

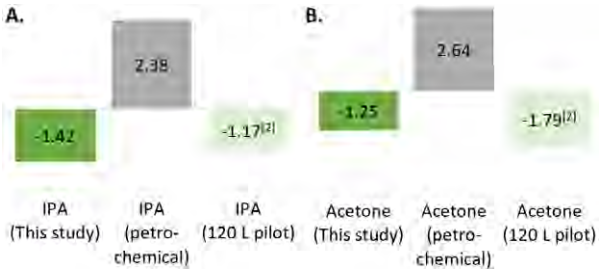

**Figure 3:** The cradle-to-gate global warming potential of the modelled syngas fermentation to 47.5 kton/year of >99 w% isopropyl alcohol and acetone (left, dark green) compared to the GWP of petrochemical-derived IPA (middle, grey) from ECOINVENT V3.11, and the reported 120 L pilot-scale based LCA [2]. Both this study and [2] assumed the steel mill offgas to be prevented carbon emissions.

matter formation and land use are about one order of magnitude smaller for the syngas fermentation process. On top of that, the freshwater eutrophication could be net zero due to the prevented steel mill emissions and net electricity generation. A common concern for fermentation processes is the high fresh water use. However, for the modelled gas fermentation process the freshwater use is only about threefold that of the petrochemical processes, ranging from 62-70 L/$kg_{product}$ (see Table 2). The designed process already has about maximum fresh water recycle and reuse. Therefore, efficient water management is important for developing more sustainable chemical production through (syngas) fermentation.

## CONCLUSIONS

- Converting steel mill off gas through (syn)gas fermentation at a product titer of 50 g/L and 85% gas conversion can produce high purity (>99 wt. %) isopropyl alcohol (isopropanol, IPA) and acetone. This process is both economically sustainable (unit production costs ≈ 1/3 market price) and environmentally sustainable, potentially achieving net zero GWP.
- Effective downstream processing of the volatile products, isopropyl alcohol (isopropanol, IPA) and acetone, can be obtained through vacuum distillation with broth recycling, followed by acetone distillation, pre-concentration, and extractive distillation of IPA with ethylene glycol.
- Effective heat integration, utilising both the latent and chemical energy of the steel mill off gas, results in net zero steam consumption and net electricity generation (2 MWh) in the modelled syngas fermentation process, producing 47.5 $kton_{product}$/ year.
- The method of accounting for the environmental impacts and substitution, when utilising a waste stream or generating a byproduct, respectively, is crucial to the LCA outcome. When the steel mill off gas is considered as prevented emissions, the modelled syngas fermentation process can have a net zero GWP.

**Table 2:** Environmental impacts, besides the global warming potential for the cradle-to-gate LCA of the modelled syngas fermentation of steel mill off gas to 47.5 kton/year of >99 wt. % isopropyl alcohol (IPA) and acetone (Ac).

| Product: | **Isopropyl alcohol** (This study) | **Petrochemical IPA** (ECOINVENT V3.11) | **Acetone** (This study) | **Petrochemical Acetone** (ECOINVENT V3.11) |
|---|---|---|---|---|
| Stratospheric ozone depletion ($kg_{CFC11\text{-}eq}$ / $kg_{product}$) | 4.17E-07 | 4.60E-07 | 3.66E-07 | 3.24E-07 |
| Fine particulate matter formation ($kg_{PM2.5\text{-}eq}$ / $kg_{product}$) | 3.23E-04 | 2.77E-03 | 2.84E-04 | 3.31E-03 |
| Freshwater eutrophication ($kg_{P\text{-}eq}$ / $kg_{product}$) | -2.89E-05 | 4.15E-04 | -2.54E-05 | 4.28E-04 |
| Marine eutrophication ($kg_{N\text{-}eq}$ / $kg_{product}$) | 9.12E-05 | 2.59E-05 | 8.01E-05 | 2.33E-05 |
| Human carcinogenic toxicity ($kg_{1,4\text{-}DCB\text{-}eq}$ / $kg_{product}$) | 0.021 | 0.057 | 0.018 | 0.061 |
| Land use ($m^2_{crop\text{-}eq}$ / $kg_{product}$) | 4.94E-03 | 1.81E-02 | 4.34E-03 | 1.61E-02 |
| Water consumption ($m^3$ / $kg_{product}$) | 0.070 | 0.016 | 0.062 | 0.028 |

## RECOMMENDATIONS

- To evaluate the effect of titer and product selectivity on the downstream process design, techno-economic performance and environmental sustainability of syngas fermentation, future work should look into both lower isopropyl alcohol and acetone product titer and higher acetone selectivity.
- To study the influence of different (volatile) by-products on the process performance.
- To perform experimental studies on the effect of isopropyl alcohol concentration on the volumetric mass transfer.

## ABSTRACT

Acrylonitrile is a critical commodity chemical used to produce a variety of industrial polymers, such as carbon fibers, plastics, etc. Currently 90% of the global acrylonitrile production is based on propylene ammoxidation. However, there is no literature reporting the whole process holistically in detail, and which also looks into the energy utilization of the whole process including the reaction heat as well as the energy demands of the downstream separation. This original study provides a rigorous process design of the full process from a holistic viewpoint, covering 7 sections of acrylonitrile production (reaction, acid quenching, absorption-desorption, hydrogen cyanide recovery, acrolein recovery, acrylonitrile-acetonitrile-water separation, acetonitrile recovery sections). In order to further improve the energy efficiency, three energy integration strategies are proposed (1) Energy integrated downstream processing; (2) Systematic heat integration utilizing the heat of reaction; (3) Power generation by process surplus heat. Design 1 employs a direct heat exchanger network, recovering 30.1 MW heat through multiple heat exchanges, saving 86.91% fuel gas, 17.38% low pressure steam and 43.96% cooling utilities. Design 2 and 3 recovers 58.39 MW heat, and 12.20 MW low pressure steam is output as waste heat recovery in design 2, whereas 11.06 MW low pressure steam and 7.8 MW electricity are generated in design 3. The pro/con each options are also discussed for further guidance. As the first comprehensive description of the design of the entire acrylonitrile production process, this work highlights the potential for improved energy efficiency in the acrylonitrile production.

**Keywords**: Process Design, Process Intensification, Distillation, Energy Efficiency, Heat Exchanger Network

## 1. INTRODUCTION

Acrylonitrile (AN) is a widely used commodity chemical in industry, primarily as a monomer for the production of acrylic fibers, acrylonitrile-butadiene-styrene (ABS) resins, adiponitrile, acrylamide, nitrile rubbers, and carbon fibers. Driven by the increasing demand for acrylonitrile from end-use industries, such as construction,, the global acrylonitrile market size valued at USD 11.87 billion in 2021 is expected to grow at a compound annual growth rate (CAGR) of 1.3% from 2022 to 2030 [1].

Over 90% of the world's acrylonitrile is commercially manufactured via the propene ammoxidation process, described by Equation 1:

$$CH_2{=}CHCH_3 + NH_3 + 3/2O_2 \rightarrow CH_2CHCN + 3H_2O \quad (1)$$

However, this global reaction involves a complex reaction mechanism and is accompanied with the formation of acetonitrile, hydrogen cyanide, acroleine, acrylic acid, carbon oxides (COx), and large amounts of water. Therefore, to separate the products, the whole process can be described as the following sections, according to the descriptions given by Dimian and Bildea [2]: (1) reactor, (2) acid-quench, (3) absorption-desorption, (4) removal of hydrogen cyanide (5) separation of acrolein, (6) separation of acrylonitrile, (7) separation of acetonitrile.

The reaction is performed at temperatures of 400-510°C and pressures of 1.5-3 bar. The high exothermicity of the reactions involved ($\triangle H = -123$ kcal/mol) requires very efficient cooling to maintain the reaction temperature in the desired range. The downstream separation and purification of AN involves several distillation

columns, which are very energy intensive, however, energy costs and environmental concerns associated with energy consumption were not critical in the past, the energy consumption and the improvement of the energy usage and integration did not draw much attention. Thus, in the current climate, better utilization of the energy for the whole process is essential, and before investigating this, a detailed design of the whole process is also necessary.

The objectives of this study are: (1) to develop an optimized complete process flowsheet using thermodynamic analysis and literature information, (2) to implement process intensification technologies for downstream processing (DSP), such as dividing wall columns, exploring also the mechanical vapor recompression heat-pumping potentials, (3) to explore heat integration potentials by heat exchanger network design, utilizing the heat from reactions for the whole process, (4) to evaluate and compare different designs in terms of the energy intensity of each process.

## 2. PROBLEM STATEMENT

Acrylonitrile production process by propylene ammoxidation involves high exothermicity reactions, multi co-products which need to be separated, and complex downstream separation and purification processes. Developing a comprehensive flowsheet involving both reactions and separations to understand the whole process is essential, and energy integrated options should be considered in order to develop more energy-efficient flowsheets. Different designs should be evaluated and compared based on key performance parameters such as economics and sustainability, and suggestions are given based on the different advantages and disadvantages of each design.

## 3. DESIGN AND SIMULATION APPROCH

### 3.1 Process design

Aspen Plus V12 is used for rigorous simulations in this work. According to the process proposed by Dimian and Bildea [2], fifteen components are present in the process: acetonitrile, acrolein, acrylic acid, acrylonitrile, ammonia, ammonium sulphate, carbon dioxide, carbon monoxide, hydrogen cyanide, nitrogen, oxygen, propane, propylene, sulfuric acid, and water. The UNIQUAC-RK model is selected in Aspen Plus as suitable property model to calculate all physical properties required for the process simulation. The stoichiometric reactor model is used to model the reactions based on the activity data for a molybdenum/bismuth-modified catalyst reported in the patent (US 6,596,897 B1, 2003 [3]), in order to achieve a reliable description of the conversion of reactants into products, co-products, and other impurities. The simulation is developed based on VLE data, ternary diagrams combined with RCM, reaction conditions, separation specifications, and product purity requirements. Plant production capacity is 120 ktpy (acrylonitrile 99.4 wt% purity, 99.9 wt% recovery) with a corresponding reactor production rate of 272.34 kmol/h acrylonitrile.

### 3.2 Energy integration methodology

#### 3.2.1 Process intensification opportunities for DSP to enhance energy efficiency

Process intensification (PI) technologies are considered to have great potential in reducing the high costs and energy requirements of the separation and purification step, enhancing productivity while improving process safety, reducing waste without sacrificing product quality. The intensified distillation technologies considered in this work include dividing wall column (in which one column shell with the middle wall is used to replace the conventional two columns and avoid re-mixing effect); and heat pump assisted distillation (in which the overhead vapor can be upgraded and re-used to heat the bottom reboiler), which addresses heat transfer bottlenecks by increasing the temperature of cold streams to create a feasible temperature driving force, thereby expanding heat transfer opportunities for integration.

#### 3.2.2 Heat exchanger network (HEN) design to utilize the heat of the process

The HEN is synthesized by a stage-wise superstructure optimization approach, integrating systematically direct heat integration and heat pumps. In addition, it allows the integration of multiple hot utility options, waste heat recovery, and mechanical heat pump applications, to enhance energy efficiency and reduce costs. Direct stream-stream transfer, indirect transfer via heat pumps, and utility-mediated heat transfer for waste heat are automatically selected for each heat transfer match. Heat exchangers are positioned at optimal locations between hot and cold streams, enabling efficient heat recoveries. A detailed description of this HEN synthesis method can be found in literature [4]. Initial and target temperatures of the streams, heat capacities, and stream film heat transfer coefficients are required for a new HEN design. The superstructure formulation is modelled as a mixed-integer nonlinear program (MINLP) and solved by BARON/GAMS, the objective function of this model is minimizing the total annualized cost (TAC). The fixed and area costs of heat exchangers, compressor size costs, and utility costs are considered as the cost-related parameters. The capital costs related to heat exchangers are taken from the literature [5]. The minimum approach temperature difference for heat transfer is set at 10°C.

## 4. RESULTS AND DISCUSSIONS

### 4.1 Base case design

Figure 1 presents the base-case flowsheet comprising the reaction and separation section. The fluid-bed reactor operates at 2.0 bar and 440°C. The reactants - propylene, ammonia, and air - are separately fed in the molar ratio 1, 1.2, 9.8 to fulfill reaction chemistry and safety constraints. After cooling at 220°C, the reaction mixture enters the quench column A-Q operated at 1.9 bar with a view to removing the excess ammonia as ammonium sulphate through neutralization with sulfuric acid (30 mol%). The bottom stream is sent to the recovery of ammonium sulphate that is a co-product of this process. After acid quenching and cooling at 30°C, the cleaned gas enters the absorption/desorption section. First, the column ABS equipped with 24 stages and operating at 1.6 bar, separates non-condensable components ($N_2$, $O_2$, $CO_2$, CO and propene) by absorption in water at 5°C. Next, the recovery of acrylonitrile from the aqueous bottom stream is sent to the column REC (36 stages). Top-vapor condensation at 30°C followed by liquid-liquid splitting in the DECANT1 ensures the recovery of the organic components (acrylonitrile, acetonitrile, hydrogen cyanide, and acrolein) in the organic phase and recycles the aqueous phase to the stripper.

The organic phase enters the column ACR for splitting the mixture in acrylonitrile/acetonitrile and HCN / acrolein fractions (1.1 bar). In the hydrogen cyanide section, hydrogen cyanide is recovered from the hydrogen cyanide-acrolein overhead (1.01 bar). The product stream leaving the bottom of the acrolein section is fed to the acrylonitrile-acetonitrile-water section, operating around atmospheric pressure, targeting the recovery of acrylonitrile as desired product. An extractive distillation is performed using water as mass-separating agent. The feed stream from the previous separation is combined with the aqueous stream from the decanter and the entrainer water stream to form the combined stream. The combined stream is separated in the first column to obtain a near-azeotropic distillate at the top, water at the bottom, and an acetonitrile-water mixture as a side stream. The organic phase from the decanter is sent to a second column (C2) to obtain a near-azeotropic distillate at the top and pure acrylonitrile at the bottom.

Finally, the side stream from the acrylonitrile-acetonitrile-water section is fed to the acetonitrile recovery section, which performs a pressure-swing distillation. Extractive distillation has good performance for recovering acetonitrile from water, yet there is only 4% acetonitrile in the feed resulting in low absolute value of the separating duties. Therefore the difference between different separation methods is small. Pressure swing distillation does not require introducing a third component so this is preferable. The pressure of the columns are 4.4 bar and 1.1 bar respectively. Overall 48.42 MW hot utilities and 43.15 MW cold utilities are needed by the process (after the heat recovery by HX1, 11.88 MW). Of the total 43.15 MW cold utility requirement, 3.39 MW of refrigerant is needed to cool the “ABS-H2O” stream in the absorption-desorption section (25°C–5°C), while 0.16 MW of chilled water is required for HCN column condenser (25.7°C–24.7°C). The remaining cooling duties are covered by cooling water. As the temperatures of ABS-H2O stream and the HCN condenser are too low for heat integration, they are excluded from the heat exchanger network (HEN) optimization process but re-added as cooling utilities in the optimized solution. Thus the refrigerant and chilled water requirements remain constant across all designs.

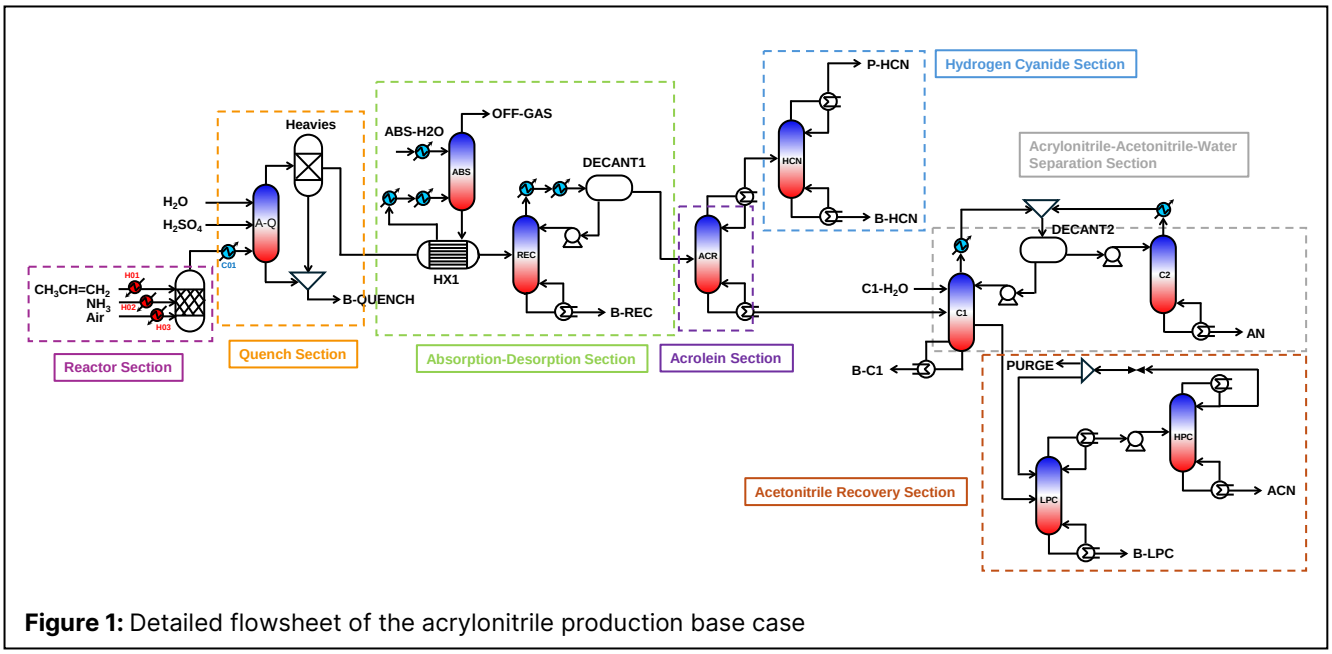

**Figure 1:** Detailed flowsheet of the acrylonitrile production base case

## 4.2 Process Energy integration

Propylene ammoxidation is an exothermic reaction - the reactor operates at 440°C and generates surplus heat amounting to 59.74 MW, which must be removed using a heat medium to ensure process stability. The heat can be removed directly by cooling medium to ensure effective cooling *(Section 4.2.1)*, the focus of the energy integration is then on the downstream separations; or the heat of the reaction can also be integrated into the process *(Section 4.2.2)*, by transferring its heat to a utility stream (hot oil, 400°C), and a heat exchanger network is developed by utilizing the reaction heat as well as the process to process heat integration;

Alternatively, the heat generated from the reaction can be utilized to produce power (very high pressure (VHP) steam to a steam turbine) and low-pressure (LP) steam. The generated power can be exported, while the LP steam serves as a hot utility within the process. The optimal heat integration solutions are presented through a HEN, as detailed in *(Section 4.2.3)*.

### 4.2.1 Energy integration of DSP taking into account process intensification options – Design 1

As heat pump assisted distillation has great potential to be able to enhance the energy efficiency, it is involved in the systematic heat integration approach. Taking vapor recompression as an example, the overhead vapor from the distillation column is compressed to a higher pressure, and used as heat source for the reboiler. However, when the process in complex (e.g., has multiple heat exchangers as well, providing heat integration potentials), a systematic heat exchanger network design is necessary, as an effective process to process heat transfer could also be potentially more effective than using heat pumps.

For heat pump assisted distillation, the lower the temperature lift (i.e., the temperature difference between the overhead vapour and the condenser), the higher the coefficient of performance [6,7]. When analysing the process, there are three potentials opportunities by integrating heat pumps in the acrylonitrile production process: (1) The overhead vapour from the recovery column (89°C) and the reboiler of the ACR column (81°C); (2) The overhead vapor of the first column of ACN/AN/$H_2O$ separation section (BD-C1, 76°C) to its reboiler (113°C); (3) The overhead vapor of second column of ACN/AN/$H_2O$ separation section (BD-C2, 76°C) to its reboiler (82°C).

However, an effective process to process heat integration might integrate the heat well without heat pumps, therefore a systematic heat exchanger network design (described in Section 3.2.2) is carried out, which includes the flexibility of choosing to use heat pumps is it brings more benefits. **Figure 2** presents the optimal heat exchanger network design of the process, and shows that in this case no heat pumps are needed. The target HEN configuration includes 10 hot streams, 11 cold streams, and two hot utilities: fuel gas and low-pressure steam. The heat exchanger HX1 (11.88 MW) in the conventional design was released as a degree of freedom in the new HEN design. Cooling water (20-25°C) and chilled water (5-15°C) refrigerant (-20°C) are employed to meet the cooling demands of system [8]. 10 heat exchangers are installed with a total heat transfer area of 3706 m², strategically placed within the network.

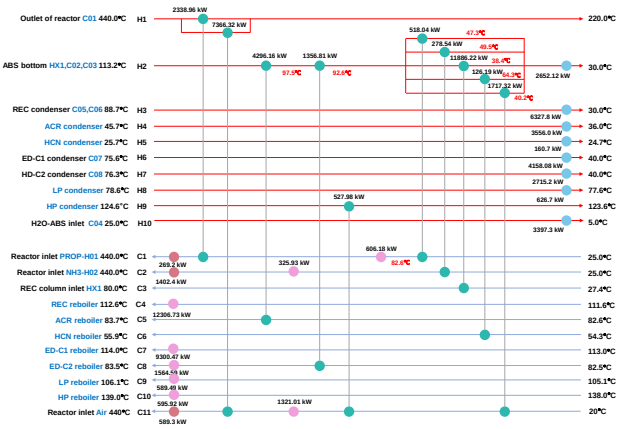

**Figure 2.** Heat exchanger network design via systemetic energy utilization for downstream processing without reaction-separation integration

These exchangers enable heat recovery of 30.41 MW, comparing to the conventional process. 28.87 MW hot utilities are needed (2.26 MW fuel gas, 26.61 MW LP steam), and 23.60 MW cold utilities are needed. Overall 20.60 MW hot utilities and 20.60 MW cold utilities are saved comparing to the conventional process, effectively utilizing heat from the reactor outlet stream (H1) and the ABS bottom stream (H2). The number and ratio of stream splits are shown in the HEN, maximizing the use of temperature driving forces to efficiently transfer heat to multiple cold streams. LPS is placed at the intermediate stage of cold stream C1, C2 and C11 by multiple utility optimization, to avoid the extra usage of fuel gas.

Note that the option of using dividing wall columns in this process does not bring benefits after calculations, therefore it will not be discussed further.

### 4.2.2 Systematic heat integration utilizing the heat of reaction – Design 2

Differently, the surplus heat from the reaction can also be first utilized to preheat the reactor feed inlets - propylene, NH3, and air - from 420°C to 440°C. The remaining surplus heat is then transferred to generate hot oil (200°C–400°C, 301.8 t/h), which is introduced as a new hot stream. The use of hot oil allows the HEN to operate with single-phase heat transfer, avoiding operational challenges associated with phase-change heat transfer in steam networks. A new HEN synthesis is

proposed in **Figure 3**, incorporating the hot oil stream. This design problem involves 11 hot streams, 11 cold streams, and two hot utilities. Additionally, LPS is used as a cold utility for automated waste heat recovery (steam generation). The LPS generated by the hot oil stream is exported from the system, further increasing energy benefits and enhancing overall efficiency.

**Figure 3** illustrates the optimal HEN design, which includes a total of 16 heat exchangers with a total heat transfer area of 2308 m². This improves process energy efficiency by achieving 58.39 MW of heat recovery compared to Section 4.2.1. The hot oil (59.74 MW) heat transferred by the reaction surplus heat covers all the hot utilities needed in this process, and additionally 12.20 MW LPS is generated/output as a form of waste heat recovery. 43.15 MW cold utilities are needed.

The previous design relied on a complex HEN with stream branches to utilize H1 and H2, yet the HEN in this section focuses on maximizing cost efficiency by utilizing the hot oil stream (H11). Half of the heat exchangers are placed in the hot oil stream, recovering 47.54 MW to cold streams. Overall, this HEN achieves complete heat integration without requiring any hot utility input, showcasing efficient energy utilization and cost-effectiveness.

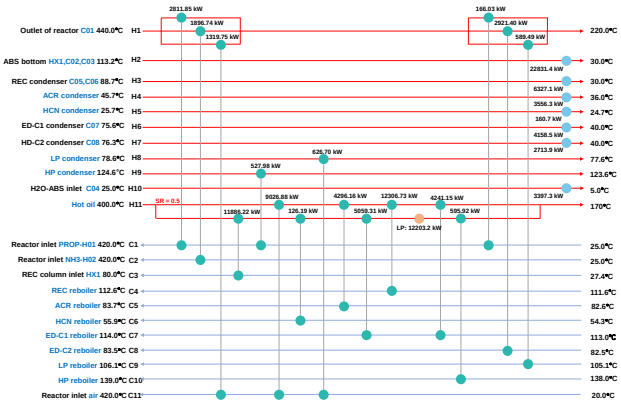

**Figure 3.** Reaction-separation integration via hot oil (to take the reaction surplus heat for integration) and systematic heat exchanger network design

### 4.2.3 Taking the reaction heat to generate power – Design 3

A steam network is established to generate electricity and provide heating for cold streams. The surplus heat (59.74 MW) from the reactor is first used to generate VHP steam (40 barg, 251.8°C), with 1.40 MW of heat transferred to the reaction inlet (air, C3) stream. The remaining VHP steam (58.35 MW) is passed through a steam turbine to generate electricity and produce LP steam (6 barg, 160°C) for process heating requirements. A partial HEN is synthesized using an optimization approach, incorporating only H1, C1, C2, and C11 within a multiple utility system. The remaining cold streams are directly heated by the steam network, simplifying the overall configuration while ensuring efficient energy utilization.

In this case, the steam network sufficiently meets the main heating requirements of 42.02 MW for cold streams C3–C10. Cold streams C1, C2, and C11 require an additional 5.28 MW from the steam network, while H1 compensates for the remaining 9.71 MW of heating. Overall 58.39 kW heat recovery can be achieved by this HEN. The key advantage of this solution is that the steam network not only meets heating demands but also generates 7.8 MW of electricity and 11.06 MW of LP steam as waste heat recovery. The turbine is simulated in Aspen Plus V12, with isentropic efficiency of 0.85 and mechanical efficiency of 0.98. However, integrating a steam network into the whole design introduces added complexity, particularly regarding control and safety considerations.

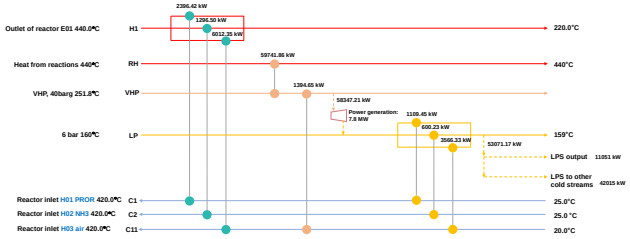

**Figure 4.** Reaction-separation integration via steam network and power generation (to take the reaction surplus heat for integration) by systematic heat exchanger network design; Hot (cold) streams that are directly cooled (heated) are not included in this diagram.

## 4.3 Comparisons of different design cases

The comparison of the different design cases is shown in Table 1 and 2. Overall, Design 1 employs a direct HEN that recovers 30.1 MW through multiple heat exchangers, balancing network investment and energy efficiency. This solution requires multiple stream splits to maximize the utilization of driving forces, resulting in a more complex network. Compared to the non heat integrated case, all the heat is needed by the fuel gas (assuming that no multiple-utility is used in heat exchangers), however in Design 1 (see figure 2), part of the heat is provided by heat recovery, therefore less fuel gas is required.

Design 2 introduces a hot oil stream to heat cold streams, enabling single-phase heat exchange and increasing heat recovery to 58.39 MW. This substantial improvement demonstrates that incorporating alternative heat transfer fluids can significantly enhance energy efficiency by extracting energy from exothermic reactions. Design 3 integrates a steam network to achieve multifunctional energy utilization. It generates both electricity and low-pressure steam while meeting the primary heating demands, offering a comprehensive solution for energy recovery and utilization.

Both Design 2 and 3 meet the heating requirements

for cold streams while generating low-pressure steam (LPS) of 12.2 MW and 11.06 MW, respectively. However, Design 3 relies on a steam turbine and high-pressure systems, which introduce additional complexities in control, safety, and integration with existing process streams, despite its ability to generate 7.8 MW electricity. In contrast, Design 2 includes additional equipment, such as hot oil loops and associated heat exchangers. This approach simplifies the challenges associated with phase-change heat transfer, offering a more straightforward and manageable solution for heat integration.

**Table 1:** Comparison between the conventional design and the Design 1 (downstream separations only)

| | Conv. | Design 1 | Savings |
|---|---|---|---|
| CU for reactor (MW) | 59.74 | 59.74 | - |
| Fuel gas (MW) | 17.26 | 2.26 | 86.91% |
| LP steam (MW) | 32.21 | 26.61 | 17.38% |
| CU (MW) | 44.20 | 23.60 | 43.96% |
| Area ($m^2$) | - | 3706 | - |
| No. HEx | - | 10+19 | - |
| Power Gen. (MW) | - | - | - |
| Energy ($kWh/kg_{AN}$) | 3.42 | 1.99 | 41.81% |

**Table 2:** Comparison between the Design 2 and 3 (including the reactions surplus heat)

| | Design 2 | Design 3 |
|---|---|---|
| Hot oil (t/h) | 301.8 | - |
| HU (MW) | 0 | 0 |
| CU (MW) | 43.15 | 44.30 |
| Area ($m^2$) | 2308 | 3036.2 |
| No. HEx | 16+8 | 3+12 |
| LPS Gen. (MW) | 12.20 | 11.06 |
| Power Gen. (MW) | - | 7.8 |
| Energy ($kWh/kg_{AN}$) | -0.84 | -1.30 |

**Note:** HU - hot utility required; CU – cold utilities required; Area – heat exchangers area; No. HEx – Number of heat exchangers, the number of heat exchangers for utilities is underlined; LPS Gen – low pressure steam generated; Power Gen. – power generated; AN production 120 ktpy

## 5. CONCLUSIONS

The comprehensive process developed in this study demonstrates the efficiency of integrated process design, coupling rigorous reaction modeling with thermodynamically and economically optimized separation strategies. Systematic heat integration can save around a half of the utility requirements compared to the conventional design. When utilizing the surplus reaction heat, generating LP steam and associated power has the lowest energy intensity, comparing to taking the reaction heat by heat oil and use it again as a hot stream in the process. However, relying on steam turbines and high-pressure systems might not be favorable due to the additional complexities. The energy integration strategies proposed in this research can be chosen based on different needs.

Including different designs and the quantification of their associated trade-offs ensure reliable performance and applicability in industrial processes. The flexibility of the resulting heat exchanger networks and utility configurations ensures that the findings can be appropriate to specific operational requirements. The results not only bridge an important knowledge gap in acrylonitrile production design but also offer a solution for optimizing similar exothermic processes characterized by complex product distributions and energy-intensive separations.

## ABSTRACT

Plastic recycling is prevalently mechanical, which is inefficient at removing contaminants and produces low-grade materials. Solvent-based polymer dissolution and precipitation is emerging as a low-energy alternative to mechanical recycling when tackling highly contaminated plastic waste streams. We present a computer-aided molecular and process design (CAMPD) formulation for the selection of optimal solvents and process temperatures for polymer recycling via a dissolution and precipitation process. A mixed-integer nonlinear programming (MINLP) model is proposed to minimize the energy requirement for the dissolution of commercial low-density polyethylene, a ubiquitous polymer in industrial and municipal plastic waste, while minimizing the solvent viscosity and toxicity through multiobjective optimization. We integrate the SAFT-$\gamma$ Mie group-contribution equation of state in the optimization framework to predict key thermodynamic properties and to ensure that the desired phase behaviour is achieved. A ranked list of solvents and the corresponding process temperatures is obtained using integer cuts. Two polyethylene molecular weights are considered. In each case, we construct a Pareto front to quantify the trade-offs between the energy requirements of the process and the selected solvent properties. Furthermore, we investigate the simultaneous design of the dissolution and cooling precipitation to analyse the effect of varying the precipitation temperature on the energy of dissolution. The current study provides valuable insights into selecting optimal solvents for polyethylene dissolution, advancing the design of more efficient plastic recycling processes.

**Keywords**: Plastic recycling, CAMPD, SAFT-$\gamma$ Mie.

## INTRODUCTION

The recycling of plastics via solvent-based processes is an emerging alternative to the more established mechanical recycling technologies, particularly when addressing highly contaminated and multilayer plastic waste, and targeting high-quality recycled polymers [1]. Amongst solvent-based recycling technologies, physical recycling processes, that do not involve any chemical modifications of the molecular species, lead to significantly less carbon dioxide ($CO_2$) emissions compared to chemical recycling, which requires the energy-intensive cleavage of polymer bonds to produce monomers, the building blocks of polymers [2]. This is particularly the case when considering polyolefins like polyethylene and polypropylene, which have highly unreactive carbon-carbon bonds. However, dissolution and precipitation methods are more energy intensive than mechanical recycling and are often not suitable to produce food-grade recycled polymers due to the use of toxic solvents [3], which also pose general concerns with respect to environmental impact. Identifying new solvents and improved process designs is therefore key to advancing solvent-based dissolution and precipitation to levels comparable with mechanical recycling and to make it competitive with virgin polymer production.

Polymer solubility experiments are expensive and time consuming, so that the availability of predictive tools

for relevant properties to make informed decisions about the process and solvent choice is critical. The selection of solvents based on Hansen solubility parameters (HSPs) has been proposed [4]. While HSPs are useful for rapid solvent screening, they do not provide the required properties for process optimization, such as the solubility or the enthalpy at different process conditions. Recently, COSMO-RS, which can account for polymer–solvent molecular detail, has been used to predict the solubility of polymers in solvents for dissolution applications [5]. However, the prediction of the solubility of the polymer with COSMO-RS is computationally expensive, requiring molecular simulation to identify representative polymer conformations. Furthermore, there has been limited validation of the approach in terms of the polymer molecular weight and of the temperature range. The SAFT-γ Mie [6,7] equation of state offers an alternative route to predict solid–liquid equilibrium and liquid–liquid demixing in polymer-solvent mixtures, as well as other thermodynamic properties. It has been shown to deliver accurate properties of complex mixtures, including polymers and solvents [6-8], and, as a group-contribution method, it is naturally suited for use in solvent (molecular) design. It has for example recently been used in computer-aided molecular and process design (CAMPD) to identify better solvents and process conditions for pharmaceutical manufacturing [9] and for $CO_2$ capture [10]. Crystallization processes in drug manufacturing also depend heavily on solubility (solid–liquid equilibrium), providing a foundation for the model-based design of dissolution-precipitation processes. The use of SAFT-γ Mie to support the design of physical recycling processes is investigated in our current study, building on previous work on multiobjective optimization (MOO) to understand the tradeoffs between different objective functions, such as the solvent toxicity [11], the crystal yield and the solvent consumption [9].

The CAMPD framework is applied for the first time to solvent-based dissolution and precipitation recycling of plastics. As case studies, we explore the selection of optimal solvents and process conditions that minimize the energy requirements for the recycling of two types of low-density polyethylene (LDPE) while ensuring a homogeneous liquid polymer–solvent mixture is formed. This scenario is relevant to a plastic recycling problem where LDPE is mixed with solid waste impurities, such as secondary plastics and the presence of metals or cardboard [12]. We provide a ranked list of optimal solvents and process conditions and explore the trade-offs between the energy requirements and two key solvent properties: toxicity and viscosity. Furthermore, we analyse the relationship between the objective function and the precipitation temperature.

## DESIGN METHODOLOGY

### Problem definition

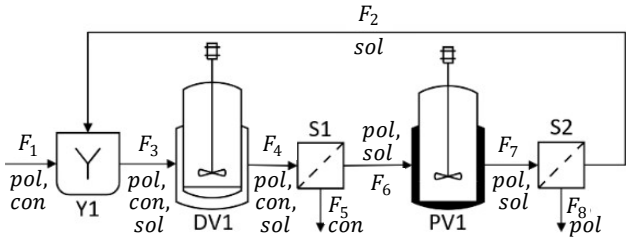

**Figure 1:** Schematic of an idealised polyethylene dissolution and cooling precipitation flowsheet.

In the CAMPD problem we focus on a general approach to designing a polymer dissolution and precipitation system. This involves identifying the optimal solvent molecules, weight fractions, and process temperatures to minimize the performance objective, which in this case is the energy of dissolution. The process configuration is shown in Figure 1, assuming perfect separation in each unit. A stream of plastic waste consisting of LDPE ($pol$) and a solid contaminant ($con$), with a flowrate $F_1$ , is mixed with a solvent ($sol$) recycle stream $F_2$ in a mixer Y1. The two-phase slurry $F_3$ is fed to a dissolution vessel DV1, where heat is provided through a heating jacket to dissolve the solid polymer. The outlet of DV1 is passed through a filtration unit S1, where the undissolved solid contaminants are filtered out. The filtrate $F_6$ then enters a precipitation vessel PV1, where the polymer–solvent mixture is cooled down to obtain solid polymer. Finally, the solvent is recovered in filter S2, and the purified

**Table 1:** Key model equations.

|---|---|---|
| Energy consumption | $Q = Q_{pol} + \left[F_4^L\, h^L(T_4, P_4, x_4^L) - F_3^L x_{3,pol}^L h_{pol}^L(T_3, P_3) - F_3^L x_{3,sol}^L h_{sol}^L(T_3, P_3)\right]$ | (1) |
| Heat required to obtain a liquid polymer at $T_3$ | $Q_{pol} = F_3^s x_{3,pol}^s [c_{P,pol}^S (T_{pol}^{\text{fus}} - T_3) + \Delta h_{pol}^{\text{fus}}] + F_3^L x_{3,pol}^L [h_{pol}^L(T_3, P_3) - h_{pol}^L(T_{pol}^{\text{fus}}, P_3)]$ | (2) |
| Solid–liquid equilibrium model | $\ln \boldsymbol{x}_{i,pol}^L + \ln \gamma_{i,pol}(T_i, P_i, \boldsymbol{x}_i^L) = -\frac{\Delta h_{pol}^{\text{fus}}}{R}\left[\frac{1}{T_i} - \frac{1}{T_{pol}^{\text{fus}}}\right],\ i = 4{,}7,\ 0 \le w_{7,pol}^L \le 10^{-6}$ | (3) |
| Polymer and solvent form a single stable liquid phase | $\tilde{S}_l\ (T_4, P_4\ , x_4^L) = 1$ | (4) |

polymer leaves S2 in stream $F_8$.

## Model formulation

All separations are assumed to be perfect. The polymer is a solid in streams $1, 3, 7,$ and $8$, and in the liquid phase in streams $4$ and $6$. Stream $2$ is pure solvent, stream $5$ pure solid contaminant and stream $8$ pure polymer. The material balances for the system are easily derived and not shown.

Other key model equations are shown in Table 1. $Q$ is the energy consumption in dissolution vessel DV1, neglecting any energy required for agitation as well as the enthalpy change due to the solid contaminant. It is derived from an energy balance around DV1, given as Equations (1) and (2) in Table 1, where $F_i^L$ denotes the liquid flowrate in stream $i$, $F_i^S$ the corresponding solid flowrate, and $h_i^L(T_i, P_i, \boldsymbol{x}_i^L)$ the liquid-phase enthalpy of stream $i$ at temperature $T_i$, pressure $P_i$ (here assumed to be atmospheric throughout) and mole fraction vector $\boldsymbol{x}_i^L$. $h_{i,pol}^L$ and $h_{i,sol}^L$ denote the pure component liquid-phase enthalpies for the polymer and the solvent, respectively. $\boldsymbol{x}_{i,k}^L$ denotes the mole fraction of component $k$ ($pol$ or $sol$) in the liquid phase in stream $i$, while $\boldsymbol{x}_{i,pol}^S$ denotes the corresponding solid-phase mole fraction. $Q_{pol}$ is the enthalpy change of the polymer on going from solid to liquid. $c_{P,pol}^S$ is the solid-phase molar heat capacity of the polymer, $T_{pol}^{\text{fus}}$ is the melting temperature of the polymer, and $\Delta h_{pol}^{\text{fus}}$, its enthalpy of fusion at $T_{pol}^{\text{fus}}$.

Solid–liquid equilibrium must hold in DV1 and PV1. This is enforced by Equation (3). $\gamma_{i,pol}(T_i, P_i, \boldsymbol{x}_i^L)$ is the activity coefficient of the polymer at the specified conditions, and $R$ is the ideal gas constant. In addition, the mass fraction of polymer in the liquid phase in PV1 (i.e., in $F_7^L$) is set to be very close to zero to ensure full precipitation.

Finally, in order to ensure that the polymer and solvent form a single stable liquid phase in DV1, a logical stability function $\tilde{S}_l$ $(T_4, P_4, \boldsymbol{x}_4^L)$ is constrained to $1$. A value of $1$ indicates that a temperature-pressure flash calculation at the specified conditions does not detect a second liquid phase or a vapour, while 0 indicates the presence of another fluid phase.

SAFT-$\gamma$ Mie is used to calculate the activity coefficients and the liquid-phase enthalpies with group interaction parameters taken from [8] or combining rules [8] where no group parameters have been developed.

## CAMPD formulation

The model equations are integrated within a Mixed Integer Nonlinear Programming (MINLP) that takes as input a list $\mathcal{L}$ of candidate solvents. Each solvent $l$ is characterized by a set of functional group numbers, $n_{g,l}$, $g \in G$, where $G$ is the set of SAFT-$\gamma$ Mie groups, as well as its toxicity $\tau_l$, taken as $\text{LC}_{50}$ from [16], and an experimental viscosity $\eta$ at $298\ \text{K}$, taken from the DETHERM database [17]. A binary variable $y_l$ is introduced to denote whether solvent candidate $l$ is selected and is defined such that only one solvent can be chosen:

$$\sum_{l \in \mathcal{L}} y_l = 1. \tag{5}$$

Assignment constraints are used to set the values of the SAFT-$\gamma$ Mie group numbers, the toxicity, and the viscosity to be those of the selected solvent. The number of groups of type $g$ in the solvent is given by

$$n_g = \sum\nolimits_{l \in \mathcal{L}} y_l n_{g,l}, \tag{6}$$

and the toxicity and viscosity are given by

$$\tau = \sum\nolimits_{l \in \mathcal{L}} y_l \tau_l; \quad \eta = \sum\nolimits_{l \in \mathcal{L}} y_l \eta_l \tag{7,8}$$

A constraint is also imposed on the maximum mass fraction of polymer in DV1, to prevent the formation of gel.

The problem is formulated using up to two objectives that must be minimized, one of which is always $Q$ and the other $\tau$ or $\eta$.

# CASE STUDIES

## Case study description

LDPE is one of the most widely present polyolefins in plastic products and is highly valued for its durability and versatile nature. However, its durable qualities make its recycling challenging and energy intensive. Two molecular weights of polymer are considered, $270\ \text{kg mol}^{-1}$ and $4\ \text{kg mol}^{-1}$, and the designs are developed on a basis of $1\ \text{kg}$ of polymer. The primary objective of the design problems considered is to identify optimal solvents and corresponding process conditions to minimize the energy consumption, $Q$, in a process to remove a solid contaminant from LDPE via dissolution-precipitation. A secondary objective is also considered in some cases, chosen as either the minimization of the toxicity $\tau$ or of the viscosity $\eta$.

The specific heat capacity $c_{P,pol}^S$ is assumed to be independent of molecular weight and set equal to the experimental value measured at $1\ \text{atm}$ and $298\ \text{K}$, $46.5\ \text{J mol}^{-1}\ \text{K}^{-1}$ [15]. The experimental values for $T_{pol}^{\text{fus}}$ values are either obtained through differential scanning calorimetry (DSC) in our current work or from [13], and the experimental values for $\Delta h_{pol}^{\text{fus}}$ are obtained from [14] (see Table 2).

Polythermal solubility measurements are conducted for selected polymer-solvent mixtures, corroborating the reliability of the SAFT-$\gamma$ Mie model.

**Table 3:** Ranking of optimal solvents generated with integer cuts for both polymers considered. Energy consumption ($Q$), polymer mass fraction ($w$), dissolution temperature ($T_4$), mixture stability ($\tilde{S}_l$), solvent toxicity ($\tau$) [16], and viscosity ($\eta$) [17] at the solution of the CAMPD problem with $T_7$ =298.15 K.

| LDPE | Rank | Solvent selected? | $Q$/kJ | $w_{pol}$ | $T_4$ /K | $\tau(-\log[\mathrm{LC}_{50}])$ | $\eta$ / (mPa s) |
|---|---|---|---|---|---|---|---|
| 4 kg mol$^{-1}$ | 1 | Decalin | 366.03 | 0.3 | 341.05 | 3.88 | 2.47 |
| | 2 | Mesitylene | 401.38 | 0.3 | 343.42 | 4.19 | 0.66 |

| 270 kg mol$^{-1}$ | 1 | Decalin | 439.04 | 0.3 | 356.07 | 3.88 | 2.47 |
| | 2 | Mesitylene | 458.70 | 0.3 | 356.33 | 4.19 | 0.66 |
| | 3 | Xylene | 462.83 | 0.3 | 357.31 | 3.81 | 0.61 |
| | 4 | Toluene | 479.05 | 0.3 | 359.85 | 3.42 | 0.55 |
| | 5 | Cymene | 582.59 | 0.3 | 373.93 | 3.61 | 0.82 |

**Table 2:** Molecular weight and melting properties of the polymers of interest [14]. [*] denotes the property is measured in our current work.

| | **Short LDPE** | **Long LDPE** |
|---|---|---|
| $\boldsymbol{M_w/(\mathrm{kg\ mol^{-1}})}$ | 4 | 270 |
| $\boldsymbol{u}$ /(-) | 142 | 9623 |
| $\boldsymbol{T_i^{\mathrm{fus}}/\mathrm{K}}$ | 375.15 [*] | 389.15 [13] |
| $\boldsymbol{\Delta h_i^{\mathrm{fus}}/(\mathrm{kJ\ mol^{-1}})}$ | 8.22$u$ [14] | 8.22$u$ [14] |

To construct the list of candidate solvents we conduct an HSP analysis to identify solvents that exhibit low relative energy difference (RED) values with LDPE, using a threshold of 0. The solvents used in dissolution and precipitation experimental studies reported by Li et al. [1] and Ügdüler et al. [4] are considered. This results in 17 candidate molecules. To evaluate the effects of the precipitation temperature ($T_7$) on the design problem, ten design scenarios are considered with different allowed temperature differences between DV1 and PV1.

## Results and discussion

The formulation is implemented in gPROMS Process version 2023.1.0 and solved using the MINLPOA (outer approximation) local solver. The built-in stability function is used for Equation (4).

The ranked list of optimal solutions shown in Table 3, obtained for a base case of $T_7 = 298.15$ K, indicates that decalin, mesitylene, xylene, toluene, benzene and cymene are promising solvent candidates that require the least energy to dissolve LDPE. The first four solvents are the same for both polymer samples, while benzene and cymene rank fifth for the $4\ \mathrm{kg\ mol^{-1}}$ LDPE and 270 kg mol$^{-1}$ LDPE, respectively. The polymer solubility ($w_{pol}$) reaches the $0.30$ upper bound in each iteration, indicating that high solubility and, thus, low solvent use minimizes the energy requirements of the process. Trade-offs between $Q$ and $\tau$, and between $Q$ and $\eta$, are explored by solving bi-objective problem using the $\varepsilon$-constraint

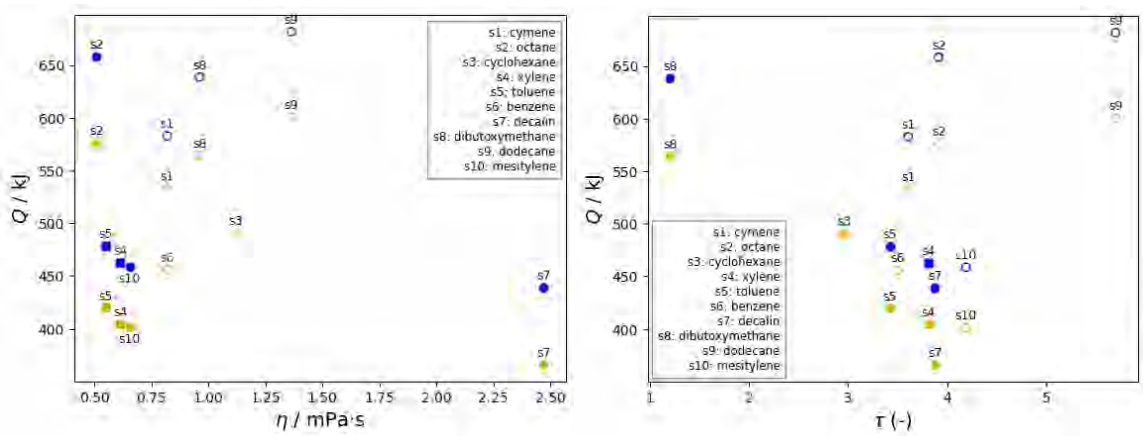

**Figure 2:** Pareto optimal solutions (filled circles) obtained when solving the optimization problem with two competing objectives: energy consumption $Q$ and solvent viscosity $\eta$ (left), and energy consumption $Q$ and solvent toxicity $\tau$ (right). Empty circles depict feasible solvents. The colour indicates the type of polymer: 270 kg mol$^{-1}$ polyethylene (blue) and 4 kg mol$^{-1}$ polyethylene (orange). Note that the filled circles denote Pareto points found via the $\varepsilon$-constraint method and the filled squares Pareto points found only via integer cuts due to the $\varepsilon$ steps.

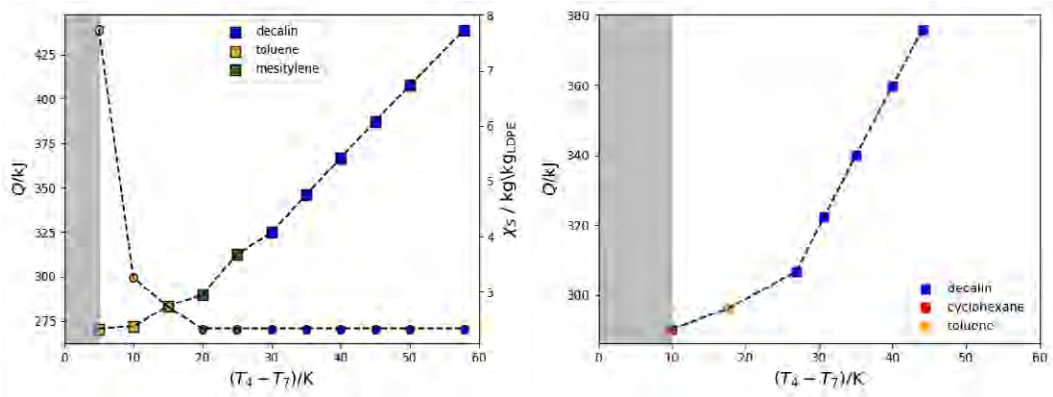

**Figure 3:** Minimum energy requirement $Q$ as a function of the minimum allowed temperature difference between dissolution and precipitation $(T_4 - T_7)$ for 270 kg mol$^{-1}$ LPDE (left plot) and 4 kg mol$^{-1}$ LPDE (right plot). $\chi_S$ indicates the solvent inventory. The point with the largest value of $(T_4 - T_7)$ corresponds to the temperature difference when $T_7$ =298.15 K. Gray shading indicates infeasible regions. The dashed curves are included to aid visualisation.

method for 10 equally spaced $\varepsilon$ values. Pareto optimal solvents are depicted in Figure 2, together with feasible solvents. These were obtained by adding integer cut inequality constraints to the optimization problem. According to the Multi Objective Optimization (MOO) solutions, mesitylene may be a more suitable solvent to dissolve polyethylene than decalin due to its significantly lower $\eta$ with only a slightly higher $Q$. A solvent with a lower viscosity is desirable as it may offer faster dissolution and lower processing costs due to a lower energy input for pumping and mixing. On the other hand, no solvent offers a significantly lower toxicity than decalin without a large increase in energy requirements. However, toxicity may be considered less critical than viscosity if the polymer is fully recovered and the solvent is efficiently recycled, minimizing solvent loss to the environment. Employing cymene, a bio-derived solvent that ranks fifth (cf. Table 3) for $270\ \mathrm{kg\ mol^{-1}}$ LDPE, offers a potentially sustainable alternative to conventional organic solvents by reducing the reliance on fossil feedstocks for solvent production—aligning with the core objective of polymer recycling to promote environmental sustainability. On the other hand, a high recycling efficiency can reduce the greenhouse gas emissions associated with the need for fresh solvent input, potentially justifying the use of conventional organic solvents, particularly if they contribute to lower overall process energy demands. A broader lifecycle analysis is required to quantify these trade-offs. Dibutoxymethane, the least toxic solvent considered is associated with a high energy consumption, likely due to its polarity. An expanded solvent design space may help us to identify additional feasible solvents and explore the empty regions of the multiobjective spaces shown in Figure 2. This could be achieved by allowing the design of solvent mixtures [18].

The impact of the precipitation temperature, $T_7$, on the energy consumption is investigated by varying the temperature limit constraint. As shown in Figure 3, by reducing the extent of cooling in PV1, the optimal solvent, toluene for $270\ \mathrm{kg\ mol^{-1}}$ LDPE and cyclohexane for $4\ \mathrm{kg\ mol^{-1}}$ LDPE, can be supplied to DV1 at a higher temperature and thus the energy consumption decreases. This trend is a result of the steep decrease in solubility of LDPE as a function of temperature in the vicinity of the pure solvent limit. Based on the analysis in Figure 3, the optimal operating temperatures for PV1 are $347.19\ \mathrm{K}$ for $270\ \mathrm{kg\ mol^{-1}}$ LDPE and $342.54\ \mathrm{K}$ for $4\ \mathrm{kg\ mol^{-1}}$ LDPE when a margin of at least 5 K between $T_4$ and $T_7$ is enforced. These guarantee $100\%$ LDPE precipitation and energy requirements of $283.32\ \mathrm{kJ}$ and $290.37\ \mathrm{kJ}$ for $270$ and $4\ \mathrm{kg\ mol^{-1}}$ LDPE, respectively. The operating point for $270\ \mathrm{kg\ mol^{-1}}$ LDPE offers a good compromise between $Q$ and a solvent inventory ($\chi_S$) equal to $3.26$. While for all $4\ \mathrm{kg\ mol^{-1}}$ LDPE points a $\chi_S$ of $2.33$ is achieved.

## CONCLUSIONS

We have developed a general formulation for the optimal process and solvent design for solvent-based dissolution and precipitation recycling of plastics based on a CAMPD framework with a simple initial process model and rigorous thermodynamics. In this framework, the optimal solvent candidate, the polymer solubility, and the dissolution (and precipitation) temperatures required to minimize the energy consumption can be obtained simultaneously. The general model is applied to the dissolution and precipitation of two types of LDPE, for which separate ranked lists of optimal solvents are produced. In both cases, only apolar solvents appear in the solvent rankings, with decalin identified as minimizing the energy consumption. MOO is employed to consider the trade-offs between the energy consumption and toxicity or viscosity of the solvent. Mesitylene is found to have a lower viscosity and similar $Q$ when compared to decalin. The

simultaneous optimization of the dissolution and precipitation temperatures leads to improved results when compared to the case where the precipitation temperature is fixed and highlight the impact on the solvent inventory, which also has implications on the cost and environmental impact of the process and have not yet been quantified.

The current study provides a foundation for optimizing the dissolution-precipitation process, to make this recycling technology both economically viable and environmentally friendly. In future work, we plan to extend the design formulation to treat multilayer plastic waste, including polyethylene mixed with polypropylene, and solvent mixtures. We also aim to include a technoeconomic and lifecycle analysis for a more advanced flowsheet of the physical recycling process.

## ABSTRACT

Biomass conversion to chemical derivatives and essential intermediates is regarded as a long-term strategy for the chemical sector. Among the numerous valuable chemicals obtained from biomass, 5-hydroxymethylfurfural (HMF) is considered an industrially relevant compound due to its capacity to be converted into a variety of value-added chemicals. Compared to conventional catalytic synthesis, bio-catalysis has emerged as a potential greener substitute for HMF conversion to value-added compounds. HMF conversion through bio-catalysis, although more sustainable, seldom leads to the production of a single derivative. Thus, the development of efficient purification and separation processes of several products are crucial to scalability. The downstream process for the novel enzymatic conversion of HMF to high value-added chemicals (i.e., 1-phenylethylamine, 2,5-bis(hydroxymethyl)furan, 1-phenylethylalcohol, and 5-(aminomethyl)-2-furanmethanol) was designed by means of rigorous simulations in Aspen Plus®. The proposed process resulted in product streams with 97 wt% or larger for their respective component, and at least 95% product recovery is attained for each value-added HMF derivative. The global greenhouse gas emissions for the manufacture of a kg of product is 2.26 $kg_{CO_2e}$/ $kg_{product}$, while 0.086 $m^3_{wastewater}$/ $kg_{product}$ is generated. The proposed downstream sequence offers an overview of the feasibility for the scalability of the enzymatic process, crucial in developing sustainable bioprocesses.

## 1. INTRODUCTION

Sustainable development is a concept that responds to the challenges posed by the needs of a rapidly growing population and rapidly increasing industry demands for petroleum-based carbon sources for energy and chemical synthesis [1].

Biomass has become an attractive carbon-neutral resource (as its emissions are of biogenic origin) due to its widespread availability (approximately 18 trillion tons on land and 4 billion tons of aquatic biomass) and renewable nature [2]. One particularly valuable chemical produced from glucose or fructose obtained from biomass is HMF [3]. Due to fructose's high cost and low availability, glucose can replace fructose as a feedstock to synthesise HMF. This process requires an additional step for the isomerisation of glucose to fructose. Current research focuses on biowaste and lignocellulosic biomass as feedstock for HMF synthesis due to their low cost, lack of impact on the food chain supply, and carbon-neutral nature. Processes starting from biowaste employ a pretreatment step followed by hydrolysis to liberate glucose from the starting polysaccharides [4,5].

HMF is an important intermediate in synthesising renewable polymers, pharmaceuticals, resins, solvents, fungicides and fuels. HMF is composed of a furan ring on which hydroxymethyl and formyl functional groups are grafted. Hence, complex chemicals can be obtained from simple chemical reactions such as oxidation, reduction, esterification or condensation [6]. As such, HMF has been evaluated in the Top 10 biobased chemicals by the U.S. Department of Energy [1].

The chemical synthesis of HMF derivatives typically involves metal-based catalysts (Pd, Ru, Pt, Mn, V and Au), elevated reaction temperatures and pressures, and organic solvents like dimethyl sulfoxide,

dimethylformamide, or toluene [5,7].

In contrast, enzymes are recognized as an alternative to chemical catalysis due to their alignment with the twelve principles of green chemistry. These biocatalysts require mild reaction conditions for temperatures and pressures and utilize water as a solvent. Additionally, enzymes demonstrate high specificity, which helps eliminate the need for protection and deprotection steps. They are also characterized by low toxicity and generate less harmful waste, primarily in the form of wastewater [8].

The oxidative products, including 5-hydroxymethyl-2-furancarboxylic acid, 2,5-diformylfuran, 5-formyl-2-furancarboxylic acid, and 2,5-furandicarboxylic acid, find applications in the polymer industry (such as polyurethanes, polyesters, copolyesters, polyamides, polyimides, and epoxy resins) [7]. Compounds such as 2,5-dihydroxymethylfuran and 2,5-bis(hydroxymethyl)furan (BHMF) are derived from HMF through hydrogenation, and both are valuable in polymer synthesis, particularly for polyurethanes, polyesters, and polycarbonates [7,9]. BHMF could also be utilized as a fuel source[9].

Various enzymatic oxidase systems, have been evaluated for their ability to produce oxidative products from HMF. These enzymatic systems showcase high conversion rates of HMF, however, in most cases several products are obtained. As such, product separation and purification play an essential role in scalability [10].

Chemical synthesis already produces value-added derivatives of MHF at an industrial scale [11]. For the feasibility of enzymatic synthesis on an industrial scale, downstream techniques that are both cost-effective and process-efficient need to be developed [9]. In conclusion, the viability of enzymatic synthesis as a green alternative is reliant on developing efficient downstream processes. The plethora of studies that aimed to develop new and effective enzymatic catalysts seldom researched or discussed the downstream processes necessary to separate and purify the obtained products.

The current study aims to bridge the mentioned gap and design a sustainable downstream process considering a novel enzymatic pathway for the conversion of HMF to value-added chemicals. The separation and purification process of a mixture of four products obtained from an enzymatic conversion of HMF to value-added products was designed in Aspen Plus®. To the best of the authors' knowledge the separation of 1-phenylethylamine (PEAM), BHMF, 1-phenylethylalcohol (PEA), and 5-(aminomethyl)-2-furanmethanol (HMFA) has yet to be discussed in the literature.

## METHODOLOGY

The enzymatic conversion of HMF and 1-phenylethylamine (PEAM) was studied which results in a mixture of BHMF, 1-phenylethylalcohol (PEA), PEAM and 5-(aminomethyl)-2-furanmethanol (AMFM).

For the separation of alcohols and amines that come from the bioreactor, ion exchange was opted for. Mineral acid (i.e., HCl) solution is added to the mixture until pH of 2 is reached in order to form the salts of the amines, while the alcohols remain in a neutral state. As such, a cation exchange material can be utilized to form an ionic bond with the amines while the alcohols pass through the ion exchange separator.

The amines can then be recovered when regenerating the cation exchange material, which involved the use of a mineral bases (i.e., NaOH). As a result, NaCl would form in the mixture which was removed before continuing with other product purification processes. In order to eliminate the mineral salt from the solution, their crystallization was considered by evaporation of the mixture to obtain an oversaturated solution of higher temperature. This solution, when cooled results in the crystallization of said mineral salt that was filtered from the aqueous solution.

The next steps in the downstream process relate to the separation and purification of the products. In case of the stream containing the alcohol products, BHMF can be separated from the aqueous solution through distillation. As PEA forms a well-known azeotrope with water (Figure 1), these compounds cannot be separated in the same manner, a liquid-liquid extraction process was opted for. Hexane was utilized as the solvent, as it was demonstrated to be the most efficient in similar systems [12]. This is further separated from hexane by a distillation column.

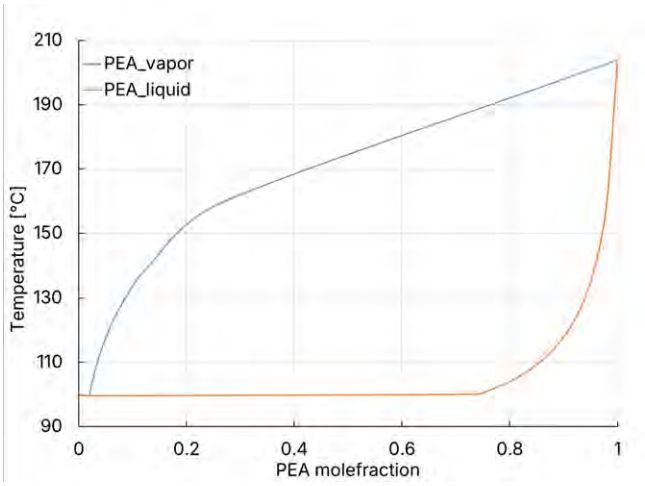

**Figure 1.** T-xy diagram of the PEA and water binary system.

On the other side, the aqueous solution containing the amine products goes through a crystallization process similar to the above mentioned to rid the solution of the mineral salts. In this case the separation of each

individual product from the aqueous solution can be performed by distillation. However, the intensification of these processes can be achieved through fractional distillation. The previously described downstream separation and purification processes are presented in Figure 2.

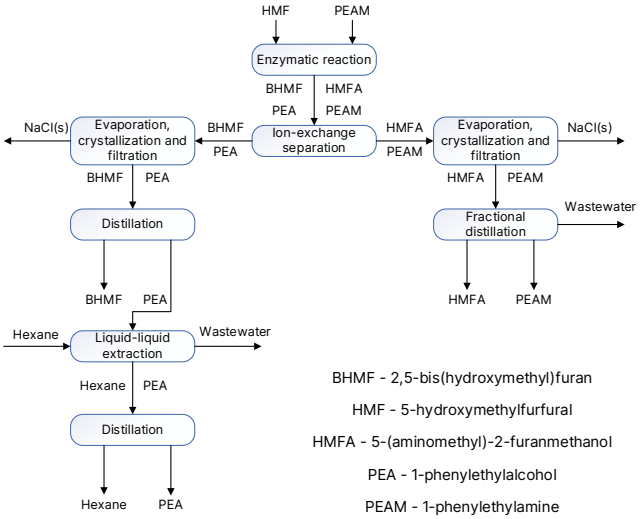

**Figure 2.** Simplified flowsheet of the HMF biocatalytic transformation to value-added products, their separation and purification.

The design of the separation and purification processes took into account laboratory scale experimental results, as well as the following assumptions. Firstly, full conversion of HMF is considered resulting in an equimolar mixture of BHMF, PEA, PEAM and HMFA. Secondly, the separation of amines and alcohols was assumed to be ideal in the ion exchange system. Thirdly, the solubility of the mineral salt was considered to be solely influenced by the water's mass fraction of the solution.

## RESULTS AND DISCUSSION

The proposed downstream process (Figure 3) was simulated in Aspen Plus® V11 software environment. The ion-exchange separation process (IEX) is presented in a simplified form as it was not the main focus of the current study. ELECNRTL and SOLIDS property methods were utilized to model the various processes involved. ELECNRTL was used as it is the most flexible property technique since it can handle both very low and high concentrations of aqueous and mixed solvent systems. The same method cannot be used to compute the characteristics of both solids and fluid phases. Therefore, for computations involving solid components, the SOLIDS property approach was employed. The incoming, purified and other relevant material streams of the simulation are summarized in Table 1.

It can be observed that the salt (i.e., NaCl) could not be fully removed through crystallization and filtration, and it will influence the purity of the bottom product streams of the first distillation process both for the amine and alcohol products (i.e., AMFM and BHMF).

In both cases, the process occurs under vacuum

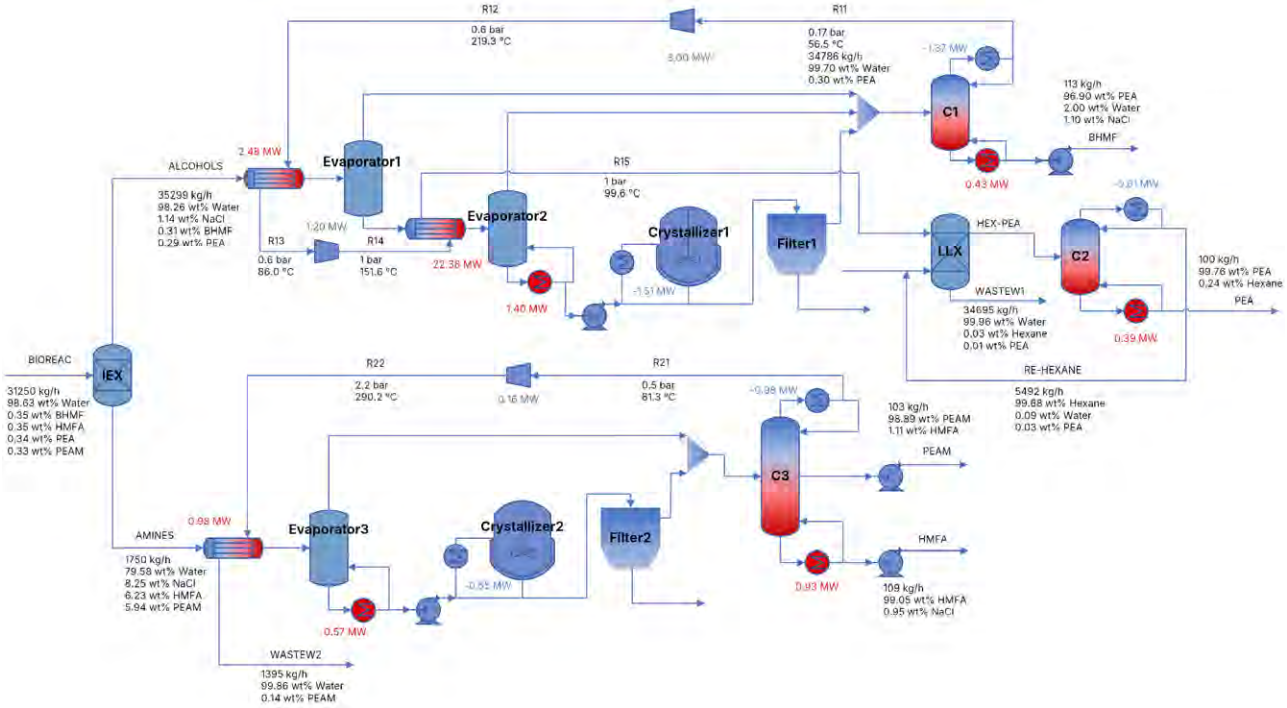

**Figure 3:** Schematic of product separation and purification processes implemented in the Aspen Plus® simulation

**Table 1:** Parameters and composition results of the most important streams from Figure 3.

| Stream | BIOREAC | HMFA | BHMF | PEA | PEAM | RE-HEXANE | HEX-PEA |

conditions in order to maintain the obtained products in their reported thermal stability range. In regards to BHMF, the streams containing this compound were kept at temperatures below 120 °C [13]. A partial-vapor condenser was set for both columns (i.e., C1 and C3) in order to ensure the desired reflux ratio, as well as to utilize the vapor distillate in a heat pump system to preheat the respective streams before the evaporation process. As the streams containing BHMF had to be maintained at lower temperatures, this thermal integration could only be realized in two steps, as it can be observed in Figure 2.

The optimal conditions for each unit operation were searched for by conducting sensibility analysis for each design parameter that applied to the respective unit operation (e.g.., reflux ratio, heat duty, number of stages, feed stage, by-product stage, etc.). In this manner, the desired product purity of 97 wt% or higher was obtained for all three products that could be separated in the first distillation steps (i.e., BHMF, PEAM and HMFA). Higher purity product can be obtained by evaporating a larger portion of water, thus improving the crystallization process of NaCl. However, the trade-off with the thermal energy required for the evaporation has to be considered, and the temperature constraints should also be taken into account. In case of the amine products, a single fractional distillation column was utilized for their separation and purification. The parameters of this ternary system were defined based on the study by Wen et al. 2017 [14].

The separation and purification of PEA further required a liquid-liquid extraction due to the azeotrope it forms, and a distillation process afterwards. Hexane was utilized for the extraction of PEA, based on its reported close to ideal recovery rate of PEA, also validated by the ternary diagram shown in Figure 4. The proposed process extracted more than 95% of PEA from the aqueous solution. A more efficient extraction can be achieved with a larger quantity of hexane, however that would also imply an increase in the reboiler duty of the distillation column that follows. Although the usage of an organic solvent influences the sustainability of the process, it is recovered in a high purity stream which can be recycled. In this manner, high purity PEA is obtained with a weight percent of 99.

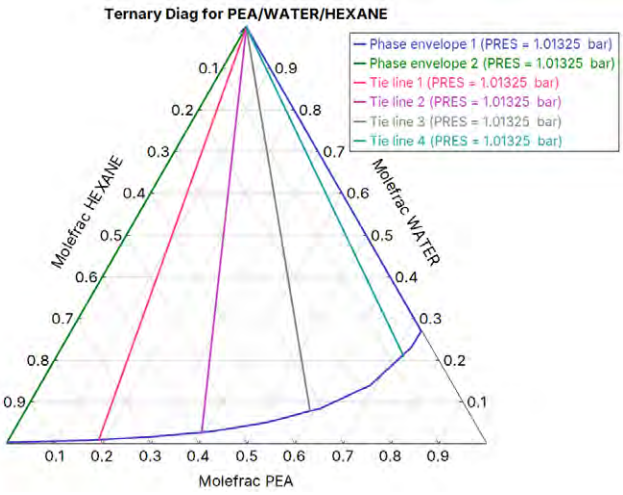

**Figure 4:** Ternary diagram with tie lines for the PEA-water-hexane system at atmospheric pressure.

Other than the purity of product streams, It is also important to note that the four compounds of interest are recovered from the reaction mixture in 98.9%, 99.8%, 95.3% and 96.4% for HMFA, BHMF, PEA and PEAM, respectively. To measure the sustainability of the downstream process, the specific material intensity, energy intensity, wastewater intensity, greenhouse gas (GHG) emissions, toxic emissions and pollutant emissions were calculated for a unit of output. The unit of output was

considered as a kg of product (i.e., HMFA, BHMF, PEA and PEAM).

The material intensity refers to the mass of wasted materials per unit of output. The non-recovered products were considered as wasted material resulting in a value of 0.020 $kg_{wasted}/kg_{product}$. The energy intensity criterion took into account both thermal and electric energy consumers (e.g., pumps, reboilers, etc.). The proposed process requires 4.36 MW electrical energy and 3.72 MW thermal energy. The overall energy requirement was calculated utilizing an electrical-to-thermal conversion factor of 2.5 [15] resulting in a value of 34.88 kWh/ $kg_{product}$. This value is mostly due to the low concentration of the mixture after reaction, the incoming stream containing 30.82 tonnes of water. The significant energy intensity does not thwart the feasibility of the process as the prices of the obtained products range from 0.5$/kg to 50$/kg.

In the calculation of wastewater intensity water that requires wastewater treatment per kilogram of product was considered (i.e., stream WASTEW1 and WASTEW2) resulting in 86.04 $kg_{wastewater}$/ $kg_{product}$. The large wastewater intensity can be attributed to the enzymatic process, which leads to a mixture of products from 20 to 30 mM. In addition, the usage of less concentrated solutions in the downstream process necessary to avoid the formation of Bronsted acids/bases (e.g., 2M NaOH) increases both the processes' energy and wastewater intensity.

For the calculation of GHG emissions, only off-site emissions were considered as there are no gaseous emission in the designed process. The off-site emissions considered were those related to electricity and steam generation. For calculations, the data from 2023 regarding EU-27 GHG emissions intensity for electricity generation used, i.e., 0.21 $kg_{CO_2e}$/kWh [16]. The emission factor for steam generation was considered as 19.46 $kg_{CO_2e}$/MWh [17]. The GHG emissions value per unit of output is 2.26 $kg_{CO_2e}$/ $kg_{product}$. These emissions could be reduced utilizing regenerable energy sources, however a more in-depth study is required to investigate the trade-off with other sustainability indices.

Toxic emissions were calculated as the mass of toxics and hazardous materials for the operating personnel present in the output streams per unit of output, other than the intended product streams. The compounds' toxicity was determined based on their material safety data sheet, as such, toxic emissions value of 0.042 $kg_{toxic}$/ $kg_{product}$ was obtained. Pollutants were considered as the non-toxic material present in the output streams, except the four product streams. In this manner, pollutant emissions were calculated as $2.00 \square 10^{-5}$ $kg_{pollutant}$/ $kg_{product}$. The negligible amount of pollutants is due to the toxicity of most materials present in the system, therefore special attention should be paid towards the treatment of generated wastewater.

## CONCLUSIONS

The proposed downstream process concerning the four value-added HMF derivatives (HMFA, BHMF, PEA and PEAM) showed that each product can be separated with purities of at least 97 wt% comparable to those found on the market, obtained through non-enzymatic pathways. This efficient downstream configuration presents an overall recovery of over 98% of the value-added derivatives.

The studied process is suitable for production of natural chemicals, which can be essential taking into account the use of the obtained products such as food and pharmaceutical industry. Although high value-added products are obtained in the studied system, an economic assessment is required to investigate the influence of the proposed separation and purification process on the feasibility of the industrial scale from an economic standpoint, which is the scope of future work.

## ACKNOWLEDGEMENTS

This study was supported from the project "Advanced (multi)-enzymatic synthesis and purification processes for bio-based furan derivatives – ASPIRE" (CF 25/14.11.2022).

## ABSTRACT

Engineering can be made simple and more impactful by observing and understanding how organisms in nature solve eminent problems. For example, scientists around the world have observed green plants thriving without organic food inputs using the complex photosynthesis process to kick-start a self-sustaining biochemical food chain. In this study, two biological analogues for advanced water treatment, i.e., visible-light photocatalysis using porphyrin-$Bi_{12}O_{17}Cl_2$ and $BiOIO_3$ compounds and interfacial solar desalination by a by Reduced Graphene Oxide-Black $TiO_2$ (rGO-Black $TiO_2$) were investigated. For the visible-light photocatalytic process for dye decolouration, a porphyrin@$Bi_{12}O_{17}Cl_2$ system was applied to successfully degrade Rhodamine B dye in batch experiments, achieving up to 79% degradation within 240 minutes. These results show that more advances and more efficient engineered systems can be achieved by observing nature and how these systems have survived over billions of years. The rGO-Black $TiO_2$ system achieved increases in temperature for 25oC to 60oC in less than 5 seconds. Based on these observations, the research group from the Water Utilisation Group at the University of Pretoria have studied and developed fundamental processes for the degradation and remediation of unwanted compounds such as disinfection byproducts (DBPs), volatile organic compounds (VOCs) and pharmaceutical products from water.

## INTRODUCTION

### Desalination

The crucial demand for sustainable and eco-friendly desalination technologies propelled by renewable energy is essential for overcoming global water scarcity. Solar desalination has been recognised as a prominent technology as it exploits solar energy to produce clean water through sufficient thermal management and the localisation of heat using a solar absorber [1].

Currently, Reverse osmosis (RO) is the most broadly used process for saline water treatment, as well as industrial and drinking water. Roughly 53 % of the feed water for RO systems is seawater followed by mostly brine, fresh water, and treated wastewater. The multi-stage flash (MSF) and multi-effect distillation (MED) are the second and third most used technologies, respectively. Reverse osmosis, MED and MSF technologies constitute 94 % of the overall desalinated water produced. Solar-powered desalination via photovoltaic desalination and solar thermal evaporation constitute less than 1 %. Of the global freshwater desalinated, membrane-based processes account for 71 % of the total capacity produced and thermal processes make up the other 29 %. This displays the historical mass application of membrane-based desalination technologies. The advantage of utilising seawater RO or brackish water RO is due to the total energy costs of seawater RO (3 – 4 kWh·m-3) and brackish water RO (0.5 – 2.5 kWh·m-3) desalination being lower than the energy required for thermal desalination

technologies such as MSF (14 – 25.5 kWh·m-3) and MED (6.5 – 11 kWh·m-3) which requires the use of electrical and thermal energy. The energy cost difference between seawater RO and brackish water RO is due to brackish water having a substantially lower osmotic pressure compared to seawater and thus requiring less energy. The high salinity concentration of seawater limits the osmosis process due to affecting the osmosis pressure, requiring more energy. However, the economic cost of seawater desalination using MSF or MED is proportionate to that of RO as a result of the lower investment costs. The availability and cost of energy account for more than 30 % of the total desalination cost. It is estimated that the present global desalination capacity roughly consumes a minimum of 75.2 TWh annually, which is equivalent to 0.4 % of the global electricity usage.

Solar-driven absorbers generally involve a mono or bi-layer design, comprising a solar-light absorber and a floating substrate. The solar absorber converts incident light into heat energy, while the floating substrate facilitates water transfer to the active vapour generation site and minimising heat energy loss through conduction [2].

The ongoing challenge of salt accumulation on the surface of the solar absorber as a result of the high salt concentration in the bulk water body leads to the obstruction of light absorption, subsequently hindering freshwater vapour release and efficient photothermal efficiency [1].

Recent research motivated by the modification of natural saline inhabiting vegetation (halophyte plants) has been employed to embrace the biomimetic principle for numerous engineering practices such as freshwater steam generation and salt rejection [3] Naturally, plants possess inherent capabilities which harness solar energy and groundwater in the photosynthesis process to create oxygen and carbohydrates. For example, trees make use of their trunk and leaves for continuous nutrient and water transfer for nourishment. This principle has inspired wood-based solar absorbers for solar steam generation. For example, carbon nanotube-modified flexible wood membranes [4] and graphite-coated wood solar absorbers [5] have demonstrated great potential.

Sun *et al.* proposed a three-dimensional (3D) solar evaporator inspired by the outer shell structure of Vasticardium vertebratum, demonstrating a 95% evaporation efficiency and a superb evaporation rate of 1.73 kg/m$^2$·h while effectively preventing salt accumulation [3]. Furthermore, mangrove-inspired configurations [6] provide promising potential aimed at bio-mimicking solar absorbers. This is driven by the inherent water transfer and salt-tolerant characteristics of mangrove trees which regulate water and ion absorption [6]. Solar absorbers utilising a graphene oxide-reduced graphene oxide (GO-rGO) lotus leaf-inspired Janus film [7] or mangrove-mimicked designs have displayed efficient photothermal conversion performance and high evaporation rates of seawater [8].

Black titanium dioxide ($TiO_2$) has the ability to absorb immense ultraviolet-visible (UV-Vis) light for chemical or electrical energy conversion owing to the enhanced photocatalytic performance from the introduction of lattice disorder. Black $TiO_2$ can be obtained by establishing oxygen vacancies and $Ti^{3+}$ doping into the $TiO_2$ lattice using chemical reduction [9]. The combination of carbon-based materials such as GO with $TiO_2$ has displayed a synergistic effect between the two constituents as the photoactive $TiO_2$ integrates with the adsorption potential imparted by carbon. Carbon can assist in charge separation and obstruct electron-hole recombination in $TiO_2$ [10] .

The bio-inspired structural fabrication of rGO was designed for water and heat transfer abilities similar to that of plant root cells. Black $TiO_2$ can be utilised to minimise light reflection and efficiently absorb light across the UV-near infrared region, inspired by black snake scales.

## Photocatalysis

Recently, photocatalysis has garnered attention for pollution mitigation. The technology is amenable to visible light activation which make up 42%–43% of the solar spectrum [11]. To cut down on greenhouse gases emission, the leaning towards solar-driven processes is unavoidable. Solar energy is renewable and abundant.

In Photocatalytic process semiconductor photocatalyst, materials are activated by sufficient photon to generate electrons ($e^-$) and holes ($h^+$) [12]. The $e^-$ and $h^+$ in subsequent reaction with dissolved $O_2$ and $H_2O$ produce superoxide anion radicals ($\bullet O_2^-$) and hydroxyl radicals (.OH), with the ability to destroy adsorbed pollutant on the photocatalyst [13-15].

Generation of abundant $e^-$ and $h^+$, separation and boosting redox ability is crucial for material performance. These have been achieved via plasmon resonance effect [16]heterojunction formation [17], ion doping [18], photosensitization effect [19] and other strategies. In photosensitization strategy light sensitive or absorbing material such as porphyrin are apply to photocatalyst enhance visible light utilization [20], and ultimately the photocatalytic ability of photocatalyst.

Porphyrins are organic molecules are similar to the structure of chlorophyll in plant. They are efficient absorber of visible light, producing a photochemical reaction [21]. Porphyrin can be modified into different shapes sucha s rods, hexagonal, hollow spheres, tubes [22]. The complexity of versatility of in terms of assembly of the molecules make them useful in various application including photocatalysis. Porphyrin have been combined with graphite carbon nitrides [23]; $Fe_3O_4$ [24]; $TiO_2$ [25], BiOCl [26], ZnO nanofiber composite [27], graphene [28] and $Bi_{12}O_{17}Cl_2$ [29], where they demonstrated enhanced

photodegradation in comparison with individual porphyrin and the inorganic photocatalyst components.

Solar desalination is viewed as one of the most sustainable ways of dealing with the global energy challenge with emerging technological advancements. The technology is highly efficient in that the solar energy is targeted at the interface between a water surface and solar absorbing material to achieve evaporation with minimal energy losses. In addition, notable innovations can be found in adsorption desalination and energy-efficient freeze desalination. The work outlined here has been patented by several leading researchers around the world but no full-scale plant has not yet been built to demonstrate the economic feasibility of this technology at the date of publication of this article.

## APPLICATIONS AND PERFORMANCES OF MATERIALS

### Performance of $TiO_2$/rGO in Desalination

Excellent solar absorption potential across the UV-Vis solar spectrum for solar absorbers is crucial for achieving efficient desalination [30]. As presented in Figure 1, the black $TiO_2$/rGO composite exhibited remarkable light absorption potential across the ensure UV-Vis region in comparison to white $TiO_2$ which displayed good UV light absorption with almost no visible light absorption and rGO showed excellent visible light absorption, however, the light absorption across the UV spectrum was similar to that of white $TiO_2$. Therefore, demonstrating the enhanced light absorption performance of the composite where the beneficial attributes of each component act synergistically.

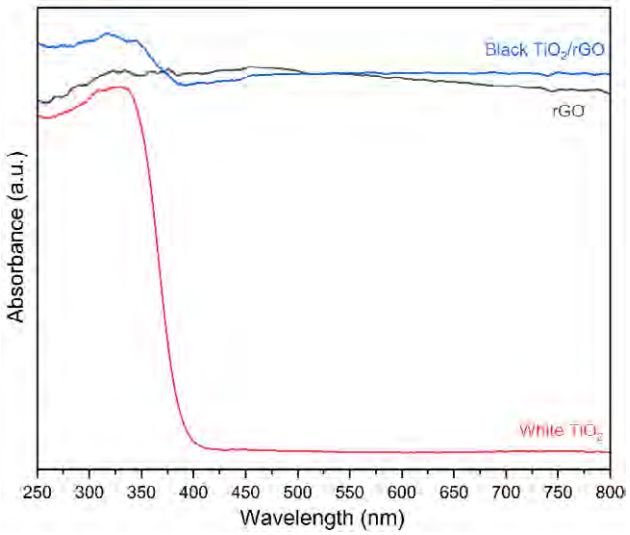

**Figure 1.** UV-Vis DRS spectra of rGO, white $TiO_2$, and black $TiO_2$/rGO.

In solar-driven desalination, the water evaporation rate can be determined using [31].

$$v = \frac{\Delta m}{A \times t} \quad (1)$$

Where v is the evaporation rate (kg/m²·h), Δm is the change in mass due to water evaporation (kg), A represents the evaporation area (m²), and t is the duration of the evaporation process (h). The photothermal conversion or steam generation efficiency, $\eta$, can be determined using [5] :

$$\eta = \frac{v \cdot H_{LV}}{P} \quad (2)$$

$$H_{LV} = h_v + C\Delta T \quad (3)$$

Where $H_{LV}$ is the total liquid-vapour phase change enthalpy, P is the solar power density (1 kW/m²), $h_v$ represents the latent heat of vaporisation (kJ/kg), C is the specific heat capacity of water (4.2 kJ/kg·K), and ΔT is the temperature increase of water (K). The freshwater vapour generation (Figure 2b) was determined to be 1.19 kg/m²·h with an 82.38% photothermal conversion efficiency. The solar absorber displayed a surface temperature increase of 23.8°C (Figure 2a) within 120 min of commencing the desalination test. Furthermore, the bio-inspired solar absorber demonstrated effective salt rejection of the surface owing to the small interlayer spacings and the negatively charged surface of the rGO nanopores.

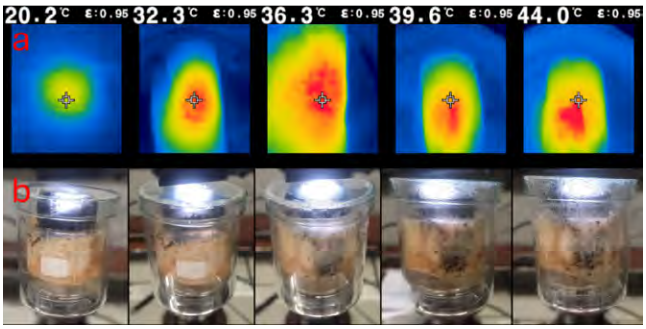

**Figure 2.** IR thermal images of the black $TiO_2$/rGO solar absorber (a) and photos of the solar desalination test (b) taken every 30 min.

### Performance of Porphyrin/$Bi_{12}O_{17}Cl_2$ in Pollutant Degradation

Tetrakis (4-carboxyphenyl) porphyrin (TCPP), a member of porphyrin, coupling with $Bi_{12}O_{17}Cl_2$ improved its performance. First, TCPP was modified to a rod shape and applied to $Bi_{12}O_{17}Cl_2$ to form composites.

The degradation study was carried out using Rhodamine as a model pollutant. The experiment involved a simple batch degradation study in a beaker, where TCPP-Bi12O17Cl2 composite was dispersed in the solution of Rhodamine dyes. The reaction was sufficiently stirred in

the dark to achieve absorption-desorption equilibrium. Thereafter, it was irradiated with visible light to initiate the photocatalytic degradation of the dye. The result of dye degradation overtime on the materials 0.02%wtTCPP-$Bi_{12}O_{17}Cl_2$,0.4%wtTCPP-$Bi_{12}O_{17}Cl_2$ 1%wtTCPP-$Bi_{12}O_{17}Cl_2$, $Bi_{12}O_{17}Cl_2$, TCPP are presented in Figure 3. Within 240 min, the 52%, 68%, 79%, 40% and 20% degradation were achieved.

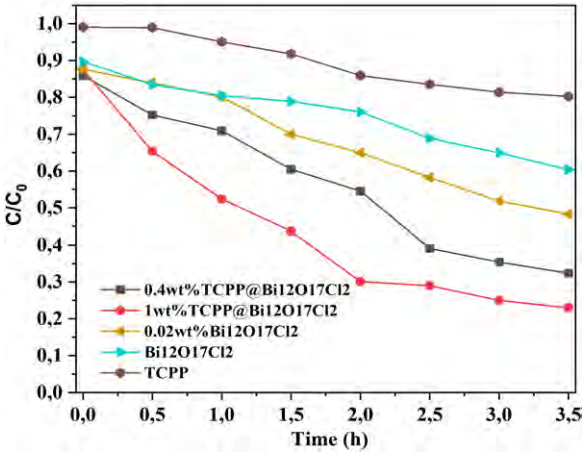

**Figure 3**. Photocatlytic decolourization of Rhodamine B dye

The performance of the TCPP/$Bi_{12}O_{17}Cl_2$ was attributed to the expanded visible light response and composite/heterojunction formation. Figure 4(a) shows the shift of the absorption edge of pristine $Bi_{12}O_{17}Cl_2$ with the introduction of TCPP. The enhanced visible light response favoured increased electrons and hole generation from the sufficient capture of the visible light by the porphyrin molecules. Figure 4(b) shows the material's Electrochemical impedance spectroscopy (EIS). Data from EIS provide transport and separation of electrons and holes. A smaller semi-circle observed with TCPP-load $Bi_{12}O_{17}Cl_2$ indicates superior transport and separation of the photogenerated electron and hole, the reason for the strengthened photodegradation activity of the dye.

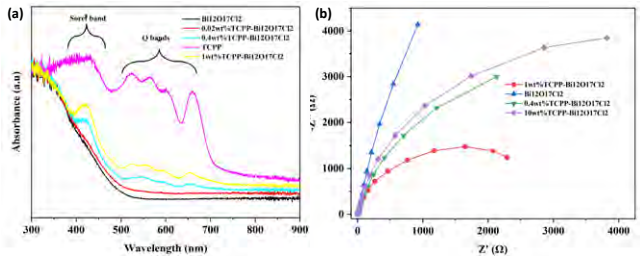

**Figure 4**. UV vis DRS (a) and EIS spectra of material (b)

When porphyrin-$Bi_{12}O_{17}Cl_2$ is exposed to visible light, electrons are excited from the highest occupied molecular orbital (HOMO) to the lowest unoccupied molecular orbital (LUMO) [32]. These excited electrons in the LUMO are subsequently transferred to the conduction band (CB) of the host material [25], effectively separating them from the corresponding holes [33]. This separation enhances the photocatalytic efficiency of the system.

## CONCLUSION AND FUTURE WORK

In summary, the bioinspired 3D black $TiO_2$/rGO solar absorber demonstrated efficient freshwater evaporation and photothermal conversion efficiency. This can be attributed to the successful mimicking of plant root cells for water transfer and the light absorption ability of black snake scales. These results show the promising potential for further advancing bioinspired photothermal solar absorbers.

Also, using porphyrin, a biological analogue of chlorophyll, proved advantageous for visible light capture in the porphyrin-$Bi_{12}O_{17}Cl_2$ system for pollutant degradation.

This work reported on one example of the porphyrin-$Bi_xO_yX_z$ system, TCPP-$Bi_{12}O_{17}Cl_2$. The porphyrin-$Bi_xO_yX_z$ system is diverse considering the many forms of porphyrin structures and morphologies available, as well as $Bi_xO_yX_z$. Further exploration of the combinations, therefore, in the system holds potential in photocatalysis. Porphyrin-$BiOIO_3$ is also proposed, where the visible light absorption of $BiOIO_3$ enhancement is envisaged. Comparatively, $BiOIO_3$ has good electron and hole separation upon activation. However, it cannot be activated due to the wide gap energy, hence the proposed composite with porphyrin.

## ABSTRACT

Climate and environmental problems caused by increasing $CO_2$ concentration in the atmosphere make the direct air capture (DAC) technology having great prospects for development. As the widely used solvent in carbon capture based on chemical absorption processes, MEA still fails to address the issues of high energy consumption and high costs when used in DAC process. In this study, piperazine (PZ) was used as the new solvent for DAC process. The new configuration was simulated in Aspen Plus® V11 and the model was validated through experimental data and model comparison. It is followed by investigation of the potential for energy efficiency and cost reduction. The standard DAC-PZ configuration could reduce the reboiler duty from 10.7 GJ/t$CO_2$ to 8.9 GJ/t$CO_2$ for DAC-MEA process. Economic analysis will be carried out through Aspen Process Economic Analyzer®. Further analysis (e.g. sensitivity analysis for different parameters and optimisation) will be performed to further reduce the energy consumption and cost for the DAC-PZ process with different configurations.

**Keywords**: direct air capture, chemical absorption, process simulation

## INTRODUCTION

### Background and motivation

The concentration of $CO_2$ in the atmosphere is increasing for several decades. In November 2024, it has reached 423 ppm [1]. Carbon capture is essential to combat the ecological problems such as global warming associated with increased carbon emissions. Among all the carbon capture technologies, direct air capture (DAC), as a negative emission technology, has great potential for development to capture 980Mt $CO_2$ in 2050 according to the IEA Net Zero Emissions Scenario.

In the conventional solvent-based carbon capture process, MEA is the most commonly used solvent [2]. Nevertheless, MEA has a series of disadvantages which affects the improvement of the performance for carbon capture process. In comparison, PZ offers better performance and is more economical. Replacing MEA with PZ in the DAC process provides a new alternative for the DAC process to reduce energy consumption and costs.

### Literature review

The solvent-based carbon capture process is widely used. The process is based on chemical reactions between solvent and carbon dioxide which enables selective capture of specific components from the flue gas. In Canepa et al. [3], a solvent-based carbon capture process using MEA solvent was integrated with a combined cycle gas turbine (CCGT) power plant. Exhaust gas recirculation (EGR) technology was proposed to reduce the energy consumption for solvent regeneration. Luo and Wang [4] combined the solvent-based carbon capture process with nature gas combined cycle (NGCC) power plant. In addition to the traditional power plants, Hu et al. [5] applied the carbon capture process using MEA for treating flue gas from thermal cracking furnace in ethylene manufacturing. By recovering the excess heat from the gasoline fractionator, the energy consumption and capture cost could be reduced.

With minor modification of solvent-based carbon

capture, it can be used for DAC. Kiani et al. applied a conventional carbon capture process using MEA solvent for DAC. An economic performance analysis of the whole system confirmed the potential of this approach to reduce the cost of DAC [6]. Michailos integrated the air absorber with a traditional post-combustion carbon capture (PCC) absorber column to reduce the energy consumption for DAC. [7].

PZ is a better replacement of MEA in carbon capture studies due to its higher absorption capacity and heat degradation resistance. The performance parameters of two different concentrations of PZ comparing with MEA are presented in Table 1. Otitoju et al. used PZ in PCC process for NGCC power plant. PZ with higher performance could reduce the total energy consumption from 5.34GJ/t$CO_2$ with 30wt% MEA to 3.56GJ/t$CO_2$ with 30wt% PZ [8]. Ma et al. also used PZ instead of MEA in the carbon capture process for the ethylene plant. With flue gas heat recovery, the energy consumption could be reduced by 37.71% compared to the standard MEA configuration, while costs can be lowered by 36.76% [9]. These highlighted the significant potential of PZ solvents in the carbon capture field.

**Table 1:** Performance parameters of different solvents [8]

| Parameter | 30wt% MEA | 30wt% PZ | 40wt% PZ |
|---|---|---|---|
| $K_L$@313K (mol/s Pa $m^2$) | 4.3 | 11.3 | 8.5 |
| Viscosity (Pa s) @313K | 0.0025 | 0.003 | 0.011 |
| $CO_2$ capacity ($mol_{CO2}/mol_{amine}$) | 0.5 | 0.63 | 0.79 |
| Thermal stability $T_{max}$ (K) | 393 | 436 | 436 |
| Max. regeneration Pressures (bar) | 2.2 | 14.3 | 14.3 |

## Novelty of this study

Several studies on the DAC process use packed bed column as shown in the literature review part. High energy consumption and high cost remain significant challenges to the commercial deployment of DAC technology. However, use of PZ solvent in DAC process offers the possibility to optimize the process. In this study, PZ was selected as solvent for DAC process inside a packed bed column. Through simulation, new results on energy consumption and capture cost will be obtained. In future work, sensitivity analysis for different process parameters and optimisation will be performed to further reduce the energy consumption and cost for the DAC.

## PROCESS DESCRIPTION

The process of standard solvent-based absorption process for DAC process using PZ solvent is shown in Fig. 1. The process contains absorber, stripper, splitter, pump and heat exchanger. The absorber and stripper are all packed bed column using Mellapak 250X packing. In contrast to the PCC process, since $CO_2$ concentration in the air is much lower than in the flue gas from power plants or chemical plants, the rich solvent from absorber needs to be diverted by a splitter. Majority of the solvent is returned to the top of absorber for re-absorption. This is to increase the liquid/gas ratio in absorber to meet the design requirements of a conventional packed bed column. The remaining small portion goes to the stripper for solvent regeneration. The regenerated solvent from stripper then undergoes a heat exchange process with the small portion rich solvent to decrease the energy penalty.

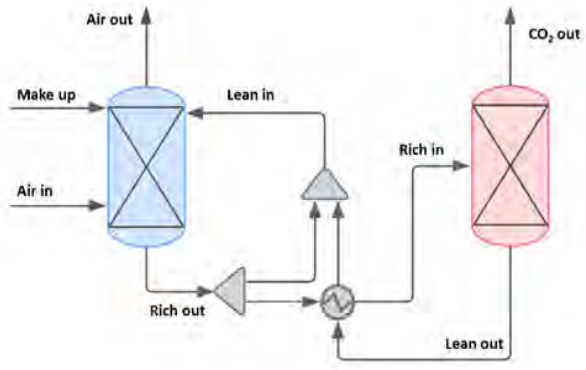

**Figure 1.** The process of standard DAC process using PZ.

## MODEL DEVELOPMENT

In this study, the DAC process using PZ was developed in Aspen Plus ® V11. The absorber and stripper are all rate-based models using RadFrac Block in the software. The rate-based model was used for reactions and physical properties. The liquid phase was calculated with Electrolyte Non-Random Two-Liquid (ElecNRTL) method. The vapour phase was calculated with the Redlich-Kwong equation of state. Equations (1) -(7) are equilibrium reactions for describing chemistry of $CO_2$ absorption with PZ solvent.

$$2H_2O \rightleftharpoons H_3O^+ + OH^- \quad (1)$$

$$CO_2 + 2H_2O \rightleftharpoons HCO_3^- + H_3O^+ \quad (2)$$

$$H_2O + HCO_3^- \rightleftharpoons CO_3^{2-} + H_3O^+ \quad (3)$$

$$PZH^+ + H_2O \rightleftharpoons PZ + H_3O^+ \quad (4)$$

$$PZ + HCO_3^- \rightleftharpoons PZCOO^- + H_2O \quad (5)$$

$$H^+PZCOO^- + H_2O \rightleftharpoons PZCOO^- + H_3O^+ \quad (6)$$

$$PZCOO^- + HCO_3^- \rightleftharpoons PZ(COO^-)_2 + H_2O \quad (7)$$

The equilibrium constants ($K_{eq}$) was calculated by equation (8) based on molar concentration scale. All

these chemical reactions and coefficients of the equilibrium constant are coming from reference studies [8].

$$In\ K_{eq} = A + \frac{B}{T} + C\ In\ T + DT \quad (8)$$

Equations (9) -(14) are kinetically controlled reactions for describing the rate of absorption.

$$CO_2 + OH^- \rightarrow HCO_3^- \quad (9)$$

$$HCO_3^- \rightarrow CO_2 + OH^- \quad (10)$$

$$PZ + CO_2 + H_2O \rightarrow PZCOO^- + H_3O^+ \quad (11)$$

$$PZCOO^- + H_3O^+ \rightarrow PZ + CO_2 + H_2O \quad (12)$$

$$PZCOO^- + CO_2 + H_2O \rightarrow PZ(COO^-)_2 + H_3O^+ \quad (13)$$

$$PZ(COO^-)_2 + H_3O^+ \rightarrow PZCOO^- + CO_2 + H_2O \quad (14)$$

The power law is described in equation (15) which determines the reaction rates ($k_j$). All parameters pre-exponential factor $k_j^o$ and activation energy $E_j$ for calculating the reaction rates of kinetically controlled reactions (9)-(14) are shown in Table 2.

$$k_j = k_j^o exp\left(-\frac{E_j}{RT}\right)\prod_N^{i=1} C_i^{aij} \quad (15)$$

**Table 2:** Kinetic parameters for reactions (9) -(14)

| Reaction No. | $k_j^o$ (m³/kmol s) | $E_j$ (kJ/kmol) |
|---|---|---|
| 9 | 4.32 e + 13 | 5.55 e + 4 |
| 10 | 2.38 e + 17 | 1.23 e + 5 |
| 11 | 4.14 e + 10 | 3.36 e + 4 |
| 12 | 7.94 e + 21 | 6.69 e + 4 |
| 13 | 3.62 e + 10 | 3.36 e + 4 |
| 14 | 5.56 e + 25 | 7.69 e + 4 |

## MODEL VALIDATION AND COMPARISON

Model validation is essential to verify the accuracy of the model. For this case, there is no experimental data for DAC process using PZ solvent. The model validation and comparison is divided into two parts: (a) The accuracy of PZ solvent for $CO_2$ capture is validated using experimental data from pilot plant at the University of Texas at Austin as presented in [10]. (b) The accuracy of the DAC process simulation using MEA is verified by comparing the simulation results of a DAC process using MEA solvent with those presented in [6].

### Model validation for Carbon Capture process using PZ solvent

The validation part for PZ used pilot plant data to test the model prediction accuracy for the absorber-only process. The pilot plant data is from the University of Texas at Austin. The flue gas mass flow rate is 0.165 m³/s. The $CO_2$ concentration in flue gas is 12vol%. The height of absorber is 6.1m, diameter is 0.427m and packing material is chosen as Mellapak 2X [10].

In this part, 5 cases were chosen with different concentration of PZ, L/G ration and lean loading as input. Two model prediction outputs: rich loading and capture level are compared with the experimental results. The relative error for different cases are shown in Table 3. By comparing model prediction results with experimental data, the errors across different cases were all kept within 10%. It proved that the model can simulate the performance of $CO_2$ absorption by PZ in the absorber.

### Model comparison for DAC process using MEA solvent

The DAC process using MEA solvent is simulated. The MEA concentration is chosen as 30 wt%. The capture level from air is set as 50%. The inlet air mass flowrate is 943t/h and $CO_2$ concentration in the air is assumed as 400 ppm. The ratio of rich solvent recirculation splitter is set the same to reach 2.54 L/G ratio (kg/kg) for absorber [6]. The impact of lean loading on the reboiler duty for DAC was considered and used as results for comparison. The simulation results compared with Kiani et al. [6] are shown in Figure 2. The simulation results have the same trend as Kiani et al. [6]. The relative error range is setting as 10% in the figure.

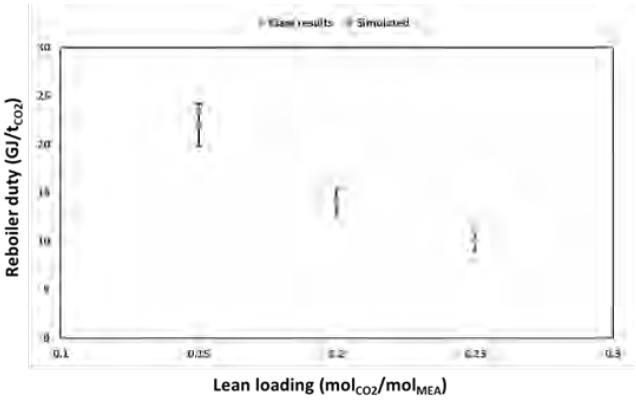

**Figure 2.** Comparison of simulation results with reference [6] on DAC process.

## CASE STUDY TO DETERMINE PZ SOLVENT CONCENTRATION

As we mentioned in the literature review, PZ has better performance as a replacement for MEA. Since the DAC-PZ process is different from other conventional PZ-based carbon capture studies, it is essential to determine the optimal PZ concentration.

This case study compared 30wt% PZ with 40wt% PZ in the absorber only DAC process. The lean loading was setting as 0.2 mol $CO_2$/mol alkalinity, the capture level of $CO_2$ from air was setting as 50%. The sensitivity analysis

**Table 3:** Validation results of comparing 5 experimental cases to model prediction values with relative error

| Input | | | Output 1 | | | Output 2 | | |
|---|---|---|---|---|---|---|---|---|
| PZ wt% | L/G (mol/mol) | Lean loading | Experimental Rich loading | Prediction Rich loading | Relative error | Experimental Capture level % | Model prediction Capture level % | Relative error |
| 30 | 5.5 | 0.257 | 0.360 | 0.391 | 8.6% | 78.3 | 82.4 | 5.3% |
| 30 | 6.8 | 0.274 | 0.360 | 0.386 | 7.2% | 88.6 | 90.2 | 1.8% |
| 40 | 5.5 | 0.285 | 0.340 | 0.355 | 4.4% | 85.9 | 88.6 | 3.2% |
| 40 | 6.7 | 0.267 | 0.340 | 0.334 | 1.9% | 92.2 | 91.3 | 1.0% |
| 40 | 5.5 | 0.308 | 0.370 | 0.358 | 3.2% | 66.6 | 61.1 | 8.3% |

of solvent flowrate on rich loading for 30wt% and 40wt% is shown in Figure 3. The solubility of aqueous solutions of PZ is also labelled in the right side. As indicated by the orange dashed line in Figure 3, excessively high or low loading can lead to solid formation in PZ solvent. 40wt% PZ has significantly narrow operational range compared to 30 wt% PZ although it has a higher $CO_2$ capacity. Meanwhile, the higher mass transfer rate and lower viscosity of 30 wt% PZ make it more suitable for the DAC-PZ process.

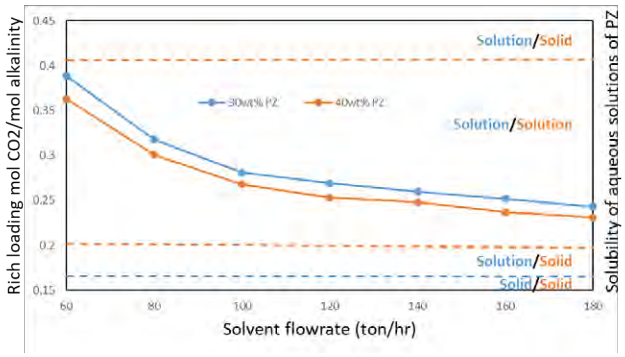

**Figure 3.** Sensitivity analysis of different solvent flowrate on rich loading with solubility area.

## CASE STUDY OF STANDARD DAC-PZ PROCESS

The standard DAC-PZ process was simulated as the closed-loop model. The operating parameters were listed in the Table 4. Due to the higher absorption capacity of PZ solvent compared to MEA, the rich solvent entering the stripper has a higher rich loading. The impact of solvent flowrate to stripper on the reboiler duty is shown in Figure 4 through sensitivity analysis. When the solvent flowrate is too low to the stripper, the rich loading of solvent will be above the highest operating range for PZ. When the solvent flowrate is too high, the reboiler duty will increase significantly because of the increasing heat requirement for water in solvent. In this case, the separation ratio of the splitter controlling the solvent circulation is different to DAC-MEA, with a different L/G ratio as 2.03 and liquid flowrate to stripper as 8.81 ton/hr.

**Table 4:** Operating conditions

| Operating conditions | |
|---|---|
| Inlet air temperature (K) | 298 |
| Air relative humidity (%) | 100 |
| $CO_2$ concentration in inlet air (ppm) | 400 |
| $CO_2$ captured (ton/hr) | 0.291 |
| $CO_2$ capture efficiency (%) | 50 |
| Flow rate of air (ton/hr) | 943 |
| PZ concentration (wt%) | 30 |
| L/G ratio in absorber (ton/ton) | 2.03 |
| Flooding capacity of absorber/stripper (%) | 70/65 |
| Packing type (Absorber and Stripper) | Mellapak 250X |
| Absorber pressure (bar) | 1 |
| Stripper pressure (bar) | 2 |
| Absorber diameter (m) | 9.8 |
| Absorber packing height (m) | 4 |

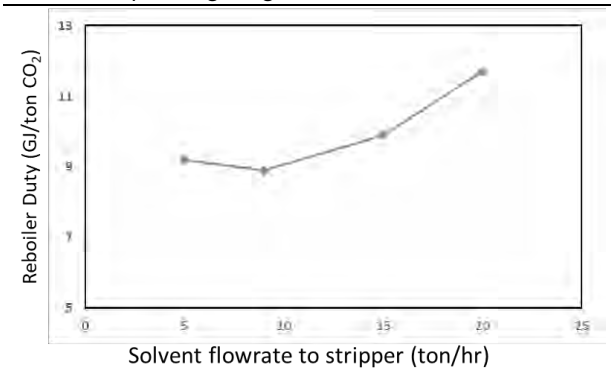

**Figure 4.** Impact of solvent flowrate to the stripper on reboiler duty.

The simulation results were presented in the Table

5. At a $CO_2$ production rate of 0.289 ton/hr, the reboiler duty is 8.9 GJ/t$CO_2$, which is 16.8% lower than the reboiler duty of 10.7 GJ/t$CO_2$ observed in the DAC process using MEA.

**Table 5:** Compare of simulation results between DAC-PZ and DAC-MEA process.

| Simulation results | DAC-PZ | DAC-MEA |
|---|---|---|
| Absorption liquid flow to stripper (ton/hr) | 8.81 | 9.12 |
| Absorber recirculation liquid flow (ton/hr) | 1905 | 2396 |
| $CO_2$ lean loading ($mol_{CO2}/mol_{alk}$) | 0.2 | 0.2 |
| $CO_2$ rich loading ($mol_{CO2}/mol_{alk}$) | 0.4 | 0.35 |
| Reboiler temperature (K) | 394 | 396.2 |
| $CO_2$ production (ton/hr) | 0.289 | 0.288 |
| Reboiler duty (GJ/hr) | 2.57 | 3.08 |
| Reboiler duty (GJ/t$CO_2$) | 8.9 | 10.7 |

## CONCLUSION AND FUTURE WORK

Using PZ solvent to replace MEA solvent in standard configuration of DAC process, the reboiler duty could reduce 16.8%. As a more efficient solvent with lower energy consumption, this study demonstrates that the application of PZ in the DAC process is promising.

Due to page limitations, the economic analysis of the standard DAC-PZ process is not presented in this paper. This part will be addressed in future work which will be carried out through Aspen Process Economic Analyzer®. Building on the standard configuration, this study will conduct further analyses, such as examining the impact of the separation factor of the circulating solvent on this system and the effect of different $CO_2$ concentration in the atmosphere on DAC-PZ process. Through different configurations, such as utilizing advanced flash stripper(AFS) and rich-split process, this study will perform energy and economic optimizations for the DAC-PZ system. Optimal design and operation for DAC process using PZ can be achieved.

## ABSTRACT

By-product fuel gases from refinery operations are a major heat source in fossil refineries and their availability poses a challenge to the deployment of low-carbon heat sources. This study evaluates the valorization of refinery fuel gases (RFG) into low-carbon methanol via co-processing with residual biogenic gas streams from biomass thermochemical conversion. Results from techno-economic analysis indicate that up to 44 wt.% of biogenic blend is possible without the need for external hydrogen supply, while electricity and heat requirements per tonne of methanol change by -4 % and + 80% respectively. Nevertheless, at the 44 wt.% blend, the estimated methanol cost increases only by 2.4 % (0.43 EUR/kg), while the reduction in methanol carbon intensity is approximately 40 %. This highlights promising benefits that can contribute to the integration of bio-oils producing technologies within fossil refineries.

**Keywords**: Technoeconomic Analysis, Biomass, Refining, Biofuels, Process Design.

## INTRODUCTION

Heat decarbonization is a major strategy for fossil refineries to achieve emission reductions in the short/medium term. Direct electrification and other low carbon heat sources are expected to play a key role, however, availability of surplus refinery fuel gases (RFG) – a mixture of residual gases rich in hydrocarbons used for on-site heat generation - may limit decarbonization efforts if alternative uses for surplus RFG are not explored.

Excessive production of RFG and the challenge it brings for the implementation of energy reduction projects in refineries is not a new topic. Over the years, increasing emphasis on higher energy efficiency and lower emissions has resulted in less fuel consumption, making energy reduction projects less attractive in cases where these could result in flaring the RFG produced [1]. Some options discussed in literature to reduce RFG disposition are to increase hydrogen recovery in PSA/membrane units, improve liquid recovery in separators to reduce $C_{3+}$ components in the gas, optimize fuel system control to minimize fuel imports, or include co-generation units that use RFG to produce additional heat and power [1–3]. Nevertheless, there is a lack of studies that explore further utilization options, particularly in the context of the integration of biomass technologies that represent a valuable source of renewable carbon for refineries.

In recent years, there has been increasing interest in biomass thermochemical conversion technologies and particularly in bio-oil producing technologies such as fast pyrolysis (FP) and hydrothermal liquefaction (HTL) due to their potential to deliver drop-in biofuels that can be integrated within existing refinery infrastructure. Although co-processing of bio-oils has been extensively discussed in literature [4–6], there is a lack of studies that explore the integration of by-products within a refinery context to increase biogenic carbon conversion into valuable products.

This study presents a techno-economic assessment of co-processing by-product gases from biomass thermochemical conversion with RFG to produce methanol, a key chemical with high demand in industry and as shipping fuel. The impact of co-feeding HTL gas or FP gas

with RFG is evaluated in terms of overall carbon efficiency to methanol, energy requirements, methanol production cost and carbon intensity.

# METHODS

## Process description

A simplified process flow diagram of the system evaluated is presented in Figure 1. A mixture of surplus RFG and HTL or FP gas is converted into methanol following a two-step process: steam reforming to produce syngas and methanol synthesis via $CO_2$/CO hydrogenation. The RFG and HTL/FP gases are by-products of the refinery and biomass thermochemical conversion processes, respectively and are the starting point of this analysis.

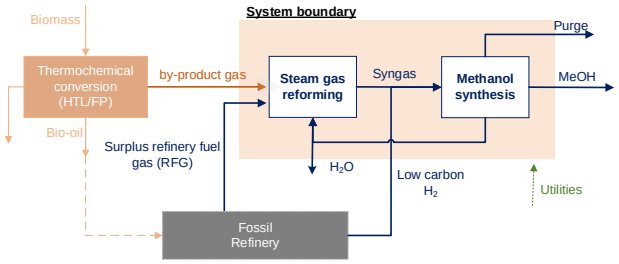

**Figure 1.** Simplified diagram of integrated biomass liquefaction in refinery context with co-processing of by-product gases for methanol synthesis.

**Table 1:** Composition of refinery fuel gas (RFG) and by-product gases from hydrothermal liquefaction (HTL) and fast pyrolysis (FP) of forestry residues (dry basis).

| | RFG | HTL gas | FP gas |
|---|---|---|---|
| Temperature [C] | 40 | 30 | 30 |
| Pressure [bar a] | 5.15 | 1 | 1 |
| Composition [mol%] | | | |
| $CO_2$ | 1.50 | 90.20 | 34.72 |
| Hydrogen | 38.22 | 0.90 | 0.00 |
| CO | 2.21 | 0.00 | 45.94 |
| Methane | 33.85 | 3.00 | 12.82 |
| Ethane | 16.44 | 2.50 | 1.50 |
| Ethylene | 0.00 | 0.00 | 5.02 |
| $C_3$ | 2.18 | 1.90 | - |
| $C_4$ | 2.23 | 1.50 | - |
| $C_{5+}$ | 1.78 | - | - |
| $H_2S$ | 1.59 | - | - |
| LHVstd [MJ/kg] | 46.96* | 3.30* | 9.99* |

The process is modelled in Aspen HYSYS V12.1 assuming a fixed RFG input of 25 tonne/h, which corresponds to an estimated RFG surplus in a refinery case study after initial emission reduction measures. The impact of gas co-processing is evaluated for increasing ratios of HTL gas or FP gas blended with RFG, from 0% (RFG case) to 100% (full biogenic carbon case), in terms of hydrogen requirement, carbon conversion to methanol, overall water balance and energy consumption. The analysis is performed for the HTL gas and FP gas separately. The composition of the input gas streams is presented in Table 1. The main process steps are briefly described in the following sections.

## Steam gas reforming (SMR)

The feed gases are pressurized to 30 bar, mixed with steam (steam/carbon ratio S/C= 4), pre-heated to 400 ℃ to enter the pre-reformer, and sent to the main steam reformer at 900 ℃. In the pre-reformer, conversion of $C_{2+}$ hydrocarbons to methane and hydrogen is favored at relatively lower temperatures, while endothermic steam reforming reactions are favored at higher temperatures in the main reformer. The produced syngas is cooled down to 30 ℃ to condense water that is reused for steam generation. The reformer is simulated as a furnace and a Gibbs reactor, so the heat requirement is the sum of the furnace duty and the reaction heat at 900 ℃. This configuration allows heat integration between the flue gases, reformer products and feeds, including the furnace fuel ($CH_4$) and air, resembling typical SMR configurations. Removal of $H_2S$ upstream the reactor is required to avoid catalyst poisoning and it is implemented for the RFG via caustic wash with NaOH; however, this step is not included for the HTL/FP gases since $H_2S$ was not reported in the data consulted [8].

## Methanol synthesis

Methanol is produced via catalytic hydrogenation of $CO_2$ and CO, in which a minimum ratio between hydrogen and carbon oxides is required (stoichiometric number, $SN=H_2-CO_2/CO_2+CO=2$). After reforming, the SN of the syngas is calculated and, if required, hydrogen is added to satisfy the minimum SN. The adjusted syngas is pressurized to 60 bar and preheated to 220 ℃ to enter the methanol synthesis reactor (Gibbs reactor) in which a reaction temperature of 250 ℃ is specified based on [7]. The reactor products are cooled down to 30 ℃ and separated at high pressure, with the unreacted gases being recirculated and the liquid products sent to distillation to obtain high purity methanol. A purge of 3% is included to avoid accumulation of inerts (unconverted hydrocarbons) in the system, and its potential use as fuel in the reformer furnace is evaluated (85 % furnace efficiency). Water obtained as by-product (99.9 mol%) is recirculated to the reforming process to decrease external water consumption for steam generation.

## Economic evaluation

An economic evaluation is conducted to assess the impact of co-processing in the methanol minimum selling price at increasing HTL/FP gas ratios. Capital and

operational expenses are estimated using the cost parameters in Table 2. In terms of Capex, purchase equipment costs of the SMR (including the heat supply system) and methanol production process reported in literature with reference year 2020 are adjusted to 2021 euros (EUR) and scaled to the required size using the CEPCI index and a scaling factor of 0.7. Fixed (FCI) and total capital investment (TCI) are estimated from the total purchase equipment costs (TPE) multiplied by a factor of 4.8 and 5.8 respectively [9]. In terms of feedstock, there is no reported selling price of RFG, HTL or FP gases since these are not traded as products but used (or expected to be used) for heat purposes. Consequently, their price is assumed to be proportional to the price of methane times the LHV ratio. Operation and maintenance (O&M) and other fixed costs (local taxes, insurance, plant overhead and administrative costs) are estimated based on detailed methodology in literature [10]. The methanol price is then estimated using a net present value (NPV) analysis with a 10% discount rate, straight line depreciation and a plant lifetime of 25 years.

**Table 2:** Cost parameters and assumptions used in the economic evaluation.

| | Base case | Low case | High case |
|---|---|---|---|
| **Equipment cost** | | | |
| SMR [$MEUR_{2020}$] [11] | 24.5 | -- | -- |
| (kt/d feed [a]) | (9.9) | | |
| MeOH synthesis [$MEUR_{2020}$] [12] | 15.7 | -- | -- |
| (kt/d MeOH) | (0.3) | | |
| **Variable costs** | | | |
| Natural gas (NG) price [EUR/GJ] [13] | 6.63 | 5.43 | 7.54 |
| RFG price [b] [EUR/GJ] | 6.23 | 5.10 | 7.08 |
| HTL gas price [b] [EUR/GJ] | 0.44 | 0.36 | 0.50 |
| FP gas price [b] [EUR/GJ] | 1.33 | 1.09 | 1.51 |
| Low carbon $H_2$ price [EUR/kg] | 2.50 [c] | 2.20 [d] | 4.60 [e] |
| Electricity price [EUR/MWh] [f] | 60.00 | 40.00 | 68.00 |
| Demineralized water price [EUR/$m^3$] | 0.51 | -- | -- |
| Cooling water price [EUR/$m^3$] | 0.42 | -- | -- |
| **Other parameters** | | | |
| Scaling factor | 0.70 | -- | -- |
| Hourly labor cost | 31.40 | -- | -- |
| Operators per shift | 6 | -- | -- |
| Furnace efficiency | 0.85 | -- | -- |
| Annual operation hours | 8000 | -- | -- |

a. SMR including heat supply system, scaled based on total feed mass flow (steam + natural gas).
b. Price estimated based on the gas calorific value relative to natural gas ($LHV_{gas}/LHV_{NG} * NG_{price}$).
c. Blue $H_2$ (NG SMR with carbon capture) based on natural gas price of 5.4 EUR/GJ [13].
d. Produced via electrolysis based on an electricity consumption of 53 kWh/kg H2 and capex of 315 EUR/kW [13]
e. Produced via electrolysis based on an electricity consumption of 59 kWh/kg H2 and capex of 575 EUR/kW [13]
f. Price range in line with wholesale electricity prices reported in Denmark and The Netherlands in 2021 [16]

## Carbon intensity of methanol

The impact of co-processing biogenic streams in the methanol carbon intensity is evaluated based on the main scope 1 emission reported in Table 3. $CO_2$ emissions from the RFG are calculated based on the carbon content, while no $CO_2$ equivalent is allocated to the HTL/FP gases. This assumption is considered reasonable since these are by-products of the bio-oil production process with very low energetic or economic value and would only yield biogenic $CO_2$ if they were to be used for heat purposes in the upstream process. Regarding the electricity and $H_2$ contributions, low and high emission scenarios are considered due to the well-known impact of the hydrogen source in the carbon intensity of synthetic fuels. An electricity carbon intensity between 50 and 250 kg $CO_2$eq/MWh is considered based on 2023 data for European countries such as France, Denmark and Netherlands [14]. Natural gas is assumed as make-up heating source, but up-stream leakage is not included in the analysis. The methanol carbon intensity is then estimated as the sum of the listed contributions for 0% to 100% biogenic blends with RFG.

**Table 3:** Scope 1 emission sources included in methanol carbon intensity estimation.

| Emission source | Base case | Low case | High case |
|---|---|---|---|
| Refinery fuel gas (RFG) [kg $CO_2$eq/h] | 65.48 | 65.48 | 65.48 |
| HTL/FP gas [kg $CO_2$eq/h] | 0.00 | 0.00 | 0.00 |
| Heating (Natural gas) [kg $CO_2$eq/MWh] | 15.58 | 15.58 | 15.58 |
| Electricity [kg $CO_2$eq/MWh] | 150.00 | 50.00 | 250.00 |
| Low carbon $H_2$ [kg $CO_2$eq/kg $H_2$] | 3.00[a] | 2.65[b] | 3.38[c] |

a. Defined in EU taxonomy based on GHG emission savings of 73.4% in comparison to the fossil fuel comparator of 94 g $CO_2$eq/MJ (https://ec.europa.eu/sustainable-finance-taxonomy/faq).
b. Calculated for electrolytic hydrogen based on an electricity consumption of 53 kWh/kg $H_2$ and carbon intensity of 50 kg $CO_2$eq/MWh.
c. Threshold in RFNBO regulation of 70 % reduction relative to fossil comparator of 94 g $CO_2$eq/MJ.

# RESULTS

## Impact of co-processing in mass balance

Figure 2 shows the distribution of reactants and products for increasing shares of HTL gas in the feed (see results of the FP gas case in the supplementary material). Regarding the reactants, there is a steady decrease in water consumption due to a combined effect of less hydrocarbons in the feed gas that reduce the steam input for SMR, plus increased water production from the methanol synthesis that gets recirculated. The reduction in the hydrocarbons content results in less $H_2$ in the syngas until SN=2 at 42.8 wt% blend, above which make-up

$H_2$ is required. This condition is met at a 44 wt% blend with FP gas due to its higher hydrocarbon content, however, for simplicity, the neutral-$H_2$ blend used for both cases is 44% in the rest of the discussion.

In terms of products, methanol production drops at increasing HTL gas shares, going from 41.2 t/h in the RFG case to 18.9 t/h in the HTL gas case (23.8 t/h for FP). This is a direct result of less carbon in the gas blend by increasing the $CO_2$ content. Although the carbon conversion is estimated between 84 and 90%, future studies including reaction kinetics are recommended for a more detailed assessment of the impact in conversion.

Figure 3 shows the overall mass balance for the $H_2$ neutral blend of 42.8 % HTL gas. Despite of not being within scope of the present study, the indirect biomass consumption for bio-oil production in the HTL process is estimated in 1.5 kt/d, being in the range of relatively large biomass conversion plants (2.2 kt/d in the FP gas). More detailed information on streams composition and process conditions can be found in the supplementary material.

## Impact of co-processing in energy needs

Electricity and heat requirements are summarized in Table 4 for 0%, 44 % and 100 % HTL gas blend with RFG. Overall, the total electricity use in the 44% case is the lowest evaluated due to a lower syngas flow, absence of external hydrogen, and thus less work required for compression (see details in supplementary material). Nevertheless, the specific electricity consumption is approximately the same as in the RFG case (0.2 MWh/t MeOH) due to the lower methanol production. The full biogenic cases exhibit much higher specific electricity consumption (0.44 and 0.39 MWh/t MeOH respectively) despite having about the same total requirement as the RFG case due to reduced methanol throughput.

**Table 4:** Energy consumption in 0%, 44 % and 100 % HTL gas blend with RFG.

| | 0 % | 44 % | 100 % |
|---|---|---|---|
| **Heat [MW]** | | | |
| Total heat requirement | 135.2 | 87.7 | 27.5 |
| Heat potential vent (LHV) | 111.1 | 35.3 | 12.3 |
| Net Heat requirement | 40.8 | 57.7 | 17.1 |
| Specific heat [MWh/t MeOH] | 1.0 | 1.9 | 0.9 |
| **Electricity [MW]** | | | |
| Total electricity requirement | 8.2 | 5.6 | 8.3 |
| Specific electricity [kWh/t MeOH] | 198.3 | 189.3 | 440.9 |

In terms of heat, the total demand decreases with increasing biogenic gas share due to less steam needed to maintain the same SMR S/C ratio. For all three cases, the unconverted gases have potential to reduce the SMR fuel input significantly; however, the specific heat required is substantial, being almost twice in the 44% blend (+82.8 % in the FP blend). Process modifications such as electrified SMR [15] or advanced distillation concepts for methanol production [7] are recommended in future studies to lower the heat requirement.

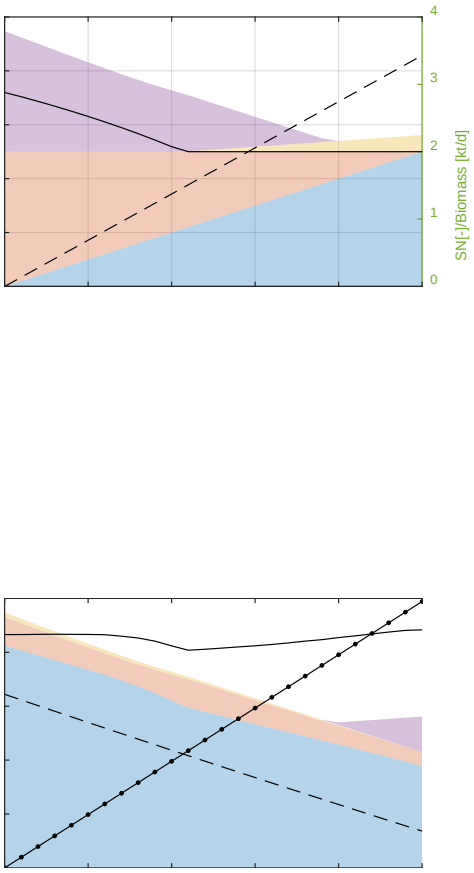

**Figure 2.** Change in mass flows with increasing share of HTL gas in blend with RFG (% in mass basis).

## Methanol production costs and carbon intensity

The results in Figure 4 show the trade-off between methanol cost and carbon intensity at increasing ratios of the biogenic carbon feeds. Co-processing of HTL gas increases the methanol production cost from 0.42 EUR/kg to 0.71 EUR/kg in the full HTL gas case. However, as observed in the plot, the increase is only marginal until 44% blend (+2.4 %) and becomes significant from this point onwards due to the growing $H_2$ requirement. The FP gas case shows the same trend, but the increase in cost is

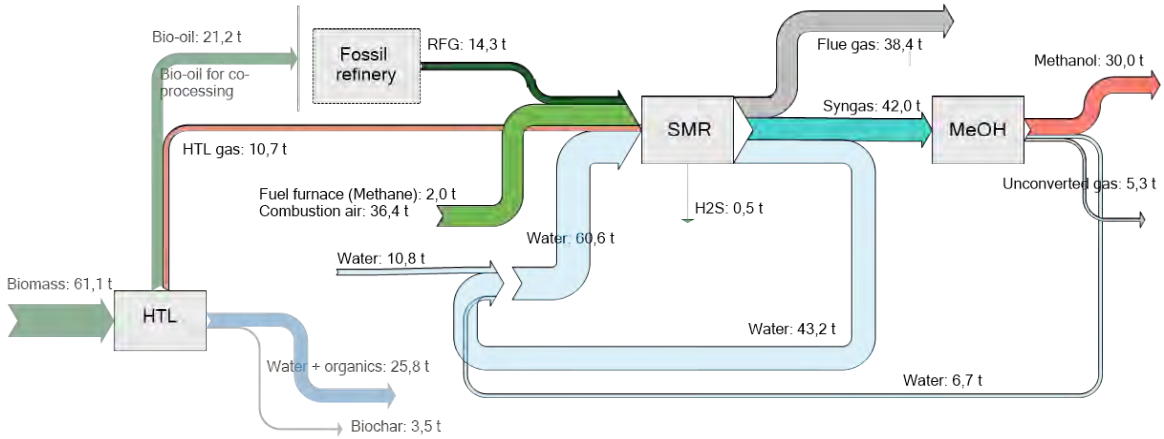

**Figure 3.** Mass Sankey diagram of HTL gas co-process with RFG (42.8 % case).

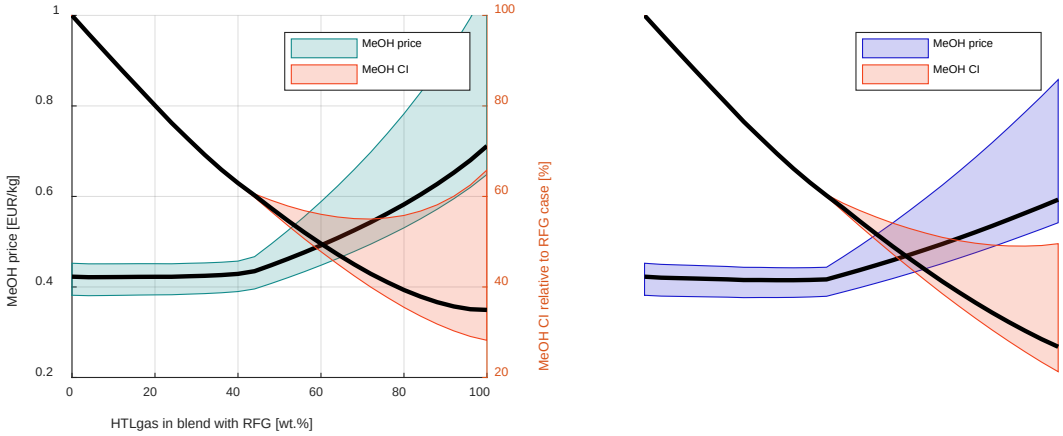

**Figure 4.** Mass Sankey diagram of HTL gas co-process with RFG (42.8 % case).

lower than for HTL due to slightly lower hydrogen needs and higher methanol production.

In the full biogenic feed cases, the estimated methanol carbon intensity is 27 and 36 kg $CO_2$eq/GJ, being in the range of the 65 % GHG reduction target by the REDIII relative to the fossil comparator (35.6 kg $CO_2$eq/GJ methanol). In these results, $H_2$ has by far the largest carbon footprint contribution followed by the electricity, causing variations in the estimated carbon intensity between -5% and + 30 % in the low and high scenarios considered. These could result in even higher emissions of the full biogenic case compared to the co-processing route, represented by the shadow areas in Figure 6. Lower variations in price and carbon footprint are observed up to the 44% blend since the $H_2$ impact is avoided. A life-cycle assessment of the integrated system is recommended in future studies for a more detailed evaluation of environmental impacts.

## CONCLUSIONS

- Co-processing by-product gases from thermochemical biomass conversion is deemed as a favorable strategy to valorize surplus RFG into low-carbon methanol, adding to the potential benefits of integrating bio-oil producing technologies within oil refineries.
- Co-processing 44% biogenic gas is identified as a suitable strategy that avoids the need of external $H_2$ supply. At this point, the estimated methanol cost is only 2.4 % higher than the RFG reference (0.43 EUR/kg), while the reduction in carbon intensity is approximately 40 %.
- The main impact of co-processing rich $CO_2$ streams with RFG is the reduction in methanol throughput. Although this increases the specific heat consumption (+89.5 %), the methanol cost is not affected significantly and the increased share of biogenic carbon in the product has a dominant positive impact.
- Detailed kinetics and LCA studies are recommended in the future to address the limitations of this study and further improve the analysis.

## ABSTRACT

Triethylene glycol (TEG) or mono-ethylene glycol (MEG) absorption are the commercial technologies for natural gas dehydration processes. Nevertheless, the necessity of regenerating solvents under high temperatures results in environmental footprint and complex operation. Membrane with advantages in small footprint and high feasibility operation in hostile conditions is considered as promising technology for natural gas dehydration processes. In this work, system scale design and mesoscale modelling are synchronously adopted to optimize natural dehydration process design. Aspen HYSYS with ChemBrane extension is used for natural gas dehydration process. Taking pressure ration, membrane area and sweep gas flowrate as decision variables for minimizing specific process cost is optimized through NSGA-II algorithms. The minimum specific cost of < $3.06\times10^{-2}$ \$/m$^3$ natural gas is estimated to achieve the separation requirement of <100 ppm. Then, the module length, and membrane thickness of the hollow fiber membrane design is investigated using Computational fluid dynamics (CFD), which better configures the simulation results and concentration, velocity profile to analyze the simulation results. The system scale engineering design and mesoscale modelling provide an in-depth insight into natural gas dehydration process.

**Keywords**: Natural gas dehydration, System scale design, Mesoscale design

## 1. INTRODUCTION

Natural gas (NG) proves to be a notably secure energy commodity during its transportation, storage and utilization processes [1]. Natural gas must be dried before enters distribution pipelines, otherwise it may corrode pipelines or form hydrocarbon [2]. Triethylene glycol (TEG) or mono-ethylene glycol (MEG) absorption are the commercial method for NG dehydration. However, the volatile organic compounds especially benzene, toluene, ethylbenzene, and xylenes will vent during absorption processes [3] and complex operating and control system restrict its application in remote and harsh environment [4,5]. Gas separation membrane with small footprint and no necessity for frequent parameter adjustments [6,7] is an attractive alternative for natural gas dehydration.

At the laboratory scale, the selectivity of water/methane can reach several thousand or even tens of thousands [8–12]. The gutter layer exists in membrane shows significant resistance to water vapor permeation which leads to the disparity in selectivity between laboratory-scale and pilot-scale conditions[13]. Lin et al. [13]evaluated a spiral-wound module for natural gas dehydration processes, results show that a low selectivity of 47 at 30-60 bar under field testing. However, the optimization of crucial parameters such as pressure ratio, sweep gas flowrate, and membrane area was not addressed in the aforementioned researches. He et al. conducted a hybrid membrane process for natural gas dehydration and sweeting, sensitivity analysis taking outlet pressure of each stage membrane as decision variable to minimize the specific NG processing cost. The research gap exists in the impact of flow and diffusion patterns of membrane is not been fully conducted.

In this work, a system scale design using Aspen HYSYS software with ChemBrane [14,15] extensions is used for natural gas dehydration process modeling, and pressure ratio, sweep gas flowrate, membrane area as decision variables to minimize the processing cost. The fluid

dynamic simulation of gas separation membranes is modeled by coupling laminar flow module and transport of concentrated species module. The effect of velocity distribution field and concentration field at the mesoscale on membrane efficiency are discussed.

## 2. METHODLOGY

### 2.1 Simulation basis

The natural gas produced from a natural gas processing plant in Qinghai Province, China. The natural gas with a total molar flowrate of 2571.29 kmol/h in water saturated at 308K, 4500kPa. The water content in the residue side of the gas separation membrane system must below 100ppm. Aspen HYSYS in conjunction with ChemBrane [15] was used to simulate the process conditions. The membrane used has a water vapor permeance of 983 gpu and water/methane selectivity of 47, the detailed information of other components permeance is shown in Table 2. The system scale design minimizes the specific cost of the natural gas dehydration process, taking pressure ratio, membrane area, and sweep gas flowrates as decision variables. Furthermore, the mesoscale design delves into the influence of parameters such as the inner and outer diameter and aspect ratio of the membrane on its performance. By examining the influence of different parameters across two distinct scales on membrane performance, aim to provide enhanced guidance for membrane structural design and industrial parameter selection.

**Table 1.** Typical compositions of gas streams at natural gas processing plant.

| Component | Molar flowrate(kmol/h) | Molar fraction (%) |
|---|---|---|
| Methane | 2502.5 | 0.9733 |
| Ethane | 1.77 | 0.0007 |
| Propane | 0.64 | 0.0003 |
| Hydrogen | 0.10 | 0.00004 |
| Water | 3.74 | 0.0015 |
| Carbon dioxide | 18.61 | 0.0072 |
| Nitrogen | 36.05 | 0.014 |
| Helium | 0.15 | 0.00006 |
| Oxygen | 7.70 | 0.003 |

**Table 2.** Gas permeance of membranes.

| Component | Gas permeance(mol(STP)/($m^2$·h·kPa)) |
|---|---|
| Methane | 0.023 |
| Ethane | 0.046 |
| Propane | 0.071 |
| Water | 1.217 |

### 2.2 System scale Design

#### 2.2.1 Process description

Natural gas dehydration process was conducted by HYSYS integrated with ChemBrane unit. The natural gas with saturated water content is gradually condensed through the cooler and then introduced into a gas-liquid separator to remove condensed water and heavy hydrocarbons. Subsequently, sent to the dehydration membrane unit, where the nitrogen gas used as sweep gas. The membrane unit operated in counter-current form and outlet natural gas water content need be less than 100 ppm. By system design, the appropriate pressure ratio, membrane area, and sweep gas flowrates can be determined to maximize the process economics. However, the system design is unable to determine parameters such as the inner and outer diameter thickness, aspect ratio, and distribution form of the membrane.

#### 2.2.3 Process parameters optimization

The most critical parameters in gas separation membranes unit are pressure ratio, sweep gas flowrate, and membrane area, as these factors directly determine the hydrocarbon loss and cost associated with dehydration processes. The membrane cost of \$50 per $m^2$ was used to estimate the dehydration membrane unit cost and a life time of the membrane was 5 years [14]. The cost functions regarding the heat exchanger, and separator are neglected. An annual interest rate of 7% was used for the calculation of annual capital cost. The price of electricity is 0.05\$/kWh used for operating cost of the compressors. The specific process cost model is shown in equation (1) [16].

$$CC^s = \frac{Capital\ related\ cost + OPEX}{Total\ NG\ production} \quad (1)$$

Figure 1. displays the schematic diagram of the optimization process. The range of variables is initially obtained through sensitivity analysis. Subsequently, generate the initial values of variables and input into the Aspen HYSYS software. Optimize the specific process cost while ensuring outlet natural gas water content is below 100 ppm. Provided that the obtained values do not meet the pre-defined criteria, the new parameters will be generated for next iteration.

### 2.3 Mesoscale modeling

#### 2.3.1 Computational fluid dynamic (CFD) simulation model

To date, the CFD simulation about natural gas dehydration process through membrane technology has not been reported. The optimized parameter values obtained through system design are incorporated into CFD model. In system design, the calculation can be performed by inputting the defined membrane area. At the CFD scale, the impact on membrane performance can be investigated by adjusting parameters such as the inner and outer

diameters, aspect ratio, and distribution of individual hollow fiber membranes. Modeling the mass transfer process and flow pattern of natural gas dehydration using the COMSOL software. Figure 2. illustrates the membrane structure in the simulations, encompassing the feed gas side, selective membrane, porous layer, and permeate side. The simulation process is conducted with the utilization of laminar flow module and transported of the concentrated spices. Given that the flow patterns and diffusion characteristics of the gas significantly influence this process, it is crucial to preserve the reliability of the flow pattern and diffusion mechanisms while simplifying the model. The following assumptions are considered during modeling.

1. The modeling is under steady-state conditions and in adiabatic conditions;
2. The diffusion mechanism is Fick's law;
3. The simulated fluid is Newtonian-type fluid and adheres to the ideal gas assumption;
4. The driving force for the transportation is pressure difference between feed and permeate side;
5. Hollow fiber membrane has uniform outer and inner diameters.

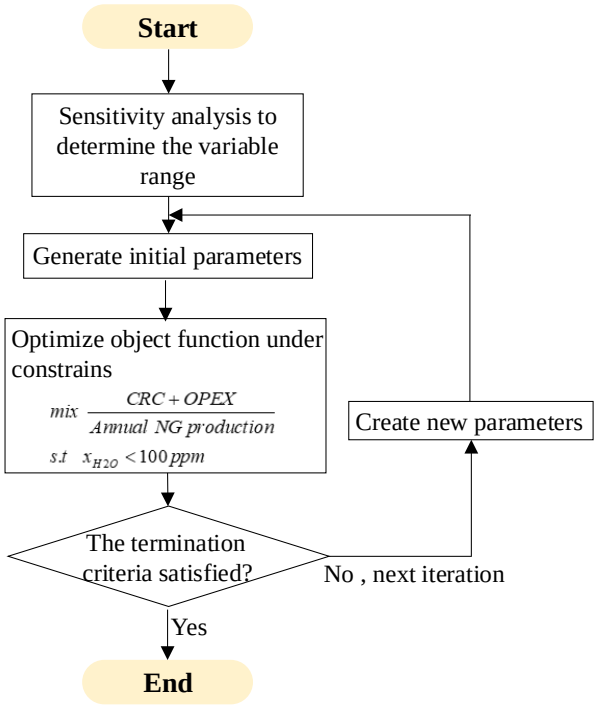

**Figure 1.** Schematic diagram of optimization process.

### 2.3.2 Numerical methods

The natural gas dehydration membrane modeling governing equation with the boundary conditions were solved utilizing COMSOL Multiphysics (6.2) software with the finite element method. Figure 2. displays the detailed mesh partitioning of the modeling, encompassing 404,487 degrees of freedom. The time required to solve a set of governing equations is 180 seconds. Table 3. presents pivotal parameters in CFD simulations, including the temperature and pressure distribution in both side of the membrane [17].

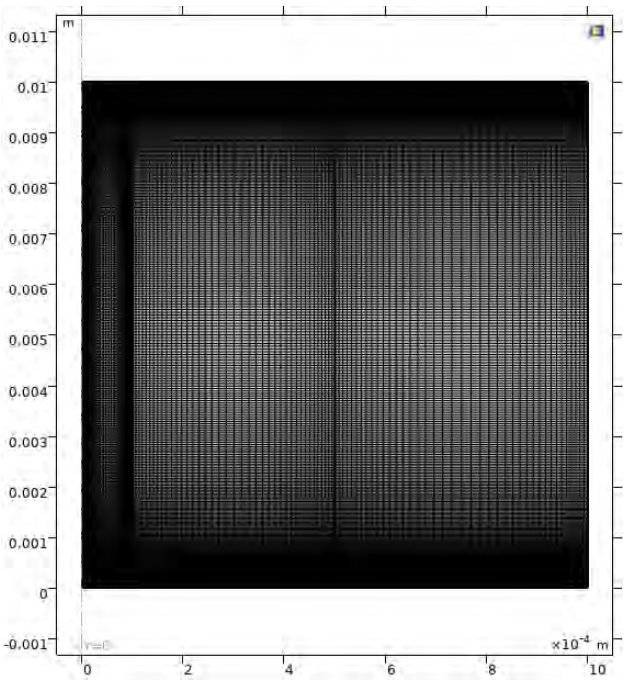

**Figure 2.** Mesh partitioning of the proposed model.

**Table 3.** The key input parameters for the proposed model.

| Parameters | Value | units |
|---|---|---|
| Temperature of inlet gas | 323 | K |
| Pressure of feed | 45 | Bar |
| Pressure of sweep gas | 0.8 | Bar |
| Permeance of $CH_4$ | 0.023 | mol(STP)/($m^2$·h·kPa) |
| Permeance of $H_2O$ | 1.217 | mol(STP)/($m^2$·h·kPa) |
| Diffusion coefficients of $CH_4$ | $2.32\times10^{-5}$ | $m^2/s$ |
| Diffusion coefficients of $H_2O$ | $1.66\times10^{-5}$ | $m^2/s$ |
| Dynamic viscosity of $CH_4$ | $1.058\times10^{-5}$ | Pa·s |
| Dynamic viscosity of $H_2O$ | $1.3\times10^{-5}$ | Pa·s |

## 3. RESULTS AND DISCUSSION

### 3.1 Process parameters optimization results

The optimization process selects specific costs as the objective function, using pressure ratio, membrane area, and sweep gas usage as decision variables, and applies the NSGA-II algorithm for optimization. The optimization range of decision variables is determined based on the results of sensitivity analysis.

**Table 4.** Decision variables ranges of the optimization process.

| Decision variables | Optimization range |
|---|---|
| Pressure ratio | [30,60] |
| Membrane area | [650,950] |
| Sweep gas flowrate | [150,300] |

The optimization process involves selecting the point with the minimum process cost to be incorporated into the operation. In this case, the permeate pressure is 0.8 bar, the membrane area is 850 $m^{2,}$ and the amount of sweep gas used is 150 kmol/h.

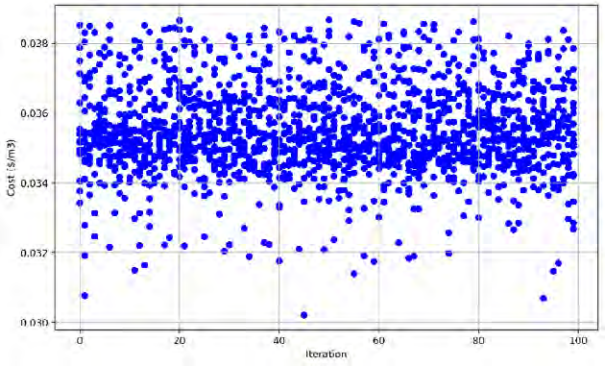

**Figure 3.** Optimization process scatter distribution.

At 4500 kPa, saturated natural gas passes through heat exchanger 1 (HX-1) and heat exchanger 2 (HX-2) to gradually lower the temperature before being sent to the gas-liquid separator (Sep). After removing condensate water and some heavy hydrocarbons, the gas is warmed up by HX-1 and then directed into a gas separation membrane unit for deep dehydration. By incorporating optimized parameters into the model, the water content in the outlet natural gas is 96 ppm, meeting the dehydration requirements, with a hydrocarbon loss rate of 3.00% and the specific cost of the process is 0.0306 $/$m^3$.

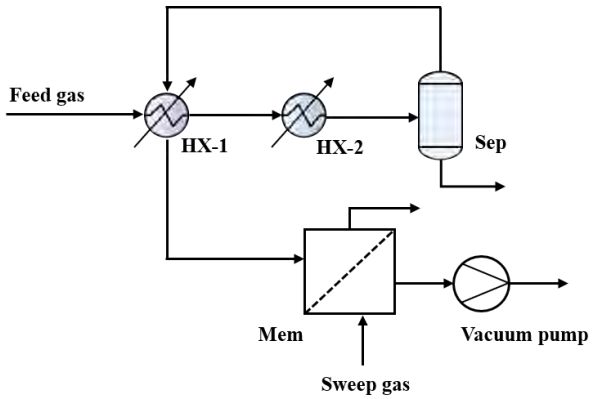

**Figure 4.** The flowchart of the natural gas dehydration process.

### 3.2 CFD simulation results

The velocity field and concentration field of water profile in the gas separation membrane are shown in Figures 5-6.

The velocity profile exhibits a parabolic distribution form, with the maximum flow velocity of 0.063m/s at the center of the pipe, while the velocity is reduced to 0.023m/s at the pipe wall due to the frictional force acting between the membrane selective layer. Furthermore, it is evident that the velocity remains undeveloped at the entrance zones of the feed side, with full development occurring as distance from the entrance increases. This observation underscores the significance of inlet effects on fluid flow hydrodynamics on the feed side. The velocity distribution on the shell side is determined through the solution of the Navier-Stokes equations and material balance equations.

Figure 6. describes the water concentration in the feed side of the feed side. The molar concentration of water in the natural gas feedstock decreased from 1.2 $mol/m^3$ to 0.18 $m^3/s$ at the outlet, successfully meeting the dehydration requirement of less than 100 ppm in the outlet natural gas. Moreover, the dehydration process exhibited a rational design as evidenced by the gradient changes in concentration curve, which showed good consistency with simulations performed using Aspen HYSYS software.

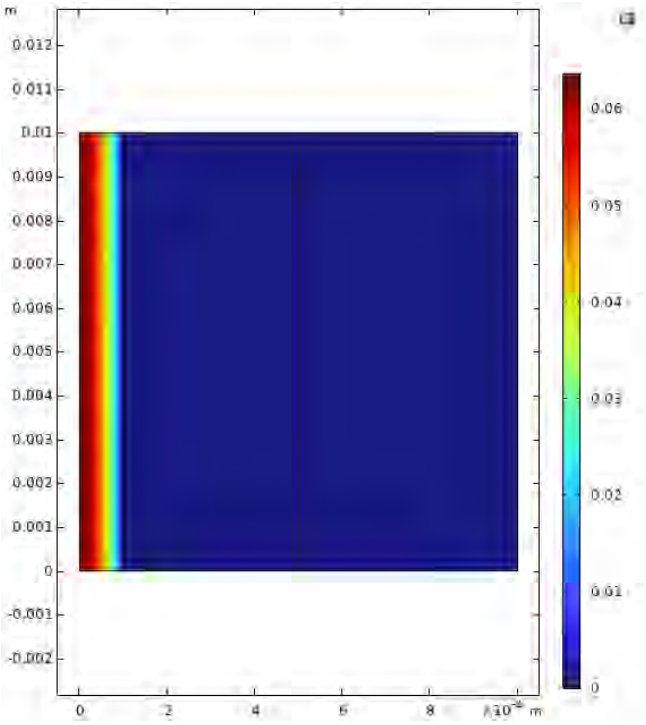

**Figure 5.** Field of velocity in the gas separation membrane

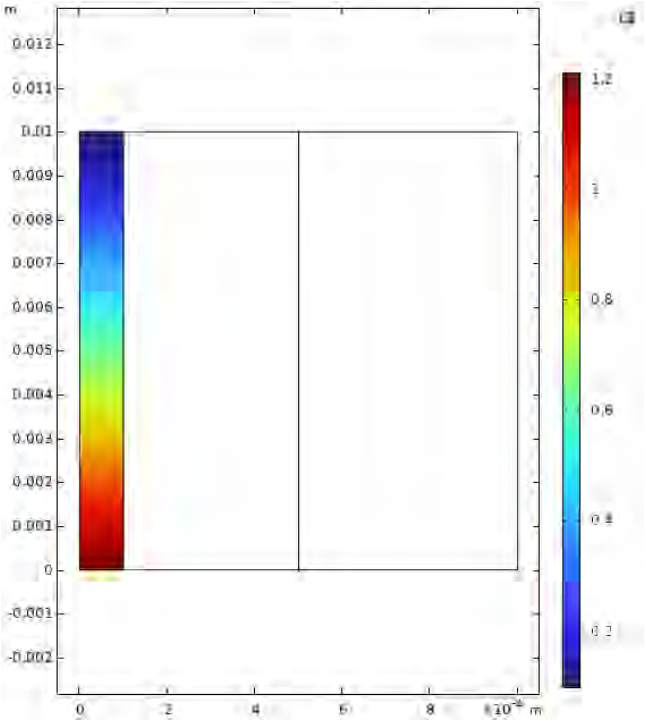

**Figure 6.** Concentration field of water in the feed side of the gas separation membrane.

## 4 CONCLUSION

The study employs a simultaneous approach of system scale design and mesoscale modeling to enhance the efficiency of natural dehydration process design. The natural gas dehydration process is conducted using Aspen HYSYS with ChemBrane extension. Decision variables such as pressure ratio, membrane area, and sweep gas flowrate are considered to minimize the specific process cost through optimization with NSGA-II algorithms. A minimum specific cost of 3.06×10-2 $/m$^3$ natural gas is projected to meet the separation requirement of 100 ppm. Subsequently, Computational Fluid Dynamics (CFD) is utilized to analyze the hollow fiber membrane design from the velocity and concentration profile, resulting in improved simulation outcomes. The integration of system scale engineering design and mesoscale modeling offers a comprehensive understanding of the natural gas dehydration process.

## ABSTRACT

The pharmaceutical and specialty chemical industries are challenged with the requirement of faster time-to-process to meet market demands. Here, Modular Plants made up of predesigned process equipment assemblies (PEAs) are advantageous. Moreover, equipment-based Digital Twins of these modules can further reduce the time-to-process when combined with methods such as Quality by Design (QbD) and model-based design of experiments (MBDoE) to reduce uncertainty. This paper presents a lab scale-based workflow using an equipment-based Digital Twin, which applies QbD and MbDoE methods to identify the Design Space in the lab scale which can be transferred to production scale equipment as part of a Digital Twin based workflow for scale-up in Modular Plants.

**Keywords**: Digital Twins, Model-based Design of Experiments, Quality by Design, Scale-up

## MOTIVATION

In the specialty chemical and pharmaceutical industries, faster time-to-process is a significant measure of success. Here the use of predesigned modules according to VDI 2776 [1] are advantageous. Additional benefit can be derived by creating equipment-based Digital Twins of these modular process equipment assemblies which can be combined with multiple product descriptions. This further supports and expedites the process development phase in multipurpose plants by providing Digital Twin supported prior knowledge of equipment capabilities with multiple product descriptions. In addition to these Digital Twins, another method to support faster time-to-process is reducing experimental efforts in the process development phase using model-based methods. Here, Digital Twin workflows which incorporate methods such as Quality by Design (QbD), Global System Analysis, model-based design of experiments (MBDoE), and the identification of the Design Space as well as leveraging prior knowledge of the equipment capabilities can be utilized to reduce the experimental load [2]. Prior knowledge of equipment capabilities and limits is supplied by the Digital Twin and is used to pre-screen combinations of Critical Process Parameters (CPP), Critical Material Attributes (CMA), and model parameters to identify suitable parameter combinations for inclusion in the MBDoE optimization problem [3].

In this paper, the relevant methodology and background is presented. Then, a Digital Twin workflow in the using a Capability Model of a Digital Twin of the lab scale equipment is introduced, explained, and applied using the process simulation tool gPROMS® for the specific example of an esterification process in a stirred tank reactor module. The use case highlights the benefits of combining these methodologies such as improved reduced experimental effort compared to traditional DoE and increased knowledge of Critical Process Parameters. We conclude this work with a critical evaluation of the applied methods and an outlook to future work.

## METHODOLOGY

### Digital Twins in Modular Plants

Modular Plants (MPs) are defined in the VDI 2776 [1] and VDI 2658 [4] set of specifications and consist of Functional Equipment Assemblies (FEAs) grouped into

reusable and adaptable Process Equipment Assemblies (PEAs). The functional capabilities of the PEAs are described by services, which can be orchestrated into recipes in the process orchestration layer (POL)[5].

For the context of this paper, a Digital Twin is defined as a semantically linked collection of digital artifacts [6]. These digital artifacts can be organized into partial models following a Product-Process-Resource-Model [7]. For Modular Plants, the Digital Twin is created from knowledge that is shared between PEA manufacturers and owner/ operator (O/O). The PEA manufacturer knowledge is a **Capability Model** describing the equipment capabilities independent of the product. The owner/operator knowledge is a **Transformation Model**, which is equipment independent and product specific. The Digital Twin combines these two models to form an **Operation Model**, which is used for recipes and process optimization. Similar separation-of-concern approaches are discussed in the domain of discrete manufacturing with a focus on standardized description of tasks and skills of machinery, e.g. [8], [9], [10]. For this purpose of this work, the Digital Twin is an equipment-based Digital Twin of a PEA which should be understood as a well characterized **Capability Model** that can be flexibly combined with a **Transformation Model** and uncertainties of a new product.

## Quality by Design

The Quality by Design (QbD) methodology is outlined in the ICH Q8 - 10. The QbD methodology combines different scientific methods such as Design Space identification, design of experiments, and risk management with the result of guaranteed product quality [11]. The two most relevant sub-concepts in QbD methodology are statistical DoE and the Design Space (DS). Statistical DoE is used to identity which experiments must be run to collect data required to describe the Knowledge Space. From the Knowledge Space, the Design Space can be identified. The Design Space describes the relationship between Critical Process Parameters (CPPs) and Critical Material Attributes (CMAs) which are inputs to a process and the acceptable ranges of Critical Quality Attributes (CQAs) of the product.

## Model-based Design of Experiments

As an alternative to statistical design of experiments, Model-based Design of Experiments (MBDoE) is a methodology which integrates differential and algebraic equation (DAE) type models and Design of Experiments (DoE). Here, the goal is to select the experiment variables with the highest sensitivities to the model parameters, yielding improved information from experiments [12], [13]. Prior knowledge (model structure from the Capability Model and initial parameter estimates from the Transformation Model) are used to design an experiment [14]. The result is quick identification of optimum process conditions based on the Critical Process Parameters for experiments, this aims to reduce experimental load as the information obtained from experiments increases. This is advantageous in process development workflows where time-to-process is critical and with additional benefit of supporting situations where experiment budget is limited.

## Digital Twin Workflow

The application of QbD and MBDoE methodologies into smart PEAs to reduce uncertainty in the process qualification phase has been explored by [3], [15] . The workflow presented in Figure 1 extends the workflow from [15] and is intended for scale-up based on a Digital Twin as shown in [2], [16]. This work focuses on the pre-

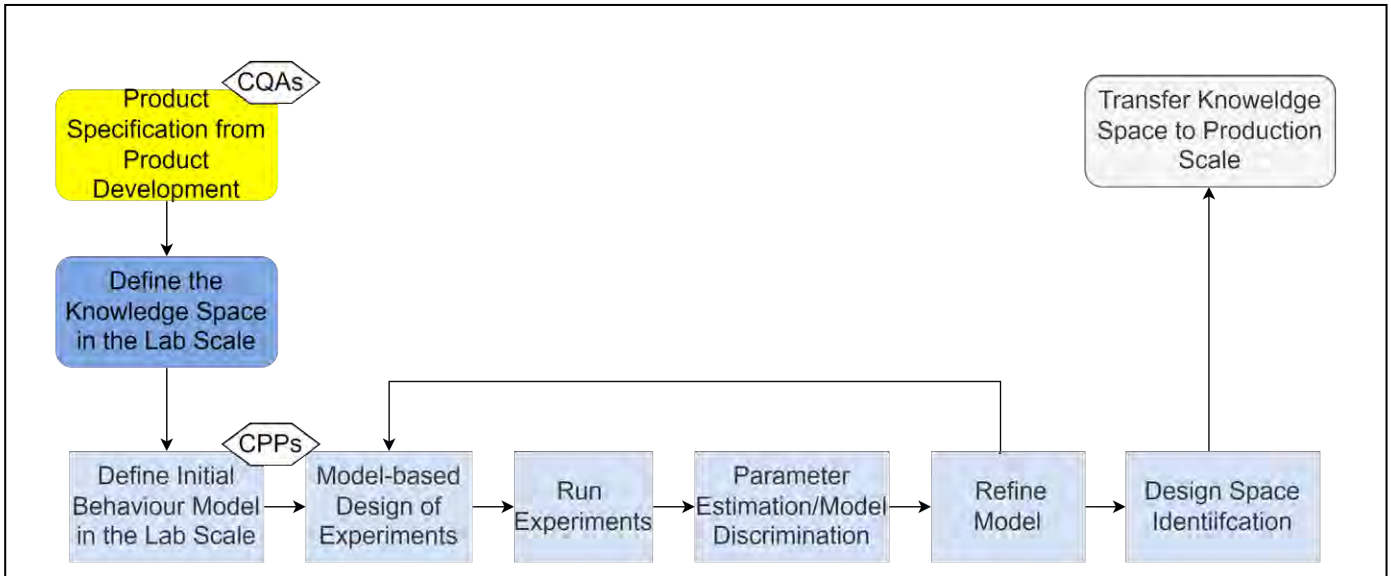

**Figure 1:** Digital Twin based workflow using the equipment-based Digital Twin in the lab scale with input from product specification and CQAs from product development.

screening using Global System Analysis, MBDoE, and identification of the Design Space in the lab scale using a Digital Twin of a PEA. This Digital Twin in this work combines a Capability Model [7] of the PEA with a Transformation Model of the product yielding an Operation Model. In the workflow in Figure 1, first Critical Quality Attributes are identified based on a product specification provided by product development. Then the Digital Twin of the lab scale is utilized. Using this Operation Model of the lab scale equipment, first Global System Analysis and variance-based sensitivities are used identify Critical Process Parameters and Critical Material Attributes based on the identified Critical Quality Attributes from the product specification. Critical model parameters for the MBDoE optimization problem are also identified.

