies to address problem scalability are discussed as part of research outlook.

**Table 2:** Computational statistics of MU vs SU optimization: constraints, integer (binary) and continuous variables, optimality gap.

| Case | CPU(s) | Cons. | Int. (Bin.) | Cont. | Gap(%) |
|---|---|---|---|---|---|
| MU | 25,715 | 878,916 | 1,369,544 (1,120,280) | 878,916 | 7.80 |
| SU | 36,513 | 2,258,780 | 1,379,864 (1,130,600) | 878,916 | 4.19 |

# RESULTS & DISCUSSION

## Techno-economic analysis

Outputs of techno-economic analysis correspond to the optimization cost coefficients $c$, defined for each cost category *VAR*, *FAC* and *LAB*, process section $s$, scale $a$ and product $i$. Figure 3 illustrates cost breakdowns for LV and AdV platforms implementing either SU or MU

equipment, with a focus on the $a = 2000$.

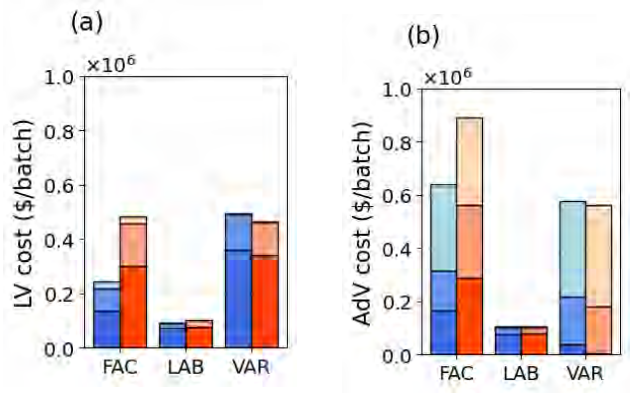

**Figure 3:** Cost breakdown for SU vs MU manufacturing platforms for LV manufacturing (a) and AdV manufacturing (b).

In Figure 3a, facility cost reductions up to 50% are achieved in the SU case for the production on LV in all parts of the process. This mostly holds for AdV too; however AdV facility costs of F&F are critical and are equivalent for both the MU and SU case, since only the formulation equipment is less costly through the use of disposable plastic bags alternatives (Figure 3b).

In comparison, labor-related costs are reduced by approximately 10% with respect to MU labor cost because of resulting shorter process times in the SU process. An underlying assumption of the techno-economic model is the linear relation between process times and total labor cost per batch which is obtained by multiplying process time by a predefined hourly rate. Due to shorter process times with removed steam-in-place/clean-in-place (SIP/CIP) steps, SU equipment results in lower labor costs per batch. Focusing on variable costs, the cost per batch in SU equipment is larger than the MU case (Figure 3a). This is due to a larger number of consumables being required in SU manufacturing compared to MU. This is also seen in AdV manufacturing (Figure 3b), where variable costs for USP, DSP and F&F result higher than the MU counterpart. Overall the percentage increase varies due to process differences, due to materials (LV) and process steps (AdV).

Figure 3 displays costs normalized *per batch*, showing that SU results in lower costs per batch compared to MU. Reductions in facility-dependent cost outweigh the marginal larger variable costs and this already suggests the selection of SU equipment for all process sections, if a cost optimization is performed.

## Optimization problem solution

In this work, early-stage throughput uncertainty is integrated in a multi-stage stochastic planning problem on the demand side, via a two-stage worst-case optimization approach on the process side, considering a time-dependent single uncertainty realization. The impact of this risk-averse approach to decision-making is mainly seen in first-stage decisions and initial investments. In Figure 4a, the MU case optimization (WO) installs a 4-times larger volumetric capacity compared to the deterministic-process (DET) stochastic solution. This is also seen in the cumulative volume trends in Figure 4a. In later

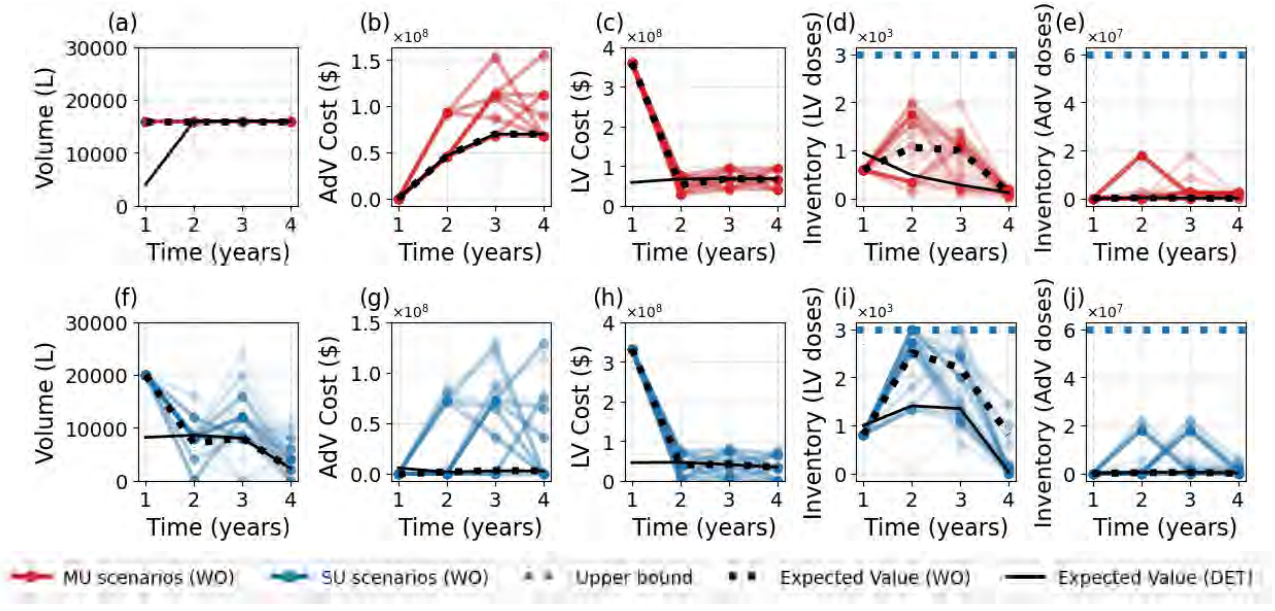

**Figure 4:** Stochastic optimization results for MU case (a-e) and SU case (f-j). Results integrating worst-case optimization w.r.t. to process uncertainty (WO) are displayed, alongside a deterministic (process side) benchmark (DET).

time periods, new investments are not required and capacity remains constant, fulfilling all demand scenarios and converging to the same investment plan proposed by the deterministic model. In the SU case, a significantly initial larger capacity is installed compared to the deterministic case (Figure 4e).

The initial overdesign of a WO approach propagates mainly to expected costs of LV productions, which result significantly higher initial costs compared to the DET stochastic solution (Figure 4c,h). Instead, AdV expected costs result similar in both the WO and DET approach (Figure 2b-g). In this case, risk-averse decision-making does not propagate to later stages of planning because of manufacturing of AdV starting only at $t > T_1$, whereby before $D_{AdV}^{T} = 0$ for all scenarios. Hence, process uncertainty impacts products manufactured within the time period of interest and its integration leads to 4-fold increases in cost for both MU and SU.

Furthermore, an impact is seen in terms of operational decisions, specifically with respect to LV inventory planning. In Figure 4d, the WO approach leads to a stochastic plan with smaller expected inventories in early stages, as these are expected to be more costly to manufacture due to the worst-case performance assumed. To make up for lower initial inventories, LV inventories are accumulated in later time periods in both the MU case and SU case (Figure 4e,i). Specifically, in the SU case, given the expected lower costs, the optimization makes use of the assets available to accumulate inventories early on, allowing a shaper reduction in production levels at $t = T_3$ and $t = T_4$.

Finally, when comparing the expected costs and performance of SU-based equipment and the MU-based counterpart, the short recourse actions and adaptability of SU-based networks allows for a reduction in expected costs, especially for AdV manufacturing (Figure 4b). This mainly relates to scenario-independent equipment installation decisions, forcing designs to cater for pandemic scenarios irrespective of their probability of occurrence. This assumption can be modified to manufacturer-specific set-up timelines; however, options with better flexibility, allowing on-demand manufacturing, will be likely be tied with the most cost reductions during operation, which become more significant that those related solely to nominal techno-economic performance.

## CONCLUSIONS & OUTLOOK

As the pharmaceutical industry requires the establishment of increasingly flexible and responsive manufacturing networks, the development of advanced planning tools that integrate various sources of quantifiable uncertainties becomes critical. In this work, stochastic optimization-based tools are developed to assess the flexibility of fixed multi-use manufacturing equipment compared to single-use manufacturing and quantify expected cost benefits. The problem also considers the integration of early-stage process uncertainty through deterministic approaches and allows the assessment of the impact of risk-averse decision-making versus disregarding this uncertainty. Overall, modular single-use equipment promises improvements in pandemic preparedness and reductions in expected costs, including cases whereby process uncertainty is considered. Effectively, this paves the way to resilient networks which can better withstand unforeseen events.

As further research, the integration of a product-dependent trajectory of the worst-case approach would allow process uncertainty to be considered at the first-stage with respect to the first realization of the corresponding demand. Additionally, investigating the integration of a formal two-stage robust optimization approach could reduce the conservativeness of worst-case solutions, as feasible solutions are sought and optimization is not performed considering the worst-case scenario exclusively, but rather the entirety of the uncertainty set. Finally, scalability issues could be addressed through shorter planning horizons, clustering scenario-outcomes or using decomposition-based approaches. In the former case, a rolling horizon approach would be suitable, thereby solving at each time step a reduced stochastic problem considering demand uncertainty and integrating process uncertainty once a demand for a new product is realized.

## ABSTRACT

This work introduces a *Python*-based interface that couples cradle-to-gate Life Cycle Assessment (LCA) with advanced process simulations in continuous biomanufacturing, resulting in dynamic process inventories and thus to dynamic LCA (dLCA). The open-source *Brightway2.5* framework is used to dynamically track environmental inventories of the foreground process and LCA indicators (e.g. damage to ecosystems according to ReCiPE 2016) from the v3.10 cut-off *ecoinvent* database. The framework is applied to KTB1, a dynamic *MATLAB–Simulink* benchmark model of continuous Lovastatin production. 580 data points are computed across four different 24-hour scenarios. The difference between the hourly and the averaged foreground scenario is between 20-30%; a more pronounced deviation is observed when both background and foreground are averaged. The dLCA framework precisely identifies optimal periods for cleaner electricity usage, enabling future work on direct environmental feedback into process control and optimization for greener high-quality biomanufacturing.

**Keywords**: Dynamic Life Cycle Assessment, Continuous Biomanufacturing, Python-Based Process Optimization, Life Cycle Assessment.

## INTRODUCTION

Increasing sustainability targets have shift the paradigm in Process Systems Engineering (PSE), now requiring process simulation and optimization to incorporate broader sustainability metrics alongside economic and operational considerations. In the biopharmaceutical sector, continuous manufacturing is still in its early stages, offering potential advantages such as stable operation, enhanced product consistency, and improved operational control compared to traditional batch approaches. While continuous processes offer new opportunities, sustainability assessments of such systems typically rely on the E-factor as an environmental indicator[1]. This approximation neglects the transient behaviour and time-dependent changes in input-output flows. Dynamic LCA (dLCA) seeks to address this gap by integrating temporal resolution into life cycle inventories. Recent examples include real-time IoT-based LCAs for wind turbines[2].The importance of this temporal dimension is amplified when considering fluctuating energy inputs and operational strategies designed to meet product quality and environmental objectives simultaneously[3].

This study applies Brightway2.5, an open-source LCA framework[4], to the KTB1 MATLAB–Simulink biomanufacturing benchmark[5]. KTB1's hourly energy usage can be paired with v3.10 cut-off *ecoinvent* database under Danish electricity mixes[6]. The integration of dLCA with process control enables real-time environmental impact feedback, facilitating operational adjustments aligned with cleaner electricity periods.

This analysis opens the door to real-time or near real-time operational adjustments incorporating "environmental signals", establishing a foundation for further exploration into how time-resolved inventories can improve the accuracy of dLCA's , not only by diagnosing environmental impacts but also optimizing them on the fly, taking advantage of electricity mix fluctuations and process flexibility, underscoring the value of aligning operating strategies, such as maintenance scheduling and

process restarts, with greener electricity profiles, thus guiding more sustainable continuous production.

## METHODOLOGY

### System Description & Functional Unit

The selected application is the production of the biopharmaceutical product, lovastatin, in a continuous process flow (the KTB1 model)[5]. KTB1 model provides a comprehensive dynamic representation of the entire biomanufacturing chain, including upstream (fermentation or bioreaction) and downstream (purification and finishing) stages. The functional unit is defined as the production of 40 mg of pure API Lovastatin, a representative maintenance dose commonly encountered in pharmaceutical formulations.

**Table 1:** Process Units and Corresponding Models of KTB1

| Unit | Name | Model |
|---|---|---|
| Mixer | M-101 | Dynamic mass balance |
| Fermenter | R-101* | Dynamic mass balance & Monod kinetics |
| Hydrocyclone | HC-101* | Mass balance fractionation, and separation factor |
| Centrifugue | C-101-102* | biomass removal with separation factor |
| Pump | VSP-101* | Pressure-driven flow |
| Nano-filtration | NF-101 | pressure-driven nanofiltration, lactose rejection factor |
| HPLC | LC-101-106 | Langmuir isotherm & film transfer |

* Units explicitly considered in the dLCA

**Figure 1** shows the boundaries of the system. **Table 1 briefly** concisely summarises the included process units and their respective models. For this dLCA, we specifically capture hourly electricity usage in the core upstream and downstream equipment's marked with an asterisk (*) in Table 1 as the dominant resource consumption relevant to time-varying impacts. Other flows (e.g., chemicals, water) can be treated as minor or average inputs and are not dynamically tracked in this study. Further methodological details are available in[5].

### Dynamic Process Modeling & Scenario Design

The KTB1 simulation model captures the nonlinear behavior of continuous biomanufacturing, accounting for upstream and downstream interactions under changing operating conditions. We track hourly electricity consumption over a 24-hour horizon to capture a typical full operational day and reflect that the system stabilizes after a few hours, making longer observation periods less informative for this particular case study. The framework, however, allows flexibility to choose any time frame as long as the process consumption data and the electricity mix data are temporally synchronized at identical sampling intervals (e.g., a consumption measurement at 14:00 aligns with the 14:00 grid share of the same day). The study combines two operational modifications with two Danish electricity profiles:

- Case 1: Reactor working volume reduced from 5000 L to 4900 L at hour 0.
- Case 2: Feed carbon lowered from 20 g/L to 16 g/L at hour 0.
- Winter: Electricity mix on 2025-01-14.
- Summer: Electricity mix on 2024-08-08.

This results in the following scenarios: Scenario 1 (S1): case 1 + winter; scenario 2 (S2): case 1 + summer; scenario 3 (S3): case 2 + winter; scenario 4 (S4): case 2

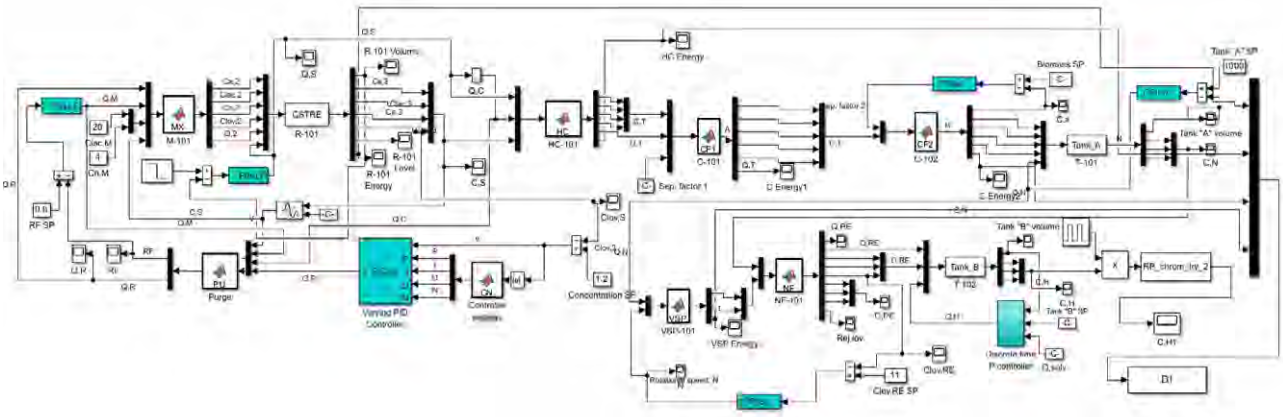

**Figure 1:** Visual representation of the process flow diagram for the production of the Active Pharmaceutical Ingredient (API) lovastatin.

+ summer]. **Figure 2** shows the graph obtained when representing the variation of electricity demand in case 1. For each hour, the model records energy usage in Watt for these critical units*. By tracking how these two operational adjustments shift consumption profiles, we construct time-resolved inventories for dynamic LCA (electricity demand databases available in supplementary material).

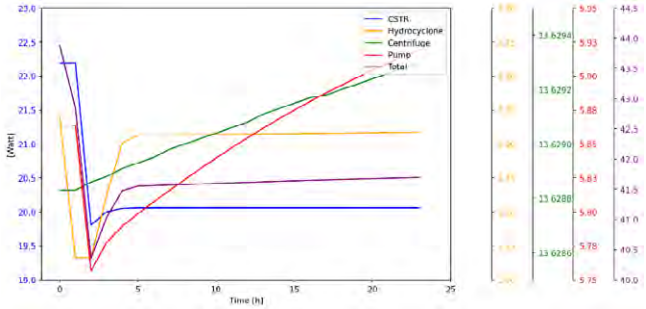

**Figure 2.** Foreground dynamism: CSTR, feed Pumps, Hydrocyclone, Centrifuge and Total hourly electricity consumption profile in Watt for the KTB1 model over a 24-hour horizon, illustrating how the reduction of the reactor working volume leads to varying power demands.

Thus, the dLCA framework can operate in real-time or near-real-time conditions (e.g., hourly electricity consumption data can also be captured by the sensors in CSV files). This can enable adjustments to improve operational conditions during the process based on a richer "signal" that contains environmental impact information, while of course meeting the production specifications (e.g., productivity, and product quality). This adaptive approach highlights the framework's potential to optimize decision-making during continuous operation rather than relying solely on retrospective analysis.

## Electricity Mix Variation

Denmark's electricity supply fluctuates hourly, as it draws on a diverse range of sources: Wind Onshore, Wind Offshore, Solar, Waste, Fossil Oil, Hydro (Run-of-River and Poundage), Biomass, Fossil Hard Coal, Fossil Gas, and Other Renewables (see **Figure 3**). Each source carries distinct environmental intensities, and their proportional contributions vary significantly across the day. In this study, ENTSO-E data is used for 2025-01-14 (winter) and 2024-08-08 (summer) to obtain each hour's share of these generation types (electricity share databases available in supplementary material)[7]. The hourly share fraction of each electricity source type is determined from ENTSO-E database, and proportionally allocated to the Life Cycle Inventory (LCI) for that hour, reflecting the evolving grid mix in real time. Two representative days (winter and summer) were chosen. More extensive periods or alternative dates could equally be modeled if longer-term or season-specific trends were of interest. This background data can also be captured in CSV files and integrated hourly in real time or near-real time.

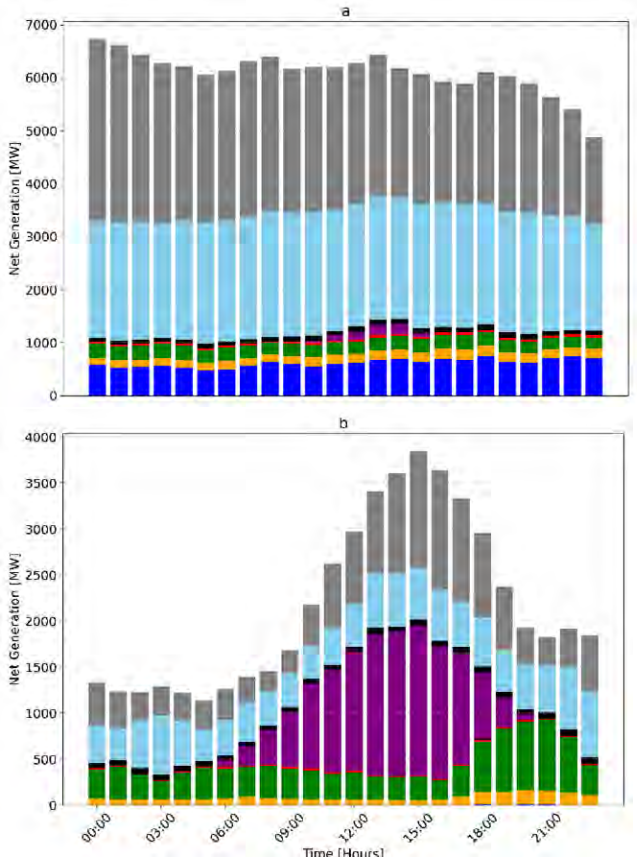

**Figure 3.** Background dynamism: Hourly net electricity generation in MW by technology for a 24-hour Danish grid profile. The stacked bars illustrate the contribution of different energy sources: Biomass (blue), Fossil Gas (orange), Fossil Hard Coal (green), Fossil Oil (red), Solar (purple), Waste (black), Wind Offshore (sky blue), and Wind Onshore (gray). (a) represents the winter electricity mix on 2025-01-14, while (b) illustrates the summer electricity mix on 2024-08-08.

## Dynamic Life Cycle Inventory & Impact Assessment

A dynamic LCI is constructed by mapping each hour in KTB1 (demand in the foreground) to the corresponding electricity flows from Denmark's grid mix (background). Because the grid composition (wind, solar, fossil gas, waste, etc.) varies hourly, each equipment–hour node is matched to the relevant *ecoinvent* v3.10 activities. For instance, at hour 5 in the winter scenario, the grid shows 1.37 % waste incineration and 36.0 % wind offshore for the winter scenario; partial consumption is allocated to "electricity, from municipal waste incineration" and "electricity production, wind, 1–3 MW turbine, offshore."

Technically, each hour × equipment pair is treated

as a distinct demand entry in Brightway25, forming a demand matrix that scales the appropriate *ecoinvent* processes by the hour's measured consumption in Watt. To perform the integral of energy use over each one-hour interval, we apply the following approximation given the relatively small variation:

$$\int_{t_i}^{t_i} \mathrm{X(t)dt} \approx \left[\mathrm{X(ti)} + \frac{X_{(t_{i+1})} - X_{(t_i)}}{2}\right] \times (t_{i+1} - t_i) \quad (1)$$

X(t) represents the time-varying energy-demand function, while $X_{(t_i)}$ and $X_{(t_{i+1})}$ denote its values at the start and end of the *i*-th hour, respectively.

A Python interface performs these conversions and compiles the time-resolved inventory, using *Temporalis*, a *Brightway25* extension, to run LCIA with the method *ReCiPe 2016 v1.03 endpoint (E), total: ecosystem quality*. Although only electricity is dynamically tracked here, the methodology readily supports adding other utilities or flows. By automatically updating the foreground model's consumption nodes each hour and linking them to background activities in *ecoinvent*, the approach captures temporal variations in environmental impacts. Consequently, it can continuously calculate any chosen LCIA indicators, given dynamic inventory data for any region or timescale.

### Calculation strategy for dynamic and average scenarios

To systematically capture how variations in both the foreground (X(t)) and background (Y(t)) affect the results, we analyze four scenarios (S1–S4) as follows:

We perform a fully dynamic pairing of hourly equipment demands (foreground) with the hour-by-hour Danish electricity mix (background), yielding 24 points per scenario for five process units (CSTR, Hydrocyclone, Centrifuge, Pump, and "Total"). That is 480 points total across the four scenarios. These results are integrated and multiplied:

$$\int_{t_i}^{t_i} \mathrm{X(t)Y(t)dt} \quad (2)$$

We then create a "dynamic-background, average-foreground" variant by combining each scenario's average demand with the same hourly grid mix, producing 96 points in total:

$$\overline{\mathrm{X(t)}} * \int_{t_i}^{t_i} \mathrm{Y(t)dt} \quad (3)$$

Lastly, we use a single "average demand" and the *ecoInvent* average electricity mix, giving 4 points total:

$$\overline{\mathrm{X(t)}}\ \overline{\mathrm{Y(t)}} \quad (4)$$

## RESULTS

### Dynamic Life Cycle Assessment Profiles

In **Figure 4**, each sub-figure (4.a–4.d) shows the hourly ReCiPe endpoint (ecosystem quality) scores for one of the four scenarios (S1–S4). In Case 1, the reactor volume reduction (5000 L to 4900 L at hour 0) transiently changes each unit's power demands. **Figures 4.a** and **4.b** show the hour-by-hour impact of the CSTR, hydrocyclone, centrifuge, and pumping tasks, plus a "Total" curve, under winter and summer Danish grid compositions, respectively. This operational shift slightly lowers the equipments' electricity demand in the first few hours (see **Figure 2**). However, whether that translates to a larger or smaller overall score at each hour also depends on the background mix (e.g., higher fossil fractions or more renewable sources, see **Figure 5**). Comparing the purple curves (total impact calculated with hourly foreground × hourly background (2)) with the total black curves (total impact calculated with average foreground × hourly background (3)) shows that both the foreground and background influence the results. If the effect of hourly foreground changes were negligible, these lines would follow an identical pattern.

**Figure 4.b** and **Figure 4.d** illustrate two different foreground operational adjustments while sharing the same seasonal background profile (see **Figure 3.b**). Around hour 15, all impact score curves show a slight dip, coinciding with hours that have higher proportions of lower-impact technologies (e.g., solar and wind onshore). The strong fluctuation in the electricity mix seems to have significant relevance in the impact score around this hour.

Winter vs. Summer reveals how hour-to-hour variations in technology shares combine with the equipment's consumption changes. In some winter hours, a heavy fossil fraction (e.g., fossil hard coal) markedly increases the score for that time step, while summer hours with higher solar or wind can lower it. Comparing the LCA factor for each technology explains these patterns: one MWh from fossil oil may yield ~5 × 10^(-5) in ecosystem quality, whereas one MWh from solar might be near 1 × 10^(-5) (see **Figure 5**). Hence, an hour with 40 % fossil oil has a more pronounced impact than an hour with 40 % wind offshore (tables with numerical values available in supplementary material). Because these variations are applied each hour to whichever process unit is consuming energy at that time, the resulting ReCiPe scores (blue, orange, green, red lines in **Figure 4.a.** and **4.b**) do not simply mirror the consumption shape from **Figure 2**, but also reflect the changing background. Taken together, these results show that operational changes at hour 0 (Case 1 or Case 2) intersect with dynamic technology shares to yield unique hourly ReCiPe scores.

### Comparative Analysis between Dynamic vs. Single-Average LCA

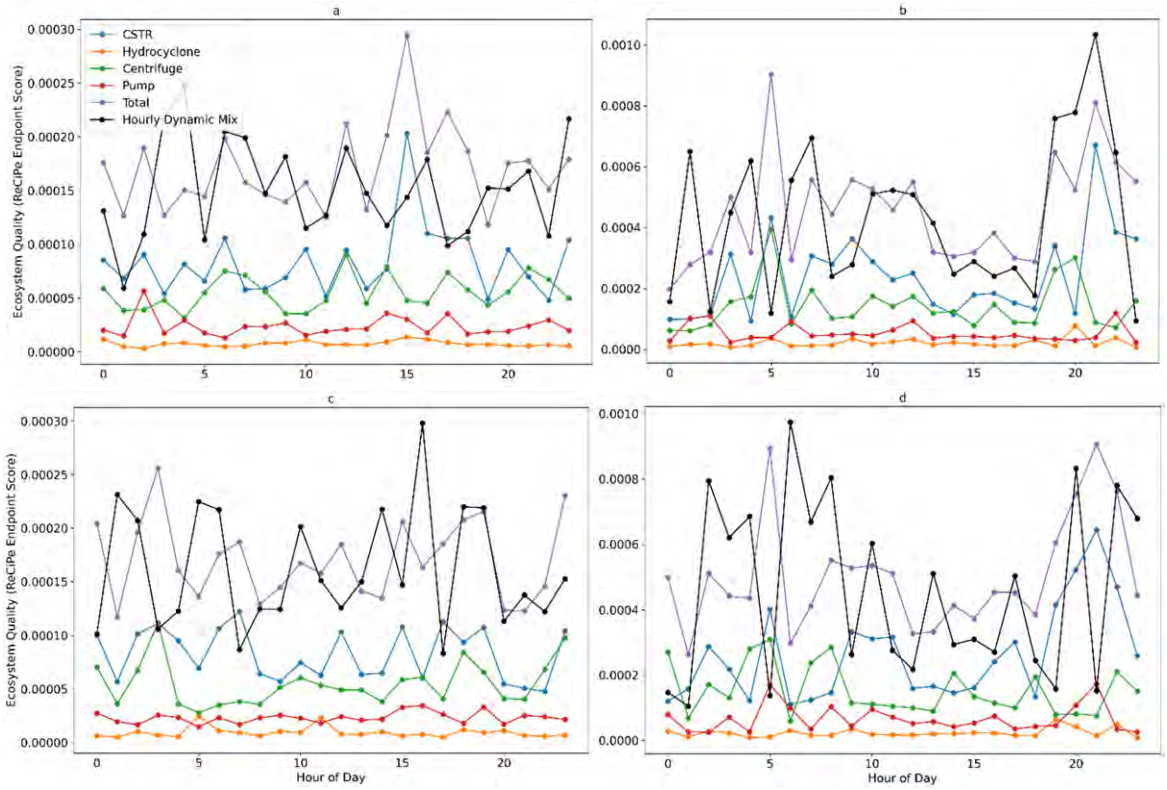

**Figure 4:** Hourly ReCiPe Endpoint (ecosystem quality) scores for the four scenarios, showing each KTB1 unit. Colored lines depict the foreground demand contributions of each critical unit calculated with (2): CSTR (blue), Hydrocyclone (orange), Centrifuge (green), Pump (red), while purple shows the hour-by-hour total. The black curve ("Hourly Dynamic Mix") represents a background-only dynamic approach where the average demand is allocated to the hourly electricity grid mix, calculated with (3). 4.a: S1; 4.b: S2; 4.c: S3; 4.d: S4.

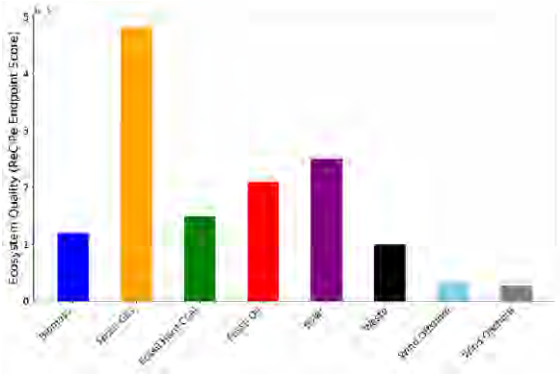

**Figure 5.** LCA Score *ReCiPe 2016 v1.03 endpoint (E), total: ecosystem quality* for 1 MWh Electricity by Technology from *ecoinvent*.

**Table 2** reports the ReCiPe 2016 (ecosystem quality) results for four scenarios (S1–S4), each evaluated under three approaches: (2) fully dynamic (hourly foreground × hourly background), (3) dynamic background, average foreground, and (4) single-average (both foreground and background). For instance, S1 (Case 1, winter), dynamic calculation yields $4.08 \times 10^{-3}$, approach (3) gives $5.08 \times 10^{-3}$, and approach (4) is $2.73 \times 10^{-2}$.

**Table 2:** Comparison of Single-Average vs. Hourly-Summed LCA Scores

| Scenario | (2) | (3) | (4) |
|---|---|---|---|
| S1 | 4.08E-03 | 5.08E-03 | 2.73E-02 |
| S2 | 1.10E-02 | 1.56E-02 | |
| S3 | 4.09E-03 | 5.83E-03 | 2.87E-02 |
| S4 | 1.21E-02 | 1.65E-02 | |

Moving to S2, the single-average approach (4) remains constant (2.73 × 10^(-2)) irrespective of winter or summer, because the same average activity and identical average demand are used in both seasons to perform the calculation. The comparisons between (2) and (3) in the four scenarios underscore how hourly fluctuations in the foreground (electricity demand) can shift the LCA score by 19.75%, 29.52%, 29.77%, and 26.93% for S1-S4. The order of magnitude difference with respect to (4) is influenced by the way the average of the electricity mix is cal-

culated in the *ecoinvent* inventory. By collapsing the dynamic variability into one blend, single-average LCA may underestimate or overestimate real burdens. Although the absolute scale of electricity demand in a typical biopharmaceutical process might appear smaller compared to large-scale chemical production, the energy consumed per kilogram of final product could have a cumulative energy demand (CED) 20 times higher, and a global warming potential (GWP) 25 times higher than typical large-scale basic chemical production[8] . In our KTB1 case, we measured an average electricity usage of 135 MJ $kg^{-1}$ of product. Thus, even if the total energy consumption appears moderate in an absolute sense, the environmental burden per kilogram of pharmaceutical product remains substantial. This observation highlights why this application is a pertinent demonstration of the relevance of time-resolved LCA. With these hour-by-hour signals, a multi-objective scheduling algorithm could, for instance, delay a high-power centrifugation step by two hours until the fossil fraction drops, reducing its endpoint score by more than 25%. Similarly, model predictive control can exploit forecasted grid mix data to adjust flow rates, turn down certain pumps temporarily, or time process restarts so that the bulk of the energy draw coincides with greener electricity. In contrast, relying on a single, static grid-mix average overlooks these opportunities for optimization, potentially overestimating or underestimating true impacts and missing out on practical ways to cut emissions.

## DISCUSSION & CONCLUSIONS

This work presents a dynamic LCA framework integrated with a continuous biomanufacturing model (KTB1). By linking a *Python*-based interface with the *Temporalis* (*Brightway2.5*), and utilizing the *ecoinvent* 3.11 database and ReCiPe characterization methods, we capture time-resolved environmental impacts that account for hourly fluctuations in the Danish electricity mix.

A total of 580 LCA points and 4640 nodes (580 × 8 activities) were computed in only 24 hours of operation considering electricity demand of a few equipments.

From an LCA perspective, two key conclusions emerge. Collapsing hourly variability into one mix can over- or underestimate actual burdens, especially in high-energy or fossil-heavy hours. A dynamic approach ensures that each operational load is mapped to the correct background technology, giving a more faithful representation of life-cycle impacts. The fine-grained LCA signals from hour-to-hour identify ideal windows presents a potential in continuous biomanufacturing to schedule energy-intensive operations (e.g., re-starts following contamination, maintenance).

Beyond these findings, the underlying framework and interface are generalizable. Any LCIA method may be substituted here, provided the user has time-resolved foreground consumption and background data. The approach scales to longer production cycles, larger databases (e.g., multiple regions, multiple seasons), or additional scenarios (e.g., different feed compositions, varied capacity expansions). In particular, other fields that could strongly benefit from dLCA are, for instance, batch processes due to its substantial variability in the foreground. Similarly, high-energy consuming operations can exploit background fluctuations for scheduling or control interventions. Regarding the background control, dLCA is particularly relevant in energy system optimization.

Future work will focus on extending programs to run longer cycles (e.g., multiple days or weeks), implementing advanced scheduling, and evaluating the economic–environmental trade-offs through *multi-objective optimization*. This logic extends to advanced *multi-objective model predictive control*, where real-time data on electricity sources could guide setpoints to concurrently optimize throughput, product quality, and environmental performance.

## DIGITAL SUPPLEMENTARY MATERIAL

Digital supplementary materials for this study, including electricity demand datasets for cases 1 and 2, electricity share databases for Denmark, and numerical tables with results, are available at the following GitHub repository: https://github.com/AdaRobinsonMedici/ES-CAPE-35

## ACKNOWLEDGEMENTS

The authors acknowledge DTU for the open-source development of the KTB-1 benchmark simulation model, as well as Charles Breton, Nathalia Silva de Souza Lima Cano, and De Santier organization for the contributions during Autumn School 2024.

## ABSTRACT

Reactive crystallization (RC) is a chemical process in which the reaction yields a crystalline product. It is used in various industries such as pharmaceutical manufacturing or water purification. In some cases, RC is the only feasible process pathway, such as the precipitation of certain ionic solids from solution. In other cases, a reaction can become a RC by changing the reaction environment to a solvent with low product-solubility. Despite the utility and prevalence of RC, it is not often emphasized in process design software. There are RC models that simulate the inner reactions and dynamics of a RC, but each has limiting assumptions, and are difficult to integrate with the rest of a process-line simulation. This modeling gap complicates RC process design and limits the exploration of the possible benefits to using RC as well as the ability to optimize a system that relies on it. To fill this gap, we built an open-source, customizable model that can be integrated with other unit operations in the Python process simulator package PharmaPy. This model focuses on the reaction-crystallization interactions and dynamics to predict reaction yield and crystal critical quality attributes given inlet streams and reactor conditions. In this way, RC can be integrated with other unit operations to capture the effects RC has on the process overall. The model and assumptions are described in this work. The model space, limitations, and capabilities are explored. Finally, the potential benefits of the RC system are shown using three example cases.

**Keywords**: Process Intensification, Process Design, Crystallization, Reactive Crystallization

## INTRODUCTION

Crystallization is a complex process highly relevant to numerous fields ranging from pharmaceuticals to agricultural chemicals [6]. It can be used to produce a solid product or simply as a separation technique for product purification. Reactive crystallization (RC) is the intensification of the crystallization process with the reaction that generates the crystallizing product.

The intensification of RC leads to multiple unique advantages. First, if the desired product exists in equilibrium with the reactants or a byproduct, or if the desired product is an intermediate species, RC provides a method for isolating the species away from the reaction. As solids are much more stable than liquid or gases, the crystallization renders the species effectively inert, pushing the reaction towards the crystallizing species due to Le Chatelier's principle thus increasing yield. Another advantage is a reduction of the process footprint. Because RC combines the tasks of a reactor with a crystallizer, a single unit is sufficient instead of the two in series. The final advantage of RC is the potential to remove a recrystallization/separation process if the produced crystals follow the desired critical quality attributes (CQAs).

Intensification comes at the cost of degrees of freedom, increasing the difficulty of control [8]. More difficult control may deter adoption of the technology and therefore must be balanced with the potential benefit [5, 8]. As such, it is necessary to design RC processes with control in mind. Most modern design techniques require the use of a digital model.

Modeling and predicting RC systems is notoriously difficult. Both reaction and crystallization dynamics are governed by concentration; this leads to highly coupled and inseparable numerical systems. Additionally, due to the system's general sensitivity to mixing effects, fluid dynamics are often considered as well. Salami et al. [7],

Tang et al. [9] are excellent examples of such approaches.

High resolution modeling of this nature can require more time to execute the simulation model than for the phenomenon to actually transpire. This prohibits the use of these types of models for real-time control or prediction. To address this problem, an open-source model is created which can simulate faster than real-time but it achieves this by neglecting mixing effects. The goal of this model, therefore, is to capture the overall behavior of the system even if the accuracy is lower than the high-resolution models mentioned. This model can then be customized to include other factors while potentially solving in real-time to be used in applications such as optimization and control.

# METHODS

## Mathematical Model

The RC system can be modeled using differential equations that capture the material and energy balances of the specific operations. A reactive mixed suspension, mixed product removal (RMSMPR) configuration was chosen as the target unit operation to model. This operation has the following assumptions:

1. All reactions only occur in the liquid/dissolved phase. Solids are inert.
2. Reactor volume is considered constant.
3. Agglomeration and breakage are negligible.
4. Crystal growth is size-independent and 1-dimensional.
5. Perfect mixing.
6. Total crystal volume is much smaller than the total reactor volume.

The material balance must include all inlet and outlet streams, as well as describe reactions and crystallization. The material balance used is given in equation 1. Here, equation 1 is written for the concentration $c$ of each species $j$. In this system, $\epsilon$ is the liquid fraction, $W_j$ is the amount of species $j$ that crystallizes, $q_k$ is the flow rate of each stream $k$, $V$ is the volume of the reactor, and $R_j$ is the reaction rate relevant to species $j$.

To capture crystallization behavior, a population balance was used and is shown in equation 2. Here, $L_0$ is the critical length required for the crystal to nucleate, and $\rho_s$ is the density of the slurry. G and B are the growth rate and nucleation rate, respectively. $L$ is the length of the crystal, $n$ is the particle density function of the slurry, and $n_k$ is the particle density function of the stream $k$, and $\delta$ is the dirac delta function. Equation 3 gives the nucleation and growth expressions. Here $S$ is supersaturation, $E$ is the activation energy for growth or nucleation, $k_v$ is the shape factor and $\mu_3$ is the third moment of the crystal size distribution (CSD). $k_b$, $k_s$, and $k_g$, follow the form in equation 4. $k_0$, $b_1$, $s_1$, $s_2$, $g_1$ are empirical parameters. $R$ is the gas constant.

$$\frac{\partial \epsilon c_j V}{\partial t} = \sum_k c_{j,k}\, q_k \epsilon_k + V R_j + V \frac{dW_j}{dt} \quad (1)$$

$$\frac{\partial n(t,L)}{\partial t} + G\frac{\partial n(t,L)}{\partial L} = B \cdot \delta(L - L_0) + \sum_k \frac{q_k}{V} \cdot n_k \quad (2)$$

$$B = k_s S^{s_1} (k_v \mu_3)^{s_2} + k_b exp\left(\frac{-E_b}{RT}\right) S^{b_1} \quad (3a)$$

$$G = k_g exp\left(\frac{-E_g}{RT}\right) S^{g_1} \quad (3b)$$

$$k_x = k_0 exp\left(\frac{-E_a}{RT}\right) \quad (4)$$

## Digital Implementation

PharmaPy is an open-source process simulator with a library of unit operations ranging from reactors and crystallizers to filters and dryers [2, 4]. The package is object oriented, using different classes to represent each unit operation. Instances of each unit operation can then be serially connected to create a flowsheet and solved sequentially to give the predicted behavior of the entire process.

PharmaPy reduces the partial differential equations to ordinary differential equations (ODEs) via the method of lines [2]. These ODEs are then solved using a numerical integrator. To solve the population balance, the one-dimensional finite volume method (FVM) is used. This method involves discretizing across the crystal length coordinate to create a balance for each length step. These equations are then solved using the CVode method from SUNDIALS [3], connected to python via the python package Assimulo [1].

An RC class was created following the PharmaPy syntax. Equations 1, 2 and 3 were used to describe the unit operation behavior, although the exact equations are easily modifiable if other effects such as agglomeration or breakage are desired. By following the PharmaPy layout, the RC class could be added into any flowsheet previously possible in PharmaPy. This flexibility allows the direct comparison of results between flowsheets using RC and those using reactors and crystallizers in series.

# RESULTS

Using the PharmaPy RC model, several example systems were simulated. Each simulation generates outputs which include the predicted reaction profiles, dynamic CSDs, and temperature profiles. Figure 1 shows the crystallization information of the RC for the reaction system: A + B→ C↓ + D, where species C is crystallized as denoted by the downward arrow. The first five subplots (A-E) show the CSD against time in seconds. Figure 1F shows the liquid concentration of the target species, its solubility, and the absolute supersaturation. The parameters for this system are the same as case “A” given in Table 1, where $k_r$ is the reaction rate constant and $E_r$ is the reaction activation energy.

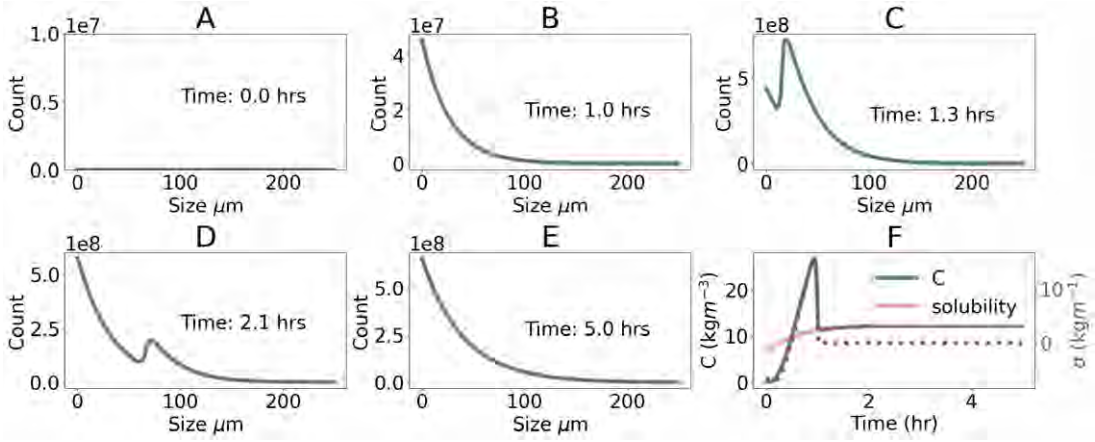

**Figure 1:** The crystal moments (zeroth through third), the unit's temperature, and the concentration/saturation levels throughout time (s) for the simulated reaction system: A + B → C↓ + D

**Table 1:** Parameters for the different runs.

| | $k_b$ $\left(\frac{\#}{\mathrm{m^3 s}}\right)$ | $E_b$ $\left(\frac{j}{mol}\right)$ | b | $k_s$ $\left(\frac{\#}{\mathrm{m^3 s}}\right)$ | s | *s*2 | $k_g$ $\left(\frac{\mu m}{s}\right)$ | $E_g$ $\left(\frac{j}{mol}\right)$ | g | $k_r$ $\left(\frac{mol}{m^3 s}\right)$ | $E_r$ $\left(\frac{j}{mol}\right)$ |
|---|---|---|---|---|---|---|---|---|---|---|---|
| 1, 2A/2B | 8.188 | 0 | 1.124 | 4.18 E+10 | 0.35 | 1 | 9.73 | 11280 | 0.2337 | 1 e-4 | 0 |
| 2C/2D | 8.188 | 0 | 1.124 | 4.18 E+10 | 0.35 | 1 | 9.73 | 11280 | 0.2337 | 2e-4; 1.3e-4 | 0 |
| 2E/2F | 8.188 | 0 | 1.124 | 4.18 E+10 | 0.35 | 1 | 9.73 | 11280 | 0.2337 | 2e-4; 1.3e-4 | 0 |

Figure 1 was generated using the simulator and demonstrates crystallization behavior consistent with a RC system. At t=0, there are no crystals in the RC. As the reaction progresses, the concentration exceeds the solubility, leading to a supersaturated solution as shown in Figure 1F. At a certain point (around 1 hour) nucleation occurs and the liquid concentration quickly reduces to and equilibrates at the solubility point. This results in a sudden uptick in counts of small crystals as seen in Figure 1B. The crystals from the large nucleation event then grow larger while more crystals are nucleating from the continuous addition of reactants. This results in a distribution with high counts of crystals near the nucleation length, and a higher count of crystals slightly larger than the nucleation length. This can be seen in Figure 1C. This batch of larger crystals continues to grow while more crystals nucleate and grow. At the same time, crystals leave the system through the outlet, lowering the count of older, larger crystals. Eventually, the larger crystals from the initial nucleation all leave and the steady state CSD is reached. This can be seen in Figure 1E.

Figure 2C-F showcases the advantage mentioned earlier of increased yield for reversible reactions or reactions where the target is an intermediary. Each column in the figure corresponds to a different reaction setup where species C is the target product, and each row corresponds to either a reactor with no crystallization or a RC. The liquid concentration shown decreases as species C crystallizes in the RC environments. The first reaction case (Figure 2A-B) is simple, and both the reactor and RC behave similarly as expected. If product D were the desired product, then using RC effectively removes the need for an additional separation step if the solubility of C is within the impurity tolerance allowed within D.

The second reactive case is reversible. Figure 2C-D shows that by crystallizing the product, the RC drives the reversible reaction forward due to Le Chatelier's principle. The black line is the overall accumulation of the target product. The figure depicts how the RC in a reversible reaction with these conditions results in a higher yield of the target product, generating 27.5 moles from the RC compared to 25.7 moles in the reactor. In the last reaction case (Figure 2E-F), the target species (C) is an intermediate product. The figure shows that the RC system successfully isolates species C before much of it can further react to form the undesired product E. This results once again in a higher yield of the target product than what a reactor could achieve in the same conditions, producing 25.8 moles from the RC compared to 21.2 moles in the reactor. The parameters used for each case can be found in Table 1. The crystallization parameters used were based on known parameters for paracetamol

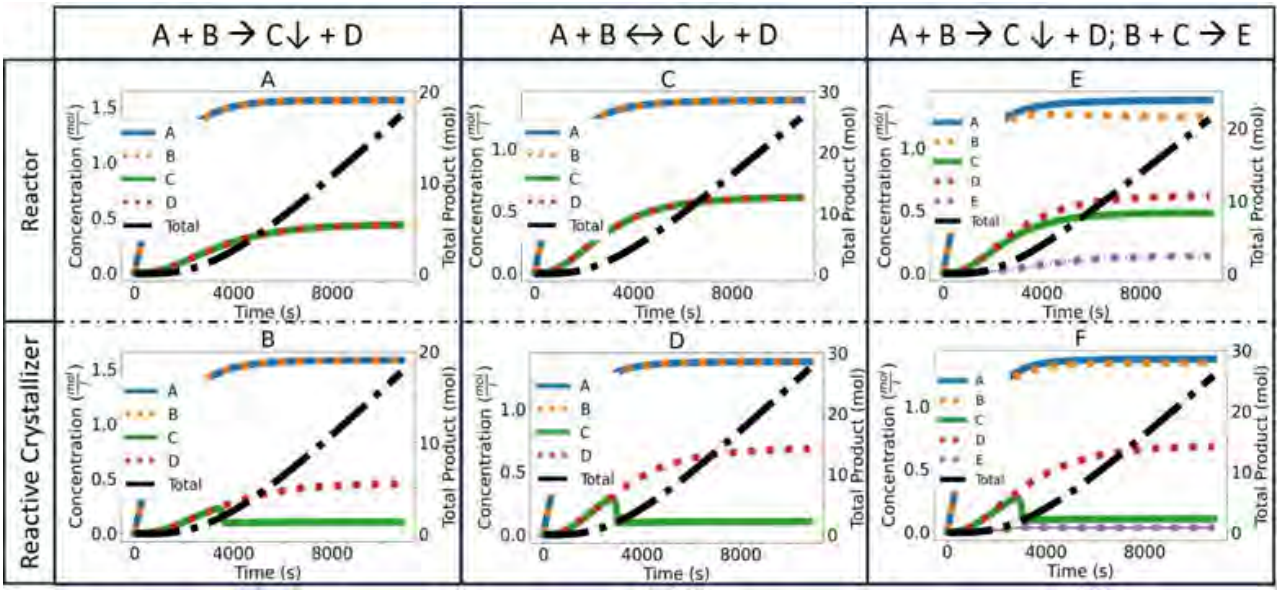

**Figure 2:** Figure comparing RC concentration profiles and non-crystallizing species profiles for different cases. Table 1 has the respective parameters of each case.

[10].

While these results are promising and demonstrate behavior consistent with RC, there are limitations to the model. In many RCs, the reaction is very fast with very quick precipitation and limited by mixing. This model assumes perfect mixing and therefore is less reliable with increasing effects of mixing non-idealities. If the solution can be considered homogeneous before nucleation occurs, then the model should accurately represent the system. Should the mixing become a significant limitation, a different model, such as one employing computational fluid dynamics balances, would be needed to account for the effects. This would introduce other limiting assumptions and is not the particular system of interest.

The cases discussed represent a non-exhaustive list of possible use cases of the model. They were chosen to showcase the potential advantages to RC and to establish that the model followed the expected behavior of a RC system. In each case explored, the reaction is exothermic; endothermic reaction effects have yet to be simulated. All of the cases discussed assumed the same crystallization kinetics, and so the full interaction between crystallization kinetics and reaction kinetics has yet to be determined.

Other reaction systems are conceivable, such as a reversible reaction with a competing byproduct, or a system where the byproduct influences solubility of the target species. Such cases were not simulated in this work for two reasons. First, cases A-F have results which are easily predicted, and so model behavior could be easily validated conceptually. The more complicated reaction systems would be harder to predict and validate conceptually, leading to less certainty of the model overall. Second, in the situation of the byproduct influencing the target species' solubility or other similar complications, cases A-F can be easily modified for the model to capture the behavior. The chosen cases were therefore considered reasonably representative of the systems of interest.

It should also be noted that, with certain parameter regimes, the model struggled to converge. While the exact relationship is still be investigated, increasing differences between the reaction rate and crystallization rate by magnitudes necessitated decreasing step sizes for the integrator to properly solve the equations. This consequently resulted in longer solve times. The parameters listed in Table 1 behave well together in the integrator. This could be caused by the fact that the chosen parameters closely resemble those of a real system whereas other parameter sets explored may not have had physical analogs resulting in difficulty converging. Further work is needed to truly define the reason for the convergence issues and determine how to avoid the issues.

## CONCLUSION

In this work, a simulation model of a reactive crystallization (RC) was developed and demonstrated. The mathematical description of the system was provided, and the digital implementation was described. Three different case studies were used to show the behavior and yield of the RC system compared to that of a system using reactors and crystallizers in series. Irreversible reactions showed no differences in product yield whether using the RC or the reactor and crystallizer route was used. In other cases, which had reversible

reactions or a reaction system where the species of interest was an intermediary product, the RC improved yield. This behavior matched the predicted outcome and verified that the model predictions at least match the behavior expected of RC in various situations. Work is now being done to confirm the model predictions experimentally.

## ABSTRACT

Understanding the complex dynamics of continuous processes in pharmaceutical manufacturing is essential to ensure product quality across the production line. This paper presents a data-driven modeling approach using Sparse Identification of Nonlinear Dynamics with Control (SINDYc) to capture the dynamics of a continuous direct compression (CDC) tableting line. By incorporating delayed control inputs into the candidate function library, the model effectively captures deviations from steady state in response to dynamic changes. The proposed model was developed by finding a balance between accuracy and sparsity, with focus on the ability to generalize to a wide range of operating conditions.

## INTRODUCTION

Continuous manufacturing has emerged as a crucial innovation in pharmaceutical tableting production, bringing substantial improvements in process efficiency, scalability, and product quality assurance. However, the complex dynamics of continuous processes pose significant challenges for modeling, especially in ensuring consistent quality across the production line. In continuous manufacturing lines, residence time distribution (RTD) is a key concept describing how material flows through the system. In practice, RTD is usually modeled using a sequence of ideal reactor units (e.g., combinations of continuous stirred-tank reactors and plug-flow reactors). These models often rely on idealized assumptions that may not capture the complexities of real-world processes. This can lead to discrepancies between model predictions and actual system behavior [1]. Additionally, these models may lack the flexibility to generalize across different setups or scenarios, making it challenging to predict performance under untested conditions [2].

One promising approach to modeling nonlinear and time-varying systems is through data-driven methods. The Sparse Identification of Nonlinear Dynamics (SINDy) framework is a powerful tool for identifying system dynamics from experimental data without assuming a predefined structure. The SINDy algorithm has the ability to derive parsimonious models, with fewer terms.

In this study, SINDy was applied to model a Continuous Direct Compression (CDC) tableting line, using simulated data generated with the gPROMS flowsheet modeling environment. This approach provides the flexibility to simulate a wide variety of experimental conditions, producing the data needed to train the SINDy model. The control input for this model is the mass flow rate of the active pharmaceutical ingredient (API) from the feeder, while blend uniformity and content uniformity are defined as state variables. A key challenge in this system is the presence of inherent time delays between changes in the mass flow rate and their observed effects on blend uniformity. To effectively capture these delayed dynamics, the SINDy with control (SINDYc) algorithm was used, allowing for the explicit inclusion of delayed control inputs into the system's dynamic equations.

## THEORY AND METHODS

### SINDy method

The SINDy algorithm described in Brunton et al. [3] uses sparse regression to identify a parsimonious set of

terms governing the system's dynamics. Consider a nonlinear dynamical system in the form

$$\frac{dx}{dt} = f(x) \quad (1)$$

where $x \in \mathbb{R}^n$ are the state variables over time and the function f represents the dynamics. SINDy uses sparse regression to identify the few active terms out of a library of candidate nonlinear functions $\Theta(X)$. From the time derivative of the state variables $\dot{x}$(t), SINDY finds a sparse matrix Ξ such that:

$$\dot{X} = \Theta(X)\Xi \quad (2)$$

where Ξ contains the coefficients for each candidate function. In this case, the derivatives $\dot{x}$(t), are numerically calculated from the state data.

To incorporate the effects of control inputs in the CDC tableting line, an extension of SINDy known as SINDy with control (SINDYc) is used [4]. SINDYc allows the inclusion of external inputs, in this case the mass flow rate of API in the feeder, directly into the dynamic equations, capturing the influence of these inputs on the system's response variables. The expression of Eq. (1) and (2) can be rewritten as:

$$\frac{dx}{dt} = f(x,u) \quad (3)$$

$$\dot{X} = \Theta(X,U)\Xi \quad (4)$$

where U(t) represents the control inputs and Θ(X,U) is a library matrix containing candidate functions of both the state variables X and control inputs U. Commonly used candidate functions include constant, polynomial, trigonometric and exponential terms or a combination of them:

$$\Theta(X,U) = [1 \;\; X \;\; U \;\; X^2 \;\; U^2 \;\; XU \;\; sin(X) \;\; sin(U) \;\; e^X \;\; e^U \cdots] \quad (5)$$

In many systems, the dynamics can be accurately represented using only a few active terms from a larger set of candidate functions. To identify these terms, sparse regression is used to find the coefficients in the matrix Ξ, minimizing the following objective function:

$$\Xi = arg\min_{\Xi} \frac{1}{2}\left\|\dot{X} - \Theta(X,U)\Xi\right\|_2^2 + \lambda\|\Xi\|_1 \quad (6)$$

where λ is a sparsity-promoting hyperparameter that determines the degree of sparsity in the model. This term penalizes non-zero elements in Ξ, encouraging the model to retain only the most significant terms. During the optimization process, any coefficients in Ξ that fall below a threshold set by λ are set to zero, effectively removing less important terms from the model. This optimization problem can be solved by sequential threshold least squares (STLSQ), where λ serves as the threshold [5].

## Flowsheet model of a Continuous Direct Compression line

In this work, we consider a Continuous Direct Compression (CDC) process, where the API is mixed with the excipients and lubricant to finally move into the tablet press. A flow diagram of the CDC process is shown in Figure 1. CDC was chosen because it is the simplest tableting configuration, resulting in more resources being available in the literature for building the model.

The data used in this work was generated with a flowsheet model of a Continuous Direct Compression (CDC) line implemented in gPROMS FormulatedProducts 2023.1.1. Its modeling environment allows us to connect the models of the different unit operations needed for the flowsheet model [6].

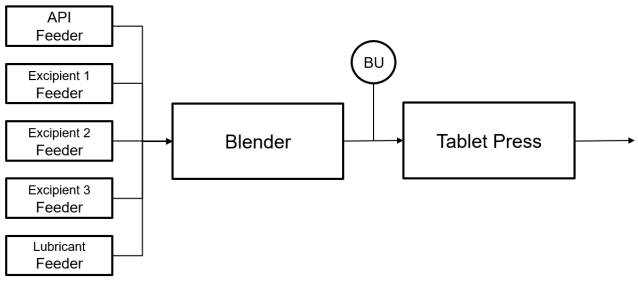

**Figure 1.** Process flow diagram of the Continuous Direct Compression line.

The data generated for this study consists of a series of step changes on the API mass flow rate, which in this work represents the control input $u$,and its response at the end of the blender in terms of blend uniformity (BU), that serves as our state variable $x$, as it is commonly done when characterizing the RTD. To guarantee unit consistency between the control input and the state variable, the mass flow rate and the blend uniformity are expressed as % from the target value. Additionally, unusual control input signals were generated to test the generalization ability of the model identified with the SINDy approach.

## SINDy with control for a CDC line

One of the key steps in implementing SINDy is selecting a candidate function library that best captures the dynamics of the system. A common approach is to start with a set of polynomial functions and then increase the library's complexity by incorporating additional terms, as shown in Eq. (4). Typically, SINDYc includes the control input $u$ as a separate variable in the library [7]. However, in this study, we opted to represent the control input as $u - x$. This formulation is particularly suited to continuous direct compression (CDC) systems, which generally operate in a steady state for extended periods before experiencing a dynamic change, such as a step change or

pulse input in the API mass flow. By defining the control input as $u - x$, it effectively captures the relative difference or deviation between the control signal and the state. This deviation term can better capture how the control input drives the system response away from the current state.

An effective approach to selecting the functions of the candidate library is using the knowledge of the process. In a continuous line, there is usually a time delay in the response after a change occurs upstream. To account for this time delay, we propose to include a possible discrete delay $\tau$ on the control input terms as part of the candidate function library as follows:

$$\Theta(x,u) = [1 \;\; x \;\; u \;\; u(t-\tau_1) \;\; u(t-\tau_2) \;\; u(t-\tau_3) \;\; \dots \;\; u(t-\tau_n)]. \quad (7)$$

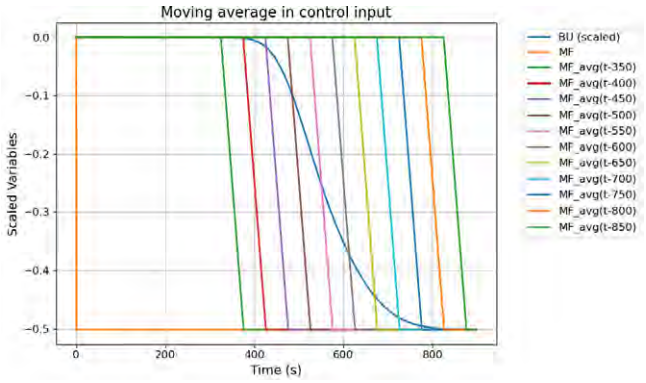

**Figure 2.** Example of using the moving average on the delayed control input functions used in the candidate library

The magnitude and number of delays are selected based on the approximate duration of the step change response of the training data. Additionally, to increase the amount of information captured by including the delayed versions of $u$, we opted to use a moving average $\hat{u}(t-\tau_i)$ over a time window around each delayed signal $u(t-\tau_i)$. For example, if the delay of the response is around 400 seconds and that response stabilizes at around 800 seconds, a list of delayed versions of $u$ from 350 until 850 seconds every 50 seconds is chosen. For each delayed term, we calculate a moving average over a ±25 s window rather than using a single point in time. This approach helps capture the short-term variations that would otherwise be lost when discretizing the input to $u(t-\tau_i)$. In other words, by including the surrounding data points, we account for small fluctuations around the delayed term, instead of relying only on a single value. This can improve both the smoothness of the input signal and the model's ability to learn the underlying dynamics. This example is represented in Figure 2, where the control input $u$ is defined as mass flow rate (MF) and the response or state variable is the blend uniformity (BU).

## RESULTS

The SINDYc with delay approach was trained on simulated data representing step changes of various sizes around the target value. Pre-processing included scaling the data, with a target value of 0 for both the API mass flow (control input) and the API concentration (response), while 1 and -1 were set as the extreme values for the training data. The SINDy model was implemented using the PySINDY package in Python [8, 9]. The derivatives of the state variable were approximated using second-order finite differences. After constructing the model, the resulting ordinary differential equation (ODE) was solved numerically with the fourth order Runge-Kutta method to generate predictions of the state variable. Model performance was evaluated using root mean-square error (RMSE), calculated as follows:

$$RMSE = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(x_i - \hat{x}_i)^2} \quad (8)$$

where $x_i$ represents the actual value of the response

**Table 1:** Root mean square error (RMSE) of SINDy models under various configurations for training and two test datasets. "AW" = Averaging Window (±s), "DI" = Delay Interval (s). The values in bold indicate the selected model configuration.

| Regularization | Configuration | RMSE | | |
|---|---|---|---|---|
| $\lambda$ | (±AW, DI) | Training | Test 1 | Test 2 |
| $\lambda = 0.001$ | (±25 s, 25 s) | 0.7278 | 0.8045 | 0.7372 |
| | (±25 s, 50 s) | 0.2585 | 0.2888 | 0.2600 |
| | (±50 s, 25 s) | 0.4931 | 0.5460 | 0.4801 |
| | (±50 s, 50 s) | **0.1709** | **0.1632** | **0.1765** |
| $\lambda = 0.0001$ | (±25 s, 25 s) | 0.1162 | 0.0835 | 0.3958 |
| | (±25 s, 50 s) | 0.2158 | 0.2109 | 0.3263 |
| | (±50 s, 25 s) | 0.1094 | 0.0872 | 0.1673 |
| | (±50 s, 50 s) | 0.1256 | 0.0845 | 0.1362 |

(blend uniformity) and $\hat{x}_i$ stands for the predicted value from the SINDYc model.

To determine the level of sparsity from Eq.(6) various values of $\lambda$ were tested. Lower $\lambda$ generally improves RMSE because the regression is less penalized for including more terms; however, it can result in a model with many active terms, undermining the sparsity objective of SINDy. On the other hand, higher $\lambda$ forces the solution to discard more terms, reducing complexity but sometimes increasing prediction error. At $\lambda$=0.001, the model achieved the highest level of sparsity before all coefficients were reduced to zero. While decreasing $\lambda$ to 0.0001 improved model performance, it resulted in most coefficients being selected, which could reduce robustness in the presence of noisy data.

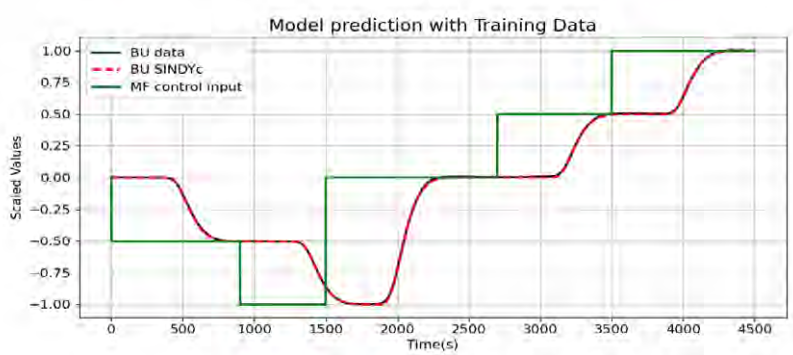
In this SINDy approach, two additional hyperparameters related to the delayed control input need to be tuned: the delay interval and the averaging window. Based on the system's dynamics, where the response to a step change begins around 400 s after the control input and stabilizes around 800 s, a delay range from 350 to 850 s was chosen. Within the estimated response range, we tested two delay interval increments, every 25 s and every 50 s, to control the model complexity. Using 25 s intervals resulted in more terms in the model, while 50 s intervals produced fewer. In either case, each delayed control input was further smoothed using a moving average of either ±25 s or ±50 s to capture the input's gradual effect. These window lengths were chosen so that ±25 s partially covers the 25 s delay interval around the nominal delay, while ±50 s fully spans the 50 s delay increment. In this way, the moving average captures the gradual or integrated effect of the control input in the immediate surroundings of each delay, ensuring that small timescale fluctuations are included without unnecessarily increasing the complexity of the model.

Table 1 summarizes the root mean square error (RMSE) obtained for each configuration of the SINDYc model on three data sets: the original training data, a first test set with a conventional control input profile (test 1), and a second test set with a more challenging input profile (test 2). In training and test 1 data sets, the control input profiles mimic typical conditions during process development in a continuous direct compression (CDC) line, with step changes of moderate magnitude and duration. By contrast, test 2 data set explores significantly different operating conditions, including a different initial condition, sinusoidal variation, and sudden spikes, to test the model's robustness well beyond the scenarios used for training.

Each configuration in Table 1 varies two key factors: the regularization parameter $\lambda$, which controls the sparsity of the model, and the delay/averaging combination used to create candidate functions (e.g., 25 s vs. 50 s increments, ±25 s vs. ±50 s moving average windows.

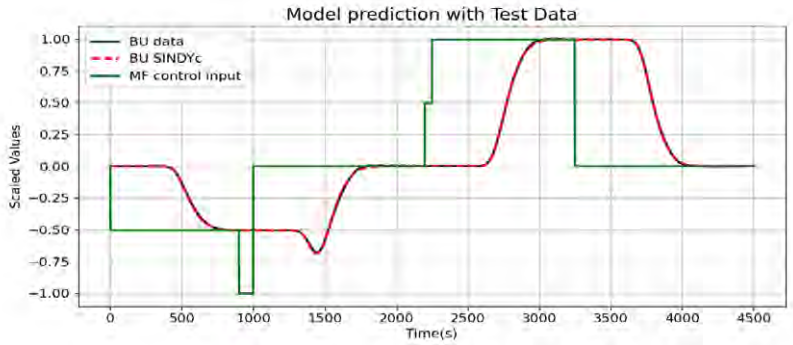
As shown in Table 1, the highlighted configuration achieves a good balance of accuracy and parsimony across all three data sets. Although the configuration with $\lambda$=0.0001 shows slightly lower RMSE values in some cases, it selects nearly all candidate terms, resulting in a much more complex model that could lead to potential overfitting. In contrast, the chosen configuration with $\lambda$=0.001 retains comparable predictive accuracy on both test 1 and test 2, while maintaining a significantly smaller number of terms. This aligns with the SINDy principle of favouring parsimonious models that capture essential dynamics without overfitting.

To demonstrate how the chosen regularization parameter $\lambda$ affects the model sparsity, we present in Eq.(8) the final form of the obtained model with $\lambda$=0.001, and in Eq.(9) the corresponding model when $\lambda$=0.0001. Both models use the same delay/averaging configuration (i.e., ±50 s averaging windows and 50 s delay increments), but differ in the strength of their sparsity.



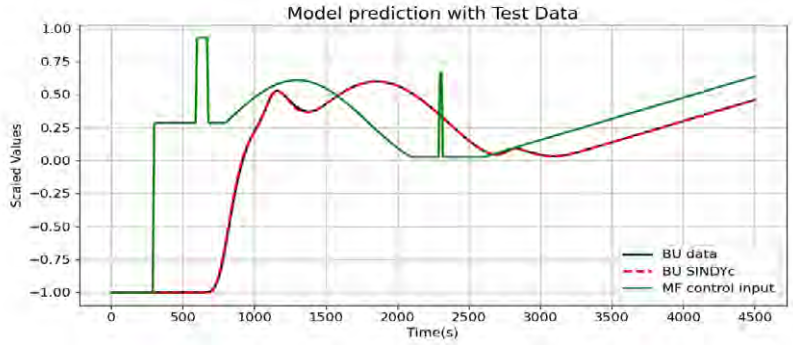
$$\dot{x} = 0.008(\hat{u}(t-450)-x) + 0.004(\hat{u}(t-500)-x) + 0.005(\hat{u}(t-550)-x) + 0.001(\hat{u}(t-650)-x) \quad (9)$$

$$\dot{x} = 0.0008(\hat{u}(t-400)-x) + 0.003(\hat{u}(t-450)-x) + 0.002(\hat{u}(t-500)-x) - 0.002(\hat{u}(t-550)-x) - 0.0006(\hat{u}(t-600)-x) - 0.001(\hat{u}(t-650)-x) - 0.0007(\hat{u}(t-700)-x) - 0.0008(\hat{u}(t-750)-x) - 0.0001(\hat{u}(t-850)-x) \quad (10)$$



In Eq. (8), only four terms are present, which manage to capture the main time delays while preserving interpretability. But, when $\lambda$ is reduced to 0.0001 in Eq. (9), the regularization penalty on additional terms is much weaker, so, more delayed terms remain active, offering a marginally lower RMSE (as shown in Table 1) but at the expense of simplicity.

In addition to selecting $\lambda$=0.001, we also explored two key parameters for constructing our candidate functions: the averaging window (±25 s vs. ±50 s) and the delay interval (25 s vs. 50 s). From Table 1 it can be seen that at $\lambda$=0.001, widening the averaging window from ±25 s to ±50 s results in a slight improvement in RMSE, but the more influential factor is the choice of delay interval. When the model is forced to choose fewer delayed terms (i.e., using a 50 s delay interval rather than 25 s), it performs slightly better. This indicates that at higher regularization, including too many candidate terms (as occurs with the finer 25 s interval) might dilute the model's ability to identify a compact set of truly relevant dynamics. In other words, a coarser delay interval can sometimes help the algorithm focus on the most dominant time lags in the process, improving predictive performance and interpretability.



When $\lambda$=0.0001, the effect of averaging window and delay interval becomes less straightforward. Because the

a)

b)

c)

**Figure 3.** Training (a) and test 1 (b) , and test 2 (c) data sets. The in silico BU process data ($x$) is compared with the SINDYc model prediction given a control input signal $u$ (mass flow rate or MF)

penalization of extra terms is much lower, the model can retain many more active terms in the final solution—potentially benefiting from finer resolution of time delays (25 s intervals). The trade-off is that these extra terms may capture minor effects rather than main dynamics. As a result, some configurations with 25 s intervals and smaller averaging windows at $\lambda$=0.0001 can show lower RMSE on the training set, but at the cost of reduced sparsity and potentially greater risk of overfitting. Future work may employ cross-validation to further refine these hyperparameter selections.

Figure 3a-3c illustrate representative time-series predictions for each data set at the chosen model configuration (i.e., $\lambda$=0.001, ±50 s averaging windows and 50 s delay increments). For the training data (Figure 3a), the model prediction (dotted red line) closely tracks the observed blend uniformity or BU (black line) across successive step changes in the mass flow rate (green line). In test 1 (Figure 3b), the same model continues to perform well, with only minor deviations from the true signal in the transitions. Test 2 (Figure 3c) tries far more drastic input variations. While the prediction error increases slightly, the model still manages to capture major trends, indicating that it generalizes reasonably well to unseen input profiles.

Overall, these results indicate that a careful choice of $\lambda$, along with a suitable delay-averaging configuration, can result in a compact, interpretable SINDy model that remains robust to diverse control input scenarios—ranging from typical operating conditions (test 1) to more extreme or unconventional inputs (test 2).

## CONCLUSIONS

In this study, a SINDy-based model with delayed control input terms was developed and tested to capture the dynamics of a continuous direct compression (CDC) line. By incorporating delayed versions of the control input in the candidate function library and systematically optimizing the delay intervals and averaging windows, the resulting model effectively balances accuracy and sparsity. The selection of an appropriate regularization parameter $\lambda$ was crucial to achieving this balance, as higher values promoted interpretability by enforcing sparsity, while lower values, although with lower RMSE, led to overfitting with an excessive number of active terms.

The analysis of different configurations showed that using a coarser delay interval (50 s) resulted in improved model performance compared to a finer interval (25 s) when a higher regularization parameter was applied. This suggests that fewer, well-chosen delay terms allow the model to focus on capturing the dominant dynamics of the system, potentially reducing the risk of overfitting to noise or minor effects. The choice of the averaging window also played a role in enhancing the model's robustness, with a ±50 s window providing a more smoothed representation of the input that improved predictive accuracy across various operating conditions. These findings highlight the importance of tuning hyperparameters to achieve an optimal trade-off between model complexity and predictive capability.

The chosen model configuration showed strong generalization performance when applied to test data, including both typical operating profiles encountered in CDC lines and more challenging scenarios such as sinusoidal variations, constant increasing slopes, and sudden spikes. Overall, this approach demonstrates the feasibility of using SINDy for data-driven modelling in CDC processes and provides a foundation for future work to address more complex dynamic responses and noisy data.

## ABSTRACT

The promising properties of lipid nanoparticles (LNPs) as drug carriers have been attracting significant attention in the field of drug delivery. However, further research is still required for a better understanding of their integration in the pharmaceutical industry. The Quality by Design (QbD) approach aims at ensuring the safety and efficiency in the development of new drugs, through an holistic, risk-based approach that gathers all sources of knowledge available about the system under analysis. One key resource of the QbD framework is the rich toolkit of Design of Experiments (DOE), to deepen the understanding of how the synthesis of LNPs by microfluidics can be effectively conducted and controlled. This study aimed to explore and understand the effectiveness of different DOE strategies, through an *in silico* study focused on the impact of factors related to the LNPs synthesis, namely the molar ratio of each lipid component in the lipidic mixture and the N/P ratio, while also considering potential economic constraints without disregarding the need for a statistically valid analysis. A simulation model of the LNP synthesis derived from real experiments was adopted as a basis to assess the potential efficacy of estimated models with different levels of complexity, to extract useful insights in future DOEs in these types of systems, given the high cost of each experimental run. The statistical metrics used were the coefficient of determination ($R^2$) and the Root Mean Squared Error (RMSE). With the results obtained, it was possible to verify that different responses from the same system could require quite different model structures, namely, the models developed for potency and for size of the LNPs differed significantly in their complexity. Furthermore, a number of experiments of the order of 30 can be anticipated as necessary for a DOE in a real process, involving similar factors.

**Keywords**: Lipid nanoparticles (LNPs), Quality by Design (QbD), Design of Experiments (DOE).

## INTRODUCTION

Lipid nanoparticles (LNPs) have recently attracted considerable interest, particularly for their role in the development of COVID-19 mRNA vaccines by Pfizer-BioNTech and Moderna. Their ability to efficiently encapsulate nucleic acids, while simultaneously ensuring effective intracellular delivery and endosomal escape, has sparked increasing interest from both the industrial and research communities for exploring their unique properties as promising drug carriers.

A widely used technique for the synthesis of these LNPs, is microfluidics. This method allows for the efficient mixing of an organic solution, which contains the necessary lipid components dissolved in ethanol, with an aqueous solution that contains the intended payload (nucleic acid).

To ensure the successful and safe synthesis of these LNPs attributes, the pharmaceutical industry typically recommends following a Quality by Design (QbD) approach. This approach aims to guarantee that manufacturing is able to deliver the expected quality of the drugs, rather than relying solely on testing the final product and reject any lot that is non-conforming. QbD can also reduce costs associated with product optimization and ensure that patients receive higher-quality drugs in a shorter time frame [1]. One of the key aspects of the QbD approach is the use of Design of Experiments (DOE) to establish the Design Space that guarantees the quality requirements of the LNPs are met [1]. However, before

defining a design space, several DOE stages may be necessary for screening the important factors, modelling the system's behaviour accurately, and finding the optimal operational conditions.

## GOLDEN STANDARD MODEL

As previously highlighted, one of the key aspects of the QbD approach is the use of the DOE. However, the employment of this statistical method can greatly benefit from a preliminary simulated *in silico* study approach, especially when economic constraints play a significant role. This is especially true in the case of LNPs' synthesis by microfluidics, where each experiment is expensive due to the high cost of the formulation components. Therefore, there is a justified interest in making this process as efficient and informative as possible.

In light of this information, we have adopted an *in silico* system, using a model that was developed from real experimental data collected in a closely related experimental and technological scenario. This *in silico* study provides a suitable test bed to analyse and compare the different DOE strategies that may be adopted and collect insights about a reasonable number of experiments to accommodate within a designated budget, while ensuring a statistically valid analysis.

Therefore, we have conducted a systematic study based on the work developed by Karl et al. [2], who provided a simulation model of the LNP synthesis, referred to as the Golden Standard (GS) Model. This model was derived from 23 real experiments and codified in the JMP Pro software using a recently proposed methodology called self-validated ensemble model (SVEM).

The GS Model considers the molar ratio of individual lipid components in the lipid mixture (Ionizable lipid (IL), Structural lipid (SL), Helper lipid (HL) and PEG lipid), the ionizable lipid type, the molar N/P ratio (ionizable amine from ionizable lipids to phosphate from nucleic acid ratio) and the total flow rate (TFR). These factors were established within the ranges, shown in **Table 1**.

**Table 1:** Ranges of the factors in the GS Model.

| Factors | Ranges |
|---|---|
| IL | [0,1; 0,6] |
| HL | [0,1; 0,6] |
| SL | [0,1; 0,6] |
| PEG | [0,01; 0,05] |
| Ionizable lipid type | H101 or H102 or H103 |
| N/P ratio | [6,14] |
| TFR | [1,3] mL/min |

It is important to note that the GS model is quite complex in its structure and it was considered, for all practical purposes, unknown throughout this study. Moreover, it has terms that were not included in the DOEs strategies considered. This structural mismatch brings more realism to the *in silico* study carried out, which will be lay down in the next section.

Finally, this model considered as responses the "potency in vivo" and "size of the LNP", with the goal being to maximize potency and minimize size.

## METHODOLOGY

The study conducted is based on the GS Model, and followed a methodology that is schematicaly illustrated in **Figure 1**. This figure that depicts the principal steps of the study, organized into two distinct phases: 1) Initial setup; 2) Comparison study.

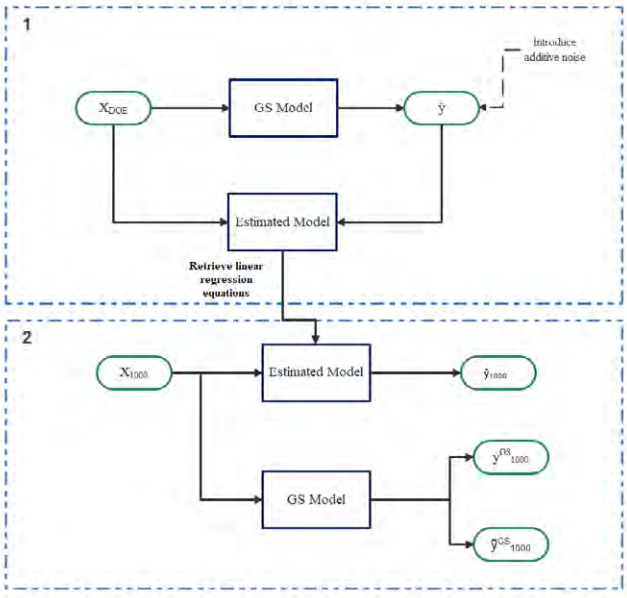

**Figure 1:** Methodology for the *in silico* study.

### Initial Setup

Firstly, the DOE levels ($X_{DOE}$) for the factors selected, need to be established. For such, an interval of acceptability for each factor was established while respecting the ranges established by the GS model, as shown in **Table 1**. The ranges established and the chosen factors are shown below in **Table 2**.

**Table 2:** Ranges for the factors considered in $X_{DOE}$.

| Factors | Ranges |
|---|---|
| IL | [0,3;0,6] |
| HL | [0,1;0,28] |
| SL | [0,185;0,555] |
| PEG | [0,01;0,045] |
| N/P ratio | [ 6,14] |

Taking into account the constraints in **Table 2**, the $X_{DOE}$ was generated by a D-optimal design approach for different model structures, spanning different levels of modeling complexity. These model structures present an increasing number of terms (complexity), by considering more effects to be estimated from data. Consequently, more experiments were necessary to estimate them. The models were designated as Model 1 (M1), Model 2 (M2), and Model 3 (M3), with M3 being the most complex in terms of considered effects. In M1 only the main effects associated with the factors were considered. On the other hand, M2 considered the same effects as M1, except for the main effect associated with the N/P ratio. Additionally, M2 considered the effects related to the non-linear blending of two mixture components and the interactions of mixture components with the process factor (N/P ratio). Finally, M3 incorporated the same effects as M2, along with some third-order terms, considering the Scheffé cubic model effects, such as the non-linear blending associated with three components. The effects considered for each model are presented in **Table 3**.

With regard to the number of experiments, between 10 to 30 experiments were considered, in accordance with the corresponding minimum limits suggested by optimal design software (JMP Pro), that increase according to the increment of their complexity. Therefore, a designation of the number of experiments was explicitly included together with that for the corresponding model. For example, M1-10 represents the model M1 that was generated considering a total of 10 experiments.

Next, the $X_{DOE}$'s elaborated were introduced in the GS Model to obtain the simulated responses with additive noise ($\tilde{y}$). Note that, when introducing the levels for the selected factors in the model ($X_{DOE}$), the levels for the other factors not considered in the designs have also to be set to run the simulation; therefore, the following factors were established as constants for the GS Model to run: a TFR of 2 mL/min and H103 as the ionizable lipid type.

Moreover, three levels of noise in the response were considered: the originally estimated noise level (during the development of the GS model) and two additional levels corresponding to an increase of 10% or 20%. This alternative is indicated by a dashed arrow in **Figure 1** and was implemented in an effort to better reflect the reality of having different levels of reproducibility of the measured responses.

Based on the $X_{DOE}$'s and the corresponding outputs, $\tilde{y}$, with or without additive noise, a linear regression model was estimated for each model structure, as mentioned above, by fitting these models using the least square method. These models will be collectively referred throughout this article, as Estimated Models (EM).

## Comparison study

In the second part of the study, a new input space of 1000 points ($X_{1000}$) was generated at random for the mixture components and the N/P ratio. The new input space was generated to guarantee a proper assessment of the predictive capability of the different models and, therefore, the comparison between the GS Model and the EM Models. In other words, this new dataset is not used for conducting any estimation task, but simply to compare the GS Model responses with and without noise ($\tilde{y}^{GS}_{1000}$ and $y^{GS}_{1000}$) with the EM Models responses ($\hat{y}_{1000}$).

One of the metrics used for this comparison was the coefficient of determination, $R^2$, which measures the quality of fit of the EM Model in relation to the GS Model responses (with or without noise). A higher $R^2$ value indicates a superior fit to the GS data, i.e., a higher proportion of variation that is explained by each EM Model.

Another metric used was the Root Mean Squared Error (RMSE), which describes the average difference between the GS values (with or without noise) and the estimated values, as shown below in Equation (1) and Equation (2).

$$\mathrm{RMSE}_{\mathrm{w/o\ noise}} = \sqrt{\frac{1}{n} \times \sum_{i=1}^{n} \left( y^{GS}_{1000}(i) - \hat{y}_{1000}(i) \right)^2} \quad (1)$$

$$\mathrm{RMSE}_{w/noise} = \sqrt{\frac{1}{n} \times \sum_{i=1}^{n} \left( \tilde{y}^{GS}_{1000}(i) - \hat{y}_{1000}(i) \right)^2} \quad (2)$$

Note that the metrics mentioned above were computed for the test set. Therefore, they are actually measures of quality of prediction (prediction metrics).

# ANALYSIS AND DISCUSSION OF THE RESULTS

**Figure 2** summarizes the $R^2$ and RMSE for each response (potency and size) that were computed for each EM Model by comparison with the GS Model with or without noise.

Firstly, it is important to note that the $R^2$ and RMSE trends of the different EM Models remained

**Table 3:** Effects considered for models M1, M2 and M3.

| Models | Effects |
|---|---|
| M1 | PEG, HL,IL, SL and N/P ratio |
| M2 | PEG, HL, IL, SL, PEG×IL, PEG×HL, PEG×SL, PEG×N/P ratio, HL×IL, HL×SL, HL×N/P ratio, IL×SL, IL×N/P ratio and SL×N/P ratio |
| M3 | PEG, HL, IL, SL, PEG×IL, PEG×HL, PEG×SL, PEG×N/P ratio, HL×IL, HL×SL, HL×N/P ratio, IL×SL, IL×N/P ratio, SL×N/P ratio, PEG×HL×IL, PEG×HL×SL, PEG×IL×SL, HL×IL×SL, PEG×HL×(PEG-HL),PEG×IL×(PEG-IL), HL×IL×(HL-IL), PEG×SL×(HL-SL),HL×SL×(HL-SL) and IL×SL×(IL-SL) |

consistent regardless of the presence of noise in GS Models outputs, as well as considering additional levels of noise. The only difference occurs when considering the various levels of noise, where the values reported were lower and higher for $R^2$ and RMSE, respectively.

The $R^2$ for the EM Models differed for potency and size. For size, it was reported a better fit of the EM Models to the GS Model with values typically around between 0,97 and 0,99. Moreover, when compared to potency, the shift in the behaviour of the $R^2$ values in accordance with the models was slightly less significant; see **Figure 2 (b)**.

For potency, the $R^2$ values displayed a general increasing trend, **Figure 2 (a)**, as the complexity of EM Models and the number of experiments increased, with the exception of M3, which exhibited a slightly lower $R^2$ value compared to M2. On the other hand, the RMSE values displayed a general decreasing trend, **Figure 2 (c)**, as the complexity and the number of experiments increased, with the exception of M3 which exhibited a slightly higher RMSE value compared to M2.

According to these findings, M2-30 appears to be the most effective alternative due to its high $R^2$ and a low RMSE. However, if a reduced number of experiments was necessary, M2-20 would still be a viable option, as it presented a slightly lower $R^2$, but a lower RMSE in comparison with M2-30.

On the other hand, regarding size, the $R^2$ and RMSE values showed different trends across the number of experiments and models' complexity. In the case of the $R^2$ values, an increment in the number of experiments did not necessarily lead to an increase in $R^2$, **Figure 2 (b)**. In fact, there was a slight decrease in $R^2$ values from M1-10 to M1-20, and an increase in M1-30. Following the sequence in this figure, there is then a decrease in M2-20 and an increase in M2-30 and M3-30, with M3-30 showing the highest value.

With regard to RMSE, **Figure 2 (d)**, an increase in the number of experiments and complexity from M1-10 to M2-10 resulted in a decrease in values similar to the previous case. However, there was an increase in RMSE at M2-20, and a subsequent decrease until M3-30, which corresponds to the lowest RMSE value.

According to these findings, the M3-30 would likely be a viable option as it reported the highest $R^2$ and lowest RMSE value. It is important to note, that for size the $R^2$ values reported generally only showed changes around their 3rd or 4th decimal place. Therefore, M2-30, would also be a viable option, despite being the 3rd highest $R^2$ value. Moreover, it had the lowest RMSE value.

Based on these findings, in both cases, rather surprisingly, the M2-30 model was considered a good possibility, although it was not the first choice for size. Therefore, using the same model is still a viable option.

Nevertheless. the most effective EM Model for potency and size differed: M2-30 for potency and M3-30 for size. Thus, it is also likely that different responses may not necessarily require the same EM Model. Still, the suggested number of experiments is the same, which is informative for future studies involving similar factors.

It is important to note that, as previously stated, there was a notable disparity between size and potency in $R^2$ values, with $R^2$ values for size being consistently higher (around 0,97 to 0,99), in comparison to those for potency (around 0,30 to 0,88). The reason behind these results was also object of analysis.

This discrepancy could be attributed to the fact that not all the responses, as previously stated, behave necessarily equally, and may follow different mechanisms, which may differ in their inner complexity.

Furthermore, the measurement systems may also be more limited in some cases, inputting more uncertainty in data, which is transferred to the model development stage; this also may affect more extensively one type of model than the other.

Moreover, the fact that the models being

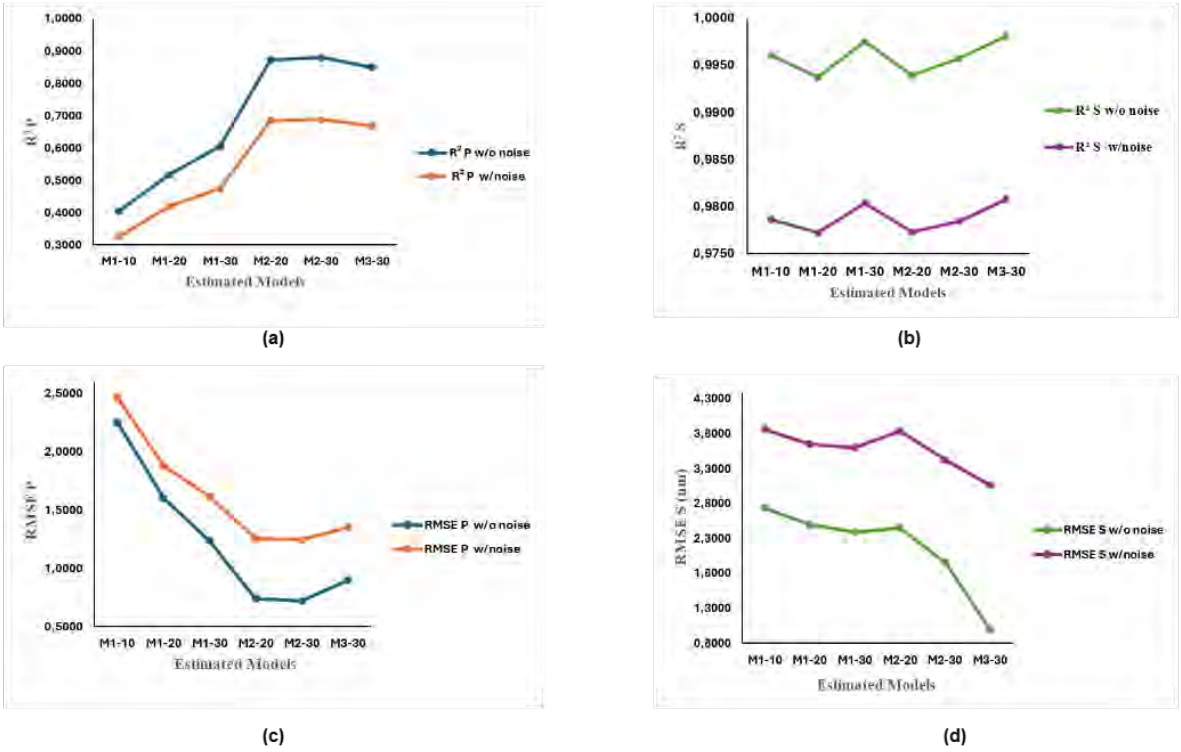

**Figure 2**: Results of $R^2$ and RMSE according to the Estimated Models: (a) $R^2$ of potency (P) with and without noise; (b) $R^2$ of size (S) with and without noise; (c) RMSE of potency (P) (units not referred in the original article [2]) with and without noise (d); RMSE of size (S) with and without noise.

considered in the $R^2$ metric (EM Model and GS Model) are structurally different could also be a possibility for this discrepancy. This mismatch between them is due to the fact, that the GS Model for potency was generated considering additional effects (e.g. PEG×PEG×N/P ratio, HL×HL×PEG, emphasized in bold in Equation 3) along with an intercept term, the same occurring in size for GS Model. A portion of the equation of GS Model for potency is shown below in Equation 3:

$$\text{Potency}_{GS} = -4{,}6532 + 1{,}0608 \times \left(69{,}1343 + 0{,}3518 \times \left(\frac{(\text{PEG}-0{,}01)}{0{,}69}\right) + 0{,}0697 \times \left(\frac{(\text{HL}-0{,}1)}{0{,}69}\right) - 1{,}8941 \times \left(\frac{(\text{IL}-0{,}1)}{0{,}69}\right) + 0{,}1734 \times \left(\frac{(\text{SL}-0{,}1)}{0{,}69}\right) + \text{Ionizable lipid type} + 0{,}0005 \times \left(\frac{(\text{N/P ratio}-10)}{4}\right) - 66{,}0252 \times \left(\frac{(\text{PEG}-0{,}01)}{0{,}69}\right)\left(\frac{(\text{PEG}-0{,}01)}{0{,}69}\right)\left(\frac{(\text{HL}-0{,}1)}{0{,}69}\right) - 270{,}8798 \times \left(\frac{(\text{PEG}-0{,}01)}{0{,}69}\right)\left(\frac{(\text{PEG}-0{,}01)}{0{,}69}\right)\left(\frac{(\text{IL}-0{,}1)}{0{,}69}\right) + 30{,}8712 \times \left(\frac{(\text{PEG}-0{,}01)}{0{,}69}\right)\left(\frac{(\text{PEG}-0{,}01)}{0{,}69}\right)\left(\frac{(\text{SL}-0{,}1)}{0{,}69}\right) + \left(\frac{(\text{PEG}-0{,}01)}{0{,}69}\right)\left(\frac{(\text{PEG}-0{,}01)}{0{,}69}\right) \text{Ionizable lipid type} - 164{,}3110 \times \left(\frac{(\mathbf{PEG}-\mathbf{0{,}01})}{\mathbf{0{,}69}}\right)\left(\frac{(\mathbf{PEG}-\mathbf{0{,}01})}{\mathbf{0{,}69}}\right)\left(\frac{(\mathbf{N/P\ ratio}-\mathbf{10})}{\mathbf{4}}\right) - 103{,}2265 \times \left(\frac{(\text{PEG}-0{,}01)}{0{,}69}\right)\left(\frac{(\text{PEG}-0{,}01)}{0{,}69}\right)(\text{TFR}-2) - 1{,}1640 \times \left(\frac{(\mathbf{HL}-\mathbf{0{,}1})}{\mathbf{0{,}69}}\right)\left(\frac{(\mathbf{HL}-\mathbf{0{,}1})}{\mathbf{0{,}69}}\right)\left(\frac{(\mathbf{PEG}-\mathbf{0{,}01})}{\mathbf{0{,}69}}\right) + 1{,}1584 \times \left(\frac{(\text{HL}-0{,}1)}{0{,}69}\right)\left(\frac{(\text{HL}-0{,}1)}{0{,}69}\right)\left(\frac{(\text{IL}-0{,}1)}{0{,}69}\right)(\ldots) - 1{,}3789 \left(\frac{(\text{IL}-0{,}1)}{0{,}69}\right)\left(\frac{(\text{SL}-0{,}1)}{0{,}69}\right)\left(\frac{(\text{IL}-0{,}1)}{0{,}69} - \frac{(\text{SL}-0{,}1)}{0{,}69}\right)\right) \quad (3)$$

As previously shown in **Table 1** and **Table 2**, the GS Model factors' ranges differed from the ones considered for the EM Model.