Next, model-based design of experiments combines the prior knowledge of the CPPs from the Capability Model to identify the ideal set of process conditions to yield the maximum amount of information from experiments. The model parameters can be divided according to the PPR model [7], where the product specific parameters (i.e. activation energy, $k_\infty$, heat of reaction) are described by the Transformation Model and resource specific parameters (i.e. heat transfer coefficients, mixing time) are described by the Capability Model. Here, it is assumed that the uncertainty regarding the Transformation Model is significantly higher than model parameters which are described by the Capability Model, which has been characterized and validated from characterization experiments and previous processes run in the equipment. Following the MBDoE, experiments are run, and the experimental data is used to improve the parameter estimates in the model. These improved parameter estimates are then implemented into the model and validated with experimental data which has not been used for the parameter estimation. If the predictive capabilities of the model are sufficiently accurate based on the validation data, the model can be used to define the Knowledge Space. The final step of the workflow in Figure 1 in the lab scale is to use the CQAs to identify the Design Space from the Knowledge Space. Based on the identified Design Space, the relevant model parameters and uncertainty from the Transformation Model are transferred from the Operation Model of the lab reactor to the Capability Model of the production equipment. This yields an Operation Model of the production equipment which is then used to characterize the Knowledge Space and subsequently identify the Design Space in the production scale.

# CASE STUDY

## Application Example

To illustrate the methods of the workflow presented in Figure 1, an esterification reaction in a 2 L stirrer tank reactor was selected. The butyl acetate synthesis [17] is a homogeneously catalysed reaction. The catalyst in this example is sulfuric acid. The CQA for the product specification is the concentration $C_{butyl\ acetate} \geq 0.5\ mol/L$ of the target product butyl acetate the outlet of the reactor.

$$butanol + acetic\ acid \leftrightarrow butyl\ acetate + water \quad (1)$$

The kinetic behavior of the process can be described with the following set of equations:

$$r = c_{sulfuric\ acid}\,(k_1 * c_{butanol} * c_{acetic\ acid} - k_2 * c_{butyl\ acetate} * c_{water}) \quad (2)$$

$$K_{eq} = k_1/k_2 \quad (3)$$

$$k_i = k_{i,\infty} \exp\left(\frac{-E_{A,i}}{R\,T}\right) \quad (4)$$

To mimic the real conditions in process development, initial estimates for the kinetic parameters and uncertainties was estimated by fitting real experimental data from [17] to Arrhenius' law given by Equation 4.

$$E_{A,1} = 36281\ \frac{J}{mol};\ k_{1,\infty} = 31.5\,\frac{L^2}{min \cdot mol^2}$$

$$E_{A,2} = -478.34\ \frac{J}{mol};\ k_{2,\infty} = 1.6E^{-5}\ \frac{L^2}{min \cdot mol^2}$$

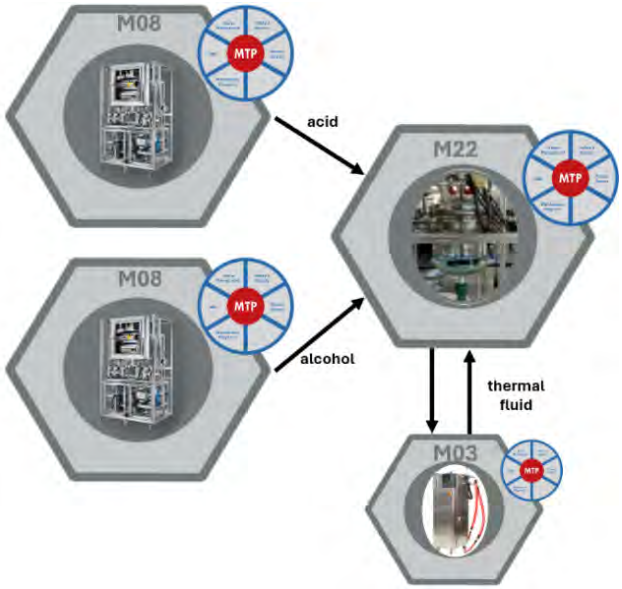

**Figure 2.** Modular plant configuration for butyl acetate synthesis.

Figure 2 provides an overview of the modular configuration which is used to carry out the esterification process. Here, three different modules are used:

- M08 is a doubling dosing module which is used to store and supply the reactants to the reactor

- M22 is a 2 L stirred tank reactor which is used to carry out the reaction
- M03 is a thermostat module used to supply mono ethylene glycol to the M22 reactor jacket.

We can describe our system with the following set of variables:

- **x** describes the state of the system at time ($t$)
- $\mathbf{u}_{CMA}$ describes independent inputs related to CMAs
  - Purity of the reactants ($x_{Acid,1}, x_{Alcohol,2}$)
- $\mathbf{u}_{CPP}$ describes independent inputs related to CPPs
  - Reactor temperature ($T$) controlled by the Temperature of the heating medium $T_{HM}$ with the Service *Tempering*
  - Feed ratio of reactants ($\dot{n}_{Alcohol}, \dot{n}_{Acid}$) controlled by the *Dosing* Services
  - Mixing speed $n_{Stirrer}$ controlled by the *Stirring* Service
- $\boldsymbol{\theta}_{TM}$ describes the parameter values related to the Transformation Model of the product:
  - Activation energy ($E_{A,1}, E_{A,2}$)
  - Pre-exponential factor ($k_{inf,1}, k_{inf,2}$)
- $\boldsymbol{\theta}_{CM}$ describes the parameters contained in the Capability Model of the PEA:
  - Heat transfer coefficient ($k_D$)

In the system described by the variable set, the significant uncertainty in the model is the Transformation Model parameters ($\boldsymbol{\theta_{TM}}$) as outlined in the methodology.

To better understand the effect that the uncertainty of the estimated model parameters in the Transformation Model $\boldsymbol{\theta_{TM}}$ has on the predictive capabilities of the Digital Twin, a Global System Analysis is carried out with respect to $\boldsymbol{u}_{CPP}$ the described by the resources model and $\boldsymbol{u}_{CMA}$ described by the product model. The parameter screening uses the GSA tool in gPROMS®, which combines a Monte-Carlo-Simulation and Sensitivity analysis based on variance-based indices. The result of the pre-screening is a series of scatter plots that serve two purposes: (1) identify relationships between CPPs $u_{CPP}$ and CMAs $u_{CMA}$ and model parameters $\boldsymbol{\theta_{TM}}$ and (2) identify relationship between model parameters $\boldsymbol{\theta_{TM}}$ and the CQAs. A selection of two GSA scatter plots is shown in Figure 3. The effects of model parameter from the Transformation Model $\theta_{TM}(E_{A,1})$ and CPP from the resource model $u_{CPP}(T_{HM})$ are shown. Here, it is evident that the estimated value of model parameter of the activation energy of the forward reaction $E_{A,1}$ has a significant influence on the target CQA, while the CPP of the temperature of the heating medium $T_{HM}$ does not have a clear effect.

## MBDoE Problem

To describe the Knowledge Space prior knowledge from the equipment capabilities from the PEA manufacturer is combined with initial parameter estimates provided by the owner/operator. These initial parameter estimates can be obtained with short cut models or group contribution estimation methods. This yields a Digital Twin built from combined knowledge of a characterized equipment model with less characterized product model.

Using this behavior model of the Digital Twin, MBDoE methods [14] are applied for parameter estimation and for model discrimination.

$$y_i = m(u_i, \boldsymbol{\theta}_{TM}) + \epsilon_i \quad (5)$$

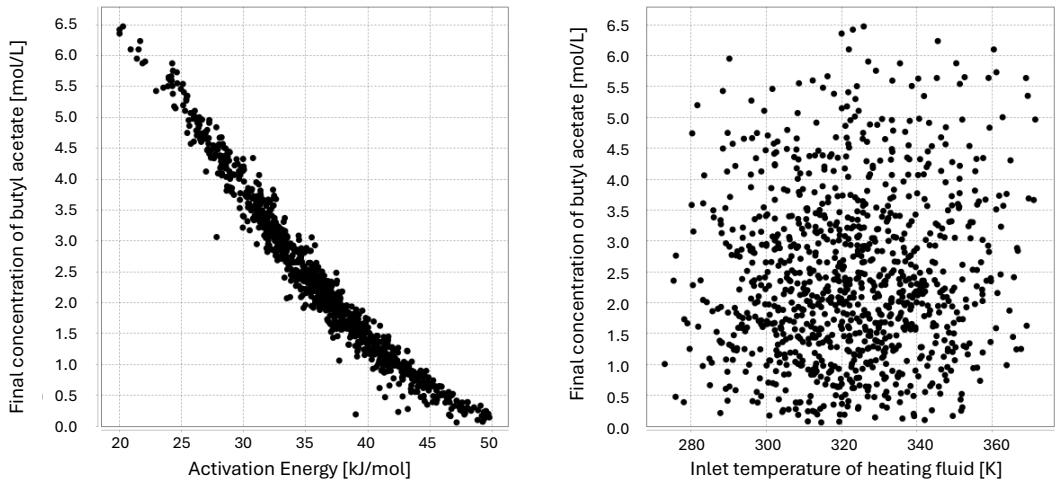

**Figure 3:** Influence of the Transformation Model parameter of Activation Energy $\theta_{TM}(E_{A,1})$ on the CQA ($C_{butyl\ acetate}$) (left). Influence of the CPP of temperature of the heating medium $u_{CPP}(T_{HM})$ on the the CQA ($C_{butyl\ acetate}$) (right).

Here, $y_i$ are the measurements (concentration samples), $m$ is the DAE model, $\theta_{TM}$ is the set of model parameters to be optimized ($E_{A,1}$, $k_{1,\infty}$ ), $u_i$ are the control variables based on the service specification and parameterization of the module which can be manipulated in the optimization problem. For the MBDoE optimization problem, the experimental budget was determined to be six experiments: five for model-based experiments and one for model validation. The data collected during these experiments is used to estimate parameters in the Transformation Model $\boldsymbol{\theta}_{TM}$ including uncertainty estimates, applying e.g., the maximum likelihood method [14].

## Identification of the Design Space from the Knowledge Space

Once the model has been revised with the parameter estimates from the experiment data. The design spec can be identified. To describe the Knowledge Space a system of nonlinear algebraic equations (NAEs) based on the previously described set of variables is proposed:

$$\mathbf{0} = \boldsymbol{h}(\boldsymbol{x}, \boldsymbol{u}_{\mathrm{CMA}}, \boldsymbol{u}_{\mathrm{CPP}}, \boldsymbol{\theta}_{\mathrm{TM}}, \boldsymbol{\theta}_{\mathrm{CM}}) \quad (6)$$

To identify the Knowledge Space, prior knowledge is required. The prior knowledge of CPPs is based on the resource model, specifically the operational limits of the model and the service specification described by the Capability Model of the Digital Twin. Then, the model according to Equation (1) is revised with the improved estimates of the model parameters. To identification of the Design Space from a Knowledge Space described in Equation (6), an Extended Flexibility Analysis approach such as described by [18] and illustrated in [3], [15] is applied. In the Flexibility Analysis, the range of the CQAs are described by the feasibility function

$$\boldsymbol{g}_{\boldsymbol{j}}(\boldsymbol{x}, \boldsymbol{u}_{\mathrm{CMA}}, \boldsymbol{u}_{\mathrm{CPP}}, \boldsymbol{\theta}_{\mathrm{TM}}, \boldsymbol{\theta}_{\mathrm{CM}}) \leq 0 \quad (7)$$

An example of the Knowledge Space according to Equation 6 as well as the identification of the Design Space from the Knowledge Space as part of the flexibility analysis applying Equation 7 is shown in Figure 4.

# DISCUSSION

The Digital Twin workflow based on the Capability Model of the lab scale equipment presented in the methodology and illustrated using the application example of the esterification process shows how application of MBDoE methods reduces the required number of experiments required to estimate new parameter values to improve the prediction accuracy of the lab scale model. In the example here, an experimental budget of six experiments was selected, whereas statistical plans to describe the Knowledge Space require a minimum of nine or more experiments. Although real experimental data was used to generate initial estimates for the model parameters, the experimental data for the MbDoE optimization problem was simulated using models based on the real equipment geometry and capabilities. The incorporation of real experimental data into MBDoE step of the workflow would strength the results of the use case. However, the benefit of the workflow is still illustrated by the presented results. Moreover, metrics based on heuristics are needed to compare the results of this method both in terms of time saved as well as information gained.

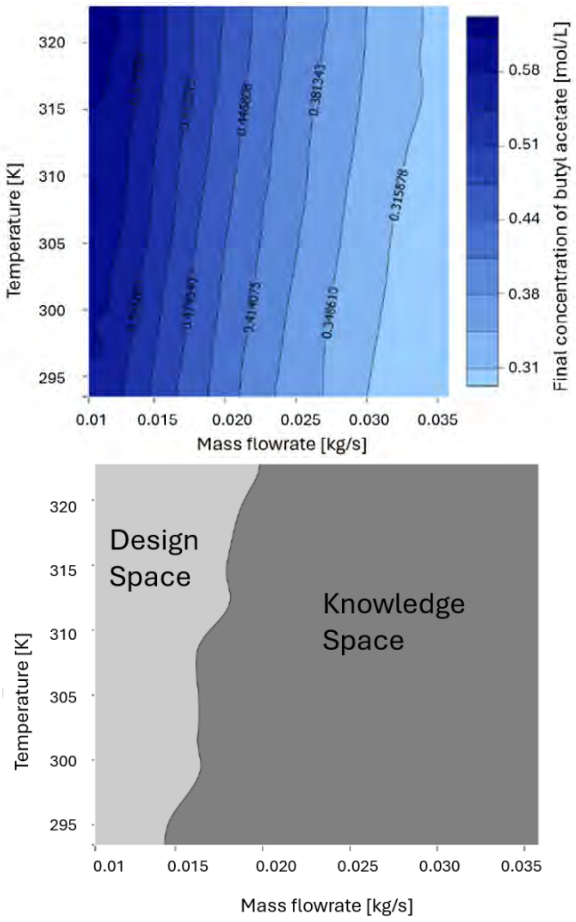

**Figure 4.** Identification of the Knowledge Space (top), identification of the Design Space from the Knowledge Space based on the CQA criteria from the product model (bottom).

# CONCLUSION AND OUTLOOK

This paper presented a Digital Twin based workflow using a Capability Model of a lab scale PEA incorporating MBDoE and QbD methodology for simultaneously increasing information about the Knowledge Space and resulting Design Space, while using model-based methods to reduce experimental load in the process development phase resulting in a faster time-to process. In a next step, the workflow should be illustrated using real experimental data. Future work will also focus on the specific

challenges in scaling-up between dimensions as well as the benefits of scale-up in Modular Plants where the advantages of process intensification can be retained. A specific challenge is to integrate the identified parameter values from Transformation Model along with uncertainty factors into the Capability Model of the production scale equipment. These Capability Models are for equipment that is functionally similar, but of different scales and different PEA Manufacturers.

## ACKNOWLEDGEMENTS

The authors would like to thank our partners Merck Electronics KGaA and Siemens AG in the industrial research project Lab2Plant for the fruitful discussions as well as P2O-Lab Learning Factory at TU Dresden's Process-to Order Group for the information about their modules M02, M08, and M22.

## ABSTRACT

Acetic acid is an important bulk chemical and one of the major downstream products of methanol. However, it has received less attention from an environmental sustainability perspective. Here, we evaluate the absolute sustainability of several acetic acid synthesis routes, considering both fossil and renewable feedstocks. More specifically, we studied the business-as-usual (BAU) methanol carbonylation and the novel, low technology readiness level (TRL) methane carboxylation and semi-artificial photosynthesis routes. Using process simulation and life cycle assessment (LCA), our results reveal that the alternative routes have the potential to outperform the fossil BAU in at least 14 out of the 16 evaluated impact categories. However, despite the overall improvements, their performance in SDGs 3, 6, 13, 14 and 15 remains poor in any of the studied scenarios, which could potentially be addressed by hybridizing fossil and renewable feedstocks. All in all, our analysis underscores the importance of absolute sustainability to contextualize the environmental footprint of alternative chemical synthesis pathways, going beyond climate change to embrace a broader sense of categories relative to absolute thresholds.

**Keywords**: green acetic acid, alternative chemical synthesis pathways, semi-artificial photosynthesis (SAP), sustainable development goals (SDGs), absolute environmental sustainability assessment (AESA)

## 1. INTRODUCTION

Identifying pathways to replace fossil carbon with renewable carbon (i.e., captured $CO_2$, chemical waste and biomass) in chemical production is one of the most sought-after solutions for mitigating the greenhouse gas emissions associated with the chemical industry [1]. However, while this shift to renewable carbon often reduces $CO_2$ emissions, it can also lead to burden shifting, where improvements in one environmental category come at the expense of worsening others [2].

Acetic acid is an important chemical with an annual demand of over 17 Mt and serves applications, including the synthesis of plastics, dyes, insecticides and drugs. The standard route to synthesize acetic acid relies on fossil natural gas-based methanol and carbon monoxide in the so-called Cativa process, involving four energy-intensive reaction steps [3]. In the context of sustainable acetic acid synthesis, existing environmental studies are scarce and primarily focus on carbon footprint, rarely addressing other impact categories [4-7]. Moreover, current studies employ conventional life cycle assessment (LCA), which evaluates the relative differences against a benchmark, often set by the standard fossil-based process. While this methodology is useful for comparing technologies, it fails to capture the true environmental implications of the assessed processes at an Earth-system level. Consequently, absolute environmental sustainability assessment (AESA) methods are gaining popularity [8]. These methods are built on the concept of planetary boundaries (PBs), which define the safe operating space (SOS) for humanity to interact with the planet, enabling direct comparisons with the Earth's carrying capacity [9].

To address this research gap, here we compare the environmental performance of alternative, more efficient, single-step acetic acid synthesis routes with both fossil and green-based conventional processes. Moreover, for the first time, we assess the absolute sustainability level of these synthesis pathways based on the Sustainable

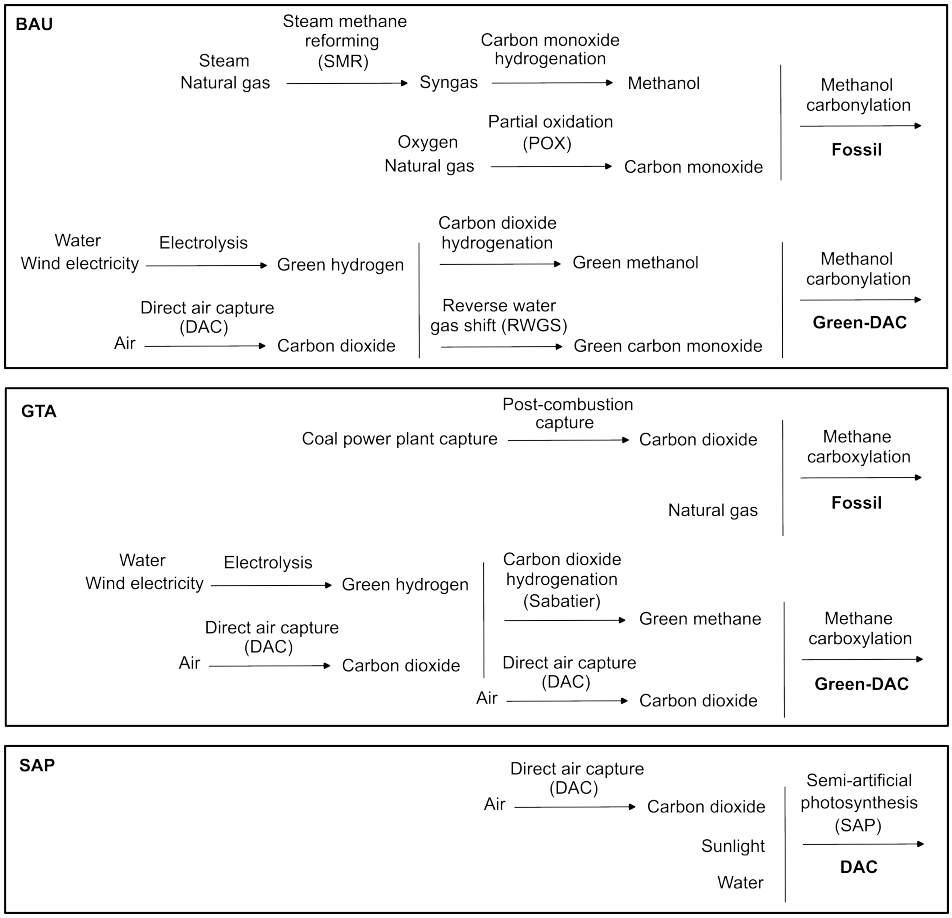

**Figure 1:** Assessed acetic acid synthesis scenarios.

Development Goals (SDGs), which are computed considering the transgression levels attained relative to the PBs [10].

Our results uncover that despite significantly improving climate change impacts, in addition to other 13 impact categories, none of the studied alternative acetic acid synthesis routes can simultaneously stay within the SOS of the impact categories connected to the SDGs. Moreover, we highlight the potential of hybridizing the feedstocks to enhance their environmental performance.

## 2. METHODOLOGY

We study five acetic acid synthesis pathways from an absolute sustainability perspective (Figure 1). These scenarios combine three different technologies (business-as-usual, BAU; gas-to-acid, GTA and semi-artificial photosynthesis, SAP), with two different feedstocks: fossil-based (natural gas, coal power plant captured $CO_2$) and renewable (wind-powered electrolytic green H2 and direct air captured (DAC) $CO_2$). We use process simulation (Aspen Plus v12) and literature data to model all proposed scenarios. An overview of the routes is shown in Figure 1.

For the life cycle assessment (LCA), we follow the guidelines of the ISO 140040/44 framework [11]. We perform a cradle-to-gate assessment with a cut-off attributional approach for acetic acid synthesis, with a functional unit of 1 kg of acetic acid. The foreground system is based on energy and material streams extracted from process simulations developed using Aspen Plus v12, and was retrieved from a previous work [4]. The background system is defined from the Ecoinvent v3.9.1 [12] database and includes all upstream activities related to electricity, energy and raw material production. The life cycle impact assessment (LCIA) is computed with Brightway2 v2.4.6 [13] using the EF v3.1 (15 impact categories) and LANCA v2.5 (land use) methods for the analysis.

The AESA is carried out following the methodology developed by Sala and collaborators [10]. Using Eq.(1), we quantify the transgression level (TL) of category $i$ ($TL_i$) based on the environmental impact of category $i$ per kg of acetic acid ($impact_i$) and the global demand of acetic acid in 2022 ($market^{acetic}$, 17.48 Mt). This calculation is performed relative to the PB of said category i ($PB_i$),

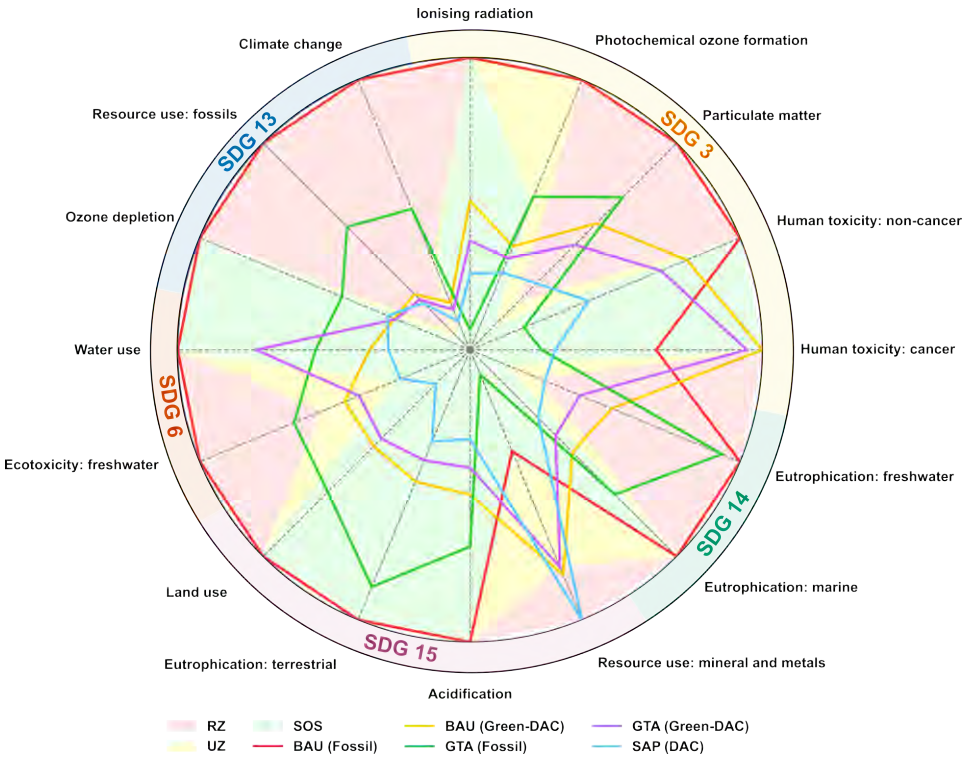

**Figure 2:** Overview of the absolute sustainability results for the studied scenarios. The background colors showcase the level of transgression: SOS, safe operating space (green), UZ, uncertainty zone (yellow); RZ, risk. zone (red). Scenarios are defined in Figure 1.

and is multiplied by a downscaling factor ($DF$). This downscaling factor (Eq.(2)) allocates a fraction of the total PBs to acetic acid production based on some sharing principles [14]. Here, we adopt a utilitarian approach based on the global market value of acetic acid in 2022 ($GVA^{acetic}$, 14.15 B$) and the world ($GVA^{world}$, 88570 B$) gross value added (GVA) for the same year. Finally, we link the TL of each impact category to the SDGs following the guidelines outlined in Sala et. al [10].

$$TL_i = \frac{impact_i \cdot market^{acetic}}{PB_i \cdot DF} \quad \forall\, i \in I \tag{1}$$

$$DF = \frac{GVA^{acetic}}{GVA^{world}} \tag{2}$$

We consider that the level of impact on an SDG is within the associated thresholds when the TL of every impact category associated with that SDG is below one, that is, it operates within the allocated fraction of the PB, also referred to as the SOS [15, 16]. Values of the TL between one and two are considered within the so-called uncertainty zone, while values over two belong to the risk zone.

## 3. RESULTS

As seen in Figure 2, the fossil BAU scenario is outperformed in 14 out of the 16 studied categories by all the proposed alternative synthesis routes, while the fossil GTA and the SAP scenarios perform better in 15 of them. Overall, most of the synthesis pathways are unable to operate within all the thresholds of all the impact categories linked to an SDG, except for the fossil BAU and GTA in SDG 15 (life on land), and SAP attaining SDG 6 (clean water and sanitation). Across scenarios, SDG 3 (good health and well-being) is hindered by high impacts, well into the risk zone, of particulate matter; SDG 6 is affected by high freshwater ecotoxicity levels; SDG 13, (climate action) suffers from high fossil resource use; SDG 14 (life below water) is adversely affected by freshwater eutrophication levels and, finally, the SOS associated with SDG 15 is transgressed from high mineral and metals resource use.

Despite the fossil BAU scenario performing worse in most cases, it already operates within the SOS in 9 out of 16 categories: ionizing radiation, non-cancer human toxicity, cancer human toxicity, marine eutrophication, mineral and metals resource use, acidification, terrestrial eutrophication, land use, water use and ozone depletion. In contrast, it transgresses the SOS (uncertainty zone) for photochemical ozone formation, and it is well into the risk zone in the remaining five categories: particulate matter, freshwater eutrophication, freshwater ecotoxicity, fossil

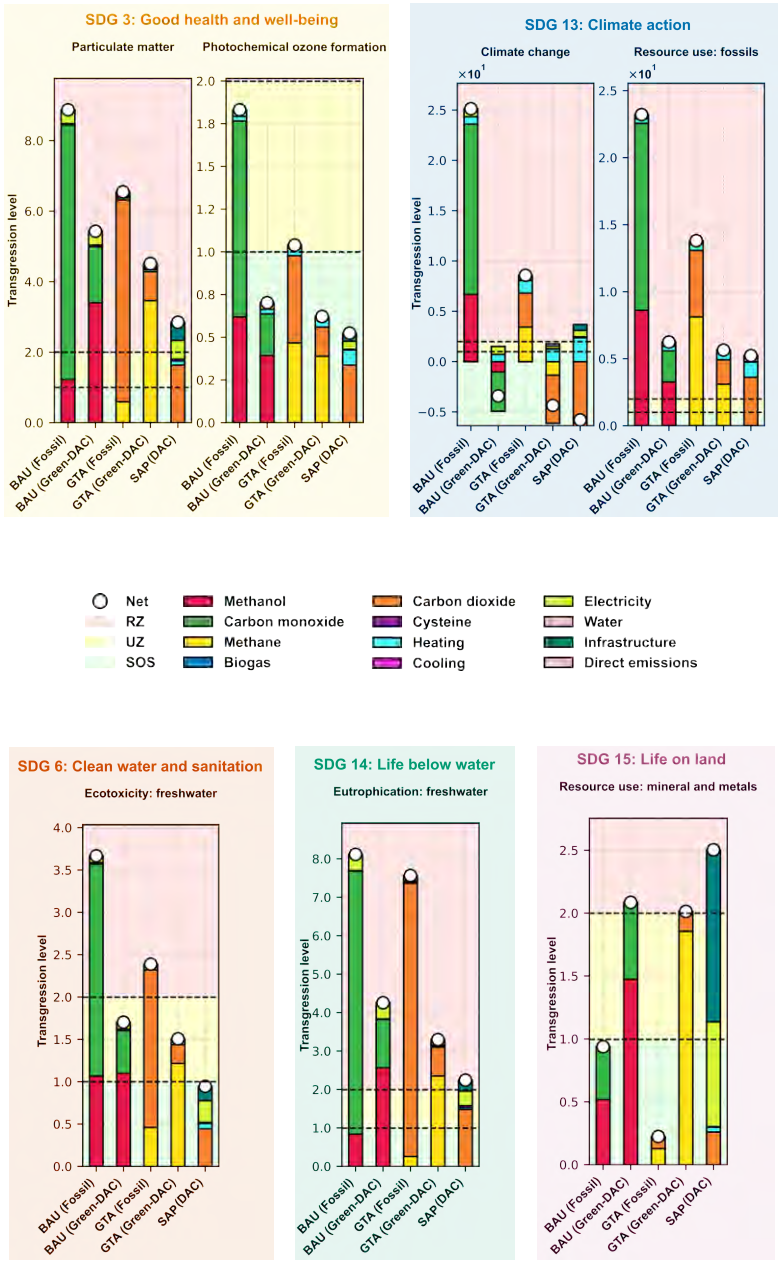

**Figure 3:** Transgressed impact categories process contributions.

resource use and climate change.

By switching the feedstock to green methanol and carbon monoxide synthesized from DAC $CO_2$ and renewable electricity, the green-DAC BAU scenario shows improvements over its fossil analog in all categories except cancer human toxicity and mineral and metals resource use. However, it is worth noting that the absolute sustainability assessment reveals that for cancer human toxicity, this collateral damage occurs within the limits of the SOS. Despite these overall improvements, the green-DAC BAU scenario is still unable to stay within the SOS of any SDG, as the impacts on particulate matter, freshwater eutrophication, mineral and metals resource use, freshwater ecotoxicity and fossil resource use, associated with SDGs 3, 6, 15, 14 and 13, respectively, transgress the maximum threshold.

The fossil GTA, that is, the direct synthesis of acetic acid from methane (natural gas) and coal power plant-captured $CO_2$, outperforms the fossil BAU in all categories due to the reduced energy and material requirements of the one-step process compared to the four steps required for the standard synthesis. However, despite this

excellent performance, SDGs 3, 6, 13 and 14 lie still outside the SOS due to high impacts in the categories cited above. On the other hand, SDG 15 is within the SOS due to a particularly low mineral and metals resource use impact compared to the other scenarios. The green variant of the GTA, which uses DAC $CO_2$ and renewable energy, performs slightly better than the green-DAC BAU scenario but also transgresses the SOS in all categories studied.

Finally, the SAP using DAC $CO_2$ as a carbon source emerges as one of the best-performing synthesis routes, being the only pathway to operate within the SOS in freshwater ecotoxicity and thus attaining SDG 6. Conversely, this scenario also exhibits the highest impact on mineral and metal resource use due to the utilization of solar power, batteries and specialized infrastructure, as detailed below.

Figure 3 shows the material and energy contributions of the transgressed impact categories for all evaluated scenarios. Overall, the main sources of impact in all categories for the fossil BAU are the raw materials, methanol and carbon monoxide, followed by very small contributions from process heating and electricity. From these results, it is evident that fossil carbon monoxide singlehandedly prevents staying within the SOS of SDGs 3, 6, 13 and 14, while the contribution from methanol is much lower. On the contrary, for the green-DAC BAU scenario, green methanol shows overall higher impacts than green carbon monoxide, especially in mineral and metals resource use (SDG 15), particulate matter (SDG 3), freshwater ecotoxicity (SDG 6) and freshwater eutrophication (SDG 14). These results suggest that partially shifting to green carbon monoxide from renewable electricity and captured $CO_2$ could significantly improve the performance of the BAU. More specifically, this hybrid configuration could help operate within the SOS of SDG 6, particularly for photochemical ozone formation, without causing significant burden-shifting (i.e., the collateral damage remains below the SOS).

The GTA process shows some parallelism with the BAU. The main impact contributions of the fossil variant of the GTA are the raw materials, methane from natural gas and $CO_2$ captured from a coal power plant, with negligible contributions from energy. However, $CO_2$ dominates in most of the transgressed categories (particulate matter, photochemical ozone formation, climate change, freshwater ecotoxicity and eutrophication). In contrast, the green-DAC GTA suffers from high impacts from synthetic methane. Hence, shifting to a hybrid natural gas with DAC $CO_2$ GTA could potentially help the technology operate within the SOS of SDGs 6, 14 and 15 despite still using fossil methane as feedstock.

Finally, the SAP scenario behaves differently depending on the impact category with DAC $CO_2$ being the most important contribution in air, water and fossil resource use-related categories. However, renewable solar electricity and the borosilicate/aluminum photochemical reactor account for over 90% of the impacts on mineral and metal resource use.

From these results, we can infer that the hybridization of fossil and renewable feedstocks could potentially help operate within the SOS of a higher number of SDGs, such as SDGs 6, 14 and 15. More specifically, using fossil methanol with green carbon monoxide in the BAU, or fossil methane with DAC $CO_2$ in the GTA, could minimize the trade-offs derived from using electrolytic hydrogen and renewable electricity of a hypothetical complete shift to renewable energy sources.

## 4. CONCLUSIONS

In this work, we studied the absolute sustainability of alternative acetic acid synthesis routes and compared them to the BAU using fossil methanol and carbon monoxide. Our results show that all evaluated acetic acid synthesis pathways outperform the fossil BAU in terms of climate change impact and 13 other categories. However, burden-shifting still manifests in two categories: human toxicity, and minerals and metals resource use. The AESA reveals that the human toxicity collateral damage occurs within the SOS, rendering it less important. Despite the overall improvements in most impact categories, all the evaluated scenarios transgress at least one of the impact categories associated with the assessed SDGs. However, hybridization of the feedstocks could help in balancing the trade-offs, with a fossil-renewable hybrid GTA scenario potentially operating within the SOS of SDGs 6, 14 and 15. All in all, we show how it is possible to improve the sustainability level of acetic acid synthesis and demonstrate that AESAs provide very valuable insights in the evaluation of alternative synthesis pathways.

## ABSTRACT

This work investigated synergies for improved energy efficiency between integrated first- (1G) and second-generation (2G) sugarcane ethanol distillation, an energy-intensive unit operation, especially for stand-alone 2G ethanol. For this investigation, integrated and separated 1G2G distillation simulations were conducted using Aspen Plus v.10 assuming a dilute 2G fermentation beer with titer varying from 5 to 40 g/L. The results were then assessed in heating energy demand savings for distillation, and it was measured the potential of saved bagasse (boiler fuel) for valorization in either electricity or 2G ethanol. A life cycle assessment was also performed for a consequential approach to carbon emission reductions from energy savings. As our main result, distillation integration can maintain the heat demand of a stand-alone 1G mill, regardless of the 2G ethanol beer titer. This means energy savings between 9 and 15% in total ethanol heat demand, and between 46 and 92% in 2G ethanol heat demand. The savings are due to the reflux ratio associated with 2G ethanol distillation becoming close to the host 1G distillation process. However, although the energy savings may result in economic gains, not assessed in this study, by using saved bagasse for either electricity (between 0.14 and 0.23 $MJ_{Electricity}/kg_{Ethanol}$) or 2G ethanol production (between 6.8 and 4.1 $g_{2G\ Ethanol}/kg_{Ethanol}$), the boiler fuel savings do not significantly decrease carbon emissions of ethanol production (less than 1%). Nonetheless, the lower energy demand has the potential to debottleneck the operational cost challenge of distillation for 2G ethanol production without associated trade-offs.

## INTRODUCTION

Achieving a sustainable future requires shifting from non-renewable to renewable energy sources. Among several strategies for energy decarbonization, biofuels are of economic and environmental interest because they produce energy while being carbon-negative if the production process is integrated with carbon capture technologies [1]. Ethanol is one of the most studied biofuels, being produced commercially in Brazil mainly by fermenting sugars from sugarcane juice (first-generation ethanol) and sugarcane bagasse (second-generation ethanol), resulting in fermentation beer containing mostly ethanol and water.

Among many technologies for ethanol separation, distillation is the traditional choice in industry. However, distillation is also known for being energy-intensive and thermodynamically inefficient [2]. Such energy waste creates unnecessary emissions and costs to the production of ethanol. Although this inefficiency can be

improved by heat integration strategies, such as side heat exchangers and heat pumps [2], first-generation (1G) sugarcane ethanol has already achieved commercial viability in Brazil. Meanwhile, the production scale of second-generation (2G) bagasse ethanol increases yearly with the opening of new mills in Brazil by Raízen [3].

Despite this growth, 2G bagasse ethanol is more energy inefficient than its 1G counterpart because 2G ethanol fermentation beer has lower ethanol titer, increasing heat duty and production costs per ethanol mass produced [4]. This increased production cost can become a limiting factor for 2G bagasse ethanol economic viability in titers below 40 g/L, which is the case of most 2G ethanol fermentation technologies, in stand-alone mills [4]. For this reason and because of the logistics involving transporting sugarcane bagasse, 2G bagasse ethanol is currently commercially produced in plants annexed to 1G ethanol plants, and this configuration can likely become one path of evolution for ethanol production in Brazil.

In the context of 1G2G integrated sugarcane ethanol plants, mixing ethanol fermentation beer from both processes may reduce the production costs of 2G ethanol (personal communication with a 2G ethanol producer). Another approach is to perform an initial stripping of 2G ethanol and then integrate the resulting vapor into a host 1G distillation column. However, the energy advantages of this integrated model compared to its stand-alone counterparts remain unclear. Thus, a preliminary comparison with rigorous simulations is needed to measure the benefits of integrating the distillation of 1G and 2G ethanol from an energy efficiency point of view, as well as the consequences from potential energy savings for the reduction of carbon emissions and residue (boiler fuel) valorization.

## METHODOLOGY

This investigation presents an integrated distillation approach that utilizes a first-generation (1G) distillation column for processing second-generation (2G) ethanol. In this proposed configuration, it is crucial that the rectification section, particularly its condenser duty, remains unaffected by the addition of diluted ethanol.

Whereas the integration can be accomplished through a single-column system that processes beer from both 1G and 2G processes, this work proposes a two-column system, featuring a dedicated column for stripping the 2G beer. The vapor generated in this column is then directed to an integrated column that processes the 1G beer. This dual-column configuration is favored for economic reasons, as it allows for the separation of 1G and 2G bottoms (i.e. stillage), facilitating potential residue valorization through other processes.

This investigation does not compare its findings with other energy-saving distillation strategies, such as double-effect and heat-pumped distillation. A comprehensive comparison would necessitate an in-depth analysis of the technical, economic, and environmental metrics, given the differing theoretical frameworks of these strategies.

Simulations of separated (Figure 1) and integrated (Figure 2) 1G2G distillation were conducted using Aspen Plus v.10. The nonrandom two-liquid (NRTL) thermodynamic model was used to represent the liquid-vapor equilibrium. The separated distillation configuration comprised two RadFrac columns designed to distill the fermentation beer from both first-generation (1G) and second-generation (2G) processes until reaching near azeotropic levels. In contrast, the integrated distillation setup features an initial column that strips the 2G beer into a vapor phase, followed by an integrated column that distills both the 2G vapor and the 1G fermentation beer until they also reach azeotropic levels. The RadFrac distillation columns were simulated with 40 stages for operation near the minimum reflux condition and to isolate changes in energy demand for only interactions between distillation columns and not due to possible distillation inefficiencies by additional feeds. The RadFrac 2G stripping column was simulated with 20 stages for the same reasons as the distillation columns. In both integrated and separate situations, the final distillate is assumed to be in the vapor phase for the subsequent dehydration step in the ethanol mill. For the purpose of the preliminary analysis reported here, it was assumed that both mixtures enter the columns as saturated liquids, comprising primarily water and ethanol to facilitate a generalized analysis. Additionally, other components, such as residues from the fermentation process, were not included in this assessment. This exclusion is based on the typically low mass fractions of these residues, which can vary depending on the fermentation conditions, and their minimal impact on the overall energy demand of the process.

The distillation system operates at 1 atm, and the 1G beer titer was kept at 100 g/L to represent a typical 1G sugarcane fermentation and the 2G fermentation beer titer was varied from 5 to 40 g/L to study and compare the energy impacts for low titer 2G beer. This analysis assumes that the annexed 2G plant is smaller than the host 1G plant, so it was proposed to use a proportion of 3 kg of 1G to 1 kg of 2G fermentation beer. The mass flow of 1G fermentation beer was assumed to be 500 t/h to be in the same order of magnitude as real ethanol biorefineries [5], but this value will not affect the results because they are measured on a distilled ethanol basis. Additionally, the adopted ethanol mass fraction of distillate was 92.5%wt and of stillage (bottoms) was 0.05% wt to match industrial specifications [5]. Finally, while the proposed distillation system employs a simplified approach, note that there are studies that utilize rigorous simulations of simplified water-ethanol systems specifically for the

energy analysis of distillation [6].

An energy analysis based on the heating energy demand was conducted to quantify and compare the reboilers' duty and distilled ethanol production. In the case of the 1G2G integrated arrangement, the 2G ethanol net duty was considered to be the sum of the 2G rectification column with the heat duty change of the 1G distillation column compared to the separated counterpart.

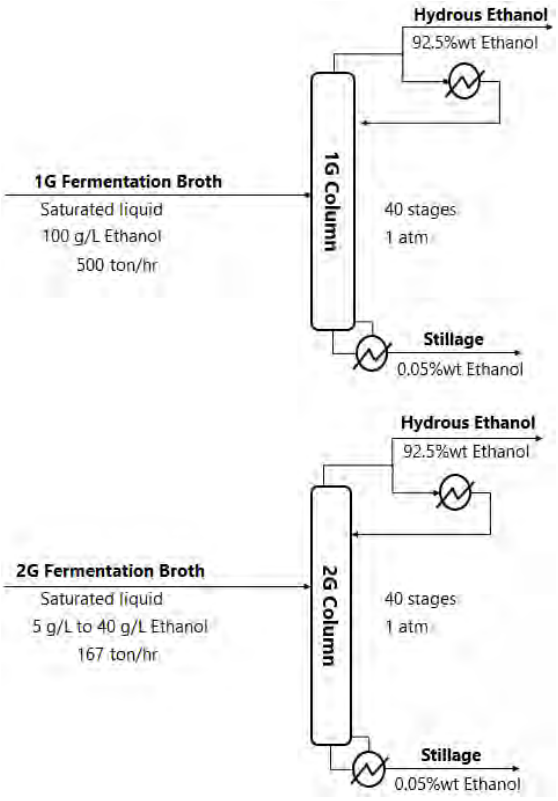

**Figure 1.** Schematic diagram for separated distillation configuration.

The results of the energy analysis were evaluated in terms of biomass demand required to generate the necessary distillation utilities. In other words, the amount of bagasse needed for cogeneration to meet distillation's steam demand. For an accurate estimation, a conversion factor between steam production and bagasse combustion was obtained using the cogeneration spreadsheet model developed for a modern 1G sugarcane ethanol biorefinery boiler system by Bonhivers *et al.* [7].

By estimating the amount of bagasse saved due to energy savings in the distillation, valorization of the saved bagasse was assessed in terms of either electricity production by cogeneration or 2G ethanol production by fermentative route. Whereas electricity production was calculated using a conversion factor obtained from the previously mentioned cogeneration spreadsheet model [7], 2G ethanol production was calculated using a conversion factor between bagasse and 2G ethanol in an integrated 1G2G sugarcane biorefinery simulated by Bonomi *et al.* [8]. Table 1 contains the conversion factors used in this work.

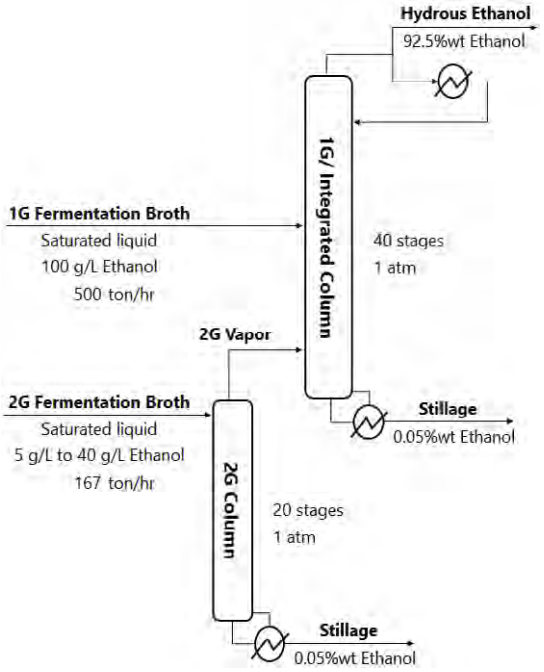

**Figure 2.** Schematic diagram for integrated distillation configuration.

**Table 1:** Conversion factors to calculate dry bagasse saving and its possible valorization (adapted from [7] and [8]).

| Conversion factor | Unit | Value |
|---|---|---|
| Bagasse to steam production | $MJ_{Steam}/kg_{Bagasse}$ | 9.97 |
| Saved bagasse to electricity | $MJ_{Electricity}/kg_{Bagasse}$ | 4.12 |
| Saved bagasse to 2G ethanol | $kg_{2G\ Ethanol}/kg_{Bagasse}$ | 0.12 |

Furthermore, considering the energy savings in distillation, a life cycle assessment was conducted using a consequential approach to evaluate carbon emissions associated with bagasse (boiler fuel) consumption reduction, following the ISO 14040 standard [9]. The adopted system boundary was the boiler and distillation system considering bagasse entering the boiler as an input and distilled ethanol from distillation as output. This system was chosen because it would link steam savings by energy demand reductions in the distillation integration with steam generation by bagasse in the boiler unit. As an observation, the fermentation beers were not considered as input due to not changing in the consequential approach. The functional unit used was 1 kg of distilled ethanol due to ethanol being the product of interest. Multifunctionality was not addressed because there was no

generation of other products. The 2016 ReCiPe Methodology (Hierarchist) was used, the impact category measured was "Climate change", and it was used the greenhouse gas (GHG) emissions inventory for bagasse for a Brazilian 1G sugarcane boiler by Capaz *et al.* [10].

## RESULTS AND DISCUSSION

From a column operation point of view, distillation integration allows the stripping of 2G beer and the distillation of 1G2G ethanol without efficiency loss when compared with the separated scenario (Figures 3 and 4). Considering a dilute 2G beer feed, the operating lines of the integrated distillation column and the pure 1G column are overlapping, meaning that the reflux ratio does not change. It may be because the 2G ethanol vapor entering the integrated column does not have sufficient mass flow to disrupt the column's operating line. Therefore, the reflux ratio is comparable to that of a standalone first-generation (1G) distillation system, enabling substantial energy savings in the distillation of second-generation (2G) ethanol, particularly at initial low ethanol concentrations.

Note that the rectification section of the 2G column does not operate in the integrated scenario. In this configuration, the reboiler duty is primarily linked to the vaporization of the feed, and there is no additional heat requirement associated with the condensing process at the top stage. However, this does not imply that the overall energy demand of the column is significantly reduced compared to a complete distillation process. The stripped vapor has a considerably higher mass flow rate that must be processed, owing to a lower concentration of ethanol.

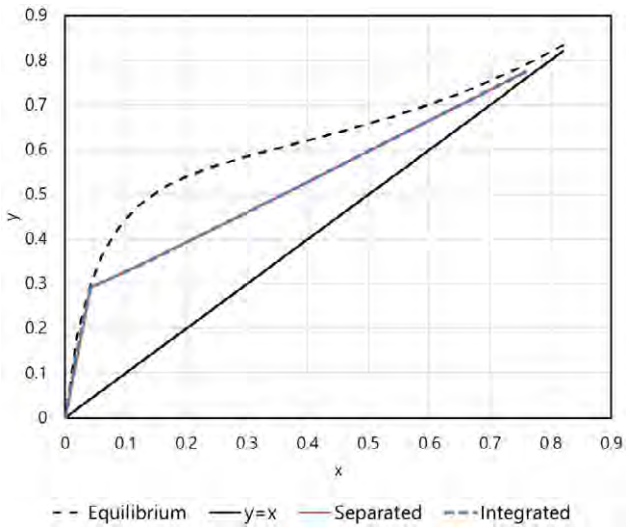

**Figure 3.** Operating lines for distillation in a stand-alone 1G column (Separated) or an integrated column with 1G fermentation beer and 2G ethanol vapor (Integrated).

Distillation integration is a viable strategy for the energy demand to remain close to a 1G ethanol plant. 1G2G integration resulted in an overall heating energy demand for ethanol distillation at a near-constant value of 3.30 $MJ/kg_{Ethanol}$, regardless of the 2G ethanol titer (Figure 5). Furthermore, the energy demand of the integrated scenario differs by only 0.4% compared to the calculated 1G fermentation beer (3.29 $MJ/kg_{Ethanol}$). Meanwhile, the energy demand of the separated scenario ranges from 3.64 (at 40 g/L 2G beer titer) to 3.85 (at 5 g/L 2G beer titer) $MJ/kg_{Ethanol}$, resulting in energy savings of 9.3% to 14.6%, respectively (Figure 5). The main reason for this result is that the energy demand for distilling 2G ethanol decreases in the integrated 1G2G column due to the reflux ratio being similar to that of a stand-alone 1G system. This alignment with the 1G distillation conditions contributes to enhanced energy efficiency. However, note that the reflux ratio and energy demand of the integrated 1G2G distillation system may vary based on the proportion of 1G to 2G beer and the ethanol titer of the 1G process. This could be observed by a slight increase in energy demand within the integrated system as the ethanol titer rises, specifically around 0.4% when moving from 5 to 40 g/L. This increase is attributed to the higher volume of 2G vapor, which has a subtle impact on the overall operation of the column by increasing the reflux ratio.

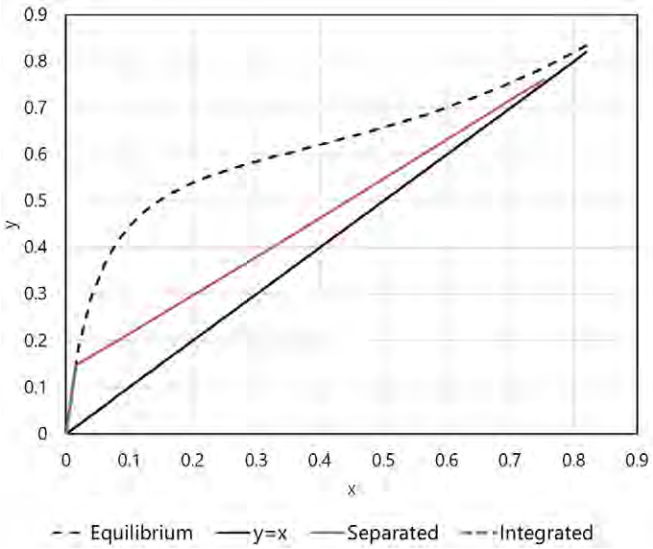

**Figure 4.** Operating lines for distillation in a stand-alone 2G column (Separated) or a 2G stripping-only column (Integrated).

The new reflux ratio condition leads to increased energy savings in the distillation of 2G ethanol. While in the separate scenario, the heat demand varies from 6.34 (at 40 g/L 2G beer titer) to 41.52 (at 5 g/L 2G beer titer) $MJ/kg_{Ethanol}$, the demand is near constant at 3.45 $MJ/kg_{Ethanol}$ in the integrated scenario (Figure 6). The corresponding energy savings range from 91.5 to 45.9%, respectively which are significant values in the context of cellulosic ethanol distillation. Additionally, the energy demand

of the integrated scenario is close to the energy demand of 1G ethanol. The relative difference between the integrated 2G ethanol energy demand and 1G ethanol is around 4%, making the operational costs of 2G ethanol distillation close to the stand-alone 1G operation, regardless of the 2G beer titer. Thus, the integration may significantly decrease the typical high distillation operating costs of 2G ethanol production.

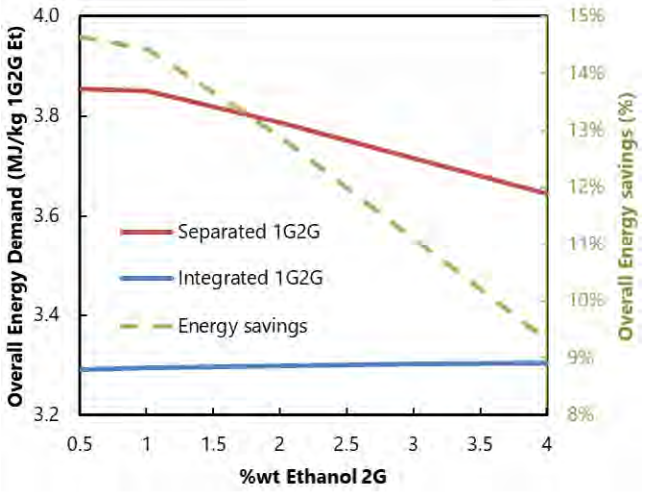

**Figure 5.** Overall energy demand and energy savings comparison between separated and integrated 1G2G distillation.

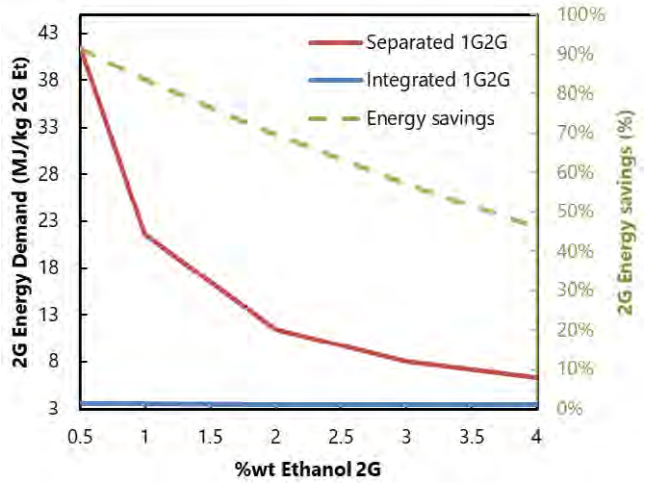

**Figure 6.** 2G ethanol energy demand and energy savings comparison between separated and integrated 1G2G distillation.

The decrease in energy demand obtained with integration results in savings of bagasse (boiler fuel), which can potentially increase either the electricity or 2G ethanol production (Figure 7). The bagasse savings can vary from 57 (at 5 g/L 2G beer titer) to 34 $kg_{Bagasse}/ton_{Ethanol}$ (at 40 g/L 2G beer titer) and it could generate 0.23 and 0.14 $MJ_{Electricity}/kg_{Ethanol}$, respectively. This electricity production represents an increase of approximately 5% in electricity output in 1G2G sugarcane ethanol plants, which typically produce 3.29 $MJ_{Electricity}/kg_{Ethanol}$ [8]. Equally interesting, the bagasse available could produce 6.8 and 4.1 $g_{2G\ Ethanol}/kg_{Ethanol}$.

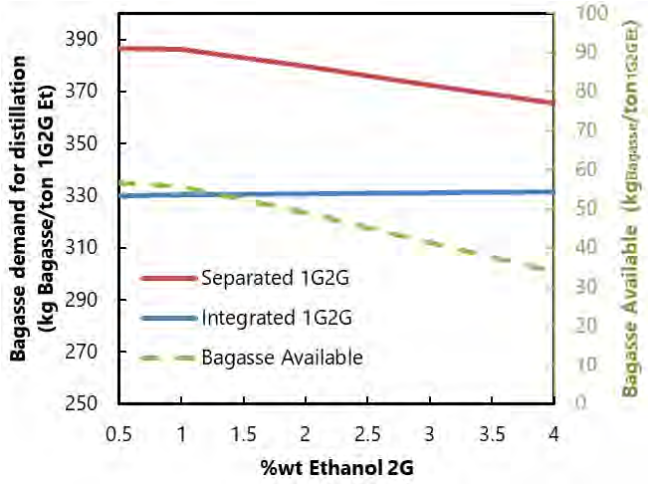

**Figure 7.** Comparison between bagasse demand for distillation in the separated and integrated 1G2G scenario.

Despite the robust energy savings, the environmental performance is not altered significantly (Figure 8). The corresponding decrease in bagasse demand for cogeneration decreases the GHG emissions by nearly 1 $gCO_2eq/kg_{Ethanol}$, which is a small amount compared to typical values of sugarcane ethanol production in Brazil [761 (integrated 1G2G ethanol) and 241 $gCO_2eq/kg_{Ethanol}$ (stand-alone 2G ethanol)] [11]. This result was expected because the bagasse used to provide heat for distillation is a renewable fuel and corresponds to a small portion of the environmental profile of sugarcane ethanol production. Nonetheless, in the context of processes with a more energy-intensive distillation that uses fossil fuels such as natural gas in corn ethanol mills in the United States, the energy savings could provide a more significant reduction in the product's emission profile.

## CONCLUSIONS

The integration of distillation processes for first- and second-generation sugarcane ethanol significantly reduces the overall energy demand for distillation, achieving reductions between 10% and 15%. Furthermore, it significantly decreases the heat duty required for distilling second-generation ethanol, with reductions ranging from 47% to 92%. Under the conditions examined, characterized by dilute second-generation feeds, the low concentration of second-generation ethanol led to an integrated distillation setup with both reflux ratio and heat demand closely aligned with the standalone first-generation (1G) conditions, irrespective of the 2G

ethanol titer. Although potential economic benefits may be realized by converting the saved bagasse into electricity or additional ethanol, it is important to note that these energy savings have a limited impact on the carbon emissions associated with sugarcane ethanol production.

Finally, unlike other energy integration strategies such as heat pumps and double-effect distillation, distillation integration offers a straightforward process integration method that achieves energy savings without significant trade-offs.

## ABSTRACT

Emerging technologies require sophisticated design and optimization due to their rapid advancement and potential to alter material flows and life cycles. However, their future development remains uncertain due to sociotechnical factors such as regulations, infrastructure, and market dynamics. Multiple technologies are often considered simultaneously, but their interactions and synergies are not systematically evaluated. This study addresses pre-emptive life cycle design in social challenges by integrating emerging technologies into superstructures, which help visualize alternative candidates for design problems. Case studies on battery chemistry, plastics, and regional resource circulation demonstrate this approach. For battery technology, nickel-manganese-cobalt lithium batteries have dominated over lithium iron phosphate alternatives. Superstructures were developed to assess recycling technologies and were refined through communication with managers of Japanese national battery projects. In plastics, system designs integrating biomass-derived and recycled carbon sources were explored, and scenario planning with life cycle assessment (LCA) was shared with stakeholders. Regional resource circulation was studied through technological integration and local stakeholder engagement, leading to demonstration tests. Findings suggest that superstructures and technology assessments enhance understanding of applicable technologies and their trade-offs. Given the critical role of social acceptance in technology implementation, computer-aided process engineering (CAPE) tools should facilitate discussions on socio-technical and socio-economic aspects of process systems engineering.

**Keywords**: Life cycle assessment, Co-creation, Scenario planning, Social engagement, Policy making

## INTRODUCTION

The rapid advancement of emerging technologies [1] necessitates a comprehensive approach to their design and optimization, incorporating considerations of social systems and regulatory frameworks. These

technologies possess the potential to transform material flows and life cycles; however, their future development remains highly uncertain due to the evolving sociotechnical landscape, including regulatory policies, societal infrastructure, and market dynamics [2]. The concurrent exploration of multiple technological solutions for a given challenge further complicates the assessment of their respective boundaries and potential synergistic interactions. A systematic evaluation framework is, therefore, imperative to ensure the effective integration of emerging technologies into optimized systems.

In this study, we address the pre-emptive life cycle design (LCD) of emerging technologies within the context of societal challenges, focusing on case studies in battery chemistry, plastics, and regional resource management. To achieve this, we construct comprehensive frameworks that encapsulate a range of technological alternatives and facilitate the visualization of potential design pathways by superstructures. These superstructures, developed in collaboration with industrial stakeholders and national initiatives, serve as the basis for modeling life cycle scenarios using life cycle assessment (LCA) methodologies.

## MATERIALS AND METHODS

### Framework Development of Pre-Emptive LCD

Pre-emptive LCD requires the steps of process systems engineering, e.g., alternative generation, analysis, evaluation and optimization, and sensitivity analysis. Forward-looking LCA has become an important tool for examining the future applicability of emerging technologies considering the scenarios in line with shared socioeconomic pathways [3]. New technologies are constantly being developed, and while they may solve one particular problem, they can also cause other problems, which can have a complex impact on the processing system. In this situation, it can be effective to use superstructure-based visualization to support communication while implementing forward-looking LCA and designing the life cycle, while proposing appropriate alternative solutions.

In the case study described below, we conducted pre-emptive LCD based on the individual problems and conditions. The extracted works and functions of pre-emptive LCD are framed and visualized as a model represented in integrated definition type 0 modeling language (IDEF0) [4].

### Case Examples of Pre-Emptive LCD

In the alternative generation of pre-emptive LCDs, we consider not only technology candidates that have reached a certain level of technological maturity, as evidenced by patents and academic papers, but also cutting-edge technological development issues that are currently being addressed in national projects. Even for technology candidates with low technological maturity, it is possible to consider the impact on the life cycle in advance using future LCA combined with computer-aided process engineering (CAPE) [3]. This makes it possible to design the life cycle appropriately, taking into account resource recycling, environmental impact, socio-economics, and socio-technical regimes. At this time, it is important to consider the elements of the life cycle other than the target technology, even in projects that are developing elemental technology, and there is a possibility that an appropriate evaluation range and purpose can be set by building a superstructure.

The superstructure in this study encompasses all potential pathways in cradle-to-grave life cycles of target functions. Concerning the cases below, both technological options and socio-economic/technical options could influence the future performance of these life cycles. Wherever possible, such options were gathered from national projects, experts, and relevant government officials.

#### Circulation of battery chemicals

In the realm of battery chemistry, nickel-manganese-cobalt (NMC) lithium-ion batteries (LiB) have emerged as the dominant technology, although lithium iron phosphate (LFP) batteries remain a viable alternative. Superstructures were formulated to evaluate recycling technologies, incorporating insights from Japanese national battery technology initiatives [5]. The required data was obtained from industries and authorized LCA databases. The mathematical models from the previous studies [5] were applied.

#### Plastic life cycles with renewable carbon sources

In the plastics sector, the transition to biomass-derived and recycled carbon sources necessitates systematic design considerations. Scenario planning and LCA based on superstructure-based analyses were conducted and shared with stakeholders to inform sustainable carbon strategies [6, 7]. The required data was obtained from industries and authorized LCA databases. The mathematical models from the previous studies [9] were applied. The social situation was obtained from surveys, e.g., on bioplastics [9].

#### Circulated use of regionally available resources

A shift from imported fossil fuels to local renewable resources and empowering rural areas is crucial for regional sustainability. Regionally available resources, e.g., biomass from agriculture and forestry, renewables such as solar and wind, and wastes to be treated, have been examined with technologies for their valorization. In this regard, however, not individual use but combined application of such regional resources is effective [10]. Superstructure-based analysis supported by technology

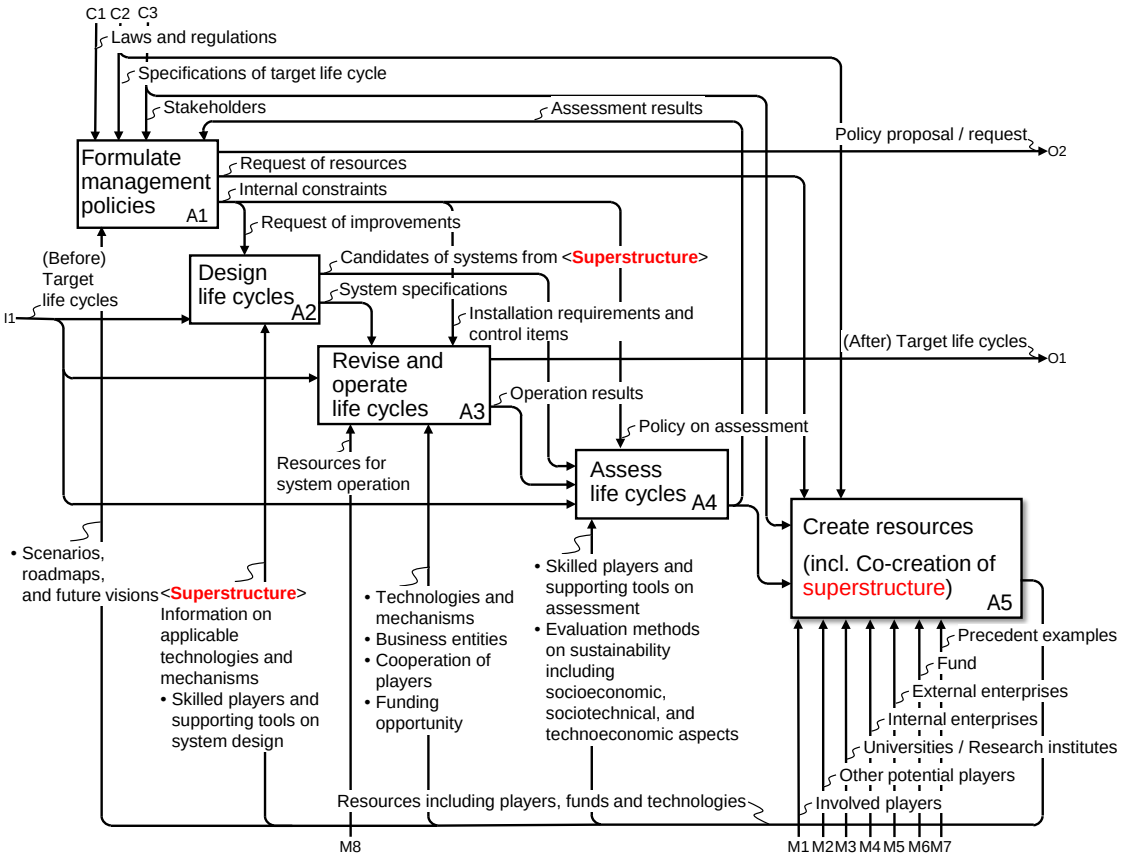

**Figure 1:** Activities and information flows associated with the utilization of superstructure model in pre-emptive life cycle design represented in IDEF0 manner.

assessments such as LCA and consumer surveys is needed to address stakeholder concerns and reveal the socioeconomic impacts of technology options. As a regional case study, regional resource circulation in a remote island, Tanegashima, was explored through the integration of multiple technologies, with demonstration tests conducted in collaboration with local communities and stakeholders [10].

## RESULTS AND DISCUSSION

### Pre-Emptive LCD with Superstructure

Figure 1 shows the activities and information flows associated with the utilization of the superstructure model in pre-emptive LCD, represented in an IDEF0 manner. The framework consists of five activities (A1–A5) that follow a continuous improvement cycle similar to the plan-do-check-act model. A1 (planning) and A2 (acting) define policies and generate alternative solutions, while A3 (doing) implements system revisions, and A4 (checking) assesses outcomes. A5 provides necessary resources and supports stakeholder engagement.

A1 formulates regional policies based on external and internal feedback. A2 generates alternative systems in response to improvement requests and assesses their socioeconomic, technoeconomic, and sociotechnical impacts. A3 converts current life cycles into revised ones by integrating specifications from A2 and assessment results from A1. A4 examines operated systems and feeds back insights for further refinement. A5 serves as an open platform, supplying resources and fostering co-learning among stakeholders.

Assessment methods such as socioeconomic and technoeconomic evaluations guide decision-making. Stakeholder involvement in A5 ensures inclusive development, similar to biodiversity conservation and community-based participation models. The framework facilitates social transformation in target life cycles by continuously improving system operations and stakeholder collaboration.

The superstructure can be seen as a source of design information in the pre-emptive LCD shown in Figure 1. The superstructure itself is expanded and strengthened through co-creation, but here it is adapted to the characteristics of the lifecycle in each case study.

### Findings in Battery Systems Case

A comprehensive superstructure was developed to

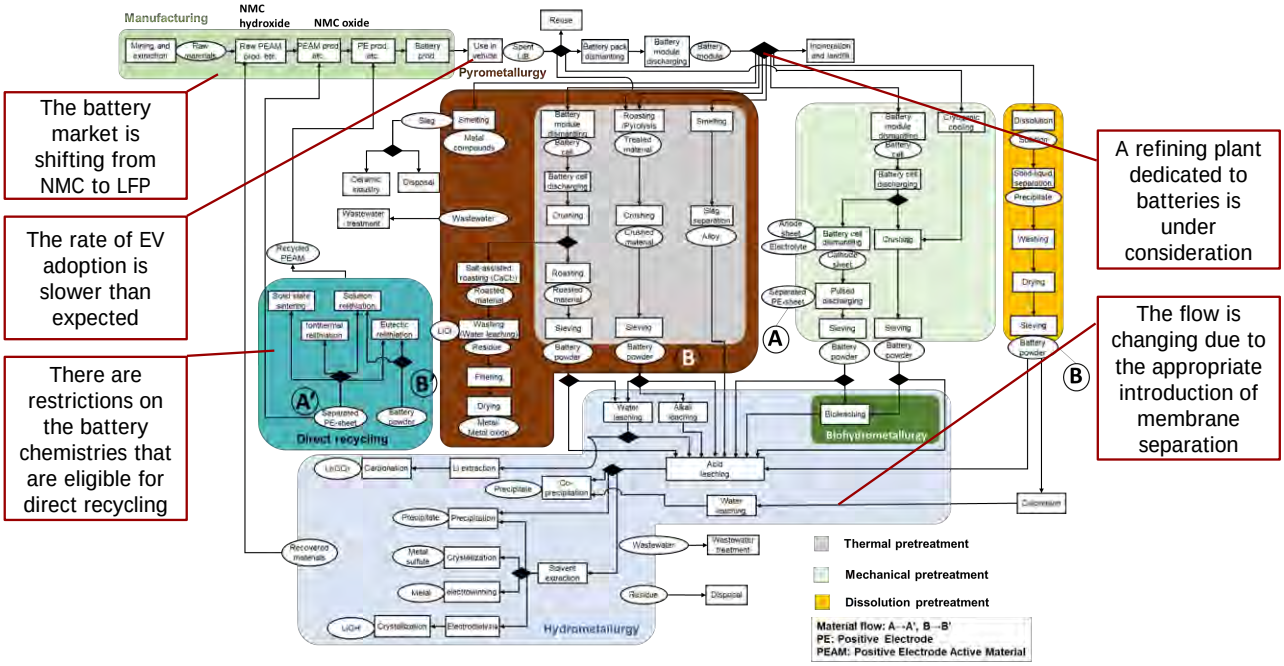

**Figure 2:** Superstructure constructed in a previous study [5]. The comments were examples of the content discussed through co-creation with stakeholders of LiB life cycles.

visualize the potential life cycle of LiBs and serve as a decision-support tool for life cycle design as shown in Figure 2. This study constructs the superstructure for LiB cathode recycling through an integrative approach, incorporating a systematic literature review, bibliometric analysis, and expert discussions. The literature review identified key technological pathways for LiB end-of-life (EoL) management, including landfill/incineration and resource recovery via recycling. Cathode recycling processes are classified into pyrometallurgical, hydrometallurgical, and direct recycling techniques. Pyrometallurgy involves smelting, pyrolysis, and roasting [11], whereas hydrometallurgy encompasses leaching and solvent extraction [12]. Direct recycling, in contrast, enables the regeneration of cathode materials without complete metal separation, utilizing processes such as sintering [13]. Through co-creation with national projects and stakeholders of LiBs in Japan, it was found that the superstructure that had been constructed could be used to gain a common understanding of the issues in the LiB life cycle and to consider countermeasures. Some of these are shown in Figure 2. With regard to LiBs, there is a great deal of uncertainty as an emerging technology, and the infrastructure for recycling is also incomplete. Therefore, we must be aware that the optimization of the current life cycle will become a constraint in future designs, narrowing down the options.

## Findings in Plastic Systems Case

Figure 3 illustrates the production flow of petroleum-derived plastics, detailing oil refining and petrochemical processes. At the end of the plastic life cycle, waste plastics are managed through resource recycling methods such as mechanical recycling, monomerization, and catalytic cracking, or alternative disposal routes, including energy recovery (ER), gasification, and metallurgical reduction processes.

As shown in Figure 3, crude oil is refined into naphtha, which undergoes petrochemical processing to yield basic chemicals such as olefins and BTX. Catalytic cracking converts waste plastics into hydrocarbons resembling conventional refinery products through solvent mixing, cracking reactions, and distillation, which are categorized by carbon chain length: Product A (C1–C4) serves as a raw material for cryogenic separation, Products B (C5–C7) and C (C8–C9) substitute for naphtha, and Product D (>C10) undergoes further cracking via fluid catalytic cracking (FCC).

We carried out co-creation with the relevant parties regarding the plastic system based on the constructed superstructure. There are many different materials used in plastics, and the manufacturing methods are complex, but at the same time, there is a lot of interest from consumers, and they are also recognized as being able to be used as alternatives to paper and metal. For this reason, in addition to raw materials, manufacturing technology, applications and recycling, it is a system that also involves consumer preferences, and the superstructure was effective for visualizing the overall picture of plastics.

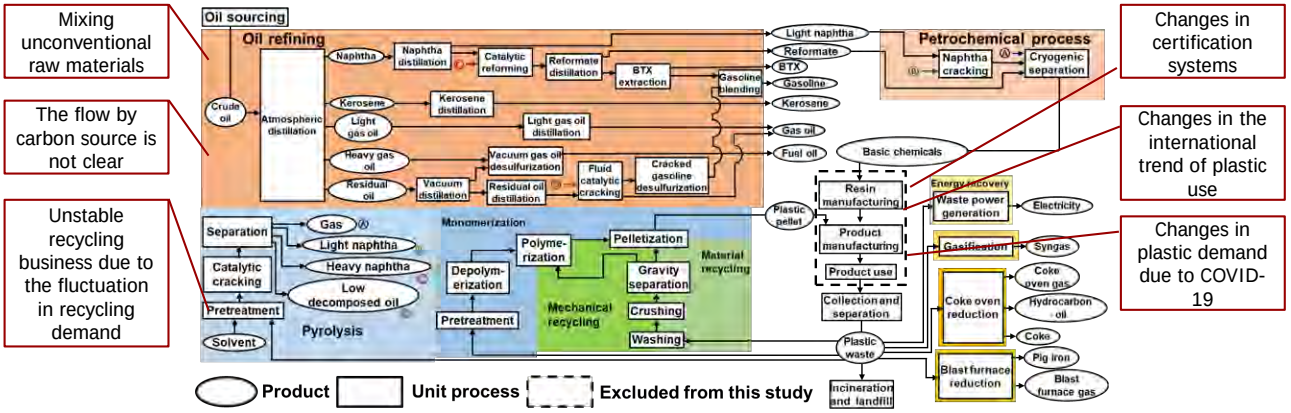

**Figure 3:** Superstructure constructed in a previous study [9]. The comments were examples of the content discussed through co-creation with stakeholders of LiB life cycles.

## Findings in Regional Systems Case

Tanegashima hosts a diverse range of agricultural, forestry, and livestock industries, with sugarcane cultivation playing a central role in regional culture and economy. The sugar industry, which processes locally grown sugarcane into raw sugar, is a key economic driver. Historically, sugarcane bagasse has been utilized as fuel within sugar mills, but previous studies indicate that the available bagasse-derived energy exceeds the demand for sugar production, presenting an underutilized resource [14]. Additionally, the island's forests suffer from aging tree populations and a low proportion of high-quality timber suitable for sawmilling. Expanding the use of woody biomass for energy could simultaneously reduce reliance on fossil fuels and improve forest health [15]. Industrial symbiosis is emerging as a transformative strategy for fostering fossil-free resource utilization in agricultural and forestry regions. The combined application of bagasse and woody biomass has the potential to serve as a stable biomass feedstock for fuel production via torrefaction [16]. Furthermore, advances in sugarcane cultivar breeding could enhance industrial sustainability, as confirmed by rigorous assessments of potential impacts on sugar production [17].

Based on such regional problems and conditions, the superstructure of regional-resource circulated systems was proposed [10, 18] and used for the co-creation with regional stakeholders. Regional residents may not have a comprehensive understanding of the potential of the regional resources, and it can be said that they were motivated by the possibility of simultaneously achieving regional revitalization, de-fossilization, and green transformation. At the same time, we also found that clarifying the challenges that require reform also creates friction regarding the details.

## CONCLUSION

The findings of this study highlight the critical role of superstructure-based technology assessments in facilitating a comprehensive understanding of technological feasibility, trade-offs, and viable implementation pathways. As technological adoption is intrinsically influenced by social acceptance, it is imperative that computer-aided process engineering (CAPE) tools are designed to integrate sociotechnical and socio-economic dimensions within process systems engineering frameworks. By embedding these considerations, CAPE can enhance decision-making processes, promote stakeholder engagement, and support the development of sustainable and resilient technological solutions. This interdisciplinary approach is essential for advancing the practical implementation of emerging technologies in complex industrial and regional systems.

## ABSTRACT

This study explores an energy transition strategy that leverages reversible solid oxide cells (rSOC), power-to-gas (PtG) conversion, and $CO_2$ management to enhance the efficiency and sustainability of secondary aluminum production. A comparative analysis between conventional and integrated energy scenarios highlights the benefits of multi-technology integration. The results indicate that the integrated system increases total energy demand by 27% due to additional energy conversion steps, but eliminates natural gas consumption, reducing dependency on fossil fuels. Additionally, net $CO_2$ emissions are reduced more than fivefold, demonstrating the potential of carbon capture and utilization strategies. The seasonal storage of synthetic natural gas (SNG) and biogenic $CO_2$ further enhances system flexibility, allowing excess renewable electricity to be converted into storable fuels for winter use. Despite higher capital expenditures, the operational costs of the integrated system are 11% lower than the conventional approach due to improved energy efficiency and $CO_2$ taxation savings. These findings underscore the importance of process integration, energy storage, and renewable electricity utilization in achieving a low-carbon, resilient aluminum industry and urban heating networks.

**Keywords**: Secondary aluminum, renewable energy integration, power-to-gas, reversible solid oxide cells, $CO_2$ utilization, process optimization.

## INTRODUCTION

Aluminium industry relies on fossil natural gas and emits 2% of global industrial emissions [1]. To reduce this dependency, an increased use of renewable energy and advanced conversion systems is aimed. Due to the intermittency of renewable energy, a set of technologies is needed to improve the energy integration and enhance the process resiliency in the heavy industry. Another untapped savings potential is waste heat [2], which can be recovered from stack gases or casting water. Aluminium is processed in semi-batch steps with metallurgical and technical constraints, adding complexity to waste heat valorization. To tackle this issues, advanced technologies including storage units, oxycombustion furnaces, carbon abatement and power-to-gas systems, biomass thermochemical conversion systems, as well as electrified annealing furnaces [3, 4] can be integrated to handle seasonal renewable energy storage, targeting its utilization during periods of high electricity and natural gas prices. Meanwhile, high temperature reversible solid oxide cells can meet the energy balance of the overall system, while increasing exergy efficiency of the integrated facility. Power-to-gas-to-power systems can use renewable electricity and biogenic $CO_2$ to produce synthetic natural gas [5] to replace fossil fuels in the aluminium plant and supply the necessary power to other industrial and urban systems. In this way, a cyclic fuel production and utilization in an integrated aluminium remelting plant behaves as an industrial battery, which can use firstly high-grade waste heat for industrial applications, followed by air and

scrap metal preheating [2, 6], to finally cascade the low-grade waste heat to an urban system [7, 8]. In this work, a scenario of waste heat valorization and renewable energy integration is presented, in which the high-temperature waste heat from the aluminium processing plant is used to reduce the energy consumption in the power-to-gas and biomass energy conversion systems. Those systems facilitate the energy and $CO_2$ management and offset the problem of renewable energy resources intermittency. The performance of the decarbonization route is analyzed in the light of thermal, economic and environmental indicators and compared to a conventional setup based on fossil fuel furnaces and biomass boilers.

## METHODOLOGY

Waste heat from the aluminium furnaces and the biomass energy conversion favors the integration of high temperature reversible solid oxide cells (rSOC). The post-combustion of the tail gas from the rSOC can partly supply the heat needed in the melter furnace, whereas the electricity generated in the cell can be used elsewhere, such as in electrical furnaces, rolling process, ancillary demands, and heat pumping systems of district heating network. Integration of renewable energy resources and technologies, such as gasification, has shown promising potential to attain net negative emissions when combined with electrification, power-to-gas systems, and carbon sequestration methods, adding flexibility to the energy and carbon management systems [9, 10,11].

In the aluminium plant, pure aluminium ingots are preheated from 25°C to 250°C. Next, the pure aluminium is mixed with scrap aluminium and sent to a melting furnace at 660°C. A holder furnace operates as a buffer for the subsequent direct chill casting process (DCC), where aluminium solidifies into ingots using groundwater. This hot water (50 °C) is rejected to the environment. In an improved scenario, the casting water is a heat sink integrated to a $CO_2$ network to supply heating requirements to a city. In the rolling plant, ingots are surface-polished and heated up to 550°C in pusher furnaces, before they go through a hot rolling process followed by an intercooling step and a subsequent cold rolling process powered by electricity. Some coils are sent to an annealing continuous line (ACL), wherein they are chemically and thermally treated.

In the gasification section, biomass moisture is reduced to 10% in a rotary dryer before is chipped consuming ~ 3% of biomass energy (LHV) [12]. In the gasifier (900°C), biomass is converted into syngas rich in CO, $H_2$, $CO_2$ and $CH_4$, among other components, using steam as the gasification agent (S/B ratio 0.75). Syngas is cooled to 400 °C and water-scrubbed to remove impurities and compressed to 35 bar. Downstream water gas shift reactors increase hydrogen content. Syngas can be used for producing hydrogen or synthetic natural gas, whereas gasification waste heat is used for combined heat and power production instead of merely burning biomass. In addition, waste heat is used to produce the steam necessary to feed a solid oxide electrolysis cell (SOEC). As a result, an oxygen-rich stream is also produced. SOEC technology operates typically between 600 °C and 850 ºC, which brings about higher thermodynamic efficiency and faster kinetics [13]. SOEC is operated at a thermoneutral voltage of 1.29 V and electricity consumption of 35 kWh/kgH2. In the context of sustainable energy transition, SOECs are expected to play a role in harvesting and transforming renewable electricity into storable chemicals and fuels [14,15]. The reversible electrolysis cell also works as fuel cell (SOFC) consuming hydrogen and oxygen or air to produce electricity, which requires preheating reactants up to 850 ºC [16]. The inefficiency of SOFC is exploited to harvest waste heat in a downstream post-combustion system using oxygen to drive high temperature aluminium melting furnaces. Meanwhile, the produced electricity can be used to drive other heating furnaces and appliances in the aluminium plant, as well as heat pumps of the district heating network. All in all, the integration of an rSOC enables energy storage and power generation [17], facilitated carbon separation, post-combustion carbon capture, and waste heat valorization. It occurs first at high-temperature for the melting of the aluminium, and later for the low-temperature $CO_2$ district heating network, composed of a closed loop of $CO_2$ that harvests waste heat from the industrial, biomass conversion and power-to-gas systems. $CO_2$ evaporates at 50 bar (~14°C) and can later release the condensation enthalpy in a heat pump that supplies space heating or domestic hot water to a nearby urban system. A superstructure used to provide the energy demands of the aluminium and the urban agglomeration also include heat pumps; gasification, methanation and gas treatment systems; $CO_2$ abatement units, electrification technologies, storage units and cogeneration cycles (Figure 1).

In view of multiple technological options and trade-offs between electricity, gas or biomass import, a systemic approach is developed to evaluate the most cost-efficient configuration to supply combined heat and power to the aluminium remelting process. OSMOSE platform [11] is used to solve a minimum energy requirements (MER) of the overall process. Subsequently, this framework handles the mixed integer linear programming problem (MILP) that works out the best energy technologies and their operating conditions. Aspen Plus® software is used to simulate different energy conversion systems. In this regard, the number of decarbonization options increases, calling for a systemic study to evaluate the most suitable processes and carbon neutral technologies to

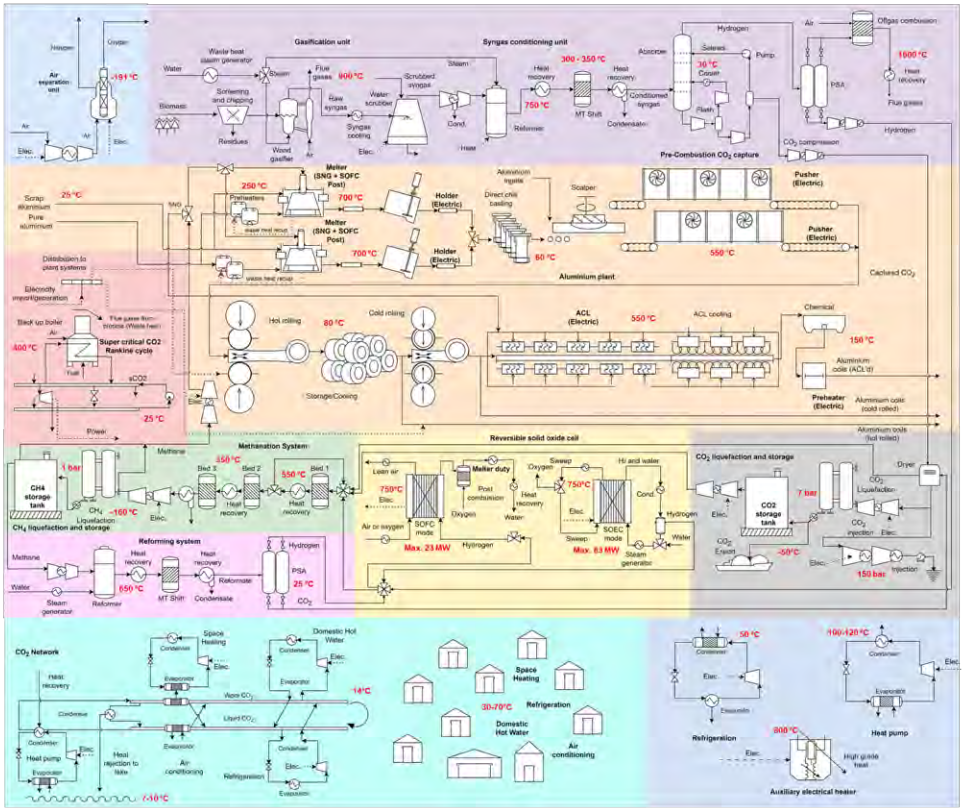

**Figure 1:** Integrated aluminium production plant and potential utility and decarbonization technologies.

supply the energy requirements to aluminium industry without significantly impacting the operational settings and process reliability. To this end, a mixed integer linear problem is conducted using OSMOSE platform [11] to maximize waste heat recovery and define the most economically, thermodynamic and environmentally favorable configurations to integrate the aluminium plant, the biomass conversion units and the grid into the urban system, considering the temporal variation of the prices and energy demands. The solver minimizes the total operating cost, Eq. (1), where Cop1 and Cop2 represent the fixed and variable operating costs of a unit (u) and Cinv1 and Cinv2 are the fixed and variable investment costs of a unit (u). $Y_u$ is a binary variable related to the presence or absence of a unit (u), while $M_u$ is its respective continuous load factor.

$$\min C_{tot} = \sum_{u\in U}\left[\sum_{t\in T}\left(Cop1_u \cdot Y_{u,t} + Cop2_u \cdot M_{u,t}\right)\cdot \Delta t + Cinv1_u \cdot Y_u + Cinv2_u \cdot M_u\right] \quad (1)$$

This objective function is subject to multiple constraints including unit existence and load conditions:

$$Y_{u,t} \cdot Fmin_u \le M_{u,t} \le Y_{u,t} \cdot Fmax_u \;;\; \forall u \in U,\ \forall t \in T \quad (2)$$

$$M_{u,t} \le M_u \quad (2)$$

$$Y_{u,t} \le Y_u \quad (3)$$

Mass and energy balance constraints:

$$\sum m_{\text{Input streams}} = \sum m_{\text{Output streams}}\;; \qquad \forall T \quad (5)$$

Power production or consumption constraints:

$$\sum_{w=1}^{N_w} M_w \cdot w_{w,utilities} + \sum_{Processes} W + W_{import} - W_{export} = 0\,, \forall T \quad (6)$$

Heat cascade constraints and balance at the temperature interval r:

$$\sum_{w=1}^{N_w} M_w \cdot q_{w,r} + \sum_{i=1}^{N} Q_{i,r} + R_{r+1} - R_r = 0\;;\ \forall r = 1 \ldots . N \quad (7)$$

And solution feasibility:

$$R_1 = 0, R_{N+1} = 0, \qquad R_r \ge 0\,; W_{import} \ge 0, \quad W_{export} \ge 0 \qquad \forall r = 1 \ldots . N \quad (8)$$

where;

- *N* is the number of temperature intervals based on supply and target temperatures of streams [-]
- *Q* is the heat exchanged between process streams [kW],
- *R* is the heat cascaded from higher (r+1) to lower

(r) intervals of temperature [kW],

- $N_w$ is the number of utility units available [-],
- $q_{w,r}$ is the specific heating or cooling flow supplied by a utility unit *w* within an interval *r* [kW],
- *W* is the power produced or consumed by the utilities and process units, or the grid [kW].

The mathematical formulation of the problem can be solved using any open-source mixed integer linear programming solver, compatible with AMPL® community edition. The costs of the commodities are assumed based on the current European market and are set as 3.50 Eur/m$^3$ for water, 0.15 Eur/kWh winter - 0.05 Eur/kWh summer for electricity, 0.08 Eur/kWh winter - 0.06 Eur/kWh summer for biomass, 0.07 Eur/kWh for natural gas, and 100 Eur/t for the $CO_2$ tax.

## RESULTS AND DISCUSSION

Table 1 compares the energy consumption of the conventional scenario (i.e. only natural gas-fired furnaces and biomass combustion-based district heating network) and the integrated solution proposed to decarbonize the aluminium plant and the city demands. The energy consumption in advanced integrated scenario is 27% higher than that of the conventional scenario since biomass needs to be converted internally in the battery limits of the integrated aluminium plant and urban system. However, the conventional scenario is strongly dependent on the consumption of fossil gas, which is subject to volatile market conditions and increasing surveillance due to associated direct and indirect atmospheric emissions. Also, it is worth noting an opportunity to increase the share of renewable input in aluminium industry and urban systems by importing nine times more electricity from the grid, which has lower associated indirect emissions than the fossil gas. In the rSOC, the power consumption during the electrolysis mode averages 57 MW, whereas the fuel cell power generation is 15 MW.

The rSOC together with the storage systems help managing the $CO_2$ and SNG streams. $CO_2$ produced and captured in the reformer, the auxiliary oxy-furnace, and syngas pre-treatment (see Table 3) can be later used to generate SNG that is stored in the summer season and consumed later on the winter season. By harnessing renewable electricity in summer, total biomass energy consumption can be reduced to 25% of the total amount consumed in less efficient biomass boilers for space heating and domestic hot water production. Yet, the most striking outcome is the complete replacement of fossil natural gas by renewable energy resources, such as biomass and electricity. Table 2 summarizes the $CO_2$ emissions balance including direct and indirect emissions for both conventional and integrated scenarios. Net $CO_2$ emissions of the conventional scenario can be reduced more than five times if an integrated carbon management and sequestration system is employed. Captured and injected biogenic $CO_2$ allows offsetting indirect emissions associated to the supply chains of electricity and biomass

In the integrated scenario, total energy demand is around 30% higher, and total incremental cost is about 35% higher due to the additional investment (~22 MEur/y). Carbon tax associated to fossil direct and indirect $CO_2$ emissions in the conventional scenario adds a penalty of more than 4 MEur/y.

**Table 1.** Energy consumption remarks of decarbonization solutions for the aluminium remelting and the district heating network.

| Parameter | Conventional solution | Integrated solution |
|---|---|---|
| Biomass consumption [GWh/y][1] | 218.04 | 51.95 |
| Electricity import [GWh/y] | 70.00 | 570.28 |
| Natural gas import [GWh/y] | 200.00 | 0.00 |
| Total energy demand [GWh/y] | 488.04 | 622.23 |
| Electricity export [GWh/y] | 0.00 | 0.00 |

1. In the conventional case, biomass is only consumed in a decentralized hot water boiler (eff. 70%) for district heating purposes

**Table 2.** Direct and indirect emissions $CO_2$ emissions for conventional and integrated aluminium plant and the district heating network.

| Parameter | Conventional solution | Integrated solution |
|---|---|---|
| Direct $CO_2$ emissions from natural gas consumption [kt/y] | 40 | 0 |
| Indirect $CO_2$ emissions from electricity consumption [kt/y][2,3] | 1.60 | 13.30 |
| Indirect $CO_2$ emissions from biomass consumption [kt/y] [1,2] | 2.00 | 0.467 |
| Indirect $CO_2$ emissions from natural gas consumption [kt/y][2] | 9.90 | 0 |
| $CO_2$ injection (biogenic sequestered) [kt/y] | 0 | -5.19 |
| Net $CO_2$ emissions to environment [kt/y] | 53.50 | 8.58 |

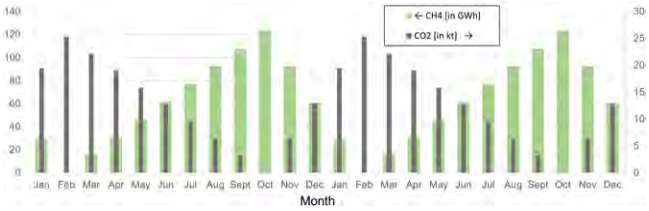
1. Biogenic $CO_2$ emissions are considered as circular emissions and they do not contribute to the net $CO_2$ emission to environment if eventually released. 2. Specific indirect emissions of biomass 0.0025 $g_{CO2}/kJ_{biowood}$; Specific indirect emissions of electricity 23.32 $g_{CO2}/kWh_{elec}$, Specific indirect emissions of natural gas 0.0138 $g_{CO2}/kJ_{CH4}$; 3. Maximum electrolyzer capacity 85 MW.

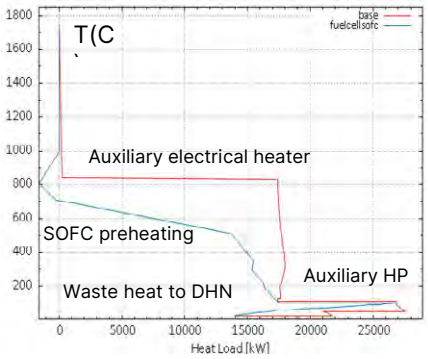
Figure 2 illustrates seasonal storage profiles for SNG and $CO_2$ gases. Loading of SNG tanks occurs during summer season when surplus electricity from renewable energy resources is available. It renders more attractive to harvest electricity and store it in the form of fuel to be

used later in the colder season. Biomass resource harvested during the summer season can be used to produce syngas or synthetic natural gas consumed in the SOFC. The $CO_2$ gas is used to refill the storage tanks that store $CO_2$ until is reacted in a methanation section to produce SNG in summer season. The benefit to store renewable energy in the form of gas is twofold: biomass consumption is drastically reduced and biogenic $CO_2$ produced is used to offset the $CO_2$ losses. Annualized investment and operational costs calculated for the conventional and integrated systems, are summarized in Table 3. Total cost of advanced technologies is 28% higher than for the conventional route, due to twenty times higher annualized investment. Yet, the annualized operational expenditure of the conventional solution is higher (11%) than for the integrated approach, due to cheaper biomass resources and use of electricity during the summer season to produce and store fuel using biogenic $CO_2$.

**Table 3.** Annualized investment and operational costs.

| Cost [Eur/y] | Conventional solution | Integrated solution |
|---|---|---|
| Electricity consumption cost | 6,074,580 | 31,861,130 |
| Biomass consumption cost | 15,537,550 | 4,155,900 |
| Natural gas consumption cost | 13,648,440 | 0 |
| Fossil $CO_2$ emissions taxation | 5,313,070 | 518,640 |
| Annualized operational cost | 40,573,650 | 36,535,680 |
| Annualized capital cost | 1,456,350 | 21,869,870 |
| Total annualized cost | 42,030,000 | 58,405,550 |





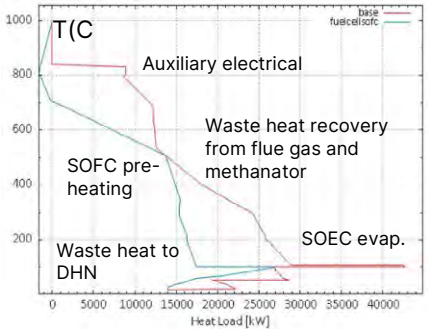


**Figure 2:** Seasonal gas storage

Figure 3 shows the integrated curves of the integrated aluminium plant, including the biomass energy conversion units, the power-to-gas system and the seasonal storage demands. These plots are useful to quantify the amount of waste heat available at different temperature levels, as well as to point out more rational energy uses and integration solutions, such as prioritizing the utilization of high-grade chemical and thermal energy in applications running at high temperatures, and only cascading waste heat down to lower temperatures after the high temperature energy demands have been meet. In this way, the irreversibility of the overall energy system is minimized, and other energy technologies, such as heat pump systems, can be rather activated at the adequate temperature levels of heat supply. According to Figures 3a and b, the waste heat recovery from flue gases, gasifier effluent, SOFC tail gas combustors, as well as auxiliary oxy-furnaces allows integrating the aluminium plant and the biomass conversion processes to the power-to-gas system. The solid oxide cell operates at elevated temperatures in order to increase the process efficiency and minimize the electrochemical losses, thus an internal waste heat recovery is fundamental to reduce the external energy imports. In summary, the high-grade chemical energy of the valuable biomass resource is used firstly at high temperatures in the most suitable applications, such as the aluminium melting process and the solid oxide cell, to be next cascaded down for being used at lower temperatures, such as in space heating and domestic hot water production. In this regard, the heat cascading efficiency principle allows reducing the biomass consumption, which otherwise would be burnt in a biomass boiler to merely produce hot water below 70 °C.

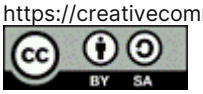
## CONCLUSIONS

In this work, the advantages and challenges of the use of renewable energy resources and more advanced energy technologies for process integration and decarbonization of an aluminium remelting plant and a district heating network are presented. As a result, the energy consumption in more advanced integrated scenario is 30% higher than that of the conventional scenario based on natural gas. It can be explained by the fact that biomass needs to be converted internally in the

battery limits of the integrated scenario. The power-to-gas-to-power and the renewable energy storage systems also entail inherent inefficiencies while aiming to internalized fuel supply and emissions management. On the other hand, in the integrated aluminium decarbonization scenario, the direct fossil fuel consumption is completely avoided, despite the fact that indirect emissions linked to electricity mix are still significant, especially if electricity from the grid is partly composed of a non-renewable share at different scopes. In any case, the net CO2 emissions of the conventional scenario using natural gas and biomass boilers achieve values higher than 50 kt/y, which is roughly 0.2 tCO2/tAl. This value can be reduced by more than three times if an integrated carbon management and sequestration system is implemented. A district heating network can help to distribute the waste heat available through all the industrial process, but only after the high-grade chemical, electrical and thermal energy has been used at high temperature in the melting furnaces and solid oxide cells. The post-combustion of the tail gas from the SOFC cell can supply the heat needed in the melter furnace, whereas the electricity generated in the cell can be used elsewhere in the plant, such as in other electrical furnaces, rolling processes, ancillary power demands, and heat pumping systems of the district heating network.

## ACKNOWLEDGEMENTS



The authors would like to thanks the Swiss Federal Office of Energy and Suisse Energie for funding this research work within the NetZero Lab Consortium.

## ABSTRACT

The growing concern over climate change and rising carbon dioxide ($CO_2$) emissions have spurred the development of strategies to upcycle greenhouse gases. One promising solution is the synthesis of green methanol via catalytic hydrogenation of captured $CO_2$ using renewable hydrogen ($H_2$). This provides a versatile chemical feedstock for fuels and industrial processes while reducing $CO_2$ levels. Recent advancements in $CO_2$ capture technologies achieve purities ranging from 83% to 98% (v/v), enabling a sustainable integration with green hydrogen for methanol production. While research has largely focused on $CO_2$ purities above 96%, such models overlook the variability and lower purities typical of industrial carbon capture streams. Addressing this gap, this study examines the economic impacts of $CO_2$ purity on methanol synthesis. Using Aspen Hysys V14, the hydrogenation process is simulated to assess the effects of varying $CO_2$ purities on operational costs, yield, and profitability, providing a realistic evaluation under actual industrial conditions. The results reveal that even slight changes in $CO_2$ purity markedly influence both costs and profitability, highlighting the importance of studying $CO_2$ capture technologies for methanol production. This study quantifies the relationship between $CO_2$ purity and operational cost, contributing critical insights for process operation. By emphasizing the role of $CO_2$ purity in enhancing both sustainability and economic feasibility, it advances the understanding of green methanol production as a viable strategy for climate change mitigation.

**Keywords**: $CO_2$ hydrogenation, Green methanol production, Techno-Economic Analysis.

## INTRODUCTION

Anthropogenic emissions of carbon dioxide ($CO_2$) have surged dramatically in the past century, becoming a central focus of climate change mitigation efforts. The overwhelming scientific consensus indicates that the increase in atmospheric $CO_2$ concentration is strongly correlated with the rise in global temperatures, prompting the development of technologies to capture and utilize $CO_2$ [1]. Among these, the conversion of $CO_2$ into value-added products has garnered significant attention as a strategy to mitigate emissions while supporting the transition to a circular carbon economy.

Approximately 35% of global anthropogenic $CO_2$ emissions stem from industrial processes and power generation reliant on fossil fuels [2]. While capturing $CO_2$ from these sources is technically feasible, the associated costs remain high due to the energy-intensive nature of capture and compression processes [3]. Integrating $CO_2$ utilization into this framework offers an opportunity to offset costs by transforming $CO_2$ into marketable products, such as methanol, thereby enhancing the economic viability of carbon capture initiatives.

Methanol is a key platform chemical widely used in the production of formaldehyde, acetic acid, and methyl tert-butyl ether. It is also an alternative fuel with excellent combustion properties, presenting fewer environmental pollutants compared to conventional fossil fuels [4].

The quality of the CO2 feedstock is crucial for the upcycling process. Research has largely focused on $CO_2$

purities above 96% (v/v) [5]. However, recent advancements in $CO_2$ capture technologies achieve purities ranging from 83% to 98% (v/v) [6]. Hence, this study aims to evaluate the impact of $CO_2$ purity on the production of fuel-grade methanol, considering the technical and economic implications of integrating $CO_2$ capture and utilization processes efficiently. By focusing on the catalytic hydrogenation of $CO_2$ under varying purity levels, the research quantifies the potential for emission abatement and economic feasibility, thus contributing to the broader adoption of sustainable methanol synthesis technologies.

## Methanol production process

Traditionally, methanol is synthesized from synthesis gas—a mixture of carbon monoxide (CO), $CO_2$, and $H_2$—derived predominantly from natural gas via steam methane reforming [7]. The increasing emphasis on sustainability has driven interest in alternative feedstocks and processes for methanol production. Among these, the production of methanol from captured $CO_2$ through catalytic hydrogenation using renewable hydrogen ($H_2$) represents a genuinely green alternative, offering a pathway to reduce dependency on fossil fuels while enabling the recycling of $CO_2$ into valuable chemicals.

The direct hydrogenation of $CO_2$ to methanol in a single reaction step is simpler and more efficient [8] This method eliminates the need for intermediate processes, such as syngas production, required by traditional methods. Streamlining the reaction pathway not only reduces energy consumption but also lowers process complexity, improving overall economic feasibility and making it more suitable for large-scale applications. Additionally, it avoids the complex handling of CO and $CO_2$, which further enhances its compatibility with carbon capture and storage technologies [9].

This process not only facilitates $CO_2$ recycling but also contributes to the substitution of fossil feedstocks in methanol production, reducing the overall carbon footprint of the chemical industry. This process typically employs $Cu/ZnO/Al_2O_3$ catalysts, which operate under moderate conditions (210–270°C, 50–100 bar) with high selectivity (<99%) for methanol [10].

Yet, the economic and environmental impact of this process is highly dependent on the purity of the captured $CO_2$ and the energy used for hydrogen production.

## $CO_2$ hydrogenation

Methanol can be synthesized from $CO_2$ through two main pathways: a one-step process or a two-step process. The one-step pathway involves the direct hydrogenation of $CO_2$ to methanol, while the two-step process first converts $CO_2$ to CO via the Reverse Water Gas Shift (RWGS) reaction, followed by hydrogenation of CO to methanol. In this study, the one-step hydrogenation of $CO_2$ was selected as the conversion method.

The $CO_2$ utilized in these processes can be sourced from flue gases emitted by thermal power plants (e.g., coal or natural gas-based), as well as from industrial facilities such as steel mills, cement plants, and other significant $CO_2$ emitters.

The hydrogen required for this reaction must be produced sustainably, for instance, via biological methods using algae or through water electrolysis powered by carbon-neutral electricity sources [11].

The production of methanol is achieved through highly exothermic reactions (Eqs. 1, 2), while the RWGS reaction (Eq. 3) may also proceed in parallel. These reactions collectively enable the valorization of $CO_2$ into a versatile chemical with broad industrial applications.

$$CO_{(g)} + 2H_{2\,(g)} \leftrightarrow CH_3OH_{(l)} \quad \Delta H_{298K} = -128\ \frac{kJ}{mol} \tag{1}$$

$$CO_{2\,(g)} + 3H_{2\,(g)} \leftrightarrow CH_3OH_{(l)} + H_2O_{(l)} \quad \Delta H_{298K} = -87\ \frac{kJ}{mol} \tag{2}$$

$$CO_{2\,(g)} + H_{2\,(g)} \leftrightarrow CO_{(g)} + H_2O_{\,(l)} \quad \Delta H_{298K} = 41\ \frac{kJ}{mol} \tag{3}$$

The hydrogenation of $CO_2$ to produce methanol has garnered significant attention in recent years. Joo et al. investigated a two-step methanol production process and observed higher yields compared to the one-step alternative [12]. Mignard et al. proposed a process that synthesizes methanol from $CO_2$ captured from coal-fired power plant flue gases, using electrolytic hydrogen. Their findings highlighted that the availability of waste heat from the power plant is crucial to supply the thermal energy needed for substantial $CO_2$ abatement [13]. Without this thermal integration, $CO_2$ mitigation is negligible.

Methanol production emerged as the most energy-efficient route. Pontzen et al. compared the performance of $CO_2$-based methanol production over a $Cu/ZnO/Al_2O_3$ catalyst with conventional synthesis gas processes, finding that the $CO_2$-based process exhibited lower productivity levels [14].

Soltanieh et al. conducted an economic analysis for co-producing methanol and electricity from captured $CO_2$ and carbon-free hydrogen, emphasizing the potential for integrated systems [15]. Van Der Ham et al. proposed a $CO_2$-to-methanol process utilizing a fluidized-bed membrane reactor, which achieved significant $CO_2$ reduction [16]. However, the process faced challenges related to economic feasibility.

These studies collectively underscore both the technical promise and the economic hurdles associated with methanol production from $CO_2$ hydrogenation.

# METHODOLOGY

Operational analysis and simulation were carried out using Aspen HYSYS V14 with stoichiometric feed conditions tailored to the methanol synthesis reaction. Thermodynamic properties of high-pressure streams (>10

bar) were modeled using the Redlich-Kwong-Soave equation of state, while the NRTL model was employed for streams at lower pressures (<10 bar). These thermodynamic models ensure robust and reliable process representation, optimizing performance across varying conditions. Sensitivity analysis of $CO_2$ purity were carried out for a given operational case study in methanol hydrogenation, evaluating its impact on process performance and efficiency. The simulated data obtained were used for the subsequent economic analysis. Hence, a relationship between feed purity and overall process economics was set by correlating these data with operating costs.

## Case study

The process utilizes $CO_2$ sourced from any industrial facility emitting significant amounts of $CO_2$, coupled with hydrogen produced via water electrolysis, as feedstock for methanol synthesis. A schematic representation of the process is shown in **Figure 1**.

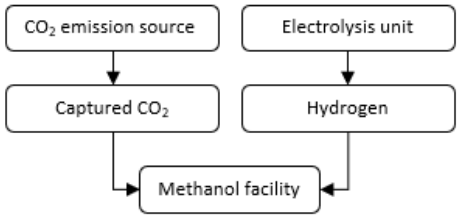

**Figure 1.** Scheme of methanol synthesis.

Water electrolysis is powered by carbon-free electricity sources such as renewables (e.g., hydroelectric, wind, solar, or biomass) or nuclear power. The entire system, including both hydrogen production and methanol synthesis, is designed to operate as an integrated unit, minimizing energy losses and simplifying logistics. This integration ensures that the hydrogen generated is directly utilized within the methanol synthesis process, avoiding storage and transportation challenges.

### Water electrolysis unit

The production of hydrogen via water electrolysis (Eq. 4) requires an energy input of 60 kWh/kg $H_2$ [17]. The hydrogen exits the electrolyzer at 6 bar and 25 °C, ready for direct use in the methanol synthesis process.

$$H_2O_{(l)} \rightarrow H_{2\,(g)} + 0.5\,O_{2\,(g)} \quad (4)$$

Electrolysis also produces a significant quantity of oxygen as a by-product. This oxygen could be internally used in the power plant for oxycombustion, enhancing $CO_2$ concentration in flue gases and lowering the energy requirements for its capture. Alternatively, it can be marketed. This study analyses the first option.

### $CO_2$ capture unit

The $CO_2$ capture unit considered in this paper relies on physical adsorption using adsorbents materials. In this process, $CO_2$ is captured from flue gases of industrial sources through its interaction with the adsorbent.

Flue gases containing $CO_2$ are first compressed to offset the pressure drop in the adsorption system. These gases are then introduced into the adsorbent bed, where the $CO_2$ is physically adsorbed due to the adsorbent's microporous structure. The system operates by cycling the pressure, with $CO_2$ being adsorbed at higher pressures. Once the zeolite becomes saturated with $CO_2$, the desorption process is initiated. This is achieved by reducing the pressure or increasing the temperature, which allows $CO_2$ to be released and collected for further utilization.

The adsorbent material can be regenerated after each cycle by applying pressure or temperature swing adsorption (PSA/TSA) methods [18], allowing it to be reused multiple times without significant loss of efficiency. The desorbed $CO_2$ is then captured and fed to the methanol synthesis unit, where it is combined with hydrogen.

The overall performance of the system depends on the adsorption capacity of the adsorbent, the frequency of regeneration cycles, and the efficiency of the desorption process [19].

$CO_2$ capture performance and associated energy use are influenced by the purity of the incoming $CO_2$ stream. Typically, the purity of captured $CO_2$ in industrial applications ranges from 83% to 98%. For $CO_2$ with a purity of 83%, the energy consumption for $CO_2$ capture can range between 1.00 kWh and 1.20 kWh/kg $CO_2$ [20]. When the $CO_2$ purity increases to 98%, the energy consumption for the same processes increases, typically between 1.50 kWh and 2.00 kWh/kg $CO_2$ [6], due to the need for higher efficiency in separating and adsorbing the $CO_2$ at greater purity levels. Estimations from industrial practice are shown in **Figure 2**. $CO_2$ is fed to the methanol plant at 6 bar and 25°C.

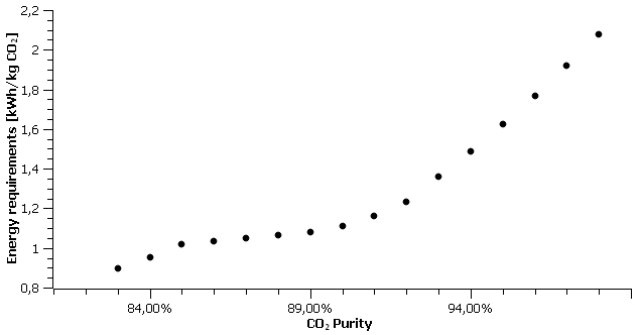

**Figure 2.** Energy demand for $CO_2$ purification.

## Methanol synthesis and purification unit

The process flowsheet is presented in **Figure 3**. To analyze the operating modes of methanol production via $CO_2$ hydrogenation, a process flowsheet was developed for the methanol synthesis and purification stages. The conversion process utilizes a conversion reactor for $CO_2$

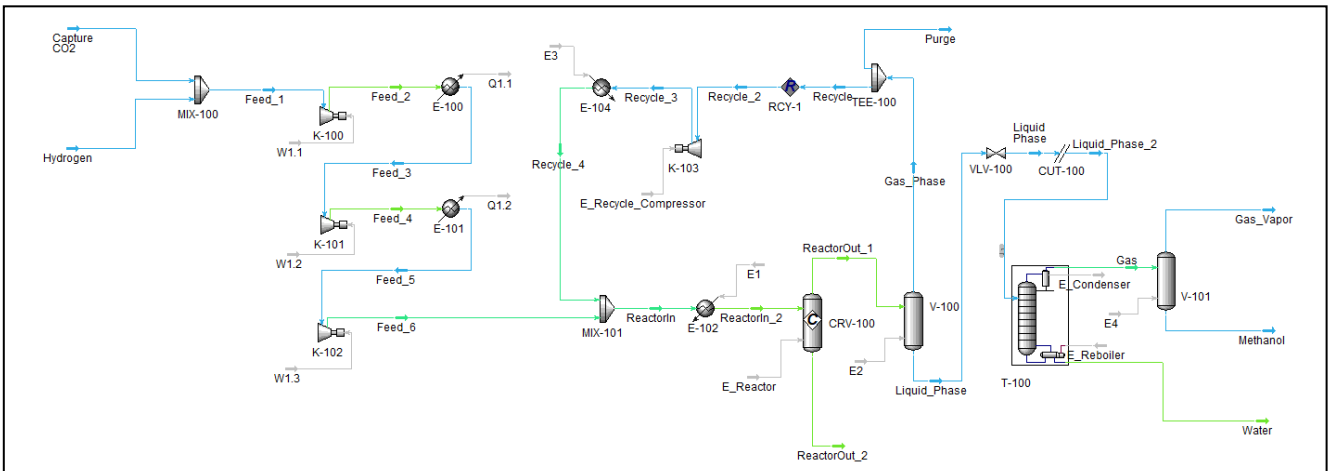

**Figure 3.** Flowsheet of the process for green methanol production from captured $CO_2$ and renewable hydrogen.

hydrogenation. Conversion reactor used for production of methanol works with 17.25 % of $CO_2$ conversion and the pressure is 60 bar [21].

The economic analysis assumes a base price of 50€/MWh for the energy cost [22]. Production cost is measured in kWh per kilogram of feed, reflecting the efficiency of the process and the energy requirements for transforming raw materials into the final product.

### Process description

$CO_2$ and hydrogen is fed into the system at 6 bar, both at an initial temperature of 25 °C. The feed undergoes compression to the reaction pressure of 60 bar through a series of compressors with intercooling. The two compressed gases are initially mixed in MIX-100 and subsequently combined with the recycle stream.

The mixed stream is heated in E-102 to the desired reaction temperature (215ºC) before being introduced into the conversion reactor system. In these reactors, methanol synthesis occurs via the catalytic hydrogenation of $CO_2$. Heat generated during the reaction is managed through the reactor heat exchanger (E-Reactor).

The reactor outlet stream is sent to a flash separation unit (V-100), where it is divided into two phases. The gas phase, composed of non-reacted gases and by-products, is split into two streams: a small fraction is purged (5%) to prevent the accumulation of inerts and by-products, while the majority is compressed (K-103) and recycled back into the process, ensuring efficient use of unreacted reactants.

The liquid phase, containing methanol and water, is sent to the distillation column (T-100) for further purification. The crude methanol mixture undergoes pressure reduction via a valve system (VLV-100). The water by-product exits from the bottom of the column, while purified methanol vapor exits the top, where it is cooled and condensed to liquid form for collection.

## RESULTS & DISCUSSION

The influence of $CO_2$ purity on the methanol synthesis process was analyzed, focusing on energy requirements (kWh/kg methanol), productivity (kg/h), recycle ratio, and production cost (€/kg methanol). Results are shown in **Figure 4**.

The recycle ratio decreases as $CO_2$ purity increases. At lower purities, higher amounts of inerts are recycled for the methanol synthesis, leading to increased operational demands on the system. Conversely, higher purities reduce recycle ratio, minimizing the energy for recycling equipment and improving overall system efficiency.

Methanol productivity increases proportionally with $CO_2$ purity. From an economic perspective, this increase in productivity directly offsets operational costs, making higher-purity $CO_2$ streams more favorable despite the potential increase in capture costs.

Lower purities result in greater energy demand due to the recycling of inert gases and increased compression requirements. As purity rises, energy consumption decreases significantly. This energy efficiency translates directly into reduced operational costs, particularly for systems where energy-intensive recycling and compression are dominant expenses.

The results highlight a non-linear relationship between $CO_2$ purity and methanol production costs. At lower purities, the cost remains relatively stable, suggesting that impurities within this range do not significantly impact the overall process economics.

As purity increases towards 89%, production costs rise and then fall for higher purities (>92%). This trend can be attributed to the balance between purification expenses and process efficiency. Intermediate purities like-

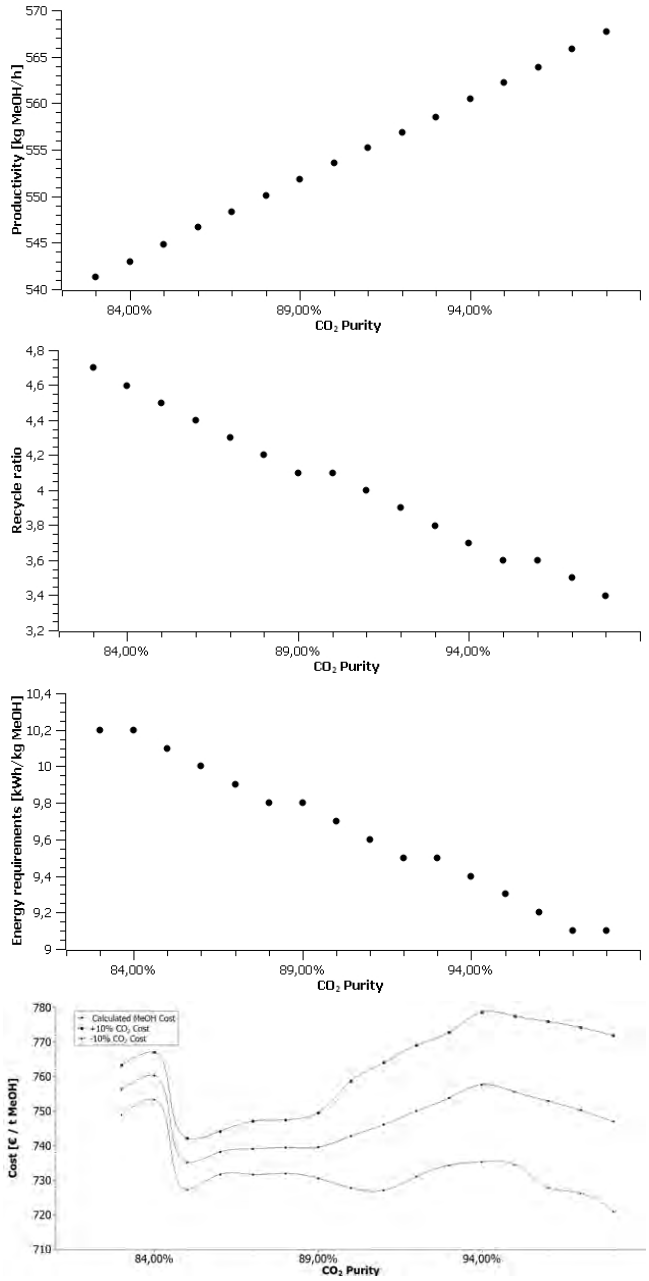

**Figure 4**. Effect of $CO_2$ purity on 1) Methanol productivity 2) Recycle ratio 3) Energy requirements 4) Cost of methanol production.

ly require additional separation steps, increasing operational costs. In contrast, at higher purities, methanol productivity increases while the energy requirements per unit of methanol decrease, leading to a reduction in overall production costs. As $CO_2$ purity increases toward 89%, production costs rise and can reach 770–780 €/t MeOH, indicating a local maximum. The ±10% cost lines bracket this baseline scenario, revealing how incremental shifts in $CO_2$ capture expenses can shift the overall cost curve by approximately 10–15 €/t.

$CO_2$ purity emerges as a decisive factor influencing operational costs. Lower purities introduce inefficiencies across multiple aspects of the process. Higher purities not only enhance productivity but also reduce operational costs, particularly in energy-intensive systems. The trade-off lies in balancing the cost of achieving higher $CO_2$ purity against the operational savings realized during methanol synthesis.

## CONCLUSION

This study highlights the critical impact of $CO_2$ purity on green methanol production through catalytic hydrogenation, addressing a key gap in existing research focused primarily on high-purity $CO_2$ streams (>96%). Results demonstrates that higher $CO_2$ purity leads to reduced energy consumption, streamlined operational dynamics, and lower production costs, enabling optimal process performance. In contrast, lower $CO_2$ purities increase inert loads, energy demand, and recycle ratios, while excessively high purities elevate upstream costs, resulting in diminishing economic returns despite improved yields. These findings highlight the critical role of energy-efficient $CO_2$ capture technologies in enhancing the sustainability and economic viability of methanol synthesis. Moreover, it provides a foundation for further investigation into system optimization, supporting the development of green methanol production as a viable strategy for climate change mitigation.

This work contributes to the broader discourse on climate change mitigation by offering actionable insights into the interplay between $CO_2$ capture, purification, and utilization technologies.

## ABSTRACT

This study presents a gate-to-gate Life Cycle Assessment (LCA) evaluating the sustainability and environmental impacts of utilising $CO_2$ for Enhanced Oil Recovery (EOR) in Dukhan Field. The assessment employs a detailed model that encompasses $CO_2$ capturing, transportation, injection, and oil production processes. Utilising Gabi software, the study assesses $CO_2$ emissions across different stages of the EOR process and evaluates the environmental efficiency using two functional units: '1 kg of $CO_2$ captured' and '1 kg of oil produced'. Results indicate that Post-Combustion Capture (PCC) contributes the highest emissions, accounting for 76% of the total Global Warming Potential (GWP), while transportation pipelines and separators contribute only 2% and 4%, respectively. By Year 21, emissions drop by over 98%, with a corresponding GWP reduction from 4.73 billion $kgCO_2e$ in Year 1 to 94.97 million $kgCO_2e$. Emission rates for $CO_2$ capture and oil production also decrease significantly, reaching 0.01 $kgCO_2e$ per kg of $CO_2$ captured and 0.03 $kgCO_2e$ per kg of oil produced. These findings highlight the transformative potential of closed-loop $CO_2$ management, where recycling reduces reliance on external $CO_2$ sources and enhances the sustainability of EOR operations. This study provides actionable insights for optimising $CO_2$-EOR systems, contributing to both economic and environmental sustainability goals.

**Keywords**: Life Cycle Analysis, Carbon Dioxide, Carbon Capture, Optimisation, Environment.

## INTRODUCTION

Global $CO_2$ emissions have risen significantly, reaching 37.9 Gt in 2018, contributing over 75% of total greenhouse gases (International Energy Agency, 2023). The oil and gas sector alone accounts for 10% of these emissions (Kamkeng et al., 2021). Carbon Capture and Utilisation (CCU) is a promising approach to mitigating these emissions by capturing $CO_2$ and repurposing it for Enhanced Oil Recovery (EOR).

The environmental performance of CCU technologies has been widely evaluated in literature through the Life Cycle Assessment (LCA); a holistic approach that examines both resource consumption and pollutant release across all phases of a product's life cycle (Faber et al., 2022). Building on established LCA frameworks, Müller et al., (2020) introduced guidelines tailored to CCU in collaboration with over 40 experts, aiming to quantify the environmental benefits of CCU products and processes relative to conventional fossil-based alternatives. One key challenge when applying LCA to CCU arises from its multifunctional nature: $CO_2$ serves both as a waste product and a valuable resource. This dual role creates a direct link between $CO_2$ emission sources and its subsequent use in CCU, making the assessment more complex. To address this, the guidelines recommend a systematic approach aligned with ISO 14040/44 standards, which involves segmenting the process, expanding the assessment scope, and allocating impacts based on chemical or physical criteria. This methodology helps navigate the complexities introduced by CCU's multifunctionality.

Several studies have critically evaluated $CO_2$-EOR using LCA, highlighting both its potential and limitations as a carbon sequestration strategy. Jaramillo et al. (2009) examined lifecycle emissions from $CO_2$ capture at power

plants through to the combustion of the produced oil, questioning $CO_2$-EOR's net benefits for carbon sequestration. In contrast, Jensen et al. (2018) compared $CO_2$ EOR with conventional oil and natural gas production, illustrating that $CO_2$ EOR could reduce lifecycle greenhouse gas emissions, with outcomes heavily influenced by factors such as $CO_2$ capture rate and oil recovery efficiency.

Morgan et al. (2021) conducted a gate-to-gate LCA over a decade of $CO_2$-EOR operations, using 100% anthropogenic $CO_2$. The study demonstrated that $CO_2$-EOR has the potential to achieve net-negative emissions, citing a 92% storage rate for injected $CO_2$ and identifying operational improvements as key to enhancing environmental outcomes.

Similarly, Abuov et al. (2022)'s study indicated that $CO_2$-EOR can yield lower GHG emissions than conventional oil production, particularly under favorable carbon pricing and when $CO_2$ is sourced from coal-fired or NGCC power plants, thereby maintaining economic viability while reducing emissions.

Despite extensive research on $CO_2$-EOR, most studies focus on short-term assessments of $CO_2$ capture, injection, and sequestration, with limited analysis of long-term environmental performance. The transition from external $CO_2$ supply to a closed-loop recycling system remains underexplored, particularly in oil reservoirs in Qatar, such as the Dukhan Field.

Existing evaluations do not comprehensively quantify the long-term emissions reduction potential, sequestration efficiency, or overall sustainability of such systems. A systematic, long-term assessment of $CO_2$-EOR operations is essential to address this gap, providing critical insights into emissions dynamics, sequestration effectiveness, and the feasibility of achieving a self-sustaining carbon management approach.

## Study Objectives

This study aims to fill that gap by focusing on a detailed, gate-to-gate LCA that examines the environmental impacts of direct $CO_2$ injection for oil recovery, offering new insights into emissions reductions over an extended timeline. It also evaluates the operational efficiency of $CO_2$ sequestration under specific conditions unique to Dukhan Field, thereby contributing to a more targeted understanding of EOR's sustainability potential. To achieve this, the objectives of this research are to:

- Evaluate the environmental impacts of direct $CO_2$ injection for EOR using LCA.
- Quantify emissions and environmental efficiencies through two functional units: '1 kg of $CO_2$ captured' and '1 kg of oil produced.'
- Simulate operational efficiency and emissions reductions over 21 years, transitioning from external $CO_2$ to recycled $CO_2$.
- Analyse the feasibility of closed-loop $CO_2$ management in achieving long-term emissions reductions of over 90%.
- Provide recommendations to policymakers and industry leaders for implementing sustainable $CO_2$-EOR practices.

# METHODOLOGY

Building on the $CO_2$ reinjection closed-loop model developed by (Sawaly et al., 2022) for Dukhan Field, this study evaluates the feasibility and environmental impact of direct $CO_2$ injection for Enhanced Oil Recovery (EOR) in Dukhan Field, Qatar, without prior water injection. Initially, the model depends on externally sourced $CO_2$ but progressively transitions to recycling recovered $CO_2$ from previous cycles, with the potential to operate solely on reinjected $CO_2$ by the 21st year (Figure 1).

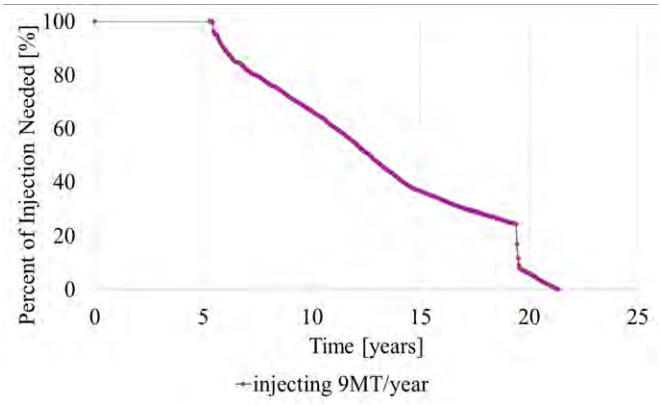

**Figure 1:** $CO_2$ utilisation process with reinjection.

## Model description

This gate-to-gate Life Cycle Assessment (LCA) examines the $CO_2$-EOR process from capture through oil production, excluding downstream refining and end-of-life emissions. Gabi software is used for environmental impact assessment, quantifying emissions and energy use. The system boundary extends from the flue gas stream exiting the source to crude oil production, incorporating $CO_2$ capture, compression, transportation, injection, separation, and reinjection to form a closed-loop system. The field specifications and production rate over time are detailed in (Sawaly et al., 2022). The model simulates a progressive transition from externally sourced $CO_2$ to internally recycled $CO_2$ over the 21-year period. As $CO_2$ recycling efficiency increases, the need for additional $CO_2$ purchases declines, and the production rate is adjusted dynamically based on reservoir performance and injection efficiency. The $CO_2$ composition of the produced stream is also accounted for through changes in

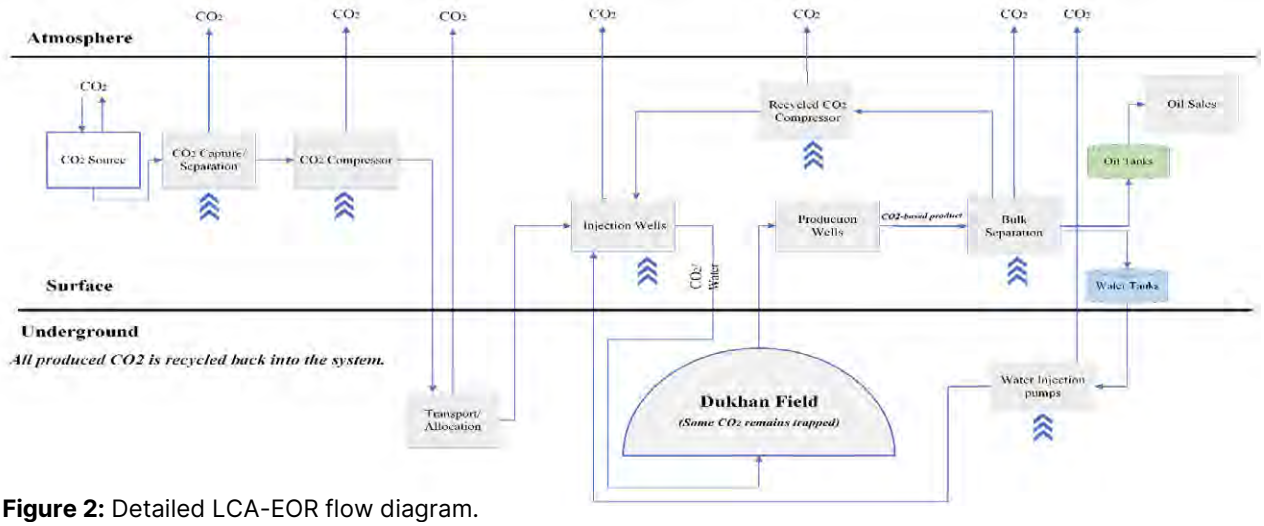

**Figure 2:** Detailed LCA-EOR flow diagram.

**Table 1:** Key operational and environmental metrics.

| Category | Term | Value | Unit | Reference |
|---|---|---|---|---|
| **Operational Metrics** | Feed Flowrate | 9000000 | t/y | (Sawaly et al., 2023) |
| | Production Rate | 0.2 | tonOil/ton$CO_2$ | (Sawaly et al., 2023) |
| | Distance | 100 | km | (Sawaly et al., 2023) |
| **Energy Metrics** | Capture | 3.32 | GJ/ton$CO_2$ | (Azzolina et al., 2017) |
| | Compression and transportation *(pipeline, 100km)* | 1.3 | kWh/ton$CO_2$ | (Azzolina et al., 2017) |
| | Injection Well | 64.5 | kWh/ton$CO_2$ | (Azzolina et al., 2017) |
| | Uplift (pump) production | 20 | kWh/bbl of oil | (Azzolina et al., 2017) |

separation efficiency and reinjection rates over time. These dynamic changes are integrated into the model to reflect realistic long-term operational scenarios.

Two functional units are used: '1 kg of $CO_2$ captured', assessing emissions per unit of injected $CO_2$, and '1 kg of oil produced', quantifying the carbon footprint of recovered oil. As illustrated in Figure 2, $CO_2$ is initially captured and purified at the source, compressed, and transported to injection wells, where it enhances oil recovery while storing $CO_2$ underground. During production, $CO_2$ resurfaces with oil and water, is separated, recompressed, and reinjected, minimising reliance on fresh $CO_2$ and maximising sustainability and efficiency. This approach supports a low-carbon oil recovery strategy, demonstrating the long-term potential of EOR as an emissions-reduction solution.

## Available data and assumptions

This section outlines the key operational and environmental parameters used to simulate the Enhanced Oil Recovery (EOR) process and assess its environmental impacts. These parameters include $CO_2$ capture emissions, energy consumption during capture, transportation, and injection, as well as $CO_2$ production rates and oil recovery yields.

$CO_2$ is captured using amine-based Post-Combustion Capture (PCC) technology with a 90% purity assumption, ensuring less than 10% impurities for efficient processing. The capture process requires both electricity and heat—electricity powers pumps and mechanical components, while heat regenerates the amine solvents in a desorption cycle, allowing solvent reuse and improving process sustainability. Emissions at this stage include direct emissions from PCC operations and indirect emissions linked to energy consumption, depending on the carbon intensity of the power source.

After capture and purification, $CO_2$ is transported via pipeline to the EOR site, requiring electricity-powered pumps to maintain flow and pressure. This ensures efficient delivery while minimising pressure losses. Emissions stem from pump and compressor operations, as well as energy consumption associated with transport. At the Dukhan Field, $CO_2$ is injected directly into the reservoir to enhance oil recovery, displacing hydrocarbons and reducing viscosity. This stage requires electricity to power injection pumps, as well as energy for drilling and completing wells. Emissions at this phase include direct emissions from drilling operations and indirect emissions from power consumption. Oil extraction involves drilling and well operations, requiring energy to operate lifting

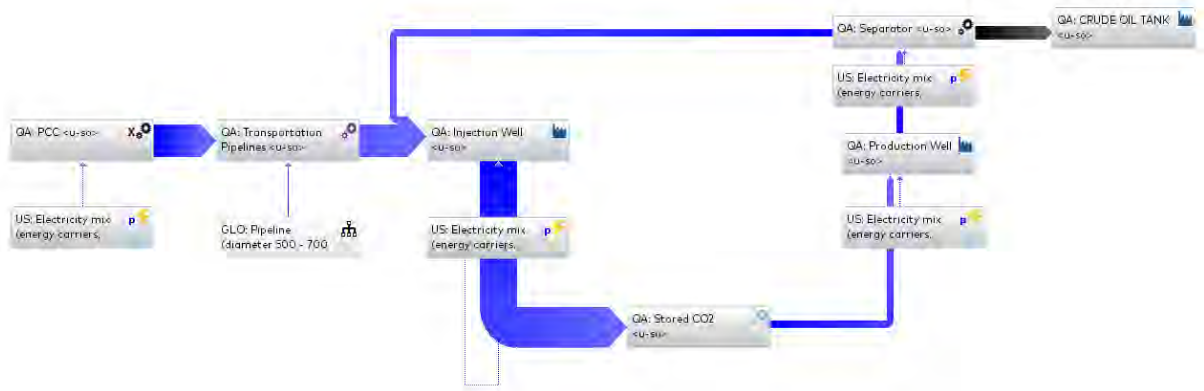

**Figure 3:** Gabi Screenshot of the model.

systems and production pumps. Emissions from this stage stem from both direct drilling activities and indirect energy use. Post-production, $CO_2$ is separated from oil and water using thermal and mechanical processes, requiring heat for thermal separation and electricity for compression and mechanical separation. Recovered $CO_2$ is then recompressed and reinjected, minimising the need for additional $CO_2$ purchases and supporting a closed-loop EOR system. Emissions include direct emissions from separation and indirect emissions from energy use. The emissions for each stage were calculated by multiplying the energy consumed at that stage by the $CO_2$-intensity factor for Qatar's electricity generation, which is primarily based on natural gas. The $CO_2$ intensity of Qatar's electricity grid is approximately 0.111 $tCO_2/GJ$ (or ~0.40 $tCO_2/MWh$)(IEA, 2019). This value represents the emissions released per unit of power generated in a natural gas system. In the case of pipeline transportation, a direct emission factor of 0.0001986 t $CO_2$/t $CO_2$ transported (per 100 km) is applied, as reported by Azzolina et al. (2017). This value reflects fugitive or operational emissions—such as small leaks and routine venting—rather than emissions from the electricity used to operate pumps or compressors.

The methodology acknowledges that brine is excluded from the analysis due to a lack of specific data, which is a recognised limitation of the current LCA scope. Table 1 summarises the key operational and environmental metrics, providing essential data for assessing the sustainability and efficiency of $CO_2$-EOR in Dukhan Field.

## RESULTS AND DISCUSSION

This section presents the key findings from the gate-to-gate LCA of the $CO_2$-EOR process in Dukhan Field. The analysis evaluates the environmental and operational impacts of $CO_2$ injection, focusing on enhanced oil recovery, reduced emissions, and the benefits of closed-loop recycling to support optimisation and sustainable development.

The LCA provides a detailed assessment of various operational scenarios over several years. The system boundaries extend from $CO_2$ extraction from the flue gas stream to oil production, excluding the life cycle impacts of crude oil products and upstream LNG production. Figure 3 illustrates the model employed in this assessment, highlighting the interactions between key variables and processes involved in $CO_2$-EOR.

Figure 4 presents a breakdown of the Global Warming Potential (GWP) across different stages of the $CO_2$-EOR process, offering critical insights into environmental performance. The stages include the injection well, post-combustion capture (PCC), the separator, transportation pipelines, and the total cumulative impact. The chart also shows the emission rates per kilogram of $CO_2$ captured and per kilogram of oil produced, providing a comprehensive view of the environmental footprint at each stage.

The PCC stage is the most emission-intensive, with a GWP of 1.20 billion $kgCO_2e$, highlighting the high energy demand of $CO_2$ capture, particularly when powered by non-renewable sources. In contrast, the injection well demonstrates a relatively low GWP of 0.29 billion $kgCO_2e$, indicating efficient $CO_2$ utilisation in oil recovery with minimal contribution to overall emissions. Emissions from the separator and transportation pipelines are significantly lower, at 0.07 billion $kgCO_2e$ and 0.02 billion $kgCO_2e$, respectively, reflecting effective management of these processes to minimise environmental impact. The total GWP across all stages is 1.58 billion $kgCO_2e$, with emission rates of 0.53 $kgCO_2e$ per kilogram of oil produced. This underscores the challenge of managing emissions throughout the $CO_2$-EOR process while identifying PCC as a critical area for potential improvement to reduce overall emissions.

Figure 5 illustrates the evolution of $CO_2$ utilisation and its impact on environmental performance over time through four distinct scenarios, each representing different stages of the $CO_2$-EOR process at Dukhan Field. These scenarios, spanning from Year 1 to Year 21, demonstrate the shift from external $CO_2$ sourcing to increased internal recycling. Each scenario reflects varying proportions of $CO_2$ sourced from external versus

internally recycled $CO_2$, highlighting the system's progression toward greater sustainability and efficiency. The gradual reduction in $CO_2$ allocation from external sources, combined with increased recycling and reinjection of $CO_2$ produced during oil extraction, emerges as a pivotal factor in enhancing the environmental and operational performance of the entire process.

As shown in Figure 5, in Year 1, when 100% of the required $CO_2$ is sourced externally, the system exhibits a high Global Warming Potential (GWP) of 4.73 billion $kgCO_2e$, reflecting the substantial environmental impact associated with early reliance on external $CO_2$ sources. However, as internal recycling mechanisms are adopted, the need for external $CO_2$ supply diminishes progressively. By Year 21, when no $CO_2$ is sourced externally, the GWP drops to 94.97 million $kgCO_2e$, representing a reduction of over 98% compared to Year 1. This decline underscores the success of the closed-loop $CO_2$ management strategy, wherein most of the $CO_2$ required for EOR operations is derived from recycled sources. Consequently, the emission rates per kilogram of $CO_2$ captured and per kilogram of oil produced decrease to 0.01 $kgCO_2e$ and 0.03 $kgCO_2e$, respectively, further demonstrating the efficiency gains achieved through internal $CO_2$ recycling.

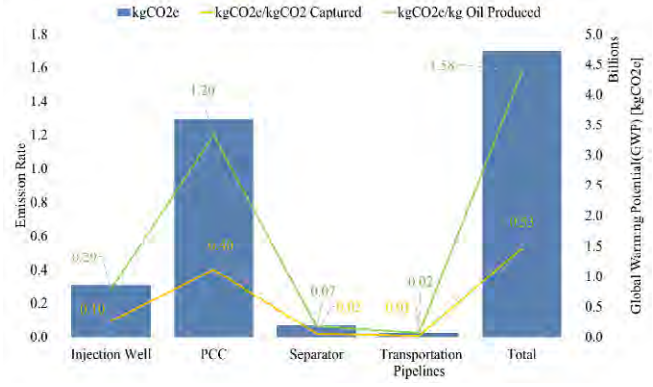

**Figure 4:** GWP of the base case scenario (year 1).

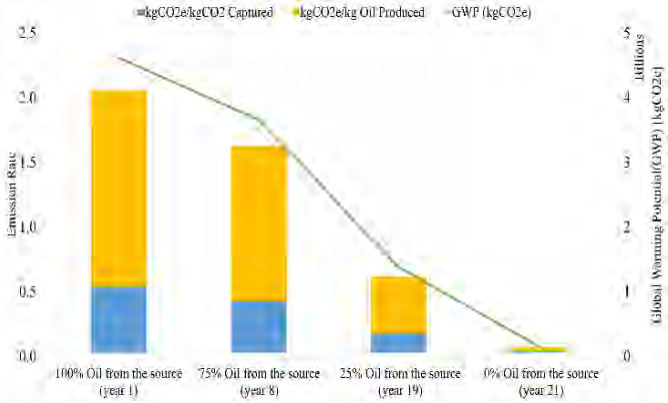

**Figure 5:** Comparison of 3 GWP Scenarios for 4 different years.

By improving $CO_2$ utilisation and reducing reliance on external supply, the system enhances oil production while simultaneously lowering emissions, thereby optimising the need for additional $CO_2$ input and improving the overall carbon efficiency of the EOR process. The reduction in PCC-related emissions over time reinforces the broader environmental benefits of transitioning towards a more self-sustaining $CO_2$-EOR operation. Overall, the results highlight the significant potential of internal $CO_2$ recycling to enhance the sustainability and environmental performance of $CO_2$-EOR operations. By reducing reliance on external $CO_2$ sources and optimising internal recycling processes, the system achieves substantial reductions in emissions while supporting a more economically viable and environmentally responsible oil recovery process.

The findings of this study align closely with those of previous $CO_2$-EOR LCA studies. Nuñez-López et al. (2017) reported an emission rate of 2.7 $kgCO_2e$ per kilogram of oil produced, which is consistent with the overall trend observed in this analysis. Slight variations may stem from differences in reservoir properties, energy sources, and operational conditions. Despite these variations, both studies underscore the potential of $CO_2$-EOR to enhance oil recovery while managing environmental impacts.

## CONCLUSION

This This study presents a detailed gate-to-gate Life Cycle Assessment (LCA) of $CO_2$ utilisation in Enhanced Oil Recovery (EOR) at Dukhan Field, Qatar, demonstrating the environmental and operational benefits of direct $CO_2$ injection without water flooding. The results show that implementing internal $CO_2$ recycling can reduce net emissions by over 90% by Year 21, confirming the effectiveness of closed-loop $CO_2$ management in cutting the carbon footprint of EOR operations. This reduction is primarily driven by the progressive replacement of externally sourced $CO_2$ with recycled $CO_2$, decreasing reliance on external carbon inputs.

The analysis evaluates $CO_2$ capture, transportation, injection, and recycling using functional units ("1 kg of $CO_2$ captured" and "1 kg of oil produced") to provide objective performance benchmarks. The findings underscore that Post-Combustion Capture (PCC) is the most emission-intensive stage, contributing approximately 76% of the total Global Warming Potential (GWP) in Year 1. Improving PCC energy efficiency and exploring alternative capture technologies, such as membrane-based systems or cryogenic separation, could significantly reduce the overall carbon footprint of $CO_2$-EOR.

While the findings highlight the potential of $CO_2$-EOR in reducing emissions and enhancing oil recovery, the study's scope is limited to the specific geological and

operational characteristics of Dukhan Field. This may restrict the direct applicability of the results to other fields with different reservoir conditions. Future research should extend the system boundaries to include downstream emissions from refining and combustion and assess the impact of $CO_2$ purity and reservoir pressure on sequestration efficiency and oil recovery rates. Comparative studies across different reservoir profiles would strengthen the generalisability of these findings.

The demonstrated reduction in emissions through internal $CO_2$ recycling also enhances economic feasibility by lowering the need for external $CO_2$ supply. This reinforces the strategic role of $CO_2$-EOR in supporting a transition toward low-carbon oil production, providing a viable path for balancing energy security with environmental responsibility.

## ABSTRACT

This study investigates the design of a two-column distillation (TCD) process to separate a dilute ternary Ethyl Acetate (EtAc)-Methanol (MeOH)-water waste solvent into nearly pure components. The separation is complicated by the presence of a homogeneous EtAc-MeOH azeotrope and a heterogeneous EtAc-water azeotrope, creating a distillation boundary that divides the ternary composition space into two distinct regions. To address this, the proposed flowsheet incorporates liquid-liquid phase separation to cross the distillation boundary, enabling feasible separation. Additionally, the pressure sensitivity of the distillation boundary is exploited to reduce the recycle rate, enhancing energy efficiency. The basic TCD flowsheet consists of a decanter, a high-pressure simple column, and a low-pressure divided-wall column (DWC). Heat integration (HI) is achieved using external process-to-process heat exchangers and vapor recompression (VR)-driven reboilers. The resulting energy-efficient HIVR-TCD configuration is more cost-effective and energy-efficient than existing designs in the literature. Specifically, the total annualized cost (TAC) of the proposed HIVR-TCD process is 15.4% lower than the literature best design, with reductions in energy consumption and $CO_2$ emissions of 34.3% and 31.4%, respectively, representing a significant improvement.

**Keywords**: Sustainable, Azeotrope, DWC, Distillation

## INTRODUCTION

Spent solvents are widely generated in the pharmaceutical industry. Due to rising sustainability concerns and stricter waste disposal rules, there is a growing emphasis on recovering, recycling, and reusing the organic compounds within these solvents. Achieving minimal waste discharge requires addressing challenges such as azeotropes that limit simple distillation. Advanced techniques like pressure swing, extractive, and azeotropic distillation are utilized to efficiently recover and purify components based on the solvent mixture's composition.

Ethyl acetate (EtAc) and methanol (MeOH) are frequently used solvents in pharmaceutical manufacturing. Spent solvents typically contain a mixture of EtAc, MeOH, and water. However, minimum boiling binary azeotropes like EtAc-$H_2O$ and EtAc-MeOH hinder the recovery of pure components from this ternary mixture. Therefore, an advance distillation-based sequence is required to efficiently separate these components.

**Table 1**: Normal boiling point of components

| Component | Boiling Point ($^oC$) |
|---|---|
| MeOH/EtAc azeotrope | 62.3 |
| MeOH | 64.5 |
| Water/EtAc azeotrope | 70.8 |
| EtAc | 77.2 |
| Water | 100 |

In the literature various designs for separating EtAc-MeOH-water mixtures have been proposed, with Yang's design [1] proving most efficient. It uses a liquid-liquid phase split to overcome distillation boundaries and features a heterogeneous triple-column distillation (HTCD) system with a decanter and three columns. Energy efficiency is enhanced through heat integration (HI) and heat pump–vapor recompression (HP-VR), forming the hybrid-HTCD process. This design reduces total annual cost by 16% and 11% compared to HTCD and HI-HTCD systems, respectively, making it the most economical option.

The azeotropes of EtAc-water and MeOH-EtAc are known to be pressure-sensitive, with EtAc showing limited solubility in water and MeOH being fully miscible with both. This results in a significant liquid-liquid phase separation region in the ternary composition diagram. Thus, exploring pressure-swing distillation and liquid-liquid phase splitting offers a potential pathway to cross distillation boundaries and develop a more efficient flowsheet for separating MeOH-EtAc-water mixtures into pure components. This study focuses on achieving this goal.

This work employs residue-curve maps (RCMs) to design a distillation process with a decanter and two columns operating at different pressures, one of which is a divided-wall column (DWC), to separate a dilute MeOH-EtAc-water mixture. Energy efficiency is enhanced through process-to-process heat exchange and vapor recompression for column reboil. An economic steady-state design is developed and compared to existing flowsheets, evaluating energy consumption, $CO_2$ emissions, and total annualized cost (TAC) to quantify savings. The work concludes by highlighting its key contributions.

## PROCESS MODELLING

Aspen plus is used for steady state simulation the thermodynamic properties are modelled by NRTL equation for liquid phase activity coefficient and vapor phase is modelled as an ideal gas. The binary interaction parameters as well as liquid phase envelope data is provided in the NIST database based on that a regressed NRTL parameter are provided in the Table 2 below.

**Table 2**: Regressed NRTL interaction parameter

| Comp i | Comp j | $A_{ij}$ | $A_{ji}$ | $B_{ij}$ | $B_{ji}$ | $C_{ij}$ |
|---|---|---|---|---|---|---|
| MeOH | Water | 3.65 | -2.47 | -1556.8 | 1460.8 | 0.13 |
| MeOH | EtAc | 4.56 | -5.52 | -1196.9 | 2216.8 | 1.11 |
| Water | EtAc | -3.8 | -3.64 | 2229.9 | 1699.1 | 0.36 |

## FLOWSHEET SYNTHESIS

This study examines a dilute mixed solvent with a mole fraction of [0.05, 0.05, 0.90] for EtAc–MeOH–water, similar to Yang et al. Figure 1 displays residue-curve maps (RCMs) at different pressures, showing EtAc and water as stable nodes, MeOH as a saddle, and two minimum boiling binary azeotropes: a homogeneous MeOH–EtAc azeotrope and a heterogeneous EtAc–water azeotrope, both unstable nodes. Table 1 provides the boiling points of the pure components and azeotropes. A distillation boundary between the azeotropes divides the ternary composition space into two distinct distillation regions.

Figure 1 illustrates that azeotrope positions are pressure-dependent, with the distillation boundary shifting leftward as pressure increases. This shift, along with the liquid-liquid phase split enabling spontaneous separation, allows for energy-efficient separation. The dilute fresh feed, within the liquid-liquid phase envelope, can be decanted at 1 bar to cross the boundary, producing an EtAc-rich organic layer in region II and a water-rich aqueous layer in region I. The organic stream is stripped to obtain pure EtAc, while the overhead vapor near the boundary is condensed and recycled for further phase separation.

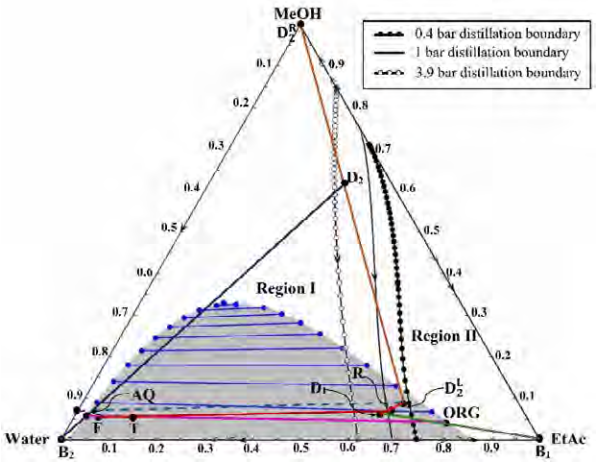

**Figure 1:** RCM at different pressure

As the distillation boundary and the overhead condensate composition shift leftward with increasing column pressure, the separation should occur at a moderate pressure above 1 bar, such as 4 bar. This increases the gap between the overhead condensate and bottom compositions, reducing the recycle rate to the decanter according to the lever rule.

The aqueous stream from the decanter, with a composition in region I, can be stripped to produce an EtAc-free bottom product near the MeOH–water binary edge and an overhead ternary vapor within the liquid-liquid envelope in region I, close to the distillation boundary. This vapor can be condensed and recycled to the decanter. The EtAc-free MeOH–water bottoms can then be distilled to obtain pure MeOH distillate and a water bottom product. To maximize relative volatility and reduce energy consumption, aqueous separations should be performed at low pressure.

The basic TCD flowsheet includes a decanter and two distillation columns: the high-pressure (HP) stripper. Figure 1 displays the material balance lines for each unit operation based on the recommended design and operating conditions. The decanter tie-line (magenta) indicates the compositions of the organic (ORG) and aqueous (AQ) phases. The $C_1$ bottoms ($B_1$) are at the EtAc vertex, while the distillate ($D_1$) lies in region II, near the 3.9 bar distillation boundary, along the line connecting the organic phase and EtAc vertex.

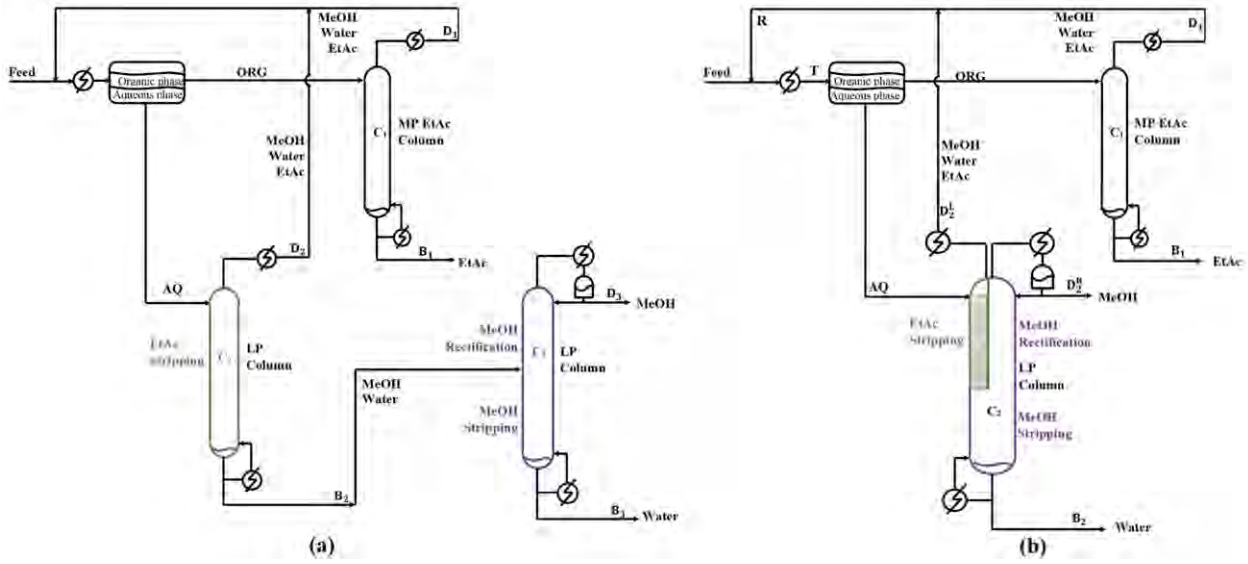

**Figure 2**: Synthesis of a) Conventional distillation scheme b) Intensified two column distillation scheme

Column $C_2$ separates the aqueous stream into nearly pure water bottoms ($B_2$), pure MeOH distillate ($D_2^R$), and ternary left distillate ($D_2^L$). The intersection of the $B_2$-AQ and $D_2^R$-$D_2^L$ lines defines the total overhead product ($D_2$). The distillates from $C_1$ ($D_1$) and $C_2$ ($D_2^L$) form the mixed recycle stream (R), with the tie-line intersection of the fresh feed (FF) and R determining the total feed (T) to the decanter. The HP and LP columns shift the distillation boundaries, reducing the recycle rate and improving energy efficiency. The boundary is crossed through liquid-liquid phase separation in the decanter. The next step is to develop the economic steady-state design.

## ECONOMIC STEADY-STATE DESIGN

An economic steady-state design for the TCD process, shown in Figure 2b, uses a fresh feed rate of 100 kmol/h with a composition of [5, 5, 90] mol % MeOH–EtAc–water, as per Yang et al.'s [1] conditions. The desired product purities are 99.91 mol % for EtAc, 99.9 mol % for MeOH, and 99.99 mol % for wastewater, matching those in Yang et al.'s most economical hybrid-HTCD [1] design for comparison.

For a fully specified fresh feed, the process has four steady-state operating degrees of freedom (DOFs) and seven equipment design DOFs. These are optimized to minimize the total annual cost (TAC), which is defined as:

$$TAC = \frac{TCC}{PBP} + YOC$$

where TCC represents the total capital cost, PBP is the payback period, and YOC refers to the yearly operating cost. A typical PBP value of 3 years is used, with cost correlation and pricing data adapted from Turton [2] and Luyben [3].

Minimizing TAC using the available degrees of freedom (DOFs) is a mixed-integer nonlinear programming (MINLP)problem, solvable with an optimization algorithm. In this case, MATLAB's Mult objective genetic algorithm (MOGA) is used, with Aspen Plus as the steady-state flowsheet solver. The two objectives for minimization are TCC/PBP (the first term of TAC) and YOC (the second term of TAC).

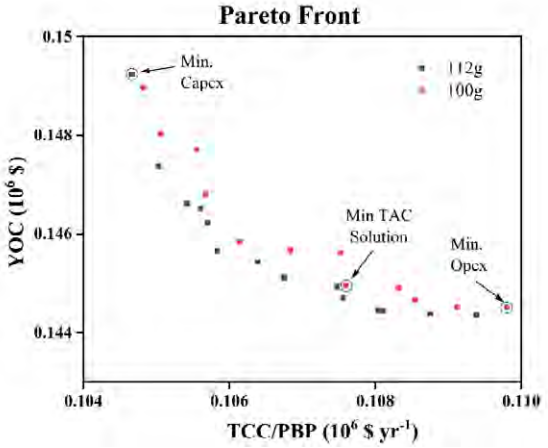

**Figure 3**: Pareto optimal front for TCD process

Among the 11 DOFs, three are fixed by product purity and one by the decanter temperature, leaving seven DOFs. The geometric constraint of equal trays on both sides of the DWC reduces this to six DOFs for optimization. These are optimized using MOGA, with bounds for the decision variables. For brevity, the details of the variables are omitted here. The optimization uses MATLAB's

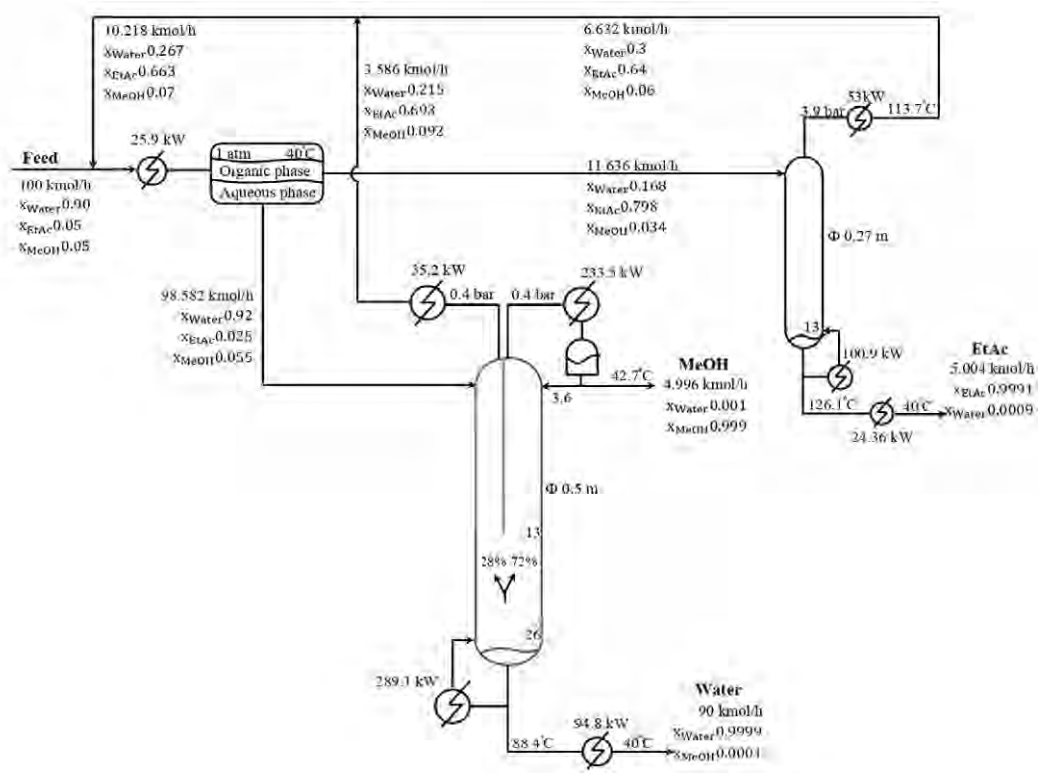

**Figure 4**: Nominal design and operating condition of TCD process

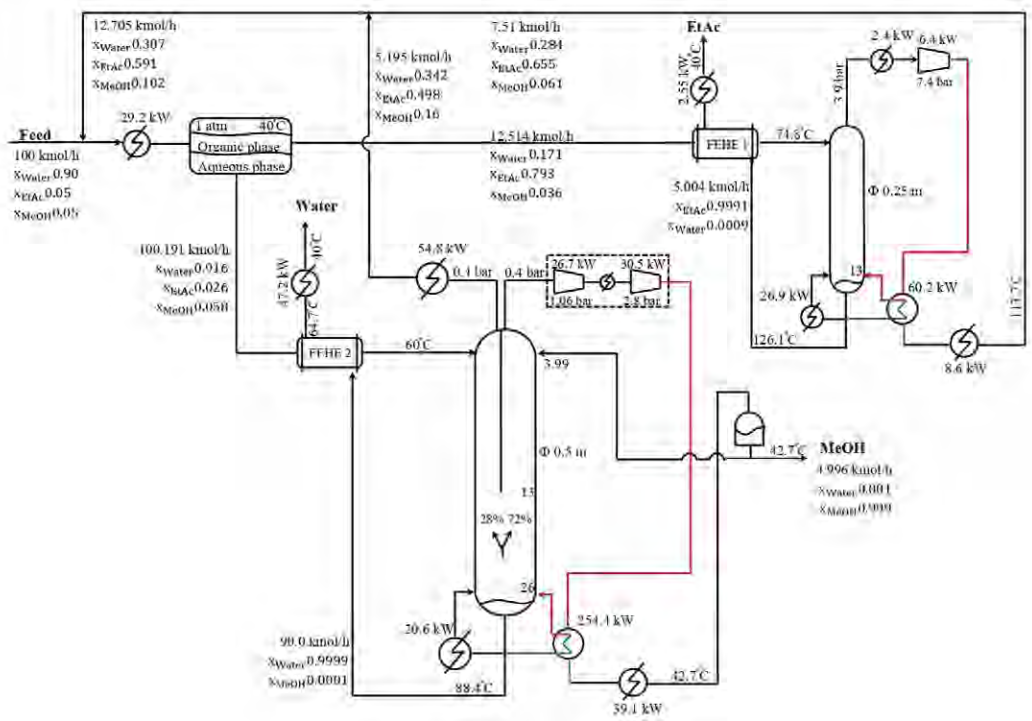

**Figure 5**: Nominal design and operating condition of Hybrid TCD process

*gamultiobj* function with a population size of 50 and a maximum of 200 generations. The converged Pareto optimal front after 112 generations is shown in figure 3, with the minimum TAC solution indicated.

The key steady-state conditions for the recommended basic TCD process design are shown in Figure

4, with an optimum TAC of \$0.252 × $10^6$ per year.

### Heat Integrated Hybrid TCD

Condensing the overhead vapor for reboil in both columns enhances the energy efficiency of the basic TCD flowsheet. Vapor recompression (VR) is effective when the coefficient of performance (COP) between the reboiler and condenser is high. Studies suggest VRHI is unsuitable for COP < 5, ideal for COP > 10, and requires further evaluation between 5 and 10. In our design, the COP values for the high-pressure column ($C_1$) and low-pressure dividing wall column ($C_2$) are 31.2 and 6.91, respectively. Applying VRHI to $C_2$ resulted in a significant TAC reduction, prompting its implementation in both columns along with feed-effluent heat exchangers (FEHEs), greatly improving energy efficiency.

In implementing vapor recompression (VR), process limitations are considered [4], including a maximum compressor outlet temperature of 190°C and a maximum compression ratio of 4. The overhead vapor is pressurized so that the bubble point of the condensed liquid exceeds the reboiler temperatures by 20–25°C, ensuring sufficient heat transfer. As a result, the overhead vapor from columns $C_1$ and $C_2$ are compressed to pressures of 7.4 bar and 2.8 bar, respectively. Due to the high compression ratio of 7, $C_2$'s overhead vapor undergoes two-stage compression with interstage cooling.

The final proposed design and operating conditions for the near-optimal flowsheet are shown in Figure 5. This design achieves a total annual cost (TAC) of \$0.198 × $10^6$ per year, marking a 21% reduction compared to the basic TCD design, with a notable 70% reduction in energy consumption.

## COMPARISON WITH LITERATURE DESIGN

We compare the energy consumption, $CO_2$ emissions, and total annual cost (TAC) of the most energy-efficient hybrid-TCD design with the best design from Yang's work, the hybrid heterogeneous triple column distillation (HTCD), shown in Figure 6. The hybrid-HTCD process includes a decanter and three columns. In this setup, the aqueous phase undergoes distillation to produce a MeOH-EtAc-water ternary distillate with reduced water content and an EtAc-free MeOH-water bottoms stream. The bottoms stream is further distilled to separate pure MeOH and water, while the organic layer is distilled to recover pure EtAc and recycle a MeOH-lean distillate to the decanter.

To improve energy efficiency, vapor recompression is applied to all three columns, along with feed-effluent heat exchange, as shown in Figure 6. Similar to our proposed flowsheet, a multi-objective genetic algorithm was used to minimize the TAC of the literature flowsheets. The figures display key design and operating parameters of the optimized hybrid-HTCD processes derived from this approach.

The Table 3 compares the total energy consumption, $CO_2$ emissions, and TAC of the alternative process designs. For the hybrid-HTCD process, energy consumption and $CO_2$ emissions are 172.8 kW and 69.59 kg/h, respectively, while the hybrid-TCD process developed in this study achieves 113.5 kW and 47.64 kg/h. This shows that the hybrid-HTCD process consumes 52.2% more energy and produces 45.9% higher $CO_2$ emissions than the proposed hybrid-TCD design.

The superior energy efficiency and lower $CO_2$ emissions of the hybrid-TCD design are due to its reduced total recycle rate, leverage of azeotrope pressure sensitivity, integration of process-to-process heat exchange, and use of vapor recompression-driven column reboil. Additionally, the proposed hybrid-TCD design is 15.4% more cost-effective than the best-in-literature hybrid-HTCD design.

The quantitative analysis shows that, from both economic and sustainability perspectives, the proposed hybrid-TCD process design is a significant improvement over existing literature designs for separating a dilute EtAc-MeOH-water mixed solvent into its pure components. This advancement is due to several factors, including the use of spontaneous liquid-liquid phase splitting to overcome distillation limitations, exploitation of azeotrope pressure sensitivity to reduce the total recycle rate, energy savings from process-to-process heat exchange, and enhanced energy efficiency through vapor recompression-driven column reboil. Additionally, the integration of a divided wall column (DWC) further boosts the process's efficiency and effectiveness.

## CONCLUSION

**Table 3**: Ecconomic and sustainability metric for alternate designs

| Metric | Hybrid-TCD | Hybrid-HTCD |
|---|---|---|
| Total Energy (kW) | 113.5 | 172.84 |
| $CO_2$ emission (kg/h) | 47.64 | 69.59 |
| TAC×$10^6$ (\$/yr) | 0.198 | 0.2341 |

This study presents an environmentally friendly, two-column compact flowsheet for separating a dilute EtAc-MeOH-water solvent into its pure components. The basic flowsheet incorporates a decanter and two columns, utilizing liquid-liquid phase separation to overcome distillation limitations and the pressure sensitivity of azeotropes to minimize the total recycle rate. Enhancements include process integration with a divided wall column (DWC) and energy optimization through process-to-process heat exchange, along with condensing compressed overhead vapor to supply a substantial

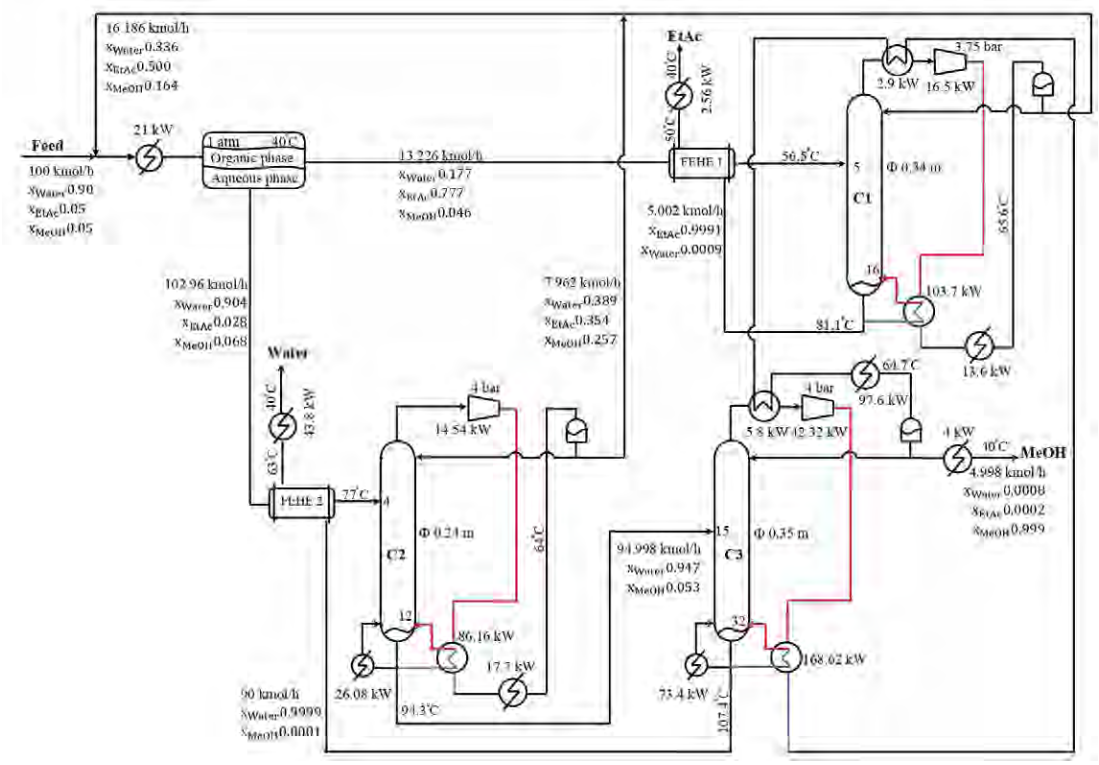

**Figure 6:** Nominal design and operating condition of Hybrid HTCD process

portion of the reboiler duty in both columns, resulting in an economically and energy-efficient design.

A quantitative comparison with the best existing design, the hybrid heterogeneous triple column distillation (hybrid-HTCD), reveals that the proposed hybrid two column distillation (hybrid-TCD) design reduces TAC by 15.4%, while also cutting energy consumption and $CO_2$ emissions by 34.3% and 31.4%, respectively. Thus, the developed hybrid-TCD process marks a significant advancement over the current state-of-the-art for separating a dilute EtAc-MeOH-water mixed solvent.

## ABSTRACT

This work presents a robust flowsheet design for the recovery and purification of waste solvent streams containing ethyl acetate (EtAc), methanol (MeOH), and water. Separation of this mixture is challenging due to the presence of two azeotropes: a homogeneous EtAc-MeOH azeotrope and a heterogeneous EtAc-water azeotrope. These azeotropes create a distillation boundary that divides the ternary composition space into two distinct regions, making separation via conventional distillation difficult. Additionally, the wide variability in waste solvent compositions requires a versatile design, as flowsheets optimized for dilute mixtures may not be feasible for concentrated ones. The key to this design is using a liquid-liquid extractor (LLX) with recycled water as the solvent, ensuring the mixture remains within the liquid-liquid equilibrium (LLE) split region, which facilitates spontaneous separation across the distillation boundary and promotes energy-efficient separation. The raffinate composition lies near the EtAc-water edge in the EtAc-rich region and is stripped to recover pure EtAc, while the extract phase is processed to yield pure MeOH and water. Converged designs are developed for equimolar, EtAc-rich, MeOH-rich, and water-rich compositions, with the proposed robust structure validated for all four compositions. This study represents a significant advancement in sustainable solvent recovery by eliminating the need for separate designs tailored to specific compositions, offering a unified, robust solution for separating various solvent feed mixtures.

**Keywords**: Liquid Liquid Envelope, Liquid Liquid Extractor, Azeotropes, Robust Flowsheet

## INTRODUCTION

Ethyl acetate (EtAc) and methanol (MeOH) are widely used solvents in the pharmaceutical, textile, dyes, and paints industries [1,2]. Significant volumes of organic waste streams containing EtAc and MeOH are generated varying composition based on the specific processes and conditions. Stricter waste discharge regulations and sustainability concerns now mandate the complete recovery, recycling, and reuse of organic solvents. The global shift towards sustainable practices and circular economy principles has intensified the focus on waste minimization, making solvent recovery and recycling from industrial waste streams essential for both environmental and economic reasons.

The separation and recovery of organic solvents from water are challenging due to the presence of two azeotropes—a homogeneous EtAc-MeOH azeotrope and a heterogeneous EtAc-water azeotrope. A line connecting these azeotropes creates a distillation boundary that divides the ternary composition space into two regions, complicating the separation process and making conventional distillation ineffective.

Separation facilities that process waste streams into pure components often face significant variability in EtAc, MeOH, and water concentrations, depending on the source process and operational parameters. This variability poses a design challenge, as flowsheets optimized for dilute compositions may not be suitable for concentrated ones, while those designed for concentrated mixtures may be too costly for dilute streams. Traditional solutions typically involve multiple processing units for different compositions or frequent adjustments to operating conditions, both of which can compromise the economic viability of the recovery process.

Industrial plants typically operate with fixed

equipment configurations, such as the number of trays, column diameter, and heat exchangers, which cannot be easily modified once installed. As a result, there is a pressing need for robust flowsheet designs that ensure operational feasibility across the full range of potential feed compositions. Developing such flowsheet structures requires careful consideration of operational constraints and innovative approaches to process synthesis and design. The goal of this work is to design a robust flowsheet capable of handling substantial variability in feed composition for the separation of EtAc-MeOH-water.

The article is organized as follows: the next section discusses the thermodynamics of the process, followed by the synthesis of a flowsheet for MeOH rich feed composition. We then present a near-optimal economic design for that composition. Finally, we explore the robust design that effectively handles variations across all ranges and conclude the article with its main findings.

## PROCESS MODELLING

Aspen Plus is used for steady-state simulation, with thermodynamic properties modeled using the NRTL equation for the liquid-phase activity coefficient and the vapor phase treated as an ideal gas. The binary interaction parameters are adapted from the work of Srivastava et al. [3]. Steady-state designs are developed for an inlet feed stream flow rate of 100 kmol/h, considering four distinct feed compositions. These compositions (all in molar percentages) represent different mixture: (1) 33.34% EtAc, 33.33% MeOH, 33.33% Water; (2) 80% EtAc, 10% MeOH, 10% Water; (3) 10% EtAc, 10% MeOH, 80% Water; and (4) 10% EtAc, 80% MeOH, 10% Water. The targeted purities are 99.5% for EtAc and MeOH, and 99.9% for Water.

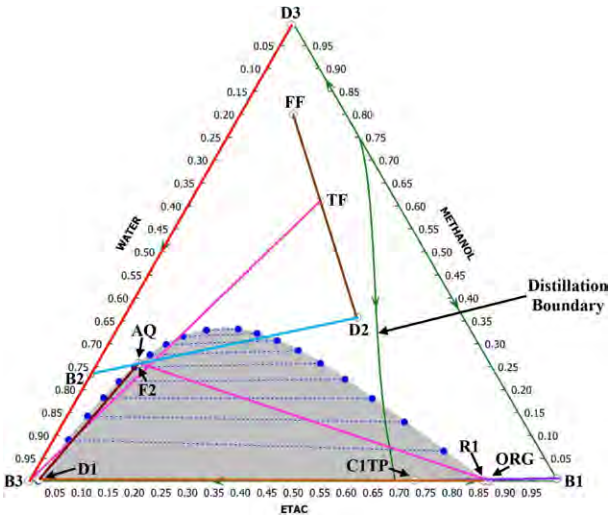

**Figure 1**: Residue Curve Map at 1 bar

## PROCESS FLOWSHEET SYNTHESIS

Figure 1 shows the Residue Curve Map (RCM) for the MeOH rich feed composition, revealing the presence of a Liquid-Liquid Envelope (LLE) and two minimum boiling azeotropes: EtAc/MeOH and EtAc/Water. We leverage the LLE to design the separation process flowsheets. In systems with LLE, the efficient method is to use a decanter to cross the distillation boundary and obtain pure products. However, the RCM indicates that the feed point lies outside the LLE. To address this, we propose using a Liquid-Liquid Extractor (LLX) with recycled water as a solvent to bring the feed point into the LLE. The proposed design is shown in Figure 2.

The fresh feed, mixed with the recycle stream (D2), is fed into the LLX as a total feed (TF) from the bottom, with recycled water introduced from the top in a counter-current manner. This setup brings the feed point within the LLE split region, as shown in Figure 1. The mixture then spontaneously separates into an EtAc-rich organic phase (ORG) and a water-rich aqueous phase (AQ), crossing the distillation boundary without any external energy input. The organic phase is fed into Column 1 (C1), where pure EtAc is recovered at the bottom (B1). The distillate composition (C1TP) remains within the LLE region and is decanted in an adjacent decanter, separating it into an organic phase (R1) and an aqueous phase (D1). The EtAc-rich organic phase (R1) is refluxed back into C1, while the water-rich aqueous phase (D1) is mixed with the aqueous stream (AQ) from LLX.

The resulting F2 stream is fed into Column 2 (C2), which prevents EtAc leakage into the bottom stream

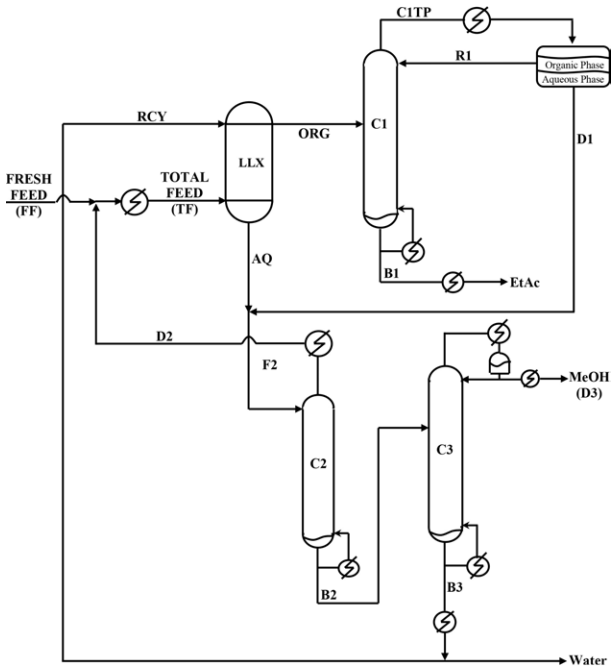

**Figure 2**: Proposed flowsheet structure

**Table 1**: Degrees of Freedom and Specifications

| S.N. | Degrees of Freedom | Equimolar | EtAc rich | MeOH rich | Water rich |
|---|---|---|---|---|---|
| | **Steady State DoFs** | | | | |
| 1 | Fresh feed rate (kmol/hr) | 100 | 100 | 100 | 100 |
| 2,3 | EtAc and MeOH product mole fraction | 0.995 | 0.995 | 0.995 | 0.995 |
| 4 | Water product mole fraction | 0.999 | 0.999 | 0.999 | 0.999 |
| 5 | C2 bottom stream EtAc impurity (ppm) | 24 | 74 | 20 | 160 |
| 6 | Water recycle rate (kmol/hr) | 98 | 104 | 252 | 14.71 |
| 7 | LLX operating temperature (°C) | 40 | 40 | 40 | 40 |
| 8,9,10 | Product temperature (°C) | 40 | 40 | 40 | 40 |
| | **Design DoFs** | | | | |

| 10 | Feed tray location in column C3 | 12 | 14 | 12 | 14 |

(B2). The distillate (D2) lies outside the envelope, so it is recycled back to the LLX for further separation. The methanol-water bottoms (B2) are then distilled in Column 3 (C3) to produce pure methanol distillate (D3) and pure water bottoms (B3). A portion of the bottoms is recirculated to the LLX as the solvent feed. In the next section we will discuss the economic steady state design of the proposed process.

## ECONOMIC STEADY STATE DESIGN

The proposed design, depicted in Figure 2, has 20 degrees of freedom (DoFs), comprising 10 steady-state DoFs and 10 design DoFs. These DoFs are adjusted to minimize the Total Annualized Cost (TAC), resulting in an economic steady-state design.

$$TAC = \frac{TCC}{PBP} + \text{YOC}$$

where TCC is the Total Capital Cost, PBP is the Payback Period, and YOC is the Yearly Operating Cost. A payback period of 3 years is used.

We have used engineering heuristics to fix these DoFs, with details provided in Table 1. However, the economically dominant DoFs are optimized for minimizing the TAC using the Aspen Plus *sensitivity analysis* tool. For the MeOH-rich feed composition design, we identified three economically dominant DoFs among the 20: the total number of trays in the LLX ($N_{LLX}$), the EtAc impurity $x_{EtAc}$ in the C2 bottom stream (B2), and the water flow rate $F_{Water}$ for the recycled water to the LLX.

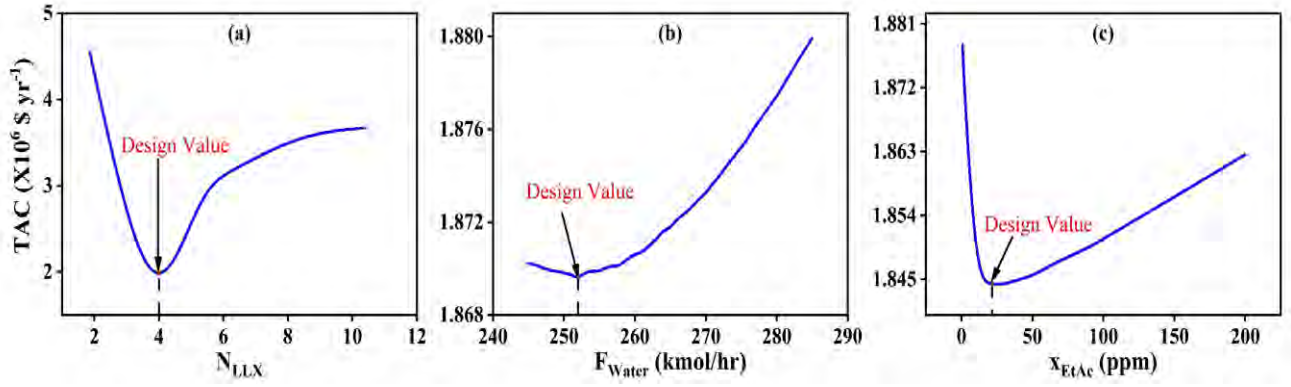

**Figure 3:** Optimization parameters for MEOH rich composition (a) Number of stages in LLX (b) Water recycle rate to LLX (c) EtAc impurity in B2 stream

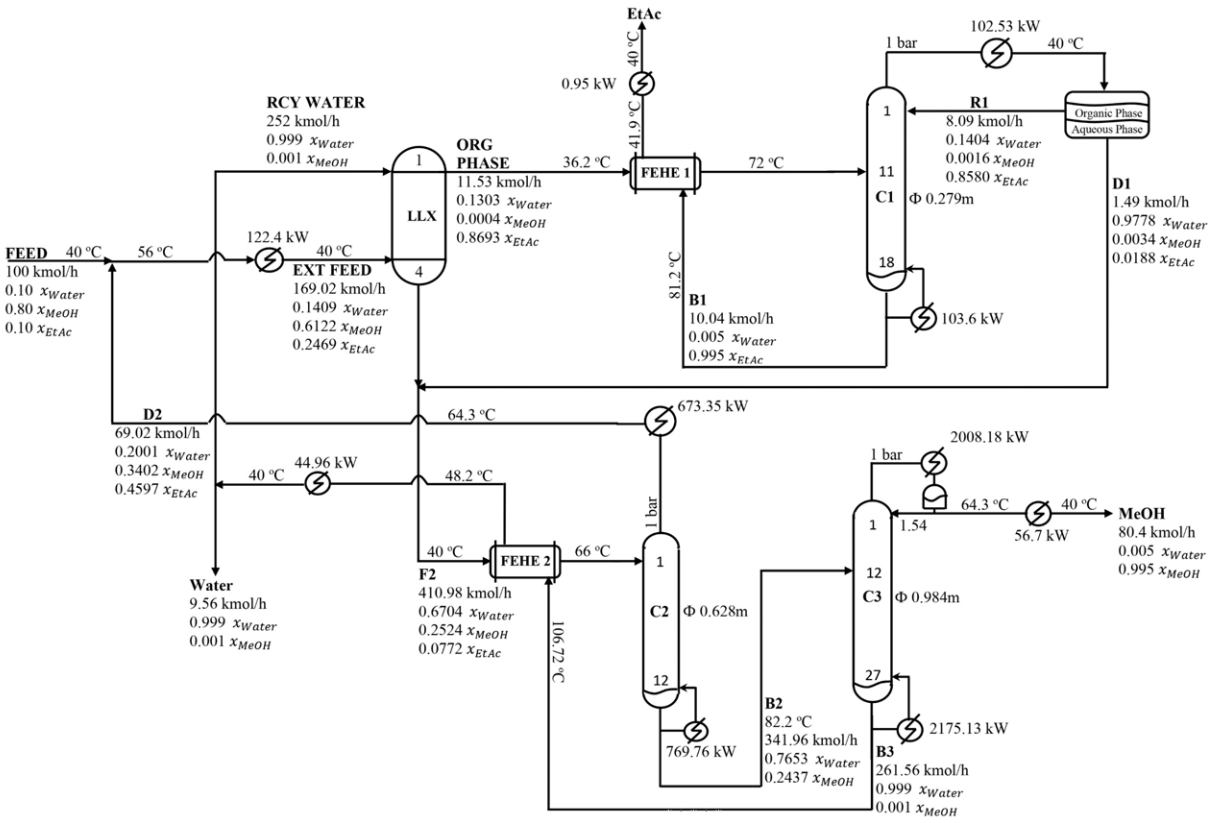

**Figure 4:** Nominal Design and Operating Condition for MeOH rich Feed

Figure 3 illustrate the variation of TAC with respect to the recommended design values corresponding to the optimum TAC. The optimum $N_{LLX}$ was determined to be 4. Above this value, TAC increases due to the higher capital cost of the LLX, while below it, TAC rises because of the increased water recycle rate needed to maintain the feed point in the LLE region, which increases the total reboiler duty. The optimum $x_{EtAc}$ is set at 20 ppm; exceeding this value leads to higher TAC due to increased reboiler duty in the C3 column, whereas falling below this value raises TAC due to the increase in reboiler duty of the C2 column. The optimum water flow rate $F_{Water}$; above this value, TAC increases due to a higher solvent water recycle rate, which elevates the reboiler duties of both C2 and C3. Conversely, below this optimum, TAC rises because of the increased reboiler duty in the C1 column, resulting from higher recycling associated with the C1 column.

Similarly, the other three steady-state designs can be developed. For brevity, the details are omitted here, but the DoFs are provided in Table 1. In the next section, we will synthesize the robust flowsheet.

## SYNTHESIS OF ROBUST FLOWSHEET

Based on the insights from Table 1, the robust flowsheet is designed by selecting the maximum stage or tray requirement for each unit to ensure effective separation across all compositions. In the LLX unit, the number of stages varies from 4 for MeOH-rich feeds to 6 for EtAc-rich feeds; therefore, 6 stages are incorporated into the robust design to maintain separation efficiency in all scenarios. For column C1, 18 trays are optimal across all compositions, which is retained in the robust configuration. In column C2, 12 trays are selected to facilitate effective separation across all four compositions. Similarly, for column C3, 30 trays are selected in the robust design to ensure reliable performance under all operating conditions. In the LLX, the liquid level corresponds to the dispersed phase, which has a low volume fraction. As seen from Table 1, the water flow rate has a low flow rate, which is why it is considered the dispersed phase here, except for the MeOH-rich composition, where it is the continuous phase. Therefore, the liquid level is in the aqueous phase for all compositions, except for the MeOH-rich case, where the level is in the organic phase. As the composition shifts from MeOH-rich to any other case, the LLX level changes from organic to aqueous, which is not feasible in the design. To address this, the water flow rate is maintained as the continuous phase for all composition cases to ensure effective separation. Thus, the water is in a ratio with the total feed to the LLX ($F_{LLX}$), which varies from 0.14 to 1.46. We selected the

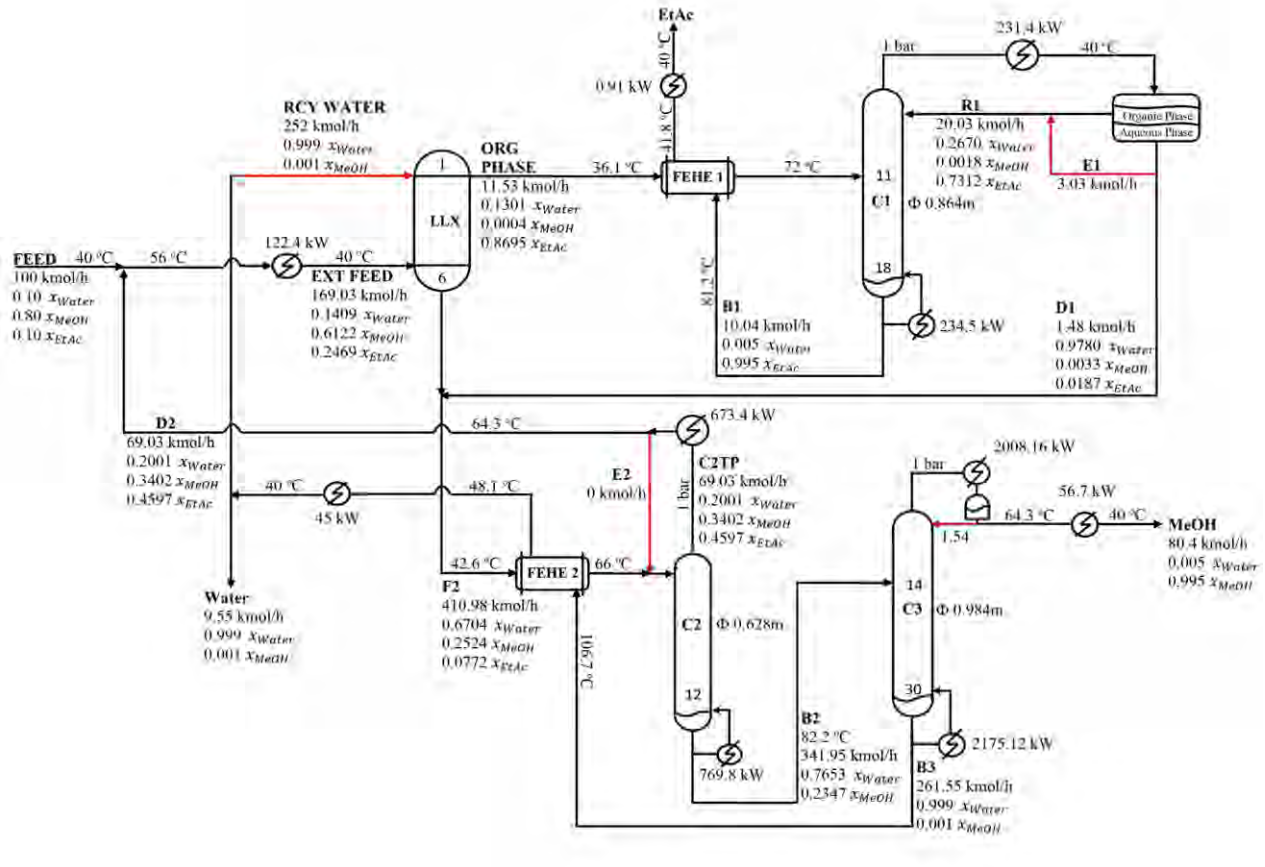

**Figure 5:** Robust Design and Operating Condition for MeOH rich Feed

highest ratio of 1.46 for the robust design to ensure effective extraction while maintaining operational efficiency across all scenarios.

Having established the basic design parameters, it was crucial to address the operational challenges posed by feed composition variations. As the composition changes from EtAc-rich to MeOH-rich, the feed to column C1 decreases while the feed to columns C2 and C3 increases. These variations significantly impact the reboiler duties required for the desired separation. Increased duties in columns C2 and C3 may lead to flooding, while the decreased duty in column C1 risks low boil-up rates, which can result in weeping and reduced tray efficiency. If the vapor rate falls below a critical point, it may trigger the low vapor boil-up limit, leading to weeping, which adversely affects tray efficiency and separation. The minimum allowable boil-up rate is determined using the turndown ratio, defined as the ratio of normal operating vapor throughput to the minimum allowable vapor throughput. We chose bubble cap trays for their 8:1 turndown ratio [4,5], which offers greater operational flexibility compared to sieve and valve trays. To

**Table 2**: Economic and sustainability metric for alternative feed composition

| Metric | Equimolar | | EtAc rich | | MeOH rich | | Water rich | |
|---|---|---|---|---|---|---|---|---|
| | Optimized Design | Robust Design | Optimized Design | Robust Design | Optimized Design | Robust Design | Optimized Design | Robust Design |
| Energy (kW) | 1601.4 | 1703.2 | 1437 | 2112.6 | 3048.5 | 3189.8 | 648.4 | 1048.8 |
| TCC×$10^6$ ($/yr) | 1.73 | 2.56 | 1.90 | 2.56 | 2.12 | 2.56 | 0.99 | 2.56 |
| YOC×$10^6$ ($/yr) | 0.60 | 0.64 | 0.54 | 0.79 | 1.14 | 1.19 | 0.24 | 0.39 |
| TAC×$10^6$ ($/yr) | 1.18 | 1.50 | 1.17 | 1.64 | 1.85 | 2.04 | 0.57 | 1.24 |

determine the minimum vapor throughput, we compared the vapor throughput across all four flowsheets and selected the highest value for each column as its design basis. While the 8:1 turndown ratio theoretically permits operation down to 12.5% of normal throughput, operating at this boundary risks weeping conditions. Therefore, we set 25% of normal throughput as the lower operational limit during turndown conditions to maintain a safety margin against weeping. Consequently, the reboiler duties in all columns can safely be reduced to this limit during operation, as required for different feed compositions.

To maintain the minimum vapor throughput of 25%, an additional degree of freedom (DoF) is required for each column to prevent weeping when the feed composition shifts from one composition to the other. In column C1, this involves partial recycling of the D1 stream back into the column, effectively maintaining minimum vapor rates while preserving separation efficiency. Column C2 employs a similar strategy by partially recycling the top product stream. For column C3, separation performance is sustained by carefully adjusting the reflux ratio, which ensures both product purity and operation above the minimum vapor rate limits. The detailed robust flowsheet, incorporating these strategies, is depicted in Figure 5, illustrating the design modifications and their alignment with operational requirements.

Table 2 presents an economic and energy comparison between the optimized flowsheet and the robust flowsheet for all considered feed compositions. As shown in the table, the robust design incurs a higher TCC than the optimized design due to the addition of an extra DoF and changes in design conditions. For a fair comparison, the TAC of the robust design should be compared with the sum of the TAC values for each optimized design. The cumulative TAC of all four optimized designs is **$4.77 \times 10^6$ $/yr**, whereas the TAC of the robust design—calculated as **(TCC/3 + YOC of individual feed composition)**—is **$3.86 \times 10^6$ $/yr**, which is **20% lower**. Thus, the robust design demonstrates a lower TAC while offering enhanced operational flexibility and reliability across varying feed compositions. This contributes to the sustainability of the overall process by ensuring long-term efficiency and minimizing the need for frequent process adjustments.

## CONCLUSION

This work presents a robust flowsheet design for the recovery and purification of waste solvent streams containing EtAc, MeOH, and water. The design effectively addresses challenges such as azeotropes and the variability in feed compositions. Crux to the design is the use of LLX, with recycled water as the solvent. This ensures that the total feed mixture remains within the LLE split region, regardless of the fresh feed composition. This enables spontaneous separation across the distillation boundary. The design has been validated across a wide range of feed compositions, including equimolar, EtAc-rich, MeOH-rich, and water-rich mixtures.

The robust design shows significant TAC savings of 20% than the cumulative TAC of all four optimized design and also offers greater flexibility in handling diverse feed mixtures. Additionally, it eliminates the need for multiple, composition-specific designs, leading to significant savings in land costs. Ultimately, the proposed design enhances operational flexibility and supports more scalable separation processes, representing a significant advancement in waste solvent recovery technology.

## ABSTRACT

Trichlorosilane (TCS) is a platform chemical used in the manufacture of silicon metals, silicones, and functional silanes. Despite this, very little information is available on the environmental impact (EI) associated with its manufacture. This work addresses this gap by developing estimates for the EI of reagent grade TCS (RG-TCS) based on a combination of process modelling & optimisation and life cycle assessment (LCA). Two production methods are considered: 1) direct chlorination (DC) producing RG-TCS as a main product, and 2) the Siemens process (SP) producing RG-TCS as a co-product. Results of a bi-objective process optimization suggest that the DC approach provides consistently better pareto-optimal (PO) trade-offs between the global warming potential (GWP) of RG-TCS and process profit; predicted GWPs are 3.2 to 3.3 $kgCO_2$-eq/kg for DC-derived RG-TCS and 3.8 to 4.9 $kgCO_2$-eq/kg for SP-derived PO designs. This suggests that processing history is important when considering the EI of RG-TCS. Nonetheless, further discussions of model uncertainty stress that these GWP estimates should be considered as preliminary, with improvements to modelling being required to refine EI predictions of RG-TCS in the future.

## INTRODUCTION

Trichlorosilane (TCS) is a platform chemical used in the manufacture of silicon metals, silicones, and functional silanes. Knowing the environmental impact (EI) of TCS is thus key to understanding the EI of many products, ranging from electronics to adsorbent materials.

Despite the importance of TCS, very little information is available on the environmental impact (EI) of TCS manufacturing. Thus, it is difficult to understand the EI of producing TCS, and TCS-derived products.

One reason for the lack of EI information may be variable production history. For example, reagent grade TCS (RG-TCS, 98wt%) can be produced as a main product of the direct chlorination (DC) of metallurgical grade silicon (MG-Si) [1], or as a co-product of the Siemens process (SP) for high purity silicon metal (≥99.9999 wt%) [2].

While both the DC and the SP rely on the chlorination of MG-Si, they differ in their energy intensity. This suggests the possibility of an importance of processing history in governing the EI of RG-TCS.

One way in which the EI of RG-TCS could be established is through Life Cycle Assessment (LCA). Nonetheless, this would require knowledge of material and energy use associated with gate-to-gate production of RG-TCS. In the absence of real plant data, prior research suggests that process modelling may be the preferred approach for accurately gathering this kind of information [3].

Herein, process modelling-informed LCA models are developed to quantify the EI of RG-TCS with the aim of:

1) detailing typical process designs by which RG-TCS is produced by DC and the SP,
2) identifying pareto optimal (PO) trade-offs in the EI and profitability of DC and the SP designs.
3) establishing the importance of processing history on the EI of RG-TCS products.

This has been done with modelling specific to China given its large share in global SG-Si production [2].

# METHODS

## Process Description

### Direct Chlorination

In the DC method (Figure 1a), hydrogen chloride (HCl) is produced through the reaction of hydrogen ($H_2$) and chlorine (Cl2) in reactor R1 (Equation 1). HCl is then reacted with MG-Si to produce chlorosilanes in R2 (Equation 2 and 3) [1].

$$H_2 + Cl_2 \rightarrow 2HCl \quad (1)$$

$$3HCl + Si_{MG} \rightarrow SiCl_3H + H_2 \quad (2)$$

$$4HCl + Si_{MG} \rightarrow SiCl_4 + 2H_2 \quad (3)$$

Chlorosilanes in the effluent of R2 are then separated by flash condensation in unit F1 and refined into RG-TCS and silicon tetrachloride (STC, 98wt%) products by distillation in C1 [2]. Residual gases leaving F1 are separated into chlorosilanes and hydrogen in adsorption column (A1) [4]. Recovered hydrogen is recycled and the chlorosilanes are fed to C1 [2].

### Siemens Process

The SP (Figure 1b) extends the DC method by further purifying TCS in columns C2 and C3, yielding an RG-TCS product (C2 tops), an ultra-high purity TCS (C3 tops, 99.99 wt%) and residual waste (C3 bottoms) [2]. The TCS from C3 is heated in a furnace (E5) and reduced using hydrogen (3:1 $H_2$:TCS mole ratio [2]) in reactor R3 to produce solar grade silicon (SG-Si, 99.9999 wt%) according to Equations 4 and 5 [2]. The resulting gases are recycled and STC is hydrogenated to form TCS in R4 [2] (Equation 6); R4 effluent is fed to column C4 for material recovery.

$$SiCl_3H + H_2 \rightarrow Si_{SG} + 3HCl \quad (4)$$

$$2SiCl_3H + HCl \rightarrow SiCl_4 + H_2 \quad (5)$$

$$Si_{MG} + 2H_2 + 3SiCl_4l \rightarrow 4SiCl_3H \quad (6)$$

## Process Modelling

Models for the DC and SP methods were built in the Aspen Plus V11 software according to process flow diagrams shown in Figure 1. Vapour-liquid equilibria was modelled using the NRTL-RK method. Equipment with fixed operating conditions are listed in Table 1.

Reaction performance associated with each process was based on patent and academic literature (Table 2). Compressor performance was modelled according to isentropic compression. Distillation was modelled according to the MESH equations.

The production scale of both DC and the SP was based on a 24.1 kmol/hr feed of HCl to reactor R2 [6].

It was assumed that 75% of heat generated by reactors R1 and R2 could be recovered as steam.

**Table 1:** Thermodynamic information for equipment assumed to have fixed conditions.

| Unit | Temperature, C | Pressure, bar | Ref. |
|---|---|---|---|
| R1 | 250 | 2.5 | [7] |
| R2 | 350 | 5.0 | [8] |
| R3 | 1100 | 1.1 | [6] |

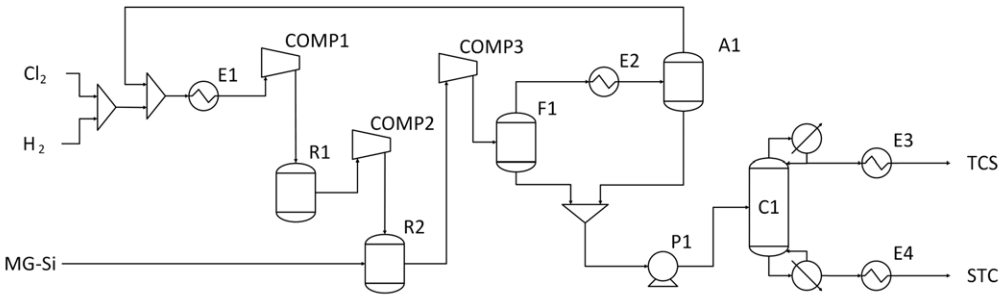
## Process Optimization

The NSGA-II algorithm [16] (100 individuals, PYMOO package [17]) was used to find PO frontiers for maximisation of the total annualised process profit, $TAP$ ($/yr), and minimization of the Global Warming Potential of RG-TCS ($GWP$, kg$CO_2$-eq/kg) for DC and the SP. In each case, optimization was run until a minimum of 4000 profitable designs were found.

$$\min\ [-TAP,\ GWP] \quad (7)$$

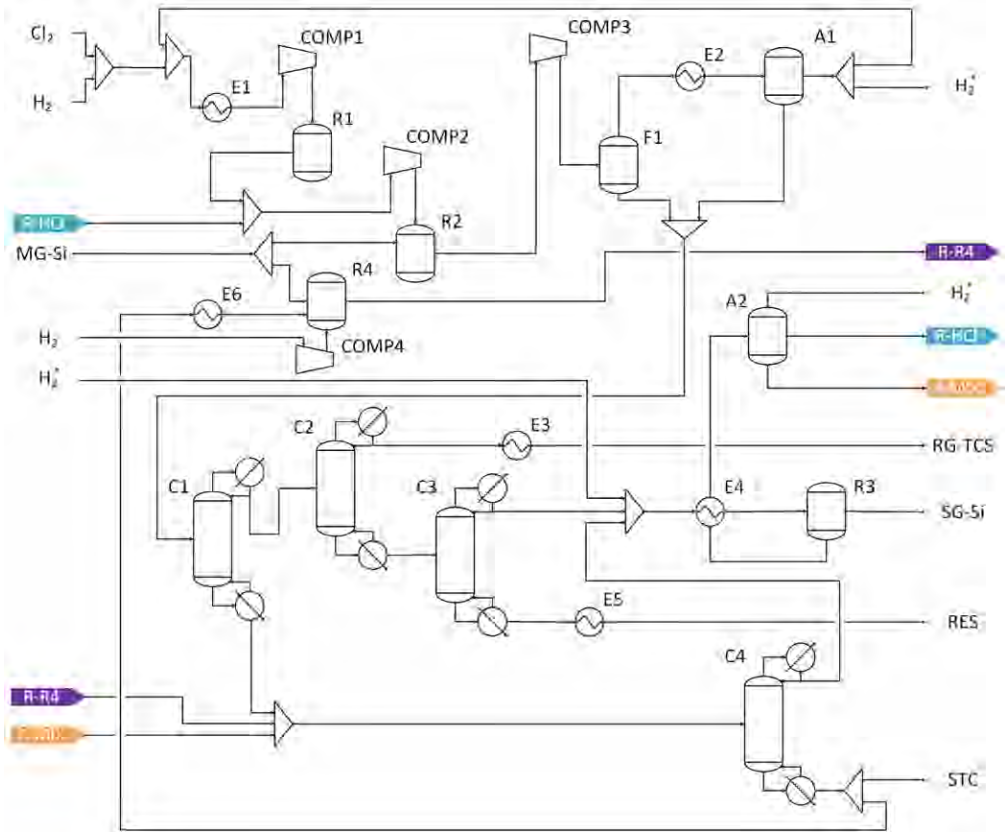
$$\text{given: } TAP = f_1(x) \quad (8)$$

$$GWP = f_2(x) \quad (9)$$



$$\text{s.t.: } g(x) \leq 0 \quad (10)$$

$$x^{lb} \leq x \leq x^{ub} \quad (11)$$



Where $g(x)$ is a black-box function based on the underlying process model, Equation 10 represents practical constraints associated with product purity in the black box model, and $x^{lb}$ and $x^{lu}$ represent the lower and upper bounds associated decision vector $x$. Minimum purities of 98 wt% were set for sale of RG-TCS and STC. A minimum purity of 99.99 wt% TCS was set for the top product of column C3 used to produce SG-Si in the SP method [6].

## Process Economics

The $TAP$ of each process was calculated by subtracting the sum of total annualised capital and operational expenditures, $TAC$ and $TAO$ ($/yr), from the total annualised revenue, $TAR$ ($/yr), as shown in Equation 12.

**(a)**

**(b)**

**Figure 1:** Process flow diagrams for production of trichlorosilane by the direct chlroination (top) and Siemens process (bottom) methods. TCS: trichlorosilane, STC: silicon tetrachloride, RES: residual waste chlorosilanes, MG-Si: metallurgical grade silicon, SG-Si: solar grade silicon, $H_2$: reagent grade hydrogen; $H_2^*$: high purity hydrogen.

It was assumed that costs reflected the implementation of a grass-roots plant based on the year 2019.

$$TAP = TAR - (TAC + TAO) \quad (12)$$

## Total Annual Revenue

$TAR$ was calculated based on product sales according to Equation 13 and Table 3.

$$TAR = \sum_p P_p \dot{m}_p \quad (13)$$

Where $P_p$ is the sale price of product $P_p$ ($/kg) and $\dot{m}_p$ is the annual production amount of product $p$ ($/kg).

## Total Annual Capital Expenditure

$TAC$ was calculated using Equation 14, considering costs associated with compressor, heat exchanger, pump, and distillation units only.

$$TAC = \frac{\sum_e CAPEX_e}{A} \quad (14)$$

Where $CAPEX_e$ is the capital expenditure of unit $e$ ($), and $A$ is an annualization factor (yr) assuming a 30-year payback period and 3% interest rate. $CAPEX$ calculation included bare module costs [15], materials choice [16], and geographic location [16].

**Table 3:** Assumed material and utility fuel source prices

| Material | Price, $/unit | Unit | Ref. |
|---|---|---|---|
| MG-Si | 1.75 | kg | [18] |
| $Cl_2$ | 0.28 | kg | [19] |
| $H_2$[a] | 0.15/4.00 | kg | [19,20] |
| RG-TCS | 1.00 | kg | [21] |
| STC | 1.00 | kg | [21] |
| SG-Si | 12.00 | kg | [18] |
| Electricity | 0.088 | kWh | [22] |
| Coal[b] | 4.022 | GJ | [22] |

[a] prices reflect 98 and 99.99 wt% hydrogen product purities, [b] assuming energy conversion factor of 30 GJ/tonne of coal

### Total Annual Operational Expenditure

$TAO$ was calculated including consideration for feedstock use (Table 2), utility use and waste handling (Table 3, as per [17]), and operator labour (as per [15]) according to Equation 15.

$$TAO = \sum P_f \dot{m}_f + \sum P_u \dot{Q}_u + \sum P_w \dot{Q}_w + 4.8 P_{OL} \quad (15)$$

Where $P_f$ and $\dot{m}_f$ are the price ($/kg) and annual usage (kg/yr) of feedstock $f$, and $P_u$ and $\dot{Q}_u$ are the price ($/kJ) and annual usage (KJ/yr) of utility, $u$; $P_w$ and $\dot{Q}_w$ are the price of waste treatment ($/kg) and annual amount of waste produced (kg/yr); and $P_{OL}$ is the price of labor four process operators each with a 36,000 $/yr salary.

### Life Cycle Assessment

#### Goal and Scope Definition

The goal of LCA in this work is to estimate the EI of RG-TCS produced by DC and the SP. An attributional LCA approach was used, considering a cradle-to-gate scope, with 1 kg of RG-TCS as a functional unit.

#### Inventory Modelling

Life cycle inventories were generated using material and energy use estimates from process modelling & optimization. The EcoInvent Database (v3.10, APOS) [23] was used to model background life cycle activity.

#### Impact Assessment

The EI of RG-TCS has been estimated using the ReCiPe 2016 (H) method [24] considering the GWP ($kgCO_2$-eq) as a proxy for EI. Calculations include a cut-off factor of 0.1%. Co-product impacts have been allocated according to the mass of product produced.

## RESULTS AND DISCUSSION

Results of bi-objective optimization are shown in Figure 2. This data includes three expected trends.

Firstly, results for both processes display a positive correlation between the GWP and profitability of PO process designs for DC and the SP – reflecting the presence of a trade-off between process profit and product GWP.

Secondly, the GWP of SP-derived RG-TCS is observed to be consistently larger than that of DC-derived

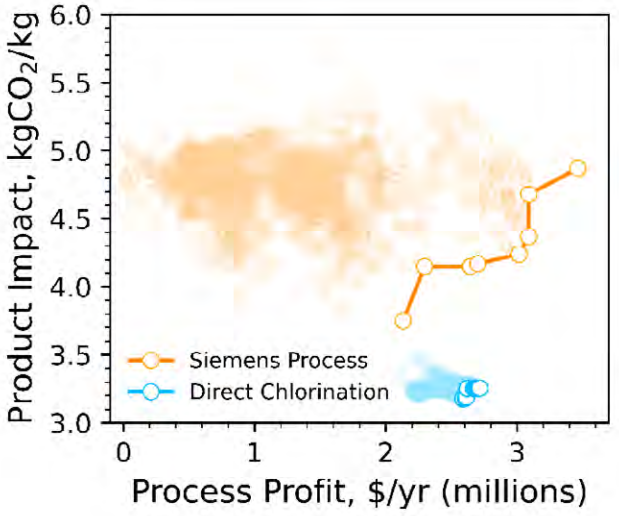


**Figure 2:** Trade-offs in global warming potential and profitability identified during design optimization. Solid lines outline pareto-optimal designs. Dull markers represent other feasible, non pareto-optimal designs.

RG-TCS for all pareto optimal designs. This is intuitive given the high energy intensity of distillation and production of SG-Si in the SP (see Figure 1).

Thirdly, the PO frontier of DC designs covers a small range of profitability, which may be attributed to the simplicity of DC and lack of competition between reducing EI and maximising profit during design.

On the contrary, Figure 2 also shows two unexpected results.

Firstly, PO designs of the SP cover a very similar range of possible profitability when compared to that of PO DC designs. This is unexpected given the high value of SG-Si produced by the SP method (see Table 3) and complexity of the SP (see Figure 1), which may lead to the expectation of greater return in process profit.

Secondly, the GWP of RG-TCS produced by PO designs of DC and the SP are found to be relatively similar (i.e. 3.2 to 3.3 and 3.8 to 4.9 kg $CO_2$-eq/kg respectively). This may contradict the expected scale of GWP associated with energy intensity of SG-Si production in the SP.

### Relation to Trichlorosilane Yield

To explain unexpected results in Figure 2, further consideration is needed for process designs of PO solutions. Results in Figure 3 illustrate the relationship of RG-TCS yield and process profit for DC and SP designs.

Surprisingly, results for both DC and the SP show designs with high RG-TCS yields (90 to 92 % and 76 to 91 % respectively). This is intuitive for DC designs as the yield of RG-TCS does not compete directly with the yield of STC (see Figure 1), making high yields of RG-TCS likely to reflect materially efficient design implementations.

Conversely, high RG-TCS yields are counterintuitive

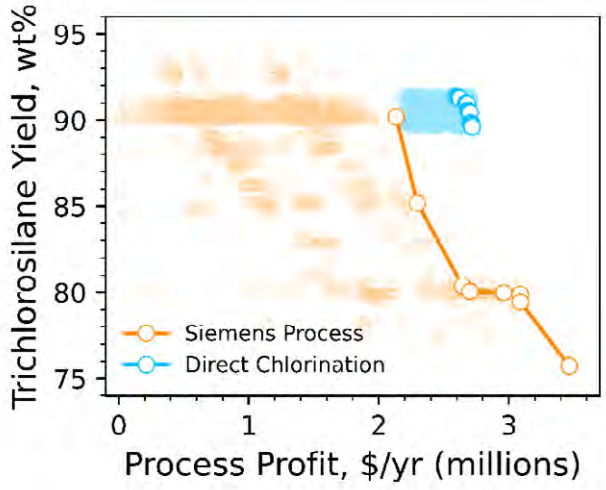

**Figure 3:** Relationship of trichlorosilane yield and process profit identified during design optimization. Solid lines highlight the location of pareto-optimal designs shown in Figure 2. Dull markers represent other feasible designs.

for the SP - given that the yield of RG-TCS competes directly with the yield of SG-Si (Figure 1). Consequently, the observed PO SP designs must minimise the production of SG-Si - the intended main product of the SP.

To understand why this is, three aspects of the modelling method used must be further considered.

## Relation to Impact Allocation Method

One way in which the observed PO SP designs may tend toward maximising RG-TCS yield is through an inherent bias introduced by using a mass-based impact allocation method during LCA. This is because of the relatively high molar mass of TCS (135 g/mol) when compared to Si (28 g/mol), which suggests that the conversion of feedstock to RG-TCS in high yield is likely to minimise the GWP of RG-TCS products by maximising the total mass of products produced by the SP.

## Relation to Optimization Algorithm

Another reason why the observed PO SP designs may tend to maximise RG-TCS yield is because of limitations in the optimization algorithm used. Specifically, the optimizer used may have failed to identify regions of the search space in which feasible high-profit, high-impact designs exist - e.g. as a result of maximizing SG-Si yield at the expense of RG-TCS yield and GWP.

This may be corroborated by the fact that multiple high-profit, high-impact SP designs were observed during the early stages of optimization but lost as optimization proceeded due to violating constraints associated with RG-TCS (≥98 wt%). Such designs may have failed to evolve toward feasible solutions due to the use of a strict "feasibility first" constraint handling approach, which prioritises feasible designs over search diversity [17].

Thus, it is possible that the PO frontiers visualised in Figure 3 represent only the low-impact, low-profit subset of the true PO design space available to the SP.

Further research is needed to explore the SP design space more rigorously.

## Relation to Process Modelling Uncertainties

Finally, four major sources of uncertainty in process modelling must be considered when interpreting data.

Firstly, the SP modelled (Figure 1) considers only one method for recycling of the chlorosilane-rich effluent which arises after the deposition of SG-Si (see R4, Figure1) [2]. Thus, the reported GWP of SP-derived RG-TCS may not accurately reflect the GWP of RG-TCS produced by SP designs using different material recycling methods.

Secondly, the SP modelled does not consider the possibility of thermally integrating distillation columns. This can cause up to a 50% reduction in energy requirements associated with distillation in the SP [2] – suggesting that reported GWPs may be overestimated in this regard.

Thirdly, the effect of impurities on distillation efficiency has not been modelled. This may cause the GWP to be underestimated due to inaccuracy in material and energy estimates associated with distillation in the SP.

Fourthly, the separation of chlorosilanes, hydrogen and hydrogen chloride via adsorption (see Figure 1) has not been modelled rigorously in this work. This may cause the GWP to be underestimated due to failing to account completely for energy and material efficiency in both DC and SP designs.

# CONCLUSIONS

Understanding the environmental impact of trichlorosilane (TCS) is crucial in enabling the impact assessment of many products. Consequently, this work has set out to establish estimates for the impact of reagent grade TCS (RG-TCS) produced according to two approaches - direct chlorination (DC), and the Siemens process (SP) for manufacturing solar-grade silicon (SG-Si).

Using global warming potential (GWP) as a proxy for impact, bi-objective optimization suggests that the impact of SP-derived TCS (3.8 to 4.9 kg $CO_2$-eq/kg) is larger than that of DC-derived TCS (3.2 to 3.3 kg $CO_2$-eq/kg). This suggests that the processing history of RG-TCS may be an important factor governing the impact of RG-TCS.

Interestingly, it is also observed that results of the work tend to highlight PO SP designs which prioritise the production of RG-TCS in high yield over SG-Si. This is despite SG-Si being the intended main-product of the SP. This is explained as arising from three main factors affecting modelling and optimization: 1) the use of a mass-basis of impact allocation (which biases PO SP designs to SP designs with high TCS yield), and 2) limitations in the

optimization method used, which has possibly failed to identify PO SP designs of high-impact and high-profit, and 3) uncertainty in process modelling, particularly in the case of modelling designs of the SP.

Consequently, though results suggest that processing history is important in governing the impact of RG-TCS, the absolute value of GWP reported for SP-derived RG-TCS should be considered to be a preliminary estimate with room for future improvement. Findings of the work may be of interest to individuals working to produce chlorosilane materials and TCS-derived products.

## ACKNOWLEDGEMENTS

This work has been made possible by funding provided by Scottish Water, the UK EPSRC SSCP Doctoral Training Program, and UKRI Innovate UK. EE also thanks Alex Durkin and Benjamin Lyons of Imperial College London for formative discussions on process systems engineering (inc. process modelling and optimization).

## ABSTRACT

As anthropogenic $CO_2$ emissions continue to drive global warming, innovative approaches to repurpose $CO_2$ into valuable products emerge as pivotal solutions to mitigate its environmental impact. $CO_2$ utilization encompasses a range of technologies, including its conversion into fuels, chemicals, and materials, leveraging $CO_2$ as a resource rather than treating it solely as a waste. This shift not only reduces greenhouse gas emissions but also supports the circular economy by integrating industrial processes with carbon capture and storage technologies. Specifically, in the Waste-to-Energy (WtE) context, sodium bicarbonate production can be an attractive solution, considering that it is required in the plant for $SO_x$ and acidic gases abatement. In this work, the carbon dioxide utilization to give sodium bicarbonate in a WtE context is analyzed. With reference to an existing waste-to-energy plant in Italy, the potential of this $CO_2$ utilization method is highlighted by means of process simulation. A preliminary feasibility study is presented, based on heat and material balances retrieved from Aspen Plus® V14, properly set for the accurate modeling of the system's behaviour. Process performances are discussed, in view of the pilot plant engineering and construction.

**Keywords**: CO2 utilization, NaHCO3, waste-to-energy, CO2 emissions, carbon neutrality.

## INTRODUCTION

Waste-to-energy (WtE) plants play a dual role in modern waste management, generating energy and reducing landfill dependency at the same time. Nevertheless, they significantly contribute to greenhouse gas emissions [1]. Therefore, the integration with $CO_2$ capture and utilization technologies can enhance sustainability, enabling for both waste reduction and climate change mitigation [2]. When $CO_2$ is captured from the flue gas, it can be eventually converted into high value-added products, following the circular economy principles. $CO_2$ utilization technologies hold promise particularly where the waste-to-energy plant is far away from the injection point for $CO_2$ sequestration, such that its transportation becomes costly. Key conversion technologies include chemical, electrochemical or biological methods for $CO_2$ valorization to methanol, syngas, plastics, minerals or fuels. However, challenges remain about the cost-effective implementation of these solutions at the commercial scale.

One promising application is the production of sodium bicarbonate ($NaHCO_3$). $NaHCO_3$ is often used for waste-to-energy flue gas treatment to abate various harmful pollutants, as sulfur oxides ($SO_x$) and acidic gases as hydrogen chloride (HCl). Therefore, bicarbonate production *in situ* from captured $CO_2$ can be interesting for simultaneously lowering the plant environmental impact and improving the economic balance.

To explore sodium bicarbonate as an alternative for the carbon dioxide chemical fixation, its production from sodium carbonate ($Na_2CO_3$) is analyzed within an existing waste-to-energy context in Italy [3-4]. In view of performing a preliminary feasibility study, the thermodynamic framework has been properly set up in Aspen Plus® V14, taking into account the vapor-liquid and liquid-solid

equilibria involved in the system. The process scheme has been designed to minimize wastes and water demand. $CO_2$ coming from the carbon capture section, with traces of $N_2$ and $O_2$, is fed at the battery limits, together with solid $Na_2CO_3$. Sodium carbonate powder has to be dissolved in water, such that a solution at 30 wt.% of $Na_2CO_3$ is fed to the reaction section. Inlet $CO_2$ flowrate is fixed to guarantee a bicarbonate output of about 30% of the annual need of the waste-to-energy plant. $NaHCO_3$ is produced in the form of a slurry to be dried in the downstream section. Process performances are technically discussed referring to heat and material balances. As a result, the technology feasibility is analyzed, in view of the pilot plant engineering and construction.

This research project, the result of a collaboration between A2A SpA, Acinque Ambiente Srl and the GASP (Group on Advanced Separation Processes & GAS Processing) of Polytechnic University of Milan, is part of a broader vision of research activities to achieve the decarbonization objectives of A2A SpA.

## THERMODYNAMIC FRAMEWORK

### Chemical and physical equilibrium

For process simulation purposes in Aspen Plus® V14, the thermodynamic framework has to be carefully set up. Many species are available in the system, not only in the vapor phase ($N_2$, $O_2$, $H_2O$, $CO_2$) or liquid phase ($H_2O$), but also as ionic species ($HCO_3^-$, $CO_3^{2-}$, $Na^+$, $H_3O^+$, $OH^-$) and solids (the main ones are $NaHCO_3$, $Na_2CO_3$, however several hydrates can exist).

The process thermodynamics involves both physical (liquid-vapor and liquid-solid phase equilibria) and chemical (liquid phase reactions) equilibrium. The approach used for modeling purposes is schematized in Table 1.

**Table 1:** Schematization of the thermodynamic package as specified in Aspen Plus® V14.

| **physical equilibrium** | |
|---|---|
| thermodynamic quantities | $\Delta G_f^0$, $\Delta H_f^0$ for solid species |
| liquid phase activity coefficient model | ELECNRTL |
| vapor phase EoS | Kwong (RK) |
| **chemical equilibrium** | |
| ionic dissociation | 1a) $H_2O + HCO_3^- \rightleftharpoons CO_3^{2-} + H_3O^+$<br>2a) $2\ H_2O + CO_2 \rightleftharpoons HCO_3^- + H_3O^+$<br>3a) $2\ H_2O \rightleftharpoons OH^- + H_3O^+$ |
| salt formation | 1b) $Na_2CO_3 \rightleftharpoons CO_3^{2-} + 2\ Na^+$<br>2b) $NaHCO_3 \rightleftharpoons HCO_3^- + Na^+$ |

For the vapor-liquid equilibrium in the presence of ionic species, a γ/φ approach (2° group) is used. Accordingly, the activity coefficient has been evaluated with the ELECNRTL model, while the fugacity coefficient is calculated by means of the Redlich-Kwong equation of state (RK EoS). $CO_2$, $N_2$ and $O_2$ have been defined as Henry components.

As for the liquid-solid equilibrium, it has been accounted for as in equation (1), in which the solid phase fugacity is calculated through thermodynamic quantities referred to the solid phase. To ensure a reliable estimation, $\Delta G_f^0$, $\Delta H_f^0$ for solid species available in the simulation software have been compared with literature [5], finding a good agreement for all the values (the maximum relative deviation was found to be 0.25% for $NaHCO_3$).

$$x_i \gamma_i f_i^0 = f_i^0 \exp\left(\frac{\Delta h_{i,fus}}{R}\left(\frac{1}{T_{fi}} - \frac{1}{T}\right) + \frac{c_{pi}^L - c_{pi}^S}{R}\left(\frac{T_{fi}}{T} - 1 - \ln\left(\frac{T_{fi}}{T}\right)\right)\right) \quad (1)$$

Considering the chemical equilibrium, both ionic dissociation and salt formation reactions have been introduced, each one with its equilibrium constant. There are two different approaches to evaluate the equilibrium constant, as shown in equations (2) and (3). In the approach 1, as in equation (2), $K_{eq}$ is evaluated from the Gibbs free energy of the reaction.

$$lnK_{eq} = \frac{\Delta G_R^0}{RT} \quad (2)$$

$$lnK_{eq} = A + \frac{B}{T} + \mathrm{ClnT} + \mathrm{DT} \quad (3)$$

On the other hand, the approach 2, as in equation (3), involves a built-in correlation for the $K_{eq}$ calculation, whose constants are specified in Table 2 for each reaction.

**Table 2:** Constants for the ionic dissociation and salt formation reactions of Table 1.

| reaction | A | B | C | D |
|---|---|---|---|---|
| 1a | 216.050 | -12431.7 | -35.4819 | 0 |
| 2a | 231.465 | -12092.1 | -36.7816 | 0 |
| 3a | 132.899 | -13445.9 | -22.4773 | 0 |
| 1b | -30.468 | 6566.26 | 0 | 0 |
| 2b | -63.4345 | -1296.96 | 11.9061 | -0.029058 |

The values *A*, *B*, *C* for the dissociation reactions 1a, 2a, 3a are in line with literature [6].

Regarding the carbonate and bicarbonate formation reactions (1b and 2b of Table 1), to select the most accurate approach for $K_{eq}$ evaluation, Figure 1 shows the

comparison between equilibrium constants from literature [7] and Aspen Plus® V14 predictions according to equations 2 and 3. As can be observed from Figure 1, the $K_{eq}$ evaluated using equation 2 in Aspen Plus® are much closer to the literature data. Therefore, this approach was chosen for the calculation of the equilibrium constants for carbonate and bicarbonate production from ionic species.

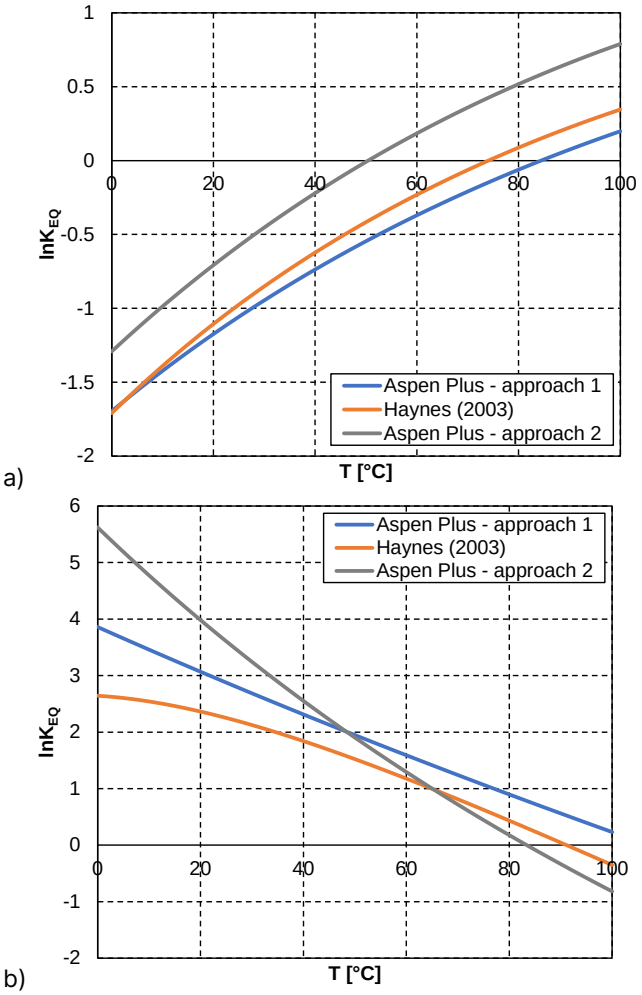

**Figure 1.** ln $K_{eq}$ for the production of: a) bicarbonate and b) carbonate as a function of temperature ($T$). Comparison between literature models and Aspen Plus® V14 models predictions according to approach 1 (blue) and approach 2 (grey).

## Solubility analysis

To verify the predictions of the simulation software, the Aspen Plus® solubility analysis tool was used. This tool evaluates the solid species solubility in liquid, gaseous and supercritical solvents. Firstly, solubility of single salts (*i.e.*, $NaHCO_3$ and $Na_2CO_3$) in $H_2O$ has been calculated as a function of temperature. The obtained results have been compared with the available literature [8], once again obtaining a good agreement. Then, the effect of the presence of one salt on the solubility of the other was assessed. This analysis allows to get an idea of the possible critical issues related to the precipitation of carbonate and bicarbonate. With reference to the specific case study, the soda ash carbonation reaction (4) proceeds consuming $Na_2CO_3$ to produce $NaHCO_3$.

$$Na_2CO_3 + H_2O + CO_2 \leftrightarrow 2\ NaHCO_3 \quad (4)$$

The concentration of $Na_2CO_3$ in solution, at the beginning equal to 30 wt.%, decreases as the reaction proceeds in the range of 0-30 wt.%. Assuming complete conversion for $Na_2CO_3$, the mass fraction of $NaHCO_3$ in solution (*i.e.*, the maximum possible) is almost equal to 50 wt.%.

For this reason, to analyse the precipitation equilibria of the system, the $Na_2CO_3$ solubility and $NaHCO_3$ solubility have been considered, respectively, at variable $NaHCO_3$ concentration in solution in the range 0-50 wt.% and at variable $Na_2CO_3$ in solution in the range 0-30 wt.%. Since bicarbonate must be recovered in solid phase, it is necessary for $NaHCO_3$ to precipitate, while $Na_2CO_3$ must be kept in solution.

Results are plotted in Figure 2: from Figure 2a, as the $Na_2CO_3$ content increases, the solubility of $NaHCO_3$ decreases. On the other hand, Figure 2b shows the solubility of $Na_2CO_3$ in $H_2O$ at different concentrations of $NaHCO_3$: as the $NaHCO_3$ content increases, the solubility of $Na_2CO_3$ decreases significantly.

Referring to reaction (4), it is possible to determine, at a fixed $Na_2CO_3$ conversion, the produced $NaHCO_3$ and the residual $Na_2CO_3$ in solution.

Table 3 shows the mass fraction of $Na_2CO_3$ and $NaHCO_3$ in solution depending on the $Na_2CO_3$ conversion. Comparing the concentrations of Table 3 with the curves of Figure 2b, there are no critical issues regarding the precipitation of $Na_2CO_3$ if the conversion of $Na_2CO_3$ is > 85%: in this case, the residual $Na_2CO_3$ in solution is within the solubility limit. At lower conversions, the possible precipitation of $Na_2CO_3$ together with that of $NaHCO_3$ is to be verified in the simulation phase.

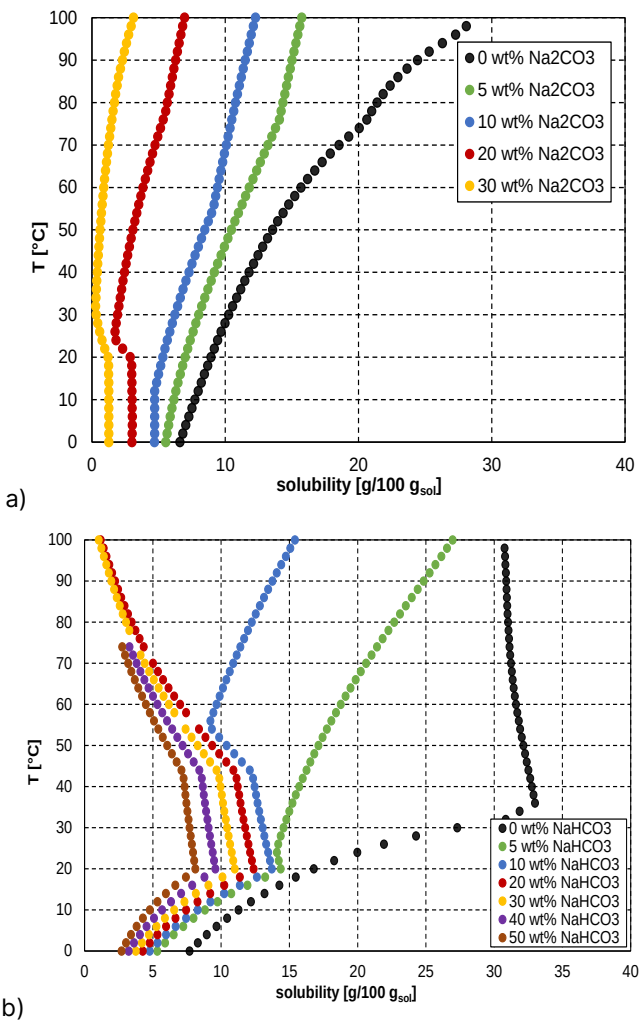

**Figure 2.** Solubility of: a) $NaHCO_3$ in $H_2O$ at different $Na_2CO_3$ concentrations and b) $Na_2CO_3$ in $H_2O$ at different $NaHCO_3$ concentrations.

**Table 3:** Conversion of $Na_2CO_3$ and corresponding mass fractions of $Na_2CO_3$ and $NaHCO_3$.

| conversion [%] | $Na_2CO_3$ [wt.%] | $NaHCO_3$ [wt.%] |
|---|---|---|
| 100 | 0.0 | 47.55 |
| 85 | 4.5 | 40.42 |
| 70 | 9.0 | 33.28 |
| 55 | 13.5 | 26.15 |
| 40 | 18.0 | 19.02 |
| 25 | 22.5 | 11.89 |
| 10 | 27.0 | 4.75 |

## PRELIMINARY FEASIBILITY STUDY

Set up and validated the thermodynamic package, the process simulation has been performed.

Figure 3 shows the process scheme for $NaHCO_3$ production as simulated in Aspen Plus® V14. The scheme is composed of different sections, each of them described in the following.

- Preparation of $Na_2CO_3$ solution. Solid $Na_2CO_3$ is dissolved into fresh $H_2O$ (stream 13 in Figure 3) and recycled (stream 11 in Figure 3). The make-up water flow rate was modulated to guarantee a $Na_2CO_3$ solution concentration of 30 wt.%. This value is close to the solubility limit at the operating temperature of the process. The dissolution of $Na_2CO_3$ in $H_2O$ is exothermic: Aspen Plus® V14 predicts a temperature increase up to about 50 °C: it is, therefore, necessary to provide a jacketed tank with cooling water.
- Reaction. The $CO_2$ from the carbon capture section, together with the sodium carbonate solution, react in T-101, which is the carbonation tower operated at constant temperature and pressure. The $CO_2$ flow rate is fixed to guarantee, at complete

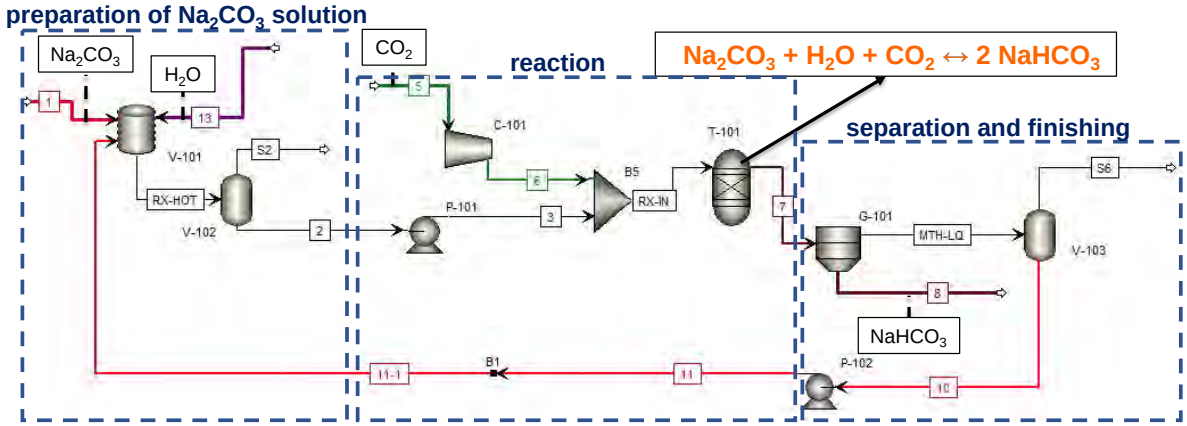

**Figure 3.** Process scheme for $NaHCO_3$ production. Simulation in Aspen Plus® V14

conversion, the productivity detailed in the Introduction. Pressure, temperature and $CO_2$ composition are defined by the upstream capture section. On the other hand, the $Na_2CO_3$ flow rate entering the process battery limits is stoichiometric to the inlet carbon dioxide. The operating pressure for the carbonation reactor is in the range 1.5-2.5 bar from literature [9-10]. Since the reaction is in the liquid phase, pressure has no influence on the kinetics, but on the $CO_2$ solubility only (*i.e.*, on the transfer of carbon dioxide from the gas phase to the liquid phase). $P$ = 1.8 bar has been fixed and kept constant for simulation purposes. As for the operating temperature, it is in the range 35-60 °C from the literature [9-10]. Temperature has an effect on reaction thermodynamics and kinetics: it must be limited to avoid decomposition of $NaHCO_3$ (left-shifted equilibrium in reaction (4)), favored at high temperatures. $T$ = 40 °C has been fixed for simulation purposes. The carbonation reaction is exothermic: it is necessary to provide a reactor jacketed with cooling water for isothermal operation. A bicarbonate slurry is produced, which must be separated and dried before storage.

- Separation and finishing. The solid-liquid separation is carried out in a centrifuge (G-101 in Figure 3). The fraction of liquid retained by the solid, preliminarily assumed to be 15% [10], depends on the specifications of the downstream dryer. For the drying unit operation, the most suitable equipment (which cannot be simulated in Aspen Plus®) must be chosen on the basis of experience and experimental tests. The mother liquor is recycled to the preparation of the $Na_2CO_3$ solution section.

The heat and material balances for the process of Figure 3 are reported in Table 4, Table 5 and Table 6.

**Table 4:** Cooling duty for the process of Figure 3.

| Equipment | $T_{in}$ [°C] | $T_{out}$ [°C] | $Q$ [kW] |
|---|---|---|---|
| V-101 + V-102 | 52.84 | 40 | -1.270 |
| T-101 | 62.47 | 40 | -4.226 |

**Table 5:** Electric power consumption for the process of Figure 3.

| Equipment | $P_{in}$ [bar] | $P_{out}$ [bar] | $W$ [kW] |
|---|---|---|---|
| P-101 | 1.0 | 1.8 | 0.0064 |
| P-102 | 1.7 | 1.8 | 0.0008 |
| C-101 | 1.8 | 3.0 | 0.1194 |

The performances of the process are good: no thermodynamic limitations or particular critical issues were detected. From Table 6, it can be noted that the outlet $CO_2$ in gas phase (stream S6 in Figure 3) is negligible. Cooling is all to be carried out with cooling water as a utility. Electric power consumption is negligible and is due to liquid and gas circulation only.

In addition to the electric power and cooling duty retrieved from process simulation, it is necessary to consider the power consumption of the G-101 centrifuge and the heating duty of the dryer.

## CONCLUSIONS

The integration of sodium bicarbonate production from captured $CO_2$ into waste-to-energy plants represents an innovative synergy between waste management and carbon utilization. By leveraging emissions to create a high-demand product, WtE plants can enhance their economic and environmental performance. This approach holds significant promise for transforming WtE facilities into more sustainable and resource-efficient operations while contributing to global efforts to combat climate change.

In this work, the $CO_2$ to $NaHCO_3$ conversion is explored with reference to an existing waste-to-energy plant in Italy. A preliminary feasibility study is presented, based on heat and material balances retrieved from Aspen Plus® V14, properly set for the accurate modeling of the system's behaviour. Process performances are discussed, in view of the pilot plant engineering and construction.

Due to the encouraging outcomes and the easy implementation to the existing infrastructures, the potential of carbon dioxide conversion to bicarbonate is demonstrated, proving that it can became a feasible $CO_2$ utilization choice within the waste-to-energy context.

Although the potential benefits are significant, challenges such as managing operational costs and optimizing the chemical process for scalability must be addressed. For this reason, future developments of this work will regard:

1. a sensitivity study, depending on the reactant ratio $CO_2/Na_2CO_3$ fed to the battery limits, to identify optimal operating conditions;
2. the pilot plant sizing and layout, to evaluate its footprint;
3. the economic assessment and the overall $CO_2$ emissions evaluation, both direct and indirect, to establish the real process feasibility at the industrial level.

The deepening of these three aspects will provide a

## ABSTRACT

A simple mathematical model of the co-precipitation of Ni-Mn-Co hydroxides is developed and applied to investigate the effect of pH, initial concentration of ammonia in the solution, concentration of the ammonia feed, nucleation rate constant and exponent, growth rate constant and growth exponent over the model output. The model is shown to produce a correct representation of the precipitation variables, and the general trends obtained for different sets of parameters are found in agreement with results presented elsewhere. A sensitivity analysis is carried out and the sensitivity indices are calculated. It is found that pH, initial concentration of ammonia and growth rate constant are the input parameters with the most relevant effect over the model input.

## INTRODUCTION

As the world transitions to cleaner energy sources like solar and wind, which are inherently intermittent, lithium-ion batteries have emerged as a suitable solution due to their high energy density, versatility, and long cycle life. Li-ion batteries excel in storing excess energy generated during periods of high production and releasing it when supply falls short, enabling a stable and reliable energy supply. Widely used in portable electronics, electric vehicles, and stationary energy storage systems [1-4], lithium-ion batteries also play a pivotal role in the electrification of transportation, significantly reducing reliance on fossil fuels and lowering greenhouse gas emissions. Their integration into energy systems not only facilitates the adoption of renewable energy but also supports global efforts to achieve net-zero carbon goals. By bridging the gap between energy production and consumption, lithium-ion batteries are indispensable in building a sustainable and resilient energy future.

The widespread adoption of batteries in daily life faces significant challenges, particularly regarding performance, cost, and sustainability. A key hurdle lies in optimizing cathode materials, which critically influence a battery's energy density, lifespan, and overall efficiency [5, 6]. These properties are largely inherited from the chosen materials for cathode's precursors and from the synthesis route, which determines relevant features of the particles such as their mean size, PSD, porosity and morphology.

Ni-Mn-Co hydroxides can be synthesized by different methods, e.g. solvo/hydrothermal, solid state, or co-precipitation [5, 7, 8]. The latter involves the mixing of stoichiometric amounts of transition metal salts with a complexing agent (e.g. ammonia) and a precipitating agent (e.g. sodium hydroxide) under controlled reaction conditions to produce quasi-spherical particles and tailor the particle morphology and density. Key parameters to optimize such particle properties are the reaction environment pH, stirring velocity, temperature and reaction time [5, 9, 10].

The optimization of the parameters mentioned above can be troublesome, particularly because the precipitation environment is very scale-dependent and an observed behaviour at a lab facility might not be reproduced at an industrial precipitator, hence, following an experimental route may prove costly and ineffective [11]. To tackle this problem, it is useful to turn to mathematical models that can produce a fair representation of the phenomena at a low cost. Because of that, in this investigation we develop a mathematical model of a semi-batch precipitator to study the effect of input parameters in the response of the model regarding the particle size distribution (PSD), the supersaturation and the particle mean

sizes $d_{4,3}$ and $d_{3,2}$. A few studies regarding the modelling of co-precipitation of Ni-Mn-Co hydroxides are available in the open literature. Barai et al. [2] developed a multi-scale model considering nucleation, growth and aggregation of particles and simulated a continuous stirred tank crystallizer to study the effect of pH and ammonia concentration over the PSD and mean particle size. Shiea et al. [1] applied a CFD-PBE modelling approach to a multi-inlet vortex micromixer and simulated the effect of varying the flowrate and concentration of the feed, they reported a decrease in mean particle size as the feed concentration and flowrate increase. Para et al. [3] applied the same approach to simulate a similar system and fitted the model output to experimental datapoints of mean particle size. Mugumya et al. [12] investigated the co-precipitation of NMC111; their modelling work was limited to solving the equilibrium conditions and did not include any description of the formation and growth of crystals. Querio et al. [13] compared the computational performance of the CFD-PM approach versus a compartment model and found that the latter approach render less accurate, yet less computationally expensive qualitatively correct predictions. In this work, we utilize a simple transient model of a semi-batch crystallizer to study the sensitivity of the response of the model to the variation of relevant operating parameters like pH and ammonia concentration, but also to the changes of the kinetic parameters of crystal nucleation and growth. The intent of this work is to obtain a simple, representative model capable of producing a reliable output regarding PSD and particle size, which will be integrated in the context of a whole manufacturing plant model in future work.

# METHODS

## System description

The system to be modelled is a stirred crystallizer operating in a semi-batch mode as illustrated in Figure 1. The crystallizer is initially charged with a solution of aqueous ammonia prepared according to the specifications outlined in Table 1. During the process, a 2M transition metal solution containing an 8:1:1 ratio of nickel, manganese and cobalt is gradually introduced into the reactor, along with a 10M sodium hydroxide solution and an aqueous ammonia solution with concentration varying from 1.14 – 5.7M. The operating parameters of the crystallizer are summarized in Table 1.

## Model assumptions.

The development of the crystallizer model is based on the following key assumptions, which simplify the representation of the system while maintaining its relevance to practical applications:

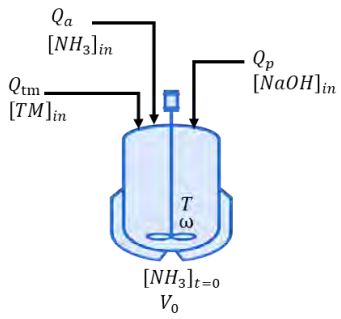

**Figure 1.** Schematic representation of the modelled crystallyzer.

**Table 1:** Operating conditions of the crystallizer.

| Param. | Description | Value |
|---|---|---|
| $T$ | Temperature | 60°C |
| $\omega$ | Stirring velocity | 1000 rpm |
| $V_0$ | Initial solution volume | 0.0008 $m^3$ |
| $[TM]$ | Molar concentration of the transition metal solution. | 2M |
| $[NaOH]$ | Molar concentration of the precipitating agent. | 10M |
| $Q_{TM}$ | TM solution volumetric flowrate | $4.8x10^{-5}$ $m^3$ $h^{-1}$ |
| $Q_a$ | Chelating agent sol. volumetric flowrate | $2.4x10^{-5}$ $m^3$ $h^{-1}$ |
| $Q_p$ | Precipitating agent sol. volumetric flowrate. | $1.92x10^{-5}$ $m^3$ $h^{-1}$ |
| $t_a$ | Reagent addition time. | 10.4h |

1. Crystal particles are modeled as having spherical geometries to streamline the mathematical treatment of shape-dependent phenomena.
2. The formation of transition metal hydroxides is considered negligible. The primary reaction pathway is assumed to involve the formation of transition metal ion complexes, followed by their conversion into combined transition metal hydroxides.
3. The reaction rates for both ionic complex formation and hydroxide formation are assumed to be fast. As a result, the rate-controlling processes are the nucleation and growth of crystals.
4. Aggregation and breakage of crystals are neglected, focusing the model on the nucleation and growth mechanisms.
5. The crystallizer is assumed to operate isothermally, with a consistent and uniform temperature maintained throughout the process.
6. It is assumed that no seed crystals are present in the feed entering the crystallizer.

## Model development.

The particle size distribution is mathematically described by the population balance equation (PBE). For a semi-batch crystallizer, the PBE is [14]:

$$\frac{\partial Vn}{\partial t} + G\frac{\partial Vn}{\partial L} = 0 \quad (1)$$

Where $V$ is the crystallizer volume, $n$ is the number density, $t$ is the batch time, $L$ is the crystal size and $G$ is the crystal growth rate. Equation (1) neglects the agglomeration and breakage of particles in the crystallizer. Since the crystallization process starts from a clear solution, the following initial condition applies to Equation (1):

$$n(0, L) = 0 \quad (2)$$

Additionally, the following boundary condition is applied depending on the level of supersaturation of the desired product in the crystallizer:

$$n(t, 0) = \begin{cases} 0 \; if \; S \leq 1 \\ \frac{B}{G} \; if \; S > 1 \end{cases} \quad (3)$$

Where $S$ is the supersaturation and $B$ is the nucleation rate; the supersaturation, and by extension the nucleation and growth rates relate to the equilibrium concentration of the ions of nickel ($[Ni^{2+}]_{eq}$), manganese ($[Mn^{2+}]_{eq}$), cobalt ($[Co^{2+}]_{eq}$), and hydroxyl ions ($[OH^-]$) and are defined as:

$$S = \left( \frac{[Ni^{2+}]_{eq}^{x}[Mn^{2+}]_{eq}^{y}[Co^{2+}]_{eq}^{z}[OH^-]_{eq}^{2}}{K_{sp}^{Ni_xMn_yCo_z(OH)_2}} \right)^{1/3} \quad (4)$$

$$B = k_B(S-1)^b \quad (5)$$

$$G = k_G(S-1)^g \quad (6)$$

Where $k_B$ is the nucleation kinetic constant, $k_G$ is the growth kinetic constant, $b$ is the nucleation exponent, $g$ is the growth exponent and the exponents $x$, $y$ and $z$ are determined by the desired stoichiometry of the combined hydroxide; for the case of NMC811, these values are $x = 0.8$, $y = 0.1$ and $z = 0.1$. The equilibrium concentrations of the ionic species in the solution are calculated by solving the complex chemical equilibrium relationships expressed in Equations (7) – (13):

$$[Ni^{2+}] = [Ni^{2+}]_{eq} + \sum_{i=1}^{6}\left[Ni(NH_3)_n{}^{2+}\right]_{eq} \quad (7)$$

$$[Mn^{2+}] = [Mn^{2+}]_{eq} + \sum_{i=1}^{4}\left[Mn(NH_3)_n{}^{2+}\right]_{eq} \quad (8)$$

$$[Co^{2+}] = [Co^{2+}]_{eq} + \sum_{i=1}^{6}\left[Co(NH_3)_n{}^{2+}\right]_{eq} \quad (9)$$

$$[NH_3] = [NH_3]_{eq} + [NH_4^+]_{eq} + \sum_{n=1}^{6} n\left[Ni(NH_3)_n{}^{2+}\right]_{eq} + \sum_{n=1}^{4} n\left[Mn(NH_3)_n{}^{2+}\right]_{eq} + \sum_{n=1}^{6} n\left[Co(NH_3)_n{}^{2+}\right]_{eq} \quad (10)$$

$$K_n^{M^{2+}} = \frac{\left[M(NH_3)_n{}^{2+}\right]_{eq}}{[M^{2+}]_{eq}[NH_3]_{eq}^{n}} \quad (11)$$

$$K_w = [H_3O^+]_{eq}[OH^-]_{eq} \quad (12)$$

$$K_b = \frac{[NH_4^+]_{eq}[OH^-]_{eq}}{[NH_3]_{eq}} \quad (13)$$

Where the equilibrium constants of the coordination of transition metal ions with ammonia ($K_n^{M^{2+}}$), the dissociation of water ($K_w$), and dissociation of ammonia ($K_b$) are taken from [15]. To solve Equations (7) – (13) the total concentrations of nickel ($[Ni^{2+}]$), manganese ($[Mn^{2+}]$), cobalt ($[Co^{2+}]$), and ammonia ($[NH_3]$) are required; the concentration of these species evolve dynamically throughout the process and are given by:

$$\frac{d[Ni^{2+}]V}{dt} = Q_{tm}[Ni^{2+}]_{in} - \frac{0.8Vk_v\rho_c}{MW_c}\frac{dm_3}{dt} \quad (14)$$

$$\frac{d[Mn^{2+}]V}{dt} = Q_{tm}[Mn^{2+}]_{in} - \frac{0.1Vk_v\rho_c}{MW_c}\frac{dm_3}{dt} \quad (15)$$

$$\frac{d[Co^{2+}]V}{dt} = Q_{tm}[Co^{2+}]_{in} - \frac{0.1Vk_v\rho_c}{MW_c}\frac{dm_3}{dt} \quad (16)$$

$$\frac{d[SO_4^{2-}]V}{dt} = Q_{tm}[SO_4^{2-}]_{in} \quad (17)$$

$$\frac{d[NH_3]V}{dt} = Q_a[NH_3]_{in} \quad (18)$$

$$\frac{d[Na^+]V}{dt} = Q_p[Na^+]_{in} \quad (19)$$

$$\frac{dV}{dt} = Q_s + Q_a + Q_p \quad (20)$$

$$\frac{dm_3}{dt} = 3Gm_2 \quad (21)$$

$$m_2 = \int_0^{\infty} n\,L^2 dL \quad (22)$$

Where $Q_s$, $Q_a$, and $Q_p$ are the volumetric flowrates of transition metal solution, ammonia and precipitant agent; $k_v$ is the volumetric factor, $\rho_c$ is the crystal density, $MW_c$ is the precipitate molecular weight, $m_2$ and $m_3$ are the second and third moments of the particle size distribution.

## Model solution.

The model equations were implemented and solved using the method of lines in Aspen Custom Modeler. A total of 250 simulations were conducted, varying key parameters, including the initial concentration of ammonia, the ammonia concentration fed to the crystallizer, the solution pH, and the crystallization kinetics parameters for crystal nucleation and growth. These variables were randomly sampled using the Latin hypercube sampling method, ensuring efficient exploration of the parameter space within the ranges specified in Table 2.

# RESULTS

The results of the simulation of four selected cases for key variables like supersaturation, mean particle sizes and particle size distribution are presented in Figures 2 through 5. As mentioned before, the input parameters

utilized for these simulations were randomly sampled, and for quick reference are presented in Table 3.

**Table 2:** Parameter ranges utilized to simulate the co-precipitation of Ni-Mn-Co hydroxides.

| Param. | Description | Value |
|---|---|---|
| $[NH_3]_{t=0}$ | Initial ammonia conc. | 0.3–1.5M |
| $[NH_3]_{in}$ | Ammonia feed conc. | 1.14–5.7M |
| $pH$ | Solution pH | 9.5–11.5 |
| $k_B$ | Nucleation constant | $10^4$–$10^{10}$ |
| $b$ | Nucleation exponent | 1–5 |
| $k_G$ | Growth constant | $10^{-6}$–$10^{-10}$ |
| $g$ | Growth exponent | 0.5 – 2.5 |

**Table 3:** Input parameters utilized to generate the results presented in this paper.

| Param | Units | (a) | (b) | (c) | (d) |
|---|---|---|---|---|---|
| $[NH_3]_{t=0}$ | mol $m^{-3}$ | 1.17 | 0.51 | 0.74 | 0.63 |
| $[NH_3]_{in}$ | mol $m^{-3}$ | 3.32 | 1.66 | 2.43 | 3.79 |
| $pH$ | - | 11.4 | 9.9 | 9.8 | 10.2 |
| $k_B x10^{-6}$ | $m^{-3}\,h^{-1}$ | 0.014 | 22.3 | 0.057 | 0.131 |
| $b$ | - | 4.5 | 2.8 | 4.7 | 4.0 |
| $k_G x10^{10}$ | $m\,h^{-1}$ | 81.7 | 27.0 | 3.7 | 3.44 |
| $g$ | - | 1.0 | 1.5 | 2.4 | 1.7 |

Figure 2 presents multiple supersaturation profiles generated by the model using different sets of input parameters. As anticipated for a semi-batch system initially containing only one of the reacting species, the supersaturation levels increase over time, reaching a peak before gradually declining until the end of the process.

In all cases, an initial induction period is observed at the start of the run, marking the addition of reagents to the crystallizer. After this phase, supersaturation breaks through and builds up at a rate dictated by crystallization kinetics and reactant concentrations. The magnitude of supersaturation is determined by the availability of transition metal and hydroxyl ions in the solution [1], with the highest levels in Figure 2 corresponding to simulation cases with the highest pH. Conversely, the position of the supersaturation peak is influenced by crystallization kinetics, particularly the crystal growth rate, which governs how quickly reactants are consumed to form Ni-Mn-Co hydroxide crystals.

Figures 3 and 4 are plots of the evolution of the volume-weighted mean size and the surface-weighted mean size, respectively. In both cases, the growth of the NMC particles breaks trough after 3 hours which coincides with the development of the supersaturation curves discussed above. For Case (a), both the volume- and surface-weighted mean sizes seem to have an initially fast growth but then plateau at the lowest mean size of the four cases. Conversely, for case (c) the growth is sustained for longer, yielding the highest mean particle sizes among all of them. This behaviour seems obvious given the rapid decline of the supersaturation for case (a), which in turn renders a decline of the crystal growth rate. On the other hand, for case (c), even when the supersaturation does not reach very high values, its decline is less severe and, in addition, the value of the growth exponent magnifies the crystal growth rate.

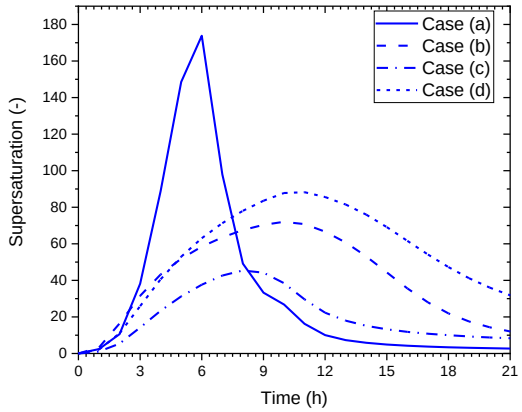

**Figure 2.** Supersaturation of Ni-Mn-Co hydroxide at different operating conditions of pH and ammonia concentration, and with different sets of kinetic parameters.

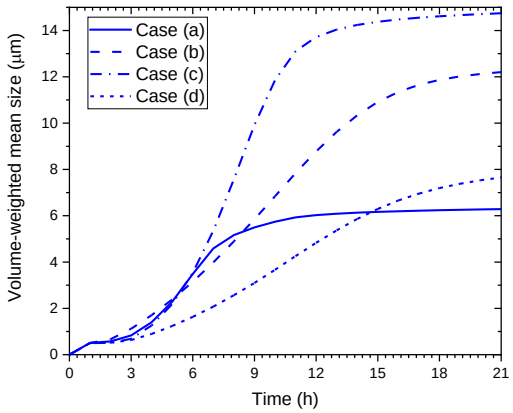

**Figure 3.** Volume-weighted mean size of the selected numerical experiments simulated.

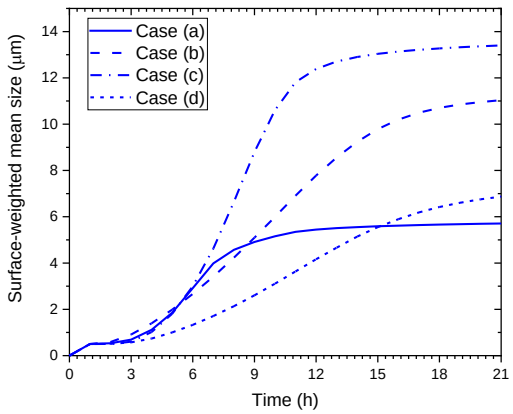

**Figure 4.** Surface-weighted mean size of the selected numerical experiments simulated.

Figure 5 displays the particle size distribution (PSD) for simulation cases (a), (b), (c), and (d), highlighting the significant impact of varying input parameters. All PSD curves exhibit unimodal distributions skewed toward the smaller particle size range, with a decreasing coefficient of variation as pH increases. The coefficient of variation refers to the 'width' of the distribution and it reflects the degree of polydispersity in crystal size; in the results presented here, the most uniform product is achieved at pH 11.5, albeit with the smallest particle size. The trends identified align with previous studies [2], albeit the optimal pH condition depend upon the desired product to be synthesized [5].

Determining the importance of the input parameters is complex due to the interplay among factors both physically and in the mathematical model. To support the investigation of the relevance of the input parameters, the sensitivity indices were calculated and are presented in Table 4. This analysis was carried out considering the mean sizes $d_{4,3}$ and $d_{3,2}$ as the outputs of interest. By inspecting the values summarized in Table 4, it is evident that the $k_G$, $g$, $pH$ and $[NH_3]_{t=0}$ have a strong influence over the output of the model.

**Table 4:** Sensitivity indices of the investigated parameters.

| Parameter | Indices |
|---|---|
| $[NH_3]_{t=0}$ | 0.1341 |
| $[NH_3]_{in}$ | 0.0036 |
| $pH$ | 0.0809 |
| $k_B$ | 0.0001 |
| $b$ | 0.0023 |
| $k_G$ | 0.6378 |
| $g$ | 0.1413 |

## CONCLUSIONS

A simple mathematical model of a semi-batch crystallizer has been presented. The model has been solved by the method of lines utilizing the commercial solver contained in Aspen Custom Modeler® and applied to conduct a sensitivity and uncertainty analysis to verify the effect of pH and ammonia concentration, and the kinetics of nucleation and growth over the particle size distribution and mean particle sizes.

Despite the simplicity of the model, it produces a fair representation of the precipitation variables, and the prediction of relevant particle properties agrees with the observations of previous work conducted for this type of system. The model can be enhanced by incorporating the

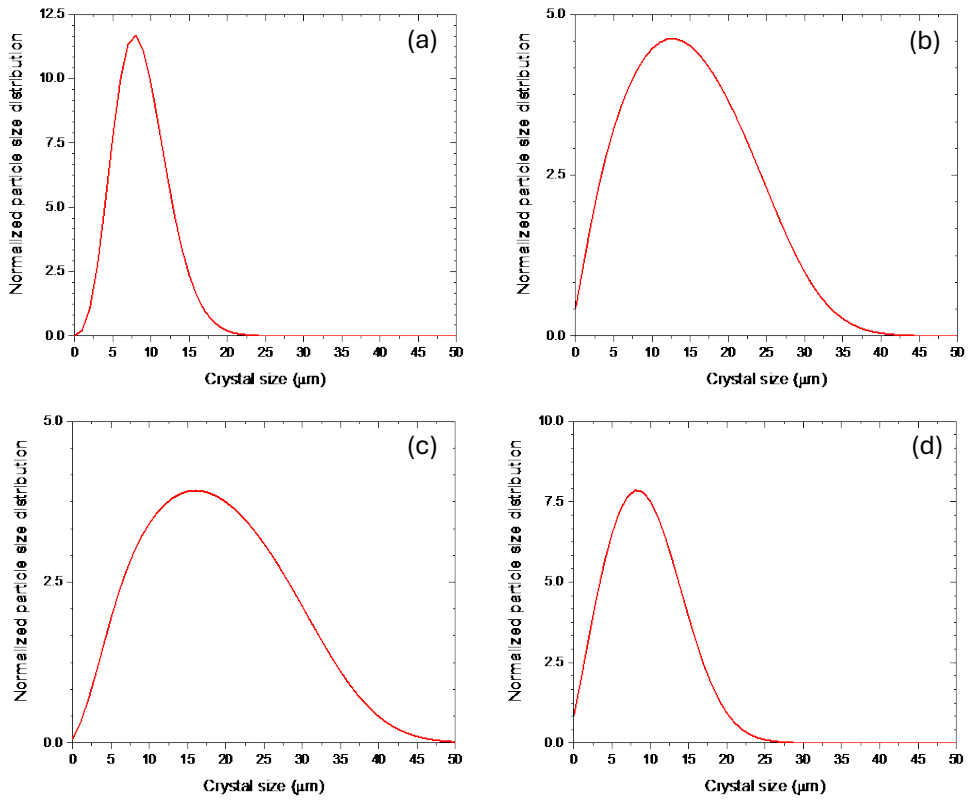

**Figure 5:** Particle size distribution (PSD) curves of selected numerical experiments simulated in this work.

aggregation/breakage phenomena into the PBE and by incorporating the thermal effects over the crystallization kinetics.

The sensitivity analysis indices indicated that the crystallization of Ni-Mn-Co hydroxides with stoichiometry 0.8:0.1:0.1 is primarily sensitive to the growth kinetics, the solution pH and the initial concentration of ammonia. Less relevant is the kinetics of nucleation, whereas the concentration of ammonia feed seems to be irrelevant.

## FUTURE WORK

The resulting model is to be improved by incorporating the agglomeration/breakage term to the population balance. Similarly, the effect of temperature over the crystallization kinetics was not incorporated in this work, this is an important piece to enable a better understanding and optimization of the process. This model will be used to conduct studies regarding the kinetics of crystallization.

## ACKNOWLEDGEMENTS

The authors would like to thank the UK Engineering and Physical Sciences Research Council (EPSRC) for funding the SuMMa project, grant reference EP/W018950/1.

# A System-Dynamics Based Approach for Modeling Circular Economy Networks: Application to the Polyethylene Terephthalate (PET) Supply Chain

**Daniel Pert[a], Ana Inés Torres[a]***

[a] Carnegie Mellon University, Department of Chemical Engineering, Pittsburgh, PA, USA
* Corresponding Author: aitorres@cmu.edu.

## ABSTRACT

The transition to a circular economy (CE) requires agents in circular supply chain (SC) networks to take a variety of different initiatives, many of which are dynamic in nature. We use a system dynamics (SD)-based approach to develop a generic framework for dynamic modeling of CE networks and propose a prototypical circular SC network by combining dynamic models for five actors: a manufacturer, consumer, material recovery facility (MRF), recycling facility, and the Earth. We apply this framework to the supply chain for Polyethylene Terephthalate (PET) plastic packaging by considering different scenarios over a 65-year time horizon in the US. We include both "slow-down-the-loop" initiatives (i.e., those that extend product use time through demand reduction or reuse) and "close-the-loop" initiatives (i.e., those that reintroduce product to the supply chain through recycling) by the consumer, as well as sorting and recycling capacity expansion. We find that, given the current recycling infrastructure in the U.S., "slow-down-the-loop" initiatives are more effective than "close-the-loop" initiatives for improving circularity and minimizing environmental impact. However, combining the two initiatives eliminates the need for capacity expansion and leads to the highest circularity in the shortest amount of time.

**Keywords**: Dynamic Modelling, Circular Economy, Plastic recycling

## INTRODUCTION

The current "take-make-use-dispose" paradigm of the current extractive "linear economy" has led to unnecessary waste, pollution, and extraction of natural resources. The "circular economy" (or CE) paradigm aims to eliminate waste, pollution, and resource extraction through restorative circular flows [1].

Circular *initiatives* are actions that an *actor* (e.g. a firm or consumer) in a supply chain (SC) network can take to improve their level of "circularity." Initiatives can be categorized into those that "slow down the loop" by using products for longer, "narrow the loop" by using fewer resources per product, or "close the loop" by reintroducing the product to the SC through recycling [2].

Since most frameworks for studying CE networks operate at steady state and do not include the time dimension, they cannot consider the time-delayed effects of CE initiatives on upstream and downstream actors or time-dependent initiatives such as those that extend product use time. Thus, dynamic models that incorporate the time dimension are needed to model CE networks.

The use of system dynamics (SD), a framework that, in addition to stocks and flows, incorporates auxiliary variables, coflows, and nonlinear feedback mechanisms [3], would enable a more detailed understanding of what external driving forces are needed to enable these changes and any possible unintended consequences of CE initiatives. Previous studies have already begun to use SD to study various aspects of CE transitions [4-7]. However, none of these studies are systematic in nature or provide clear mathematical models of CE initiatives at the actor level.

The main objective of this work is to develop a modular SD-based framework that can be used to study the effects of CE initiatives taken by different actors. First, we develop a dynamic model for a generalized actor and propose a systematic method for quantifying material

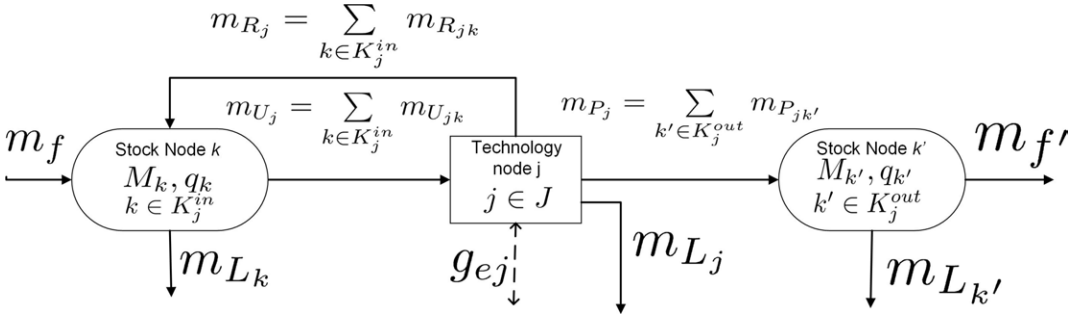

**Figure 1:** Stock-and-flow diagram for a generalized actor in a circular SC network, including technology node $j \in J$ and stock nodes $k \in K$. $m_{L_k}$ is the rate of disposal from stock node $k$, $m_{U_{jk}}$ is the rate of usage of material from stock node $k$, $m_{P_{jk'}}$ is the rate of production of output $k'$, and $m_{R_{jk}}$ is the rate of recirculation of input $k$. Environmental impact flows ($g_{ej}$) and denoted by the dashed arrow.

quality loss. Then, we combine different actors in a prototypical circular SC to form a synthetic "block" network and formulate a dynamic model governing the network on multiple time scales. Finally, we apply this framework to compare the long-term effects of different CE initiatives on the PET plastic packaging SC.

## GENERIC MODEL FOR AN ACTOR

The stock-and-flow diagram for a generalized actor is shown in **Figure 1**. Each actor exchanges material with other actors, performs a composition transformation on the material via a *technology node*, and stores material as inventory in one or more *stock nodes*. Let *F* be the set of material flows *J* be the set of technology nodes, *K* be the set of stock nodes, $K_j^{in}$ (and $K_j^{out}$) be the sets of stock nodes that feed into (and are fed to) by node $j \in J$, $F_j^{in}$ (and $F_j^{out}$) be the sets of flows entering (and exiting) node *j*, $F_k^{in}$ (and $F_k^{out}$) be the sets of material flows entering (and exiting) stock *k*, *E* be the set of environmental impact flows (e.g., natural resource inputs and pollution), $g_{ej}$ be the rate at which technology node *j* contributes to environmental impact *e*, $M_k$ be the quantity of material stored in stock node *k* at a given time, $m_f$ be the material flow rate of flow *f*, and $q_k$ (and $q_f$) be the material qualities of stock node *k* and flow *f*. Material quality is modeled as a coflow and discussed below.

Using this notation, the material balances on stock node *k* and technology node *j* are given by **Equations 1-2**. The total rates of material input and production of technology node *j* are denoted by $m_{U_j}$ and $m_{P_j}$, which are related by the process yield $\eta_j$ (**Equation 3**). The remainder of the input is either discarded at a rate of $m_{L_j}$or recirculated at a rate of $m_{R_j}$.

$$\frac{dM_k}{dt} = \sum_{f \in F_k^{in}}(m_f) - \sum_{f' \in F_k^{out}}(m_{f'}) \quad \forall k \in K \tag{1}$$

$$m_{U_j} = m_{P_j} + m_{L_j} + m_{R_j} \quad \forall j \in J \tag{2}$$

$$m_{P_j} = \eta_j m_{U_j} \quad \forall j \in J \tag{3}$$

Material stocks (or flows) may also have some quality attributes, such as desirable physical properties, and they are modeled using the co-flow structure [3]. We normalize quality to be between zero and one, with virgin material having a quality of one and increasing quality being more desirable. We assume quality follows a linear mixing rule; that is, the quality of a mixture of two streams is given by the mass flow-weighted average of their qualities. The quality of stock node $k$ is governed by **Equation 4,** while **Equation 5** specifies that technology node $j$ reduces material quality by some constant factor ($\omega_j$).

$$\frac{dq_k}{dt} = \frac{1}{M_k}\sum_{f \in F_k^{in}} m_f [q_f - q_k] \quad \forall k \in K \tag{4}$$

$$q_{P_j} = \omega_j q_{U_j} \quad \forall j \in J \tag{5}$$

We assume $m_{U_j}$, the rate of material input to technology node *j*, is limited by some maximum processing capacity ($Capacity_j$). If the rate of material influx exceeds the maximum capacity or downstream demand for material produced by the node, any excess inventory may be discarded at a rate of $m_{L_k}$.

To adjust to increased (or decreased) demand or inflow, an actor may expand the capacity of a technology node. However, capacity expansion requires planning and construction, leading to a time delay ($\theta_j$) between the time that capacity expansion is initiated and completed. The time scale ($\tau$) on which capacity expansion occurs is much longer than the time scale (t) on which production does. If $Inst_j(\tau)$ is the rate of initiation of capacity expansion at time $\tau$, the installed capacity of technology node *j* and the quantity of capacity currently under construction ($Con_j$) are governed by **Equations 6** and **7**.

$$\frac{dCapacity_j}{d\tau} = Inst_j(\tau - \theta_j) \quad \forall j \in J \tag{6}$$

$$\frac{dCon_j}{d\tau} = Inst_j(\tau) - Inst_j(\tau - \theta_j) \quad \forall j \in J \tag{7}$$

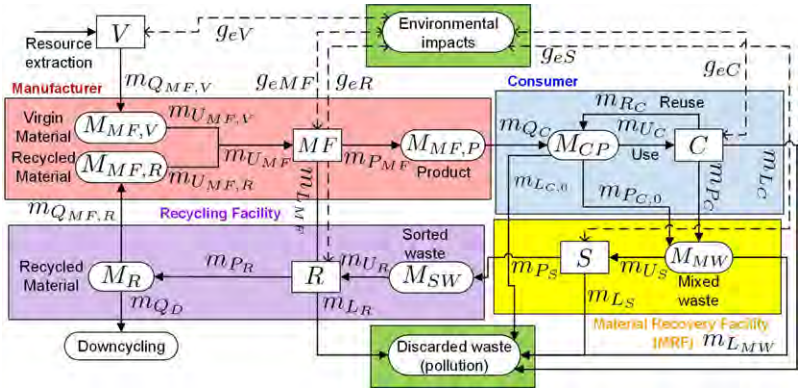

**Figure 2:** Schematic of CE network for PET packaging SC with manufacturer (red), consumer (blue), MRF (yellow), recycling facility (purple), and the Earth (green). Blocks represent technology nodes and ovals represent stock nodes. The flow rate associated with each flow f is denoted by $m_f$ and shown by a solid arrow, and the rate at which technology node j contributes to environmental impact e (i.e. resource use or pollution) is denoted by $g_{ej}$ and shown by a dashed arrow.

We assume capacity expansion is governed by a proportional control-like policy (**Equation 8**). That is, the rate of initiation of capacity expansion is proportional to the difference between $m_{j,in}$, the total inlet flow rate to stock nodes that feed into node $j$ from outside the system boundary of the actor and the current capacity plus the capacity currently under construction (**Equation 9**):

$$Inst_j(\tau) = \max\{0, \kappa_j[m_{j,in} - Capacity_j(\tau) - Con_j(\tau)]\} \quad (8)$$

$$m_{j,in} = \sum_{f \in F_k^{in}} \sum_{k \in K_j^{in}} (m_f) - m_{R_j} \quad (9)$$

Here $\kappa_j$ is a proportional control parameter, which we assume is inversely proportional to construction time $\theta_j$ required to install new capacity: $\kappa_j = 1/\theta_j$.

## SYNTHETIC CIRCULAR SUPPLY CHAIN NETWORK

**Figure 2** shows a stock-and-flow diagram for a synthetic CE network including a manufacturer, who produces a product from raw material, a consumer who uses product and generates waste material, a material recovery facility (MRF) who collects and sorts mixed post-consumer waste into purified waste streams, a recycling facility who converts these purified waste streams into useful products, and the Earth, who supplies virgin material and is a sink for disposed waste.

The manufacturing process (technology node *MF*) requires a single input, which may be sourced from virgin material extracted and produced via technology node *V* or recycled material produced via technology node *R*. The manufacturing process requires a minimum quality of $q_{min}$. We assume none of the actors recirculate processing waste except for the consumer, who recirculates product for reuse at a rate of $m_{R_C}$. The fraction of end-of-life product recycled by the consumer is given by the "recycle rate" $r_C$. The recycling facility produces recycled material at a rate of $m_{P_R}$, which reduces quality by a constant factor of $\omega_R$. Any unpurchased recycled material is downcycled at a rate of $m_{Q_D}$.

### Sustainability Assessment

To quantify absolute environmental sustainability, or the extent to which the environmental impact of a CE network exceeds the restorative capacity of the Earth [8], we use the planetary boundaries (PBs) framework [9], which proposes a "safe operating space" for humanity by defining threshold values (i.e., planetary boundaries) for different "control variables" describing human impacts on nine "Earth-system processes" beyond which there is increasing risk of environmental destabilization.

The Earth system impact metric (ESIM) measures the aggregated impact of a network on multiple Earth-system processes while accounting for current levels of global PB transgression [10]. For the sake of space, details on the calculation of the ESIM are not shown here and are left for a full journal publication.

### Circularity Assessment

The circularity of a CE network is quantified using the Material Circularity Indicator (MCI) proposed by the Ellen MacArthur Foundation [1, 11]. The MCI is given by **Equation 15** and is a function of the Linear Flow Index (LFI), or the fraction of material flowing in a linear fashion (**Equation 16**), and the product utility $\overline{\chi}$ (the mean utility, or number of uses) relative to the industry average ($\chi_{av}$). Here $m_{L_{tot}}$ is the total rate of discarded waste.

$$MCI = 1 - \frac{LFI}{\overline{\chi}/\chi_{av}} \quad (15)$$

$$LFI = \frac{m_{Q_{MV}} + m_{L_{tot}}}{2m_{U_M}} \quad (16)$$

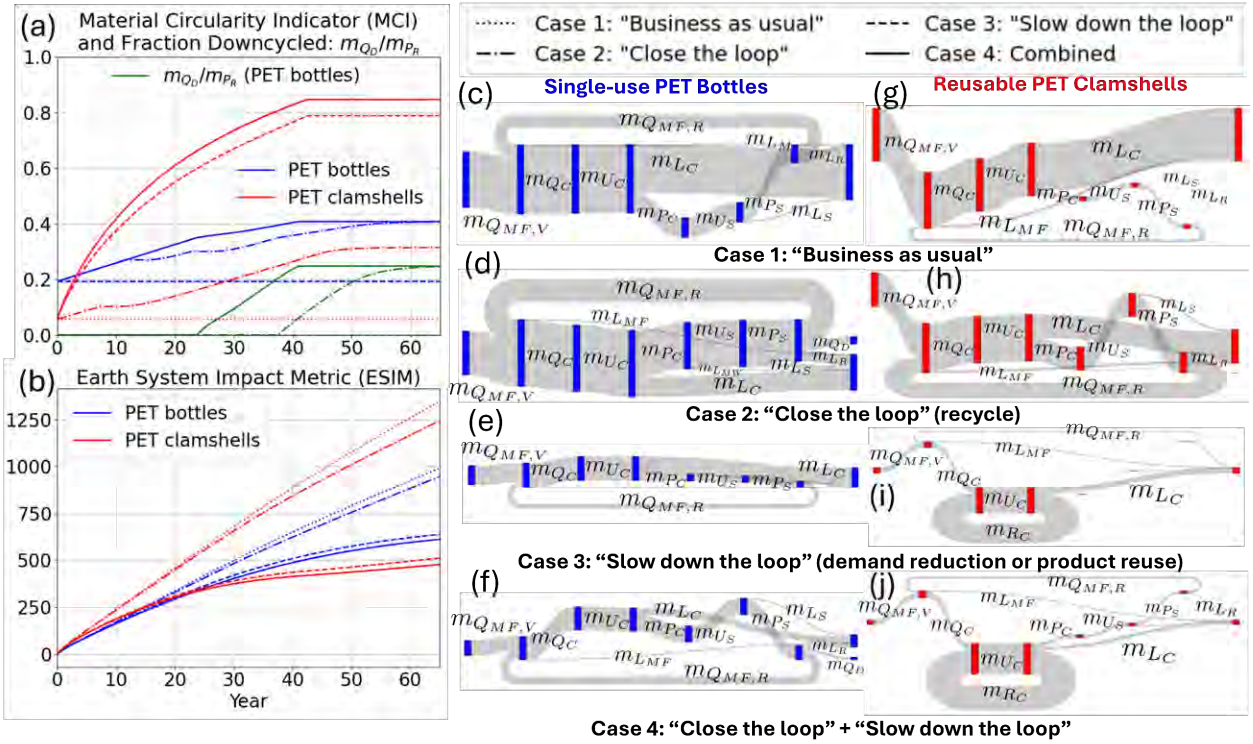

**Figure 3:** Behavior of PET packaging supply chain over 50-year horizon under four scenarios described above. (a) Evolution of Material Circularity Indicator (MCI) and fraction of recycled PET bottles that are downcycled to textiles ($m_{Q_D}/m_{P_R}$) in green. No PET clamshells are downcycled to textiles. The MCI for bottles and clamshells are shown in blue and red, respectively. (b) Evolution of Earth System Impact Metric (ESIM) for PET bottle and clamshell SCs in blue and red, respectively. In (a-b), the four scenarios are shown by the dotted, dashdotted, dashed, and solid lines, as indicated by the legend. (c-j) Sankey diagrams comparing the relative values of the different material flow rates for cases 1-4 for PET bottles (c-f) and clamshells (g-j).

## CASE STUDY: PET SUPPLY CHAIN

We apply the generic model described above to the supply chain for single-use polyethylene terephthalate (PET) bottles and reusable PET clamshell packaging (a type of thermoform) in the U.S. We choose PET since it is relatively easy to recycle yet suffers from low recycling rates in the U.S., representing an opportunity for improved circularity [12]. In addition, a wide variety of circular pathways can be applied to PET, including reuse or repurposing of packaging [13], downcycling to textiles [14], and conversion to pyrolysis oil [15].

Given the current recycling infrastructure in the U.S., we assume the recycling facility uses mechanical recycling; the maximum capacities of the MRF and recycling facility are based on current recycling infrastructure in the U.S. [19]. Since most recyclers only accept PET bales with up to 10% thermoform content, we assume the maximum capacity for clamshell recycling is 10% of total recycling capacity [20]. As a measure of PET material quality, we use the intrinsic viscosity (IV) of the polymer melt, which determines what applications it can be used for [14] and is reduced by mechanical recycling [16].

## RESULTS AND DISCUSSION

The dynamic model for the PET SC network was implemented in Python using the JiTCDDE package [17] and simulated for a 65-year time horizon, from 2022 to 2087, with parameters initialized at their current baseline values. We consider four scenarios: case 1 ("business as usual"), with recycling rates remaining at their current levels of 9% and 29% for clamshells and bottles and with no consumer reuse, case 2 ("close-the-loop" initiatives), or a recycle rate increase of 1% per year for 41 years, case 3 ("slow-down-the-loop" initiatives), or an increase in the fraction of clamshells reused of 2% per year until reaching 85% and a decrease in bottle demand of 1% per year, and case 4 (a combination of "close-the-loop" and "slow-down-the-loop" initiatives). For simplicity, we consider the SCs for PET clamshells and bottles separately. The behavior of the PET bottle and clamshell SC over the 50-year horizon for the four scenarios described above

is shown in **Figure 3**. Panels (a-b) show the temporal evolution of the Material Circularity Indicator (MCI), Earth System Impact Metric (ESIM), and fraction of recycled PET that is downcycled to textiles ($m_{Q_D}/m_{P_R}$) over the simulation. Sankey diagrams with line widths proportional to the final values of the different material flow rates are shown in panels (c-f) and (g-j) for bottles and clamshells, respectively. Case 1 ("Business as usual") results in both the lowest circularity and highest environmental impacts, while case 3 ("slow-down-the-loop") is significantly more effective than case 2 ("close-the-loop") for both increasing circularity and lowering environmental impact.

This is illustrated by the Sankey diagrams. Product reuse (i) results in significantly more circular flow than increased clamshell recycling (h), and demand reduction (e) reduces the amount of linear flow more than increased bottle recycling (d). The difference in environmental impact between cases 2 and 3 is even greater since product reuse is less resource-intensive than recycling and preserves the value of the product, not just its material. Additionally, due to quality loss, a product can be reused far more times than it can be recycled.

For PET bottles, although both cases 2 and 4 achieve the highest final circularity (MCI), the MCI increases faster in case 4 due to the time delay associated with capacity expansion in case 2. Nonetheless, it is important to note that since the LFI is normalized by total product flow, the MCI is insensitive to demand reduction, unless such a reduction is reflected by an increase in product utility (as with product reuse). These results demonstrate that more holistic circularity indicators are needed to account for "slow-down-the-loop" and "narrow-the-loop" initiatives such as a reduction in consumer demand or the mass per unit of product.

However, due to quality loss, mechanically recycled PET must be blended with virgin PET to meet the minimum intrinsic viscosity requirements of the manufacturing process, which puts an upper bound on the fraction of product that can be sourced from mechanically recycled PET. As a result, once the bottle recycles rate exceeds a threshold of around 50%, the manufacturer does not purchase any additional recycled PET, and it must be downcycled to textiles. This was not observed in the PET clamshell results since the minimum quality requirement for clamshell manufacturing is lower than for bottles, although it would be observed for a recycle rate above 85%. Mitigating this effect would require more costly and resource-intensive chemical recycling techniques that produce virgin-grade PET resin [18].

## CONCLUSIONS

Here, we developed a generic framework for dynamic modeling of circular economy networks, which can be used to better understand the effects of circular initiatives taken by individual actors in a supply chain on upstream and downstream actors, including the Earth. We start by developing a dynamic model for a generic actor and then combine different actors into a synthetic CE network. We use the planetary boundaries framework to quantify the absolute environmental sustainability of the network. We apply this framework to study the supply chain for PET clamshells and bottles in the U.S. by comparing the effects of different initiatives.

We find that "slow-down-the-loop" initiatives like consumer reuse and demand reduction are more effective than "close-the-loop" initiatives like recycling. Additionally, increased recycling associated with the "close-the-loop" scenario requires recycling capacity expansion and an associated time delayed circularity increase. However, when combined with "slow-down-the-loop" initiatives, the need for capacity expansion, and thus the time delay, is reduced or eliminated.

However, even with increased consumer reuse, recycling, and capacity expansion, closed-loop circularity is still limited by the quality loss associated with the mechanical recycling process widespread in the U.S. Thus, although "slow-down-the-loop" initiatives are more promising short-term solutions, investments in chemical or solvent-based recycling technologies that reduce or eliminate quality loss are needed in the long term to maximize circularity.

Since the framework is modular, it can easily be extended to other supply chain structures by constructing alternative networks to the one considered here. For example, such a network could include multiple product manufacturers and recyclers or additional actors such as a government agency, who regulates the network, a "repairer," who extends product lifetime by making repairs, and a "refurbisher," who converts end-of-life products to alternative applications through refurbishment.

In future work, we aim to extend the framework to combine the supply chains for multiple PET products, including bottles, clamshells, and textiles. We hope this framework will enable the identification of which initiatives favor win-win scenarios by maximizing circularity while balancing trade-offs among different actors' objectives and avoiding burden-shifting.

## ABSTRACT

L-lactic acid (L-LA), a key monomer in biodegradable plastics, is a sustainable alternative that can be derived from LCB. The L-LA production process typically involves various technologies such as fermentation, filtration, and distillation. In the L-LA production process, large amounts of buffers are used to maintain proper pH during fermentation, so conventional buffers (e.g., $CaCO_3$) are often selected because of their low cost. However, these buffers cannot be recycled efficiently, and the potential for alternative buffers remains uncertain. In this work, we aim to develop and evaluate novel processes for sustainable L-LA production using the alternative buffer (i.e., KOH). The processes involve a series of different unit operations such as pretreatment, fermentation, extraction, and electrolysis. An efficient buffer regeneration process using membrane electrolysis is implemented to recycle the buffer with minimal energy input. Then, we evaluated the viability of the proposed processes compared to the conventional process based on minimum selling price (MSP), and global warming potential (GWP). The MSP for L-LA was evaluated to be 0.83 USD /kg L-LA, and the GWP was assessed to be 2.93 kg $CO_2$-eq/kg L-LA. These results represent a 25% reduction in MSP and a 32% reduction in GWP compared to the conventional process. Additionally, a sensitivity analysis was performed to identify the major cost drivers of MSP, such as interest rate, and the price of biomass. The proposed process, as a cost-effective and eco-friendly process, promotes biotechnology practices for sustainable production of L-LA.

**Keywords**: L-lactic acid, lignocellulosic biomass, alternative buffer, process development, techno-economic analysis

## INTRODUCTION

Climate change and food security remain critical challenges for sustainable development [1]. The global dependence on petroleum-based chemicals continues to drive environmental degradation and climate change [2]. To address these challenges, there is growing interest in producing chemicals and materials from renewable resources. Lignocellulosic biomass (LCB) offers a promising sustainable alternative to produce various bio-based materials [3]. One significant LCB-based chemical is lactic acid (LA), which has emerged as a key platform chemical, particularly important in the production of biodegradable plastics [4]. LA exists in two enantiomeric forms, with L-lactic acid (L-LA) being crucial for industrial applications due to its influence on the mechanical and thermal properties of polylactic acid (PLA) [5]. Consequently, numerous studies on LA microbial fermentation technologies focusing on high enantiomeric purity of L-lactic acid (L-LA) have been published, demonstrating the potential to improve the quality and application potential of LA-based products across various industries.

Microbial fermentation is widely used to produce L-LA with a high enantiomeric purity. As with other fermentation processes, the L-LA fermentation process requires various feedstocks, including fermentation medium and

other necessary materials. Buffers are particularly important for maintaining an optimal pH level to ensure the efficiency and yield of the process [6]. Notably, calcium-based buffers (e.g., $Ca(OH)_2$ and $CaCO_3$) are commonly preferred in commercial L-LA production due to their cost-effectiveness. However, using these buffers typically results in solid byproducts, such as gypsum ($CaSO_4$), which require disposal and create waste management challenges [7]. Therefore, an alternative buffer system could potentially address these issues by reducing waste and improving the sustainability of the L-LA production process.

In this work, we aim to develop and evaluate novel approaches for sustainable L-LA production using an alternative buffer (i.e., KOH). To achieve this goal, we first established a conventional L-LA production process as a baseline and developed a KOH recycling-based L-LA production (KRL) system incorporating buffer recycling technologies. We then evaluated the economic and environmental impacts of the proposed KRL systems and compared them with those of the conventional process. Additionally, sensitivity analysis was conducted to identify major cost drivers of proposed processes for cost reduction.

## TECHNOLOGY OVERVIEW AND ANALYSIS METHODS

### Process configuration

Fig. 1(a) represents the baseline L-LA production process, which uses $Ca(OH)_2$ as a buffer in the fermentation stages. After fermentation, $H_2SO_4$ is mixed to convert L-lactate to L-LA, and the gypsum is filtered out by centrifugation. Crude L-LA is separated and purified by reactive distillation units coupled with the synthesis and hydrolysis of methyl lactate. This baseline process demonstrates the established methodology and operational simplicity of the purification method. However, the generation of gypsum causes significant waste management problems.

In this study, we propose two novel KOH recycling-based L-LA production (KRL) configurations that incorporate advanced buffer recovery and regeneration technologies, as shown in Fig. 1(b) and (c). In the fermentation steps, KOH is used as a buffer to maintain the optimal condition for microbials. $H_2SO_4$ is substituted with HCl to convert L-lactate to L-LA. The use of HCl allows the KOH to be regenerated using alternative downstream processes. Solvent extraction and back-extraction units are employed for buffer recovery, L-LA separation, and purification. Solvent extraction effectively separates the impurities from the L-LA, while KCl releases the salts. The distillation unit purifies L-LA to high concentration by removing water and residual impurities while operating under vacuum conditions. The stream containing KCl is subjected to membrane filtration for conditioning. Alkaline water electrolysis decomposes KCl and water to regenerate KOH. This reaction also produces hydrogen ($H_2$) and chlorine ($Cl_2$) gases as byproducts. In addition, the first alternative configuration (KRL #1) employs gas treatment units to clean the byproduct gases. The purified byproduct gases can be sold, contributing to the economic potential of the process.

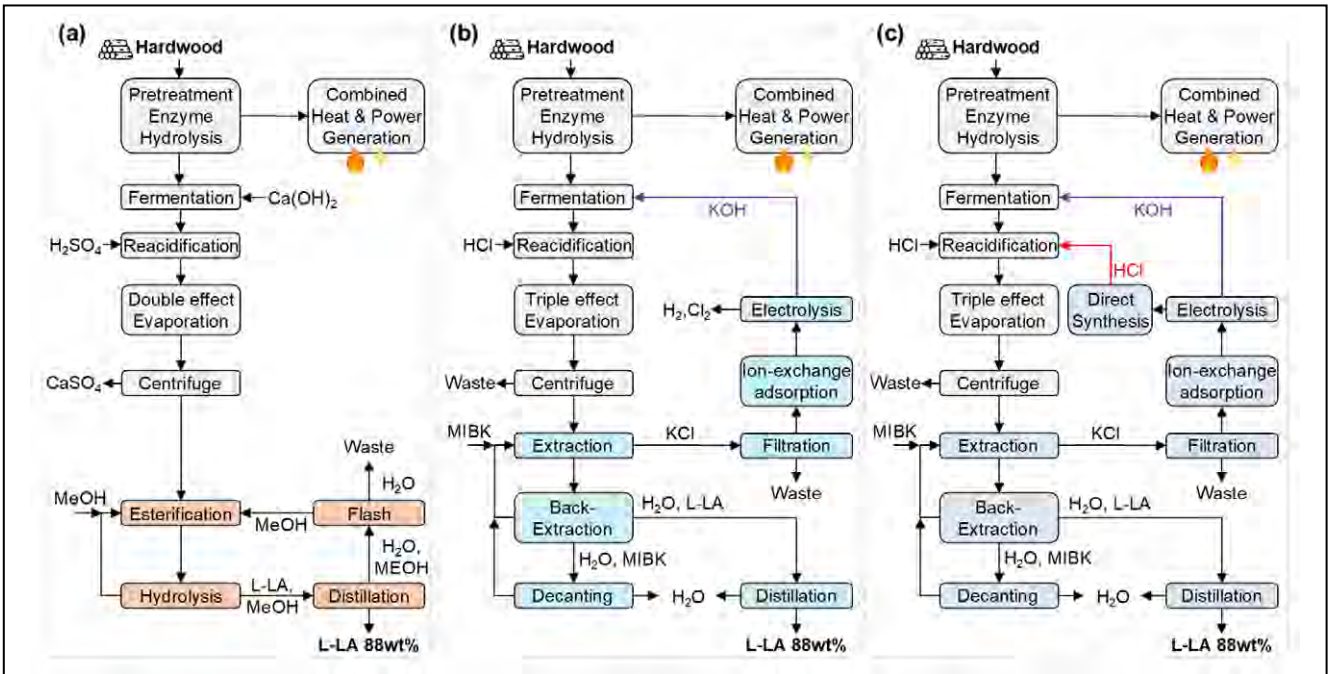

**Figure 1:** Block diagrams of the L-lactic acid production from lignocellulosic biomass. (a) baseline process; (b) KRL #1: KOH recycling-based process; (c) KRL #2: KOH and HCl recycling-based process.

On the other hand, as shown in Fig. 1(c), the second alternative configuration (KRL #2) includes HCl regeneration steps where $H_2$ and $Cl_2$ gases are reacted to produce an HCl solution. This HCl solution is then used in the reacidification unit to enhance the recycling loop. Accordingly, the novel KRL system offers key advantages over the conventional process through integrated recycling technologies. These improvements minimize raw material consumption and waste generation, thereby enhancing both economic viability and environmental sustainability.

## Technology overview

### Pretreatment and enzymatic hydrolysis

Pretreatment converts hemicellulose to sugars, degrading LCB for efficient enzymatic hydrolysis. In this area, LCB is treated in high-temperature dilute $H_2SO_4$ for degradation. It is then neutralized with ammonia to pH 5 for optimal enzymatic hydrolysis. This technique directly conditions the entire hydrolysate slurry without the need for solid-liquid separation, thereby improving sugar recovery [8]. Table S1 in Digital Supplementary Information (SI) presents the major reactions and process conditions.

In this study, the feedstock for the process is 1000 dry tons/day of Eastern cottonwood, a hardwood species. Hardwoods are widely used in bioprocessing due to their high cellulose and hemicellulose content and low inhibitor content compared to other biomass species. The composition of Eastern cottonwood is provided in Table S2 in SI. This composition is implemented in Aspen Plus V12.0 software using an in-house physical property NREL database to ensure an accurate representation of the biomass components [9].

### L-LA fermentation

Microbial fermentation is a preferred method for L-LA production due to its ability to achieve high optical purity. In this process, sugars derived from LCB are converted to L-LA by microbial metabolism. As a microbial strain, thermophilic Bacillus coagulans was used in this study due to its capability to co-utilize hexose and pentose sugars efficiently [10,11]. This co-utilization of carbon sources minimizes by-product formation and maximizes L-LA yield. The fermentation process uses $Ca(OH)_2$ or KOH as a buffer to maintain optimal pH levels. The buffer reacts with the L-LA released by the microbes to form L-lactate. This ensures stable microbial activity and improves L-LA productivity.

### Separation and purification

After fermentation, insoluble cellular material is first separated from the broth by centrifugation. Then, the crude L-lactate mixture is treated with a strong acid to convert L-lactate to L-LA in the acidification reactor. The crude L-LA stream is concentrated via a multi-effect evaporator unit. The conventional process employs the reactive distillation units to separate other impurities and purify L-LA. L-LA in the concentrated stream is converted into methyl L-lactate by esterification coupled with a distillation. Then, another reactive distillation unit for hydrolysis is used to decompose methyl L-lactate into L-LA and purify L-LA. The raw L-LA is purified to over 88wt% in the distillation column.

The novel configurations (KRL #1 and KRL #2) employ liquid-liquid extraction units with methyl isobutyl ketone (MIBK) as the extraction solvent to effectively remove heavy impurities from the concentrated stream. The extracted solution is back-extracted with water to transfer the L-LA and ions to the aqueous phase, leaving the light impurities to remain in the solvent. The MIBK solvent is then recovered by decanting and distillation. Finally, the aqueous L-LA stream is further concentrated and purified by evaporation and distillation to achieve the L-LA product of over 88wt% purity.

### Alkaline water electrolysis and acid gas synthesis

The regeneration of KOH is achieved through an integrated system involving the electrolysis of KCl. In the alkaline water electrolysis step, a fluorinated cation exchange membrane was used to decompose water and KCl. The membrane enables high current efficiency and low voltage operation, achieved through its selective ion transport properties and enhanced chemical stability under alkaline conditions [12]. Additionally, the electrolysis reaction also generates $H_2$ and $Cl_2$ gases as byproducts. In KRL #1, these by-product gases are purified and prepared for sale as chemical products. The $H_2$ gas from the alkaline water electrolysis achieves 99.97% purity through pressure swing adsorption using a molecular sieve hierarchical adsorbent. The adsorption columns operate at 30°C-35°C with pressure cycling up to 34 bar, resulting in the $H_2$ recovery of 91.9% [13]. The chlorine gas is dried through desorption using concentrated sulfuric acid, which effectively removes moisture to achieve a final purity of 99.99%. These high-purity byproducts provide a significant source of revenue. By contrast, KRL #2 uses these gases directly in the acid gas synthesis unit. The $H_2$ and $Cl_2$ gases react to form dry HCl gas. This gas is absorbed into deionized water to make an aqueous HCl solution, which is used in the reacidification unit.

## Process analysis method

The proposed processes were simulated and modeled using Aspen Plus V.12 software. We evaluated the economic and environmental impacts of the developed process with mass and energy balances obtained from the process simulation. In this study, the viability of the proposed process was evaluated against the conventional process based on minimum selling price (MSP), and global warming potential (GWP).

For the economic evaluation of the L-LA production

processes, the MSP was used as a primary indicator of economic viability. The MSP represents the product's sale price at the break-even point, where total revenue matches total expenses. The total revenue is generated from the sales of L-LA, while the total expenses include the annualized return on investment (ROI), fixed operating costs, and taxes.

The ROI was determined based on the total project investment (TPI), the interest rate, and the process lifetime, as in Eq. (1).

$$ROI = TPI \times \frac{i \times (1+i)^r}{(1+i)^r - 1} \quad (1)$$

where $i$ represents the interest rate, and $r$ denotes the lifetime of the process. The TPI, which includes both direct and indirect costs, was determined using cost estimation and scaling methods applied to simulation results. In addition, mass and energy balance data obtained from the process simulation were used to estimate the fixed and variable operating costs. Depreciation was calculated using Eq. (2). Income tax was determined based on the net income and applicable tax rate, as detailed in Eq. (3).

$$Depreciation = \frac{TPI}{Lifetime} \quad (2)$$

$$Tax = (Profit - Depreciation) \times Tax\ rate \quad (3)$$

Finally, the MSP was calculated by dividing the sum of the annualized ROI, total operating expenses, and taxes by the total amount of L-LA produced annually, as shown in Eq. (4).

$$MSP = \frac{ROI + Expense + Tax}{The\ amount\ of\ L\text{-}LA} [\$/kg_{L-LA}] \quad (4)$$

The GWP was assessed as an environmental performance metric through life cycle assessment (LCA) methodology, representing the total $CO_2$ equivalent emissions per unit of L-LA produced. The system boundary encompasses raw material extraction, transportation, utility, and waste treatment from manufacturing operations. The GWP analysis quantifies direct $CO_{2eq}$ emissions from process vent streams and indirect $CO_{2eq}$ emissions from utility consumption. It also takes account of emissions associated with waste disposal, input material production, and transport. The assessment followed ISO 14040 and 14044 standards, with inventory factors sourced from the Greenhouse gases, Regulated Emissions, and Energy use in Technologies (GREET) model [14].

## RESULTS AND DISCUSSION

### Simulation results

In this section, key operational parameters are discussed to provide a detailed understanding of the performance of each process. The operability of the proposed processes was assumed to be 7980 h operation per year. The baseline L-LA production process can produce 88wt% L-LA of 178,752 tons/year. The supplied amount of $Ca(OH)_2$ is 78,204 tons/year on a dry basis and then gypsum waste of 152,418 tons/year is removed via centrifugation after the reacidification unit. The downstream esterification and hydrolysis steps demonstrated a recovery efficiency of 94.9%.

Both KRL #1 and KRL #2 processes achieved an annual production of 197,673 tons/year of 88wt% L-LA. The supplied amount of KOH is 11,387 tons/year on a dry basis. The liquid-liquid extraction steps efficiently removed impurities, with an L-LA recovery efficiency of 85.7%. Separation and electrolysis units regenerated over 96.5% of the KOH supplied to the fermenters. The electrolysis units in KRL #1 produced byproduct gases, $H_2$ and $Cl_2$, at rates of 2,394 tons/year and 84,588 tons/year, respectively. In KRL #2, the HCl recovery rate exceeded 87.0% of the HCl supplied to the reacidification reactor,

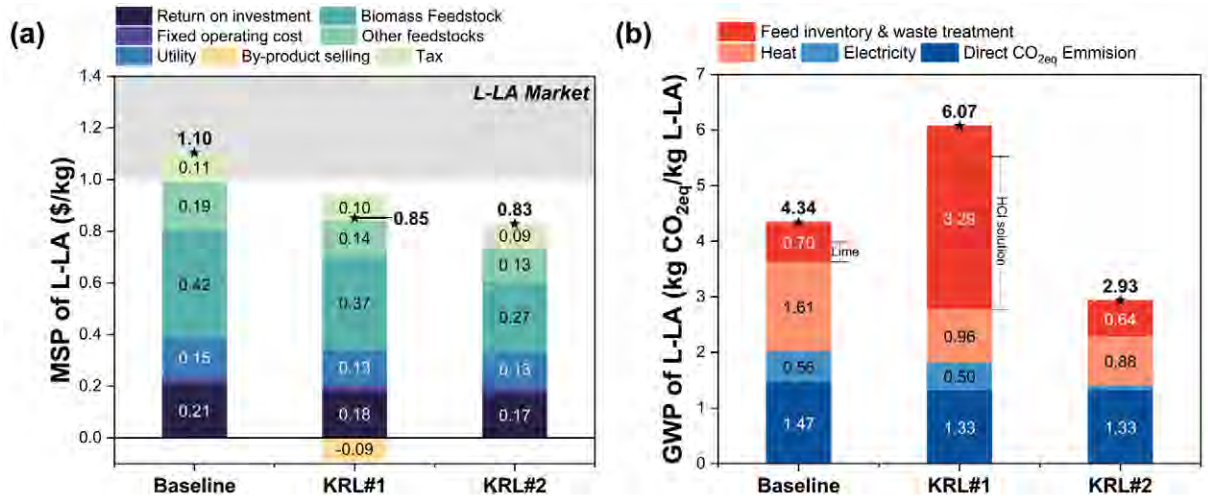

**Figure 2.** (a) MSP and (b) NCE of produced L-LA via the baseline and proposed processes

reducing the reliance on external inputs.

## Techno-economic and environmental analysis

The economic and environmental performance of the developed processes were evaluated using the MSP and GWP as key indicators. As shown in Fig. 2, the proposed KRL system leads to a decrease in the MSP of L-LA. One of the major drivers of this cost reduction was the higher L-LA production rate in the KRL processes compared to the baseline process. Additionally, the introduction of KOH, together with the implementation of advanced buffer recycling technologies, reduced the cost of buffer materials and waste disposal. The favorable results of KRL #2 can be attributed to the integration of effective regeneration and reuse of KOH, which are also present. These elements were further enhanced in KRL #2 through the integration of the HCl recycling loop, optimizing material utilization and reducing production costs. As a result, KRL #2 achieved an MSP of 0.83 $/kg, representing a 25% reduction compared to the baseline MSP of 1.10 $/kg.

In terms of environmental performance, the baseline process demonstrated a relatively higher GWP compared to KRL #2, attributed to the substantial use of $Ca(OH)_2$ and the indirect emissions from utility consumption. KRL #1 exhibited a GWP of 3.45 kg $CO_{2\text{-eq}}$/kg L-LA, which represents an increase of 40% compared to the baseline process. This is due to the energy-intensive electrolysis and high consumption of HCl. Conversely, KRL #2 exhibited the lowest GWP of 2.93 kg $CO_{2\text{-eq}}$/kg L-LA, showing a reduction of 51% relative to the baseline process. The recycling of HCl in KRL #2 significantly reduced material consumption, reducing the $CO_{2eq}$ inventory of raw materials.

## Sensitivity analysis

A sensitivity analysis was performed to identify the key economic parameters influencing the MSP of L-LA. The sensitivity analysis evaluated how much MSP of L-LA would change if the economic parameters varied by ±20%, as presented in Fig. 3. The detailed values of major economic parameters used in the sensitivity analysis are provided in Table S3 in SI. For the baseline process, the interest rate was the most sensitive factor on MSP, affecting a change of up to +4.69%. The biomass feedstock price was the second largest influential factor, with a ±2.63% variation. For the KRL processes, the interest rate was also the most sensitive factor, with a change of up to 5.20%. Biomass feedstock is another sensitive factor, causing a variation of ±3.08% and ±3.17% in KRL #1 in KRL #2, respectively. Consequently, we identified the interest rate and biomass feedstock price as the main cost drivers influencing the MSP of the developed processes. These results indicate the importance of optimizing these parameters to improve the economic viability of L-LA production.

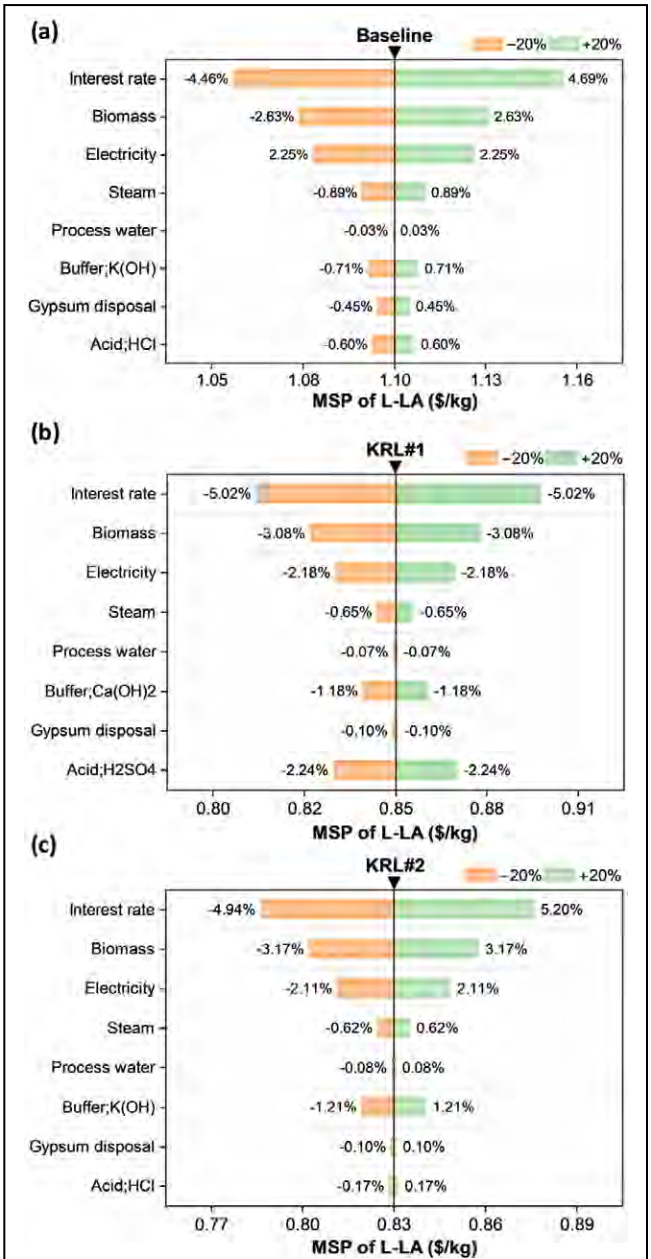

**Figure 3.** Sensitivity of the major economic parameters on the MSP

## CONCLUSIONS

This study developed the conventional L-LA production process and the novel KOH recycling-based L-LA production system for producing high enantiomeric purity of L-LA from LCB. Then we evaluated the economic and environmental performances of the developed

processes. Then we evaluated the economic and environmental performances of the developed processes. In economic evaluation, KRL #1 exhibited improved economics due to cost reduction from buffer recycling and byproduct utilization. KRL #2 demonstrated the best improvements in economic performance by incorporating HCl solution synthesis units. The MSP of L-LA was 0.83 $/kg for KRL #2 and 0.89 $/kg for KRL #1, representing cost reductions of 23% and 25%, respectively, compared to the baseline process. However, the environmental performance of KRL #1 was limited by the significant electricity demand and the extensive use of HCl. Conversely, the GWP of L-LA via KRL #2 was 2.93 kg $CO_{2\text{-eq}}$/kg, representing a 51% reduction compared to the baseline process. Furthermore, the sensitivity analysis revealed that the interest rate and biomass feedstock price are the main cost drivers. Addressing these key economic drivers will be essential to further enhance the viability of the developed L-LA production processes. This study highlights the potential of integrating advanced recycling technologies to achieve both economic and environmental benefits, promoting biotechnology practices for sustainable production of L-LA.

## ABSTRACT

Hydrogen ($H_2$), as the promising alternative to fossil fuel-based energy carriers, faces the critical challenge of diversifying its sources and lowering production costs. Biogas, produced from organic waste, offers a renewable and carbon-neutral option for $H_2$ production, but its high $CO_2$ content requires a pre-separation process of $CO_2$ from $CH_4$ or specialized catalysts for use in existing reforming processes. Chemical looping reforming (CLR), as an advanced $H_2$ production process, uses an oxygen carrier (OC) as the oxidant, allowing raw biogas to be used directly in the reforming process. Recently, numerous studies on CLR design and analysis have demonstrated their growing economic feasibility. However, deploying the CLR process in the biogas treatment industry requires further research to analyze its technical, economic, and environmental performance under target capacities and $H_2$ purity. This study proposes biogas-based CLR processes and analyzes the capability of the processes from techno-economic and environmental perspectives: i) chemical looping partial oxidization (CLPO), ii) chemical looping steam reforming (CLSR), iii) chemical looping water splitting (CLWS), and iv) chemical looping $CO_2$ splitting (CLCS). Evaluation metrics include energy efficiency, exergy efficiency, unit production cost (UPC), and net $CO_2$ equivalent emission (NCE) to compare technical, economic, and environmental performance, respectively. Each process is simulated in Aspen Plus to obtain mass and energy balance data. The heat exchanger network (HEN) is optimized to maximize heat recovery and achieve autothermal conditions. As a result, we comparatively analyze the economic and environmental capability of the proposed processes by identifying the major cost drivers and $CO_2$ emission contributors.

**Keywords**: Renewable and Sustainable Energy, Process Synthesis, Hydrogen, Chemical Looping, Technoeconomic Analysis.

## INTRODUCTION

As the demand for sustainable energy systems intensifies, hydrogen ($H_2$) has emerged as a significant energy carrier capable of decarbonizing in heavy industry and long-distance transportation [1]. Currently, most of the global $H_2$ production relies on fossil fuel-based processes, notably steam methane reforming (SMR), which emits substantial amounts of $CO_2$ into the atmosphere [2]. While water electrolysis powered by renewable energy offers a carbon-neutral alternative, its widespread implementation faces significant economic and logistical barriers, particularly due to the high cost and the intermittent availability of renewable energy sources [3]. As such, innovative reforming technologies that achieve a balance between cost-effectiveness and environmental sustainability are needed to enable a smooth energy transition.

Biogas, a renewable energy source produced through the anaerobic decomposition of organic waste, presents an attractive feedstock for sustainable $H_2$ production [4]. Unlike natural gas, biogas is composed primarily of $CH_4$ and $CO_2$. The high $CO_2$ content of biogas poses technical challenges for conventional reforming technologies, requiring either costly pre-separation of $CO_2$ from $CH_4$ or advanced systems capable of directly

processing $CO_2$-rich feedstocks [5][6]. However, when its $CO_2$ content is effectively utilized, biogas can offer a carbon-neutral pathway. Therefore, the need for reforming technologies that can efficiently exploit the potential of biogas without incurring additional separation costs is increasing.

Chemical looping reforming (CLR) has emerged as a next-generation $H_2$ production technology capable of overcoming many of the limitations associated with traditional reforming technologies. In CLR processes, a solid metal oxygen carrier (OC) facilitates redox reactions, enabling the direct utilization of raw biogas without the need for prior $CO_2$ removal [7]. This innovative process can achieve autothermal conditions that improve both energy and operational efficiencies while integrating inherent $CO_2$ capture capabilities that reduce carbon management costs. These combined advantages make CLR processes a cost-competitive pathway for sustainable $H_2$ production [8].

Despite the promising characteristics of CLR process, its practical application in the biogas industry remains limited. Further research is necessary to evaluate the performance of CLR processes under various configurations and operating scales. This study aims to evaluate the performance of four different CLR process configurations: i) chemical looping partial oxidation (CLPO), ii) chemical looping steam reforming (CLSR), iii) chemical looping water splitting (CLWS), and iv) chemical looping $CO_2$ splitting (CLCS). Through a comprehensive analysis of their technical, economic, and environmental performance, this research seeks to identify viable processes for integrating CLR processes into sustainable $H_2$ production systems, while also identifying key cost drivers and key environmental impact variables.

## TECHNOLOGY OVERVIEW AND METHODOLOGY

### Technology overview

### Chemical looping partial oxidization (CLPO)

The CLPO process consists of two reactors: a reducer and a combustor. In the reducer, biogas is partially oxidized with the OC, producing syngas while reducing the OC. The reduced OC is then transported to the combustor, where it is fully regenerated with air, releasing significant heat. This heat is used to sustain the endothermic reactions in the reducer as the OC circulates back, ensuring efficient heat transfer. The overall thermal balance is maintained by an optimized heat exchanger network (HEN). The reducer employs a moving bed reactor design, which facilitates countercurrent contact between the biogas and the OC, thereby enhancing reaction efficiency and maximizing syngas yield [9]. Conversely, the combustor utilizes a fluidized bed reactor to ensure uniform temperature distribution and efficient heat transfer [10]. Downstream of the reducer, the syngas undergoes a water-gas shift (WGS) reaction to increase its $H_2$ content. A monoethanolamine (MEA)-based $CO_2$ absorption process is then used to capture $CO_2$ and reduce greenhouse gas emissions, followed by pressure swing adsorption (PSA) is employed to produce high-purity $H_2$.

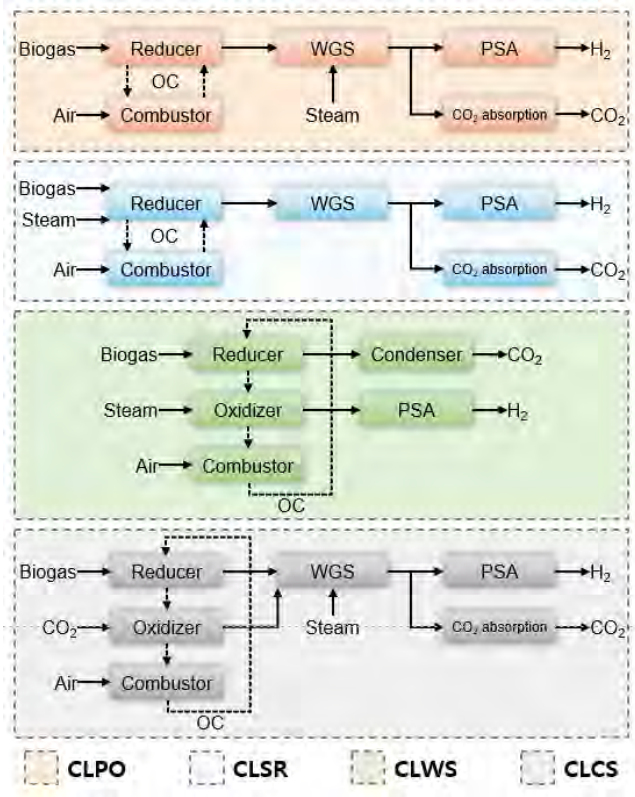

**Figure 1.** Process flow diagram of CLR processes.

Key reactions in the CLPO process:

Reducer:

$$Fe_2O_3 + CH_4 \rightarrow Fe/FeO_{0.947} + CO + H_2, \Delta H > 0 \quad (1)$$

Combustor:

$$Fe/FeO_{0.947} + O_2 \rightarrow Fe_2O_3, \Delta H < 0 \quad (2)$$

WGS reactor:

$$CO + H_2O \rightarrow CO_2 + H_2, \Delta H < 0 \quad (3)$$

### Chemical looping steam reforming (CLSR)

Building on the CLPO configuration, the CLSR process introduces steam into the reducer to enable simultaneous SMR reaction. While the addition of steam requires more energy, it substantially increases the $H_2$ yield due to the SMR reaction. The reduced OC is subsequently regenerated in the combustor, as in CLPO, while the syngas undergoes WGS to enhance $H_2$ content, MEA-based $CO_2$ absorption for carbon capture, and PSA for $H_2$ purification. Similar to CLPO, the CLSR process uses a

moving bed reducer for enhanced biogas and steam reactions, paired with a fluidized bed combustor for efficient heat recovery.

Key reaction in the CLSR process:

SMR reaction in reducer:

$$CH_4 + H_2O \rightarrow CO + 3H_2, \Delta H > 0 \quad (4)$$

## Chemical looping water splitting (CLWS)

In addition to the reducer and combustor, the CLWS process introduces a third reactor, the oxidizer. In the reducer, the biogas undergoes complete oxidization with the OC, producing flue gas containing only $N_2$, $CO_2$ and $H_2O$. The water in the flue gas is removed by condensation, leaving $CO_2$, which is then captured at a relatively low quality. The reduced OC is partially re-oxidized with steam in the oxidizer, directly producing $H_2$. By enabling water splitting, the CLWS process eliminates the need for a WGS and MEA-based $CO_2$ absorption process and simplifies the downstream $H_2$ purification steps to just a condenser and a PSA unit. The oxidizer is designed as a moving bed reactor, ensuring an efficient water splitting reaction. The OC is fully regenerated in the combustor before being returned to the reducer.