These conjectures were further analyzed and corroborated through a comparison of the prediction profiles of the GS Model for potency and size, with the prediction profiles of the EM Models (M2-30 for potency and M3-30 for size).

The predicted behaviour for size in the profiles for the GS Model did not differ much when compared to the M3-30. However, when comparing for potency between the GS Model and M2-30, the M2-30 was not capable of capturing completely the impact that certain factors held

on the response behaviour (e.g. PEG and N/P ratio). Such profiles for potency are shown below in **Figure 3**.

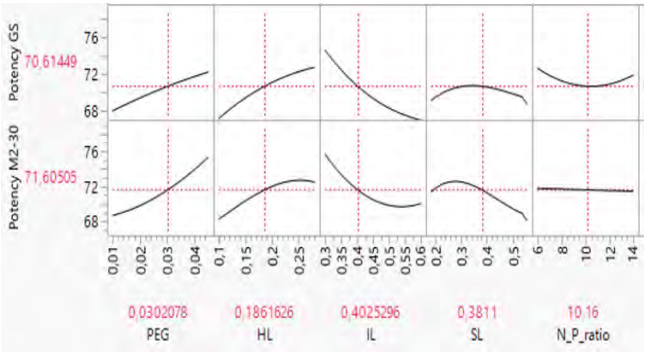

**Figure 3:** Prediction profiles for potency in GS Model and M2-30.

According to the findings, the proposed methodology provides a better understanding of the number of experiments and complexity of the models required for each response, thereby preventing unnecessary expenses. Furthermore, given that distinct results for each response were obtained, our approach also points out to the need to carefully tailor the DOE model case-by-case. In summary, this approach has demonstrated potential in addressing upfront challenges associated with the design space through *in silico* experiments to streamline the development of the design space in real systems while balancing cost-effectiveness and quality effectiveness.

## CONCLUSIONS

In the preliminary study conducted to test the effectiveness of different DOE strategies, considering the selected metrics ($R^2$ and RMSE), it was found that the responses (potency and size) were modelled with different levels of accuracy according to the EM Models obtained. From our findings, the main viable options considered were M2-30 for potency and M3-30 for size. Therefore, it is expected that for exploring the formulation space with a similar number of factors, a number of experiments of the order of 30 may be anticipated.

In the future, further research using different models with varying factors, will be conducted, such as incorporating only the lipidic composition of three components as factors, as it could substantially contribute to advancing the understanding of the models' effectiveness, thereby facilitating the future experimental application of the DOE, and consequently pave the way for a more comprehensive QbD approach. Furthermore, the DOE methodologies adopted in this study (optimal DOE) will be compared with other Active Learning methods, such as Bayesian Optimization, on their ability to efficiently reach optimal values for the properties, or optimal compromises between them.

## ABSTRACT

The pharmaceutical industry is a highly specialized field where strict quality control and accelerated time-to-market are essential for maintaining competitive advantage. Spherical crystallization has emerged as a promising approach in pharmaceutical manufacturing, offering significant potential to reduce equipment and operating costs, enhancing drug bioavailability, and facilitating compliance with product quality regulations. Emulsions, as an enabling technology for spherical crystallization, present unique advantages. However, the quality of spherical crystallization products derived from emulsions is significantly influenced by the intricate interactions between crystallization phenomena, formulation variables, and solution hydrodynamics. These complexities pose substantial challenges in determining optimal operational conditions to achieve the desired product characteristics. In this study, Bayesian optimization (BO) is employed to refine and optimize the operational conditions for the spherical crystallization of a representative drug, ibuprofen. The primary goal is to improve product flowability, measured by angle of repose, while maintaining the median particle size within a specified range. The optimization process focuses on key variables such as temperature, stirring speed, duration, and BSA concentration. With the help of acquisition functions, BO enables the identification of a high-quality product with fewer experimental trials compared with traditional design of experiments (DoE) methods.

**Keywords**: Spherical crystallization, Bayesian optimization.

## INTRODUCTION

Spherical crystallization is an innovative technique in pharmaceutical manufacturing that has obtained increasing attention due to its ability to enhance both product quality and process efficiency[1]. By combining crystallization and agglomeration in a single step, spherical crystallization enables the production of spherical crystal forms that are easier to handle and have improved flow properties, which are crucial for downstream processes such as tablet formation and capsule filling[2]. However, the quality of spherical crystallization products obtained from emulsions is highly dependent on the complex interactions between crystallization processes, formulation parameters, and solution hydrodynamics[3]. These interrelated factors introduce significant challenges in determining the optimal operating conditions necessary to achieve the desired product characteristics, such as consistency in particle size and crystal morphology. This complexity underscores the necessity for a carefully structured experimental design[4]. Through such experimentation, it is possible to identify the most favorable conditions, thereby optimizing the process for consistent, high-quality product development.

Traditional experimental design methods, such as one-factor-at-a-time (OFAT) and factorial designs, are widely used to study the effects of process parameters. However, these approaches can be inefficient, particularly when dealing with complex systems where interactions between variables are significant[5]. Definitive screening designs (DSD), in combination with response surface methodology (RSM), offer a more efficient and

comprehensive strategy for process optimization[6]. DSD is particularly effective in identifying the most influential factors with a minimal number of experimental runs, while accounting for potential interactions and nonlinear effects. Once key factors are identified, RSM is applied to further refine the understanding of the process by modeling the relationship between these factors and the desired output. This combined approach allows for an efficient exploration of input spaces.

Building on the efficiency of definitive screening designs and response surface methodology, Bayesian optimization (BO)[7, 8] presents a newer approach for optimizing complex processes in product development. This method offers a more efficient way to explore parameter spaces by using a probabilistic model to guide the selection of the most promising experimental conditions, thus reducing the need for exhaustive testing. This technique has demonstrated considerable potential across multiple domains, including pharmaceutical manufacturing[9], environmental monitoring[10], and the food industry[11]. In the context of spherical crystallization, where multiple interacting variables influence product quality, BO can help identify optimal conditions more quickly, contributing to faster development of new formulations.

This paper presents a comprehensive investigation into the optimization of spherical crystallization processes for pharmaceutical manufacturing. The second section outlines the experimental procedure for the spherical crystallization of a representative drug, ibuprofen, illustrating the practical application of the technique. In the third section, two experimental design methods are discussed: (1) Definitive screening designs combined with response surface methodology, and (2) Bayesian optimization. The fourth section presents and analyzes the experimental results obtained from these approaches. Finally, Potential directions for future research are discussed in the conclusion.

## EXPERIMENTAL PROCEDURE: SPHERICAL CRYSTALLIZATION OF IBUPROFEN

This study aims to develop a standard-compliant spherical crystallization product of ibuprofen by optimizing experimental conditions. The spherical crystallization process will be introduced in this section.

### Spherical Crystallization Process

The ibuprofen used for spherical crystallization was sourced from *Rhawn* (China). Distilled water and dichloromethane (DCM) (*SCR*, China) were utilized in the crystallization process. Bovine serum albumin (BSA) (*Shyuanye*, China) and quinoa starch served as Pickering particles to stabilize the emulsions. Ethyl cellulose (EC) (*Macklin*, China) was employed as a crystallization additive. The spherical crystallization process was performed in Pickering emulsions, with the procedure adapted from the authors' previously published work[12, 13].

As shown in Fig. 1, an oil-in-water (O/W) emulsion was prepared with dichloromethane as the dispersed phase (which is also the oil phase) and a 0.1 wt% BSA solution as the continuous phase (which is also the aqueous phase). Ibuprofen and EC were dissolved in the oil phase, while quinoa starch was added to the aqueous phase and dispersed via ultrasonication for 10 minutes. The oil and aqueous phases were then combined in a 100 mL round-bottom flask and mixed by handshaking for 1 minute to form the O/W emulsion, after which the Pickering emulsion was obtained. Subsequently, the emulsion was transferred to a 250 mL flask for the evaporation and crystallization processes. Evaporation was carried out in an oil bath (DF-101S, Shanghai Lichenbangxi Instrument Co., Ltd.) equipped with a top stirrer (*WIGGENS*, WB2000-B). Upon completion of crystallization, the resulting product was transferred to a filtration flask and filtered using a recirculating water vacuum pump (SHZ-D (III), Shanghai Lichenbangxi Instrument Co., Ltd.) to remove residual aqueous phase. The product was then washed twice with 100 mL of distilled water and dried in an oven at 50°C for 24 hours. Further analysis of the product includes flowability analysis and particle size analysis.

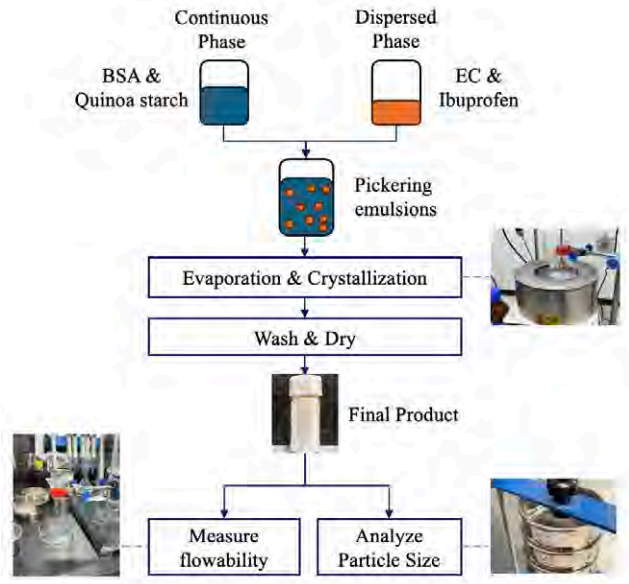

**Figure 1.** Crystalization process and analysis flowchart .

### Flowability Measurements

The flow properties of the spherical agglomerates were assessed indirectly by measuring the angle of repose (AVA). The experimental setup for measuring the angle of repose is illustrated in Fig. 2.

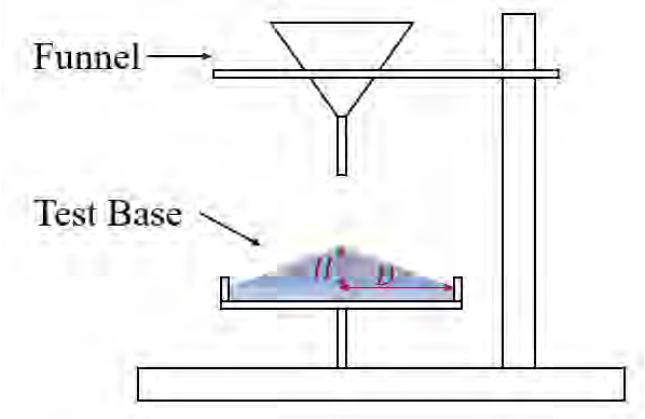

**Figure 2.** Measurement of the angle of repose.

To minimize the influence of varying compaction states of the powder on measurement accuracy, the powder samples were pre-sieved through a screen with a mesh size of 1.0 mm prior to testing. The funnel used for the measurement had a neck length of 4 cm and a neck diameter of 8 mm. The test base had a diameter of 10 cm and featured a raised edge. To reduce errors caused by particle dispersion upon initial impact, a layer of powder was retained on the base during the test. The angle of repose, denoted as α, was calculated using the formula[2]:

$$\alpha = arctan\left(\frac{H}{D}\right) \quad (1)$$

where $H$ represents the height of the powder cone, and $D$ is the radius of the test base. A lower angle of repose indicates superior flowability. Each sample was measured twice, and the average value was reported to ensure reliability.

### Particle Size Analysis

The particle size parameters, marked as $d_{10}$, $d_{50}$, and $d_{90}$ of the product were determined through sieving. These parameters represent the 10%, 50%, and 90% points in the cumulative undersize particle size distribution. The analysis was performed using a series of sieves with uniformly spaced apertures ranging from 0.05 to 1 mm, arranged on a standard testing sieve shaker. The sample was introduced onto the top sieve, and the sieving process was carried out using mechanical vibration. Upon completion of the sieving, the particles retained on each sieve layer were carefully weighed and recorded. This data enabled the characterization of the particle size distribution and the calculation of the $d_{10}$, $d_{50}$, and $d_{90}$ values.

## METHODOLOGY

### Product Requirements and Constraints

In the case of spherical crystallization of ibuprofen, AVA is directly linked to its flowability, which is critical for its processing and formulation in pharmaceutical applications. A lower angle of repose indicates better flowability, which is essential for ensuring uniform mixing, accurate dosing, and efficient tableting during production. Good flowability of ibuprofen crystals reduces issues such as clogging in machinery and inconsistent tablet weights. Additionally, controlling the particle size of ibuprofen is vital because it affects not only its flowability but also its dissolution rate and bioavailability. Hence, in our research, the aim is to achieve an angle of repose that is as small as possible while ensuring that the median particle size ( $d_{50}$) falls within a certain range, which is specified of 300-450 μm in this study. The mathematical expression for the optimization problem can be formulated as follows:

$$\min_{\boldsymbol{u}} \ tan(\alpha(\boldsymbol{u})) \quad (2)$$

$$s.t. \ 300 < d_{50}(\boldsymbol{u}) < 450$$

$$\boldsymbol{u}_{lower} < \boldsymbol{u} < \boldsymbol{u}_{upper}$$

where $\boldsymbol{u}$ is the 9-dimensional operating condition shown in Table 1, and $\boldsymbol{u}_{lower}$ and $\boldsymbol{u}_{upper}$ correspond to the lower and upper bound of $\boldsymbol{u}$, respectively. It should be noted that the relationship between the input operating conditions $\boldsymbol{u}$ and output (tan $(\alpha)$ and $d_{50}$) is unknown, so both the objective function and the constraints are inferred from experimental observations. In addition, the optimization would be performed based on trial data or feedback from experimental results, without a predefined mechanistic model.

**Table 1:** Experimental conditions $\boldsymbol{u}$ and its upper & lower limits.

| No. | Experimental condition | Lower bound | Upper bound |
|---|---|---|---|
| 1 | Temperature (℃) | 40 | 60 |
| 2 | Stirring speed (rpm) | 300 | 800 |
| 3 | Stirring time (min) | 10 | 20 |
| 4 | Oil-to-water ratio (ml) | 0.25 | 1 |
| 5 | Starch concentration (g/ml) | 3.75 | 20 |
| 6 | Bridging agent concentration (mg/ml) | 2 | 15 |
| 7 | BSA concentration (mg/ml) | 0.05 | 3 |
| 8 | Ibuprofen concentration (mg/ml) | 100 | 350 |
| 9 | Total volume (ml) | 40 | 100 |

### Design of Experiments: DSD-RSM Combination

This section outlines how the problem is addressed through the integration of Definitive Screening Designs and Response Surface Methodology. Initially, DSD is employed to conduct 25 experimental runs, which systematically screen the nine factors involved. This screening process facilitates the identification of the two most

influential factors by evaluating their main effects. Through this approach, the number of factors is effectively reduced, focusing on those that significantly impact the response.

In the second phase, RSM is applied to the two factors selected during DSD. To explore the interactions between these two factors and their effects on the response, a set of 20 experimental runs is designed. This number of experiments allows for a thorough investigation of the factor space, ensuring that both linear and quadratic effects, as well as potential interactions, are captured. Specifically, the process begins with 10 experimental runs to refine the upper and lower bounds of the two factors identified in the screening phase. Subsequently, 10 additional experiments are conducted using Central Composite Design (CCD), a specific approach within RSM, to explore the relationship between the factors within the newly established boundaries. This CCD phase consists of 9 factorial points and 1 center point. The factorial points represent all possible combinations of the three levels (low, center, and high) for each of the two selected factors with newly established boundaries. These points allow for a detailed exploration of the main effects, as well as the quadratic and interaction effects between the factors.

## Bayesian Optimization

In both DSD and RSM methods, experiments are designed at once based on the input space. At the same time, no handling of constraints is performed. This section primarily discusses how BO can adaptively replace the traditional experimental design methods mentioned above, while also addressing unknown constraints.

BO works by constructing a surrogate model (which is a Gaussian Process model in this work) to predict the target function, and it uses a balance between exploration and exploitation to select the next points most likely to improve the objective function, thus efficiently finding the optimal solution. The acquisition function plays a crucial role in determining the next sampling point. It helps balance "exploration" (searching unknown areas of the design space) and "exploitation" (focusing on areas known to give high objective function values). The Lower Confidence Bound (LCB) is one of the acquisition functions used in Bayesian optimization, particularly with Gaussian Process (GP) regression models. LCB is based on a trade-off between the predicted mean and the uncertainty of the target function, allowing for exploration of uncertain regions while also exploiting known good areas. In our problem, the LCB acquisition function can be expressed as follows:

$$\min_{\boldsymbol{u}} \ \mu(\boldsymbol{u}) - \rho.\sigma(\boldsymbol{u}) \tag{3}$$

where $\mu$ and $\sigma$ are the mean and variance of $\tan(\alpha)$ inferred from GP, and $\rho$ is a hyperparameter that controls the balance between exploration and exploitation. While a higher value of $\rho$ encourages exploration of areas with high uncertainty, a lower value encourages exploiting regions with known good performance. Exploration may be more important because GP will have more uncertainty in its predictions initially. Over time, as the model becomes more confident about the objective function's shape, more exploitation can be encouraged. Thus, $\rho$ is related to experimental step $N$ in this paper. Their relationship is as follows:

$$\rho = e^{-\frac{N}{10}+1} \tag{4}$$

As for the constraints, GP is also built for $d_{50}$. In this way, the probability density functions can be calculated, ensuring that the probability of constraints being satisfied is within a given interval[14]. Here, the probability of satisfying the unknown constraints is set to be greater than 80%. Therefore, the acquisition function is updated with the following two additional constraints. They can be expressed as follows:

$$\begin{aligned} &\min_{\boldsymbol{u}} \ \mu(\boldsymbol{u}) - e^{-\frac{N}{10}+1}.\sigma(\boldsymbol{u}) \\ &s.t. \ p(\,d_{50} > 300) > 80\% \\ &\qquad p(\,d_{50} < 450) > 80\% \end{aligned} \tag{5}$$

where $p(.)$ represents he probability density function. Before the optimization process begins, 10 experimental points (e.g., operating condition $\boldsymbol{u}$) will be initially sampled using the Latin Hypercube Sampling method to construct the preliminary GP model. Starting from the 11th point, each subsequent experimental point will be selected sequentially based on Eq. (5).

# RESULT & DISCUSSION

This section examines the outcomes of two experimental design methodologies: traditional DoE and BO. The experimental results for the DSD-RSM combination method are presented in Table 2, while those for BO are detailed in Table 3. Physical insights are also presented.

## Result of DSD-RSM Combination

As shown in Fig. 3, firstly in DSD, two relatively important factors were identified: stirring speed and oil-to-water ratio through DSD. Subsequently, 10 experimental runs were conducted to refine the bound for stirring speed from [300, 800] to [400, 600], and for oil-to-water ratio from [0.25, 1] to [0.6, 1], as illustrated in Table 2. After narrowing the ranges for these key factors, an additional 10 experiments were performed using CCD, a three-level design focusing on stirring speed values of 400, 500, and 600, and oil-to-water ratio values of 0.6, 0.8, and 1, respectively. The experimental results in Table 2 indicate that the smallest AVA identified using the DSD-

RSM combination, while meeting the $d_{50}$ constraints, occurs at the center point of the CCD phase with the value of 35.78. Interestingly, this center point was tested twice during the CCD phase—once satisfying the constraints and once failing to do so (see "Response Surface Methodology", No. 12 and 19 in Table 2). This is because each experiment inevitably involved some deviations. The $d_{50}$ boundary we set ranges from 300 to 450 μm. In the two repeated experiments, one yielded a $d_{50}$ value of 442.8, while the other resulted in 459.8. This also indicates that under the experimental conditions of 12$^{th}$ and 19$^{th}$ runs, $d_{50}$ is generally close to the upper boundary of 450.

The experimental results align with the underlying physical principles governing the crystallization process. Higher stirring speed results in finer particles with rougher surfaces, increasing friction and reducing flowability. However, very low stirring speeds can lead to unsuccessful crystallization. Meanwhile, a higher oil-to-water ratio improves size uniformity, enhancing flowability through reduced friction and narrower particle size distribution. To conclude, these two factors—stirring speed and oil-to-water ratio—significantly affect both $d_{50}$ and

**Table 3:** Experimental results of BO.

$\alpha$, and they were selected as critical variables in the experimental design. For stirring speed, a lower value tends to produce larger particles with smoother surface comparing to the fines, which corresponds to the smaller values observed in our optimized results. The initial range was 300 to 800, with 500 as the traditional experimental design value. For the oil-to-water ratio, a relatively higher value produces more uniform particles. The initial range was 0.25 to 1, and the traditional experimental design value was 0.8.

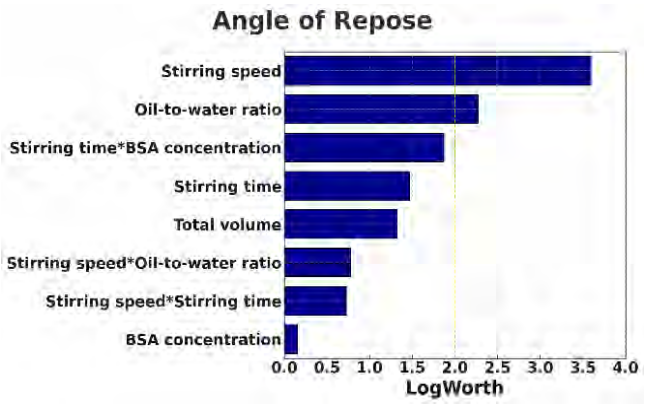

**Figure 3.** Analysis of definitive screening design.

## Result of BO

As illustrated in Table 3, the smallest AVA identified while meeting the $d_{50}$ constraints using BO occurs at the third experiments, with the value of 35.84. In the sequential Bayesian experiments, runs 19, 20, 21, 23, 24, and 25 were all very close to the third experimental design. This indicates that the Bayesian optimization is nearing convergence. However, it is unfortunate that despite searching around the current optimal region, no experimental condition was found that outperforms the result of 35.84 achieved in the third run.

Comparing BO to DSD-RSM combination where a total of 45 experiments were conducted, BO only required 25 experiments, thus saving 55% of the experimental time up to 80 hours. In BO, 16 out of 25 experiments satisfied the constraints, resulting in a proportion of 64%. In contrast, in the DoE, 18 out of 45 experiments satisfied the constraints, with a proportion of 40%. In terms of costs, optimizing spherical crystallization conserves nearly half of the solvent and drug materials, making it highly efficient in resource usage.

At the same time, BO shows consistency with DSD-RSM combination in the final optimization results. The ranges for the two key variables identified through DSD-RSM combination: stirring speed [400, 600] and oil-to-water ratio [0.6, 1]. The optimal experimental values obtained through BO for stirring speed and oil-to-water ratio are 452.5 and 0.74, respectively. In the last 8 experiments of BO, 7 of the experiments yielded data within this range.

## CONCLUSION

In summary, this study compared two experimental design methods: the traditional DoE and BO, to identify the optimal conditions for stirring speed and oil-to-water ratio. Overall, both methods produced similar optimal values, with BO providing a more efficient way to identify optimal conditions while maintaining reliability. It is important to note that the research in this paper is purely data-driven, and the integration of mechanistic insights could provide additional improvements in the optimization process. Therefore, future research may focus on incorporating mechanistic knowledge into BO to enhance the efficiency of experimental design. For example, if key factors influencing experimental outcomes are known in advance through mechanistic knowledge, the focus can be directed toward these critical factors, thereby reducing the number of experiments required. Additionally, the presence of a mechanistic model may accelerate the experimental process further.

## ABSTRACT

Design space identification (DSId) and flexibility analysis are critical in process systems engineering, enabling efficient design of operating conditions. For bioprocess, these tasks are often hindered by the absence of reliable mechanistic models and limited experimental data. This paper presents an algorithm to address these challenges in bioprocesses. The methodology begins by constructing a Gaussian process (GP) model to predict key performance indicators (KPIs) from process inputs. Leveraging the probabilistic nature of GP predictions, we perform probabilistic design space identification (PDSId), characterizing each input point by its probability of feasibility which is the likelihood that constraints imposed on KPIs are satisfied. To visualize and analyse the feasibility space, contours at varying probability levels are identified using alpha shapes, which define deterministic boundaries corresponding to different confidence levels. This enables the quantification of volumetric process flexibility and operating ranges for each confidence level. The proposed methodology is applied to an antibody-producing Chinese hamster ovary (CHO) cell culture process, optimizing culture temperature and osmolality with respect to product yield and purity. Results are presented through probability heat maps and flexibility metrics, providing both qualitative and quantitative insights into feasibility and operational flexibility, thereby supporting informed decision-making in process design.

## INTRODUCTION

Achieving efficient and reliable operations in complex large-scale systems, such as bioprocesses, requires carefully designed process conditions. In the biopharmaceutical industry, operational reliability is commonly assessed through key performance indicators (KPIs) like yield and purity meeting the established standards consistently. In this regard, design space identification (DSId) is a critical method for evaluating the feasibility of operating conditions. DSId involves isolating a subset of the broader knowledge space that encompasses all possible process inputs and satisfies the constraints imposed on the KPIs [1]. This subset, known as the design space, facilitates the evaluation of operating points and serves as a practical tool for process operators to assess the feasibility of the operating conditions.

Design space identification (DSId) methodologies are broadly classified into model-based and data-driven approaches. In the context of bioprocesses, model-based methods are generally preferred due to the impracticality of extensive experimentation. For instance, Yang and Ierapetritou [2] developed a modeling framework for DSId of a bioreactor producing monoclonal antibodies (mAbs). Similarly, Sachio et al. [3] proposed a model-based methodology for design space identification in chromatographic separation columns, encompassing the construction of geometric boundaries to enclose the design space and the quantification of its size to evaluate operational flexibility.

While mechanistic model-based approaches are effective in capturing the complexities of bioprocesses, they are often computationally demanding for DSId applications, primarily due to the need for extensive

sampling across the knowledge space to identify the design space accurately. To mitigate this computational burden, adaptive sampling techniques have been introduced, aiming to reduce the number of model evaluations required [4, 5]. Additionally, surrogate models have emerged as an efficient alternative for feasibility assessments, leveraging less computationally intensive techniques. Surrogate models such as Kriging regression [6] and artificial neural networks [7] have demonstrated significant potential in approximating complex process behaviors while minimizing computational overhead.

Process models are often parameterized using experimental data, which introduces stochasticity and parametric uncertainties, often related to measurement noise. As a result, the compliance of the KPI constraints cannot be determined definitively but only with a degree of confidence. Probabilistic design space identification (PDSId) addresses this by assigning each point in the knowledge space a probability of feasibility instead of a binary classification of feasible or infeasible. PDSId, however, increases computational complexity, requiring additional simulations across the uncertain parameter space. To address this, Laky et al. [8] proposed an optimization-based PDSId and flexibility analysis approach. Kusumo et al. [9] introduced a nested sampling strategy that prioritized maintaining high sample density in regions with a high probability of feasibility. Kucherenko et al. [10] developed an adaptive sampling method leveraging a metamodel that directly predicted the probability of feasibility based on the parameter space.

Research in DSId and PDSId typically assumes the availability of a mechanistic model. However, for complex systems like upstream biopharmaceutical processes, developing reliable mechanistic models is challenging due to a limited understanding of underlying mechanisms (e.g., host cell protein generation) or the need for simplifying assumptions. Consequently, data-driven approaches may be preferred as alternatives due to their ease of modeling. However, they often require extensive experimentation, which can be expensive and impractical, leading to sparse datasets. Such sparsity also means that data uncertainty becomes a significant factor that needs to be addressed.

We present a data-driven approach to address the challenges of modeling uncertainties in complex bioprocess systems. Specifically, we use Gaussian Process (GP) models to account for real-world data uncertainties stemming from measurement noise and inherent inter-experimental variability, enabling a probabilistic characterization of the design space. The framework consists of two main components. First, the GP model predicts key performance indicators (KPIs) based on input process variables, facilitating probabilistic modeling of these KPIs. The probability of feasibility is then calculated based on performance constraints, which indicates the likelihood of meeting the KPI constraints for a given input. The second step of the framework conducts a quantitative analysis of operational flexibility for a given point. Following the method proposed by Sachio et al. [3], alpha shapes are used to define deterministic boundaries at varying levels of feasibility probabilities, allowing the quantification of process flexibility and operational ranges. This enables a detailed examination of trade-offs between process flexibility, performance, and confidence levels.

The framework is applied to experimental data from a fed-batch Chinese hamster ovary (CHO) cell culture producing a mAb to study the effects of osmolality and temperature on mAb yield and cell-derived impurity (host cell protein, HCP) generation. The results are visualized through probabilistic heat maps and flexibility metrics, offering valuable insights for process development.

## METHODOLOGY

### Experimental Setup

This study aims to investigate the effects of two critical upstream process parameters, culture temperature and osmolality, on HCP generation in mAb-producing CHO cell culture and their subsequent clearance in affinity and cation exchange chromatographic purification. Fed-batch culture was initiated at a seeding density of $2 \times 10^5$ cells/ml in 30 ml shake flasks using CD CHO medium (ThermoFisher Scientific, U.K.). The culture was incubated at 36.5°C with 8% $CO_2$ humidified air, shaking at 140 rpm. Every two days, 10% v/v EfficientFeed™ C+ AGT™ Supplement was added to each culture (ThermoFisher Scientific, U.K.). On day 5, as the culture entered the exponential phase, temperature and osmolality were manipulated while maintaining the desired viable cell count.

The study employs a central composite face-centered (CCF) design with two replicates, resulting in a total of 18 experimental runs manipulating three levels of temperature and osmolality. Specifically, temperature is varied between 32°C and 36.5°C, with 34°C as the middle level, on day 5. Osmolality is set between 410 mOsm/kg and 500 mOsm/kg, with a midpoint of 455 mOsm/kg, again on day 5 of the culture, starting from a value of 410 mOsm/kg. Osmolality was adjusted using 5M sterile NaCl, and OsmotechXT (Advanced Instruments Companies, U.K.) was used to measure the osmolality with a tolerance of 20 mOsm/kg. The culture was harvested when cell viability dropped below 80%.

Cell density and viability were determined daily using the trypan blue dye exclusion method and inverse microscopy. The extracellular mAb concentration was quantified using the biolayer interferometry BLItz system (Sartorius Stedim, U.K.). Residual HCP concentration was measured using the CHO cell HCP ELISA kit from Cygnus

Technologies, U.S.

## Probabilistic Design Space Identification

The proposed methodology performs PDSId based on a GP model identified using the data obtained from the experiments described earlier.

### GP model to predict KPIs

In this study, we assume that the uncertainties in the system model and measurement noise can be modeled using Gaussian distributions. Hence, we adopt the GP modeling framework to model the KPIs. GP regression is a nonparametric, nonlinear modeling technique that is particularly effective in scenarios with limited data and inherent model uncertainty. Its strong interpolation capabilities make it well-suited for cases where data is obtained through factorial designs that emphasize the extreme ends of input variability.

Let $y$ and $u$ represent the KPIs and input actions, respectively. The Gaussian process model used to predict the KPIs is expressed as follows.

$$\mathrm{y} = \mathrm{f}(u) + \mathrm{e} \tag{1}$$

Here, $\mathrm{f}(\cdot)$ represents the system model and $e$ represents the measurement noise which is Gaussian with a mean of zero and variance of $\sigma^2$, represented as $\mathcal{N}(0, \sigma^2)$. A GP model learns the function $\mathrm{f}(\cdot)$ as a Gaussian probability distribution function rather than a deterministic entity. Hence, the predictions of KPIs would also be gaussian distributions. Let $\mathcal{U}_\mathcal{T}$ and $\mathcal{Y}_\mathcal{T}$ represent training data used to train the GP model. For any new point $u_*$ in the knowledge space, the KPI prediction is a Gaussian distribution with the mean $\mu_*$ and variance $\Sigma_*$ expressed as follows:

$$\mu_* = \mu(u_*) + \Sigma(u_*, \mathcal{U}_\mathcal{T})(\Sigma(\mathcal{U}_\mathcal{T}, \mathcal{U}_\mathcal{T}) + \sigma_\epsilon^2 \cdot I_{N\times N})^{-1}(\mathcal{Y}_\mathcal{T} - \mu(\mathcal{U}_\mathcal{T})) \tag{2}$$

$$\Sigma_* = \Sigma(\mathrm{u}_*, \mathrm{u}_*) - \Sigma(\mathrm{u}_*, \mathcal{U}_\mathcal{T})(\Sigma(\mathcal{U}_\mathcal{T}, \mathcal{U}_\mathcal{T}) + \sigma^2 \cdot \mathrm{I}_{\mathrm{N}\times\mathrm{N}})^{-1}\Sigma(\mathcal{U}_\mathcal{T}, \mathrm{u}_*) \tag{3}$$

Here, $\mu(\cdot)$ and $\Sigma(\cdot)$ represent the mean and covariance functions of the prior distribution of the function. For the sake of brevity, the detailed explanation of GP modeling is omitted here, and readers are directed to Schulz et al. [11] for further information.

### Estimating the probability of feasibility

Let us consider the DSId problem for the system with the following model and the constraints.

$$y = f(u); \quad u \in [u_l, u_u] \tag{4}$$

$$g(y) < 0 \tag{5}$$

In Eq. (4), $u \in [u_l, u_u]$ represents the knowledge space and Eq. (5) represents the constrains on the system. In this work we consider the case where the constraints are directly imposed on the KPIs $y$ which are represented as given below.

$$y_l \leq y \leq y_u \tag{6}$$

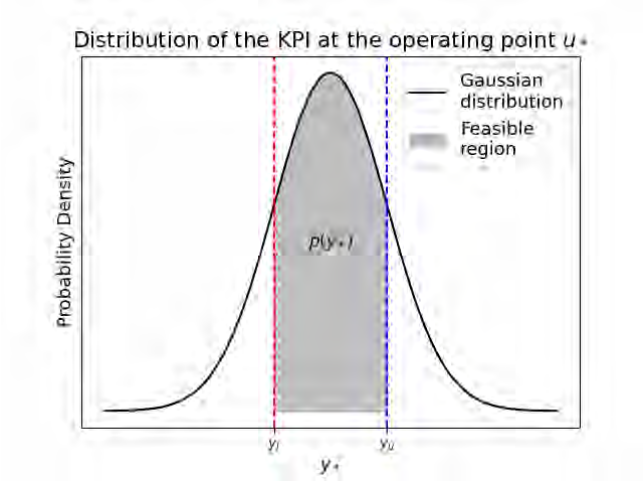

**Figure 1.** Depiction of the calculation of the probability of feasibility.

Here, $y_l$ and $y_u$ represent the lower and upper limits on the KPIs. With every point in the knowledge space being associated with its corresponding predicted KPI distribution, as described in the previous section, we proceed to estimate the probability of feasibility for the corresponding input point. In PDSId, the probability of feasibility for a given input $u_*$ is defined as the probability with which the constraints specified in Eq. (6) are satisfied. Mathematically, it can be expressed as:

$$\mathrm{p}(u_*) = \int_{y_l}^{y_u} p(y_*|u_*)\, dy_* \tag{7}$$

The above equation calculates the area under the distribution of the KPI at the operating point of $u_*$ in the feasibility region. The quantity $p(u_*)$ hence denotes the probability at which the given operating point $u_*$ is guaranteed to satisfy the constraints imposed on the KPIs. For the case of a Gaussian distribution and a single KPI, the probability of feasibility is represented as follows:

$$\mathrm{p}(u_*) = \Phi\left(\frac{y_u - \mu_*}{\Sigma_*^{0.5}}\right) - \Phi\left(\frac{y_l - \mu_*}{\Sigma_*^{0.5}}\right) \tag{8}$$

Here, $\Phi(\cdot)$ represents the cumulative distribution function of a Gaussian distribution. The calculation of $p(u_*)$ is depicted in Fig. 1 where the shaded area between $y_l$ and $y_u$ represents the probability of feasibility. To characterize whole knowledge space with a probability of feasibility, we sample uniformly from the knowledge space using Sobol sequence. For each sample of $u_* \in [u_l, u_u]$ generated, the predicted KPI distribution is obtained using Eq. (2) and (3), following which the probability of feasibility is evaluated as per Eq. (8). This results in every possible

point in the knowledge space being characterized by a probability of feasibility. The results are visualized through the usage of probability heat maps which are presented in the Results and Discussion section.

While the probability of feasibility provides valuable information regarding feasibility, to facilitate further analysis, we draw contours at different probability levels and quantify the operational flexibility at each level, as described in the next section.

## Quantitative Flexibility Assessment

To further enhance process understanding, we propose a deterministic quantitative flexibility assessment approach that builds upon the identified probabilistic design space. This method enables the quantification of process flexibility by defining deterministic boundaries at varying levels of probability of feasibility and computing a volumetric flexibility index for each level. By integrating both probabilistic information and geometric representations, this approach provides a structured way to assess the robustness and adaptability of the design space.

To achieve this, we employ alpha shapes as a geometric tool to delineate deterministic boundaries of the probabilistic design space. An alpha shape defines the spatial extent of a given set of points and can represent both convex and non-convex regions by adjusting a parameter known as the alpha radius. At large alpha radius values, the alpha shape becomes identical to a convex hull. As the alpha radius decreases, the alpha shape becomes increasingly non-convex. Alpha shapes can be exploited to identify design spaces as described in Sachio et al [3]. Briefly, the method has three major steps:

**Step 1. Model sampling.** The GP model is sampled via quasi-random Sobol sampling to obtain a dense dataset containing 16384 ($2^{14}$) input combinations and their corresponding probability of feasibility. In this work, we are working with 2D problems and hence 16384 samples is more than enough for an accurate analysis [3].

**Step 2. Point cloud classification.** A set of $n_p$ different levels of feasibility probability is defined which is used as the constraints to characterize $n_p$ alpha design spaces [3]. For a single feasible probability level, for example ≥ 95%, the dataset is screened by separating the points which satisfy ≥ 95% from those which violate it. The group of points which satisfy this constraint forms the satisfied point cloud. The rest of the points form the violated point cloud.

**Step 3. Alpha shape construction.** An alpha shape is formed by solving for the alpha radius which defines the space occupied by the satisfied point cloud and does not capture any violated points. The resulting alpha shape is the alpha design space, with an explicit definition of the boundary and quantifiable size (volumetric flexibility metric). The schematic of the proposed methodology is presented in Fig. 2.

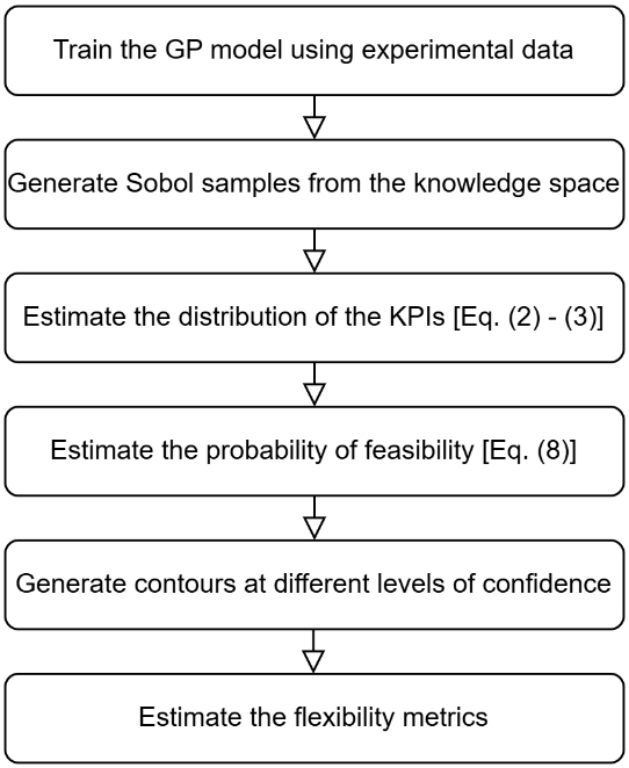

**Figure 2.** Schematic representation of the proposed methodology.

# RESULTS AND DISCUSSION

The experimental data comprises 18 data points derived from a 2-factor, 3-level factorial design with two replicates for each operating condition. The inputs are the Osmolality ($O$) and Temperature ($T$) while the outputs are the Yield and the ratio of HCP to mAb concentration. A general heuristic regarding GP regression is that it requires 10 points per regressor, which would be 20 for two regressors. This is close to 18 points; however, 9 of these are at the same input conditions.

Of the 18 points, 12 are used to train the GP model, and 6 are reserved for validation. Gaussian process regression with a co-regionalized RBF kernel is trained in Python. The average values for mAb yield and HCP-to-mAb concentration ratio (HCP/mAb) in the experiments are 1.25 and 0.25, respectively. Therefore, the KPI constraints are defined such that the minimum mAb yield is 1.25, and the maximum HCP/mAb ratio is 0.25. Consequently, the constraints for the KPIs are as follows:

$$1.25 \leq Yield\,; \quad \mathrm{HCP/mAb} \leq 0.25 \tag{9}$$

## KPI Predictions in the Knowledge Space

First, the GP model is trained, and the Sobol samples generated from the knowledge space are used to predict

the distribution of the KPIs. Figure 3 illustrates the mean of the KPIs for each input in the knowledge space, providing a convenient way to visualize KPI variability within the knowledge space. It can be observed that higher temperatures and mid-level osmolality values generally favor higher yields, with mid-level osmolality also resulting in lower HCP concentrations.

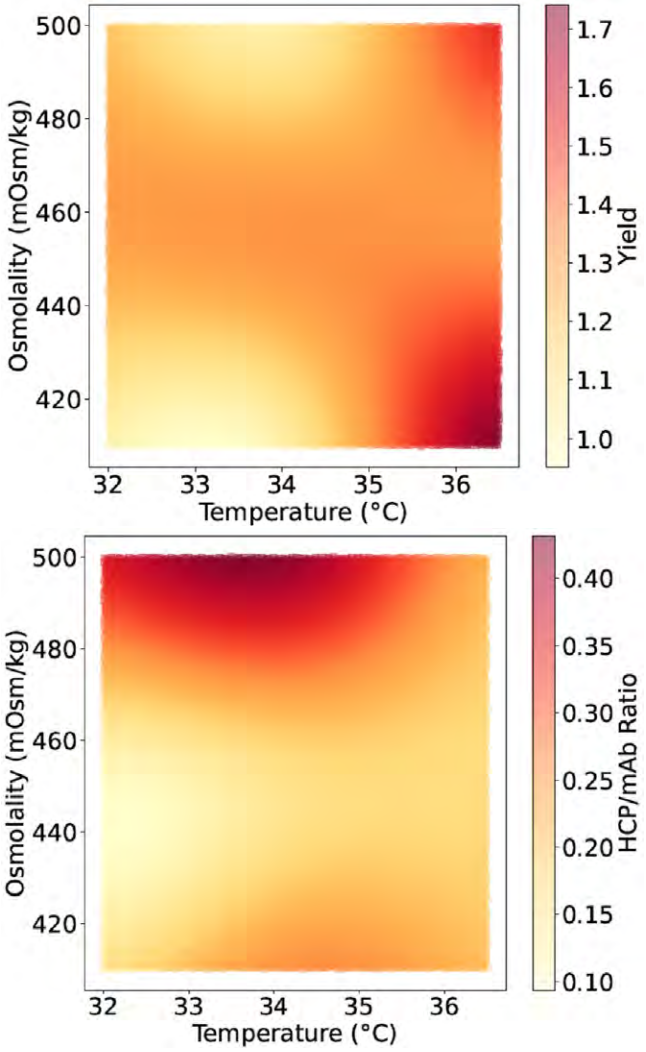

**Figure 3.** Heat map depicting the means of the predicted KPIs.

However, there are operating points, such as [$T$, $O$] ≈ [32 – 33, 440-440] which can achieve high purity but low yield. Hence, one must combine all the KPI constraints to better assess these trade-offs, which is the DS representation of the feasibility analysis.

## Probabilistic Design Space Identification

To visualize the design space with respect to both KPIs, the probability of feasibility is estimated for each point in the knowledge space, and the results are presented in Fig. 4. This heatmap, shows regions with higher probabilities of satisfying the constraints in warmer red tones, while lower probability regions are represented in yellow tones.

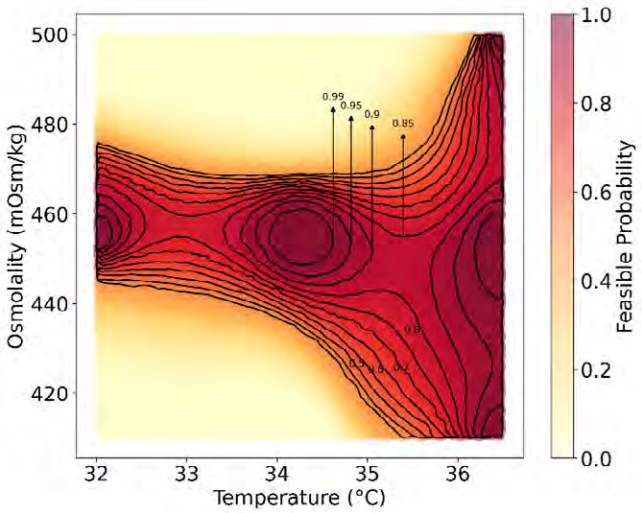

**Figure 4.** Probability heat map with the contours at different levels of confidence.

The results indicate that the constraints in Eq. (9) are likely to be satisfied in the regions where [$T$, $O$] are [34.25, 455] and [36.5, 410-500]. Thus, higher temperatures allow for more variability in osmolality while satisfying the KPI constraints. This is because higher temperatures promote cell growth and productivity, while lower temperatures may prolong the culture duration but can also lead to increased host cell protein accumulation. To gain further insights, the alpha shapes-based boundary detection method is applied to obtain contours at different probability levels. A contour at a confidence level $\alpha$ encloses all points with a probability of feasibility greater than or equal to $\alpha$. In Fig. 4, contours are provided for probability values of [0.99, 0.95, 0.90, 0.85, 0.80, 0.77, 0.70, 0.65, 0.60, 0.55, 0.5], with the lowest level set at 0.5, as this is typically the threshold for accepting or rejecting an operating point. The heatmap representation provides a convenient way to visualize the design space and derive insights into how feasibility varies across the knowledge space.

## Flexibility Assessment

To quantify the information depicted in the contours, the volumes of the space enclosed by each contour can be calculated. This provides a means of assessing the flexibility of operation at different confidence levels. The volumes for the heatmap in Fig. 4 are presented in Fig. 5. These volumes are normalized to represent the fraction of the total knowledge space enclosed within the contour. For instance, operating at a probability of feasibility of at least 90% probability of feasibility offers flexibility within up to 10% of the total knowledge

space. In addition to assessing flexibility, this approach allows for the evaluation of the trade-off between flexibility and confidence level, where a higher confidence level reduces flexibility and vice versa.

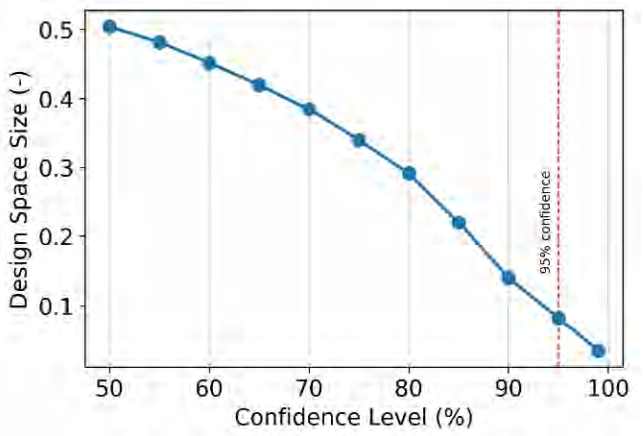

**Figure 5.** Design space size at various levels of confidence as a metric of flexibility in operation.

## Design space for different KPI constraints

Finally, if the DS for a particular KPI constraint does not meet the desired criteria, alternative constraints can be explored to assess feasibility and flexibility for different operating goals. Figure 6 illustrates this exploration across four scenarios. To maintain clarity, we plot the contours of 50% probability of feasibility, and the flexibility metrics for all the levels mentioned earlier are shown in Fig. 7.

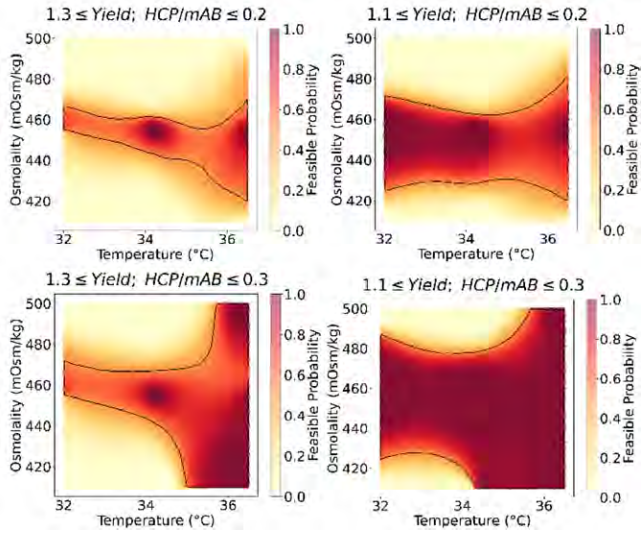

**Figure 6.** Probability heat map for different KPI constraints

The first scenario represents a stringent case, requiring a yield of at least 1.3 and an HCP/mAb ratio of at most 0.2. In the second scenario, the yield constraint is relaxed to 1.1, which increases the DS. In this case, mid-level osmolality and lower temperatures are preferred. The third scenario sets the minimum yield to 1.3, while relaxing the HCP/mAb constraint to 0.3. Here, higher temperatures and lower osmolality are generally favored. Finally, both yield and purity constraints are relaxed to 1.1 and 0.3, respectively, resulting in a significantly larger DS. These trends align with empirical expectations. This can also be observed in Fig. 7, which compares the size of the design space at different levels of probability of feasibility for various KPI constraints. The most ambitious constraints, such as high yield and low impurity, lead to a smaller design space at every probability level, while relaxed constraints result in a larger design space. This representation provides a bird's-eye view of the trade-offs between the required probability of feasibility, operational flexibility, and the ambitiousness of the KPI constraints. Experimental validation of these computational findings is underway.

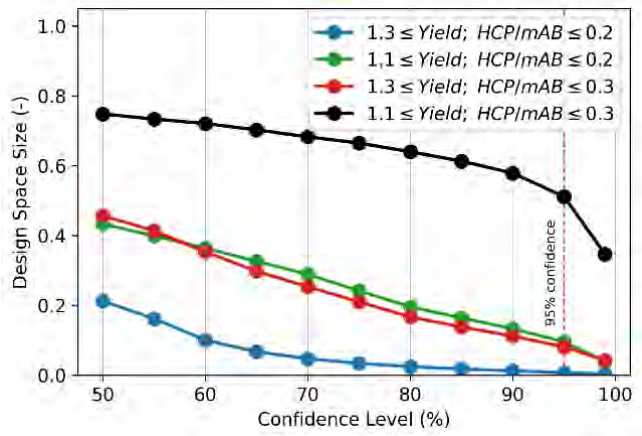

**Figure 7.** Comparing the design space sizes for various KPI constraints

## CONCLUSION

Assessment of the feasibility of operating points and the flexibility of those operations is vital for novel and complex processes such as bioprocesses. This paper presents a methodology to achieve these goals for systems with limited understanding. The methodology includes three key features: estimating the probability of feasibility of an operating point, identifying the design space for a given probability of feasibility or confidence level, and quantifying the flexibility of operations at a given confidence level. The obtained results are presented through probabilistic heat maps and flexibility metrics, providing actionable insights for process development scientists. In the presented CHO cell study, initial experimental data was used to develop a GP model of how two process conditions, temperature, and osmolality, affect recombinant product yield and purity.

Subsequent system analysis using the proposed methodology provided insights for balancing purity-yield trade-offs and guide further experimentation and process design. The future research focus is on performing additional experiments to confirm the DS and improve the accuracy of the model.

## ABSTRACT

This study presents a comprehensive comparison of the three alternative downstream manufacturing technologies for pharmaceuticals: i) Dry Granulation (DG) through roller compaction, ii) Direct Compaction (DC), and iii) Wet Granulation (WG) based on the economic, environmental and product quality performances. Firstly, the integrated dynamic mathematical models of the different downstream (drug product) processes were developed using gPROMS formulated products based on data from the literature or/and our recent experimental work. The process models were developed and simulated to reliably capture the impact of the different design options, process parameters, and material attributes. Uncertainty analysis was conducted using global sensitivity analysis to identify the set of critical process parameters (CPP) and critical material attributes (CMA) that mostly influence the quality and performance of the final pharmaceutical tablets in each case, captured by the critical quality attributes (CQAs). Based on the set of CPP and CMA, the combined design spaces, which guarantee the attainment of the targeted CQA, were identified and compared. Additionally, based on the process simulations results and inventory data, the techno-economic Analysis was performed alongside life cycle assessment (LCA). The LCA provided an in-depth evaluation of the environmental impacts associated with each manufacturing method, considering aspects such as energy consumption, raw material usage, emissions, and waste generation based on a cradle-to-gate approach. By integrating the CQAs and critical emission categories within a Quality and and Sustainability by Digital Design (QSbDD) paradigm, this study offers a holistic analysis that captures both the environmental and product quality performance.

## INTRODUCTION

Pharmaceutical manufacturing plays a crucial role in ensuring the delivery of safe, effective, and high-quality medicines to patients worldwide. However, the development of robust and efficient manufacturing processes remains a complex challenge. The pharmaceutical industry operates under stringent regulatory requirements to guarantee product safety and efficacy, adding complexity to decision-making and process development. Compounding these challenges is the growing pressure to adopt sustainable manufacturing practices, driven by increasing environmental concerns and evolving regulatory standards. Tablets account for the most important dosage forms [14], yet the selection of the most suitable downstream (drug product) technologies, such as direct compaction (DC), dry granulation (DG), or wet granulation (WG), remains a critical decision. This process is often hindered by a reliance on traditional trial-and-error approaches, which are resource-intensive and

inefficient.

One promising approach to address quality related challenges is the adoption of Quality-by-Design (QbD), a systematic framework endorsed by regulatory agencies such as the FDA and EMA. QbD is increasingly adopted to deliver more effective quality management strategies, ensuring that product quality is built into the process rather than tested at the end. By linking critical quality attributes (CQAs), critical process parameters (CPPs), and critical material attributes (CMAs), QbD enhances process reliability and facilitates regulatory compliance. However, these methods do not inherently consider economic and environmental criteria, leaving a glaring critical gap in the decision-making process. Emerging digital tools are opening new avenues for more effective decision-making in pharmaceutical manufacturing. Flowsheet and plant wide models are critical in all design stages to help identify the most economic and environmentally friendly options, optimize process operation, and develop plant wide control strategies [1-3]. For example, an end-to-end ibuprofen process has been developed to identify optimal and sustainable design with adjustment of operating conditions to achieve the quality assurance [4]. Techno-Economic Analysis (TEA) evaluates the cost-effectiveness of manufacturing processes, analyzing both capital (CaPEx) and operational expenses (OpEx). Continuous manufacturing is frequently highlighted as economically advantageous due to its higher yield and scalability [5]. There also applications of TEA to plant wide biopharma processes [6].

Life Cycle Assessment (LCA) provides a comprehensive evaluation of the environmental impacts of manufacturing processes, using frameworks like ReCiPe 2016. Prior studies emphasize the environmental advantages of continuous manufacturing over batch processes [5, 7]. LCA has successfully been applied to both lab scale and plant wide processes to identify environmental footprints [8 ,9]. However, there is still a critical need for more systematic and robust cradle-to-gate and cradle-to-cradle strategies within the pharmaceutical and biopharmaceutical sectors.

This study advances the field by linking LCA to QbD and TEA, creating a more rigorous and holistic decision-making framework. The approach is validated by considering three downstream tablet manufacturing approaches namely: Direct Compaction (DC), Dry Granulation (DG) via roller compaction, and Wet Granulation (WG). The holistic approach evaluates and compares these alternative downstream methods in terms of quality, cost, and environmental impact. Additionally, a combined robust design space, the ranges of CMAs and CPPs which deliver quality assurance, is identified to ensure consistent attainment of critical quality attributes (CQAs). The study further explores alternative process designs, such as closed-loop recycling systems, to enhance the environmental performance of the plant while meeting quality requirements. This integrated framework aims to guide sustainable and efficient pharmaceutical manufacturing practices.

## METHODOLOGY

### Process modelling and simulation

The first step consisted in the development of integrated process models for three downstream tablet manufacturing methods (DC, DG and WG) shown in Figure 1. The dynamic models were constructed using gPROMS Formulated Products®, leveraging a combination of literature data and experimental results from recent studies. The tablet consists of paracetamol, the active pharmaceutical ingredient (API), lubricant, and several excipients: microcrystalline cellulose (MCC), lactose, crospovidone (disintegrant), and magnesium stearate (lubricant). All processes are operating continuously starting with the blending of API, excipients, and lubricant to deliver uniform blends, followed by different tableting approaches, in which DC is the most straight forward approach, mixed particles were sent directly to the tablet press machine and then the dissolution test. The DG route will go through the roller compactor and a mill to remove large particles. The WG is conducted in a twin-screw granulator and requires the addition a solvent which consists of water and hydroxypropyl methylcellulose (HPMC) at 94% and6% wt% respectively. The wet granulation step is followed by the drying then the tablet press. Each process model was designed to capture the intricate interactions between process parameters and material attributes. Key parameters such as compaction force, granule size distribution, the impact of the blending residence time and drying and the targeted moisture content were captured to ensure that the models accurately represent the real industrial-scale operations. The dissolution tests were configured at the end of the model simulations to predict the critical quality attributes (CQAs), including dissolution rate, time and residual impurities/solvents, alongside the other CQAs such as tablet tensile strength, hardness and porosity which are predicted by the models of each downstream processing routes. This modelling approach allows for the systematic exploration and optimization of various process configurations and design options.

### Quality and Sustainability by Digital Design

A new Quality and Sustainability by Digital Design (QSbDD) approach leveraging model-based methods is proposed allowing specifically the identification of the CPPs and CMAs which significantly influence the CQAs [4]. The uncertainty analysis further evaluated how variations in these parameters impact the quality of the final pharmaceutical tablets. The results were used to define

a combined robust design space for each manufacturing process, ensuring compliance with the quality requirements under varying operating conditions.

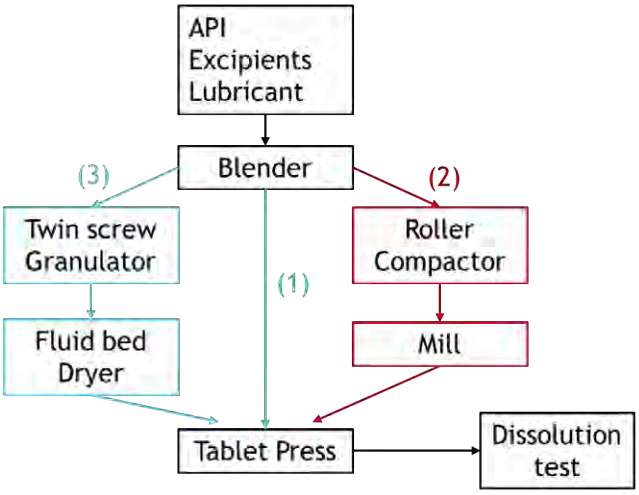

**Figure 1** Simplified paracetamol tabletting process flowsheets via (1) Direct compaction (DC), (2) Dry granulation with roller compaction (DG), and (3) Wet granulation (WG).

## Sensitivity Analysis

A Global Sensitivity Analysis (GSA) was performed to systematically assess the impact of all process parameters and material attributes on the CQAs and identify the optimal set of CPP and CMA. The Sobol method, a variance-based approach, was chosen due to its robustness in handling non-linear and interactive effects. The sensitivity indices were evaluated using Monte Carlo simulations, which allowed for an accurate quantification of the influence of each input parameter.

### Lifecycle Assessment

A cradle-to-gate life cycle assessment (LCA) was performed to quantify the environmental impacts of each manufacturing process. The proposed LCA is consistent with the ISO 14040/44 standards, covering four key phases: goal and scope definition, inventory analysis, impact assessment, and interpretation. Environmental impacts were assessed across multiple categories, including global warming potential, energy use, and waste generation.

### Goal and Scope

Perform the LCA for all case model simulations with the functional unit of 1 kg paracetamol tablet products.

### Life cycle inventory

Based on the process simulation outputs, detailed inventory data were gathered for each manufacturing approach. This data encompassed material usage, energy consumption, waste generation, and emissions at each processing stage.

### Impact assessment

The impact assessment is based on the method ReCiPe 2016 in SimaPro with the Ecoinvent 3 environmental footprint database. The ReCiPe 2016 captures three endpoint categories (human health, ecosystems, and resources) and seventeen midpoint categories. These different categories provide a comprehensive basis to compare the different design options.

### Interpretation of results

Finally, the results obtained from the previous steps are interpreted and the environmental hotspots are identified.

The overall LCA was structured into distinct system boundaries to capture the contributions of key process stages. The defined system boundaries include:

- API production: The environmental impacts associated with the synthesis of the API, including raw material extraction, energy use, and waste generation during API production. In compliance with ISO standards, the inputs required for paracetamol API synthesis were modeled using data from literature. [10-12]
- Drug product manufacturing: This boundary includes all unit operations involved in the downstream tableting processes. It accounts for material inputs, such as excipients and binders, as well as operating energy and utilities (e.g., electricity, steam). Additionally, the impacts of excipient production were included, alongside emissions and waste generated at each stage.
- Quality control: The LCA incorporated the energy and material requirements for quality control procedures, including dissolution tests, hardness tests, and content uniformity assays. These tests are essential for ensuring compliance with regulatory standards and maintaining product quality.

## Technoeconomic Analysis

The TEA were performed based on the capital expenditure (CapEX) and operational expenditure (OpEX) based on standard methodologies [7]. The economics were evaluated based on:

- Direct and indirect costs: Equipment cost estimates were derived from vendor quotes and literature sources.
- Operating expenses (OpEx): Included material costs (API, excipients), utilities (electricity, steam), labour, and maintenance costs.

## RESULTS AND DISCUSSIONS

### Simulation results and Design Space analysis

The simulations of three downstream tableting approaches (DC, WG, DG) in a continuous manufacturing setting were performed. The dissolution profiles and tensile strength prediction were compared against experimental data. Across all manufacturing methods, the final products consist of 500 mg paracetamol tablets, with a targeted API content of 23%. According to the United States Pharmacopeia (USP) criteria for paracetamol tablets, during the dissolution test use at least 80% of the API must dissolve within 30 minutes. This requirement is considered as the first CQA. Additionally, the tensile strength must exceed 1.2 MPa.

Based on the model predictions at some nominal values, all three methods can deliver the required CQA bounds. However, this is enough to guarantee built-in quality assurance based on rigorous implementation of QbD. Firstly, it is key to identify the minimum set of CPPs and CMAs which capture most of the variability within the CQAs. This criticality assessment was achieved based the GSA. The CPPs and CMAs were selected based on their total-order Sobol index, which represents their overall contribution to the variance in CQAs such as tablet tensile strength and API dissolution rate [12, 13]. For instance, for the DG process, the CPPs and CMAs are the roller compaction force, tablet press compaction force, and moisture content.

The proposed GSA-based approach revealed the optimal sets of CPPs and CMAs in each process which allows the identification of the design space which is multidimensional space where the product's CQAs are proven to meet their acceptable ranges. Figure 2 illustrates the design space for the DG process, considering two CPPs: the compaction force applied by the tablet press and the roller compactor. The red-shaded region in the figure represents the feasible design space where dissolution exceeds 80% within 30 minutes. The results indicate that an increase in roller compaction force negatively impacts dissolution performance, due to the formation of highly dense granules, which hinder drug disintegration and dissolution.

In the WG process, the CQA that needs to be further improved is the tensile strength as it tends to deliver a tensile strength below 1.2 MPa. Here we identified one CPP which is the compaction force of tablet press and one CMA: the targeted moisture content in the fluid bed dryer. As shown in Figure 3, increasing compaction force from 95 MPa to 125 MPa leads to a gradual improvement in tablet tensile strength, where higher pressure enhances interparticle bonding and reduces tablet porosity, thereby increasing mechanical strength. Moisture content plays a more nuanced role in the wet granulation process. The contour map indicates that tensile strength increases moderately as moisture content rises from 3.6% to 4.4%, suggesting that optimal moisture levels improve granule cohesiveness. This observation aligns with established granulation principles, where adequate moisture enhances binder activation and particle agglomeration, leading to stronger compacts. From a pharmaceutical manufacturing perspective, optimizing compaction force within 110–125 MPa while maintaining moisture content around 4.0–4.4% appears to provide a balanced approach for achieving robust tablet manufacturing as indicated by the design space in figure 3.

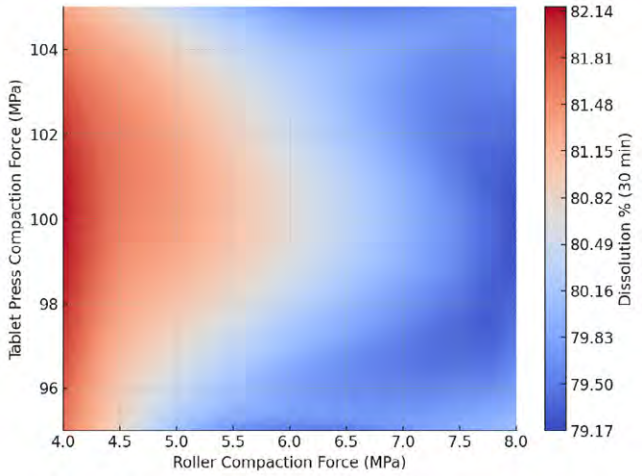

**Figure 2**. Design Space of the DG process

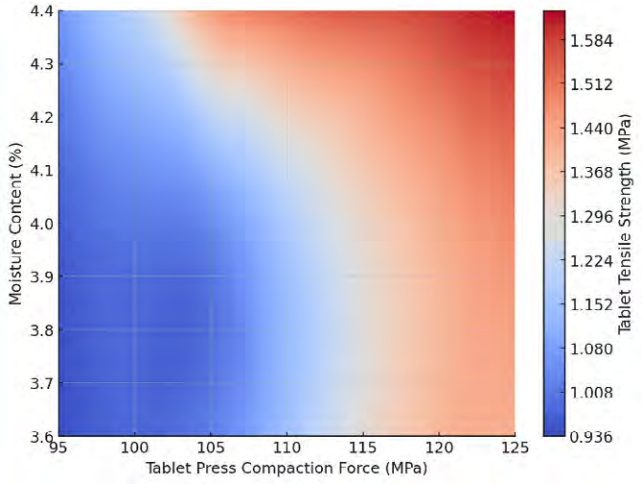

**Figure 3**. Design Space of the WG process.

### Lifecycle Assessments

The life cycle impact assessment of the three downstream manufacturing processes was conducted using the ReCiPe 2016 method and based on the methodology described earlier. As shown in Figure 4, among the three methods, DC demonstrated the lowest environmental impacts. This can be attributed to the simplification and intensification based as shown by the reduced number of unit operations, such as the absence of granulation or

drying steps, which significantly reduces utility consumption and waste generation. In contrast, DG and WG involve additional energy-intensive operations, such as roller compaction or fluid-bed drying, which contribute to their relatively higher environmental impacts. The normalized Midpoint categories comparison of three continuous processes show in which the most impacted categories are human carcinogenic toxicity (HCT), fresh water ecotoxicity (FWET) and marine ecotoxicity (MET). The paracetamol API production contributes the most impact scores as it is the main material for the tablet and the multistep reaction pathways require a variety of chemicals which inherently generate substantial hazardous wastes. This also happens with the production of excipients.

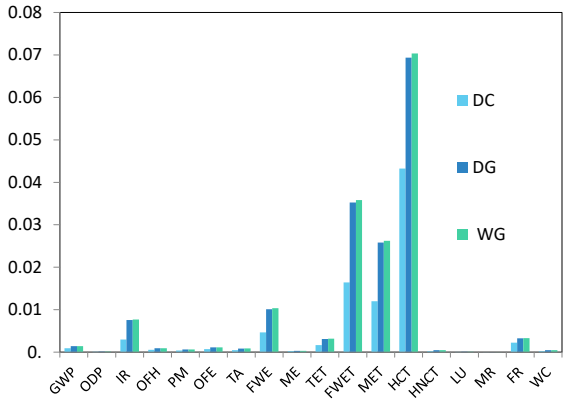

**Figure 4** ReCiPe 2016 Midpoint Comparison of three tabletting methods.

## Technoeconomic Analysis

The TEA is based on the simulation results from gPROMs and unit price from literature and row material suppliers. The TEA of the three three downstream manufacturing processes reveal significant trade-offs between process complexity, operational costs, and product quality. As shown in Figure 5, direct compaction emerged as the most cost-effective method, with a total annual cost of £100,857 and a production cost of 12.56 £/kg. This highlights the DC's advantages for low-dose formulations with robust powder flow properties. However, DC's reliance on homogeneous blending poses risks for segregation at scale, necessitating stringent process controls or glidant additives (e.g., colloidal silica).

While DG is 25% more expensive than DC (15.70 £/kg), it offers improved powder flowability and reduced segregation risks, critical for scaling continuous manufacturing. The elevated costs stem from capital-intensive roller compaction (£70,000) and milling equipment, compounded by 20% higher maintenance costs. Despite its moderate dissolution performance (79% at 30 min), DG's tensile strength (5.08 MPa) surpasses pharmacopeial standards (>1.4 MPa), suggesting viability for moisture-sensitive APIs.

WG achieves superior content uniformity, incurred to the highest operational costs (16.08 £/kg) due to energy-intensive drying and HPMC binder expenses. The critically low tensile strength (0.98 MPa) observed in WG tablets underscores the need for process optimization, particularly increasing the tablet compaction force and refining binder distribution.

Notably, labor costs dominated all methods (52% of total costs), emphasizing the economic potential of automation in small-scale pharmaceutical production. Future work may explore hybrid approaches (e.g., DC with external lubrication) or advanced process analytics (PAT) to deliver better trade-offs between cost and performance.

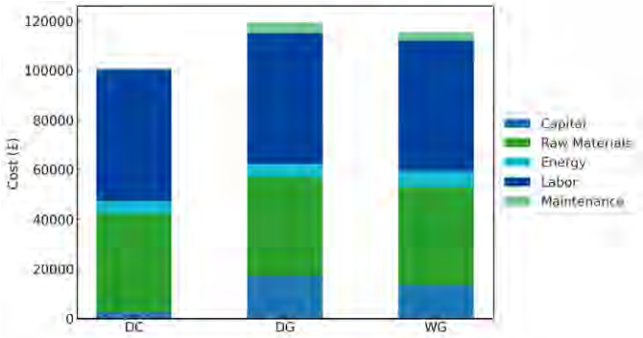

**Figure 5** Technoeconomic Analysis of three tabletting methods

## CONCLUSIONS

This study proposed a comprehensive methodology based on systematic evaluation of the techno-economic, environmental, and quality key performance indicators. The methodology was implemented to evaluate the most common downstream pharmaceutical manufacturing routes, operating continuously, namely: Direct Compaction, Dry Granulation, and Wet Granulation. This work highlights the role of digital transformation and process system engineering in the delivery of more rigorous and robust decision-making strategies in the pharmaceutical industry by capturing product quality, process flexibility and cost-efficiency, and environmental footprints. Most importantly the proposed method lays the foundation for a new Quality and and Sustainability by Digital Design (QSbDD) paradigm which will be further consolidated with more applications in near future, opening new avenues for quality and emission management.

## ABSTRACT

This study aims at developing a holistic approach to establish robust mathematical models of integrated and interactive multistep processes, while systematically identifying the corresponding design space and acceptable operating region (AOR). The overall objective is to reduce the experimentation costs, enhance accuracy of integrated metathetical models, and deliver built-in quality assurance based on a new Quality by Digital Design (QbDD) paradigm. This methodology starts with the construction of a set of model candidates for different unit operations, based on the prior knowledge and inherent assumptions. Several model candidates of the integrated multistep process are considered. A model discrimination based on model prediction performance reveals the best integrated model for the multistep process. In the next step, the estimability analysis and model-based design of experiment (MBDoE) are implemented to deliver information-rich data and systematically refine the integrated model. With the acquisition of the new experimental data, the reliability and robustness of the multistep mathematical model is dramatically enhanced. A blending-tableting process is considered to validate the methodology. The model captures the effects of the blender as well as the composition and porosity of the tablet on the tablet tensile strength. Model discrimination and automated model refinement are then performed to identify and improve the optimal integrated model for this two-step process, and the enhanced model is applied for the design space identification under specified CQA targets and associated bounds.

**Keywords**: Multistep process, Model builder, Model Based DoE, Design Space, Acceptable Operating Region (AOR), Quality by Digital Design (QbDD), Blending, Tableting.

## 1. INTRODUCTION

The mathematical models of different processing units within a manufacturing process or plant are usually established and optimized individually, even when these processes are sequentially combined in the real world, particularly in continuous operating plants. Although this traditional modeling approach may help reduce complexity, it can lead to suboptimal solutions or/and overlook the interactions between the unit operations, which also potentially increase the development time, wastes, and experimental costs inherent to the raw materials, solvents, cleaning, etc.

The quality assurance of pharmaceutical products is traditionally performed through Quality-by-Testing (QbT), which is an experiment-intensive a-posteriori approach, leading to poor flexibility and higher failure risks. The advent of Quality-by-Design (QbD) has open new avenues to adapt more effective risk-based quality management methods in Pharma. Nonetheless, current applications of QbD are still heavily reliant on expensive designs of experiments (DoE) and driven by data intensive methodologies.

As required in QbD, the quality assurance of pharmaceutical product must be built-in from the development phase and throughout the life cycle, where the critical quality attributes (CQAs) of the product should be always satisfied during manufacturing. This requirement

may be effectively driven by mathematical models and digital tools which must exhibit higher levels of reliability and prediction capabilities. Additionally, the robustness of the mathematical models can play a vital role in identification of robust design space and cost-effective operating/control strategies in QbD [2]. However, the traditional approaches for the construction of reliable and predictive mathematical models can be labour-intensive, resource-demanding and time-consuming, which is often not an available option, especially at the early stage of process development where the availability of large quantities of active pharmaceutical ingredients (APIs) may be compromised by the lack of scalable units. Another challenge comes from the competition of multiple model candidates originating from different assumptions of the system behaviour, where the lack of identifiability of the model parameters exacerbates the problem and result in unreliable models or poor prediction performance. Importantly, the mathematical models of individual units are commonly developed with the risk of overlooking or neglecting the interactions between unit operations in a complete pharmaceutical process.

One potential solution to address these challenges lies in the improvement of the experimental designs, based on which the data for model calibration are acquired. The information content and the cost-efficiency of different experimental designs can vary significantly. Standard DoE techniques are commonly applied in traditional methods, which may become cost prohibitive for complex systems due to the unrealistically high number of required experiments [8]. Moreover, they are not necessarily optimally designed in terms of obtaining information content for model calibration. Hence, model-based design of experiment (MBDoE) emerges as an effective solution offering enhanced flexibility, maximized information content, and reduced experimental costs. Here, our proposed methodology extends the MBDoE capabilities to multistep integrated or interactive processes [11]. The approach is further enhanced by incorporating effective capabilities for systematic model discrimination and estimability analysis, followed by a model-based identification of robust design space and acceptable operating region (AOR), laying the ground for novel Quality by Digital Design (QbDD) paradigms.

## 2. METHODS

The proposed holistic methodology is outlined in Figure 1, which upgrades the capabilities of the previously presented framework to the case of multiple processes and design space identification [11]. Since various assumptions can be applied at the early stage of process development, this approach begins with the construction of model candidates for different unit operations, which are then combined to give a series of integrated models for the complete process. Instead of evaluating the model candidates of each unit independently, parameter estimation and model discrimination will focus on the integrated models, thus the risk of omitting the interactions between different units is inherently reduced. The parameter estimation can utilize the prior knowledge of the system if available (e.g., previous experimental data, nominal values of parameters), as well as the preliminary experimental data. Afterwards, the model discrimination is conducted through the computation of the Akaike information criterion (AIC) [1] of each model candidate, where the model with the lowest AIC value is the best in capturing the system feature with the lowest model complexity. Subsequently, the automated model refinement is initiated with the estimability analysis by applying sequential orthogonalization algorithm [9] using a threshold value of 0.1 on the best integrated model, which identifies the estimable parameter subset. It should be noted that

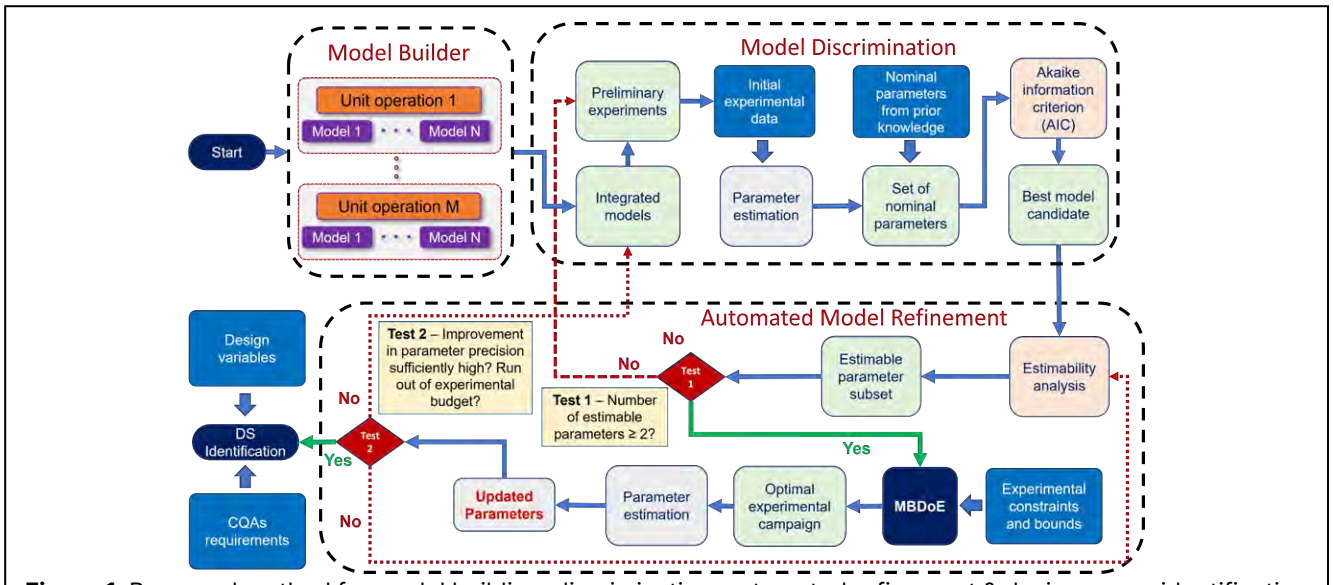

**Figure 1:** Proposed method for model building, discrimination, automated refinement & design space identification

extremely low information content in the preliminary experimental data can lead to a very small number of estimable parameters (less than two) (Test 1), thus extra preliminary experimental runs are required, or alternatively another integrated model may be selected. Once Test 1 is passed, MBDoE focusing on the Fisher information matrix (FIM) of the estimable parameter subset is performed, where the new experimental data are utilised to update the parameter estimates and uncertainties. The model refinement workflow can be executed automatically until the improvement of the parameter precision becomes insignificant, or the experimental budget is depleted (Test 2). Once the stopping criterion is triggered, the automated model refinement procedure is terminated, and the design space identification based on the enhanced process model is performed, where the best nominal operating point (NOP) and the corresponding acceptable operating region (AOR) are identified, delivering a multi-dimensional space where the variations of the critical process parameters (CPP) meet the CQAs requirements.

## 3. CASE STUDY

A two-step blending-tableting process was investigated to validate the proposed holistic framework. The preliminary data or prior knowledge was obtained from the literature [4]. In blending-tableting system, the tablet composition can be varied by changing the weight fraction of the lubricant (magnesium stearate, MgSt) and three different diluents MCC Avicel PH102, Fast Flo Lactose 316 and dibasic calcium phosphate (we will denote them as MCC, LAC and DCP), while the lubrication is conducted by blending the powder in TURBULA® blenders, where the size and headspace fraction of the blender and the number of blending cycles can vary. There are 143 experimental runs available from the literature [4] with different compositions, porosity and blender settings.

### 3.1 Model equations

For blending and tableting processes, several models were proposed in [3], [5] and [6] to capture the dependence of the tablet tensile strength on either the tablet porosity, composition, or the blender operating variables. The model proposed in [3] consists of Equations 1 to 3, where $\sigma_0$ is the tablet tensile strength at zero porosity, $\sigma_{nobld}$ denotes the tensile strength before blending, $\varepsilon$ refers to tablet porosity, $k_b$ represents bonding capacity, $k$ refers to lubrication extent, $\alpha_b$, $V_b$, $F_h$, $\omega_b$, $t_b$ are the equipment dependent factor, volume, headspace fraction, rotation speed and blending time of the blender, $\beta$ signifies lubrication sensitivity, $\gamma$ is the lubrication rate constant of the blend, and $\sigma$ is the final tensile strength.

$$\sigma_{nobld} = \sigma_0 exp(-k_b \varepsilon) \quad (1)$$

$$k = \alpha_b V_b^{\frac{1}{3}} F_h \omega_b t_b \quad (2)$$

**Table 1:** Comparison of blending-tableting models proposed in [3], [5] and [6].

| Model | Porosity | Composition | Blending |
|---|---|---|---|
| [3] | Eq. 1 | N/A | Eq. 2 and 3 |
| [5] | Eq. 4 or 5 | N/A | Eq. 2 and 3 |
| [6] | Eq. 1 | Eq. 6 and 7 | Eq. 8 |

$$\sigma = \sigma_{nobld}[(1-\beta) + \beta exp(-\gamma k)] \quad (3)$$

Equation 1 is commonly referred as Ryshkewitch equation which capture the interdependence between tablet tensile strength and porosity. With Equations 2 and 3, the effects of the blender features and the operating variables are captured. Compared with [3], [5] directly linked the lubrication sensitivity $\beta$ with the porosity $\varepsilon$ with linear/exponential assumptions, resulting in Equations 4 or 5, where $a_1$ and $a_2$ are the parameters to be estimated. The blender effects are modelled with the same equations (2 and 3) in [5].

$$\beta = a_1 \varepsilon + a_2 \quad (4)$$

$$\beta = a_1 \exp(-a_2 \varepsilon) \quad (5)$$

The main limitation of the models in [3] and [5] is the lack of tablet composition effects. Thus, the model developed in [6] simulated the effect of weight fraction changes of the lubricant and diluent, where the bonding capacity $k_b$ of the mixed powder is depends on the ratio of the specific surface area between the lubricant and diluent ($S_{lub/dil}$), which is calculated by Equation 6, where the specific surface area of the lubricant and diluent $S_{BET,lub}$ and $S_{BET,dil}$ as well as their weight fractions $w_{lub}$ and $w_{dil}$ are used. Afterwards, $k_b$ is obtained in Equation 7, where $\kappa$ is the coefficient corresponding to $S_{lub/dil}$, and $k_{b,dil}$ is the bonding capacity of diluent.

$$S_{lub/dil} = \frac{S_{BET,lub} w_{lub}}{S_{BET,dil} w_{dil}} \quad (6)$$

$$k_b = \kappa S_{lub/dil} + k_{b,dil} \quad (7)$$

The effect of tablet porosity is also captured in [6] by Ryshkewitch equation. However, the blender effects are not included. Instead, the tensile strength of the tablet made of the mixed powder at zero porosity is predicted (Equation 8), where $\sigma_{dil,0}$ is the tensile strength of the tablet only made of the diluent at zero porosity.

$$\sigma_0 = \sigma_{dil,0} exp(-\beta S_{lub/dil}) \quad (8)$$

Table 1 summarizes the models proposed in [3], [5] and [6]. All models capture the effect of tablet porosity. Only [6] models the effect of composition, but [3] and [5] are more comprehensive in modelling the blender effects. Therefore, there is an opportunity to build a more sophisticated integrated model for this process.

### 3.2 Set of multistep model candidates

With the aim of capturing the effect of tablet porosity, composition and the blender by adapting the model

equations in [3], [5] and [6], four candidates of the blending-tableting process are constructed, where Equation 1 is applied in all the candidates to model the influence of porosity, while the blender effects are simulated by Equations 2 and 3. The main adaptation focuses on the composition. In [6], the equations were developed for a single lubricant – single diluent tablet system, while the system in [4] involves one lubricant and three diluents. Therefore, we first propose the equations calculating the tensile strength of the tablet made of mixed diluents at zero porosity ($\sigma_{dil,0}$), where linear assumption (Equation 9) and exponential assumption (Equation 10) of $\sigma_{dil,0}$ on the weight fraction of each diluent ($w_{dil,i}$) are adopted. In Equation 9, $\sigma_{dil,i,0}$ is the tensile strength of the tablet only made of diluent $i$ at zero porosity; in Equation 10, $\sigma_{dil,0,max}$ is the maximum tensile strength of the tablet made of the mixture of the diluents that can be achieved at zero-porosity; $p_i$ are the parameters to weigh the contribution of different diluents on $\sigma_{dil,0}$.

$$\sigma_{dil,0} = \sum_{i=1}^{n} p_i w_{dil,i} \sigma_{dil,i,0} \tag{9}$$

$$\sigma_{dil,0} = \sigma_{dil,0,max}\left[1 - exp\left(-\sum_{i=1}^{n} p_i w_{dil,i}\right)\right] \tag{10}$$

Inspired by [5], we assume the lubrication sensitivity $\beta$ to be linearly/exponentially dependent on $S_{lub/dil}$ (Equation 11/12), while $S_{lub/dil}$ is assumed to be the ratio of the weighted sum of the specific surface area of the lubricant and diluent (Equation 13), and the bonding capacity $k_b$ is also assumed to be relevant to the weighted sum of the bonding capacity of each diluent (Equation 14). The candidates of integrated models are summarized in Table 2.

$$\beta = a_1 S_{lub/dil} + a_2 \tag{11}$$

$$\beta = a_1 \exp\left(-a_2 S_{lub/dil}\right) \tag{12}$$

$$S_{lub/dil} = \frac{\sum_{i=1}^{m} S_{BET,lub,i} w_{lub,i}}{\sum_{j=1}^{n} S_{BET,dil,j} w_{dil,j}} \tag{13}$$

$$k_b = \kappa S_{lub/dil} + \sum_{j=1}^{n} k_{b,dil,j} w_{dil,j} \tag{14}$$

The data in [4] are divided into two groups randomly for parameter estimation (70%) and validation (30%). Once the best integrated model is identified, automated model refinement will be performed, minimizing the dimensionless normalized confidence ellipsoid volume of the estimable parameter subset $V_{est,norm,dimless}$. This first requires the computation of the sensitivity matrix $Z$ of the model parameters (Equation 15), where $\sigma_{exp,i}$ refers to the tablet tensile strength obtained from experiment $i$, while $\theta_j$ denotes the $jth$ model parameter. Then the FIM of the integrated model is computed by Equation 16. Let $FIM_0$ be the FIM of the parameters calculated with the preliminary experimental data (the data from [4]), its diagonal entries $D_0$ (Equation 17) is used to normalize the

**Table 2:** Proposed model candidates of the integrated blending-tableting process

| Model | Porosity | Composition | Blending |
|---|---|---|---|
| 1 | Eq. 1 | Eq. 9, 11, 13 and 14 | Eq. 2 and 3 |
| 2 | | Eq. 9, 12, 13 and 14 | |
| 3 | | Eq. 10, 11, 13 and 14 | |
| 4 | | Eq. 10, 12, 13 and 14 | |

FIM (Equation 18), and the normalized FIM of the estimable parameter subset ($FIM_{est,norm}$) is its sub-matrix by extracting the rows and columns of corresponding to the estimable parameters. Finally, as the number of the estimable parameters $N_{est}$ can change at each MBDoE cycle in the automated model refinement, $V_{est,norm,dimless}$ is calculated based on Equation 19, which is in essence a normalized form of the D-optimal criterion.

$$Z = \begin{bmatrix} \frac{\partial \sigma_{exp1}}{\partial \theta_1} & \cdots & \frac{\partial \sigma_{exp1}}{\partial \theta_N} \\ \vdots & \ddots & \vdots \\ \frac{\partial \sigma_{expM}}{\partial \theta_1} & \cdots & \frac{\partial \sigma_{expM}}{\partial \theta_N} \end{bmatrix} \tag{15}$$

$$FIM = Z^T Z \tag{16}$$

$$D_0 = \mathrm{diag}(FIM_0) \tag{17}$$

$$FIM_{norm} = D_0^{-\frac{1}{2}} FIM D_0^{-\frac{1}{2}} \tag{18}$$

$$V_{est,norm,dimless} = \left(\sqrt{\det\left(FIM_{est,norm}^{-1}\right)}\right)^{\frac{1}{N_{est}}} \tag{19}$$

In each automated model refinement cycle, the MBDoE procedure presented by Equation 20 is conducted to identify the optimal experimental design that minimizes parameter uncertainties, where the decision variables include the volume ($V_b$) and headspace fraction ($F_h$) of the blender, blending cycles ($N_b$), mass fractions of MgSt ($w_{MgSt}$), MCC ($w_{MCC}$) and LAC ($w_{LAC}$), and the tablet porosity ($\varepsilon$). The mass fraction of DCP acts as a constraint that should lie between $0\%$ and $100\%$.

$$\begin{aligned} \min_{V_b, F_h, N_b, w_{MgSt}, w_{MCC}, w_{LAC}, \varepsilon} \; & V_{est,norm,dimless} \\ \text{s.t. } & V_b = \{30\text{mL}, 1250\text{mL}\} \\ & 30\% \le F_h \le 70\% \\ & 24 \le N_b \le 190512 \\ & 0.5\% \le w_{MgSt} \le 2\% \\ & 0\% \le w_{MCC} \le 100\% \\ & 0\% \le w_{LAC} \le 100\% \\ & 5\% \le \varepsilon \le 30\% \\ & 0\% \le 1 - w_{MgSt} - w_{MCC} - w_{LAC} \le 100\% \end{aligned} \tag{20}$$

The stopping criteria of the automated model refinement are presented in Equations 21 and 22. Equation 21 captures the relative reduction in the overall parameter uncertainties over a consecutive MBDoE cycles. If the improvement of parameter precision is not sufficiently high between the two consecutive MBDoE cycles, the automated model refinement will be stopped. Equation 22

defines the available experimental budget which represents a maximum of 5 MBDoE cycles in this case.

$$\eta_i = \frac{V_{est,norm,dimless,i-1} - V_{est,norm,dimless,i}}{V_{est,norm,dimless,i-1}} \leq 10\% \quad (21)$$

$$N_{exp,budget} = 5 \quad (22)$$

Once the automated model refinement is completed, a model-based risk assessment is conducted to identify the set of critical process parameters (CPPs) and critical material attributes (CMAs) [10], then followed by a model-based identification of the design space and normal operating range of the blending-tableting process. The CQA bounds are captured by the constraints in Equation 23, which specifies that the tablet tensile strength should be at least 4 MPa with ≥85% probability, where Equation 24 summarizes the design variables $\boldsymbol{x}$. The design space identification is performed with the Python-based tool DSIDE [7], and all the computation is performed on a 11th Gen Intel(R) Core (TM) i5-11400 @ 2.60GHz 2.59 GHz CPU with 16GB RAM.

$$\mathrm{DS} = \{\boldsymbol{x} \in \boldsymbol{X} | E[Pr(\sigma \geq 4MPa) | \boldsymbol{\theta}] \geq 85\%\} \quad (23)$$

$$\boldsymbol{x} = [V_b, F_h, N_b, w_{MgSt}, w_{MCC}, w_{LAC}, \varepsilon] \quad (24)$$

## 4. RESULTS & DISCUSSION

The parameter estimation and model discrimination of the four model candidates was conducted. Figure 2 shows the parity plots of the candidates comparing the model prediction with the experimental data, revealing that Models 3 and 4 outperform Models 1 and 2, thus the exponential assumption (Equation 10) outperforms the linear assumption (Equation 9) for $\sigma_{dil,0}$ . Since Model 3 has the lowest AIC value (Table 3), it is the best candidate in this case study.

The automated model refinement of Model 3 is performed subsequently. Table 4 shows that the number of estimable parameters and overall precision of the model parameters were both improved with the increase of the number of MBDoE cycles. Initially, six parameters were

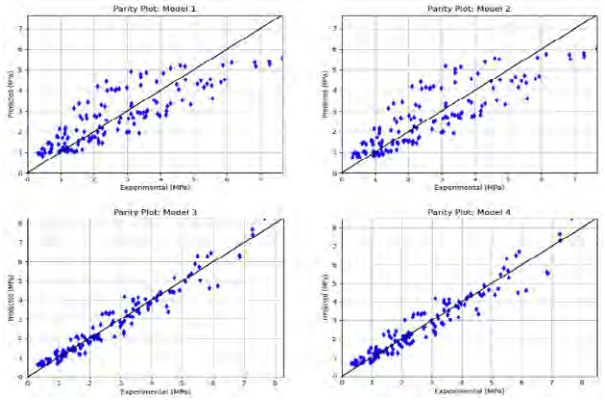

**Figure 2.** Parity plots (model prediction vs. experimental data) of the candidates. Top left: model 1. Top right: model 2. Bottom left: model 3. Bottom right: model 4.