Key reactions in the CLWS process:

Reducer:

$$Fe_2O_3 + CH_4 \rightarrow FeO_x + CO_2 + H_2O, \Delta H > 0 \quad (5)$$

Oxidizer:

$$FeO_x + H_2O \rightarrow FeO_y + H_2, \Delta H < 0 \quad (6)$$

Combustor:

$$FeO_y + O_2 \rightarrow Fe_2O_3, \Delta H < 0, (x \leq y \leq 1.33) \quad (7)$$

## Chemical looping $CO_2$ splitting (CLCS)

The CLDR process, like the CLWS process, consists of a reducer, oxidizer, and combustor, but differs in that $CO_2$ is used as the oxidant in the oxidizer, allowing for a $CO_2$ splitting reaction. In the reducer, biogas goes through partial oxidation, to produce syngas, while $CO_2$ in the oxidizer partially regenerate the OC, producing CO. The resulting syngas and CO are sent to the WGS reactor along with steam, which increases the $H_2$ production by converting $H_2O$ and CO into $H_2$ and $CO_2$. The $H_2$-rich stream undergoes MEA-based $CO_2$ absorption for carbon capture, followed by PSA for further $H_2$ purification. Unlike other CLR processes, the CLDR process involves a highly endothermic $CO_2$ splitting reaction, using $CO_2$ as an oxidant in the oxidizer. Thus, to maintain autothermal conditions, heat generated in the combustor is recovered and transferred to the oxidizer through a jacketed reactor. This ensures that the energy required for oxidizer is supplied efficiently, providing stable and energy-efficient operation.

Key reaction in the CLDR process:

Oxidizer:

$$FeO_x + CO_2 \rightarrow FeO_y + CO, \Delta H > 0, (x \leq y \leq 1.33) \quad (8)$$

## Model description

For process simulation and optimization, the commercial process simulator Aspen Plus is used as the primary modeling tool. The Peng-Robinson-Boston-Mathias (PR-BM) equation of state is selected to accurately represent the thermodynamic properties of all units. The CLR reactions are simulated using the Gibbs free energy minimization method, to achieve equilibrium-based calculations for the redox reactions. The CLR reactors are designed to operate near atmospheric pressure. All processes are designed to operate under heat-neutral conditions. To ensure thermal balance and enhance $H_2$ yield, heat integration is performed using an optimized HEN. The HEN is designed using Aspen Energy Analyzer to ensure efficient energy recovery and the autothermal operating conditions. Product specifications are set for high-purity $H_2$ and $CO_2$ streams at industrially relevant pressures. In all configurations, biogas and other feed streams, such as water and air, are preheated to the same temperature before entering the reforming reactors to ensure consistent evaluation criteria, with feedstock and OCs also having identical compositions.

## Evaluation method

The performance of the CLR processes is evaluated from three perspectives: thermodynamic efficiency, economic performance, and environmental impact. From a thermodynamic perspective, energy efficiency and exergy efficiency are calculated to assess the ability of the process to convert input energy to useful $H_2$ with minimal losses. Energy efficiency, expressed as $\eta_{energy}$, is defined as the ratio of the chemical energy in the $H_2$ product to the total energy input, including feedstock and external utilities.

$$\eta_{energy} = \frac{\dot{P}_i \times LHV_i}{\sum(\dot{F}_i \times LHV_i) + \sum U_j} \quad (9)$$

Here, $\dot{P}_i$ represents the molar flow rate of the $H_2$ product, while $LHV_i$ denotes the lower heating value of each material. Similarly, $\dot{F}_i$ corresponds to the molar flow rate of the feedstock, and $\sum U_j$ indicates the total external energy input.

Exergy efficiency, denoted as $\eta_{Exergy}$, measures the capacity of the process to minimize the loss of energy during the conversion processes.

$$\eta_{Exergy} = \frac{\dot{E}x_{in,total} - \dot{E}x_{des,total}}{\dot{E}x_{in,total}} = \frac{\dot{E}x_{out,total}}{\dot{E}x_{in,total}} \quad (10)$$

In eq. 10, $\dot{E}x_{in,total}$ is the total input exergy, $\dot{E}x_{out,total}$, is the total output exergy, and $\dot{E}x_{des,total}$ represents the exergy destroyed within the process.

The economic performance of the processes is evaluated using the unit production cost (UPC) of $H_2$. The total investment cost includes both capital expenditure (CAPEX) and operating expenditure (OPEX). CAPEX is calculated from the annualized capital investment (ACI), which is derived from the total capital investment (TCI). TCI comprises direct plant cost (DC), indirect plant cost (IDC), and working capital (WC). The capital recovery factor (CRF), calculated using Eq. 11, is used to annualize the capital costs.

$$CRF = \frac{i \times (1+i)^r}{(1+i)^r - 1} \tag{11}$$

Where $i$ is the interest rate and $r$ is the plant lifetime. Using the CRF, the ACI is calculated based on eq. 12.

$$ACI = TCI \times CRF \tag{12}$$

OPEX accounts for both variable operating costs (VOC) and fixed operating costs (FOC). Finally, the UPC of $H_2$ is determined by dividing the total annualized cost by the annual $H_2$ production ($P_{H_2}$).

$$UPC = \frac{ACI + VOC + FOC}{P_{H_2}} \tag{13}$$

From an environmental perspective, the processes are analyzed based on their net $CO_2$ equivalent emission (NCE), which reflects the total $CO_2$ emissions per kilogram of $H_2$ produced. NCE includes direct $CO_2$ emissions (DCE) from the process, indirect $CO_2$ emissions (ICE) associated with energy inputs, and carbon credits (CC). The CC is calculated as the net difference between the $CO_2$ reduction effect of biomass and the $CO_2$ emissions from biogas production [11]. The NCE is calculated using eq. 14.

$$NCE = \frac{DCE + ICE - CC}{P_{H_2}} \tag{14}$$

## RESULT AND DISCUSSION

### Techno-economic and environmental analysis

The energy and exergy efficiencies of the four CLR processes are shown in Fig. 2. The CLSR process demonstrates the highest thermodynamic performance, achieving energy and exergy efficiencies of 49% and 47%, respectively, due to its high $H_2$ yield from SMR reaction and effective heat recovery strategies via the HEN. Closely following CLSR, the CLCS process achieve comparable efficiencies of 48% and 47%. Although its high $H_2$ production contributes significantly to performance, the strong heat demands of the $CO_2$ splitting reaction slightly limits its overall efficiency. In contrast, the CLPO process shows the lowest performance, with efficiencies of 23% and 22%, mainly due to the imbalance between endothermic heat in the reducer and excessive heat generation in the combustor, resulting in significant thermal losses. The CLWS process shows intermediate performance, with efficiencies of 43% and 42%, respectively. While its effective heat recovery strategy supports reasonable performance, its lower $H_2$ yield limits its thermodynamic efficiency compared to CLSR and CLCS.

Taken together, the CLR processes, except CLPO, exhibit similar process efficiencies due to HEN designs optimized for autothermal conditions. The CLPO process exhibits lower efficiency due to heat imbalance, suggesting that advanced heat recovery strategies such as combined heat and power plant can effectively address this limitation and improve performance.

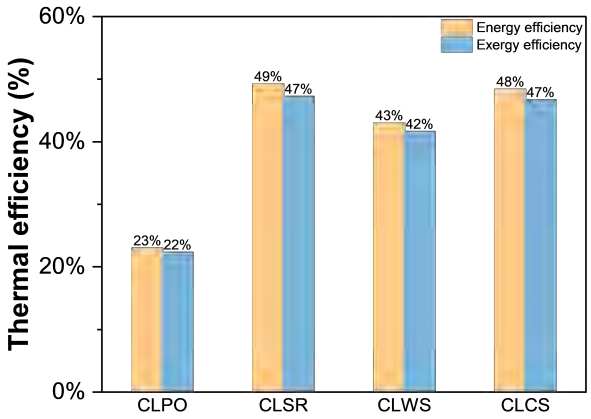

**Figure 2.** Thermal efficiencies of CLR processes.

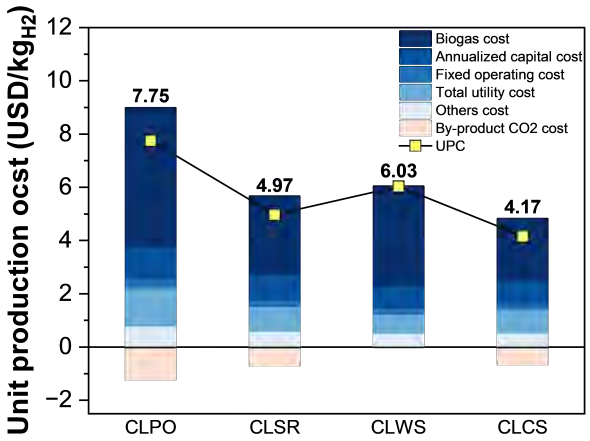

**Figure 3.** Unit production costs of CLR processes.

The economic performance of the four CLR processes is evaluated based on their UPC (USD/kg$_{H_2}$), as shown in Fig 3. Among the processes, the CLCS process achieves the lowest UPC of 4.17 USD/kg$_{H_2}$, benefiting from reduced biogas cost by producing additional $H_2$ through the utilization of CO. In contrast, the CLPO process has the highest UPC at 7.75 USD/kg$_{H_2}$, primarily due to its higher operating energy requirements and lower $H_2$ yield. The CLSR and CLWS processes show mid-range

UPC of 4.97 USD/$kg_{H_2}$ and 6.03 USD/$kg_{H_2}$, respectively. The relatively lower cost of CLSR can be attributed to the integration of steam reforming, which enhances the $H_2$ yield. On the other hand, the CLWS process has higher UPC due to a lack of by-product $CO_2$ credit, attributed to the relatively low-quality of the captured $CO_2$. A comprehensive evaluation of the results shows that biogas cost, energy inputs, and capital expenditures emerge as the primary cost drivers for all processes.

The environmental performance of the CLR processes is evaluated based on their NCE ($kg_{CO_2eq}/kg_{H_2}$), as shown in Fig. 4. Among the processes, the CLWS process demonstrates the most environmentally favorable

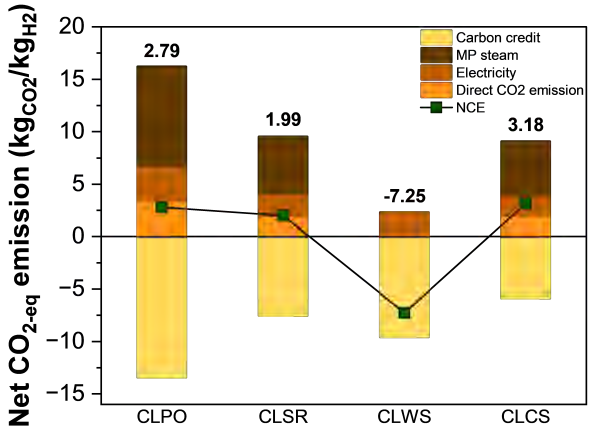

**Figure 4.** Net $CO_2$ equivalent emissions of CLR processes.

outcome, achieving a negative emission of -7.25 $kg_{CO_2eq}/kg_{H_2}$. This carbon-negative result stems from the ability to capture $CO_2$ internally without the need for an MEA-based $CO_2$ absorption process, thereby significantly reducing both indirect and direct $CO_2$ emissions. In contrast, the CLCS process exhibits the highest emissions at 3.18 $kg_{CO_2eq}/kg_{H_2}$, primarily due to the significant thermal energy required for $CO_2$ capture. The CLSR and CLPO processes show moderate results, with net emissions of 1.99 $kg_{CO_2eq}/kg_{H_2}$ and 2.79 $kg_{CO_2eq}/kg_{H_2}$, respectively. The results highlight the significant environmental benefits of the CLWS process and demonstrate its potential for carbon-negative $H_2$ production. It is also observed that the presence or absence of an MEA-based $CO_2$ absorption process has the greatest impact on the overall $CO_2$ equivalent emissions of the process. Therefore, further in-depth research on $CO_2$ separation technologies is essential to improve the environmental performance of CLR processes.

## Sensitivity analysis

A comprehensive techno-economic assessment of the four CLR processes identify biogas cost, energy inputs, and capital expenditures as critical factors influencing the UPC of $H_2$. To quantify their economic impact, a sensitivity analysis is conducted on key parameters, including biogas price, interest rate, plant lifetime, and utility prices.

The sensitivity analysis results for the four CLR processes (Fig. 5) highlight that biogas price is the most

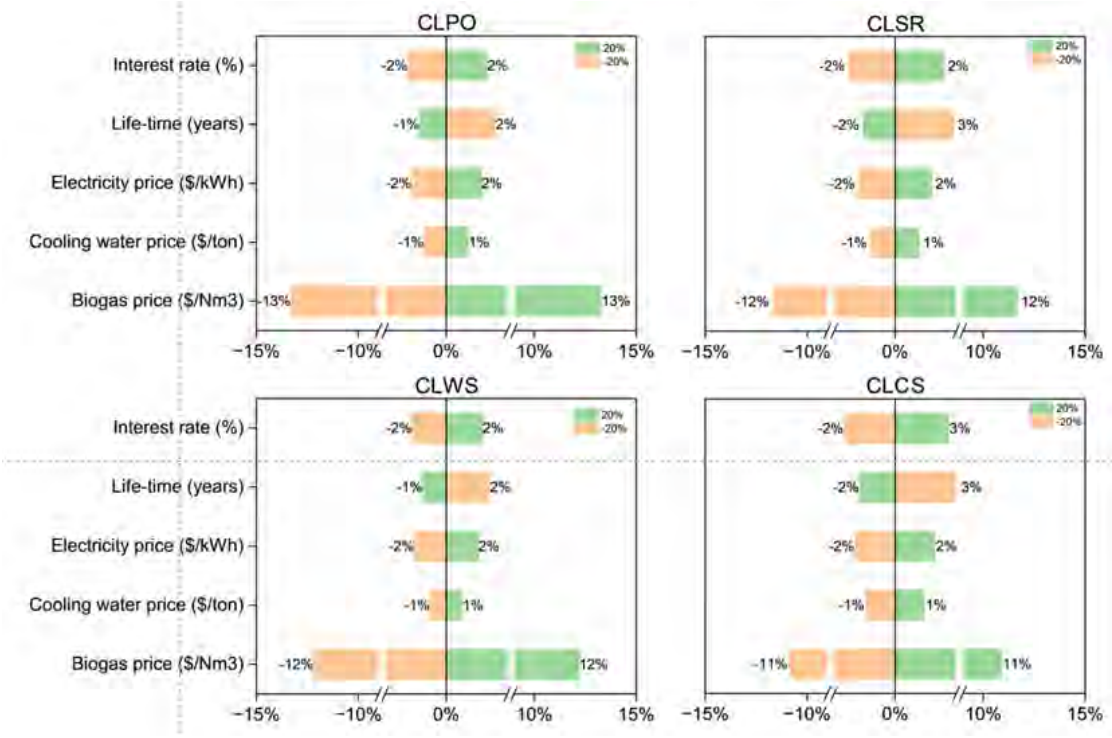

**Figure 5.** Sensitivity anlaysis results of CLR processes.

influential factor affecting the UPC of $H_2$. A 20% increase in the biogas price leads to a corresponding UPC rise of approximately 11-13% across all processes, highlighting the critical role of the biogas price in the economics of $H_2$ production. Moreover, capital related parameters such as interest rate and plant lifetime have an impact. A 20% increase in the interest rate increases UPC by about 2% while extending the plant lifetime by 5 years decreases it by 2%. Similarly, operational parameters such as electricity price and cooling water price show effects, with UPC variations of ±2% and ±1%, respectively. The analysis identify biogas price, capital related parameters, and utility prices as the dominant factors influencing the economics of CLR processes. Prioritizing strategies to reduce biogas costs and optimize capital and operating expenditures will be essential for improving economic viability of CLR processes.

## CONCLUSION

This study evaluated four CLR processes: CLPO, CLSR, CLWS, and CLCS for $H_2$ production from biogas, focusing on their techno-economic and environmental performance. Among the processes, CLCS emerged as the most promising option, offering a balanced performance with thermal efficiency and economic benefits due to effective $CO_2$ utilization and reduced biogas costs. The CLSR process showed strong potential with competitive production costs and high $H_2$ yields. The CLWS process achieved carbon reduction, demonstrating its potential as a negative carbon emission technology, although its higher cost remains a challenge. In contrast, the CLPO process had the lowest performance across all criteria, indicating the need for further advancement to enhance its feasibility and performance. To enable the industrial application of CLR processes in the biogas industry, advances in $CO_2$ capture technologies, heat integration, and process optimization are essential. This study demonstrates the feasibility of biogas-based CLR processes for scalable, sustainable $H_2$ production, providing a pathway toward carbon-neutral energy solutions.

## ABSTRACT

Electrified steam methane reforming has emerged as a promising technology for electrifying the hydrogen production process industries. Unlike conventional fossil fuel-based steam methane reforming, the electrified steam methane reforming process relies exclusively on electrical heating, eliminating the need for fossil fuel combustion. Beyond that, however, significant amounts of electricity required for the electrified process should be imported from the renewable energy-based system rather than fossil fuel-based grid electricity to have an environmental advantage over the conventional process. This study suggests a framework for integrating renewable energy systems into the electrified process for decarbonized hydrogen production. Considering the variability of renewable energy, wind and solar power are supplemented by battery storage, to facilitate a stable electricity supply to the electrified hydrogen production process. A Mixed-Integer Linear Programming (MILP) model is developed to optimally size and operate both the renewable system and potential grid imports. Case studies under various carbon tax scenarios, using historical weather data from a region in Germany, are conducted, followed by a techno-economic assessment to estimate the Cost of Hydrogen (COH). The results show that higher carbon taxes and reduced capital costs for wind, solar, and storage technologies significantly increase the share of renewable-based electricity. These findings highlight the importance of more stringent carbon taxation and improvements in the technology readiness level (TRL) of renewable energy are critical for accelerating large-scale, clean hydrogen production and industrial decarbonization.

**Keywords**: Hydrogen, Renewable energy, Electrification

## 1. INTRODUCTION

Interest in sustainable hydrogen production has increased as hydrogen becomes more widely recognized as a clean energy source and a vital chemical feedstock. Among the different strategies for producing hydrogen, furnace heated steam methane reforming (SMR) is widely regarded as an economic solution for large-scale hydrogen production. However, it requires significant heat energy, which results in a large amount of $CO_2$ emissions. To address these challenges, Wismann et al. [1], in collaboration with Haldor Topsoe, developed an innovative "Electric Heating Steam Methane Reformer", providing a promising eco-friendly alternative to the conventional fossil fuel-based furnace heating technology.

Several studies were investigated, regarding the process design and economic analysis of electrified hydrogen production [2-5]. However, these studies mainly focused on the electrified hydrogen production process itself, with relatively limited consideration of feasibility about introducing renewable energy sources at a commercial scale of the electrified process. Nava et al. [6] considered renewable energy integration for hydrogen production process, but it mainly focused on biogas-based hydrogen production and a relatively small scale of the process [7].

This study provides conceptual guidelines for the clean and sustainable production of hydrogen through

renewable-powered electrification, contributing to the decarbonization of the hydrogen industry and the global energy transition.

## 2. METHODOLOGY

Building upon our previous work on process guidelines and techno-economic analysis for large-scale electrified hydrogen production hydrogen production [5], this study introduces a renewable energy system (RES) model to supply electricity for the process. The integration of renewable energy sources, such as solar and wind, into hydrogen plants requires systematic consideration of their intermittent characteristics due to their dependence on weather conditions.

To ensure a reliable energy supply for the electrified hydrogen plant, battery storage systems and grid are introduced to store any surplus energy or supplement energy in deficit. To effectively manage these fluctuations, a system-wide optimization approach is employed to integrate renewable energy systems, ensuring reliable energy supply and high energy efficiency.

The proposed framework includes process modelling and simulation for the electrified hydrogen plant (**Figure 1**) is developed, with a focus on renewable energy integration. Case studies are conducted to investigate configurational and operational changes of renewable energy systems integrated with electrified hydrogen production process. A techno-economic assessment for these case studies is to estimate the Cost of Hydrogen (COH), which enhances our understanding on the economic feasibility of renewable-based electrification for hydrogen production.

## 3. PROBLEM DEFINITION

In this study, among various configurations of the electrified hydrogen production, the most cost-effective $CO_2$ capture integrated electrified hydrogen production process alternative is selected. Heat integration is applied throughout the electrified hydrogen production process, and an electric boiler is used to provide the additional low-pressure steam required for the $CO_2$ capture process. Based on simulation results using Aspen HYSYS, the estimated total power consumption for this large-scale electrified hydrogen production process is 424.1 MWe. The techno-economic analysis of the large-scale electrified hydrogen production process was conducted, assuming that an unlimited and consistent supply of renewable energy is available at a given renewable energy-based electricity cost. A break-even point of the renewable electricity cost was identified, at which the electrified hydrogen production option might be more economical than the conventional hydrogen production process.

However, in practical circumstances, it is difficult to continuously provide 424.1 MWe of renewable-based power [8]. Therefore, in this study, the large-scale electrified hydrogen production process is reduced in size to a tenth of its initial size, requiring 42.4 MWe of constant power, which is still a commercial-scale hydrogen plant, as shown in **Table 1**.

The main objective of this study is to develop a model of a renewable energy system (RES) employing an optimized combination of wind turbines (WT), solar photovoltaic (PV) arrays, and electrical energy storage (EES), with grid electricity support, to provide the steady power required for the electrified hydrogen production process.

The 2023 annual weather data for the German region of Freiburg im Breisgau, including wind speed and solar radiation, is adopted for the case study [9]. By using realistic weather data, the time-dependent characteristics of solar and wind power generation are fully considered in the RES model. The capacity of each renewable power generation facility, including WT, PV, and EES, and their hourly operating conditions, are determined using an optimization framework to minimize the COH.

COH breakdown of the electrified hydrogen production hydrogen plant, without electricity and the carbon tax is shown in **Table 1**. The utility cost, including natural gas and grid electricity, has been updated to 2023 German industrial price of 41€/MWh and 95.18 €/MWh, respectively [10-11]. The other economic parameters used are referred to the previous study [5]. The COH for electricity and carbon tax is estimated in the case study section that provides a full breakdown based on the modeling and simulation results of renewable energy system.

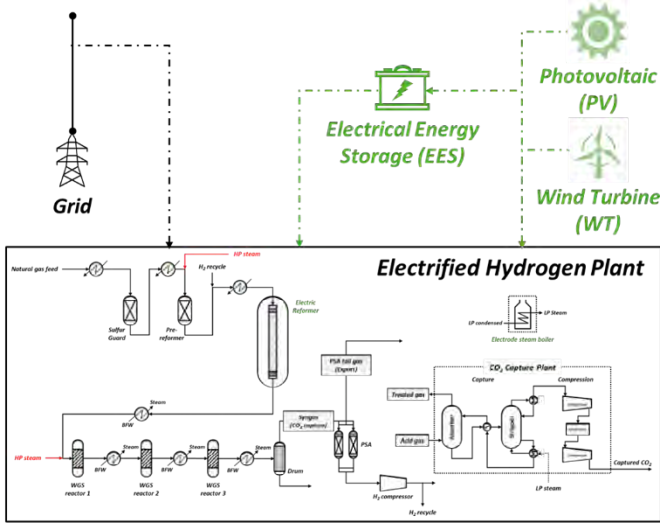

**Figure 1.** An electrified hydrogen production hydrogen plant integrated with renewable energy and grid

**Table 1:** Key Process Performance Data & Cost of Hydrogen Breakdown for the Electrified Hydrogen Production Process

| | Unit | Ref. [5] | Case study |
|---|---|---|---|
| **Performance** | | | |
| Natural gas | t/h | 63.9 | 6.4 |
| Power consumption | $MW_e$ | 424.1 | 42.4 |
| $H_2$ Production | t/h | 22.8 | 2.3 |
| **Cost of Hydrogen** | | | |
| Capital | $/kg | 0.26 | 0.82 |
| Fixed O&M | $/kg | 0.09 | 0.31 |
| Variable O&M | $/kg | 0.07 | 0.15 |
| Natural gas | $/kg | 1.81 | 1.81 |
| Electricity (RES) | $/kg | 1.91 | TBD |
| Carbon tax | $/kg | - | TBD |
| Total | $/kg | 4.14 | TBD |

## 4. OPTIMIZATION MODEL

A mathematical model is developed for a renewable energy system (RES) to provide electricity required for the electrified hydrogen production process. The values of design parameters of the RES model are presented in **Table 2**.

**Table 2:** Design Parameters of RES

| Parameter | Description | Value |
|---|---|---|
| $\eta$ | PV efficiency | 0.19 [12] |
| $\theta$ | Static loss of EES | 0.05 [13] |
| $\chi$ | Charge rate | 0.1 [13] |
| $\Delta\chi$ | Discharge rate | 0.15 [13] |
| $Demand$ | Electricity demand (MWh) | 42.4 [5] |
| $Rad(t)$ | Solar radiation (kWh/m$^2$) | Hourly data [9] |
| $v(t)$ | Wind Speed (m/s) | Hourly data [9] |
| $I_{POA}(Rad)$ | Plane of array irradiance (kWh/m$^2$) [12] | |
| $uE_{WT}(v)$ | Power performance of unit wind turbine [14] | |

The resulting MILP model of the RES is shown below. The equations regarding wind turbine and solar power generation are (1)-(3), and equations regarding electrical energy storage are (4)-(10). When the amount of renewable energy produced exceeds the demand for the electrified hydrogen production process, the renewable energy system is designed to use the generated renewable energy directly ($E_{DU}$) for the electrified hydrogen production process and store the remaining electricity in electrical energy storage (StoreIn) (Equations (4)-(6)). Static loss, charge rate, and discharge rate are all taken into consideration with the State of Charge (SOC) of the electrical energy storage (Equations (8)-(9)). Additionally, it is designed to have the same initial and final SOC, considering multiple-period operation (Equation (10)).

$$E_{WT}(t) = N_{WT} \cdot uE_{WT}(v(t)) \quad (1)$$

$$E_{PV}(t) = A_{PV} \cdot I_{POA}(Rad(t)) \cdot \eta \quad (2)$$

$$E_{Ren}(t) = E_{WT}(t) + E_{PV}(t), \quad \forall t \quad (3)$$

$$StoreIn(t) = E_{Ren}(t) - E_{DU}(t), \quad \forall t \quad (4)$$

$$Demand(t) = StoreOut(t) + Grid(t) + E_{DU}(t), \quad \forall t \quad (5)$$

$$SOC(t+1) = (1-\theta) \cdot SOC(t) + (1-\chi) \cdot StoreIn(t+1) - \frac{StoreOut(t+1)}{1-\Delta\chi}, \quad \forall t \quad (6)$$

$$SOC(t) \le CAP_{EES}, \quad \forall t \quad (7)$$

$$(1-\theta) \cdot SOC(t) + (1-\chi) \cdot StoreIn(t+1) \le CAP_{EES}, \quad \forall t \quad (8)$$

$$\frac{StoreOut(t+1)}{1-\Delta\chi} \le (1-\theta) \cdot SOC(t), \quad \forall t \quad (9)$$

$$SOC(0) = SOC(8760) \quad (10)$$

To determine the optimal design and operating condition of the renewable energy system, the cost of hydrogen (COH) is defined as an objective function of optimization. As shown in equations (11)-(20), the cost of hydrogen (COH), is estimated considering the total annual cost (TAC) and the annual hydrogen production ($Prod_{H2}$). Capital expenditures (CAPEX) considering maximum capacity for WT, PV systems, and electrical energy storage (EES), as well as operating expenditures (OPEX) for these facilities are included in TAC. Grid electricity import and carbon tax considering $CO_2$ emission factors for each technology are also included in TAC. All the costing parameters for the COH estimation of renewable energy system are shown in **Table 3**. The optimal set of design variables for the renewable energy system is determined by using the MATLAB optimization solver "intlinprog" to minimize COH while considering the set of constraints (Equations (1)-(10)).

**Table 3:** Costing parameters of RES

| Parameters | Unit | Values [15] |
|---|---|---|
| Natural gas price | €$_{2023}$/MWh | 41 [10] |
| Grid power unit price ($GP$) | €$_{2023}$/MWh | 95.18 [11] |
| $CO_2$ emission factor ($EF$) | g$CO_{2e}$/kWh | 13 (WT) [16]<br>43 (PV) [16]<br>744 (Grid) [16] |
| WT capital cost ($CC_{WT}$) | $$_{2023}$/kW | 1010.2 (Advanced)<br>1809.6 (Current) |
| WT O&M cost ($AOC_{WT}$) | $$_{2023}$/kWyr | 16.394 (Advanced)<br>32.252 (Current) |
| PV capital cost ($CC_{PV}$) | $$_{2023}$/kW | 562.6 (Advanced)<br>1610.9 (Current) |
| PV O&M cost ($AOC_{PV}$) | $$_{2023}$/kWyr | 11.381 (Advanced)<br>22.219 (Current) |
| EES capital cost ($CC_{EES}$) | $$_{2023}$/kW | 190.5 (Advanced)<br>520.1 (Current) |
| EES O&M cost ($AOC_{EES}$) | $$_{2023}$/kWyr | 15.879 (Advanced)<br>47.674 (Current) |
| Plant lifetime | yr | 30 [7] |
| Fixed charge rate ($FCR$) | 1/yr | 0.0586 [7] |
| Capacity factor | % | 90 [7] |
| Unit carbon tax ($CTAX_{unit}$) | $$_{2023}$/t$CO_2$ | 0 - 180 |

$$TAC = FCR \cdot (\sum CAPEX) + \sum(OPEX + CTAX) \quad (11)$$

$$CAPEX_{PV} = CC_{PV} \cdot \max_t E_{PV}(t) \quad (12)$$

$$CAPEX_{WT} = CC_{WT} \cdot \max_t E_{WT}(t) \quad (13)$$

$$CAPEX_{EES} = CC_{EES} \cdot CAP_{EES} + SOC(0) \cdot (GP + EF_{Grid} \cdot CTAX_{unit}) \quad (14)$$

$$OPEX_{PV} = AOC_{PV} \cdot \sum_t E_{PV}(t) / 8760 \quad (15)$$

$$OPEX_{WT} = AOC_{WT} \cdot \sum_t E_{WT}(t) / 8760 \quad (16)$$

$$OPEX_{EES} = AOC_{EES} \cdot \sum_t StoreOut(t) / 8760 \quad (17)$$

$$OPEX_{Grid} = EC_{Grid} \cdot \sum_t Grid(t) \quad (18)$$

$$CTAX_{total} = CTAX_{unit} \cdot (\sum_t E_{PV}(t) \cdot EF_{PV} + \sum_t E_{WT}(t) \cdot EF_{WT} + \sum_t Grid(t) \cdot EF_{Grid}) \quad (19)$$

$$COH_{total} = TAC / Prod_{H2} \quad (20)$$

## 5. CASE STUDY RESULTS

In this contribution, a total of eight case studies are conducted by varying the carbon tax (0 - 180 $/tCO$_2$) under two different scenarios: one reflects the comparatively high capital and operating costs corresponding to the current state of renewable energy (WT, PV, and EES) technical maturity, while the other reflects the potential expenses in 2050, when renewables will be expected to be advanced and more economical. For each case study, the mathematical model of the RES determines the optimal solution for combination of WTs, PV system, EES, and grid electricity imports. The optimized annual operating conditions of RES & Grid for each case study are shown in **Figure 2**.

The optimization results for each case study are presented in **Tables 4** and **Table 5**, with a breakdown of the grid's and the renewable energy facility's performance and cost of hydrogen. In the current technology scenario without carbon tax, the most economical option to supply the electrified hydrogen production power demands is to rely mainly on grid electricity while 27% of the total demand is supplied by the renewable energy systems. However, as the carbon tax increases, the renewable energy system introduction is encouraged by increasing tax on indirect $CO_2$ emissions from grid electricity. When the carbon tax is increased to $180/tCO$_2$, the renewable energy ratio increases from 27% to 51%. As technological maturity increases and the unit cost related to renewable energy system decreases, the ratio of renewable energy increases from 27% to 56%, even without the carbon tax. Furthermore, if the carbon tax is increased to $180/tCO$_2$, the renewable energy ratio increases to 72%.

As shown in **Table 5**, the overall cost of hydrogen varies from 1.78-3.27 $/kgH$_2$ depending on the carbon tax when the technical maturity is at its current level. However, the overall cost of hydrogen is expected to vary from 1.38-2.28 $/kgH$_2$, when the technical maturity reaches the advanced level in the future, indicating a cost reduction of 22.5-30.3% can be achieved depending on the carbon tax.

**Table 4:** Optimal Solution for Renewable Energy Supply

| Carbon tax | | 0 | 60 | 120 | 180 |
|---|---|---|---|---|---|
| **Current state** | | | | | |
| Capacity | WT [MW] | 23 | 39 | 47 | 51 |
| | PV [MW] | 37 | 50 | 63 | 71 |
| | EES [MWh] | 5 | 74 | 135 | 178 |
| Annual power gen. [GWh] | WT | 34 | 60 | 71 | 78 |
| | PV | 54 | 73 | 92 | 103 |
| | EES | 0 | 2 | 7 | 12 |
| | Grid | 246 | 203 | 176 | 163 |
| Renewable ratio | | 0.27 | 0.39 | 0.47 | 0.51 |
| **Advanced state** | | | | | |
| Capacity | WT [MW] | 53 | 62 | 69 | 74 |
| | PV [MW] | 85 | 126 | 132 | 137 |
| | EES [MWh] | 246 | 467 | 518 | 572 |
| Annual power gen. [GWh] | WT | 80 | 94 | 106 | 113 |
| | PV | 124 | 184 | 192 | 199 |
| | EES | 20 | 46 | 53 | 58 |
| | Grid | 147 | 108 | 100 | 94 |
| Renewable ratio | | 0.56 | 0.68 | 0.70 | 0.72 |

**Table 5:** Economic Results of Cost of Hydrogen (COH)

| Carbon tax [$/tCO$_2$] | | 0 | 60 | 120 | 180 |
|---|---|---|---|---|---|
| **Current state cost of hydrogen (COH) [$/kgH$_2$]** | | | | | |
| CAPEX | WT | 0.14 | 0.25 | 0.29 | 0.32 |
| | PV | 0.21 | 0.28 | 0.35 | 0.40 |
| | EES | 0.01 | 0.13 | 0.24 | 0.32 |
| OPEX | WT | 0.01 | 0.01 | 0.01 | 0.02 |
| | PV | 0.01 | 0.01 | 0.01 | 0.01 |
| | EES | 0.00 | 0.00 | 0.00 | 0.00 |
| | Grid | 1.41 | 1.16 | 1.01 | 0.93 |
| CTAX | | 0.00 | 0.52 | 0.91 | 1.26 |
| Total COH | | 1.78 | 2.36 | 2..84 | 3.27 |
| **Advanced state cost of hydrogen (COH) [$/kgH$_2$]** | | | | | |
| CAPEX | WT | 0.19 | 0.22 | 0.24 | 0.26 |
| | PV | 0.17 | 0.25 | 0.26 | 0.27 |
| | EES | 0.16 | 0.31 | 0.34 | 0.38 |
| OPEX | WT | 0.01 | 0.01 | 0.01 | 0.01 |
| | PV | 0.01 | 0.01 | 0.01 | 0.01 |
| | EES | 0.00 | 0.00 | 0.01 | 0.01 |
| | Grid | 0.84 | 0.62 | 0.57 | 0.54 |
| CTAX | | 0.00 | 0.30 | 0.56 | 0.80 |
| Total COH | | 1.38 | 1.72 | 2.01 | 2.28 |

These case studies suggest that either an aggressive carbon tax to reduce grid-based electricity use or a significant reduction in capital costs accompanied by the technological innovation of RES is required to increase the use of renewable energy for the commercial-scale, low-carbon hydrogen production process.

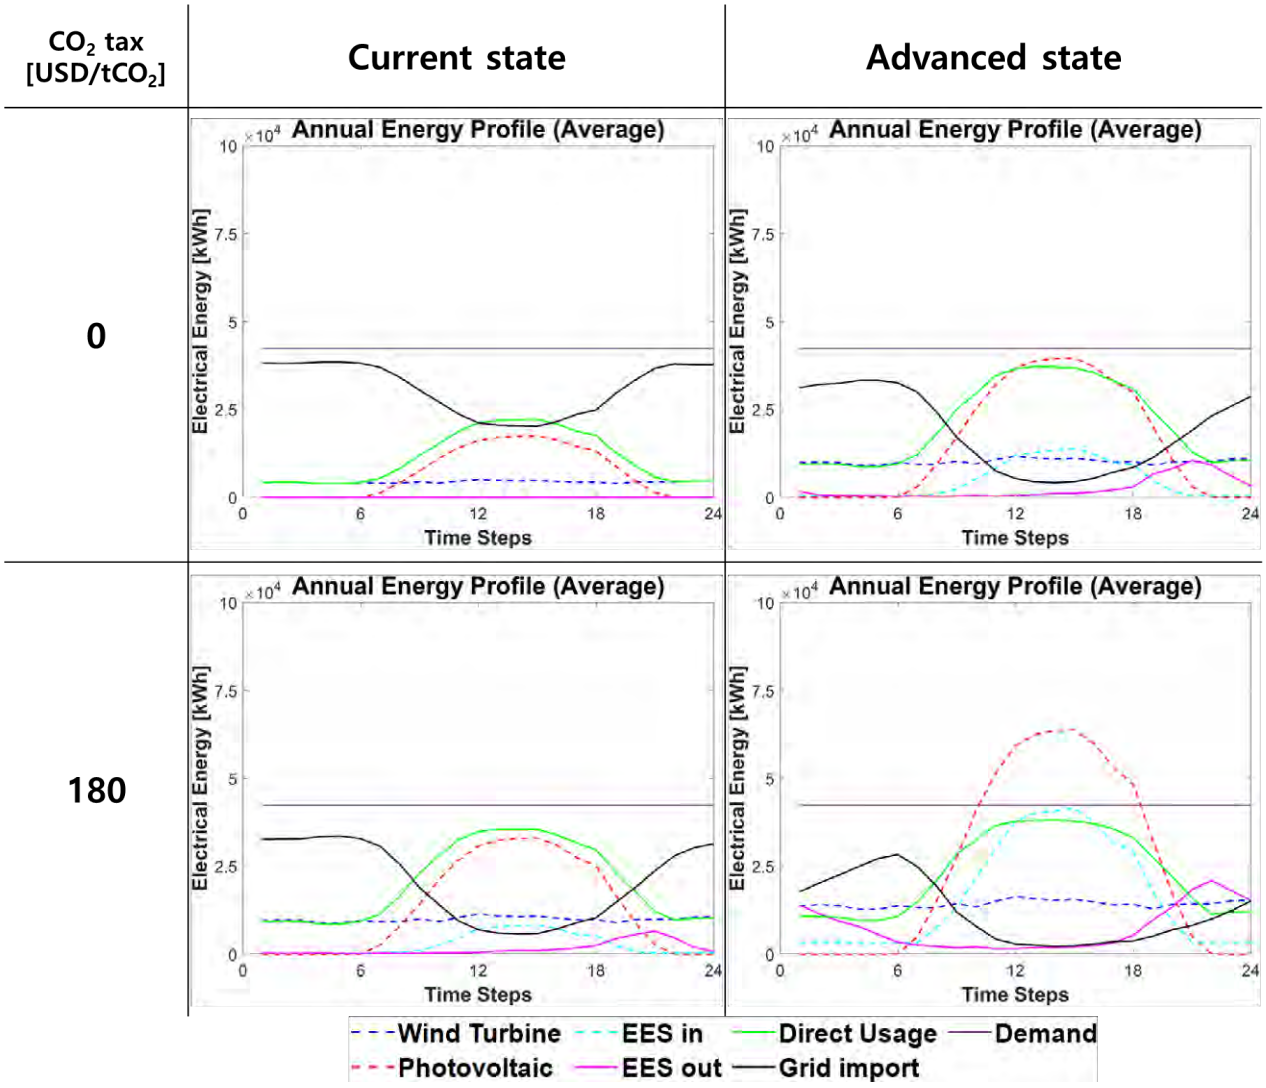

**Figure 2:** Annual Everage Electricity Supply Profiles of Renewable Energy System & Grid

## 6. CONCLUSION

This study proposes a comprehensive framework to determine the optimal design and operation of a combined renewable energy system & grid electricity supply for the electrified hydrogen production process. The MILP model is designed to optimize the operating conditions of the electricity supply system and to minimize the total cost including capital and operating costs of the renewable energy system, grid electricity costs, and carbon tax. The case studies investigated show that the optimized combination of the electricity mix is significantly influenced by the carbon tax levels and that the reducing capital costs with advanced technological maturity is crucial for the economic feasibility of the renewable energy system integration.

Future work will extend this framework to scenarios where the electrified hydrogen production process requires additional thermal energy, thereby exploring integrated renewable heat and power supply systems. Time-varying operational strategies that optimize both electricity and heat requirements under different policy conditions would further enhance understanding of the potential pathways toward large-scale, low-carbon hydrogen production.

## ABSTRACT

As greenhouse gas emissions continue to increase worldwide, the growing energy demand must be met using low-carbon technologies. Renewable energy and carbon capture and storage are the two important technologies that can mitigate $CO_2$ emissions. The two technologies have been primarily developed independently. However, their hybridization can offer complementary benefits and lower the costs of greenhouse gas abatement. Accordingly, in this article, we develop a novel carbon-neutral process that combines concentrated solar power (CSP) and fuel-based combustor with redox-based thermochemical energy storage (TCES) materials. The TCES materials are used for energy storage and as a source of oxygen ($O_2$) for combusting fuel. We optimize the process' economic performance considering variability in solar irradiance by developing a two-stage stochastic programming model. We illustrate that compared to the CSP-TCES process employing the $Mn_2O_3/Mn_3O_4$ TCES system, the proposed hybrid process has a 25% lower levelized cost of electricity (LCOE) for an 80% capacity factor. We also compare the economic performance of our process with another hybrid configuration containing CSP-TCES, boiler for fuel combustion, and air separation unit (ASU) to produce $O_2$, which is then used to combust fuel. We conclude that the LCOE of the proposed process is 11.5% lower than the LCOE of the process with an ASU.

**Keywords**: Concentrated solar power, energy storage, stochastic programming, carbon capture and storage, hybrid energy systems

## 1. INTRODUCTION

As the energy demand continues to increase, there is an urgent need to develop technologies to reduce $CO_2$ emissions. Two classes of technology that can mitigate $CO_2$ emissions are carbon capture and storage (CCS) and renewable energy generation from sources such as solar and wind. While CCS aims to prevent $CO_2$ from being released into the atmosphere, renewable energy generation technologies avoid $CO_2$ emissions. While using a combination of photovoltaic (PV) or wind power with battery can provide reliable electricity, another promising strategy to deliver cost-effective, reliable, and dispatchable renewable power is integrating concentrated solar power (CSP) with thermal energy storage (TES). Among various TES technologies, thermochemical energy storage (TCES) is reported to be especially appealing for the next generation CSP plants because of their high energy density and ability to deliver heat at a high temperature (> 1000 °C). A recent material screening study concluded that due to the low energy density of TCES materials, even the most economically favorable reaction system leads to more than 50% higher levelized cost of electricity (LCOE) than the monthly average electricity retail price [1]. This is mainly due to a lower energy density of the TCES materials. Thus, hybridizing CSP with energy-dense fossil fuel power plants equipped with carbon capture can reduce the cost of producing clean power.

Attempts have been made to integrate solar thermal energy into post-combustion $CO_2$ capture (PCC). Parvareh et al. [2] showed that by utilizing solar thermal energy to support the thermal demand of the stripper, the energy penalty can be reduced, and more power can be produced. Qadir et al. highlighted the potential of

dynamic, flexible operation to reduce $CO_2$ capture costs [3]. Hong and Jin used solar thermal energy as a heat source to drive the endothermic reaction of a metal oxide with $CH_4$ [4] and reported that solar energy can be converted to chemical energy at a low temperature and released at a higher temperature. Jafarian et al. [5] proposed the use of metal oxide for thermal energy storage and reported a lower fuel consumption and reduced $CO_2$ emissions by 50% compared to natural gas combined cycle with carbon capture.

Kumar and Tiwari summarized the potential of solar thermal energy in coal-fired power plants retrofitted with a PCC system. Specifically, they discussed various PCC and solar thermal integration techniques, economic and environmental impacts, benefits and challenges [6]. Dalvi et al. indicated that solar thermal systems can be easily integrated into Rankine-cycle power plants. They further showed that solar heat can offset up to 50% of fossil fuel consumption and this strategy is more economical than installing CCS for mitigating an equivalent amount of GHG emissions [7]. Most previous studies focussed on the feasibility aspect of hybridizing renewable energy and carbon capture, often ignoring the optimization of both the design and operational decisions.

While there is consensus on the economic and environmental benefits of integrating solar thermal heat and carbon capture technologies, no previous work has sought to employ TCES materials for energy storage and as a source of oxygen for fuel combustion. Accordingly, in this article, we develop a novel carbon-neutral process referred to as CSP-TCES-OFC. The process combines CSP and fuels-based combustor to generate power and redox-based TCES materials for energy storage and a source of oxygen, which is used to combust fuel, like an oxy-fuel combustion (OFC) process. The process has three advantages. First, the power cycle can be operated at a higher temperature during the night compared to a standalone CSP-TCES process, wherein the reversible reaction temperature limits the temperature of the power cycle. This would lead to higher overall efficiency of the CSP-TCES-OFC process compared to CSP-TCES. Second, oxygen separation occurs using thermal energy, a low-grade energy source compared to electricity, the primary energy source for an air separation unit used in a traditional OFC process. Third, the process enables energy storage and carbon capture simultaneously. We develop a stochastic programming-based optimization model that considers variability in solar irradiance to minimize the levelized cost of electricity (LCOE). We also compare the economic performance of our processes with other processes and show that our process results in a lower LCOE.

## 2. SYSTEM DESCRIPTION

Figure 1(A) shows the schematic of the CSP-TCES-OFC process. The system operates as follows. During the day, the collector focuses sunlight onto a receiver, where photons are absorbed, and the heat transfer fluid (HTF) is heated. The flow of HTF is split such that a part of it flows through the reactor (R1) to provide heat to the forward endothermic decomposition reaction ($M_xO_z \leftrightarrow M_xO_y + \frac{z-y}{2}O_2$), and the remaining flows through the power block to provide heat to the working fluid (WF). The oxygen ($O_2$) released due to the forward endothermic reaction is compressed and stored. It is then used for fuel combustion when solar energy is unavailable. Since $O_2$ from R1 is at a high temperature and compressing a gas at a lower temperature results in a lower power consumption, its sensible heat is extracted using a sensible heat storage unit. A multistage compressor is employed to compress $O_2$. An intercooler is used after each compressor so that the temperature of $O_2$ after each stage is 35 °C. The compressed $O_2$ is stored underground or in a pressure vessel.

During the night, the reverse exothermic reaction occurs in the presence of air to regenerate the metal oxide in a higher oxidation state. The heat stored in the sensible heat storage unit is used to increase the temperature of air entering R2. The energy from the high-pressure $O_2$ is recovered using a pressure recovery turbine (PRT) such that the pressure of $O_2$ entering the combustor is 1 atm. In the combustor, $O_2$ is combusted with fuel to produce heat. In this article, we consider natural gas as the fuel. Thus, energy is obtained during the night operation by reversible exothermic reaction, combusting fuel, and recovery energy from compressed $O_2$ using PRT. After exchanging heat with the combustor and R2, WF is sent to a power cycle to generate electricity. Since natural gas is combusted in the presence of $O_2$, the exhaust from the combustor mainly contains $CO_2$ and $H_2O$. The $CO_2/H_2O$ stream is at a high temperature, and the stored $O_2$ is at a lower temperature. We employ a heat exchanger to increase the $O_2$ stream temperature and decrease the $CO_2/H_2O$ stream temperature because increasing the $O_2$ temperature will result in a higher PRT efficiency, and decreasing the $CO_2/H_2O$ stream temperature will aid in separating $CO_2$ and $H_2O$. The $CO_2/H_2O$ stream temperature is further decreased to room temperature and separated using a flash column. The $CO_2$ stream is then compressed to 150 bar by four multistage compressors with intercoolers. The compressed $CO_2$ is then transported and stored underground.

## 3. ALTERNATIVE PROCESSES

We compare the economic performance of CSP-TCES-OFC with two alternative processes. The first process is the CSP-TCES with redox-based TCES material, illustrated in Figure 1(B). There are two key differences

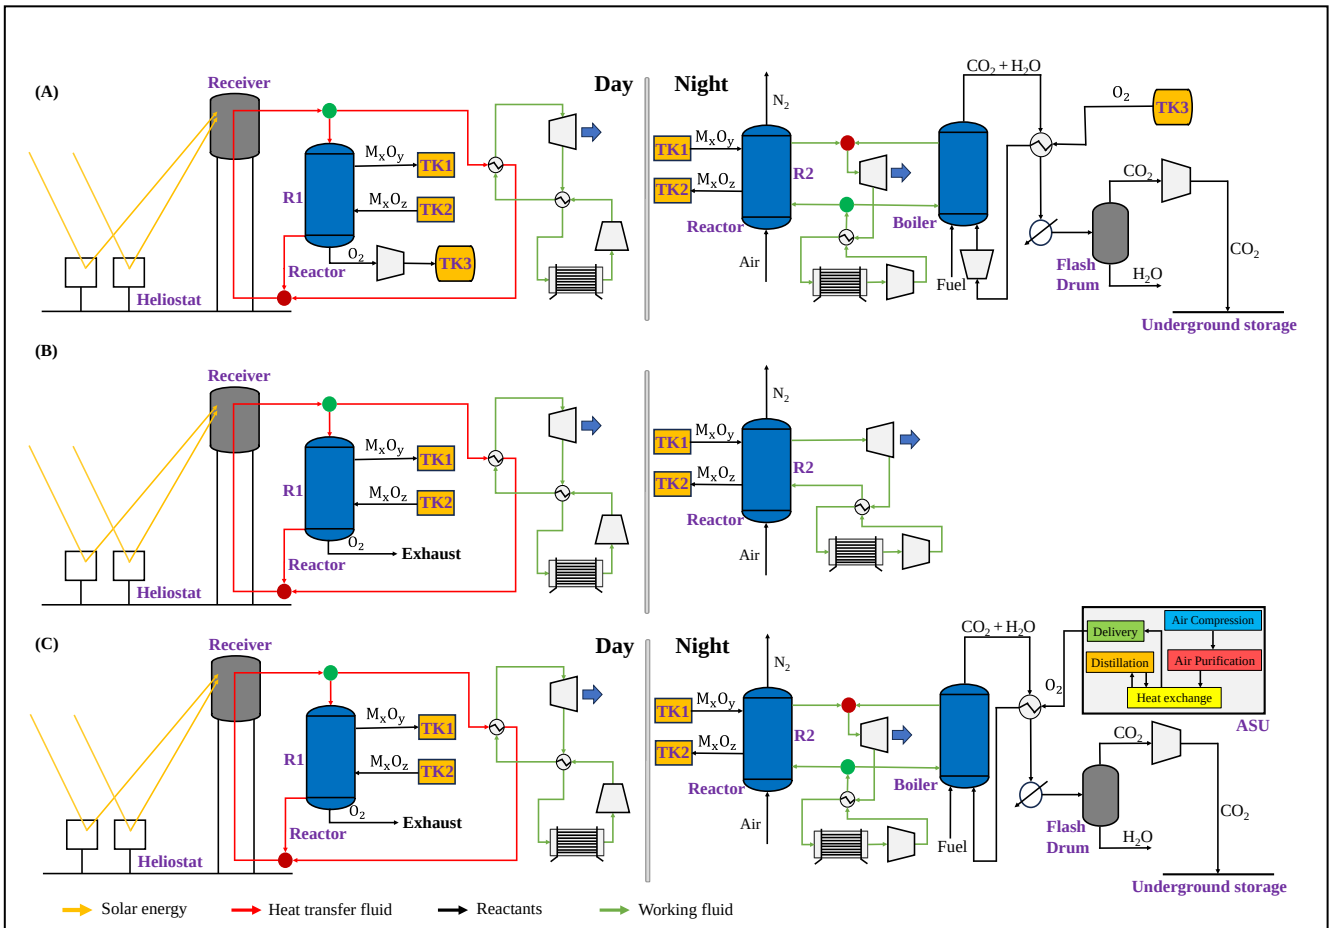

**Figure 1.** Schematic of (A) CSP-TCES-OFC, (B) CSP-TCES, (C) CSP-TCES-ASU processes.

between the CSP-TCES and CSP-TCES-OFC processes. First, oxygen is not stored, and second, no fuel is combusted. The proposed process has several advantages over the CSP-TCES process. First, the power cycle can be operated at a higher temperature at night than a standalone CSP-TCES process. Second, oxygen separation occurs using thermal energy, a low-grade energy source compared to electricity, which is the primary energy source for an air separation unit used in a traditional OFC process. Third, the process enables energy storage and carbon capture simultaneously. Fourth, there is no direct contact between metal oxide and $CO_2$, thus avoiding the carbonation of the metal oxide and improving reversibility.

The schematic of the second process, referred to as CSP-TCES-ASU, is shown in Figure 1(C). Instead of storing oxygen formed during the forward endothermic reaction, an ASU produces oxygen needed to combust fuel during the night. We assume that 250 kWh of electricity is needed to produce 1 tonne of $O_2$.

## 4. METHODOLOGY

We evaluate the techno-economic performance of the CSP-TCES-OFC process via optimization of the energy system design, considering variability in solar irradiance. We develop a stochastic programming (SP) model to account for variability in solar irradiance. Based on the previous works [1,8], we extend the SP model developed for CSP-TCES to CSP-TCES-OFC. The inputs required by the model are (1) solar irradiance data, (2) plant capacity, (3) TCES and combustion reactions and properties (reaction enthalpy, equilibrium temperature), and (4) cost parameters.

We selected the plant location as Daggett, California. We used its solar irradiance data from the National Solar Irradiance Database and use k-means clustering to obtain six representative scenarios. We assume that the plant operates in day and night modes. The plant capacity is chosen to be 100 MW. The TCES system is $Mn_2O_3/Mn_3O_4$ because it is one of the most well-studied systems, and we assume that natural gas is combusted using $O_2$. The objective of the model is to minimize the LCOE subject to the constraints that include the physical model of the plant components (i.e., collector, receiver, TCES reactors, storage tanks, compressors, combustor, power cycle), unit mass and energy balances, equipment sizing, and cost correlations. The model solution results

in optimal design and scenario-dependent operating variables. The overall framework is given in Figure 2. The resulting model is a mixed integer nonlinear programming model formulated and solved using Gurobi's Python API. The cost parameters and complete model equations for CSP-TCES-OFC and CSP-TCES-ASU can be found in the

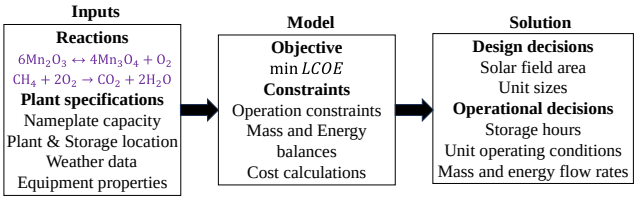

**Figure 2.** Overwiew of the optimization model for CSP-TCES-OFC process.

supplementary material, and the model for CSP-TCES can be found in the ESI of Bajaj et al. [1].

## 5. RESULTS

We consider two sets of cost parameters for transporting and storing $CO_2$ and $O_2$, which are given in Table 1. The two cases for $CO_2$ storage and transportation costs are the typical values given in the literature. The case 1 for storing $O_2$ corresponds to pressure vessel and case 2 corresponds to underground storage. Figure 3 shows the LCOE distribution for the three processes, and Table 2 lists the important decision variables. The subscript 'h' and 'l' denote the higher and lower cost parameters (case 1 and case 2), respectively. The LCOE of the CSP-TCES-OFC process ranges between 8.66 – 9.67 ¢/kWh, and lowest among the three processes, suggesting that the proposed integrated process synergistically combines energy storage and carbon capture. The capital investment required for CSP-TCES-OFC, CSP-TCES, and CSP-TCES-ASU are $ 605.18 million, $ 658.8 million, and $ 711.9 million, respectively. The total electricity produced is 870 GWh, 649 GWh, and 897 GWh, respectively.

**Table 1**: Cost of storage and transportation of gases for CSP-TCES-OFC model considered for different cases.

| Case | $CO_2$ storage price ($/ton) | $CO_2$ transportation price ($/km ton) | $O_2$ storage price ($/m$^3$) |
|---|---|---|---|
| 1 | 15 | 2 | 5700 |
| 2 | 5 | 1 | 50 |

For all the processes, the solar field/collector and receiver are the main contributing factors to LCOE, followed by the power block. Compared to the CSP-TCES process, the LCOE contribution of solar field and receiver is lower for the CSP-TCES-OFC process because of their lower sizes (Table 2). This is primarily due to (1) the higher efficiency of the power cycle during the night due to a higher working fluid temperature (Table 2) and (2) energy production from low-cost and energy-dense natural gas and compressed $O_2$. The power cycle operates at a lower temperature in the CSP-TCES process because the thermal energy is provided by the reversible exothermic reaction, which due to thermodynamic limitations, can only occur at a temperature lower than the equilibrium temperature. Although the cost of the power block is the same for all the processes, its contribution to CSP-TCES-OFC is lower because of higher electricity production.

The TCES material requirement is the lowest for the CSP-TCES-OFC process due to additional lower-cost energy production sources (methane and compressed $O_2$) at night. This also results in lower reactor and solid storage tank costs. The operating cost is higher for the CSP-TCES-OFC process due to natural gas and cooling requirements. Additionally, the CSP-TCES-OFC requires compressors and gas storage infrastructure to store $O_2$ and $CO_2$. The LCOE contributions for both CSP-TCES-OFC and CSP-TCES-ASU processes differ mainly by the capital expenses needed for the air separation unit in the latter and the $O_2$ compressor and storage in the former. However, the cost associated with compressing and storing $O_2$ is much lower than that of an ASU. The analysis illustrates that it is more economical to use redox-based TCES materials for both energy storage and a source of $O_2$ for fuel combustion.

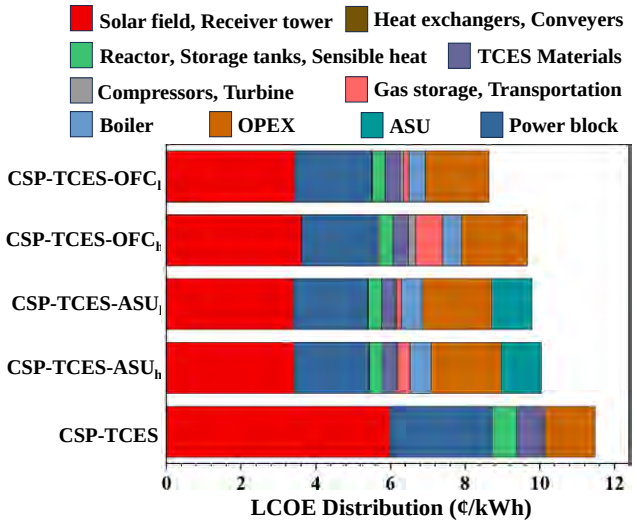

**Figure 3**. LCOE distribution for various processes.

A key decision variable is the storage pressure of $O_2$. While high storage pressure results in a lower tank cost and more power production by PRT, it also produces higher power consumption during the day and a higher compressor cost. We can observe from Table 2 that $O_2$ storage pressure is higher when $O_2$ is stored in a pressure

**Table 2:** Comparison of key decision variables of the three processes.

| Decision variables | CSP-TCES-OFC$_l$ | CSP-TCES-OFC$_h$ | CSP-TCES | CSP-TCES-ASU$_l$ | CSP-TCES-ASU$_h$ |
|---|---|---|---|---|---|
| Power cycle temperature during day (TIT) (K) | 1377.1 | 1382.5 | 1415.3 | 1385.2 | 1394.4 |
| Power cycle temperature during night (TIT) (K) | 1048.1 | 1048.3 | 967.3 | 1017.5 | 1007.8 |

| Collector area ($m^2$) | 913.1 | 955.4 | 1182.3 | 927.2 | 929.2 |
| Receiver size ($MWh_t$) | 493.7 | 514.9 | 635.5 | 497.9 | 500.3 |
| CF (%) | 79.8 | 78.9 | 74.1 | 81.1 | 80.8 |
| Oxygen storage pressure (bar) | 5.3 | 39.3 | - | - | - |
| Yearly $CH_4$ consumption ($10^3$ tonnes) | 25.9 | 27.6 | - | 33.4 | 33.6 |
| Yearly $O_2$ consumption ($10^3$ tonnes) | 103.6 | 110.5 | - | 133.6 | 134.1 |
| Power generated at night (MW) | 42.3 – Combustion<br>59.3 – Reactor<br>1.9 - PRT | 44.1 – Combustion<br>62.7 – Reactor<br>3.6 - PRT | 100.0 – Reactor | 54.7 – Combustion<br>56.7 - Reactor | 54.2 – Combustion<br>62.2 - Reactor |
| Power consumed at night (MW) | 1.7 - Compressor | 1.8 - Compressor | - | 2.1 – Compressor<br>8.0 - ASU | 2.2 – Compressor<br>8.1 - ASU |

vessel (case 1), resulting in the production of a higher amount of power.

Capacity factor (CF) is the ratio of the actual amount of energy produced by the plant to the amount of energy that could have been produced by that plant when operated at its full power rating during the same period. Mathematically, CF is defined as follows:

$$CF = \frac{\sum_{t\in T} \pi_t \left(DT_t^c + NT_t^d\right)}{\sum_{t\in T} 24 \times \pi_t}$$

where $\pi_t$ is the probability of occurrence of scenario $t$, $DT_t^c$ is the charging time, and $NT_t^d$ is the discharging time.

Figure 4 shows the variation of LCOE with CF. The LCOE of the CSP-TCES-OFC process is the lowest among the three processes for CF varying between 60 – 85%. The difference in LCOE between the CSP-TCES and CSP-TCES-OFC processes becomes larger as CF increases to more than 80%. The cost of the CSP-TCES process increases more with CF because as CF increases, power needs to be produced during low DNI scenarios, which requires a larger collector and receiver. Furthermore, increasing CF requires more energy storage to provide power during nighttime, resulting in more TCES material requirements, larger reactors, and storage tanks. The optimal CF for CSP-TCES, CSP-TCES-ASU, and CSP-TCES-OFC processes are given in Table 2. The corresponding charging and discharging times for the three processes are shown in Figure 5.

We observe that the charging time for the CSP-TCES process in all the scenarios is the highest, whereas the discharging time is the lowest. This occurs because of the lower energy density of TCES materials. However, the amount of material stored is still insufficient to provide power for longer discharging times. The presence of an additional source of energy (natural gas combustion) in CSP-TCES-OFC and CSP-TCES-ASU results in longer discharging times, resulting in a higher overall CF for the two processes.

## 6. CONCLUSIONS

We proposed a hybrid process that combines concentrated solar thermal and fossil-fuel-based power production with redox-based TCES materials for energy storage and carbon capture. We develop a stochastic programming-based optimization model that considers the variability in solar irradiance to evaluate the economics of the process. We compare the economic performance of our process with CSP-TCES and show that the optimal LCOE of our process is 15.9% – 24.6% lower. This illustrates that the redox-based TCES materials enable synergistic energy storage and carbon capture, reducing overall electricity production costs at higher capacity factors. Our analysis provides critical insights into the benefits of redox-based TCES materials, and we hope more experimental studies will follow to elucidate the $O_2$ formation and energy storage capabilities of TCES materials.

## ABSTRACT

Biomass gasification is a promising technology for sustainable energy production. To date, extensive research has been conducted on biomass gasification, particularly focusing on the reaction models of the process. However, existing models are too complex to apply to the control system or to optimize the process operating conditions effectively, limiting their practical use for industrial applications. To address this, a simple reaction model for biomass gasification was developed and validated. A steady state simulation of the biomass gasification process is conducted to analyze gasifier behavior and provide insights into reaction dynamic. The findings in this study align well with existing literature, confirming the reliability of the approach. This simulation serves as a foundation for further study in process control and optimization. Future work will include experimental validation to enhance model accuracy and applicability.

**Keywords**: Biomass, Modelling and Simulations, Gasification

## INTRODUCTION

The urgency to tackle environmental challenges such as climate change, pollution, and resource depletion has become increasingly evident. As a result of the consequences of unsustainable practices, technology offering innovative solutions to mitigate environmental degradation and foster long-term resilience has garnered significant public attention.

Biomass gasification appears to be such a technological innovation, offering a sustainable alternative to traditional energy generation methods. It is one of the most effective technologies which has great potential for biomass energy recovery. Biomass gasification converts biomass into syngas ($CH_4$, CO, $H_2$ and $CO_2$) which can be further converted into electricity and biofuel [1], [2]. This technology aligns with the global shift toward sustainable development by promoting waste utilization and reducing carbon footprint.

There is a wide variety of biomass feedstock, including agriculture, forestry residue and municipal waste. Among all these biomass, woody biomass has shown great potential as a good-quality feedstock due to its high energy content and relatively high fixed carbon content [3]. Japan's forest covers about 25 million hectares, which accounts for two-thirds of the country's land. Approximately 40% of the forest planted, predominantly with Japanese cedar (Cryptomeria japonica), is valued for its adaptability and growth, but its pollen causes allergies affecting 40% of the population. Thus, Japan government implement measures in 2024 to reduce pollen dispersal by promoting sustainable wood utilization [4].

With the growing interest in biomass gasification, numerous studies have been conducted to study this multifaceted and complicated process focusing on areas such as modelling, optimization, process analysis and gasifier design [5]. Mathematical models can be an effective tool to evaluate the plant's performance, optimize its operation and improve its efficiency [6]. These reaction models enable more computationally efficient predictions of the yield and composition of various gas and tar species, making it feasible to simulate complex reactor configurations without compromising accuracy. Most of the simulation studies focus on thermodynamic equilibrium modelling. Many researchers have found a high degree of similarity between modelling and theoretical predictions based on equilibrium modelling [7]–[9].

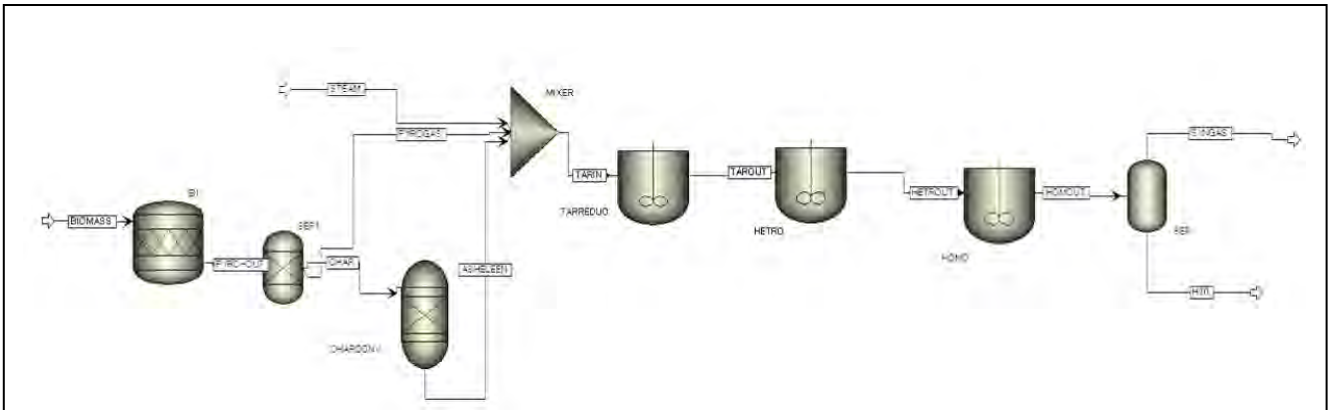

**Figure 1:** Flow chart of biomass gasification simulation using Aspen Plus

However, for dynamic simulations and control applications, a model which able to capture the time-dependent behaviour of the process is necessary. This model needs to employ reaction kinetic to capture the time-dependent evolution of the process.

Several authors discuss the kinetic model of steam gasification on wood biomass especially on pyrolysis [10] - [14]. However, the existing models are too complex and not suitable to apply to the control system or to optimize the process operating conditions effectively, limiting their practical use for industrial applications.

To overcome this limitation, the present paper aims to bridge this gap by creating a kinetic model to investigate wood biomass gasification.

## MATERIALS AND METHOD

### Biomass samples

Japanese waste wood was chosen as a feedstock for this biomass gasification simulation. The proximate and ultimate value of the biomass used in this research is presented in Table 1.

**Table 1**: Proximate and ultimate analysis of feedstock

| **Proximate analysis wt.%** | **Japanese Waste Wood [10]** |
|---|---|
| Moisture Content (as determined basis) | 21.8 ± 7.5 |
| Volatile Material (dry basis) | 84 ± 4.1 |
| Fixed Carbon (dry basis) | 51.4 ± 2 |
| **Ultimate analysis, wt.% (dry ash free basis)** | |
| C | 51.4 ± 0.2 |
| H | 6.2 ± 0.3 |
| N | 0.3 ± 0.3 |
| O | 42.2 ± 2.1 |
| **HHV, MJ/kg** | 21.1 ± 0.9 |

### Process Assumption

There are a few assumptions considered in this process modelling:

- Temperature and pressure drop in processes are neglected.
- Ash is inert and does not participate in the reaction.

### Modelling and Simulation Software

The biomass gasification discussed in this paper is based on uncoupling the downdraft biomass gasifier into different parts based on the main reactions, biomass pyrolysis and reduction. These parts are linked with different types of reactors in Aspen Plus version 14.

The Peng-Robinson-Boston-Mathias (PB-RM) property method is used in this simulation. This method is recommended for hydrocarbon processing applications such as gas processing in all temperatures and pressures [16]. Biomass, Char and Ash were defined as non-conventional components in this process. The enthalpy and density models used for the non-conventional components were DCOALIGT and HCOALGEN. The stream classes defined as MIXCINC.

### Aspen Plus Model Description

The wood biomass gasification flowsheet has been developed as shown in Figure 1 while the unit operation blocks used in the flowsheet are summarized and presented in Table 2.

The feed stream “Biomass” was dry basis biomass, specified as a non-conventional stream with the proximate and ultimate analysis value as shown in Table 1. The mass flow rate was set as 50kg/hr. The biomass was directly fed to pyrolysis reactor “B1” as the temperature of the feed stream was higher than the wood drying temperature [17]. Pyrolysis is a complicated thermochemical process. It can be modelled by a stoichiometric reactor to simulate the reaction based on the following empirical equations in Table 3 where $Y_i = aT^2 + bT + c$, [kg h$^{-1}$] is a

**Table 2:** Reactor block description used in the simulation

mass yield of pyrolysis product, T [K] is a reaction temperature, and a [kg $h^{-1}$ $K^{-2}$], b [kg $h^{-1}$ $K^{-1}$], and c [kg $h^{-1}$] are coefficients obtained from experimental data. This empirical model can be applied for the reactor temperature between 700 and 1000 °C [18]. This empirical equation is a simplified method to present the yield of pyrolysis including the primary and secondary tar. The char mass yield is calculated based on mass balances after other product determinations. The pyrolysis gas is then introduced into a separator "SEP 1" to separate the char. The char is turned into conventional elements according to its yield distribution data at "CHARCONV" reactor. The gas produced is mixed with pyrolysis gases and steam at "MIXER". The gases undergo tar reduction with the reaction R3 listed in Table 4. Following tar treatment, the gases were introduced into the 'HETRO' reactor to undergo a heterogeneous gasification process at 850 °C and 1 bar, facilitated by reaction R1. Subsequently, homogenous gasification was conducted under the same pressure and temperature at "HOMO" reactor with reaction R2.

**Table 4:** List of reactions involved

| No | Reaction | Kinetic | Source |
|---|---|---|---|
| R1 | $C + CO_2 \leftrightarrow 2CO$ | $4.4Te^{(\frac{-1.62\times10^8}{RT})}[CO_2]^{0.6}$ | [1] |
| | $C + H_2O \leftrightarrow CO + H_2$ | $1.33Te^{(\frac{-1.47\times10^8}{RT})}[H_2O]^{0.6}$ | [1] |
| R2 | $CH_4 + H_2O \rightarrow CO + 3H_2$ | $3.0\times10^5 e^{(\frac{1.25\times10^8}{RT})}[CH_4]^1[O_2]^1$ | [23] |
| | $CO + H_2O \rightarrow CO_2 + H_2$ | $2.78\times10^6 e^{(\frac{-1.26\times10^7}{RT})}\left([CO][H_2O] - \frac{[CO][H_2O]}{k_p(T)}\right)$ $k_p(T) = 0.0265e^{(\frac{4.55\times10^7}{RT})}$ | [1] |
| R3 | $C_6H_6 + 2H_2O \rightarrow 3C + 2CH_4 + 2CO$ | $4.0\times10^{16} e^{(\frac{-4.43\times10^5}{RT})}[C_6H_6]^{1.3}[H_2]^{-0.4}[H_2O]^{0.2}$ | [18] |
| | $C_7H_8 + H_2 \rightarrow C_6H_6 + CH_4$ | $1.04\times10^{12} e^{(\frac{-2.47\times10^5}{RT})}[C_7H_8]^1[H_2]^{0.5}$ | [18] |
| | $C_6H_6O \rightarrow CO + 0.4C_{10}H_8 + 0.15C_6H_6 + 0.1CH_4 + 0.75H_2$ | $10^7 e^{(\frac{10^5}{RT})}[C_6H_6O]^1$ | [18] |
| | $C_{10}H_8 \rightarrow 9C + 0.16667C_6H_6 + 3.5H_2$ | $3.4\times10^{14} e^{(\frac{3.5\times10^5}{RT})}[C_{10}H_8]^{1.6}[H_2]^{-0.5}$ | [18] |

## RESULT AND DISCUSSION

### Effect of temperature on syngas composition

Figure 2 presents the effect of temperature on the syngas composition at a steam-to-biomass ratio of 3. The temperature was varied in the range of 750 ˚C to 1050 ˚C as the suitable temperature for gasification to occur is more than 750 ˚C [19].

Raising the temperature increases the yield of $H_2$ and decreases the contents of $CO_2$ and $CH_4$. H2 has increased 36% from 750 ˚C to 1050 ˚C. This result is almost consistent with the results by Talero et al. in 2022 [15]. In particular, similar CO synthesis trend was also reported in several previous papers [9], [20], [21].

From the R1 and R2 reactions listed in Table 4, only the water gas shift reaction is exothermic. When increasing the temperature of the gasification, Boudourd reaction, water gas reaction and steam methane reforming which are endothermic reactions favour the forward reaction, resulting in an increase in $H_2$ and CO composition and decreasing in $CH_4$ and C composition. The exothermic properties of the water gas shift reaction hinder the production of $H_2$ and $CO_2$.

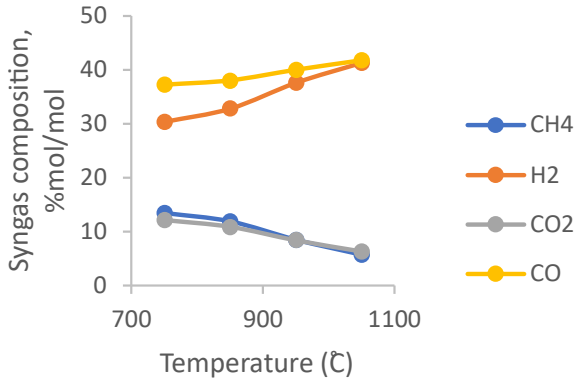

**Figure 2:** Effect of temperature on syngas composition

### Effect of steam to biomass ratio on syngas composition

The effect of steam to biomass ratio is one of the critical parameters that affect gasification efficiency, syngas composition and reaction mechanism. Figure 3 shows the effect of steam to biomass ratio on the syngas composition at a gasification temperature of 850 ˚C. There is a slight increase in the $H_2$ value when increasing the steam-to-biomass ratio. This can be explained according to Le Chatelier's Principle as the increase in the

steam will favour the $H_2$ formation reaction, especially in steam methane reforming and water gas reaction. $CH_4$ and CO will decrease to maintain the equilibrium of the reaction. A similar result is obtained by Huang where the syngas composition is studied from the range of 0.5 to 3.0 [22] whereas a similar increasing trend is also discussed by Paiva and Florin with lower steam-to-biomass ratio [7], [21].

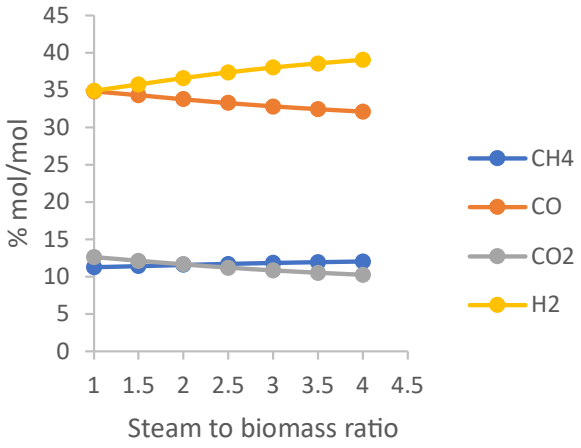

**Figure 3:** Effect of steam to biomass ratio on syngas composition

The introduction of steam during the gasification process promotes the further pyrolysis and gasification of tar and coke. This can improve the syngas quality as shown in Figure 4.

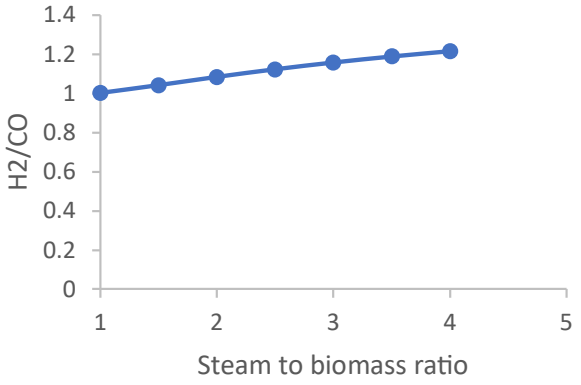

**Figure 4:** Effect of steam to biomass ratio on H2/CO ratio

It can be seen that the proposed kinetic biomass gasification models showed the consistent results with the previous research. From these results, the authors concluded that the proposed models capture the characteristics of the gasification reaction, although the proposed models are much simpler than others counterparts. Furthermore, it can be said that the control system can be designed based on these models for optimizing the process operation.

## CONCLUSION

A simple kinetic biomass gasification model is developed in the Aspen Plus simulator to discuss the syngas production during the steam gasification of Japan waste wood. Each kinetic reaction captured in the model affects the biomass gasification process.

In this study, we compared our simulation model with those presented in previous research to assess its relative performance and validity. This study helps develop a control system in future studies which able to capture the complex interactions between the factors that influence the performance of gasifiers and optimize them for improved efficiency and scalability in industrial applications.

While our current analysis is based on simplified models, we recognize the importance of validating these findings through experimental data. Therefore, in future work, we plan to conduct experiments which will allow us to rigorously compare our simplified models with experimental outcomes, ensuring greater accuracy and reliability in our conclusions.

## ABSTRACT

In this contribution, a thermodynamic model-based approach for the optimal design of a solid-state hydrogen storage and release system utilizing the reversible iron oxide/iron thermochemical redox mechanism is presented. Existing storage processes using this mechanism face significant limitations, including low hydrogen conversion, high energy input requirements, limited storage density, and slow charging/discharging kinetics. To address these challenges, a custom thermodynamic model using NIST thermochemistry data is developed, enabling an in-depth analysis of redox reaction equilibria under different conditions. Unlike previous studies, this approach integrates a multi-objective optimization framework that explicitly balances competing objectives: maximizing hydrogen yield while minimizing thermal energy demand. By systematically identifying optimal trade-offs, the study provides new insights into improving process efficiency and reactor design for thermochemical hydrogen storage. These findings contribute to advancing energy-efficient and scalable hydrogen storage technologies.

## INTRODUCTION

As the European Union (EU) aims to reach net zero emissions by 2050, green hydrogen ($H_2$) has emerged as a clean alternative to existing mainstream hydrocarbon fuels and even unabated hydrogen. One of the major challenges with hydrogen, however, is that it is relatively difficult to store at large scale. Moreover, gaseous and liquefied hydrogen storage processes are energy intensive and expensive [1]. More recently, there has been growing interest in the development of cost-effective and energy-efficient solid-state processes for hydrogen storage. Thermochemical storage (TCS) is emerging as a promising method. As defined by De Rosa et al. [2], thermochemical storage is any storage method based on reversible chemical reactions in which heat is stored and released during the forward endothermic and reverse exothermic reactions respectively. The principle behind thermochemical hydrogen storage is the reversible reduction and oxidation of a metal oxide/pure metal pair. The balanced chemical equation for this reaction is written as:

$$Fe_3O_4\,(s) + 4H_2\,(g) \rightleftharpoons 3Fe\,(s) + 4H_2O\,(g)$$

In the forward endothermic reaction, the solid metal oxide ($Fe_3O_4$) is reduced to a pure metal (Fe) with hydrogen acting as the reducing agent. The hydrogen feed is thus converted to steam. In the reverse exothermic reaction, the pure metal (Fe) is re-oxidised to a metal oxide ($Fe_3O_4$) with water/steam acting as the oxidising agent. Essentially, hydrogen is stored in the reduction reaction and the metal oxide acts a solid-state storage medium. The stored hydrogen may be recovered in the reverse oxidation reaction. Figure 1 shows the schematic of a thermochemical storage system.

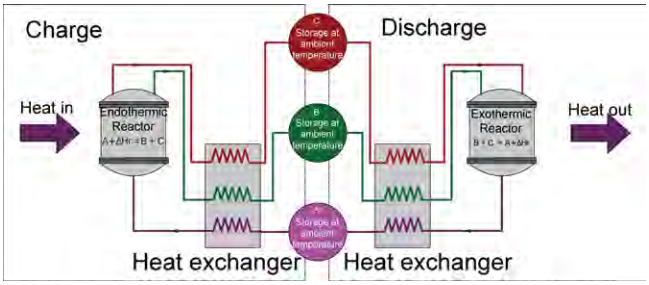

Figure 1. Schematic of a thermochemical storage system

To underscore the suitability $Fe_3O_4$/Fe pair, Brinkman et al. [3] evaluated various other metal oxide/pure metal candidate pairs such as ZnO/Zn, $SnO_2$/Sn, $GeO_2$/Ge, $WO_{2.722}$/W, $MoO_2$/Mo, for use as solid-state storage mediums for hydrogen. Considering evaluation criteria such as process conditions, energy requirements, material costs, and storage density, they identified $Fe_3O_4$/Fe as the optimal candidate pair. However, it is important to note that Otsuka et al. [4] were the first to propose this storage method for hydrogen fuel cell vehicles (FCVs). Brinkman et al. [3] highlighted that the strict performance requirements - such as energy density, process conditions, and charging/discharging response times - make it unlikely that this cyclical storage method will adequately meet the demands of FCV applications. Conversely, they suggested that for large-scale, long-term storage applications, where cost and safety are the primary concerns, the hydrogen TCS method could serve as a viable alternative.

From this perspective, chemical reactor design, a vital step in the development of hydrogen TCS processes, is the overall aim of this work. Different reactor types being studied include fixed bed or fluidised bed reactors.

In this contribution, Section 2 presents a novel fixed-bed single reactor concept. Additionally, it outlines a custom thermodynamic model developed using the NIST Standard Reference Database 69: *NIST Chemistry WebBook* [5] and details its model-based optimisation. Section 3 presents and discusses the results. Finally, conclusions are drawn in Section 4.

# 2. METHODOLOGY

## 2.1 Single-Reactor Concept

Most research on hydrogen TCS has been carried out based on a two-reactor system (Figure 1) – an endothermic reactor for reduction and an exothermic reactor for oxidation [3]. To maximise energy efficiency, such systems include heat exchangers and other equipment units. Thus, overall, the CAPEX and OPEX outlays for these systems are high. Thus, a fixed bed type single reactor concept is proposed that combines the endothermic and exothermic reactors into a single unit with the primary aim of minimising energy input through heat integration. The proposed concept consists of four main operating modes that include: standby/factory mode; storage process; cold storage mode; and release process. Figure 2 illustrates the proposed operating modes.

In *standby mode*, the outer shell of the reactor is packed with beds of Fe while the inner shell is packed with beds of $Fe_3O_4$. In the *storage process*, a green hydrogen feed which is available to be stored, flows into the inner shell for reduction of the metal oxide while steam is introduced into the outer shell to oxidise the pure metal into a metal oxide. A portion of the thermal energy released from the exothermic oxidation reaction in the outer shell meets the heat input requirements of the endothermic reduction reaction in the inner shell. Once almost all the pure gaseous products of hydrogen from the outer shell and the steam from the inner shell are removed, the storage process completes, and the unit may be allowed to cool down and enter a *cold storage mode* which theoretically may be long term durations. It is important to note that once the storage process is complete, the outer shell shall consist of beds of $Fe_3O_4$ while the inner shell contains Fe. To initiate the hydrogen *release mode*, on-site hydrogen is fed to the outer shell for reduction of $Fe_3O_4$ to Fe while steam is fed to the inner shell for oxidation of Fe to $Fe_3O_4$. A portion of the thermal energy released from this exothermic oxidation reaction thus, feeds the endothermic reaction in the outer shell. The net effect of these alternating redox reactions in the outer and inner shells results in the minimisation of the overall energy input required for hydrogen TCS.

Moreover, besides the comparative advantage of lower costs, this proposal offers several other advantages such as the potential for miniaturisation for mobile applications such as in FCVs. Some potential challenges with this concept may include maintainability problems, challenges with its dynamic operations nature, temperature controllability challenges, heat transfer management between shells, special high temperature materials requirement, and so on.

## 2.2 Thermodynamic Model

The objective of the proposed model is to predict the reaction temperature that maximises equilibrium conversion. Integration of thermodynamic and chemical reaction equilibrium yields this powerful model; to predict the reaction equilibrium constant and other key thermodynamic physical properties (temperature, pressure, etc.) as well as thermodynamic functions such as enthalpy, entropy and Gibbs free energy of the reacting system. This algebraic thermochemical equilibrium model is given as:

$$\Delta_r G^o(T) = -RT\ ln\ K_{eq} \quad (1)$$

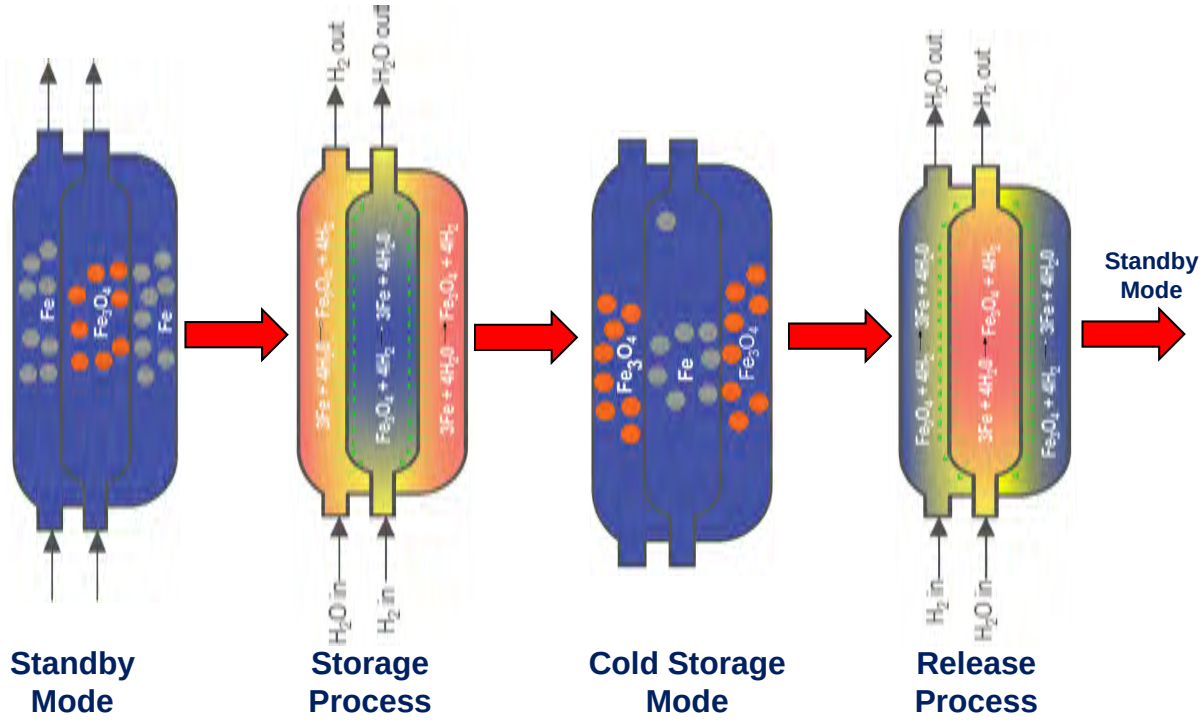

**Figure 3.** Operating modes of a proposed single reactor concept for thermochemical storage

The standard change in Gibbs free energy, $\Delta_r G^o$, at a fixed temperature and pressure is estimated from the relation:

$$\Delta_r G^o(T) = \Delta_r {H_f}^o - T\Delta_r S^o \quad (2)$$

From the NIST Thermochemistry data [5], the magnitude of the standard enthalpy change of a reaction $\Delta_r H_f^o$ is the sum of the standard enthalpies of formation of the products, each multiplied by its appropriate coefficient, minus the sum of the standard enthalpies of formation of the reactants, also multiplied by their coefficients. The standard entropy change of a reaction, $\Delta_r S^o$, is estimated similarly. The equilibrium constant as a function of the reaction temperature, $T$, for each reaction is estimated from the relation:

$$K_{eq}(\mathrm{T}) = exp^{\left(-\frac{\Delta_r G^o(T)}{RT}\right)} \quad (3)$$

Brinkman et al. [3] reported that under the idealisations similarly applied for this work, varying the reactor pressure had no significant effect on equilibrium conversion ($x$).

The equilibrium conversion ($x$) in dimensionless units and as a function of temperature is thus, estimated as follows:

$$x_{H_2}(\mathrm{T}) = \left(\frac{SC_{H_2}}{SC_{H_2O}}\right) \cdot \frac{\left[K_{eq}(\mathrm{T}).q_{n,H_{2-in}}\right]}{\left[q_{n,H_{2-in}} + K_{eq}(\mathrm{T}).q_{n,H_{2-in}}\right]} \quad (4)$$

$$x_{H_2O}(\mathrm{T}) = \left(\frac{SC_{H_2O}}{SC_{H_2}}\right) \cdot \frac{\left[K_{eq}(T).q_{n,H_2O-in}\right]}{\left[q_{n,H_2O-in} + K_{eq}(T).q_{n,H_2O-in}\right]} \quad (5)$$

Where SC is the stoichiometric coefficient (dimensionless); $K_{eq}(T)$is equilibrium constant (dimensionless) and $q_{n,}$ is molar flow rate (kmol/hr). The heat flow for the forward reduction reaction, $Q_f(T)$ and that for the reverse oxidation reaction, $Q_r(T)$, both in kW, are estimated from the relations.

$$Q_f(\mathrm{T}) = Q_{products}(\mathrm{T}) - Q_{reactants}(T) \quad (6)$$

$$Q_r(\mathrm{T}) = Q_{products}(\mathrm{T}) - Q_{reactants}(T) \quad (7)$$

Where the heat flow for the products or reactants may be determined from the relation:

$$Q_i = \sum_{i=1}^{n} q_{n,i} \cdot \Delta {h_i}^o(T) \quad (8)$$

Where $n$ is the number of chemical components. The total enthalpy in kJ/kmol of the reactant and product streams are estimated from the relation:

$$\Delta h^o(\mathrm{T}) = \sum y_i \cdot \left[{h_{f,i}}^o + h^o(T)\right] \tag{9}$$

The temperature dependent enthalpies $h^o(T)$ for each chemical component are estimated from the component specific NIST thermochemistry data heat capacity (Shomate equation).

## 2.3 Optimisation Model

The purpose of the optimisation study is to identify optimal operating conditions in the presence of trade-offs between conflicting objectives; maximisation of equilibrium conversion and minimisation of energy input in both the reduction and oxidation processes. The presence of these conflicting objectives gives rise to a multi-objective optimisation problem (MOOP).

Eq. (10) shows the general structure of a MOOP for the forward reduction reaction with the reaction temperature, $T$, as the decision variable.

Equation (1) sets thermodynamic boundaries on the total energy changes occurring during the reactions. Equation (2) establishes feasibility limits on the composition of the reaction system at equilibrium.

The decision variable, $T$, was constrained to operate within a range of 25°C and bounded at approximately 80% of the melting point temperature of iron (Fe) reported by [6]. In practical terms, this helps prevent melting and other forms of physical degradation of the solid particles, such as sintering, agglomeration, and so on.

MOOP differs from a single objective optimisation problem (SOOP), in that two or more objective functions are required to be solved within the specified constraints simultaneously. Moreover, whereas a unique optimal solution may exist for SOOPs, a set of trade-off solutions may typically exist for MOOPs.

$$\begin{gathered} max \;\; f_1(T) = x_{\mathrm{H2}}(T) \\ min \;\; f_2(T) = Q_f(T) \\ s.t. \\ Eqn.(1) \\ Eqn.(3) \\ T^{LB} \leq T \leq T^{UB} \end{gathered} \tag{10}$$

Several methods currently exist for solving MOOPs. The epsilon($\varepsilon$)-constrained method (ECM) first proposed by Haimes et al. [7] was applied in this study as it yields the set of exact Pareto-optimal solutions efficiently. In applying the ECM, a so-called primary objective function is selected to be optimised while the other remaining objective functions are converted into constraints with predefined upper bounds $\varepsilon_i$. The $\varepsilon_i$-values were selected based on industrial-scale constraints to guarantee feasible solutions.

Notwithstanding, it is essential to highlight that all objectives hold the same level of importance, in that, no weights of preference are assigned to the objective functions as with some other methods. However, in general, the successful implementation of ECM requires careful specification of feasible $\varepsilon_i$ values and consideration of computational efficiency.

In the reduction step, equilibrium conversion of hydrogen was specified as the primary objective function in the description of the MOOP in ECM form as shown in Eq. (11).

$$\begin{gathered} min \;\; -f_1(T) = -x_{\mathrm{H_2}}(T) \\ s.t. \\ f_2(T) = Q_f(T) \leq \varepsilon \\ Eqn.(1) \\ Eqn.(3) \\ T^{LB} \leq T_f \leq T^{UB} \end{gathered} \tag{11}$$

Similarly, the ECM form for the reverse oxidation reaction is shown in Eq. (12):

$$\begin{gathered} min \;\; -f_1(T) = -x_{\mathrm{H_2O}}(T) \\ s.t. \\ f_2(T) = Q_r(T) \leq \varepsilon \\ Eqn.(1) \\ Eqn.(3) \\ T^{LB} \leq T_r \leq T^{UB} \end{gathered} \tag{12}$$

The gradient-based MATLAB nonlinear solver fmincon was used to solve the resulting SOOPs within the practical bounds of the decision variable (reaction temperature) and by systematically varying the constraints which includes the $\varepsilon_i$ values.

The results generated from solving the MOOP is a set of non-dominated or Pareto-optimal solutions of the entire feasible decision space. The superiority of the final solution (best compromised solution) over the other solutions is determined by the decision-maker mostly based on a combination of technical and economic considerations.

In this work, the fuzzy based method as proposed by Yalcin & Erginel [8] was used to identify the best compromised solutions out of the set of Pareto efficient solutions for each of the objective functions. For each reaction, the optimum is a set of solutions that define the best trade-off between the competing maximisation (Eq. 13)

and minimisation (Eq. 14) objective functions.

$$\mu_k(T) = \frac{f_k(T) - f_k^*}{f_k^* - f_k'} \quad (13)$$

$$\mu_k(T) = \frac{f_k' - f_k(T)}{f_k' - f_k^*} \quad (14)$$

Maximum and minimum values of the maximization and minimisation objectives are calculated from Eqs. (15) and (16) under the problem constraints, respectively.

$$f_k^* = max\big(f_k(T)\big), \quad f_k' = min\big(f_k(T)\big) \quad (15)$$

$$f_k^* = min\big(f_k(T)\big), \quad f_k' = max\big(f_k(T)\big) \quad (16)$$

The best compromised solution being the first solution point with the largest numerical value for $\mu_k(T)$.

## 3. RESULTS & DISCUSSION

Figure 3 shows a plot of the model predicted equilibrium conversion vs. reaction temperature for the reduction (red curve) and the oxidation (blue) curves.

The reduction step is favoured by high temperatures; equilibrium conversion of hydrogen in the range $0.50 \leq x_{H_2} \leq 0.9999$ were predicted to occur within operating temperature range of $792\ \text{K} \leq T_f \leq 1307\ \text{K}$, respectively.

Conversely, the oxidation step is favoured by lower temperatures; such that within similar equilibrium conversion bounds for steam ($x_{H_2O}$), the predicted temperature range is $792\ \text{K} \leq T_r \leq 568\ \text{K}$, respectively.

Although the results suggest that conducting the reduction step at high temperatures enhances conversion rates, it is essential to account for the drawbacks of high operating temperatures, including safety risks, increased energy consumption, higher costs, and other related factors. Moreover, Spreitzer and Schenk [9] have reported, referencing the Baur-Glassner diagram, that at reduction temperatures > 570 °C, $Fe_3O_4$ is first reduced to wüstite (an intermediate oxide) before being further reduced to pure Fe. While the chemical thermodynamic effects of wüstite formation was ignored in this work, it may be important to characterise its overall effect on the model.

To identify optimum operating conditions for the redox reactions, Pareto front diagrams, the boundary marked out by the set of all points plotted from the Pareto-optimal set were developed.

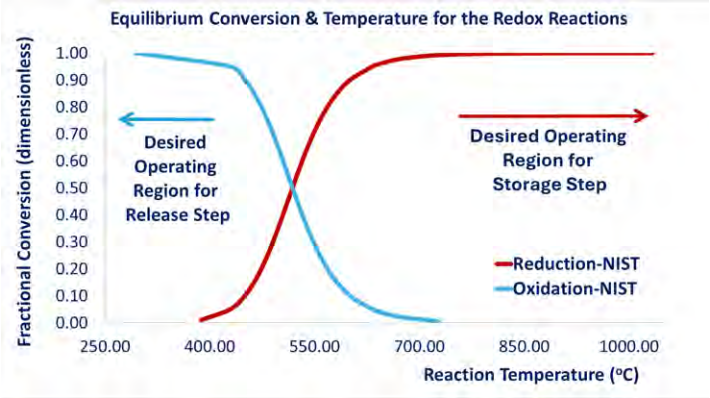

**Figure 3.** Equilibrium equilibrium conversion vs temperature of the redox reactions

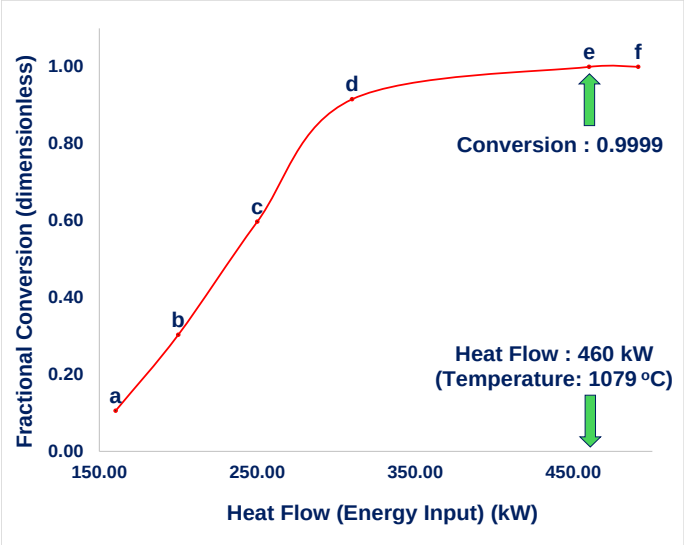

**Figure 4**. Pareto front diagram showing the best compromised solution for reduction

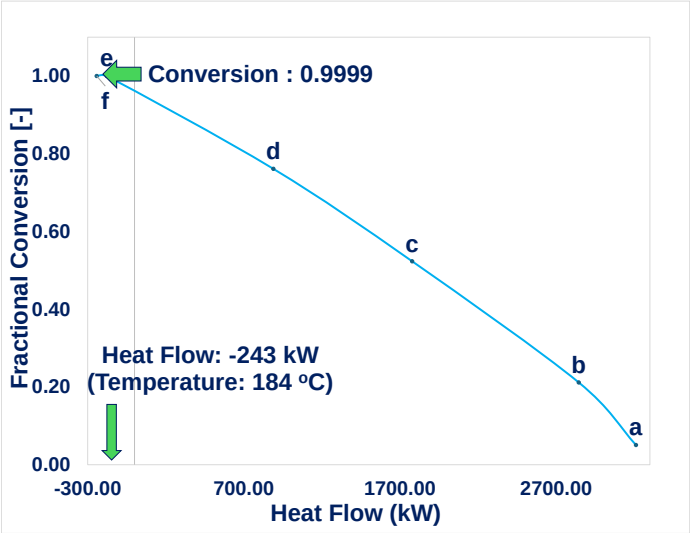

**Figure 5.** Pareto front diagram showing best compromised solution for oxidation

Figure 4 shows the Pareto front considering heat flow (energy input) and equilibrium conversion for the endothermic forward reduction reaction, while Figure 5 illustrates the Pareto front considering heat flow and equilibrium conversion for the exothermic reverse oxidation reaction.

Furthermore, the best compromised solutions for the endothermic reduction and exothermic oxidation reactions were determined and spot-lighted in Figures 4 and 5, respectively, using the fuzzy-based method.

Overall, the results obtained show that for once-through process storage step, reduction should be conducted at a temperature of about 1079 °C while oxidation for the release step should be conducted at about 184 °C. The results obtained also show potential for energy savings owing to configuration of the single reactor concept through heat integration.

As highlighted by Smith [10], it is important to note that the predicted equilibrium conversion values are independent of the reactor design and represent the absolute maximum conversions of reactants in a reversible reaction mixture at a given temperature and pressure.

## 4. CONCLUSIONS

In this work, the thermo-chemical feasibility of a reactor concept for hydrogen storage and release has been established. Through thermodynamic modeling and optimization, ideal operating conditions have been identified, maximizing hydrogen conversion while minimizing energy input. The proposed reactor concept demonstrates the potential for significantly lower specific energy requirements compared to conventional compressed and liquefied hydrogen storage methods, offering a promising alternative for efficient hydrogen storage.

To further refine the system, detailed kinetic studies using the shrinking core model have been conducted to determine lab-scale charging and discharging times. Ongoing experimental work is focused on assessing the long-term stability of the $Fe_3O_4$/Fe system and exploring performance enhancements through the incorporation of metal oxide/metal pairs as structural supports.

Future work includes the development of a dynamic distributed parameter model to capture spatial and temporal variations within the reactor. Further efforts will focus on improving energy efficiency, optimizing key performance metrics, and advancing the scalability of this storage technology for practical applications.

## ABSTRACT

This study investigates the development of a probabilistic design space (DS) for a tableting process, focusing on the uncertainty in critical model parameters. A an empirical model is used to assess the impact of critical process parameters (CPPs), including lubrication extent and porosity, on tablet tensile strength (CQA). By incorporating Monte Carlo and Bayesian techniques, the uncertainty of five model parameters is propagated, allowing the estimation of feasibility probabilities for achieving CQAs with a reliability greater than 0.95. The resulting probabilistic DS provides manufacturers with a tool to assess the likelihood of meeting CQAs under varying production conditions. The findings indicate that specific combinations of lubrication rate and porosity define a robust DS within the acceptable operating region, ensuring consistent tableting performance even in the presence of uncertainties. This approach emphasizes the importance of probabilistic DS in optimizing manufacturing processes and delivering built-in quality assurance.

**Keywords**: Probabilistic design space, Tableting process, Bayesian inference, Operational flexibility, Acceptable Operating Region, Nominal Operating Point inference

## 1. INTRODUCTION

Pharmaceutical manufacturing operates under stringent regulatory constraints, requiring a thorough understanding of the interplay between raw material attributes, process parameters, and product quality[1–3]. To meet these requirements, Quality by design (QbD) has emerged as a key approach to achieve consistent, high-quality production by identifying critical material attributes (CMAs) and critical process parameters (CPPs) that impact critical quality attributes (CQAs). The International Council for Harmonization (ICH) introduced the QbD initiative through guidelines ICH Q8–12, emphasizing a scientific and risk-based approach over traditional quality-by-testing methods[4,5]. This transformation in pharmaceutical development has enabled the development of robust process designs through the concept of design space (DS), which allows for safe operation without the need for additional regulatory approvals. DS can be identified using various strategies, such as empirical models, data-driven models, response surface methodologies, multivariate experimental design, and high-dimensional model representation, all grounded in existing literature, prior experiences, and process knowledge. However, conventional DS models often assume constant model parameters, overlooking the inherent uncertainty in both model parameter and the manipulated variables[6]. By incorporating these uncertainties, which typically can be captured by probabilistic distributions, the DS evolves from a deterministic framework to a probabilistic DS. This transformation provides a more realistic and adaptable approach to ensuring consistent product quality under variable conditions.

Bayesian approaches have been used to identify probabilistic DSs, in various process such as spray drying processes[7], crystallization of casopitant mesylate[8], and solid oral dosage form[9]. The DS is a subset of the knowledge space, which represents the operating envelope explored, studied, and well understood. To effectively characterize the probabilistic DS, computational methods are crucial, particularly in addressing uncertainties within model parameters[10]. Sampling algorithms

method discretizes the model parameter space by generating samples that account for probabilistic distributions of uncertainties. Techniques such as uniform gridding or (quasi) Monte Carlo simulations are commonly employed to propagate uncertainty and ensure all quality constraints are met with the desired level of reliability. This sampling-based approach is particularly effective in capturing the complexities of probabilistic DS offering robust solution for compliance with quality requirements. As number of parameters increases, these sampling methods suffer from the "curse of dimensionality", making them computationally expensive. In addition, these methods distribute samples uniformly, wasting computational resource on low-probability regions while undersampling high-probability areas.

To address these challenges, a Monte Carlo technique based on nested sampling method was developed in conjunction with a Bayesian inference based parameter estimation. The algorithm works by progressively sampling within nested contours of increasing likelihood, maintaining a dense sample in high-likelihood regions. This adaptive approach helps overcome the limitations of traditional methods, allowing particularly the handling of multimodal posteriors and high-dimensional spaces. Additionally, it allows for flexible adjustment of feasibility probability thresholds to meet industrial reliability requirements. Nested sampling integrates seamlessly with Bayesian parameter estimation, providing a unified probabilistic approach to probabilistic DS characterization. Overall, nested sampling provides a more efficient, flexible, and accurate tool for ensuring robust product quality in pharmaceutical manufacturing.

## 2. METHOD

### 2.1 Case study: Tablet Lubrication process

Lubrication plays a critical role in tablet manufacturing, particularly in direct compression process, as it enhances tablet ejection during compression. However, the extent of lubrication must be carefully controlled, as it significantly impacts the overall quality and efficacy of the drug product. The interaction between lubrication and compression processes influences key quality attributes, such as tablet tensile strength. An increase in lubrication may lead to a reduction in tensile strength, a challenge that can potentially be mitigated by increasing compaction pressure.

Kushner and Moore (2010)[11] developed an empirical model to capture lubrication and compaction performance across various blending conditions and scales, given by:

$$\sigma = \sigma_{sf=0.85,0}\big((1-\beta)+\beta exp(-\gamma k)\big) \quad (1)$$

where $\sigma_{sf=0.85,0}$ is the initial tensile strength at 0.85 solid fraction, $\beta$ is the total fraction of tensile strength that can be lost due to lubrication, and $\gamma$ is the lubrication rate constant of the blend.

Based on this initial approach, Nassar et al. (2022)[12] proposed a simplified model that relates the Kushner model parameters ($\sigma_{sf=0.85,0}$, and β) with the porosity:

$$\sigma_{sf=0.85,0} = a_1 exp\big(b_1(1-sf)\big) \quad (2)$$

$$\beta = a_2(1-sf)+b_2 \quad (3)$$

This model involves five unknown parameters: $\theta = [a_1(MPa);\ b_1(-);\ a_2(-);\ b_2(-);\ \gamma(dm^{-1})]$ and captures the effects of solid fraction and lubrication extent on tablet tensile strength which are identified as CPPs, while tablet tensile strength is regarded as a CQA.

### 2.2 Bayesian parameter estimation

In this study, the uncertainty associated with model parameters ($\theta$) is quantified using Bayesian inference. Experimental data published by Kushner et al. (2012)[13] for the Turbula mixer was utilized to estimate these parameters and identify the uncertainties in the model relationships. This dataset includes tensile strength measurements under varying conditions of lubrication and compaction, providing a reliable basis for parameter estimation.

Bayesian methods provide a powerful framework for parameter estimation, incorporating prior knowledge and experimental data to obtain a posterior distribution for each model parameter. This distribution provides the most likely values of the parameters and quantifies the associated uncertainty, which is crucial for model validation and identifying the robust design space.

Bayes' Theorem combines prior knowledge about the model parameters with the experimental data to update the probability distribution of the parameters. This approach is mathematically expressed as:

$$p(\theta|D) = \frac{\mathcal{L}(D|\theta)\varphi(\theta)}{P(D)} \quad (4)$$

Here, $\varphi(\theta)$ is the prior knowledge about the true value of the model parameters, $p(\theta|D)$ is the posterior distribution representing an updated belief about model parameter value after observing the experimental data. $\mathcal{L}(D|\theta)$ is likelihood distribution and $P(D)$ is marginal likelihood, which normalizes the posterior. The posterior distribution offers not only the most likely parameter values but also quantifies the uncertainty surrounding these estimates.

### 2.3 Nested sampling

The mathematical model describing the relationship between the CPPs, CMAs and CQAs is expressed as:

$$CQAs = f(x,\theta) \quad (5)$$

Here $x$ represents the vector of CPPs within the knowledge domain ($\chi$) in real space ($R^s$), while $\theta$ is the uncertain model parameter defined in $m$-dimensional real

space ($R^m$) with a probability density function (pdf).
The constraints on the CQAs, which can be combined with additional process constraints, are given as

$$G(x,\theta) := g(x, f(x,\theta)) \geq g^* \tag{6}$$

where $g^*$ represents a vector of predefined bounds for the CQAs. If the uncertainty in the model parameter is disregarded, the nominal DS is designed as

$$DS_{nom} := \{x \in \chi | g(x, G(x,\theta_{nom})) \geq g^*\} \tag{7}$$

where $\theta_{nom}$ represents a specific nominal value of the model parameter. However, since $\theta$ is inherently uncertain, whether due to limitation in parameter estimation or to the nature of modeling and data, ignoring this uncertainty may lead to oversimplified DS representations.

To address this, a probabilistic DS is expressed as

$$DS = \{x \in \chi | E_\theta[p(CQAs \in \Lambda) | X = x, \theta] \geq \alpha\} \tag{8}$$

According to equation (8), the DS is a subset of the knowledge space ($\chi$), mapping a set of CPPs ($x$) where the probability of CQAs satisfying the specified limit ($\Lambda$) exceeds a specified reliability value ($\alpha$), while accounting for the uncertainty in the model parameter $\theta$. The reliability value should be kept between $0 < \alpha \leq 1$.
A Bayesian framework addresses this challenge by treating $\theta$ as a random variable with joint probability distribution $p(\theta)$, representing the belief about its potential value of $\theta$. For example, $p(\theta)$ can be estimated from experimental data using Bayesian inference. In this framework, the model is primarily used to predict the probability that the manufacturing process is feasible for a given set of conditions.

$$\mathbb{P}[G(x,\cdot) \geq g^* | p(\theta)] := \int_{\{\theta: G(x,\theta) \geq g^*\}} p(\theta) d\theta \tag{9}$$

Hence, the probabilistic DS can be presented as

$$DS = \{x \in \chi | [\mathbb{P}[G(x,\cdot) \geq g^* | p(\theta)]] \geq \alpha\} \tag{10}$$

In general, at fixed manipulated variable $x,\cdot$ sampled from $S_d$, the probability of meeting CQA constraint is estimated via an ensemble of simulation over uncertainty scenario in $S_\theta$.

$$\hat{\mathbb{P}}[G(x_i,\cdot) \geq g^* | S_\theta] := \sum_{(\theta_j,\omega_j) \epsilon S_\theta} \mathbb{I}[G(x_i,\theta_j)]\omega_j \tag{11}$$

where $\mathbb{I}[\cdot]$ is an indicator function, which takes the value 1 if the constraint is satisfied, and 0 if they are not satisfied. The model parameters $\theta_i$ with corresponding weights $\omega_i$ are sampled from the posterior distribution function $p(\cdot)$. This method requires running full model $N_d \times N_\theta$ times, where $N_d$ and $N_\theta$ are the number of sample points taken from $S_d$ and $S_\theta$ space, respectively, which can be exceedingly costly for practical test cases.

In Nested sampling, the posterior distribution $p(\theta)$ can be derived using Bayes' theorem, which was explained earlier. The equation for the posterior distribution in the context of nested sampling is:

$$\left.\begin{aligned} p(\theta) &= \frac{\mathcal{L}(\theta)\varphi(\theta)}{\mathrm{Z}} \\ \mathrm{Z} &:= \int \mathcal{L}(\theta)\varphi(\theta)\, d\theta \end{aligned}\right\} \tag{12}$$

where Z is referred to as the Bayesian evidence, and it represents the integral of the likelihood weighted by the prior. Unlike the traditional Markov Chain Monte Carlo (MCMC) methods, which aim primarily to approximate the posterior distribution $p(\theta)$, nested sampling focuses on directly estimating Z as its primary target. This is achieved by iteratively sampling within nested contours of increasing likelihood, ensuring a systematic exploration of the parameter space. As a result, regions of high likelihood are densely sampled, enabling accurate estimation of Z. This feature is particularly advantageous for Bayesian model selection, as the evidence Z quantifies the overall fit of a model to the data while accounting for model complexity.

To implement nested sampling in DS characterization, $N_L$ points in the set of live points ($S_L$), can be initialized via uniform sampling in the design space. Nested sampling begins by estimating the feasibility probability at each of these points, according to equation (12), which calculates the likelihood of meeting the CQA constraints as described in equation (11). Estimating the feasibility probability for a given live point requires process model runs for the uncertainty set $S_\theta$. The number of models run for $N_\theta$ parameters in the uncertainty set $S_\theta$ is a critical computational cost of the algorithm.

During each iteration, the worst point $x$, having the lowest feasibility probability, is identified. This point is determined by calculating minimum feasibility probability ($\hat{\mathbb{P}}_{min}$) across all the live points, as shown in equation (13):

$$\hat{\mathbb{P}}_{min} = min_i\{\hat{\mathbb{P}}[G(x_i,\cdot) \geq g^* | S_\theta] : i \in S_L\} \tag{13}$$

The corresponding live point $x$ is the one that minimizes this probability is identified using equation (14), expressed as:

$$x = argmin_i\{\hat{\mathbb{P}}[G(x_i,\cdot) \geq g^* | S_\theta] : i \in S_L\} \tag{14}$$

Once the worst point is identified, it is replaced by a new point selected from the set of replacement point ($N_R$). To accelerate the process, the evaluation of a replacement candidate can be interrupted if the cumulative feasibility probability mass and the remaining samples are below a certain threshold. This strategy reduces unnecessary computations by rejecting unlikely candidates early. Rejected points are not added to the result set, ensuring that the focus remains on finding $N_L$ points with feasibility probabilities greater than or equal to the target reliability ($\pi$).

The replaced live points, along with their associated feasibility probabilities, are then stored in the result set for further analysis. The main iteration concludes when all live points meet or exceed the target probability. These points are then added to the result set, which may

also include dead points. If multiple replacements occur during the final iteration, the result set may exceed $N_L$. Conversely, if the set of live points becomes empty, the algorithm stops prematurely. This situation can be detected by monitoring the rate of improvement in feasibility over several iterations, ensuring that the algorithm doesn't waste resources when progress slows, or the reliability threshold is set too high.

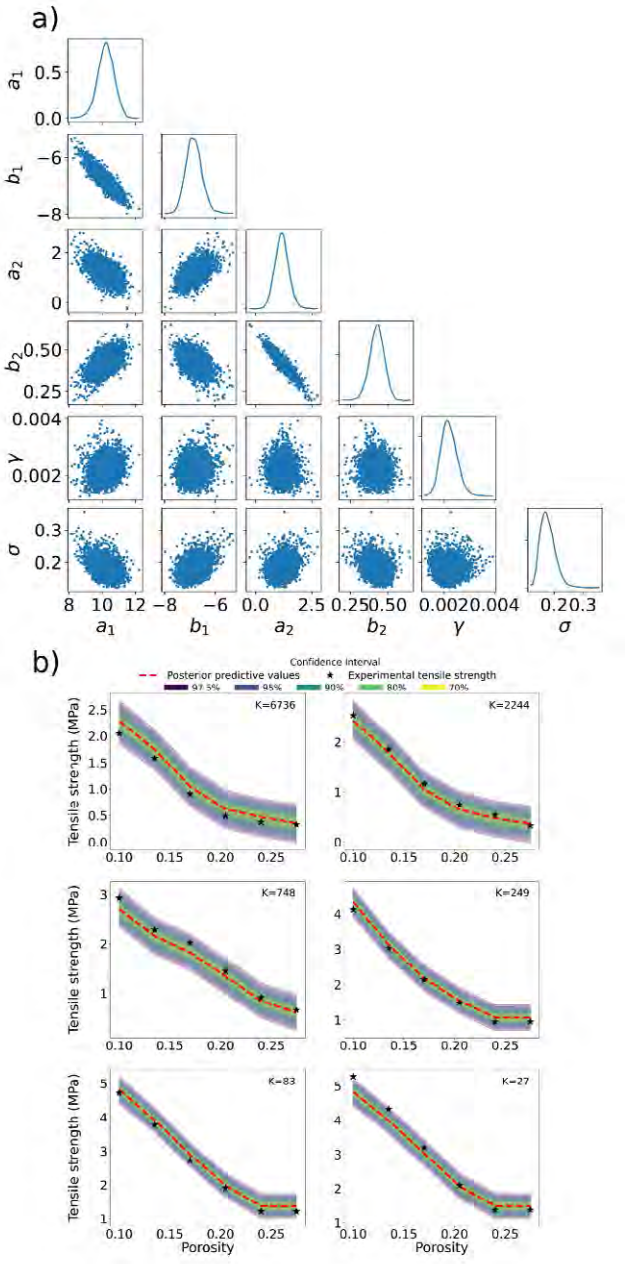

**Figure 1.** (a) Pair-wise plots of posterior distributions and (b) Model predictions with the confidence bands based on Bayesian inference.

The total number of process model runs ($N_{total}$), which is required for $N_{iter}$ iterations of nested sampling, can be expressed as:

$$N_{total} = N_\theta(N_L + N_{iter}N_R) \quad (15)$$

where, $N_L$ is total number of live points, $N_R$ is total number of replacement points, and $N_{iter}$ number of nested sampling iterations.

### 2.4 Flexibility Analysis and the Acceptable Operating Range (AOR)

The flexibility of a system is dictated by the size and shape of its Acceptable Operating Range (AOR) around the Nominal Operating Point (NOP). A larger AOR indicates greater flexibility, allowing the system to operate effectively across a wider range of conditions, while a smaller AOR reflects more constrained operating conditions, limiting the system's ability to adapt to variations[14]. The AOR is identified through a bisection search starting from a NOP and expanding uniformly in all directions until one of its vertices hits the boundary of the design space. The selection of points is entirely dependent on the constraints and nature of the problem. The algorithm terminates when either the maximum number of iterations is reached or when all vertices in the expansion are within the acceptable operating range, and the difference between the upper and lower bounds is smaller than the specified bisection tolerance. If the algorithm reaches the maximum number of iterations before convergence, it may indicate that the vertices haven't expanded sufficiently or the bisection tolerance hasn't been met, in which case increasing the number of iterations may help achieve better convergence.

## 3. RESULTS

The proposed Bayesian parameter estimation framework was implemented using experimental data from Kushner et al. (2012)[13] to quantify the uncertainties in the model parameters described in Sections 2.1 and 2.2. The pair-wise plot for all five model parameters ($\theta = [a_1, b_1, a_2, b_2, \gamma]$ constructed using the posterior samples obtained from Markov Chain Monte Carlo (MCMC), is illustrated in Figure 1(a). The plot shows the marginal posterior distributions along the diagonal as kernel density estimates and joint distributions of parameter pairs as contour plots below the diagonal. The sharpness of the marginal posterior probability density functions (PDFs), along with small coefficients of variation (CV), indicates that the parameter uncertainties are well quantified. The contour plots also provide key insights into the correlations between model parameter pairs [15], which are further explained by the Pearson correlation matrix in figure 2. For example, a strong negative correlation was observed between certain parameter pairs, such as $a_1$ & $b_1$, and $a_2$ & $b_2$. The covariance matrix, which captures these relationships, provides a more realistic measure of model uncertainty, as it reflects the actual behavior of the

system based on the posterior samples. Table 1 presents the sample mean, standard deviation, and CV values of the posterior MCMC samples. Furthermore, figure 1(b) shows the posterior predictive simulations (PPS), generated using the values of $\theta$ and $\sigma$ obtained during the inference. The mechanistic model used for the PPS is the same as the one used for the inference, facilitating direct comparison with the "experimental" data. The PPS confidence ranges are shown by the colored areas in figure 1(b), while the "experimental" values are indicated by the black stars overlaid on the prediction plots.

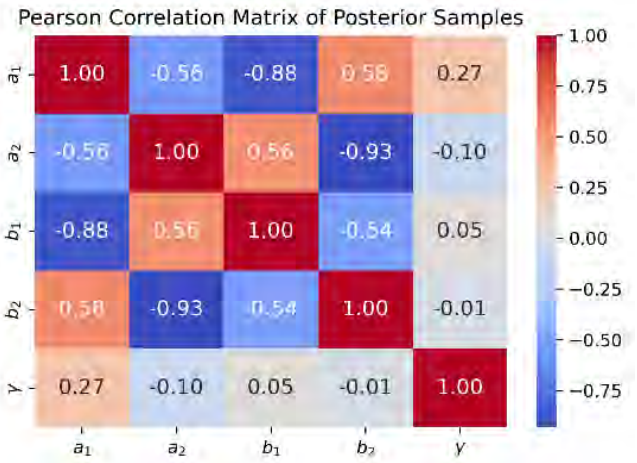

**Figure 2.** Pearson correlation matrix of model parameters. (Darker shades indicate stronger correlations).

**Table 1**. Summary of the Bayesian inference posterior statistics for all model parameters

| Model parameter | Mean | Std deviation | coefficients of variation (CV) |
|---|---|---|---|
| $a_1$ | 10.2268 | 0.508 | 0.0497 |
| $b_1$ | -6.83272 | 0.3116 | -0.045 |
| $a_2$ | 1.1765 | 0.3126 | 0.265 |
| $b_2$ | 0.4268 | 0.0492 | 0.115 |
| $\gamma$ | 0.00222 | 0.00033 | 0.150 |

The knowledge space for this analysis is defined in terms of two CPPs: (i) the lubrication extent $k(dm^{-1}) \in [27, 7000]$, and (ii) porosity, $\mathcal{E} \in [0.01, 0.31]$. The feasible operating region is further constrained by the CQA limits for 8 mm flat faced tablets, $Ts(MPa) \in [2,\ 6]$, ensuring the tableting tensile strength delivers the required quality attributes. The CQA constraints provide essential constraints, limiting the parameter space and ensuring that the system remains within acceptable performance limits. Next, the impact of uncertainty is captured by the probabilistic design space by propagating the model parameter uncertainties, represented as a set of weighted samples $\{\theta_j, \omega_j\}_{j=1,\dots N_\theta}$.

A nested sampling algorithm with a reliability target value of α=0.95 is implemented to focus on higher likelihood samples. To ensure the sufficiently high sample density, 500 live points and 100 uncertainty model descriptions, each with equal weights, are drawn from the posterior density function. The resulting samples are depicted in different colors according to their reliability membership, providing a clear visualization of the probabilistic design space and highlighting areas of high and low reliability in figure 3. On comparison with quasi MCMC, it is observed that nested sampling method efficiently focusing on high-probability region of knowledge space and eliminate the least-probability sampling points. This targeted approach not only enhances the precision of the estimates but also significantly reduces the computational resources required compared to more exhaustive sampling methods.

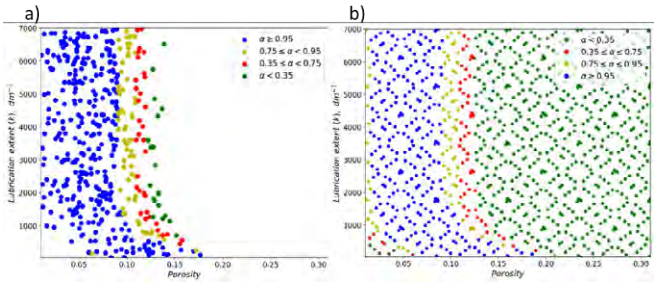

**Figure 3.** Probabilistic design space identified using (a) Nested sampling and (b) Quasi MCMC for the tableting process

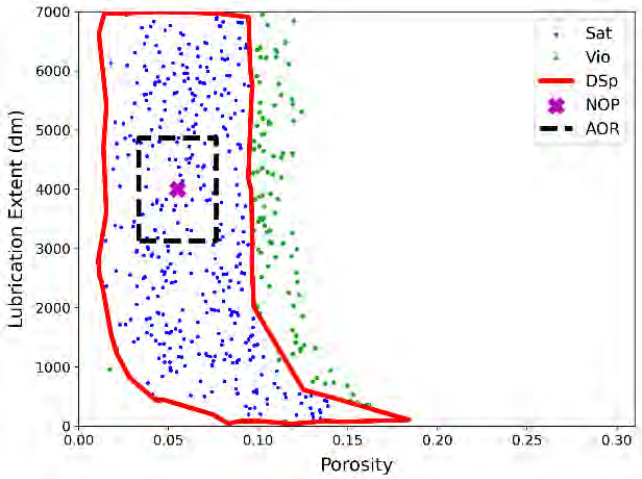

**Figure 4.** Acceptable Operating Region and Nominal Operating Point. 4

To visualize the AOR, probabilistic design space is segmented into satisfied (blue) and violated (green) regions, as shown in figure 4. The black line represents the AOR, encompassing the range of porosity and lubrication extent values that satisfy predefined constraints. The NOP, marked by a purple star at [0.055, 4000], serves as a reference for optimal system performance. The red line

indicates the DS boundary, beyond which the system may exhibit undesirable behavior. . A bisection search method is applied to expand a uniform square region outward from the NOP in all directions until one of the vertices reaches the boundary, ensuring that the AOR remains within acceptable design constraints. The final AOR size of 0.0625 $dm^{-1}$, derived from this iterative process, represents the largest feasible region centered around the NOP's lubrication extent and porosity values. This indicates improved process flexibility and robustness without violating constraints, providing a systematic approach to assess the system's operational limits under varying conditions.

## 4. CONCLUSION

This study successfully developed a probabilistic design space for a pharmaceutical tableting process using Bayesian inference and nested sampling. The approach effectively quantified and propagated uncertainties in model parameters, ensuring consistent tablet tensile strength (CQA) with over 95% reliability. The nested sampling method efficiently identified high-probability regions, reducing computational costs and enhancing precision. The acceptable operating range analysis demonstrated significant process flexibility and robustness. This work underscores the value of probabilistic DS in optimizing manufacturing processes and maintaining regulatory compliance, offering a powerful tool for consistent product quality and operational robustness. Future research will explore extending this methodology to other processes and parameters, with a focus on using iterative selection of nominal points to further explore process robustness and identify optimal operating conditions.

# Separation Sequencing in Batch Distillation: An Extension of Marginal Vapor Rate Method

**Prachi Sharma[a], Sujit S. Jogwar[a]***

## ABSTRACT

Multi-component batch distillation, wherein multi-component mixtures are separated using a single column, is a crucial separation technique in the chemical industry. Traditionally, the components are separated in the descending order of volatility (direct sequence). Similar to continuous distillation, a specific separation sequence can optimize batch distillation. This work aims to generate such optimal sequence for a batch distillation in a computationally efficient manner. Specifically, the proposed approach extends the marginal vapor rate method, which is used for sequencing continuous distillation to multi-cut batch separation. The approach addresses challenges arising due to dynamic nature of batch distillation. The proposed methodology is validated using simulation case studies.

**Keywords**: Batch Distillation, Separation Sequencing, Marginal Vapor Method

## INTRODUCTION

Batch distillation is an important separation technique which is used in the fine and specialty chemical, pharmaceutical, biochemical and food industries. With batch distillation, separation of multi-component mixture can be achieved using a single column where products are recovered in a particular sequence (also known as multi-cut operation). Conventionally, the feed is added in the reboiler and products are withdrawn as distillate in the decreasing order of their volatilities (direct sequence, Figure 1 (a)). On the other hand, in an inverse configuration, the feed is added in the reflux drum and the products are withdrawn from the bottom in the increasing order of volatility (indirect sequence, Figure 1 (b)). Although these sequences can yield the products with the same purity, they require different capital and operating costs. A key question in the design of batch distillation processes is to obtain the optimal sequence of separation. As the number of components to be separated increases, the number of potential separation sequence alternatives increase drastically, necessitating a systematic approach to obtain the best sequence. Optimal sequencing leads to reduced cost and improved efficiency in industrial distillation operations. However, very few studies address this aspect of batch distillation [1-3].

On the other hand, there are numerous studies published in literature discussing design of continuous distillation separation sequences [4-9]. These articles deal with choosing of split sequences to separate a multi-component feed stream into relatively pure, typically single component, product streams making up the majority of the design decisions. Most of

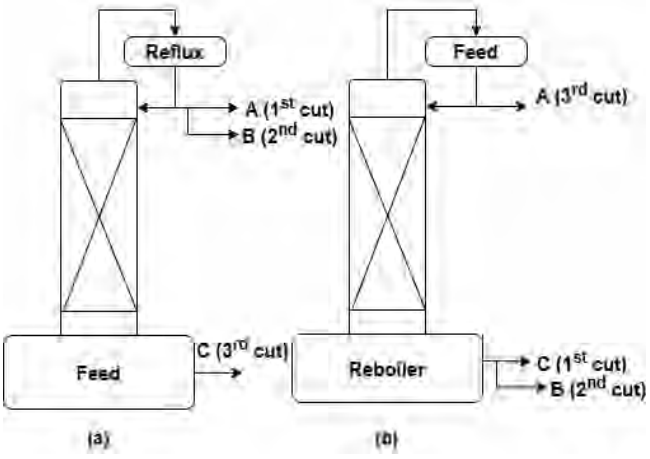

**Figure 1.** Batch distillation sequences (a) direct, (b) indirect for a ternary mixture

these articles either uses heuristics or rigorous optimization. Heuristic approaches offer rapid and low-data requirements for investigation, but often have one dominant rule, leading to miscalculations or contradictory rules. Employing these rules in a structured way is challenging. Mathematical programming methods employ optimization strategies to create ideal separation structures, offering rigorous and optimal solutions. However, they are usually computationally inefficient [9]. One of the most popular methods for continuous distillation column sequencing is marginal vapor rate method [10]. In this method, marginal vapor accounts for capital cost (column diameter) as well as the operational cost (reboiler duty). The sequence with the lowest marginal vapor rate is considered to be optimal.

This article extends this marginal vapor method to solve the sequencing problem for batch distillation. This extension faces two significant challenges. Firstly, in batch distillation, the feed and product compositions vary over time, in contrast to steady state operation in continuous distillation. Secondly, there are material balance limits on total moles rather than molar flow rate. These two challenges are addressed in this work by approximating the batch distillation as a sequence of continuous distillation tasks with varying feed composition [11]. Multiple simulation studies are used to demonstrate and validate performance of the proposed method.

## SEPARATION SEQUENCING

Separation sequencing refers to the process of determining the most efficient order of separating different components of a mixture based on their boiling points or volatility. This study investigates how a specific separation sequence can be employed in a batch distillation column to separate a mixture of N components (A, B, C, etc.) into N relatively pure single component products. N components can be separated into pure components using the number of sequences ($N_s$) provided by Thompson and King [7]:

$$N_s = \frac{[2(N-1)]!}{N!\,(N-1)!} \quad (1)$$

Consider a quaternary mixture of A, B, C and D, where A being the most volatile component and D the least. There are five potential sequences (Table 1) and their respective configurations are shown in Figure 2. Table 1 shows the labelling used to assign numbers to the five sequences. For example, in sequence 1, the first task is to separate the most volatile component A as the first cut. The second tasks is to separate component B as the second cut and the last separation task is perform separation between C and D to obtain C as the third cut. The last product D is collected in the reboiler. Kindly note that only main product cuts are listed in these sequence. In many cases, intermediate slop cuts are also taken during multi-cut separation. The objective of separation sequencing is to find the optimal separation sequence among these alternatives.

**Table 1**: Possible sequences for separation of quaternary mixture

| Sequence | Task I | Task II | Task III |
|---|---|---|---|
| 1 | A/BCD | B/CD | C/D |
| 2 | A/BCD | BC/D | B/C |
| 3 | AB/CD | A/B | C/D |
| 4 | ABC/D | A/BC | B/C |
| 5 | ABC/D | AB/C | A/B |

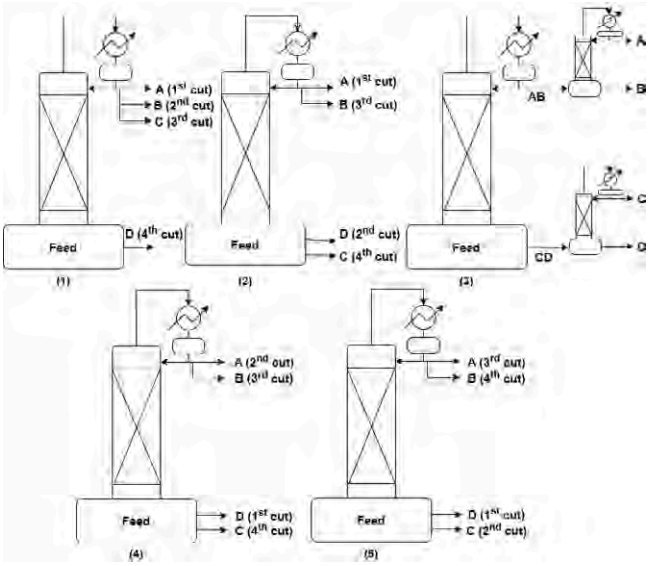

**Figure 2**: Possible configurations for separation of quaternary mixture

## MARGINAL VAPOR METHOD FOR CONTINUOUS DISTILLATION SEQUENCING

Westerberg introduced the marginal vapor method which finds its motivation from marginal price, for solving the sequencing problem for multi-component ideal mixtures in continuous distillation column. Marginal price (annualized cost) assesses the cost of performing a split in the presence of non-key components [10]. The marginal annualized cost (MAC) is evaluated as the cost difference between separation in the presence and absence of non-key components. The MAC is used to select tasks which are least affected by the presence of non-key components. Those separations most affected by the presence of non-key components are operated after the non-keys are no longer present. They demonstrated that MAC can be estimated from the marginal vapor rate

(MVR). Since vapor rate is a key determinant of column diameter, reboiler and condenser areas, and reboiler and condenser duties, it can be a cost metric accounting for the estimate.

Marginal vapor (MV) is the difference in vapor flow (V) of a distillation column in the presence and absence of non-key components. The marginal vapor of a separation task $l \ldots lk/hk..h$ is given by:

$$MV(l \ldots lk/hk..h) = V(l \ldots lk/hk..h) - V(lk/hk) \quad (2)$$

where $V(l \ldots lk/hk..h)$ is the vapor rate of the separation task $l \ldots lk/hk..h$ in the presence of non-key components, and $V(lk/hk)$ is the vapor rate of the separation task $lk/hk$. For example, MV of a quaternary mixture (A, B, C and D) where component A is separated from component B in the presence of other two non-key components will be:

$$MV(A/\mathrm{BCD}) = V(\mathrm{A/BCD}) - V(A/B) \quad (3)$$

Marginal vapor method is based on Underwood's equation. To compute marginal vapor for a separation task, the vapor flow for the column is calculated first using Underwood's equation which assumes constant molar overflow in the column. The Underwood's equations for a distillation column are given by:

$$\sum_{i=l}^{h} \frac{\alpha_i d_i}{\alpha_i - \emptyset} = D(R_{min} + 1) \quad (4)$$

$$\sum_{i=l}^{h} \frac{\alpha_i f_i}{\alpha_i - \emptyset} = F(1 - q) \quad (5)$$

where $l$ is the lightest component in the feed, $h$ is the heaviest component, $F$ and $D$ are feed and distillate flow rates respectively, $\alpha_i$ is the relative volatility of component $i$, $d_i$ is its quantity in the distillate, $f_i$ is its amount in the feed, $R_{min}$ is the minimum reflux ratio of the column, $\emptyset$ is the root of the Eq. (5), and $q$ is the thermal condition of the feed, which is equal to 1 for a saturated liquid. The actual reflux ratio of a column is given by:

$$R = \beta R_{min} \quad (6)$$

where $\beta > 1$ and typically taken as 1.2-1.3. The vapor rate in a column, $V$, is given by:

$$V = D(R + 1) \quad (7)$$

where $D$ is distillate flow rate and $R$ is the reflux ratio.

These equations are solved to estimate vapor flows $V(l \ldots lk/hk..h)$ and $V(lk/hk)$. Then, using Eq. (2), marginal vapor rate for the separation task $(l \ldots lk/hk..h)$ is computed. Subsequently, the MV for entire sequence is computed by adding MV of each separation task in that sequence. Lastly, the sequence with the least MV is considered to be optimal.

## MARGINAL VAPOR METHOD FOR BATCH DISTILLATION SEQUENCING

In the proposed approach, the MV method for continuous distillation as described above is extended for batch separation. This extension faces two significant challenges. Firstly, there are material balance limits on total moles rather than molar flow rate (feed $F$ and products $D$ are specified in total mol instead of molar flow rate). Secondly, in batch distillation, the feed $(x_{fi})$ and product $(x_{di})$ compositions vary over time, in contrast to steady state operation in continuous distillation. This results in varying $R_{min}$ and vapor flow, $V$, during the batch period. To address these challenges, it is considered that batch distillation is equivalent to continuous distillation with varying feed composition [11]. Therefore, by calculating the variation in feed composition as a function of time, the variation in vapor rate during batch distillation can be estimated. Subsequently, this vapor rate profile is integrated along the batch to compute the total vapor required for a given separation task. Lastly, instead of computing marginal vapor rate, marginal total vapor is computed for a separation task. Marginal total vapour is the difference between total vapor required for a given batch separation task in the presence and absence of non-key components. The analytical equations enabling the calculation of this marginal total vapor are presented below.

The first step is to derive equations capturing dynamic evolution of feed composition. Consider a multicomponent mixture (A, B, C....N) separation in a traditional batch distillation, where feed is introduced at the reboiler with A being the most volatile component. Assuming negligible tray and reflux drum holdup, the overall material balance for the column is given as:

$$\frac{dH_F}{dt} = -D \quad (8)$$

where $H_F$ is the total holdup in the still at any time instant and $D$ is the product withdrawal rate. The component mass balance for the $i^{th}$ component in the reboiler is given by:

$$\frac{d[H_F x_{Fi}]}{dt} = -\mathrm{D}x_{Di} \quad \forall\, i \in \mathrm{A, B, C \ldots N} \quad (9)$$

where $x_{Fi}$ and $x_{Di}$ are the composition of component $i$ in the still and distillate respectively. Integrating Eq. (8) over time with $F_0$ being the initial feed amount at the start of operation, for constant distillate flow rate, $D$, the variation of $H_F$ with time is given by:

$$H_F = F_0 - Dt \quad (10)$$

Assuming sharp separation and that the components are collected into pure streams without any slop-cuts (i.e. $x_{DA} = 1, x_{Dj} = 0\ \forall\, i \in \mathrm{B, C, D \ldots N}$), and substituting Eq. (8) in Eq. (9), the Eq. (9) can be rearranged as:

$$\frac{dx_{FA}}{dt} = \frac{D(x_{FA} - 1)}{H_F} \quad (11)$$

Integrating Eq. (11), the relation of $x_{FA}$ with time is given by:

$$x_{FA} = \frac{F_0(z_{FA} - 1)}{F_0 - Dt} + 1 \quad (12)$$

where $z_{FA}$ is the initial feed composition of component A. Similarly, the compositions of all the other components are given by:

$$x_{Fi} = \frac{F_0(z_{Fi})}{F_0 - Dt} \qquad \forall\, i \in \mathrm{B, C, D \ldots} \quad (13)$$

The Underwood's equations (Eq. (4) and (5)) are reformulated in terms of compositions of the components:

$$\sum_{i=l}^{h} \frac{\alpha_i x_{di}}{\alpha_i - \emptyset} = (R_{min} + 1) \quad (14)$$

$$\sum_{i=l}^{h} \frac{\alpha_i x_{fi}}{\alpha_i - \emptyset} = (1 - q) \quad (15)$$

The feed compositions computed by Eq. (12) and (13) are used to find the roots of Eq. (15) at each time instant, $t$. Accordingly, $R_{min}$ and $V$ variations as a function of time are obtained.

For an indirect sequencing of the same mixture in an inverted batch column, feed is introduced at the top of the column and the least volatile product (N) is withdrawn first from the reboiler. The overall material balance is:

$$\frac{dH_F}{dt} = -L \quad (16)$$

where $H_F$ is the total holdup in the reflux drum at any time instant and $L$ is the product withdrawal rate. Integrating Eq. (16) over time with $F_0$ being the initial feed amount at the start of operation for constant withdrawal rate, $L$ , the relation of $H_F$ with time can be written as:

$$H_F = F_0 - Lt \quad (17)$$

The component mass balance for the $i^{\text{th}}$ component in the reflux drum is given by:

$$\frac{d[H_F x_{Fi}]}{dt} = -L x_{Bi} \qquad \forall\, i \in \mathrm{A, B, C \ldots N} \quad (18)$$

where $x_{Bi}$ and $x_{Fi}$ are the composition of component $i$ in the still and reflux drum respectively. Assuming sharp separation i.e. $x_{Bj} = 0\ \forall\, j \in \mathrm{A, B, \ldots N-1}$ and $x_{BN} = 1$, the composition profiles for the components are given by:

$$x_{FN} = \frac{F_0(z_{FN} - 1)}{F_0 - Lt} + 1 \quad (19)$$

$$x_{Fi} = \frac{F_0(z_{Fi})}{F_0 - Lt} \qquad \forall\, i \in \mathrm{A, B, \ldots N-1} \quad (20)$$

where $z_{Fi}$ is the initial feed composition of component $i$. For each time instant, the amount of vapor produced is computed similarly to the direct sequencing approach but in a reverse manner. The total amount of vapor is then integrated over time.

Eventually, marginal vapors for each separation task in a sequence are added together to obtain its marginal total vapor. Lastly, the sequence with the lowest marginal total vapor is recommended as the optimal sequence.

## CASE STUDIES

Let us now consider few case studies to illustrate and validate the proposed approach.

### Case study 1: Pentane-Hexane-Heptane

In the first case study, a mixture of pentane (A), hexane (B), and heptane (C) is to be separated into pure components. Using the above-mentioned methodology, marginal total vapor is estimated for the direct and indirect sequences.

**Table 2**: Data for case study 1

| Component | α | $z_F$ |
|---|---|---|
| Pentane | 7.1352 | 0.25 |
| Hexane | 2.6292 | 0.50 |
| Heptane | 1.0000 | 0.25 |

In the direct sequence, consider the separation A/BC where pentane is separated first from hexane in the presence of heptane. Using the initial feed conditions shown in Table 2, variation of $x_F$ with time is computed using Eq. (12) and Eq. (13) for a constant distillate rate (D) of 1.5 mol/min. These $x_F$ values are then used to find the roots ($\emptyset$) of Eq. (15) to calculate the reflux ratio of the column which is further used to estimate the vapor generated at each time instant.

Figure 3 shows the vapor rate at each time instant for A/BC and A/B respectively. The vapor generated is integrated over batch time to compute the total vapor for the column ($V(\mathrm{A/BC})$) which comes out to be 3627 mol. In a similar way, the total vapor required for binary separation of pentane and hexane ($V(\mathrm{A/B})$) is computed as 2853 mol. The marginal total vapor for the direct sequence is 774 mol.

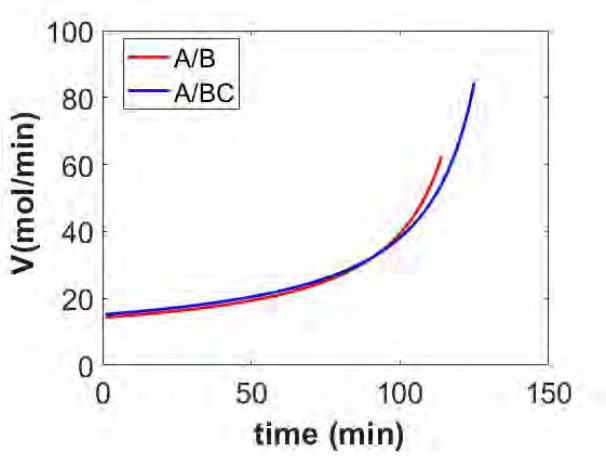

**Figure 3**: Vapor flow for the separation task A/BC and A/B

Alternatively, for the indirect sequence, heptane is separated first from hexane in the presence of pentane. Using the same initial conditions used for the direct sequencing method (Table 2), the total vapor is calculated for both ternary $V(\mathrm{AB/C})$ and binary separation $V(\mathrm{B/C})$. The corresponding values are 5772 mol and 2804 mol, respectively. Thus the marginal total vapor is 2968 mol. It is clearly evident that the direct sequence is better than the indirect sequence.

In order to validate this claim, dynamic simulations are performed for this batch distillation in both conventional (direct sequence) and inverted (indirect sequence) configurations. The operating conditions required for this simulation are specified in Table 3 and Table 4 respectively. For the direct sequence, the time required to separate pentane from hexane in the presence of heptane is 150 minutes. As the simulation used a constant vapor rate of 20 mol/min, the total vapor required is 3000 mol. Similarly, total vapor required for the separation of binary mixture (pentane-hexane) is 2220 mol. Thus, marginal total vapor for direct sequence based on dynamic simulation is 780 mol.

Similarly, for the indirect sequence, the time required to separate hexane from heptane in the presence of pentane is 203 minutes, and the total vapor required is 4060 mol. Total vapor required for the corresponding binary separation (hexane-heptane) is 1140 mol. This results in marginal total vapor of 2920 mol.

**Table 3**: Operating conditions for case study 1 in a direct sequence

| Separation | A/BC | A/B |
|---|---|---|
| No. of trays | 42 | 42 |
| Feed (mol) | 1000 | 750 |
| $Z_F$ | [0.25 0.50 0.25] | [0.333 0.667] |
| V (mol/min) | 20 | 20 |

**Table 4**: Operating conditions for case study 1 in an indirect sequence

| Separation | AB/C | B/C |
|---|---|---|
| N | 42 | 42 |
| Feed(mol) | 1000 | 750 |
| Z | [0.25 0.50 0.25] | [0.667 0.333] |
| V(mol/min) | 20 | 20 |

Table 5 shows the marginal vapor for the sequences as calculated from the proposed approach and simulations. The differences in the values of marginal total vapor are because of the assumption of negligible tray holdup as during simulations, 5% of the initial feed amount was taken as total tray holdup.

**Table 5**: Marginal total vapor for case study 1

| Sequence | Proposed (mol) | Simulation (mol) |
|---|---|---|
| Direct | 774 | 780 |
| Indirect | 2968 | 2920 |

It can be seen from the table above that the marginal vapor of the direct sequence is less than that of the indirect sequence and hence, the direct sequence is the optimal separation sequence for this mixture. As the simulation study used constant vapor rate, smaller total vapor for direct sequence also corresponds to smaller batch time as compared to indirect sequence.

The concentration profiles of three components in the still and reflux drum over time for a traditional batch column (direct sequence) are displayed in Figure 4 (a) and (b). There are five phases to the operation. Phase 1 involves operating the column under total reflux circumstances until the reflux holdup achieves a certain level of purity. The pure product is then gathered in phase 2. Phase 3 involves the withdrawal of an impure mixture of A and B called slop cut. Pure product B is gathered in the following stage, and the process is finished when the holdup in the still is pure C. Similarly, Figure 4 (c) and (d) shows the concentration profile of three components in the reflux drum and the still respectively over time for an inverted batch column (indirect sequence). The product is removed from the bottom and the reboiler holdup is maintained constant. Here also there are 5 operational phases with product C removed in phase 2, product B in phase 4 and product A in the fifth phase. For Figure 4, it can again be seen that the direct sequence is faster than the indirect sequence. This further validates the conclusion drawn from the proposed approach.

## Case study 2: Benzene-Toluene-o-Xylene

Similar study is performed for a mixture of Benzene-

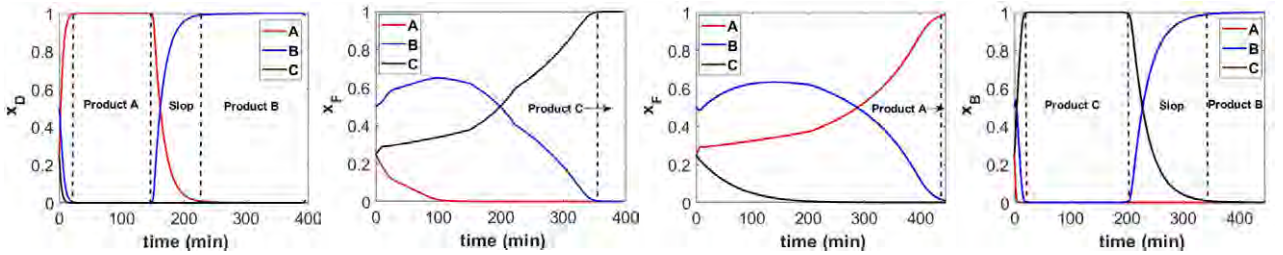

**Figure 4:** Concentration profile of case study 1 in (a) reflux drum, (b) still in direct sequence and (c) reflux drum, (d) still in an indirect sequence

Toluene-o-Xylene with a different set of operating conditions. The information for the problem specification of this mixture is given in Table 6.

**Table 6**: Data for case study 2

| Component (i) | α | $z_F$ |
|---|---|---|
| Benzene | 6.2314 | 0.2 |
| Toluene | 2.6436 | 0.6 |
| o-Xylene | 1.0000 | 0.2 |

The application of the proposed approach results in marginal total vapor of 1047 mol for indirect sequence and 2890 mol for direct sequence. Thus, indirect sequence (inverted configuration) is better for this mixture. This was validated using simulation study where direct sequence required almost three times the amount of total vapor as compared to indirect sequence.

**Table 7:** Marginal total vapor for case study 2

| Sequence | Proposed (mol) | Simulation (mol) |
|---|---|---|
| Direct | 2890 | 2880 |
| Indirect | 1047 | 1060 |

## Quaternary Mixture

Lastly, let us consider a four-component alkane mixture of i-Butane (A), n-Butane (B), i-Pentane (C), and n-Pentane (D) with operating conditions given in Table 8 [9]. Each of the five alternate sequences with ten different separation tasks are indicated in Table 1. Table 9 lists the marginal total vapor values for this mixture using simulation and the proposed approach. The five sequences are then ranked, where the sequence with least marginal total vapor value is ranked first and the sequence with the highest value is ranked the last.

Sequence 3 which is an intermediate sequence is ranked first based on proposed approach as well as dynamic simulation. This sequence is favored as the separation of n-Butane from i-Pentane is easier than that from i-Butane or n-Pentane according to the relative volatility difference.

**Table 8**: Data for quaternary mixture

| S. NO. | Component | $z_F$ | α |
|---|---|---|---|
| 1 | i-Butane | 0.2 | 2.0 |
| 2 | n-Butane | 0.3 | 1.8 |
| 3 | i-Pentane | 0.2 | 1.2 |
| 4 | n-Pentane | 0.3 | 1.0 |

**Table 9**: Marginal total vapor for quaternary mixture

| Sequence | Proposed (mol) | Simulation (mol) | Rank |
|---|---|---|---|
| 1 | 1410 | 1492 | 5 |
| 2 | 1200 | 1251 | 4 |
| 3 | 570 | 596 | 1 |
| 4 | 1050 | 1042 | 3 |
| 5 | 870 | 874 | 2 |

Based on these three case studies, it can be argued that the marginal total vapor method proposed in this work correctly captures the optimal separation sequence for batch distillation.

## CONCLUSION

In this article, we have effectively extended the marginal vapor rate method for optimal sequencing of continuous columns to batch column operations for ideal systems. By applying this method to batch columns, we can deduce the optimal separation sequence in a computationally efficient manner. The proposed approach offers computational advantage over rigorous optimization as well as helps identifying optimal non-trivial separation sequences. The methodology is validated with simulation case studies involving separation of ternary and quaternary mixtures.

In the current form, the work can be directly applied to zeotropic systems. In order to extend this to non-ideal mixtures, one needs to check the feasibility of a separation task before evaluating the separation sequences.

One of the popular approaches to this end is the residue curve maps (RCM) [12]. Thus, the extension of the proposed work to non-ideal mixtures will involve using RCM to identify feasible regions for separation and subsequently determine the optimal sequence of distillation steps. This work is under progress in our group.

## ABSTRACT

Traditional steel processes are energy-intensive and rely heavily on fossil fuels, contributing to significant greenhouse gas emissions. By adopting electrification technologies, such as electric boilers and compressors, particularly when powered by renewable energy, steel plants can reduce their carbon footprint, enhance process flexibility, and lower long-term operational costs. This transition also aligns with increasing regulatory pressures and market demand for greener practices, positioning companies for a more competitive and sustainable future. This work investigates the potential of replacing conventional steam crackers in a steel plant that relies on the use of fossil fuels, with electrically driven heating systems powered by renewable energy sources. The overall aim was to significantly lower greenhouse gas emissions by integrating electric furnaces and heat pumps into the steel production process. This study evaluates the potential carbon savings from the integration of solar energy in a steel plant with a production capacity of 300,000 tons per month. The solar field required for this integration was found to span an area ranging from 122,142 to 362,360 m², while the wind field area required is estimated at 550.373 m2. By incorporating solar power into the plant's energy mix, the analysis reveals a significant reduction in carbon emissions, with an estimated saving of 707,597 tons of $CO_2$ per year.

**Keywords**: Electrification, Steel, Carbon Reduction, Optimization, GHG, additional keywords separated by commas

## INTRODUCTION

The steel industry is among the most energy-intensive sectors globally, with traditional processes heavily dependent on fossil fuels. This reliance not only drives significant greenhouse gas (GHG) emissions but also poses challenges in meeting evolving environmental regulations and market expectations for sustainability. With the increasing availability of renewable energy and advancements in electrification technologies, steel plants have a transformative opportunity to decarbonize their operations.

Electrification of key processes, such as heating systems, using technologies like electric boilers, compressors, and heat pumps, offers a pathway to significantly reduce carbon emissions. These systems, when powered by renewable energy, not only lower the carbon footprint but also enhance process efficiency and flexibility, positioning companies for long-term economic and environmental sustainability. Furthermore, transitioning to electric systems aligns with the growing demand for greener practices. Wei, McMillan and de la Rue du Can [1] reviewed the latest research on the potential for industry electrification to support decarbonization efforts. Sun, Wang [2] analysed carbon emission reduction strategies in the industry through the interconnection of carbon, electricity, and hydrogen, highlighting potential development directions. Hadera, Harjunkoski [3] developed a continuous-time scheduling model to incorporate energy-awareness, optimizing electricity purchases and load commitments. Luh, Budinis [4] used a global energy system simulation to assess the impacts of $CO_2$ reduction measures, including fuel

switching, electrification, and Carbon Capture and Storage (CCS), on investment and operations. Several scenarios that evaluate the role of $CO_2$ pricing as a policy tool for decarbonizing the industrial sector were presented. Sun, Harjunkoski and Castro [5] used the Resource Task Network (RTN) examined the effect of fluctuating electricity prices on production scheduling the economic benefits of the steel plant's participation in incentive-based demand-side management (iDSM) programs. This study explores the feasibility of replacing conventional fossil-fuel-based steam crackers in steel production with electrically driven heating systems powered by renewable energy. The focus is on integrating electric furnaces and heat pumps into the steelmaking process to achieve substantial reductions in greenhouse gas emissions.

## METHODOLOGY

Electrification offers a promising pathway to reduce carbon footprints by replacing fossil-fuel-based technologies with electric-driven alternatives powered by renewable energy sources such as wind, solar, or hydroelectric power. This paper explores the integration of electrification technologies, including electric furnaces, heat pumps, and renewable energy systems, like solar PV, wind, or CSP, into the steel production process. (**Figure 1**) By optimizing energy consumption and incorporating sustainable power sources, the methodology aims to significantly reduce greenhouse gas emissions and enhance operational efficiency. A critical aspect includes evaluating the feasibility of these technologies, assessing their environmental benefits, and performing cost analyses to ensure economic viability

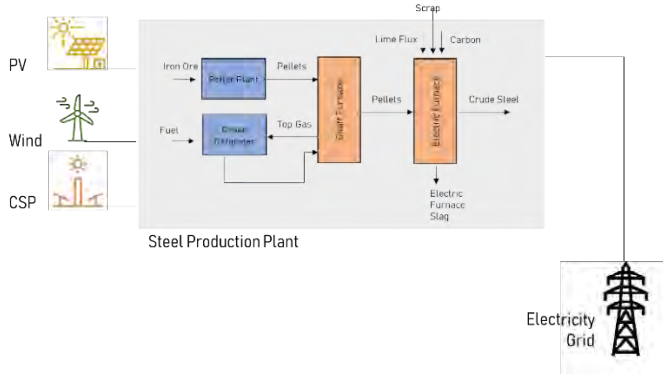

**Figure 1.** The integration of solar PV, wind, and CSP, into steel production

In this paper, a comprehensive approach to assessing the electrification options for a steel plant was made. **Figure 2** below summarizes the approach that was utilized in this work. First, the plant's current energy demand, including the total consumption, peak load, and base load, was evaluated to identify how much can be replaced by renewable sources. This was then followed by an analysis of local renewable energy resources, such as wind and solar, based on site-specific conditions like wind speeds and solar irradiance, to estimate the potential energy generation from wind and photovoltaic (PV) systems. The feasibility of integrating these renewable sources into the plant's electrical system is then assessed, considering factors like land availability, grid connectivity, and required infrastructure upgrades. Economic modeling was then conducted by calculating the Levelized Cost of Electricity (LCOE) for both wind and PV technologies, factoring in CAPEX and OPEX expenditures. Additionally, the environmental impact of the steel plant was then evaluated after electrification options were introduced, focusing on the reduction of greenhouse gas emissions through the adoption of renewable energy. Finally, the most cost-effective and sustainable mix of wind and PV systems that supply the plant's energy needs while meeting the environmental constraints was identified.

## CASE STUDY INFORMATION

The steel plant that was considered in this case study is a high-capacity facility with significant energy demands. The plant's operations require 186.264 MW of electrical power for various industrial processes, including smelting, rolling, and ancillary systems, which rely on a continuous and stable electricity supply. Additionally, the plant consumes 522.5 tons per hour of low-pressure (LP) steam at 3 bars, utilized for processes such as heating, drying, and maintaining operational conditions in different stages of steel production. To meet these intensive energy requirements sustainably, the proposed energy alternatives come from renewable energy sources, including solar PV, wind, and CSP, alongside advanced energy storage and conversion technologies. A lead-acid battery storage system is included to buffer the variability inherent in renewable energy generation, providing grid stability and ensuring uninterrupted power delivery during periods of low generation [6]. This is very important for processes that demand consistent power, as fluctuations can disrupt operations and reduce efficiency. Moreover, in order to meet the plant's steam requirements, electric boilers are incorporated to convert any surplus electricity into thermal energy, hence producing the required low-pressure steam for the plant's operation.