**Table 3:** AIC values of the model candidates

| Model | 1 | 2 | 3 | 4 |
|---|---|---|---|---|
| AIC value | 175.51 | 167.85 | 47.87 | 61.24 |

estimable based on the preliminary data. The 1st MBDoE improved the overall parameter precision ($\eta_i$) by 98.68%. In the 2nd MBDoE, $\eta_i$ significantly dropped (-117.40%), but this is due to the increase of the number of estimable parameters (from 6 to 7), showing that the estimability of the parameters become higher with the new data. With the 3rd, 4th and 5th MBDoE, the overall parameter precision was further enhanced with the increased data size and information content. Since the experimental budget was depleted, the model refinement was terminated.

The improvement in parameter precision can be visualized by the 95% confidence ellipse plots. Figure 3 illustrates the evolution of the joint confidence domain of two selected parameters $\kappa$ and $k_{b,DCP}$. Over the MBDoE cycles, the nominal estimates are updated, and the confidence ellipse generally becomes smaller, indicating that the knowledge of the model parameters is augmented through the proposed automated model refinement.

After successful model refinement based on the combined estimability and MBDoE, the criticality analysis is conducted to identify the set of CPPs and CMAs based on the approach proposed in [10]. Finally, a design space identification was carried out based on the refined mathematical model and the set of CPPs and CMAs by considering the targeted CQA bounds. To further visualize the improvement of the model, we compared the design space and acceptable operating region (AOR) obtained with the initial model against the refined model. Figure 4 visualizes the design space by the green zones, showing that larger AOR is obtained with the refined model, indicating better operating flexibility and robustness.

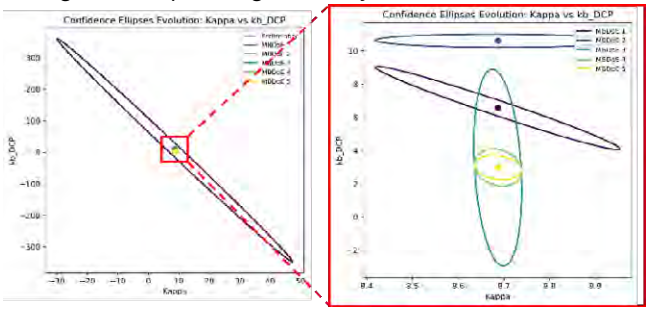

**Figure 3.** 95% joint confidence ellipses for the parameters $\kappa$ and $k_{b,DCP}$ after each MBDoE cycle.

**Table 4:** Improvement of the number of estimable parameters and parameter precision over the MBDoE cycles.

| MBDoE | $N_{est}$ | $\eta_i$ |
|---|---|---|
| 0 (Preliminary) | 6 | N/A |
| 1 | 6 | 98.68% |
| 2 | 7 | -117.40% |
| 3 | 7 | 30.40% |
| 4 | 7 | 26.34% |
| 5 | 7 | 11.31% |

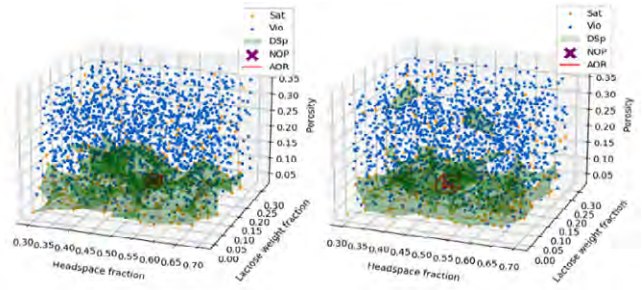

**Figure 4**. Design space of the blending-tableting process based on the model before (left) and after (right) automated model refinement. Sat: satisfying points. Vio: violating points. DSp: design space. NOP: nominal operating point. AOR: acceptable operating region.

Hence, the proposed holistic framework for model building, discrimination and automated model refinement provides a cost-effective option to establish robust model for the blending-tableting process in this case study, resulting in lower uncertainty and a larger AOR offering enhanced flexibility. The proposed framework constructs a new Quality-by-Digital-Design (QbDD) paradigm offering enhanced capabilities compared to the current Quality-by-Design which heavily relies on expensive designs of experiments and time-consuming costly risk assessment methods. Most importantly, the proposed framework addresses the cases of multistep processes and lay the ground for the implementation of effective QbDD in the integrated pharmaceutical manufacturing.

## 5. CONCLUSIONS

In this paper, a new integrated approach for model construction, discrimination, automated refinement and design space identification for multistep processes is proposed, which aims at establishing robust mathematical models for the processes involving multiple interactive unit operations in a cost-effective way and laying the ground for a new Quality-by-Digital-Design framework. The validation of the approach on a two-step blending-tableting process has demonstrated the power of the proposed methodology, indicating its potential effectiveness to be extended for wider applications in the development of multistep process models.

## ABSTRACT

The environmental impacts of pharmaceutical production underscore the need for comprehensive life cycle assessments (LCAs). Offshoring manufacturing, a common cost-saving strategy in the pharmaceutical industry, increases supply chain complexity and reliance on countries like India and China for active pharmaceutical ingredients (APIs). The COVID-19 pandemic exposed Europe's vulnerability to global crises, prompting initiatives such as the French government's re-industrialization plan to relocate the production of fifty critical drugs. Paracetamol production has been prioritized, with recent shortages highlighting the urgency to address supply chain risks while considering environmental impacts. This study uses process engineering to generate life cycle inventory (LCI) data for paracetamol production, offering an eco-design perspective. Aspen Plus was employed to model the API manufacturing process, integrating mass and energy balances to address the scarcity of LCI data. The results highlight significant differences in emissions between India and France. For 1 kg of API, India's emissions are 0.0826 kg $CO_2$ eq for electricity and 1.3845 kg $CO_2$ eq for heat from steam, compared to France's significantly lower values of 0.005228 kg $CO_2$ eq and 1.1828 kg $CO_2$ eq, respectively. These differences emphasize the environmental benefits of relocating production to regions with cleaner energy sources. The study demonstrates the value of process modeling for generating robust LCI data, enabling detailed LCAs to support eco-design in pharmaceutical manufacturing. This approach can be extended to other chemicals, facilitating sustainable decision-making in the sector's re-industrialization.

**Keywords**: Aspen Plus, LCA, LCI

## INTRODUCTION

Sustainability in the pharmaceutical industry has become a priority as concerns grow about the environmental impact of Active Pharmaceutical Ingredients (APIs) and the increasing complexities of global supply chains. In this context, paracetamol, one of the most widely used APIs in the world, has become a relevant case study due to its current production practices, which rely almost exclusively on large-scale facilities in India and China. These facilities can produce up to 40,000 tons annually, serving as an important economic source but posing sustainability and supply security challenges. Centralized production far from major consumption centers, like Europe, creates a heavy dependence on foreign API sources.

This dependence became evident during the COVID-19 pandemic when disruptions in essential medicine supply chains were experienced due to external factors and geopolitical tensions, which underscored Europe's vulnerability to global crises and prompted policies advocating the strengthening of local production capacity. Within this framework, the European Pharmaceutical Strategy, launched in 2020, advocates the relocation of the production of essential medicines on the continent, seeking to create shorter and more sustainable value chains that are less susceptible to international disruptions. The reindustrialization of pharmaceutical production in Europe aims to ensure access to high-quality medicines, minimize the environmental impacts associated

with transportation, and promote cleaner energy sources.

The global paracetamol API market is projected to reach USD 13.72 billion by 2029, with a compound annual growth rate (CAGR) of 4.41% between 2024 and 2029[1]. The COVID-19 health contingency underscored the critical role of paracetamol. This surge in demand highlighted the global dependency on India and China for the medication supply. In response, initiatives like the French government's reindustrialization plan aim to localize the production of 50 essential medications, including paracetamol, addressing supply chain vulnerabilities observed during shortages in 2022 and early 2023 [2].

Despite its market significance, sustainability analysis of APIs faces challenges, mainly due to limited Life Cycle Inventory (LCI) data. To address this challenge, this study applies Life Cycle Assessment (LCA) methodology to evaluate two locations for paracetamol API production focusing on the environmental benefits of local production in France. A notable contribution is developing LCI data through chemical process modeling, addressing the data gap in LCA studies of pharmaceuticals.

By integrating process simulation with LCA methodologies, the goal is to improve the accuracy and comprehensiveness of LCI data. This approach aims to ensure a more detailed and reliable assessment of environmental impacts, thus supporting better decision-making for sustainable development within the pharmaceutical sector.

## RELATED WORK

The pharmaceutical industry leverages simulation and process design to improve efficiency and sustainability, addressing the significant environmental challenges of API production. Recent advancements integrate simulation with LCA to minimize environmental impacts, focusing on generating LCI data through process modeling. This section reviews key studies in this area.

The environmental impact of excipients in the production of ibuprofen tablets is investigated in [3] through simulation at each stage of the manufacturing process. This approach helped authors collect energy consumption and emissions data for the LCI. Their findings highlight that auxiliary materials, such as excipients, significantly impact the environmental footprint of pharmaceutical products, stressing the need to optimize these materials for better sustainability.

A continuous production framework for synthesizing zuclopenthixol is proposed in [4], demonstrating simulation integration to gather process data in continuous production. This included modeling solvent use and separation operations, enabling analysis of material and energy flows in API production. Similarly, simulation is used in [5] to develop a continuous flow model in the synthesis of ibuprofen, using a series reactors to optimize solvent use and reduce the environmental impact of production. These studies highlight how continuous production can significantly reduce the environmental footprint and improve process sustainability in producing commonly used APIs.

The scope of simulation and process modeling is extended to encompass common anesthetics in [6]. Their approach included industrial-scale simulations that enabled detailed data collection for the LCI of 20 anesthetics, quantifying greenhouse gas emissions at each stage. This work provides a framework for comparing sustainability options in anesthesia.

The environmental impact of the catalytic synthesis of nopal is explored in [7]. This study used simulation to construct the LCI of two synthesis alternatives. The authors found that selecting solvents and reusing materials can significantly reduce the environmental footprint in synthesizing specialty chemicals, including those of pharmaceutical relevance.

The literature demonstrates that integrating chemical process simulation with process engineering is key to generating an accurate LCI in the pharmaceutical industry, allowing energy and materials flow to be comprehensively captured throughout production stages, facilitating more complete environmental assessments. The studies reviewed highlight that simulation can optimize the use of excipients, solvents, and continuous processes, contributing to reducing the environmental footprint of APIs and other specialty chemicals.

Despite these advances, the literature scarcely mentions the application of this approach to the environmental assessment of acetaminophen production, leaving a gap in the sustainability analysis for this medication. Implementing process modeling and simulation methodologies for acetaminophen could provide critical data for the LCI, contributing to more sustainable manufacturing practices in the future.

## MATERIALS AND METHODS

Paracetamol, also known as acetaminophen, is a medication with analgesic and antipyretic effects. It is widely used for headaches, muscle aches, arthritis, backaches, toothaches, colds, and fevers due to its efficacy and low side effects. Its proven effectiveness makes it essential in over-the-counter and prescription pain management, justifying its selection for this case study developed.

This study uses LCA methodology and process modeling to assess the environmental impacts of various supply chain scenarios for active pharmaceutical ingredients, particularly evaluating the benefits of relocating production to France.

- The flowsheet development outlines the API

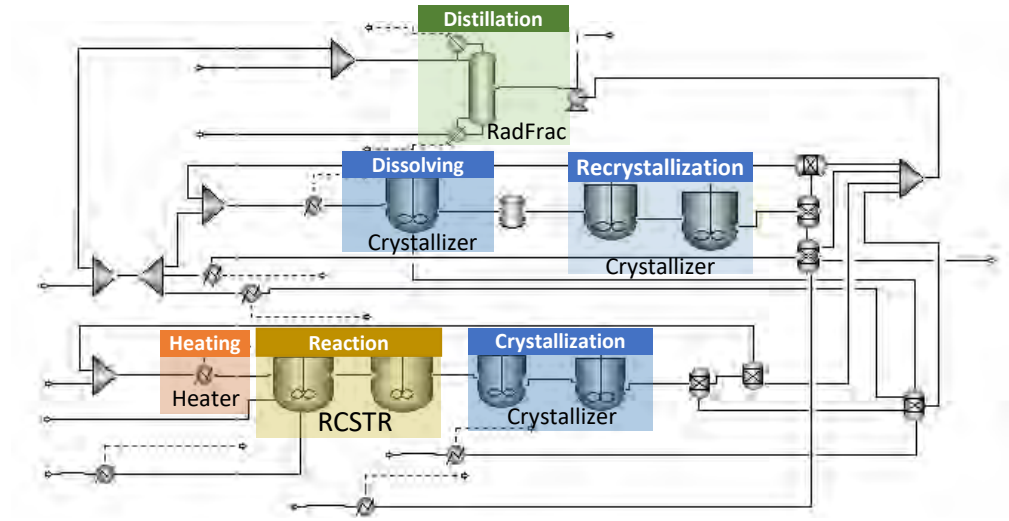

**Figure 1**: Simulation flowsheet and main equipment for API production

production process in Aspen Plus V14, providing energy and material balances for the LCA.

- The life cycle assessment compares the impacts of API production in France and India.

## Process modeling

Simulating acetaminophen production in Aspen Plus helps analyze its environmental impact by providing data on material and energy balances. In this system, two reactions are characterized: (1) the reaction of p-aminophenol and acetic anhydride to form acetaminophen and acetic acid, and (2) the reaction of acetic anhydride and water to produce acetic acid. According to [8], (1) can be modeled as an irreversible pseudo-first order reaction when acetic anhydride is in excess relative to p-aminophenol. Regarding (2), three irreversible steps, characterized by first-order kinetics, are involved [9]. The reactions are as follows:

$$(CH_3CO)_2O + C_6H_7NO \rightarrow C_8H_9NO_2 + CH_3COOH \quad (1)$$

$$(CH_3CO)_2O + H_2O \rightarrow CH_3COOH \quad (2)$$

Both reactions must take place within a reasonable time frame; to characterize their rates, the Arrhenius equation is used:

$$k = Ae^{(-Ea/RT)} \quad (3)$$

According to [8], the activation energy for (1) is 37310 J/mol. That study compared the reaction rate as a function of temperature and used the reaction rate, activation energy, gas constant, and temperature to determine the pre-exponential Arrhenius factor over a range of 323 K to 343 K, which corresponds to the operating temperature range used in the simulation, with a value of k equal to 11,293$s^{-1}$.

The production process begins with water mixed with a recycle stream at 15°C, which is preheated to 53.7°C using 5 atm steam for the reaction in a Continuously Stirred Tank Reactor (CSTR). Acetic anhydride is also preheated to the same temperature, and p-aminophenol is added to the reactor. After the reaction, the fluid is cooled in a crystallizer (to 40°C and then 15°C) and sent to filtration and washing. A portion of the slurry (35%) is recycled for preheating, while the rest (65%) and wash drains go to a distillation column.

Recycled drain water and acetic acid are heated and mixed with the acetaminophen cake and purified through a column with activated carbon, then undergoes a second recrystallization, filtration, and washing process. Seventy-five percent of the drain water is recycled into the solvent, and the wash drains are sent to the distillation column. The acetaminophen cake is sent to storage. Distillate, mainly water and acetic acid, is reused in the solvent and wash processes, with the remainder stored. The bottom residues from the distillation column, considered waste, are stored separately. Figure 1 complements the description.

## Life cycle assessment

The LCA evaluates a product or service's environmental impacts by examining all stages of its life cycle based on a defined functional unit. Its objective is to identify opportunities to improve its environmental performance. The LCA consists of four main stages: goal and scope definition, inventory analysis, impact assessment, and interpretation.

The goal of this LCA is to carry out a comparative analysis of the environmental impacts associated with the production of acetaminophen API in two locations: France and India. The system boundary, depicted in Figure 2, includes all material and energy inputs related to API production, following a “cradle-to-gate” approach. This approach covers resource use and emissions from raw material extraction to the final API manufacturing

stage. The functional unit is defined as 1 kg of API acetaminophen, ensuring consistency in mass and energy balance calculations in the different scenarios. Data on the API production process is taken from [8].

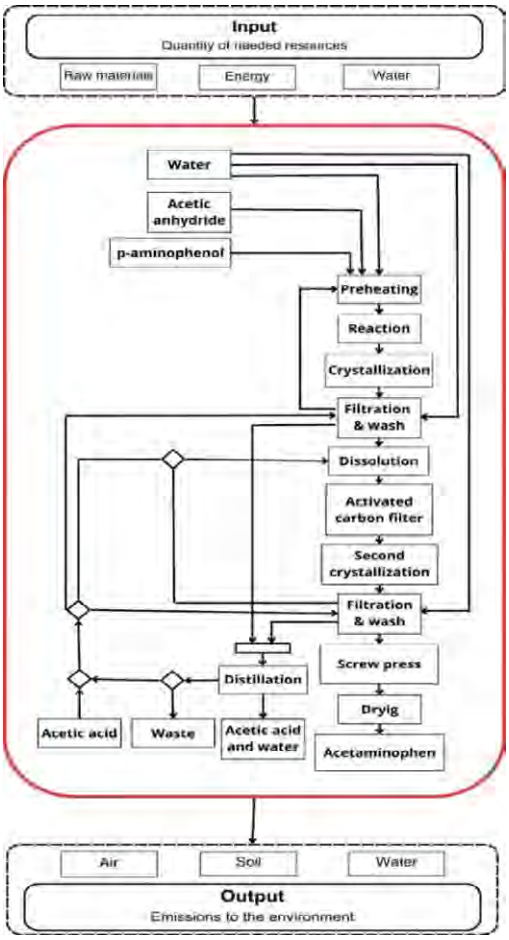

**Figure 2:** System boundary

The LCI phase quantifies all material and energy flows that cross the system boundary. This involves linking the units or services required to produce a functional unit with the corresponding emissions and resource extraction for each unit process. Although literature sources provide reference data on raw materials, they are often insufficient for high-quality LCA. To address this limitation, process simulation with Aspen Plus was used to generate detailed mass and energy balances of acetaminophen production. This approach allows for accurate estimation of inputs and outputs, improving the LCI accuracy and strengthening the assessment reliability of as a whole. To ensure robust and complete data collection, the LCI was developed by combining process modeling with literature-based information

For the LCIA phase, LCI data is linked to environmental impact categories. This evaluation follows the EF 3.0 (Environmental Footprint) method, implemented using the SimaPro version 9.4.0.2 software. This method aligns with European sustainability policies and industry standards, providing a comprehensive framework for assessing environmental impacts at intermediate and endpoints. In addition, the ecoinvent database complements the information on emissions, guaranteeing coherence in characterizing impacts in all the evaluated processes.

## RESULTS AND DISCUSSION

This section compares the environmental impacts of acetaminophen API production in France and India to illustrate the effectiveness of the proposed methodology.

Results (see Figure 3) show that the climate change category presents higher values in India (16,35 kg $CO_2$ eq) compared to France (13,91 kg $CO_2$ eq). Similarly, non-carcinogenic human toxicity is higher in India (2.13 E-07 CTUh) compared to France (1,95 E-07 CTUh). In contrast, ozone depletion presents higher values in France (2.07 E-06 kg CFC11 eq) compared to India (1.93 E-06 kg CFC11 eq). These results highlight key areas of environmental impact in the acetaminophen production process, indicating potential opportunities for improvement of emissions related to each impact category.

Figure 4 shows the normalized energy consumption results for production in India and France. Normalization addresses unit incompatibility and compares an indicator to a reference value such as the average annual environmental load per inhabitant in a country or continent, so that the results are expressed as a "relative impact," making them easier to understand through familiar comparisons. Normalization unifies impact category indicators, aids in category comparisons, enhances the understanding of each impact's scope, and enables a more coherent analysis of results.

The results focus on energy-related processes which were explicitly selected based on the country or the corresponding geographical area and account for significant emissions and resource consumption. The impact categories with the highest environmental impacts are freshwater ecotoxicity, fossil resource use, and climate change. The freshwater ecotoxicity category shows a significantly higher impact for “heat from steam” in India compared to France. Although the values for “electricity” and “cooling energy” in both countries are similar and lower, “heat from steam” in India stands out as the major contributor to ecotoxicity, likely due to the release of specific contaminants during steam production that adversely affect aquatic ecosystems.

Regarding the use of fossil resources and climate change, both electricity and “heat from steam” in India exhibit higher values compared to the same resources in France. Electricity generation in India predominantly relies on coal-fired power plants [9]. Despite ongoing efforts to diversify the energy mix, coal remains the most cost-effective option due to India's substantial coal

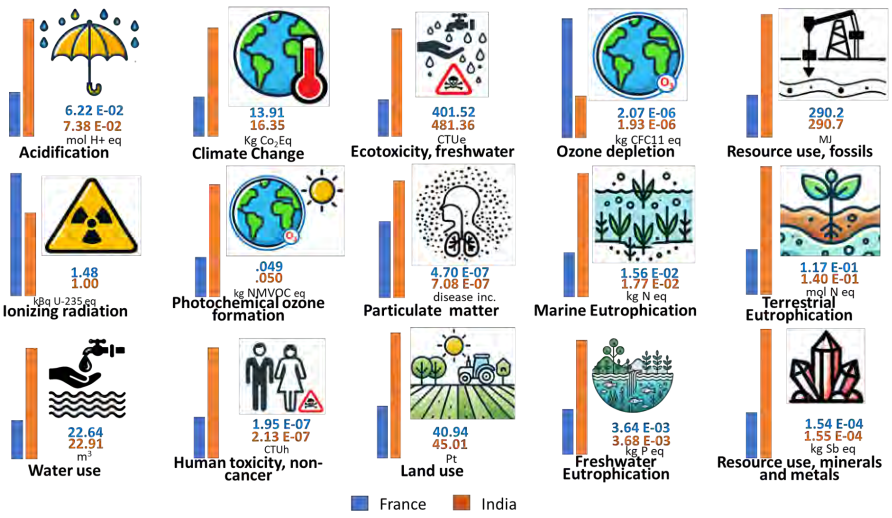

**Figure 3**: Characterization results per impact category for API production

reserves. In contrast, electricity production in France is predominantly nuclear-based, which plays a crucial role in reducing $CO_2$ emissions [10].

India and France's energy infrastructures differ significantly. India needs to enhance energy efficiency, waste treatment, and adopt renewables to mitigate environmental impacts, while France predominantly uses nuclear and renewable energy. Developing strategies to lower energy consumption and emissions is vital, focusing on energy-efficient technologies and process optimization. Transitioning to renewable energy is also crucial.

Incorporating advanced waste treatment minimizes toxic contaminants, particularly in freshwater. Recycling solvents and by-products cuts raw material use and waste. Redesigning supply chains and relocating production to greener energy regions can lessen climate impacts and carbon footprints.

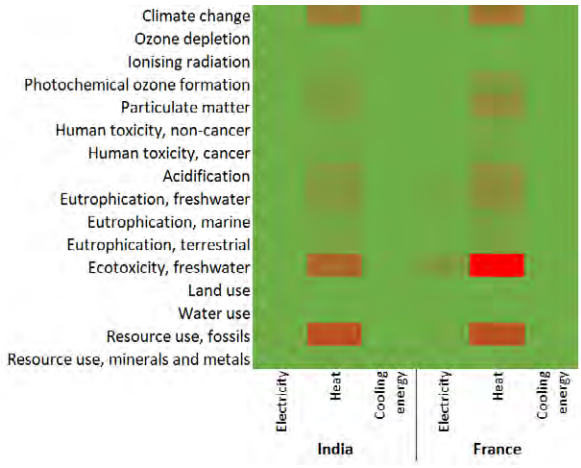

**Figure 4:** Normalized energy consumption results for production in India and France

It is important to highlight that France has implemented strategies to reduce the pharmaceutical industry's carbon footprint, such as government energy transition initiatives and environmental regulations. However, as some essential inputs are still imported, their impact on the overall carbon footprint must be considered [11].

Beyond domestic efforts, a key challenge is ensuring international suppliers meet sustainable standards. The French pharmaceutical industry has advanced in responsible sourcing, focusing on materials with lower environmental impact and suppliers committed to sustainability. However, the level of sustainability in supply chains outside France varies significantly, potentially affecting the $kgCO_2$/kg API value. This underscores the need for enhanced monitoring across the supply chain to maintain sustainability consistency [12].

To further reduce its environmental impact and promote sustainable production, the pharmaceutical industry must adopt a holistic approach. This includes improving energy efficiency, enhancing waste treatment, optimizing supply chains, innovating in raw materials, and integrating clean technologies. By addressing these aspects collectively, the industry can move toward a more sustainable and resilient production model.

## CONCLUSIONS

The relocation of paracetamol production facilities to French territory represents a strategic response to the need for enhanced supply security and a reduced environmental impact associated with its manufacturing. This shift underscores the urgency of implementing long-term sustainable solutions that promote more resilient supply chains with a smaller ecological footprint.

This research addresses a key limitation in LCA in the pharmaceutical industry: the need for more detailed LCI data on specific processes. By using advanced process modeling tools, both LCI data collection steps and

accuracy are significantly improved. Integrating process simulation with LCA methodologies allows for an exhaustive and precise evaluation of environmental impacts. This approach not only reinforces the reliability of LCA data but also provides a solid basis for sustainability-oriented decision-making in the pharmaceutical sector.

The methodology used in this study allows the construction of a detailed and reliable LCI for the paracetamol production process, facilitating a precise quantification of the associated environmental impacts. This level of detail supports more informed sustainability decisions, allowing pharmaceutical industry players to develop production strategies with lower environmental impacts and greater alignment with sustainable development goals.

The study also highlights a gap in traditional LCA methodologies, as they lack impact factors tailored to the pharmaceutical sector. To address this, the industry relies on specific indicators to enhance sustainability like Process Mass Intensity (PMI), which measures material efficiency in API synthesis and promotes more sustainable manufacturing practices [13].

Future work will explore scenarios for producing APIs such as waste recycling, treatment, and heat recovery which can reduce environmental impact and optimize resources for a sustainable pharmaceutical production.

## ABSTRACT

In 2023, the International Council for Harmonisation (ICH) guideline for the development, implementation, and lifecycle management of pharmaceutical continuous manufacturing (PCM), was implemented in Europe. It promotes quality-by-design (QbD) and quality by control (QbC) strategies as well as the appropriate use of mathematical modelling. This development urges a harmonizing understanding across academia and industry for adoption of interpretable models instead of black-box models for advanced control strategies such as model predictive control (MPC), especially when applied in Good Manufacturing Practice (GMP) regulated areas. To this end, we first propose a comprehensive model development using Dynamic Mode Decomposition with Control (DMDc)to represent complex dynamics in a lower-dimensional space, disambiguating between underlying dynamics and actuation effects. Using data from a digital twin of PCM, our model demonstrates low computational complexity while effectively capturing nonlinear dynamics with significant improvements observed in the performance metrics. Additionally, we demonstrate enhanced uncertainty propagation performance when compared to state-space models obtained with N4SID and Sparse Identification of Nonlinear Dynamical systems with control algorithms. Finally, we develop a closed-loop workflow that seamlessly connects data exchanges between Python (DMDc), GAMS (MPC optimisation) & gPROMS to evaluate the controller performance with setpoint tracking and disturbance rejection studies achieving high accuracy in real-time monitoring and control of granule size. This study offers a novel, interpretable control strategy for PCM. The results demonstrate the potential for real-time release testing, reduced reliance on end-product testing, and improved process control in the pharmaceutical industry.

**Keywords**: Quality by control, Data-driven control, Continuous pharmaceutical manufacturing

## INTRODUCTION

For pharmaceutical continuous manufacturing (PCM)applications, model predictive control (MPC) was first used in 2010 [1] to control a continuous roller compaction process comparing a PID, linear MPC (DMC), and nonlinear MPC. The nonlinear MPC showed better performance, but it was found not practical due to the high computational cost whereas the linear MPC could track the set point change and reject the disturbances of roll speed and in the inlet bulk density. Obregón et al. (2013) addressed the control of a fluidized bed dryer (FBD) using MPC alongside inline near-infrared (NIR) moisture sensors while maintaining optimal moisture content, minimizing energy consumption, and adhering to physical constraints such as air flow and temperature limits [2]. They showcased MPC's advantages in achieving the desired set points faster and more efficiently than traditional control methods. However, the model required adjustments when operating conditions deviate from the original fitting parameters showing inability to generalize to unseen data. The application of MPC for controlling blending units in continuous pharmaceutical manufacturing has also been investigated [3]. The authors described

the use of the System Identification Tool in MATLAB to develop the blending model, focusing on outlet mass flow and holdup as key outputs. The linear MPC incorporated constraints on blender speed and mass flow to enhance process performance. Although it demonstrated superior control capabilities compared to conventional methods, it was considered disadvantageous for systems with high sampling frequencies. Additionally, they indicated that measuring the outlet mass flow to estimate the states of the blender model may not be feasible in a continuous production line. A novel control concept utilizing MPC with a local linear model tree (LOLIMOT) algorithm for hopper levels in the tablet press was developed previously [4]. Recently, a hybrid model integrating mechanistic and machine learning approaches to optimize a continuous dry granulation process with MPC was developed [5]. Artificial Neural Networks (ANN) and Nonlinear Model Predictive Control (NMPC) showed effectiveness in managing the granulation process.

The implementation and assessment of MPC strategies, tailored for a holistic plant-wide control framework in continuous pharmaceutical manufacturing, have been proposed [6]. This work was conducted at the Novartis-MIT Center for Continuous Manufacturing. Two distinct MPC designs were proposed, employing different modeling approaches: subspace identification and linearization of nonlinear differential-algebraic equations. These approaches resulted in low-dimensional and high-dimensional state-space models, respectively. The simulation results demonstrated that the plant-wide MPC effectively regulates critical quality attributes (CQAs) while accommodating various uncertainties, including fluctuations in reaction kinetics and disturbances in filtration unit efficiency. Additionally, the approach incorporated quality-by-design principles by integrating input and output constraints, ensuring that the process remains compliant with regulatory requirements. The findings demonstrated that the MPC framework not only improves operational efficiency but also ensures consistent product quality.

While some applications of MPC for pharmaceutical continuous manufacturing have been reported, barriers to the adoption of this advanced process control exist [7]. Celikovic et al. (2020) identified two challenges in implementing MPC algorithms: i) handling potentially high computational burden to solve the control problem fast enough within the small sampling intervals and, ii) having the reliable process analytical technology (PAT) equipment for real-time monitoring of CQAs [3]. An implementation issue arises that when nonlinear models are used, this leads to non-convex optimization problems with multiple local optima, which requires much more computational power and offers no guarantees for global optimality and stability of the solution.

Given that MPC is employed to regulate a dynamic process system whilst considering constraints that can include operational limits on the controlled variables and rate-of-change limits on the manipulated variables, undoubtedly a key part on adopting this control strategy is mathematical modelling. As an alternative to computationally demanding mechanistic models, reduced Order Models (ROMs) offer an entirely data-driven means to represent reliable yet computationally intensive models in a lower-dimensional space. ROMs representations can be deduced with several system identification techniques, many of them based on a form of dynamic regression that fits models based on input- output data. These techniques have been examined since the 1950s and some examples include autoregressive moving average with exogenous inputs (ARMAX) models, Multivariable Output- Error State Space (MOESP), Observer Kalman Identification (OKID), Sparse identification of nonlinear dynamics (SINDy) and Dynamic Mode Decomposition with Control (DMDc) [8]. Particularly, DMDc has been increasingly recognized for its ability to systematically uncover simplified relationships within intricate systems operating using discrete-time snapshots of the states and corresponding control inputs of the system to extract the underlying effect of both on the system dynamics.

Our approach differs from previous surrogate models for two reasons. First, the interpretability in our framework comes from the algorithmic or mathematical transparency of how a dynamic model is obtained with Dynamic Mode Decomposition with control which avoids the black-box nature of data-driven techniques found in the literature such as LoLiMoT, ARMA or neural network models. Second, to enhance interpretability, the reduced-order model is formulated as a simple linear discrete-time state-space equation, for which we also quantify its uncertainty propagation performance.

## METHODOLOGY

### Data-driven model identification with DMDc

Dynamic mode decomposition with control (DMDc) was introduced in 2016 [8] as a modal decomposition technique that extracts dynamically relevant spatial structures and whose goal is to disambiguate between the underlying dynamics and the effects of actuation.

Since the mathematical foundations of DMDc lie on the assumption that the next state of a dynamic system $y_t \in R^n$ is determined from a function of the current state $y_{t-1} \in R^n$ and current input $u_{t-1} \in R^p$, a dynamic system can be then approximated by a linear state-space model described in equation (1) for n observed snapshots, where A $\in R^{nxn}$ is the system matrix and B $\in R^{nxp}$ is the control matrix.

$$y_t^{DMDc} = Ay_{t-1} + Bu_{t-1} \quad (1)$$

$$where\ y_t \in R^n, u_{t-1} \in R^p,\ A \in R^{nxn}\ and\ B \in R^{nxp}$$

We tested the performance of DMDc to identify a model, as part of an offline stage of our proposed framework (Fig. 1), to predict four granule size distribution quantiles D5, D10, D50, and D90 for a twin-screw granulation process with three control variables Avicel (AFR), binder (BFR), and lactose flow rates (LFR). Data was collected from simulations using a gPROMS FormulatedProducts® 2023.2.1 process model flowsheet of integrated TSG and fluidized bed drying which was customized for the GEA ConsiGma™-25 Continuous Tableting Line CTL, at the Diamond Pilot Plant (DiPP) of the University of Sheffield. The TSG consists of a feeding section for powder transport and a working section for mixing powder with granulation liquid. Dry powders and granulation liquid are delivered via loss-in-weight dosing units. Wet granules are transferred to a six-segment fluidized bed dryer, where they are dried sequentially and discharged for further processing, enabling continuous operation until tableting is complete. For the full details of the process flowsheet, we refer the interested reader to [9].

Duration of the simulations was 3000s, with 1 dataset for training and 3 datasets for validation, varying randomly the powder (lactose and Avicel) and binder (water) flowrates. Noise was added to all data imposing periodical disturbances on the flowrates with a frequency 1 min-1 and a minimum/maximum deviation of 5% directly in gPROMS. For the uncertainty quantification study, 1000s extra were sampled for the training dataset.

Alternative system identification methods were used to compare the performance of DMDc. First, a state-space equation is obtained with a data-driven method called Sparse Identification of Nonlinear Dynamical systems with control (SINDyc), which regresses the coefficients for a nonlinear ordinary differential equation [10]. Second, the N4SID tool for Multivariable Output Error State Space (MOESP) from the MATLAB system identification toolbox [11] was employed.

## Uncertainty quantification for state-space models

After identifying A and B matrices for the DMDc, SINDyc and MOESP models, the covariance matrix of the process noise and posterior covariance, as detailed in Digital Supplementary Material, was calculated for each model following:

$$\Sigma_\varepsilon = \frac{1}{n}\sum_{t=2}^{n} \left(y_t - \hat{A}y_{t-1} - \hat{B}u_{t-1}\right)^T \left(y_t - \hat{A}y_{t-1} - \hat{B}u_{t-1}\right) \quad (2)$$

$$V\left[y_{t*+1}|Y,\hat{A},\hat{B},\hat{\Sigma}_\varepsilon\right] = \sum_{i=0}^{t*-n} \hat{A}^i \hat{\Sigma}_\varepsilon \left(\hat{A}^i\right)^T + \sum_{i=0}^{t*-n} \hat{A}^i \hat{B} \hat{\Sigma}_u \hat{B}^T \left(\hat{A}^i\right)^T \quad (3)$$

For simplicity, $\hat{\Sigma}_u$ was assumed to be a diagonal matrix containing the standard deviations of each component (independent of the others) of the control input vector used for the training dataset.

Then, 95% confidence interval (CI) are calculated as:

$$CI = y_{t*} \pm 1.96 \cdot diag\left(V\left[y_{t*}|Y,\hat{A},\hat{B},\hat{\Sigma}_\varepsilon\right]\right) \quad (4)$$

The numerical criteria include the predictive root of mean squared error (RMSE) and the average length of the 95% predictive intervals (L(95%)):

$$RMSE = \left(\sum_{j=1}^{m}\sum_{t*=n+1}^{n+n*}\left(\hat{y}_{j_{t*}} - y_{j_{t*}}\right)^2\right)^{\frac{1}{2}} \quad (5)$$

$$L(95\%) = \frac{1}{mn*}\sum_{j=1}^{m}\sum_{t*=n+1}^{n+n*} \text{length}\{\text{CI}_{j,t*}(95\%)\}) \quad (6)$$

where $\hat{y}_j(x_{t*})$ is the prediction of the output for state j and length $\{\text{CI}_{j,t*}(95\%)\}$ denotes the length of the 95% predictive interval.

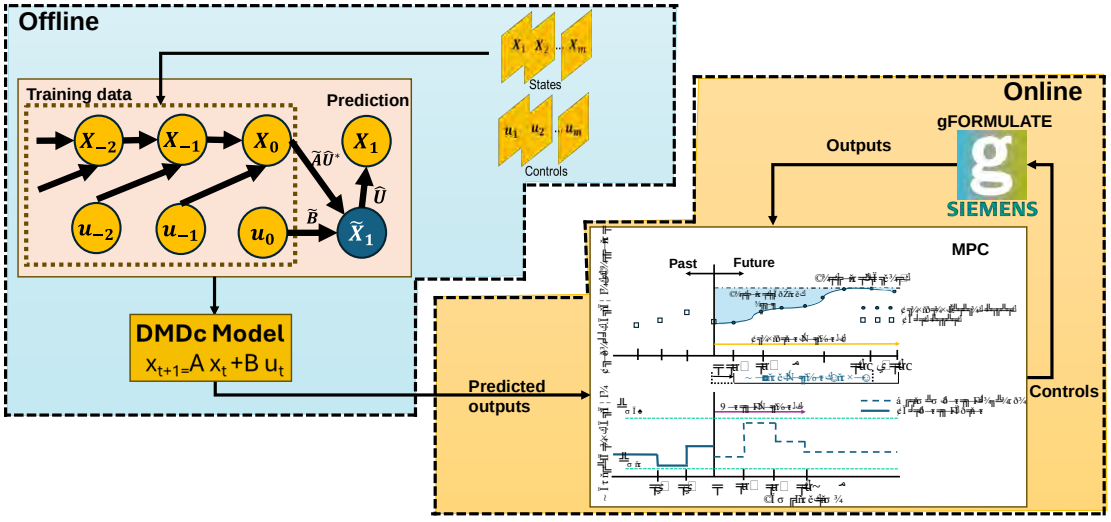

**Figure 1.** Proposed framework for a model predictive control (MPC) with a DMDc model

## Closed-loop data-driven control framework

The DMDc model developed offline was integrated into a linear model predictive control in an online stage (Fig. 1), coded in General Algebraic Modelling System (GAMS®) using the solver Gurobi 11.02, in a closed-loop manner. A prediction horizon of 30 seconds and a control horizon of 10 seconds were empirically tuned to balance control performance and computational efficiency.

Every control period of 1 second, a customized gPROMS FormulatedProducts® flowsheet sent data employing gO:Python, which used the model as an estimator to predict future states of the system. These predicted outputs were sent to the optimizer using GAMSPy to find optimal control inputs in real time by solving an optimization problem with an average computation time of 0.034 ± 0.01s that minimized the error between predicted and desired setpoints. At each time step (1s), the optimization was repeated, updating the control sequence over the control horizon and applying the first control action to the system using gO:Python + GAMSPy. The interaction between the process, estimator, and optimizer ensured that the system operates efficiently, maintaining stability and optimizing performance in response to changing process conditions.

Setpoint tracking and disturbance studies were conducted, to evaluate the MPC, introducing white Gaussian noise on the states with 1% standard deviation. Stepwise changes of the granule size references were introduced at certain times, and the solid/liquid feed rate control moves were analyzed.

Three types of disturbance scenarios were explored separately: binder flow rate disturbance, lactose flow rate disturbance, and Avicel flow rate disturbance. To conduct this study, each disturbance simulation, was applied as two manual step changes using gO:Python of either +10% or +20% of the flowrate at 40 seconds and either -10% or -20% of the flowrate at 80 seconds. The objective was to assess the controller's ability to detect, respond, and adjust control actions to maintain the desired reference values.

# RESULTS AND DISCUSSION

## Model comparison

The model obtained for DMDc in Python, MOESP in Matlab and SINDyc in Python has the form of a discrete-time first-order state-space equation where matrix A was the system matrix and determined how state variables change over time and B was the control matrix which determines how the system inputs affected the state change.

The model performance can be visualized in Fig. 2 where the DMDc model demonstrates enhanced accuracy and performance when dealing with unseen values (validation phase) even when working with noisy data. The deteriorated performance for MOESP can be related to its algorithmic complexity and overfitting trend and for SINDyc because of elimination of coefficients of the A matrix in the ROM that described, for example, the effect of D90 on D10 state, as detailed in Digital Supplementary Material.

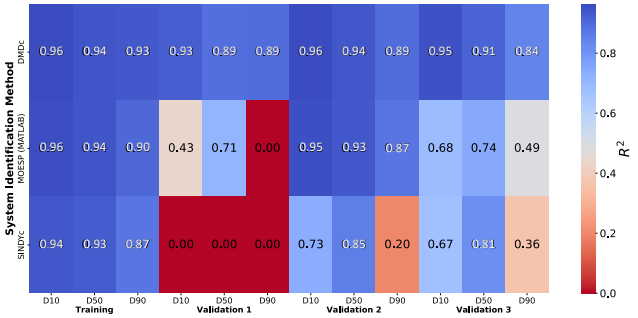

**Figure 2.** Heatmap for error metrics study $R^2$

The eigenvalues of the generated system state space models are shown in Table 1. Following conventional control theory, the DMDc eigenvalues provide stability guarantee on the model performance.

**Table 1:** Eigenvalues of ROMs.

| Method | Description |
|---|---|
| DMDc | $[0.63\,;\ \ 0.99\ ;\ 0.99\,;\ \ 0.97]$ |
| SINDyc | $[0.6-0.13i\,;0.6+0.13i;\ 0.9\,;1.0005\,]$ |
| MOESP | $[0.3+\ 0.2i;\ \ 0.3-0.2i\,;\ \ 0.99\,;\ 0.97\,]$ |

Regarding the uncertainty study, as displayed in Table 2, DMDc was found to be the most accurate method because it had a small predictive error quantified by RMSE and shorter average length of 95% predictive interval, also shown in Fig. 3.

High RMSE and wide confidence intervals for SINDyc and MOESP methods suggest that these models are more sensitive to noise and could be overfitting or underfitting the data, with very large uncertainty.

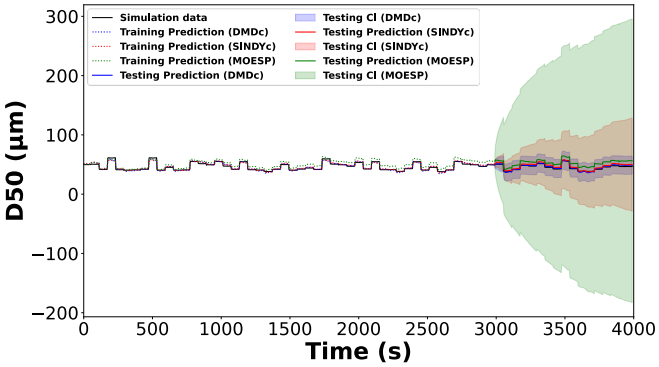

**Figure 3. Uncertainty measurement for D50** for a prediction of 1000 steps by DMDc (blue), SINDYc (orange) and MATLAB (green) after 3000s for training.

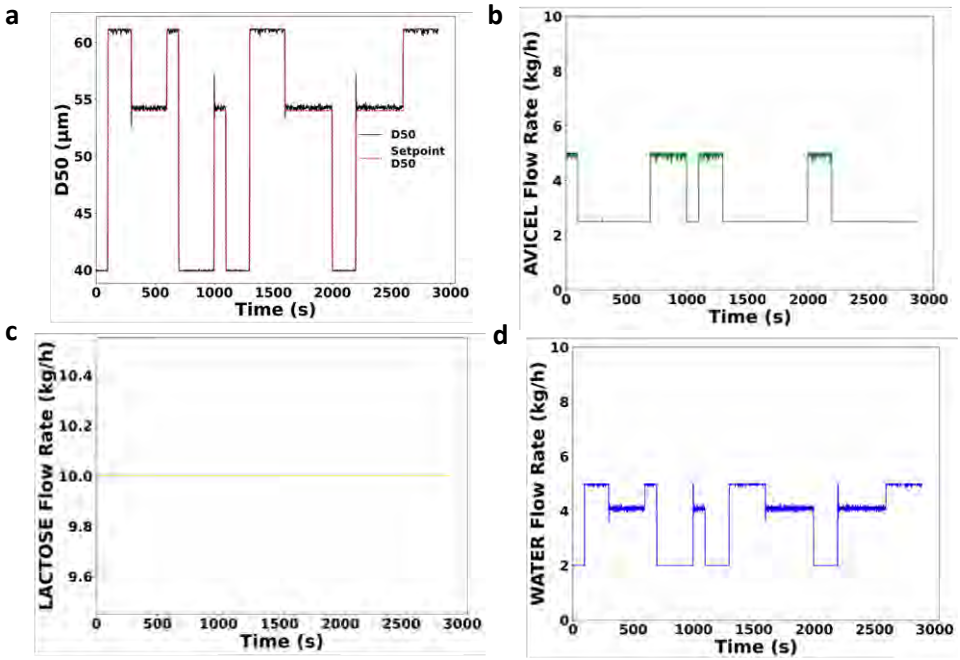

**Figure 4.** Setpoint tracking study for DMDc-MPC: a. Controlled variable (D50 shown) b-d. Manipulated variables

The 95% predictive intervals per each model are envisaged as shaded areas.

**Table 2:** Uncertainty quantification

| **1000-steps test** | | |
|---|---|---|
| | **RMSE** | **L(95%)** |
| DMDc | 6.18 | 57.85 |
| SINDyc | 13.29 | 424.66 |
| MOESP(MATLAB) | 57.17 | 1548.82 |
| **2000-steps test** | | |
| | **RMSE** | **L(95%)** |
| DMDc | 6.89 | 58.98 |
| SINDyc | 16.08 | 717.86 |
| MOESP(MATLAB) | 66.95 | 1981.83 |

## Closed-loop MPC performance

As shown in Suppl. Table 1, the selected prediction and control horizons provided the best trade-off for a control interval of 1s. As we can see in Suppl. Fig. 1, the setpoint for the controlled variable D50 is better reach with strategy H3 and longer horizons (PH = 100s, CH = 20s) led to over-tuning, as evidenced by increased peaks in the Avicel flowrate and higher CPU times."

The choice of a 1-second control interval was justified by the granulation process dynamics, which require frequent adjustments to maintain stability because it is known the binder concentration control is extremely important to maintain a desired oversized fraction of granules for lactose/Avicel-based formulations, also deviations in powder mass flow rate which might occur during volumetric feeding must be considered [12]. Nevertheless, less frequent sampling rates can be facilitated.

For the closed-loop evaluation, performance monitoring methods were used to assess how effectively the control system follows setpoint changes. Fig. 4 confirms the MPC's capability to track the reference by adjusting the input flow rates (D50 shown as an example)

Furthermore, the controller's ability to handle introduced disturbances was analyzed, especially because regulatory-level process control loops are commonly used in plants to respond to variations in binder flow rates.

In all cases, the disturbances were well rejected, as shown in Suppl. Figs. 2-4. The interested reader can refer to Digital Supplementary Material for other graphs. The most interesting aspect revealed is that introducing disturbances to the Avicel flowrate does not affect the other manipulated variables (MVs). In contrast, disturbances applied to either the lactose or binder flowrates affect both. In all cases, the manipulated flow rates stabilize after a short transient period.