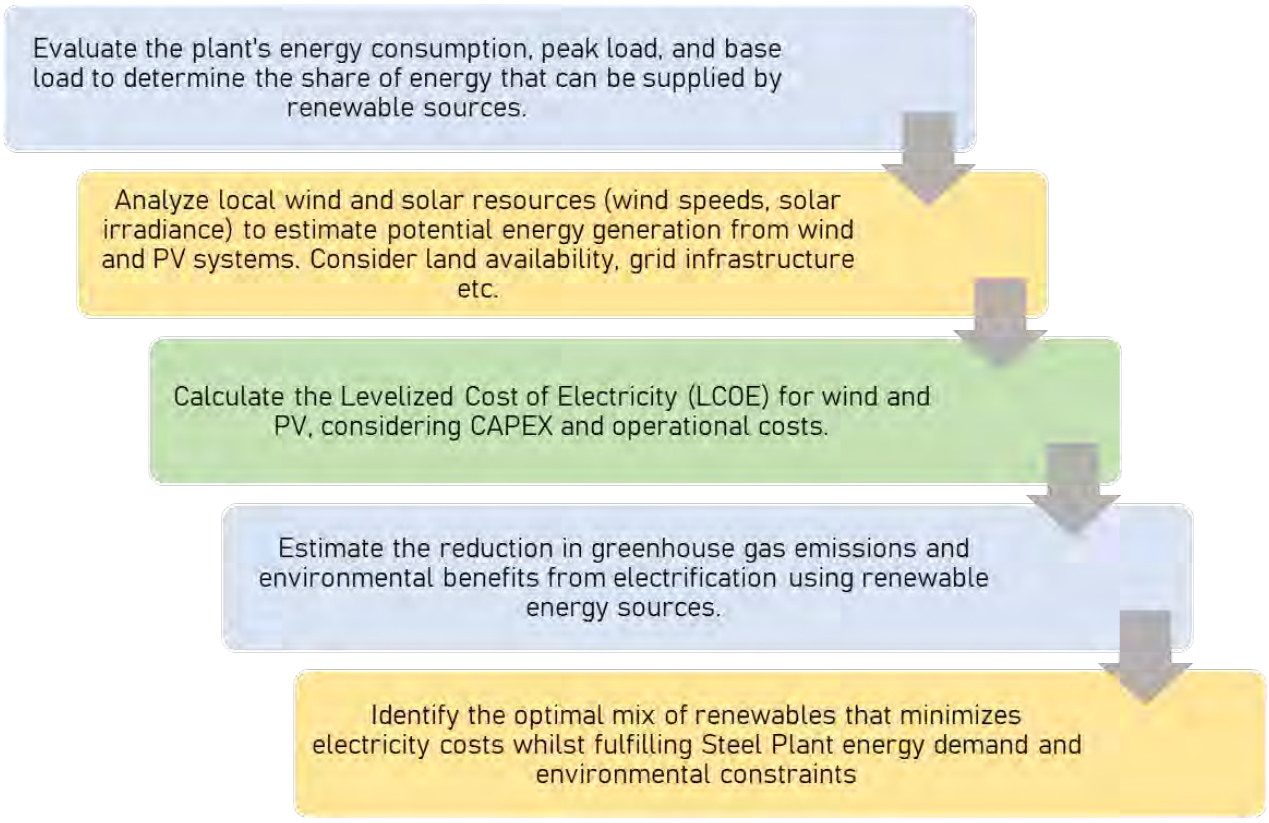

**Figure 2:** Summary of Research Framework

## RESULTS AND DISCUSSION

The results of the study are summarized in **Table 1,** which highlights the differences in land use, energy cost, and CO2 savings for each renewable energy option

**Table 1:** Summary of Parameters associated with CSP, PV and wind energy

| Parameter | CSP | PV | Wind |
|---|---|---|---|
| Land Area ($m^2$) | 122,142 | 362,360 | 550,373 |
| No. Panels /Turbines | - | 181,180 | 272 |
| Cost (USD/kWh) | 0.165 | 0.096 | 0.055 |
| $CO_2$ Savings (tons/y) | 629,868 | 569,413 | 675,930 |

CSP systems use solar thermal technology to generate electricity and heat, making them an ideal candidate for dual production of electricity and steam. In this study, CSP requires a land area of 122,142 m² to meet the plant's energy demands. Although CSP inherently supports thermal energy storage, the integration of Pb-acid batteries ensures continuous operation during periods of low solar irradiance. The levelized cost of energy (LCOE) for CSP was calculated at $0.165/kWh, the highest among the technologies evaluated. PV systems are assessed for their cost-effectiveness and scalability. Covering an area of 362,360 m², the PV system includes 181,180 panels to generate the required power. Since PV systems produce only electricity, electric boilers are incorporated to fulfill the steam demand. The LCOE for PV is $0.096/kWh with storage and $0.049/kWh without storage, showcasing its competitive advantage. However, the dependency on battery storage for consistent operation poses challenges related to cost and efficiency. Wind turbines were evaluated at an average wind speed of 7 m/s. To meet the plant's energy requirements, 272 turbines occupying 550,373 m² were proposed. With an LCOE of $0.055/kWh, wind energy proves to be the most economical option with storage. The cost drops further to $0.032/kWh when storage is excluded. Interestingly, if wind speeds increase to 9 m/s, the LCOE reduces to $0.047/kWh, demonstrating the high sensitivity of wind energy costs to wind conditions. Despite the variance in cost and land area, the CO2 emissions reduction from operation is identical across the three technologies and estimated at 707,597 tons/y. This uniformity arises

from the complete replacement of natural gas with renewable sources. However, when considering the $CO_2$ life cycle assessment (LCA) of each technology, the actual net emissions reduction differs due to the embedded emissions in manufacturing, transportation, installation, maintenance, and decommissioning. CSP, with a lifecycle emission factor of 27 g $CO_2$/kWh, achieves a reduction of 629,868 tons/year. PV, having a higher emission factor of 48 g $CO_2$/kWh, results in a slightly lower reduction of 569,413 tons/year. On the other hand, wind energy, with the lowest lifecycle emissions at 11 g $CO_2$/kWh, leads to the highest reduction of 675,930 tons/year [7]. These results highlight the importance of considering full life cycle emissions when assessing the environmental impact of renewable technologies. While all three sources significantly reduce emissions compared to fossil fuels, wind energy emerges as the most effective in minimizing $CO_2$ footprint, followed by CSP and then PV.

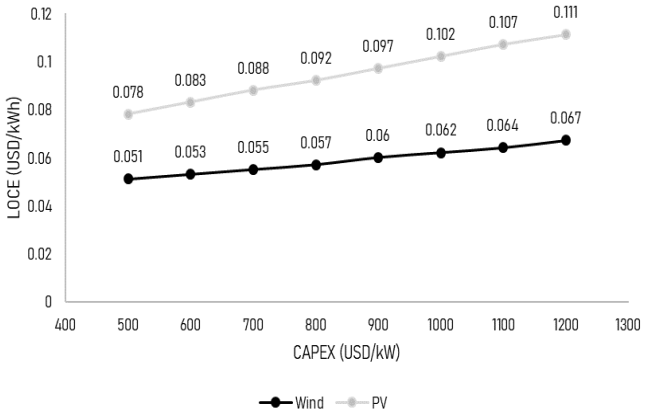

**Figure 3.** Optimal costs attained for Steel Electrification via PV and Wind technologies

The use of electric boilers is a pivotal adaptation for PV and wind systems, as these technologies generate electricity exclusively. This ensures that the steel plant's LP steam requirements are met without compromising its operational integrity. The integration of Pb-acid batteries across all systems addresses intermittency issues, though the added cost impacts overall feasibility. From an economic standpoint, wind energy emerges as the most viable option, particularly in regions with high average wind speeds. The reduced LCOE at higher wind speeds further enhances its competitiveness. However, the extensive land requirement for wind turbines and PV systems poses logistical challenges, especially in densely populated or land-constrained areas. CSP, while requiring less land, is the most expensive option and may be less attractive unless thermal energy storage provides significant operational advantages. Further studies could explore alternative storage technologies, such as lithium-ion batteries, which may offer improved efficiency and lower costs. Additionally, hybrid solutions that combine CSP with PV or wind could optimize resource utilization and mitigate individual technology limitations.

A sensitivity analysis was performed to assess the impact of the capital expenditure on the levelized cost. **Figure 3** shows the results that were attained for wind and PV energy systems. The results indicate that as CAPEX increases from 500 to 1200 units, the LCOE for both wind and PV systems also increases. For wind, the LCOE increases from 0.051 to 0.067 USD/kWh, while for PV, it increases from 0.078 to 0.111 USD/kWh.

It is evident that PV systems have a higher LCOE compared to wind systems at all CAPEX levels, reflecting higher costs for generating electricity from PV systems under these conditions. The rate of increase in LCOE appears consistent for both technologies, suggesting a proportional relationship between CAPEX and operational costs. Moreover, while wind energy appears more cost-effective for the steel plant in this case study, regional factors such as resource availability, land use, and grid infrastructure can influence the decision-making process.

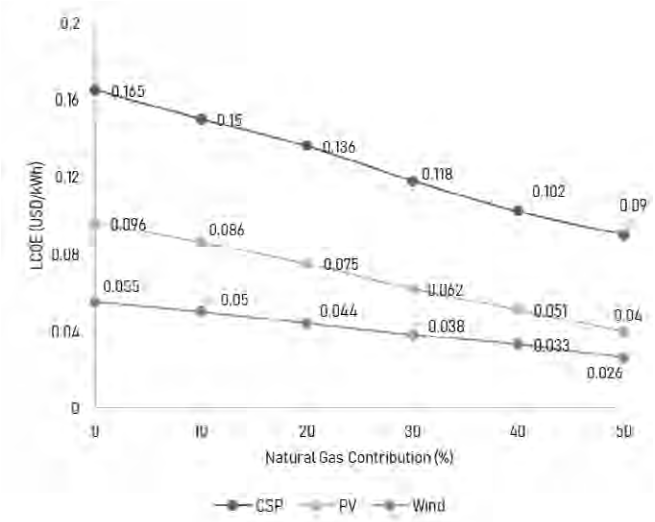

**Figure 4.** Natural gas (NG) proce sensitivity on the levelized cost of electricity (LCOE) for CSP, PV and wind

**Figure 4** demonstrates the sensitivity analysis conducted on the effect of natural gas (NG) contribution on the levelized cost of electricity (LCOE) for CSP, PV, and wind technologies. A clear tread is observed; increasing the share of NG in the energy mix leads to a reduction in LCOE across all three renewable technologies. This trend is expected since NG is typically a lower-cost generation source compared to renewable technologies, especially when considering the high capital expenditure (CAPEX) of CSP and PV systems.

At 0% NG contribution (i.e., fully renewable operation), CSP exhibits the highest LCOE (0.165 $/kWh), followed by PV (0.096 $/kWh), and wind (0.055 $/kWh). As NG contribution increases to 50%, the LCOE for all

technologies decreases significantly, reaching 0.09 $/kWh for CSP, 0.04 $/kWh for PV, and 0.026 $/kWh for wind. This reduction can be attributed to the lower cost of NG electricity production and the reduced reliance on high-capital-cost renewable infrastructure. Among the three technologies, CSP experiences the most significant absolute decrease in LCOE (from 0.165 $/kWh to 0.09 $/kWh), reflecting its higher initial cost and greater sensitivity to hybridization with conventional power sources. On the other hand, wind, which starts with the lowest LCOE, exhibits the least reduction, dropping from 0.055 $/kWh to 0.026 $/kWh, indicating that its cost structure is already competitive with NG.

These findings highlight the economic advantage of incorporating a certain percentage of NG into renewable energy systems to reduce costs. However, the trade-off between cost reduction and carbon emissions should be carefully considered when optimizing the energy mix for sustainability goals.

## CONCLUSIONS

The adoption of electrification technologies, particularly when combined with renewable energy sources, offers a promising pathway for decarbonizing the energy-intensive steel industry. This study demonstrates the potential of replacing conventional fossil-fuel-based steam crackers with electrically driven heating systems, such as electric furnaces and heat pumps, powered by solar or wind energy. The integration of wind and solar power into the steel plant's energy mix resulted in a substantial reduction in carbon emissions, with an estimated annual savings of 2,831 tons of $CO_2$. By integrating renewable energy sources like CSP, wind, or PV, steel plants can easily shift from fossil fuel dependence to cleaner electricity, reducing their environmental impact.

## ABSTRACT

This work aims to develop an energy storage system that allows fluctuating energy inputs (*i.e.* from process sections driven by renewable sources) to power two process units that are operated continuously at different temperatures. The system consists of two vessels storing diathermal mediums: one for the hotter- and the other for the colder-energy fluxes. The investigated solutions include sensible-heat-, latent-heat-, and thermochemical-TES (thermal energy storage). Organic Rankine cycles (ORCs) with lithium-ion batteries and thermoelectric generators were also assessed. Indeed, all these technologies allow the exploitation of low-temperature thermal energy to supply the high-temperature unit during periods of energy scarcity. Both vessels aim for total self-sufficiency; however, the option to rely on external utilities has been included to meet the energy demand of both units when sufficient process-side power is unavailable. Two energy profiles were investigated to assess the proposed storage systems' performance: one showing only solar energy inputs and the other showing only wind energy inputs. Finally, an optimization problem was formulated to estimate the optimal size of both storage vessels. Indeed, increasing their capacities would lead to higher capital expenses (CAPEX) and lower operating expenses (OPEX). As a result, the assessed process-integrated configurations (*i.e.* those featuring any energy storage system) proved competitive with the non-integrated solution (*i.e.* the one fully relying on external sourcing of electricity) only if referring to high electric energy prices (300 USD/MWh). Conversely, when considering an electricity price of 100 USD/MWh, all the assessed process-integrated configurations proved more expensive than the non-integrated solution.

**Keywords**: Energy storage, Heat recovery, Process integration, Renewable energy, Solar power, Wind power.

## INTRODUCTION

Powering the chemical industry with renewable energy represents a significant challenge for process engineers today. The primary obstacle to achieving a fully integrated green solution lies in harmonizing inherently intermittent energy production with processes that require predominantly continuous operation. Energy storage has emerged as a highly effective approach to address this challenge, with various methods aiming to regulate oscillatory renewable energy inputs for processes requiring operational steadiness. Scientific literature offers several innovative energy storage methods, such as fluid heating via electrical resistances [1], or storage by batteries [2] or reversible reactions (being exothermic or endothermic according to the direction taken) [3], *i.e.* electrochemical storage. Other technologies involve evaporating liquefied air to drive turbines for electricity generation during the discharge phase, complemented by compression cycles during the energy storage charging phase [4]. Lastly, even Brayton cycles and subsequent storage of working fluids may play a role in continuous electricity production [5]. This work aims to model and optimize the heat recovery system powering two different process units (*aka* "users") relying entirely on the thermal energy recovered from upstream process sections exposed to significant

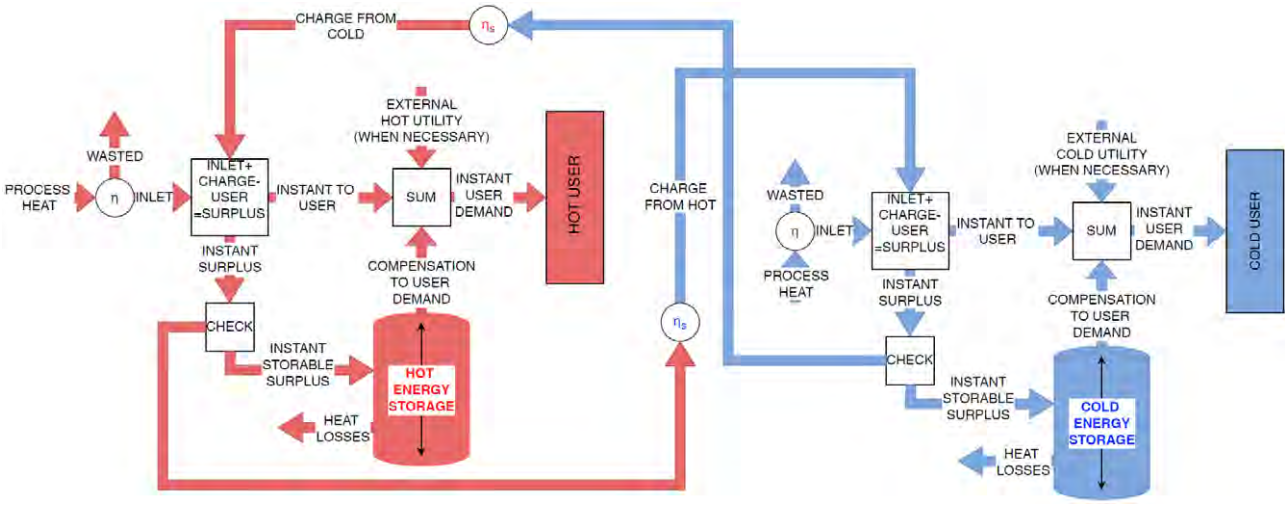

**Figure 1:** Block flow diagram of the integrated system model.

thermal load fluctuations due to renewable energy inputs. To ensure the continuous operation of the investigated process units, it is crucial to identify the optimal configuration according to the technologies employed and the storage capacities to be installed (as it concerns the CAPEX). Also, such an integrated solution should minimize the reliance on external utilities (as it concerns the OPEX).

## METHODOLOGY

Operating at two different temperatures, the two users are supplied by two streams at distinct temperatures: the "hot" (*i.e.* 185 °C) and the "cold" (*i.e.* 95 °C) one. The system incorporates two storage tanks amidst the users' incoming energy inputs and departing energy demands. Both tanks are interconnected to optimize energy integration, allowing energy transfer between them in cases where a surplus exceeds the storage capacity. In this regard, the "hot-to-cold" energy transfer efficiency is approximately 90% [6]. Conversely, the "cold-to-hot" energy transfer efficiency significantly changes according to the technologies employed for energy conversion.

Three distinct energy storage technologies are evaluated: latent-heat-, sensible-heat-, and thermochemical-TES (thermal energy storage). On the other hand, an organic Rankine cycle (ORC), combined with an electric resistance and a battery to manage short-term fluctuations and ensure the continuous operation of the turbine, has been assessed to convert cold thermal energy into hot thermal energy. Also, a process configuration featuring a thermoelectric reactor coupled with thermal resistance has been considered. **Figure 1** illustrates how the system was modeled. To run the optimization problem, the sizes of the storage tanks act as degrees of freedom. Larger tanks would increase capital investment costs but reduce external energy purchases. Conversely, smaller tanks would reduce investment costs but increase operational costs and emissions, as they require more external energy, which might also be associated with a high carbon footprint. Going into the modeling details of both energy storage systems (*i.e.* the "hot" and the "cold" ones), $Instant\ Surplus$ is a variable of key importance, accounting for the difference between the energy demand of the users and the energy supplied by the heat recovery system (plus any eventual energy coming from the other vessel). Accordingly, it is defined as:

$$InstantSurplus(t) = Inlet(t) \cdot \eta - User(t) + ChargeFromSystem(t) \cdot \eta_c \quad (1)$$

where $\eta$ accounts for the energy losses due to storage, and $\eta_c$ is the conversion efficiency (*i.e.* "hot-to-cold" or "cold-to-hot"). Hot-to-cold energy transfers typically feature near-unity efficiencies, while cold-to-hot energy transfers generally show much lower efficiencies due to thermodynamical and conversion limitations. Hereafter, the $ChargeFromSystem$ variable is defined as:

$$ChargeFromSystem(t) = max\big(InstantSurplus(t) - \big(MAXEnergyStorage - EnergyStorage(t)\big), 0\big) \quad (2)$$

Equation 2 quantifies the energy that can be transferred between the systems when immediate use or storage is not possible, according to the installed capacity of the storage system ($MAXEnergyStorage$). The $EnergyStorage$ variable tracks the filling and emptying of storage vessels over time, incorporating heat losses:

$$EnergyStorage(t) = \min(\max(EnergyStorage(t-1) + InstantSurplus(t), 0), MAXEnergyStorage) \cdot (1 - HeatLosses) \quad (3)$$

This ensures full compliance with physical and operating limitations in both storage systems. When neither stored

**Table 1:** The proposed technologies for energy storage and conversion.

| Technology | Medium (hot and cold storage) | Plant section | Efficiency | Lifetime | Ref. |
|---|---|---|---|---|---|
| Latent heat | $KNO_3$ KOH<br>$H_2C_2O_4$ | Energy storage | $\eta$ = 90%<br>Heat losses = 1%/h | 15 y | [7] |
| Sensible heat | $NaNO_3$ NaOH<br>$H_2C_2O_4$ | Energy storage | $\eta$ = 90%<br>Heat losses = 1%/h | 15 y | [7] |
| Thermochemical | $CaAl_{0.02}Mn_{0.8}O_{2.68}+0.16O_2$<br>$\leftrightarrow CaAl_{0.02}Mn_{0.8}O_3$<br>[Unfeasible] | Energy storage | $\eta$ = 90%<br>Heat losses = 1%/h | 15 y | [8] |
| ORC + Battery | – | Energy conversion | $\eta_c$ = 30% | 20 y | [9] |
| Thermoelectric generator | – | Energy conversion | $\eta_c$ = 5% | 12 y | [10] |

nor transferred energy is enough to meet the users' demand, any remaining imbalance is compensated by the $ExternalUtility$ variable, calculated as:

$$\boldsymbol{if}\ InstantSurplus < 0 \quad AND \quad |InstantSurplus(t)| > EnergyStorage(t)$$

$$ExternalUtility(t) = |InstantSurplus(t)| - EnergyStorage(t)$$

$$\boldsymbol{else}$$

$$ExternalUtility(t) = |InstantSurplus(t)| - EnergyStorage(t) \quad (4)$$

Thus, the optimizer iteratively adjusts the maximum hot and cold storage capacities ($MAXEnergyStorage$) through an exhaustive grid-search to identify the configuration minimizing the total costs. Such calculations, based on the energy demand vs. production profiles, describe the storage dynamics, the power needed for the conversion technology, and the utility requirements accounted for by the objective function. The maximum storage size matches to $MAXEnergyStorage$, the maximum required conversion power corresponds to the highest value by the $ChargeFromSystem$ time-array, and the total external utility demand comes from integrating the $ExternalUtility$ vector throughout the assessed time frame.
Two distinct objective functions have been considered. The former distributes the investment costs over the lifetime ($LT$) of each process unit:

$$\Phi_{OBJ}^{(1)} = HotMediumCost/LT_{HotMedium} + HotTankCost/LT_{HotTank} + ColdMediumCost/LT_{ColdMedium} + ColdTankCost/LT_{ColdTank} + \left(\sum_{t=1}^{t_{end}} ColdUtility(t) + \sum_{t=1}^{t_{end}} HotUtility(t)\right) \cdot ElectricityCost + EnergyConversionCost/LT_{conversion} \quad (5)$$

The latter incorporates a Capital Recovery Factor ($CRF$), calculated as $\frac{IR(1+IR)^{LT-1}}{(1+IR)^{LT}-1}$, with an 8% interest rate ($IR$) to account for the time value of money. Several factors may influence the interest rate, including project risk (higher perceived risk results in higher interest rates), financial market considerations, and the type of financing used (as equity and debt involve different costs). Consequently, a range between 5% and 8% (hence the 8% choice has a conservative nature) is suggested for the interest rate as green projects often benefit from incentives and more favorable conditions compared to traditional sectors, though frequently facing major risks related especially to technological innovation or regulatory variability.

$$\Phi_{OBJ}^{(2)} = HotMediumCost \cdot CRF_{HotMedium} + HotTankCost \cdot CRF_{HotTank} + ColdMediumCost \cdot CRF_{ColdMedium} + ColdTankCost \cdot CRF_{ColdTank} + \left(\sum_{t=1}^{t_{end}} ColdUtility(t) + \sum_{t=1}^{t_{end}} HotUtility(t)\right) \cdot ElectricityCost + EnergyConversionCost \cdot CRF_{conversion} \quad (6)$$

For both objective functions (defined in Equations 5 and 6, respectively), an operating time of 8760 hours per year (*i.e.* assuming non-stop plant operations) was assessed. Indeed, as the upstream process sections (*i.e.* those providing the "process heat" reported in **Figure 1**) are powered by renewable energy inputs, they typically exhibit large oscillations throughout the year, especially due to solar and wind seasonal trends. In this regard, **Table 1** reports all the technologies proposed for the investigated system and their respective efficiencies and lifetimes. Finally, the optimization problem was assessed through a brute-force but exhaustive grid-search routine in MATLAB™ R2024a. As mentioned above, this problem shows two continuous degrees of freedom (*i.e.* decision variables): the installed capacity of the hot and the cold energy storage systems.

## RESULTS AND DISCUSSION

The model underwent two distinct input thermal-

**Table 2:** The investigated process configurations.

| # | Hot storage | Cold storage | Energy conversion |
|---|---|---|---|
| 1 | Sensible | Sensible | ORC + Battery |
| 2 | Latent | Sensible | ORC + Battery |
| 3 | Thermochemical | Sensible | ORC + Battery |
| 4 | Sensible | Sensible | TEG |
| 5 | Latent | Sensible | TEG |
| 6 | Thermochemical | Sensible | TEG |
| 7 | Sensible | Latent | TEG |
| 8 | Latent | Latent | TEG |
| 9 | Thermochemical | Latent | TEG |
| 10 | Sensible | Latent | ORC + Battery |
| 11 | Latent | Latent | ORC + Battery |
| 12 | Thermochemical | Latent | ORC + Battery |

energy profiles, "A" and "B", based on solar (the former) and wind (the latter) energy inputs. In both cases, the primary purpose of the optimization process is to identify the most effective process-integration technique and determine whether energy storage is more cost-effective than relying on external utilities. Please note that both objective functions disregard carbon emissions entirely. However, integrated heat recovery systems typically reduce carbon intensity due to their lower dependence on external utilities (which usually are highly carbon-intensive, especially those used for heating).

The technologies listed in **Table 2** were combined to assess the three storage methods for both (*i.e.* "hot" and "cold") tanks with the proposed two conversion methods. Considering all possible combinations, 18 configurations (*i.e.* = 3·3·2) were obtained. However, excluding those 6 featuring thermochemical energy storage for the cold tank (since the investigated scientific literature does not report any storage medium available at such temperatures) resulted in 12 viable and technically feasible configurations.

From the proposed optimization problem, one can expect two opposite scenarios: the former, minimizing the OPEX, almost nullifies the need for external utilities by contemplating heavy energy transfer from the cold to the hot tank through a conversion technology; the latter, minimizing the CAPEX, rejects any integrated conversion feature: *i.e.* it increases reliance on external utilities (thus potentially leading to higher emissions) but also reduces investment costs and spatial requirements associated with the energy conversion system.

Another critical aspect of the analysis concerns the competitiveness of the process integration compared to purchasing external energy whenever needed to mitigate renewable energy fluctuations. Therefore, even buying electrical energy from an external power grid has been evaluated as a reference benchmark (such configuration has been referred to as "NI", *i.e.* "non-integrated"). Accordingly, we assumed an electricity cost equal to 100 USD/MWh. However, we also performed a parallel estimation referring to the European peak electric price of 300 USD/MWh, as reported by Eurostat [11] for the last decade, to account even for scenarios with high energy prices.

**Figure 2** shows the results for those two different electricity prices in the case of Profile A. The first couple of columns report the costs associated with the non-integrated configuration. In this context, when the instantaneous energy supply is insufficient to meet user requirements, any deficit is compensated by purchasing electricity from the grid. A similar trend can be observed when referring to Profile B. While Profile A leads to process configurations ranging between 118.1 kUSD/y and 707.7 kUSD/y (100 USD/MWh) and 200.2 kUSD/y and 795.6 kUSD/y (300 USD/MWh), Profile B leads to process configurations ranging between 125.1 kUSD/y and 543.5 kUSD/y (100 USD/MWh) and 262.3 kUSD/y and 695.2 kUSD/y (300 USD/MWh). Concerning Profile A, when referring to 100 USD/MWh, all the assessed energy storage technologies lead to higher costs than the non-integrated configuration (NI). However, when considering 300 USD/MWh, all the configurations except #4, #5, and #6 are cheaper than NI. Concerning Profile B, when referring to 100 USD/MWh, all the assessed energy storage technologies lead to higher costs than the non-integrated configuration (NI). However, when considering 300 USD/MWh, only the #8 and #11 configurations are cheaper than NI.

Therefore, the assessed case study does not show remarkable economic benefits from integrating energy storage systems into the process compared to external sourcing of electricity (*e.g.*, from the power grid) unless significant electric energy price increases.

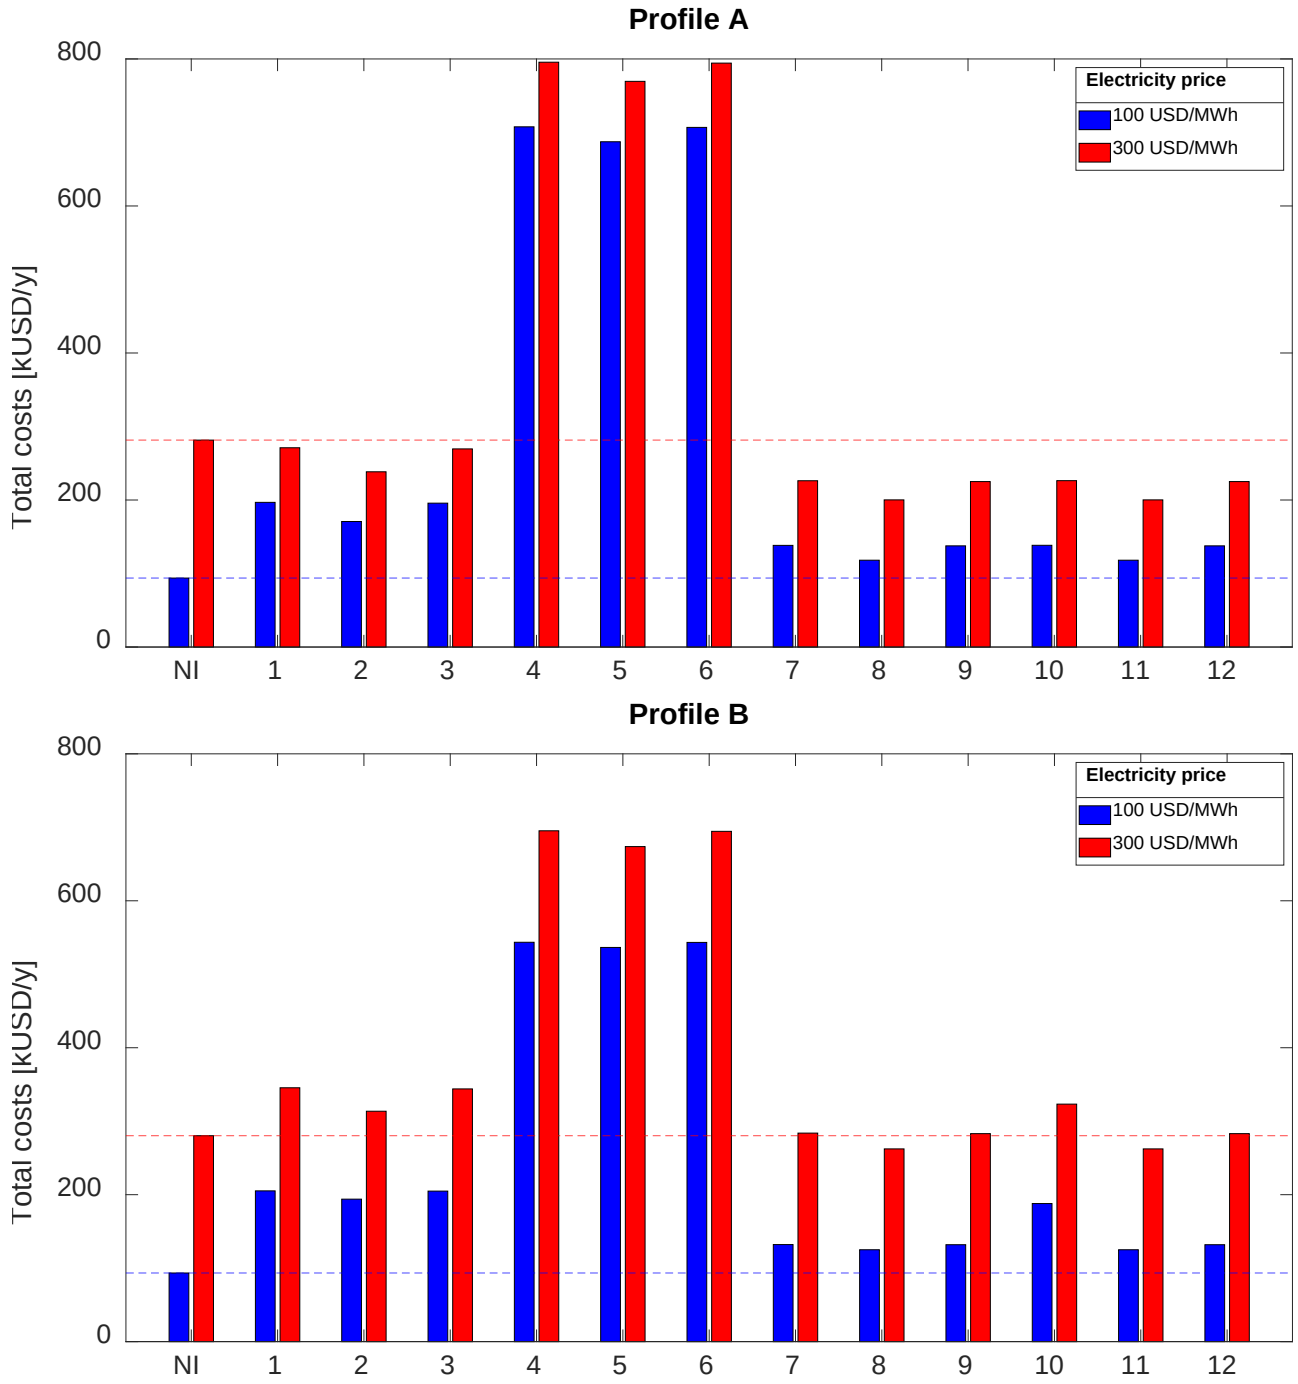

**Figure 2:** Annual total costs ($\Phi_{OBJ}^{(2)}$) by the 12 assessed configurations (see **Table 2**) compared to the non-integrated one (NI) when referring to Profile A (Panel A, top) or Profile B (Panel B, bottom).

## CONCLUSIONS

This study highlights the critical role of energy storage in improving both economic and environmental outcomes in chemical plants. Process integration and energy storage systems allow for reducing carbon emissions and even operating costs when energy prices are particularly high. The results underscore that large-scale integration of renewable energy into chemical processes is only feasible through effective storage systems that consistently outperform external energy purchases during peak demand and production shortfalls. Also, higher economic benefits are expected due to the environmental benefits

of process integration (*e.g.*, less dependence on external electricity and/or heat sourcing, which is typically carbon-intensive).

The presented optimization demonstrated the potential benefits of process-integrated energy storage solutions. While this work performed a sensitivity analysis of electricity prices, dynamic conceptual design techniques accounting for price variations over time may provide additional insights. Nevertheless, including energy storage consistently resulted in reduced external utility consumption when renewable energy sources were used.

An innovative aspect of this study lies in assessing energy conversion between two interconnected tanks whose sizes are to be optimized. Although promising, the feasibility of this method depends heavily on energy profiles and economic factors, as shown by the different results obtained with the two objective functions, two profiles, and two electricity prices. As such, industrial-scale implementation of energy conversion must be rigorously evaluated, accounting for several techno-economic assumptions.

Lastly, this work proves that coupling renewable energy inputs with energy storage systems allows for the operation of large-scale chemical processes according to the need for smooth variations in mass and energy flows by only calling for minor modifications to existing units. This approach aligns with process sustainability goals, especially the transition to greener industrial solutions.

## ABSTRACT

This study presents a comparative analysis of various configurations for sustainable olefins production via chemical recycling of plastic/biomass wastes, integrating $CO_2$ capture, storage and management technologies. The co-gasification, methanol synthesis and methanol-to-olefins process models were developed on the Aspen Plus® software. Optimization of processing conditions is achieved through the OSMOSE Lua platform, for minimizing the total cost of operation while accounting for seasonal variability in the electricity prices. $CO_2$ valorization processes have been shown to increase carbon efficiency from 55% up to 97% compared to steam naphtha cracking, making chemical recycling of plastics an appealing alternative. In addition, direct $CO_2$ emissions can be fully eliminated, resulting in up to 70% lower net $CO_2$ emissions even when fossil-based plastic waste is used as feedstock. Seasonal $CO_2$ storage can extend the economic benefits by acting as a buffer against high electricity costs and serving as a feedstock for $CO_2$ valorization processes when excess renewable electricity is available. The benefits of the proposed configurations are expected to become increasingly significant with the decarbonization of the electricity generation, relying more on renewable resources.

**Keywords**: Plastic Waste, Light Olefins, Gasification, Renewable and Sustainable Energy, Process Integration, Circular Economy

## INTRODUCTION

Currently, plastic usage exceeds 400 Mt and with continued economic growth, the production is expected to triple in volume by 2060 [1]. Steam cracking is the dominant method for producing olefins, with naphtha—derived from oil refineries—as the primary feedstock in Europe. This process, however, is highly energy-intensive, as cracking furnaces use fossil fuel combustion to provide the necessary reaction energy. Annually, 400 Mt $CO_2$ is emitted to produce light olefins, which represents 30% of the emissions of the chemicals sector[2]. Chemical recycling of plastic waste offers an alternative that fosters a circular economy, reduces emissions, and enhances resource efficiency. Waste plastic gasification, followed by methanol synthesis and methanol-to-olefins (MTO), is one of the alternative pathways that can promote waste valorization, minimizing the need for virgin plastics. $CO_2$ capture and storage, when combined with processes such as methanation, rWGS, and co-electrolysis, can broaden the benefits of sustainable chemical recycling. This study presents a comparative analysis of various configurations for sustainable light olefins production, accounting for the changing electricity prices driven by renewable energy availability.

## METHODS

### Process Modeling and Simulation

The superstructure for olefins production based on plastics and biomass wastes is presented in Figure 1. The inputs to the overall process are represented by High-Density Polyethylene (HDPE) for the waste plastics and pinewood for the biomass (see Table 1). The downdraft co-gasifier is modeled in Aspen® Plus, featuring 4 main stages, namely internal drying, pyrolysis, tar reforming, and reduction. Modeling of pyrolysis of plastic waste is based on experimental data at 500-550 °C, yielding 11% gas, 47% oil, and 42% wax, which is further broken down

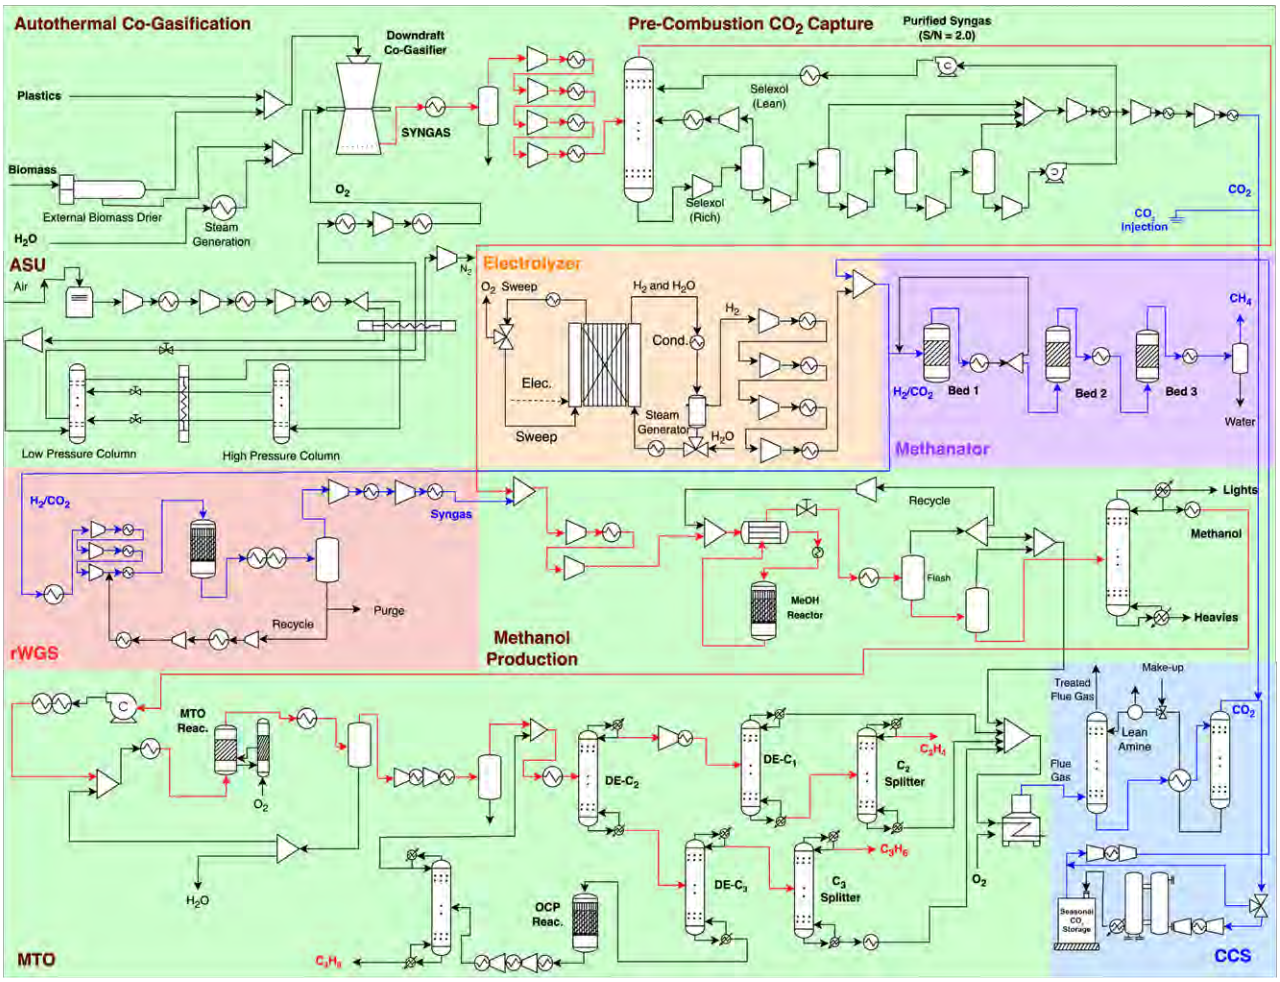

**Figure 1:** Superstructure for olefins production from plastic and biomass wastes mixture through gasification, methanol synthesis and MTO process.

in the tar reforming stage into solid carbon, CO, $CO_2$, and $H_2$ [3]. Biomass pyrolysis yields are determined by temperature-dependent empirical relations using FORTRAN subroutines [4]. The steam reduction stage is modeled using a REquil reactor with water-gas, water-gas-shift(WGS), and steam methane reforming reactions, for which the approach-to-equilibrium (ATE) temperature difference is tuned through sensitivity analysis compared with the experimental data [5]. The model exhibits a relative error of 4.7% and a root-mean square error (RMSE) of 2.2 under operating temperature of 850 °C, pressure of 1 bar, steam-to-feed ratio of 1.0, and plastics-to-feed ratio of 0.5 (dry mass basis). The gasifier is autothermal and the heat is supplied by combustion of char and syngas with $O_2$ supplied from the air separation unit. The dry molar composition of the syngas is 58.4% $H_2$, 18.0% CO, 22.7% $CO_2$, and 0.5% $CH_4$. The stoichiometric number, defined as:

$$SN = (x_{H_2} - x_{CO_2})/(x_{CO} + x_{CO_2})$$

which favors methanol synthesis when slightly > 2.0. This condition is met by $CO_2$ removal via physical absorption using Selexol® solvent at 30 bar, resulting in a syngas composition of 69.2% $H_2$, 21.2% CO, 9.9% $CO_2$, and 0.1% $CH_4$.

**Table 1:** Proximate and ultimate analysis of biomass and plastic feedstocks (dry mass basis)[6]

| Composition | | Pinewood | HDPE |
|---|---|---|---|
| Proximate Analysis [%] | M | 11.5 | 0.02 |
| | FC | 15.4 | 0.30 |
| | VM | 84.2 | 99.7 |
| | Ash | 0.45 | 0 |
| Ultimate Analysis [%] | C | 51.4 | 84.9 |
| | H | 4.90 | 15.1 |
| | N | 0.90 | 0 |
| | O | 42.4 | 0 |

Methanol synthesis is modeled based on Lurgi's Mega-Methanol® technology and the kinetic modeling by

Kiss et al., occurring at 210°C and 90 bar [7, 8]. The process could reach 96% methanol yield (depending on $CO_2$ content in the feed), including a recycle loop with a purge stream that is combusted with pure oxygen, releasing $CO_2$. After the distillation step providing >99.5% w/w purity methanol, it is sent to MTO process for light olefins synthesis.

This stage consists of a MTO reactor integrated with a catalyst regenerator that uses pure $O_2$ to combust deposited coke, an olefin cracking reactor for breaking down $C_4$+ olefins into valuable light olefins, and a series of cryogenic distillation columns to produce polymer-grade final product. The MTO reactor is modeled with a RYield reactor based on experimental data[9]. The yields based on infeed methanol are 19.0% for polymer-grade ethylene and 19.5% for polymer-grade propylene. $H_2O$ formed within the MTO reactor is recycled back into the process as steam. The undesired organic products, such as alkanes and out-of-spec natural gas are combusted with pure oxygen to recover waste heat, whereas $CO_2$ in the flue gas is captured and valorized after heat recovery.

$CO_2$ abatement and other energy technologies are integrated to improve process efficiency and offset emissions. The two possible routes for capturing $CO_2$ are pre-combustion carbon capture, operated at 30 bar using Selexol® solvent, where $CO_2$-rich solvent is decompressed, flushed and recycled, and post-combustion carbon capture, with 90% efficiency, using chemical absorption in an absorber-desorber column configuration with a di-ethanol amine (DEA) solvent, which enables a high adsorption rate while reducing desorber energy requirements [10]. Pre- and post-combustion captured $CO_2$ can either be injected for permanent geological storage, upgraded into $CH_4$, or used as feedstock for syngas production to enhance olefins production. The possible configurations considered in the scope of this work are given bellow:

1. **pre-combustion carbon capture and injection (preCCS & Inj):** Pre-combustion $CO_2$ captured during the syngas treatment is injected for geological storage, while combustion gases are released into the environment, therefore no $CO_2$ upgrading is considered. Seasonal $CO_2$ storage is not implemented in this configuration.

2. **methanation-based:** Both pre-combustion and post-combustion captured $CO_2$ is seasonally stored in liquid form or upgraded with methanation process depending on the electricity prices.

3. **reverse water gas shift-based (rWGS):** Both pre-combustion and post-combustion captured $CO_2$ is seasonally stored in liquid form or upgraded with rWGS process for syngas production depending on the electricity prices.

4. **co-electrolysis-based (co-SOEC):** Both pre-combustion and post-combustion captured $CO_2$ is only seasonally stored in liquid form or upgraded with co-electrolysis process for syngas production depending on the electricity prices.

5. **steam naphtha cracking (SNC):** steam fossil naphtha cracking without CCS unit.

Permanent $CO_2$ storage is considered only in configuration 1, as $CO_2$ is already captured as a requirement for methanol synthesis. Unlike other configurations that aim to increase olefins production by eliminating $CO_2$ emissions, no additional technologies for $CO_2$ capture from flue gases are included in configuration 1.

The necessary $H_2$ for configurations 2 and 3 is supplied with a solid oxide electrolyzer (SOEC), which operates at 800°C and 1 bar, with a specific electricity consumption of 35.2 kWh/kg$H_2$ [11, 12]. In terms of $CO_2$ and energy management, since most configurations entail high electricity consumption, they are vulnerable to fluctuations in electricity prices. As an alternative to buffer against these costs, $CO_2$ can be seasonally stored in liquid form at 7 bar and -50 °C during periods of high electricity prices, and processed when prices are lower [13]. A steam network system is also considered to recover waste heat for electricity generation.

## Optimization Problem Definition

The process integration of the proposed configurations is handled by Osmose Lua platform [14]. It works out the optimal operating conditions of the technologies of the superstructure, based on an objective function that minimizes the total cost.

$$\min Cost_{tot} = \sum_{u \epsilon Units} \left[ \sum_{t \epsilon Time} \left[ \left( Cop1_u \cdot Y_{u,t} + Cop2_u \cdot M_{u,t} \right) \Delta t + Cinv1_u \cdot Y_u + Cinv2_u \cdot M_u \right] \right]$$

- $Cop1_u$ [EUR/h]: fixed operating cost of unit u,
- $Cop2_u$ [EUR/kWh or EUR/kg]: variable operating cost of unit u,
- $Y_{u,t}$ [-]: integer variable standing for the activation of the unit u at a time t,
- $M_{u,t}$ [kg/h or kW]: continuous variable standing for the load of the unit u at a time t,
- $Cinv1_u$ [EUR/y]: fixed annualized cost of unit u,
- $Cinv2_u$ [EUR/kWh or EUR/kg]: variable annualized cost of unit u,
- $Y_u$ [-]: integer variable for the activation of the unit u, maximum value of $Y_{u,t}$,
- $M_u$ [kg/y or kWh/y]: maximum load of the unit.

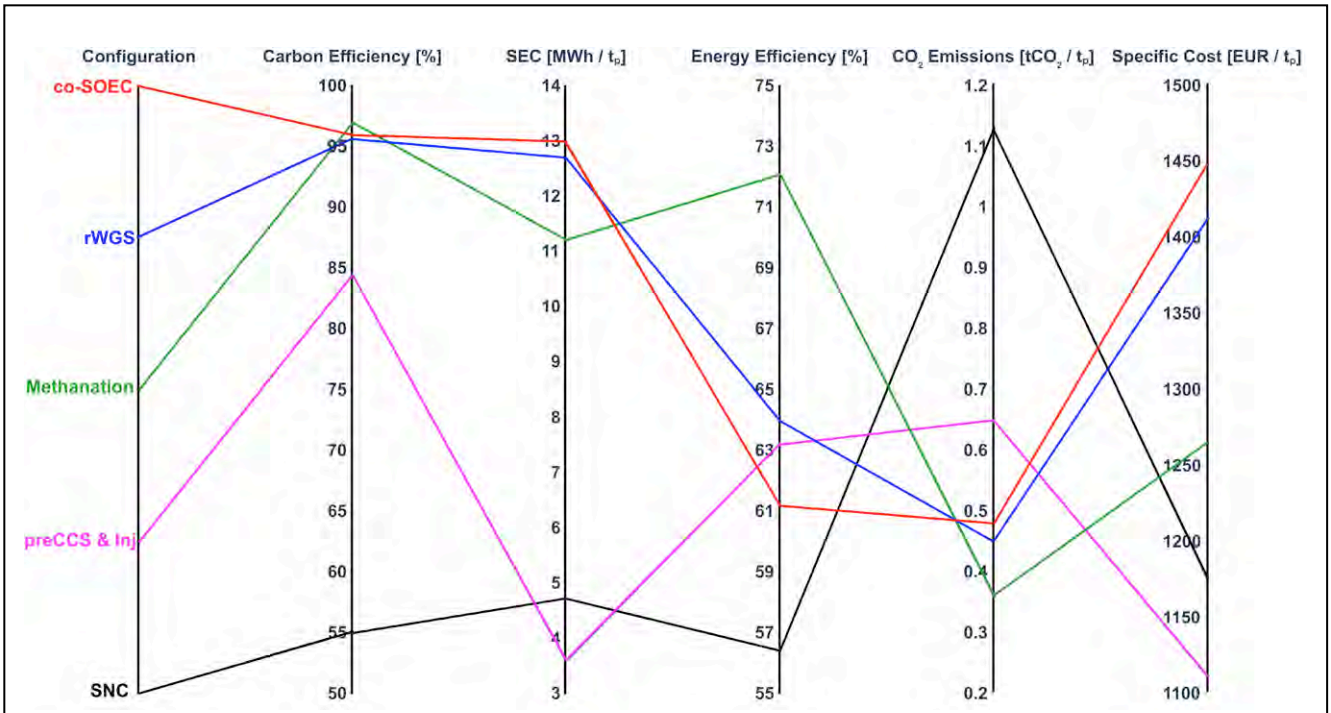

**Figure 2:** Key performance indicators for process configurations. $t_p$: tonne of products.

The defined problem is solved over an entire year (8760 h), divided into 12 monthly periods. Based on the availability of renewable electricity throughout the year, the electricity cost is set at 0.05 EUR/kWh from March to October and 0.15 EUR/kWh from November to February. The energy mix is based on the Swiss grid, with an environmental impact of 0.048 $kgCO_2e/kWh$. A carbon tax of 120 $EUR/t_{CO2}$ is assumed. The prices set for the main products and raw materials are as follows: ethylene at 1,200 EUR/t, propylene at 1,100 EUR/t, butene at 1,000 EUR/t, $CH_4$ at 0.07 EUR/kWh, permanently stored $CO_2$ with a carbon permit valued at 8.4 EUR/t, plastic waste at 454 EUR/t, and biomass at 73 EUR/t.

## Key Performance Indicator Definitions

For comparing the proposed configurations, several key performance indicators (KPIs) are established. These are carbon efficiency (CE), specific energy consumption (SEC), process energy efficiency ($\eta_{Energy}$), environmental impact ($CO_2e$), and specific cost (SC). The definitions of the established KPIs are provided below:

- CE [%] = $\frac{Carbon\ in\ products}{Carbon\ in\ feedstock}$
- SEC $\left[\frac{kWh}{kg}\right] = \frac{E_{el}}{m_{products}}$
- $\eta_{Energy}[\%] = \frac{m_{products} \cdot LHV_{products}}{m_{feed} \cdot LHV_{feed} + E_{el}}$
- $CO_2e\ \left[\frac{kgCO_2e}{kg}\right] = \frac{Direct\ CO_2\ . + Indirect\ CO_2\ . - \text{Avoided } CO_2}{m_{products}}$
- SC$\left[\frac{EUR}{t}\right] = \frac{CAPEX + OPEX}{m_{products}}$

Where $E_{el}$ is the electricity consumption of the overall process within a year [MWh]; m is the total mass within a year [kg or t], LHV refers to the total lower heating value within a year [MWh]. For calculation, the considered specific LHVs are: 5.42 kWh/kg for biomass, 9.47 kWh/kg for HDPE, 13.1 kWh/kg for $C_2H_4$, 12.7 kWh/kg for $C_3H_6$, 12.6 kWh/kg for $C_4H_8$ and 13.9 kWh/kg for $CH_4$. The considered impact factors are: 0.048 $kgCO_2e/kWh$ for electricity, 1.6 $kgCO_2e/kg$ for HDPE and 0.05 $kgCO_2e/kWh$ for pinewood. The total products could consist of olefins, and $CH_4$ depending on the configuration.

The carbon content within biomass, is biogenic, therefore capture of biogenic carbon within product or with injection, it is counted towards avoided(negative) emissions, however since carbon content within plastic is fossil based, it cannot contribute to negative emissions. It is also assumed that, initially the carbon content within plastics is consumed for product formation and injection. After all the fossil carbon is accounted for, additional carbon is considered to be consumed from biogenic source. Therefore, if the carbon contents within the product is exceeds the carbon content of plastics, all emitted $CO_2$ should incorporate biogenic carbon, leading to zero direct $CO_2$ emissions. For indirect $CO_2$ emissions, the impact of electricity, fossil HDPE production and biomass supply chain are accounted.

## RESULTS AND DISCUSSION

The key performance indicators of the optimal configurations are provided in Figure 2. By integrating $CO_2$

management technologies, the carbon efficiency can reach up to 97%, nearly doubling the produced amount of olefins considering the same amount of feedstock.

## $CO_2$ Emissions, Capture and Utilization

As shown in Table 2, none of the alternative configurations entails direct $CO_2$ emissions. Moreover, the net $CO_2$ emissions for the proposed setups are 40-70% lower compared to 5. SNC process. Particularly, in the 2. methanation configuration, lowest $CO_2$ emissions are reached, due to capturing the highest amount of biogenic carbon within the products.

Since the feedstock consists of waste plastics derived from fossil resources, indirect $CO_2$ emissions are significant for all configurations. The impact associated with plastics waste accounts for 60-80% of the emissions depending on the studied configurations. The introduction of SOEC introduces an additional impact of 0.5-0.6 $tCO_2/t_p$ due to the high electricity consumption. However, the increased process carbon efficiency offset the impact of raw materials, leading to lower indirect $CO_2$ emissions in the configurations with SOEC when compared to the 1. preCCS & Inj case.

**Table 2:** Fossil $CO_2$ emissions balance for the process configurations[15].

| **$CO_2$ emission** ($t_{CO2}/t_p$) | **1** | **2** | **3** | **4** | **5** |
|---|---|---|---|---|---|
| Direct | 0 | 0 | 0 | 0 | 0.50 |
| Indirect | 2.21 | 1.46 | 1.58 | 1.63 | 0.63 |
| Avoided (-) | 1.57 | 1.10 | 1.14 | 1.14 | - |
| **Net** | **0.64** | **0.36** | **0.44** | **0.49** | **1.13** |

Figure 3 highlights that the optimal strategy during high electricity price periods is to store liquid $CO_2$, which can later be used to enhance syngas production capacity when electricity prices drop.

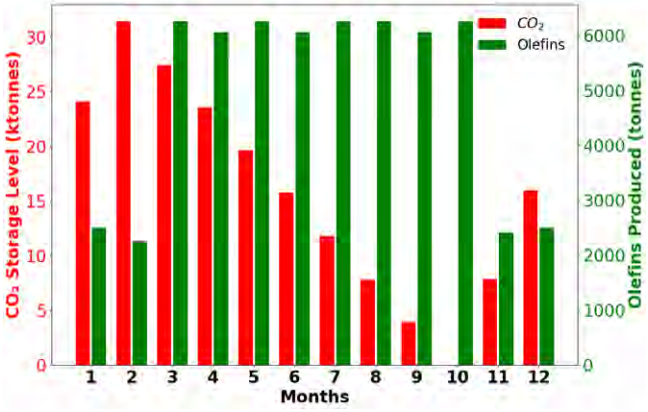

**Figure 3:** Monthly storage level and olefins production capacity for co-SOEC configuration.

## Energy Input and Management

The integration of SOEC causes an increase in energy consumption, making up 60-70% of the overall electricity demand. On the other hand, SOEC boosts the carbon efficiency by 75% compared to 5. SNC and 15% compared to the 1. preCCS & Inj configuration while the energy efficiency is improved by 4 to 16 percentage points with respect to 5. SNC. 1. PreCCS & Inj configuration shows the lowest SEC, due to not leveraging SOEC, and a good integration of the steam network, which provides 78% of the electricity demand of the process. Meanwhile, this power self-generation ratio is limited to 15-20% for the other configurations. None of the processes requires heat from combustion and are autothermal in meeting their heating demands thanks to extensive internal waste heat recovery.

## Economic Evaluation

The specific cost of production for SOEC-integrated processes show an increase of 20-50% compared to the 5. SNC. The 1. preCCS & Inj setup has the lowest SC (1111 EUR/$t_p$), while 4. co-SOEC exhibits the highest cost (1450 EUR/$t_p$). Operating expenditures (OPEX), account for 65-75% of the total specific cost, mainly due to electricity costs, leading to higher impact for all SOEC-integrated configurations. The capital expenditure (CAPEX) is annualized for 40 years with an interest rate of 6%. The highest CAPEX is linked to the 3. rWGS configuration (504 EUR/$t_p$), and the lowest cost is that of the 1. preCCS & Inj configuration (318 EUR/$t_p$).

# CONCLUSIONS

This study proposes and analytically compares various routes for the chemical upgrading of plastic wastes to olefins, integrating $CO_2$ management and energy technologies. This approach offers a globally applicable process that consumes plastic wastes as a widely available feedstock and reduces the dependency on fossil fuels. Furthermore, these configurations not only prevent direct $CO_2$ emissions but also cut down the emissions linked to the virgin plastic production and the treatment of plastic waste, establishing the foundations of plastics circular economy.

The alternative configurations evaluated using high temperature electrolyzers (SOEC) require a significant amount of seasonal, renewable electricity. However, seasonal $CO_2$ storage can address this issue by optimizing the process for both process efficiency and operational costs, increasing the production capacity by 40%. In the long term, with increased share of renewable electricity mixes, these routes are expected to economically outperform traditional processes of plastics manufacturing and plastics waste treatment.

## ABSTRACT

In this study, we evaluate the economic and environmental impacts of integrating waste polyethylene (PE) pyrolysis with naphtha-based steam cracking for 660 Mt/y ethylene production. We compare six integration scenarios to both business-as-usual (BAU) steam cracking and greenfield waste PE pyrolysis plant. We perform process simulations and equipment design in Aspen Plus® V12, followed by a techno-economic analysis (TEA) and a life-cycle assessment (LCA. The integration capacity we considered corresponds to one full-capacity PE pyrolysis furnace, reducing naphtha feed by 7% in BAU steam cracking. Through the TEA, we identify the most cost-effective scenario by merging the PE pyrolysis gas with the steam cracker furnace outlet after preheating the PE feed. This integration reduces production costs by 6.46MM€/y, improving costs a 0.3% compared to BAU and 30% compared to the pyrolysis greenfield design. LCA results show that the greenfield pyrolysis plant achieves the lowest global warming potential (GWP), reducing emissions by 14% compared to BAU. Among the integration scenarios, lowest GWP occurs when PE pyrolysis gases, also with feed pre-heating, merge before the main compressor train, obtaining a 0.12% GWP reduction compared to BAU. This analysis highlights the potential of introducing circular technologies in existing plants to progressively shift from fossil fuel usage.

**Keywords**: process integration, circular economy, ethylene, sustainable feedstock, chemical recycling

## INTRODUCTION

Circularity in the chemical industry is essential for achieving sustainability, especially as the sector moves away from linear, fossil-based production models. Circular processes aim to minimize waste, optimize resource use, and closing carbon loops by utilizing renewable and waste resources. This approach is a key strategy to address both environmental and economic challenges [1].

Plastics account for the largest share of oil usage outside fuel production [2]. Their widespread use has led to vast global waste accumulation, particularly from single-use packaging. In the European Union, packaging represents approximately 40% of plastic demand, generating large volumes of waste that often escape effective management systems [3].

Compared to disposal methods like landfilling and incineration, recycling faces challenges related to cost and material quality. Mechanical recycling is one of the least energy-intensive options, but it is limited by the number of cycles the material can endure [4]. In contrast, chemical recycling is a more expensive alternative but avoids degradation by breaking plastics down into their monomers [5].

In Europe, the most produced polymer is the polyethylene (PE) families of plastics, with a share of 22% of the production [3]. Given that PE is the most widely produced plastic and is predominantly used in single-use packaging, it represents the most promising candidate for chemical recycling.

Among the diverse chemical recycling methods, pyrolysis is the most researched since it converts plastic into lower molecular weight products [5], which allows the recovery of monomers and the closure of carbon loops.

Waste PE Pyrolysis plants are already existing at a commercial scale, and many companies have announced collaborations between projected pyrolysis plants and their refineries [5]. However, repurposing existing infrastructure for circular processes offers a more cost-

**Table 1:** Integration scenarios summary

| Scenario | Integration concept | Pyrolysis product feed location |
|---|---|---|
| 1.a | Waste LDPE pyrolysis integrated without the need of additional equipment | Outlet of naphtha furnace reactor |
| 2.a | - Increase the heat recovery of pyrolysis gas to generate power. The absence of heavy component in the product gas, allows more efficient cooling. Heat exchanger(s) EX1-P perform this task.<br>- Duty reduction in primary fractionator (T1), bypassing the unit since pyrolysis gas contains no heavy components | After primary fractionator |
| 3.a | - All from 2.a<br>- Reduce the energy requirements of the distillation units for light components by separating the $C_4$+ components prior to integration. Flash separator SEP3-P performs this task, with the aid of compressor C2-P to reach the adequate pressure for the integration point, and heat exchanger EX2-P to lower the gas temperature to allow gas to condense in the flash drum. | Intermediate stage compressor and T7 feed |
| 1.b, 2.b, 3.b | Use heat from the pyrolysis gas to preheat waste PE feed in the first pyrolysis (low temperature) reactor | To corresponding scenario (1.a-3.a) |

effective and resource-efficient solution [6]. This study explores different integration strategies for incorporating PE pyrolysis into existing ethylene production. The proposed scenarios are compared against both a greenfield design of waste LDPE pyrolysis plant and naphtha steam cracking.

## APPROACH AND METHODOLOGY

### Integration Strategy

We first replicated the design from Somoza et al. [7] for a greenfield ethylene plant based on waste PE pyrolysis, and the design from Spallina et al. [8] for a brownfield olefins plant based on naphtha steam cracking (SC). As reference for pyrolysis of PE, we used the conversion and yields from Kannan et al. [9], whose experiments focused on maximizing the ethylene yield in the flash pyrolysis of waste low density polyethylene (LDPE).

Both designs share a substantial similarity, due to their comparable main reactor outlets, since both processes' main products are polyolefins. Both plants can be briefly described with their major common elements by having the high-temperature reactor, a following cooling stage, a compressor train to raise the pressure enough to enable the separation of the light hydrocarbons and the consequent distillation column cascade. The SC contains additional processes, such as a removal of water and $C_9$+ fraction preceding the compression train, and intermediate reaction steps between the cascade distillation, with the aim to increase the ethylene and propylene yields.

Given these similarities, we developed six integration scenarios to incorporate LDPE pyrolysis into an existing steam cracking process. The goal is to achieve a competitive cost compared to the grass-roots design of a standalone pyrolysis plants, and with the second aim to reduce the cost of ethylene production by steam cracking. A brief summary of the proposed integration scenarios is provided in Table 1.

Figure 1 illustrates the SC layout alongside with the proposed integration scenarios, highlighting the similarities between the SC and the greenfield pyrolysis design. The color coding emphasizes the units that perform equivalent tasks in the waste pyrolysis plant design.

### Simulation and Assessment Methods

We performed process simulations and equipment design for both independent plant designs and the integration scenarios, in Aspen Plus® V12, using PolyNRTL as property package, to enable LDPE to be handled in mass and energy balances.

For each integration scenario, we conducted a comprehensive techno-economic assessment (TEA) and life cycle assessment (LCA) to evaluate both the economic viability and environmental impact of incorporating LDPE pyrolysis into the naphtha steam cracking process.

For the TEA, we followed the cost evaluation guidelines from Towler and Sinnott [10], supplementing with additional sources [8] [11] for equipment not covered in [10].

For the LCA, we applied the ISO 14040:2006 standards for life cycle assessment methodology, using the Ecoinvent3 database in SimaPro software to assess environmental impacts, focusing primarily on Global Warming Potential (GWP).

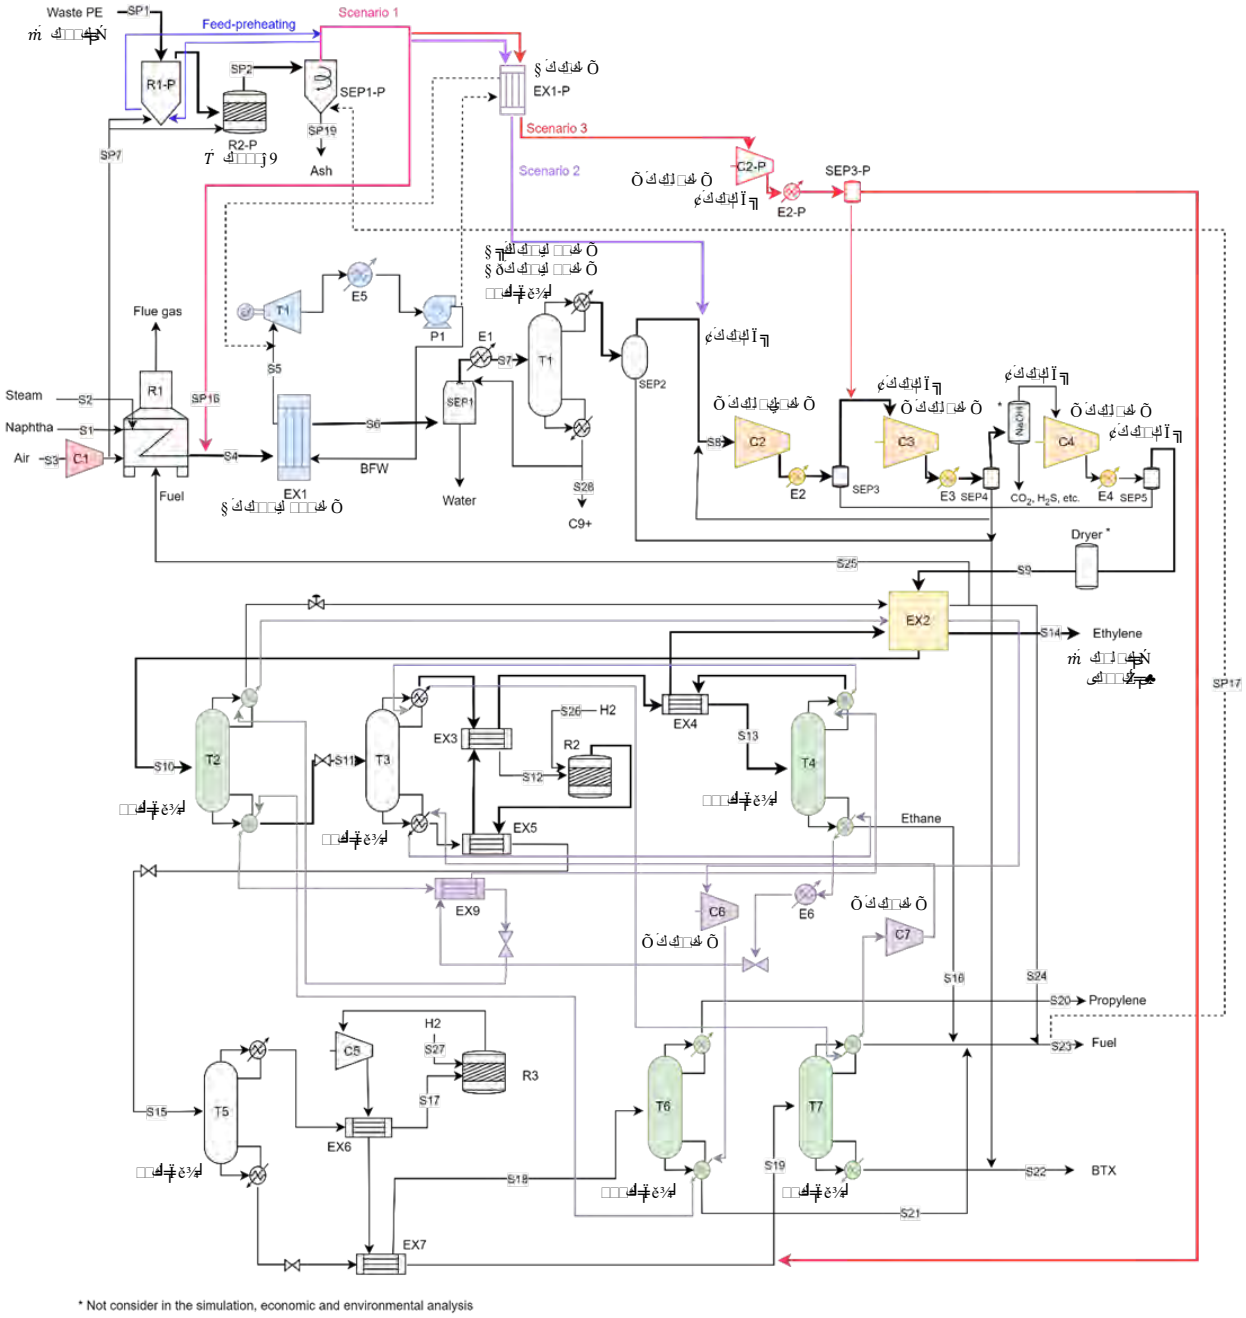

**Figure 1:** Steam Cracking plant layout with PE pyrolysis integration scenarios. Colored units correspond to the coinciding units in a standalone PE pyrolysis plant, highlighted for similarity.

## RESULTS AND DISCUSSION

### Techno-Economic Assessment (TEA)

To compare both standalone plants, we allocated the cost of production per kg of ethylene. The feed from the greenfield design for a waste PE pyrolysis plant, corresponds to one full-capacity pyrolysis furnace, representing approximately a 7% of the steam cracking naphtha feed. Using this cost allocation, we estimate that the standalone waste PE pyrolysis plant produces ethylene at 1.045€/kg of ethylene, while the cost at the steam cracking plant is 0.7429€/kg of ethylene. This significant cost difference is what motivated this study.

For the integration scenarios, we set the ethylene production capacity to 660Mt/y. Introducing one LDPE pyrolysis furnace at full capacity, the naphtha feedstock can be reduced by the aforementioned percentage.

Figure 2 illustrates the cost differences between the average of all integration scenarios and the business-as-usual (BAU) standalone steam cracking process. Since ethylene production remains fixed, this output remains unaltered across all scenarios.

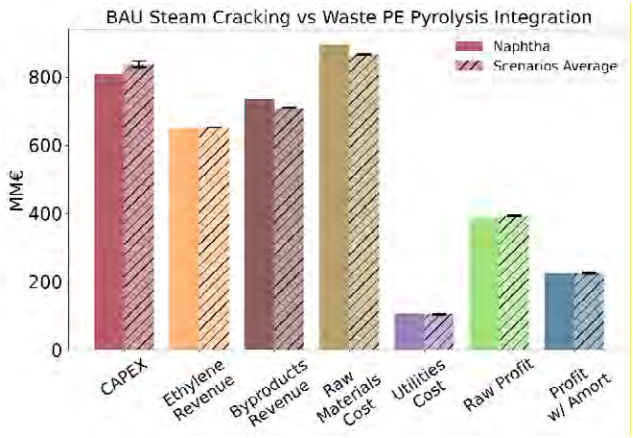

**Figure 2.** Comparison of business as usual steam cracking vs average of integration scenarios.

Figure 3 breaks down the main costs and revenues for each scenario, using the BAU steam cracking as reference. The ethylene production (and revenue) remains

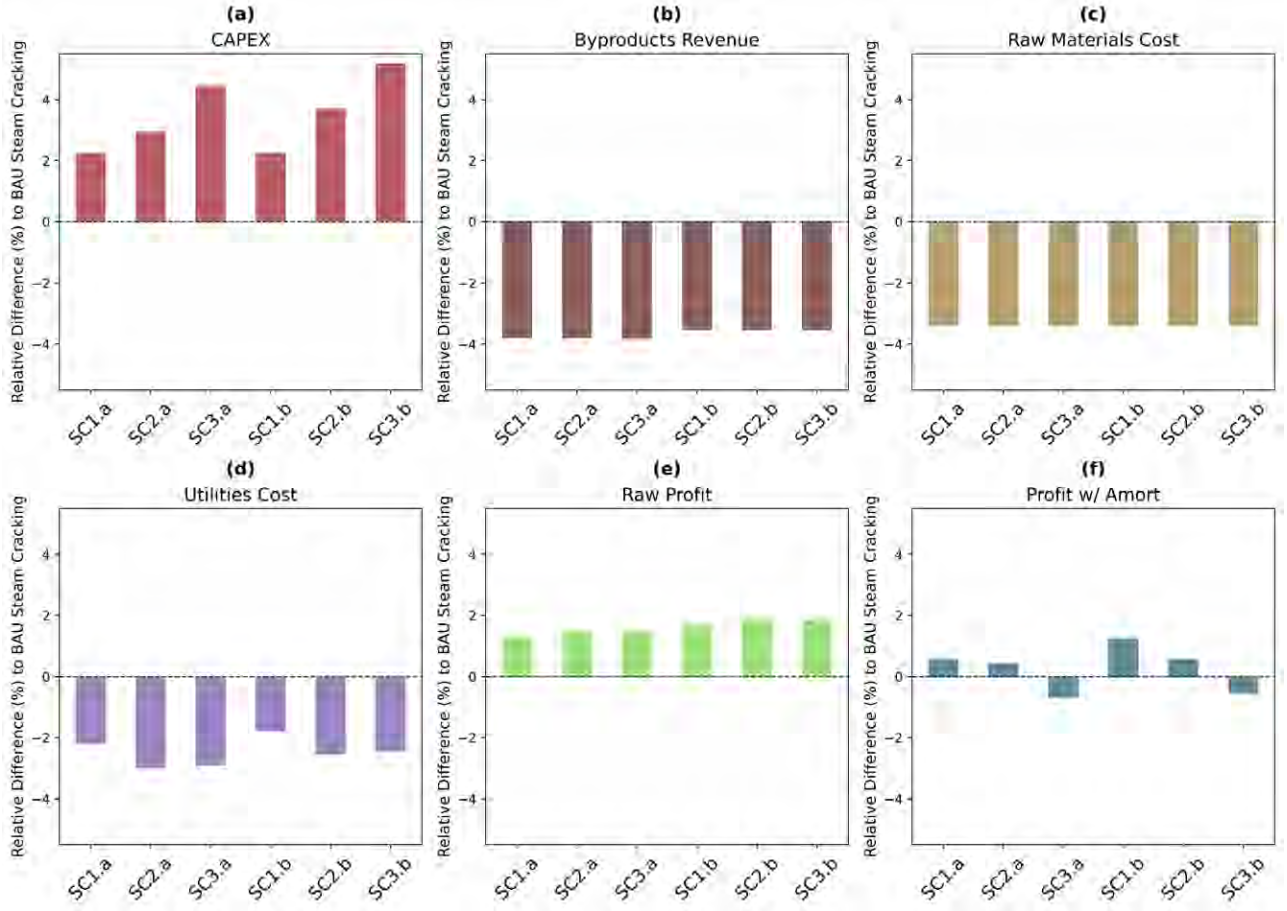

**Figure 3:** Comparison of economic and operational metrics for naphtha-based steam cracking and waste PE pyrolysis scenarios

constant across all scenarios. However, the revenue from other products decreases in all integration cases. This reduction occurs because (high temperature) flash pyrolysis is targeted towards maximizing ethylene yield [9]. Among the byproducts, propylene production is the least affected, with only a 0.82% reduction (2.4M€/y) from the BAU case. The revenue from $C_{9+}$ stream decreases by 7.5% (2.4M€/y), while the BTX revenue drops by 3.3% (7.7M€/y), with minimal differences between the integration cases. Fuel products experience the largest revenue loss, averaging 11% (12.6M€/y) in cases without feed pre-heating and 10% (10.6M€/year) in cases with pre-heating. Overall, the average reduction in revenue across the scenarios is a 3.6% (27M€/y).

Despite revenue losses, utility expenses decrease by approximately 5% (3M€/y) across all integration scenarios. Scenario 2 achieves greater utility savings than Scenario 1, as expected. The utilities reduction for Scenario 3 are, however, lower than Scenario 2, due to the low substitution ratio that hinders the potential energy savings in distillation. This trend applies to both cases with and without feed pre-heating.

Differences in feedstock prices result in a yearly cost reduction of 3.6% (30M€/y) for a 7% of reduction in naphtha consumption. However, revenue losses offset most of this benefit. In the best-performing scenario (Scenario 1 with feed pre-heating), this translates into an overall raw profit increase of 1.67% (6.5M€/y), primarily due to lower utility costs. After accounting for the CAPEX amortization of the equipment and overhead expenses, the final cost of ethylene production drops minimally to 0.7407€/kg, compared to 0.7429€/kg of BAU case.

## Life Cycle Assessment (LCA)

The Life Cycle Assessment (LCA) evaluates the Global Warming Potential (GWP) across different configurations: BAU steam cracking, greenfield plant of waste LDPE pyrolysis, and six integrated scenarios.

As shown in Figure 4 a), the greenfield pyrolysis process has a lower GWP than the BAU naphtha steam cracking (1.243 vs. 1.441 kg $CO_2$ eq./kg ethylene), largely due to reduced reliance on fossil naphtha. In the naphtha steam cracking process, the highest emissions are from fossil feedstock (35% of total) and direct emissions from furnace combustion (28%). In contrast, standalone pyrolysis sees direct emissions contribute approximately 54% of its GWP due to higher energy demand, with electricity also a significant factor (26%).

The integration scenarios, which substitute only 7%

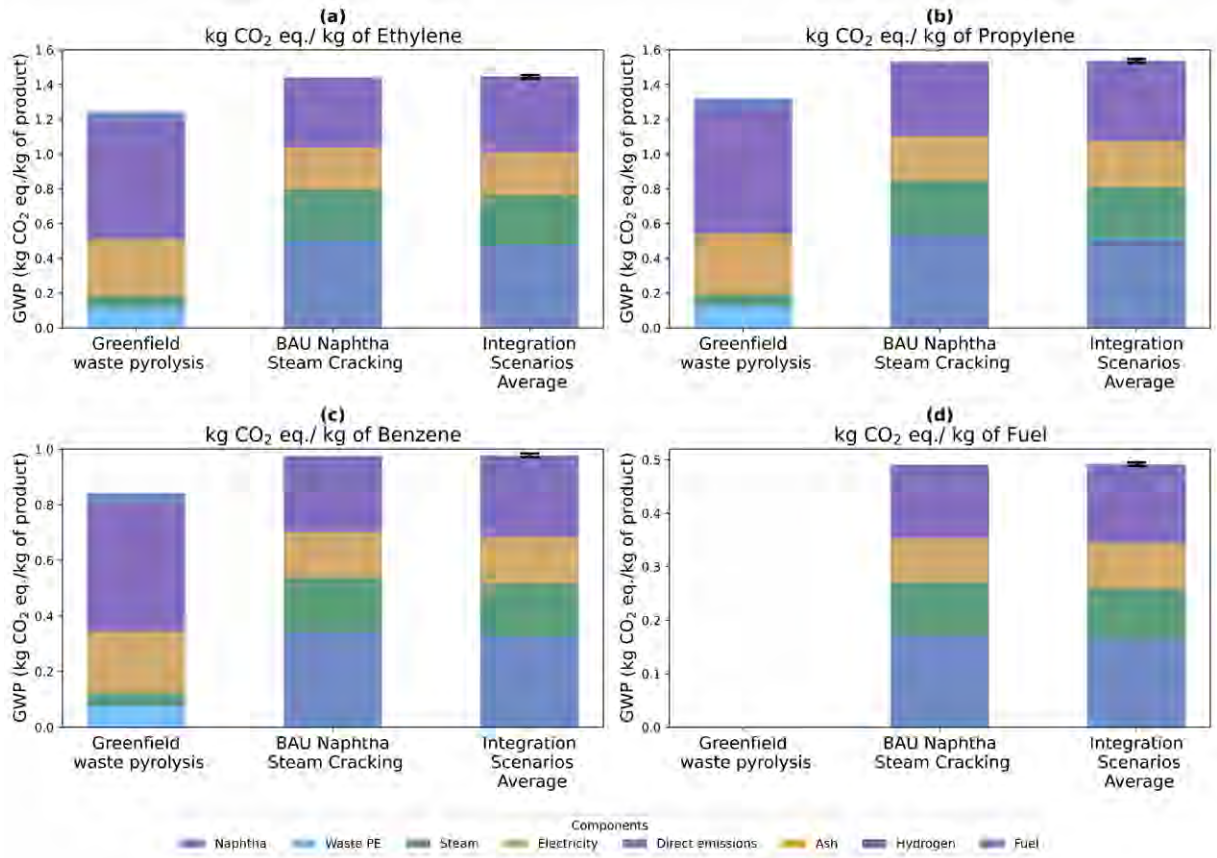

**Figure 4:** Comparison of LCA results of Standalone plants and average of integration scenarios

of naphtha with pyrolysis gas, yield marginal GWP reductions. Although they reduce GWP contributions from naphtha, steam, and hydrogen, these benefits are partially offset by increased direct emissions and electricity use. Among the integration options, Scenario 2.b achieves the lowest GWP (1.439 kg $CO_2$ eq./kg ethylene), demonstrating that preheating lowers emissions. Overall, all products—ethylene, propylene, BTX, and fuel—exhibit similar GWP trends across the processes.

From the rest of the mid-point categories we evaluated in the LCA analysis, fossil resource scarcity is the category most positively impacted by pyrolysis integration scenarios. All of them show a reduction respect to BAU steam cracking, with also Scenario 2.b achieving the highest reduction of a 4.8%(from 1.817 kg of oil eq. to 1.729 kg of oil eq.).

## CONCLUSION

A 7% of substitution of naphtha with pyrolysis gas offers an economically feasible way for the industry to gradually introduce sustainable technology and gain operational experience, however, the cost improvements remain marginal. However, the key factor that makes pyrolysis of waste plastic attractive is the price gap between naphtha and waste plastic.

In this study, we identified Scenario 1 with feed preheating the most economically viable integration option, achieving annual operating cost savings of 6.5 million euros compared to business as usual operation of steam cracking.

From an environmentally perspective, the pyrolysis process has a lower GWP than both naphtha steam cracking and integration scenarios. Among the integration options, Scenario 2 with feed preheating achieves the lowest GWP at 1.439 kg $CO_2$ eq./kg $C_2H_4$, demonstrating that heat integration is key to reduce environmental impact.

The divergence between economic and environmental assessments highlights the challenges of integrating waste plastic pyrolysis at low substitution ratios. Nevertheless, since the factor that determines Scenario 1.b as the best candidate in economic terms is the low CAPEX, a higher substitution ratio might favour Scenario 2.b since it showed the highest raw profits among the integration possibilities.

In addition, LCA indicators support Scenario 2.b as the best candidate, however, since the waste PE pyrolysis is carried at higher temperatures compared to steam cracking, increasing the share of PE pyrolysis integrated might change the preferred integration scenario, and affect sustainability indicators.

Therefore, a study of higher substitution ratios is highly recommended.

## ABSTRACT

The Life Cycle Assessment (LCA) of a solid oxide electrolyser (SOE) has been performed using publicly available data. The system for producing 1 kg of hydrogen at 25bar and 99.9% purity is represented by a modular structure, which includes the 20-kW solid oxide stack manufacturing, balance of plant equipment, operation consumables, and end-of-life processes. A parametrized life cycle inventory modeling approach was developed. The results illustrate that SOE performs better than steam methane reforming only if supplied by electricity from renewable or nuclear sources. The operation consumables have been identified as the most contributive life stage (67%-89% of potential impacts), followed by equipment manufacturing (7%-22%) and stack manufacturing (4%-11%). Considering the predominant contribution of electricity supply in the consumables, no compromise should be made on ensuring clean electricity sourcing and on the stack energy conversion efficiency. The lifetime of the stack and the balance of plant equipment, as well as the heat mix have been identified as sensitive parameters to minimize the environmental impact of the hydrogen technology. These LCA results have been used to produce a tailored eco-design process for hydrogen projects: (i) organization of an eco-design workshop to present LCA results & environmental hotspots and related key parameters where to leverage eco-design innovations through an open discussion (brainstorm); (ii) provide an eco-design tool obtained from a simplified version of the LCA model parametrized around a limited number key life cycle inventory parameters, enabling the designers/developers to independently test the environmental performance of their innovations.

## INTRODUCTION

Hydrogen technologies are promising solutions for ecological transition in energy and industry. Electrolysers can produce hydrogen through water electrolysis powered by renewable electricity to replace fossil-based hydrogen obtained by Steam Methane Reforming (SMR), providing industrial processes such as steel production and chemical synthesis with low-impact feedstock. Hydrogen can also serve as an energy carrier to facilitate the shift toward a renewable energy mix. Fuel Cell technologies can convert hydrogen back into electricity, so that hydrogen would provide a flexible energy storage to balance the grid [1]. As the fuel cells and electrolysers (FC&EL) are still emerging technologies, they present an opportunity to integrate effective eco-design strategies early in their conception, when the degree of freedom in design choices are higher. Eco-design refers to the objective of minimizing the potential environmental impacts of a technology while conserving its functionalities [2]. To define these eco-design strategies, assessing the potential environmental impact of the FC&EL is crucial. Life Cycle Assessment (LCA) is a methodology for evaluating the environmental impacts of a product or system throughout its entire life cycle, from raw material extraction to disposal. LCA has been widely used for eco-design [3]. It allows identifying the hotspots and key technological parameters that mostly contribute to the potential impacts along the supply chain of the product, and to anticipate unexpected burden shifting between impact

categories.

The hydrogen technologies studied in this paper rely on solid oxide cells (SOCs). The particularity of this technology is the high-temperature operation (500°C-1000°C) and the possible reversibility of the cells (rSOCs) [4]. It means that the same cells can be used either for electrolyser mode (SOE) or for fuel cell mode (SOFC). Few LCA have already been developed for SOFC system [5], [6], [7], for SOE system [8], [9], [10], [11] and for reversible system [12] but they raised some methodological issues. First, the system boundaries of some studies focus solely on the production of one stack (cradle-to-gate), while others include the operation phase (cradle-to-grave) that represents the largest contributor to the overall environmental impact scores (70-100% depending on energy sourcing and technology). Second, the quality of hydrogen produced (purity, pressure) were rarely explicitly defined. Third, modeling of the balance of plant and the end-of-life of the system have been neglected by many studies. Finally, these LCA have been developed for comparative studies (with other FC&EL technologies or SMR) rather than specifically for eco-design process.

This paper aims (1) to develop a consistent LCA modular structure across all hydrogen technologies, facilitating comparability and harmonization in modeling and interpreting their environmental performances; (2) illustrate its application performing the LCA of a SOE from publicly available data; and (3) to support an eco-design process with quantified metrics from these LCA results.

## METHODS

This section describes the methodology followed to compute the LCA of a solid oxide baseline, and to derive eco-design principles from these LCA results. Figure 1 gives a graphical representation of this approach. The LCA has been performed according to ISO 14040 and ISO 14044 standards [13], [14]. The following sections detail each phase of the methodology.

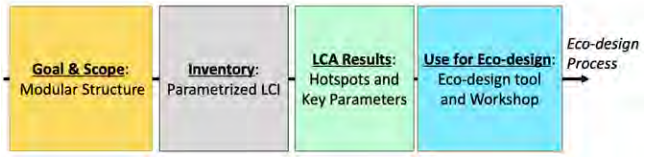

**Figure 1.** Graphical representation of the methodology for developing an eco-design process based on LCA.

### Goal & Scope and Modular Structure

Existing guidelines for the LCA of hydrogen technologies provide valuable guidance for practitioners [2], [15], [16], [17]. However, they lack a standardized framework for defining the goal and scope of hydrogen technologies, limiting the interpretation, comparability of LCA results and hindering interoperability of datasets. This paper offers a first attempt to improve consistency and harmonization defining the LCA scope for H2 technologies: terminology and classification of key processes and their organization in hierarchical supply tiers, providing a structured approach that can be applied across all other hydrogen technologies (Figure 2). This approach requires an explicit functional unit which incorporates pressure and purity conditions, but also the stack power, to enable fair comparisons between systems. For the case study, the functional unit is defined as "producing 1 kg hydrogen @25bar and 99.9% purity, using a 20kW stack, in Europe in 2024". The process tree delivering the functional unit is organized in hierarchical supply tiers. Tier 1 encompasses the following main life cycle stages: the stack manufacturing, the balance of plant equipment, the operation consumables, and the end-of-life of the system. Each of them links to specific upstream supply processes at Tier 2. Typically, the BoP contains standard equipment, and a compressor to ensure the hydrogen is delivered at 25bars (the hydrogen reaches 99.9% at this pressure without additional equipment). Tier 3 maps suppliers of each Tier 2 process, and so on. Tier 4 represents the background system, consisting in processes for which primary data on supply material, energy, and services are not generally available and for which generic datasets are used to estimate cradle-to-gate life cycle inventories of the respective supply chains. Such generic datasets are taken from commercial life cycle inventory databases.

### Parametrized Life Cycle Inventory

The LCI data collection mainly concerns the materials used, the energy consumed, and the amount and type of wastes and emissions generated by each process included in the system boundaries. To ensure reproducibility and adaptability of the study, and to facilitate the eco-design process, a parametrized life cycle inventory (p-LCI) is developed. This practice consists in structuring the inventory with raw parameters linked with explicit equations, instead of introducing computed numbers [18].

The parameters introduced in this p-LCI describe the stack geometry, the stack composition, the industrial processes involved in component production, the operational performance of the electrolyser and the energy mixes. The illustrative case study assumes a 100% renewable electricity mix supply and 65% of heat valorized from waste heat supplied by an industrial site where the SOE is operated. This waste heat is assumed impact free. The remaining 35% of heat is assumed to be provided by electric heaters. Table 1 presents the parameters for calculating Tier 1 process flows.

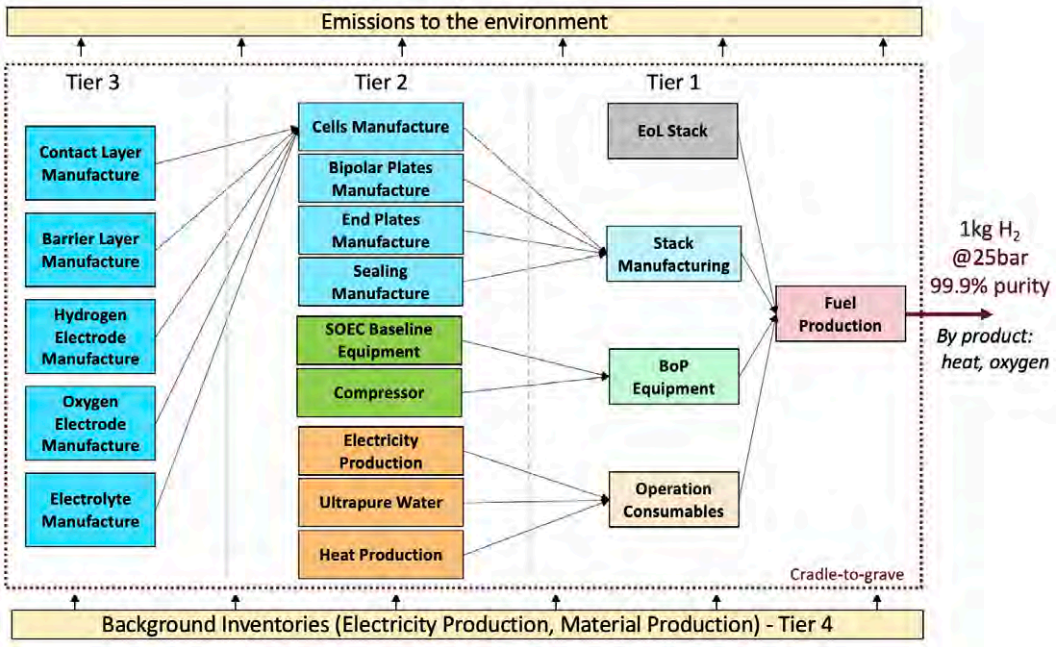

**Figure 2:** System boundaries of the screening LCA to deliver the functional unit, ordered by supply tier. Tier 1 encompasses the main life stages. Each element is further subdivided in common Tier 2 sub processes and so on.

**Table 1:** Main foreground parameters introduced in the study for SOE baseline values.

| Component | Description | Baseline Value | Source |
|---|---|---|---|
| Cell | Active Surface | 0.02 $m^2$ | [7], [8] |
| Stack | Stack Power | 20 kW | FU |
| Stack | Current Density | 1 A/$cm^2$ | [10] |
| Stack | Voltage | 1.3V | [8], [11] |
| Stack | Degradation Rate | 1%/kh | [11] |
| BoP | BoP lifetime | 80,000h | [19] |
| Operation | Beginning of life LHV-based System Efficiency | 85% | [9] |
| Operation | Water Demand | 14 L/$kgH_2$ | [20] |
| Operation | Heat Demand | 9 kWh/$kgH_2$ | [10] |
| Electricity Mix | Wind Power | 75% | [21] |
| | PV Power | 7% | |
| | Hydraulic Power | 18% | |
| Heat Mix | Waste heat available | 65% | [9] |
| | Heaters (electricity) | 35% | |

The complete set of parameters is available in Supplementary Information. Most of secondary data comes from the life cycle inventory (LCI) modules available in the European *Ecoinvent v3.10* database [19].

## LCA results

The impact profile has been computed using the Footprint version of the Impact World+ v2.0 method [22]. Five categories of impacts are assessed: the *Carbon footprint (CC)* in $kgCO_2eq.$, the *Water Scarcity footprint* in $m^3$ world-eq., the *Fossil and Nuclear Energy Use* in MJ deprived, the *Remaining Human Health (Rem. HH)* in DALY and the *Remaining Ecosystem Quality (Rem. EQ)* in PDF.$M^2$.yr. The categories *Remaining of human health* and *of ecosystem quality* exclude the contributions of *climate change* and *water availability,* avoiding double counting. The OpenLCA 2.0.3 software was used to compute the potential impacts associated with the inventoried emissions.

First, the environmental profile of the production of 1kg of $H_2$ (@25bar, 99.9% purity) using the 20-kW stack is performed. The efficiency of the system (78%) is determined as the average efficiency that includes a typical ohmic degradation of the stack over its useful life (based on a 10% maximum degradation) and the energy for compression. A comparison is made with hydrogen production from Steam Methane Reforming (SMR) (@25bar and 99.9% purity). The SMR process is modeled using the *Ecoinvent* database, specifically tailored to the European context. Second, a contribution analysis is performed to take a deep dive into the results. The contribution analysis is made stepwise, by progressively disaggregating the processes following the tiers of the modular structure. This work clarifies which life cycle stages, unit processes, then components mainly contribute to the overall impact scores and therefore identify the hotspots of the SOE baseline layout. Third, sensitivity analyses are

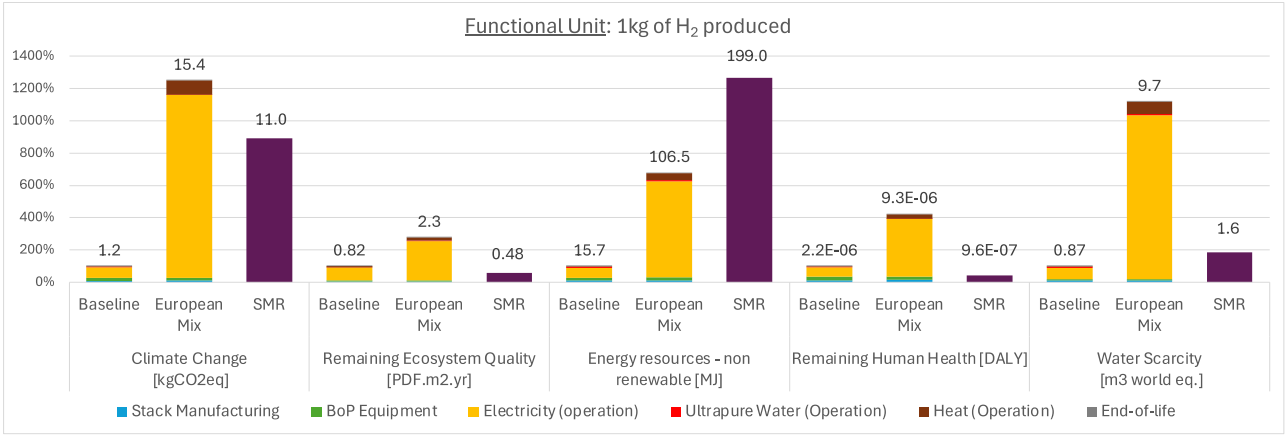

**Figure 3:** Comparative environmental profile of the SOE baseline scenario (Green Mix), the European Mix Scenario (sensitivity analysis) and the production of $H_2$ by SMR. Absolute values of the different indicators are given on the

performed to check the results robustness to the scenarios, and to provide valuable insights on the most critical processes and key parameters for reducing the environmental impacts. The sensitivity to energy mixes, to the purity requirement and to the system size are performed. A systemic sensitivity analysis of the foreground parameters introduced in the p-LCI is also performed.

## Deriving an eco-design process from LCA results

The interpretation of the LCA results provides the foundation for defining the key eco-design messages. The eco-design process relies on two complementary elements. First, an eco-design workshop is organized to translate the LCA findings into actionable design innovations. The workshop initiates with a knowledge-sharing presentation. The principles of life cycle thinking, and the risks of burden shifting are introduced to the project partners. The LCA results are communicated to the participants, emphasizing the most contributive processes, components, and the most sensitive parameters, fostering a collective understanding of the key priorities and key leverages for reducing the environmental impacts. The second part of the workshop aims at stimulating the creativity of the engineers/designers around the innovations aimed to improve the environmental performance of the baseline technology. The eco-design wheel developed by the HEU eGhost, which outlines eight core eco-design principles [2], was used as a step-by-step framework for guiding partners discussions. The second element consists in providing an eco-design tool obtained from a simplified version of the LCA model parametrized around a limited number of key LCI parameters. This tool enables designers to independently test the environmental performance of their innovations, providing immediate feedback on the environmental performance of their ideas and fostering an iterative improvement process.

## RESULTS

The LCA of the SOE baseline has been performed to evaluate the impact scores across the five different categories to produce 1 kg of hydrogen. The 'Baseline' bars in the figure 3 illustrate this environmental profile compared with the SMR impact scores (in purple). The baseline performs better than SMR for *Climate Change* (factor 9), *Energy Resource* (factor 12.5) and *Water Scarcity* (factor 2), while the results are reversed for *Remaining Ecosystem Quality* (factor 2) and *Remaining Human Health* (factor 2) impact scores. An additional comparison using the IW+ expert version, which aggregates the five categories of the footprint version into two damage indicators (*Human Health* and *Ecosystem Quality*), has been performed to clarify the trade-offs illustrated by the footprint version. This work reveals that the SOE baseline outperforms SMR for both indicators (see Supplementary Information).

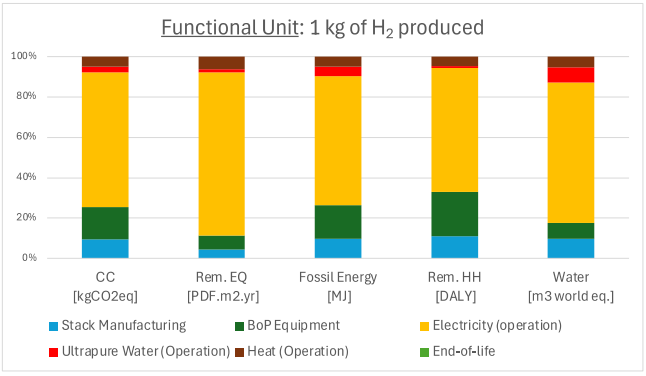

**Figure 4.** Contribution Analysis of the main life stages of the baseline SOE supplied with a 100%-renewable electricity mix. Operation phase is detailed at Tier 2 level.

## Contribution analyses

The contribution analysis shows that the operation phase dominates all impact categories by contributing 67%-89%, followed by the Balance of Plant (7%-22%), while stack manufacturing remains low at 4%-11%, and End-of-Life is negligible (Figure 4).

The Tier 2 analysis of the operation life stage highlights that electricity consumption drives the consumables impact scores (61%-81%), while heat consumption (5-6%) and ultrapure water consumption (1%-7%) are less contributive.

Figure 5 shows the contribution analysis of the stack manufacturing according to two different groupings of processes, with results normalized to the impacts of the production of 1 unit of stack of 20kW (cradle-to-gate).

**Figure 5.** Contribution Analysis of the solid oxide stack manufacturing. The processes are decomposed following (A) the tier 2 of the stack manufacturing and (B) the tier 4 of the stack manufacturing.

The first group (A) corresponds to the Tier 2 elements of the stack as presented in the Figure 2 (SOC, Bipolar Plates, Gasket and End Plates). The second group (B) aggregates the impact scores of the Tier 4 processes (Energy, Material, Chemical and Waste). Figure 5A illustrates that the stack manufacturing impacts are driven by the cells, the bipolar plates, and the end plates productions. The cells manufacturing dominates the *Remaining Ecosystem Quality* and the *Water Scarcity* with respectively 61% and 66% of the impacts of the stack production. The end plates are the largest contributor to *Climate Change* (39%) and *Energy Use* (36%). The bipolar plates dominate the *Remaining Human Health* (36%) category. Moreover, the Figure 5B highlights that the materials used to produce the stack components are the main source of impacts for all categories with a relative contribution of 70-86% of the impact scores. The impact contribution of waste treatments generated during manufacturing are negligible. Energy required for manufacturing is the second highest contributor (15-25%), followed by the chemicals production used as solvent during the manufacturing (2%).

## Sensitivity Analyses Results

The sensitivity analysis on the electricity mix supply illustrates that low-carbon electricity from renewable or nuclear sources is essential for the SOE to outperform the environmental performance of hydrogen production by SMR (Figure 3). Supplying the SOE with the 2024 European electricity grid instead of the 100% renewable mix of the baseline would considerably increase the impacts of hydrogen production, for all impact categories between a factor of 6.5 and 12. Hydrogen produced by the SOE baseline supplied with this 2024 European electricity mix would lead to higher impacts than SMR for all categories except the Energy Resources indicator.

Other sensitivity analyses on heat supply, scalability of the SOE at market scale, hydrogen purity and other key technical parameters are provided in Supplementary information with numerical and graphical results. The use of natural gas to supply heat should be avoided as it increases *Climate Change* and *Energy Resources* scores (factor 2.5-3). As the scalability of SOE is more sensitive to the system size than the stack itself [23], we modeled a scenario scaling the BoP equipment to the power of the system by applying the method developed by Zhang et al. [24]. Scaling up the BoP from 20kW to 20MW may reduce the system's potential impacts by 7-19%. Moving from 99.9% to 99.999% hydrogen purity using a Pressure Swing Adsorption process increases the potential impacts by 9-11%. A systematic sensitivity analysis of key parameters was performed on the *Climate Change* indicator by independently varying each foreground parameter by 10% and calculating the corresponding relative change in impact scores. This analysis highlights stack efficiency being the most critical parameter causing an 8.4% change in impact score, followed by BoP equipment lifetime (1.5%) and stack degradation rate (0.9%). Parameters influencing stack manufacturing are less sensitive: end plates, bipolar plates, and hydrogen electrode thicknesses (around 0.2%).

## Interpretation for eco-design

The results emphasize that no compromises should be made regarding stack efficiency. Achieving a high

energy conversion efficiency is the most critical objective to minimize environmental burdens of hydrogen production. Any innovation that would affect energy efficiency of the stack has a high risk to decrease the environmental performance of the SOE technology. While the stack and the equipment processes are less impactful than the operational phase, their design plays a role in reducing the project's overall impact. Extending the lifespan of equipment and components has also been identified as sensitive eco-design strategies. The materials used, particularly for the cell elements, bipolar plates, end plates, but also for the BoP, are the most contributive processes of the manufacturing of the stack components. Potential solutions include minimizing material use through redesign and exploring alternative low emission materials, if these solutions do not affect system efficiency.

## DISCUSSION

The limitations of both the LCA model and the eco-design process are discussed here. Regarding LCA limitations, as few datasets of the Balance of Plant equipment have been found in the literature, the representativeness of the equipment potential impacts is low, while being quite contributive. Some life stages, such as the maintenance phase, have not been modeled due to lack of accurate datasets in the literature. Future efforts should focus on these processes to improve the completeness of the inventory. Moreover, solid oxide electrolysers are still an emerging technology, and it induces at least three limitations. (a) The background inventories may contain data gaps and uncertainties for the modeling of specific processes, like specific materials production (e.g. Yttrium, Zirconium); (b) A prospective electricity mix needs to be selected to anticipate the grid conditions in which the technology will be used, but this prospective approach is intrinsically associated with uncertainties; (c) As the hydrogen industry is in rapid evolution, the presented inventories may not be representative of state-of-the-art technologies. Finally, the electrolysers are known to consume critical raw material [2], [17]. Yet, the impact assessment methods selected do not offer indicator to assess this environmental issue which is still poorly addressed in LCA [25].

Regarding the eco-design process, three main limitations have been identified. First, economic viability of the innovations was not assessed. Future works should focus on developing a common structure to couple LCA model with economic approaches such as Techno-Economic Assessment (TEA) or Life Cycle Costing (LCC) to identify correlations and trade-offs between environmental and cost dimensions of design choices such as increasing efficiency, reducing the thickness of materials, etc. Second, the influence of the operation context (load range, flexible operation) on the use phase parameters (lifetime, efficiency) are still missing and should be modeled. And third, as a 20kW-stack is not representative of the potential scaled-up technology that would penetrate the market, the model of SOE should be improved by incorporating prospective life cycle inventories, and by considering potential improvements in materials and in manufacturing processes associated with large-scale development.

## DIGITAL SUPPLEMENTARY MATERIAL

Data sheets presenting the LCA model, including the p-LCI, unit processes, and results, are available at LAPSE:2025.0030.

## ABSTRACT

A generally applicable framework for the evaluation of the sustainability of distillation processes is proposed by aligning indicators directly to selected sustainable development goals (SDGs) created by the United Nations. The indicators are related to the goals good health and well-being (SDG 3), clear water and sanitation (SDG 6), affordable and clean energy (SDG 7), decent work and economic growth (SDG 8), industry, innovation and infrastructure (SDG 9), responsible consumption and production (SDG 12), climate action (SDG 13) and life below water (SDG 14). A total of 12 sustainability indicators, including human toxicity potential, wastewater generation, water consumption, renewable energy share, energy demand, material footprint, profit, waste generation, recycling ratio of waste, greenhouse gas emission, eutrophication potential and acidification potential are assigned to selected SDGs. The application of the indicators is illustrated by two case studies: a batch (BD) and a continuous (pressure-swing) distillation process. Case BD6, where the $CO_2$ emission was minimized, proves to be the most sustainable BD process. It has the lowest greenhouse gas emission, acidification potential and waste generation. Although it has the lowest profit, the variations across the BD cases are minimal. By the pressure-swing distillation, L4 (feeding into low-pressure column, heat integration with optimization) is the best case, with the highest profit and the lowest energy demand, material footprint and greenhouse gas emission values.

**Keywords**: Distillation, Continuous Distillation, Batch Distillation, Environment, Energy, Sustainability

## INTRODUCTION

There has been a growing interest in sustainability in chemical engineering as industries aim to reduce their environmental footprint without compromising economic performance. This research proposes a set of sustainability indicators aligned with the United Nations' Sustainable Development Goals (SDGs) [1] for the evaluation of the sustainability of distillation processes, offering a structured way to assess and improve these systems. The use of these indicators is illustrated in two case studies: (1) a continuous pressure-swing distillation (PSD) of a maximum-azeotropic mixture without and with heat integration and (2) the recovery of acetone from a waste solvent mixture by batch distillation (BD). These processes were selected due to their widespread industrial use, their potential to benefit from improvements in their sustainability, and to show the general applicability of the indicators proposed.

Distillation is one of the most commonly used methods for the separation of liquid mixtures. It is performed in a continuous way when large processing capacities are needed (e.g. refining). Batch distillation is also used frequently (e.g. in the pharmaceutical industry) because of its flexibility in separating mixtures with varying quantity and composition, including waste solvent mixtures. However, distillation is very energy-intensive, leading to high operational costs and greenhouse gas emissions. In fact, distillation stands out as the most energy-consuming process in the chemical industry, using more than 40% of the total energy demand of an industry itself responsible for 30% of industrial energy usage in the US.

This study aims to address these issues by propos-

ing sustainability indicators that account for environmental, economic and social aspects. By aligning these indicators with the SDGs, as globally recognized sustainability standards, the research also aims to encourage industries towards more sustainable practices. To our knowledge, this work is the first to propose sustainability indicators aligned with SDGs in the field of distillation.

The case studies illustrate how to apply the proposed indicators to evaluate the sustainability aspects of distillation processes. In the PSD example [3], the process was optimized without and with heat integration, which led to a significant decrease in both the total annual cost (TAC) and environmental impact ($CO_2$ emission). In the acetone recovery by BD case [4], either the profit or the $CO_2$ emissions were optimized. In this work, we determined how the proposed sustainability indicators improved due to the optimization and heat integration performed in these previous works.

This study focuses on addressing a key gap by aligning the evaluation of distillation processes directly with the SDGs. This ensures that the results contribute not only to advancing methodological approaches but also directly support global sustainability goals. Therefore, in this study, we propose a set of sustainability indicators aligned with SDGs.

Another key novelty of this study is that, while traditional techno-economic analysis (TEA) focuses on economic feasibility and life cycle assessment (LCA) on environmental impact, our approach simultaneously incorporates both dimensions.

This framework could also be applied to any process with well-defined inputs and outputs where emissions and products are generated.

## METHODOLOGY

The following potentially distillation-related SDGs are selected: good health and well-being (3), clean water and sanitation (6), affordable and clean energy (7), decent work and economic growth (8), industry, innovation and infrastructure (9), responsible consumption and production (12), climate action (13), life below water (14). For each SDG, the UN has selected different targets, each of which has one or more numerical indicators assigned. However, these SDG indicators can only be interpreted at regional or higher levels, making them unsuitable for assessment of technological processes. Within the selected SDGs, the following relevant targets are identified: reduction of deaths and illnesses from hazardous chemicals and environmental pollution (3.9), improving water quality by reducing pollution and increasing water-use efficiency across all sectors (6.3 and 6.4), increasing the share of renewable energy in the global energy mix and improvement of energy efficiency by 2030 (7.2 and 7.3), improving global resource efficiency in consumption and production (8.4 and 12.2), added manufacturing value (9.2), reduction of $CO_2$ emission and greenhouse gases (9.4, 13.2), proportion of hazardous waste treated (12.4), recycling rate (12.5), marine pollution by eutrophication (14.1) and acidification (14.3) [1].

After selecting the relevant targets and the more specific SDG indicators proposed by the UN that could be linked to distillation studies, sustainability indicators were aligned to the SDG indicators and defined. The selected SDG indicators and their aligned sustainability indicators can be found in Table 1.

The indicators could be expressed either as absolute or relative (specific) values. In the latter case, which is selected here, they are expressed relative to the total mass or mass flow rate of the product(s) ($m_p$). It must be noted that many of the quantities used for the calculation of the indicators have different units depending on whether the process is batch or continuous. In the former case, masses are used, in the latter, mass flow rates. Nevertheless, the indicators always have the same units.

Human toxicity potential (HTP) [5] weighs thethe masses of potentially toxic components (for components i=1...n, where n is the number of components) in the waste streams with their characterization factor (CF). Wastewater generation (WwG) and water consumption (WC) contain the total wastewater mass flow rate ($m_{ww}$) and the total mass flow rate of water used in the process, respectively. Renewable energy share (RES) is the ratio of total energy from renewable energy sources ($E_r$) to total energy demand (E); the latter value is used in the energy demand (ED).

The material footprint (MF) takes into account the mass of equipment ($m_{eq}$) and additional materials consumed during the operation, such as entrainer or reagents. Since the installation of the equipment only happens once, the mass of additional materials and $m_p$ should be calculated for the lifetime of the plant to ensure a fair comparison. Profit (P) is calculated by net income (I) after the costs (C). I typically includes the value of the products. Waste generation (WG) contains the total mass of liquid waste ($m_{lw}$). Recycling ratio of waste (RRW) is the ratio of the mass of the recycled waste ($m_r$) to $m_{lw}$. The greenhouse gas emission (GHG) [6] expresses the total mass emissions of the process in $CO_2$ equivalents. This value could be calculated with different time horizons of GWP (e.g., 20 y). $CO_2$ emissions as an indicator could be aligned with 9.4.1, but it would be redundant as it is already included in GHG. By the eutrophication potential (EP) [7] the emissions of components in waste streams are weighted by their potency factor (PF). The acidification potential (AP) [6] refers to only the aquatic acidification potential, calculated from the total mass of released $H^+$ ions ($m_{H^+}$), as we assume, as a worst-case scenario from the point of view of aquatic life, that gaseous emissions would be completely absorbed in surface waters.

**Table 1:** Selected UN SDG indicators and their aligned indicators with the equations.

| SDG Indicators | Indicator Name | Indicators | Formula | |
|---|---|---|---|---|
| 3.9.1<br>3.9.3 | Air pollution mortality rate<br>Unintentional poisoning mortality | Human toxicity potential (HTP) | $HTP = \frac{\sum_{i=1}^{n}(m_i \cdot CF_i)}{m_p}$ | (1) |
| 3.9.2<br>6.3.1<br>6.3.2 | Water and sanitation mortality rate<br>Wastewater treated safely<br>Good ambient water quality | Wastewater generation (WwG) | $WwG = \frac{m_{ww}}{m_p}$ | (2) |
| 6.4.1<br>6.4.2 | Water-use efficiency change<br>Water stress level | Water consumption (WC) | $WC = \frac{m_w}{m_p}$ | (3) |
| 7.2.1 | Renewable energy share | Renewable energy share (RES) | $RES = \frac{E_r}{E}$ | (4) |
| 7.3.1 | Energy intensity | Energy demand (ED) | $ED = \frac{E}{m_p}$ | (5) |
| 8.4.1 | Material footprint | Material footprint (MF) | $MF = \frac{m_{eq} + m_a}{m_p}$ | (6) |
| 9.2.1<br>12.2.1 | Manufacturing value added<br>Material footprint | Profit (P) | $\mathrm{P} = \frac{I-C}{m_p}$ | (7) |
| 12.4.2 | Hazardous waste generation | Waste generation (WG) | $\mathrm{WG} = \frac{m_{lw}}{m_p}$ | (8) |
| 12.5.1 | Recycling rate | Recycling ratio of waste (RRW) | $RRW = \frac{m_r}{m_{lw}}$ | (9) |
| 9.4.1<br>13.2.2 | $CO_2$ emission<br>Total GHG emission | Greenhouse gas emission (GHG) | $GHG = \frac{\sum_{i}^{n}(m_{GHG,i} \cdot GWP_i)}{m_p}$ | (10) |
| 14.1.1 | Coastal eutrophication | Eutrophication potential (EP) | $EP = \frac{\sum_{i}^{n}(m_i \cdot PF_i)}{m_p}$ | (11) |
| 14.3.1 | Marine acidity | Acidification potential (AP) | $AP = \frac{m_{H^+}}{m_p}$ | (12) |

RES and WC are not calculated, as renewable energy sources and freshwater were not used in the case studies. However, they were added as indicators to propose a framework that could be applied to all distillation processes.

## CASE STUDIES

### Pressure-swing distillation

A maximum-boiling azeotropic water(A)–ethylenediamine(B) mixture is separated by PSD [3]. The flow rate of the fresh feed is 100 kmol/h with a composition of 35 mol% A. As calculated by the UNIQUAC model, the azeotrope contains 44.1% A at 0.10 bar and 25.6 % A at 2.02 bar, which are the two column pressures. Since the feed composition is between the azeotropic ones, it can enter either the high- (HPC) or the low-pressure column (LPC), resulting in two possible sequences: HP-LP (Figure 1) and LP-HP. The distillate of HPC is A with a purity of 99.5 %. The bottom product of HPC is fed into LPC, where B is produced as distillate in a purity of 99.5 %, and the bottom product, whose composition is near the azeotropic one at the pressure of LPC, is recycled to HPC.

By the PSD cases (Table 2), H and L identify the column sequences HP-LP and LP-HP. H1 and L1 refer to cases without heat integration (NHI) and optimization, and H2 and L2 mean optimized NHI cases. H3 and L3 denote the application of heat integration to the optimal NHI without further optimization, while H4 and L4 refer to optimized heat-integrated cases. TAC was the objective function. Heat integration is achieved by heating the reboiler of the LPC by condensing the top vapor of HPC. The integration is partial in all cases except H4, meaning that an auxiliary condenser is needed to fully condense the vapor. By H4, full heat integration is optimal, where the heat duties of the condenser of HPC and reboiler of

LPC are equal.

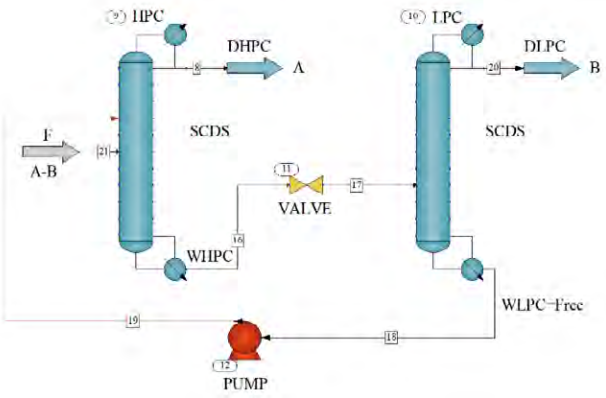

**Figure 1.** ChemCAD flowsheet for the separation of the A-B mixture with feeding into HPC.

By L2, surrogate model-based optimization was used with models fitted to the simulation results by using ALAMO. By H2, H4 and L4, TAC was minimized by an elitist, real-coded genetic algorithm.

HTP is not calculated since CF of B is not available. The only waste stream is the distillate of HPC, and it is considered as wastewater. Thus, WG equals WwG. The total energy demand is the sum of the two reboiler duties. MF takes the shell weight of the columns (calculated by CHEMCAD) into account during their lifetime (assumed to be 10 y), while GHG consists of the $CO_2$ emissions related to the production of heating steam. RRW is zero since there is no waste recycling. AP is also zero because the waste stream is basic. P was calculated as the yearly income minus TAC, the former of which is the mass of the B product and the price of B (1682 US$/t [8]). For the calculation of EP, the mass of B in the waste is multiplied by its COD value and PF of 0.022, as well as its nitrogen content with a PF of 0.42 [9].

## Recovery of acetone by batch distillation

From an aqueous waste solvent mixture containing dichloromethane (A) and methyl tert-butyl ether (B) as pollutants, acetone (C) is recovered by BD [4]. The composition of the feed is 1 mass% A, 1% B, 49% C and 49% water (D). The purity requirements for the acetone product are: ≤0.1 mass% A, ≤0.1% B and ≤ 0.25% D.

The components form three minimum-boiling (A-D, B-C, B-D) and one maximum-boiling (A-B) binary azeotropes, as well as a ternary saddle azeotrope (A-B-C). The VLLE calculations were performed by UNIQUAC.

The recovery of C is performed in a BD column with 25 theoretical trays (not including the reboiler and the condenser) at atmospheric pressure. The volume of the charge is 20 $m^3$ (17,785.9 kg). The reboiler duty is 1800 MJ/h. The steps of the process are as follows:

1. A and the majority of B are removed in Fore-cut1, although with a considerable loss of C due to the B-C azeotrope. This fore-cut is incinerated. The reflux ratio of the step ($R_1$) and its stopping criteria ($Cr_1$) are optimized.

2. Fore-cut2 is taken to remove the remaining amount of B. It is recycled to recover its C content. $R_2$ and $Cr_2$ are parameters optimized.

3. The main cut is high purity C. A relatively high $R_3$ (optimized) is needed due to the C-D tangent azeotrope.

4. The C content of the still residue (wastewater) is decreased to the necessary extent (0.2 %) for biological purification by taking an after-cut. $R_4$ is optimized.

The cases of BD (Table 3) are as follows: by BD1 Fore-cuts 1 and 2 are taken as a single fore-cut. By BD2 the fore-cut is divided into two parts with no other modification. BD3 and BD4, respectively, denote the cases with the highest profit and lowest specific $CO_2$ emission obtained by modifying a single input variable by sensitivity studies. BD5 and BD6 refer to cases with maximum P and minimum $CO_2$, optimized by the complex method.

In HTP, the HCl emission (CF=24) from the incineration of the A content of the fore-cut and the C emission (CF=0.079) in the still residue are taken into account [9]. WwG includes the wastewater from the still residue. MF was calculated by the shell weight of the column (1727 kg) divided by the total mass of the product for the lifetime of the plant (10 y). In WG, the total mass of liquid waste includes the fore-cut(s), the after-cut and the still residue. To calculate RRW, the recycling of the after-cut and second fore-cut was considered. GHG considers the $CO_2$ emissions resulting from the incineration of the fore-cut and that from the generation of heating steam. EP is calculated from the emission of C in the still residue multiplied by its COD value and PF=0.022. For AP, the mass of $H^+$ ions was calculated from the HCl emission.

# RESULTS

## Pressure-swing distillation

Table 2 shows the results of PSD cases. WwG=WG and EP were constant (0.163 kg/kg and 3.10 mg/kg) in all cases as the waste stream and $m_p$ were the same. Therefore, these values are not given in Table 2.

H1 had the highest ED, making it the most energy-intensive case. H1 also had the lowest P and highest GHG. While MF remained high due to larger diameters and shell weight of the columns. These factors indicate that H1 is the least favorable case in terms of overall sustainability. This is due to the fact that it did not benefit either from the heat integration or from the optimization.

L1 performed slightly better than H1 with a reduced ED (by 15%) because of lower heat duties while maintaining a comparable P. It also showed a lower GHG(by 15%) due to its reduced ED, reducing its overall environmental footprint.

By H2, the optimization reduced both the capital cost and the heat duties of the columns. H2 had a much

**Table 2:** Calculated sustainability indicators for PSD cases.

| Indicators | PSD cases | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | H1 | L1 | H2 | L2 | H3 | L3 | H4 | L4 |
| ED, MJ/kg | 8.71 | 7.38 | 7.26 | 6.97 | 4.60 | 4.20 | 4.44 | 4.18 |
| MF, mg/kg | 285 | 294 | 293 | 240 | 293 | 240 | 269 | 178 |
| P, $/kg | 1.59 | 1.60 | 1.60 | 1.61 | 1.63 | 1.63 | 1.63 | 1.63 |
| GHG, kg/kg | 0.13 | 0.11 | 0.11 | 0.11 | 0.07 | 0.06 | 0.07 | 0.06 |

lower ED (by 17%) than H1 and a slightly higher P. It also had a much lower GHG (by 15%), while its MF increased slightly (by 3%).

L2 had a lower ED (by 5%) and a reduced MF(by 18%) compared to L1. Its P was slightly (by 1%) higher than that of L1, with a similar GHG value. L2 is more favorable than H2 in all respects.

H3 had a much lower ED (by 47% and 17%) compared to H1 and H2 due to the usage of the top vapor of HPC to heat the reboiler of LPC. Thus, compared to H2, it also had a higher P (by 3%) while. its GHG () was significantly (by 36%) reduced, making it one of the better cases. However, MF remained high.

L3 showed further improvement, having a lower ED (by 40%) compared to L2 due to the heat integration. It maintained a high P and a similar MF, as well. With the second lowest GHG, L3 emerges as one of the most environmentally sustainable cases, balancing profitability and reduced emissions.

H4 had an even lower ED (by 3%) than H3, although it was still higher than that of L3. It maintained a high P and its MF was also lower than that of H1 (by 6%) or H2 (by 9%) but still higher than L2. Its GHG was comparable to H3, showing a good sustainability performance.

L4 was the most sustainable case, with the lowest ED (7.86 MJ/kg), MF (178 mg/kg), and GHG (0.06 kg/kg) values, while its P (1.63 $/kg) was the highest. These factors indicated that L4, benefiting from both heat integration and optimization, is the most sustainable option.

## Batch distillation

Table 3 shows the results of BD cases. As it had the highest amount of incinerated fore-cut, BD1 had the highest HTP among all cases. For the same reason, it also had the highest GHG, making it the least sustainable in terms of environmental impact. WwG was 1.12 kg/kg. It had the second lowest P and RRW. It had a high MF and a relatively moderate EP and the highest AP. Additionally, BD1 generated the second most waste and had a high ED, contributing to its lower sustainability profile. These results could be explained by the fact that BD1 had a single fore-cut that was incinerated, thus causing more environmental impact and incineration cost.

BD2 showed a significantly lower HTP (by 14%) since the amount of incinerated material decreased. It had the highest P due to the high $m_p$ and lower incineration cost. The values of WwG, ED, WG, MF, EP, and AP did not change compared to BD1. RRW was the highest among all cases. Its GHG was reduced considerably (by 26%) compared to BD1 because less fore-cut was incinerated. BD3, where $R_2$ was considerably decreased, benefited from the sensitivity study and had slightly lower HTP and WwG values than BD1 and BD2. It had the lowest ED, one of the lowest MF and WG, and performed slightly better in terms of GHG (by 5%) than BD2. P was between BD1 and BD2. It also had a reduced AP (by 6%) and EP (by 3%) compared to BD2, indicating a more sustainable process than BD1 and BD2. These changes can be explained by a higher $m_p$ and lower operation time.

**Table 3:** Calculated sustainability indicators for BD cases.

| Inds. | BD cases | | | | | |
|---|---|---|---|---|---|---|
| | BD1 | BD2 | BD3 | BD4 | BD5 | BD6 |
| HTP, kg/kg | 0.56 | 0.48 | 0.46 | 0.47 | 0.46 | 0.46 |
| WwG, kg/kg | 1.12 | 1.12 | 1.09 | 1.10 | 1.08 | 1.08 |
| ED, MJ/kg | 5.84 | 5.84 | 5.29 | 5.87 | 5.37 | 5.90 |
| MF, mg/kg | 95.3 | 95.3 | 92.5 | 93.7 | 92.1 | 92.4 |
| P, $/kg | 1.18 | 1.21 | 1.19 | 1.20 | 1.19 | 1.17 |
| WG, kg/kg | 1.33 | 1.33 | 1.26 | 1.29 | 1.23 | 1.23 |
| RRW, kg/kg | 0.03 | 0.07 | 0.05 | 0.07 | 0.03 | 0.05 |
| GHG, kg/kg | 0.44 | 0.32 | 0.31 | 0.30 | 0.29 | 0.26 |
| EP, mg/kg | 0.35 | 0.35 | 0.34 | 0.33 | 0.41 | 0.25 |
| AP, mg/kg | 83.0 | 71.0 | 66.9 | 68.6 | 66.3 | 66.7 |

By BD4, R1 was increased compared to its value by BD2. This decreased the mass of both fore-cuts and increased $m_p$. BD4 had a similar HTP to BD3. It also had the second-highest ED value due to a slight increase in the operation time. MF and WwG were both slightly (by 2%) lower than by BD2. It had a lower GHG (by 6%), as well as slightly reduced WG (3%) and AP (by 3%) compared to

BD2. It had the second-highest P and the second-lowest EP.

By BD5, the profit (in $) was maximized. It had the lowest HTP and WG, and the second lowest ED. WwG was relatively low. P was very similar to BD3. Its GHG value was relatively low. While it showed the lowest AP, its EP was the highest. Overall, BD5 is favorable in terms of sustainability.

BD6, where the $CO_2$ emission was minimized, emerged as the most sustainable case. It had the lowest GHG and EP, second-lowest HTP and AP WG values. However, it had the highest ED and lowest P value mostly because of the increased operation time. However, the difference in P among the BD cases was very small.

## CONCLUSIONS

To assess the sustainability of distillation processes, a set of sustainability indicators, directly linked to sustainable development indicators of the United Nations, were proposed. Sustainable development goals (SDGs), targets and, finally, the sustainable development indicators were selected by considering their fit to distillation studies.

8 out of 17 SDGs were selected, and they include good health and well-being, clear water and sanitation, affordable and clean energy, decent work and economic growth, industry, innovation and infrastructure, responsible consumption and production, climate action and life below water.

A set of (12) sustainability indicators aligned with those of UN's included human toxicity potential (HTP), wastewater generation (WwG), water consumption (WC), renewable energy share (RES), energy demand (ED), material footprint (MF), profit (P), waste generation (WG), recycling ratio of waste (RRW), greenhouse gas emissions (GHG), eutrophication potential (EP) and acidification potential (AP).

This framework was applied to a batch (BD) and a continuous (pressure-swing, PSD) distillation case study to evaluate their performance in terms of sustainability. Six cases were studied for BD evaluating the effects of the division of the fore-cut, sensitivity studies and optimization of the profit or the $CO_2$ emissions. PSD cases include scenarios such as no heat integration and no optimization, optimized without heat integration, heat integration without optimization, and optimal heat integration. These scenarios were studied for two column sequences differing in whether the feed was introduced into high- or the low-pressure column.

In the case of PSD, the most sustainable operation was L4 (heat-integrated and optimized by GA, feeding into the low-pressure column). It had the lowest ED, MF and GHG, while the highest P value. Among the BD cases, BD6 (minimized $CO_2$ emission) had the best overall sustainability: lowest GHG, WwG and EP and second lowest HTP, MF, WG and AP values.

## ABSTRACT

Direct Air Capture (DAC) technology has gained significant attention as a promising solution for mitigating $CO_2$ emissions and meeting climate goals. However, the current challenges of high energy demand, capital costs, and scalability present critical challenges to the widespread deployment of DAC systems. Integrating DAC with Heating, Ventilation, and Air Conditioning (HVAC) systems in buildings offers a potential solution by enhancing indoor air quality while capturing $CO_2$, thus lowering energy consumption and capital investment compared to standalone DAC systems. This study evaluates the techno-economic performance of an integrated DAC-HVAC system against a standalone DAC system. This analysis combines thermodynamic estimation of $CO_2$ and $H_2O$ loadings and energy requirements with an economic evaluation of capital and operating costs to calculate the levelized cost of $CO_2$ capture (LCOD) for both DAC-HVAC and DAC-standalone. A sensitivity analysis explores the effects of varying climatic conditions, specifically temperature and humidity, on the economic performance of the DAC-standalone system. Further sensitivity analysis examines the impact of discount rates and electricity prices on both systems' economic viability. Results show that the DAC-HVAC integration achieves lower energy consumption and capital costs, with an LCOD of approximately 219 \$/ton $CO_2$, compared to the DAC-standalone system, which ranges from 349–429 \$/ton $CO_2$ depending on climatic conditions. In addition to offering a lower levelized cost, the DAC-HVAC system also provides resilience against climate and cost fluctuations. This study demonstrates the significant economic benefits and scalability potential of integrating DAC technologies within existing building infrastructures.

**Keywords**: DAC, CO2 capture, HVAC, Energy efficiency, Techno-economics.

## INTRODUCTION

As the global climate crisis intensifies, the need for effective negative emission technologies (NETs) to remove $CO_2$ from hard-to-abate industries and address historical emissions has become increasingly urgent [1]. Among the various NETs, Direct Air Capture (DAC) with carbon storage is considered a promising complementary solution to meet climate goals, with the potential to significantly reduce atmospheric $CO_2$ levels [2]. However, despite the significant promise of DAC, the energy and economic costs of its implementation remain uncertain, with estimates ranging between \$100 and \$1000 per ton of $CO_2$ captured. Furthermore, DAC is projected to require substantial energy resources if deployed at scale, potentially consuming around 50 EJ annually by 2100 which is more than half of the current global electricity production [2]. This highlights the critical need to explore innovative solutions to reduce the energy requirements associated with DAC systems.

One promising approach is the integration of DAC into existing Heating, Ventilation, and Air Conditioning (HVAC) infrastructures. This coupling offers dual benefits; it not only reduces the energy demands of DAC systems but also enhances the efficiency of HVAC systems by enabling air recirculation and $CO_2$ recycling. Additionally, the integration provides an opportunity to maintain high indoor air quality (IAQ), which is crucial for the well-being of building occupants. Research has shown that $CO_2$ concentrations above 1000 ppm can lead to adverse

health effects, such as the Sick Building Syndrome (SBS), while concentrations below 1000 ppm are generally considered acceptable for IAQ, provided that appropriate ventilation measures are in place [3,4]. Moreover, elevated $CO_2$ levels have been associated with reduced cognitive performance, further emphasizing the importance of maintaining optimal air quality [4].

Although limited studies have examined the integration of DAC with HVAC systems, few have addressed the fluctuations in $CO_2$ and $H_2O$ loadings with varying outside temperatures and humidity, which directly impact the energy requirements of DAC standalone systems [5]. Other studies explored DAC-standalone economics without consideration of varying climatic conditions [6].

The goal of this study is to evaluate the techno-economics of integrating DAC with HVAC systems and compare it with the performance of standalone DAC systems. In standalone DAC, the energy requirements for the Temperature-Vacuum Swing Adsorption (TVSA) process vary with changes in external climate condition such as temperature and humidity, as these factors influence the $CO_2$ and $H_2O$ adsorption capacities. This study aims to assess the fluctuations in $CO_2$ and $H_2O$ loadings in response to changes in outside temperature and pressure and examine how these fluctuations affect energy requirements, and consequently, the operating expenses of the DAC standalone system. This will provide a comprehensive comparison with the proposed DAC-HVAC integration, which remains unaffected by external temperature and humidity conditions.

## SYSTEM DESCRIPTION

The proposed system integrates a direct air capture (DAC) unit into the Heating, Ventilation, and Air Conditioning (HVAC) infrastructure of buildings to optimize energy use during adsorption and desorption while also improving indoor air quality. The DAC-HVAC system is strategically positioned at the exhaust stream, where $CO_2$ concentrations are highest, to maximize the $CO_2$ capture efficiency. This placement within the HVAC system has been shown to optimize $CO_2$ capture for DAC-HVAC integration, when air recirculation is considered [7]. A target $CO_2$ concentration of 400 ppm is assumed for $CO_2$ capture in this study.

Both the DAC-HVAC and DAC-standalone systems operate through temperature vacuum swing adsorption (TVSA) process, which includes vacuum application, heating for desorption, cooling, pressurization, and adsorption. The DAC system operates continuously with two parallel adsorbent filters, one in adsorption mode while the other undergoes desorption. A cooling jacket-type heat exchanger is used to meet the thermal needs of the TVSA process, providing heating and cooling as required.

Lewatit VP OC 1065 is used as the sorbent material in both configurations. While the DAC-HVAC system benefits from utilizing existing HVAC blowers, reducing capital expenditures, the DAC-standalone system requires additional blowers, increasing its capex. The consistent filter design and TVSA process across both systems allow for a direct techno-economic comparison of DAC-HVAC integration versus the standalone DAC system.

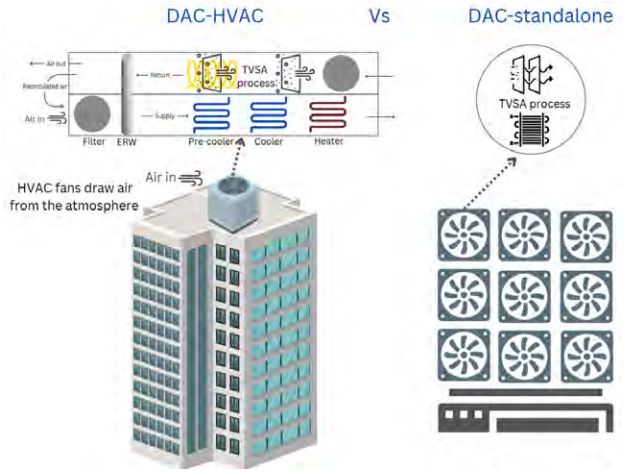

**Figure 1.** Schematic of DAC-HVAC and DAC-standalone systems.

## METHODOLOGY

This study is structured into two key components; a thermodynamic analysis to estimate $CO_2$ and $H_2O$ loadings and assess the energy requirements of the TVSA process and an economic analysis to evaluate capital and operational costs and determine the levelized cost of $CO_2$ capture (LCOD).

### Thermodynamic analysis

This study entails a thermodynamic analysis of the DAC system to evaluate its energy requirements, which include operating the vacuum pump, heating the sorbent during desorption and cooling the sorbent before adsorption. Additionally, blower power is considered to account for the pressure drop from the filters in the system. Equations 1–6 quantify these energy demands, detailing the heating load for desorption (Equations 1–3), the cooling load before adsorption (Equation 4), the vacuum pump work (Equation 5), and the additional blower power required to compensate for pressure drop from the filters (Equation 6). These calculations are essential for estimating the system's variable operational costs in terms of electricity consumption and for determining the appropriate sizing of equipment required. Table 1 presents the various thermodynamic variables utilized in the analysis.

$$\dot{Q}_{heating} = Q_{sens} + Q_{latent} \quad (1)$$

$$\dot{Q}_{sens} = \dot{m}\left(\frac{c_{p,ads}}{\Delta_{qCO2}} + c_{p,CO2} + c_{p,H20}\frac{\Delta_{qH2O}}{\Delta_{qCO2}}\right)(T_{des} - T_{ads}) \quad (2)$$

$$\dot{Q}_{latent} = \dot{m}\left(\Delta H_{H2O}\left(\frac{\Delta_{qH2O}}{\Delta_{qCO2}}\right) + \Delta H_{CO2}\right) \quad (3)$$

$$\dot{Q}_{cooling} = \dot{m}\frac{c_{p,ads}}{\Delta_{qCO2}}(T_{des} - T_{ads}) \quad (4)$$

$$\dot{W}_{pump} = \dot{m}\frac{R.T_{pump}}{\eta_{pump}}\ln\left(\frac{P_{amb}}{P_{des}}\right) \quad (5)$$

$$\dot{W}_{blower} = 2.72 \text{ x } 10^{-5}\frac{\dot{V}_{air}\Delta P}{\eta_{fan}} \quad (6)$$

Where $\dot{Q}_{heating}$ is the total heating load including sensible heat ($Q_{sens}$) and latent heat ($Q_{latent}$). $\dot{Q}_{cooling}$ is the cooling load, $\dot{W}_{pump}$ is the work of the pump, $\dot{W}_{blower}$ is the fan power, $\dot{V}_{air}$ is the incoming air flowrate, $\Delta P$ is the pressure drop, $\eta_{fan}$ is the fan efficiency, and $\dot{m}$ is the $CO_2$ mass flowrate.

Moreover, the water and $CO_2$ adsorption capacities are determined using mechanistic co-adsorption models, which describe the isotherm behavior as outlined in Equations 7 and 8. These models provide a detailed understanding of how the sorbent interacts with both $CO_2$ and $H_2O$, enabling the calculation of adsorption capacities under varying conditions [5].

$$q_{CO2} = \frac{\phi}{\phi_{dry}}\,\mathrm{f}(p_{CO2}, T, \Delta H) \quad (7)$$

$$q_{H2O} = \frac{q_m kcx}{(1-kx)(1+(c-1)kx)} \quad (8)$$

Where $q_{CO2}$ is the $CO_2$ loading, $\phi$, and $\phi_{dry}$ are amine efficiencies under actual and dry conditions, f is the partial pressure ($p_{CO2}$) and temperature dependent isotherm function, and $\Delta H$ is the average heat of adsorption of wet and dry states. $q_{H2O}$is the $H_2O$ loading, $q_m$ is the monolayer loading, x is the humidity and k and c are affinity parameters taken from Young et al. [5].

**Table 1:** Thermodynamic analysis variables.

| Variable | Description | Value |
|---|---|---|
| $c_{p,ads}$ | Specific heat of adsorbent | 1.58 kJ/kg/K |
| $c_{p,CO2}$ | Specific heat of $CO_2$ | 0.03868 kJ/mol/K |
| $c_{p,H20}$ | Specific heat of $H_2O$ | 0.07528 kJ/mol/K |
| $T_{ads}$ | Adsorption temperature | 23.7 °C |
| $T_{des}$ | Desorption temperature | 90 °C |
| $P_{des}$ | Desorption pressure | 25 kPa |
| $\Delta H_{CO2}$ | $CO_2$ heat of desorption | 70 kJ/mol $CO_2$ |
| $\Delta H_{H2O}$ | $H_2O$ heat of desorption | 44.2 kJ/mol $CO_2$ |

## Economic analysis

To evaluate the overall economic performance, the levelized cost of direct air capture (LCOD) is calculated using equation 9. LCOD is a crucial metric for comparing the costs of different DAC technologies. In this study, it is used to compare the DAC-HVAC and DAC-standalone systems by consolidating both fixed and variable operating costs, as well as capital expenditures providing an overall cost comparison between the two systems based on the amount of $CO_2$ captured. The economic analysis of the DAC system involves estimating both capital expenditures (CAPEX) and operating expenditures (OPEX) of both the DAC-HVAC and DAC-standalone systems. Equipment base costs are determined using an exponential method that incorporates capacity-ratio exponents to calculate equipment costs based on their capacity, as previously estimated in the thermodynamic analysis. These equipment costs are then estimated in terms of delivered, installed, and escalated cost projections. The variable operating costs include electricity for heating and cooling, pumping, and additional fan power requirements. The fixed operating cost includes ongoing costs such as maintenance, insurance, labor, and other administrative expenses that remain constant regardless of the system's operation.

$$LCOD = \frac{Capex\,.\,CRF + Opex_{fix}}{CO2} + Opex_{var} \quad (9)$$

Where CAPEX represents the capital expenditures, CRF is the capital recovery factor, $CO_2$ is the annual amount of $CO_2$ captured, and $Opex_{fix}$ and $opex_{var}$ denote fixed and variable operating expenditures, respectively. The CRF is calculated using equation 10.

$$CRF = \frac{i(1+i)^n}{(1+i)^n - 1} \quad (10)$$

In this equation, i is the annual discount rate (7%), and n is the system's lifetime (20 years). The CRF is used to calculate the annualized capital cost, enabling the distribution of CAPEX over the system's lifespan.

A sensitivity analysis is conducted to evaluate the effect of varying temperature and humidity on $CO_2$ and $H_2O$ adsorption capacities, and the resulting changes in LCOD for the DAC-standalone system. This analysis considers humidity ranges between 20-90% and temperatures between 25-45°C. Additionally, actual data points for temperature and humidity from Qatar, based on hourly data collected over four months (May to August), are studied to assess the range of LCOD changes for this case study. This sensitivity analysis, however, is not applicable to the DAC-HVAC system, as it maintains a constant temperature and humidity within the HVAC infrastructure, which helps stabilize conditions and mitigate the fluctuations observed in the standalone system.

Moreover, a sensitivity analysis is performed to evaluate the impact of varying discount rates (5-15%) and electricity prices ($0.30-$0.14/kWh) on the levelized cost of direct air capture (LCOD) for both the DAC-HVAC and DAC-standalone systems. This analysis allows for an assessment of how fluctuations in these key economic factors influence the overall cost-effectiveness of the systems.

## RESULTS AND DISCUSSION

At a discount rate of 7% and an electricity price of 0.0351 $/kWh, the levelized cost of direct air capture (LCOD) for the DAC-HVAC system is 219 $/ton $CO_2$, while the DAC-standalone system has a significantly higher LCOD of $374/ton $CO_2$. This disparity highlights the cost advantages of integrating DAC with HVAC systems.

The DAC-HVAC system benefits from the synergy between the two processes. By utilizing the heating and cooling capabilities of the HVAC system to enhance the $CO_2$ loading and reduce the $H_2O$ loading, the DAC-HVAC system can capture $CO_2$ more cost-effectively. This integration results in improved energy efficiency, reducing the energy consumption per ton of $CO_2$ captured, which is a key driver of its lower LCOD. On the other hand, the DAC-standalone system operates independently and is subject to fluctuations in climate conditions, which influence $CO_2$ and $H_2O$ adsorption capacities, thereby affecting energy requirements and operational expenses. Additionally, the DAC-HVAC system can leverage existing HVAC blowers, while the DAC-standalone system incurs additional capital expenditure due to the need for separate blowers.

The LCOD of the DAC-standalone system is highly sensitive to variations in temperature and humidity due to their impact on $CO_2$ and $H_2O$ adsorption capacities. A contour plot was generated to visualize the fluctuations in LCOD across a range of temperature (4–25°C) and humidity (20–90%) conditions as presented in Figure 2. Additionally, actual hourly temperature and humidity data over four months in Qatar were plotted on the contour map to assess variations in LCOD.

The results indicate that LCOD fluctuates between 349–429 $/ton $CO_2$, with the highest LCOD observed at high temperatures and high humidity levels. This can be attributed to the increased presence of $H_2O$ in the air under these conditions, which competes with $CO_2$ for adsorption on the sorbent material. As a result, $CO_2$ capture efficiency declines, leading to higher energy requirements for desorption and subsequently increasing LCOD. The lowest LCOD values occur at low temperatures and low humidity levels, where $CO_2$ adsorption is more favorable, and less energy is required for regeneration.

For the Qatar case study, the results indicate that when temperature is high, humidity is relatively lower, leading to a maximum LCOD of approximately 405 $/ton $CO_2$. Notably, there are no data points corresponding to conditions where both temperature and humidity are high for the studied dataset of three months, which means the LCOD does not reach the maximum value of 429 $/ton $CO_2$.

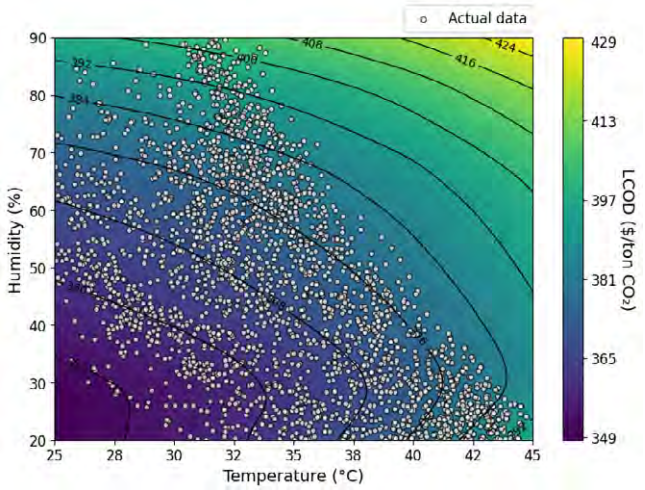

**Figure 2.** Contour plot of LCOD with respect to temperature and humidity for DAC-standalone system.

The sensitivity analysis of LCOD with respect to varying electricity prices and discount rates further illustrates the cost dynamics of both systems. As electricity prices increase, the LCOD for both DAC-HVAC and DAC-standalone systems rises (Figure 3). For example, at an electricity price of 0.14 $/kWh, the LCOD for the DAC-standalone system increases to 536 $/ton $CO_2$, while the DAC-HVAC system reaches 381 $/ton $CO_2$. This significant difference highlights that in regions where electricity prices are volatile or high, DAC-HVAC systems may offer a more cost-effective solution.

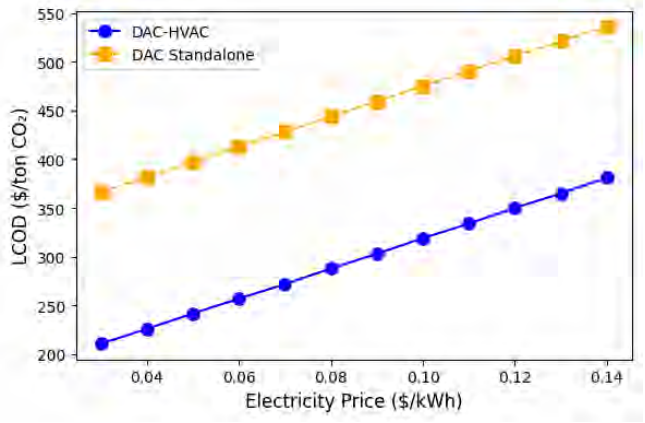

**Figure 3.** Effect of electricity price on LCOD.

Similarly, the LCOD values for both systems are sensitive to changes in the discount rate. While both systems experience a rise in LCOD with higher discount rates, the DAC-HVAC system consistently maintains a lower cost compared to the DAC-standalone system (Figure 4). This suggests that the DAC-HVAC system is more resilient to long-term financial considerations, owing to its lower operational and capital costs, making it a more attractive option for long-term projects.

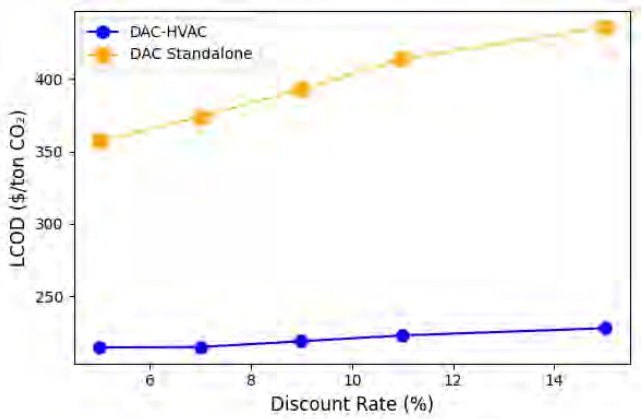

**Figure 4.** Effect of discount rate on LCOD.

The DAC-HVAC integration mitigates several technical and financial barriers of standalone DAC. However, key technical challenges remain, including managing pressure drop from the filters and ensuring efficient adsorbent regeneration, both of which are considered in this study. Financially, DAC-HVAC integration reduces capital and operational costs by leveraging existing HVAC infrastructure, as demonstrated by its economic advantage over standalone DAC.

## CONCLUSION

This study highlights the techno-economic benefits of integrating direct air capture (DAC) with Heating, Ventilation, and Air Conditioning (HVAC) systems compared to standalone DAC. The results show that the levelized cost of direct air capture (LCOD) for the DAC-HVAC system is significantly lower (219 $/ton $CO_2$) than that of the DAC-standalone system (374 $/ton $CO_2$) at an electricity price of 0.0351 $/kWh and a 7% discount rate. This cost reduction is attributed to the synergy between DAC and HVAC, which improves energy efficiency by leveraging existing heating, cooling, and ventilation infrastructure. Additionally, the DAC-HVAC system benefits from more stable operating conditions, avoiding the fluctuations in $CO_2$ and $H_2O$ adsorption capacities that significantly impact the energy requirements of standalone DAC. A sensitivity analysis of the DAC-standalone system further reveals that LCOD is highly dependent on external climate conditions. Temperature and humidity variations influence $CO_2$ and $H_2O$ loadings, leading to LCOD fluctuations between 349 and 429 $/ton $CO_2$.

## ABSTRACT

The rising levels of carbon dioxide ($CO_2$) in the atmosphere significantly contribute to climate change, highlighting the need for effective $CO_2$ mitigation strategies. While capturing and storing $CO_2$ is important, converting it into useful products offers additional environmental and economic benefits. One promising method is the reverse water gas shift (RWGS) reaction, which transforms $CO_2$ into carbon monoxide (CO). Membrane reactors (MR), which integrate selective membranes with equilibrium limited chemical reactions, have the potential to intensify processes based on the RWGS reaction. In such reactors, by-products like water are removed in-situ from the reaction zone, effectively shifting the reaction equilibrium to favor higher $CO_2$ conversion. This study develops a comprehensive multi-scale mathematical model for RWGS membrane reactors. We integrate the microscale permeance model (for LTA-4A membrane) with the RWGS MR unit scale and the system's scale models. The effectiveness of applying sweep gas has been suggested, and the optimal $H_2$ perm-selectivity is found in the range from 30 to 50. A detailed membrane permeance model for LTA-4A membranes is integrated in the MR model to assess how species permeance changes with varying reactor conditions. We propose a sweep recycle configuration and compare it with the conventional sweeping configuration commonly assumed in most literature. A thermal efficiency analysis is conducted to evaluate the proposed recycling configuration, providing insights into the practical feasibility of membrane reactors for $CO_2$ utilization.

## INTRODUCTION

Current environmental challenges necessitate the mitigation of $CO_2$ emissions. However, $CO_2$ emissions from certain industries are expected to remain significant in the foreseeable future. $CO_2$ utilization presents an innovative approach to reducing atmospheric $CO_2$ by using it as a feedstock to produce valuable products [1].

Process intensification through steam separation is a promising concept that enables the development of novel $CO_2$ utilization pathways [2], since most $CO_2$ utilization processes produce $H_2O$ as a side product. Water-permeable membranes enable in-situ selective water transfer to shift the reaction forward, according to the Le Chatelier's principle. Membrane reactors (MRs) combine the selective permeable membranes with traditional catalytic processes, enhancing production, separation, and energy efficiency [3].

The core principle of water-permeable membrane reactors lies in their selective permeability, allowing water molecules to pass while retaining other reactants and products. This permeability is typically achieved through the use of hydrophilic membrane [4], made from materials like polymers, ceramics, and composite materials, which exhibit hydrothermal stability, good permeance and perm-selectivity [5]. Among the various types of

membranes, LTA zeolite membranes have garnered significant attention [6]. LTA-4A is well-reported for its high hydrophilicity, small pore size (0.42 nm) comparing to other zeolites (0.735 nm for FAU, 0.65 nm for MOR, 0.51 nm for ZSM-5) [7]. The excellent performance of LTA membranes can be attributed to their unique structural properties, excellent thermal and chemical stability at high temperature and pressure, and high affinity for water. The modeling of gas species permeation in the presence of water through LTA membrane has been investigated [8].

The application of membrane reactors technology to conduct various reactions utilizing $CO_2$ as a reactant have been recently reviewed [7,10,11]. Some key reactions of interest are the conversion of $CO_2$ to CO, methane, methanol and dimethyl ether. Among the various $CO_2$ utilization pathways, the reverse water gas shift (RWGS) reaction, eq. (1), has gained significant attention due to its ability to produce syngas, a mixture of $H_2$ and CO [11]. Syngas serves as a fundamental feedstock for synthesizing a wide array of chemicals and fuels, including methanol, higher alcohols, and hydrocarbons via the Fischer–Tropsch synthesis. Despite its importance, the RWGS reaction has been rarely investigated within MR modeling [12].

$$CO_2 + H_2 \rightleftharpoons CO + H_2O \quad (1)$$

Although a few RWGS MR models exist, they tend to oversimplify membrane characteristics and overlook practical aspects. For example, a $N_2$ stream has frequently been considered as the sweep gas by default [13,14,15], which is not practical in industrial application. The sweep stream will contain $H_2$, which is difficult to recover from $N_2$. The evaluation of sweeping conditions still requires more attention. Additionally, although numerous simulations have been conducted to assess the performance of MRs under the assumption of constant species permeance, the lack of detailed models that accurately represent membrane characteristics has limited the predictive capabilities of these systems. The $H_2O/H_2$ permselectivity has been suggested the value greater than 100, though this remains a topic of debate.

This work provides insights into the use of RWGS MRs for $CO_2$ utilization. We develop a dimensionless MR model and, under the assumption of constant membrane permeance, evaluate reactor performance across various sweeping conditions and species permeance-selectivity. Additionally, we integrate a detailed membrane permeance model for an LTA-4A zeolite membrane to assess how species permeance changes with varying reactor conditions, an area currently under explored in the literature. Furthermore, we propose a recycling configuration and compare it with the conventional sweeping configuration that is commonly assumed in most literature. A thermal efficiency analysis is conducted to examine the proposed recycling configuration.

## MODELING

In this section, the RWGS process is modeled at three different scales: The microscale permeance in LTA-4A membrane and its dependence on local conditions, the RWGS MR unit scale, and the system's scale including recycling.

### Permeance model of the membrane

The LTA-4A membrane is selected to model the species permenace for its good performance in selective permeation of water. Zito et al. propose a validated permeance model for light gases in the presence of water for the 4A zeolite [8]. The trans-membrane flux is given as the sum of surface and gas translation diffusion flux [15] :

$$J_i = \rho C_{\mu s_i} D_{SD} \Gamma \frac{d\theta_i}{dl} + \frac{\epsilon\left(C_{\mu s_i}\right)}{\tau\left(C_{\mu s_i}\right)} \frac{1}{\zeta} \frac{\lambda}{RT} \sqrt{\frac{8RT}{\pi M}} e^{-\frac{E_{GT}}{RT}} \frac{dP_i}{dl} \quad (2)$$

The permeance is described as the ratio between the transmembrane flux and the driving force:

$$Q_i = \frac{J_i}{\left(P^R y_i^R - P^P y_i^P\right)} \quad (3)$$

$$Q_i = \rho C_{\mu s} D_{\mathrm{SD},i} \Gamma_i \frac{\theta_i^R - \theta_i^P}{\left(P^R y_i^R - P^P y_i^P\right) \cdot \delta_{\mathrm{membrane}}} + \frac{\varepsilon\left(C_{\mu s}\right)}{\tau\left(C_{\mu s}\right)} \frac{\lambda}{\zeta \mathrm{RT}} \sqrt{\frac{8\mathrm{RT}}{\pi M_i}} \frac{e^{-\frac{E_{\mathrm{GT}}}{\mathrm{RT}}}}{\delta_{\mathrm{membrane}}} \quad (4)$$

The permeance is then integrated into the MR model proposed in the following section, including the impact on membrane selectivity, $S_i = \frac{Q_{\mathrm{H2O}}}{Q_i}$.

### Membrane reactor model

A packed-bed tubular and concentric membrane reactor is illustrated in Figure 1. In this configuration, the catalyst particles bed is placed in the annular chamber, through which the reactant stream is introduced, serving as the retentate side. Inside the membrane (the tubular chamber) sweeping stream can be introduced in co-current direction with respect to the feed stream. The model obeys the following assumptions: One-dimensional flow, isothermal operation, assuming heat supplied continuously from the furnace, no pressure drops in both retentate and permeate side, assuming pressure regulator implemented to maintain constant pressure,, and absence of internal and external mass transfer resistance. The RWGS reaction kinetic rate expression is taken after Gine et al. 's work for $CuO/Al_2O_3$,[16], the dimensionless component balance equations are given as follows:

$$\frac{d\,\widetilde{F_i^R}}{d\,Pe_m} = \alpha_i B \left(y_{CO_2} y_{H_2} - \frac{y_{CO} y_{H_2O}}{Keq_1}\right) - \frac{1}{S_i}\left(y_i^R - P_r^{-1} y_i^P\right) \quad (5)$$

$$\frac{d\,\widetilde{F_i^P}}{d\,Pe_m} = \frac{1}{S_i}\left(y_i^R - P_r^{-1} y_i^P\right) \quad (6)$$

The dimensionless variables are defined as follows:

$$\widetilde{F_i^R} = \frac{F_i^R}{F_{\mathrm{CO2},0}^R}, \quad \widetilde{F_i^P} = \frac{F_i^P}{F_{\mathrm{CO2},0}^R}, \quad \widetilde{F_{\mathrm{N2}}^P} = \frac{F_{\mathrm{N2}}^P}{F_{\mathrm{CO2},0}^R}, \quad P_r = \frac{P^R}{P^P},$$

$$S_i = \frac{Q_{\mathrm{H2O}}}{Q_i}, Pe_m = \frac{(2\pi R_{\mathrm{in}} Q_{\mathrm{H2O}} P^R)z}{F_{\mathrm{CO2},0}^R}, B = \frac{A^R \rho_s (1-\varepsilon) k_1 C_{FP}}{2\pi R_{\mathrm{in}} Q_{\mathrm{H2O}} P^R}$$

The $F_{\mathrm{CO2},0}^R$ represents the $CO_2$ inlet flow rate. It is assumed that only $CO_2$ and $H_2$ are fed into the reactor, with $n$ is defined as the feed molar ratio between $H_2$ and $CO_2$. $Q_i$ refers to the permeance of species $i$. $P^R$ and $P^P$ are the pressures on the retentate and permeate sides, respectively. $A^R$ is the cross-section area of the retentate side and $R_{in}$ is the radius of inner tube, $k_1$ is the rate constant for the RWGS reaction, $Keq_1$ is the RWGS reaction equilibrium constant, $\rho_s$ is the catalyst solid density, $\varepsilon$ is the void fraction of the catalyst bed, $Q_i$ is the permeance of species $i$, $C_{FP}$ is the reaction correction factor. The conversion of $CO_2$ is expressed as follows:

$$X = \frac{F_{CO_2,0} - F_{CO_2}}{F_{CO_2,0}} = 1 - \frac{F_{CO_2}}{F_{CO_2,0}} = 1 - \widetilde{F_{CO_2}^R} - \widetilde{F_{CO_2}^P} \quad (7)$$

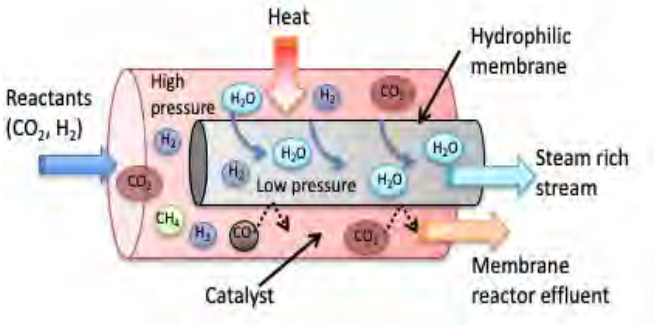

**Figure 1.** Schematic of a membrane reactor utilizing a hydrophilic membrane.

## Reactor system flowsheet

A simple reactor system flowsheet including the upstream and downstream operations is proposed to further evaluate the MR performance. In the conventional design as shown in Figure 2, two streams are fed into the reactor, the compressed feed stream serves as the retentate side while a low pressure pure $H_2$ stream serves as the sweep gas in the permeate side. In Figure 3 we propose a recycle configuration, where instead of using an extra stream for sweeping, the retentate effluent is recycled to the permeate side serving as the sweep gas, after pressure reduction. In both designs, the heat integration is considered, and the product streams are all cooled down and fed to a flash unit for water separation. The feed, sweep and product streams in both configurations are all set to standard conditions for thermal efficiency comparisons. The reactor system is simulated in Aspen Plus, where the detailed MR model developed in MATLAB is embeded.