# CONCLUSION

This study highlights the effectiveness of DMDc as an explainable machine learning method for CM. The DMDc-MPC system not only maintained desired process conditions and granule size but also demonstrated superior performance in uncertainty analysis, outperforming other data-driven models. This approach enhances transparency, reliability, and regulatory acceptance, potentially accelerating the adoption of predictive models in pharmaceutical manufacturing. Future work in our group is focusing on exploring the application of DMDc to more

complex unit operations that exhibit highly nonlinear dynamics. This will allow us to further explore potential limitations of the proposed method and fuel further developments.

## ABSTRACT

Crystallization is a relevant process in the pharmaceutical industry for product purification and particle production. An efficient crystallization is characterized by crystals produced with the desired attributes. Therefore, modeling this process is a key point to achieve this goal. In this sense, the objective of this work is to propose a hybrid model to describe paracetamol dissolution in ethanol. The universal differential equations methodology is considered in the development of this model, using a neural network to predict the dissolution rate combined with the population balance equations to calculate the moments of the crystal size distribution (CSD) and the concentration. The model was developed using experimental batches. The dataset is composed of concentration measurements obtained using attenuated total reflectance-Fourier transform infrared (ATR-FTIR). The objective function of the optimization problem is to minimize the relative absolute difference between the experimental and the predicted concentration. The hybrid model efficiently predicted the concentration compared to the experimental measurements. Furthermore, the hybrid approach made predictions of the moments of the CSD similar to the population balance model proposed by Kim et al. [1], being able to successfully calculate batches not considered in the training dataset. Moreover, the performance of the hybrid model was similar to the phenomenological one based on population balance. Therefore, the universal differential equations approach is presented as an efficient methodology for modeling crystallization processes with limited information.

**Keywords**: Crystallization, hybrid model, pharmaceutical industry.

## INTRODUCTION

Crystallization is a separation and purification process that is characterized by a phase change in which crystalline product is obtained from a solution [1]. It is a relevant unit operation and is commonly used for purification, separation and production. It is a practical method that produces pure, concentrated, appealing and convenient to handle chemical substances. Thus, crystallization processes are present in many industries such as pharmaceuticals, food and agrochemicals. Many active ingredients in pharmaceutical industries are produced in the form of crystals, such as paracetamol [2], praziquantel [3] and amoxicillin [4].

For the development of an efficient crystallization process, the product should present the desired characteristics, such as size and shape. Therefore, modeling the crystallization kinetics to calculate the crystal size distribution (CSD) is a key point to predict these characteristics and to optimize the process. Population balance

model (PBM) is the methodology usually applied for modeling crystallization processes. This approach was used to model the batch crystallization of many compounds, such as potassium dihydrogen phosphate (KDP) [5], paracetamol [2, 6, 7] and potassium sulfate [8].

Over the last years, advancements in machine learning have been fueled by greater computational power, the abundance of extensive experimental data, and the development of more efficient algorithms. Machine learning techniques have achieved significant success in analyzing and predicting complex behaviors from large datasets, as demonstrated by applications such as web searches, email filtering, and image recognition [9, 10]. In the field of crystallization, machine learning is emerging as a valuable tool for predicting and optimizing processes to meet specific product requirements [11, 12].

Even with these positive points of machine learning models, they are usually empirical models and do not consider the physical laws that describe the system. Hybrid models present as an alternative to solve these problems. Hybrid models are a combination of data-driven and first principles models [13]. These approaches combine the flexibility of data-driven with the knowledge of physical laws from first principles models [14].

Regarding crystallization processes, Lima et al. [15] combined neural networks and PBM for modeling the nucleation, crystal growth and dissolution for the potassium sulfate batch crystallization. Wu et al. [16] proposed a physics-informed recurrent neural network (PIRNN) for modeling the crystallization process of aspirin. Sitapure and Kwon [17] developed hybrid modeling approach combining time-series-transformers (TSTs) to population balance model. They used TSTs to obtain the nucleation and growth rates for the batch crystallization of dextrose. Then, the rates were used in the population balance equations to obtain the crystal size distribution (CSD). There are also hybrid model applications used to describe the batch crystallization of sugar accounting for nucleation, growth and agglomeration [18, 19].

The goal of this work is to propose a hybrid model based on universal differential equations (UDEs) approach with a neural network as a universal approximator to describe the dissolution for the paracetamol batch crystallization in ethanol. According to Xiouras et al. [9] and Lima et al. [10], the use of hybrid models for crystallization processes is not new, but there are few applications of these methodologies. Most studies proposed hybrid models for sugar crystallization. There is a lack of hybrid model applications for the pharmaceutical field and none of them considered paracetamol. Paracetamol is a pharmaceutical compound whose crystallization has been extensively explored in the literature for modeling and control studies. The hybrid model is composed of a neural network to calculate the dissolution rate combined with the population balance equations to predict the concentration and the moments of the CSD. The concentration measurements obtained by Kim et al. [2] were used to develop the hybrid model. Therefore, the hybrid approach presents flexibility to model the dissolution rate compared to the PBM.

# METHODOLOGY

## Population Balance Model

Kim et al. [2] proposed a PBM to describe the paracetamol batch crystallization in ethanol. The model accounts for nucleation, crystal growth and dissolution. The method of moments was applied to solve this problem.

Eq. 1 describes the $i^{th}$ order moment, in which $L$ is the characteristic crystal size, and $n(L)$ is the number density of crystals. The moments $\mu_0$, $\mu_1$, $\mu_2$and $\mu_3$ are proportional to the total number, length, surface area, and volume of crystals, respectively.

$$\mu_i = \int_0^\infty L^i\, n(L) dL,\ i = 1,2,3,\ldots \tag{1}$$

The paracetamol dissolution PBM is described by Eq. 2, where $k_v$ is the volume shape factor, $\rho_c$ is the solid density of crystals (g/cm$^3$), and $D$ is the dissolution rate.

$$\frac{d\mu_0}{dt} = 0 \tag{2a}$$

$$\frac{d\mu_1}{dt} = D\mu_0 \tag{2b}$$

$$\frac{d\mu_2}{dt} = 2D\mu_1 \tag{2c}$$

$$\frac{d\mu_3}{dt} = 3D\mu_2 \tag{2d}$$

$$\frac{dC}{dt} = -3k_v\rho_c\, D\mu_2 \tag{2e}$$

The dissolution rate is described by Eq. 3, where $k_d$ is the pre-exponential rate constants for the crystal growth $((\mu m/min)(g/g)^{-\gamma_d})$, $E_{a_d}$ is the activation energy (J/mol) and $\gamma_d$ is a exponential parameters on supersaturation. $R$ is the universal gas constant (J/(mol K)) [20].

$$D = k_d exp\left(\frac{-E_{a_d}}{RT}\right)(C_S - C)^{\gamma_d} \tag{3}$$

In Eq. 3, $C$ (g solute/g solvent) is the concentration in the solution and $C_S$ (g solute/g solvent) is the saturated concentration at the system temperature. The saturated concentration can be calculated by the polynomial described by Eq. 5, in which $T$ is the temperature in Kelvin.

$$C_S = -8.707 + 9.669x10^{-2}T - 3.610x10^{-4}T^2 + 4.590x10^{-7}T^3 \quad (5)$$

To estimate the parameters of this PBM, Kim et al. [2] performed seven experimental batches, which five were used to develop the model and two to validate it. All experimental batches were developed at constant temperatures; two of them were performed at 10°C, one at 15°C, three at 20°C, and one at 30°C. The initial concentration was also changed for the batches, considering values between 0.142 and 0.202 g/g. The model was developed using concentration measurements obtained during the experimental batches with attenuated total reflectance Fourier transform infrared (ATR-FTIR).

## Universal Differential Equations

Universal differential equations (UDEs) are differential equations enhanced by the inclusion of one or more universal approximators. Various functions and series have been recognized as universal approximators due to their versatility and adaptability. Neural networks excel as universal approximators in higher-dimensional settings. Their layered architecture and the use of nonlinear activation functions allow them to effectively approximate functions within multidimensional spaces [15].

In this work, a hybrid model was developed to describe the dissolution kinetics of paracetamol in ethanol based on the UDE approach. A neural network is used to calculate the dissolution rate, while the moments of the CSD and the concentration are obtained by the population balance equations. The neural network uses concentration measurements and the saturated concentration to calculate the dissolution rate. Before being used by the neural network, the inputs were scaled between zero and one. Figure 1 presents a scheme of the proposed UDE.

The model was developed using the concentration measurements obtained by Kim et al. [2] during the batch experiments. Similarly to Kim et al. [2], two experimental batches were used to test the model. However, four batches were used to train and one to validate the model to avoid overfitting. The optimization problem consisted of designing the neural network that minimizes Eq. 6, where $C_i$ is the experimental concentration, $\hat{C}_i$ is the predicted concentration and $N$ is the number of measurements. As this model accounts only for undersaturated conditions, the constraint described in Eq. 7 was considered for the optimization problem.

$$F_{obj} = \frac{1}{N}\sum_{i=1}^{N}\left|\frac{\hat{C}_i - C_i}{C_i}\right| \quad (6)$$

$$\hat{C}_i / C_S(T_i) \leq 1 \quad (7)$$

The hybrid model was developed in Python using the deep learning library, Pytorch [21] and the neural differential equations library TorchDyn [22]. The optimizer Adam was used to train the hybrid model. Early stopping was also considered in the training to avoid overfitting with a criterion of stopping the training whenever the model exceeded 70 epochs without lowering validation error.

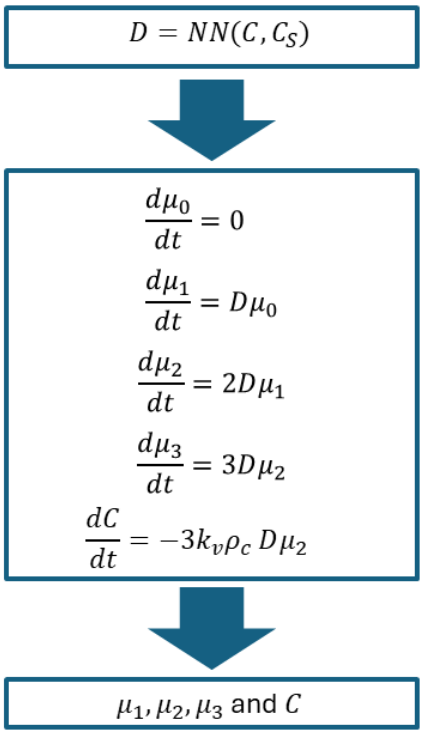

**Figure 1.** Hybrid model scheme.

## RESULTS AND DISCUSSION

The hybrid model was composed of a neural network with one hidden layer containing 30 neurons and using hyperbolic tangent as the activation function. An adaptive learning rate was considered with an initial value equal to $10^{-5}$. The learning rate is reduced to 10% of the initial value after 500 epochs.

Table 1 presents the relative mean absolute error (RMAE) between the predicted and measured concentrations for the PBM and the hybrid model. While the performance of the PBM was better for the test dataset, the hybrid model was able to make predictions closer to the experimental values for the training and validation datasets. However, both approaches presented close values of RMAE in all cases.Fig. 2 presents the performance of the hybrid model and the PBM to predict the solution concentration for the validation batch. The PBM and the hybrid model showed close performances. Their concentration predictions presented a similar behavior and achieved the same equilibrium concentration at the end of the batch. Compared to the experimental values, the UDE model made predictions closer to the concentration

measurements than the PBM.

**Table 1:** Relative mean absolute error (RMAE) between the concentration measurements and the predicted values by the PBM and the hybrid model.

| Model | Training | Test | Validation |
|---|---|---|---|
| PBM | $6.50 \times 10^{-3}$ | $5.18 \times 10^{-3}$ | $4.31 \times 10^{-3}$ |
| UDE | $3.50 \times 10^{-3}$ | $8.29 \times 10^{-3}$ | $3.18 \times 10^{-3}$ |

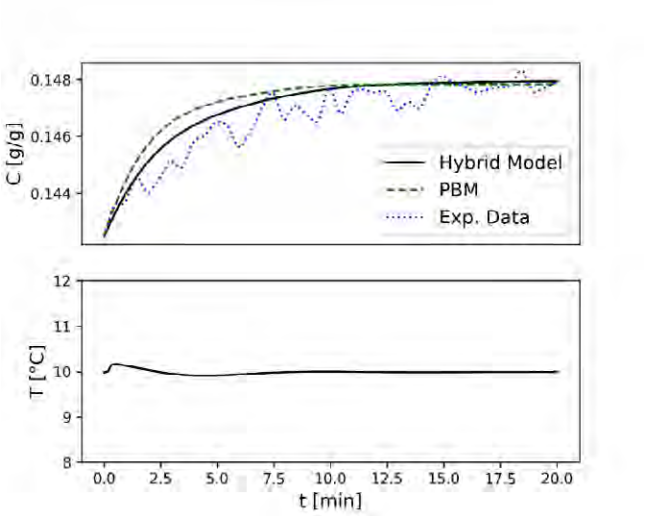

**Figure 2.** Performance of the PBM and hybrid model to predict the concentration for the validation batch.

Fig. 3 presents the performance of the hybrid model and the PBM to predict the solution concentration for one of the test batches. Once again, both methodologies were able to make close concentration predictions. The RMAE value, in Table 1, for the hybrid model for the test dataset was higher than the PBM because of the offset that the UDE model left in the equilibrium concentration compared to the experimental data.

The values presented in Table 1 and the performances showed in Figs 2 and 3 suggest that the hybrid model presented a better performance for the training and validation dataset. On the other hand, the PBM was more efficient for the test dataset. These facts suggest that the UDE model is able to make efficient predictions, but the PBM was more effective for conditions not considered in the training dataset. Therefore, the performance of the PBM was better for extrapolation. This can be expected as the PBM is based on physics laws.

Fig. 4 presents a simulation of one experimental batch using the hybrid model and the PBM. In this simulation, $\mu_1, \mu_2, \mu_3$ and the solution concentration were calculated. Regarding the concentration predictions, both approaches were able to achieve the same equilibrium concentration at the end of the batch. However, PBM presented a faster response compared to the UDE trajectories. This behaviour was also observed in Fig. 2, showing that the PBM is overestimating this characteristic when compared to the experimental data. The same thing happens for the predictions of the moments of the CSD. Both models were able to achieve similar equilibrium values at the end of the batch. The same differences in the transient response are also present in the moments.

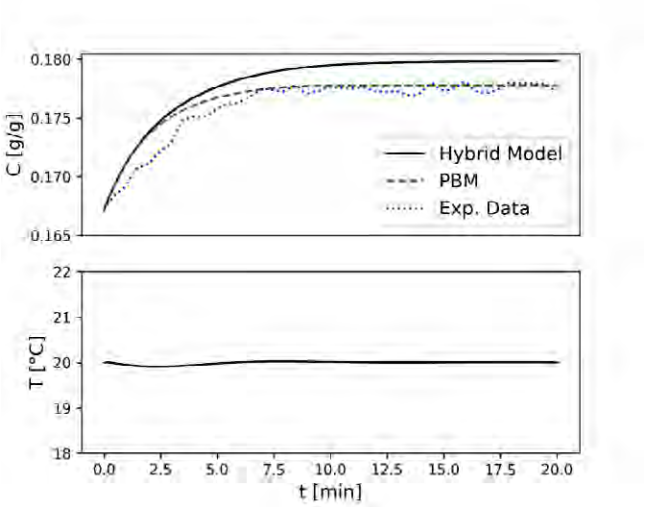

**Figure 3.** Performance of the PBM and hybrid model to predict the concentration for one of the test batches.

The differences presented in Fig. 4 between the predictions of the hybrid model and the PBM are consequence of the challenge when dealing with dissolution. The dissolution is a quick phenomenon. Therefore, when the crystals are added in the undersaturated solution during the batch, they are quickly dissolved until the equilibrium is reached. This fact makes it difficult to find an efficient model for dissolution. The errors calculated in Table 1 and the profiles obtained in Figs. 2 and 3 suggest that the hybrid model was able to make predictions closer to the real measurements when the crystals are dissolving compared to the PBM.

The proposed hybrid approach based on UDE presented a good performance for modeling the dissolution of paracetamol in ethanol. The PBM presented the best performance for extrapolations. On the other hand, the UDE model was able to make better predictions than the PBM when the crystals were dissolving. Even with these advantages and disadvantages, replacing the dissolution rate by a neural network was an effective alternative for modeling this phenomenon, as suggested by Lima et al. [15].

## CONCLUSION

In this work, a hybrid model based on UDE was developed for describing the paracetamol dissolution in ethanol. There is a lack of studies proposing hybrid models for crystallization or dissolution of pharmaceutical compounds and none of them considered paracetamol

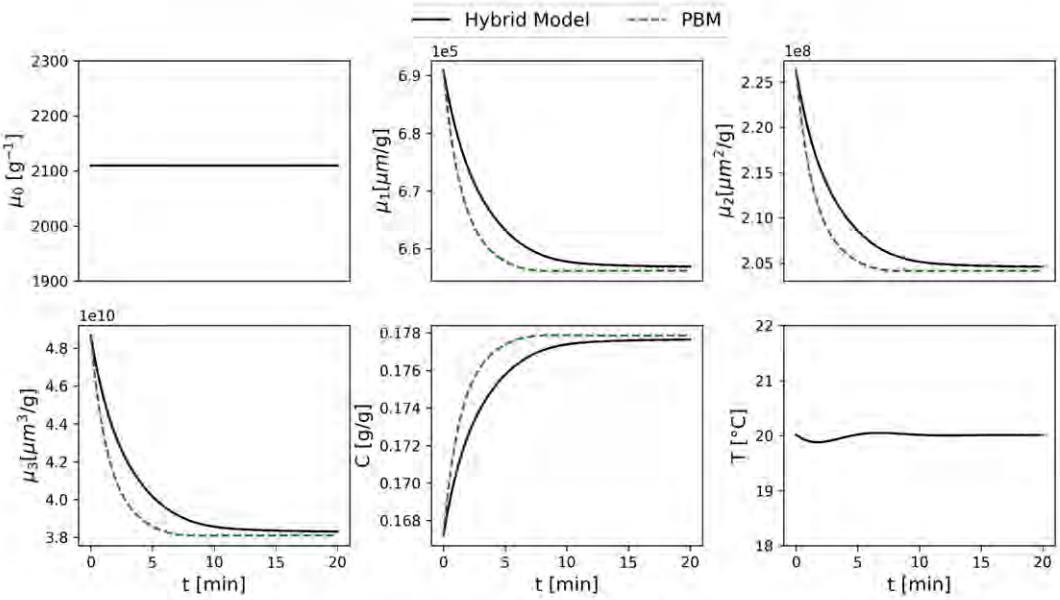

**Figure 4:** Performance of the hybrid model and the PBM to predict the moments of the CSD and the concentration of the solution considering the same conditions of one experimental batch.

[9, 10]. The dataset used in this work consisted of seven experimental batches developed by Kim et al. [2], where four of them were used to train the model, one for validation and two to test it. The developed hybrid model was able to make predictions of the solution concentration close to the experimental measurements, presenting low RMAE values.

The performance of the hybrid model was also compared to the PBM developed by Kim et al. [2]. The values calculated by the hybrid model of solution concentration and moments of CSD were close to the one obtained with the PBM. The RMAE between the concentration measurements and the predicted values by the PBM was similar to the RMAE calculated with the hybrid model. The hybrid methodology based on UDE presents as an efficient alternative for modeling crystallization kinetics. As a future work, the nucleation and crystal growth will be considered for developing the hybrid model of paracetamol crystallization in ethanol.

## ABSTRACT

Tableting is a dry granulation process for compacting powder blends into tablets. In this process, a blend of active pharmaceutical ingredients (APIs) and excipients are fed into the hopper of a rotary tablet press via feeders. Inside the tablet press, rotating feed frame paddle wheels fill powder into dies, with tablet mass adjusted by the lower punch position during the die filling process. Pre-compression rolls press air out of the die, while main compression rolls apply the force necessary for compacting the powder into tablets. In this paper, process variables such as feeder screw speeds, feed frame impeller speed, lower punch position during die filling, and punch distance during main compression have been systematically varied. Corresponding responses, including pre-compression force, ejection force, and tablet porosity have been evaluated to optimize the tableting process. After implementing an open platform communications unified architecture (OPC UA) interface, process variables can be monitored in real-time. To enable in-line monitoring of tablet porosity, a novel UV/Vis fiber optic probe has been implemented into the rotary tablet press. To further analyze the overall process, a data-driven modeling approach is adopted. Data-driven modeling is a valuable alternative to modeling real-world processes where, for instance, first principles modeling is difficult or infeasible. Due to the complex nature of the powder compaction process, several model classes need to be explored. To begin with, linear autoregressive models with exogenous inputs (ARX) have been considered. Thereafter, nonlinear autoregressive models with exogenous inputs (NARX) have been considered. Notably, several experiments have been designed to gather the data required for the development of the model.

## INTRODUCTION

The pharmaceutical industry is increasingly striving for autonomous control of their processes [1]. In this context, process and product data are continuously generated, evaluated and interpreted in order to assess the quality of the drug product and to control the corresponding process based on this data. Thereby leading to improved product quality and reduced costs [2].

Tableting represents a vital process step in the production of tablets, the most common dosage form, and is therefore a particular focus of research [3]. Here, in a rotary tablet press, powder is filled into a die, pressed into a tablet by a two-stage compression process of the upper and lower punch and then ejected by an upward movement of the lower punch [4]. These tablet presses are characterized by a particularly high throughput and double-sided compression of the tablets.

Traditionally, individual samples are taken after tableting and subsequently evaluated off-line and used to assess the quality of the entire batch. In order to ensure real-time data, the implementation of an OPC UA connection and process analytical technology is crucial. This enables process and product data to be generated in real-time [5].

Process parameters that influence drug product

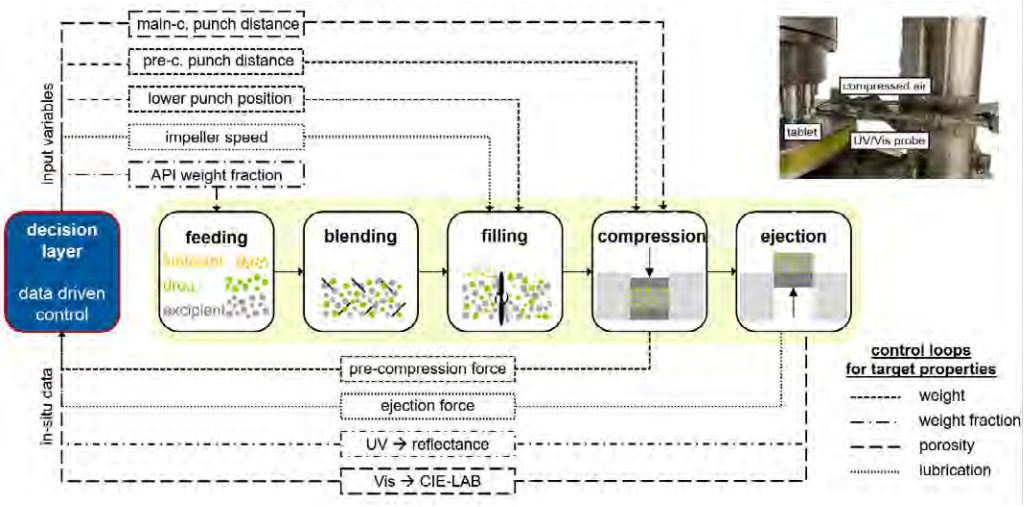

**Figure 1.** Powder compaction process.

quality, referred to as critical process parameters, are in particular the feed frame speed when filling the die with powder, the pre-compression force, the main-compression force, the compression roll distance and the ejection force. In order to evaluate these critical process parameters in real-time, an OPC UA interface was implemented.

Spectroscopic methods have proven particularly valuable for critical quality attribute (CQA) monitoring, as they are non-destructive, non-invasive and fast [6]. CQAs such as the active pharmaceutical ingredient (API) content and porosity are particularly important here, as these have a significant influence on the quality of the drug product. Near-infrared spectroscopy has proven to be useful for monitoring the active pharmaceutical ingredient content or porosity [7]. However, simultaneous determination was not possible and the evaluation was carried out by multivariate data analysis. In this work, a comparatively new method was used that is based on UV/Vis diffuse reflectance spectroscopy, measures API content and porosity simultaneously and can be evaluated univariately. For this purpose, the spectrum is separated into the ultraviolet and the visible range whereby the ultraviolet range is utilized to determine the active pharmaceutical ingredient content and the visible range to determine the porosity. Therefore, the visible range was transformed into the CIELAB color space.

To further analyze the process, we used the experimental data to develop a mathematical model. Recently, data-driven modeling has received a great deal of attention to model real-world applications. Parametric and nonparametric approaches are prevalent in the literature [8]. In this work, we are interested in the parametric modeling approach. In the parametric modeling approach, a model class is chosen a priori. Thereafter, the parameters are estimated, for instance, by using output-error methods [8, Chapter 7]. Here, we use nonlinear auto-regressive with exogeneous inputs (NARX) approach [9] to develop a parametric model for the process. Remarkably, NARX models have already found several applications in the literature [10-12]. As the powder compaction process is a complex process consisting of several subprocesses, it is challenging to determine a model class. In this regard, both linear and nonlinear autoregressive models with exogeneous inputs are considered to model the process. As is shown, the whole process is modeled as a combination of linear autoregressive and nonlinear autoregressive equations. We now summarize the contributions of this study. We collect experimental data for the powder compaction process on a rotary tablet press. We analyze full factorial experimental designs using multiple linear regression analysis to identify significant factors influencing product quality. We then combine process parameters with data obtained from a real-time spectroscopy method based on UV/Vis spectroscopy. To gain further insights about the relationships among various inputs and outputs of the process shown in Figure 1, we develop a parametric model based on the collected experimental data. This data-driven model of the process is developed using the NARX modeling approach.

## MATERIAL AND METHODS

### Materials

The formulation consists of 10 wt% theophylline monohydrate (Theophylline Monohydrate, Thermo Fisher Scientific, Waltham, USA) used as the active pharmaceutical ingredient, 0.5 wt% magnesium stearate (Ligamed MF-2-V, Peter Greven, Bad Münstereifel, Germany) used as the lubricant and lactose monohydrate (Foremost NF Lactose 310, Foremost Farms USA, Baraboo, USA) used as the filler and binder. Accordingly, the lactose content was changed when the active pharmaceutical ingredient

content was adjusted to 7 and 13 wt%.

## Tableting

The tableting process is carried out on a rotary tablet press (102i, Fette Compacting, Schwarzenbek, Germany). The throughput was set to 20,000 tablets per hour. In a first step, the material is fed into the hopper of the tablet press via loss-in-weight feeders (KT-20, Cooperion, Niederlenz, Switzerland). The powder is then filled into the dies via the feed frame equipped with round spokes paddle wheels (Fill-O-Matic (FOM), Fette Compacting, Schwarzenbek, Germany). Each die is mounted on the die table and rotates in a circular motion with the pairs of punches. The die table then continues to rotate and pre-compression rolls press air out of the die, followed by the actual material compression step via the main-compression rolls. Finally, the finished tablet is ejected by an upward movement of the lower punch. A full-factorial experimental design containing three stages was developed for the investigations. The active pharmaceutical ingredient content was varied from 7 to 13 wt\%, the main-compression force from 5 to 15 kN and the speed of the FOM from 40 to 120 rpm. Here, the responses were the ejection force, the reflectance value and the CIELAB color space. Furthermore, another experimental design was performed to investigate the influence of the powder mass on the pre-compression force as a possible surrogate parameter for real-time monitoring of the tablet weight. Tablet masses from 280 to 360 mg were set by varying the filling depth. Also, the influence of the pre-compression punch distance was investigated.

## Critical process parameter monitoring

Real-time monitoring of critical process parameters requires the implementation of an OPC UA interface. This guarantees real-time data exchange between the tablet press and the corresponding server. In this study, the ejection, pre- and main-compression force were recorded and evaluated using the OPC UA interface.

## Critical quality attribute monitoring

In this study, the weight and porosity of the tablets were determined off-line and additionally supported by real-time UV/Vis spectroscopy data to capture the dynamics of the process.

### Off-line determination

Tablet porosity (ε) (Eq. (1)) was determined by correlating the tablet density ($\rho_t$) derived from geometry and weight measurements (ST50, Sotax, Aesch, Switzerland) to the solid density ($\rho_s$) measured by helium pycnometry according to European Pharmacopoeia 11 (Chapter 2.9.23):

$$\varepsilon = \left(1 - \frac{\rho_t}{\rho_s}\right) 100\%. \quad (1)$$

### Real-time UV/Vis spectroscopy

Real-time monitoring of the active pharmaceutical ingredient content and porosity was carried out using a UV/Vis diffuse reflectance probe (Inspectro X, ColVisTec, Berlin, Germany). For this purpose, the probe was implemented in the ejection position of the tablets. Here, the probe is oriented orthogonally to the tablet side wall meaning measurements are taken on the tablet side wall. The distance between the probe and the tablet is set to 4 mm. In this way, radiation from 224 to 820 nm is guided to the tablet via the six outer glass fibers, where the radiation is absorbed. The reflected light is guided back via the middle glass fiber and evaluated. In order to keep the 6 in 1 array of glass fiber optics free of particles, an additional air flow and an extraction system have been implemented. For the measurement, 35 light flashes are emitted per measurement, each lasting 2 ms leading to a measurement frequency of 1.5 Hz.

For data analysis and evaluation with regard to the API content, the reflectance (R) was formed on the basis of the intensity of the reflected light (I) and the emitted light ($I_0$). In addition, Kubelka-Munk was applied to establish a correlation between absorption and reflection. Here, the transformed reflectance (f(R)) is the quotient of absorption and scattering coefficients (k and s) (Eq. (3)):

$$R = \frac{I}{I_0} \quad (2)$$

$$f(R) = \frac{k}{s} = \frac{(1-R)^2}{2R}. \quad (3)$$

For the assessment, the reflectance intensity in the UV range, specifically in the wavelength range from 320 to 330 nm, was correlated with the active pharmaceutical ingredient content.

The porosity was evaluated on the basis of the Vis range (380 to 780 nm) and the corresponding spectral information were converted into the CIELAB color space. This describes the range of visible light for humans via three values (L*, a* and b*) ordered in a Cartesian coordinate system. From this, the color saturation chroma (C*) can be determined, which correlates with the surface roughness and in consequence with the porosity.

## Multiple linear regression analysis

Multiple linear regression analyses were carried out using Modde software (MODDE 10, Sartorius, Göttingen, Germany) at a significance level of α=0.05 to visualize the effects of the individual factors on the responses. Therefore, models were developed for each set of factors ($\beta$) and response ($Y_R$ )(Eq. 4).

$$Y_R = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_{1,2} x_1 x_2. \quad (4)$$

The results of the analyses are graphically represented by contour plots using the developed models. Here, the factors are on the axes while the response is represented by the color scale. The centre points were

performed in triplicate.

## Data-driven modeling approach

We use nonlinear auto-regressive with exogeneous inputs (NARX) models to develop a mathematical model for the considered tabletting process. The NARX formalism contains both model identification and model validation. Model identification step involves two steps: selecting model class, for example, polynomial NARX and parameter estimation. The identified model is then validated by using a different dataset. As our process contains multiple-input, multiple-output (MIMO), we model it using a MIMO NARX model. Assuming that we have $m$ input variables and $p$ output variables, the $j$th output of the NARX model is given by

$$y_j(k) = F_j\left(U_1(k), \dots, U_m(k),\ Y_1(k-1), \dots, Y_p(k-1)\right) + e_j(k), \quad (5)$$

where

$$U_i(k) = \left[u_j(k), u_j(k-1), \dots, u_j(k-n_u)\right], \qquad i = 1,2,..,m,$$

$$Y_j(k-1) = \left[y_j(k-1), \dots, y_j\left(k-n_y\right)\right], \qquad j = 1,2,..,p.$$

Here $u_i(k), y_i(k), e_i(k)$ denote, respectively, control input, process output, and noise terms. Function $F_j$ is unknown. However, as we consider the model class of polynomial NARX to model the process, $F_j$ is an unknown polynomial function. Finally, the parameters $n_u, n_y$ represent the maximum lags for the input and output, respectively.

# RESULTS

## Experimental results

The experimental results are illustrated as contour plots in Figure 2. Here, increasing the feed frame speed during die filling leads to an increase in the amount of applied shear and the hydrophobic lubricant spreads over the binder particle surface. Friction between the die, punch and powder is reduced, resulting in a lower ejection force [13]. Likewise, an influence of the main-compression force is noted, whereby an increase leads to a stronger consolidation of the powder and thus to a higher ejection force. Based on the powder component properties, a correlation to the ejection force is also evident here. Furthermore, combinatorial effects can be identified. Thus, the ejection force can be utilized, taking into account the associated additional effects, to obtain information about the lubrication.

The color saturation chroma (C*), however, only indicates a significant influence of the main-compression force. Increasing the main-compression force results in decreased roughness on the surface of the tablet, which intensifies specular reflection and thus leads to a higher chroma (C*) value. Moreover, this decreases the volume of the tablet and causes an increase in porosity. This makes the chroma value (C*) particularly suitable for monitoring porosity.

The reflectance in the range from 320 to 330 nm serves to monitor the active pharmaceutical ingredient content. Here, the reflectance value increases with higher active pharmaceutical ingredient content. The experimental results provide an additional effect of the main-compression force as well as combinatorial effects. Thus, further models need to be developed to fully describe the process and to enable autonomous control.

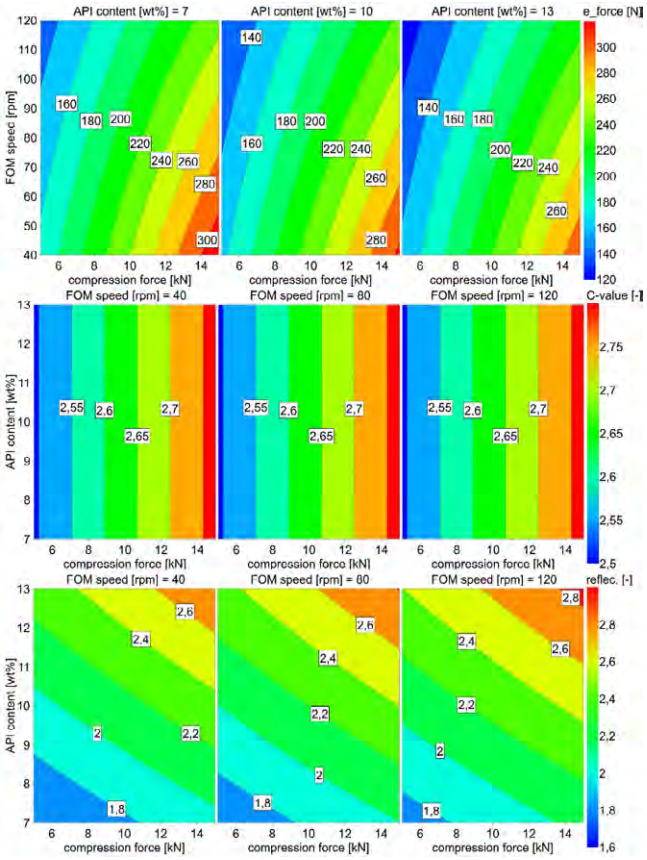

**Figure 2.** MLR results illustrated as contour plots for ejection force (e_force, top), chroma value (C-value, middle), and reflectance value (reflec., bottom).

In the second sub-experiment, the pre-compression force and the mass of the tablets were examined in relation to the filling depth and punch distance (Figure 3). The pre-compression force increases with decreasing the pre-compression roll distance. Here, more force is required to compress the same amount of powder into a smaller volume. In addition, an increased quantity of powder in the die leads to an increased force required to compact the powder to the defined height. Combinatorial effects can also be recognized here. However, the mass of the tablet only depends on the filling depth as this defines the volume filled with material prior to compression,

if the time for material filling in the die is sufficient.

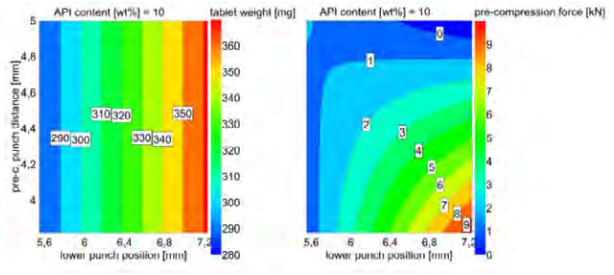

**Figure 3.** MLR results illustrated as countour plots for tablet weight (left) and pre-compression force (right).

Simulation results

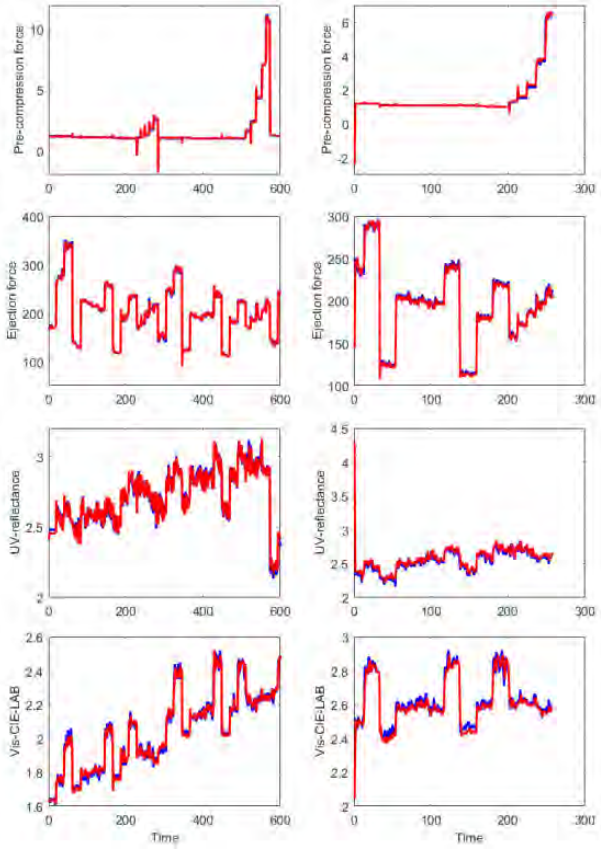

**Figure 4.** Identification (left) and validation (right) plots for all the outputs. The blue solid lines indicate the measured outputs, whereas red solid lines indicate computed outputs.

We aim to develop a parsimonious model for the process on the basis of gathered experimental data. Remarkably, several sets of experiments are performed to gather the necessary data. These data are then used for both identification and validation of the developed model. Total $859$ samples of data are collected for various inputs and outputs mentioned in Figure 1. We split the dataset as follows: $70\%$ for identification (training) and $30\%$ for validation (generalization or testing).

We denote all the five input variables by $u$ and all the four output variables by $y$. Furthermore, we denote the four outputs, namely, pre-compression force, ejection force, UV-reflectance, Vis-CIE-LAB, respectively, by $y_1, y_2, y_3, y_4$. With this notation in place, using the NARX approach, we obtain, based on the gathered dataset, the following model:

$$y_1(k) = \alpha_1 u(k) + \beta_1 u(k-1) + 0.9425 y_1(k-1)$$

$$y_2(k) = \alpha_2 u(k) + \beta_2 u(k-1) + \gamma_2 u^2(k) + \delta_2 u^2(k-1) + 0.9 y_2(k-1)$$

$$y_3(k) = \alpha_3 u(k) + \beta_3 u(k-1) + 0.9181 y_3(k-1)$$

$$y_4(k) = \alpha_4 u(k) + \beta_4 u(k-1) + \gamma_4 u^2(k) + \delta_4 u^2(k-1) + 0.6516 y_4(k-1) - 0.0756 y_4(k-2) + 0.0012 y_4^2(k-1) + 0.0510 y_4^2(k-2), \quad (6)$$

where

$$\alpha_1 = [0.0135 \ -1.7538 \ -0.4880 \ -0.7282 \ 2.5461]$$

$$\beta_1 = [-0.0129 \ 1.5106 \ 0.4653 \ 0.7258 \ -2.3407]$$

$$\alpha_2 = [2.6 \ 96.9 \ 1092.7 \ -74.6 \ -425.5]$$

$$\beta_2 = [2.5 \ -103.7 \ -1010.1 \ 730 \ 396]$$

$$\gamma_2 = [0 \ -12.5 \ -190.1 \ 2.4 \ 43.7]$$

$$\delta_2 = [0 \ 13.1 \ 176 \ -2.4 \ -40.7]$$

$$\alpha_3 = [0.0100 \ -0.1067 \ -0.7568 \ 0.2428 \ 0.5787]$$

$$\beta_3 = [-0.0096 \ 0.1160 \ 0.6993 \ -0.2406 \ -0.5288]$$

$$\alpha_4 = [-0.0007 \ -1.0966 \ -6.3087 \ 0.0093 \ 4.5086]$$

$$\beta_4 = [0.0011 \ 0.7916 \ 5.1898 \ 0.0104 \ -3.5830]$$

$$\gamma_4 = [0 \ 0.1243 \ 0.8290 \ 0.0010 \ -0.3157]$$

$$\delta_4 = [0 \ -0.0904 \ -0.6881 \ -0.0010 \ 0.2515].$$

For the purposes of illustration, both the identification and validation plots for all the four outputs are shown in Figure 4. It can be seen that the computed ones almost agree with the measured ones both in identification and validation plots. Thus, the model is generalizable and can be used for further analysis and control tasks. Moreover, the performance of the model is evaluated by computing the relative percentage error between measured and computed outputs defined as

$$\frac{\|y_{measured} - y_{computed}\|}{\|y_{measured}\|} \ 100\%.$$

The relative percentage error for both identification and validation of all the four outputs are given in Table 1. It can be seen that the errors are in the acceptable range. Hence, we conclude that the identified NARX model represents the process. In the future, we will use this identified model in real-time control of the process for desired product properties.

**Table 1:** Relative percentage error for id. (identification) and val. (validation) of various outputs.

| Outputs | Id. | Val. |
|---|---|---|
| Pre-compression force | 12.23 | 13.90 |
| Ejection force | 3.02 | 4.39 |
| UV-reflectance | 2.32 | 5.42 |
| Vis-CIE-LAB | 1.56 | 1.86 |

## CONCLUSION

In this study, experimental data were collected for the powder compaction process on a tablet press. Full factorial experimental designs were analyzed in terms of multiple linear regression analysis and significant factors associated with product quality were identified. Thereby, process parameters were combined with data from a real-time spectroscopy method based on UV/Vis spectroscopy. These collected data and gained insights from the process were further utilized in developing a parametric data-driven model of the process based on the NARX modeling approach. An avenue of future research work would be the application of this developed data-driven model in real-time control of the process.

## ABSTRACT

Mechanistic population balance modeling (PBM) has advanced the design of pharmaceutical crystallization processes, enabling the production of active pharmaceutical ingredient (API) crystals with desired critical quality attributes (CQAs), such as purity and crystal size distribution. However, PBM development can sometimes be resource-intensive, requiring extensive design of experiments (DoE) and high-quality process data, making it impractical under fast-paced industrial development timelines. This study proposes a machine learning (ML)-based workflow for developing 'fit-for-purpose' digital twins of crystallization processes, leveraging industrially available DoE data to link operating conditions with CQAs. Validated on industrial data for a commercial API with complex crystallization challenges, the workflow efficiently identifies optimal operating conditions, demonstrating the potential of data-driven digital twins to accelerate the development of pharmaceutical processes.

**Keywords**: Artificial Intelligence, Machine Learning, Process Design, Modelling and Simulations, Optimization

## 1. INTRODUCTION

Crystallization is a critical purification and particle control operation in the pharmaceutical industry, influencing critical quality attributes (CQAs) such as crystal size distribution (CSD), yield, and polymorphic form. These attributes, substantially affect pharmaceutical drug properties, including bioavailability, tablet stability, and manufacturability. As a result, designing robust crystallization processes is crucial for the consistent production of Active Pharmaceutical Ingredients (APIs) that meet stringent quality and regulatory standards. To do so, mechanistic population balance model (PBM)-based digital design has become prominent in the industry, facilitating the optimal design and control of crystallization processes through in-silico simulations, mathematical optimization, and model-based control [1]. However, accurately determining PBM kinetic parameters for specific API-solvent systems poses challenges, requiring a well-designed design of experiments (DoE), along with high-quality real-time process data (e.g., concentration, CSD) from process analytical technology (PAT) tools or offline analyses [2]. The extensive resources—time, material, and labor—required for data acquisition, combined with rapid industrial timelines, often render PBM-based digital design resource-intensive and impractical [2,3].

Recently, there has been growing interest in data-driven digital design approaches to overcome the limitations of traditional crystallization process development methods. Xiouras et al. [3] provide a detailed review of studies on the application of data-driven modeling and control techniques in crystallization. While significant progress has been made in dynamic crystallization process modeling, such frameworks rely on the availability of real-time or historical time-series data from PAT tools. However, as previously noted, obtaining reliable PAT data is industrially challenging due to issues such as stringent calibration requirements, probe fouling, and availability constraints.

To address these limitations, data-driven frameworks must align with the realities of industrial pharmaceutical process development by leveraging available DoE data. This data typically includes only the process operating conditions and the output CQA measurements

obtained at the end of the batch. Operating in the absence of real-time state measurements places these frameworks in a low-data regime, which makes ML model development particularly challenging. Generative modeling techniques offer a promising approach to construct data-driven models under data-scare conditions by training models with synthetic experimental data generated from existing experimental inputs, thus mitigating data limitations [4, 5]. This study evaluates the effectiveness of various generative models in addressing data scarcity and enabling the development of accurate predictive models. Building on this, a generalized framework is proposed for developing data-driven digital twins and deploying them through mathematical optimization to identify operating conditions that yield the desired CQAs.

## 2. PROPOSED METHODOLOGY

### 2.1 Generalized data-driven digital twin development workflow

A systematic workflow is essential for building robust data-driven digital twins that generalize across diverse problem statements (Figure 1). The workflow begins with 'System definition' (Step 1), where the CQAs of interest are identified as model outputs, and the operational parameters to be varied are defined. Step 2 focuses on experimental data collection from historical or newly executed DoEs, designed using heuristics, statistical, or model-driven approaches. Step 3 involves data pre-processing, including missing value removal, reserving 10-15 % of data as a hold-out test set, and standardizing inputs for robust model training.

The 'ML model architecture selection and hyperparameter optimization', evaluates and trains multiple regression models including Random Forest (RF), gradient-boosted trees (GBT), Support Vector Regressors (SVR), and Distributed gradient-boosted trees (e.g., XGBoost). Given the limited size of the training dataset, simpler models are prioritized over deep neural networks to reduce the risk of overfitting and maintain model interpretability. Hyperparmater tuning is conduced using an exhaustive search over specified parameters for each model architecture (GridSearchCV) with a K-fold cross validation strategy (K = 3 or 5), optimizing for mean squared error (MSE) as the loss function. The best-performing models for each CQA were selected based on lowest validation MSE across folds and highest test $R^2$.

When constructing data-driven digital twins using operating parameter-CQA structures, the absence of dynamic interaction with the physical system necessitates the development of static digital twins. These models provide predictions alongside quantified uncertainty measures [2], which can be achieved using ensemble-based uncertainty quantification (UQ) methods such as Monte Carlo cross-validation, bootstrapping, and out-of-bag estimation.