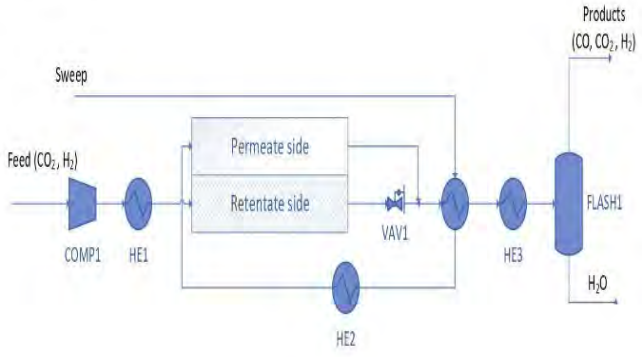

**Figure 2.** The conventional design for MR model with heat integration, $H_2$ stream serves as the sweep gas.

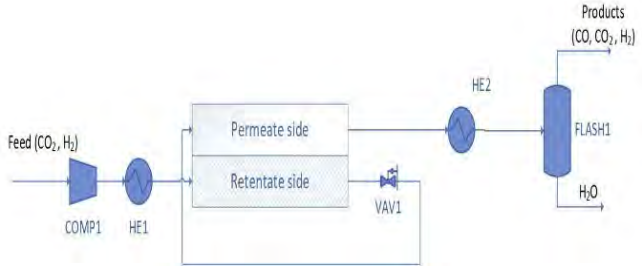

**Figure 3.** The recycle configuration for MR model with heat integration. The outlet of the retentate side serves as the sweep gas.

The thermal efficiency is defined as the ratio between the heating value of the produced syngas to the total used hydrogen and the external heat and power demands for the system, which is defined as:

$$\eta_{en} = \frac{n_{\mathrm{CO}} \cdot \mathrm{LHV_{CO}} + n_{\mathrm{H2,out}} \cdot \mathrm{LHV_{H2}}}{n_{\mathrm{H2,in}} \cdot \mathrm{LHV_{H2}} + E_{MR} + E_{vav1} + E_2 + P_{\mathrm{COMP}}} \quad (8)$$

where LHV is the lower heating value, $n$ is the molar flow rate, $E_i$ represents the required heat for block $i$, $P_{COMP}$ represents the power input for the compressor.

# RESULT AND DISCUSSION

## Membrane reactor performance analysis

The effect of different sweeping scenarios on $CO_2$ conversion, as a function of $H_2$ perm-selectivity and $Pe_m$, is shown in Figure 4. The membrane permeance is assumed constant along the reactor.

In the no-sweep gas scenario (Figure. 4a), increasing $S_{H_2O/H_2}$ initially enhances $CO_2$ conversion, as the removal of reaction product $H_2O$ is more significant than the leaking of reactant $H_2$, which shift the equilibrium toward higher $CO_2$ conversion, according to Le Chatelier's

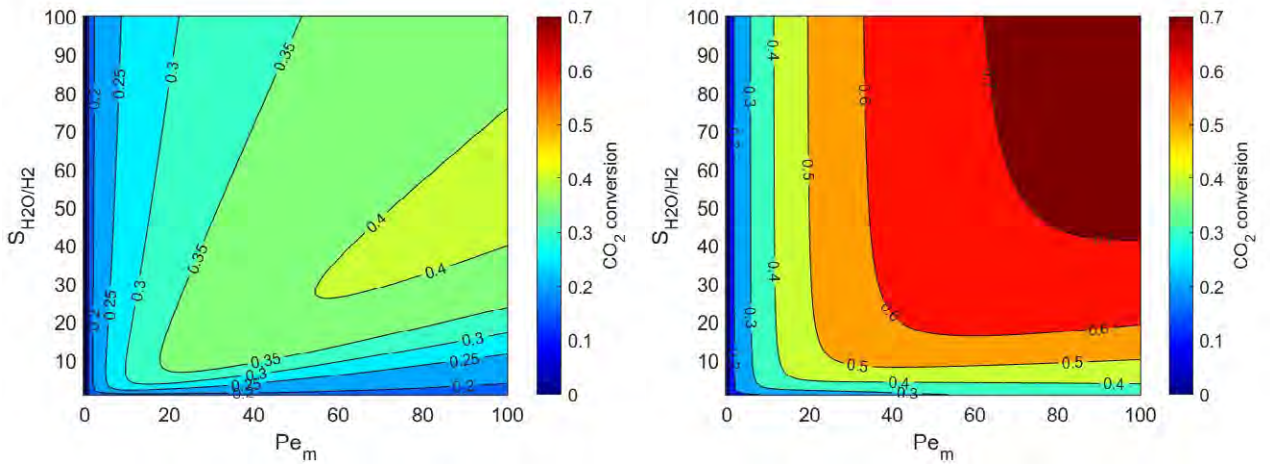

**Figure 4:** Comparison of $CO_2$ conversion varying with $Pe_m$ under different $S_{H_2O/H_2}$ . T = 300°C, $H_2/CO_2$ ratio= 3, pressure ratio Pr = 20, dimensionless number B = 1. The membrane is impermeable to CO and $CO_2$. Co-current configuration. (a) No sweep gas applied in the peremeate side. (b) $H_2$ sweep gas ratio of 10.

principle. However, once the perm-selectivity exceeds a certain threshold, increasing $S_{H_2O/H_2}$leads to a $CO_2$ conversion decline. This is due to reduced $H_2$ leakage to the permeate side, which increases the partial pressure of water in the permeate side. The increased water partial pressure decreases the driving force for the forward reaction, thus limiting the $CO_2$ conversion potential. This effect is more pronounced at low membrane permeances.

In the applied sweep gas scenario (Figure 4b), a high sweep flow rate significantly improves the $CO_2$ conversion for the entire range of $Pe_m$ and $S_{H_2O/H_2}$ values compared to the case represented in Figure 4a. The sweep gas facilitates the continuous removal of $H_2O$, maintaining a favorable partial pressure gradient and preventing water accumulation in the reactor. Nevertheless, there is a threshold value for $S_{H_2O/H_2}$, beyond which further increases do not significantly improve in $CO_2$ conversion. These simulations suggest that high $S_{H_2O/H_2}$ and $Pe_m$ are not always desirable in any cases, applying sweep gas can significantly improve the MR performance.

## Permeance analysis

The detailed permeance model reveals that the permeance of species is also influenced by the differences in their partial pressures, which vary continuously within the reactor. We integrated this permeance model into the MR model to examine how membrane properties change along the reactor as species' partial pressures change.

Figure 5 shows the permeance of different gas species through the LTA-4A membrane as $Pe_m$ increases. The $H_2O$ permeance is the highest and remains nearly constant as $Pe_m$ increases, primarily due to the membrane's strong affinity for water and its hydrophilic nature. $CO_2$ permeance is the lowest and decreases as $Pe_m$ increases. The $H_2$ and CO permeance also declines as $Pe_m$ increases. Additionally, the $H_2$ and CO permeance are similar in value compared to $CO_2$ and $H_2O$. And for $Pe_m$ values smaller than 20, $H_2$ permeance is higher, while the CO permeance becomes higher as $Pe_m$ exceeds 20. This is due to the fact that $H_2$ permeance experiences a larger decline compared to CO permeance as $Pe_m$ increases.

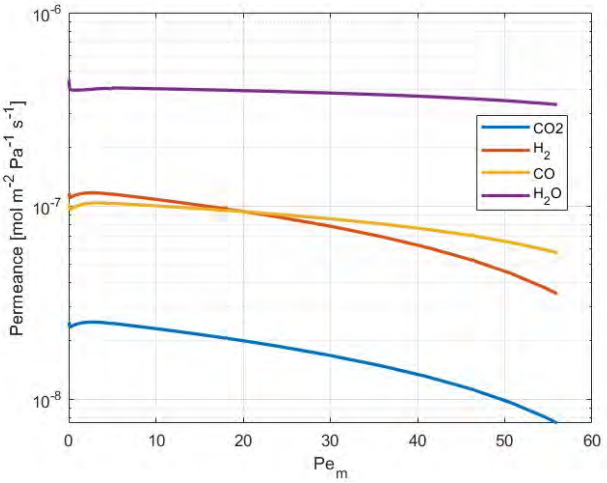

**Figure 5.** The gas species permeance of LTA-4A membrane along the reactor for different gas species. T = 300°C. $H_2/CO_2$ feed ratio = 3, reaction pressure is 10 bar, permeate pressure is 1 bar. Co-current configuration.

The varying permeance of these species plays a critical role in the MR performance. Figure 6 shows that perm-selectivity for all gas species increases as $Pe_m$ increases. $CO_2$ perm-selectivity ranges from 15 to 45 along the whole MR. The large boundary highlights the importance of integrating the permeance model into the MR

model for process simulation. Additionally, CO perm-selectivity shows similar value to $H_2$ perm-selectivity. Since most literature only considers $H_2$ perm-selectivity in simulations, the competing CO perm-selectivity values raise the question of whether it is appropriate to assume only $H_2$ permeation in the MR model.

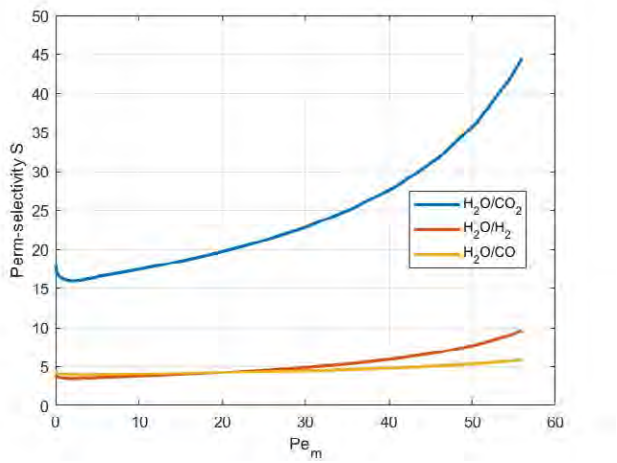

**Figure 6.** The species perm-selectivity of LTA-4A membrane along the reactor for different gas species. T = 300°C. $H_2/CO_2$ ratio=3, reaction pressure is 10 bar, permeate pressure is 1 bar. Co-current configuration.

## Thermal efficiency comparative analysis

Figure 7 shows the thermal efficiency of the RWGS process with varying $CO_2$ conversion in the product stream, achieved by changing the reactor length. The recycling configuration has higher thermal efficiency compared to the conventional one across the entire range of $CO_2$ conversion. Additionally, the efficiency of the recycling configuration remains almost constant as $CO_2$ conversion increases, while that of the conventional design drops. The sweep gas used in conventional design requires a significant amount of heat to maintain the temperature of the sweep gas. This additional heating leads to a decrease in thermal efficiency. As operating pressure increases from 10 bar to 20 bar, thermal efficiency declines for both configurations. This is because higher pressures increase the enthalpy of the flows, requiring more energy to maintain the system's operational temperature. However, the decrease in thermal efficiency for the conventional design is more significantly affected by the increase in operating pressure, showing a reduction of around 15%, while the recycling configuration experiences only about a 5% decrease in thermal efficiency. This suggests that the recycling configuration remains preferable when the system operates at high pressure.

## CONCLUSIONS

This study presents a multi-scale modeling approach to evaluate RWGS performance in MR for CO2 utilization. Through the development of a dimensionless model, integration of a detailed membrane permeance model for LTA-4A zeolite, and the simulation of a simple process system, we provided insights into the performance of membrane reactors under various conditions.

Our findings highlight the importance of optimal sweeping conditions and membrane properties in enhancing $CO_2$ conversion. Specifically, sweep gas improves conversion significantly compared to the no-sweep configuration. The analysis reveals that one can locate the optimal $H_2$ perm-selectivity, beyond which the performance gains diminish. It could be in the range around 30 to 50 for $Pe_m$ smaller than 70. Additionally, the species variable permeance was found to be a critical factor that should be considered in modeling the MR, with

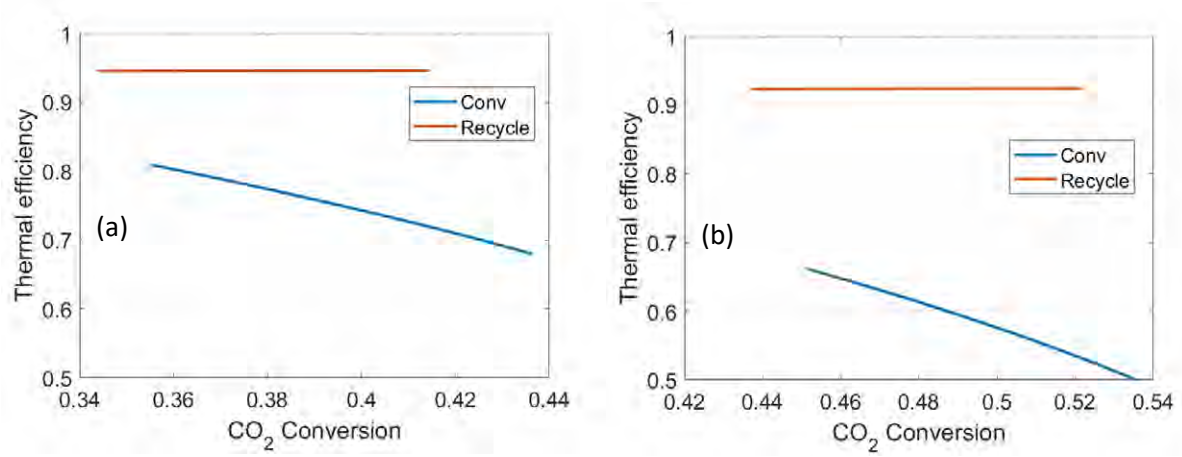

**Figure 7:** Thermal efficiency for different configurations as a function of $CO_2$ conversion. $H_2/CO_2$ feed ratio= 3. T = 300°C. (a) Reaction pressure of 10 bar. (b) Reaction pressure of 20 bar.

$H_2O$ showing the highest permeance, which remained almost constant across the reactor, while CO, $CO_2$ and $H_2$ permeance decreased with increasing reactor length.

Thermal efficiency analysis shows that the recycling configuration outperforms the conventional configuration for all $CO_2$ conversion values, maintaining a more stable thermal efficiency as $CO_2$ conversion increases. This suggests that the recycling design is more energy-efficient, particularly under high-pressure conditions, and offering significant advantages in practical applications.

## ABSTRACT

This work develops process options using a novel protonic membrane reformer (PMR) and liquefaction-based $CO_2$ capture process for low-carbon hydrogen production from natural gas. Several hybrid concepts of the PMR and liquefaction process are suggested based on the strategies to handle the residual gas from the reformer. The process intensification and optimization results indicate that the hybrid system with a water-gas-shift reactor and off-gas recycling guarantees high $H_2$ and $CO_2$ recovery rates for the PMR operating at relatively low $H_2$ recovery. The hybrid concept also has 74% energy conversion efficiency, which is higher than a conventional steam-methane reforming (SMR)-based $H_2$ production with chemical absorption $CO_2$ capture.

**Keywords**: Hydrogen, Carbon Dioxide Capture, Energy Efficiency, Process Design, Process Intensification, proton conducting membrane.

## INTRODUCTION

To achieve low-carbon hydrogen production, a novel protonic membrane reformer (PMR) has been developed that uses electricity to convert natural gas into pure hydrogen while generating a $CO_2$-rich retentate gas [1,2]. This syngas composition enables efficient low temperature-based carbon capture, achieving high $CO_2$ capture rates with reduced complexity and cost [3]. Thus, the PMR system produces hydrogen with a low carbon intensity, which can be further reduced with low-carbon electricity.

For process intensification, the integration of the PMR with $CO_2$ liquefaction offers several potential configurations that optimize energy efficiency and maximize hydrogen and $CO_2$ recovery. In particular, the hybrid concept allows the PMR to operate at relatively low $H_2$ recovery rates with less electricity input, guaranteeing high system throughput at a wide range of operating conditions in the reformer. It should be noted that the PMR stacks can achieve very high $H_2$ recovery rates over 99 % [2], indicating that the PMR-based concepts are not bound to lower recovery scenarios.

This hybrid approach has also been examined in an autothermal reforming (ATR)-based $H_2$ production system [4]. Previous studies, however, have only analyzed a single configuration of this hybrid system in detail [5]. Therefore, this study extends earlier work by proposing several hybrid configurations that explore different approaches integrating hydrogen production and $CO_2$ capture. This comparative analysis aims to identify the optimal configuration that balances energy efficiency, hydrogen and $CO_2$ recovery, and economic viability, covering a wide operating range of the PMR.

## PMR AND HYBRID PROCESS OPTIONS

The focus of this work is on the management of the residual gas from the $CO_2$ liquefaction process, which has a significant impact on system performance. In particular, (1) the residual gas may contain significant amounts of hydrogen, which directly affects the hydrogen recovery rate of the system, and (2) its flow rate affects both power consumption and capital cost when recycled to the PMR for further hydrogen recovery. Based on the two considerations, four possible hybrid process options are suggested.

### Hybrid process without off-gas recycling (Option 1)

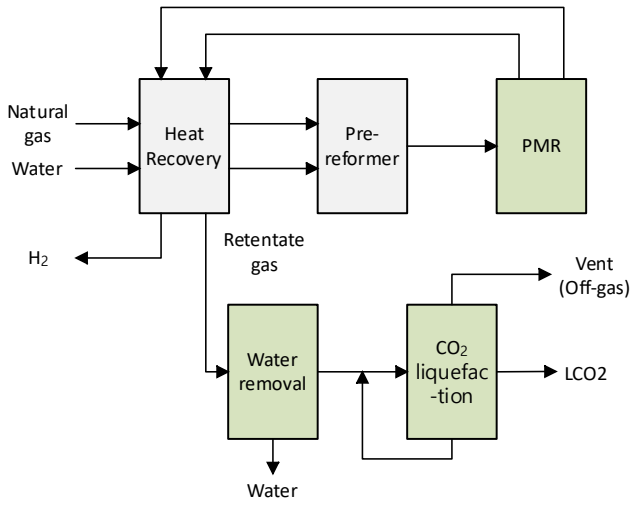

**Figure 1.** Block diagram of the hybrid process without off-gas recycling (Option 1) (white blocks: process without energy input, green blocks: process with energy input).

A simple cascade of the PMR and liquefaction is a promising option for a low process complexity and easy operation. However, other process steps are required for PMR-based $H_2$ production, as presented in Figure 1. The first step is heating the two feed streams (natural gas, water) before sending them to a pre-reformer. The heat duty is supplied by the $H_2$ and retentate gas from the PMR, which has a high temperature. In the pre-reformer, heavier hydrocarbons are converted to methane, which is then fed to the PMR. In the pre-reformer, some $CO_2$ and $H_2$ will also already be produced.

The PMR feed stream is further heated by the heat generated from the PMR and supplied to the membrane reformer. The PMR has a net endothermic reaction with steam-methane reforming (SMR) and water-gas-shift (WGS), which is compensated by heat produced during hydrogen separation and compression through the membrane with electricity input. As a result, high-pressure pure $H_2$ from methane is produced in one step through the PMR while generating a $CO_2$-rich retentate stream. The internal heat exchange also makes the membrane reformer efficient by eliminating the need for external heating, often regarded as the primary loss point for natural gas-based $H_2$ production systems. After delivering heat to the heat recovery unit, the retentate stream is dehydrated and condensed through the liquefaction process to capture high-purity $CO_2$. The impurities in the captured $CO_2$ are removed via off-gas purging.

Although this configuration efficiently produces hydrogen, the overall hydrogen recovery rate of the hybrid system will be limited by the PMR operation at a relatively low-performance region. This is due to the vent stream, which contains considerable amounts of hydrogen. The hydrogen left in the PMR is sent to the liquefaction process through the retentate gas. Since the $H_2$ is not condensed in the $CO_2$ capture process, it is wasted through the vent gas, resulting in a low system hydrogen recovery rate. In addition, the retentate gas from the PMR contains a relatively high CO fraction, which is difficult to separate from $CO_2$ while keeping the $CO_2$ capture rate high in the liquefaction process.

## Hybrid process with off-gas recycling (Option 2)

To minimize the $H_2$ loss of the hybrid system, the off-gas from the liquefaction process can alternatively be recycled to the PMR, as seen in Figure 2. Although recycling will increase the size and capital cost of the system, valuable hydrogen products can be collected from the off-gas, achieving a very high hydrogen recovery rate while maintaining the energy input to the PMR low. However, purging of a part of the recycled off-gas will be required in this configuration to avoid inert gas (such as $N_2$) accumulation in the hybrid system.

Although the recycled off-gas will improve the system performance with a higher $H_2$ recovery rate, the retentate gas from the PMR will still contain a considerable amount of CO. Thus, the possible drawbacks of this configuration are (1) the separation of CO in the liquid $CO_2$ stream will result in a lower $CO_2$ capture rate, (2) a higher content of impurities in the retentate gas will lead to larger specific power consumption of the $CO_2$ capture process and thus the hybrid system.

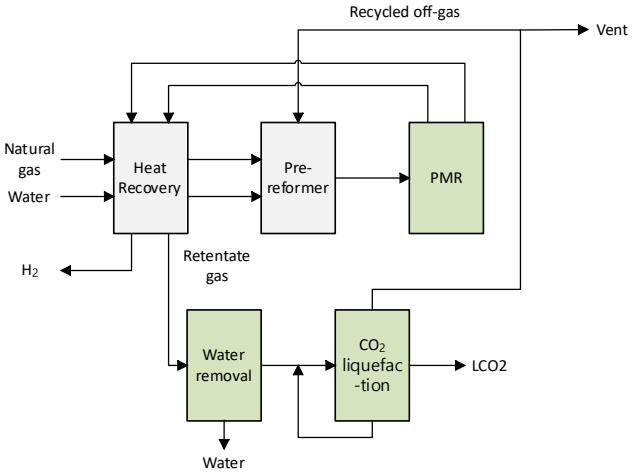

**Figure 2.** Block diagram of the hybrid process with off-gas recycling (Option 2) (white blocks: process without energy input, green blocks: process with energy input).

## Hybrid process with off-gas recycling and extra WGS after liquefaction (Option 3)

To handle the issues of CO, an extra WGS reactor is considered to convert CO to $CO_2$ in the hybrid system. However, the configuration and the performance of the system will vary depending on the location of the extra WGS reactor.

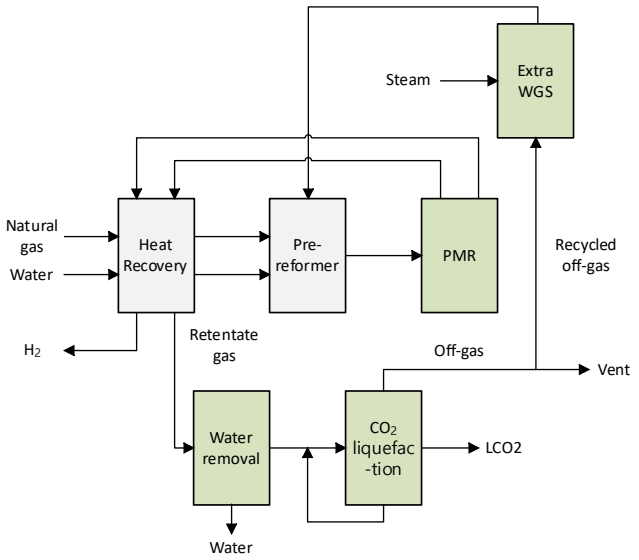

**Figure 3.** Block diagram of the hybrid process with off-gas recycling and extra WGS after liquefaction (Option 3) (white blocks: process without energy input, green blocks: process with energy input).

Possible locations of the extra WGS reactor are either on the recycled off-gas or the retentate gas. The former configuration is Option 3, where the extra WGS is located before the pre-reformer for the recycled off-gas, as illustrated in Figure 3. In this configuration, the size of the extra WGS is minimized as it is only responsible for the recycled off-gas. This option is considered one of the promising options to be evaluated in detail. However, the extra WGS will not handle the CO in the retentate gas, which is fed to the $CO_2$ capture part. Thus, this option will also result in poor performance of the liquefaction process and, hence, the hybrid system. In addition, due to the low temperature of the off-gas from the liquefaction process, an extra heat supply will be needed to preheat the recycled stream, thereby reducing the energy efficiency of the hybrid concept.

### Hybrid process with off-gas recycling and extra WGS after liquefaction (Option 4)

As shown in Figure 4, another possible hybrid configuration with an extra WGS is to place it on the retentate gas in front of the water removal unit to convert the CO in the feed gas to the liquefaction process. Consequently, almost no CO in the retentate gas is sent to the $CO_2$ separation process, giving lower specific power consumption and a higher $CO_2$ capture rate. Another possible advantage is that the vent stream will not require additional equipment to handle the CO. Therefore, this hybrid system will achieve high hydrogen and $CO_2$ capture rates.

However, the size of the extra WGS reactor will be significantly larger than for Option 3, where the extra WGS is only responsible for the recycled off-gas. Nevertheless, the high temperature of the retentate gas will not require any additional heat supply system for the reactor, which is essential for Option 3. Thus, an objective comparison of Options 3 and 4 using economic analysis will be necessary to identify the cost-optimal process for the hybrid concept.

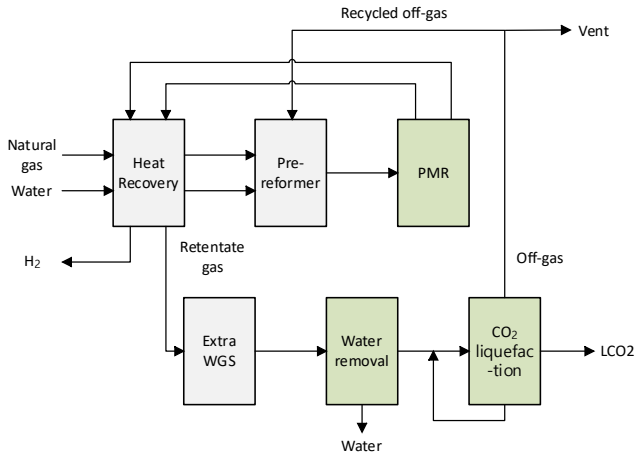

**Figure 4.** Block diagram of the hybrid process with off-gas recycling and extra WGS after PMR (Option 4) (white blocks: process without energy input, green blocks: process with energy input).

## SYSTEM MODELING AND DESIGN BASIS

The hybrid system is modeled using the PMR model in C, which is validated against the data supplied by previous work [1]. The reformer model is integrated with Aspen HYSYS where other process units are modelled to build the hybrid process. This framework uses Matlab to interface the PMR model in C and the HYSYS model. To identify optimal operating conditions for the four different configurations, the hybrid systems are optimized to minimize their specific power consumption (SPC), while the energy conversion efficiency of the system is calculated.

$$SPC_{\mathrm{sys}} = \frac{Power_{\mathrm{net}}}{\dot{m}_{\mathrm{H_2\ product}}} \quad (1)$$

$$\eta_{\mathrm{energy\ conversion}} = \frac{LHV_{\mathrm{H_2\ product}}}{Power_{\mathrm{net}} + LHV_{\mathrm{NG}}} \quad (2)$$

This enables an objective comparison of the different configurations, identifying the most promising option for the hybrid concept. The Particle Swarm Optimization (PSO) algorithm is used for the optimization work as it is a derivative-free approach that can be easily applied to complex or black box models such as this hybrid process.

During the optimization, the system hydrogen recovery rate (HRR) and $CO_2$ capture rate (CCR) are constrained to be larger than or equal to 95 % and 90 %, respectively. It is worth noting that the operating condition of the PMR is set to give 90% of HRR to identify the benefit of the hybrid concept under a relatively mild operating region for the membrane reformer.

$$HRR_{sys} = \frac{\dot{n}_{H_2}}{\dot{n}_{H_2\ pre-reformer} + \dot{n}_{H_2PMR} + \dot{n}_{H_2WGS}} \quad (3)$$

$$CCR_{sys} = \frac{\dot{n}_{CO_2,Captured\ CO_2}}{\sum \dot{n}_{C,Natural\ Gas}} \quad (4)$$

In addition, the $CO_2$ loss from the $CO_2$ capture process is limited to be smaller than or equal to 5 % so that enough $CO_2$ in the retentate gas is either captured through the liquid $CO_2$ or recycled via the off-gas. Considering the trade-off between cost and energy efficiency, the minimum approach temperature of heat exchangers is set differently for heat exchangers operating above (20 °C) and below ambient temperature (3 °C).

For the energy-efficient operation of the hybrid concept, the heat generated from the PMR should be matched with the heat required in the heat recovery part to avoid using external heaters. Thus, the system heat balance is constrained to be equal to or larger than zero, which means the system will always have net surplus heat [6].

The thermodynamic performance of the hybrid concept is also affected by the operating conditions of the PMR (temperature, pressure, current density). Yet, their values are fixed in this work for a comparative analysis of different process configurations.

The hybrid system assumes a natural gas feed rate of 3000 kmol/h, with a lower heating value of 50 MJ/kg, to generate around 500 t/d of $H_2$. $CO_2$ is specified for delivery at 150 bara with a purity of 99 mol% while maintaining CO levels below 0.5 vol% for pipeline transport [7]. Other key design conditions are listed in Table 1.

**Table 1:** Design basis for the PMR and the $CO_2$ capture process [1,5].

| Parameters | Unit | Value |
|---|---|---|
| PMR SC ratio | - | 2.5 |
| PMR temperature | bara | 26 |
| PMR pressure | °C | 800 |
| PMR current density | A/m$^2$ | 7000 |
| PMR retentate pressure | bara | 26 |
| PMR retentate temperature | °C | 800 |
| Pre-reformer temperature | °C | 450 |
| Extra WGS temperature | °C | 200 |
| $H_2$ product pressure | bara | 26 |
| $CO_2$ product pressure | bara | 150 |
| Compressor efficiency | % | 80 |
| Pump efficiency | % | 75 |
| Gas expander efficiency | % | 85 |

## RESULTS

This section compares the performance of the hybrid process with that of a conventional $H_2$ production method with $CO_2$ capture [8]. The conventional process consists of SMR and WGS reactors, a solvent-based $CO_2$ capture process, and a pressure swing adsorption $H_2$ purification step. As seen in Table 2, the hybrid concept gives a higher $H_2$ and $CO_2$ recovery rate than the conventional technology.

In addition, the hybrid concept provides a higher energy conversion efficiency than the conventional process, except for Option 1. Another advantage of the hybrid concept is that $CO_2$ is captured at transport conditions while the conventional system needs purification and compression steps for the captured $CO_2$, requiring extra power. The simple heat integration performed in the hybrid system also means that a detailed study on the heat integration with the surplus heat from the PMR will further increase the energy conversion efficiency. Thus, the hybrid system will be a less carbon-intensive solution for natural gas-based hydrogen production than the conventional method.

Among the four configurations of the hybrid process, Option 1, which is a simple cascade of the PMR and the liquefaction process, cannot meet the minimum HRR and CCR requirements. In Option 2, both the HRR and CCR can be satisfied by recycling 90 % of the off-gas to the PMR. However, the CO content in the pre-reformer and the retentate gas is too high, which can be an operational burden to the PMR and the $CO_2$ capture system.

To handle the potential issues with CO, an extra WGS reactor is considered for the recycled off-gas in Option 3. It is observed that the CO in the recycled off-gas is successfully removed. However, a considerable amount of CO generated in the PMR will still exist in the retentate gas, leading to a poor performance of the $CO_2$ capture process.

In Option 4, an extra WGS reactor is placed after the PMR. The CO in the retentate gas is then removed, and better $CO_2$ capture performance (SPC and CCR) is achieved. The reduced SPC for the CCS also gives the smallest system SPC compared to other alternatives. Although Option 4 has a slight reduction in system HRR, the lowest system SPC and $CO_2$ loss will make it the most promising hybrid concept. The detailed process configuration of Option 4 is presented in Figure 5.

## CONCLUSION

A hybrid process comprising protonic membrane reformer technology and $CO_2$ liquefaction is developed in this work for efficient hydrogen production with integrated carbon capture. The hybrid system without recycling the off-gas can have a smaller equipment size and capital cost while having a significant $H_2$ loss through the off-gas, which is wasted as a vent stream. Therefore, this simple hybrid concept will be practical when the PMR is

**Table 2:** Performance of the PMR-based hybrid process options and a conventional SMR-based $H_2$ production with $CO_2$ capture.

| Parameter | SMR with CCS | Option 1 | Option 2 | Option 3 | Option 4 |
|---|---|---|---|---|---|
| $p_{H2}$ [bara] | 22.3 | 26.0 | 26.0 | 26.0 | 26.0 |
| $p_{CO2}$ [bara] | 1.3 | 150.0 | 150.0 | 150.0 | 150.0 |
| $HRR_{sys}$ [%] | 87.0 | 91.1 | 99.7 | 98.9 | 96.8 |

| $\eta_{energy\ conv}$ [%] | 71.1 | 64.0 | 76.4 | 76.6 | 74.3 |

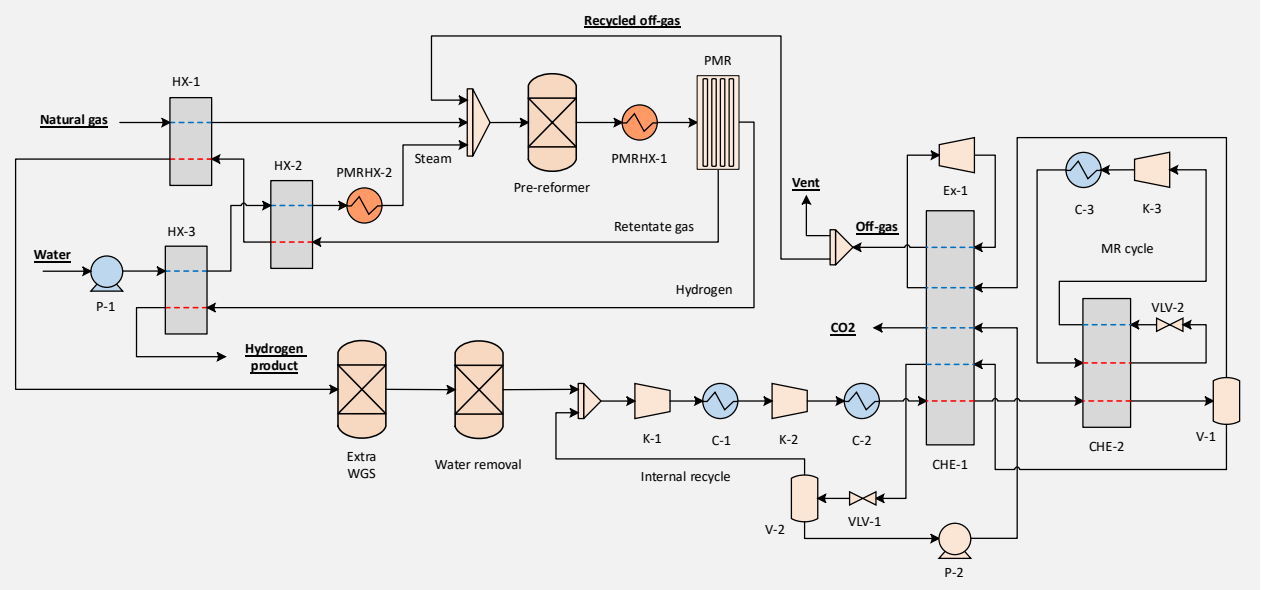

**Figure 5:** Detailed process flow diagram of hybrid process with off-gas recycling and extra WGS after PMR (Option 4).

in a high-performance operating region where hydrogen recovery is high.

Although the configurations recycling the off-gas will minimize the hydrogen loss, it is found that the CO content in the retentate gas needs to be treated for the downstream carbon capture process. Thus, using a WGS reactor with off-gas recycling is deemed necessary to achieve both high $H_2$ recovery and carbon capture rates when the PMR is operated at a lower load condition.

In particular, the configuration with the WGS reactor for the retentate gas is the most promising option as it can effectively remove CO in the liquefaction process feed stream, maximizing the carbon capture rate of the system with reduced energy consumption. Therefore, this hybrid concept is considered for further evaluation to explore its potential and role in the hydrogen economy.

Since the PMR-based hybrid utilizes both heat and electricity, their price and $CO_2$ intensity will be key factors influencing the techno-economic viability. Therefore, a detailed analysis considering uncertainties in energy prices and $CO_2$ intensity will be conducted to characterize the economic performance of the hybrid system.

## ABSTRACT

Despite the potential of electrification in transportation, diesel will remain one of the main fuels for decades. The replacement of diesel with biodiesel is one of the solutions to decrease the net emissions of diesel engines. However, biodiesel has limited performance in cold weather and requires fuel additives. In this context, choosing additives from non-edible, inexpensive, renewable sources is important. Ethyl levulinate, an ester derived from levulinic acid that can be produced from sugarcane, is a promising option because it improves the cold-flow properties of fuels and reduces soot emissions. In this work, a reactive distillation column was designed to produce ethyl levulinate. Because of the volatility order of the components involved in this reaction, levulinic acid was chosen as the excess reactant. Production cost was calculated based on ethanol price, capital cost, and operating expenses for several scenarios. The results showed that the optimized reactive distillation column using excess levulinic acid provides a production cost 29% lower than that of a similar esterification process with a continuous stirred tank reactor followed by distillation.

## INTRODUCTION

The biochemical biorefinery platform has been a focus of research because of the potential of using cellulosic sugars in fermentation processes [1]. However, in biomass hydrolysis, part of the sugars is lost in dehydration reactions, yielding furans such as 5-hydroxymethylfurfural and furfural [2]. Generally, furans negatively impact fermentation performance by depleting microorganisms of reducing power [3]. Alternatively, the thermolytic transformation of biomass into products such as furans has great economic potential and avoids fermentation problems [4,5]. Therefore, it is key to explore biorefinery processes based on furans.

Hydrolysis of cellulose yields glucose, which, under severe reaction conditions, is dehydrated to 5-hydroxymethylfurfural (HMF) and subsequently rehydrated to yield levulinic acid and formic acid [6]. Levulinic acid is a γ-keto acid widely recognized as a building block: the carbon chain length and the presence of two organic functions open a myriad of applications [7]. Esters of levulinic acid have a great potential in the fuels market, especially ethyl levulinate [8].

Studies demonstrate that ethyl levulinate enhances combustion efficiency and cold-flow properties of diesel and biodiesel. It also reduces soot emissions in diesel engines [9,10]. The effective replacement of fossil fuels by biofuels depends on the production of high-performance biofuel blends that include key biofuel additives [8], such as ethyl levulinate. Despite the growing interest in electrification, liquid fuels are likely to remain the main energy source for transportation around the world up until 2050 [11], and the decrease in $CO_2$ emissions by electric vehicles using current battery technology and non-renewable electricity sources is questionable [12]. Additionally, efforts to decarbonize hard-to-electrify sectors, such as the development of marine biofuels, hold a promising future for ethyl levulinate as a fuel additive [13].

The feasibility of ethyl levulinate production on a large scale depends on the production cost of levulinic acid [8]. Production processes for levulinic acid and ethyl levulinate are not well-established in the industry [7]. Besides the bottlenecks in reactor development, there are many subprocesses with cost reduction potential, such as esterification [8]. Process intensification has demonstrated successful results in the esterification of

carboxylic acids in reactive distillation columns [14]. Another important aspect is that distilling ethyl levulinate and levulinic acid requires high temperature, which could otherwise be used to drive the esterification.

The volatility ranking of species is fundamental to deciding upon feed position and size of the reactive section in reactive distillation columns [15,16]. In the case of autocatalysis, all stages are reacting stages. The volatility ranking for the ethyl levulinate reaction represents the least favorable case since both products are the intermediate keys in the distillation [15]. Therefore, conventional approaches for the design of reactive distillation columns cannot be applied thoroughly in this case. A previous study evaluated this system, but it used the traditional excess alcohol strategy, which ended up contributing to increased cost, thus indicating that the opposite approach might be more suitable [17]. Therefore, this work explores an alternative strategy: excess carboxylic acid.

This work investigated the process design of an autocatalyzed reactive distillation column for ethyl levulinate production, assuming an excess carboxylic acid ratio, coupled with techno-economic analysis. A surrogate model was used to optimize operating conditions to improve economic indicators. The developed process design was then compared to a conventional autocatalyzed esterification process working at similar conditions.

## METHODOLOGY

Process design consisted of three steps: i) initial assessment based on thermodynamics and kinetic limitations; ii) use of design of experiments to obtain a surrogate model for optimization; and iii) simulation and assessment of optimized operating conditions.

Thermodynamic and kinetic analyses were conducted using Aspen Plus 14 (AspenTech, Inc., USA, 2022). Carboxylic acids associate in the vapor phase and lead to a negative deviation in the molar volume, which is accounted for by the Hayden-O'Connell equation of state [18]. The NRTL (non-random, two-liquid) model was chosen for the liquid phase; binary interaction parameters of the water-ethanol pair were obtained from the Aspen Plus 14.0 database, and parameters for the other pairs were obtained from Resk *et al.*, 2014 [18].

The conversion of levulinic acid at equilibrium conditions was calculated using the *REquil* model in Aspen Plus, which considers chemical equilibrium conditions. A similar analysis was carried out considering reaction kinetics using an *RCSTR* model (residence time: 60 min). The esterification reaction is presented in Figure 1, and the kinetics of the autocatalyzed reaction is described by Eq. (1). In this equation, the driving force is the concentration of species on molar basis ($C_{LA}$ for levulinic acid, $C_{EtOH}$ for ethanol, $C_{EL}$ for ethyl levulinate, $C_w$ for water), mediated by the equilibrium constant $K_{eq}$. Other factors include the pre-exponential factor ($k_0$, 100 m³/kmol.s), the activation energy ($E_A$, 49 kJ/mol), the universal gas constant ($R$), and the temperature ($T$) [19].

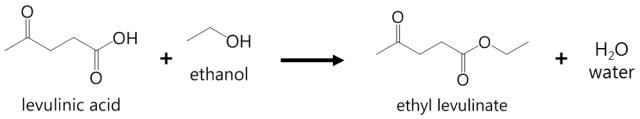

**Figure 1.** Esterification of levulinic acid with ethanol.

$$r = k_0 \exp\left(\frac{-E_A}{RT}\right)\left(C_{LA}C_{EtOH} - \frac{C_{EL}C_w}{K_{eq}}\right) \quad (1)$$

Optimization was carried out using a surrogate model based on a central composite design with face-centered star points to facilitate convergence. This approach also allows the statistical analysis of the process. The following parameters of the reactive distillation column were considered in the surrogate model: weir height ($WH$), ethanol to levulinic acid ratio ($ELA$), number of stages ($NST$), and reboiler temperature ($RT$). The column diameter was calculated in Aspen Plus (Fair correlation). The column diameter and weir height determine the liquid holdup needed for the reaction. The design space (Table 1) was defined based on simulations of distillation columns (shortcut method) for feeds in the conversion range of 10–100% of the reaction depicted in Figure 1.

**Table 1:** Design space used in the process optimization.

| Variable | -1 | 0 | +1 |
|---|---|---|---|
| WH (mm) | 100 | 150 | 200 |
| ELA | 0.2 | 0.6 | 1.0 |
| NST | 20 | 40 | 60 |
| RT (°C) | 160 | 180 | 200 |

The design included 25 cases since there are four factors and the process was simulated (replicates to calculate error are unnecessary). For each case, the cost of ethyl levulinate ($CEL$) was calculated. $CEL$ is defined as the sum of operating and capital expenses divided by the production rate of ethyl levulinate (excluding the cost of levulinic acid), $x$ represents each coded variable, and $c$ represents the coefficients of the surrogate model. Capital cost was calculated according to the literature [20] and added to the $CEL$ after a discount rate of 10% on an equipment life span of 10 years. The material of construction was SS316. The column uses bubble cap trays. The statistical analysis was completed using the software Statistica 13.3 (TIBCO Software Inc., Palo Alto, USA, 2017). Utility cost was estimated according to the literature [21]. Ethanol cost was based on the monthly average from 2019 to 2023 [22]. Data of the 25 cases were regressed into the surrogate model shown in Eq. (2).

$$CEL = c_0 + \sum_{i=1}^{n} c_i x_i + \sum_{i=1}^{n} c_{ii} x_i^2 + \sum_{i=1}^{n} \sum_{j \geq i}^{n} c_{ij} x_i x_j \quad (2)$$

Levulinic acid (recycled and fresh) was fed at 90 °C to the top tray of the reactive distillation column (*RadFrac* block). The levulinic acid to ethanol ratio was adjusted via the Design Spec tool of Aspen Plus according to each simulated case. Ethanol (1.5 bar, 150 °C) was fed at the bottom of the reactive distillation column as vapor. The esterification reaction was set to occur on all stages with kinetics described by Eq. (2). Residence time in each tray was set according to the calculated velocity obtained as a function of the diameter of the column. As a simplification due to the volume of simulations, vapor-liquid equilibrium was reached in any stage of the column.

The bottoms flow rate was fixed via the Calculator tool of Aspen Plus equal to 99.5% of the levulinic acid and ethyl levulinate entering the column. The reflux ratio was varied to recover a bottom product containing 99.9% levulinic acid and ethyl levulinate. The distillate contained water and unreacted ethanol. Ethanol and water were separated using molecular sieves. For this processes, operating conditions and investment were based on data available in the literature [23]. Unreacted ethanol was recycled into the column. The bottom stream of the reactive distillation column was distilled to separate ethyl levulinate and levulinic acid, the latter recycled to the esterification process. This last column was designed using shortcut methods. Ethyl levulinate was obtained at a purity of 99.5 wt%.

Other parameters considered in the process simulation include: pressure in the condenser of the reactive distillation column was varied to attain any specified $RT$ (design variable); stage pressure drop was 4-6 mbar (depending on $RT$); tray spacing of 0.6 m in both the reactive distillation column and second distillation column; residence time in the reflux drum and reboiler sump was 5 min; streams of wastewater, levulinic acid, and ethyl levulinate leaving the second column and the ethanol dehydration were used in heat integration to preheat ethanol, considering a temperature approach of 10 °C in a series of *HeatX* models; streams of ethyl levulinate and wastewater were cooled to 50 °C; service life of molecular sieves used in dehydration of ethanol was equal to the project lifespan (10 years); saturated steam was available at 28 bar and 8 bar (returning as saturated liquid); cooling water was available at 30 °C (returning at 40 °C); chiller water was available at 0 °C (returning at 10 °C). The system was sized to a production rate of 100 kt/y of ethyl levulinate, operating 8000 h per year.

The validity of the surrogate models was attested using the Fisher test with the analysis of variance table. The surrogate model was used as the objective function to minimize $CEL$ using the gradient-based method of the Solver tool of Microsoft Excel. The obtained results were then simulated to validate the optimization, and the reactive distillation column was analyzed in terms of profiles (composition, temperature, etc.).

For the sake of comparison, an esterification via a conventional process composed of a stirred tank reactor followed by a distillation train was simulated as well. The reaction kinetics were the same as Eq. (2). Among the variables of Table 1, only $ELA$ was considered an optimization variable in this scenario. The optimum was searched in the range of 0.6 to 1.4. The reactor temperature was fixed at 200 °C to ensure a high reaction rate, and pressure was chosen to ensure the reactor operated at subcooled conditions. The residence time was varied to attain 99% of the equilibrium conversion at any specified $ELA$ condition.

## RESULTS AND DISCUSSION

### Basis for process design

According to Figure 2a, increasing the $ELA$ from 1 to 2 increases the conversion at equilibrium conditions on average by 13% (temperature range of 0-200 °C). Regarding the kinetics of the autocatalyzed reaction (Figure 2b), increasing the $ELA$ from 1 to 2 increases the conversion in a reaction time of 20 minutes at 200 °C by 31% and at 150 °C by 38%. Different from $ELA$, temperature has little effect over the maximum possible conversion at equilibrium conditions (Figure 2a). However, high temperature is fundamental to achieving desirable conversion in the autocatalyzed reaction (Figure 2b). This scenario – high $ELA$ and high temperature – corresponds to the conditions expected at the bottom of the distillation column since the unreacted levulinic acid is in contact with the total feed of ethanol at the reboiler temperature.

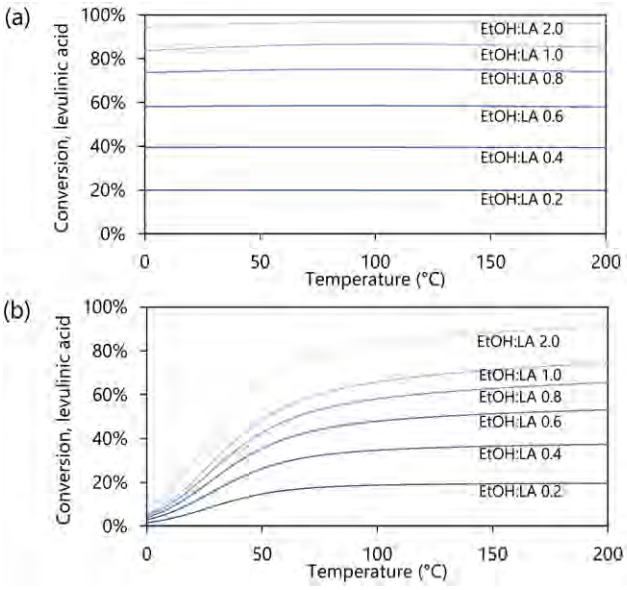

**Figure 2.** Conversion of levulinic acid at equilibrium and at 60 minutes for different temperatures and ethanol to levulinic acid (EtOH:LA, $ELA$) ratios of 0.2 to 2.0.

The absence of an efficient catalyst and the unfavorable volatility ranking (products are intermediate keys) gives rise to a problem: a design to attain complete conversion of reactants is unfeasible. Moreover, other two factors play an important role: i) ethanol and water present an azeotrope, which requires special treatment, and ii) the light key components are considerably more volatile than the heavy key components. Therefore, the design used in this work was based on the potential of contacting a high excess of reactants on both the top and bottom of the column to drive conversion.

## Surrogate model

Simulations were run considering the design of experiments, and the resulting $CEL$ was calculated for each case. Ethanol accounts for 83% of the $CEL$. The data were analyzed with a confidence interval of 95%. The $R^2$ (coefficient of determination) was 0.976. The calculated F-test ratio in both scenarios exceed 10 by a large margin, thus indicating that the surrogate model is useful for prediction and, consequently, can be used in process optimization despite being a simplistic approach. Figure 3 shows the response surfaces obtained from the data.

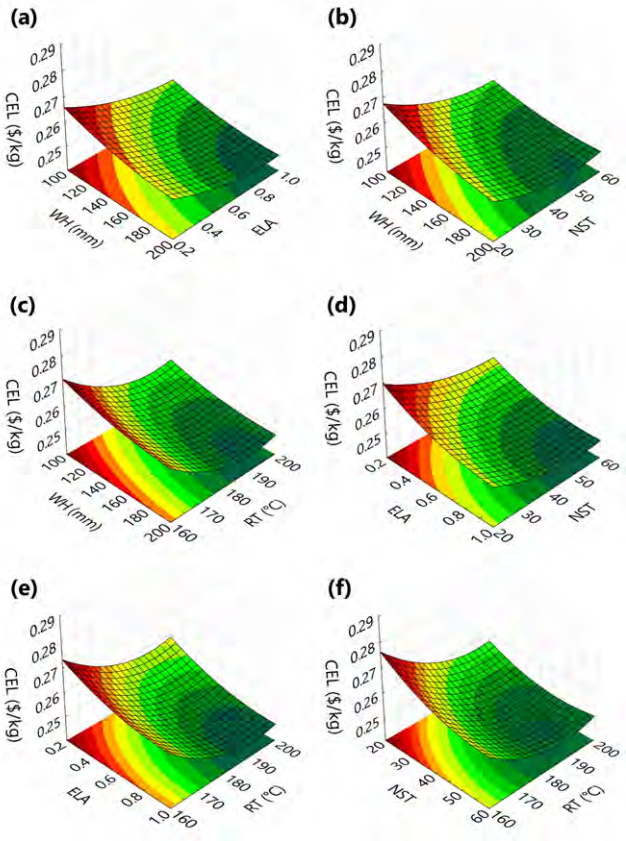

**Figure 3.** Response surfaces: a) $WH$ *vs.* $ELA$, b) $WH$ *vs.* $NST$, c) $WH$ *vs.* $RT$, d) $ELA$ *vs.* $NST$, e) $ELA$ *vs.* $RT$, and f) $NST$ *vs.* $RT$. In each case, values of the other variables were fixed at their central points.

Based on the surrogate model, conditions that minimize CEL are as follows: $WH$ of 185 mm, $ELA$ of 0.93, $NST$ of 46, and $RT$ of 190 °C. The CEL was estimated via process simulation based on these conditions: \$0.243 $kg^{-1}$. The value predicted by the model differs only by 0.26% from the value calculated via process simulation. This demonstrates the potential of the surrogate model in predicting the results of the rigorous model.

Analysis of graphs a, b, and c of Figure 3 shows that $CEL$ decreases when $WH$ is increased (n.b.: the axis direction in some graphs was inverted to aid visualization). High $WH$ means that the column needs to be reinforced to withstand the large liquid holdup, which in turn means an increase in capital cost. However, the obtained increase in residence time as a consequence of the high $WH$ demonstrated to be effective in reducing the $CEL$. The increase in $NST$ also contributes to lower $CEL$, as observed in graphs b, d, and f of Figure 3. However, it can be observed that this effect levels off around 50 stages, with a clear minimum. Similar behavior occurs for $RT$ (graphs c, e, and f of Figure 3) around 190-200 °C. Even though high temperature substantially increases the conversion rate, it demands more corrosion allowance, which increases capital cost.

Graphs a, d, and e of Figure 3 demonstrate the effect of $ELA$. Excess of one reactant is interesting to achieve higher conversion at equilibrium conditions (Figure 1). However, since the reaction is autocatalyzed, the system never reaches near-equilibrium conditions. Therefore, the equilibrium is not a limitation to justify the use of high excess of any reactant. It was observed that the extreme condition of large excess of one reactant implies in a low concentration of the other, which in turn decreases the reaction rate.

## The optimized design

The design of the optimized esterification process is presented in Figure 4. The reaction rate (Figure 5a) averaged 1.9 kmol $h^{-1}$ on column trays. The condenser drum, which operated at low temperature and a residence time of 5 min, presented a reaction rate of 0.001 kmol $h^{-1}$ mainly because of the low levulinic acid concentration (Figure 5b). The reboiler has by far the highest temperature and it presented a reaction rate in the same order as the rest of the column (2.0 kmol $h^{-1}$) despite the low ethanol concentration. Ethanol was fed one stage above and preferentially flows to the upward stages.

Temperature (Figure 5a) grew steadily from top to bottom in almost the entirety of the column, growing rapidly after ethanol concentration in the liquid phase peaks (stages 41-45). The slow increase in temperature is a consequence of volatility and concentration of components along the column. In bottom stages, the concentration of components is ranked as ethyl levulinate, levulinic acid, and ethanol, with the latter (the lightest component)

reaching concentrations up to 9 mol% in the liquid phase (Figure 5b). In the top stages, ethyl levulinate has a low concentration, at the same region where water concentration peaks. Therefore, the change in temperature is both a consequence of column fractionation and reaction, which is an expected behavior. Similar behavior was observed by the other investigators [16].

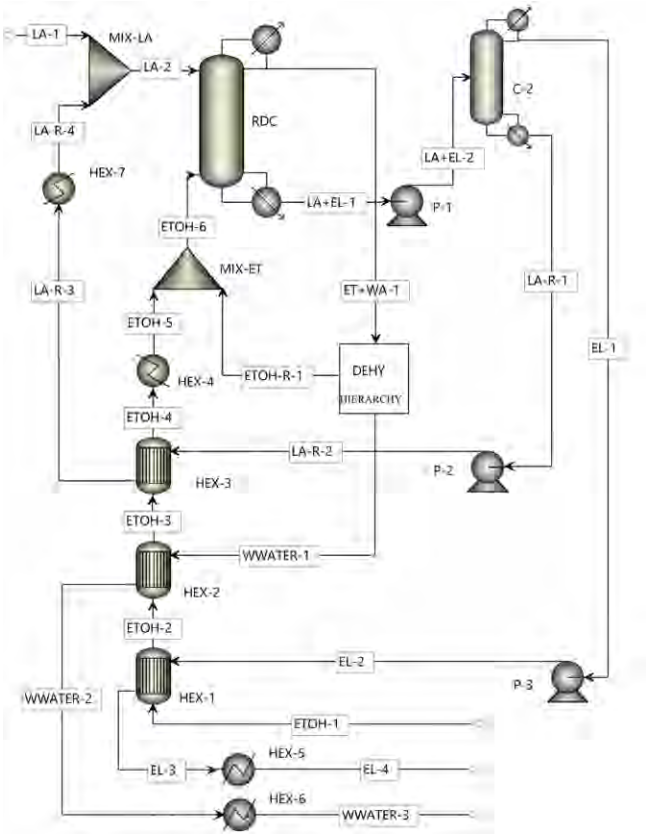

**Figure 4.** Simulation flowsheet of the optimized process.

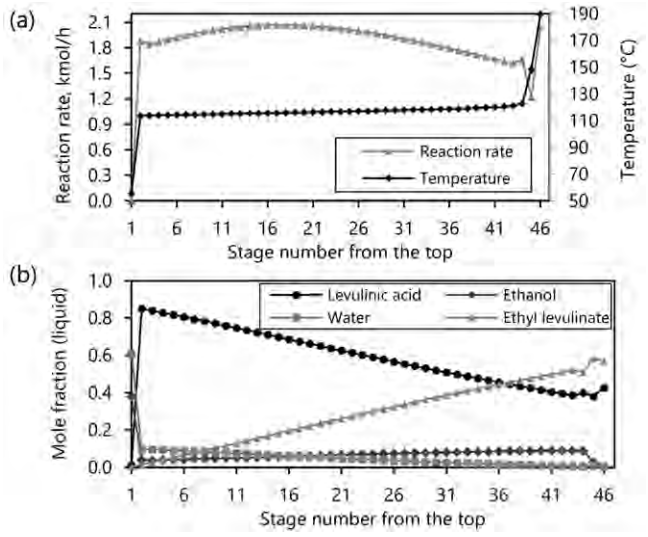

**Figure 5.** Simulation flowsheet of the optimized process.

The reaction rate is almost constant throughout the column, decreasing towards the bottom (stages 18-46). Consequently, concentration profiles (Figure 5b) are nearly straight lines. The concentration profile of levulinic acid in the liquid phase decreases according to the reaction rate because levulinic acid flows downward, its concentration in the vapor phase is too low. As the reaction slows down in the bottom stages, the concentration of levulinic acid tends to become constant.

Stages 45 and 46 have temperatures beyond 130 °C. High temperature is expected at the bottom stages because of the reboiler, thus contributing to a higher reaction rate as the ester product becomes more concentrated. On the other hand, trays on stages 2-40 operate between 110-120 °C. This result suggests that the trays of the upper stages of the column require less corrosion allowance, which could reduce their cost.

## Comparison to other process option

Optimization via a surrogate model of the conventional setup (stirred tank reactor followed by distillation) indicated that an $ELA$ of 1.09 results in a $CEL$ of \$0.253 $kg^{-1}$, 4.05% higher than that of the optimized reactive distillation. Ignoring ethanol cost in both scenarios, the difference regarding equipment cost and operating expenses becomes more evident: the conventional process costs 41% more than the reactive distillation process.

# CONCLUSIONS

This work assessed a reactive distillation column that produces ethyl levulinate via autocatalyzed esterification of levulinic acid. Optimized operating conditions were estimated via a surrogate model obtained via design of experiments. Statistical analysis demonstrated that the quadratic surrogate model has desirable confidence level inside the explored data space. Optimized parameters indicated that the lowest cost of ethyl levulinate was obtained at high reboiler temperature, high number of stages, high liquid holdup, and ethanol to levulinic acid molar ratio slightly lower than one. Single-pass conversion was not feasible because of the low reaction rate and recycle of unconverted reactants showed a large impact on operating costs. Nevertheless, the design was effective: the cost of ethyl levulinate on a conventional set of stirred tank reactor and distillation train excluding ethanol and levulinic acid costs was estimated to be 41.1% higher than the upgrading cost using a reactive distillation column. These results indicate the opportunity of carrying out the esterification of levulinic acid in a reactive distillation column.

## ABSTRACT

In this work, a Claus reaction furnace was analyzed in a sulfur recovery unit (SRU) of the Abadan Oil Refinery where the combustion operating temperature is important since it ensures optimal performance in the reactor, this study focused on temperature of control of 1400, 1500 and 1600 K and excess air of 10, 20 and 30% to improve the reaction yield and $H_2S$ conversion. The CFD simulation was carried out in Ansys Fluent in transitory state and in 3 dimensions, considering turbulence model κ -ε standard, energy model with transport by convention and mass transport with chemical reaction using the Arrhenius Finite – rate/Eddy dissipation model for a Kinetic model of destruction of acid gases $H_2S$ and $CO_2$, obtaining a good approximation with experimental results of industrial process of the Abadan Oil Refinery, Iran. The percentage difference between experimental and simulated results varies between 0.5 to 5 % depending on species. The temperature of 1600 K and with excess air of 30% was the best, with one fraction mol of 0.054 of $S_2$ at the outlet and with conversion of the acid gas ($H_2S$) of 97.64%, which is quite good compared to the experimental one.

**Keywords**: CFD, SRU, Claus Reaction, Furnace, Sulfur.

## INTRODUCTION

High concentrations of sulfur and nitrogen are produced in crude oil processing, increasing the formation of hydrogen sulfide ($H_2S$) and ammonia ($NH_3$). Most of the H2S is absorbed by the circulation of an amine solution (DEA process), and much of the ammonia is absorbed, along with proportional amounts of $H_2S$, in the wash with water (stripper of sour waters).

Applying a Claus process, the Sulfur Recovery Unit (SRU) converts $H_2S$ present in sour amine gas and sour NH3 gas to elemental (pure) sulfur. Environmental regulations have become stricter on sulfur dioxide emissions. One of the main strategies to reduce sulfur emissions is to increase the performance of sulfur recovery units (SRU) [1]. The modified Claus process is one of the main processes that convert toxic hydrogen sulfide into elemental sulfur from acid gas during natural gas processing and upgrading the refinery [2]. The main reactions of a sulfur recovery unit occur in two stages:
A highly exothermic reaction occurs in which a large amount of heat is released, and a partially exothermic reaction occurs in which sulfur dioxide ($SO_2$) is produced in the reactor, and unreacted $H_2S$ are burned together to produce sulfur elements [3]. The modified Claus process in which hydrogen sulfide is converted to sulfur can be represented by;

$$H_2S + 0.5O_2 \rightarrow 0.5S_2 + H_2O \quad (1)$$

The sulfur recovery in the modified Claus process is obtained through thermal and catalytic reactions. The first step is thermal, where one-third of the hydrogen sulfide ($H_2S$) is partially oxidized, and Sulfur dioxide ($SO_2$) is produced at very high temperatures. The second step involves the reaction between unreacted hydrogen sulfide and sulfur dioxide over a catalytic bed at lower temperatures:

$$H_2S + 1.5O_2 \rightarrow SO_2 + H_2O \quad (2)$$

$$2H_2S + SO_2 \rightarrow 1.5S_2 + 2H_2O \quad (3)$$

The conversion of $H_2S$ to $SO_2$ in the modified Claus process is carried out in the reaction furnace, which is a cylindrical vessel with a refractory lining. The acid gas stream at a pressure typically ranging from 130 to 180 kPa is fed to the reaction furnace burner along with an appropriate amount of air to oxidize the feed contaminates and results in a 2:1 ratio of $H_2S$:$SO_2$ in the reactor effluent. The combustion of acid gases in the RF is carried out in temperature ranges of 975-1300 °C, and residence times of the gas are 0.5-2.0 s [4]. Another experimental investigation was on the effect of $O_2$ enrichment on the yield of the Claus process. It was observed that the rate of COS formation increased with $O_2$ enrichment due to the availability of higher amounts of CO, while that of $CS_2$ (carbon disulfide) decreased.

A tool that has been used lately is CFD (Computational Fluid Dynamics), where you can work with the kinetics of chemistry and the transport of mass, momentum, and heat, which helps us predict the temperature of combustion, recovery of sulfur and molar fractions of the products. The Abadan Oil Refining Company in Iran has introduced CFD to analyze the effect of $O_2$ enrichment on dry air, combustion temperature, sulfur recovery, and pollutant production [5].

A current study develops a new reduced kinetic model for simulating the destruction of acid gases in the industrial sector in a sulfur recovery unit reaction furnace. The proposed CFD model includes the reactions of the new kinetic mechanism and stationary laminar flamelet model. The relative error of the H2S conversion calculated by CFD, using the new kinetic model, is 9.48% compared to industrial data [6].

The present work has focused on the effects of the operating temperature of the Claus reactor and excess air on the combustion and SRU emission characteristics, using a kinetic model of acid gas destruction (H2S and CO2) with Fluent to improve the reaction yield. The experimental data of a reaction furnace of Abadan Oil Refining Company in Iran was taken as a reference. [7] The kinetic studies Kinetic Modeling and Optimization of the Claus Reaction Furnace by Samane Zarei [8] and the evaluation of kinetic models to simulate Claus reaction furnaces in sulfur recovery units under different feeding conditions. This work has the following objective:

1. Simulate with Fluent the kinetic model of the destruction of acid gases H2S and CO2 and mass transfer in the furnace of the Claus reactor of SRU of the Abadan Oil Refinery. The novelty of this work is the study of different control temperatures 1400, 1500 and 1600 K, with excess air of 10, 20 and 30% to increase and ensure that more reactions occur in the reaction oven, since in other works only modified operating conditions.
2. Use CFD to improve the reaction performance by modifying the operating temperature of the Claus reactor and removing excess air from the combustion.

## METHODOLOGY

The following equations are involved in solving the problem posed by the physical phenomenon to be modelled: Navier-Stokes Reynolds average equation (RANS), turbulence model $(k-\varepsilon)$ standard, equations of state and coupled methods; FLUENT 16TM uses the method of finite volumes as a numerical method to solve the governing equations and those mentioned above [9]. The partial differential equations that describe the phenomenon of mass transport are the following:

The equation of conservation of mass or continuity.

$$\frac{\partial \rho}{\partial t} + \nabla.(\rho \vec{v}) = S_m \quad (4)$$

The conservation equation of momentum or the m mentum theorem in inertial reference frame is;

$$\frac{\partial}{\partial t}(\rho \vec{v}) + \nabla.(\rho \vec{v}\vec{v}) = -\nabla \mathrm{p} + \nabla.(\vec{\tau}) + \rho \vec{g} + \vec{F} \quad (5)$$

Where p is the static pressure, τ is the stress tensor, ρg is the gravitational force and F is the external force.

The stress tensor is given by:

$$\bar{\tau} = \mu\left[(\nabla \vec{v} + \nabla \vec{v}^T) - \frac{2}{3}\nabla.\vec{v} I\right] \quad (6)$$

Where μ is the molecular viscosity, I is the unit tensor and the second term on the right side is the effect of volume expansion.

Standard turbulence model $(k-\varepsilon)$

$$\frac{\partial}{\partial t}(\rho k) + \frac{\partial}{\partial x_i}(\rho k u_i) = \frac{\partial}{\partial x_j}\left[\left(\mu + \frac{\mu_t}{\sigma_k}\right)\frac{\partial k}{\partial x_j}\right] + G_k + G_b - \rho\varepsilon - Y_M \quad (7)$$

$$\frac{\partial}{\partial t}(\rho \varepsilon) + \frac{\partial}{\partial x_i}(\rho \varepsilon u_i) = \frac{\partial}{\partial x_j}\left[\left(\mu + \frac{\mu_t}{\sigma_\varepsilon}\right)\frac{\partial \varepsilon}{\partial x_j}\right] + C_1\frac{\varepsilon}{k}(G_k + C_3 G_b) - C_2\rho\frac{\varepsilon^2}{k} \quad (8)$$

κ is the turbulence kinetic energy, ε is the dissipation rate, $G_k$ represents the generation of turbulence kinetic energy due to the mean velocity gradient, $G_b$ is the generation of turbulence kinetic energy due to buoyancy.

The above equations are considered in Cartesian coordinates, $C_1$, $C_2$, $C_3$, $\sigma_\kappa$, and $\sigma_\varepsilon$ are closure coefficients and the values of these coefficients are: 1.44, 1.92, 0.09, 1.0 and 1.3, respectively for the standard turbulence model (κ - ε) equations 7 and 8 (Launder and Spalding 1972).

The energy conservation equation is given by the

following expression:

$$\frac{\partial}{\partial t}(\rho E) + \nabla \cdot \left(\vec{v}(\rho E + p)\right) = \nabla . \left( k_{eff} \nabla T - \sum_j h_j \bar{J}_j - (\bar{\tau}_{eff} . \vec{v}) \right) + S_h \quad (9)$$

where $k_{eff}$ is the effective conductivity (k + $k_t$, where $k_t$ is the turbulent thermal conductivity, defined according to the turbulence model being used), and $\bar{J}_j$ is the diffusion flux of species j. The combustion process in the Claus reaction furnace was modeled and simulated using Ansys Fluent to study the influence of furnace temperature and keep it under control and from excess intake air for sulfur recovery and pollutant production, The temperatures used were 1400 K, 1500 K and 1600 K, varying various excesses of air 10, 20 and 30 %.

The dimensions of the reaction furnace in SRU of the Abadan Oil Refinery were taken from Abdoli et al. (2018) and a representation is shown in Figure 1. The inner surface of the reaction furnace is covered by refractory to protect its wall.

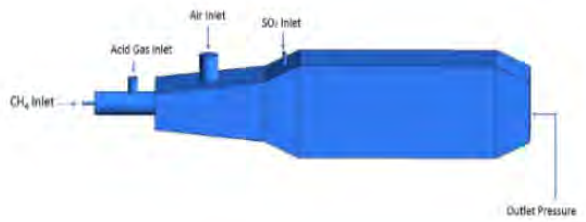

**Figure 1.** Reaction furnace in SRU of the Abadan Oil Refinery.

The reaction furnace consists of 4 inputs: $CH_4$ input, acid gas ($H_2S$) input, air input are located in the burner and $SO_2$ input is in the reaction furnace, there is a product output.

For the simulation the walls were assumed to be adiabatic, the mixture was treated as an incompressible, ideal gas, and there is no slip on the walls.

The furnace produces sulfur, but also oxidizes $H_2S$ to $SO_2$. After the furnace there are catalytic reactors that produce sulfur from $SO_2$, but at lower temperatures than the reaction furnace. Also at the exit of the furnace there is a heat exchanger that cools the gases before the catalytic stage.

The study of hydrodynamics and mass transfer was carried out with CFD tools in Fluent 16.0, which will give us the profile of products obtained. A computer with 16 GB RAM and an Intel (R) Core™ i 7 -2600 CPU was used.

The essential parameters to carry out a study of this type were to obtain an adequate mesh that represents our study area, propose ANSYS models to represent our process, turbulent model, reaction equations.

**Table 1.** shows the input operating conditions of the reagents.

| Mole Fraction | acid gas | air | $SO_2$ | $CH_4$ |
|---|---|---|---|---|
| Inlet temperature (k) | 353.15 | 463.15 | 324.15 | 3113.15 |
| Mass flow (kg/s) | 1.338 | 0.09028 | 0.25167 | 3.1025 |
| Species | | | | |
| $H_2$ | 0.00197 | 0 | 0 | 0 |
| $O_2$ | 0 | 0.19291 | 0 | 0 |
| $H_2S$ | 0.68952 | 0 | 0 | 0 |
| $SO_2$ | 0 | 0 | 0.90728 | 0 |
| $H_2O$ | 0.147 | 0.07948 | 0.09272 | 0 |
| $CH_4$ | 0.00725 | 0 | 0 | 1 |

## Simulation in CFD Preprocessing

Reactor meshing was performed in ANSYS ICEM software and boundary conditions were also entered into the mesh. The mesh was made with a hexahedral structure with a size of 364456 cells (see Figure 2).

**Figure 2.** Mesh generated for the reactor.

## Processing

The simulation in Fluent version 16.0 was performed in 3 dimensions, in transient state, using the viscous model of $k - \varepsilon$ standard, the species transport model and for the reaction the Finite-rate/Eddy - Dissipation model. To simulate the combustion reaction in the Claus SRU furnace, the following reaction mechanism was followed [Amer Mehmood, 2020];

$$H_2S + 1.5O_2 \rightarrow SO_2 + H_2O$$
$$2H_2S + SO_2 \rightarrow 1.5S_2 + 2H_2O$$
$$CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O$$
$$CO_2 + H_2 \rightarrow CO + H_2O$$
$$CO + 0.5S_2 \rightarrow COS$$
$$CH_4 + 2H_2S \rightarrow CS_2 + 4H_2 \quad (10)$$

The transport equation was solved for each species.

## Postprocessing

The profiles and temperature contours were obtained, the profiles of the products will be obtained, as well as those of the acid gas conversion profiles at various temperatures 1400, 1500 and 1600 K with excess air

10, 20 and 30 %, the mathematical model in Fluent will be validated with the experimental data.

## RESULTS

The numerical results of the simulation are presented below, Figure 3 shows the behavior of the molar fraction of $S_2$ along the reactor at a temperature of 1400 K at 10, 20 and 30% excess air at 300 seconds of simulation. The air and acid gas inlets are the same in the reactor causing the concentration to increase in the first 2 meters by 0.032 which is where the chemical reaction takes place the most, the molar fraction of 0.043 at the exit for 10% excess air and a value of 0.045 for 20 and 30% excess air at 1400 K.

Figure 4 shows the profile of the $S_2$ molar fraction in the reactor at a temperature of 1500°K with 10, 20 and 30% excess air at 300 seconds of simulation. The concentration increases in the first 3 meters up to 0.032 because it is where the reaction gases come together and where the greatest reaction takes place and at the end it has a value of 0.042, for 10% excess air and 0.045 for 20% and 0.046 for 30% excess air at 1500°K.

Figure 5 shows the profile of the molar fraction of $S_2$ in the reactor at a temperature of 1600 ° K at 10, 20 and 30% excess air at 300 seconds of simulation. As in the other cases, the concentration increases in the first meters of the reactor length up to 0.042 and at the exit there is less reaction and a value of 0.046 is obtained for 10% excess air and 0.055 for 20% and 0.054 for 30% excess air at 1600 K. It is observed that there is a greater conversion of $S_2$ at 1600 ° K and at 30% excess air.

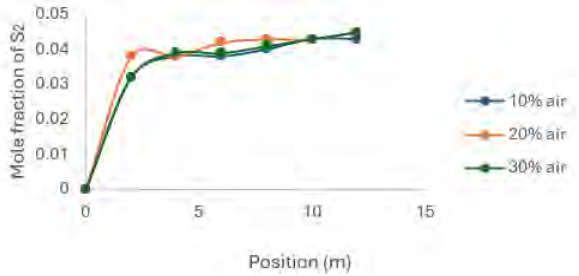

**Figure 3.** Mole fraction profiles of $S_2$ at 1400 K with 10, 20 and 30% excess air in the SRU reaction oven.

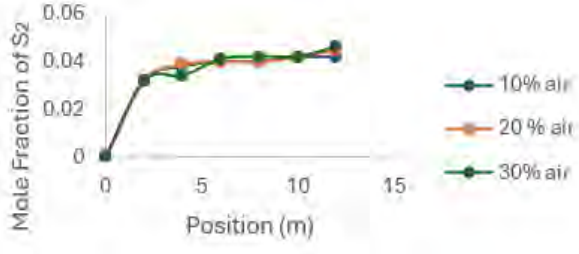

**Figure 4.** Mole fraction profiles of $S_2$ at 1500 K with 10, 20 and 30% excess air in the SRU reaction oven.

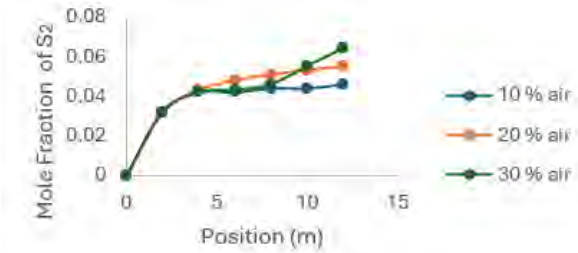

**Figure 5.** Mole fraction profiles of $S_2$ at 1600 K with 10, 20 and 30% excess air in the SRU reaction oven.

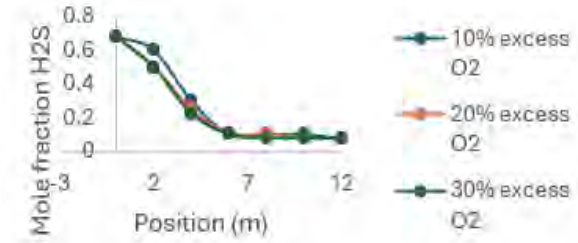

**Figure 6.** Mole fraction profiles of $H_2S$ at 1400 K with 10, 20 and 30% excess air in the furnace at 300 seconds of simulation.

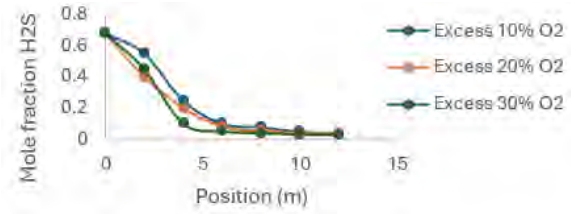

**Figure 7.** Mole fraction profiles of $H_2S$ at 1600 K with 10, 20 and 30% excess air in the furnace at 300 seconds of simulation.

The following results show the acid gas ($H_2S$) conversion profile at the various temperatures 1400, 1500 and 1600 K and with the various excesses of air 10, 20 and 30% respectively. The fluctuations in figures 3, 4 and 5 depend on the reaction turbulence and the equipment design.

Figure 6 shows the H2S conversion profiles in the reactor at 1400 K at different air excesses 10, 20 and 30%, it starts with a value of 0.68 molar fraction of acid gas, after 4 and 5 meters it consumes up to 0.1, and at the reactor exit it reaches a value of 0.075, with a conversion of 89.12%, due to the design of the equipment, it could be raised if there was more contact and turbulence of the reactants.

Figure 7 shows the $H_2S$ conversion profiles in the reactor at 1600 K at different air excesses 10, 20 and 30%, it starts with a value of 0.68 molar fraction of acid gas at the inlet, after 4 and 5 meters it is consumed up to 0.05 is where the reaction takes place, at the reactor outlet it reaches a value of 0.03, a conversion of 97.64% is

obtained, this is similar to the experimental conversion with a value of 97.98%.

The results are presented only as a function of axial position (graph 1-D) to analyze the behavior profiles on action lines in the reactor. No experimental points were added in the figures to show how the model compares to reality, because I do not have all the experimental data from the company, only output results.

The temperature as a function of the molar fraction of $CO_2$, CO and COS, $H_2O$ species with 30% excess air was the best result, compared with the industrial data of Abadan Oil Refining Company. $S_2$, $SO_2$ and $H_20$ species tend to increase at the exit of the Claus furnace, and $CO_2$, COS and CO tend to decrease.

The results of the simulation were compared with the experimental data of the Abadan Oil Refining company. Th results of the simulation for 30% excess air and the experimental data for the species of $S_2$, $SO_2$, CO, $CO_2$, $H_20$, COS and $H_2S$. The relative error with respect to the temperature of 1400, 1500 and 1600 K is 0.02, 0.01 and 0.02% respectively.

## CONCLUSIONS

In this work, the SRU (sulfur recovery unit) process was analyzed to improve the performance of the reaction and sulfur recovery using the CFD tool, a standard k-ϵ turbulence model, an energy model with convective transport and mass transport were used. with chemical reaction using the Finite - rate/Eddy model. - Proposed model for the destruction of acid gases ($H_2S$ and $CO_2$).

This work presents a CFD analysis controlling the temperature and excess air of 10, 20 and 30% to improve the reaction performance, outlet temperature, sulfur recovery. It was obtained a good approximation with the experimental results of the industrial process of the Abadan Oil refinery, Iran. Control temperatures of 1400, 1500 and 1600 K were analyzed, as well as excess air of 10, 20 and 30% respectively. It was found that at the highest temperature of 1600 K and at 30 of excess air there is a higher reaction yield, producing 0.0728 mole fraction of $S_2$, compared to the experimental one of 0.0709, which has an error of 2.6 %.

For the conversion of $H_2S$, a value of 0.03 mole fraction was obtained at the reactor outlet compared to the experimental one, with an error of 4%, a good approximation to the experimental results of the process. was obtained a conversion of the acid gas ($H_2S$) of 95.64%, which is quite good compared to the experimental one. The results of simulation or numerical predictions confirm that, at higher temperatures and higher excess air, the acid gas increases combustion and sulfur conversion. The results confirm that the excess air for combustion and more than 30% and with a temperature of 1600 K improve the recovery of sulfur and reduce the amount of pollutants such as COS and $CO_2$ and CO. The experimental conversion of sulfur was 99.1% and the conversion for the temperature of 1600 K and 30% with excess air was 99.5% with a percentage deviation of 0.4%, for the other temperatures of 1400, 1500 with 30% with excess air conversion was lower with a value of 98%.

## ABSTRACT

The integration of carbon capture and storage (CCS) into coal and biomass co-firing systems (CBCCS) offers a promising solution for reducing carbon emissions in electricity generation. This study evaluates hypothetical scenarios in Malaysia and Indonesia, focusing on techno-economic-environmental transparency. The analysis shows a negligible change in plant net efficiency (~1%) across biomass co-firing ratios of 5-20% in both countries. The capture penalty increases at higher biomass ratios, particularly at 20% co-firing, due to higher auxiliary power demands and steam extraction. As biomass share increases, net $CO_2$ emissions decrease by an average of 43% in Malaysia and 34% in Indonesia. Economic evaluations show a positive revenue increase for Malaysia at a 20% co-firing ratio, while Indonesia faces a revenue deficit (0.6%) under the same condition, mainly due to an unattractive carbon price and feed-in tariff from 2027 onward. Malaysia faces a higher risk of stranded assets due to earlier retirement plans, compared to Indonesia. As the co-firing ratio increases, the risk of stranded assets decreases by 3% in Malaysia and 0.6% in Indonesia. The present work showcases the intricate and synergistic effects of energy and commodity market dynamics from a micro-sector perspective towards plant revenue. This allows both Indonesia and Malaysia to learn from each other in their quest to achieve energy independence and security. Collaboration in tapping renewable sources is one way the two countries can secure energy for their domestic needs while addressing the challenges of carbon lock-in and the impact of stranded assets.

## INTRODUCTION

The energy sector remains the largest contributor to global greenhouse gas emissions, with coal accounting for approximately 45% of total emissions from fuel combustion [1]. To address this issue, two promising strategies have been identified, which include cofiring coal with biomass for power generation (CB) and retrofitting coal-fired power plants with carbon capture and storage (CCS) technology. According to the Intergovernmental Panel on Climate Change (IPCC), these strategies play a significant role in supporting the Paris Agreement targets [2]. Many studies have been carried out on the performance of biomass cofiring integrated with CCS system (CBCCS), encompassing both technical and environmental perspectives. For instance, Cebrucean et al. [3] identified that biomass co-firing with a supercritical coal plant equipped with a carbon capture system can enhance energy and environmental performance, achieving a 2.4% increase in net efficiency and a 6% reduction in $CO_2$ emissions compared to conventional subcritical plants. How-

ever, at a 30% co-firing ratio, net plant efficiency is reduced by 1%, negatively impacting the plant's economic viability. In another study, approximately a 14% reduction in net plant efficiency was observed at a 10% biomass co-firing ratio. This significant discrepancy is influenced by the type of biomass and coal plant technology. While co-firing ratios exceeding 10% have been shown to result in net negative $CO_2$ emissions, Yang et al. [4] reported that higher $CO_2$ capture rates are directly associated with significant declines in net plant efficiency, which typically ranges from 28% to 31%. Despite several studies available on the ground, the global commercialization of CBCCS technology remains sluggish. This can be attributed to factors such as the limited availability of biomass resources, socio-economic barriers, the absence of robust policies and regulatory frameworks, and the risk of stranded assets (SA) faced by coal-fired power plants [5-6]. In this paper, we evaluate the techno-enviro-economic performance of the CBCCS system, taking into account carbon price and the impact of stranded assets on the plant's lifetime operation. This work addresses concerns raised by the International Energy Agency (IEA), emphasizing the need for a reliable framework that ensures transparency to support CBCCS technology as one of the carbon dioxide removal solutions[7].

## METHODOLOGY

### An improved genetic algorithm (GA) optimization algorithm

Present work adapts and further enhances a previously developed GA optimization algorithm executed in Mathlab software [8]. The enhancement focuses on biomass co-firing in a supercritical power plant (direct co-firing) integrated with CCS system (i.e. monoethanolamine (MEA) – based post combustion carbon capture)). For this study, it is assumed that the coal plant does not require significant modifications for the carbon capture retrofit or biomass co-firing integration. The analysis also includes the cost of stranded assets, evaluated based on both physical and economic lifetimes, alongside the feed-in tariff (FiT). This approach provides new insights into the financial risks and benefits posed by the evolving power sector.

The objective function of the enhanced GA optimization remains focused on maximizing plant revenue from 2024 to 2034 by optimizing the power plant load ($PP_N$) and $CO_2$ capture rate. Table 1 presents the details of the optimization enhancements. While this paper presents only significant and new information and approaches, readers can reference previous works for comprehensive background information [9-10].

As referenced in Table 1, the revenue formulation is illustrated in the equation (1).

$$Max(Revenue) = \int E\ (Q_e - Q_p)\ dt - \int C\ (Q_c)\ dt - PP_{op} - CCS_{op} - CCS_{cap} + \int F\ (Q_L)\ dt \quad (1)$$

Where *E, C* and *F* represent the electricity price, carbon price and feed-in-tariff for biomass, while $Q_e$, $Q_p$, $Q_c$, $Q_L$ are power plant net load, total power penalty, $CO_2$ emissions and proportion of electricity produced from biomass in co-firing power plant. Since biomass is considered as carbon neutral fuel thus burning biomass is not counted for carbon tax[11-12]. In this work, we consider a stringent and extreme condition, where no free allowance provided to the power plant.

**Table 1:** Detail of the GA optimization enhancement adapted in present study.

| **Items** | **Ref work** [9] | **Present work** |
|---|---|---|
| Power plant (660 MW) | Subcritical | Supercritical |
| Non-linear prediction model | $Q_{reb}$ =f($x_i$)<br>Aux = f($x_i$) | $Q_{reb}$ = -20% *(f($x_i$)[3]<br>Aux = - 8* f($x_i$) [3] |
| Objective function | Revenue (without FiT) | Revenue (with FiT and CCS capital cost) |
| Inequality constraint | $c_1$:$PP_N$ < $PP_G$ | $c_1$: $PP_N$ < $PP_G$<br>$c_2$: $CO_2^E$ < $CO_2^T$ |
| Fuel | Coal | Coal and biomass (palm kernel shell, PKS) |
| Stranded asset | Not evaluated | Evaluated by the influence of power plant load ($x_i$) |

On top of ensuring that the $PP_N$ of the power plant does not exceed the gross load ($PP_G$), present work incorporates carbon neutrality and emission constraints into the enhanced optimization algorithm, as follows.

```
max_CO2_threshold = 0.5
c2 = ((Total_CO2_Emissions/PP_load) -
max_CO2_threshold)
```

This constraint ($c_2$) ensures that the $CO_2$ emissions produced at each interval remain below a specified threshold (max_$CO_2$_threshold) to align with carbon neutrality/emission reduction goals. While a standard methodology (ISO 14068-1) exists for assessing carbon neutrality [13], no specific emission threshold has been formally established yet. Therefore, this work sets the threshold at 0.5 tonnes $CO_2$/MWh, based on China's coal benchmarking for power decarbonization from 2018 to 2030. This value aligns with the averaged benchmark outlined in Sustainable Development Goals (SDGs)[14]. For the evaluation of stranded asset (SA), the calculation was

adapted from [6] as shown in equation (2).

$$SA = OC_{cap} * K * \left(\frac{L_R}{C_{LT}}\right) * LF \quad (2)$$

Where $OC_{cap}$ is an overnight capital cost (USD/kW), *K*, $L_R$ and $C_{LT}$ are the plant capacity, remaining lifetime and coal plant lifetime. This work considers SA based on physical ($SA_{LP}$) and economic lifetimes ($SA_{LE}$). Where physical lifetime is generally longer (standard/technical lifetime) than the economic lifetime (early retirement). In this work, load factor (LF) is being considered to reflect the operational deficiency over the years of co-firing power plant. The LF is dynamically calculated as in equation (3).

$$LF = \frac{PP_N}{700} \quad (3)$$

While other researchers have used intricate and financially detailed methods to evaluate SA[15], this work considers a simple and tactical method as a preliminary approach.

## Scenario setting

Four scenarios representing three ranges of biomass ratios (by low heating value, LHV) are evaluated based on hypothetical situations in Malaysia and Indonesia. As both countries are the major producers of palm oil [16], there is significant potential for the adoption and development of biomass co-firing technology within their energy infrastructure. However, as developing nations with dynamic economic and policy landscapes, both countries face considerable risks of stranded assets and carbon lock-in. Therefore, understanding the technical, environmental and economic implications is critical to effectively evaluate their exposure to stranded asset risks and align with emission reduction targets, particularly for hybrid technologies like the CBCCS system. Table 2 presents the input data used in the enhanced optimization algorithm, including the associated costs for the CBCCS system. Several assumptions were made due to the unavailability of certain data. This study does not consider biomass pre-treatment, assuming that the power plant receives biomass with suitable characteristics for direct use.

**Table 2:** Input data and costs assumptions of CBCCS plant.

| Parameters | Malaysia | Indonesia |
|---|---|---|
| Plant commissioning | Tanjung Bin, 2016 [17] | Cirebon, 2012 [18] |
| PKS ratio (%) | 0, 5, 10, 20 | |
| $PP_G$ (MW) | Similar pattern [19] | |

| MEA price (USD/tonne) | 1,940[34] | |
| Transportation and storage (USD) | 25[35] | |

# RESULTS AND DISCUSSION

## Technical transparency

The net plant efficiency is a critical indicator of the energy conversion performance of a system. According to Table 3, the analysis reveals a marginal efficiency variation from 29.8% to 31% across the co-firing spectrum (0–20%) for both countries, with an approximate difference of 1% point. This noteworthy phenomenon is attributed to the sensitivity and flexibility of the optimization algorithm, which requires the power plant load to dynamically meet the objective function while adhering to the constraint ($c_1$) at each time interval. This finding is distinct with existing literature, where increasing the biomass co-firing ratio typically leads to a decline in net plant efficiency. Such depreciation is often directly related to the high $CO_2$ capture rate, commonly set at 90% [4]. In contrast, the current work considers a dynamic capture rate influenced by carbon pricing and emission constraints ($c_2$), which we believe more accurately reflects real-world flexible CBCCS operations. This aligns with the findings of [3], which showed that the net efficiency of power plants increases when the capture efficiency is reduced from 90% to 50%. This improvement is primarily due to the reduced steam extraction from the steam cycle to meet the heat requirements of the capture unit, allowing more steam to be available for power generation. Additionally, operating the power plant in a baseload scenario may not generate significant revenue for

plant owners. The $CO_2$ capture energy penalty exhibits an upward trajectory for both nations, with Malaysia's requirements increasing from 9.66 to 11.53 MJ/kg $CO_2$ and Indonesia's from 9.24 to 11.51 MJ/kg $CO_2$ as the biomass ratio escalates. This range is technically accepted since maximum energy penalty associated with MEA-capture system (retrofit with coal plant) can reach up to maximum 8.00[36] to 10.23 MJ/kg $CO_2$ [37]. Where, this escalation in energy penalty is consistent with the technical challenges including increased parasitic loads from auxiliary equipment and reboiler duty from the steam extraction/solvent regeneration [3,38]. Based on the optimization results presented in this study, it is suggested that retrofitting carbon capture technology into a supercritical plant with a co-firing ratio of 5–20% does not impose a significant efficiency penalty, provided the plant is allowed to operate flexibly. This technical transparency highlights a critical trade-off between achieving higher biomass co-firing ratios for enhanced carbon reduction and maintaining optimal plant performance, particularly in the context of emerging economies transitioning to low-carbon energy systems

**Table 3:** Technical performance of CBCCS system under the carbon price regime.

| **Co-firing ratio** | | **0** | **5** | **10** | **20** |
|---|---|---|---|---|---|
| Net plant | MAS | 29.8% | 30.6% | 30.9% | 31.0% |
| eff. (LHV %) | IND | 30.5% | 30.5% | 30.5% | 31.0% |
| $CC_{penalty}$ | MAS | 9.66 | 9.76 | 10.30 | 11.53 |
| (MJ/kg $CO_2$) | IND | 9.24 | 9.78 | 10.23 | 11.51 |

## Environmental transparency

The environmental performance analysis of the CBCCS system reveals distinct $CO_2$ emission patterns across varying co-firing ratios, demonstrating the system's potential for carbon mitigation. As shown in Figure 1, increasing the co-firing ratio results in a notable reduction in net $CO_2$ emissions. At 20% biomass co-firing, the net $CO_2$ emissions account for 43% and 34% of the total $CO_2$ emissions from co-firing plant in Malaysia and Indonesia, demonstrating a trend similar to that observed in [3]. Without co-firing, coal plants generate an average of 65% net $CO_2$ emissions, emphasizing the significant contribution of biomass co-firing to $CO_2$ emission mitigation. However, the total $CO_2$ emissions from the biomass combustion of a biomass co-firing plant increase by 17% compared to a coal plant due to the adoption of co-firing. Since $CO_2$ emissions from biomass combustion are sequestered as biomass regrows, sustainably managed biomass is considered carbon neutral. These findings underscore the effectiveness of biomass co-firing in reducing fossil-based $CO_2$ emissions by substituting a portion of fossil carbon with a renewable carbon source. The total captured $CO_2$ exhibits slight variation across different co-firing ratios, reflecting the complex interaction between maintaining $CO_2$ emissions below a specified threshold ($c_2$) and maximizing plant revenue. This observation aligns with [39] , which identified that biomass co-firing ratios significantly influence carbon capture performance due to variations in fuel composition and combustion characteristics. Notably, under higher carbon pricing scenarios, CBCCS plants in Malaysia tend to reduce their total capture percentage to optimize economic outcomes. The dynamic interplay between these emission components highlights the potential of CBCCS as a viable negative-emission technology, particularly in regions with access to sustainable biomass resources and existing coal power infrastructure.

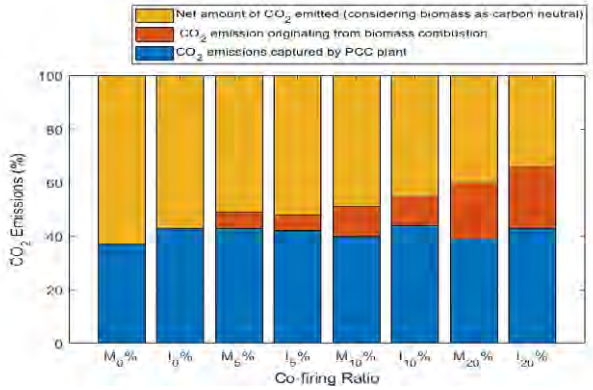

**Figure 1.** Environmental performance of CBCCS system under at various biomass co-firing ratio under carbon price regime

## Economic transparency

Figure 2 illustrates the economic performance of the CBCCS system, focusing on plant revenue, $CO_2$ emission costs, and stranded assets (SA) in Malaysia and Indonesia. In Malaysia, revenue increases modestly from USD 3 billion to USD 3.5 billion as co-firing ratios rise to 20%, while Indonesia sees higher revenue due to its higher electricity prices and low carbon price. Both countries show exponential growth in FiT rates, highlighting the need for financial incentives to offset higher operational costs. The $CO_2$ emission costs decline with higher co-firing ratios, with Malaysia consistently having higher costs due to its higher carbon price. For stranded assets under the physical lifetime, Malaysia shows a higher baseline (USD 2.1 billion) compared to Indonesia (USD 1.8 billion), but both exhibit a slight decline with higher co-firing, suggesting biomass integration helps hedge against future carbon regulations. The economic lifetime SA risk remains stable, though Malaysia consistently faces higher risks. These results indicate that CBCCS systems, while requiring significant initial investment and policy support, offer substantial benefits in reduced carbon costs and stranded asset risk. The differences system, while requiring significant initial investment policy support, offer substantial benefits in reduced and

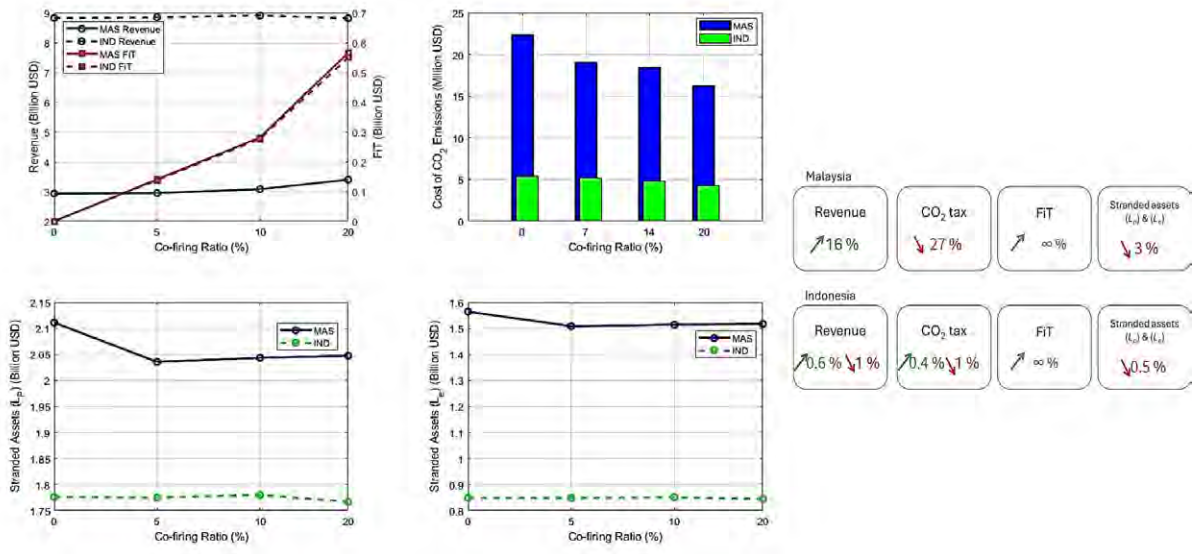

**Figure 2.** Economic performance of CBCSS system at various biomass co-firing ratio under the carbon price regime**.**

between Malaysia and Indonesia are mainly due to infrastructure age, policy frameworks, and market dynamics. The comparative dashboard (Figure 2, right) provides a scalable performance overview from 2024 to 2034, serving as a guideline for future implementation.

## CONCLUSION

Biomass co-firing (5-20%) in Malaysia and Indonesia shows minimal impact on plant efficiency (~1%) but manage to reduce net $CO_2$ emissions (43% Malaysia, 34% Indonesia). At 20% co-firing, Malaysia sees revenue growth even under the high carbon price, while Indonesia faces deficit. This preliminary work shows that Malaysia has higher stranded asset risk, though increased co-firing slightly reduces this risk in both countries**.**

# Genetic Algorithm-Driven Design of CCUS and Hydrogen Pipeline Networks: Decentralised Expansion with Complex Geographical Constraints

**Joseph Hammond[a] and Solomon Brown[a]***

[a] School of Chemical, Materials, and Biological Engineering, University of Sheffield, Sheffield, S1 3JD, UK
* Corresponding Author: s.f.brown@sheffield.ac.uk

## ABSTRACT

The development of Carbon Capture, Transport, and Storage (CCTS) and hydrogen pipeline networks is crucial for achieving deep decarbonisation in industrial sectors. However, existing network design models often assume perfect foresight, limiting their applicability to real-world infrastructure planning, which is inherently uncertain and iterative. This study introduces a novel rolling-horizon methodology for pipeline network expansion, leveraging a genetic algorithm-based approach that allows for adaptive routing and incremental infrastructure development. By comparing rolling-horizon designs to 2050-optimised networks in a case study of the Humber region in the UK, the analysis highlights the trade-offs between adaptability and cost efficiency. Results indicate that while rolling-horizon approaches better reflect real-world decision-making, they also introduce inefficiencies, increasing capital expenditures by approximately 8% for both hydrogen and CCTS infrastructure. Additionally, the study examines the economic risks associated with transitioning from blue to green hydrogen production, revealing a 20-fold increase in CCTS costs per tonne of $CO_2$ when hydrogen production shifts to green. The findings underscore the importance of integrating uncertainty-aware strategies in infrastructure planning to mitigate inefficiencies while maintaining adaptability to technological and policy changes.

**Keywords**: Carbon capture transport and storage, Hydrogen, GIS, Infrastructure, Rolling-horizon

## BACKGROUND

Transitional pipeline infrastructures, such as Carbon Capture, Transport, and Storage (CCTS) and hydrogen networks, have the potential to facilitate a low-carbon transition in fossil fuel dependent industries, particularly in foundational sectors such as iron and steel, chemicals, and power generation [1]. However, the path to sectoral and site-specific decarbonisation is paved with uncertainties [2]. These challenges arise from the dynamic evolution of technologies, shifting policy priorities, and the need to align stakeholder decisions, all of which complicate the development and long-term adaptability of these infrastructures [3].

Spatially-explicit computational models enable the design and evaluation of pipeline networks by incorporating geographical, technological, and policy-related constraints. To create resilient and adaptive infrastructures, these models must address both spatial and temporal complexities. The spatial aspect involves determining optimal routes while accounting for geographical and environmental constraints, whereas the temporality considers how these networks evolve over time in response to changing demands, technologies, and policy goals.

Static models, offering a snapshot design at a single point in time, determine the optimal topology and specifications of the pipeline infrastructure for a specific configuration of sites. Topological considerations require a spatially-explicit model to ascertain the route. This has mostly been achieved using grid-based methods and pathfinding algorithms, such as the well-known A* algorithm, to develop candidate networks that a subsequent optimisation method can utilise to optimise the infrastructure [4,5]. More recently, Hammond et al. [6] presented a graph-based, multi-stage approach for pipeline

infrastructure design that generates networks across a geographically complex region for a given set of sites. Removing the need for a candidate network structure and optimising the route directly.

While static models provide valuable insights, they fail to capture the dynamic nature of infrastructure development. Temporal dynamism is crucial for understanding the impact of changing conditions over time. Existing models often assume perfect foresight in hydrogen [7,8] and CCTS [9-11] network design, where infrastructure is designed to accommodate a known future state. André et al. applied a backward approach to describe the time development of hydrogen networks, starting with the target year and retrospectively determining the configurations, therefore optimising the infrastructure for the end point. Becattini et al. [10] provided a more advanced perfect foresight approach which leverages the uptake forecast to optimise the CCTS network across all time steps. The study examines a 25-year time horizon using both static and dynamic cases to discover that the optimal dynamic strategy delays the installation of infrastructure to reduce overall costs by leveraging discounted future flows.

These approaches simplify the design process but do not mirror real-world decision-making processes and constraints, limiting its applicability to network strategists and planners. Perfect foresight assumes a level of certainty and coordination that rarely exists in practice, overlooking the iterative, adaptive nature of infrastructure development. Delaying investments risks increased long-term costs, lost opportunities for early adoption, and challenges in stakeholder alignment.

In contrast, rolling-horizon models adopt a myopic approach, where infrastructure is developed incrementally in response to immediate needs and uncertainties. Few pipeline infrastructure network models utilise non-anticipatory rolling-horizons frameworks. Johnson and Ogden [12] demonstrated this approach with their HyPAT model, which simulates hydrogen infrastructure deployment under a staged, rolling-horizon framework. However, the model's broader limitation lies in its flexibility to adapt routing and pipeline design between time steps, reducing its ability to fully explore and optimise network evolution in response to shifting spatial and operational demands.

The advantages of rolling-horizon models are grounded in their capacity to address shortcomings of perfect foresight approaches. First, as Papadimitriou and Fortz [13] argue, rolling-horizon models better reflect real-world decision-making by breaking long-term plans into iterative and manageable stages. Second, they are inherently adaptive, enabling designs to respond dynamically to changes in demand, technology, and policy over time. Third, and central to this study, is the idea that strategic insights derived from perfect foresight models overlook the complexities of real-world uncertainties. Unlike static optimisations models, rolling-horizon models integrate recourse decision-making, where future uncertainties unfold sequentially, allowing adjustments at each stage based on updated information. This aligns with principles of stochastic control and dynamic programming, which highlight the benefits of making decisions that evolve over time rather than relying on fixed, foresight-dependent solutions [14].

Building on these principles, this study introduces a novel rolling-horizon methodology for designing pipeline networks that grow incrementally while addressing complex spatial constraints. Unlike existing models that assume straight-line connections between nodes [7-10] or rely on predefined candidate networks [4,5,11,12], this approach allows the network to evolve freely. By removing the reliance on candidate networks, the methodology accommodates adaptive routing configurations that reflect real geographical constraints.

To demonstrate the applicability of this approach, the study explores the co-design of CCTS and hydrogen infrastructures, with a focus on the transition from blue to green hydrogen production. This transition poses risks such as stranded assets and operational challenges, which the proposed methodology uncovers. As far as the authors are aware, no prior studies have investigated the co-design of these infrastructures with high spatio-temporal resolution and adaptability, further underscoring the novelty of this contribution.

The methodology is described in Section 2, which is applied to the case study described in Section 3. Section 4 discusses the findings and results, and Section 5 concludes this work.

# METHODOLOGY

## Network Design

The proposed methodology is built upon the multi-stage approach presented in Hammond et al. [15] and Hammond et al. [6], where the routing is defined using a modified Steiner tree with Obstacles Genetic Algorithm (StObGA) [16]. The premise is that the network, described by the genome, converges on an optimal network configuration by learning to traverse across the cost surface made up of polygonal obstacles which represent geographic constraints.

This study presents an algorithmic development that enables the rolling-horizon designs of spatially-aware routes across complex terrains. At each time step, the algorithm minimises the weight network length ($L_n^w$), as defined in Equation 1. This is calculated over the set of arcs $A$, where each arc $(i,j)$ consists of obstacle-constrained lengths ($L_{ij,o}^{obs}$) weighted by penalty $w_o$ for obstacles $o \in O$, and obstacle-free lengths ($L_{ij}^{free}$).

$$min(L_n^w) = \sum_{(i,j)\in A}(\sum_{o\in O_{ij}} L_{ij,o}^{obs} \cdot w_o + L_{ij}^{free}) \quad (1)$$

The genetic algorithm's genome, given in Equation 2, describes the infrastructure's network in two parts: 1) the locations of terminal nodes, Steiner points, and bifurcation nodes; and 2) fixed-length binary list that determines which corners points of the polygonal obstacles are activated. Bifurcation nodes are introduced as nodes that are placed along existing arcs to allow for flexible expansion from a previous network structure.

$$\big((x_1, y_1), (x_2, y_2), \dots, (x_s, y_s)\big) + [1\ 0\ 1\ 0\ 0\ 0\ 1\ 1\ 0\ 0] \quad (2)$$

The pipeline design optimisation is a MINLP formulation that minimises the total pipeline costs ($C$) according to the objective function given in Equations 3 and 4. The capital cost ($C_{ij}^C$) for each arc $(i, j)$ in the network is determined by the number of parallel pipelines ($N_{ij}^p$), the outer diameter ($D_{ij}^{po}$), and the weighted pipeline length ($L_{ij}^w$). The network's operating cost is assumed to be 4% of the capital cost annually. Hydraulic, structural, and commercial availability constraints are considered as described in Hammond et al. [6]. The pipeline sizes are oversized to align with the optimal final infrastructure configuration in 2050.

$$\min C = (1 + 0.04) \sum_{i|(i,j)\in A} C_{ij}^C \quad (3)$$

where

$$C_{ij}^C = N_{ij}^p(61e^{2.74D_{ij}^{po}} + 376\big(D_{ij}^{po}\big)^2 + 2290D_{ij}^{po} + 278)L_{ij}^w \quad (4)$$

## Geographic Information System

The Geographic Information System (GIS) created for this study, depicted in Figure 1, is the collation of many constraints collected from publicly available datasets. These constraints are grouped into category penalties, informed by the literature [17], technical reports [18], and confidential discussions with industry experts, presented in Table 1.

**Table 1:** Categories of geographical features with corresponding penalty weighting.

| Penalty category | Geographic features | Penalty weighting |
|---|---|---|
| Untraversable | National parks | ∞ |
| Very high | Rivers | 50 |
| High | Urban areas, conservation areas | 5 |
| Medium | Woodlands, historic landfills | 3 |
| Low | Roads, rails, peaty soils | 1.2 |

## CASE STUDY

The case study explores CCTS and hydrogen infrastructure design in the Humber region of the UK, a significant industrial hub with high emissions density. Two scenarios are compared across six time steps to assess their impact on the economic viability of CCTS infrastructure: 1) Blue hydrogen production plants transition to green hydrogen production in 2040; and 2) Blue hydrogen production plants continue operating without transitioning to green hydrogen.

The purpose of comparing these scenarios is to investigate the impact that this transition has on the economic viability of the CCTS infrastructure.

The study evaluates a network consisting of 9 hydrogen production plants, 45 hydrogen consumers, and

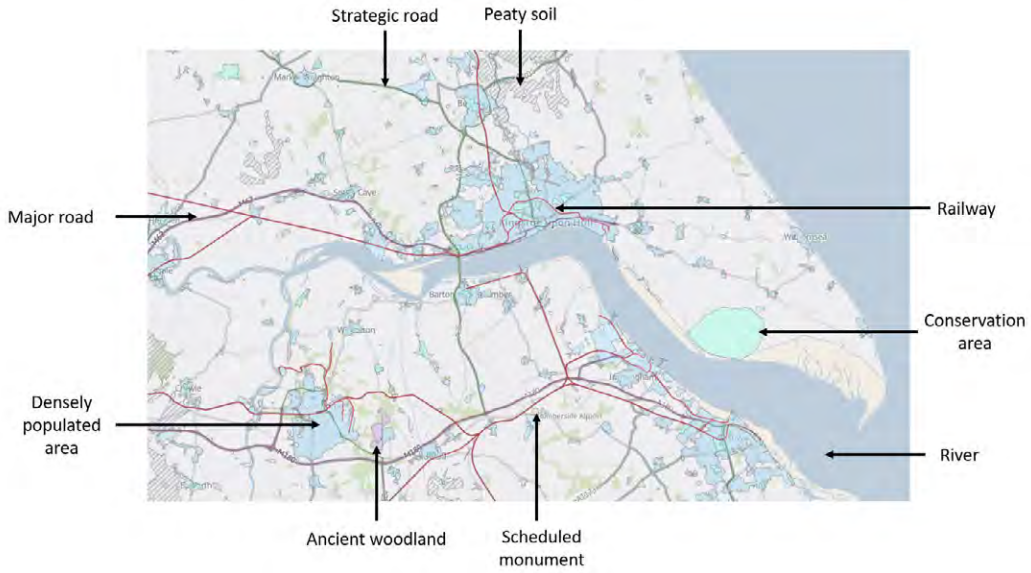

**Figure 1:** Geographical features considered for pipeline routing in the Humber, UK case study.

21 $CO_2$ capture facilities. Captured $CO_2$ is transported to a designated offtake point, where it is considered stored. The model assumes the presence of compressor stations at all sites with fluid outflows and at junctions where multiple pipelines converge. These stations compress hydrogen to 70 bar and $CO_2$ to 35 bar, ensuring efficient transport.

Pipeline design includes 817 unique combinations of inner and outer diameters, ranging from DN6 to DN2300, with a wide range of schedules. This broad range accommodates different operational and economic scenarios, ensuring flexibility in network optimisation.

## RESULTS AND DISCUSSION

### Design analysis

Figure 2 compares the rolling-horizon and 2050-optimised designs for hydrogen and CCTS infrastructure. The rolling-horizon approach (A1, B1) results in an incremental network expansion, with early-stage infrastructure aligning with immediate demand and gradually adapting over time. In contrast, the 2050-optimised design (A2, B2) represents an idealised final-state configuration, assuming perfect foresight of future requirements.

A visual analysis highlights the topological differences that emerge as a result of the iterative nature of rolling-horizon designs. As shown in B1 and B2, the 2050-optimised design takes a route south of the river, whereas the rolling-horizon planning approach follows a northern route. This divergence occurs due to the sequential nature of rolling-horizon planning – the network expands based on immediate cost and connectivity considerations, without foresight of potential long-term inefficiencies. As a result, rolling-horizon designs may lead to routing decisions that, while reasonable given the available information at each stage, may require adjustments as the network evolves.

Figure 3 illustrates the capital investment trends for the hydrogen and CCTS infrastructures over time, comparing rolling-horizon expenditures with the total cost of the 2050-optimised network. The difference in capital investment between these approaches is substantial. Given the high cost of pipeline infrastructure, even small inefficiencies in routing and capacity planning result in significant financial losses. For hydrogen infrastructure, rolling-horizon inefficiencies result in an additional 23.4 million USD in capital expenditures, accounting for approximately 8% of the total investment. Similarly, for CCTS infrastructure, the inefficiency gap amounts to 7.2 million USD, also around 8% of the required investment.

While the 2050-optimised design achieves greater cost efficiency, it assumes perfect foresight which is not attainable in real-world infrastructure planning. Rolling-horizon approaches, by contrast, reflect the iterative design-making process that network designers must navigate. This study highlights not only the financial

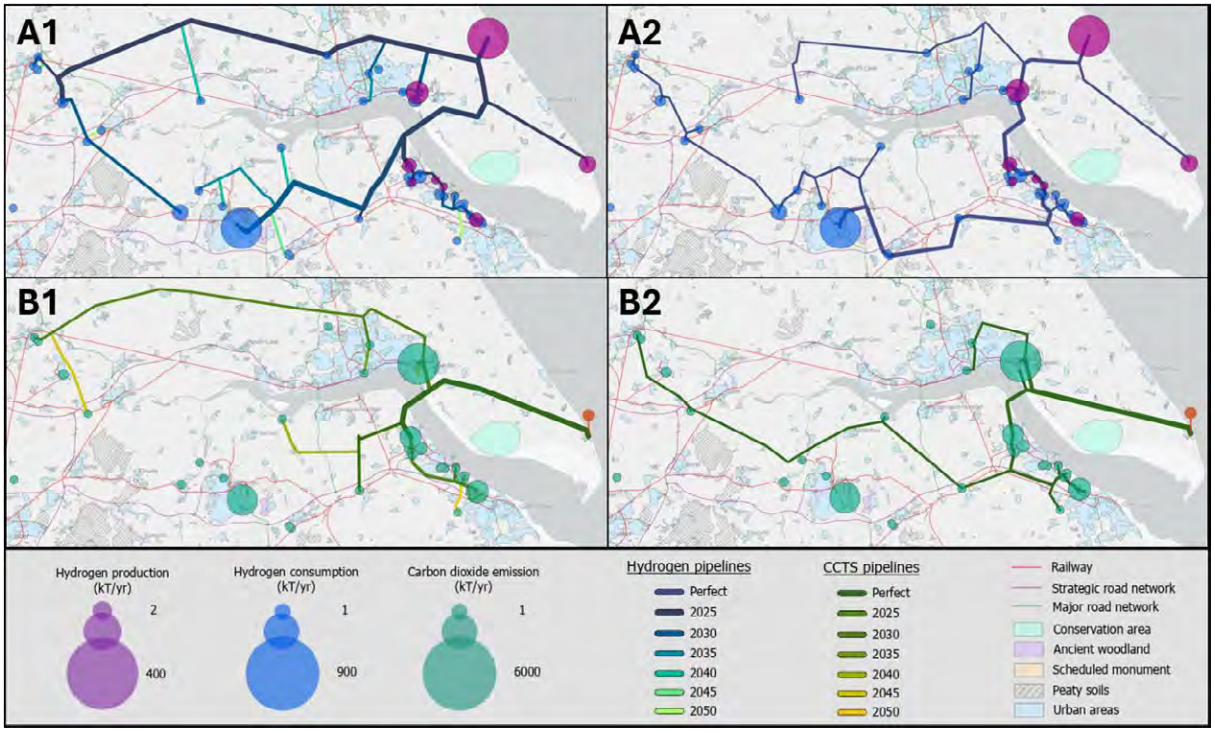

**Figure 2:** Rolling-horizon (A1, B1) vs. 2050-optimised (A2, B2) designs for hydrogen (A) and CCTS (B) infrastructure in the Humber region.

implications of rolling-horizon inefficiencies, but also the importance of developing strategies to mitigate them.
The design tool presented here provides a framework to test rolling-horizon strategies under various potential scenarios. By integrating uncertainty-aware decision-making, future iterations of rolling-horizon planning can minimise inefficiencies while maintaining the flexibility needed to adapt to evolving demands, technological advancements, and policy changes.

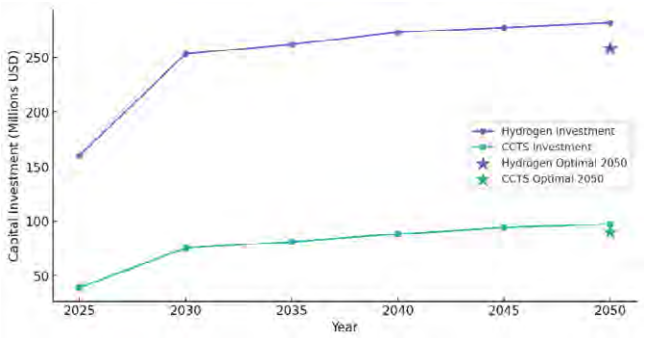

**Figure 3:** Capital investment in hydrogen and CCTS infrastructure over time, comparing rolling-horizon investments with the optimal 2050 configurations.

Table 2 compares the capital investment required per tonne of $CO_2$ saved under the two scenarios. The results indicate a 20-fold increase in CCTS infrastructure costs per tonne of $CO_2$ when blue hydrogen production transitions to green hydrogen. This surge occurs because hydrogen plants, which previously served as major $CO_2$ capture points, no longer contribute to CCTS infrastructure utilisation, reducing overall system efficiency.

It is also worth noting the operational difficulties that will coincide with such a massive reduction in fluid volume in the pipelines.

This finding underscores the interconnected nature of low-carbon infrastructure development. Decisions made in one sector, such as hydrogen production, can have significant economic and operational consequences for another, such as CCTS. As a result, strategic planning must account for cross-sector uncertainties and the evolving role of different infrastructures to avoid cost escalations and stranded assets.

**Table 2:** $CO_2$ Savings Cost ($/Tonne$CO_2$) for Hydrogen & CCTS (2025–2050). Scenario 1: Blue hydrogen; Scenario 2: Transition to green in 2040, increasing CCTS costs.

| Year | Hydrogen Infrastructure ($/Tonne$CO_2$) | CCTS scenario 1 ($/Tonne$CO_2$) | CCTS scenario 2 ($/Tonne$CO_2$) |
|---|---|---|---|
| 2025 | 423 | 128 | 128 |
| 2030 | 30 | 18 | 18 |
| 2035 | 35 | 21 | 21 |
| 2040 | 37 | 25 | 505 |
| 2045 | 42 | 28 | 544 |
| 2050 | 46 | 31 | 597 |

## Critical analysis of the model

Model validation for StObGA in a previous work [6], showed >98% accuracy in predicting route length, confirming its reliability in network design.

Unlike traditional methods, StObGA does not rely on predefined candidate networks but evolves the network by bifurcating existing pipelines. This enhances flexibility and adaptability. The model is highly scalable and provides a framework for incorporating design standards, regulations, and future scenarios testing through rules build into the genetic algorithm, making it valuable for long-term planning.

A key limitation is its inability to anticipate future uncertainties in network expansion, as it optimises only for current constraints. This may limit its effectiveness in dynamic or evolving infrastructure needs.

Simulates were run on a Precision 7875 Tower (AMD Ryzen Threadripper Pro 7945WX, 12 cores, 64 GB RAM), requiring ~2 hours for infrastructure design. Parallelisation improves performance, reducing computation time compared to sequential processing significantly.

## CONCLUSION

This study demonstrates the advantages and limitations of rolling-horizon methodologies for designing hydrogen and CCTS pipeline infrastructure in the context of heavy-industry decarbonisation. While rolling-horizon models offer a more flexible and realistic approach by accommodating evolving spatial and operational constraints, they introduce inefficiencies compared to long-term optimised designs. The case study analysis highlights how incremental infrastructure expansion can lead to higher capital expenditures and suboptimal routing decisions over time. Furthermore, the transition from blue to green hydrogen production presents significant challenges for CCTS infrastructure, with the cost per tonne of $CO_2$ increasing substantially as hydrogen plants cease to contribute to $CO_2$ capture. These findings emphasise the need for hybrid modelling approaches that balance flexibility with long-term cost efficiency. Future work should focus on integrating uncertainty-aware decision-making frameworks into rolling-horizon models to mitigate inefficiencies while ensuring adaptability to emerging technologies, policy shifts, and market dynamics.

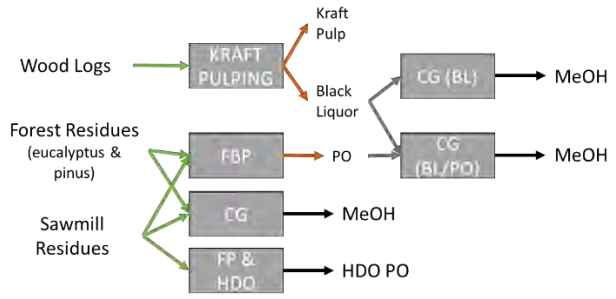
## ABSTRACT

This study introduces a mathematical programming approach to optimize biomass-to-hydrocarbon supply chain design and planning, aiming to balance economic and environmental outcomes. The model incorporates a range of residual biomass types from forestry, sawmills, and the pulp and paper industry, with the option to establish various processing facilities and technologies over a multi-period planning horizon. The analysis involves selecting forest areas, identifying biomass sources, and determining the optimal locations, technologies, and capacities for facilities converting wood-based residues into methanol and pyrolysis oil, which can be further refined into biodiesel and drop-in fuels. Using Life Cycle Assessment (LCA) in a gate-to-gate analysis, forest supply chain carbon emissions are estimated and integrated into the optimization model, extending previous research. A multi-objective framework is employed to minimize $CO_2$-equivalent emissions while minimizing present costs, with efficient Pareto points evaluated in a case study focused on the Argentine forest industry.

**Keywords**: Supply Chain, Life Cycle Analysis, Biomass, Optimization.

## INTRODUCTION

Forest supply chains (FSCs) are critical for achieving decarbonization targets [1]. FSCs are characterized by abundant biomass residues, offering an opportunity to add value to processes while contributing to the production of clean energy products. One particularly interesting aspect is their potential integration with oil refineries to produce drop-in fuels, offering a transformative pathway to mitigate traditional refinery emissions [2].



In this article, a disjunctive mathematical programming approach is presented to optimize the design and planning of the FSC for the production of hydrocarbon products from biomass, optimizing both economic and environmental objectives. Various types of byproducts and residual biomass from forest harvesting activities, sawmill production, and the pulp and paper industries are considered. Alternative processing facilities and technologies can be established over a multi-period planning horizon. The design problem scope involves selecting forest areas for exploitation, identifying biomass sources, and determining the locations, technologies, and capacities of facilities that transform wood-based residues into methanol and pyrolysis oil, which are further processed in biodiesel and petroleum refinery plants, respectively. This problem is challenging due to the complexity of the supply chain network, which involves numerous decisions, constraints, and objectives. In particular, in the case of large geographical areas, transportation becomes a crucial aspect of supply chain design and planning because the low biomass density significantly impacts carbon emissions and costs. Thus, the scope of planning the problem includes selecting connections and material flows across the supply chain. A multi-objective approach is proposed to assess economic and environmental objectives. A set of efficient Pareto points is

obtained and compared in a case study of the Argentine forest industry.

## PROBLEM STATEMENT

A supply chain superstructure is considered in this paper formed by three echelons: the feedstock areas where pine and eucalyptus logs, forest residues, and sawmill residues are obtained; the processing facilities, where biomass is converted into fuels and intermediates; and the consumer nodes (biodiesel plants or petroleum refineries). Logs are used for the paper industry, i.e., the kraft pulping process, while residues from all sources are transformed into fuel products. Stand-alone and integrated plants can be selected to produce intermediate or final products (hydrogenated pyrolysis oil for petroleum refineries and methanol for biodiesel plants).

Process alternative pathways are presented in Figure 1.

References: BL: black liquor; CG: catalitic gasification; FBP: fluidised bed pyrolysis; FP: fast pyrolysis; PO: Pyrolysis oil; HDO: Hydroxygenation; HDO PO: Hydroxygenated pyrolysis oil.

**Figure 1.** Process alternatives.

The problem studied can be stated as follows, given: processing, investment and transportation costs; environmental impact of each process, measured in equivalent carbon emissions; products' demand; capacity levels and economy scale factors; biomass availability and allowed capacity expansions in forest nodes; processing yields. The model must select over a multi-period timeframe: (i) The extent of land and types of tree species to be harvested at each forest location and within each time period; (ii) The processing facilities to be established at each location over time, including their technology, scale, and degree of integration; (iii) The output levels for each technology and processing plant in every time period; (iv) The capacity outlines for each supply chain processing facility across the entire timeline; (v) The transport flows of all materials and supply chain linkages across each time period. The goal is to minimize the present costs and the environmental impact of the supply chain.

## MULTI-OBJECTIVE APPROACH

As mentioned, this article extends previous work from Piedra-Jimenez et al. [3], where the supply chain is optimized assuming an economic objective function (minimizing total present costs). The deterministic formulation presented there is reformulated as a bi-objective model to include the minimization of the CO2 equivalent emissions.

The Life Cycle Assessment (LCA) methodology is used to estimate FSC carbon emissions. A gate-to-gate analysis is carried out for each activity in the FSC and combined with the optimization problem to obtain a cradle-to-gate LCA. The predicted LCA results are then integrated as input parameters into a mathematical programming model for FSC design and planning to optimize the bi-objective problem. This formulation is solved by assuming the Ɛ-constraint approach to obtain a set of Pareto optimal points. The total impact is presented in Eq. (1). Transportation emissions are estimated in Eq. (2), and emissions from processing facilities are estimated in Eq. (3). Due to space limitations, the rest of the formulation is not transcribed here, as it can be found in Piedra-Jimenez et al. (2024), resulting in a generalized disjunctive model (GDP) implemented as a mixed integer linear programming (MILP) model using Big M reformulation.

$$CO_2e = TCO_2e + PCO_2e \tag{1}$$

$$TCO_2e = \sum_{(r,s)\in M_{RS}} \zeta 1_{r,s} \cdot \rho 1_{j,k} \cdot F1_{r,s,j,k,m,t} + \sum_{\substack{(i,m)\in M_I \\ (i,m')\in I_M}} \zeta 2_i \cdot \rho 2_{k,k'} \cdot F2_{i,k,m,k',m',t} + \sum_{(o,m)\in M_O} \zeta 3_o \cdot \rho 3_{k,l} \cdot F3_{o,k,m,l,t} \quad \forall\, t \tag{2}$$

$$PCO_2e = \sum_{(r,s)\in M_{RS}} \vartheta 1_{r,s,m} \cdot F1_{r,s,j,k,m,t} + \sum_{\substack{(i,m)\in M_I \\ (i,m')\in I_M}} \vartheta 2_{i,m} \cdot F2_{i,k,m,k',m',t} \tag{3}$$

### Parameters

$\zeta 1_{r,s}$ carbon dioxide equivalent emission for the transportation truck used for raw material (r,s) from sources j to plants k (t CO2 Emission/ t-km)

$\zeta 2_i$ carbon dioxide equivalent emission for the transportation truck used for intermediate product i from plants k to other facilities k (t CO2 Emission/ t-km)

$\zeta 3_o$ carbon dioxide equivalent emission for the transportation truck used for product o from plants k to clients l (t CO2 Emission/ t-km)

$\vartheta 1_{r,s,m}$ carbon dioxide equivalent emission from processing raw material r from tree species using technology m (t CO2 Emission/ t feedstock)

$\vartheta 2_{i,m}$ carbon dioxide emission from processing intermediate product i using technology m (t CO2 Emission/ t feedstock)

$\rho 1_{j,k}$ distance between raw material nodes j and processing plants k (km)

$\rho 2_{k,k'}$ distance between processing plants k and k' (km)

$\rho 3_{k,l}$ distance between processing plants k and clients l (km)

## Positive variables

$F1_{r,s,j,k,m,t}$ amount of raw material r of tree species s from node j to facility node k produced with technology m in period t

$F2_{i,k,m,k',m',t}$ amount of intermediate product i produced from processing node k which applying technology m that is consumed by node k´ for further processing with technology m´ in period t

$F3_{o,k,m,l,t}$ amount of final product o produced with technology m in location k to satisfy demand node l in period t

$TCO_2e$ carbon equivalent emissions from transportation activities

$PCO_2e$ carbon equivalent emissions from processing facilities

$CO_2e$ total carbon equivalent emissions

The resulting formulation is a linear generalized disjunctive model that is reformulated with Big-M relaxation.

# CASE STUDY AND RESULTS

Open LCA and EcoInvent 3.11 were used to estimate the equivalent $CO_2$eq emissions from processes and transportation following ISO 14040 and ISO 14044 [4, 5]. The processes characteristics regarding energy consumptions, efficiency, yields, were obtained from the literature [6 - 13]. Power energy matrix from Argentinean case study is estimated considering reports from the country [14]. A 15-year horizon planning (HP) is assumed.

The resulting emissions from each process and the input and output characteristics are presented in Table 1.

Regarding transportation, EURO 3 truck technology is assumed. The capacity assumed is based on typical cargo transportation options in Argentina (28.5 t for all type of products and an additional limitation of 37 $m^3$ for liquids). Since no data for this country is available in LCA database, the rest of the world (RoW) reported emission from the EcoInvent is assumed. This value is estimated considering an average capacity load of 5.8 t.

In the Argentinean case study, the average load is quite larger than the one reported in the EcoInvent database. Therefore, the transportation emissions per ton-km are estimated according to the Argentinean load factor. This type of procedure is supported, for instance, in [15]. It is assumed that the trucks are used with 90% of the full load of a one-way trip and an empty return is considered. This estimation is presented in the last line of Table 2. For the different products, their density is used to calculate if the capacity restriction is determined by the volume or the weight of the truck. Except for the saw-mill residues, in all cases, the maximal weight is the active limitation. The calculated emission for each type of product is presented in Table 2.

The supply chain nodes considered are located in the northeast and center regions from Argentina as depicted in Figure 2. The FSC superstructure consists of 25 supply sources, 3 operational kraft pulp mills, 13 potential biorefinery locations, and 26 demand nodes (21 soybean-based biodiesel plants and 5 petroleum refineries).

**Table 1:** Process characteristics and estimated emissions from LCA analysis.

| Material Input | Flowrate input (t/h) | Technology | Material Output | Flowrate Output (t/h) | Emission (t CO2eq /t input) |
|---|---|---|---|---|---|
| Saw-mill residues | 43.29 | Fast Pyrolysis | FP Oil | 21.65 | 0.42627 |
| FP Oil | 21.65 | Hydroxgenation (HDO) | HDO Bio-oil | 14.29 | 0.20465 |
| Forest Residues | 52.70 | Catalytic Gasification (1) | Methanol | 22.7 | 0.18654 |
| Forest Residues | 20.90 | Fluidised Bed Pyrolysis | FBP Oil | 7.56 | 0.26788 |
| FBP Oil + Black Liquor | 43.4 + 173.6 | Catalytic Gasification (2) | Methanol | 62.5 | 0.62199 |
| Black Liquor | 173.60 | Catalytic Gasification (3) | Methanol | 40.1 | 0.26254 |

**Table 2:** Estimated emissions for transportation alternative and material.

| Type of truck | Emission* | Saw-mill residues | Forest residues | Forest logs | FBP Oil | HDO Bio-oil | Methanol |
|---|---|---|---|---|---|---|---|
| Euro 3 16-32 Tons | 0.196 | 0.1183 | 0.0885 | 0.0885 | 0.0885 | 0.0885 | 0.0885 |
| Average load in t | | 10 | 13 | 13 | 13 | 13 | 13 |

* Data from EcoInvent Database 3.11 for RoW assuming 5.8 t of average capacity use
All reported units are in (kg CO2eq/t-km)

The model was implemented in GAMS and executed using solver CPLEX on a 32GB RAM machine with Intel Core i9-11900K 3.50GHz CPU. The problem consists of 4,968 integer variables, 88,016 continuous variables and 59,654 constraints. Each iteration (one per Pareto point) was executed to global optimality (gap 0%) in less than 9 minutes.

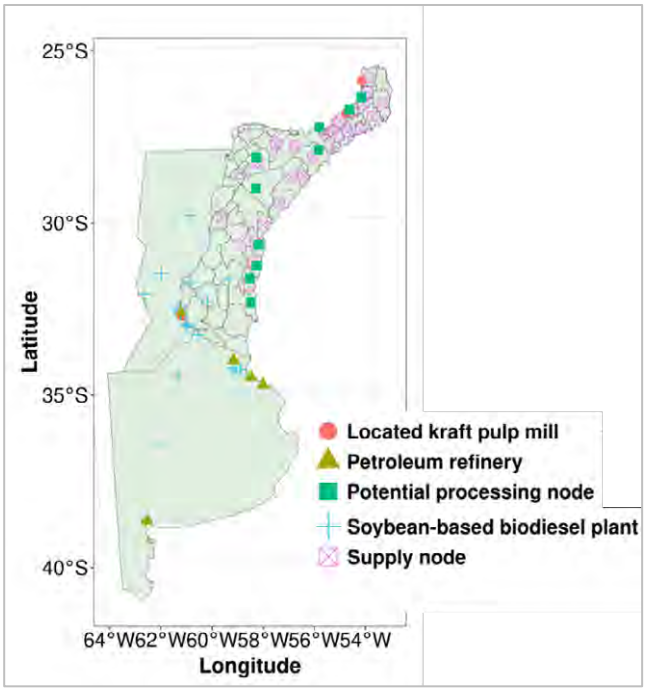


**Figure 2.** Locations for supply chain nodes.

The optimal solutions obtained are depicted in Figure 3, showing the compromise between the two proposed objectives.

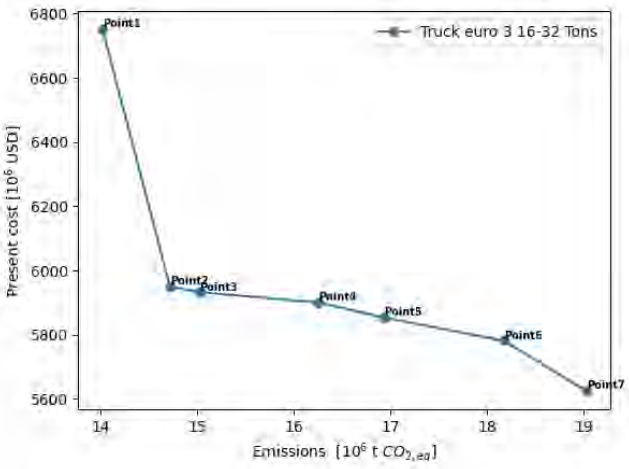

**Figure 3.** Pareto front.

Considering the relative difference between points, the best compromise solution is given in point 2, i.e. a relevant decrease in present cost is shown at an expense of small increment in CO2 emissions. In this point, total emissions for the 15-year HP are 14,719,296 ton of CO2eq while total present costs are USD 5,949,789,094.

Figures 4 and 5 present the environmental and cost functions breakdown, respectively. In all cases, process emissions are larger than the ones from transportation. Particularly, processing forest biomass is the one that most contributes to the CO2 equivalent emissions. Regarding transportation, the larger emission from transportation of final products can be explained by the distances between nodes. Considering all solutions, the main difference in the emissions scheme is observed from point 1 to 2. In the first solution, only sawmill residues and forest biomass are consumed as raw materials. To improve costs, the use of intermediate products (such as black liquor and pyrolysis oil) is increased while sawmill residues consumption diminishes.

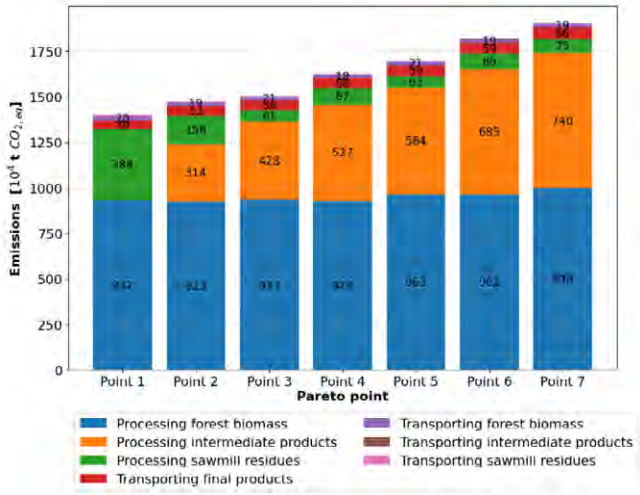

**Figure 4.** Emissions breakdown for all points

In the case of present costs, main component is given by investment cost in new plants followed by the variable cost for processing forest biomass. Except for the first point as mentioned before, the cost breakdown does not significantly change among points.

The selected technologies and plant locations are presented in Figure 6 for point 2 that is considered the best compromise solution. Two plants for producing HDO PO are installed, one located near 3 petroleum refineries and the other placed in the biomass sourcing area. Two plants are integrated to Kraft mills for producing methanol from black liquor via catalytic gasification. Another stand-alone plant is installed for producing methanol from forest residues using catalytic gasification technology.

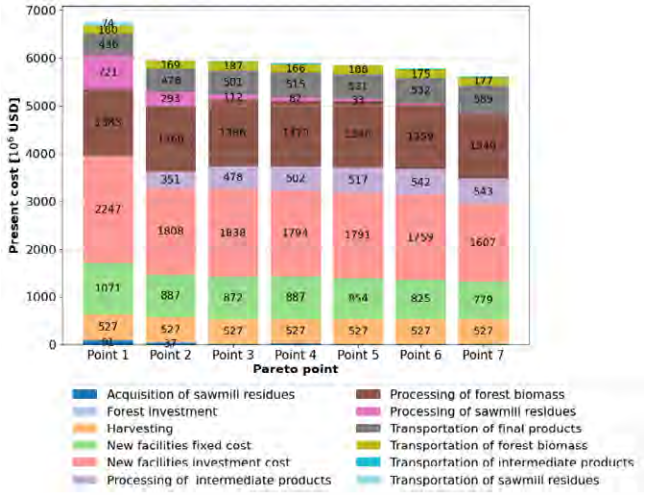

**Figure 5.** Present costs breakdown for all points

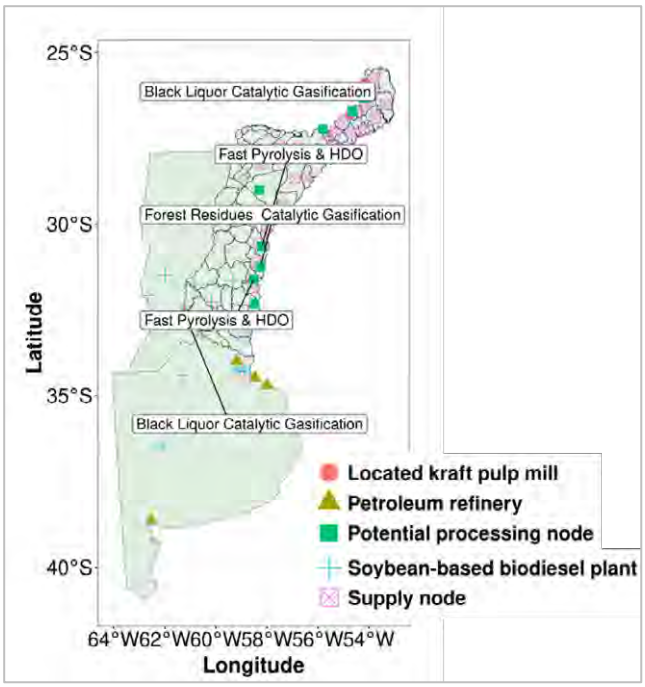

**Figure 6.** Technologies and locations selected.

**Table 3:** Carbon intensity mean values.

| Product | Co2 intensity (ton Co2eq/ton product) | Co2 intensity (g Co2eq/MJ) |
|---|---|---|
| HDO PO | 1.65129 | 55.04 |
| Methanol | 0.98780 | 43.52 |

Table 3 presents the average carbon intensity for the produced bio-methanol and hydroxigenated pyrolysis oil. The fluctuations between points on the Pareto curve in unit emissions for hydrogenated pyrolysis oil are negligible. Only very small changes are observed. In the case of methanol, although there are variations between points, the maximum difference is less than 30%.

## CONCLUSIONS

This article extends previous work by incorporating carbon emissions in the forest supply chain as a second optimization objective. The LCA methodology was applied to assess the environmental emissions of each activity within the supply chain's scope. A clear compromise solution can be selected, maintaining a good balance between present costs and total emissions.

The proposed model serves as a valuable tool for guiding the decision-making process, considering both economic and environmental perspectives in a supply chain that could reshape the wood-based industry in Argentina. The results indicate that residual biomass from this sector can be converted into value-added products, replacing their fossil-based alternatives. Future work includes testing the model computational performance for other instances considering other regions, input data and increasing problem size.

## ABSTRACT

Traditional scheduling approaches often rely on simplified process representations to reduce computational complexity, failing to capture the real-world dynamics where tasks often overlap, and their timing depends on finer operational steps. To address these limitations, this paper proposes a novel process representation that breaks down production tasks into smaller, more primitive steps called operations. Unlike traditional methods, this approach provides a more granular depiction of task timing and resource dependencies. Operations can define the start or end of other tasks, utilize shared resources, and incorporate recipe constraints that mandate task sequencing. The proposed representation is utilized to develop two MILP models to address the makespan and the cycle time minimization problems. Finally, the efficiency and practical applicability of the developed models are showcased with a help of a case study from the pharmaceutical industry.

**Keywords**: production scheduling, process representation, mixed integer programming, makespan, cycle time

## INTRODUCTION

The highly competitive industrial landscape enforces companies to strive for profit maximization. In that line, optimal production scheduling plays a significant role in ensuring the efficient utilization of the available resources and the increase of productivity. Effective schedules allow companies to improve important Key Performance Indicators (KPIs) like, customer satisfaction, mitigation of overproduction and overall profitability boost. However, the optimal production scheduling problem remains a significant challenge due to its high combinatorial complexity, arising from the dynamic and interconnected nature of modern manufacturing. More specifically, in chemical process production steps often overlap and their exact timing and duration can be influenced by dependencies between operations and shared resources usage. These production details are often overlooked in traditional process representations for production scheduling, resulting in suboptimal solutions that may not reflect real-world conditions.

A plethora of mathematical optimization models, such as mixed-integer linear programming (MILP) has been proposed to solve the optimal production scheduling problem [1]. Formulating the production scheduling problem as an MILP model requires a coherent representation of the production process. The most used representations are the State-Task-Network (STN) [2] and the Resource-Task-Network (RTN) [3]. These were initially introduced for network production environments and were later extended to include sequential and hybrid environments. Numerous extensions of the STN and the RTN have been proposed by the scientific community, that e.g. include the structural aspects of the plan [4] or consider routing limitations [5]. Recently, the General Material Task System (GMTS) representation has been proposed for systems with multiple production environments and diverse types of processes [6]. However, applying such methods in industrial practice is difficult. Simplified process representations are often used to make scheduling problems computationally feasible, but they fail to capture the complexity and flexibility inherent in production systems. Traditional approaches treat batch processing stages as rigid blocks, with fixed precedence constraints determining the order in which tasks are executed. In a real production environment, the tasks rarely follow strict sequential execution. On the contrary, they often overlap, and their exact timing is driven by

operations that are highly dependent on resource availability and inter-task dependencies. This mismatch between traditional scheduling models and real-world production highlights the need for a more flexible and accurate approach.

To address these limitations, this paper introduces a novel process representation that captures the complex interactions between tasks, their resource requirements, and timing uncertainties inherent in production environments. Tasks are broken down into smaller processing steps called procedures and operations, capturing the interdependencies between tasks and their resource requirements. Operations are tied to recipe constraints that define strict sequencing rules, but timing flexibility can be introduced using dummy operations with variable durations. This approach allows the model to handle timing uncertainties and resource-sharing scenarios more effectively, making it possible to generate optimized schedules that closely reflect real-world production realities. The proposed representation is incorporated into a MILP-based scheduling framework, improving the accuracy and reliability of scheduling decisions without significantly increasing computational complexity. Two MILP models for makespan minimization and cycle time minimization are developed with their applicability and efficiency demonstrated through case study applications.

## MATHEMATICAL FORMULATION

### Process Representation

A batch process consists of processing tasks (*procedures*) each executed in some equipment unit. Within a procedure, more primitive processing steps (*operations*) can be recognized. For example, a fermentation procedure consists of a series of operations such as SIP, loading of materials, heating, fermenting, transferring-out the broth, CIP etc. With the exception of the main equipment unit defined at the procedure level, all other resources (materials, utilities, labor etc.) are consumed at the operation level. Relative timing of all processing tasks is also done at the operation level. This is an important aspect of the proposed formulation which differentiates it from established process representations. Moreover, it offers an intuitive representation for process engineers, as it aligns perfectly with how they conceptualize and structure their process.

In batch processing, the set of all procedures comprises the process *recipe* for the production of a stable product or intermediate. Unlike discrete manufacturing industries, recipes in processing industries are, in general, rigid structures with operations executed in sequence or in parallel with fixed timings. However, in many cases, the execution of certain operations could be delayed if the required resources are not available. For example, a CIP operation can wait up to a certain time (the dirty-hold time) if the required cleaning skid is not available. This kind of flexibility in the execution of operations is introduced in the formulation in the form of flexible shifts which denote the maximum possible delay (positive for forward scheduling, negative for backward scheduling). For consistency with the rest of the representation, flexible shifts are modelled as "dummy" operations with variable duration.

Let $M$ be the set of all operations in a recipe. Each operation, $m$, in this set is given a triplet of variables for its start ($s_m$), duration ($d_m$) and end ($e_m$) which we call "timing elements". Because of the way recipes are executed, all these timing elements are interrelated (e.g. the start of one operation coincides with the end of the previous). Figure 1 shows an example of the proposed representation for a fermentation procedure. A dummy "Flexible Delay" operation has been added to the list of actual operations to represent the possible delay in the execution of the CIP operation if needed. The duration of this dummy operation is considered variable.

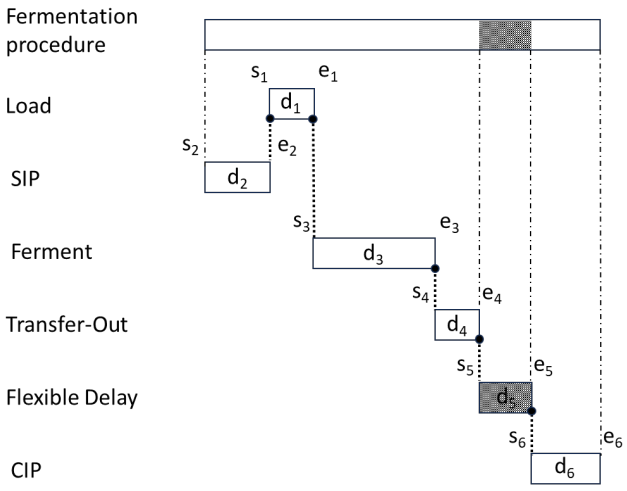

**Figure 1.** Representation of a fermentation procedure.

Let $V$ be the set of all timing elements in the recipe ordered by dependency. Then, it is possible to construct a lower-triangular matrix, $\sigma$, whose entries represent the coefficients in the dependency equations. In other words:

$$V = \sigma \cdot V + \varphi + F \tag{1}$$

In this equation, $\varphi$ is a vector of constant values (e.g. the fixed duration of certain operations) and $F$ is a vector of variable values (e.g. the duration of the dummy flexible shift operations).

The actual execution of a recipe constitutes a *batch*. When scheduling a batch, the objective is to find the appropriate timing values for the execution of all processing tasks and assign all needed resources. The set of processing tasks does not necessarily coincide with the set

of operations which give rise to the vector of timing elements, *V*, since, in scheduling, only tasks (procedures and operations) that consume resources are of interest. However, the timing of these tasks can be determined with the help of the timing elements.

Let *I* be the set of all processing tasks that need to be scheduled. If a task *i* represents a procedure, then its start ($L_i$) is the earliest start time of all contained operations, its end ($C_i$) is the latest end time of all contained operations and its duration ($Dur_i$) is the difference between the two:

$$\begin{aligned} L_i &\le V_n \quad \forall i \in I, n \in S_{i,n} \\ C_i &\ge V_n \quad \forall i \in I, n \in E_{i,n} \\ Dur_i &= C_i - L_i \quad \forall i \in I \end{aligned} \tag{2}$$

where $S_{i,n}$ are the indices *n* of vector *V* that the start $L_i$ of a task *i* depends upon and $E_{i,n}$ are the indices *n* of vector *V* that define the end $C_i$ of a task *i*.

Let *J* be the set of available equipment to be used for the execution of all tasks. Each task *i* (procedure or operation) has a specific pool of candidate equipment to be used for its execution. For this reason, a matrix $IJ_{i,j}$ of binary values is constructed with unary values in the permissible task-equipment pairs.

This framework can be extended to introduce equipment-related durations of operations and also compatibility/connectivity constraints between all equipment. For reasons of brevity, these extensions are not discussed in this paper.

## MILP formulation

The proposed novel production process representation is integrated within a MILP model to address the production scheduling optimization problem. The developed MILP model is based on the general precedence framework, which utilizes binary sequencing variables to indicate optimal task ordering and allows for a flexible and efficient approach to manage complex scheduling constraints. = It is important to note that the proposed process representation is versatile enough to be integrated with other MILP frameworks for optimal production scheduling.

Given a number of batches *B* of processing tasks to be processed in the available equipment *J*, the MILP model generates an optimal production schedule. It should be underlined that the set of processing tasks include all tasks (procedures and operations) that require the use of a resource. Two binary variable sets are employed to describe the allocation $Y_{i,b,j}$ and sequencing decisions $X_{i,b,i',b'}$. Moreover, continuous variables are introduced to model all time-related decisions like start ($L_{i,b}$) and completion ($C_{i,b}$) of tasks, value of timing elements ($V_{n,b}$) and duration of flexible operation shifts ($F_{n,b}$). All constraints of the model are presented below.

### Allocation constraints

According to constraint set (3), exactly one equipment *j* will process each batch *b* of task *i*. The subset $IJ_{i,j}$ represents the equipment capable of processing task *i*.

$$\sum_{j \in IJ_{i,j}} Y_{i,b,j} = 1 \; \forall i \in I, b \in B \tag{3}$$

### Timing constraints

In constraint sets (4), the value of timing elements related to all tasks, that represent a procedure or an operation ($n \notin Flex_n$) are calculated based on their relative timings ($\sigma_{n,n'}$). More specifically, the value of an entity *n* in batch *b* equals the summation of all values of all other entities *n'* of batch *b* that entity *n* depends on. Respectively, constraints (5) calculate the value of timing items related to flexible operation shifts. The difference here is that the duration is not known but it is rather an unknown variable to be optimized. Constraints (6) ensure that the start time of a task will be less than the value of all relative start elements plus the start time of the batch. Similarly, the completion times are calculated in the next constraint set (7). Notice that the inequalities are required since in the case of procedures a task may be comprised by numerous operations and flexible shifts ($n \in Flex_n$). Finally, constraints (8) and (9) denote that the batch *b* of a task *i* will start and finish after the start and completion of the previous batch *b-1*.

$$V_{n,b} = \sum_{n'<n} \left(\sigma_{n,n'} \cdot V_{n',b}\right) \quad \forall n \notin Flex_n, b \in B \tag{4}$$

$$V_{n,b} = \sum_{n'<n} \sigma_{n,n'} \cdot V_{n',b} + F_{n,b} \quad \forall n \in Flex_n, b \in B \tag{5}$$

$$L_{i,b} \le V_{n,b} + L_{i1,b} \quad \forall i \in I, b \in B, n \in S_{i,n} \tag{6}$$

$$C_{i,b} \ge V_{n,b} + L_{i1,b} \quad \forall i \in I, b \in B, n \in E_{i.n} \tag{7}$$

$$L_{i,b} \ge L_{i,b-1} \quad \forall i \in I, b \in B \tag{8}$$

$$C_{i,b} \ge C_{i,b-1} \quad \forall i \in I, b \in B \tag{9}$$

### Sequencing constraints

Constraints (10) and (11) are complementary sequencing constraints that make use of a big-M parameter. In particular, constraint set (10) ensures that if a batch *b* of task *i* is processed before another batch *b'* of task *i'* ($X_{i,b,i',b'}=1$) and both of them are processed in the same equipment ($Y_{i,b,j}=Y_{i',b',j}=1$) then batch *b'* of task *i'* must start after the completion of batch *b* of task *i*. Respectively, constraint set (11) considers the case where batch *b* of task *i* is processed after another batch *b'* of task *i'* ($X_{i,b,i',b'}=0$) in the same equipment. Finally, constraints (12) guarantee that batch *b'* of task *i* will start after the completion of a batch *b*<*b'* of the same task when both are processed in the same equipment.

$$\begin{aligned} L_{i',b'} \ge C_{i,b} - M \cdot (1 - X_{i,b,i',b'}) - M \cdot (2 - Y_{i,b,j} - Y_{i',b',j}) \\ \forall i \in I, i' \in I, b \in B, b' \in B, j \in (IJ_{i,j} \cap IJ_{i',j}) : i < i' \end{aligned} \tag{10}$$

$$L_{i,b} \ge C_{i',b'} - M \cdot X_{i,b,i',b'} - M \cdot (2 - Y_{i,b,j} - Y_{i',b',j})$$

$$\forall i \in I, i' \in I, b \in B, b' \in B, j \in (IJ_{i,j} \cap IJ_{i',j}) : i < i' \quad (11)$$

$$L_{i,b'} \geq C_{i,b} - M \cdot (2 - Y_{i,b,j} - Y_{i,b',j})$$
$$\forall i \in I, b \in B, b' \in B, j \in IJ_{i,j} : b < b' \quad (12)$$

### Objective function

The goal of the mathematical model is to optimize a given objective that is meaningful to the problem under study and can improve significant production KPIs. Some typical examples are the minimization of production makespan, changeover minimization, order earliness/tardiness minimization, profit maximization and changeover minimization. In the context of this model the objective of makespan minimization $C_{max}$ is considered.

$$C_{max} \geq C_{i,b} \qquad \forall i \in I, b = |B| \quad (13)$$

## Extension for Periodic Production Scheduling

The proposed process representation is also utilized to address the cycle time minimization problem in production environments that follow a periodic scheduling approach. Cyclic, and more specifically periodic, scheduling is a very popular production scheme in many industries due to its reduced shop floor nervousness and simple implementation. However, it poses some clear disadvantages mainly related to the tight timing constraints it imposes, which typically negatively affect the production makespan.

A cyclic schedule is characterized as a schedule that is repeated following a specific timing and resource allocation pattern. Timewise this pattern is specified by the cycle time *H*. This means that if the first task *i* in batch b starts at time $L_{i,b}$, then the same task will start in the subsequent batch at $L_{i,b}+H$. In traditional cyclic scheduling, the resource allocation pattern is very limited, since each task is processed by exactly one of the available equipment throughout the schedule. As expected, this significantly reduces flexibility and resource utilization, potentially lower productivity. To address this issue the concept of periodicity has been proposed [7]. For each task *i*, the periodicity $\pi_i$ denotes how often resource allocation decisions are repeated and is equal to the size of the task's equipment pool. For example, if the equipment pool consists of *J1* and *J2*, then all even batches of task *i* {$b_1$, $b_3$, $b_5$, ...} are processed by J1 and all odd ones {$b_2$, $b_4$, $b_6$, ...} by *J2*.

The mathematical formulation developed to tackle this optimization problem is based on the presented detailed process representation and the MILP model introduced in the previous section. However, this needs to be modified to properly address the specifics of the cycle time minimization problem. This also showcases the general applicability of the proposed framework and its ability to optimally deal with a wide range of production scheduling problems.

The following constraints (3') – (7') need to be adapted to the current optimization problem:

$$\sum_{j \in IJ_{i,j}} Y_{i,b,j} = 1 \qquad \forall i \in I, b \in B : b < \pi_i \quad (3')$$

$$V_{n,b} = \sum_{n'<n} (\sigma_{n,n'} \cdot V_{n',b}) \quad \forall n \notin Flex_n, b \in B : b < \pi_n \quad (4')$$

$$V_{n,b} = \sum_{n'<n} (\sigma_{n,n'} \cdot V_{n',b}) + F_{n,b} \qquad \forall n \in Flex_n, b \in B : b < \pi_n \quad (5')$$

$$L_{i,b} \leq V_{n,b} + (b-1) \cdot H \quad \forall i \in I, b \in B, n \in S_{i,n} \quad (6')$$

$$C_{i,b,n} \geq V_{n,b} + (b-1) \cdot H \quad \forall i \in I, b \in B, n \in E_{i.n} \quad (7')$$

Notice that in this case only the batches specified by the periodicity parameter are considered since the allocation decisions are repeated in the cyclic schedule. Since a cyclic scheduling approach is considered, constraints (4) – (7) need to be updated so that the required timing pattern is imposed. More specifically, constraint sets (4') and (5') are only considered for a subset of the total number of batches, which is defined by the periodicity parameter. Notice that the periodicity of a timing element $\pi_n$ is equal to the periodicity of the associated task $\pi_i$. Constraints (6') ensure that the start time of a task will be less than the value of all relative start elements plus the required cycle time. Similarly, the completion times are calculated in the constraint set (7').

### Cyclic heuristic constraints

The constraints described in this subsection are responsible for generating a cyclic rather than a typical production schedule. They ensure a periodic pattern both regarding the timing and the allocation decisions, that is specified by the cycle time and the periodicity parameter.

$$L_{i,b} + H = L_{i,b+1} \forall i \in I : i = 1, b \in B : b < |B| \quad (14)$$

$$Y_{i,b+\pi_i,j} = Y_{i,b,j} \forall i \in I, b \in B, j \in J : b \leq (|B| - \pi_i) \quad (15)$$

$$V_{n,b+\pi_n} = V_{n,b} \forall n \in N, b \in B : b \leq (|B| - \pi_n) \quad (16)$$

$$F_{n,b+\pi_n} = F_{n,b} \forall n \in N, b \in B : b \leq (|B| - \pi_n) \quad (17)$$

$$L_{i,b+\pi_i} \geq C_{i,b} \forall i \in I, b \in B : b \leq (|B| - \pi_i) \quad (18)$$

Constraint set (14) guarantees that the first task *i* of batch *b+1* must start at exactly *H* time units after the start of the same task in the previous batch *b*. It's important to emphasize that this constraint is only valid for the first task of each batch, thus increasing the timing flexibility for the rest of the tasks. The following constraint sets (15) – (18) are tightening constraints that take advantage of the schedule's cyclic nature to improve the model's computational efficiency. In particular, constraints (15) impose that the equipment allocation decisions are repeated for every $\pi_i$ batches. For example, let us assume that task *I1* of batch *B1* is processed in equipment *J1*, and the periodicity of *I1* is 3, then constraint (15) will guarantee that batch *B4* of *I1* will be processed in equipment *J1*. Similarly, constraints (16) and (17) impose the timing constraints of the schedule's cyclic nature utilizing the

periodicity parameter associated with each entity $\pi_n$. Finally, constraint set (18) denotes that task *i* of batch *b*+$\pi_i$ will start after task *i* of batch *b*.

### Cyclic scheduling objective

The goal of the mathematical model is to minimize the production cycle time *H*, which is beneficial for key production metrics, like decreased dead-times and increased throughput.

$$min\ H \tag{19}$$

In summary the mathematical model for the minimization of the cycle time consists of constraints (3') – (7'), (10) – (12), (14) – (18) and the objective function (19).

## CASE STUDY

One case study from the pharmaceutical industry is presented here to illustrate the applicability of the proposed process representation. The case study is solved both for the makespan minimization problem as well as for cyclic time minimization. The case study uses a recipe representing a single step from a multi-step organic synthesis of a small API molecule. The recipe consists of eleven procedures, each requiring several operations. The synthesis steps are executed in two reactors (R-101 and R-102) which utilize two holding tanks (T-101 and T-102) for solution preparation and material holding after each reactor process. A filtration and a drying task complete the recipe. Figure 2 shows a graphical depiction of the reaction and holding procedures and operations with their scheduling links. Blue arrows indicate internal (within a procedure) links while red arrows indicate links across procedures. As it can be seen, there exist complex operation interrelations with various scheduling links.

The reactors execute dedicated tasks; the tanks, however, can be used alternately for any holding task depending on their availability. The transfer of material into a tank from a reactor is considered inflexible but the transferring of material out of the tank to some reactor has a flexible start of 12 hours maximum. In other words, the material can be held in the tank until the destination reactor for the material becomes available.

Figure 3a shows, in the form of a Gantt chart, the optimal schedule of six batches of this process using the makespan minimization objective. For brevity, only the reactor and tank procedures are shown. The batches are identified by different colors in the chart. As seen, the optimal solution makes full utilization of reactor R-101 by inserting tasks of subsequent batch within the gaps between the tasks of each executed batch. This is made possible by the use of flexible shifts in the tank operations that delay the transfer of material to the reactors

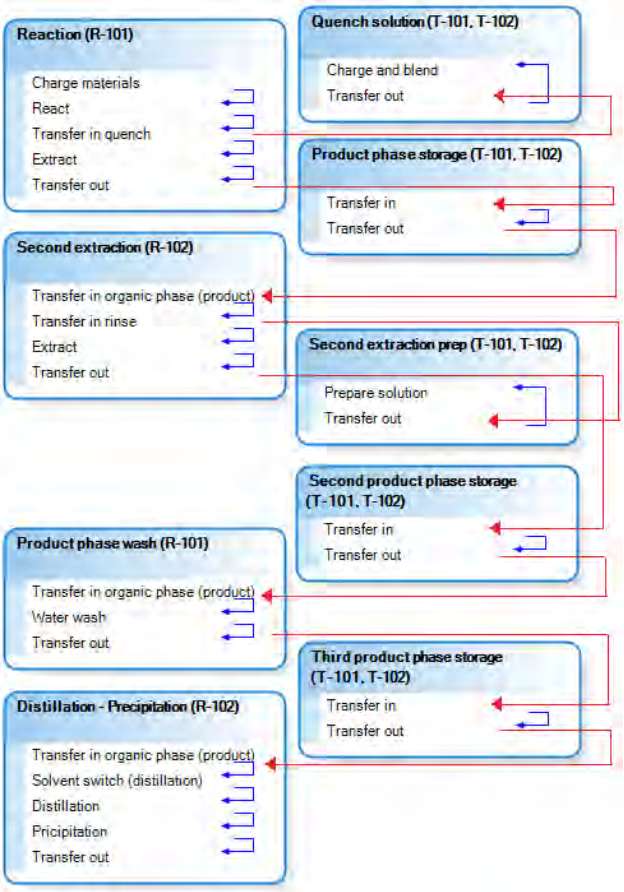

**Figure 2.** Graphical depiction of recipe.

until the latter become available. These flexible shifts are indicated in the charts by the gaps of idle time seen in the operations executed in T-101 and T-102. The optimal make span is calculated at 159 hours.