#### 2.1.1 Synthetic data generation from DoE data and augmentation

The central concept in Step 6, is the use of generative AI models to generate new datasets (referred to as 'synthetic data' ($z_i^s$)) that capture the relationship between operational parameters and CQAs, using existing experimental DoE data (referred to as 'real data' ($z_i$)). These synthetic datasets serve as proxies for new laboratory experimental data and can be combined with real data to improve the predictive capabilities of ML models [4]. In this study, three widely studied generative models were explored: the Gaussian Copula Synthesizer, Generative Adversarial Networks (GANs), and Variational Autoencoders (VAEs). Each of these models is based on distinct underlying principles and hence, generates synthetic data of varying quality, where *quality* refers to the fidelity of the synthetic data in replicating the statistical properties of the real data. The ability of generative models to accurately capture the real data distribution depends on factors such as the size and distribution of the input real data and the effectiveness of model training [4, 5].

An essential consideration in synthetic data generation is the enforcement of domain-specific constraints to ensure the generated data is meaningful. It was observed that incorporating constraints directly into the training phase of generative models yielded superior performance compared to post-processing methods that discard non-compliant synthetic samples.

Evaluating the quality of synthetic data prior to experimental testing or validation presents significant challenges. To address this, we implemented a recently proposed *weighted expected risk minimization (ERM)* framework [6]. This approach systematically integrates synthetic data with real data to enhance the predictive performance of the resulting model on unseen data. This is done using a weighted loss function (Equation 1),

$$\mathcal{L}_{n,m}(\theta;\ \alpha) = \frac{1-\alpha}{n}\sum_{i=1}^{n}\mathcal{L}\left(\theta, z_i\right) + \frac{\alpha}{m}\sum_{i=1}^{m}\mathcal{L}\left(\theta, z_i^s\right) \quad (1)$$

where the weighting parameter (α) adjusts the contribution of synthetic data based on its quality and its impact on model performance on unseen real test data. Here, $n$ and $m$ refer to the number of real and synthetic samples respectively, $\mathcal{L}$ is the training loss function such as MSE and θ are model hyperparameters. The value of α can be determined systematically for different ($n$, $m$) either theoretically, using scaling laws, or experimentally, by minimizing the test error on a validation split of the original dataset [6]. Thus, by shifting the emphasis from solely generating high-quality synthetic data to effectively leveraging it in combination with real data, this approach provides a practical framework for improving ML model performance, particularly in limited data applications.

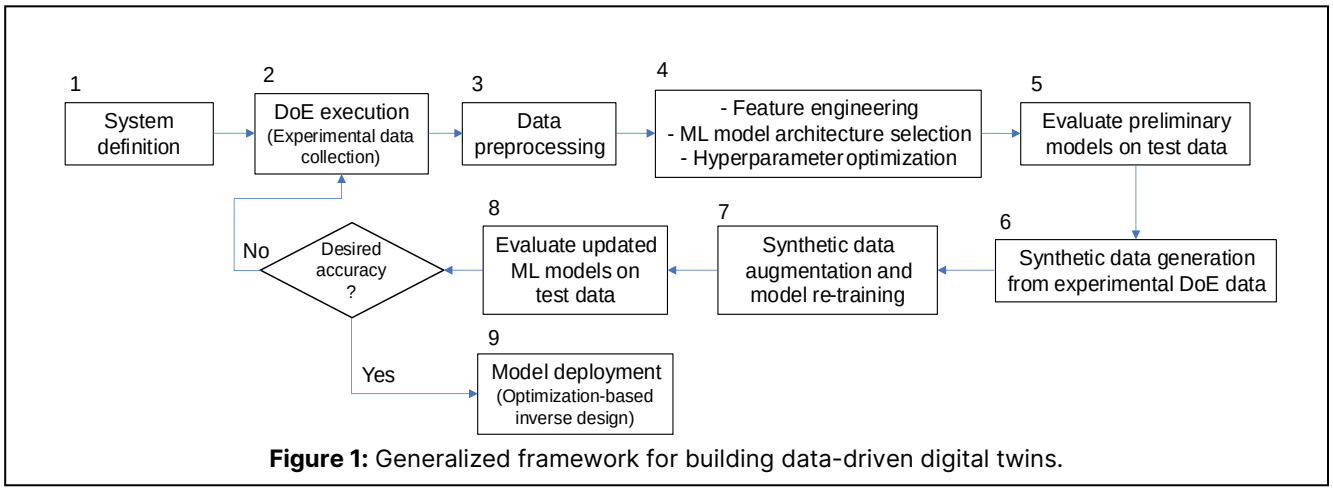

**Figure 1:** Generalized framework for building data-driven digital twins.

In Step 8, the refined models were re-evaluated using the test dataset. If the satisfactory models are obtained for all CQAs—with prediction uncertainties comparable to measurement uncertainties—the workflow proceeds to the model deployment phase. Otherwise, the process iterates back to step 2, where additional experiments were performed to augment the training data.

Step 9 involves deploying trained models through various approaches to enhance process development and understanding, including in-silico simulations, global system analysis, and optimization. This study demonstrates their use in a mathematical optimization framework to determine operating conditions that address crystallization challenges.

## 2.2 Key design objectives for the model compound

An industrial compound (Compound A) was selected as the model compound to demonstrate the proposed data-driven modeling workflow. Preliminary experimental investigations into the batch cooling crystallization of A in a fixed, proprietary solvent revealed the formation of a product mixture comprising both amorphous and crystalline particles at the end of the batch. This observation was corroborated through offline characterization techniques, including powder X-ray diffraction (PXRD), and thermogravimetric analysis (TGA). Additionally, significant agglomeration tendencies were observed in the API crystals, as indicated by inline EasyViewer, and offline particle size analysis using the Morphologi 4. Furthermore, slow crystal growth kinetics presented challenges in achieving larger particle sizes. These observations informed the formulation of three key crystallization design objectives for this compound:

1. **Increase Crystallinity**: Increase the percentage of crystalline particles in the product batch.
2. **Minimize Agglomeration**: Reduce the degree of agglomeration (DoA) in the crystals.
3. **Increase Particle size**: Increase the mean volumetric particle size (D-50).

Each of these CQAs was quantified through offline analysis of the crystals obtained at the end of batch crystallization. Crystallinity was quantified via PXRD and TGA, DoA was quantified using the Morphologi 4, and D-50 was measured using the Malvern Mastersizer. Detailed experimental protocols for crystallization experiments and offline product characterization are detailed elsewhere [7].

## 2.3 Experimental data collection and preprocessing

As per step 2 of the workflow, lab-scale experiments were conducted to collect the initial DoE for the ML model development. The DoE included 31 experiments designed using a combination of heuristic and experimental insights to systematically explore the design space. Initial experiments employed linear temperature profiles with variations in key process parameters, such as initial concentration, seed loading, cooling rates, and final batch temperature. To capture the effects of thermocycles on product CQAs, a subset of experiments incorporated thermal cycling, varying the number of cycles, cooling and heating rates, and intermediate temperature setpoints. Table 1 summarizes the distribution of experiments across four categories: linear, single-cycle, two-cycle, and multi-cycle profiles.

**Table 1:** Variability in the training dataset across the number of thermocycles in temperature profiles.

| Profile type | No. of experiments |
|---|---|
| Linear (cooling) | 18 |
| Linear (1 cooling,1 heating) | 2 |
| 1 cycle | 1 |
| 2 cycle | 4 |
| 3 cycle | 3 |
| 4 cycle | 3 |

The dataset exhibits inherent imbalance due to practical constraints, as not all CQAs were measured in every experiment. While D50 was measured across all 31

experiments, DoA and crystallinity were measured in only 21 and 15 experiments, respectively. To validate the data-driven framework, four additional experiments were conducted under optimal conditions identified in a prior mechanistic modeling study [7], which aimed to maximize D50 and minimize DoA. These experiments formed the hold-out dataset for evaluating the performance of the ML models. For ML model development, the experimental data from all thermocyclic temperature profiles were represented using 13 input and 3 output features, corresponding to the measured CQAs. The input features included initial concentration, seed loading, and parameters characterizing thermal profiles (e.g., intermediate temperatures, cooling rates, and heating rates).

Figure 2 illustrates the input feature representation across different thermal profiles.

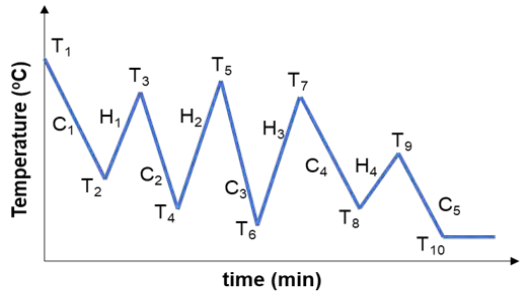

**Figure 2:** Input features that were used to describe the thermocyclic temperature profiles.

## 2.4 Computational implementation of the generalized workflow

The ML models described in section 2.1, were implemented using the scikit-learn library (version 1.4.0) and the XGBoost framework (version 2.1.1). Input features were standardized using the StandardScalar class, and hyperparameter tuning was conducted using GridSearchCV with K = 3 cross-validation, optimizing the following hyperparameters:

- RF: Number of estimators (10-200), max depth (0-30), min samples split (2, 5, 10) and min samples leaf (1, 2, 4).
- GBT: Number of estimators (10-200), learning rate (0.01-0.2), max depth (3, 5, 7), subsample (0.5, 0.75, 1.0), alpha (0.1, 0.5, 0.9).
- XGBoost: Number of estimators (10-200), learning rate (0.01-0.2), max depth (3, 5, 7), subsample (0.5, 0.75, 1.0), samples by tree (0.3, 0.7, 1.0).
- SVR: Kernels (Linear, polynomial, radial basis function, sigmoid), C parameter (0.1-20).

The best hyperparameter configuration for each model and the best model architecture were selected based on the lowest validation MSE and highest test $R^2$. For synthetic data generation, generative models were implemented using the Synthetic Data Vault (SDV) API (version 1.10.0). To ensure the feasibility of the thermocyclic profiles, the generated synthetic data were constrained according to Equations 2,3 and 4.

$$T_i \geq T_{i-1} \;\; \forall\, i = \{3,5,7,9\} \tag{2}$$

$$T_i \leq T_{i-1} \;\; \forall\, i = \{2,4,6,8,10\} \tag{3}$$

$$T_i = 0 \;\Rightarrow (T_j = 0) \wedge (H_j = 0) \wedge (C_j = 0) \;\forall\, \mathrm{j} > \mathrm{i} \tag{4}$$

Hyperparameter tuning of generative models was guided by the SDV's built-in statistical similarity metric, used as the evaluation criterion. The models' effectiveness in reducing test error was evaluated using the weighted ERM approach. For each CQA, three generative models were tested with varying quantities of synthetic samples (5, 10, 15, 20, 25) added to the existing real dataset. The optimal weighting factor for each scenario was then determined, and the corresponding hyperparameter configuration that minimized the cross-validation test error was selected. The models were then retrained with these optimized settings and saved as the final models.

## 3. RESULTS AND DISCUSSION

In Step 4 of the workflow, various model architectures were assessed for their ability to explain the variance in the collected experimental data. Random forest regressors excelled in modeling D-50 and DoA, whereas gradient boosted trees were most effective for crystallinity predictions. Figure 3 presents the parity plot for predictions across training and testing datasets using these models. Additionally, employing Monte Carlo cross-validation for UQ allowed for both the nominal predictions and their prediction uncertainties, as shown in Figure 4.

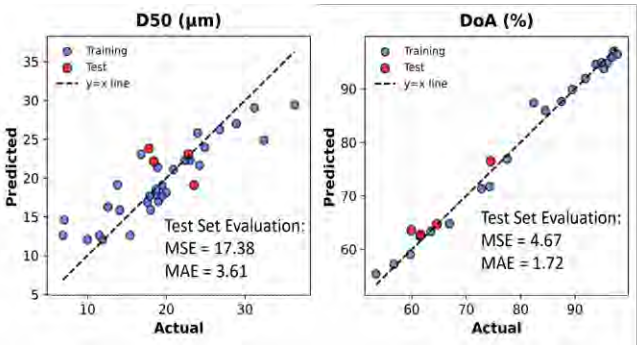

**Figure 3:** Parity plot of predictions for D-50 and DoA models before synthetic data augmentation.

To further enhance the model accuracy, Synthetic data generation and augmentation were explored. As elaborated in Section 2, synthetic data of varying sizes were

generated from the trained generative AI models, and the weighted ERM approach was used to identify the best α for each scenario. The optimal hyperparameter configuration for D-50 was using a VAE model, with m = 25 and α = 0.35. As shown in Figure 5, this configuration gave the highest reduction in the validation loss on the real dataset. The convex nature of the validation loss curve indicates a trade-off; beyond a certain α value, the inclusion of synthetic data ceased to reduce loss, likely due to deteriorating data quality acting as noise. Re-training the ML model for predicting D-50 with this optimized dataset and hyperparameter setting improved performance on the hold-out test dataset, reducing MSE and mean absolute error (MAE) by 44.6% and 26.9% respectively (Figure 6).

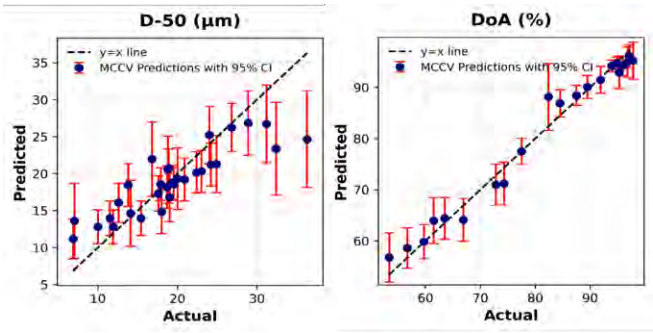

**Figure 4:** Nominal predictions with prediction uncertainties from the ML models of D-50 and DoA.

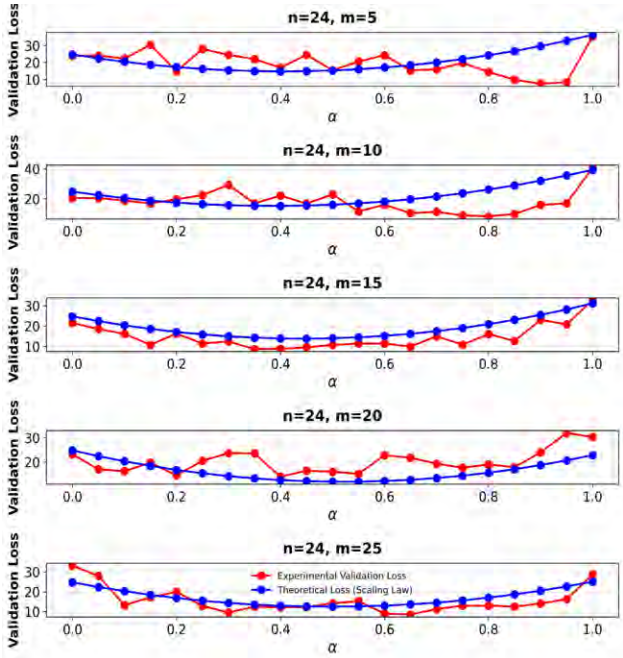

**Figure 5:** Weighted ERM approach to identify optimal α for synthetic data augmentation for D-50 model.

For DoA predictions, augmentation with synthetic data from generative models did not significantly improve outcomes, potentially due to the inferior quality of the synthetic data. While further model tuning could enhance this, it was deferred as the existing DoA model already demonstrated high predictive accuracy with the real dataset. Since the model predictions for both these CQAs were comparable with measurement errors (uncertainties), these were deployed using optimization frameworks to determine operational conditions that satisfy the crystallization design objectives (Step 9).

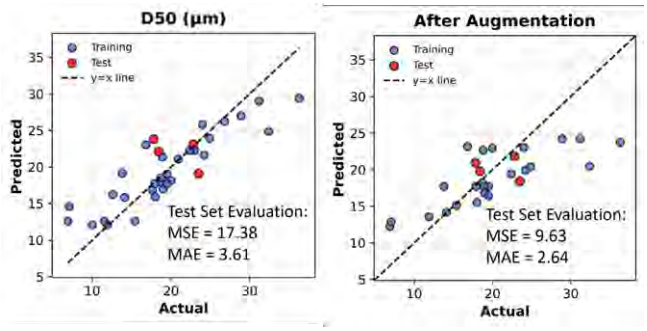

**Figure 6:** Parity plot for D-50 predictions before (left) and after (right) augmentation of Synthetic Data

The problem was formulated as a dual-objective optimization to maximize D-50 and minimize DoA. The decision variables ($\bar{x}$) represent the ML models' input features corresponding to various thermocyclic profiles. Inequality constraints (Equations 2, 3, and 4) ensured the feasibility of these profiles, with the decision variables' bounds detailed in . This problem was modeled using the Pymoo framework and solved using a derivative-free genetic algorithm. Figure 7 displays the Pareto fronts achieved with various thermocyclic profiles, confirming that increasing the number of temperature cycles from 1/2 to 3/4 enhances mean size and reduces DoA.

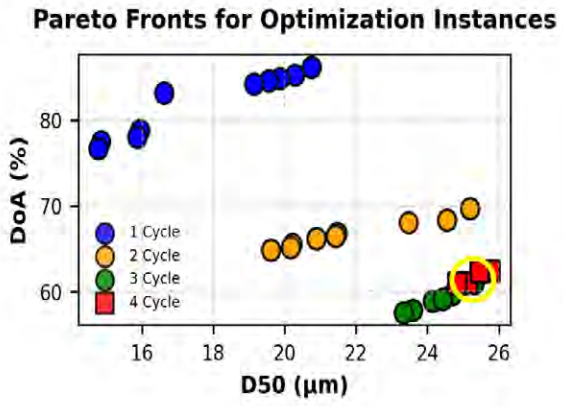

**Figure 7:** Pareto front obtained after solving the optimization problem.

Furthermore, mapping these optimized results with the crystallinity predictions (Figure 8) from the crystallinity model revealed increased crystallinity values with more thermocycles—an observation experimentally confirmed as reported in [7], where increased crystallinity

and reduced DoA were noted in samples from the end of each cycle in a 4-cycle temperature profile experiment.

**Table 2:** Lower (LB) and upper bounds (UB) of decision variables

| $\bar{x}$ | LB | UB |
|---|---|---|
| Initial Conc. (mg/g solvent) | 24.8 | 55.2 |
| Seed loading | 0.05 | 0.15 |
| $T_i$(oC) | 0 | 70 |
| $C_i$(oC/min) | 0.05 | 0.3 |
| $H_i$(°C/min) | 0.5 | 1.0 |

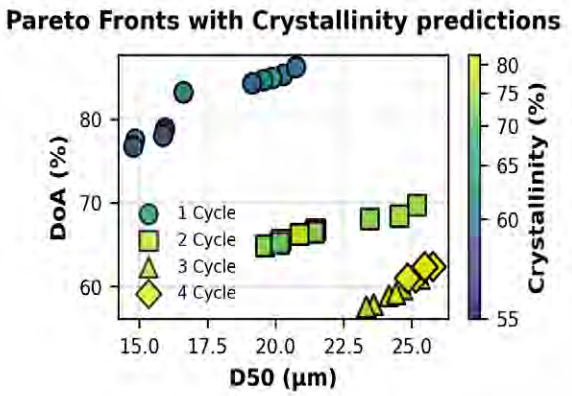

**Figure 8:** Crystallinity predictions from the Crystallinity ML model mapped onto Pareto front from Figure 7.

A 4-cycle optimal profile from the obtained Pareto front (circled in Figure 7) was experimentally validated, affirming the efficacy and impact of the data-driven digital design workflow in developing crystallization processes. Table 3 compares predictions across all CQAs at the validation point, showing consistency and reliability. Moreover, the optimized profile obtained using a data-driven framework not only matched the CQAs achieved with the mechanistic population-balance approach but also aimed to minimize batch time, thereby enhancing productivity [7].

**Table 3:** Comparison of experimental and model-predicted CQAs for the validation experiment.

| CQA | Experimental | Model-predicted |
|---|---|---|
| D-50 | 17.5±0.3 | 22.85±6.58 |
| DoA | 64.5±12.7 | 64.63±5.26 |
| Crystallinity | 79.4±6.7 | 77.22±4.16 |

## 4. CONCLUSION

This study introduces a systematic workflow for constructing 'fit-for-purpose', data-driven digital twins for crystallization process development, linking process operating conditions with CQAs obtained during product characterization. A key feature of this workflow is the integration of synthetic data derived from experimental data, which enhances the predictive capabilities of ML models, particularly in applications with limited data. The workflow's effectiveness was validated by its application to an industrial API exhibiting agglomeration and low product crystallinity. Using this workflow, reliable data-driven models were developed and integrated into an optimization framework, successfully identifying operating conditions that addressed complex industrial challenges. This demonstrates the potential of these tools in developing complex crystallization processes.

## ABSTRACT

As pharmaceutical manufacturing is transitioning from traditional batch to continuous manufacturing (CM), there is a lack of tools for CM design and development, which can integrate drug substance and drug product unit operations for overall evaluation. Recently, a Python-based PharmaPy framework was proposed to advance the design, simulation, and analysis of continuous pharmaceutical processes. However, the initial library of models only addressed upstream drug substance processing. In this work, new capabilities, including drug product unit operations such as feeder, blender, and tablet press, have been added to the PharmaPy framework, enabling end-to-end study and optimizing the effects of material properties and process conditions on solid oral dosage products. The platform supports computational efficiency and model accuracy by allowing the development of different mechanistic and semi-mechanistic models. Sensitivity analysis is performed on the integrated end-to-end simulator to identify critical input variables influencing product quality and control strategies. The analysis lowers the complexity of the model by ranking significant input variables. Finally, feasibility studies are conducted on extracted influential input variables to characterize the process design space and achieve desirable output. The enhanced PharmaPy package can now support decision-making from early research and development stages through manufacturing.

**Keywords**: PharmaPy, Process synthesis, Process analysis, Pharmaceutical manufacturing

## INTRODUCTION

The pharmaceutical regulatory agencies have recognized the need to transition from batch to continuous mode of operation due to its various advantages. Among the several benefits that drives continuous process includes scalability, increase in controllability, reduction in time to product release in the market, product quality consistency, and potential reduction in human involvement and capital costs. These advantages contribute to increased adaptability, agility, and robustness in the continuous manufacturing of pharmaceuticals. At the same time, it also provides a great opportunity for practitioners to develop continuous and efficient manufacturing processes for pharmaceutical production [1].

However, the strict regulatory mechanism of the pharmaceutical industry draws multiple challenges in this transition. In this work, we consider the integration of drug substance process, i.e., active pharmaceutical ingredient (API) manufacturing, with the drug product operations for solid oral-drug production, i.e., tablets. For the end-to-end continuous operation, the first challenge lies in the physics and chemistry-based constraints that may decide the best operation mode for the manufacture of a given API. The API manufacturing process also needs to have necessary control on the raw material properties. In addition, the optimal manufacturing route should be determined based on the process economics and the adoption of effective separation and purification steps to achieve desired API quality attributes. The second challenge is to understand the effects of material attributes on powder flowability and process dynamics between unit operations for drug product manufacturing. Finally, the process design, analysis, and optimization of the integrated process need to be performed through a systems approach which would study the effects of material properties, equipment, and process parameters on the product qualities [2]. Such an integrated system should

also be developed within the quality-by-design (QbD) or quality-by-control (QbC) framework for the construction of design space regions that ensures final product quality.

To address the aforementioned challenges, recently PharmaPy, an open source pythonic framework for flexible flowsheet modeling and simulation of discrete/continuous processes for pharmaceutical manufacturing, was developed [3]. The framework supports parameter estimation and process optimization and adopts a sequential-modular approach towards integrated simulation for drug substance. However, the goal of end-to-end continuous manufacturing using PharmaPy was unrealizable due to the absence of downstream drug product operations. In this work, new capabilities are added to the existing PharmaPy tool, and the drug product framework is presented to integrate and study the effects of raw materials, upstream processes on final product quality. The enhanced PharmaPy framework will act as a complimentary open-source platform to existing commercial flowsheet simulation tools such as Aspen Plus and gPROMS by providing flexible user control while ensuring adequate model fidelity and numerical accuracy.

## PHARMAPY FRAMEWORK

PharmaPy is a Python software application that makes use of the language's versatile scripting features and incorporates powerful computational libraries for flowsheet modelling [3]. Several in-built models in the open-source package are drawn as standard unit operations for the manufacture of drug substances and products. Furthermore, it offers the flexibility to design and accommodate customized user-generated unit operation models. These standard (and user-defined) models are used as building blocks to construct the integrated flowsheet models. PharmaPy can be used for simulation, design and optimisation of pharmaceutical manufacturing processes. It uses a sequential-modular equation solving approach and an object-oriented software architecture, which enable to perform efficient process simulation and flowsheet optimization. PharmaPy has been used successfully for drug substance manufacturing applications including its application in a simulation-optimization framework [4], and for techno-economic analysis of various flowsheet alternatives [5]. For the drug product manufacturing, which is the focus of this study, the extended PharmaPy framework adds the downstream processing units where the API is converted into final tablets.

The downstream PharmaPy implementation for flowsheet simulation and optimization starts with the input of API properties from the dryer unit operation which helps connect the upstream process with downstream operations (Figure 1). The dried API properties are estimated using the upstream PharmaPy framework [6] which also includes a filter and deliquorizer (DL) to reduce the liquid present in the pores of the filter cake. The final dried API information flows through the product operations which effects the final product quality. Other participating species such as excipients, lubricants/glidants and their material properties are also fed by the user to the downstream process. Next, the downstream unit operations and their connections are established using object-oriented programming. Following that, the flowsheet model can be executed to perform process simulation and process analysis.

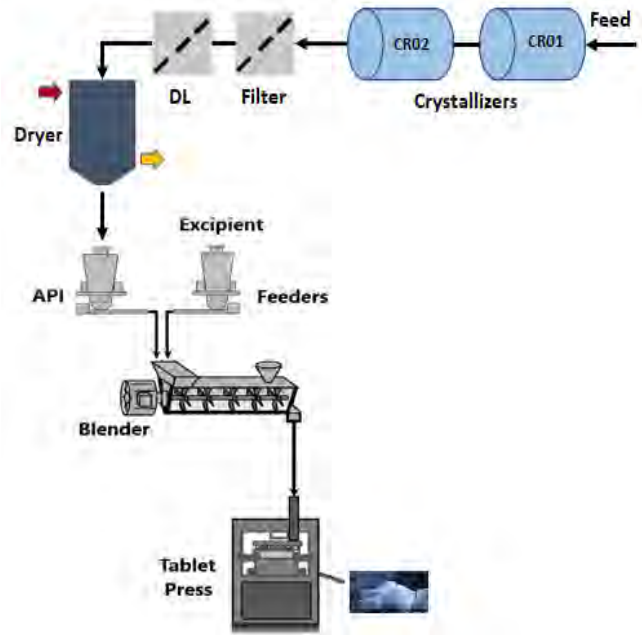

**Figure 1.** Integrated drug substance-drug product flowsheet used for simulation in PharmaPy (DL represents the deliquoring step in the filtration).

Ultimately, with the help of flowsheet optimization in the second theme which is still in development stages, the users can compare various manufacturing routes for tablet production in an automated framework. In the next section, the first theme of downstream PharmaPy is illustrated with the help of a direct compaction case study, which includes sensitivity analysis to investigate crucial input variables and feasibility studies to determine the process design space that ensures consistent product quality.

## RESULTS & DISCUSSIONS

### Case Study: Direct Compaction process

Direct Compaction (DC) process is a straightforward and popular tablet production method that directly uses the blended constituent materials and compresses them into tablets. It also requires fewer unit operations, which implies less equipment space and cost, less processing

times, lower manufacturing costs and improved productivity. In the DC process under consideration, the API from the drug substance operations and an excipient, which aids in the drug processing, are fed to loss-in-weigh feeders which deliver the materials at a desired flow rate. The API and excipient are then fed to a continuous blender to achieve a homogenous blend of the constituent ingredients. Finally, the well-mixed ingredients flow through a hopper to a rotary tablet press (TP), which fills the dies with blended powder where the tablet press compresses the mixture into tablets.

The PharmaPy package includes dynamic simulation of a variety of built-in models along with the flexibility to customize and construct their own functions. The flowsheet model includes semi-mechanistic, empirical, hybrid and data-driven models to estimate intermediate and final product quality. The unit operation models that are built and implemented for DC process are explained next.

## Feeders

Gravimetric feeders known as "loss-in-weight" feeders use direct weight measurements of the material in the hopper to reach and maintain a pre-set flow rate. The feeder also consists of an impeller to assist material flow and a rotating screw which transports the material out of the feeder. Under the gravimetric mode, the flow rate is automatically controlled by adjusting the screw speed with the help of a PID controller according to the loss in weight of the materials in the feeder over time. A semi-empirical feed factor model is deployed in PharmaPy to model the feeder that accurately predicts the relation between the mass flow rate and screw speed of the feeder [7]. The following equations represent the functioning of the feeder module.

$$F_{out}(t) = ff(t)\omega_{screw}(t) \quad (1)$$

$$ff(t) = \rho_{eff}(t)V_{sp} \quad (2)$$

$$\rho_{eff}(t) = \rho_{sat} + (\rho_{in} - \rho_{sat})e^{-\frac{\sigma(t)}{\beta}} \quad (3)$$

$$\omega_{imp}(t) = \alpha\omega_{screw}(t) \quad (4)$$

$$\sigma(t) = \frac{W(t)g}{A_f} + \cos(2\pi\omega_{imp}t)\frac{M_b R_b \omega_{imp}^2}{A_{sp}} \quad (5)$$

where $F_{out}$ is the outlet mass flow rate of API, excipient, etc. and $ff$ is the feed factor, $\omega_{imp}$ and $\omega_{screw}$ are the impeller and screw speed, respectively, $V_{sp}$ is the volume of the screw pitch, $\rho_{eff}$ is the effective density of the material, $\sigma$ is the vertical stress, $\beta$ is the density constant, $A_f$ is the feeder area, $A_{sp}$ is the screw port area where screws enter the bowl, $M_b$ and $R_b$ are the mass and radius of the impeller blade, $g$ is the gravitational constant, and $W$ is the weight of powder in the feeder.

## Blender

The continuous blender is used to reduce the variations which stems from the feeding system and plays a crucial role in maintaining strict quality constraints of the concentration uniformity in the blend and final product. The PharmaPy package uses a two-dimensional multi-compartmental model to describe the blender operation [8]. The model includes axial and radial directions of the compartments which is assumed to be equally sized and well mixed. The blend mass hold-up, flow rate from the blender, API composition and relative standard deviation of the blend samples are estimated using the compartmental model.

$$\frac{dm_{i,j}}{dt} = F_f(m_{i-1,j} - m_{i,j}) + F_b(m_{i+1,j} - m_{i,j}) + F_r(m_{i,j-1} - 2m_{i,j} + m_{i,j+1}) \quad (6)$$

$$F_f = a\omega_{blend} + b \quad (7)$$

$$F_b = c\omega_{blend} + d \quad (8)$$

$$F_r = e\omega_{blend} \quad (9)$$

$$F_{out,b} = \sum_{j=1}^{N_r} F_{f,API}\, m_{N_a,j}^{API} + \sum_{j=1}^{N_r} F_{f,EXCP}\, m_{N_a,j}^{EXCP} \quad (10)$$

$$C_{API} = \frac{\sum_{j=1}^{N_r} F_{f,API} m_{N_a,j}^{API}}{F_{out,b}} \quad (11)$$

where $F_{out,b}$ is the exit blend flow rate, $m_{i,j}$ is the mass hold-up in the ith axial and jth radial compartment, $N_a$ and $N_r$ are the number of compartments in the axial and radial directions. $F_f$, $F_b$ and $F_r$ are the forward, backward, and radial fluxes respectively, with a, b, c, d and e being the flux parameters, $\omega_{blend}$ is the blender speed, and $C_{API}$ is the API composition in the exit blend.

## Tablet Press

The incoming blend from the previous unit operation is transported through a hopper and feed frame to a series of dies where the blends are compressed into tablets. The die shape and tablet press process conditions determine the geometry and final quality of tablets. PharmaPy also includes a hopper and feed frame model to predict the hopper level ($h_{hopper}$) and feed frame flow ($F_{fframe}$) into the dies. The tablet press functions in two stages, namely pre-compression, to remove entrapped air and reduce material porosity, and main compression, to convert the pre-compressed blend into tablets. Empirical models have been deployed to correlate the material attributes such as bulk density ($\rho_b$), and process parameters like turret speed ($N_T$), main compression thickness ($M_{thick}$), dosing position ($H_{fill}$), etc., with tablet properties which includes weight ($W$), main compaction force ($F_{main}$), density ($\rho_{tab}$), and strength ($\sigma_T$). The tablet press model equations used in PharmaPy framework are summarized below.

$$\frac{dh_{hopper}}{dt} = \frac{F_{out,b} - F_{fframe}}{\rho_b A_{hopper}} \quad (12)$$

$$V_{fill} = \frac{\pi D^2 H_{fill}}{4} + \frac{\pi h(\frac{3D^2}{4} + h^2)}{6} \quad (13)$$

$$F_{fframe} = n_T N_{stat} \rho_b V_{fill} \quad (14)$$

$$W = \rho_b V_{fill} \left( -\varphi_1 \frac{N_F}{N_T} + \varphi_2 \frac{H_{fill}}{D} + \varphi_3 \left( \frac{H_{fill}}{D} \right)^2 \right) \quad (15)$$

$$F_{main} = \frac{\pi D^2 (\rho_{in-die} - \rho_c)}{4b(\rho_{in-die}(a-1) + \rho_c)} \quad (16)$$

$$V_{in-die} = \frac{\pi D^2 M_{thick}}{4} + \frac{\pi h(\frac{3D^2}{4} + h^2)}{3} \quad (17)$$

$$\rho_{in-die} = \frac{W}{\rho_t V_{in-die}} \quad (18)$$

$$\rho_{tab} = \rho_{in-die} (1 - \varepsilon_p) \quad (19)$$

$$\sigma_T = \sigma_0 \left[ 1 - e^{(\rho_{tab} - \rho_{c,\sigma})} \left( \frac{1 - \rho_{tab}}{1 - \rho_{c,\sigma}} \right) \right] \quad (20)$$

where $D$, $h$, $A_{hopper}$, $N_F$, $\varepsilon_p$ are the die diameter, cup depth, hopper cross section area, feed frame speed, and elastic recovery of the tablet, respectively. $\rho_{c,\sigma}$ and $\sigma_0$ are the tablet tensile strength model parameters.

Content uniformity of the tablets ($C_V$) is also estimated to study the effects of upstream material attributes i.e., mass fraction ($x_i$) and particle size ($d_i$) of API, and downstream material conditions ($C_{API}$) on tablet quality based on a target dosage ($T_D$) [9].

$$C_V = 100(1 - C_{API}) \left( \frac{\pi \rho}{6 T_D} \right)^{1/2} \left( \sum_{i=1}^{N} x_i d_i^3 \right)^{1/2} \quad (21)$$

The downstream process synthesis for tablet manufacture comprises a dynamic flowsheet model, which includes integrated unit operations as described above for the direct compaction process. This flowsheet model is developed within the PharmaPy framework and combines individual processes by utilizing the output of previous unit operation as the input of the subsequent one. The object-oriented programming structure in Python allows the flexible use of these unit operations and also build customized functions for the flowsheet model. The model parameter values of the individual processes are taken from existing studies towards the manufacture of 10% acetaminophen tablets [6,10-12].

## Sensitivity and Feasibility Analysis

Once the flowsheet model is developed, the next step is to perform process analysis. This includes the identification of crucial input variables, i.e., material attributes and process parameters. Then, the influential input factors are examined to estimate feasible design space regions which can then be used to develop control strategies. Statisticians and practitioners have developed various sensitivity analysis methods which studies how uncertainty in model input can be assigned to variations in model output. Among the main techniques, global sensitivity analysis stands out as it allows the determination of effects of uncertain input variables across the whole input space.

**Table 1:** Input variables for sensitivity analysis with lower (LB) and upper bound (UB).

| Input | LB | UB |
|---|---|---|
| **Crystallizer (CR01)** | | |
| Residence time (s) | 2470 | 2730 |
| Coolant jacket temp. (K) | 298 | 328 |
| **API feeder** | | |
| API flow (kg/hr) | 0.95 | 1.05 |
| **Excipient Feeder** | | |
| Excp. Flow (kg/hr) | 8.55 | 9.45 |
| **Continuous blender** | | |
| Blender speed (RPM) | 237.5 | 262.5 |
| **Tablet press** | | |
| TP fill depth (mm) | 7.6 | 8.4 |
| TP thickness (mm) | 2.85 | 3.15 |
| TP turret speed (RPM) | 19 | 21 |

PharmaPy performs global sensitivity analysis on a given set of input and output variables by utilizing in-built python libraries for qualitative and quantitative sensitivity analysis. In this study, we use variance-based Sobol's method to study quantitatively, how the variance of flowsheet output can be apportioned into terms based on input variables and their interactions. Sobol's method uses two metrics to provide sensitivity information, $S_i$ for first-order effect, and $S_{Ti}$ for total-effect defined as follows:

$$S_i = \frac{\mathbb{V}(\mathbb{E}(Y|X_i))}{\mathbb{V}(Y)} \quad (22)$$

$$S_{Ti} = 1 - \frac{\mathbb{V}(\mathbb{E}(Y|X_{-i}))}{\mathbb{V}(Y)} \quad (23)$$

where $\mathbb{V}$ is the variance, $\mathbb{E}(Y|X_i)$ refers to the expected value of output $Y$ when parameter $X_i$ is fixed, and $X_{-i}$ denotes all uncertain parameters except $X_i$. The sum of $S_i$ cannot exceed one and the sum of $S_{Ti}$ is greater than or equal to one. However, if there are no higher order interactions between the input parameters, the sum of $S_i$ and $S_{Ti}$ is one.

**Table 2:** Output variables for sensitivity analysis, and constraints (LB, UB) on the output for feasibility studies.

| Unit operation | Output | (LB, UB) |
|---|---|---|
| Blender | API comp. ($C_{API}$, %) | (9.5,10.5) |
| Tablet press | Weight ($W$, mg) | (167,183) |
| | Compaction force ($F_{main}$, kN) | (2, 50) |
| | Strength ($\sigma_T$, MPa) | (2,15) |
| | Content uniformity ($C_V$, %) | (0,6) |

Table 1 lists the input variables with their corresponding ranges for the feeders, blender and the tablet

press. Along with the downstream variables, the first crystallizer's residence time ($\tau_{CR01}$) and its cooling jacket temperature ($T_{CR01}$) are also considered. These factors affect the crystal size distribution and are investigated to quantify their impact on tablet content uniformity. Other upstream decision variables are fixed at their nominal values and can be found in the work of Inyoung et al. [6]. Table 2 elucidates the considered output variables in this study.

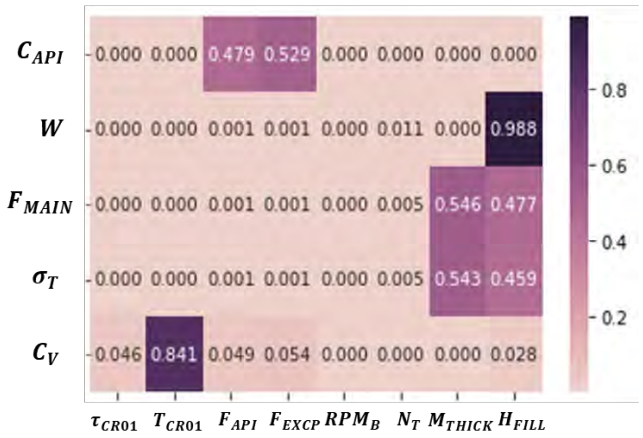

**Figure 2.** Sensitivity analysis results showing Sobol's total sensitivity index effect ($S_{Ti}$) on the drug substance-product process.

The sensitivity results based on Sobol's total effect index in shown in Figure 2. It is found that the first order effect ($S_i$) is similar to the total effect ($S_{Ti}$) which means that the interaction effect between each input variable is weak and hence the total effects are reported. The Sobol's method concluded that six out of eight input variables are most critical. Blender speed does not affect any of the output variables and turret speed affects the tablet properties only very slightly and therefore has not been retained for feasibility studies. On the other hand, crystallizer's residence time and its operating temperature, API and excipient flow rates, tablet press' main compression thickness and dosing position impact one or more output variables significantly.

After sensitivity analysis, feasibility studies can be performed on the subset of input variables to characterize the process design space. To estimate the design space, the output variables are determined based on the uncertain input variables. Based on whether the maximum and minimum value of output variables obey the constraints or not, the process feasibility is drawn. For the integrated flowsheet, feasibility analysis is conducted on the six most influential input factors and the constraints on the output variables are shown in Table 2. The feasibility studies result in a 6D problem with 10 constraints for the flowsheet model. For this high-dimensional problem, matrix plots are deployed to describe the feasibility as explained in Forrester et al., (2008). The matrix includes 15 plots, each of which represents feasibility of two input variables while the remaining four inputs are fixed at their nominal values. It should be noted that the matrix is symmetric, therefore 15 plots instead of 25 are shown accounting for all possible input combinations for feasibility studies. For each plot, 25 sample grid points are obtained through discretization of inputs, and output variables are estimated at the discretized inputs. The feasible region where all the constraints are jointly satisfied is represented by the olive contours.

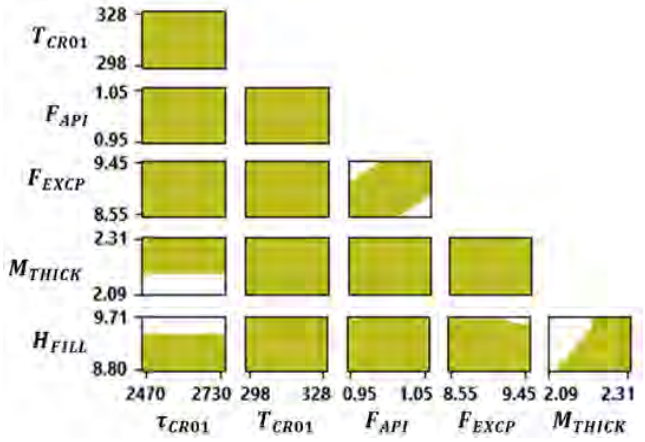

**Figure 3.** Feasibility analysis results of the DC process using PharmaPy.

The results of the feasibility analysis for the flowsheet model are shown in Figure 3. From the feasibility plots, we can observe that the operating temperature ($T_{CR01}$) and residence time of the crystallizer ($\tau_{CR01}$) are feasible over their entire range, which directly impacts the crystal size distribution in the upstream process. This implies that the process can sustain all the variations from these sources while ensuring robustness. The API flow rate ($F_{API}$) and excipient flow rate ($F_{EXCP}$) are also linearly feasible across their input space. The main compression thickness ($M_{thick}$) and dosing position ($H_{fill}$) significantly affect the tablet properties and are found to be feasible for higher and lower values, respectively. But much lower values of thickness and dosing position can result in large deviations from the desired tablet properties like weight, compaction force, and strength. Therefore, the variations in thickness and dosing position need to be strictly controlled to avoid adverse effects on tablet quality.

With the help of in-built python libraries and deployment of matrix plots, PharmaPy can execute sensitivity and feasibility analysis on a given set of input and output variables. This allows to clearly screen the important input variables and quantify the extent of tolerance to process variations which can help build robust control strategies ensuring product quality.

## CONCLUSION

This contribution demonstrates the features of the enhanced PharmaPy package to study the effects of upstream and downstream pharmaceutical processes on final tablet quality. Since the downstream processing can operate in a truly continuous mode, a direct compaction case study is used to investigate the effects of process parameters on tablet quality attributes with the help of process analysis. The process analysis helped identify crucial input variables and determined a process design space that ensures consistent product quality.

However, the downstream PharmaPy package can undergo further enhancements to fully realize the open-source prowess of PharmaPy framework. This includes flowsheet optimization and alternate routes to manufacture tablets such as dry granulation and wet granulation where key differences and challenges can be analyzed. In addition, the downstream architecture needs to be equipped with models that help quantify the effects of variations in API attributes, e.g., particle size distributions and moisture content, on the blend and tablet properties. This will help understand the changes a given blend undergoes during the drug production process. Efficient models will be built to capture such effects as part of the overall PharmaPy downstream development.

## ABSTRACT

Mathematical modeling is essential for the effective control of many chemical engineering processes, including crystallization. However, most existing crystallization models used in industry and academia assume ideal mixing. As a result, the unclear effects of imperfect mixing on crystallization, reported in experimental studies, remain largely unexplained. In this work we aim to address this gap in understanding by examining antisolvent crystallization processes on a general theoretical level, using a novel dimensionless model. To address the impact of mixing on crystallization, we employ the Engulfment model coupled with a population balance, and we nondimensionalize the model equations. Using this model, we explore the dependence of the mean particle size on the homogenization rate, represented by the Damköhler number for crystallization. Moreover, we study the impact of mixing at various values of the model's kinetic parameters to simulate difference in properties of individual products. We show that we are able to explain the complex interaction between crystallization and mixing, proving our model can serve as a tool for achieving a better understanding of the processes involved. Finally, due to its efficiency and reduced number of parameters, the model is suitable for direct fitting to experimental data.

**Keywords**: crystallization, modeling, mixing, continuous, non-dimensional

## INTRODUCTION

Crystallization is a fundamental technique used for separating and/or purifying solids in various industries, including pharmaceuticals and food production. The process conditions during crystallization significantly affect the particle size and purity of the final product. Both particle size and shape influence various material properties, such as flowability, filterability, and dissolution behavior. Effective control of the crystallization process can enhance product quality and eliminate the need for additional steps like comminution or granulation.

Unlike cooling or evaporative crystallization, reactive and antisolvent crystallization involve mixing two liquids of distinct compositions. Supersaturation is induced through mixing, either due to the product being synthesized (reactive) or the reduction of solubility (antisolvent). However, most models currently used in both industry and academia assume ideal mixing and fail to account for the system's dependence on mixing dynamics, thereby limiting our understanding of the process.

Numerous experimental studies have addressed the impact of mixing on crystallization. The effect of increasing mixing intensity on particle size is inconsistent, varying across different substances and products [1]. The mean crystal size may increase, decrease, or even reach a maximum or minimum as the mixing intensity varies. Even using the same crystallizer type for the same product may lead to qualitatively different outcomes. Additionally, the rate of homogenization has also been shown to affect the width of the particle size distribution (PSD), particle shape, and/or the extent of agglomeration.

Although these dependencies are well documented, a systematic approach to studying them has not been established. Research, both on the modeling and experimental sides, tends to focus on a single system at a time. In contrast to the current trend of developing complex models, we aim to use a relatively simple modeling framework, keeping the number of parameters low and enabling extensive parametric studies necessary for our theoretical research.

The authors have already sufficiently explained the

mechanism behind the existence of a maximum in the dependency of particle size on mixing intensity for the semi-batch case [2]. We now aim to extend our research using a novel dimensionless model for continuous crystallization. As in other areas of chemical engineering, nondimensionalization offers valuable insights by reducing the number of parameters and revealing characteristic system properties. It also provides suitable scaling of variables, improving both the precision and efficiency of numerical computations.

# MODELING

## Current Modeling Approaches

The population balance equation (PBE) is the standard approach for crystallization modeling. Depending on the level of detail in describing the hydrodynamics involved, three main modeling approaches are commonly considered:

- The ideal mixing assumption is still widely used as it allows for neglecting mixing in the model equations, thus simplifying calculations. This approach assumes an infinitely fast homogenization rate and is therefore applicable to systems that do not exhibit a dependence on the agitation rate.
- Models based on compartmentalization represent a balanced approach to account for the complexity of mixing. These models divide the studied volume into several compartments and describe the material flux between them. Within each compartment, mixing is typically assumed to be infinitely fast. One of the most popular models in this category is the mechanistic micromixing model developed by Baldyga and Bourne, also known as the Engulfment model [3].
- CFD-based approaches, where the PBE is integrated within the CFD framework, are perhaps the most rigorous. However, even CFD cannot fully capture mixing processes at the molecular level (i.e., micromixing). Since crystallization is a molecular process, these methods often require additional micromixing models. Alternatively, they assume that the homogenization process is limited only by macroscale mixing (i.e., fast micromixing). Despite the complexity and high computational cost, the improvement in accuracy over the Engulfment model appears to be limited.

## Model Description

### Coupling PBE With the Engulfment Model

We have based our approach on the Engulfment model, as we believe it provides the most suitable choice for our theoretical study. In this Lagrangian model, the system volume is discretized into two well-mixed regions: (1) the mixed zone, enriched with the reference compound, and (2) the surrounding bulk fluid. Mixing is described as the expansion of the mixed zone through the engulfment of the bulk, leading to dilution of the compound in the mixed zone if no additional source is present. This approach was initially developed in reactor engineering but has since been applied to crystallization (e.g., [4]). Although the model was originally developed based on turbulent flow mixing mechanisms, we find its framework applicable even to non-turbulent flows.

According to the Engulfment model [3], the concentration of a compound in the mixed zone evolves over time according to Eq. 1 as volume fraction of the mixed zone ($X$) expands. The rate of homogenization is determined by a single constant, the mixing time $t_{mix}$ (Eq. 2).

$$\frac{dc}{dt} = \frac{1}{X}\frac{dX}{dt}(c_b - c) + r \tag{1}$$

$$\frac{dX}{dt} = \frac{1}{t_{mix}}X \tag{2}$$

Coupling the engulfment model with PBE results in Eq. 3, accounting only for primary nucleation and growth (neglecting agglomeration and breakage). The molar balance is then described in Eq. 4. These equations are valid for both reactive and antisolvent crystallization in batch or in continuous tubular crystallizers operating at steady state, for which time corresponds to the coordinate time.

$$\frac{\partial f}{\partial t} + G\frac{\partial f}{\partial L} = \frac{1}{t_{mix}}(f_b - f), \quad f(0,t) = \frac{J}{G} \tag{3}$$

$$\frac{dc}{dt} = \frac{1}{t_{mix}}(c_b - c) - \frac{3k_v\rho_{cr}}{M}G\phi_2 + r \tag{4}$$

### Model Nondimensionalization

To study the effect of mixing on crystallization at a theoretical level, we have developed an efficient method for nondimensionalizing Equations 3 and 4. We begin by introducing the following dimensionless variables:

$$\tau = \frac{t}{t_0},\ \lambda = \frac{L}{L_0},\ \chi = \frac{c^*}{c_0},\ S = \frac{c}{c_0\chi},\ n = L_0V_0f \tag{5}$$

$$\tilde{G} = \frac{G}{G_{ref}},\ \tilde{J} = \frac{J}{J_{ref}},\ \tilde{r} = \frac{t_0}{c_0}r,\ c_0 = c_{ref} \tag{6}$$

Defining:

$$V_0 = \frac{k_v\rho_{cr}L_0^3}{M_{cr}c_{\mathrm{ref}}}, L_0 = t_0G_{ref}, t_0 = \left(\frac{c_0M_{cr}}{k_v\rho_{cr}J_{ref}G_{ref}^3}\right)^{\frac{1}{4}} \tag{7}$$

leads to significant reduction in the number of model parameters. The reference values $J_{ref}, G_{ref}, c_{ref}$ can be set arbitrarily, although they do affect scaling. The appropriate value for $c_{ref}$ is the maximal solubility while the suggested choice of $J_{ref}$ and $G_{ref}$ is discussed later.

Assuming isothermal conditions and solubility as a sole function of the solvent volume fraction $\varphi$, the final

form of our non-dimensional model is described by the following equations:

$$\frac{dS}{d\tau} = Da_{cr} S\left(\frac{S_b \chi_b}{S\chi} + \frac{(\varphi-\varphi_b)}{\chi}\frac{d\chi}{d\varphi} - 1\right) + \frac{1}{\chi}\left(\tilde{r} - 3\tilde{G}\,\Phi_2\right) \quad (8)$$

$$\frac{\partial n}{\partial \tau} + \tilde{G}\frac{\partial n}{\partial \lambda} = Da_{cr}(n_b - n), \quad n(0,\tau) = \frac{\tilde{J}}{\tilde{G}} \quad (9)$$

Derivation of the non-dimensional model leads to the emergence of a dimensionless number, $Da_{cr}$, defined as the ratio of homogenization rate to crystallization rate (Damköhler number for crystallization):

$$Da_{cr} = \frac{t_0}{t_{mix}} = \frac{v_{mix}}{v_{cr}} \quad (10)$$

We further assume expressions for growth and crystallization rates according to Eq. 11. By setting the reference values equal to the rate coefficients, we conveniently reduce the number of kinetic constants from four to two, as shown in Eq. 12.

$$G = k_G(S-1)^g, \quad J = k_J \exp\left(-\frac{j}{\ln^2 S}\right) \quad (11)$$

$$\tilde{G} = (S-1)^g, \quad \tilde{J} = \exp\left(-\frac{j}{\ln^2 S}\right) \quad (12)$$

The constants $j$ and $g$ together with the solubility data remain the only product properties needed as input to the model.

### Application to Continuous Antisolvent Process

In this study, we focus on isothermal antisolvent crystallization in a tubular device developed in our research group. The process is schematically illustrated in **Figure 1**. A solution of candesartan cilexetil, an active pharmaceutical ingredient (API), in acetone is injected perpendicularly to the length direction of the tube into a stream of water. Mixing of the two streams generates supersaturation, which leads to nucleation and subsequent growth of the product particles.

The initial conditions of the mixed zone are given by the properties of the organic phase ($S(0) = 1, \varphi(0) = 0.85$) while bulk is represented by pure water. The volume flow rate ratio of organic to inorganic phase is 1:9 (corresponds to $X(0) = 0.1$). Setting the bulk variables $S_b$, $\varphi_b$ and $n_b$ to zero and omitting the reaction term results in a simplified set of equations:

$$\frac{dS}{d\tau} = Da_{cr} S\left(\frac{\varphi}{\chi}\frac{d\chi}{d\varphi} - 1\right) - \frac{3\tilde{G}\,\Phi_2}{\chi} \quad (13)$$

$$\frac{\partial n}{\partial \tau} + \tilde{G}\frac{\partial n}{\partial \lambda} = -Da_{cr} n, \quad n(0,\tau) = \frac{\tilde{J}}{\tilde{G}} \quad (14)$$

The solubility data of candesartan cilexetil used for our study were taken from literature [5]. The model of the continuous device is implemented in the Python environment. Eq. 13 is converted into a set of ordinary differential equations (ODEs) using 1D finite volume method with Koren flux limiter. The set of ODEs is then integrated numerically using the Runge–Kutta method (RK45). All simulation results are steady with respect to the coordinate time, assuming an infinitely long tube.

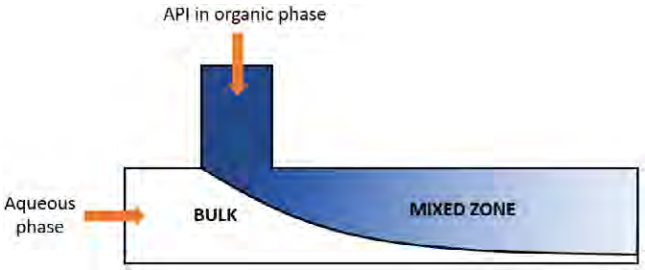

**Figure 1.** Schematic representation of the setup and spatial discretization of the continuous ASP device according to the Engulfment model (the shade of blue color represents local concentration of API).

## RESULTS

### The Mixing Impact on the Mean Particle Size

As mentioned, our model takes three product-specific inputs: parameters $j$ and $g$ and the solubility function $\chi(\varphi)$. In our study, we vary the kinetic parameters in order to address the influence of the product properties on the results of our simulations. The effects of changing the solubility curve are not presented in this study.

As $t_0$ is a constant for a given substance, increasing $Da_{cr}$ has the meaning of increasing the rate of homogenization. We proceed with a sensitivity analysis of the effect of kinetic constants $j$ and $g$ on the mean particle size ($\lambda_{43}$) and its dependence on $Da_{cr}$.

### The Influence of $g$ on $\lambda_{43}(Da_{cr})$

The results of varying $g$ along with $Da_{cr}$ at constant value of $j$ are depicted in **Figure 2**. As shown, all the reported scenarios for the dependency of the mean particle size on mixing intensity are covered by our model. In agreement with the experimental studies, the particle size according to our model may decrease, increase, reach a maximum or minimum or remain constant with change in the mixing intensity.

All the parametric curves are shaped similarly. At very low $Da_{cr}$, the particle size decreases while increasing the mixing rate. This happens as the result of monotonous increase in maximal supersaturation with $Da_{cr}$ demonstrated on **Figure 3**. At higher supersaturation, more nuclei are formed due to enhanced nucleation rate, resulting in decrease in particle size. The crystal size reaches minimum at $Da_{cr} \doteq 10^{-1}$. Interestingly, the parametric curves switch their order shortly before reaching the minimum. This happens as the maximal supersaturation reaches the value of two (the power function argument of the growth rate reaches one).

For more intense mixing, $\lambda_{43}$ grows with $Da_{cr}$. This most likely happens because the increase in nucleation rate diminishes at high supersaturation while the growth rate keeps accelerating due to the nature of the

respective equations ($\tilde{J}$ is limited unlike $\tilde{G}$). However, the increase of $\lambda_{43}$ is discontinued quite abruptly at values of $Da_{cr}$ unique for every curve. The value of the local maximum and its location increases with higher growth rate exponent.

To understand the sudden decrease, let us describe the kinetics of crystallization according to our model in the phase space of the non-dimensional concentration ($S\chi$) and the solvent volume fraction (**Figure 4**). The initial state marks the composition of the organic phase. The yellow line represents the conditions close to perfect mixing, where the mixing and crystallization events are separate. The transition from the initial state to the mixed state along the straight line is caused by dilution of the island by engulfment of the bulk. Any deviation from the yellow line represents induced crystallization while mixing. The maximal possible supersaturation is reached at the yellow line at $\varphi_{Smax} \doteq 0.42$. For $\varphi > \varphi_{Smax}$ the supersaturation always grows due to mixing while for $\varphi < \varphi_{Smax}$ mixing causes decrease in $S$. If the mixing rate is too fast relative to the crystallization rate, crystallization is not induced before reaching $\varphi_{Smax}$, causing the crystallization to begin at significantly lower supersaturation, reducing the final size of the crystals at high values of $Da_{cr}$. This behavior is encoded in Eq. 13 as the term $\frac{\varphi}{\chi}\frac{d\chi}{d\varphi} - 1$ is positive at $\varphi > \varphi_{Smax}$ and negative at $\varphi < \varphi_{Smax}$. The value of $\varphi_{Smax}$ is therefore determined only by the shape of the solubility function.

## The Influence of $j$ on $\lambda_{43}(Da_{cr})$

Let us now consider the scenario of varying $j$ along with $Da_{cr}$ at constant $g$. Overall, increasing $j$ hinters the nucleation rate and thus promotes growth, causing a general increase in particle sizes. Increasing $j$ also leads to later onset of nucleation induced at higher supersaturation, further favoring growth over nucleation. The results of the simulations are shown in **Figure 5**.

For low values of $j$, the shape of the curves remains unaltered compared to the results in **Figure 2**. However, at values roughly from 10 to 80, the system undergoes a qualitative change. In this process, the local maximum vanishes and the decrease in $\lambda_{43}$ associated with approaching perfect mixing is turned into an increase.

Previously, for $j = 1$, the reason for the decrease in particle size was sudden drop in supersaturation due to fast mixing, resulting in less pronounced growth. However, nucleation at $j = 100$ is about hundred times slower. At these conditions, lower supersaturation produces significantly smaller number of particles, resulting in seemingly paradoxical increase in particle size.

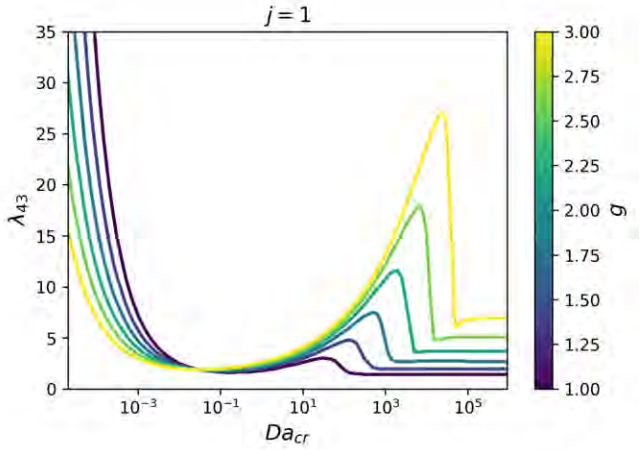

**Figure 2.** Dependence of the mean non-dimensional particle size on the Damköhler number for crystallization with varying the growth rate exponent.

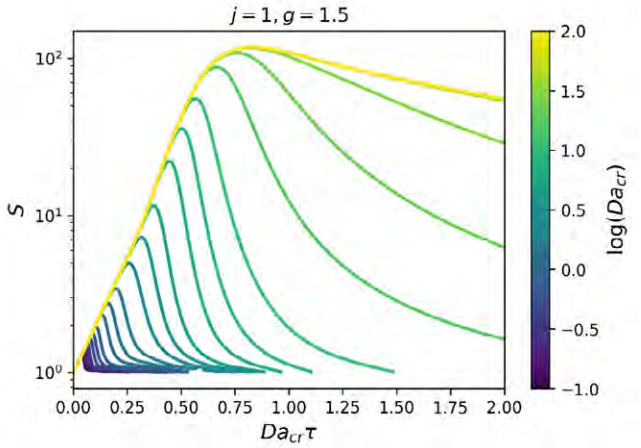

**Figure 3.** Evolution of the supersaturation over time (maximal supersaturation increases with $Da_{cr}$). The x-axis is scaled by $Da_{cr}$ for better comparison.

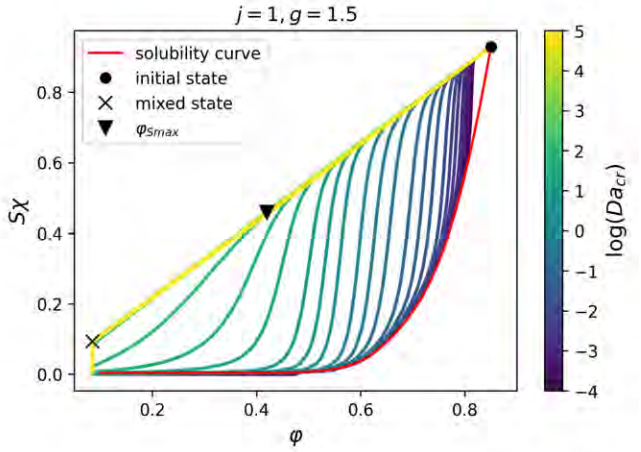

**Figure 4.** Representation of the evolution of mixing and crystallization in the phase space of the non-dimensional concentration and the solvent volume fraction.

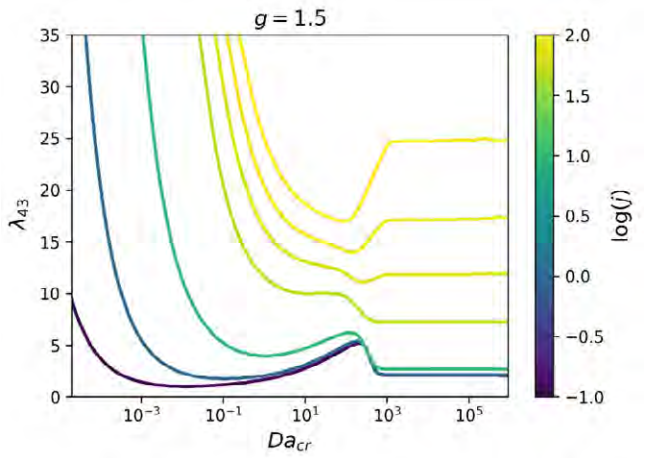

**Figure 5.** Dependence of the mean non-dimensional particle size on the Damköhler number for crystallization with varying nucleation constant.

## Parametric Fitting

As the developed non-dimensional model has only two kinetic parameters in contrast to four in the dimensional one, it is easier to fit the model to experimental data. Moreover, using the non-dimensional model requires no knowledge about the product properties other than its solubility behavior. To make use of these advantages, we further present how to use the model for parametric fitting.

Let $\boldsymbol{L}$ denote the vector of $N$ measured crystal sizes at different volume flow rates $\dot{\boldsymbol{V}}$ (the mixing rate in our system is assumed to be dependent only on $\dot{V}$). As evident from Eq. 15, dividing $\boldsymbol{L}$ by one of its elements gives the same results for both dimensional and non-dimensional data:

$$\frac{\boldsymbol{L}}{L[0]} = \frac{L_0\boldsymbol{\lambda}}{L_0\lambda[0]} = \frac{\boldsymbol{\lambda}}{\lambda[0]} \tag{15}$$

We use this identity to define the objective function as follows:

$$F = \sum_{i=0}^{N}\left(\frac{L[i]}{L[0]} - \frac{\lambda[i]}{\lambda[0]}\right)^2 \tag{16}$$

The remaining problem to be solved is finding the link between the flow rates and the corresponding Damköhler numbers. Based on the research done on similar micromixers [6], we expect the mixing time to be inversely proportional to the volume flow rate to the power of 1.5. Thus:

$$Da_{cr} = \frac{t_0}{t_{mix}(\dot{V})} = \frac{t_0}{K}\dot{V}^{1.5} = c\dot{V}^{1.5} \tag{17}$$

where the coefficient $c$ is unknown.

After applying the same strategy as for the crystal sizes, we get:

$$\frac{\boldsymbol{Da_{cr}}}{Da_{cr}[0]} = \frac{c\dot{\boldsymbol{V}}^{1.5}}{cV[0]^{1.5}} = \frac{\dot{\boldsymbol{V}}^{1.5}}{V[0]^{1.5}} \tag{18}$$

The points at which $\boldsymbol{\lambda}$ are to be evaluated from simulations are therefore:

$$\boldsymbol{Da_{cr}} = Da_{cr}[0]\frac{\dot{\boldsymbol{V}}^{1.5}}{V[0]^{1.5}} \tag{19}$$

where $Da_{cr}[0]$ is unknown and therefore it is another parameter to be optimized. Overall, finding the kinetic parameters presents an optimization problem:

$$\underset{g,j,Da_{cr}[0]}{\text{minimize}}\ F \tag{20}$$

We have used experimental data measured by our group to test the use of this method and validate our model. The best fit of the model to the experimental data is presented in **Figure 6**. In the experiments, we have used two distinct mixing units, the T-junction and the FDmiX mixer. The latter device increases the homogenization rate by passively introducing flow oscillations at otherwise laminar conditions. We have used a combination of direct grid search and the genetic algorithm to solve the optimization problem.

The model qualitatively describes the measured trends quite well. The value of $Da_{cr}[0]$ for the FDmiX was found at higher values than for the T-junction as expected. As mixing is very slow in the T-junction, the particle size drops quite rapidly before it levels out as explained in describing **Figure 2**. However, aggregation may also contribute to the larger size of particles measured at low mixing rates. On the other hand, the FDmiX seems to operate at mixing rates close to the local maximum, which is very well predicted by our model.

Ongoing CFD analysis of the flow in the T-junction has revealed that mixing is not finished before reaching the outlet, which our model is not accounting for. Expanding the model to address this issue may further improve the results in the future.

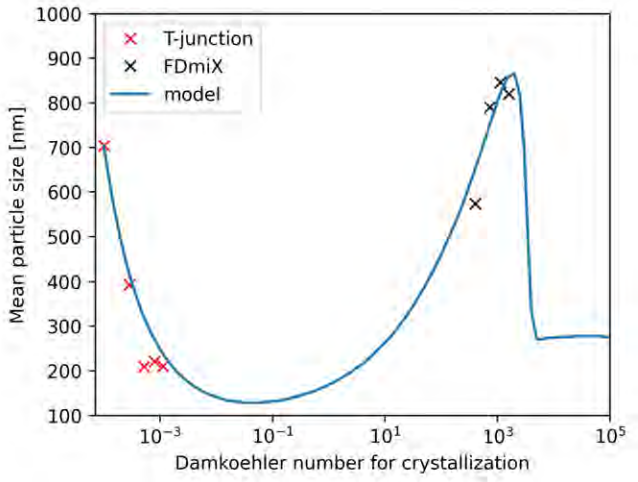

**Figure 6.** The best fit of the model to our experimental data for two different mixers.

## CONCLUSION

In this work, we present a simple, yet efficient crystallization model developed for studying the interaction between crystallization and mixing in batch and continuous tubular crystallizers. We have found an efficient way to nondimensionalize the model equations, significantly reducing the number of parameters. As a result, a new non-dimensional number has emerged during the process – the Damköhler number for crystallization – representing the ratio of homogenization and crystallization rates.

We use the model to study the process of continuous antisolvent crystallization by means of parametric sensitivity analysis. We were able to undercover the complex interaction between nucleation, growth and mixing and increase the understanding of the processes involved.

In addition to its suitability for theoretical research, our model is also convenient for fitting the kinetic parameters to experimental data as the reduced dimension of the search space streamlines solving of the optimization problem.

Despite the simplicity of the model, we have shown it is able to account for all the reported scenarios of mixing impact on particle size and to fit measured data sufficiently well.

## ABSTRACT

This study proposes a model-based approach utilizing a hybrid population balance model (PBM) to optimize temperature profiles for minimizing agglomeration and enhancing crystal growth. The PBM incorporates key mechanisms—nucleation, growth, dissolution, agglomeration, and deagglomeration—and is applied to the crystallization of an industrial active pharmaceutical ingredient (API), Compound K. Parameters were estimated through prior design of experiments (DoE) and refined via additional thermocycle experiments. In-silico DoE simulations demonstrate that the hybrid PBM outperforms traditional methods in assessing process performance under agglomeration-prone conditions. Results confirm that thermocycles effectively reduce agglomeration and promote bulk crystal formation, though their efficiency plateaus beyond a certain cycle number. This model-based approach provides a more robust strategy for agglomeration control compared to conventional methods, offering valuable insights for industrial crystallization optimization.

**Keywords**: Algorithms, Batch Process, Modelling and Simulations, Process Design, Optimization

## 1. INTRODUCTION

Agglomeration, often undesirable in crystallization, can lead to impurity incorporation [1,2], prolonged filtration and drying times, and difficulties in achieving uniform particle size and composition. While controlling supersaturation and agitation rates has been shown to reduce agglomeration [1,3], more advanced techniques, such as thermocycles, can facilitate deagglomeration and dissolve fines generated by breakage or attrition.

Optimizing thermocycles requires determining key parameters such as the number of heating-cooling cycles and the corresponding rates. This presents a complex optimization challenge, as traditional quality-by-control (QbC) methods relying on process analytical technology can be resource-intensive [4,5]. A more efficient alternative is the use of PBMs to monitor and regulate agglomeration during crystallization [6].

In this study, we propose a model-based approach to optimize temperature profiles for minimizing agglomeration and enhancing crystal size. A PBM is coupled with the number density of agglomerates to track agglomeration dynamics during thermocycles. The hybrid PBM incorporates key mechanisms, including nucleation, growth, dissolution, agglomeration, and deagglomeration, and is applied to the crystallization of an industrial active pharmaceutical ingredient, Compound K. Most parameters were estimated through DoE in a prior study, while additional thermocycle experiments were conducted to refine dissolution parameters.

Results from in-silico DoE simulations demonstrate that the hybrid PBM approach outperforms traditional methods in accurately evaluating process performance when agglomeration is present. This approach offers a more robust assessment of agglomeration control compared to methods based solely on particle bridge formation. Moreover, simulations indicate that while thermocycles effectively reduce agglomeration, their efficiency plateaus after a certain number of cycles—a trend confirmed through experiments in industrial case studies. Additionally, comparisons of different temperature profiles reveal that introducing heating-cooling cycles not only eliminates most agglomerates but also promotes the growth of larger bulk crystals.

The remainder of this article is organized as follows. Section 2 describes the experimental setup and measurement procedures. Using the experimental data, thermodynamic expressions and related parameters are defined for simulating the industrial case study. Section 3 introduces the hybrid PBMs, which are explicitly formulated to describe total number density and agglomerate number density under both heating and cooling conditions. Section 4 presents the results, including comparisons of different algorithms for agglomeration assessment and various optimal temperature trajectories. Additionally, it examines the differences between model-free and model-based QbC approaches in the industrial case study. Finally, conclusions are summarized in the last section.

## 2. MATERIALS, MEASUREMENTS, AND PROPOSED METHODOLOGY

### 2.1 Experimental setup and procedure

Batch experiments were conducted using the advanced synthesis workstation, Mettler Toledo's EasyMax 402, equipped with a 100 mL glass vessel. The vessel was sealed with a polytetrafluoroethylene lid, which provided multiple ports for PAT tools. Temperature control was achieved using a Pt100 temperature sensor and a Peltier plate, regulated by the built-in software, iControl. The process temperature was maintained between 0 and 70 °C to optimize yield while minimizing solvent evaporation.

Solvent selection for crystallization was performed through a solvent screening process. The chosen mixture consisted of dimethyl sulfoxide (DMSO, 100%, Fisher Scientific) and ethanol (EtOH, 100% absolute, Decon Laboratories, Inc.) in a volume ratio of 20:80. The industrial compound used in this study, referred to as Compound K and supplied by Takeda, exhibited a wide metastable zone—a topic explored in detail in the results section. This broad metastable zone prevented precipitation or nucleation at high supersaturation levels, allowing for a higher initial concentration to enhance productivity and yield.

Due to Compound K's poor solubility in EtOH (forming needle-like but highly agglomerated particles), it was initially dissolved in DMSO. EtOH was then introduced as an antisolvent to control the solubility of the mixture. To ensure the solid form of the final product, a tailored seeding strategy was developed for the seeded batch experiments. Wet seeding was employed to prevent particle clumping and seed aggregation. The seed suspension was prepared in EtOH and sonicated using an ultrasonic cleaner (ELMA ULTRASONICS P30H). The total solvent volume was maintained at 100 mL, with solvent evaporation carefully monitored and typically kept below 5% of the total volume.

During the experiments, an upward-pitched blade metal agitator operated at 400 rpm to ensure efficient mixing. In situ microscopy was performed using Mettler Toledo's EasyViewer with iC Vision software to capture inline particle images and monitor key process mechanisms, including nucleation, growth, dissolution, and agglomeration. Solute concentration was measured using attenuated total reflectance Fourier transform infrared spectroscopy (ATR-FTIR) with Mettler Toledo's ReactIR 702L, following probe calibration.

To constrain the design space, the seed's origin was restricted to a specific lot from the company. The seed crystals were generated using the aforementioned solvent system, resulting in needle-like particles with a crystal size distribution characterized by D10, D50, and D90 values of 2.51, 9.06, and 20.5 μm, respectively. Differential scanning calorimetry (DSC) measurements revealed that the seed was partially crystalline, with a crystallinity of 54.4%.

### 2.2 Crystal size distribution measurement

In the experimental analysis of solid samples, the crystal size distribution (CSD) was determined using the Mastersizer 3000, a Malvern instrument that utilizes light scattering. For wet measurements, heptane (100%, Fisher Scientific) with a fixed amount of Span 80 (100%, Fisher Scientific) was used as the dispersant. Prior to measurement, the slurry was sonicated at 20% intensity for 60 seconds to ensure effective dispersion.

### 2.3 Crystallinity measurement

Qualitative analyses were conducted to assess potential changes in the solid form during the experimental process using offline techniques such as X-ray Powder Diffraction (XRD). These methods were employed to identify distinctive features or fingerprints of the materials. Given the small particle size, scanning electron microscopy (SEM) images of the final products were captured using a field-emission SEM (FEI Nova NanoSEM 450) to confirm the crystal habit and evaluate the extent of agglomeration.

DSC was deemed essential in this study due to the presence of amorphous content, a factor further discussed in the results section. DSC measurements were performed using a PerkinElmer Jade DSC instrument. Notably, the primary purpose of DSC in this study was to enable quantitative comparisons rather than to determine precise thermodynamic properties. The melting heat was quantified based on the area under the melting peak, and crystallinity was calculated as the ratio of the melting heat of the sample to that of an established standard.

### 2.4 Solubility measurement

Utilizing the UPLC data, a crystalline solubility curve was constructed employing the following empirical

equation:

$$ln(C_{s,cry}) = a + \frac{b}{R*T} + \frac{c}{(R*T)^2} \quad (1)$$

where $C_{s,cry}$ represents the crystalline solubility with the unit of mg/g solvent, $T$ denotes the temperature in Kelvin, and $R$ stands for the ideal gas constant. The coefficients' values in the solubility equation are provided in Table 1.

**Table 1:** The solubility coefficients of Compound K in crystalline form.

| Coefficient | Value | Unit |
|---|---|---|
| $a$ | 44.84 | - |
| $b$ | $1.891 \times 10^5$ | $J{\cdot}mol^{-1}$ |
| $c$ | $2.016 \times 10^8$ | $J^2{\cdot}mol^{-2}$ |

**Table 2:** The solubility coefficients of Compound K in amorphous form.

| Coefficient | Value | Unit |
|---|---|---|
| $a$ | −98.06 | - |
| $b$ | 1383 | K |
| $c$ | 16.73 | - |

Following the identification of the amorphous form, the solubility data for the amorphous phase was collected and fitted using Equation 2. The parameters of the solubility curve for the amorphous form are presented in Table 2.

$$ln(C_{s,amor}) = a + \frac{b}{T} + c * log(T) \quad (2)$$

where $C_{s,amor}$ represents the amorphous solubility with the unit of mg/g solvent.

**Table 3:** The boundaries of shape descriptors for different classes of particles.

| Classes | *L | *I | *A | *C |
|---|---|---|---|---|
| Droplets | - | > 100 | - | > 0.87 |
| Needles | >2.0 | < 100 | > 0.32 | < 0.87 |
| agglomerates | >2.0 | < 100 | < 0.32 | < 0.87 |
| Fines | <2.0 | < 100 | - | < 0.87 |

* L: Length, I: Intensity Mean, A: Aspect ratio, C: Circularity

## 2.5 Degree of agglomeration measurement

To analyze the degree of agglomeration and ensure proper dispersion of the highly agglomerated final particles, the solid sample was suspended in the same dispersant used for the CSD measurement. The solid content concentration was controlled at approximately 0.7 mg/mL to prevent excessive particle overlap under the microscope. After sonication, the slurry was uniformly applied to the measurement slide, which was then dried under air.

The Morphologi 4 was used to conduct the image analysis on the prepared slide. Based on various shape descriptors, the particles were classified into four categories: fines, needles, agglomerates, and droplets, as

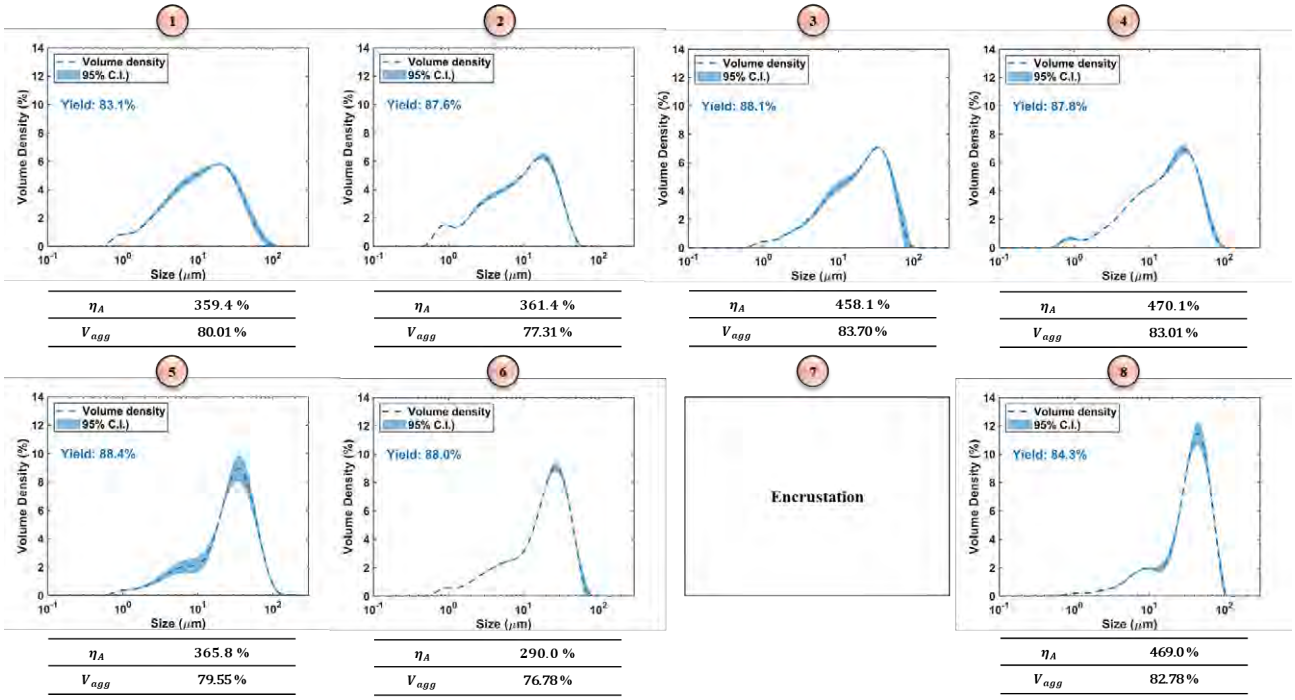

**Figure 1:** Degree of agglomeration calculation comparison based on the in-silico DoE study.

shown in Table 3. The degree of agglomeration was calculated by determining the percentage fraction of agglomerates, needles, and fines, while droplets were excluded due to their role as surfactants for particle dispersion. A minimum of 100,000 particles were captured during the analysis, ensuring that the calculated values represent the overall distribution. The remaining image analysis settings are shown in Supplemental Materials.

## 3. DEGREE OF AGGLOMERATION POPULATION BALANCE MODELING IN INDUSTRIAL CRYSTALLIZATION

Previous trial experiments have shown that the concentration trajectory intersects the amorphous solubility curve throughout heating and cooling cycles. This observation highlights a key aspect of the thermocycling process: the limited dissolution of crystalline particles, even during rapid heating. This behavior supports the continuous growth of needle-like particles across the thermocycles, leading to their eventual enlargement. Consequently, for the digital design of the process, aimed at capturing the evolution of both crystalline and amorphous materials during the desaturation phase, as well as the dissolution behavior of amorphous materials during heating, the degree of supersaturation is defined as follows:

$$\begin{cases} \sigma = \frac{C - C_{s,cry}}{C_{s,cry}}, & C > C_{s,amor} \\ \sigma = \frac{C - C_{s,amor}}{C_{s,amor}}, & C < C_{s,amor} \end{cases} \tag{3}$$

where $\sigma$ denotes the degree of supersaturation, $C_{s,cry}$ denotes the crystalline solubility, $C_{s,amor}$ denotes the crystalline solubility, and $C$ represents the solution concentration.

$$\frac{\partial f(L,t)}{\partial t} + g(t;\theta_g)\frac{\partial f(L,t)}{\partial L} = B_n(t;\theta_n)\delta(L - L_n) - f(L)\int_0^L \beta(L,\lambda)f(\lambda)d\lambda + \frac{L^2}{2}\int_0^\infty \frac{\beta\left((L^3 - \lambda^3)^{\frac{1}{3}},\lambda\right)}{(L^3 - \lambda^3)^{\frac{2}{3}}} f\left((L^3 - \lambda^3)^{\frac{1}{3}}\right) f(\lambda)d\lambda$$

$$while\ C > C_{s,amor} \tag{4}$$

The 1D PBM for this thermocycling process is expressed in equations (4) and (5). These equations are presented in two stages: the heating stage, which results in an undersaturated region, and the cooling stage, which leads to a supersaturated region.

$$\frac{\partial f(L,t)}{\partial t} - D(t;\theta_d)\frac{\partial f(L,t)}{\partial L} = -S(L)f(L,t)\int_\lambda^{L_{max}} b(L,\lambda)S(\lambda)f(\lambda,t)d\lambda$$

$$while\ C < C_{s,amor} \tag{5}$$

where $f$ is the number density function of the total number density, $g$ is the growth rate of the agglomerates with the corresponding parameters $\theta_g$, $d$ is the dissolution rate with the corresponding parameters $\theta_d$, $B_n$ is the birth of the particles due to the nucleation, $\beta$ and $b$ are agglomeration and breakage kernels. $b(L,\lambda)$ is defined as the inverse function of size-dependent Brownian collision kernel to capture the deagglomeration mechanism. $S(L)$ is the selection function for the deagglomeration process, which is a size-independent function:

$$S(L) = k_{dg}D^{g_d} \tag{6}$$

To monitor the evolution of agglomeration during thermal cycles, the PBM for agglomerate number density is coupled with the PBM for total number density, as represented by equations (7) and (8), formulated as follows:

$$\frac{\partial f_{agg}(L,t)}{\partial t} + g_{agg}(t;\theta_g)\frac{\partial f_{agg}(L,t)}{\partial L} = -f(L)\int_0^L \beta(L,\lambda)f(\lambda)d\lambda + \frac{L^2}{2}\int_0^\infty \frac{\beta\left((L^3 - \lambda^3)^{1/3},\lambda\right)}{(L^3 - \lambda^3)^{2/3}} f((L^3 - \lambda^3)^{1/3})f(\lambda)d\lambda$$

$$while\ C > C_{s,amor} \tag{7}$$

$$\frac{\partial f_{agg}(L,t)}{\partial t} - d_{agg}(t;\theta_d)\frac{\partial f_{agg}(L,t)}{\partial L} = -S(L)f(L,t) + \int_\lambda^{L_{max}} b(L,\lambda)S(\lambda)f(\lambda,t)d\lambda$$

$$while\ C < C_{s,amor} \tag{8}$$

The boundary conditions of $f_{agg}$ are defined in equation (9), to ensure that the newly formed crystals are not classified as agglomerates and to ensure that the number of agglomerates never exceeds the total number of particles.

$$\begin{cases} \lim_{L\to 0} f_{agg}(L,t) = 0 \\ 0 \le \frac{f_{agg}(L,t)}{f(L,t)} \le 1 \end{cases} \tag{9}$$

To quantify the degree of agglomeration of the particles, a volume-based degree of agglomeration ($V_{agg}$) is defined as follow:

$$V_{agg} = \frac{\int_0^\infty f_{agg}(L,t)L^3 dL}{\int_0^\infty f(L,t)L^3 dL} \tag{10}$$

In addition to the degree of agglomeration defined

earlier, an alternative method for estimating agglomeration is also employed in this work. According to the literature, the degree of agglomeration ($\eta_A$) is determined by the ratio of the "number of bridges" ($N_A$) to the total number of particles. By monitoring the formation and breakage of bridges during the process, the number of agglomeration bridges per unit volume of suspension is calculated. A detailed derivation of this method is provided in [6].

Finally, the PBMs are closed by the mass balance equations given by

$$\frac{dC(t)}{dt} = -k_v \rho_c \left[ 3G(t;\theta_g) \int_0^\infty L^2 f(L) dL + B(t;\theta_b) L_n^3 \right]$$

$$while\ C > C_{s,amor} \tag{11}$$

$$\frac{dC(t)}{dt} = 3k_v \rho_c \left[ D \int_0^\infty L^2 f(L) dL \right]$$

$$while\ C < C_{s,amor} \tag{12}$$

Where $k_v$is the volume shape factor of the crystals, $\rho_c$ is the crystal density, and $D$ represents the dissolution kinetics, which is formulated as follow:

$$D = k_d \sigma \tag{13}$$

The kinetics parameters are shown in Supplemental Materials (LAPSE:2025.0037), which most of them are directly obtained from the iterative model-based experimental design framework [7]. (Dissolution and deagglomeration kinetics are estimated with a simple factorial DoE, since their formulations are much simpler compared with those mechanisms during the desaturation.)

## 4. RESULT AND DISCUSSIONS

To assess the degree of agglomeration using this hybrid PBM framework, an in-silico case study was conducted by replicating the experimental conditions detailed in the DoE shown in Supplemental Materials, with variations in the decision variables. As illustrated in Figure 1, the degree of agglomeration derived from the hybrid PBM framework offers a more accurate estimation compared to the agglomerate degree based solely on the number of bridges. This improvement stems from the fact that within the agglomerates, there exists a considerable probability of multiple bridges forming, rendering a simple bridge count an overestimation of the degree of agglomeration.

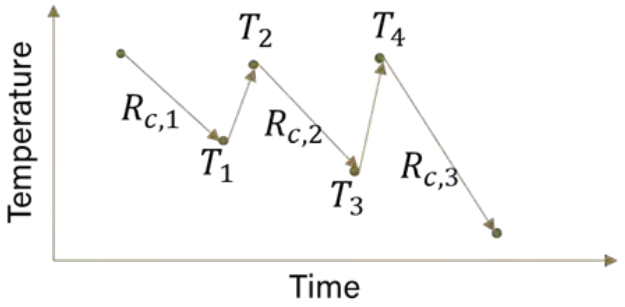

**Figure 2:** Input features that were used to describe the thermocyclic temperature profiles.

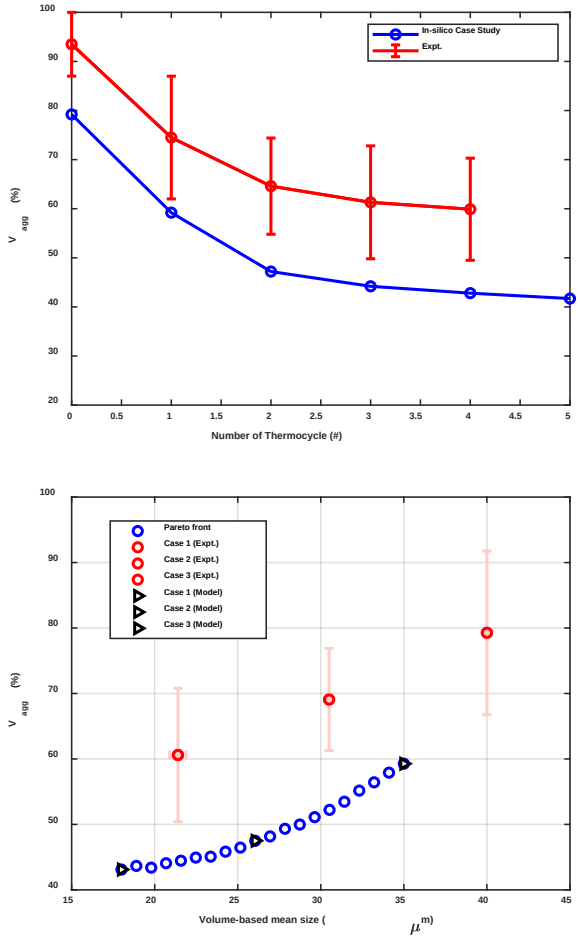

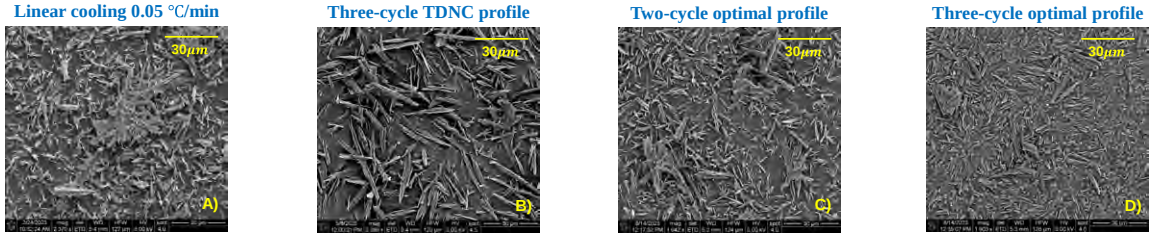

**Figure 3:** The comparison between $V_{agg}$.and different number of thermocycles (Top). The comparison between $V_{agg}$.and particle size while varying weighting factors in the optimization (N = 3) (Bottom).

In essence, the application of the degree of agglomeration derived from this hybrid framework presents a more comprehensive approach than prior methodologies. However, it is noteworthy that as the model was not trained using the degree of agglomeration from experimental results, there remains room for enhancing the predictive capacity of the model in future iterations.

| Cumulative CSD | D10 | D50 | D90 |

**Figure 4:** Experimental summaries of the linear cooling profile, the model-free QbC profile and the optimal

To reduce the degree of agglomeration of the final product, an optimization was formulated for a seeded crystallization. The decision variables are the 2N discrete temperature values that define the temperature profile as shown in Figure 2. The optimization objectives were to determine the temperature profile that minimizes the degree of agglomeration throughout the process and increase the size of the fine particles. For this, the following objective function was used:

$$\min_{\gamma \in R} OF = \omega V_{agg} + (1-\omega)\frac{1}{(\mu_1/\mu_0)}$$

$$\gamma = (R_{c,j}, T_j) \tag{14}$$

where $R_{c,j}$ is the cooling rate of each segment ($j = N+1$), $T_j$ are the temperature turning points ($j = 2N$), and $N$ denotes the number of thermocycles. $(\mu_1/\mu_0)$ represents the number-based mean size of the final products.

Various optimal temperature profiles were generated, as shown in Figure 3. As the number of thermocycles increases, $V_{agg}$ gradually decreases and eventually reaches a plateau. This trend is consistent in both the in-silico study and experimental results. By adjusting the weighting factors, the model demonstrates a similar trend to the experimental validations, despite an offset attributed to the model's limited accuracy in predicting the exact value of $V_{agg}$.

Figure 4 presents an experimental comparison of the linear cooling profiles, the model-free QbC profile—developed using a turbidity-based direct nucleation control strategy, which indirectly regulates fine particle generation and promotes seed particle growth—and the optimal temperature profiles obtained from the optimization problem discussed earlier. The results indicate that optimal temperature profiles perform comparably to the model-free QbC profile and outperform linear cooling profiles in terms of reducing the degree of agglomeration, not to mention the improvement in crystallinity. Additionally, they offer significant advantages by shortening batch time. (The optimal temperature profiles suggest that batch time could be further reduced by increasing cooling rates during the thermal cycle without compromising the degree of agglomeration.) This improvement in agglomeration has been validated through image analysis using Morphologi 4, based on the number-based degree of agglomeration analysis ($N_{agg}$) and SEM images.

## 5. CONCLUSION

This study demonstrates the effectiveness of a model-based approach using a hybrid population balance model (PBM) to optimize temperature profiles for industrial crystallization processes. The hybrid PBM, which integrates critical mechanisms such as nucleation, growth, dissolution, agglomeration, and deagglomeration, provides a more accurate and comprehensive framework for minimizing agglomeration and promoting crystal growth than traditional methods.

The in-silico design of experiments (DoE) simulations and experimental validations confirmed that optimal temperature profiles and thermocycles significantly reduce the degree of agglomeration and enhance bulk crystal formation. While thermocycles proved effective, their benefits plateau with an increasing number of cycles. Additionally, the optimal temperature profiles outperformed linear cooling strategies in both reducing agglomeration and shortening batch times, demonstrating scalability and efficiency for industrial applications.

By integrating insights from image analysis (Morphologi 4 and SEM) and validating findings through experimental data, this study demonstrates how model-based optimization enhances both process control and product quality. Future research may focus on improving model accuracy by incorporating agglomeration data from experimental results to further refine predictive capabilities. Ultimately, this approach provides a robust and

scalable strategy for crystallization optimization, offering valuable insights while effectively managing the degree of agglomeration in the pharmaceutical and specialty chemical industries. Additionally, the hybrid PBM structure has shown significant potential for application in granulation and spherical agglomeration processes, facilitating improved control over particle formulation related to aggregation and agglomeration.