In the second case shown in Figure 3b, the obtained schedule minimizes the cycle time. In this case, all tasks are executed periodically and all batches are identical. The optimization still makes use of flexible shifts to minimize the cycle time but the shifts have the same value in all batches in order to preserve periodicity. The calculated minimum cycle time is 20.5 hours, but at the expense of increased makespan which is now 171 hours. In an industrial setting, however, a periodic schedule is sometimes favored due to its simplicity in execution.

The SCIP open-source solver [8] was used for the solution of the optimization problems. The recipe representation, formulation of the mathematical optimization problem and visualization of the results were executed in the scheduling software SchedulePro (by Intelligen, Inc.).

## CONCLUSION

In this paper, a novel detailed representation capable of capturing all timing aspects of a production

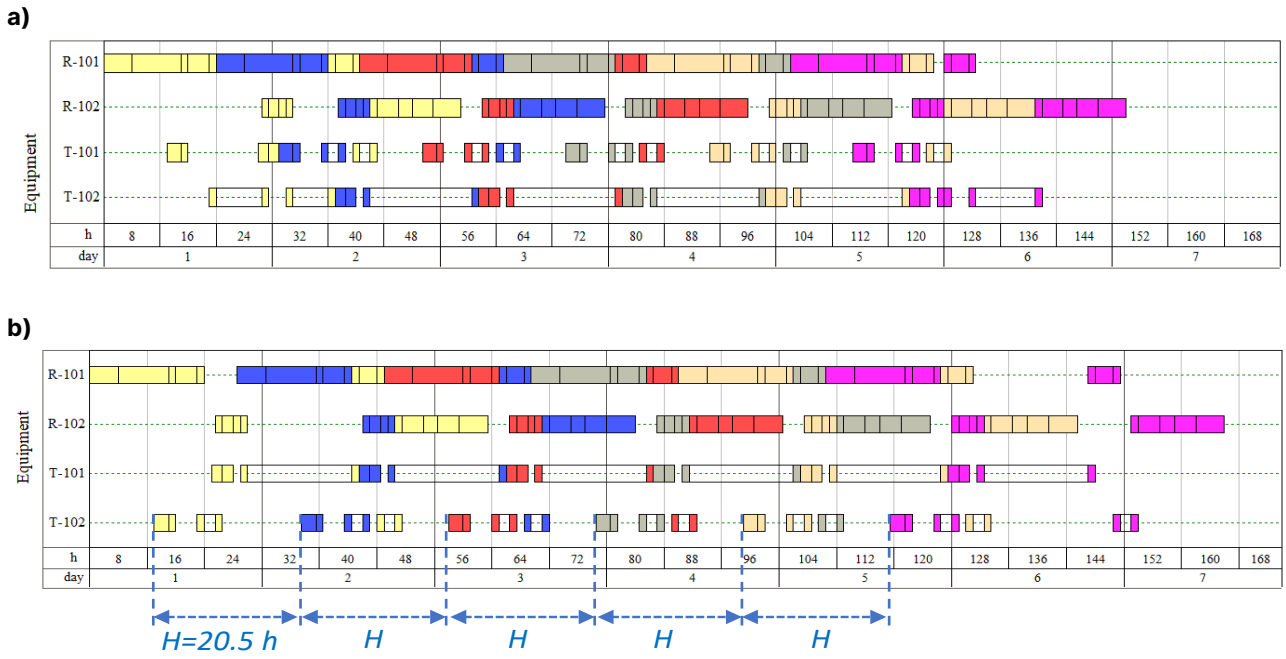

**Figure 3:** Gantt charts for a) makespan minimization and b) cycle time minimization

process is presented. The proposed approach ensures that optimal scheduling decisions even for very detailed recipes can be generated. Based on this representation, two MILP models have been developed - one focusing on makespan minimization and the other on cycle time minimization. The applicability and efficiency of these models are demonstrated through a realistic and complex case study, where optimal schedules are promptly generated. The results highlight the ability of the representation in handling complex production processes facilitating the implementation of optimization-based solutions into real industrial environments, thus reducing the gap between academic research and industrial practice.

## ABSTRACT

This study focuses on optimizing production scheduling in multi-product plants with shared resources and costly changeover operations. Specifically, two main challenges are addressed, the unknown changeover behavior of new products and the need for rapid schedule generation after unforeseen events. An innovative framework integrating Machine Learning (ML) techniques with Mixed-Integer Linear Programming (MILP) is proposed for single-stage production processes. Initially, a regression model predicts unknown changeover times based on key product attributes. Then, a representation where distances correlate with changeover times is compiled through multidimensional scaling, allowing constrained clustering to group production orders according to available packing lines. Ultimately, the MILP model generates the production schedule within a constrained solution space, utilizing optimal product-to-line allocation from cluster segmentation. A case study inspired by a Greek construction materials plant is used to validate the proposed approach. The results showed that this framework improves scheduling efficiency by providing rapid solutions, reducing downtime and facilitating the introduction of new products. Overall, a novel scheduling solution is proposed for manufacturing industries that face unknown production data and need quick schedule alternations.

**Keywords**: Scheduling, Optimization, Machine Learning, Industry 4.0, MILP

## 1. INTRODUCTION

As global competition rises and customer expectations increase, manufacturing industries must embrace digital technologies to remain competitive. Fluctuating demands, equipment breakdowns and raw material availability are some challenges that necessitate for schedules to be flexible and to adapt quickly to changing conditions without causing order delays or increased costs. This is particularly difficult in the presence of frequent and expensive product changeovers, since production schedules are typically handled manually and combinatorial complexity of real-life industrial instances does not allow exact methods to deliver optimal solutions quickly.

Recent breakthroughs in Artificial Intelligence (AI) and improvements in algorithms, computational capabilities and data accessibility, are opening up new ways to face challenges in manufacturing [1]. Today, industries have large amounts of data that are not being fully utilized. By applying techniques like ML, they could improve their decision-making processes. ML can help in demand forecasting, optimizing production schedules and managing the workforce efficiently.

Production scheduling is one of the major challenges in manufacturing environments. Fundamental research in production scheduling primarily focused on employing MILP and heuristic approaches. More specifically, Das et al. [2] and Georgiadis et al. [3] focused on reducing changeover times in flexible manufacturing systems. Notable contributions also include MILP formulations for handling sequence-dependent tasks in manufacturing environments [4,5] and decomposition strategies aimed at improving efficiency in scheduling [6,7]. While these scheduling approaches are effective for small and medium-sized problems, they often fail with larger, more complex ones, or when online scheduling is needed, highlighting the need for improvement and development of new rules to optimize solutions.

More recent studies have focused on integrating ML or Reinforcement Learning (RL) into scheduling systems.

Heger et al. [8] improved scheduling efficiency and reduced delays by dynamically adjusting dispatching rules with ML, while Gomes et al. [9] combined ML with optimization to enhance production. Additionally, studies like Hubbs et al. [10] have shown RL's effectiveness in dynamic scheduling environments. While promising, these methods have some critical limitations, including high complexity, overfitting, low data efficiency and long training times, suggesting the need to explore alternative ML approaches. Furthermore, although research on production scheduling has advanced significantly in recent years, its use in real-world industrial settings remains limited.

To overcome such restrictions, this work proposes a hybrid framework for optimizing production scheduling in multi-product, multi-line manufacturing plants that frequently require changeovers. The framework combines ML with a MILP model. Specifically, it creates a representation space where the distance between products correlates with their changeover times. Then the production orders are organized into clusters that match the available packing lines, using constrained k-means clustering. This assignment is introduced into the MILP model to restrict the solution space and allow for quicker schedule generation. Moreover, to address the problem of missing changeover data, the framework includes a ML model that predicts unknown changeover times and identifies infeasible transitions based on key product attributes. The framework is tested on a real-world scenario inspired by a Greek construction materials plant, demonstrating its effectiveness. The proposed approach improves scheduling efficiency, reduces downtime and helps facilities quickly adapt new products to the production.

## 2. PROBLEM STATEMENT

Production scheduling in multi-product industrial plants is a complex task characterized by demand variability and frequent changeovers, which can lead to substantial downtime, resource wastage and operational inefficiencies. For this reason, the establishment of effective scheduling strategies is essential.

The duration of a changeover may vary depending on characteristics of the product such as formulation, quality requirements and physical properties. It is common that the production schedules are altered during the week, thus generating extra changeover operations. Furthermore, changeover data for specific products might be unavailable. Handling changeovers is a complex task, as it requires balancing the need to meet product demand with the goal of reducing inefficiencies and minimizing waste. In response to these dynamic conditions, scheduling approaches that quickly generate optimal solutions are needed.

To address these issues, the integration of ML techniques with MILP models presents a promising approach. Specifically, clustering methods can be utilized to group products with similar changeover requirements, thus narrowing the solution space for scheduling MILP models and facilitating its solution. Moreover, ML-based predictive models can predict changeover times even with incomplete data available. In this way, the production process can become more efficient and responsive.

In this study, a real-world scheduling scenario is examined, based on a construction materials plant in Greece. The facility produces around 240 final products through a two-stage continuous process, including mixing and packaging. There are 4 packing lines available in the facility, which operates 5 days a week. The production process is characterized by frequent changeovers, which vary due to products' properties, making their allocation to the packing lines a challenging task. The production is order driven and organized in a weekly basis.

Particularly, the production process includes the following steps. First, raw materials are weighed according to the product recipe. The weighed materials are fed into a mixing tank. After mixing takes place, the produced mixture is temporarily stored before being packaged by the available packing lines and transferred to the warehouse. It is noted that the whole production process operates in a continuous manner, therefore, production scheduling can be solely focused on the slowest stage, which is the packing stage. This allows for the reduction of the problem size and computational cost.

The problem described is solved using a novel solution framework which combines mathematical modeling and ML, aiming to rapidly create optimal schedules even in the presence of missing changeover data. The aim of this work is not to develop or compare machine learning algorithms but to propose an efficient scheduling solution that addresses the specific challenges of large-scale industries.

## 3. MATHEMATICAL FRAMEWORK

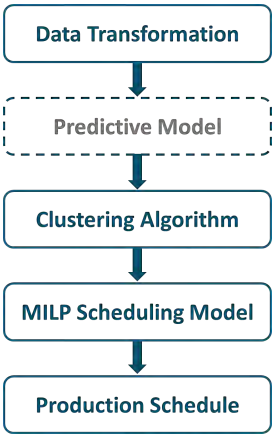

**Figure 1.** Solution strategy.

A hybrid scheduling solution is presented (Figure 1), for manufacturing industries that deal with unknown production data and need quick schedule adjustments. The detailed steps of the model are described in the following subsections.

## 3.1 Data Transformation

The production data must be properly formatted to be utilized in the proposed framework. The data transformation process involves the conversion of raw production data into a standardized format, using numerical and normalized values. Key product features, including raw material type, color, resin content and package size, are compiled into feature vectors, along with changeover duration data. All categorical features were converted into numerical values. For example, raw material type was transformed using one-hot encoding and colors were represented by their corresponding RGB codes. The transformed data serve as inputs for the next steps of the framework.

## 3.2 Predictive Model

This is an optional step, applicable in cases where there are missing data. Unknown changeover data, particularly when new products are introduced or when specific transitions have never been tested, should be predicted for smoother product transitions. ML forecasting models can be employed to estimate the unknown information. Specifically, a data-driven approach is used to predict missing changeover times. The approach uses a pair-based prediction method to estimate changeover times for any two products, whether or not they are part of the training set, based on the feature vectors of the product pair. The objective function for training the model is to minimize the difference between predicted and actual changeover times. To train the model, a regularized predictor is used, in particular Polynomial Regression with L2 Regularization, due to the small size of the dataset available. A third-order polynomial is chosen to capture the non-linear changeover behavior and to avoid excessive variance. L2 regularization is applied to penalize large coefficients and prevent overfitting. If more data were available, more advanced techniques like Deep Learning could be used, however, such models may not perform well with small datasets due to overfitting. The predicted changeover times are used to create practical production schedules.

## 3.3 Clustering Algorithm

The aim is to simplify the complex scheduling problem by decomposing it into smaller sub-problems. This is achieved by clustering products into groups corresponding to the available packing lines. The goal is to identify clusters that minimize the total expected within-cluster changeover time $T_i$, given by equation (1).

$$T_i = \frac{1}{|\mathcal{C}_i|} \sum_{p \in \mathcal{C}_i} \sum_{\substack{p' \in \mathcal{C}_i, \\ p' \neq p}} \min(ch_{p,p'}, ch_{p',p}) \tag{1}$$

Where $|\mathcal{C}_i|$ is the number of products in the $i^{th}$ cluster, and the minimum of $ch_{p,p'}$ and $ch_{p',p}$ represents the best-case changeover time between two products $p$ and $p'$, when changeovers are not symmetrical. Using the average changeover time could overestimate distances, leading to less efficient clustering, whereas using the best-case scenario results in more compact, homogeneous clusters. While $T_i$ does not represent actual changeover times for specific schedules, it serves as an estimator for the average expected changeover time within each cluster.

To facilitate the clustering process, a structured approach is proposed, inspired by clustering-oriented representation learning methods [11]. A new representation space $z_p$ is compiled for each product, where the distance between products reflects their changeover time. Particularly, a distance metric $d(z_p, z'_p)$ is learned to approximate the changeover time between two products. In this representation, products closer to each other have smaller changeover times, making it easier to group them effectively for scheduling purposes. The Euclidean distance is used as the distance metric. Since Euclidean distance is symmetric and cannot handle asymmetry, the approach focuses on the expected changeover time, which is calculated as the minimum changeover time between two products.

The learning objective minimizes the difference between the distance in the new representation space and the expected changeover time as shown in (2).

$$\min \sum_{p \in P} \sum_{\substack{p' \in P \\ p' \neq p}} \left( d(z_p, z'_p) - \min(ch_{p,p'}, ch_{p',p}) \right)^2 \tag{2}$$

This can be interpreted a classical Multidimensional Scaling (MDS) problem with distance targets equal to $\min(ch_{p,p'}, ch_{p',p})$. The application of this method produces a changeover-time driven representation space. K-means clustering can be applied on this space to group the products based on their new representations, minimizing the within-cluster distances $D_i$, which is equivalent to minimizing the expected changeover time $T_i$ within each cluster, as explained in (3).

$$D_i = \frac{1}{|\mathcal{C}_i|} \sum_{p \in \mathcal{C}_i} \sum_{\substack{p' \in \mathcal{C}_i, \\ p' \neq p}} \left|\left| z_p - z_{p'} \right|\right|_2^2 = T_i \tag{3}$$

By grouping products into clusters with small changeover time values, the complexity of the scheduling problem is significantly reduced. In this way, clusters can be assigned to specific production lines and sequencing decisions are only made for the products within a cluster. This approach enhances computational efficiency while

ensuring practical and effective production schedules.

It is noted that the clustering solution also respects production time constraints by ensuring that all products within a cluster can be produced within the available time on each production line. This is done using a constrained k-means approach. To account for the sensitivity of k-means to initial cluster centers, the algorithm is run multiple times with different random initializations, and the best clustering solution is selected after evaluating the total expected within-cluster changeover time.

### 3.4 MILP Scheduling Model

To address the production scheduling challenges described, an immediate precedence MILP model developed within our group [12] is employed. The model incorporates mass balance, assignment, timing and sequencing constraints, using a continuous time frame for precise timing decisions. The objective of the model is to minimize the production's total changeover time. The allocation of products to packing lines given from the previous step of the framework is inserted as a fixed decision into the scheduling model, thus reducing its complexity and facilitating its solution. The mathematical model is implemented in GAMS 42.5.0 and solved using CPLEX 12.0. The following represent the key constraints included in the mathematical model.

$$\sum_{j \in Pj} Y_{p,j} = 1 \quad \forall\, p \tag{4}$$

$$\sum_{p' \neq p, p' \in Pj} X_{p',p,j} \leq Y_{p,j} \quad \forall\, j, p \in Pj \tag{5}$$

$$\sum_{p' \neq p, p' \in Pj} X_{p,p',j} \leq Y_{p,j} \quad \forall\, j, p \in Pj \tag{6}$$

$$\sum_{p \in Pj} \sum_{p' \neq p, p' \in Pj} X_{p,p',j} + 1 = \sum_{p \in Pj} Y_{p,j} \quad \forall\, j \tag{7}$$

$$C_{p,j} + ch_{p,p'} \cdot X_{p,p',j} \leq C_{p',j} - r_{p'} \cdot Y_{p,j} + \omega\left(1 - X_{p,p',j}\right) \quad \forall\, j, p \in Pj, p' \in Pj, p' \neq p \tag{8}$$

$$C_{p,j} \geq (s + r_p) \cdot Y_{p,j} + \sum_{p' \neq p,\, p' \in Pj} ch_{p',p,j} \cdot X_{p',p,j} \quad \forall\, j, p \in P_j \tag{9}$$

$$C_{p,j} \leq \omega \cdot Y_{p,j} \quad \forall\, j, p \in P_j \tag{10}$$

$$\min \sum_{j, p \in Pj} \sum_{p' \neq p, p' \in Pj} ch_{p,p',j} \cdot X_{p,p',j} \tag{11}$$

Constraints (4) guarantee that each product *p* is assigned to a single packing line *j* through the binary allocation variable $Y_{p,j}$. The set $Pj$ introduces the potential assignment of products to processing lines. Constraints (5) and (6) ensure that each product assigned to a processing unit *j* has only one direct predecessor and successor *p'* in the production sequence, using the sequence binary variable $X_{p,p',j}$. Constraints (7) require that the total number of active allocation variables for the packing line must be one greater than the sum of all active sequence binary variables. Constraints (8) dictate that if two products are processed consecutively in a unit, the completion time of the second product $C_{p',j}$ minus its processing time $r_{p'}$ must be greater than the completion time of the first product plus the required changeover time between them $ch_{p,p'}$. Constraints (9) and (10) establish that the completion time of a product is greater than the sum of its setup time $s$, processing time and the required changeover time but does not exceed the available production horizon. Lastly, constraint (11) represents the objective function of the model, which is to minimize the total changeover time across all production lines.

### 3.5 Production Schedule

By implementing data preprocessing, unknown data regression and clustering, the production orders are organized into clusters with minimal changeover times. This assignment is then input into the scheduling MILP model and production schedules characterized by minimum changeover times and efficient use of packing lines are generated. The employment of this framework results in time-efficient production schedules for multi-product industrial plants with frequent changeover operations.

## 4. RESULTS & DISCUSSION

Initially, the prediction of missing changeover data was examined. This is something which can occur either when certain product-to-product transitions have not been tested or when new products are introduced into production. Accurately predicting these changeover times is essential, as selecting an unfavorable or infeasible production sequence can lead to downtime and waste.

To achieve this, key factors that influence changeover times, such as raw material type, color, resin content and package size are used as features in a predictive model. A cubic polynomial regression model is used, with a regularization hyperparameter $\lambda$ set to 0.01, as it was found to provide the best fit to the data. To prevent overfitting, L2 regularization is applied.

Eight case studies were conducted to evaluate the performance of the predictive model (Table 1). In each case, 10-12 products were removed from the initial dataset to serve as the test data, while the remaining data was used for training. Only a small proportion was chosen for testing due to the limited size of the dataset. Testing with larger proportions could potentially compromise the model's ability to learn generalizable patterns.

The model's performance was assessed based on its ability to accurately predict infeasible changeovers (Infeasible Changeover Accuracy % – ICA), as well as its

Mean Squared Error (MSE) and Mean Absolute Error (MAE). As shown in Table 1, the model exhibits high prediction accuracy across both training and testing datasets. On the training data, the model achieves an average ICA of 99.71%, with a MSE of 0.022 and a MAE of 0.072. On the testing data, it demonstrates an ICA of 99.90%, with a MSE of 0.018 and a MAE of 0.074.

**Table 1:** Predictive model metrics.

| | ICA % | | MSE | | MAE | |
|---|---|---|---|---|---|---|
| Case | Train | Test | Train | Test | Train | Test |
| 1 | 99.65 | 99.77 | 0.024 | 0.023 | 0.071 | 0.081 |
| 2 | 99.75 | 100.00 | 0.020 | 0.010 | 0.073 | 0.064 |
| 3 | 99.75 | 99.89 | 0.020 | 0.019 | 0.072 | 0.079 |
| 4 | 99.76 | 100.00 | 0.020 | 0.020 | 0.073 | 0.080 |
| 5 | 99.75 | 99.87 | 0.019 | 0.020 | 0.071 | 0.078 |
| 6 | 99.64 | 99.85 | 0.025 | 0.021 | 0.073 | 0.072 |
| 7 | 99.64 | 99.85 | 0.025 | 0.019 | 0.073 | 0.070 |
| 8 | 99.76 | 100.00 | 0.020 | 0.013 | 0.073 | 0.071 |
| Avg | 99.71 | 99.90 | 0.022 | 0.018 | 0.072 | 0.074 |

With the problem of unknown production data solved, the next part of the study focuses on improving scheduling efficiency by minimizing total changeover time across packing lines in shorter timeframes. In fast-paced industrial settings, production schedules often need to be quickly adjusted multiple times a day due to unforeseen changes. For this reason, the proposed approach was applied to assess the produced schedules and the computational times.

Four scenarios involving 100 to 130 production orders over a 120-hour horizon were investigated, since the problem size and order mixture are expected to have an impact on the production schedules obtained. First, the monolithic MILP model was used to solve the problem, with a CPU time limit of 2 hours. This time restriction was introduced due to the practical limitations of computationally expensive methods in real-world applications. For cases where the MILP model failed to find an optimal solution within this time, the best solution obtained during this period was recorded.

The proposed solution framework (PROP) was then applied to the same scenarios. The framework initially grouped production orders into clusters using the representation and clustering step, ensuring that each packing line handled products with minimal changeover times. Employing the representation step helps to separate the clusters more clearly, as shown in Figure 2. The axes represent the two dimensions of the reduced space obtained through MDS. The product mixture may lead to more dispersed clusters in some case studies, affecting clustering time, which remains minimal, but with little to no impact on optimality.

It is noted that some points may appear to fit better in a different cluster, but they were placed in neighboring clusters due to production line operating time constraints. The allocations were subsequently input into the MILP scheduling model, to reduce the solution space, improving computational efficiency.

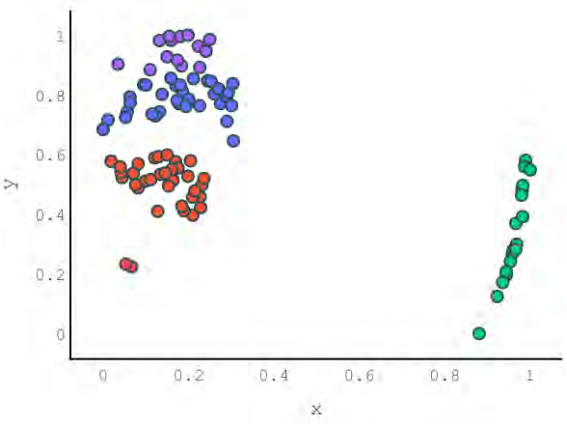

**Figure 2.** Clusters of production orders for case study A.

Table 2 summarizes the results of the case studies examined, organized by the number of weekly orders in ascending order. The two approaches are assessed based on their computational cost and the objective values.

**Table 2:** Comparison between the two approaches.

| | Objective | | | CPU (s) | |
|---|---|---|---|---|---|
| Case | MILP | PROP | Diff% | MILP | PROP |
| A | 17.41 | 14.66 | -15.8 | 7200 | 27.4 |
| B | 19.87 | 15.54 | -21.8 | 7200 | 4.1 |
| C | 24.13 | 17.54 | -27.3 | 7200 | 8.0 |
| D | 25.76 | 18.62 | -27.7 | 7200 | 3.4 |

Combining clustering techniques with optimization methods significantly improved computational efficiency, generating high-quality schedules with the smallest objective values within seconds across all case studies. While the monolithic MILP model failed to find optimal solutions within a 2-hour limit, the proposed framework consistently delivered efficient results, especially for more complex problems which showcased greater improvements. The framework seems to effectively reduce problem complexity, demonstrating its suitability for dynamic industrial environments.

## 5. CONCLUSIONS

This study proposed a framework to optimize production scheduling in multi-product manufacturing plants with parallel production lines, shared resources and frequent changeover operations. The framework integrates ML techniques with MILP to address two main challenges, minimizing product changeover times and predicting unknown changeover durations.

The ML-based predictive model addressed the

issue of missing changeover data by achieving high accuracy in its predictions. It identified infeasible transitions with over 99.6% accuracy and achieved a low prediction error, with an average MSE of 0.02 and MAE of 0.07. These outcomes make it easier to integrate new products into production schedules while minimizing disruptions and inefficiencies. Additionally, the results of the presented framework showed significant improvements in scheduling efficiency. The computational time was cut down by two orders of magnitude. Furthermore, across different case studies, the objective value was reduced by 16% to 28%, highlighting the framework's ability to generate more effective schedules.

The results indicate that the proposed approach is suitable for dynamic real-world industrial environments where changeovers are a major source of downtime and waste. However, the framework does have limitations. Since the approach is not exact, the results can vary depending on the initial clustering configuration and production order combinations. Future work could focus on taking into consideration additional plant constraints, such as due dates and raw material availability, to further improve its applicability. Furthermore, it could focus on extending the model to account for multi-stage production processes and investigating alternative objective functions. Finally, testing advanced ML techniques, like neural network-based solutions, could enhance prediction accuracy and error minimization.

## ACKNOWLEDGEMENTS

The authors would like to thank ISOMAT S.A for inspiring this research and sharing valuable insights into industrial challenges, which helped shape the problem addressed in this study.

## ABSTRACT

The growing demand for sustainable energy has driven research into renewable methane production to reduce greenhouse gas emissions and reliance on fossil fuels. Promising feedstocks include lignocellulosic dry residues, wet waste, and captured $CO_2$, converted via gasification, anaerobic digestion, and synthetic processes with renewable hydrogen. This study uses a multiscale approach to compare these sources, incorporating a techno-economic evaluation to identify key performance indicators (KPI) for facilities and renewable energy sources. A facility location problem (FLP) determines plant locations and production capacities, considering material availability and transportation costs. The analysis focuses on the decentralised use of wastes and $CO_2$ from point and diluted sources across Spain, employing an MILP model to optimise waste and $CO_2$ utilisation alongside solar and wind energy systems. Results highlight lignocellulosic dry waste and $CO_2$ captured with MEA from point sources as the most promising options. Sensitivity analysis predicts methane prices between 13.028 €/MWh and 47.216 €/MWh through 2050, requiring substantial investment for full methane self-sufficiency. With carbon taxes, the price could drop to 10.735 €/MWh by 2050, competitive with current natural gas prices.

**Keywords**: DAC, electrolysis, green hydrogen, synthetic natural gas, strategic $CO_2$ and biomass waste valorisation, methane production and distribution

## 1. INTRODUCTION

Industrial and transportation growth has increased atmospheric $CO_2$ levels from 300 ppm in the late 19$^{th}$ century to 425 ppm in 2024, contributing to a 1ºC global temperature rise [1]. The 2015 Paris Agreement aims to limit warming to 1.5ºC, reducing emissions by 55% by 2030 and achieving net zero by 2050 [2].

Meeting these targets requires transitioning to decarbonised energy systems, especially in the energy and chemical sectors. Geopolitical disruptions, mainly the Ukraine conflict, highlight Europe's energy vulnerabilities, emphasising the need for self-reliant solutions. Synthetic methane production offers a promising route to energy resilience and reduced fossil fuel dependence. The $CO_2$ capture methods include biomass growth, which absorbs $CO_2$ naturally and engineered systems that capture emissions from industrial sources and the atmosphere. Biomass can be used to produce bioethanol, DME, methanol [3], and biodiesel, but challenges such as land, water, and fertiliser limit its scalability. Dry wastes such as lignocellulosic raw material are used via gasification to produce synthetic biomethane. Manure, municipal solid waste (MSW), and sludge are processed via anaerobic digestion to produce biogas and biomethane [4], though logistics and environmental issues reduce efficiency, leading to landfill or incineration. Carbon capture, utilisation, and storage (CCUS) technologies are crucial for meeting climate targets by capturing $CO_2$ from industrial sources for storage or conversion. Methods such as physisorption and amine-based chemisorption face challenges in capturing ambient $CO_2$ due to high energy demands. Direct air capture (DAC) technologies, such as alkaline solutions and BPMED, show promise, especially

when combined with renewable hydrogen to produce methanol or synthetic methane [5].

Current research often addresses processes separately from biomass supply chain optimisation, MSW-to-liquid-fuel, and biogas and $CO_2$ utilisation, but few integrate waste, biomass, and $CO_2$ for synthetic methane production [6]. This study fills this gap by offering a multiscale framework to enhance energy security, using an extended Facility Location Problem (FLP) is formulated as a Mixed-Integer Linear Programming (MILP) across 356 Spanish shires to optimise waste utilisation into methane, integrating various feedstocks and technologies for sustainable energy independence.

## 2. METHODOLOGY

This work evaluates renewable resources and biowastes, such as lignocellulosic waste, manure, MSW, sludge, and captured $CO_2$, to reduce fossil fuel dependence. It optimises waste treatment, $CO_2$ capture, hydrogen electrolysis, and methane production, relying on decentralised utilisation powered by PV and wind energy [6].

### 2.1. Process level analysis

This section depicts technologies for waste management, $CO_2$ capture, and methane conversion, focusing on waste recovery, gasification, digestion, hydrogen production, and renewable energy harvesting.

#### 2.1.1. Waste treatment technologies

**Gasification:** This process converts lignocellulosic waste into syngas for biomethane production using an indirect gasifier-combustor. $H_2S$ is removed with ZnO, and methanation produces biomethane, refined by PSA to reduce $CO_2$ to 2% [7].

**Anaerobic digestion**: This technology processes high-water-content biowaste to produce biogas, upgrading it to biomethane with $H_2S$, $CO_2$, $NH_3$, and $H_2O$ removal [7].

#### 2.1.2. $CO_2$ capture technologies

**Point sources:** $CO_2$ is captured using aqueous amine solutions (MEA) at 25-30°C and partial pressures over 0.05 bar, achieving 90-95% removal at 0.1 bar, with a 20% MEA concentration.

**Diluted sources:** $CO_2$ is captured from the air via DAC technology. Fans pass air through KOH-based solutions, where KOH converts $CO_2$ into $HCO_3^-$ and $CO_3^{2-}$ ions. KOH is regenerated with $Ca(OH)_2$, producing $CaCO_3$, which is dried and calcinated with biogas to regenerate $Ca(OH)_2$[6].

#### 2.1.3. Electrolytic hydrogen production

Green hydrogen is produced via water electrolysis using solar or wind power, and purified by condensation, deoxygenation, and zeolite dehydration.

#### 2.1.4. Energy harvesting

**Wind energy:** A GE 1.5sle turbine with a nominal power of 1,500 kW is considered. Installation costs in 2022 are 1,600 €/kW, and operating costs are 0.026 €/kWh. $CO_2$ emissions are 0.012 $kgCO_2$/kWhe.

**Solar energy:** PV panels generate power, with each 4 $m^2$ panel producing 1 kW peak (kWp) at 25% efficiency ($\eta_{PV}$). The total panel surface reaches up to 7 $m^2$ due to installation needs. In 2022 costs are 1,050 €/kWp and 0.042 €/kWh, with $CO_2$ emissions of 0.048 $kgCO_2$/kWhe.

#### 2.1.5. Methane synthesis

e-Methane is produced from $CO_2$ via methanation using renewable hydrogen and captured $CO_2$ at 1-30 bar and 140°C-350°C. Synthetic biomethane is obtained from syngas methanation, while biomethane comes from biogas upgrading. Purification achieves over 95% methane purity.

### 2.2. Process technologies surrogate modelling and process scale-up

The formulation of the FLP requires surrogate input-output models for the waste processing technologies, including manure, 63-368 kt/year, MSW, 20-53 kt/year, and lignocellulosic biomass, 10-820 kt/year, with corresponding CAPEX and OPEX. Up to 50 designs are modelled, yielding 0.012, 0.070, and 0.285 $kg_{Biomethane}$/kg [7].

The $CO_2$ capture modelling includes yields, energy requirements, and linearised CAPEX and OPEX for MEA and conventional DAC systems. CAPEX and OPEX follows Sinnott's methodology, excluding waste disposal. Auxiliary costs (steam, water, energy) are based on mass and energy balances. CAPEX includes equipment sizing for compressors, heat exchangers, filters, and cyclones.

#### 2.3.1. Description of resources

The extended FLP model includes $CO_2$ capture, biomass availability, and processing methods across 356 Spanish shires, limiting surface use by up to 2%. It prioritizes PV panels for renewable power. Gasification processes dry lignocellulosic biomass, while wet wastes require anaerobic digestion. $CO_2$ emissions, measured in $kt_{CO_2}$/year, include industrial, agricultural, livestock, and transport sources using MEA and DAC systems. Solar and wind availability are based on annual averages of solar irradiance, and wind velocity.

#### 2.3.2. Formulation of the FLP problem

Each shire is defined by its capital city's latitude and longitude, evaluating $CO_2$ capture, sun and wind availability, and shire area for PV panels, considering:

1. Biowaste, $CO_2$ captured from point and diluted sources using MEA solutions and DAC technology, solar radiation and wind velocity data, and land availability to

build infrastructures.

2. Surrogate models using first principles such as mass and energy balances, thermodynamic equilibrium and correlations based on predicting yield, production, and costs for $CO_2$ capture, renewable energy, biomass gasification, anaerobic digestion, hydrogen production, and methane synthesis, estimating performance and costs, such as CAPEX and OPEX, based on the last processes facility capacities.

3. Network modelling for biomass, $CO_2$, and hydrogen transportation between production sites and processing installations, optimising the use of decentralised resources to reduce transportation costs.

4. An objective function to maximise $CO_2$ usage within the budget, minimising network costs. The objective is to maximise the $CO_2$ captured within the assigned budget, focusing on minimising network costs through the integration of transportation, processing, and renewable energy generation.

Key variables include selecting biomass and $CO_2$ sources, facility capacities, and locations for $CO_2$ capture, hydrogen, and renewable energy production.

#### 2.3.3. Resolution method and limitations

The resolution method optimises resource integration and cost efficiency, starting with a process-level analysis of waste treatment, $CO_2$ capture, hydrogen production, and energy generation. This is expanded into a multiscale framework that integrates different levels of analysis: a process-level evaluation, which assesses technologies and costs; a resource availability analysis, which considers the spatial distribution of biomass, waste, and $CO_2$ sources; and a country-level optimisation scale, which determines the optimal locations for facilities based on economic and geographic constraints. The FLP is formulated as an MILP model to optimise facility locations and costs, ensuring decentralised production and strategic energy security. Limitations include data availability, uncertainties in technology performance, and external factors like legislative changes, which may impact technology deployment and require further investigation.

## 3. CASE STUDY

### 3.1. General settings, constraints, and assumptions of the case study

The FLP optimisation model is formulated analysing 356 Spanish shires. It considers 29,900 kt/year of dry waste, 121,400 kt/year of manure, 9,500 kt/year of MSW, 3,400 kt/year of sludge, and $CO_2$ emissions from human activities, totalling 93,327 $kt_{CO_2}$/year and 102,250 $kt_{CO2}$/year, from point and diluted sources. Renewable energy data is sourced from Sun and Wind Atlas. The MILP considers a 10,195 M€ MITECO budget, 23,911 equations, and 91,192 variables, and is solved using CPLEX.

### 3.2. Working data, parameters, variables, and evolution over the time horizon

The study analyses waste availability in 2022, 2030, and 2050, with Spain's population of 50–60 million stabilising waste generation through improved consumption, ensuring consistent synthetic biomethane and biogas production. $CO_2$ availability is based on 2022 data, assuming constant emissions despite policy cuts. By 2050, CAPEX for PV panels drops from 1,050 to 297.8 €/kWp, and wind turbines from 1,600 to 1,138.7 €/kW. OPEX falls for PV from 0.042 to 0.009 €/kWh and wind turbines from 0.026 to 0.013 €/kWh. Synthetic methane production integrates $CO_2$ capture, water use, $H_2$ and $O_2$ generation, while carbon taxes rise to 180 €/$t_{CO_2}$.

## 4. RESULTS AND DISCUSSION

This section analyses decentralised methane production from lignocellulosic waste, manure, MSW, and $CO_2$, focusing on costs in MITECO's 2020–2050 budgets. It assesses CAPEX and OPEX, a sensitivity analysis on infrastructure, prices, and carbon tax credits, as well as limitations like data gaps and legislative uncertainty.

### 4.1. Analysis of current state: Year 2022

#### 4.1.1. Use of the different waste materials, $CO_2$ capture, and use

Without a carbon tax, synthetic bio-methane and bio-methane are produced using 26,702 kt/year of lignocellulosic dry biomass, 83,070 kt/year of manure, and 7,775 kt/year of MSW. Waste treatment needs 11,174 M€ as investment and 5,341 M€/year in operating costs. The optimal scenario prioritises lignocellulosic dry waste for its high yield, especially in river-adjacent regions like the Duero, Ebro, and Guadalquivir (Figure 1a). Manure and MSW contribute 2,750 kt/year and 1,790 kt/year of biomethane, respectively. Shires where manure is used are shown in Figure 1b, but sludge is excluded due to its moisture content [7]. $CO_2$ capture reaches 5,858 kt/year, below previous estimates of 10,000–12,500 kt/year [6]. MEA solutions, chosen for low costs, are used in northern Spain and the Balearic Islands. Carbon taxes phase out manure and MSW, cutting costs by over 50%.

#### 4.1.2. Production of renewable energy

The system requires 147 km² of PV panels, approximately 2% of Spain's available area, and 2,465 wind turbines. Combined, investment and operating costs reach up to 28,020 M€ and 2,430 M€/year, generating 7.3 GW, over 6% of Spain's 2022 electricity output. PV panels are prevalent in southeastern Spain, with wind turbines in coastal and mountainous regions (Figures 1e and 1f). With

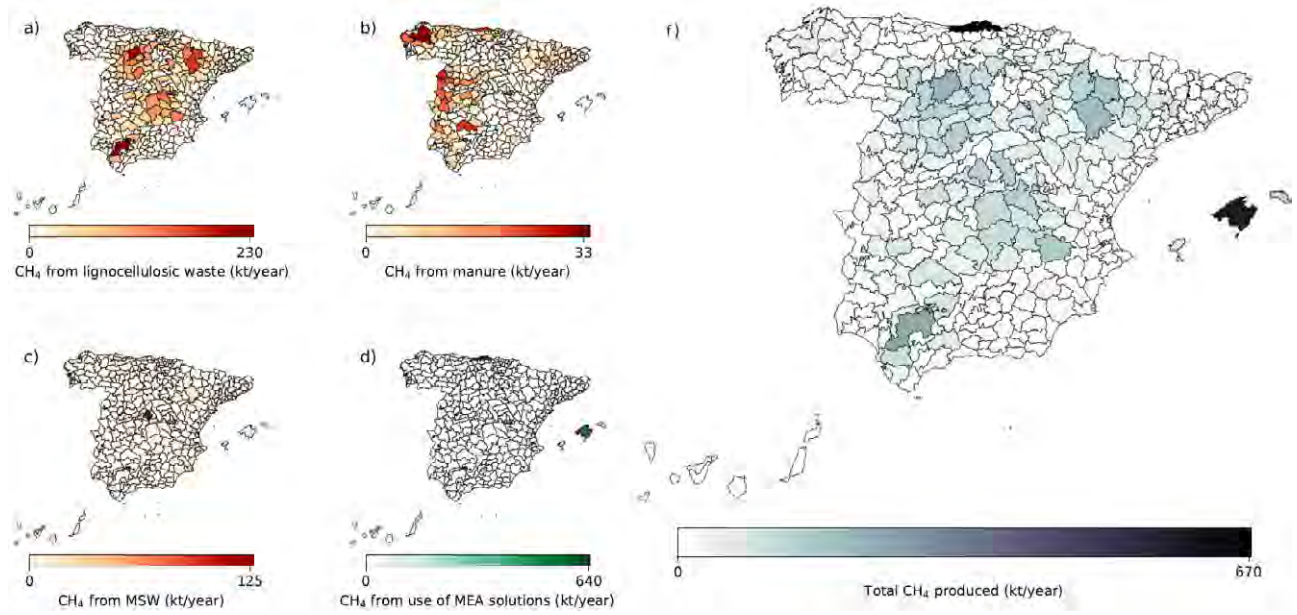

**Figure 1.** Distribution of lignocellulosic dry waste (a), manure (b), MSW (c), sludge (d), and methane production (f) by shires in Spain in 2022, without carbon tax.

a carbon tax, synthetic methane demand doubles the PV panel area to 290 km², representing an increase of almost 100%, while turbine numbers remain stable. Costs rise to 49,355 M€ and 4,282 M€/year, with energy output growing to 12.4 GW. PV panel deployment expands, but turbine locations remain unchanged.

### 4.1.3. Methane production

Synthetic methane production requires 3 $kg_{CO_2}/kg_{CH_4}$ and 0.41 $kg_{H_2}/kg_{CH_4}$ [6]. Without carbon taxes, Spain produces 11,104 kt/year of renewable methane, covering nearly 46% of national consumption in 2022 [7]. Synthetic biomethane comes mainly from lignocellulosic waste, 7,610 kt/year. Investment and operating costs are 14,440 M€ and 5,900 M€/year. Hydrogen needs are 805 $kt_{H_2}$/year, costing 3,202 M€ and 304 M€/year. With a carbon tax, lignocellulosic waste generates 7,610 kt/year of biomethane, 31.5% of consumption, and synthetic methane rises to 3,300 kt/year, with total methane production reaching 10,910 kt/year and costs dropping to 11,989 M€ and 3,284 M€/year.

### 4.1.4. Evolution of self-sufficiency methane percentage, and methane prices

In 2022, methane self-sufficiency without carbon taxes is 30.7%, with lignocellulosic waste contributing 25% of the budget. MEA solutions raise self-sufficiency to 42.9% at 300%, with full self-sufficiency needing 410.4% and methane prices reaching 124.69 €/MWh. With a carbon tax, $CO_2$ capture accelerates, favouring MEA. Lignocellulosic waste provides 31.5% self-sufficiency at 15% of the budget, while MSW replaces manure at 125%, adding 2.1%. Full self-sufficiency requires four times the budget, reducing methane prices to 100.35 €/MWh. By 2030 and 2050, MEA and DAC reduce prices and self-sufficiency.

### 4.1.5. Environmental impact of energy generation: $CO_2$ emissions, minerals required, and water use

Among renewable sources, PV panels emit 2,325 $kt_{CO_2}$/year and wind turbines 188 $kt_{CO_2}$/year, contributing 1.19% and 0.10% to Spain's 2022 $CO_2$ emissions. PV panels are preferred for cost-effectiveness, requiring 55,759 t of minerals, accounting Cu, Ni, Mn, Cr, Mo, Zn, Rare Earths, Si. Mineral extraction emits 321 $kt_{CO_2}$ for PV and 86 $kt_{CO_2}$ for wind, totalling 2,646 $kt_{CO_2}$. Water usage is $1.6 \cdot 10^7$ m³/year for PV, $6.7 \cdot 10^5$ m³/year for wind turbines, and $7.3 \cdot 10^6$ m³/year for hydrogen production. A carbon tax boosts PV panel deployment, increasing emissions from mineral extraction and resource demands. Mineral needs rise to 90,077 t of minerals. The $CO_2$ emissions reach 5,051 $kt_{CO2}$ for PV and 273 $kt_{CO2}$ for wind turbines. Water use is up to $3.06 \cdot 10^7$ m³/year for PV.

## 4.2. Analysis of the future status: Years 2030 and 2050

### 4.2.1. Use of the different waste materials, $CO_2$ capture, and its use

By 2030, lignocellulosic dry waste will produce 25,292 kt/year of synthetic biomethane, a 5.28% decrease from 2022 due to lower technology costs and improved efficiency (Figure 2a). Investment and operating costs will drop to 5,604 M€ and 1,826 M€/year, a

reduction of 49.84% and 65.81%, excluding manure and MSW (Figures 2b, 2c). Point sources will emit 29,378 $kt_{CO_2}$/year, increasing by 400% with lower costs and efficiency gains (Figure 2d). Spain's carbon tax of 150 €/$t_{CO_2}$ will reduce lignocellulosic waste use to 20,328 kt/year, lowering costs to 3,688 M€ and 1,130 M€/year, while MEA solutions capture 32,231 $kt_{CO_2}$/year (Figure 2d).By 2050, lignocellulosic waste use will drop to 24,052 kt/year, with costs at 5,044 M€ and 1,591 M€/year. With a 180 €/$t_{CO_2}$ tax, waste use will fall to 2,719 kt/year, and MEA will capture 42,258 $kt_{CO_2}$/year (Figure 2d).

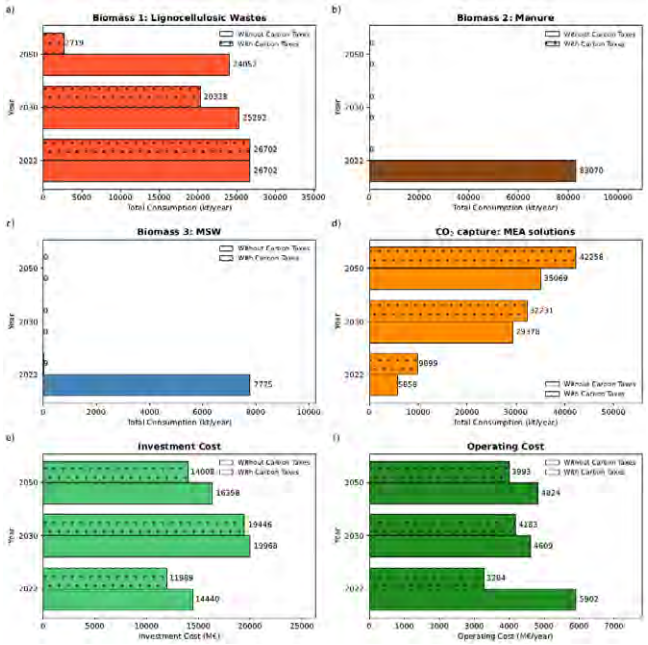

**Figure 2**. se of Lignocellulosic dry waste (a), manure (b), MSW (c), MEA $CO_2$ capture (d), total investment (e) and total operating costs (f) for 100% methane self-sufficiency, without and with carbon taxes, 2022, 2030, 2050.

### 4.2.2. Production of renewable energy

By 2030, energy production will rely on PV panels across Almería, the Canary Islands, and central regions, covering 1,042 km², up from 147 km² in 2022 (Figure 3a). Investment and operating costs will reach 59,956 M€ and 2,892 M€/year, generating 36.7 GW (Figures 3b–3d). A carbon tax boosts synthetic methane production to 40.2 GW, concerning 2022 levels, at costs of 65,910 M€ and 3,173 M€/year (Figures 3b-3d). By 2050, PV panels will cover 1,511 km², generating 52.8 GW at 64,280 M€ (Figures 3a–3c).

### 4.2.3. Methane production

By 2030, synthetic biomethane production will focus on gasifying lignocellulosic dry waste and synthesising methane from $CO_2$ captured via MEA solutions, excluding anaerobic digestion. Output will be 7,208 $kt_{Biomethane}$/year, a 5.29% decrease from 2022. Methane consumption will drop to 18,990 $kt_{CH_4}$/year [6], with synthetic production rising to 9,793 $kt_{CH_4}$/year. Costs will total 19,968 M€ and 4,609 M€/year (Figures 2e, 2f). By 2050, lignocellulosic waste use will decrease by 9.93%, producing 6,855 $kt_{Biomethane}$/year. Domestic methane consumption will drop to 13,815 $kt_{CH_4}$/year [6], while synthetic methane rises to 11,690 $kt_{CH_4}$/year. Costs will total 16,359 M€ and 4,824 M€/year (Figures 2e, 2f).

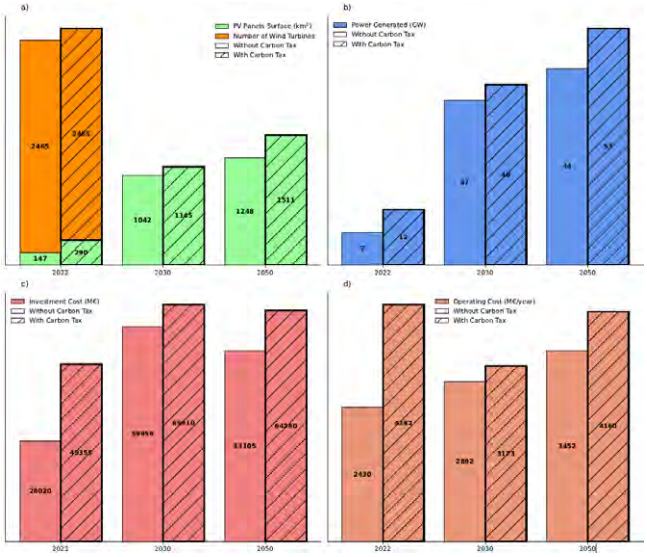

**Figure 3**. PV panel surface, wind turbines (a), power generation (b), investment (c) and operating costs (d), without and with carbon taxes, 2022, 2030, 2050.

### 4.2.4. Evolution of self-sufficiency methane percentage, and methane prices

By 2030, lignocellulosic dry waste and MEA solutions will remain key for cost efficiency. Methane prices, excluding carbon tax, will rise to 17.545 €/MWh when employing lignocellulosic dry waste. Once lignocellulosic dry waste is depleted, MEA solutions for $CO_2$ capture begin to be used until a methane price of 53.547 €/MWh is reached. However, at 100% budget utilisation, the price drops to 43.170 €/MWh. At 300% budget use, lignocellulosic waste will provide 38% of methane self-sufficiency. Carbon taxes will benefit synthetic methane over biomethane, with prices potentially dropping to 23.336 €/MWh. By 2050, advancements will favour MEA solutions. Without a carbon tax, methane will cost 17.545 €/MWh, with MEA solutions at 47.214 €/MWh. At 100% budget utilisation, methane costs 39.577 €/MWh, 40.12% lower than in 2022. Methane self-sufficiency will be achieved with 66.7% of the budget at 35.171 €/MWh, with prices dropping to 12.540 €/MWh at 100% budget use.

### 4.2.5. Environmental impact of energy generation: $CO_2$ emissions, minerals required, and water use

By 2030, PV panels will be the main energy source,

emitting 6,427 $kt_{CO_2}$/year, with 2,095 $kt_{CO_2}$ from mineral extraction, accounting for 29% of $CO_2$ captured by MEA solutions, 29,378 $kt_{CO2}$/year. Mineral requirements are $2.50 \cdot 10^5$ t, accounting for Cu, Ni, Zn, Si. PV panels use $1.06 \cdot 10^8$ $m^3$/year of water, 0.19% of Spain's capacity, while hydrogen production uses $3.64 \cdot 10^7$ $m^3$/year. Carbon taxes increase PV emissions to 7,052 $kt_{CO_2}$/year, contributing 29% of $CO_2$ captured by MEA solutions. By 2050, expanding PV panels will raise emissions, mineral demand, and water usage. PV panels emit 3,836 $kt_{CO_2}$/year, with 2,501 $kt_{CO_2}$ from mineral extraction, totalling 6,337 $kt_{CO_2}$/year, or 18.07% of $CO_2$ captured by MEA solutions, 35,069 $kt_{CO2}$/year. Mineral needs reach $2.98 \cdot 10^5$ t, and water use rises to $1.27 \cdot 10^8$ $m^3$/year.

## 5. CONCLUSIONS

This study examines large-scale renewable synthetic methane production from biomass gasification, anaerobic digestion, and $CO_2$ hydrogenation using green hydrogen. Gasification processes lignocellulosic dry waste, while anaerobic digestion whereas manure, MSW, and sludge, upgrading biogas to biomethane and producing synthetic methane using $CO_2$ captured from point and diluted sources.

Lignocellulosic dry waste gasification is the most efficient due to its high yield and low moisture content. $CO_2$ capture from point sources is preferable to DAC, potentially reducing Spain's industrial emissions by half. A land-use analysis considers decentralised deployment across 356 shires, allocating 2% for PV and wind turbines. By 2050, expanded capacity will ensure energy for $CO_2$ capture and hydrogen production.

Economic integration of lignocellulosic waste gasification with MEA-based $CO_2$ capture shows a potential 134.2% natural gas substitution. Investment costs in waste treatment, $CO_2$ capture, and power generation are projected to decrease, with cumulative costs of 14,008 M€ and 64,000 M€ by 2050.

Synthetic methane production will grow, with emission reductions between 49.8% and 59.6%. The integration of waste treatment, $CO_2$ capture, and hydrogenation offers a promising path for defossilising the energy sector, requiring strategic investments and policies.

## ABSTRACT

Data-driven decision-making is crucial in the transition to a low-carbon economy, especially as global industries strive to meet stringent sustainability goals. Traditional life cycle assessments often rely on static emission factors, overlooking the dynamic nature of the energy grid. As renewable energy penetration increases, grid carbon intensity fluctuates significantly across time and regions, due to the inherent intermittency of renewable sources like wind and solar. This variability introduces discrepancies in emission estimations if time-averaged factors are applied, leading to sub-optimal process operations and unintended environmental consequences. To this end, we present a real-time emission-aware optimization framework, which is implemented through a mixed-integer linear programming formulation that can determine optimal design configurations and operation schedules while simultaneously mitigating emissions by utilizing electricity price forecasts, time-varying emission factors, sporadic weather data, and supply and demand variability. The optimization model integrates life cycle assessment criteria to evaluate various environmental inputs, categorized into direct on-site emissions (Scope 1), indirect emissions from energy use (Scope 2), and upstream, downstream, and construction-related emissions associated with the process system (Scope 3). The framework, demonstrated through a detailed hydrogen production case study, showcases the effect of time-varying emissions by generating a set of optimal solutions that balance the trade-offs between environmentally sustainable and economical operational strategies.

## INTRODUCTION

Climate change remains a critical challenge in the 21st century, necessitating comprehensive strategies to mitigate greenhouse gas (GHG) emissions across various sectors. In this context, life cycle assessment (LCA) has emerged as a pivotal tool for evaluating the environmental impacts of products and processes. Central to LCA is the accurate quantification of emissions, which has traditionally relied on static average emission factors (AEFs) [1]. However, growing concerns about the temporal and spatial variability of emissions have highlighted the need for more dynamic approaches, such as the use of marginal emission factors (MEFs) [2]. Marginal emission factors quantify the incremental change in emissions resulting from a unit change in electricity demand or supply. Unlike AEFs, which represent the average emissions over a fixed period, MEFs account for real-time grid conditions and the specific generation mix at a given moment. This distinction is especially critical in regions with a high

share of renewable energy sources, where the marginal electricity emission factor often differs from the average emission factor calculated of the given fuel mix [3]. Consequently, MEFs provide a more accurate representation than AEFs, particularly in grids with diverse renewable sources such as wind and solar, which exhibit high intermittency. The dynamic nature of MEFs provides a more accurate representation of the environmental impact of electricity use, especially in the context of flexible and time-dependent systems like hydrogen production, electric vehicle charging, and energy storage [4]. Adopting MEFs enables policymakers and industry stakeholders to design interventions that align with low-carbon electricity availability, thereby enhancing the efficacy of decarbonization efforts. For instance, scheduling energy-intensive processes during periods of low marginal emissions can significantly reduce overall GHG impacts. Furthermore, MEFs facilitate a better understanding of the interplay between electricity demand patterns and grid emissions, offering valuable insights for optimizing energy transitions [5].

This paper explores the significance and effects of using MEFs instead of static emission factors in an energy systems modeling and optimization framework. By advocating for the adoption of MEFs, this study aims to contribute to a more nuanced and impactful approach to emission accounting, thereby advancing global efforts toward sustainable development.

## SYSTEM UNDER INVESTIGATION

### Goal, Scope, and Boundary System

The objective of this case study is to meet a daily hydrogen demand of 240,000 kg by integrating various hydrogen production technologies. The primary focus is on minimizing costs and emissions, with particular attention to the impact of employing marginal emission factors rather than static emission factors. To highlight the influence of emissions on hydrogen production, the Houston area in Texas has been selected as a representative location for potential hydrogen infrastructure development [6]. A superstructure, illustrated in Figure 3, has been developed to incorporate both conventional steam methane reforming (SMR) and proton exchange membrane (PEM) processes for hydrogen production. The system considers three energy sources: the electrical grid and two renewable power purchase agreements (PPAs), specifically solar and wind energy. The electrical grid comprises multiple energy generation sources, including nuclear, hydropower, solar, wind, natural gas, and coal/lignite, each characterized by distinct global warming potentials. Table 1 presents the global warming potentials, expressed in kg $CO_2$-eq/MWh, which are used to calculate the time-varying emission factors of the electrical grid. Figure 1 illustrates the hourly dynamic behavior of the Electric Reliability Council of Texas (ERCOT), highlighting the contributions of various energy sources to meet hourly energy demand. It is important to note that the energy mix is determined in advance through fuel mix forecasting, as performed by ERCOT. This forecasting relies on predictive models that estimate electricity demand and the availability of renewable energy sources, such as wind and solar, based on weather patterns and historical data. Figure 2 demonstrates the significant variation in emission factors resulting from fluctuations in the contributions of these energy sources. The calculated marginal emission factor of the ERCOT grid ranges from 276.06 to 403.75 kg $CO_2$-eq./MWh, with an average value of 353.80 kg $CO_2$-eq./MWh. This average aligns closely with the emission factor reported by the Environmental Protection Agency (EPA), which is 351.31 kg $CO_2$-eq./MWh [7].

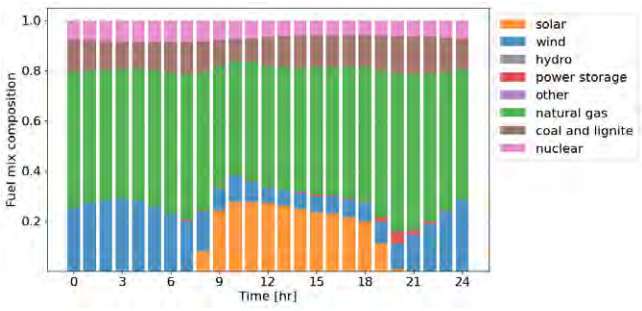

**Figure 1.** Time-varying energy mix of the ERCOT grid.

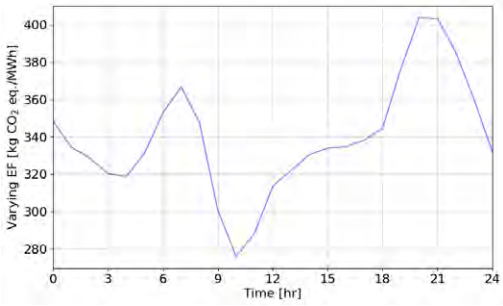

**Figure 2.** Time-varying emission factor of the grid on an hourly resolution.

**Table 1:** Various energy sources generating power within the ERCOT grid – *adapted from Ecoinvent V3.10.*

| Energy Source | GWP 100 [kg $CO_2$ eq./MWh] |
|---|---|
| Coal and lignite | 960.00 |
| Natural gas | 407.00 |
| Nuclear | 50.00 |
| Wind | ≈0.00 |
| Solar | ≈0.00 |
| Hydropower | ≈0.00 |

### Data Sourcing and Assumptions

Operational data for the SMR, and CCS, were

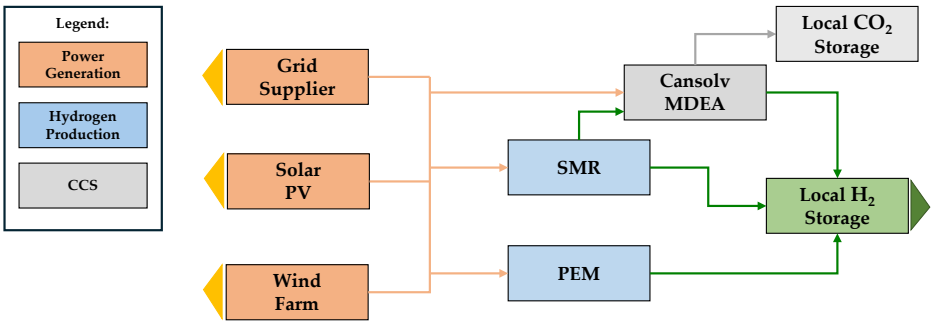

**Figure 3:** Proposed superstructure integrating two renewable energy sources—wind and solar—alongside a grid supplier, a conventional steam methane reformer, and a proton exchange membrane hydrogen production unit. The system operates within a life cycle boundary framework that accounts for both scope 1 and scope 2 emissions.

sourced from the National Energy Technology Laboratory (NETL) and Zang et al., both of which comprehensively discuss the operational aspects of hydrogen production processes [8,9]. Data for the PEM process were obtained from the National Renewable Energy Laboratory's (NREL) report on proton exchange membrane water electrolyzers and Gerloff N. [10,11]. Emission factors for all resources utilized in this study were extracted from Ecoinvent version 3.10, while characterization factors for converting emissions into carbon dioxide equivalent values were derived from the Sixth Assessment Report of the Intergovernmental Panel on Climate Change (IPCC) [12,13]. Lastly, Figure 4 presents the hourly electricity pricing data sourced from ERCOT, along with the capacity factors reflecting solar and wind variability in Texas. These data are integrated into the model to formulate a linear programming problem, enabling the development of economical and environmentally optimized production schedules. The implementation was conducted on a Windows 11 system equipped with a 13th Gen Intel(R) Core(TM) i7-13700 processor and 32 GB of DDR5 RAM, while using Gurobi to solve the optimization problem.

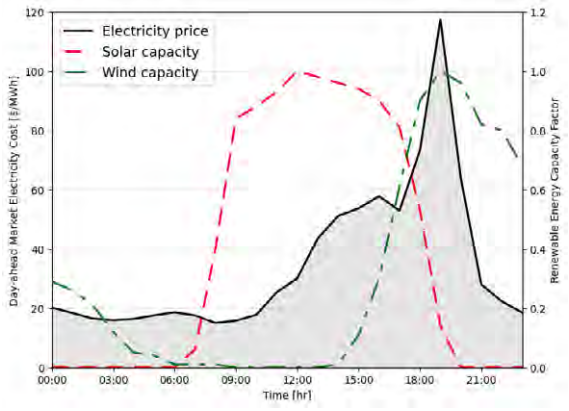

**Figure 4.** Varying day-ahead market electricity prices and renewable energy availability

## Methodology

The proposed framework is designed to be applicable and adaptable over different research sectors, extending beyond the specific case study of hydrogen production. The framework's foundation lies in a resource-process approach, which categorizes system components into resource inputs, conversion processes, and associated outputs [14]. This modular and systematic structure allows the framework to accommodate a wide range of process systems, provided they adhere to this fundamental programming structure.

By decoupling the methodological design from the specifics of any one application, the framework achieves a level of generality suitable for addressing diverse optimization problems in various sectors. Examples include chemical manufacturing, energy systems, and other industrial processes that involve resource transformation and utilization. This adaptability ensures the framework's relevance in solving problems related to cost minimization, and emissions reduction. The generalizable nature of the framework not only enhances its utility for interdisciplinary applications, but also ensures its scalability for future advancements in sustainable process system scheduling and design.

### Time-varying Emission Factor Formulation

To fully encapsulate the time-varying aspect of electrical grid power generation, Eq. 1 is utilized to quantify the varying emission factor. The total energy generation, $E_t$, must be known at each time step, which is multiplied by the contribution percentage, $Co_{r,t}$, of each energy producing source, which is then multiplied with their corresponding global warming potential, $GWP_{r,t}$.

$$EF_t = E_t \times \sum_{r \in R} Co_{r,t} . GWP_{r,t} \quad \forall\, t \in T \tag{1}$$

### Scope-wise Emission Approach

Within this quantification framework, Eq. 2 captures emissions associated with both resource consumption and discharge. The total resource emissions, $em_r$, are

calculated as the sum of emissions from resource consumption and discharge at time, $t \in T_{sch}$. Specifically, the emissions from total resource consumption, $c_{r,t}$, are determined by multiplying the consumed quantity by the corresponding emission factor, $EF_{r,t}$, for the resource, $r$. Similarly, the emissions from resource discharge, $s_{r,t}$, are calculated by multiplying the discharged quantity by its associated emission factor. This formulation ensures a comprehensive accounting of resource-related emissions within the system's lifecycle.

$$em^r = \sum_{t \in T^{sch}} \sum_{r \in R} (EF_{r,t} \cdot c_{r,t} + EF_{r,t} \cdot s_{r,t}) \quad (2)$$

Secondly, on-site emissions, referred to as process emissions, are quantified using Eq. 2. These emissions are determined by the production quantity and the emission factors associated with the resources utilized during the production phase. Specifically, the process emissions at a given location are calculated by summing the emission contributions of each resource used. This is achieved by multiplying the emission factor, $EF_{r,t}$, of a resource by the conversion factor, $\eta_{p,r,t}$, which represents the efficiency of process, $p \in P$, in converting the resource into the desired product. The result is then multiplied by the total production quantity, $p_{p,t}$, of the process at the location of interest. This formulation ensures an accurate representation of emissions directly attributable to production activities at specific locations.

$$em^p = \sum_{t \in T^{sch}} \sum_{r \in R} EF_{r,t} \times \sum_{p \in P} \eta_{p,r,t} \cdot p_{p,r,t} \quad (3)$$

## RESULTS & DISCUSSION

### The Cost Minimization Scenario

When optimizing for cost, the use of time-varying emission factors is found to have no impact on the production schedule as seen in Figure 5. Regardless of the chosen emission quantification approach, the cost-minimized optimal configuration consistently involves using SMR without CCS. This is due to the total emissions generated are not weighted in the optimization process when prioritizing profitability. However, while the production schedules remain identical, the quantification of total emissions differs between the two approaches. Using the time-varying emission factor approach results in total emissions of 2,861 metric tons (MT) of $CO_2$-eq., whereas the constant emission factor approach yields 2,864 MT of $CO_2$-eq.

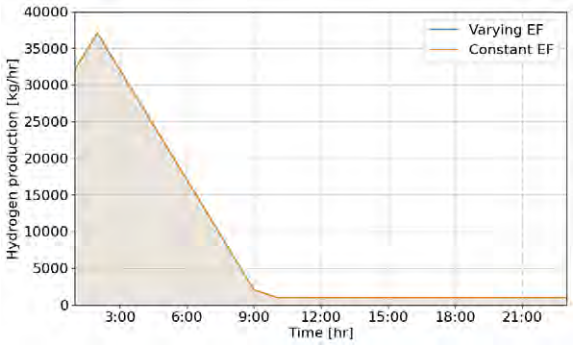

**Figure 5.** Hydrogen production profile using time-varying and constant emission factors while minimizing the cost objective.

This represents a difference of up to 3,000 kg $CO_2$-eq. within a 24-hour period. These findings highlight the influence of a dynamically changing energy mix, demonstrating that specific times of the day may be more favorable for increasing production rates due to lower emission factors. Figure 6 demonstrates that, despite the objective function being focused on cost minimization, the renewable PPAs for solar and wind energy, with fixed rates of $52.69/MWh and $60.11/MWh respectively, are more cost-effective during specific periods of the day. As a result, these renewable energy sources are prioritized over the more volatile grid electricity prices during those times.

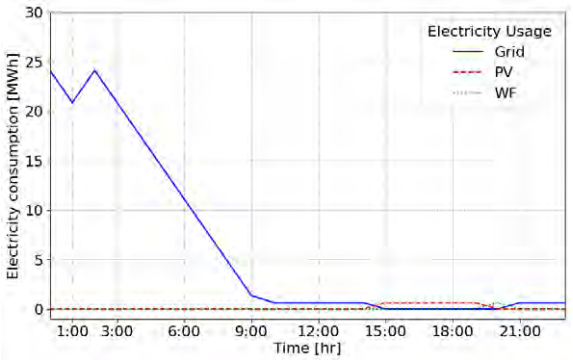

**Figure 6.** Energy consumption from different sources required to produce hydrogen in the cost minimization scenario.

### Emission Minimization Scenario

When the objective function is adjusted to prioritize minimizing total emissions, Figure 7 illustrates a shift in the optimal production schedule when utilizing time-varying emission factors. An important observation is that SMR coupled with CCS is the preferred technology configuration when minimizing emissions. In contrast, PEM is not utilized, as its high energy demand would significantly increase grid power consumption, ultimately leading to higher overall emissions. The Maximum production in Figure 7 is concentrated in the earlier hours of the day,

specifically between 9:00 AM and 12:00 PM, coinciding with the period when the grid's emission factor is at its lowest. During this timeframe, the emission factor ranges from 270 to 300 kg $CO_2$-eq./MWh consumed, highlighting the environmental benefits of strategically aligning production with periods of lower grid emissions.

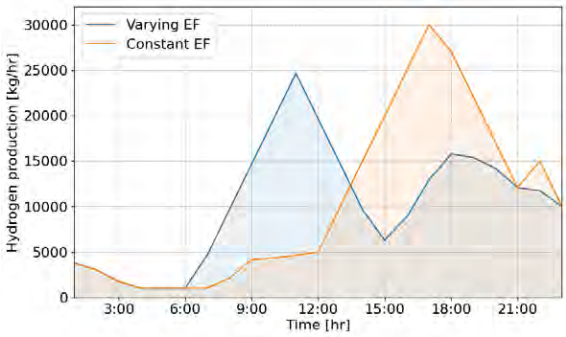

**Figure 7.** The difference in hydrogen production profiles when minimizing the total emission objective.

Table 2 reveals a significant difference in total emissions between the two carbon accounting approaches, with a disparity of 8,365 kg $CO_2$-eq. Additionally, while the change in the levelized cost of hydrogen (LCOH) is minimal, its impact becomes more pronounced when scaled to meet the daily hydrogen demand. Specifically, this minor deviation translates to a $4,800 difference in daily hydrogen value, which would accumulate to an annual difference of $1,752,000.

**Table 2:** Difference in LCOH and total emissions occurring when time-varying emission factors are utilized.

| Scenario | LCOH [kg/$H_2$] | Total Emission [kg $CO_2$ eq.] |
|---|---|---|
| Time-varying EF | 3.85 | 728,722 |
| Average EF | 3.87 | 737,087 |

A comparison of the energy consumption patterns in Figures 8 and 9 reveals that both approaches fully utilize the available solar and wind energy resources. However, the use of the grid supplier distinctly highlights the impact of varying emission factors on the timing and quantity of energy consumption required to meet the daily hydrogen production demand. In Figure 9, grid energy consumption is significantly constrained by the time-varying emission factor. In contrast, under the average emission factor scenario, there are no restrictions on when grid power can be consumed. As a result, the model is only constrained by the ramping and production limitations of the technology utilized. This demonstrates how the dynamic nature of grid emissions influences energy allocation strategies.

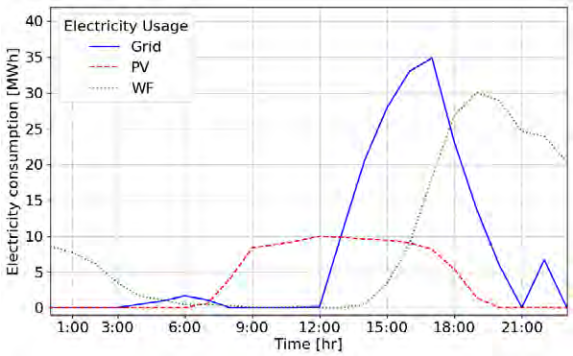

**Figure 8.** The energy consumption of different sources while utilizing an averaged emission factor approach.

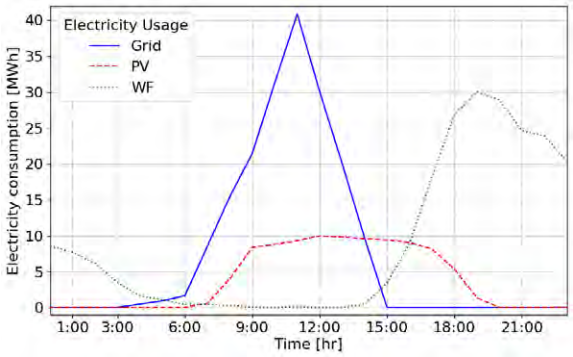

**Figure 9.** The energy consumption of different sources while utilizing a time-varying emission factor approach.

## CONCLUSION & ONGOING WORK

Time-varying environmental indicators provide deeper insights into emission accounting by addressing the uncertainty of major contributors such as grid suppliers. However, this concept can be further expanded to not only cover dynamic energy production, but also create varying emission factors for any resource that is dependent on being produced by using electricity from grid suppliers. Cooperative decision-making between energy suppliers and plant management is also essential to enhance precise and accurate real-time carbon accounting and emission factor calculation. A key area of the ongoing work is to introduce social quantification metrics into the optimization framework to evaluate broader societal impacts and have a triple-bottom-line optimization approach. Furthermore, efforts are put into investigating the temporal dynamics of greenhouse gas residence times and their influence on global warming potential over various time horizons, which could lead to having time-varying global warming potentials that can be used to calculate dynamically changing emissions present in the atmosphere. These efforts aim to refine the framework and facilitate the transition toward a more sustainable and emission-conscious hydrogen production sector.

## DIGITAL SUPPLEMENTARY MATERIAL

The supplementary materials for this study are accessible at Marcopdsousa-TAMUparametric. The data file *"RT 20 August 2024"* includes raw data for Day-Ahead Market (DAM) and natural gas prices, as well as maximum electricity production factors for solar and wind power in the Houston area, which is retrieved from ERCOT. The repository contains the optimization models used in this study. The *"Constant_EF"* model optimizes hydrogen production using the average emission factor approach, as defined by the Environmental Protection Agency (EPA). The *"Time_varying_EF"* model incorporates the calculated time-varying emission factors into the optimization framework. These resources are provided to enhance reproducibility and collaboration on the subject. For further inquiries or assistance, please contact *Marcopdsousa@tamu.edu*.

## ABSTRACT

Green hydrogen will play a key role in the decarbonization of the steel sector via the direct reduction path [1]. To meet the demand side, both a highly efficient numbering-up based scaling strategy for water electrolysis is needed as well as flexible operation strategies that follow the fluctuating electricity load. This paper presents a modularization approach for electrolysis systems that addresses both aspects by combining different electrolysis technologies into one heterogeneous electrolysis system. We present a modular design of such a heterogeneous electrolysis system that can be scaled for large-scale applications. The impact of different degrees of technological and production capacity-related heterogeneity is investigated using system co-simulation to find an optimal solution for the goal-conflict, that the direct reduction of iron for green steel production requires a constant stream of hydrogen while the renewable electricity profile is fluctuating. For this use-case the distribution of technology and production capacity in the heterogeneous plant layout is optimized regarding overall system efficiency and the ability to follow flexible electricity profiles. The simulation results are compared with conventional homogenous electrolyser plant layouts. First results underline the benefits of combining different technologies and production capacities of individual systems in a large-scale heterogeneous electrolyser plant. It is shown that the presented modular electrolysis systems can follow the current flow without losing significant efficiency. However, for a downstream system that requires a constant hydrogen mass flow, supplementary hydrogen storage is required.

**Keywords**: Energy Efficiency, Hydrogen, Process Design, Energy Systems, Renewable and Sustainable Energy, Flexibility, Lange-Große-Coefficient

## BACKGROUND

Hydrogen has a thermal and material application (purpose) in shaft furnaces. On the one hand, hydrogen is used to reduce the iron ore, and on the other hand for combustion and the associated melting of the iron ore. However, an electrolysis system is needed to provide this hydrogen. The electrolysis system presented here is to be modularly constructed and heterogeneously scaled. The concept and structure of individual modular electrolysis systems have already been explained in the past [2–4]. A heterogeneously scaled electrolysis system is understood to be the numbering-up of different electrolysis technologies in different sizes in one overall electrolysis system. That way technology-specific advantages, like high efficiency or increased energy input flexibility, can be harnessed more efficiently [5]. Due to an increasing amount of renewable energy in the grid, the price of electricity is also fluctuating more throughout the day. In general, it can be said that the electricity price is lowest when the proportion of renewable energies in the electricity mix is high [6]. These temporal fluctuations need to be harnessed by designing flexible control strategies for large-scale electrolysis systems, that can follow them. Using heterogeneous electrolysis systems can provide a bigger operational window and higher flexibility for such fluctuating power inputs while maintaining high efficiency of hydrogen production resulting in lower hydrogen cost.

## METHODS & IMPLEMENTATION

### Assumptions

An average fictional steelworks with a production capacity of 125,000 kg/h of briquetted sponge iron was set up as a boundary condition [7–9]. To produce the mass flow of briquetted sponge iron, a minimum of 6364 kg/h of H2 are required. This can be calculated from the stoichiometry in the reduction equation in (1).

$$Fe_2O_3 + 3\,H_2 \rightarrow 2\,Fe + 3\,H_2O\;\Delta H_R = 99{,}5\;kjmol^{-1} \quad (1)$$

This calculated minimum requirement shall define the lower boundary of the demand side. To define the fluctuating energy side, synthetic 'Solar Power Data for Integration Studies' data from the National Renewable Energy Laboratory for the state of New York [10] is used as a initial scenario. The data was created specifically for system integration studies, as in this study. The solar power data consists of 5-minute solar power data with hourly Day-Ahad forecasts and refers to the year 2006. The data generated from the 5-minute data set was developed by NREL using a 'Sub-Hour Irradiance Algorithm' [10]. The first week of January and the first week of July of this 5-minute time-step data were extracted and the data was normalized against the maximum within the sample set to define the operating point inputs between zero load and nominal load of the electrolysis system.

As shown in Table 1 the scaled modular and heterogeneous electrolysis system consists of aggregated blocks of both the electrolysis technologies alkaline electrolysis (AEL) and the proton exchange membrane electrolysis (PEMEL), as these two are the technologies with the highest technology readiness level (TRL). In our design an AEL block consists of eight AEL stack units with an output of 5 MW each that are connected to a lye circulation module. A PEMEL block consists of two PEMEL stack units with an output of 2 MW each that are connected to a DI-water circulation module [3,11]. A DI-water circulation module is a process engineering unit that has been specially developed for the circulation of treated water through the satellite unit. It also takes over the separation of product gases hydrogen and oxygen from the water circuit [3,11]. An efficiency of $\eta_{AEL}$= 0.68 was assumed for the AEL and an efficiency of $\eta_{PEMEL}$= 0.63 for the PEMEL relative to the lower heating value of hydrogen [11].

Another assumption is that at least one AEL block is always operated to ensure a minimum hydrogen volume flow for the subsequent process. This is since AEL cannot react as quickly to power changes and has a higher efficiency than PEMEL, which makes it more interesting for constant operation. The AEL was assumed to have a load gradient of 30 %/s ramp-up and 10 %/s ramp-down while the load gradients of the PEMEL are 50 %/s in ramp-up and 40.6 %/s in ramp-down. [11]

### Optimization problem

The hydrogen mass flow generated can be approximately calculated according to equation (1), where the nominal power of the two electrolysis technologies in hydrogen production are multiplied with their respective system efficiency and divided by the gravimetric calorific value of hydrogen, which is 33.33 kWh kg$^{-1}$ [12].

$$\dot{m}_{max}\,[\frac{kg}{h}] = \frac{A \cdot 8 \cdot 5000[kW] \cdot \eta_{AEL} + B \cdot 2 \cdot 2000[kW] \cdot \eta_{PEM}}{33{,}33\,[\frac{kWh}{kg}]} \quad (1)$$

The variables 'A' and 'B' presented in Formula (2) and (3) are used to calculate the distribution of the AEL and PEMEL. The variable 'A' represents a selected number of AEL blocks, starting with 0 blocks, scaled up step by step to 10 AEL blocks. The variable 'B' represents the corresponding number of PEMEL blocks, which can be calculated with the maximum hydrogen massflow given, using formula (2):

$$B\,[-] = \frac{\dot{m}_{max}[\frac{kg}{h}] \cdot 33{,}33[\frac{kWh}{kg}] - A \cdot 8 \cdot 5000[kW] \cdot \eta_{AEL}}{2 \cdot 2000[kW] \cdot \eta_{PEM}} \quad (2)$$

As boundary conditions, the number of respective technology blocks, A and B, cannot be below a set minimum threshold. For these first evaluations, the threshold has been set to 0.

$$A > A_{min}$$
$$B > B_{\min} \quad (3)$$

**Table 1:** Configurations of aggregated AEL and PEMEL blocks

| Config. | AEL | PEMEL |
|---|---|---|
| 0 | 0 | 109 |
| 1 | 1 | 98 |
| 2 | 2 | 87 |
| 3 | 3 | 76 |
| 4 | 4 | 66 |
| 5 | 5 | 55 |
| 6 | 6 | 44 |
| 7 | 7 | 33 |
| 8 | 8 | 22 |
| 9 | 9 | 11 |
| 10 | 10 | 0 |

As this is to be a heterogeneous electrolysis system,

both electrolysis technologies must be installed in one electrolysis system. The fifrst scaling configuration is an AEL block in conjunction with 91 PEMEL blocks. Based on this, the AEL blocks are now gradually increased up to eight AEL blocks while simultaneously reducing the number of PEMEL blocks to keep the total $H_2$ capacity (1 AEL block equals 11 PEMEL blocks). Table 1 shows the eleven possible configurations of AEL and PEMEL blocks.

The overall efficiency of the electrolysis system is calculated from the number of blocks in the system and the individual efficiencies of the electrolysis technologies using equation (4). The values of the individual efficiencies were taken from [11].

$$\eta_{sys}\,[-] = \frac{A \cdot 8 \cdot 5000[kW] \cdot \eta_{AEL} + B \cdot 2 \cdot 2000[kW] \cdot \eta_{PEM}}{A \cdot 8 \cdot 5000[kW] + B \cdot 2 \cdot 2000[kW]} \quad (4)$$

To evaluate the system flexibility the Expected Unserved Flexible Energy (EUFE) value is calculated for the described input scenario of solar power input in 5-minute time-steps [13]. The power input behavior of the electrolyzer blocks is simplified, using the load gradient parameters for a linear load ramp-up and ramp-down from Lange et al. [11]. The EUFE can now be determined from the specified operating point of the scenario and the actual operating point of the electrolysis system, following the requested load changes of the solar power input profile. Often the EUE value is also used for this, which stands for “Expected Unserved Energy”, but both describe the same thing [14]. According to equation (5), the power of the scenario is subtracted from the power of the actual operating point at each time step and integrated over the period under consideration.

$$EUFE\,[kWh] = \int abs((P_{scenario}(t) - P_{system}(t))dt \quad (5)$$

One problem with the EUFE value is the comparability of different scenarios and systems. As this is a continuous summation of the differences in output, the EUFE value is heavily dependent on the consideration of the time length of the scenario and the system under consideration. Therefore, the authors of this study aim to modify the EUFE value to consider the flexibility of a system that is more independent of the scenario under consideration and the system performance of the system under consideration. For this purpose, the EUFE value is related to the integrated power input of the scenario. The resulting value represents the share of energy in the scenario that cannot be utilized by the system under consideration. This value is referred to below as the “Lange-Große-Coefficient” (LGC) and is calculated using equation (6):

$$LGC = \frac{EUFE}{\int P_{scenario}(t)dt} \quad (6)$$

The Levelized Cost of Hydrogen (LCOH) was also calculated according to [15].

$$M = \begin{cases} y = f(\eta, LGC, LCOH, \dot{m}_{H_2}) \\ s.t.\, LGC \leq 5\% \\ s.t.\, \dot{m}_{H_2} \geq \dot{m}_{max} \end{cases} \quad (7)$$

Equation (7) describes the model of the optimisation problem.

## DISCUSSION

The system configurations listed in Table 1 were simulated in MATLAB/Simulink. The results are summarized in

Figure 2. The dots reflect the LGC (see equation (6)) against the system efficiency, the triangles the calculated LCOH against the system efficiency. The LGC increases linearly with the system efficiency, which is due to the increase in AEL in the overall system. In contrast, the LCOH behaves inversely proportional and decreases with the increase of the AEL in the overall system. If the LGC must not rise above a value of 5%, configurations 7-10 would not apply.

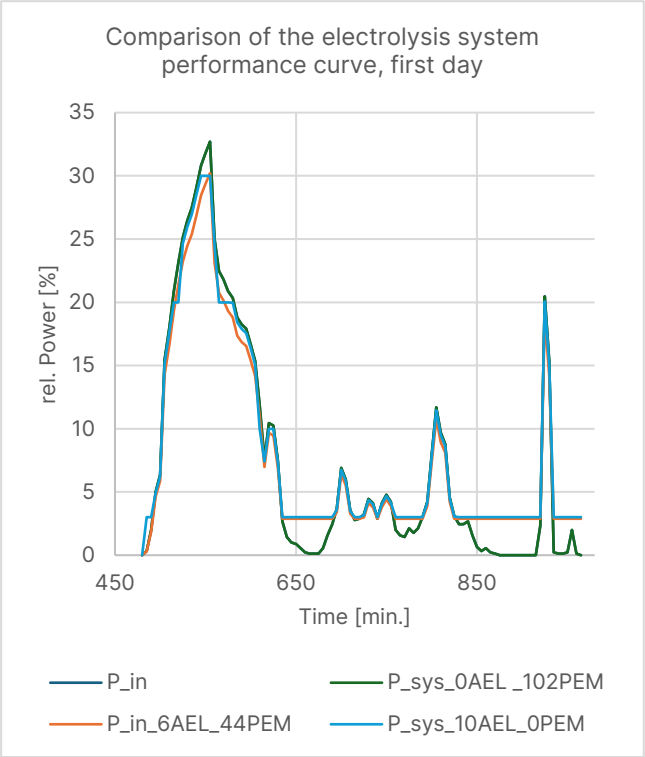

**Figure 1:** Comparison of the system outputs of the optimum case (Con. 6, orange line) and the two marginal cases (Con. 0, green line and Con. 10, blue line) with the outputs entering the electrolysis system to illustrate the ‘start-stop principle’ operating strategy [11,16]. Due to the absence of the AEL and the associated base load in Con. 0, smaller partial load ranges below 3% are also utilised.

Configuration 0 with a 100% share of PEMEL represents the first edge case. In contrast to the systems with AEL blocks there is no base load component in this edge case. As a result, every change in the input power is adopted, which means that the LGC is higher than in configuration 1. This shows, that the LGC needs further adjustments become even more independent of the flexibility requests of the input scenario. With the introduction of the base load by the AEL, the LGC decreases, while at the same time increasing the system efficiency. The second edge case is configuration 10 with a 100% AEL share. Here it is the case that when the minimum load of the AEL is reached, only the start-stop principle is used [11].

The two edge cases consisting of 100% PEMEL (configuration 0) and 100% AEL (configuration 10) are included in the analysis of the modular and heterogeneous electrolysis system. These two modular homogeneous scaling cases show anomalies, as can be seen in Figure 2. For the configuration, the increase in LGC is due to the distribution of power within the system. No minimum load was initially defined for the PEMEL, which enables the PEMEL to follow the power and the associated flexibility signals exactly. Flexibility signals are time steps at which the incoming power into the system changes, to which the system in turn must react. As soon as the AEL is added to the system, flexibility signals that are below the minimum load are ignored and are therefore not included in the calculation of the LGC, which is why the LGC drops in the first configuration.

The second edge case in configuration 10 shows a drop in the LGC. This is since anomalies also occur during system start-up, just as during system shutdown. With a start-stop strategy that only allows the system to be operated at 100% power, flexibility signals that are not sufficient to start up an entire AEL block are ignored. This leads to a reduction in the LGC. This lack of capacity was compensated for by the PEMEL in the previous configuration. One solution could be to shut down an AEL block to start a new one. This must be done on the condition that it is known that the incoming power will continue to increase. One solution could be to shut down an AEL block in order to start a new one. This must be done on the condition that it is known that the incoming power will continue to increase. The shutdown behavior of the system can also be further optimized. Here, several AEL units could initially be run in a partial load range instead of taking entire units out of operation. This would have an additional effect on the efficiency of the system, as the AEL systems are more efficient in the partial load range. Optimisation can still take place for both edge cases, as the same operating strategy was selected for the modular homogeneous systems as for the modular heterogeneous systems to establish comparability.

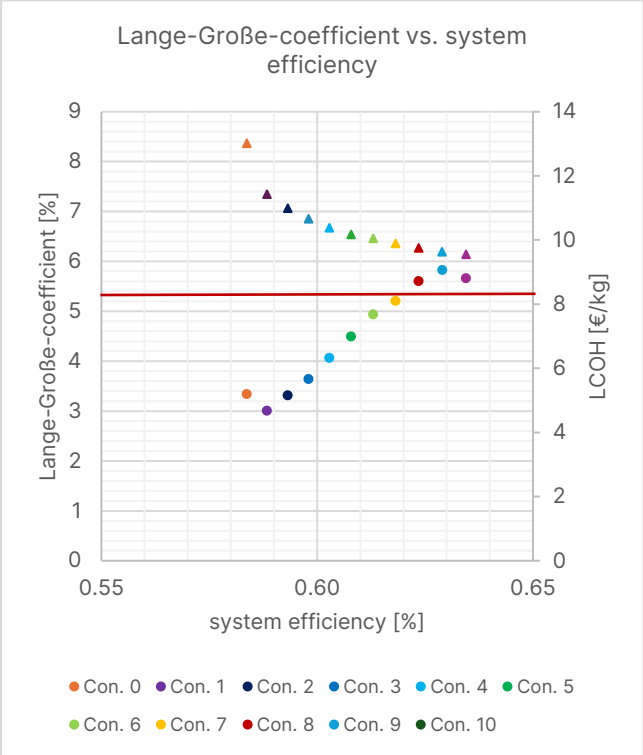

**Figure 2:** Lange-Große-Coefficient (LGC) and Levelised Cost of Hydrogen (LCOH) vs. system efficiency. All modular heterogeneous system configurations from Table 1 (Con. 1-9) are shown, including the two edge cases for modular homogeneous system configurations (Con. 0 and Con 10). The LGC is represented by a dot in the diagram, the LCOH by a triangle, and each configuration has its own colour. Dabei ist ein Abfallen der LCOH mit steigender A drop in the LCOH can be recognised with increasing system efficiency, which is the same for Con. 8 reaches a minimum. The LGC increases linearly with increasing system efficiency, if the two marginal cases are disregarded.

The weighted optimum is the sum of the system efficiency, the LGC and the LCOH. For this purpose, the LCOH is normalised and related to the lowest value. The same is done for the LGC. For both values, a low value is better than a high one. The system efficiency is also normalized to the value. The rule here is that a high system efficiency is better. The sum of these three normalized values can now only be between 0 and 3. As shown in the Figure 3 weighted optimum drops further with each configuration. With the previously established boundary condition that the LGC should not be above 5%, configuration 6 turns out to be the optimal distribution between AEL and PEMEL.

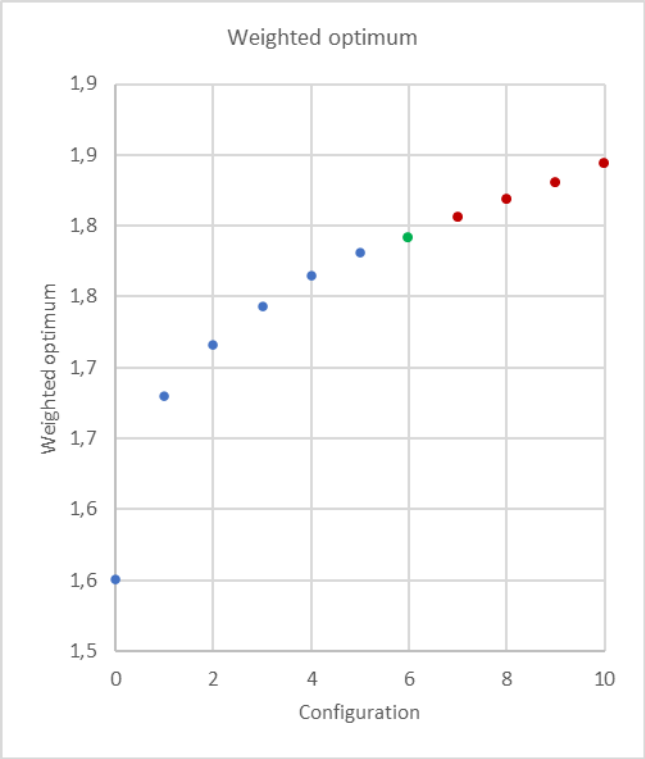

**Figure 3** The weighted optimum for all configurations. Configuration 6 is marked in green, all configurations outside the 5% limit of the LGC are marked with red dots.

## CONCLUSION

As has been shown, a fluctuating current curve can be followed with the modular heterogeneous electrolysis systems shown. This results in an optimum within the distribution of electrolysis technologies. An optimally composed electrolysis system consisting of 58% AEL and 42% PEMEL was determined for the scenario shown for an average fictional steelworks. With this composition, high efficiency at low LCOH can be guaranteed in a system that is able to respond to flexibility signals with an LGC of less than 5%. This system composition is therefore to be favored in operation. While the LCOH between configuration 6 and 10 fluctuate by 0.51 €/kg H2, the LGC between these two configurations fluctuates by 0,75%. To put this into perspective, the LCOH decreases between configurations 1 and 6 by 2.98 €/kg. Although an electrolysis system consisting purely of AEL has lower operating costs of 0.51 €/kg, it cannot react as quickly to power fluctuations. This flexibility advantage can be useful in the future, especially with flexible electricity tariffs.

## OUTLOOK

As shown in the previous section, the LGC must be made even more scenario-independent. No flexibility signals below the minimum load should be ignored. If flexibility signals cannot be served, this must be included in the LGC to ensure full comparability with the marginal cases.

Furthermore, the load distribution within an electrolysis system must be further adapted. As has been shown, the LGC can be reduced even further with a further customized operating strategy. A comparison of different operating strategies in a modular heterogeneous plant design with different electrolysis technologies must be investigated further; the foundations for this have already been laid in [11,16].

Another point is the simulative integration of high temperature electrolysis (HTEL) into a system with AEL and PEM. Here it may be possible to further increase the base load efficiency by extracting heat and the associated vaporization of water for the HTEL.

Furthermore, the relationship between a fluctuating current input and a subsequent process such as direct iron reduction after electrolysis, which requires a constant hydrogen mass flow, is still unclear. At this point, energy storage is required, either on the electricity or the hydrogen side of the process. A suitable method needs to be developed to define the right ratio between electricity and hydrogen storage.

## ACKNOWLEDGEMENTS

We would like to thank the German Federal Ministry of Education and Research and the project management organization Jülich for their financial support within the framework of the eModule research project (FKZ 03HY116A) of the H2Giga lead platform. Furthermore, the P2O-Lab Learning Factory of the TUD Dresden University of Technology is thanked for its support.

## ABSTRACT

The growing size and complexity of energy system optimization models, driven by high-resolution spatial data, pose significant computational challenges. This study introduces methods to reduce model's size and improve computational efficiency while preserving solution accuracy. First, a composite-curve-based approach is proposed to aggregate granular data into larger resolutions without averaging out specific properties. Second, a general clustering method groups geographically proximate fields, replacing multiple transportation arcs with a single arc to reduce transportation-related variables. Lastly, a two-step algorithm that decomposes the supply chain design problems into two smaller, more manageable subproblems is introduced. These methods are applied to a case study of switchgrass-to-biofuels network design in eight U.S. Midwest states, demonstrating their effectiveness with realistic and detailed spatial data.

**Keywords**: Energy and Sustainability, Biofuels, Computation Performance, Solution Quality, Optimization.

## INTRODUCTION

As a renewable energy resource, biofuels are expected to play a vital role in the transition to a low-carbon energy system, particularly in the transportation sector [1]. Although electrification has penetrated the light vehicle fleet, electrifying the heavy-duty vehicle fleet remains quite challenging [2]. In the near future, biomass-derived fuels can help alleviate the sector's reliance on fossil fuels without significantly altering the fleet [1,2].

The limitations of first-generation biofuels, mainly their competition for land use with food crops, have placed greater attention on second-generation biofuels, which are derived from ligno-cellulosic sources [3]. These crops are attractive due to their low net carbon emissions and ability to grow on non-arable lands [4]. Also, agricultural practices associated with these crops mitigate greenhouse gases (GHG) by sequestering atmospheric $CO_2$ in the form of soil organic carbon (SOC) [4,5]. However, the low bulk density of biomass and its dispersed availability often lead to expensive supply chain (SC) networks [6]. Hence, determining the optimal biofuels SC network is vital to making second-generation biofuels viable, both commercially and environmentally.

Detailed SC optimization models, typically in the form of mixed-integer linear programming (MILP) models, have been developed to investigate the economic and environmental performance of large-scale biofuels SC [7,8]. Recently, significant improvements have been made in identifying and characterizing potential fields for ligno-cellulosic crop growth, providing more detailed data on their locations and properties [6]. While highly granular data can improve the solution quality of SC models, they create significant computational issues, resulting in the formulation of models with large numbers of variables and constraints, mainly related to biomass procurement and transportation [7,8].

Spatial aggregation methods that group small fields into larger representative cells have been developed to address this issue. These approaches allow variables to be utilized at a coarser resolution, reducing model complexity. Nevertheless, this practice can reduce the accuracy of the aggregated data. The properties of the aggregated cells are typically the averages of fields' properties, failing to account for any variability in field-specific properties [9]. Furthermore, cells with fixed resolutions (e.g., counties or 25m x 25km) are commonly used for network reduction [8,9]. All fields within a cell are assumed to

share the same distances to facilities. Transportation arcs from these cells are assumed to originate from the cells' centers of mass, which are determined based on fields' locations and biomass availabilities within these cells. Given the dispersed locations of these fields, cells with fixed resolutions can lead to inaccurate transportation arcs. Such inaccuracies can reduce the solution quality of SC models.

In this paper, we propose two methods to reduce the large number of procurement and transportation variables while maintaining the accuracy of SC models: composite curves and location-based clustering. We also put forth a two-step algorithm that breaks large-scale problems into two smaller subproblems, which are solved more efficiently. The remainder of this paper is structured as follows: the Background section presents the necessary background for biofuels SC models and the terminology used in the paper. The Methods section outlines the major approaches and describes the models that can be created using the proposed methods. Lastly, a case study on biofuels SC in the U.S. Midwest is presented in the Case Study section.

## BACKGROUND

A biofuels SC model incorporates a wide range of activities and a complex set of parameters [9]. Depending on the scope and objective, implementation of SC models can help determine decisions at three distinct levels: long-term strategic, medium-term tactical, and short-term operational [9]. Long-term decisions involve facility location, technology selection, and capacity installation. Medium-term decisions include materials procurement and transportation. Short-term decisions pertain to production scheduling.

This work focuses mainly on SC models that consider medium-term decisions variables, which are specifically influenced by the granularity of spatial input data. For consistency, biomass procurement refers to the harvesting of crops at a specific location, while biomass transportation denotes the delivering of this material from a location to dedicated facilities. The cells used for aggregation are denoted as "harvesting sites" (HS).

**Table 1:** Nomenclature

| Symbol | Description |
|---|---|
| *Sets/Subsets* | |
| $f \in \mathbf{F}$ | Fields |
| $i \in \mathbf{I}$ | Compounds in the network |
| $j \in \mathbf{J}$ | Harvesting sites |
| $g \in \mathbf{G} \subset \mathbf{F}\mathbf{x}\mathbf{J}$ | Two-dimensional set of fields $f$ and the HS $j$ containing them |
| | Feedstock (biomass crop) |
| $\mathbf{I^F} \subset \mathbf{I}$ | All fields contained within an HS $j$ |
| $\mathbf{G_j} \subset \mathbf{G}$ | |
| *Parameters* | |
| $\alpha_{i,f}$ | Crop $i$ productivity in field $f$ (Mg/ha) |
| $\iota_{i,f}$ | Land available for crop $i$ in field $f$ (ha) |
| $\lambda_i^{FEED}/\lambda_i^{MAN}$ | Per-mass feedstock/management cost of feedstock $i$ ($/Mg) |
| $\upsilon_i^{HARV}/\upsilon_i^{MAN}$ | GHG emissions from harvesting/managing $i$ ($MgCO_2e/Mg$)/($MgCO_2e/ha$) |
| $\upsilon_{i,f}^{SOC}$ | SOC sequestration potential from $i$ in field $f$ ($MgCO_2e/ha$) |
| $\omega^{SCC}$ | Social cost of carbon ($/$MgCO_2e$) |
| *Variables* | |
| $H_{i,f}/\bar{H}_{i,j}$ | Procurement of $i$ in field $f$/HS $j$ (Mg) |
| $N_{i,f}/\bar{N}_{i,j}$ | Land use for crop $i$ in field $f$/HS $j$ (ha) |
| $C_{i,j}^{PRO}$ | Procurement cost of crop $i$ in field $f$ ($) |
| $J_{i,f}^{PRO}$ | GHG emissions from procuring crop $i$ in field $f$ ($MgCO_2e$) |
| $J_{i,j}^{SOC}$ | SOC sequestration from crop $i$ in HS $j$ ($MgCO_2e$) |
| $C^{TRA}$ | Transportation cost ($) |
| $OBJ$ | Objective – total supply chain cost ($) |

## METHODS

We present two complexity reduction methods and a solution method to solve large-scale SC models.

### Composite Curves

A composite curve depicts the relationship between two decision variables within an HS, such as land use and SOC sequestration, based on an optimized field selection order. This selection order is established using a ranking metric, which can change depending on the objective of the SC model. For instance, if the objective is to minimize land utilization, the ranking metric would prioritize fields based on their biomass productivity.

This leads to a distinctive land use versus biomass procurement curve. At first, the curve has a steep slope due to the use of highly productive fields, gradually flattening as less productive fields are incorporated. Using a composite curve instead of an average productivity value for the HS allows for a more precise representation of the field selection pattern inherent to the SC models. In practice, field-level optimization aims to prioritize the most productive fields to achieve minimal land utilization. Composite curves effectively capture this behavior, ensuring the alignment between field-level decisions and the aggregated outcomes at the HS level.

While the previous example emphasizes land use, which leads to a straightforward ranking metric, SC models often involve complex objectives. Then, it is crucial to systematically analyze how the procurement process contributes to the overall objective function. This involves identifying all the parameters, variables, and constraints pertaining to procurement, and modifying them to gauge how changes in procurement affect the

objective function. This rate of change derived from the analysis effectively serves as our ranking metric. To illustrate this approach, we present a case study from Christian County in Illinois (Figure 2), with an objective to minimize the total network cost, accounting for GHG emissions through the use of social cost of carbon (SCC).

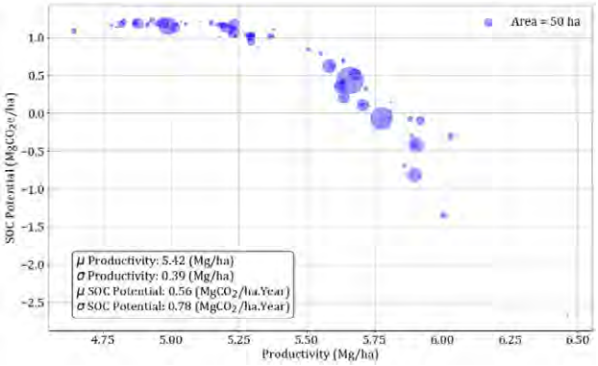

**Figure 2.** Properties of fields within Christian county for switchgrass

We first identify the contributions that biomass procurement makes to the overall network cost: procurement cost, $C_{i,f}^{PRO}$. We then identify all relevant constraints:

$$H_{i,f} = \alpha_{i,f} N_{i,f} \quad (1)$$

$$N_{i,f} \leq \iota_{i,f} \quad (2)$$

$$J_{i,f}^{PRO} = \upsilon_i^{HARV} H_{i,f} + \upsilon_i^{MAN} N_{i,f} - \upsilon_{i,f}^{SOC} N_{i,f} \quad (3)$$

$$C_{i,f}^{PRO} = \lambda_i^{FEED} H_{i,f} + \lambda_i^{MAN} N_{i,f} + \omega^{SCC} J_{i,f}^{PRO} \quad (4)$$

where Equation (1) relates land use decisions to biomass procurement decisions for each field. Equation (2) enforces an upper bound on land use. Equation (3) tracks the GHG emissions from biomass procurement, and Equation (4) calculates procurement costs. To determine how procurement costs scale with biomass procurement, we aim to convert all variables on the right-hand side of Equation (4) into $H_{i,f}$. We can make use of Equation (1):

$$N_{i,f} = \frac{H_{i,f}}{\alpha_{i,f}} \quad (5)$$

and substitute this expression into Equations (3) and (4):

$$C_{i,f}^{PRO} = \left[\lambda_i^{FEED} + \frac{\lambda_i^{MAN}}{\alpha_{i,f}} + \omega^{SCC}\left(\upsilon_i^{HARV} + \frac{\upsilon_i^{MAN}}{\alpha_{i,f}} - \frac{\upsilon_{i,f}^{SOC}}{\alpha_{i,f}}\right)\right] H_{i,f} \quad (6)$$

The rate of change of procurement cost per unit biomass procurement, described by the term in the square brackets of Equation 6, serves as the ranking metric. This ensures that the most cost-effective fields are prioritized. To aggregate field-specific variables, we introduce the following HS-level variables:

$$J_{i,j}^{SOC} = \sum_{f \in \mathbf{G}_j} \upsilon_{i,f}^{SOC} N_{i,f} \quad (7)$$

$$\bar{H}_{i,j} = \sum_{f \in \mathbf{G}_j} H_{i,f} \quad (8)$$

$$\bar{N}_{i,j} = \sum_{f \in \mathbf{G}_j} N_{i,f} \quad (9)$$

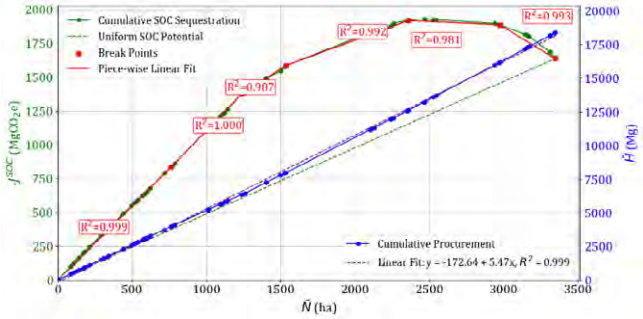

**Figure 3.** $\bar{N} - J^{SOC}$ and $\bar{N} - \bar{H}$ composite curves for Christian county with $\omega^{SCC}$ = \$65/MgCO₂e

Figure 3 displays a non-linear relationship between $\bar{N}_{i,j}$and $J_{i,j}^{SOC}$, and a linear one between $\bar{N}_{i,j}$ and $\bar{H}_{i,j}$. It is evident that we can use an average value in cases where the data has a narrow spread in values. However, composite curves are needed for data with high variability. In this example, composite curves are used to model $J_{i,j}^{SOC}$, while $\bar{H}_{i,j}$ can be assumed to scale linearly with $\bar{N}_{i,j}$.

To effectively approximate $\bar{N} - J^{SOC}$ composite curves while maintaining linearity in our model, we employ piecewise linearization. We develop a technique which seeks to maximize the linear fitting coefficients of determination $R^2$ by discretizing the $\bar{N} - J^{SOC}$ curve into consecutive linear segments. We also limit the number of segments in each curve to a maximum of six.

## Location-based Clustering

We propose using location-based clustering to define HS that better capture the geographical locations of fields for network reduction. The clustering algorithm of choice in this study is the *k*-means algorithm. The *k*-means algorithm partitions a dataset (fields) into a user-defined number *K* of distinct clusters (HS) based on selected properties (longitude and latitude):

$$min \sum_{j=1}^{K} \sum_{x \in \boldsymbol{C}_j} \left|\left|x - \mu_j\right|\right|_2^2 \quad (7)$$

where *K* is the user-defined number of HS; $x$ contains the longitude and latitude of a field; $\boldsymbol{C}_j$ is the set of fields assigned to HS $j$; $\mu_i$ contains the longitude and latitude of the centroid of HS $j$. The algorithm minimizes the within-HS variance by finding the optimal HS centroids and their member fields at the same time. With spatial coordinates as input properties, fields in the same *k*-means HS are spatially proximate, making sure that transportation arcs originating from these centroids are representative of their member fields' locations.

Because the objective function is non-convex, the algorithm is run several times with different initializations,

and the best solution is selected. The use of the *k*-means clustering for network reduction terminates the reliance on Geographical Information System (GIS) software to process geospatial data. Also, the number of HS can be easily adjusted through the parameter *K*, offering flexibility and scalability.

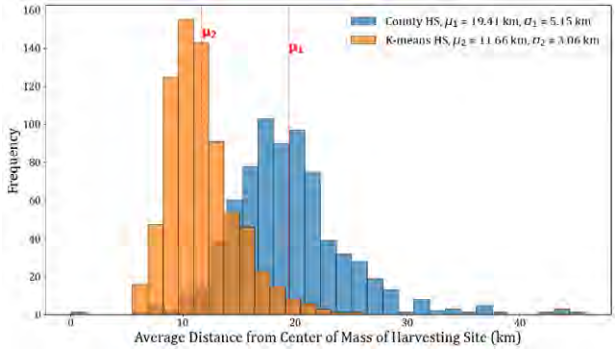

**Figure 4.** Distribution of mean distances between fields and the center of mass/centroid of their HS

To demonstrate, we apply the *k*-means algorithm to our case study, creating *K* = 734 HS. We select this *K* value because the fields in our dataset span across 734 counties in the study area. Figure 4 shows the statistics of the best solutions out of 10 *k*-means runs different initialization. As shown, the mean distances within *k*-means generated HS are more narrowly distributed than those of county-level HS.

## Two-step Algorithm

To balance computational efficiency with spatial granularity, we introduce a two-step algorithm that effectively solves large-scale network design models with high spatial resolution. In Step 1, an MILP model that incorporates at least one of the proposed complexity reduction methods is solved to attain a "coarse" solution of the large-scale model. In Step 2, this solution is refined to a higher resolution. We develop a linear programming (LP) model that takes in the HS-level procurement decisions from the Step 1 solution as parameters and re-optimizes these decisions to a field level. This second step uses field-originating transportation arcs, enabling more precise calculation of transportation costs, which can then be used to re-evaluate the objective function values found in Step 1.

The Step 1 model can have different formulations based on the methods employed, while the Step 2 model always stays unchanged. We refer to all Step 1 models by the letter M. Superscripts denote the resolution of the biomass procurement variables: field-level (*F*) or HS-level (*HS*). Subscripts describe the complexity reduction methods used. For network reduction, we can use fixed-resolution (-) or *k*-means HS (*K*). Composite curves (CC) can also be used.

Four Step 1 models are considered in this study, each having a unique combination of the proposed methods. The baseline model, $\mathrm{M}^{F}_{-,-}$, has a field resolution and uses fixed-resolution (county-level) HS for network reduction. Models $\mathrm{M}^{HS}_{-,CC}$ and $\mathrm{M}^{F}_{K,-}$ use composite curves and *k*-means HS, respectively. Finally, model $\mathrm{M}^{HS}_{K,CC}$ combines both complexity reduction methods.

# CASE STUDY

We use the four developed models to analyze a switchgrass-to-biofuels SC. The area of study includes the 8 states in the US Midwest: Ohio, Indiana, Iowa, Illinois, Michigan, Minnesota, Missouri, and Wisconsin.

All models are implemented for multiple instances. Specifiaclly, $\omega^{SCC}$ values are varied from \$0/MgCO$_2$e to \$25/MgCO$_2$e, with \$5/MgCO$_2$e increments. We also have three levels of biofuels demand, denoted as $\beta$: 500M gallons of gasoline equivalent (GGE), 800 GGE, and 1000M GGE.

We are given (i) the realistic, spatially explicit data on the biomass productivity and SOC potential of each field; (ii) potential biorefinery and preprocessing depot locations and their technology options; (iii) operating and transportation cost parameters. We also have the state-dependent prices and GHG impacts of grid electricity. Model models yield the optimal (i) fields for procurement and land utilization; (ii) facility locations, as well as their technologies and capacities (iii) transportation routing and production planning. The objective function is the minimization of total SC cost, including environmental factors, in net-present dollar amount.

All models in this study are formulated on GAMS Studio 45.7.0 and implemented with Gurobi 10.0.1.

## Effects of Composite Curves

We look into how $J^{SOC}$ values change between Step 1 and Step 2 solutions to investigate the effects of composite curves, as they are used to approximate this variable. Small differences in $J^{SOC}$ are observed between the two steps for $\mathrm{M}^{\mathrm{HS}}_{-,CC}$ in Figure 5a, showing that composite curves are able to capture the behavior of sequestration on a field level. There are, however, notable differences in $J^{SOC}$ values for both steps among models. This is due to the use of average productivity values for the HS in $\mathrm{M}^{HS}_{-,CC}$, which leads to different land use decisions, and thus different sequestration patterns in the models' solutions.

Despite this, $\mathrm{M}^{HS}_{-,CC}$ has great performance, as shown in Figure 6. The y-axis shows the fraction of all instances that are solved to optimality. The multiplier $\varepsilon$ represents how much longer it takes for each model to solve with respect to the fastest one, for that instance. The performance profile of $\mathrm{M}^{HS}_{-,CC}$ starts at y=0.39, indicating that the model is the most efficient for 39% of the instances. The

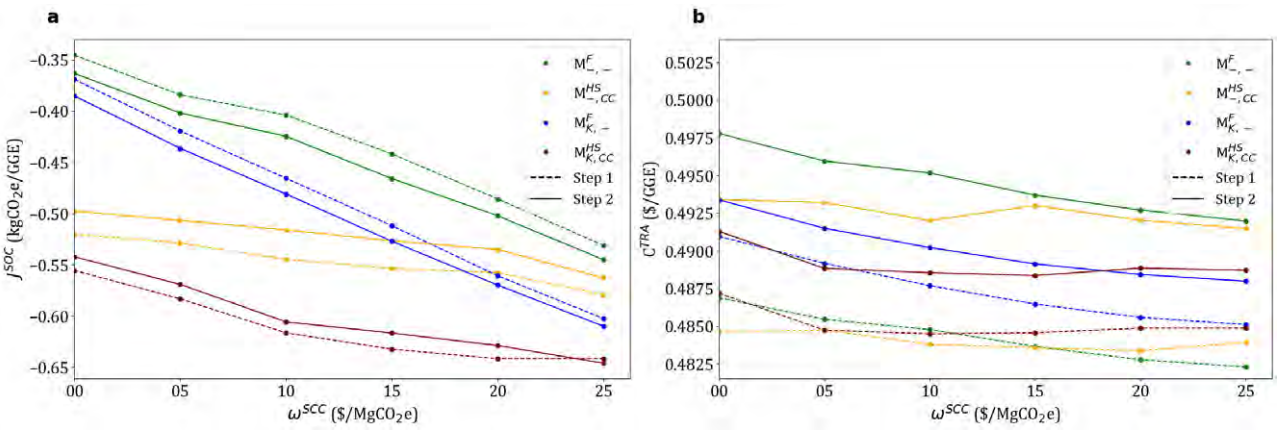

**Figure 5:** Results from the case study for all models, with $\beta$ = 500M GGE and varying $\omega^{SCC}$. a) SOC sequestration, b) transportation cost, normalized to a per GGE basis.

profile also reaches y=1.0 within a small range of $\varepsilon$, meaning that, for the instances that $M^{HS}_{-,CC}$ is not most efficient model, its run times are not significantly longer than those of the fastest model. Overall, composite curves allow us to aggregated field-level variables into HS-level ones in model $M^{HS}_{-,CC}$ without severely degrading solution quality, leading to improved run times compared to models with field-level variables.

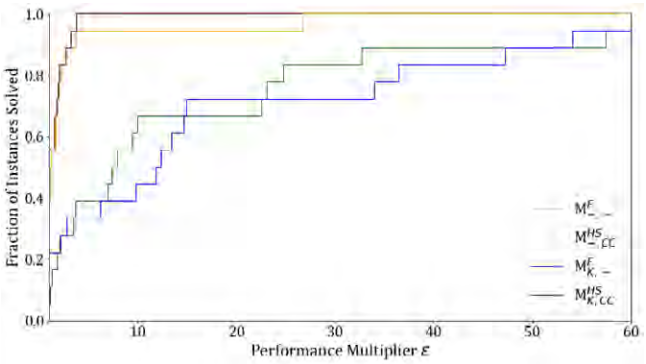

**Figure 6.** Performance chart of all models, with 18 total instances

## Effects of Location-based Clustering

For all instances, Figure 5b showcases that $M^{F}_{K,-}$ has significantly lower $C^{TRA}$ differences between Steps 1 and 2 than those of $M^{F}_{-,-}$ and $M^{HS}_{-,CC}$, which use county-level HS. These lower $C^{TRA}$ differences influence the objective in a meaningful way. For most instances, although $M^{F}_{K,-}$ finds worse $OBJ$ values than $M^{F}_{-,-}$ does, Step 2 solutions then reveal that $M^{F}_{K,-}$, in reality, attains better objective function values when $C^{TRA}$ changes are accounted for. This can lead to differences in optimal configurations. One such instance is where $\omega^{SCC}$= 15/MgCO$_2$e and $\beta$ = 800M GGE. Here, $M^{F}_{K,-}$ finds an optimal configuration that contains one more biorefinery than that of $M^{F}_{-,-}$ (circled in red on Figure 7). This result emphasizes the effects of using location-based clustering to improve the quality and accuracy of model solutions.

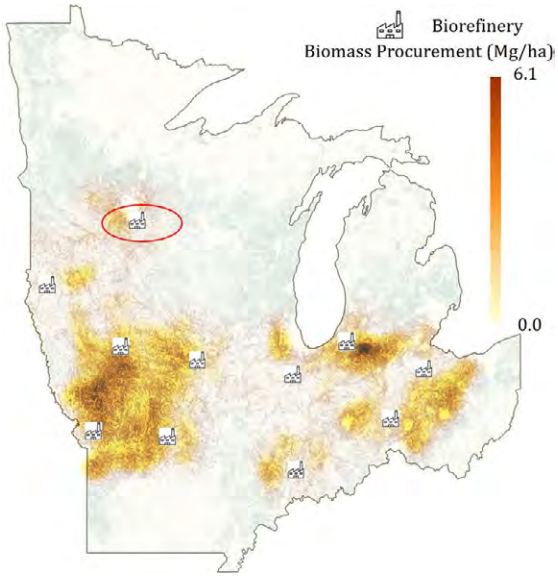

**Figure 7.** Optimal configuration of $M^{F}_{K,-}$ for instance $\omega^{SCC}$ = \$15/MgCO$_2$e and $\beta$ = 800M GGE. All refineries have pyrolysis with hydrogen purchase as the techonology

## Combined Effects

Figure 5a shows that $M^{HS}_{K,CC}$ has small changes in $J^{SOC}$ between Steps 1 and 2, illustrating the ability to capture within-HS procurement patterns of composite curves. Figure 5b exhibits similarly small $C^{TRA}$ differences between $M^{HS}_{K,CC}$ and $M^{F}_{K,-}$, highlighting the importance of *k*-means clustering. Also, $M^{HS}_{K,CC}$ displays short run times that are characteristic of composite curves. Figure 6 shows comparably fast performance between $M^{HS}_{K,CC}$ and $M^{HS}_{-,CC}$. In fact, $M^{HS}_{K,CC}$ slightly outperforms $M^{HS}_{-,CC}$. It is evident that $M^{HS}_{K,CC}$ inherits the characteristics of both

complexity reduction methods. The model maintains the field-level accuracy while using HS-level variables and having improved run times through the use of composite curves. Moreover, $M_{K,CC}^{HS}$ reduces transportation cost changes between Steps 1 and 2 through the use of *k*-means clustering. The combination of both complexity reduction methods enables $M_{K,CC}^{HS}$ to find high-quality solutions within a short amount of time.

## CONCLUSION

We investigated the use of two complexity reduction methods and a solution method, with the goal to increase the performance as well as accuracy of large-scale, spatially explicit SC models in this paper. We first introduced a composite-curves based approach, which creates characteristic curves for HS-level decision variables according to a specific ranking metric for fields. We also presented a framework to determine this ranking metric. Second, we utilized location-based network reduction, which reduces transportation-related variables by assuming the same transportation arc from multiple fields to dedicated facilities. The accurate clustering of fields for network reduction was achieved via the *k*-means algorithm, leading to more realistic transportation arcs. Lastly, a two-step algorithm was designed to decompose large-scale SC models into two more manageable sub-problems. These sub-problems can be solved sequentially and more efficiently. Lastly, we put forth a switchgrass-to-biofuels SC case study in the U.S. Midwest to probe how the proposed complexity reduction methods influence the performance and solution quality of models. Our results suggested that composite curves effectively improve the performance of models while successfully capturing the within-HS fields selection pattern, and *k*- means clustering improves models' accuracy in establishing representative transportation arcs for groups of fields. The combination of both complexity reduction methods led to better objective function value as well as more efficient performance. These ideas can be utilized in SC models that deal with large spatial datasets in order to increase their performance without trading off the accuracy of solutions.

## ABSTRACT

The ongoing energy transition involves decarbonization across different sectors. Amongst these, the transportation sector contributes significantly owing to its reliance on traditional fossil fuels as feedstock. Attaining decarbonization goals requires the adoption of novel sustainable technologies such as electric vehicles (EVs), and hydrogen fuel cell vehicles (HFCVs), amongst others. The feedstock transition towards electricity and dense energy carriers is challenged by the requirement for additional infrastructure to manage intermittency, power generation, and grid expansion which requires both materials and capital investment. By evaluating and redirecting the role of carbon value vector from fossil fuel production towards the production of carbon-based materials such as polymers to empower the energy transition, we can optimize resource allocation and maintain economic viability, all while reducing environmental impact. In this work, we propose an integrated framework to systematically address energy-materials-mobility transition nexus challenges. The proposed multiscale framework utilizes a resource-task-network (RTN) representation and a life cycle assessment (LCA) step and considers future material demand and production capacities. Its capabilities are demonstrated through a case study on the transition from gasoline-fueled vehicles to EVs, analyzing (i) the role of carbon value vectors in resources and materials production, and (ii) electricity generation, storage, and dispatch using intermittent renewables. The study reveals the interactions between energy, material, and mobility value chains while providing configurations for exploiting such synergies.

**Keywords**: Energy transition, Material transition, Carbon value vectors.

## INTRODUCTION

The energy transition necessitates the adoption of low-carbon technologies, which are inherently capital-intensive and require substantial material inputs [1]. This creates a critical nexus between energy and materials, as the development of new infrastructure demands significant quantities of resources, while the growing energy sector is required to manufacture components such as wind turbines, solar panels, and electric vehicles [2].

Renewable power systems, such as solar photovoltaics (PV), wind farms (WF), and decarbonized transportation technologies, including EVs, rely on materials like metals, rare earth elements, polymers, and concrete. However, the extraction and processing of these materials are energy and emission intensive [3]. Leveraging synergies between distinct value chains offers a pathway to promote decarbonization while managing economic expenditures.

For instance, polymers have the potential to play a pivotal role in the mobility transition, functioning as carbon sinks, and contributing to decarbonization efforts [4]. We are considering that polymers can be produced from fossil fuels and can be carbon sinks since instead of burning fossil fuels, they can be utilized to produce materials. Another case is when polymeric materials are

created from $CO_2$ captured utilizing CCUS technologies for the current BAU production and utilizing it to produce monomers for polymers through technologies such as methanol to olefins and oxidative coupling of methane. Polymers can enhance fuel efficiency by making vehicles lighter, serve as integral components in renewable energy systems and grid infrastructure, and be synthesized using carbon captured from industrial processes [5]. A promising approach to addressing these challenges involves reevaluating the role of carbon as a value vector. Repurposing existing oil and gas infrastructure for polymer production rather than traditional fuel refinement offers an opportunity to reduce carbon emissions in the mobility sector while capitalizing on existing assets [6, 7].

A holistic approach must be taken to achieve cost-effective solutions in the energy-materials-mobility transition nexus, analyzing the current and future scenarios, and considering all three interconnected aspects to ensure sustainable and efficient outcomes. This includes operational carbon footprint as well as those embedded in material extraction, manufacturing, and infrastructure development. The 3 synergetic transitions in energy, materials, and mobility (See Figure 1), face significant challenges, including managing energy storage for intermittent renewables, addressing emissions from diverse sources, optimizing production costs, and coordinating technology transitions across sectors such as power generation, and transportation [8].

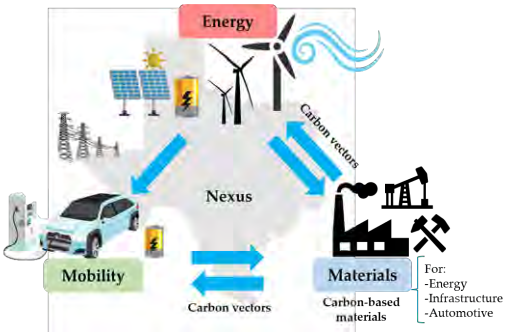

**Figure 1.** The energy-materials-mobility nexus.

This work introduces a multiscale modeling and optimization framework using the resource task network (RTN) representation which integrates network design and operation considering the nexus between energy-materials-mobility transition. A mixed-integer linear programming (MILP) integrates an LCA step for emissions from material synthesis, resource consumption, and infrastructure establishment. A case study on the transition from gasoline-fueled vehicles to EVs highlights the framework's capabilities, focusing on the role of material production and electricity generation, storage, and dispatch. This analysis implemented in energiapy uncovers synergies between energy, material, and mobility value chains, and identifies optimal configurations, and trade-offs across key parameters [9].

## CASE STUDY CONSIDERATIONS

The energy transition is driving a transformation across multiple sectors, including mobility infrastructure, manufacturing technologies, power generation, and material production. These interconnected shifts highlight a crucial nexus between energy, materials, and mobility.

**Energy Transition**: Power generation must expand to meet the increased demand from transportation and manufacturing. Requisite power generation and management systems can be established through different material alternatives. PVs can be made from monocrystalline or polycrystalline silicon, lithium for lithium-ion batteries can be sourced either through rock or brine lithium, and wind farms can be offshore or land-based each with different material requirements. Other materials required for construction include glass, steel, concrete, aluminum, silicon, copper, and cast iron [10-12].

**Material Transition**: Low-carbon technologies necessitate the production of advanced materials, such as those needed for renewable energy systems, batteries, and vehicle components. Polymer production is modeled as High-Density Polyethylene (HDPE) production and the production of vehicle parts through a combination of different methods [11].

Technological pathways for plastic production [13]:

1. Business as usual (BAU): HDPE is produced from fossil feedstock such as natural gas and oil.
2. Carbon capture utilization and sequestration (CCUS): Utilizes resources such as $CO_2$, $H_2$ and $O_2$.

Additionally, two processes are given for olefin production from $CO_2$. The pathways considered for olefin production are [14]:

1. Methanol to Olefins (MTO): Involves synthesizing methanol through $CO_2$ hydrogenation, which is then converted into olefins, primarily ethylene and propylene.
2. Oxidative Coupling of Methane (OCM): In this process, methane derived from $CO_2$ hydrogenation undergoes oxidative coupling to predominantly produce ethylene.

Moreover, the role of oil in producing polymers is introduced as a new concept of carbon value vectors utilization of the carbon-based materials that come from fossil fuel production, in which the current oil use for fuels or manufacturing polymers will change over time.

**Mobility Transition**: This sector involves adopting alternative fuels and transitioning from internal

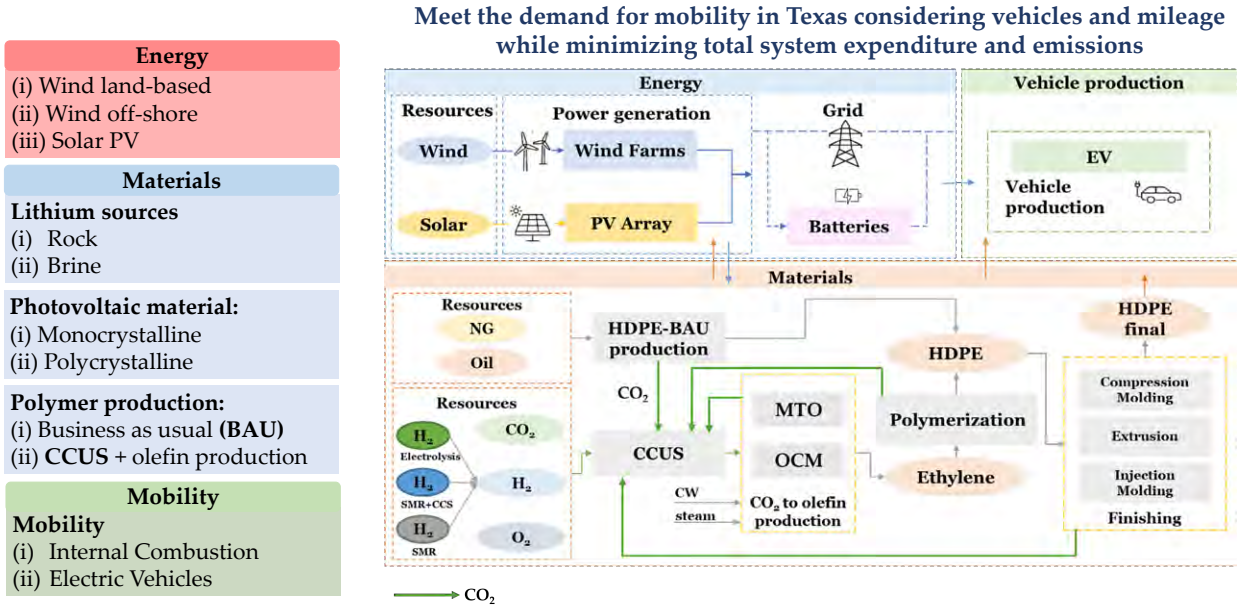

**Figure 2:** Comprehensive schematic of the mobility transition supply chain case study, illustrating the included resources and processes. The diagram comprises three key components: 1) Renewable energy-based power generation. 2) Polymer production via both fossil fuel-based (BAU) and CCUS pathways. 3) Vehicle production, focusing on three HDPE finishing processes for automotive applications.

combustion engine vehicles (ICEVs) to alternatives such as EVs [15]. This requires both new types of vehicles and the infrastructure to support them.

These transitions are highly interdependent, creating a nexus between them. For example, renewable power generation supports manufacturing and transportation, while advanced materials, including carbon-based polymers, enable the development of efficient vehicles and infrastructure. The mobility sector, in turn, influences energy demand and material production needs, creating a feedback loop within this interconnected system. The representation of the system of study is shown in Figure 2, illustrating the key components of the energy-materials-mobility transition nexus.

## METHODOLOGY AND FORMULATION

The framework operates on multiple scales, capturing phenomena that vary across space and time, such as fluctuations in renewable energy availability. Additionally, it integrates operational decisions with network planning into a unified model. The planning horizon is divided into two distinct scales: (1) a broader scale for network-level decisions and (2) a detailed scheduling scale with hourly resolution. The framework integrates the optimization of both network design and process scheduling. Mixed-integer linear programming is employed, binary variables are used for decisions such as process placement and selection of optimal material modes, while continuous variables address mass balance and economic considerations. Key constraints include material balance, emission limits, and network design requirements.

### Sets and definitions

**Table 1:** Sets

| sets | definition |
|---|---|
| $l \in L$ | location |
| $p \in P$ | process |
| $r \in R$ | resource |
| $m \in M$ | material |
| $w \in W$ | material modes |
| $e \in E$ | emissions |
| $t \in T^N$ or $t \in T^S$ | network or scheduling scale |

### Network design constraints

- Process/inventory capacity: Processes and inventories are restricted within specified minimum and maximum capacities ($Cap_{l,p/r,t}^{P/S-min/max}$). The binary variable $x_{l,p/r,t}^{P/S}$ takes a value of 1 if the capacity is expanded during that time and 0 otherwise.

$$Cap_{l,p/r,t}^{P/S-min} \cdot x_{l,p/r,t}^{P/S} \leq Cap_{l,p/r,t}^{P/S} \leq Cap_{l,p/r,t}^{P/S-max} \cdot x_{l,p/r,t}^{P/S} \forall\, l \in L, r \in R, p \in P, t \in T^N \quad (1)$$

- Capacity of material mode: The capacity of a process $Cap_{l,p,w,t}^{P-W}$ is determined by the material mode selected for constructing the process. This

capacity is constrained by the process's minimum and maximum limits. The binary variable $x_{l,p,w,t}^{P-W}$ takes a value of 1 if the material mode is active, and 0 otherwise.

$$Cap_{l,p,t}^{P-min} \cdot x_{l,p,w,t}^{P-W} \leq Cap_{l,p,w,t}^{P-W} \leq Cap_{l,p,t}^{P-max} \cdot x_{l,p,w,t}^{P-W} \forall\, l \in L, w \in W, p \in P, t \in T^N \quad (2)$$

Binary variables $x_{l,p,w,t}^{P-W}$ are introduced for each process and material mode option used. The binary variable $x_{l,p,t}^{P}$ indicates whether a process is active or not and is defined as the sum of the binary variables corresponding to the selected material modes for that process.

$$x_{l,p,t}^{P} = \sum_{w \in W} x_{l,p,w,t}^{P-W} \forall\, l \in L, w \in W, p \in P, t \in T^N \quad (3)$$

## Materials constraints

- Materials to set up a process: This quantity ($Mat_{l,p,m,t}^{P}$). is the sum of the products of material consumption ($Mat_{p,w,m}^{cons}$) for a given process, mode, and material, and the capacity of each process mode ($Cap_{l,p,w,t}^{P-W}$).

$$Mat_{l,p,m,t}^{P} = \sum_{w \in W} \left( Mat_{p,w,m}^{cons} \cdot Cap_{l,p,w,t}^{P-W} \right) \quad \forall\, l \in L, m \in M, p \in P, t \in T^N \quad (4)$$

- Materials utilized at a location: Calculated as the summation of the materials utilized across all processes.

$$Mat_{l,m,t}^{L} = \sum_{p \in P} Mat_{l,p,m,t}^{P} \forall\, l \in L, m \in M, t \in T^N \quad (5)$$

- Materials utilized in the network: Calculated as the sum of the materials utilized across all locations.

$$Mat_{m,t}^{N} = \sum_{l \in L} Mat_{l,m,t}^{L} \forall\, m \in M, t \in T^N \quad (6)$$

## Emissions constraints

Different types of emissions are identified, such as emissions coming from resources, indirect emissions from materials, and direct emissions from processes [10, 11].

- Emissions from materials: The emissions resulting from materials ($Em_{l,e,m,t}^{m}$) are calculated as the product of the emission factor for that material ($EP_{e,}^{m}$) and the amount of the material utilized at a location and time ($Mat_{l,m,t}^{L}$).

$$Em_{l,e,m,t}^{m} = EP_{e,}^{m} \cdot Mat_{l,m,t}^{L} \forall\, l \in L, e \in E, m \in M, t \in T^N \quad (7)$$

Emissions are annualized based on the lifespans of the technologies, materials, and vehicles used in the system. Technologies are designed to last 20 years, while vehicles have a lifespan of 15 years. The total emissions are calculated over the entire lifetime of the system, but for reporting purposes, only the annual emissions corresponding to yearly production are displayed.

- Total emissions at a location: This quantity includes emissions from resources ($Em_{l,e,r,t}^{r}$), materials ($Em_{l,e,m,t}^{m}$), and processes ($Em_{l,e,p,t}^{p}$). The total emissions of the network can be calculated in a similar form to equation 6.

$$Em_{l,e,t}^{L} = \sum_{r \in R} Em_{l,e,r,t}^{r} + \sum_{m \in M} Em_{l,e,m,t}^{m} + \sum_{p \in P} Em_{l,e,p,t}^{p} \forall\, l \in L, e \in E, t \in T^N \quad (8)$$

## Objective functions

Different objectives can be defined based on the decision maker's motivation, such as the minimization of the cost of the network or the environmental impact.

- Cost: Minimize the cost of the network.

$$Min \sum_{t \in T^N} \propto \cdot Capex_t^N + Fopex_t^N + Vopex_t^N \quad (9)$$

- Environmental: Minimize the emissions of the network.

$$Min \sum_{t \in T^N} Em_{e,t}^N \quad (10)$$

# RESULTS AND DISCUSSION

## Polymers for the mobility transition

A base case is established to minimize the system cost for polymer production. The network design for the base case consists of WF, PV, LiI batteries, HDPE production from the BAU pathway, and the finishing processes (Figure 3). With the base case established, the network is optimized for reducing GWP, achieving a maximum emissions reduction of 34.7%. The minimum emissions design favors the WF because it has lower material emissions than PV for energy production and integrates the CCUS with the MTO pathway for polymer production (Figure 4). This reduction corresponds to a 135.63% increase in cost compared to the base case (Figure 5).

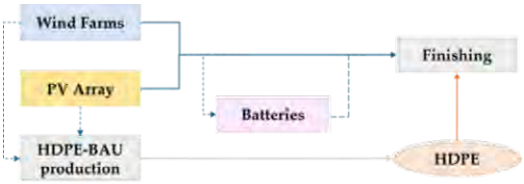

**Figure 3.** Low-cost pathway for HDPE production.

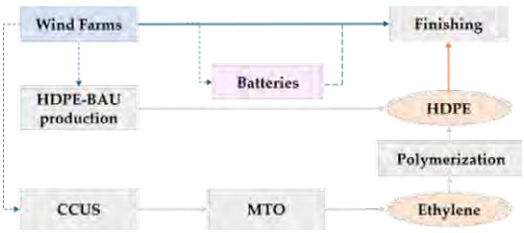

**Figure 4.** Low carbon pathway for HDPE production.

## Integration of materials in the framework

Different studies do not consider the impact of material on the design and scheduling of energy systems, resulting in a more optimistic scenario.

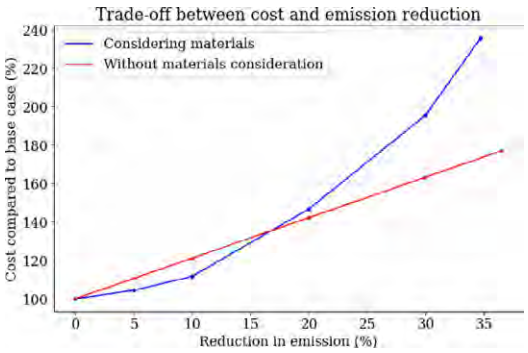

**Figure 5.** Trade-off between cost and emissions reduction for polymer production.

In this example, including materials results in a maximum emissions reduction of 34.7% with a 135.63% cost increase. However, not including the material aspect in the framework achieved a higher maximum emissions reduction of 36.5% and a lower extra cost (77.1%). These findings highlight the need to account for material aspects to achieve accurate outcomes. Additionally, Figure 6 shows the breakdown of emissions for each point in the Pareto curves above, illustrating the types of materials, resources, and processes that generate emissions in the system.

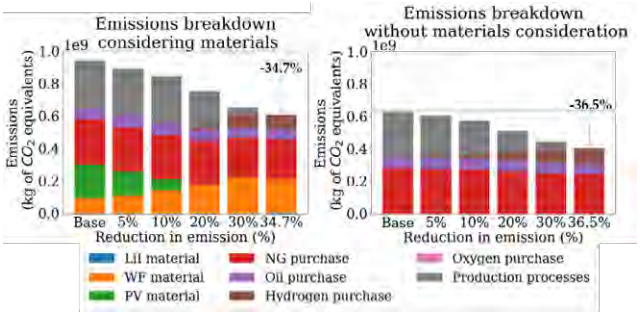

**Figure 6.** Breakdown of emissions for polymer production.

## Analysis of Texas mobility transition through the years

In the last section, only the polymer production for vehicles was considered. Here, the driving phase is also integrated into the case study. For this analysis, the projection of vehicles in Texas was considered with the future demand of cars expected every decade, using a linear model ($y = 305873x - 6 \cdot 10^8$) where $y$ is the number of cars expected in year $x$. Starting in 2025, with about 26 million vehicles, a base case with all ICE cars is considered. Three scenarios for the future are analyzed, with low, medium, and high reductions in oil consumption.

**Table 2:** Scenarios studied for mobility transition subject to reduction in oil consumption and EV adoption results.

| | Maximum oil consumption (%) | | | | | |
|---|---|---|---|---|---|---|
| **Scenario** | **Low (%)** | **EV (%)** | **Medium (%)** | **EV (%)** | **High (%)** | **EV (%)** |
| 2025 | 100 | 0 | 100 | 0 | 100 | 0 |
| 2030 | 95 | 12.3 | 90 | 18.1 | 80 | 29.6 |
| 2040 | 90 | 27.9 | 80 | 37.8 | 60 | 55.7 |
| 2050 a | 85 | 40 | 70 | 52.3 | 40 | 74.8 |
| 2050 b | | | | | 0.1 | 100 |

For each scenario, the objective is to minimize the cost of the system subject to a maximum hourly consumption of oil concerning the base year 2025 (Table 2). An extra scenario with 100% EVs by 2050 was also introduced (2050 b). The constraints in the reduction of oil consumption led to the adoption of EVs (Table 2), the number of EVs shown corresponds to the minimum cost of the network with energy coming from PVs and WFs.

## Cost of the mobility transition

For each scenario, the reduction in oil consumption affected lowering the average emissions per car over the years. Additionally, the average cost per car and yearly emissions were determined as shown in Figure 7. It is shown that the total emissions per car are reduced with a significant cost increase due to the investment in EVs and renewable energy generation. Relying solely on wind farms for power generation incurs higher costs but results in greater emissions reduction due to the lower emissions associated with materials for WFs (Figure 8).

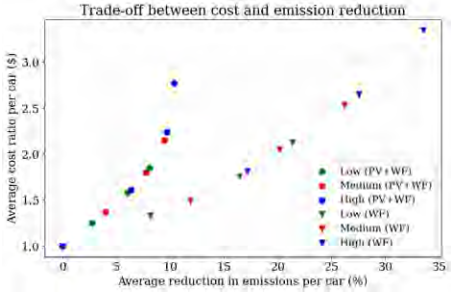

**Figure 7.** Cost vs. emissions of the mobility transition.

## Material impact on the mobility transition

The environmental impact of the mobility transition was quantified by considering materials, resources, and processes, as shown in Figure 8 (for the high reduction in oil consumption scenario). It is important to note that the total emissions of the fleet decrease in cases where all the energy is generated through WF. However, this result depends on the assumption of the fleet projections. For

example, despite the adoption of EVs, emissions may continue to rise if energy production relies on a combination of photovoltaic (PV) systems and WFs due to the material emissions associated with PVs. However, emissions will still be lower than solely relying on gasoline vehicles.

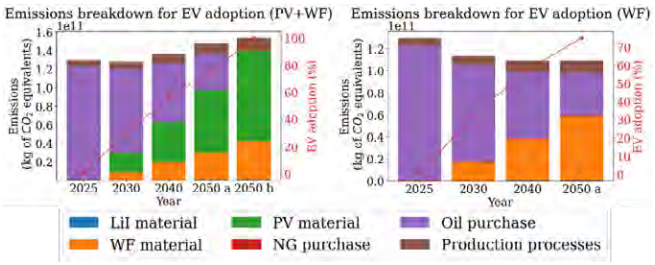

**Figure 8.** Contribution of materials, resources, and processes to emissions for high EV adoption.

## Renewable energy expansion and carbon vectors in the mobility transition

For the given scenarios the total installed capacity of renewable energy was estimated per decade as shown in Figure 9. Additionally, these capacities were compared with the current Texas grid capacity (Table 3), finding that the expansion of renewable energy can be similar to the current installed grid capacity for scenario 2050 b (100% EV).

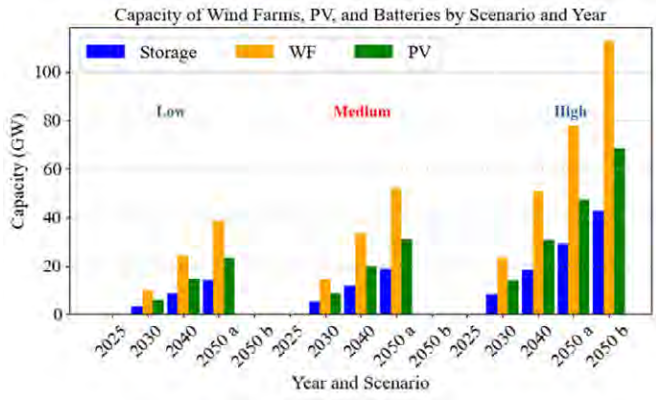

**Figure 9.** Required installed capacity of renewables and storage for the mobility transition.

Moreover, Table 3 evaluates the carbon value vectors of oil used in producing plastics in the column of oil to plastics, quantifying the amount of oil that can be redirected to valuable polymers for vehicles and charging stations over time. Given that this represents a small amount of the current oil consumption in the mobility sector, other applications for this resource can be explored.

**Table 3:** Comparison of the required capacity of WF and PV with the current grid capacity in Texas (145 GW).

| Scenario | WF capacity (%) | PV capacity (%) | Oil to plastics (%) |
|---|---|---|---|
| 2025 | 0.22 | 0.14 | 0.077 |
| 2030 | 16.05 | 9.67 | 0.081 |
| 2040 | 34.96 | 21.11 | 0.090 |
| 2050 a | 53.65 | 32.46 | 0.098 |
| 2050 b | 77.56 | 47.05 | 0.098 |

## CONCLUSIONS AND FUTURE WORK

This study served to realize interconnections between energy and materials, emphasizing the importance of an integrated energy-materials nexus approach for applications in the design of energy systems. Different aspects were addressed with the framework such as the integration of materials and energy requirements and technologies, the trade-offs between cost and emissions reduction, as well as the impact of emerging technologies. Process lifetimes and the circularity of materials can be incorporated for a more comprehensive approach, as well as carbon taxes and future reductions in EV costs.

Besides renewable intermittency, the framework can also accommodate variability in the cost of resources such as natural gas and oil and resource demand. Case studies considering such aspects and the redirection of oil resources will be presented in future publications. The inclusive framework for the Energy-Materials-Mobility Transition Nexus can coordinate options of technologies and materials to determine the minimum cost, minimum emissions scenarios, and tradeoffs. Considering material use for setting up technology infrastructure systems provides realistic emissions reduction and cost scenarios and allows the investigation of material substitution options as carbon sinks through the utilization of carbon value vectors in a circular economy framework.

## ABSTRACT

The turbulence in energy markets poses risks to energy suppliers, impacting profitability. Whilst risk mitigation is crucial for new projects, adapting existing infrastructure to evolving conditions incurs additional costs. For natural gas dependent economies, the natural gas industry faces exogenous uncertainties represented by demand and price fluctuations, and endogenous risks arising from inadequate proactive planning. This study evaluates the resilience of optimised Qatar's natural gas monetisation infrastructure under different cases by examining the network's ability to meet production targets amid process disruptions and market volatility. The analysed network includes 6 direct and indirect utilisation routes, represented by liquefaction, Haber-Bosch, methanol, gas-to-liquids, MTBE and urea processes to produce 9 products. First, process simulations and market assessments were used to obtain operational and market input data. Second, a mixed-integer linear programming model was used to optimise the natural gas allocation to processes under 9 case studies for a planning horizon of 10 year (2024-2033) with an objective of profitability maximisation. Third, the resilience% of processes and the overall network was estimated as per the model's suggested allocation strategy to evaluate the infrastructure utilisation efficiency. Process resilience below 100% indicates vulnerability to disruptions. Incorporating operational and market data increased network resilience from 74% to at least 82%, highlighting the value of flexibility in planning. Furthermore, allowing dynamic natural gas allocation improved profitability by at least 27% compared to a baseline scenario lacking operational and market considerations. The findings highlight the importance of adaptive strategies in ensuring long-term economic sustainability.

**Keywords**: Natural gas monetisation, Operational flexibility, Resilience, and Flexibility

## INTRODUCTION

The rapid global growth in populations and economies has led to an increase in energy consumption for industrialisation, transportation, urbanisation, food production, and drinking water production. Increased interest for utilising different energy resources has dominated countries for energy generation, including fossil-based fuels and renewable energy resources. However, following the adoption of the Paris Agreement on climate change in 2016, a significant transition toward cleaner energy resources has been observed to mitigate greenhouse gas emissions. Natural gas has been recognised as a cleaner energy resource in national energy and environmental roadmaps until the full transition to renewables. Overall, different chemical and physical natural gas monetisation options have been deployed to produce value-added products wherein each produced commodity has different applications, markets, and pricings. Hence, end-markets play a critical role in shaping the overall economic sustainability and growth of gas-based economies. For the state of Qatar, the country has deployed direct and indirect monetisation routes for monetising its fundamental resource. This includes direct processes, including gas-to-power liquefaction, gas-to-liquids (GTL), Haber-Bosch technology, and the methanol

SLB-Private

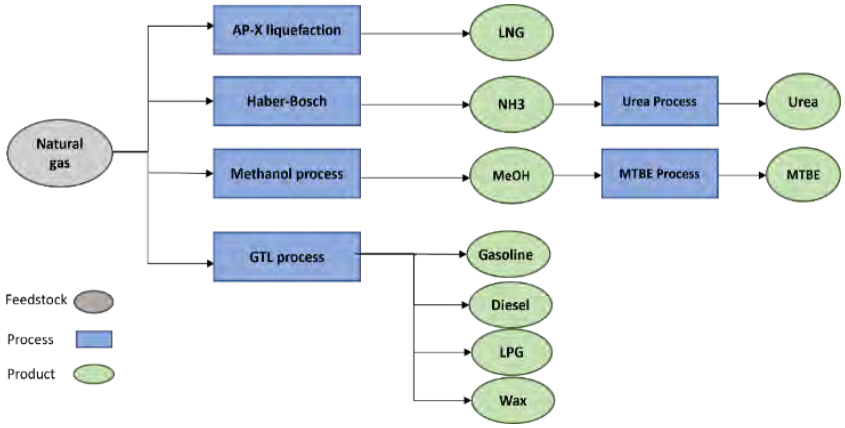

**Figure 1.** Investigated Qatar-based natural gas monetisation network, managed by QatarEnergy.

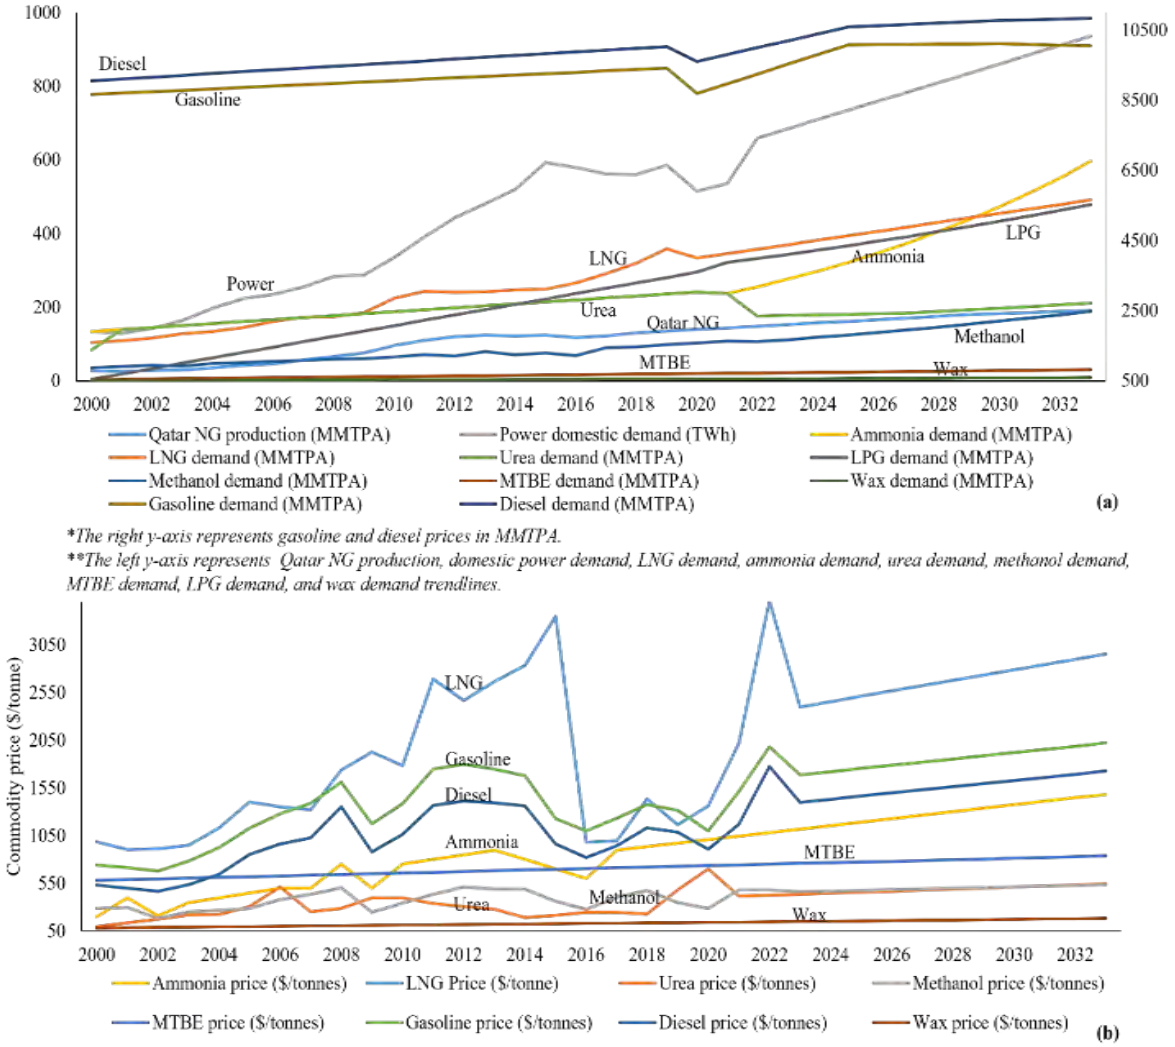

**Figure 2.** Input market data for optimising annual natural gas allocation: (a) demand data and (b) price data.

process, and in-direct routes, such as methanol to methyl tert-butyl ether (MTBE) and ammonia to urea.

With the increased uncertainties imposed on the market due to supply shocks, geopolitical tensions, and pandemics, the influence of uncertainties on existing and planned oil and gas supply became crucial for producers, consumers, and policymakers. Such assessments are especially important given the fluctuation's consequences

in terms of economic disruptions, energy security, and environmental sustainability. In the literature, researchers addressed the effectiveness of quantitative decision-making tools to evaluate the cost-effective utilisation of natural gas under market uncertainties [1,2]. Li et al., [3] utilised mathematical formulation as a decision-making tool and developed two scenario-based two-stage stochastic programming models for investigating optimal natural gas infrastructure development under market uncertainties. Additionally, Attia et. al. [4] developed a multi-objective stochastic mathematical programming model for tactical planning in the downstream sector of the oil and natural gas supply chain, addressing uncertainties in petroleum product prices and demand. On the other hand, managing an existing supply chain under uncertainties represents more challenges due to systems restrictions related to deployed infrastructure. Earlier studies investigated the optimal natural gas allocation to a multi-level network comprising different natural gas monetised products under demand and price uncertainties using quantitative decision-making tools represented by agent-based modelling and mathematical programming [5,6]. Fundamentally, the tools have been deployed for allocation under economic or environmental objectives, considering market data and operational data. The results of the studies provided crucial insights in terms of the economic added value of switching production capacities of different processes within the network based on market performance. Yet, the resilience (i.e., the ability of the network to withstand disruptions) of such a decision was not evaluated as a decision metric. This study addresses the gap in natural gas network optimisation under uncertainty by evaluating the resilience of allocation decisions proposed by decision-making tools. It focuses on optimising annual natural gas distribution within Qatar's multi-level network, considering uncertainties in demand and pricing, as well as operational constraints for flexible operations. This approach enables an understanding of the added value of operational flexibility from economic, environmental, and resilience perspectives in the context of natural gas network planning and management.

## METHODOLOGY AND DATA

This work utilises a data-driven mathematical programming model as a quantitative decision-making approach for the optimisation of natural gas allocation to processes within the Qatari natural gas monetisation network, managed by QatarEnergy. The approach aims to justify the importance of such models in addressing market volatility and enhancing economic attractiveness by adjusting the annual production capacities dynamically, based on demand, prices, and operational constraints. Figure 1 illustrates the Qatar-based natural gas monetisation network, comprising four direct natural gas utilisation processes (i.e., AP-X liquefaction, Haber-Bosch, Methanol process, and GTL process) and two indirect processes (i.e., Urea process and MTBE process) for the production of nine products (i.e., LNG, ammonia, methanol, gasoline, diesel, LPG, wax, urea and MTBE).

### Input Data

The proposed mathematical model integrates projected annual demand and commodity prices with technical data from Qatar's natural gas processes to optimise resource allocation. Demand and price historical and forecasted data for the period between 2000 and 2033 were derived from online sources, with data gaps addressed using interpolation and cross-verification techniques [7-9]. Additionally, the study herein focuses on 10-years planning horizon (2024-2033) to balance practicality and flexibility, minimising long-term forecasts risks. Figure 2 illustrates the price and demand time series associated with different products. In terms of operational data, technically validated operational bounds for the production processes were considered (Table 1).

### Mathematical Model Formulation

With an aim to optimise annual natural gas allocation to the multi-level production network, the model proposed herein is a mixed-integer linear programming model (MILP), formulated and solved using the concept of superstructure. The objective function of the model aims to maximise the overall network's profitability (revenue-cost) by optimising the annual allocation of available natural gas ($M_t$), to a process ($\mathcal{J}_k$) in the process structure $k$. Fundamentally, each product within the network is associated with a revenue that influences the first part of the objective function. While the second part of the objective function is influenced by the fixed process's cost ($\mathrm{F_i}$), the varied operating cost ($C_{it}$), and the natural gas share allocated to a process ( $\mathrm{m_{it}^{in}}$). The model can be summarised as follows:

#### Objective function, Maximise:

$$\sum_{j\in\mathcal{J}_i}\sum_{t\in\tau} R_{jt} m_{jt}^{out} - \left[\sum_{i\in I} F_i + \sum_{i\epsilon\mathcal{J}_k}\sum_{t\epsilon\tau} C_{it} m_{it}^{in}\right] \quad (1)$$

#### Constraints:

The following conservation constraint ensures continuity in flow dynamics for all process structures:

$$m_{kt}^{\circ} = \sum_{i\in\mathcal{J}_k} m_{it}^{in} \qquad \forall k \in \mathcal{K}\ \&\ t \in \tau \qquad (2)$$

For fixed operational conditions (temperature and pressure), the yield ($X_{\mathrm{ij}}$) for converting natural gas (*i*) to a product (*j*) remains the same at time *t*:

$$m_{jt}^{out} = X_{ij} m_{it}^{in} \qquad \forall i \in \mathcal{J}_k, j \in \mathcal{J}_i\ \&\ t \in \tau \ (3)$$

Each process in the network operates within variable boundaries, known as upper and lower limits. The

following constraints ensures that natural gas allocated to a process falls within the upper and lower limits (4)-(5). Additionally, constraint (6) is a non-negativity constraint, while equation (7) ensures that the total natural gas feed allocated to processes is less than or equal to the total allocated feed to the process structure $k$ at time $t$:

$$m_{it}^{in} \leq U_i y_i \qquad \forall i \in \mathcal{I}_k, j \in \mathcal{J}_i \ \& \ t \in \tau \qquad (4)$$

$$m_{it}^{in} \geq L_i y_i \qquad \forall i \in \mathcal{I}_k, j \in \mathcal{J}_i \ \& \ t \in \tau \qquad (5)$$

$$m_{it}^{in} \geq 0 \qquad \forall i \in \mathcal{I}_k, j \in \mathcal{J}_i \ \& \ t \in \tau \qquad (6)$$

$$m_{it}^{in} \leq U_i y_i \qquad \forall i \in \mathcal{I}_k, j \in \mathcal{J}_i \ \& \ t \in \tau \qquad (7)$$

Finally, as the problem focuses on optimising the network based on international market demand, equation (8) ensures that the produced product flow from a process *j* at time *t* is less than the global demand:

$$m_{jt}^{out} \leq D_{jt} \qquad \forall j \in \mathcal{J}_i \ \& \ t \in \tau \qquad (8)$$

The model and the constraints have been explained intensively in Yusuf et. al. [5]. The formulation presented herein was solved using Gurobi optimisation software (Gurobi 11.0) and implemented using python programming language within the Jupyter Notebook environment.

## Case Studies

The MILP presented herein was considered for optimising natural gas allocation in 3 main cases with 7 sub-scenarios (total of 9). Fundamentally, the cases differ based on the consideration of upper and lower limits, forecasted market data, and the decision of whether to allow the model to divert surplus natural gas to other processes. For the description, the cases can be described as the following:

- **Case 1:** considers a business-as-usual scenario wherein the model allocates natural gas to processes.
- **Case 2:** considers natural gas allocation to processes based on forecasted demand and operational limits
- **Case 3.1:** considers planned LNG shutdown for the period of 1 month every two years
- **Case 3.2:** considers planned ammonia shutdown for the period of 1 month every two years
- **Case 3.3:** considers planned GTL shutdown for the period of 1 month every two years
- **Case 3.4A:** considers *planned shutdown* of LNG, ammonia, and GTL for the period of 1 month every two years with no surplus natural gas allocation to other processes
- **Case 3.4B:** considers *planned shutdown* of LNG, ammonia, and GTL processes for the period of 1 month every two years with no surplus natural gas reallocation to other processes
- **Case 3.5A:** Considers *planned shutdown* of LNG, ammonia, and GTL processes for the period of 1 month every two years and *unplanned shutdowns* with no surplus natural gas allocation to other processes
- **Case 3.5B:** Considers *planned shutdown* of LNG, ammonia, and GTL processes for the period of 1 month every two years and *unplanned shutdowns*.

All cases considered demand and price forecasts, in addition to upper and lower limits, except for case 1. The outputs of the allocation were analysed in terms of profitability, resilience%, and production capacity.

# RESULTS AND DISCUSSION

The MILP model was implemented to optimise the allocation to the natural gas network comprising 4 direct and 2 in-direct routes on annual basis for the time horizon of 10 years (2024-2033). The model optimises with the objective of maximising the total profit of the products sales based on market performance by allowing the model to change the production capacity within the upper and lower operational limits. The allocation decision was then evaluated by estimating the resilience of each process and the overall resilience of the network. This, in turn, allows the decision-maker to employ resilience index as a decision-making metric to evaluate the added-value of flexible operations in natural gas network planning. The sub-sections below discuss the results represented by profitability, allocation strategy, and resilience.

## Profitability Assessment

With the objective to maximise profitability based on market performance and flexible allocation, Table 2 summarises the achieved profitability under different cases. Case 1 represents a baseline scenario under a business-as-usual scenario wherein natural gas is allocated to processes regardless of the global market performance and upper operational limits for processes, resulting in the lowest profitability estimate.

The results indicate that introducing market data as input data in the decision-making process have enhanced the allocation strategy by at least 21% by achieving the profitability maximisation targets in cases 2-3.5B. However, the values differed in the cases as per the considered assumptions. For example, in the cases (case 3.4A and 3.5A) where surplus natural gas was restricted for reallocation to other processes, lower profitability values have been achieved. This, in turn, justifies the economic added value of flexible operations in natural gas network planning for enhanced profitability under

dynamic market conditions.

**Table 2:** Maximum profitability estimation for all cases for optimal flexible natural gas allocation to processes.

| Case | Profit ($x10^{12}$ $) | Case | Profit ($x10^{12}$ $) |
|---|---|---|---|
| Case 1 | 2.10 | Case 3.4A | 2.66 |
| Case 2 | 2.91 | Case 3.4B | 2.87 |
| Case 3.1 | 2.87 | Case 3.5A | 2.66 |
| Case 3.2 | 2.87 | Case 3.5B | 2.87 |
| Case 3.3 | 2.91 | | |

## Resilience Assessment

While profitability values could justify the added value of flexible operations in efficiently responding to exogenous uncertainties, resilience index (resilience%) could be another metric to evaluate the added value of flexibility. Fundamentally, resilience reflects the efficiency in utilising existing infrastructure, wherein higher efficiency percentages indicate higher efficiency in utilising the deployed infrastructure. Figure 3 below demonstrates a bar chart summarising the average resilience% estimated for each case study.

For the baseline scenario where flexible boundaries of processes were not considered in the assessment, a resilience index of 74% was achieved for the model's suggested allocation strategy. Additionally, the absence of market data as an input data to the model restricted the model's efficiency in considering the performance of end markets in the decision-making process.

On the contrary, case studies considering flexible boundaries and market input data resulted in higher resilience%, with values between 85-86%, due to the model's suggested allocation strategies. Yet, in the cases (i.e., case 3.4A and 3.5A) where the model was not allowed to divert surplus natural gas feed to processes resulted in a reduced resilience value by 4% compared to the same cases that considered surplus natural gas diversion (i.e., case 3.4B and 3.5B). This justifies the importance of reallocating surplus natural gas during times of disturbance to other processes to enhance the overall network infrastructure utilisation.

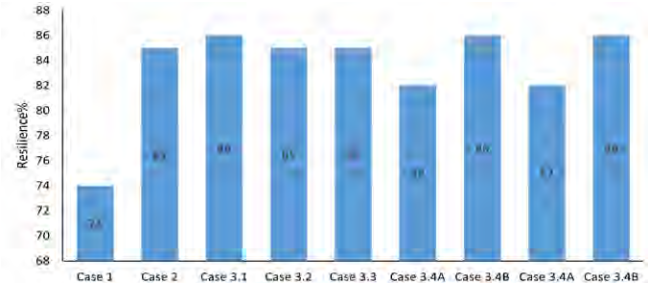

**Figure 3.** Average Resilience% estimated for each case study as per the allocation strategy for maximum achieved profitability.

## Processes assessments

To analyse the allocation strategies suggested by the model for maximising profitability under each case, it crucial to highlight that natural gas is the primary resource to the four direct processes (i.e., liquefaction, Haber-Bosch, methanol, and GTL processes). Hence, this section focuses on the natural gas allocation strategies to the primary processes under each scenario. Figures 4-7 demonstrates the natural gas allocation share% and the achieved resilience% associated with each primary process in the network under the investigated case studies.

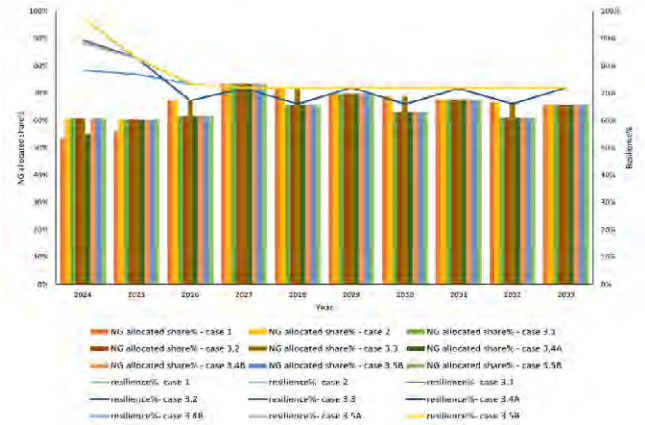

**Figure 4.** Annual natural gas allocated share% and resilience% to the liquefaction process under each case study.

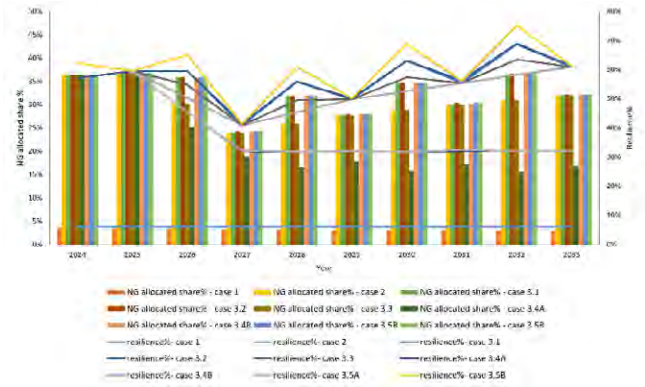

**Figure 5.** Annual natural gas allocated share% and resilience% to the GTL process under each case study.

Given that LNG is the most primary product in the Qatari natural gas portfolio, liquefaction capacities are the largest in the network, with an expected LNG production capacity to reach 142 MTPA, 85% from the current production capacity, by 2030. Hence, due to the infrastructure availability, the model prioritised allocating natural gas to the liquefaction route to meet the lower operational limits throughout the cases, as shown in Figure 4. This in turn justifies the high natural gas allocated share (more than 50%), in addition to the high resilience%. Yet, throughout the planning horizon, the resilience

associated with the cases dropped as influenced by the operational shutdowns.

On the other hand, natural gas allocated to the GTL process was the second highest after liquefaction. This is due to the infrastructure capabilities and the high market demand and prices associated with liquid fuels. Hence, the model favoured allocating natural gas to the GTL process for all process except for case 1 wherein no market data were used as an input to influence the decision-making process. This justifies the efficiency of utilising market data as an input data for informed decision-making.

As shown in Figure 6, the model allocated more than 20% of natural gas to the Haber-Bosch process to produce ammonia in case 1 when no market data and no upper operational limits were considered. This, in turn, resulted in overestimating the achieved resilience% wherein a value of 100% was achieved throughout the planning horizon for case 1. Yet, as more data were introduced to the model under the different case studies, the natural gas allocated share under cases (case2- case 3.5B) remain almost the same by achieving natural gas allocation as per the maximum available capacity, which contributed into high resilience% values.

As the methanol infrastructure in Qatar is limited and constrained by smaller scale plants, the natural gas allocated share to the methanol process was the lowest as shown in Figure 7 wherein less than 1% of the available natural gas was allocated to the methanol process. Additionally, the model allocated even less natural gas to the methanol process in case 1 in the absence of input market data and upper operational limits. Instead, the available natural gas was diverted to other processes, such as Haber-Bosch and liquefaction. For the resilience%, a value of around 85% was achieved throughout the planning period for all cases, except for case 3.4B and case 3.5B where the resilience dropped from 100% at year 2024 and 2025 to 85% at year 2026. This is attributed to the expansion of the liquefaction capacities wherein additional available natural gas share was allocated to produce LNG.

## CONCLUSION

This study highlighted the industry's vulnerability to both market fluctuations and operational disruptions, emphasing the need for proactive planning and flexible resource allocation. Findings showed that the liquefaction process received the highest allocated natural gas share for all optimised case studies due to the established infrastructure, while the methanol process had the lowest due to smaller plant capacities. Integrating operational and market data in cases 2-3.5B improved overall network resilience from 74% to at least 82%, reinforcing the value of adaptive strategies. Additionally, allowing surplus natural gas feed diversion during planned and unplanned shutdowns enhanced the economic profitability by approximately 8% and improved resilience by around 4% from case 3.4A to case 3.4B and from case 3.5A to case 3.5B. Yet, further resilience enhancements could be achieved by increasing the available natural gas feed to ensure the full utilisation of existing infrastructure.

Overall, the results emphasise the importance of resilience-based strategies in infrastructure planning and management. A dynamic natural gas approach enhanced system stability, optimises resource utilisation, and improves economic outcomes. As the global energy landscape evolves, integrating flexibility into decision-making will be key to ensuring resilience, long-term sustainability and profitability of the natural gas industry from the perspective of suppliers.

# Minimization of Hydrogen Consumption via Optimization of Power Allocation Between the Stacks of a Dual-Stack Fuel Cell System

**Beril Tümer[a], Deniz Şanlı Yıldız[b], and Yaman Arkun[a]***

[a] Koç University, Department of Chemical and Biological Engineering, Istanbul, Turkey

## ABSTRACT

A dual-stack fuel cell model was developed to simulate the hydrogen consumption a fuel cell-powered vehicle for a specific drive cycle. Two fuel cell stacks, each consisting of 65 parallel cells at different aging status and thus with different efficiency profiles (i.e., low and high) were considered. A constrained optimization for power distribution between individual stacks was performed where the objective function was to minimize the hydrogen consumption while meeting the total demand. For proper power management each stack has its own power controller which manipulates the stack current to control the stack power at its desired-set point. Computed optimal power values constitute the desired set-points for the local power PID controllers of the individual stacks. Closed-loop simulations were performed by simulating the developed mechanistic model together with optimization and PID controllers in SIMULINK platform. The closed loop simulations demonstrate how well the power demand of the drive cycle is tracked and the hydrogen consumption is minimized. To assess the impact of optimization strategy used, hydrogen consumption is compared to that of equal power sharing and a daisy-chain strategies. The results demonstrate that the optimization strategy effectively reduces the total hydrogen consumption.

**Keywords**: Proton Exchange Membrane Fuel Cells (PEMFC), Hydrogen Consumption Minimization, Power Sharing

## INTRODUCTION

Fuel cells are devices that convert chemical energy into electrical energy via transfer of electrons and protons. They possess key characteristics such as high efficiency, high power density, low corrosion, low emissions and moderate operating temperatures, and those characteristics position them as highly favorable alternative power sources in the automotive industry. To meet the high-power demand of a vehicle numerous individual cells are assembled in series or parallel configurations, forming what are known as "Fuel Cell Stack." For heavy duty vehicle applications, such as trucks and buses, multiple fuel cell stacks can be combined to increase the lifetime of the vehicle and energy efficiency.

Depending on the power management algorithm, each stack can exhibit varying efficiencies over lifetime due to differences in operating conditions and the rate of cell aging. Stack efficiency directly influences the amount of hydrogen consumed by the vehicle. Thus, efficient power distribution across multiple fuel cell stacks is crucial for minimizing total hydrogen consumption while satisfying the vehicle's power requirements.

In this study, we examine a two-stack fuel cell system, with each stack having distinct efficiency profiles (high and low) to mimic different aging status. The number of parallel cells in one stack can vary and is chosen as 65 by the authors in this work. The fuel cell stacks are modeled using first principles and simulated in MATLAB Simulink environment and the effects of aging on power allocation and hydrogen consumption were analyzed. Figure 1 illustrates the architecture of the control model where a given power demand is optimally shared between the two stacks. The local power controllers of the individual stacks manipulate their currents to meet their allocated power demands.

There are several studies in the literature for hydrogen consumption minimization [1], [2] which analyze fuel cell stacks with different efficiency profiles and compare the two common optimization strategies: equal power distribution and daisy-chain configurations. In the daisy-chain strategy, power is distributed sequentially, with one stack supplying the load until it reaches its limit, then the next stack takes over. [3] employed a geometric approach to compute the optimal power distribution and to maximize the power-efficiency. [4] proposed a power allocation strategy based on particle swarm optimization (PSO) and compared its performance with an equal power distribution strategy for two different load profiles. In these studies, the efficiency curves that are utilized in optimization were estimated from the experimental data. In this study, a mechanistic fuel cell model was used to calculate the efficiency curves for investigation of the effect of different designs and operating variables and physical parameters on the optimal power allocation.

## METHODOLOGY

The power and efficiency model for the fuel cell is taken from the work of [5] and the fundamental equations are presented below:

$$E = E^0 - \frac{RT}{nF}\ln\frac{\prod p_{products}^{v_i}}{\prod p_{reactants}^{v_i}} \quad (1)$$

$$E_{oc} = N \times E \quad (2)$$

$$V_{act,loss} = \frac{NRT}{n\alpha F}\ln\frac{j_{fc}}{j_0} \quad (3)$$

$$V_{ohm,loss} = R_{ohm} \times j_{fc} \quad (4)$$

$$V_{conc,loss} = N \times c\ln\frac{j_L}{j_L - j_{fc}} \quad (5)$$

$$V_{fc} = E_{oc} - V_{act,loss} - V_{ohm,loss} - V_{conc,loss} \quad (6)$$

$$P_{fc} = i \times V_{fc} \quad (7)$$

$$\eta_{thermo} = 0.83 \quad (8)$$

$$\eta_{fuel} = \frac{1}{ɻ} \; where \; ɻ = \frac{\frac{i}{nF}}{\dot{v}_{fuel}} \quad (9)$$

$$\eta_{voltage} = \frac{V_{fc}}{E_{oc}} \quad (10)$$

$$\eta = \eta_{thermo} \times \eta_{fuel} \times \eta_{voltage} \quad (11)$$

$$\dot{m}_{H_2} = \frac{Ni(MW_{H_2})}{nF\eta_{fuel}} \quad (12)$$

The partial pressures, $p$ in atm, in Eqn. 1 are calculated from a separate mechanistic model [6], [7].

The objective function for the optimization is to minimize the total hydrogen consumption rate (kgs$^{-1}$) of two fuel cell stacks, formulated as follows:

$$\min_{i_1,i_2} \dot{m}_{H_2,total} = \frac{Ni_1(MW_{H_2})}{nF\eta_{fuel1}} + \frac{Ni_2(MW_{H_2})}{nF\eta_{fuel2}}$$

s.t.

$$8 \le i_1, i_2 \le 300$$

$$P_{fc,1} + P_{fc,2} = P_{demand}$$

The decision variables in this optimization are the fuel cell currents. The usage of the DC-DC converter establishes the minimum current at 8, while the maximum current of 300 is defined by the limiting current density value. The algorithm computes the optimal individual stack currents, and thus the optimal power outputs of each stack, $P_{fc,1}^{opt}$ and $P_{fc,2}^{opt}$ as depicted in Figure 1. Above optimization has a global and unique optimum since the objective function is linear in the decision variables $i_1, i_2$ and the constraints define a closed convex feasible set. We used MATLAB's fmincon function with the Sequential Quadratic Programming (SQP) algorithm to solve the optimization.

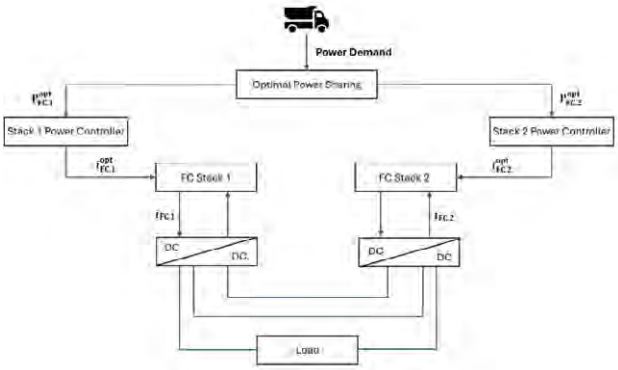

**Figure 1.** Model architecture and control strategy

## RESULTS

Aging and/or degradation are the two key factors that directly impact the lifespan and performance of fuel cell stacks. Degradation can occur in various components of the fuel cell, such as the catalyst, membrane, and gas diffusion layers. Each of these components contributes to performance losses in specific ways, such as reducing the exchange current density, increasing ohmic resistance, or decreasing the limiting current density. Collectively, these effects diminish the power output of the fuel cell stack over time.

In this study, the electron transfer coefficient ($\alpha$) is used to indicate the level of degradation/aging in the fuel cell stack. $\alpha$ values are between 0 and 1; and it is well known that [5] lower values result in increased voltage losses indicative of increased degradation/aging.

In the results to follow, the optimal power values are provided as set-points to the local PID controllers that adjust the currents. Due to the inherently slow response

time of the fuel cell, the stack powers reach their set-points within 100 sec with a smooth response.

## Case 1: Equal Fuel Efficiency and Different Degradation Levels

### Case 1.1: $\alpha_1$=0.6 and $\alpha_2$=0.4, $\lambda_1 = \lambda_2$=1.2

The first case examines the impact of different degradation levels on power distribution and compares hydrogen consumption across three different strategies. For Case 1.1 analysis, $\alpha$ values of 0.6 and 0.4 were chosen for stacks 1 and 2, respectively. The fuel efficiency $\eta_{fuel}$ of each stack is set equal to 0.8333 which corresponds to 20% of excess hydrogen feed ($\lambda_1 = \lambda_2$=1.2). Due to degradation, stack 2 has lower $\alpha$ value, which leads to a decline in power output and efficiency. The superimposed power outputs of both stacks are shown in Figure 2.

In the equal distribution strategy [2], the power produced by each stack is equal, with each contributing half of the total power demand, as shown in Figure 3. Since stack 2 experiences higher degradation compared to stack 1, its current and therefore its hydrogen consumption is higher, as shown in Table 1. In the daisy-chain strategy [8], stack 1 serves as the primary energy source due to its higher power output and efficiency. When the total power demand exceeds the maximum capacity of stack 1, stack 2 compensates for the power gap. Otherwise, stack 2 idles at its minimum power P=637 W, as illustrated in Figure 4. Since stack 1 meets most of the power demand, its hydrogen consumption is significantly higher than that of stack 2 (see Table 1). Optimization approach adjusts the power level for each stack based on the stack efficiency without using any priori rule as in equal power and daisy-chain strategies. Optimal power allocated to each stack is shown in Figure 5. Comparing with Figures 3 and 4, we see that in optimal allocation stack 2 power idles less than daisy-chain; therefore, less power is needed from stack 1. This results in lower currents in stack 1 and less hydrogen consumption, which is proportional to the current. Table 1 shows that optimization gives the least hydrogen consumption (0.4249 kg), for the given drive cycle with duration of 4000 sec. This is a 5.29% improvement over the daisy-chain algorithm. However, the improvement of the optimization strategy over the equal distribution algorithm (0.96%) is not very significant in this scenario. This is because the $\alpha$ values and the performance of the fuel cell stacks are quite similar, and the fuel efficiencies of the stacks are the same. Nevertheless, these small percentage improvements will result in significant hydrogen saving considering the overall lifetime of the vehicle.

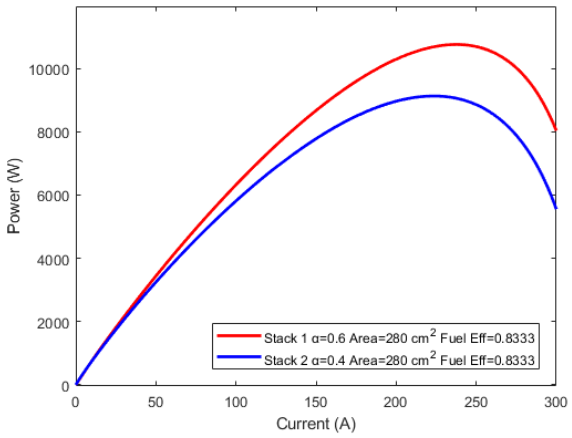

**Figure 2**. Current vs power curves for both stacks.

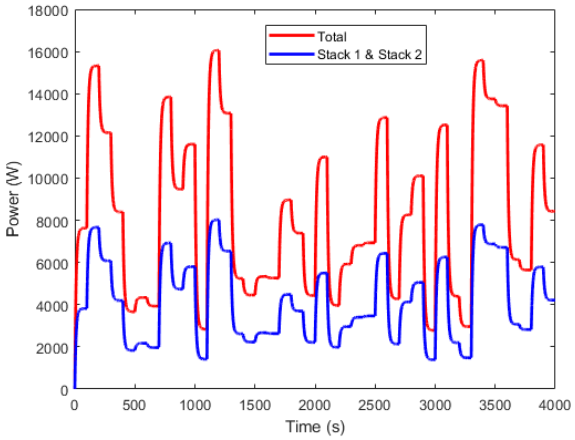

**Figure 3.** Power sharing using equal distribution strategy.

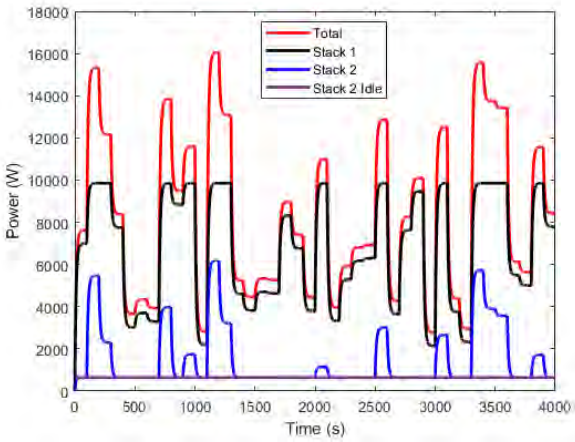

**Figure 4.** Power sharing using daisy-chain strategy.

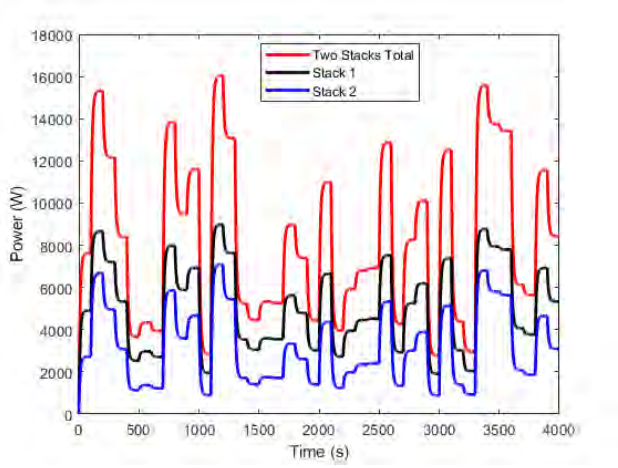

**Figure 5.** Power sharing using optimization strategy.

**Table 1:** Total Hydrogen Consumption of the Stacks with Different Strategies where $\alpha_1$=0.6, $\alpha_2$=0.4 and $\lambda_1$= $\lambda_2$=1.2

| Strategy | Stack 1 $H_2$ Consumption (kg) | Stack 2 $H_2$ Consumption (kg) | Total $H_2$ Consumption (kg) |
|---|---|---|---|
| Equal distribution | 0.2043 | 0.2247 | 0.4290 |
| Daisy-chain | 0.3727 | 0.0759 | 0.4486 |
| Optimization | 0.2582 | 0.1667 | 0.4249 |

### Case 1.2: $\alpha_1$=0.6 and $\alpha_2$=0.25, $\lambda_1$= $\lambda_2$=1.2

For Case 1.2 analysis, the $\alpha$ values were set as 0.6 and 0.25, and thus differences between the power and efficiency curves of the stacks are much larger. The same drive cycle data was used as the power demand input. With the new degradation level, stack 2 can produce a maximum of 6510 W (Figure 6). In the equal distribution scenario, when the power demand for each stack exceeds 6510 W, a power deficit occurs for stack 2 which is set to be met by stack 1. Figure 7 displays that the black and blue lines do not overlap at power demands higher than 6510 watts which is the result of modification in the algorithm. In this case, the equal distribution algorithm consumed the maximum hydrogen (0.4854 kg), as shown in Table 2. Power demand was successfully met in the daisy-chain algorithm. In this scenario, stack 1 again served as the primary power source, while stack 2 mostly operated at its idle power. Compared to the previous scenario, hydrogen consumption for stack 1 remained constant, as its $\alpha$ value did not change. However, the decrease in $\alpha$ value for stack 2 from 0.4 to 0.25 led to an increase in the current required for the same power demand in stack 2 which resulted in operating at lower efficiency. As a result, hydrogen consumption for stack 2 increased in this case (see Tables 1 and 2). Finally, the optimization algorithm successfully met the entire power demand, relying more on stack 1 (higher efficiency) and less on stack 2 (lower efficiency) (Figure 8). The increase in hydrogen consumption for stack 1 is due to the higher power production, and less power was produced by stack 2, resulting in reduced hydrogen consumption compared to the previous scenario. Similar to the previous case, the optimization strategy consumed the lowest hydrogen amount (see Table 2). However, the greater difference in $\alpha$ values made the daisy-chain scenario more favorable than in the previous case. As a result, the improvement of optimization over the daisy-chain scenario decreased but still demonstrated better performance, with 2.15% less hydrogen consumption. The equal distribution scenario showed the worst performance, with the optimization strategy achieving a 6.94% improvement over it.

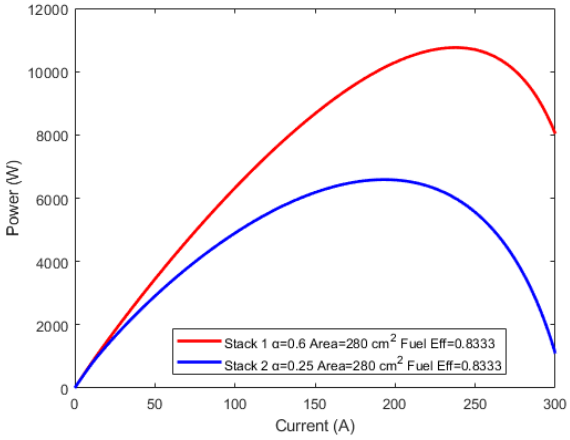

**Figure 6.** Current vs power curves for both stacks incorporating the new degradation level of stack 2.

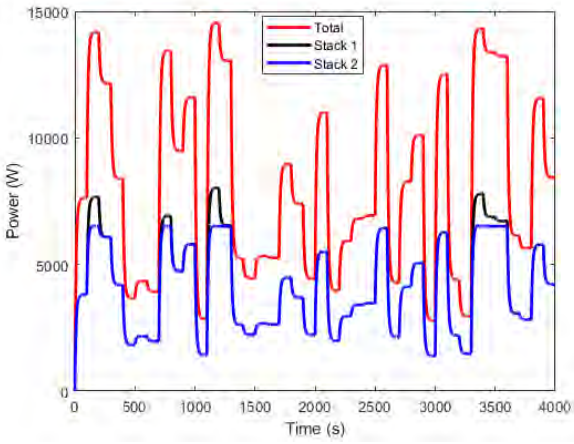

**Figure 7.** Power sharing using modified equal distribution strategy incorporating the new degradation level of stack 2.

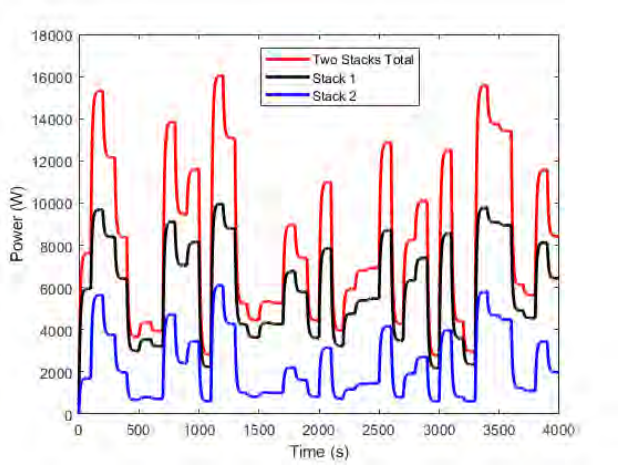

**Figure 8.** Power sharing using optimization strategy incorporating the new degradation level of stack 2.

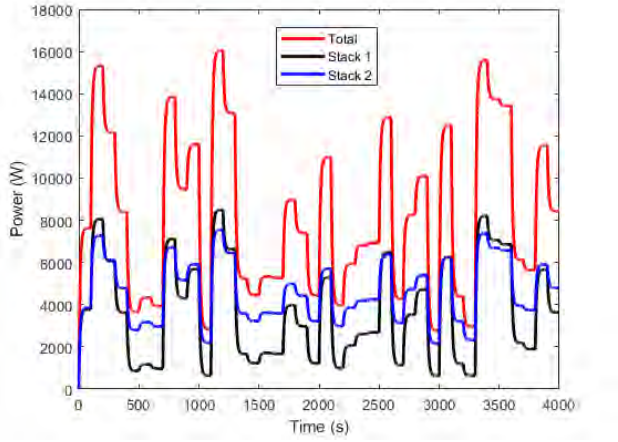

**Figure 9.** Power sharing between stacks using the optimization strategy with $\lambda_1$=1.5 and $\lambda_2$=1.2.

**Table 2:** Total Hydrogen Consumption of the Stacks with Different Strategies where $\alpha_1$=0.6, $\alpha_2$=0.25 and $\lambda_1$=$\lambda_2$=1.2

| Strategy | Stack 1 $H_2$ Consumption (kg) | Stack 2 $H_2$ Consumption (kg) | Total $H_2$ Consumption (kg) |
|---|---|---|---|
| Equal distribution | 0.2043 | 0.2811 | 0.4854 |
| Daisy-chain | 0.3727 | 0.0889 | 0.4616 |
| Optimization | 0.3166 | 0.1351 | 0.4517 |

### Case 2: Different Fuel Efficiencies and Degradation Levels ($\alpha_1$=0.6 and $\alpha_2$=0.4, $\lambda_1$=1.5 and $\lambda_2$=1.2)

Aging results in several changes in the structure of the catalyst layer of fuel cells which can hinder the smooth movement of hydrogen molecules resulting in lower fuel efficiency and higher hydrogen feed excess ratio, $\lambda$. In case study 2, $\lambda_1$ was set to 1.5. Optimal power distributions are shown in Figure 9. Since $\lambda_1$ is higher than $\lambda_2$, the power allocated to stack 2 is increased. As a result, the hydrogen consumption of stack 2 is higher than that of stack 1, as presented in Table 3. Table 3 summarizes the hydrogen consumption across all strategies, showing that the daisy-chain strategy performs the worst, while the optimization strategy achieves the best results.

**Table 3:** Total Hydrogen Consumption of the Stacks with Different Strategies where $\alpha_1$=0.6, $\alpha_2$=0.4 and $\lambda_1$=1.5 and $\lambda_2$=1.2

| Strategy | Stack 1 $H_2$ Consumption (kg) | Stack 2 $H_2$ Consumption (kg) | Total $H_2$ Consumption (kg) |
|---|---|---|---|
| Equal distribution | 0.2553 | 0.2247 | 0.4800 |
| Daisy-chain | 0.4658 | 0.0759 | 0.5417 |
| Optimization | 0.2264 | 0.2512 | 0.4776 |

## CONCLUSION

Minimizing fuel consumption of a vehicle is one of the most crucial tasks for automotive producers to be competitive in the market. Likewise, for a fuel cell-powered vehicle the focus is mainly on minimizing the hydrogen consumption via distributing the demanded power effectively between fuel cell stacks. In this study, three different power allocation strategies, namely equal distribution, daisy-chain, and optimal power sharing, were compared for dual-stack fuel cell system, each stack having different aging levels. For similar aging levels of the stacks, the performance of optimization strategy equal distribution algorithm was similar. However, as the aging levels of the stacks differ, the performance of optimization strategy is superior to that of equal distribution and aligns more closely with the daisy-chain algorithm. Additionally, the impact of fuel efficiency changes, influenced by alterations in the catalyst structure, was analyzed. In all cases, the optimization strategy resulted in the lowest hydrogen consumption.

## NOMENCLATURE

| | |
|---|---|
| $\alpha$ | Electron transfer coefficient |
| $c$ | Constant |
| $E$ | Reversible cell voltage (V) |
| $E^0$ | Ideal reversible voltage (V) |
| $E_{oc}$ | Open circuit voltage (V) |
| $F$ | Faraday's number (C) |
| $i$ | Current (A) |

## ABSTRACT

With increasing emphasis on energy efficiency, more researchers are focusing on energy-efficient flexible job shop scheduling problems. Mathematical programming is a commonly used optimization method for such scheduling challenges, offering the advantages of achieving global optima and serving as a foundation for other approaches. However, current mathematical programming formulations face several challenges, including insufficient consideration of various forms of energy consumption and low efficiency, particularly in handling large-scale instances, which struggle to converge. In this study, we propose a novel global sequence-based approach with high computational efficiency. In this model, immediate precedence relationships are identified using constraints, enabling the precise determination of idle durations within any idle slots. The proposed formulation achieves a significant reduction in energy consumption by up to 20% relative to other formulations. Furthermore, it successfully reaches feasible solutions in challenging cases.

**Keywords**: Algorithms, Energy Efficiency, Optimization, Scheduling, Energy

## INTRODUCTION

The job-shop scheduling problem (JSSP) has been widely existing in various fields such as enterprise management [1,2], transportation [3] and aerospace [4,5]. As the demands for small-volume and personalized products increases, enterprises orientate at improving the flexibility of manufacturing processes by introducing parallel machines, which is generally termed as the flexible job-shop scheduling problem (FJSSP) [6]. In this content, assignment of operations to a machine as well as their sequence on the machine should be determined, making it more challenging to solve than JSSP. The inherent flexibility of FJSSP provides potential for significant economic or energy-efficient savings reflected in a schedule solution with the best assignments and sequences. Many approaches have been developed to address FJSSP, including exact algorithms [7-8], heuristics [9], and metaheuristics [10-11]. Several excellent reviews about the development, methodologies, and applications of FJSSP have been provided in the literature [12-13].

The prior research on FJSSP primarily centered around the economic performance or makespan, neglecting the simultaneous consideration of energy consumption. As manufacturing has the predominant contribution to annual industrial energy consumption, constituting the largest share at 76% among four major industry sectors in 2022 [14], the optimal schedule without consideration of energy consumption may lead to large energy wastage. Various forms of energy consumption have been identified, including standby, processing, turn-on/off, and setup energy consumption [8,15]. Notably, it was observed that 65% of the total energy consumption (TEC) in FJSSP is unrelated to actual processing activities. Instead, this substantial portion of energy is expended during periods when processing units are either idle or in standby mode [15]. The separation between economic optimization and energy awareness in production scheduling has significant implications. Production schedules optimized solely for economic goals may inadvertently result in unnecessarily high energy consumption. Consequently, there has been a growing recognition of the importance of incorporating energy considerations into FJSSP, especially due to net-

zero strategies proposed by different countries.

Investigations have been conducted to propose optimization approaches for the energy-efficient FJSSP, which can be broadly categorized into exact methods and approximate methods. Among the exact methods, mathematical programming approaches, such as mixed-integer linear programming (MILP) formulations, are commonly utilized [16]. The MILP formulations excel in generating optimal solutions and serve as a foundation in understanding the characteristics of scheduling problems [17]. Additionally, the development of MILP formulations lays the groundwork for establishing decomposition approaches that are highly effective in handling the complexities of energy-efficient FJSSP.

Researchers [17-22] developed MILP models for energy-efficient FJSSP based on the time-grid representation. [18] and [19] discretized the time horizon into uniform time intervals and introduced binary variables to indicate whether an operation starts processing at a given time point. Unlike discrete-time representations, continuous-time representations divide the time horizon into events with unknown and variable durations. Zhang et al. [20] proposed an event-based MILP model to minimize the TEC, to establish comparison benchmarks for a gene-expression programming approach and to explicitly analyse the problem's features. Followingly, a more efficient event-based unit- specific model was proposed [21], incorporating auxiliary states to link adjacent operations within the same job and ensure their precedence constraints. These aforementioned studies comprehensively consider various forms of energy consumption, including standby energy, switch off/on energy, direct (i.e., processing) energy and indirect energy. However, these exhibit inefficiencies when applied to large-scale energy-efficient FJSSP systems. For example, they struggle to find feasible solutions within hours for problems involving more than 200 operations [20,21]. Further research on MILP models with continuous-time representations can be found in [17,22,23].

In addition to time-grid representation, MILP formulations can be developed based on the precedence relations between operations on machines. For example, [8] and [24] proposed the local-sequence-based formulation, where binary variables indicate whether an operation immediately precedes another on a machine. In contrast, the global-sequence-based formulation focuses on global precedence relations, requiring fewer binary variables, making it more efficient. This is because the binary variable denoting the first or last operations on machines are omitted. [25] presented a novel global sequence-based MILP formulation to optimize the minimization of makespan or TEC. However, they did not account for the selection between standby and switch off-on modes for machines, which is crucial for reducing energy waste during machine idle times. More specifically, their MILP model fails to accurately estimate the specific durations of each idle period on machines.

In this work, a global sequence-based MILP formulation (**MG**) is proposed to minimize TEC, encompassing direct, indirect and unload energy consumption. Its novelty lies in the incorporation of constraints that identify immediate precedence relations between operations and the optimal duration of idle slot between them. Selection between machine modes during idle slots is achieved by introducing a new set of binary variables. The proposed model is compared with MILP models based on time-grid representations and precedence relations as well as a decomposition approach.

## PROBLEM DEFINITION

Fig. 1 illustrates an energy-efficient FJSSP involving a set of jobs $k \in \mathbf{K}$ and machines $j \in \mathbf{J}$. A job $k$ is processed with a sequence of operations $i \in \mathbf{I}_k$. Machines $j$ that can process operation $i$ of job $k$ are included in a set $\mathbf{J}_{ki}$. The processing time for machine $j$ performing operation $i$ of job $k$ is denoted by $P^{\mathrm{T}}_{kij}$, and the cutting power is $P^{\mathrm{C}}_{kij}$. The objective is to minimize $TEC$, encompassing energy consumed by machines during processing operations (i.e., direct energy), idle periods (i.e., unload energy), and by auxiliary facilities (i.e., indirect energy).

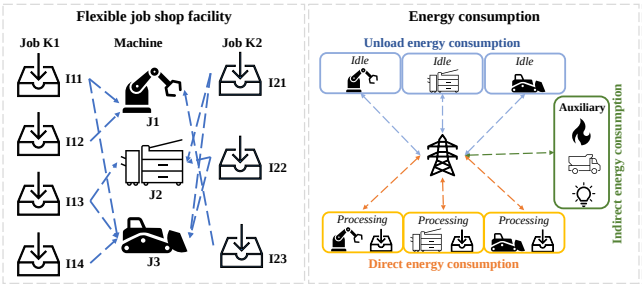

**Figure 1.** A FJSSP considering energy consumption.

To save energy, a machine $j$ can be temporarily switched off or maintain standby after processing (see Figure 2). Its switch off/on energy and unload power are expressed by $E^{\mathrm{O}}_j$ and $P^{\mathrm{U}}_j$, respectively.

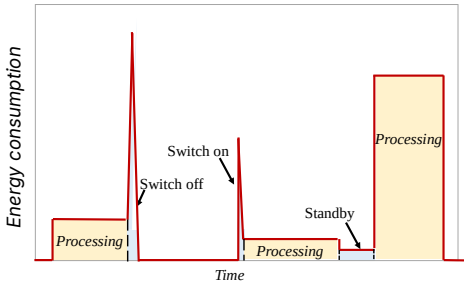

**Figure 2**. Energy consumption profile for a machine

## MATHEMATICAL FORMULATION

In the global sequence-based formulation (**MG**), we define four-index binary variables to denote the global precedence of two operations (e.g. $i$ and $i'$),

$$x_{kik'i'} = \begin{cases} 1 & \text{if } i \text{ in } k \text{ precedes } i' \text{ in } k' \text{ on one machine} \\ 0 & \text{otherwise} \end{cases}$$

Binary variables $w_{kij}$ express the assignment of operations on machines,

$$w_{kij} = \begin{cases} 1 & \text{if } i \text{ in } k \text{ is assigned on a machine } j \\ 0 & \text{otherwise} \end{cases}$$

Any operation $i$ of job $k$ must be assigned on a machine $j$.

$$\sum_{j \in \mathbf{J}_{ki}} w_{kij} = 1 \qquad \forall k, i \in \mathbf{I}_k \tag{1}$$

If operations $i, i'$ are processed on a machine, either $i$ precedes $i'$ or $i'$ precedes $i$. That is if variables $w_{kij} = 1$ and $w_{k'i'j} = 1$, then exactly one of $x_{kik'i'}$ or $x_{k'i'ki}$ should be equal to 1, indicating their precedence on $j$.

$$x_{kik'i'} + x_{k'i'ki} \geq w_{kij} + w_{k'i'j} - 1 \quad \forall k, k', j \in (\mathbf{J}_{ki} \cup \mathbf{J}_{k'i'}), i \in \mathbf{I}_k, i' \in \mathbf{I}_{k'}, (k < k') \cup (k = k' \cap i < i') \tag{2}$$

When two operations $i$ in job $k$ and $i'$ in job $k'$ are performed on different machines (e.g., $w_{kij} = 1$ and $w_{k'i'j} = 0$ ), their corresponding variables $x_{k'i'ki}$ and $x_{kik'i'}$ should be zero. The set $i' \in \mathbf{I}_{ki}^{\mathrm{G}}$ includes operations $i'$ that can share the same machine with $i$ of $k$.

$$w_{k'i'j} \geq w_{kij} + x_{k'i'ki} + x_{kik'i'} - 1 \quad \forall k, k', j \in (\mathbf{J}_{ki} \cup \mathbf{J}_{k'i'}), i \in \mathbf{I}_k, i' \in \left(\mathbf{I}_{k'} \cap \mathbf{I}_{ki}^{\mathrm{G}}\right), [k < k' \cup (k = k' \cap i < i')] \tag{3}$$

$$w_{kij} \geq w_{k'i'j} + x_{k'i'ki} + x_{kik'i'} - 1 \quad \forall k, k', j \in (\mathbf{J}_{ki} \cup \mathbf{J}_{k'i'}), i \in \mathbf{I}_k, i' \in \left(\mathbf{I}_{k'} \cap \mathbf{I}_{ki}^{\mathrm{G}}\right), [k < k' \cup (k = k' \cap i < i')] \tag{4}$$

Continuous variable $T_{ki}$ denotes the start time for operation $i$ of job $k$. An operation $i \in \mathbf{I}_k$, which is the successor of the operation $i' \in \mathbf{I}_k$ in the same job, should start after the completion of operation $i'$.

$$T_{ki} \geq T_{ki'} + \sum_{j \in \mathbf{J}_{ki'}} \left(P_{ki'j}^{\mathrm{T}} \cdot w_{ki'j}\right) \qquad \forall k, i' \in \mathbf{I}_k, i \in \mathbf{I}_k, i = i' + 1 \tag{5}$$

We define binary variables $z_{kij}$ and 0-1 continuous variables $y_{kij}$ to express the machine modes on $j$ after processing an operation $i$ of job $k$.

$$z_{kij} = \begin{cases} 1 & \text{if } j \text{ is switched off after processing } i \text{ in } k \\ 0 & \text{otherwise} \end{cases}$$

$$y_{kij} = \begin{cases} 1 & \text{if } j \text{ remains standby after processing } i \text{ in } k \\ 0 & \text{otherwise} \end{cases}$$

A machine $j$ would remain standby or be switched off after performing $i$ (see eq. 6). It ensures that $y_{kij}$ is 0 or 1 only even it is defined as 0-1 continuous variables.

$$y_{kij} + z_{kij} = w_{kij} \qquad \forall k, i, j \in \mathbf{J}_{ki} \tag{6}$$

Continuous variables $ST_{kij}$ denote the duration of a machine $j$ keeping standby mode after processing $i \in \mathbf{I}_k$. $ST_{kij}$ equals the time interval between the finish of operation $i$ and the start of its immediate precedence operation $i' \in \mathbf{I}_{k'}$ on the identical machine $j$, as handled in Eq. (7) and Eq. (8). Specifically, Eq. (7) handles that if a machine remains standby after performing operation $i$ of job $k$ (i.e., $z_{kij} = 0$), the start time of any subsequent operation $i'$ (i.e., $x_{kik'i'} = 1$) is expected to be later than the finish time of $i$ plus the standby duration.

$$T_{k'i'} \geq T_{ki} + \sum_{j \in \mathbf{J}_{ki}} \left(P_{kij}^{\mathrm{T}} \cdot w_{kij} + ST_{kij} + \frac{E_j^{\mathrm{O}}}{P_j^{\mathrm{U}}} \cdot z_{kij}\right) - M \cdot (1 - x_{kik'i'}) \qquad \forall k, k', (k \neq k') \cup (k = k' \cap i < i'), i \in \mathbf{I}_k, i' \in \left(\mathbf{I}_{k'} \cap \mathbf{I}_{ki}^{\mathrm{G}}\right) \tag{7}$$

The immediate successor $i'$ of operation $i$ on the same machine is identified by Eq. (8), where the number of preceding operations of $i'$ should be one more that of operation $i$. Here, the $M$ indicates a big number, taking the value of 10000 in this work. $N_j^{max}$ is the maximum number of jobs that can be processed on $j$.

$$T_{k'i'} \leq T_{ki} + \sum_{j \in \mathbf{J}_{ki}} \left(P_{kij}^{\mathrm{T}} \cdot w_{kij} + ST_{kij} + \frac{E_j^{\mathrm{O}}}{P_j^{\mathrm{U}}} \cdot z_{kij}\right) + M \cdot \left[\max_j \left(N_j^{max}\right)\right] \cdot (1 - x_{kik'i'}) + M \cdot \left(1 - \sum_{j \in \mathbf{J}_{ki}} y_{kij}\right) + M \cdot \left(\sum_{k''} \sum_{\substack{i'' \in \mathbf{I}_{k'i'}^{\mathrm{G}} \\ (k'' \neq k') \cup (k'' = k' \cap i'' \neq i')}} x_{k''i''k'i'} - \sum_{k''} \sum_{\substack{i'' \in \mathbf{I}_{ki}^{\mathrm{G}} \\ (k'' \neq k) \cup (k'' = k \cap i'' \neq i)}} x_{k''i''ki} - 1\right) \qquad \forall k, k', (k \neq k') \cup (k = k' \cap i < i'), i \in \mathbf{I}_k, i' \in \left(\mathbf{I}_{k'} \cap \mathbf{I}_{ki}^{\mathrm{G}}\right) \tag{8}$$

Standby energy consumption $ES_{ki}$ is calculated using Eq. (9), which is proportional to the duration of standby time and the unload power of the machine $j$. $ST_{kij}$ is enforced as zero if the machine does not remain standby after processing $i \in \mathbf{I}_k$, as indicated in Eq. (10).

$$ES_{ki} = \sum_{j \in \mathbf{J}_{ki}} \left(ST_{kij} \cdot P_j^{\mathrm{U}}\right) \qquad \forall k, i \in \mathbf{I}_k \tag{9}$$

$$ST_{kij} \leq \left[\min\left(M, \frac{E_j^{\mathrm{O}}}{P_j^{\mathrm{U}}}\right)\right] \cdot y_{kij} \qquad \forall k, i, j \in \mathbf{J}_{ki} \tag{10}$$

Makespan should be larger than the finish time of the last operation ($\mathbf{LI}_k$) in all jobs. And it is no less than cumulative processing times of all operations in any job.

$$T_{ki} + \sum_{j \in \mathbf{J}_{ki}} \left(w_{kij} \cdot P_{kij}^{\mathrm{T}}\right) \leq MS \qquad \forall k, i \in (\mathbf{I}_k \cap \mathbf{LI}_k) \tag{11}$$

$$\sum_{i \in \mathbf{I}_k} \sum_{j \in \mathbf{J}_{ki}} \left(w_{kij} \cdot P_{kij}^{\mathrm{T}}\right) \leq MS \qquad \forall k \tag{12}$$

On any $j$, the accumulated time used to process operations and keep standby should be no larger than $MS$.

$$\sum_k \sum_{i \in \mathbf{I}_{kj}} \left(w_{kij} \cdot P_{kij}^{\mathrm{T}} + ST_{kij} + \frac{E_j^{\mathrm{O}}}{P_j^{\mathrm{U}}} \cdot z_{kij}\right) \leq MS \quad \forall j \tag{13}$$

Constraint (14) is the objective function.

$$TEC = \sum_k \sum_i \sum_{j \in \mathbf{J}_{ki}} \left(w_{kij} \cdot P^{\mathrm{T}}_{kij} \cdot P^{\mathrm{C}}_{kij}\right) + \beta \cdot MS + \sum_k \sum_{i \in \mathbf{I}_k} ES_{ki} + \sum_i \sum_k \sum_{j \in \mathbf{J}_{ki}} \left(E^{\mathrm{O}}_j \cdot z_{kij}\right) \quad (14)$$

The start time of an operation $i$ of job $k$ should be always after the minimum required time for all predecessor operations in the same job.

$$T_{ki} \geq \sum_{i' < i, i' \in \mathbf{I}_k} \left\{ \min_{j \in \mathbf{J}_{ki}} \left(P^{\mathrm{T}}_{ki'j}\right) \right\} \quad \forall k, i \in \mathbf{I}_k \quad (15)$$

Upper bounds are imposed on the positive variables $MS$ and $T_{ki}$, as specified by Eq. (16) and Eq. (17).

$$MS \leq M \quad (16)$$

$$T_{ki} \leq M \qquad \forall k, i \quad (17)$$

Moreover, if an operation cannot be performed on a machine $j$ (i.e., $j \notin \mathbf{J}_{ki}$), its corresponding binary variables (e.g., $w_{kij}, y_{kij}$ and $z_{kij}$) should be set to zero.

$$w_{kij} = 0, y_{kij} = 0, z_{kij} = 0 \qquad \forall k, i, j \notin \mathbf{J}_{ki} \quad (18)$$

Precedence between operations of the same job can be confirmed on the same machine. And variables $x_{kik'i'}$ are fixed to zero if $i'$ cannot share any machine with $i$ (i.e., $i' \notin \mathbf{I}^{\mathrm{G}}_{ki}$)

$$x_{ki'ki} = 0 \qquad \forall i \in \mathbf{I}_k, i' \in \mathbf{I}_k, i < i' \quad (19)$$

$$x_{kik'i'} = 0 \qquad \forall k, i \in \mathbf{I}_k, k', i' \in \mathbf{I}_{k'}, i' \notin \mathbf{I}^{\mathrm{G}}_{ki} \quad (20)$$

Finally, equations (21-23) list all the continuous and binary variables in model **MG**. We complete the mathematical model **MG** consisting of constraints (1-23).

$$ES_{ki}, ST_{kij}, MS, T_{ki} \geq 0 \quad (21)$$

$$0 \leq y_{kij} \leq 1 \quad (22)$$

$$z_{kij}, x_{kik'i'}, w_{kij} \in \{0, 1\} \quad (23)$$

## COMPUTATIONAL STUDIES

**Table 1:** Problem size of benchmark examples.

| **Problem size** $(K * I * J)$ | **Example (Ex)** |
|---|---|
| 2*4*2 | 1-5 |
| 2*6*3 | 6-10 |
| 3*6*2 | 11-15 |
| 3*9*3 | 16-20 |
| 6*36*6 | 21 |
| 10*100*10 | 22, 39-43 |
| 10*50*5 | 24-28 |
| 15*75*5 | 29-33 |
| 20*100*5 | 34-38 |
| 15*150*10 | 44-48 |
| 20*200*10 | 49-54 |
| 30*300*10 | 55-58 |

We utilize the proposed **MG** to solve 58 benchmark examples from the literature [20,21] to evaluate its computational performance. These examples are sourced from the Hurink_DATA dataset [20], comprising 20 small-scale and 38 industrial-scale examples. Their respective problem sizes are listed in Table 1. **MG** is benchmarked against MILP-based model formulated using local sequence-based representations (**ML**) [24] and event-based continuous-time representations (**MU**) [21]. Additionally, the solution quality of **MG** is compared with a decomposition approach from Rakovitis *et al.* [21]. All examples are solved using CPLEX22.1.0/GAMS40.3.0 on a desktop computer with AMD RyzenTM 9 5950X 3.40 GHz and 96.0 GB RAM running Windows 10. A time limit of one hour is imposed for all MILP formulations.

### Comparison with mathematical programming models

Comparisons between **MG** and MILP model from literature for the small-size examples are provided in Table 2. All formulations generate identical optimal solutions, which represent the global optimum, with similar computational times of approximately 1 second.

**Table 2: TEC** computational results for small-size examples from **MG**, **MU** and **ML**.

| **Ex** | **MG, MU, ML** | **Ex** | **MG, MU, ML** |
|---|---|---|---|
| *1* | 63.03 | *11* | 166.23 |
| *2* | 122.44 | *12* | 176.75 |
| *3* | 75.74 | *13* | 121.30 |
| *4* | 146.63 | *14* | 156.86 |
| *5* | 78.40 | *15* | 163.20 |
| *6* | 220.74 | *16* | 219.46 |
| *7* | 97.54 | *17* | 306.68 |
| *8* | 146.81 | *18* | 210.60 |
| *9* | 230.66 | *19* | 269.52 |
| *10* | 161.06 | *20* | 274.94 |

**Table 3: TEC** computational time for industrial-size examples from **MG**, **MU** and **ML**

| *37* | 3473 | 3422 | 3595 | *56* | **19081** | NA | NA |
| *38* | 3457 | 3441 | NA | *57* | **15674** | NA | NA |
| *39* | 3781 | 3800 | 3713 | *58* | **21380** | NA | NA |

Table 3 presents the optimized TEC of industrial-size examples from MILP formulations. If **MG** achieves solutions that are no worse than those from **MU** and **ML**, its TEC results are highlighted in bold. And 'NA' indicates no available solutions are found. Table 3 proves that **MG** outperforms both **MU** and **ML** in examples 25, 26, 28, 35, 36, 40-44, 46, 47, and 49-58. The maximum reduction in TEC is 20% (7059 vs. 8826) in example 51, compared to **MU**. Advantage of **MG** is mainly evident in complicated examples. In detail, for cases with more than 200 operations (e.g., examples 49-58), both **MU** and **ML** fail to find feasible solutions in most instances. However, **MG** successfully provides feasible solutions for these cases.

Some examples converge within a computation time of less than 1 hour. The specific computational times for these examples are presented in Table 4, allowing for a comparison of the computational efficiency of the MILP formulations. Table 4 demonstrates that **MG** achieves shorter computational time relative to **MU** and **ML** in most cases (8 out of 9 examples). The most significant reduction is observed in example 26, where **MG** requires 1/14 of the time (248 seconds vs. 3600 seconds) to reach a better solution (1530 vs. 1623 and 1603).

**Table 4:** Computational times (Seconds) of industrial-size examples from **MG**, **MU** and **ML**.

| Ex | MG | MU | ML | Ex | MG | MU | ML |
|---|---|---|---|---|---|---|---|
| *24* | **5** | 97 | 325 | *32* | **362** | 3600 | 3600 |
| *26* | **248** | 3600 | 3600 | *33* | **218** | 1668 | 3326 |
| *28* | **209** | 3600 | 3600 | *35* | **3336** | 3600 | 3600 |
| *29* | 644 | 206 | 3600 | *36* | **1481** | 3600 | 3600 |
| *31* | **526** | 1136 | 3600 | | | | |

## Comparison with a decomposition algorithm

A decomposition algorithm [21], denoted by **GD**, is proposed to address industrial-scale problems. We compare its performance with the proposed **MG** (see Table 5). Since the computational time for **MG** is currently limited to one hour, making it suitable for real-world applications in complex cases, our focus is primarily on comparing the solution quality between **GD** and **MG**. Table 5 demonstrates the clear superiority of **MG** for examples with no more than 100 operations (i.e., examples 21-43), achieving a maximum TEC reduction of 13.6% (2996 vs. 3467 in example 35). For examples with more than 300 operations, although **MG** is capable of finding feasible solutions, it yields worse optimal solutions relative to **GD**.

## CONCLUSIONS

In this work, we presented a mixed-integer linear programming formulation for energy-efficient flexible job shop scheduling problems. The objective was to minimize total energy consumption, including energy used during processing operations, idle durations, and auxiliary facilities. The formulation was developed based on the global precedence relationships of operations on machines. Since immediate precedence relationships cannot be directly expressed using decision variables, we incorporated novel constraints to identify them. This enabled the precise estimation of idle durations between adjacent operations on machines, which in turn determined the optimal machine modes. Computational studies showed the superiority of the proposed formulation. Its advantages are reflected in reduction in total energy consumption by up to 20%. It successfully provided feasible solutions for all considered examples, including those where existing mathematical formulations failed.

## ABSTRACT

Transition from fossil fuels to clean energy technologies (CETs) is critical, but material shortages threaten to hinder progress. This study analyzes the potential deficits in 14 key materials – such as lithium, nickel, and cadmium – based on capacity projections for CETs by eight Integrated Assessment Models (IAMs) for 2020-2050. It focuses on technologies including battery storage, concentrated solar power (CSP), electrolyzers, solar photovoltaics (PV), and wind turbines. Our findings show that these materials could face shortages of up to 97% by 2050. To meet rising demand, material production rates must increase sharply, with some materials like cadmium, selenium, and tellurium requiring about 31% increases, peaking in this decade. Immediate actions are needed to accelerate production and improve recycling efforts. However, recycling targets, such as 325% for lithium, seem highly challenging to achieve. Without these measures, material shortages could delay CET deployment, risking Paris Agreement goals. To prevent these disruptions, we call for: (i) revising CET capacity projections, (ii) urgent planning for mining expansion, and (iii) a significant increase in recycling infrastructure to ensure a sustainable energy transition.

**Keywords**: Energy transition, Clean Energy, Integrated Assessment Models, Material Requirements.

## INTRODUCTION

Clean energy technologies are pivotal in reducing fossil fuel consumption, mitigating greenhouse gas (GHG) emissions, and enhancing energy security. However, as CET deployment accelerates, resource extraction grows, presenting significant challenges to meeting the energy sector's rising material demands.

The capacity requirements for CETs are a central focus of climate policies shaped by IAMs [1]. These models are used for guiding policy strategies, driving climate change mitigation, and informing global initiatives [2]. However, IAMs have faced criticism overlooking key factors such as human behaviour [3], socio-technical insights [4], and political neutrality [5]. A particular concern is the absence of materials availability to scale CETs. This undermines the credibility of their capacity projections.

This study evaluates the feasibility of CET capacity projections across 25 scenarios from eight widely used IAMs, aligned with the Paris Agreement temperature target. These scenarios, covering diverse assumptions, increase the reliability of our findings. We assess capacity projections for stationary and Electric Vehicle (EV) batteries, electrolyzers, CSP systems, PV panels, and wind turbines against realistic capacities based on the availability of 14 materials, including critical minerals, rare earth elements, and platinum group metals. Then, we develop an optimization model to identify the gap between IAM projected capacities and realistic estimates constrained by material availability. Also, we calculate the recycling rates required to meet IAM-projected capacities.

## Methodology

First part of this section focuses on estimating the material demand, while the second part introduces a model to evaluate the effect of material unavailability.

### Assessing the feasibility of IAM projections

The materials demand estimation is based on the projected capacity for each technology from 2020 to 2050, using data from 25 scenarios provided by eight widely used IAMs [6], discussed in the following.

#### Overview of selected IAMs

Recognizing that each IAM employs unique scenario designs and technological assumptions, our analysis

incorporates multiple IAMs to provide a comprehensive range of perspectives and account for differences in modelling approaches. Specifically, we include the following IAMs: GCAM 4.2, IMAGE 3.0.1, MERGE-ETL 6.0, MESSAGE-GLOBIOM 1.0, MESSAGEix-GLOBIOM 1.0, POLES ADVANCE, REMIND-MAgPIE 1.7-3.0, and WITCH-GLOBIOM 4.4. These models collectively represent 25 scenarios explained in Rostami et al. [7].

Throughout this study, references to IAMs specifically pertain to the eight models and their respective scenarios selected for analysis.

## Accounting for technology variations

IAMs provide data at a general, archetypal technology level, but in reality, technology designs – and their material requirements – vary significantly. To account for this, our analysis includes seven battery types, three CSP types, two electrolyzer types, three PV panel types, and six wind turbine types. We allocate IAM capacity projections across different technology types using two market contribution scenarios [8]: ***Continued***, which assumes a gradual evolution of existing technologies; and ***Technological Change***, which considers the potential for rapid advancements and shifts in technology design. These scenarios predict how various technology designs will contribute to the overall market. The specific selected technology types and market contribution values are detailed in supplementary information. Furthermore, we will highlight the technology types that are most recommended under materials availability constraints.

## Materials demand estimation

Material consumption per gigawatt (GW), known as material intensity, was sourced from the literature for each technology type [8], [9]. We used two material intensity scenarios: ***Current,*** reflecting present-day intensities; and ***Learning curve,*** accounting for technological advancements that may reduce intensities over time.

The material intensity values used for each technology type are available in supplementary information.

To estimate material demand, we multiplied the projected technology capacities from each of the 25 IAM scenarios by two market contribution trends (*k:"Continued"* and *"Technological Change"*) and two material intensity scenarios (*i:"Current"* and *"Learning Curve"*). This approach, illustrated in Equation 1, results in a total of 100 potential outcomes, providing a comprehensive assessment of material demand under varying assumptions.

$$MD^{T}_{m,t,n,s,k,i} = CC^{T}_{n,s} \cdot MC_{t,n,k} \cdot MI_{m,t,n,i} \quad (1)$$

$$\forall m,n,s,k,i,\ t \in TT_{T},\ T=\{BAT,\ CSP,\ ELECTZ,\ PV,\ WIND\}$$

Here, $MD^{T}_{m,t,n,s,k,i}$ [ton] represents the demand for material *m* , driven by technology type *t* within the broader technology category *T*, for year *n* as determined by IAM scenario *s*, market trend *k*, and material intensity *i*. $CC^{T}_{n,s}$ [GW] denotes the installed capacity for technology category *T* in year *n* according to IAM scenario *s*, while $MC_{t,n,k}$ [%] is the market contribution of technology type *t* in year *n* according to market trend *k*. The relationship between technology types *t* (e.g., crystallin silicon PV panels) and technology categories *T* (e.g., PV panels) is given by set $TT_{T}$, which specifies the types *t* that belong to category *T*. $MI_{m,t,n,I}$ [ton/GW] is the material intensity *i* (*"Current"* or *"Learning Curve"*) of material *m* used in type *t* of technology *T* in year *n*.

To assess the potential material shortages, we compared the material demands estimated over time with their prospective market availability, calculated projecting their current production rates. The details of these comparisons are explained in Equation 2.

$$MSh_{m,n,s,k,i} = \frac{([PR_{m,20} \cdot (1+\alpha)^{r} \cdot Sh^{CETs}_{m,20}] - \sum_{t,T} MD^{T}_{m,t,n,s,k,i}) \cdot 100}{\sum_{t,T} MD^{T}_{m,t,n,s,k,i}} \quad (2)$$

$$(\forall m,n,s,k,i,t \in TT_{T}, r = 0,1,\dots,30)$$

In Equation 2, the first term in the numerator calculates the market availability of material *m* in year *n* for CET development [ton]. Our estimation is based on the production rates for 2020 ($PR_{m,20}$) sourced from the literature [7]. The production rate might remain constant (*α=0*) or grow annually. To account for its variations, we assume an annual growth rate of *α=2.7%*, reflecting the average growth in metal mining [10]. Notably, *r* is the counter of the years in the projection period, starting at *r=0* for 2020 and increasing to *r=30* for 2050. Since materials are not solely used for CET development (i.e., they are also needed in other sectors), we limit the allocation of each material for CETs by applying the 2020 share of CET-driven demand ($Sh^{CETs}_{m,20}$). It represents the proportion of each material´s total production used for CETs in 2020 [%]. This calculation gives the market availability of material *m* for CETs in year *n*. From this, we then subtract the total demand for each material *m* in year *n*, derived by IAM scenario *s*, market trend *k*, and material intensity scenario *i* across all technology types *t* within each category *T* [ton]. The resulting difference, divided by total demand for desired material, provides the shortage in its availability for CETs development ($MSh_{m,n,s,k,i}$).

The required growth rates for material production to meet the IAM capacity projections are determined by forcing the numerator of Equation 2 to be zero, and solving the resulting equation for α.

## Estimating technology capacity shortfalls

To evaluate the impact of material shortages on CET deployment, we aim to estimate the achievable capacities of CETs. This involves developing an optimization

model, formulated and solved in General Algebraic Modeling System (GAMS), to minimize the gap between the capacities projected by IAMs and the realistic capacities constrained by material availability. In the model, variables are *italicized*, and parameters are presented in standard font for clarity throughout the equations.

$$\text{Min} \sum_{T,n,S} Diff_{n,s}^{T} \quad (3)$$

$$\text{s.t:} \quad Diff_{n,s}^{T} = CC_{n,s}^{T,Opt} - \text{CC}_{\text{n,s}}^{\text{T,IAMs}} \quad (4)$$
$$\forall n,s,T=\{BAT, CSP, ELECTZ, PV, WIND\}$$

$$Diff_{n,s}^{T} \geq 0 \quad (5)$$
$$\forall n,s,T=\{BAT, CSP, ELECTZ, PV, WIND\}$$

$$\sum_{k,t,T} CC_{n,s}^{T,Opt} \cdot \text{MC}_{\text{t,n,k}} \cdot \text{MI}_{\text{m,t,n}} \leq \text{PR}_{\text{m,n}} \cdot \text{SHARE}_{\text{m,2020}}^{\text{CETs}} \quad (6)$$
$$\forall m,s,\ n=2021, \ldots, 2050$$

$$\sum_{n,k,t,T} CC_{n,s}^{T,Opt} \cdot \text{MC}_{\text{t,n,k}} \cdot \text{MI}_{\text{m,t,n}} \leq \text{Res}_{\text{m}} \quad \forall m,s \quad (7)$$

$$Diff_{n,s}^{T},\ CCI_{t,n,s}^{T,Opt} \in \text{R}^{+} \quad (8)$$

The objective of the model (Equation 3) is to minimize capacity disparities across technology categories *T* (e.g., PV), IAM scenarios *s*, and years *n*, as denoted by $Diff_{n,s}^{T}$. These disparities are defined in Eq. 4 as the difference between the capacities projected by IAMs ($\text{CC}_{\text{n,s}}^{\text{T,IAMs}}$) and the "realistic" capacities estimated by the model ($CC_{n,s}^{T,Opt}$). For each technology, this difference should be positive to prevent situations where surplus capacity in one technology category offsets deficits in another (Eq. 5). The values for $\text{CC}_{\text{n,s}}^{\text{T,IAMs}}$ are obtained from IAMs, for the corresponding scenario *s* and year *n*. In this context, as discussed in Equation 1, the left-hand side of Equation 6 calculates the demand for material *m* driven by all types of technology *T* developed in year *n*. By incorporating multiple technology types into our models, we can determine which technologies are preferentially selected. The right-hand side reflects the portion of the realistic production rate for material *m* in year *n* ($\text{PR}_{\text{m,n}}$) allocated to CET manufacturing. Indeed, the shares observed in 2020 ($\text{SHARE}_{\text{m,2020}}^{\text{CETs}}$) are used to limit the amount of each material available for CET manufacturing. Notably, production rates for 2020 ($\text{PR}_{\text{m,2020}}$) are sourced from the literature [7]. Future production rates ($\text{PR}_{\text{m,n}}$) are obtained by applying an annual growth rate of α = 2.7%, reflecting the historical average annual growth rate of metals mining [10]. This rate was adjusted to 0.7% and 4.7% for sensitivity analysis, representing the average growth ± 2%. Finally, Equation 7 is used to constrain the cumulative demand for material *m* by year *n,* driven by all the technologies, to remain within the limits of its available reserves ($\text{Res}_{\text{m}}$), as given in literature [11].

To estimate the minimum recycling rates needed to address CET material shortages and achieve IAM capacity projections, we developed a secondary optimization model, deriving from this one. The objective of this second model is to calculate the minimum required recycling rates. The model uses constraints similar to those in the primary model but incorporates recycling as an additional supply source (i.e., recycling is added as a new variable to the right-hand sides of Eqs. 6–7). Due to space limitations, we avoid detailed explanation of this model. Further details can be found in Rostami et al. [7].

For each of the 25 IAM scenarios, we ran the model 12 times, using different combinations of two market trends, two material intensity projections, and three annual production rates (α). This results in a total of 300 (i.e., 25×12) estimates for each material´s recycling rate. Current recycling rates, sourced from various references [11], [12], are used to contextualize the results.

## Results and discussion

### Material shortage

Figure 1 illustrates the potential material shortages for CET development, shown as negative values (red shadow), and the necessary annual production growth rates to address these shortages, represented by positive values (blue shadow). The lines inside each shadow present the median results across 100 scenarios.

The red lines highlight significant material shortages, with materials such as cadmium, graphite, indium, lithium, nickel, and tellurium projected to fall short by up to 97% of demand. Materials like dysprosium, iridium, neodymium, silver, and terbium face comparatively lower deficits, still their shortages remain significant. The steep decline in the red curves indicates that the most severe shortages are likely to occur within this decade, followed by a moderate worsening trend in next decades. An exception is iridium, where based on the median values, shortages are mainly expected after 2040, aligning with the large-scale deployment of electrolyzers. However, when considering all the scenarios (i.e., the red shadow), we might face an iridium shortage starting this decade. Overall, these commodities markets will be so tight that the deployment of CETs at the pace and scale envisioned by IAMs seems impossible. It will likely translate into higher cumulative emissions, which might prevent us from meeting Paris agreement targets.

Addressing these deficits requires urgent and worthy action. Incremental production increases, such as the 2.7% annual growth shown by thin red lines (reflecting historical averages of metal mining annual growth rate), are clearly insufficient. For instance, this growth only marginally reduces lithium shortages from 97% to 93%. Without addressing these material deficits, achieving CET capacities at the scale envisioned may not be feasible. This underscores the importance of integrating material constraints into IAMs to ensure realistic projections.

For most materials, the blue lines, representing the

median of necessary annual production growth rates, start at low values in 2020 and rise sharply during the early years (2020–2025). Materials like cadmium, gallium, indium, selenium, silver, and tellurium exhibit high starting points in 2020, reflecting their early and intensive use in PV panels. Since production of these materials has not increased as necessary in recent years, we expect a challenging period, indicating that more effort will be required in the future to compensate for these shortages and achieve the CET projected capacities by 2050.

Overall, after 2025, the rate of increase slows but remains positive, suggesting that while the urgency for scaling production decreases, steady growth remains necessary. Factors such as technological maturity and improved material intensity likely contribute to this trend. Even in the long term, annual growth rates remain above 5.6%, with this median observed for iridium in 2050.

Furthermore, in the early 2030s, a second peak in the production of cobalt, graphite, and lithium will be necessary to develop batteries for EVs at the projected scale. Similarly, unachieved targets before 2030 will exacerbate the situation beyond that point, if we want to catch up the projections at some point. It is important to note that mine expansion is time-intensive, meaning that material production might not ramp up at the necessary pace in the short term. This highlights the urgency of planning for mining expansion.

Alternatively, CET development could be adjusted to require a steadier material production rate over time. Implementing this requires adjustments in CET projections and offers significant long-term benefits by ensuring more stable material production. For example, it reduces the risk of supply chain bottlenecks, provides more time to incentivize investments in recycling infrastructure, decreases market volatility and price fluctuations, and benefits industries dependent on these materials.

## CET shortfalls and required material recycling

Figure 2 highlights the shortfalls in CET capacities based on IAM scenarios and after implementing constraints on materials availability. Meeting IAM projections for batteries and PV panels is challenging. For batteries, persistent material deficits are expected starting this decade (see cobalt, graphite, lithium, and nickel in Figure 1), potentially resulting in a 94% shortfall, equating to 11.1 TW below the 2050 targets. Similarly, PV panels capacity may fall short by 1.6 TW (94% of projections) due to cadmium, gallium, indium, selenium, and tellurium, shortages.

Electrolyzer deployment appears more feasible under median scenarios. However, under pessimistic condition, iridium shortages could limit output by 752 GW. CSP faces a moderate shortfall, with a median capacity deficit of 10.4 GW by 2050. Still, under ambitious scenarios, the entire 169 GW projected capacity may be unattainable. Wind turbine deployment could also be hindered by dysprosium, neodymium, and nickel shortages, resulting in a median shortfall of 88 GW (54% below the 2050 target). All these highlight the urgent need to modify IAMs by incorporating material availability constraints.

Raw materials are unevenly distributed across the globe, which inherently creates vulnerabilities in supply chains. For instance, a substantial share of gallium reserves is concentrated in China. Therefore, geopolitical

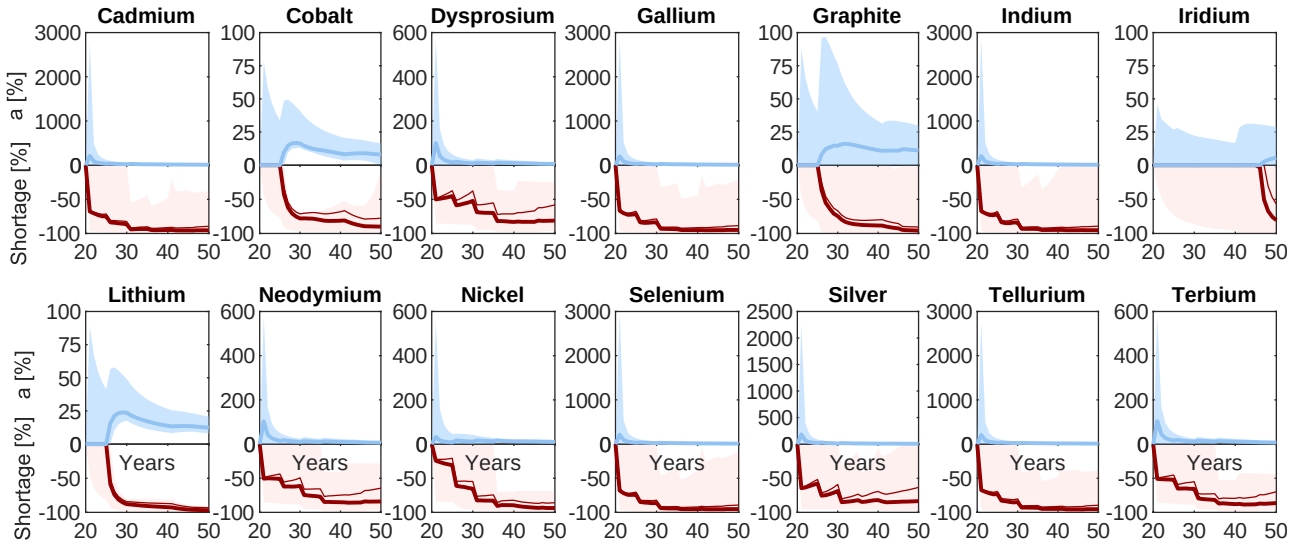

**Figure 1:** Material shortages and required annual production growth rates across 100 evaluated scenarios. The red thick line shows median material shortages (% of annual demand) based on current production rates, while the red thin line reflects shortages assuming a 2.7% annual increase in production. The blue line represents the median of required annual production growth rates. Timeframes: 20 (2020), 30 (2030), 40 (2040), and 50 (2050).

factors may further compound the challenge of securing sufficient raw materials for CETs. In the event of political conflicts, trade restrictions, or economic sanctions, these imbalances could be exacerbated, further reducing the attainable capacity of CETs or driving up their costs.

In Figure 2, the narrow bars above the panels indicate the technology types selected by the model. The findings demonstrate that, due to their unique designs and material requirements, technology types face varying levels of material shortage challenges. While some types are not selected at all, others, such as lithium ferro phosphate batteries, dominate, indicating these designs are strongly favored under materials availability constraints. For the list of technology names, refer to the supplementary information.

The data from Figure 3 underscore the magnitude of the challenge. For materials like lithium, iridium, and terbium, the recycling rates required to meet IAM projections are dramatically higher than current recycling rates. For example, based on median values, by 2050, lithium's recycling rate must reach 325% of its annual production, which indicates the amount of lithium needed for recycling would far exceed what is produced in a single year, pointing to the need for large-scale, long-term strategies for material recovery. This required a massive effort to dismantle existing infrastructure, including outdated technologies, in a feasible and sustainable way.

Materials such as dysprosium, graphite, iridium, and terbium also require substantial increases in recycling rates. For instance, for iridium it should rise from the current 17% to 64%, which highlights the significant gap between current capabilities and future needs.

## Conclusion

This study emphasizes the severe challenges posed by material shortages in the development of CETs, highlighting the urgent need to revise IAM capacity projections and take proactive measures in material production and recycling. The analysis reveals that critical materials such as lithium, nickel, cadmium, indium, and iridium are projected to experience substantial shortages, with some deficits reaching up to 97% of the required demand by 2050, based on IAM projections. For example, lithium shortfalls potentially lead to a deficit of more than 11 TW, which accounts for 94% of the projected battery capacity. Similarly, PV panel deployment could fall short by 1.6 TW (94% of projections) due to the scarcity of materials like cadmium, gallium, and tellurium. The availability of

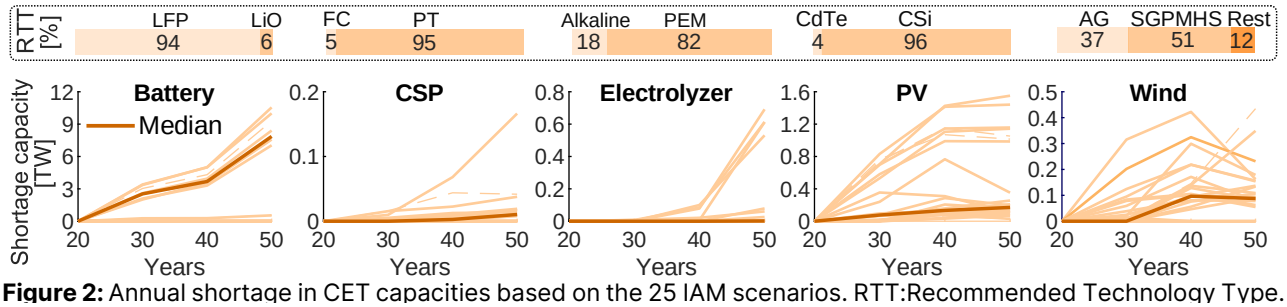

**Figure 2:** Annual shortage in CET capacities based on the 25 IAM scenarios. RTT:Recommended Technology Type.

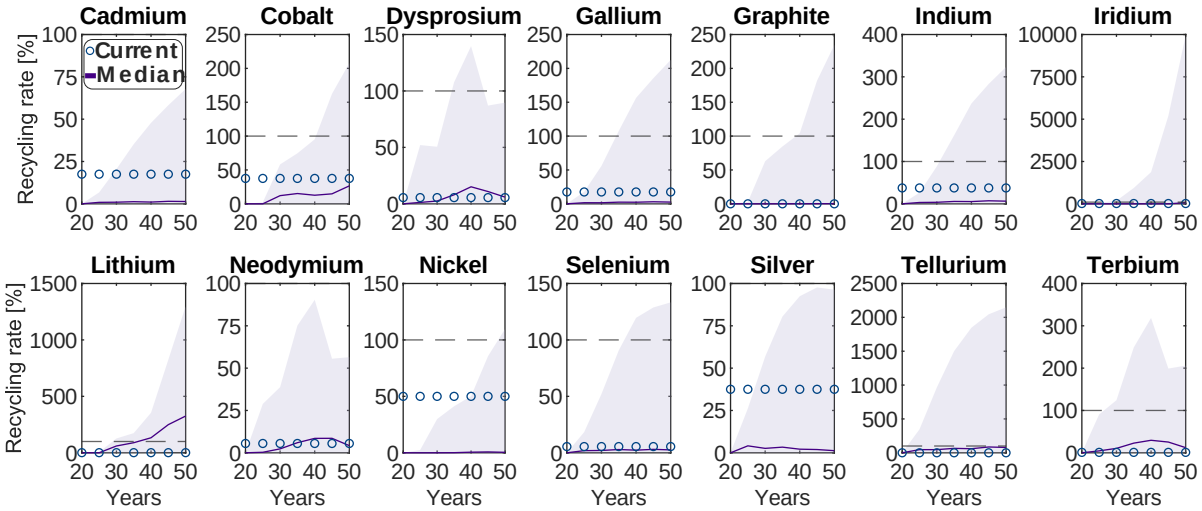

**Figure 3:** Recycling rates required to meet IAM capacity projections. The shaded area represents the range of recycling rates derived from 300 scenarios. Timeframes: 20 (2020), 30 (2030), 40 (2040), and 50 (2050).

materials for electrolyzers, CSP, and wind turbines could also be severely impacted, hindering their development.

To meet the growing material demands for CETs, production rates must increase significantly. Materials such as cadmium, selenium, and tellurium are expected to see a sharp rise in their production rate. However, the pace of production growth may not be able to keep up with this demand, emphasizing the need for immediate and strategic planning to expand mining capacity.

The unequal distribution of raw materials gives countries with domestic access a strategic advantage while disadvantaging others. This underscores the need for a free and open global market, combined with strong international collaboration, to mitigate supply chain risks and ensure that the transition to a sustainable clean energy future is not derailed by geopolitical tensions.

Investing in recycling infrastructure and circular economy initiatives helps to reduce reliance on raw material extraction. For example, by 2050, recycling rates for lithium and iridium will need to reach 325% and 64% of their annual production, respectively – an ambitious target, asking for extra efforts.

Overall, this calls for adjustment of IAMs so as to account for the availability of raw materials, enabling them to provide more realistic guidance for policy makers.

## ABSTRACT

Commodity chemicals and energy supply chains are an essential part of the hydrocarbon industry in several countries. As these supply chains are susceptible to disruptions caused by various risks, the economies of countries that depend on the hydrocarbon sector as a major source of income might be negatively affected. One major risk is the price fluctuations of the resources used in the multiple stages of the supply chains. Investment decisions in this sector aim to secure the investment portfolio's financial returns against the risk of price fluctuations. This work introduces an adaptation of a portfolio optimization technique, the modern portfolio theory (MPT) to the case of commodity chemicals and energy supply chain investments by considering all supply chain stages in formulating the MPT framework. A case study considering four chemical commodities and three potential importing countries is presented with a sensitivity analysis that studies the impact of changing the costs associated with the several stages of the supply chain on the investment portfolio. Results show the importance of integrating both the chemical production and the shipping stages of the supply chain in developing a portfolio optimization framework and its impact on the optimal investment portfolios. The developed model guides investment planners to target the desired financial returns at a minimum risk.

**Keywords**: Investment Decision, Portfolio Selection, Supply Chain, Modern Portfolio Theory

## INTRODUCTION

Since the outbreak of the COVID-19 pandemic, concerns have risen regarding the importance of sustaining energy supply chains to ensure the energy security of importing countries [1] and the financial security of exporting countries [2]. Such supply chains are susceptible to risks such as economic shocks, geopolitical disruptions, pandemics, etc. [3]. The COVID-19 pandemic has caused the highest energy market volatility [4]. It led to a sudden decrease in demand for energy, chronic disruptions to supply chains, and elevated prices after recovery [5]. Similarly, geopolitical acts and threats could drive the risk of a crash in the prices of natural gas and oil [6]. Fluctuations in the prices of the exported commodity chemicals and fuels or the raw materials used in their production can result in increased financial burdens on importing countries or a significant decrease in exporting countries' profits. The hydrocarbon industry contributes significantly to the financial stability of several countries with significant oil and gas reserves. For example, as the hydrocarbon sector has contributed to over 70% of Qatar's government's total revenue and 80% of the country's total exports since 2014 [7], ensuring the security of this sector against the risk of price fluctuations is a priority for the country. The hydrocarbon industry is very capital-intensive, and the budget for some projects is over one billion US dollars [8]. As investments in this sector require large capital, time, and technology investments, selecting investment portfolios is critical [9]. As such, an investment planning methodology is necessary for the hydrocarbon sector in such countries. Optimizing and diversifying the investment portfolio can help decrease the risk of investment return uncertainty resulting from price

fluctuations. Diversifying the investment portfolio can ensure the security of the hydrocarbon industry's returns as losses from one investment can be compensated by gains from another and portfolio optimization can help in the investment decision-making process as it aims to maximize a portfolio's expected return while minimizing the uncertainty of the return, the portfolio risk [10]. The Modern Portfolio Theory (MPT) developed by Harry Markowitz is an investment portfolio selection tool that aims to guide an investor in determining the optimal investment portfolio [11]. Markowitz formulated a mean-variance optimization problem that results after its solution in a set of Pareto optimal investment portfolios that maximizes the investment portfolio return for a given level of risk, the efficient frontier. In other words, for a portfolio on the efficient frontier, there is no other portfolio with a higher return for a specified level of risk. The theory has been widely used in several fields as a decision-making tool for investment portfolio selection. The Markowitz framework was adapted to optimize the national grain imports by reducing the cost and risk associated with the imports [12]. Due to the price fluctuations of coal, the theory was used to determine the optimal coal purchasing strategy for Taiwan Power Company [13]. The energy security of energy-importing countries also has been studied extensively using the MPT framework. The impact of the fluctuating prices of oil on China's energy import portfolio was studied [14]. Several research works adapted the MPT framework to problems related to the energy security of the exporter. An MPT framework was developed for investment portfolio diversification of major GCC oil-exporting countries [15]. A similar framework was developed to determine the exporting strategy for a natural gas exporting country [16]. The theory was adopted for selecting investment portfolios for the chemical production industry [17, 18]. The decision-making process of hydrocarbon export investments is based on a complex export system. Investors have several options considering the exported chemical commodities, transportation methods, and partner importers. In other words, the problem is of a supply chain scope. The previous adaptations of MPT to the chemical exports problem had several drawbacks: either the development of the framework did not consider a supply chain perspective ignoring the importance of selecting not only the exported commodities but also the partner importers or did not consider the foundations of chemical production and transportation processes This is reflected by disregarding the price fluctuations of all raw materials and utilities used in the export system and considering the price uncertainty of the traded commodities only. A visual representation of the hydrocarbon export problem and the associated price fluctuations is shown in Figure 1. For an exporting country, considering both the production and transportation stages affects the efficient frontier, the set of optimal investment portfolios. To counter the risk of price fluctuations associated with the hydrocarbon exports investments problem, this work develops an MPT framework by considering a supply chain perspective and the foundations of chemical production and transportation as a tool to aid investors in the investment decision-making process. Two efficient frontiers are obtained after solving the Markowitz optimization problem, the first by considering the production stage of the supply chain only and the second by considering both the production and transportation stages.

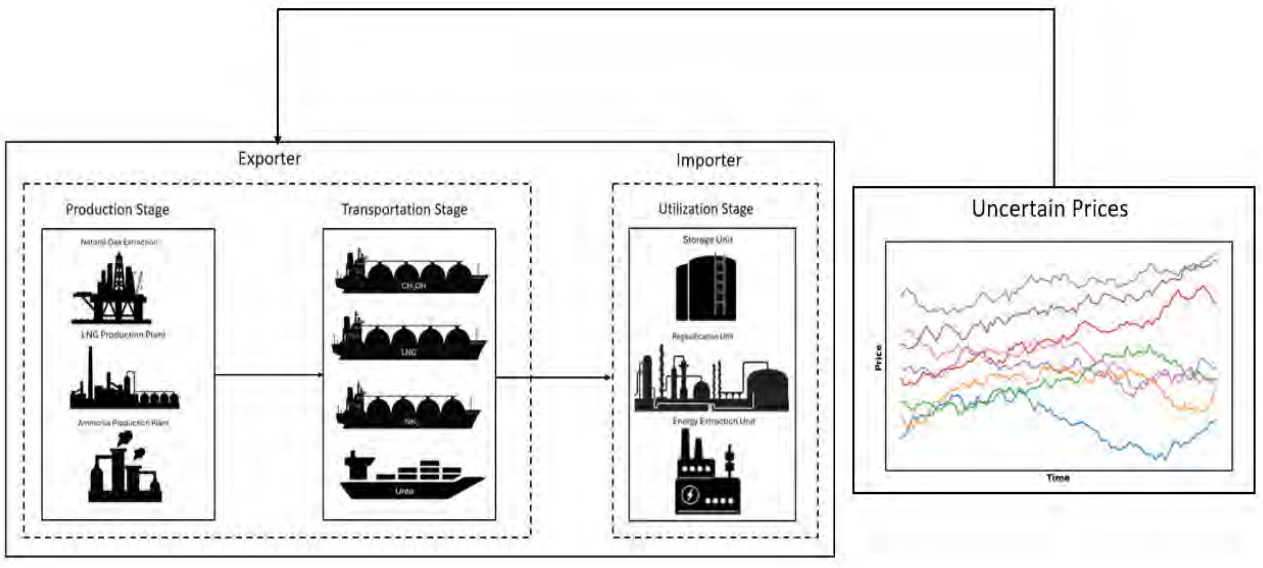

**Figure 1:** The price uncertainty associated with a hydrocarbon export system.

## APPROACH AND PROBLEM STATEMENT

The work aims to develop an MPT framework for energy and commodity chemicals supply chain investments, to determine the investment portfolios with the maximum financial returns at a given level of risk.

Given is a set of commodity chemicals $C = \{c_1, c_2, ..., c_n\}$, $n \in \mathbb{N}$ each produced by a respective production plant from the set $P = \{p_1, p_2, ..., p_n\}$, $n \in \mathbb{N}$. Let $I = \{I_{i,1}, I_{i,2}, ..., I_{i,k_i}\}$, $k_i \in \mathbb{N}$, be the set of potential importing countries of the commodity chemical $c_i$ where $k_i$ is the total number of potential importing countries of $c_i$. $I_{i,j}$ is the j-th importing country of the chemical $c_i$ where j = 1, 2, ...., $k_i$. A supply chain is defined as a combination of a commodity and an importing country. It is represented as $S_{ij} = \{(c_i, I_{i,j})\}$ where i is the index referring to the traded commodity and j is the index referring to the importer of the commodity. The weight of the capital invested in the supply chain asset $S_{i,j}$ is $w_{i,j} \in [0,1]$. The resulting supply chains represent the potential investment assets constituting an investment portfolio. The historical price data for the production plants' inputs and outputs are required. The plant inputs are the raw materials and energy requirements needed to produce the commodity chemical $c_i$, and the latter is the plant output. Further information on the plants' capital, fixed, and variable operating costs is required. Such data ensures the ability to determine the efficient frontier for a chemical production investment problem. Additionally, a transportation mode to export the commodity $c_i$ to the importing country $I_i$ is defined. Information on the distance between the exporter and the importer, the transporting ship type, its speed, capital cost, the bunker fuel, its consumption rate, and cost is required. This information is needed to account for the transportation stage of the supply chain. The total amount of capital to be invested in the supply chain portfolio is given. To be calculated is the return on each supply chain investment over a given period. The variance of the return due to fluctuation of the prices of the supply chain inputs and outputs is calculated over a given period. The standard deviation represents the risk of investing in the asset.

The optimization problem is once formulated considering the production stage of the supply chain only and then by additionally accounting for the transportation stage. Evaluating the optimization problem results in determining the efficient frontier that shows the constituting supply chain investments of an optimal portfolio, their respective return and risk, and the weight of capital allocated for each supply chain investment. The weight reflects the capacity of each production plant $p_i$ and the amount of the commodity $c_i$ that should be exported to the importer $I_i$, using the specified transportation method. The efficient frontier is generated for both cases. The difference between the two obtained efficient frontiers emphasizes the importance of using a supply chain perspective to address the hydrocarbon exports investment selection problem.

A sensitivity analysis is conducted by varying the cost of producing or transporting a commodity, $c_i$, to study the impact of such changes on the efficient frontier's constituting portfolios. The sensitivity analysis can reflect the effect of using new technologies in producing and transporting chemical commodities on the optimal investment portfolios.

## METHODOLOGY

The starting point for formulating the model is the general MPT concepts and equations [19]. Adapting the MPT framework to the commodity chemicals supply chain problem requires calculating each investment portfolio's return and risk. This requires calculating the return on each supply chain investment, $ROI_{supply\ chain,\ year}$, by considering the yearly profit of the supply chain, $Profit_{supply\ chain,\ year}$, and the total capital cost of the supply chain investment, Capital $Cost_{supply\ chain,\ year}$, which are variable over time due to fluctuations in prices as shown in Equation 1:

$$ROI_{supply\ chain,year} = \frac{Profit_{supply\ chain,year}}{Capital\ Cost_{supply\ chain,year}} \forall\ supply\ chain \quad (1)$$

The profit of the supply chain is the supply chain revenue from the sales of the chemical commodity, $Revenue_{supply\ chain}$, after deducting the fixed and variable operating costs and the cost of depreciation designated as Fixed $OPEX_{supply\ chain}$, Variable $OPEX_{supply\ chain}$, and $Depreciation_{supply\ chain}$, respectively, as shown in Equation 2:

$$Profit_{supply\ chain} = Revenue_{supply\ chain} - Fixed\ OPEX_{supply\ chain} - Variable\ OPEX_{supply\ chain} - Depreciation_{supply\ chain} \forall\ supply\ chain \quad (2)$$

However, since it is assumed that the exporter is responsible for the production and shipping stages of the supply chain, both stages contribute to cost calculation as shown in Equation 3, Equation 4, and Equation 5:

$$Fixed\ OPEX_{supply\ chain} = Fixed\ OPEX_{supply\ chain}^{Production} + Fixed\ OPEX_{supply\ chain}^{Shipping} \forall\ supply\ chain \quad (3)$$

Where Fixed $OPEX_{supply\ chain}^{Production}$ and Fixed $OPEX_{supply\ chain}^{Shipping}$ designate the fixed operating costs of the production plant and transporting ship, respectively, accounting for labor and maintenance costs. In Equation 4, Variable $OPEX_{supply\ chain}^{Production}$ and Variable $OPEX_{supply\ chain}^{Shipping}$ designate the variable operating costs of the production plant and transporting ship, respectively. These include the variable costs of raw materials and utilities required for the processing plants and the cost of

shipping fuel.

$$Variable\ OPEX_{supply\ chain} = Variable\ OPEX_{supply\ chain}{}^{Production} + Variable\ OPEX_{supply\ chain}{}^{Shipping}\ \forall\ supply\ chain \quad (4)$$

In Equation 5, $Depreciation_{supply\ chain}{}^{Production}$ and $Depreciation_{supply\ chain}{}^{Shipping}$ designate the costs resulting from the depreciation of the production plant and transporting ship, respectively.

$$Depreciation_{supply\ chain} = Depreciation_{supply\ chain}{}^{Production} + Depreciation_{supply\ chain}{}^{Shipping}\ \forall\ supply\ chain \quad (5)$$

Similarly, the capital cost of a supply chain is the sum of the capital cost of the production plant, $Capital\ Cost_{supply\ chain}{}^{Production}$, and that of the transporting ship, $Capital\ Cost_{supply\ chain}{}^{Shipping}$, as shown in Equation 6:

$$Capital\ Cost_{supply\ chain} = Capital\ Cost_{supply\ chain}{}^{Production} + Capital\ Cost_{supply\ chain}{}^{Shipping}\ \forall\ supply\ chain \quad (6)$$

The weight of the investment capital allocated to each supply chain investment is denoted as $w_{supply\ chain}$. The return of a portfolio, Portfolio Return, is defined as a weighted average of the average return of a supply chain investment over the years, $\overline{ROI_{supply\ chain}}$:

$$Portfolio\ Return = \sum_{supply\ chain} w_{supply\ chain} \times \overline{ROI_{supply\ chain}} \quad (7)$$

The variance of a portfolio is determined as follows:

$$Portfolio\ Variance = \sum_{supply\ chain} w_{supply\ chain} \times Variance\ ROI_{supply\ chain} + 2\sum_{supply\ chain} \rho_{ROI_{supply\ chain}, ROI_{supply\ chain+1}}\ SD_{supply\ chain} SD_{suply\ chain+1} \quad (8)$$

Where $\rho_{ROI_{supply\ chain}, ROI_{supply\ chain+1}}$ is the correlation coefficient between the returns of two supply chain investments and $SD_{supply\ chain}$ is the standard deviation of the investment return. The risk of a portfolio, Portfolio Risk, is defined as the standard deviation of the portfolio's variance:

$$Portfolio\ Risk = \sqrt{Portfolio\ Variance} \quad (9)$$

After developing an MPT framework for the commodity chemicals and energy supply chain problem, the multi-objective optimization problem is presented as follows:

$$\begin{aligned} &Maximize\ Portfolio\ Return \\ &Minimize\ Portfolio\ Risk \\ &Subject\ to\ \sum_{supply\ chain} w_{supply\ chain} = 1 \end{aligned} \quad (10)$$

The problem evaluation results in determining the efficient frontier, a set of Pareto optimal investment portfolios.

As a plant can produce a commodity exported to multiple countries and a ship can transport the commodity to several destinations, an investor should aim for the least number of processing plants and transporting ships required which is considered in the developed model. Moreover, as the supply chains are defined specifically with a single importing country, the capital cost associated with the production and transportation stages of the supply chain is calculated based on the demand share of the importing country.

## CASE STUDY

A case study is designed to test the developed methodology. The four commodities considered in the case study are methanol, ammonia, urea, and LNG, all of which can be produced from natural gas. It is assumed that the exporter is a country in the Middle East with abundant natural gas reserves and the considered importers are India, China, and Singapore. Chemical commodities are to be transported to destinations using ships. The case study considers 12 possible supply chain investments, which is the maximum number of possible combinations of commodities and importing countries. These supply chains are: (Methanol, India), (Methanol, China), (Methanol, Singapore), (Ammonia, India), (Ammonia, China), (Ammonia, Singapore), (Urea, India), (Urea, China), (Urea, Singapore), (LNG, India), (LNG, China), and (LNG, Singapore). The work will be based on the period between 2018 and 2023. The import demand of the countries for these chemical commodities from the exporter is obtained from the World Integrated Trade Solution database of the World Bank [20]. The historical prices of raw materials, utilities, and exported commodities obtained from the Intratec database were used in this case study [21]. After calculating the return on each supply chain investment and its associated risk, the multi-objective optimization problem presented by Equation 10 is solved twice to determine the efficient frontier: first by considering only the costs of the production stage of the supply chain and then by considering the costs associated with both the production and shipping stages. Hence, two efficient frontier curves are determined. Python's Gurobi solver was used to evaluate the optimization problem using the epsilon constraint method [22].

While Figure 2 shows the efficient frontier determined only when considering the production stage of the supply chain, Figure 3 shows the efficient frontier determined when considering both the production and transportation stages. The constituting investment portfolios of the efficient frontier curves of Figure 2 and Figure 3 are shown in Table 1 and Table 2 respectively.

As shown, developing an MPT framework based on all supply chain stages increased the number of optimal

portfolios from five to seven, decreased the maximum possible return due to accounting for transportation costs, and decreased the portfolio risk range due to the increased diversification of the investment portfolios. The constituting supply chains of the optimal portfolios differ between the two efficient frontier curves obtained due to the effect of transportation costs in altering the attractiveness of the supply chain investments. The number of optimal assets in the optimal portfolios of the efficient frontier developed based on the production stage only ranged between one and three. However, introducing a supply chain perspective while developing the MPT framework increased this number where it ranged between one and nine. As such, a supply chain perspective offers a larger number of optimal investment export portfolio options. The portfolio with the highest return in both cases is a one-asset portfolio. It is the supply chain exporting methanol to Singapore which is the asset with the highest return on investment.

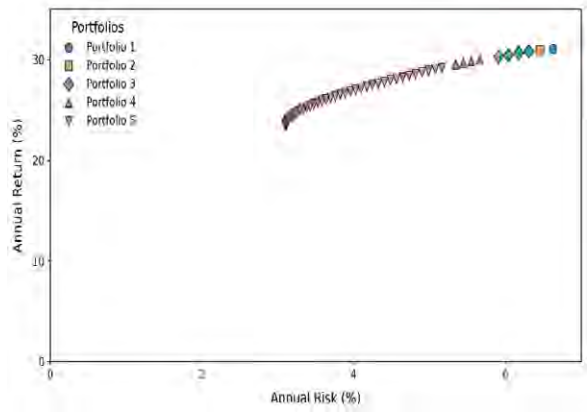

**Figure 2:** Commodity chemicals and energy production processes efficient frontier.

**Table 1:** The constituting investments of the commodity chemicals and energy production processes efficient frontier

| Portfolio | Constituents |
|---|---|
| Portfolio 1 | (Methanol, Singapore) |
| Portfolio 2 | (Methanol, China), (Methanol, Singapore) |
| Portfolio 3 | (Methanol, China), (Methanol, Singapore), (LNG, China) |
| Portfolio 4 | (Methanol, Singapore), (LNG, China) |
| Portfolio 5 | (Methanol, Singapore), (Urea, China), (LNG, China) |

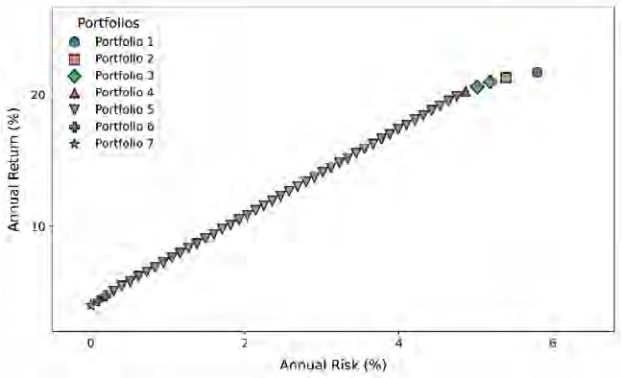

**Figure 3:** Commodity chemical and energy supply chains efficient frontier.

**Table 2:** The constituting investments of the commodity chemicals and energy supply chains efficient frontier.

| Portfolio | Constituents |
|---|---|
| Portfolio 1 | (Methanol, Singapore) |
| Portfolio 2 | (Methanol, India), (Methanol, Singapore) |
| Portfolio 3 | (Methanol, India), (Methanol, China), (Methanol, Singapore), (Ammonia, India) |
| Portfolio 4 | (Methanol, China), (Methanol, Singapore), (Ammonia, India) |
| Portfolio 5 | (Methanol, China), (Methanol, Singapore), (Ammonia, India), (Urea, India), (Urea, China) |
| Portfolio 6 | (Methanol, China), (Methanol, Singapore), (Ammonia, India), (Urea, India), (Urea, China), (Urea, Singapore) |
| Portfolio 7 | (Methanol, India), (Methanol, China), (Methanol, Singapore), (Urea, India), (Urea, China), (Urea, Singapore), (LNG, India), (LNG, China), (LNG, Singapore) |

While LNG production was a constituent of three out of five optimal portfolios in the chemical production efficient frontier, it is only a constituent of one portfolio in the supply chain perspective efficient frontier, the portfolio with the lowest risk. This is a result of the high transportation costs associated with LNG shipping. Methanol was present in all optimal portfolios of the two efficient frontier curves as investments in methanol exports are of the highest return. The production of ammonia is not considered an attractive investment based on the production stage efficient frontier. Similarly, urea is only present in Portfolio 5 of the production stage efficient frontier due to the lower return of this commodity compared to methanol and LNG. For the supply chain perspective efficient frontier, the first two portfolios with the highest returns

include only methanol supply chains. The export of ammonia and urea becomes attractive for portfolios of lower risk and return. The general trend in both cases is that decreasing the risk requires increasing the number of portfolio constituents which reflects the ability of portfolio diversification to decrease the return uncertainty, the investment portfolio risk.

The sensitivity analysis considers four alterations of the base case: twice by decreasing the production capital costs of the considered commodities, and twice by decreasing the shipping capital costs. The analysis shows that reducing all commodities' production or transportation costs increases the number of optimal supply chain portfolios as shown in Table 3. As such, using technologies with lower costs will increase the number of options an investor can consider. The constituting optimal supply chains of the five cases considered in the sensitivity analysis were different. While in the base case supplying LNG to India was an optimal investment in one portfolio only, reducing the transportation cost by 20% made this investment present in five optimal portfolios increasing its attractiveness.

**Table 3:** The impact of the changes in the cost on the number of optimal supply chain investment portfolios

| Case | Number of Optimal Portfolios of the Efficient Frontier |
|---|---|
| Base case | 7 |
| 20% decrease in production costs | 11 |
| 80% decrease in production costs | 12 |
| 20% decrease in transportation costs | 11 |
| 80% decrease in transportation costs | 11 |

## CONCLUSION

In response to the risk of price fluctuations affecting the financial security of hydrocarbon commodities exporters, a framework of MPT, an investment portfolio selection tool, has been developed for the energy and commodity chemicals supply chain problem. The developed model can determine the optimal investment options in terms of the traded commodities, capacities of production plants, partner importers, and the supply volume to each country. As the previous adaptation of MPT to the hydrocarbon exports field did not consider either a supply chain perspective or was not developed based on chemical production and transportation foundations, this work shows the impact of using a supply chain perspective in developing an MPT framework on the portfolio selection process. The developed MPT framework was applied to a case study by considering four commodities with their respective transportation modes and three potential importing countries. The results suggest that the developed framework can provide additional insight into what previous work has shown and act as a decision-making tool to aid investors in the commodity chemicals and energy export sector.

## ABSTRACT

The unit commitment problem determines the optimal strategy to meet the electricity demand at minimum cost by committing power generation units at each point of time. Solving the unit commitment problem gives rise to a challenging optimization problem due to its combinatorial complexity and potentially long solution time requirements. Our proposed solution approach utilizes a decomposition method in conjunction with alternative models from the EGRET library. Results of this decomposition approach tested against four benchmarking systems show that significant computational speed ups are achieved.

**Keywords**: Scheduling, Energy Systems, Optimization, Rolling Horizon Optimization

## BACKGROUND

The Unit Commitment (UC) problem is a foundational problem in the field of power systems. This problem tackles the decision making for the operation of the grid, defining when to switch on or off generators, and defining their power production levels to meet the forecasted energy demand. Initially it was solved using dynamic programming [1], which moved to a more sophisticated version using the heuristics based on Lagrangean Relaxation and then to mixed-integer linear programming (MILP) formulations[2]. This problem is usually solved for the day-ahead unit commitments, and bids are placed by the operator, the downside to this is that the operator has at most around 3 hours to solve the model and analyze the bids of which the most time is consumed in data verification, network analysis. Thus, the solution time requirement for solving the UC problem should be no more than 10-15 minutes. In practice, the UC problem must be solved repeatedly throughout the day, and the practical time window for the entire decision-making process is often around 20-30 minutes. This creates a stringent need for a faster solution approach. As the number of generation units increases due to the smaller distributed electricity resources (often solar and wind), this also increases the problem complexity significantly.

## PROBLEM STATEMENT

In the context of an electrical grid comprising multiple generation units, this study addresses the security constrained unit commitment (SCUC) problem, which also considers power grid transmission line limitations and other operational constraints such as reserve requirements. The objective is to determine the optimal schedule for generation units over a defined time horizon. Here we deal with the most common day-ahead unit commitment problem, and thus the time horizon remains 24 hours with hourly intervals. The grid's configuration includes the operational parameters of each generation unit, network topology, transmission line limits, and the forecasted energy demands at each node. The aim is to minimize the total generation cost, while satisfying to the energy balance constraints at each node, transmission line capacity limits, and operational limits of the generation units.

As the problem size is expected to rapidly grow due to both the increased number of generation units, as well as a trend to move to 15-minute time intervals, this work specifically focuses on efficient modeling and solution of a large-scale SCUC problem. It excludes considerations of uncertainties associated with renewable energy

sources, as well as the inclusion of energy storage. Here it is assumed that the fuel sources for all generators are non-renewable and thus fully dispatchable.

## PROPOSED METHODOLOGY

Given the extensive body of research on UC problem, this study leverages established tools and methodologies from the literature. We employ the open-source software package EGRET[3], which provides a comprehensive framework for UCP by offering 41 different model formulations drawn from the existing literature.

Among these formulations, we focus on two specific categories of models: those developed by Morales-España et al. [4], Knueven et al. [5], known for their competitive computational performance, and the models identified by Knueven et al. [3], classified as the "Tight" and "Compact" formulations based on their efficiency in computational studies.

However, these models often struggle to close the optimality gap within a reasonable time limit, when applied to larger, more complex systems. To address this limitation, we propose the use of a shrinking horizon method.

### Optimization models

To expand on the available models from the literature, we briefly examine the key characteristics and improvements introduced by each model:

a. Morales-España model (MLR): Building upon the foundational model developed by Carrion and Arroyo[6], the Morales-España model introduces tighter bounds on generation production. The proposed reformulation of the MILP model is both tight and compact, thus making it computationally competitive.

b. Knueven Ostrowski Watson model (KOW): The KOW model refines the Morales-España model by tightening the formulations of both piecewise linear production costs and start-up costs. The proposed model aggregates the thermal generators with identical characteristics into a single unit which reduces the redundancy in search space.

c. Tight Model (T): The tight model, akin to the KOW model improves on the tightness by enhancing the generation limits, tight start-up cost formulation, and it also uses two period ramping from the Damci Kurt et al. [7]. The tight model does lose on the compactness. Here the tightness of the model refers to the search space a solver needs to explore to find the optimal solution. Tighter models would have reduced search space.

d. Compact model (Co): The Compact model, is similar to the MLR model, with the difference being two period ramping from Damci Kurt et. al. [7] and improved reserve production. This formulation loses a bit on the tightness but is compact. Here the compactness of the model refers to the model size. A compact model has fewer number of variables and constraints.

### Shrinking Horizon Method

The Shrinking Horizon method was introduced by Balasubramanian and Grossmann[8], is an iterative method designed to improve computational tractability of multiperiod MILP models, particularly for large-scale systems. In this approach, the time horizon is divided into overlapping windows. During the first iteration, a window spanning from time t=1 to t=h is defined, where binary decision variables are active. For the remaining time-periods t=h+1 to t=n, the binary variables are relaxed. The model is solved within this window, and the binary decisions are recorded.

In subsequent iterations, the binary decisions for the previous window are fixed, and the window is advanced to t=h+1 to t=2h. This process is repeated iteratively, shifting the window forward until the entire time horizon is covered. This method allows for a more manageable and efficient solution process as illustrated in Figure 1.

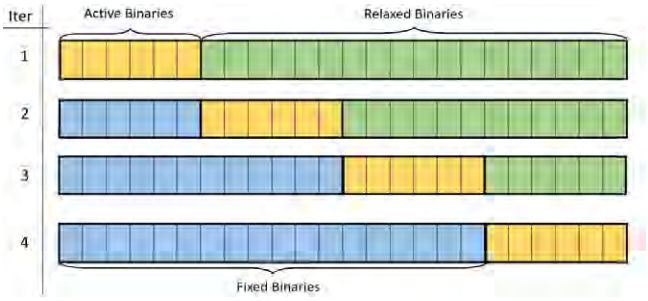

**Figure 1.** Shrinking Horizon Method

The Shrinking Horizon method inherently relies on solving a sequence of optimization problems over progressively shorter horizons, where future time periods are relaxed to facilitate computational tractability. However, the effectiveness of this approach depends on the quality of these relaxations, loose relaxations can lead to poor bounds, increased solution time, and suboptimal intermediate decisions.

Tight Model, mentioned to have the tightest relaxation amongst formulations in the UC literature [3] is particularly well-suited for the Shrinking Horizon method. The tight relaxations offer stronger bounds at each iteration and thus enhances the pruning efficiency of branch-and-cut algorithm, reducing the number of nodes explored in the tree search. Thus, the solvers can converge faster to a high-quality solution.

Furthermore, the Tight model mitigates the myopic effects of the Shrinking Horizon method by ensuring the relaxed future decisions remain closer to their integer counterparts. This reduces the risk of infeasibilities or drastic corrections in subsequent iterations, leading to a stable and efficient optimization process. By leveraging

the Tight Model within the Shrinking Horizon framework, the full computational potential of modern off-the-shelf solvers can be effectively realized.

## CASE STUDY

In this section, we present the results of applying the Shrinking Horizon method across various benchmark case studies, including IEEE118, WP2383, SP3120, and CASE6468RTE, each representing a system of varying size and complexity (Table 1). These case studies range from IEEE118, a relatively small system with 17 generating units, to the largest system, CASE6468RTE, containing 1181 units. 20 instances for each case study using a proprietary code by our collaborators at Hitachi Energy[9]. The analysis focuses on comparing the performance of the Shrinking Horizon method with the traditional monolithic approach, evaluating both computational speedup and solution quality in terms of objective deviation.

All case studies in the monolithic approach were solver to 0.01% optimality gap, except for CASE6468RTE, which was solved to a 1% gap and time limit of 3600

*** Best** values are bold and underlined. Second best values are underlined

seconds. For most part of the CASE6468RTE case study in the monolithic approach, the solver timed out with a median optimality gap of nearly 5%. Notably, the Shrinking Horizon method was solved for 0% optimality gap for each iteration across all case studies, except for CASE6468RTE, where each iteration was solved to 1% optimality gap with a time limit of 3600 seconds per iteration.

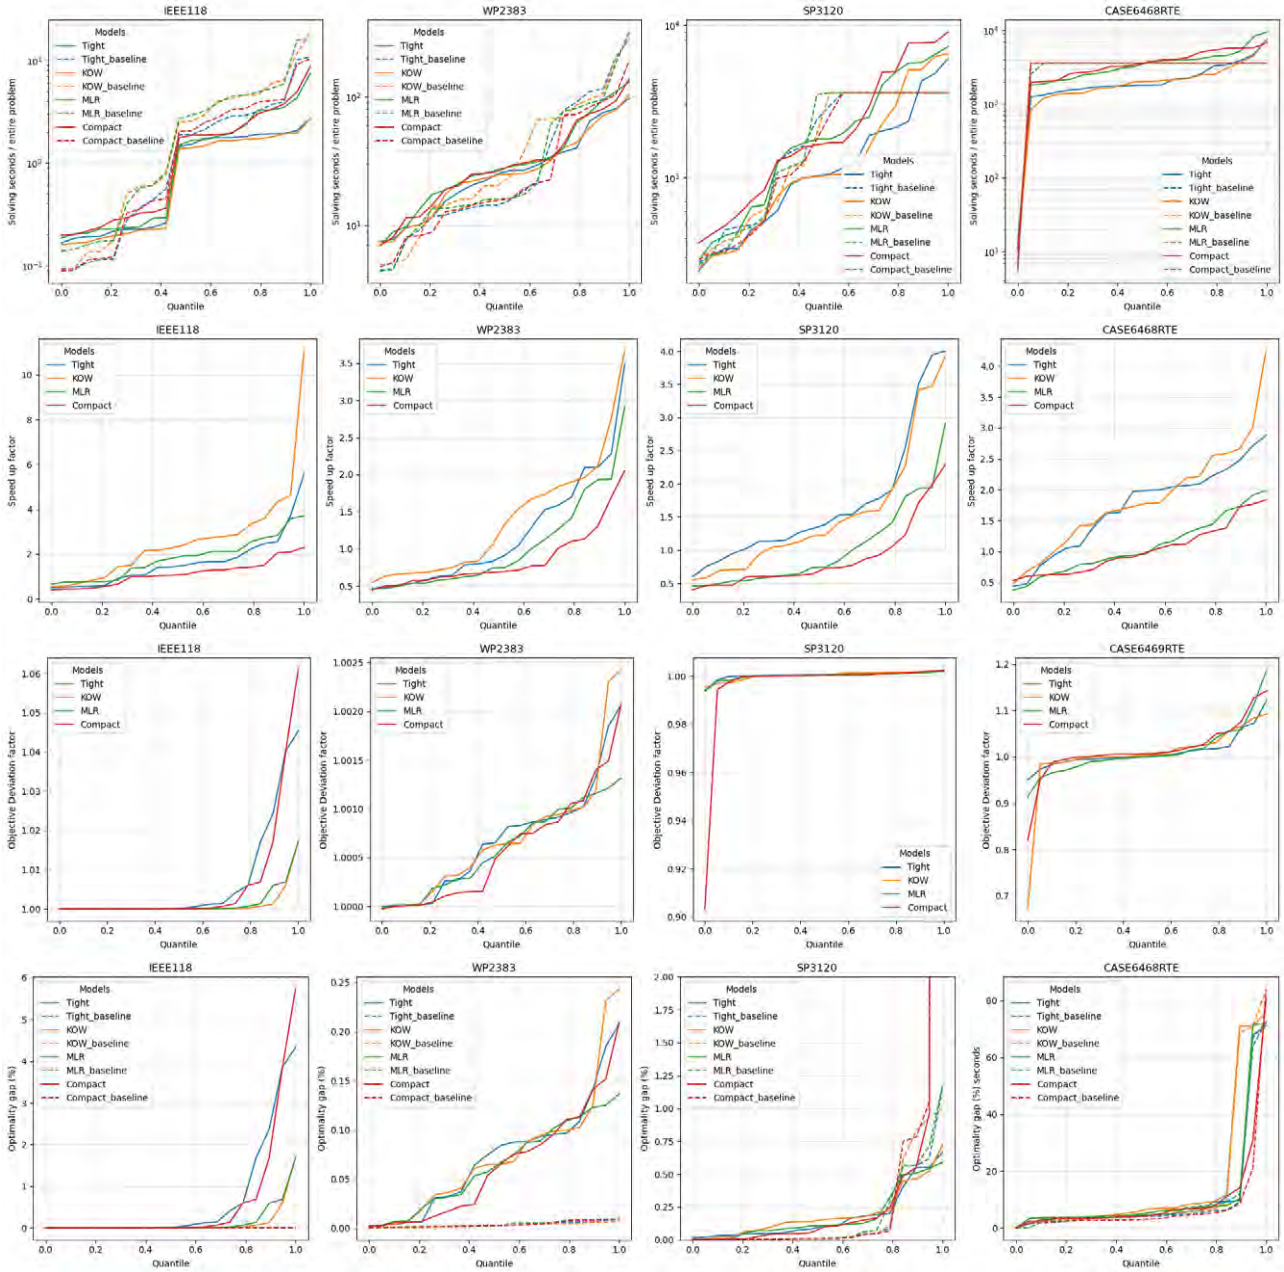
The computational study was conducted on a Linux machine equipped with 8 Intel Xeon Gold 6234 CPUs, operating at 3.30 GHz with a total of 8 hardware threads and 1 TB of RAM, all running within an Ubuntu environment. The models were constructed using EGRET's model library and solved with Gurobi v9.5.1 as the solver.

The speedup factor is calculated as:

$$speedup\ factor = \frac{solution\ time\ with\ monolithic\ model}{solution\ time\ with\ SH\ method}$$

The speedup factor reflects the efficiency gained by applying the shrinking horizon method. A factor greater than 1 suggests that the SH method is less effective than solving the problem as a whole.

Similarly, the objective deviation factor is calculated as:



$$Obj\ deviation\ factor\ \% = \frac{Obj\ value\ w/SH}{Obj\ value\ w/o\ SH}$$

This factor behaves conversely to the speedup factor: a higher objective deviation factor indicates a greater deviation from the optimal solution, meaning the SH method is less effective and results in a compromise on the objective value.

Similarly, a higher optimality gap signifies a larger deviation from the optimal solution, implying a greater trade-off in solution quality for the computational efficiency achieved with the shrinking horizon method.

The results demonstrate that the solving times for the shrinking horizon method are consistently lower, and in some cases, significantly lower, for the KOW and Tight models across most case studies (Figure 2). This indicates that these models are more effective under the shrinking horizon method compared to other models. As

**Figure 2.** Casewise analysis of models

a result, they emerge as the preferred formulations for achieving the best speedups.

Additionally, these models maintain near-optimal performance, with minimal compromise on the objective value. For example, the maximum median deviation in the objective value is approximately 0.25% for both the Tight and KOW models for all other cases except case6468rte where the median deviation is 4.18% for Tight model while KOW has 4.26% as the median deviation, demonstrating their ability to balance computational efficiency with solution accuracy.

The advantage of these models becomes even more pronounced when applied to large case studies, where their efficiency and reliability provide substantial benefits. This highlights their suitability for scaling to more complex or computationally demanding scenarios.

## CONCLUSION

In this study, we have proposed and validated a novel approach to solving the UC problem by integrating the Tight, KOW, MLR and compact model with a Shrinking Horizon method.

Our analysis of 20 random instances for each case

study further confirmed the Tight and KOW model's stability and computational efficiency, particularly excelling in larger systems like CASE6468RTE. These results demonstrate that the Tight and KOW model with the Shrinking Horizon method are effective strategies for efficiently solving large-scale UCPs while ensuring computational speedups while not losing much on the solution quality.

Future research should explore this approach's scalability in more complex grid scenarios involving renewable energy sources, storage systems, and uncertainties. Additionally, investigating alternative decomposition techniques could further enhance its performance and applicability.

## ABSTRACT

A key technology for integrating fluctuating renewable energy into the process industry is the production of green hydrogen through water electrolysis plants. Scaling up electrolysis plant capacity remains a significant challenge for the renewable energy transition. System simulation of large-scale electrolysis plants can support process design, monitoring, optimization, and maintenance scheduling. Hybrid modeling methods are promising for improving simulation reliability by combining process knowledge with process data, addressing gaps in understanding of the underlying processes. These hybrid, semi-parametric models have shown improved accuracy than purely mechanistic models. This study develops a hybrid, semi-parametric model for an anion exchange membrane electrolysis (AEMEL) stack unit. Parameters such as heat loss and heat transfer, which cannot be directly measured, are estimated using real process data. Sensors provide data on lye tank temperature, outlet temperature, and flow rate, enabling estimation of heat transfer coefficients and losses. The hybrid model is validated against operational data from different load settings of the AEMEL stack unit. To test its scalability, a large-scale electrolysis plant configuration is simulated, comprising multiple AEMEL stack units, a water supply module. Performance accuracy and efficiency of the hybrid model are compared with the mechanistic model. This hybrid model lays the foundation for future use in efficient system simulations with surrogate models, potentially enhancing large-scale electrolysis plant performance and renewable energy integration.

**Keywords**: Hydrogen, Modelling and Simulations, System Simulation, Hybrid Modeling, Modular Plants

## INTRODUCTION & BACKGROUND

A crucial technology for integrating variable renewable energy into the process industry is the production of green hydrogen through water electrolysis. Scaling-up electrolysis plant capacity remains a significant challenge in facilitating a successful transition to renewable energy. One potential pathway to successfully scale-up the hydrogen production is the numbering-up of electrolyzer systems using modular plant concepts, according to VDI 2776 [1]. This approach allows for the combination of different electrolysis technologies and electrolyzer scales within one process plant a so-called modular, heterogeneous electrolysis to achieve higher flexibility of start-up, shut-down and operation [2].

With this, the system simulation of these large-scale electrolysis plants can be utilized for process design but also for process monitoring and optimization, and maintenance scheduling [3]. Since the underlying processes for the simulation models are often not completely understood, hybrid modeling methods are a promising approach to combine process knowledge with process data for more reliable and precise simulation models [4]. These hybrid, semi-parametric models

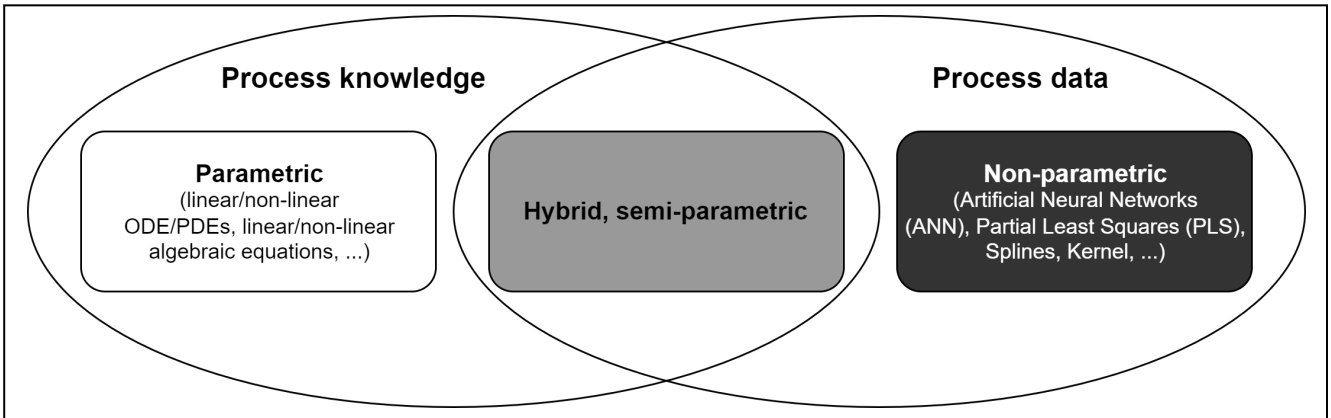

**Figure 1.** Taxonomy of hybrid, semi-parametric models.

achieved better accuracy and prediction quality than knowledge-driven mechanistic models.

In this work a hybrid, semi-parametric model for an anion exchange membrane electrolysis (AEMEL) stack unit is developed. The basis of this model is a mechanistic model of the AEMEL stack unit [5]. To evaluate the applicability of the hybrid, semi-parametric AEMEL model within a large-scale system simulation context, an electrolysis plant configuration is designed including multiple AEMEL stack modules, a water supply module and post-processing steps for the produced hydrogen. This plant configuration is then simulated using both the hybrid, semi-parametric and mechanistic AEMEL models to compare performance accuracy and simulation efficiency of both model types. In future work, this hybrid, semi-parametric model could be the basis for creating more efficient system simulations utilizing surrogate models.

## METHODOLOGY

### Modeling for flexible, heterogenous water electrolysis plants

Simulation models of entire process chains can be used to evaluate plant structures and provide virtual testing capabilities of developed automation and control concepts [6,7]. With the scale-up of water electrolysis plants following modular standards [2], the modeling approach must also follow this approach [3,8].

In the research project eModule this modular, flexible modeling approach is followed to investigate the applicability and operability of these modular heterogenous water electrolysis plants. The project aims to develop open-source model repositories. Dynamic stack unit models were designed for low-temperature electrolysis technologies, namely alkaline electrolysis (AEL), proton exchange membrane electrolysis (PEMEL), as well as anion exchange membrane electrolysis (AEMEL) [5]. Further dynamic models for the balance of plant (BoP) components like e.g., lye circulation and water supply were designed [3,8]. Additionally, a dynamic partial model for solid-oxide high-temperature electrolysis (SOEL/HTEL) was developed as a black-box model [9]. Details on the developed models can be found in [5] and the linked Github repository in the supplementary material.

To ensure accurate estimation and system simulation, process data is used to refine and validate the simulation models resulting in more accurate hybrid, semi-parametric simulation models as compared to the currently existing mechanistic models.

### Hybrid, semi-parametric modeling

Mechanistic models form a broad and transparent class, typically based on fundamental principles such as conservation laws [4]. In contrast, data-driven models rely solely on process data, offering a less transparent modeling approach [10].

Hybrid semi-parametric models, also known as gray-box models, integrate parametric and non-parametric sub-models derived from different knowledge sources. These models offer several advantages over traditional mechanistic or purely data-driven approaches [11]. An overview of hybrid semi-parametric simulation models is presented in Figure 1. Key benefits include a broader knowledge base, greater transparency in modeling, and cost-effective development [10]. In complex process simulations, hybrid approaches provide more accurate and robust estimations [11,12]. Gray-box models leverage existing process data through machine learning (ML) or artificial intelligence (AI) algorithms, effectively bridging gaps in mechanistic modeling [10].

## CASE STUDY

The presented case study covers the applicability and performance evaluation of gray-box models e.g., hybrid, semi-parametric simulations models, within system simulations of large-scale, modular water electrolysis plants.

## Anion Exchange Membrane Electrolysis

The Anion Exchange Membrane Electrolysis (AEMEL) is a low-temperature technology that combines advantages of PEMEL and AEL: operational flexibility (PEMEL) and low investment and operational costs (AEL) [13]. Currently, three AEMEL stack units, combined into one AEMEL module, exist as a demonstrator within the module pool of the Process-to-Order (P2O) Lab Learning Factory at TU Dresden.

The base level model for the hybrid, semi-parametric AEMEL stack model is a mechanistic AEMEL stack model developed in MATLAB/Simulink, modeled according to generic modular modeling principles [5]. Dimensionality is neglected for the base model since high computational power is required for 1D – 3D models and does not align with the goal of modular system design and automation. Therefore, the model is constructed as a lumped parameter (0D) model. To develop a lumped simulation model of the electrolyzer stacks, each cell side—anode and cathode—is represented as an ideal continuously stirred tank reactor (CSTR), with the separator or membrane serving as a shared interface.

To ensure a generic stack-unit model, first-principles models are prioritized, with the option to extend them using customizable empirical equations [5]. Several submodels, namely the mass accumulation/transfer, thermal, fluidic, electrochemical, and electric models, are each considered. Equations (1) – (6) show the generic mass accumulation/transfer submodel and the generic energy accumulation and thermal submodel as they are the most relevant for the hybrid, semi-parametric modeling part in the next section. Further model equations and assumptions can be found in [5].

The mass accumulation is modeled as dynamic component mass balances for each component $i$ in each cell side $j$, according to (1):

$$\frac{dm_i^j}{dt} = \dot{m}_{in}^j \omega_{in,i} - \dot{m}_{out}^j \omega_i^j + \dot{m}_{R,i}^j \pm \dot{m}_{cross,i} \quad (1)$$

with $\dot{m}_{in}^j$ as the inlet mass flow in each cell side, $\omega_{in,i}$ as the inlet mass fraction of each component, $\dot{m}_{out}^j$ out as the outlet mass flow in each cell side, $\omega_i^j$ as the mass fraction of each component in each cell side, $\dot{m}_{R,i}^j$ as the reaction rate (cf. equation 2) of each component in each cell side and $\dot{m}_{cross,i}$ as the crossover flow through the common interface.

The thermal model determines the temperature within the stack unit, which is crucial for calculating thermo-physical substance properties and cell voltage. Cell temperatures are computed using dynamic energy balances for each cell side, as described in equation (2):

$$\frac{dE^j}{dt} = \dot{m}_{in}^j e_{in} - \dot{m}_{out}^j e^j \pm \dot{m}_{cross} e^j + \dot{Q}_{loss} - \dot{Q}_{amb} - \dot{Q}_{hx} \quad (2)$$

with $\dot{Q}_{loss}$ as the heat generated due to current losses in the reaction, $\dot{Q}_{amb}$ as the heat exchanged with the surrounding environment and $\dot{Q}_{hx}$ as heat exchanged between the cell sides due to temperature difference.

$$\dot{Q}_{loss} = i\, A_{act}(U_{cell} - U_{tn}) \quad (3)$$

$U_{cell}$ is the voltage of the electrolytic cell and $U_{tn}$ the thermoneutral voltage of the water electrolysis reaction described by equation (4) with $\Delta H$ as the reaction enthalpy at operating conditions.

$$U_{tn} = \frac{\Delta H}{n\, F} \quad (4)$$

The heat exchange $\dot{Q}_{amb}$ with the environment is calculated for both cell sides according to (5) [14]:

$$\dot{Q}_{amb} = k_{amb} A_{amb}(T^j - T_{amb}) \quad (5)$$

with $k_{amb}$ as the heat transfer coefficient from the stack unit to the environment, $A_{amb}$ as half the surface area of the stack, due to the heat loss occurring in both cell sides, and $T_{amb}$ as the assumed constant ambient temperature. Similarly, the internal heat exchange between the cell sides is modeled according to (6):

$$\dot{Q}_{hx} = k_{hx} A_{hx}(T^{an} - T^{cat}) \quad (6)$$

with $k_{hx}$ as the heat transfer coefficient between the cell sides, $A_{hx}$ as the heat exchange area inside the stack unit and $T^{an/cat}$ as the respective temperatures inside the anode and cathode channel. The coefficients for $k_{amb}$ and $k_{hx}$ can be determined based on the prevailing flow regime and cell structure, derived empirically for specific stack units, or assumed constant [15]. In case of this generic modeling approach, constant values are assumed.

To enhance flexibility and reusability, the model interfaces are designed to be compatible with advanced mass and energy balance frameworks commonly used in flowsheeting tools. Additionally, the developed models are exported as Functional Mock-Up Units (FMUs), allowing for platform-independent model exchange [5].

## Hybrid AEM Model

The model parameters for the current mechanistic AEMEL model are based on literature estimations [16-18] and do not fully represent the existing lab setup (cf. [5]). The AEMEL was purchased as a pre-configured stack unit by Enapter. It offers a limited number of sensors for process data collection and cannot be retrofitted.

The heat loss within stack, pump, heat exchanger and piping cannot directly be measured and therefore must be approximated through non-parametric estimation from process data. In addition to hydrogen output $\dot{m}_{H_2,out}$, available sensors collect data for the temperature in the lye storage tank $T_{tank}$, the outlet temperature of the stack-unit $T_{out,1}$ and the flow rate into the stack $\dot{m}_{lye,out}$. Using the available data and the mechanistic stack

model, the heat loss $\dot{Q}_{amb}$ to the environment defined by $k_{amb}$ can be estimated.

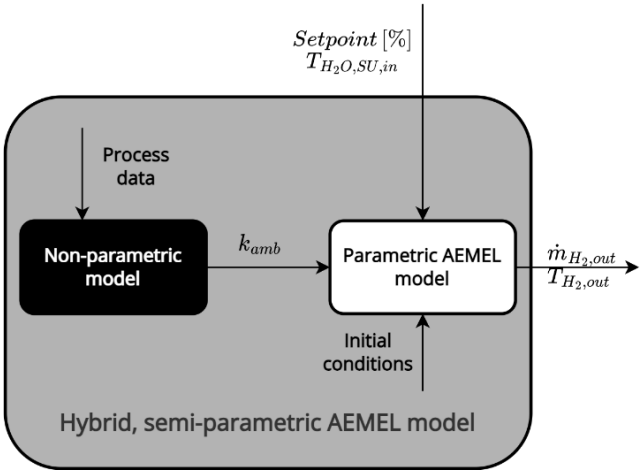

**Figure 2.** Structure overview of the hybrid, semi-parametric AEMEL stack unit model.

The hybrid, semi-parametric model was developed in MATLAB/Simulink as a light gray-box model. The model structure is shown in Figure 2. Currently, the data utilized for the non-parametric estimation within the hybrid model is synthetic process data. The load setpoint of the stack unit and the inlet water temperature $T_{H_2O,SU,in}$ were identified as the control parameters for the AEMEL. To emulate the behavior or real process data collected from the plant, random noise was added to the generated synthetic data from the simulation. The random noise is related to the maximum value of each batch run and simulation output. The Design of Experiments for the data generation is shown in Table 1.

**Table 1:** Design of Experiments (DoE) for the control parameters for synthetic data generation.

| **Control Parameter** | *Load Setpoint* [%] | | | $T_{H_2O,SU,in}$ [°C] | | |
|---|---|---|---|---|---|---|
| **Value** | 33 | 66 | 100 | 5 | 25 | 45 |

## Setup of the System Simulation

The goal of the generic modeling approach for flexible, heterogenous water electrolysis plants is to aid scale-up design and the optimization of plant operation to accommodate price-driven hydrogen production utilizing fluctuating, renewable energy [3]. Therefore, the developed simulation models are tested for their applicability and performance in medium- and large-scale system simulations. The performance of the hybrid, semi-parametric model within the system simulation is compared to the performance of the mechanistic model.

The configuration of the evaluated system simulation is shown in Figure 3. The simulation represents a medium-scale, homogenous electrolysis system which includes 18 AEMEL Stack Units, one Water Supply Unit and Distribution and Mixing Units for the material streams. For the AEMEL, three stack units are aggregated into one module unit, which reflects the laboratory setup for the M16 module in the P2O Lab Learning Factory. The nominal system size is 43.2 kW.

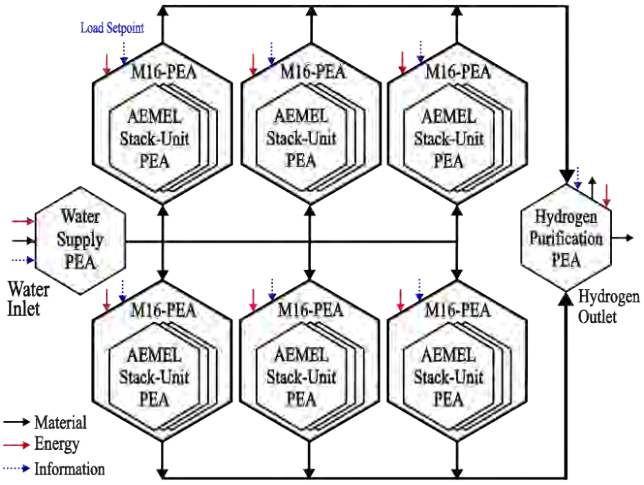

**Figure 3.** Modular plant layout for the presented system simulation with AEMEL.

The system simulation is set up in MATLAB/Simulink as a co-simulation environment shown in Figure 3. To evaluate the applicability of the hybrid, semi-parametric AEMEL model, a load input scenario into the system covering one day of solar power production was selected. The simulation scenario represents the load input for one day of solar power into the electrolysis plant with the input in 5-minute time-steps. The specifications for the simulation scenario can be found in [19]. The simulated system follows the requested load changes of the solar power input profile to emulate real price-driven plant operation.

## Performance Evaluation & Discussion

The performance of the hybrid, semi-parametric AEMEL stack unit model was compared to the previously developed mechanistic AEMEL stack unit model within a system simulation. A comparison of the simulation results for the solar power scenario is shown in Figure 4.

The results show that both the mechanistic and the gray-box system simulation are able to follow the flexible solar power profile with the hydrogen production rate $\dot{m}_{H_2O,plant}$. As shown in Figure 4 (right), the behavior of the hybrid model differs significantly in the temperature profile. The non-parametrically estimated value for $k_{amb}$

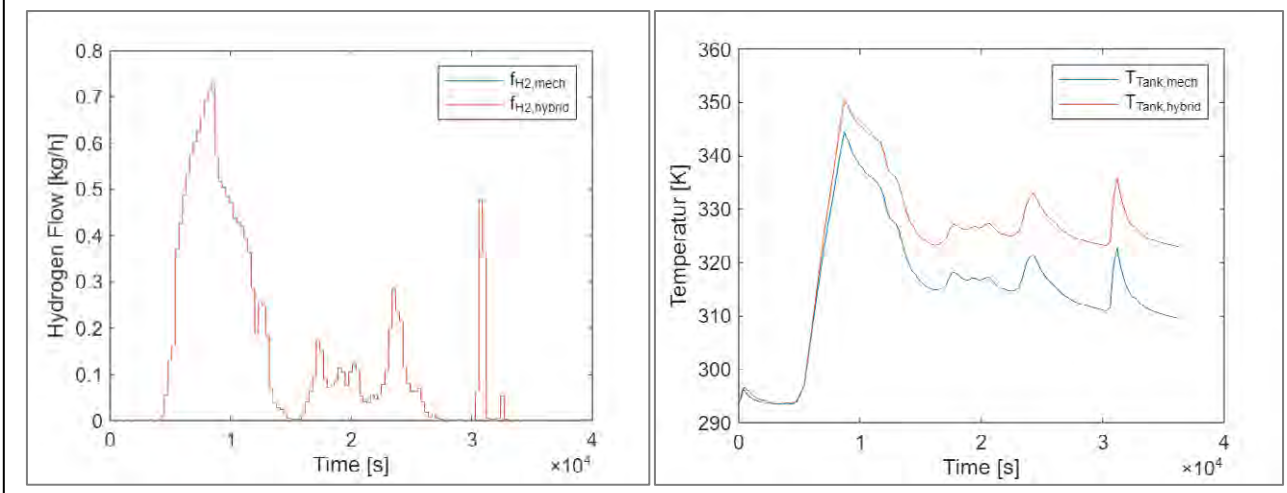

**Figure 4.** Comparison of simulation results for the system simulation: overall hydrogen production rate (left) and stack outlet temperature (right).

is lower than the originally defined value within the mechanistic model. Therefore, the overall heat loss from the system to the environment was overestimated and model reaches a higher temperature in the stack.

Due to the utilization of the synthetic process data for model development, the behavior of the hybrid, semi-parametric AEMEL model resembles the very detailed mechanistic model closely. This problem be amended once real process data can be collected from the demonstrator plant. One approach to leveraging this would be the utilization of more complex physics-informed neural networks (PINNs) [20].

Conceptually, gray-box models, not just hybrid, semi-parametric models, can be utilized in different real-time plant operation scenarios. Especially, in flexible, modular electrolysis plants, which are designed to follow fluctuating power input profiles [7,21], hybrid model structures that utilize online process data allow faster adaption to partial load production and more accurate forecasting of ramp-up and ramp-down cycles.

## CONCLUSION AND OUTLOOK

The presented case study verified the applicability of hybrid models within system simulation of modular water electrolysis systems. Currently, the significance and impact value of the developed hybrid, semi-parametric AEMEL model is limited as the model was developed using only synthetic process data. This represents the first step in the refinement of the generic simulation models for the modular water electrolysis concept. This paper builds the foundation for the concept development of a hybrid, semi-parametric simulation model pool as an addition to the already existing model pool.

A next step in the system simulation for electrolysis scale-up could be the development of faster and less computationally intensive surrogate models from the more accurate hybrid, semi-parametric simulation models. The surrogate models can further be utilized to setup more sophisticated Digital Twins to be used for real-time monitoring and optimization during plant operation.

## DIGITAL SUPPLEMENTARY MATERIAL

The P2O-Lab Learning Factory provides a Github group repository which contains the individual model repositories of the developed simulation models for the generic modular electrolysis plant. It is currently only available upon individual request at https://github.com/orgs/p2o-lab/teams/ap2_external/repositories. The repository includes the mechanistic and hybrid AEMEL stack unit models which are evaluated in this paper. It also provides the models for the balance of plant components and the other electrolysis technologies. The repositories will be openly accessible starting from October 2025.

## ACKNOWLEDGEMENTS

We would like to thank the German Federal Ministry of Education and Research and the project management organization Jülich for their financial support within the framework of the eModule research project (FKZ 03HY116A) of the H2Giga lead platform.

# Energy system modelling for studying flexibility on industrial sites

**Jon Vegard Venås[a]*, Lucas Ferreira Bernardino[a], Kasper Emil Thorvaldsen[a], Sigrid Aunsmo[a], Sigmund Eggen Holm[a], Halvor Aarnes Krog[a], Ove Wolfgang[a], and Ingeborg Treu Røe[a]**

## ABSTRACT

With an increasing share of non-dispatchable renewable energy sources in the European grid, energy flexibility will be key for the industrial sector to support the green transition. The EU-project Flex4Fact aims at finding solutions for energy and process flexibility for industry, using SINTEF's open-source energy system model EnergyModelsX to quantify the potential benefits. This work presents some extensions done in EnergyModelsX, denoted as EnergyModelsFlex, to accommodate energy and industrial flexibility, adding new functionalities to assist with industrial flexibility potential. The extended EnergyModelsX model is described and demonstrated through two case studies in the plastic and polymeric products manufacturing sector to evaluate their potential for increasing renewable generation and flexibility. The first use case, being energy intensive, consumes both natural gas and electricity. This site enables the use of heat recovery and utilization, hydrogen blending, on-site hydrogen production, which can reduce CO2 emissions. The second use case relies solely on electricity consumption, and the considered flexibility is energy shifting by electric batteries and production flexibility. The focus of this case study is on the interplay between energy storage, on-site energy production and process flexibility to increase the degree of self-produced renewable energy in the energy mix. Together, the two case studies demonstrate how the extended EnergyModelsX framework can be used to explore process and energy flexibility in the industry to aid the transition from a fossil-based society to a renewable based society.

**Keywords**: Industrial demand-side flexibility, Energy transition

## INTRODUCTION

To meet the ambitious net zero target of the EU by 2050, it is a top priority to transition from fossil fuels to renewable sources [1]. However, unlike traditional fossil fuel power plants, which can adjust output to match demand, non-dispatchable renewable sources like solar and wind are subject to natural variability and cannot be controlled to meet immediate demands. This is a challenge in the industrial sector where consistent and predictable energy usage is crucial. The EU project Flex4Fact aims to develop solutions to leverage energy and process flexibility in industry to meet a future with high renewable energy penetration [2].

A part of this project seeks to identify optimal investment strategies for enhancing energy flexibility, i.e. the capability of an industry to adapt to variable energy production. The investment strategies arise from energy system modelling, where the key is to understand how different technologies, such as solar power and electric batteries (BESS), complement the industrial site and potential process flexibility. To enable these assessments, SINTEF's open-source energy system model, EnergyModelsX (EMX) [3] has been used and further developed to specifically address flexibility requirements at industrial sites. The considered flexible aspects modelled through Flex4Fact include process flexibility modelled as energy load shifting, allowing multiple energy carriers to cover the demand of single processes, and energy storage technologies. Synergies between these mentioned flexibilities and integrated on-site renewable expansions are focused upon within this work. Sensitivity analyses are conducted to assess the robustness of the investment strategies towards changes in market prices or

scaled production, to capture optimal use of flexibility and investment decisions to the energy system.

This work is structured as follows. We first describe EMX alongside the new flexible functionalities towards industrial flexibility, then present two use cases that is related to the Flex4Fact projects alongside their implementations. Finally, we demonstrate the results regarding the new functionalities on the use cases.

## ENERGY SYSTEM MODELLING

There exist multiple other toolboxes that represent the energy system, but some are more focused on large scale energy systems with details on regional constraints like TIMES [4]. As described in [3], an advantage with EMX compared to other models for the representation and optimization of energy systems at specific sites, such as SpineOpt [5], GenX [6], and the Tulipa Energy Model [7], is the modular structure - by splitting the full model framework into separate, installable packages - with the high focus on extensibility and alternative technology formulations.

### EnergyModelsX

EnergyModelsX (EMX) is an open-source energy system modelling toolbox developed by SINTEF [3]. The toolbox is written in the Julia programming language using the JuMP modelling framework, enabling a fast and modular framework for multiple dispatch models. Emphasis is made on giving modelers a high level of flexibility. Detailed description of the model and its use can be found in [8]. The following will give an overview of the features of EMX relevant for the assessments performed in the presented work.

EMX mirrors real energy systems through generic representations of different technologies. These representations are defined in EnergyModelsBase, and include sink, source, generation and storage technologies, and links between the different technologies. Generic representations can be assigned features specific to the energy system in question such that specifications of that energy system are captured. A source can for instance be assigned emission features to mimic a natural gas source. The technologies are referred to as nodes. Three different fundamental nodes exist; source, sink and network nodes. Interactions between nodes are defined by creating links between them. Source and sink nodes can only give or receive input from the surroundings (i.e. is only linked one way) while network nodes can have two-way interactions.

While links between any nodes can be defined, modelling ease and flexibility are best achieved by defining an Availability node. The Availability node does not have any features assigned to itself but acts as a collector of all links as illustrated as the “av”-node in Figure 1. That way, new nodes can be defined in the framework without changing all the links between the existing nodes.

The modularity of the EMX framework is achieved by Julia’s multiple dispatch functionality when extending the EnergyModelsBase package. Several such extensions have been implemented to ease geographical representation (EnergyModelsGeography) and investments (EnergyModelsInvestments). In the Flex4Fact project a graphical user interface has also been developed for EMX (EnergyModelsGUI). A series of technology specific extensions has also been developed (e.g., for non-dispatchable renewable energy sources like PV power, CO2, Hydrogen and Heat).

Building upon such extensions this work has resulted in a unified extension called EnergyModelsFlex which will be described in the following.

### EnergyModelsFlex

The EnergyModelsFlex extension provides a series of technology node types for EMX enabling energy and process flexibility modeling. The following nodes are described for the present work.

#### StorageEfficiency

The StorageEfficiency node enables storage efficiency control compared to RefStorage. It’s storage resource can be any EMX Resource, and can be used for both the battery technology and the hydrogen storage technology. As for the RefStorage node, investment can be made in both charge/discharge (i.e. the inverter for batteries) and the storage level. Moreover, its generic storage behavior is also inherited from the Base-package but only CyclicStrategic has been considered in the present study. That is, the storage requires cyclic behavior within a strategic period.

### ChargeRateCapacity

The ChargeRateCapacity node is a further development of the StorageEfficiency node where a coupling between the charge rate and capacity has been added. The ChargeRateCapacity node thus mimics a BESS where the charge rate can be limited by the capacity of the battery and ensures that completely decoupled investments into charge rate and battery capacity are avoided. While the node was developed to mimic an electric battery, other types of energy storage, such as thermal storage, is also a enabled.

### PayAsProducedPPA

The PayAsProducedPPA node considers pay-as-produced power purchase agreement (PPA) from off-site solar PV. This non-dispatchable renewable energy source is similar to the node AbstractNonDisRES from the EnergyModelsRenewableProducers extension, but need to dispatch on this type in order to modify the OPEX

constrain to extend to all power produced (including curtailed production).

### LimitedFlexibleInput

The LimitedFlexibleInput node dispatches on the NetworkNode but modifies the flow in constraints by setting upper limits of the input resources. This is needed when hydrogen is to partly replace natural gas but is limited. An upper limit of 20% hydrogen volume (corresponding to a 7.01 % energy fraction) in the H2-NG gas mix is often used as it would not require major alteration in the machinery.

### LoadShifting

The LoadShifting node dispatches on the Sink node where the demand can be altered by load shifting, i.e. the transfer of a predefined quantity of energy (power and duration) from one time to another. This quantity of energy is given as an input to the node, together with the allowed time slots from and to where the load shifting can occur. The load shifting thereby represents a flexible energy demand, but the flexibility is based on (external) constraints rather than a cost benefit or penalty, meaning that the flexibility cannot be optimized from a cost perspective.

## DESCRIPTION OF THE USE CASES

In the Flex4Fact project, a total of five case studies are investigated. We here focus on two that covers much of the goal of investigating both energy and process flexibility. The two use cases are briefly described in the following.

### SPS

Standard Profil Spain (SPS) is a Spanish company specializing in automotive sealing systems for major OEMs (Ford, GM, Renault, etc.). To reduce their carbon footprint, the factory considers onsite renewable energy for hydrogen production via electrolyzers and electricity demands, while gradually replacing natural gas in furnaces with green hydrogen. Hydrogen, process flexibility and BESS storage are also under consideration to maximize energy self-consumption.

Figure 1 illustrates SPS's existing energy system along with potential extensions through investments, as represented in our EMX model implementation. Investment options are marked with dashed lines, and the red text indicates the investments being carried out in the optimization. Energy flows between nodes have a unique colors per energy carrier. The representation of the energy system is based on information provided by SPS to the project and has also been discussed with SPS.

We consider four energy sources: electricity grid, representing electricity purchase under the current contract, PPA, which is an alternative contract for electricity supplied through the grid and produced by PV, on-site PV generation, and natural gas. Four consumption sinks are considered: machinery gas consumption, electricity-specific needs, space heating, and waste heat. Additionally, the model implicitly accounts for curtailed PV and for $CO_2$ emissions.

The energy sources and energy sinks are connected through three node types: energy conversion, energy storage, and energy distribution. However, most of the connections shown in Figure 1 are logical links rather than representing a specific physical distribution system.

The energy conversion nodes are the existing gas oven for space heating, electrolyzers, and heat recovery that convert waste heat into usable space heating. Two heat recovery options are considered: From gas usage in the machinery of the facility, and from the hydrogen production in the electrolyzer. The model also includes two types of energy storage investments: batteries and hydrogen storage. One physical distribution investment is represented: The transport of recycled heat to the space heating site. Finally, there is a conversion node representing the mixing of natural gas and hydrogen to create the energy carrier "gas", which is a blend of natural gas and hydrogen with non-fixed proportions - but with a 20% hydrogen volume cap in the gas mix. For this case study, the dimensioning of each investment option, i.e. MW invested, is a continuous variable with an upper constraint.

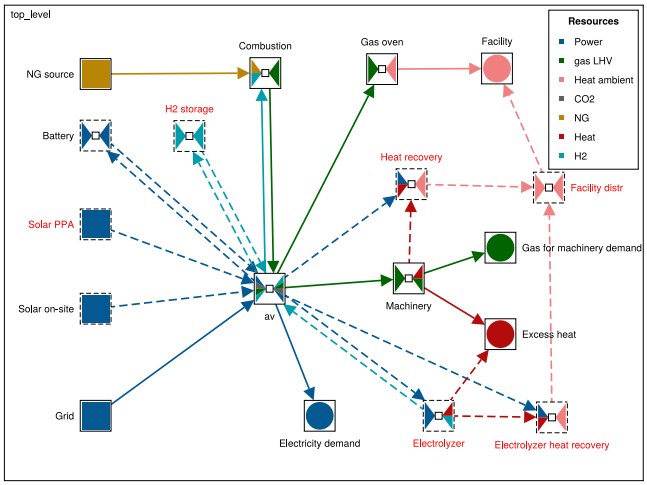

**Figure 1.** Graphical representation of the SPS energy system (current and all investments included) in EMX.

The operation of the energy system is optimized on an hourly basis across the entire year, 8760 sequential hours in total. That annual simulation is conducted for five strategic periods: 2024, 2025 - 2026, 2027 – 2030, 2031 – 2040, and 2041 – 2050. Investments carried out for a strategic period are assumed to be in operation from the start of that strategic period.

## SEAC

SEAC is an Italian producer of diving equipment. The production processes are based on molding, and run solely on electricity, which is therefore the only energy form considered in the energy system analyses. Electricity can be delivered from the power grid or on-site PV panels. The energy demand is divided into process consumption ("Production") and building and factory heating, cooling and lighting ("Base load") as illustrated in Figure 2. In the base case, the Production node is a regular sink. Load shifting-type energy flexibility is enabled by changing the Production node to LoadShifting. Load shifting is constrained to two times per week, with a duration of 8 hours and magnitude of 15 kW. Investment options (PV and BESS) are illustrated with dashed lines in Figure 2. The ChargeRateCapacity node is used to represent the BESS, ensuring that a round-trip efficiency of 0.98 is implemented, and that investments into charge rate follows the investment in charge capacity.

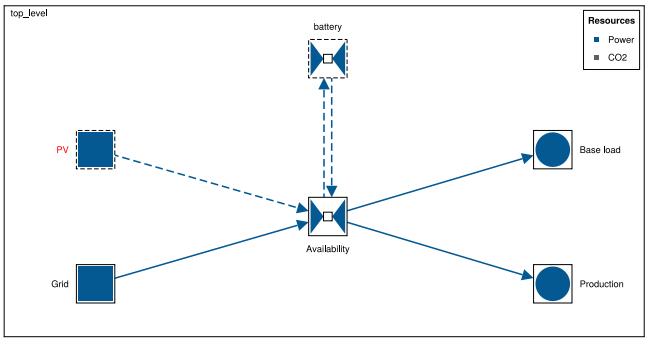

**Figure 2.** Graphical representation of the SEAC energy system (current and all investments included) in EMX.

The operation of the energy system is optimized on an hourly basis across the entire year, 8760 sequential hours in total. That annual simulation is conducted for seven strategic periods: one for each year in the timespan 2024-2030. The CAPEX of the PV and BESS technologies decrease linearly from 1000 €/kWp to 870 €/kWp, and 400 €/kWh to 200 €/kWh, respectively, in the time span 2024 to 2030 [9], [10].

Herein, the SEAC use case illustrates the utilization of load shifting within the EMX framework as a means to enhance renewable energy utilization in industry. Hence the presented results focus on and discuss the load shifting. Other aspects related to the energy system of SEAC, such as which, when and why investments are profitable, will not be discussed although they could be of interest in a different context.

# RESULTS

The following highlights the results from the two use cases that illustrate the features added to the EMX framework throughout the present work. Hence, results related to the energy system of the use cases, but not specifically the added features, are not discussed herein.

## SPS

For SPS the optimal investments are presented in Table 1. The investment in hydrogen is only profitable in the last two periods, where $CO_2$-prices increases significantly (which is not expected to happen before 2030).

**Table 1:** Optimal investments in the base case for SPS.

| Period | Type | Amount |
|---|---|---|
| 2024 | | |
| 2025 - 2026 | PPA contract, solar* | 4778 kWp |
| 2027 - 2030 | | |
| 2031 - 2040 | On-site PV generation | 418 kWp |
| | Electrolyzer | 3 kW |
| | Hydrogen storage | 49 kWh |
| 2041 - 2050 | Electrolyzer | 520 kW |
| | Hydrogen storage | 9790 kWh |

*) Upper constraint for invested amount is binding

For the current analysis we consider a pay-as-produced PPA at 50€/MWh, which is well below the price in the current electricity contract for use of grid electricity. The maximum permitted investment is therefore selected from the start (no investments allowed in 2024). Since this contract is pay-as-produced, and the model does not include a sell back to market option, there is curtailment at the weekends when there is no production in SPS's facility. This can be seen in Figure 3 where 168 hours of data have been extracted from the strategic period of 2025-2026. This thus makes "free" electricity available, but this is not enough to make hydrogen production profitable in that period.

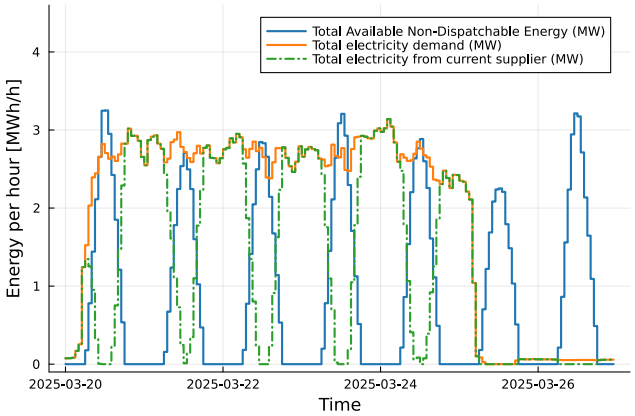

**Figure 3.** Example hours, showing PPA and electricity consumption. The difference is curtailment when PPA is highest and import through grid when electricity consumption is highest.

One of the goals of SPS is to cut $CO_2$ emissions, but with a hard limit of 20% volume of hydrogen in the H2-NG gas mix there is quite limited reduction potential even when the $CO_2$-prices reaches 500€/t$CO_2$eq [11] in the strategic period 2041-2050. This can be illustrated in Figure 3 where the 7.01% energy limit of hydrogen (corresponding to the 20 % volumetric share) is reach with "inf" $CO_2$ prices. The further reduction of $CO_2$ to 11.79% in total is due to investments in excess heat utilization (resulting in lower gas consumption).

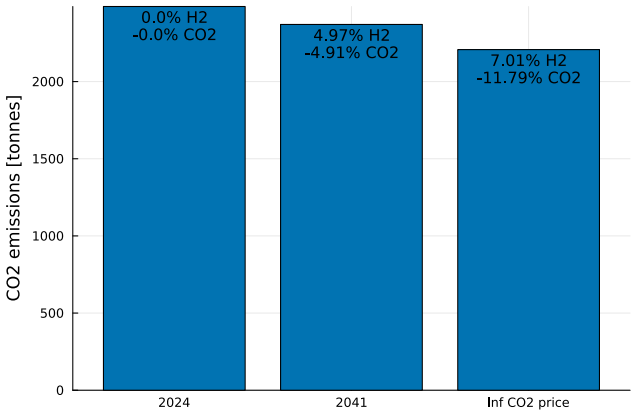

**Figure 4.** Total $CO_2$ emissions annually for the current system (2024), the final period of our analysis (2041-50), and for a case where the $CO_2$ cost is set very high. The share of hydrogen in total gas consumption (natural gas plus hydrogen) and the $CO_2$ reduction relative to the 2024 case is printed on each bar.

## SEAC

In the SEAC use case, energy flexibility modelled through the LoadShifting node is in focus. Figure 5 illustrates the implementation of load shifting, where a quantity of energy ("Energy shifted" in green), corresponding to a production batch in SEAC, may be shifted from of time of the day to another, or even to another day. In the this case, two load shifts are allowed within a working week, and only within the working hours. The figure illustrates that batches are shifted from the afternoon to the morning or midday. This corresponds relatively well with the availability of renewable energy from the PV panels as well as the price of electricity from the power grid.

Table 2 compares the load shifting to product-based rescheduling performed by SEAC. Contrary to the energy-based load shifting, the production-based rescheduling of SEAC accounts for costs, such as man hours, associated with rescheduling of production, and optimizes the production of unique products. One advantage with the production-based rescheduling compared to the load shifting is that production schedules are developed, giving additional information on the operation of the facility. However, complexity increases since detailed information on each product's energy demand and production time is necessary, along with personnel requirements, work hours and salaries. Insignificant differences between the rescheduling and the load shifting in the overall facility performance are found. We notice, however, that the load shifting is sensitive to the input, and that the energy of producing the batch must be predefined. Extensive preprocessing of data may therefore be necessary.

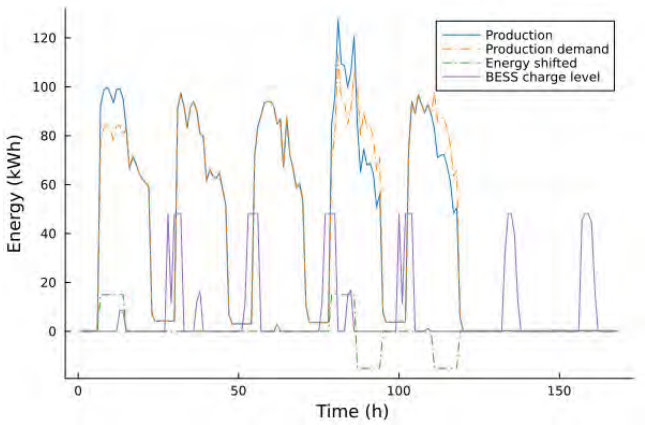

**Figure 5.** Illustration of load shifting over a week in the SEAC use case. The energy shifted (in green dashdotted) represents a production batch. The original production demand (in orange dashdotted) is optimised relative to the energy availability from on-site PV panels and the power grid prices, and results in the production (in blue). The charge of the BESS (in purple) follows the balance between energy availability and demand, and is thus affected by the load shifting.

**Table 2:** Comparison between load shifting and the production-based rescheduling of the production.

| | Cost (€/MWh) | PV consumption (%) | Grid consumption (%) |
|---|---|---|---|
| Base case | 110.4 | 50.2 | 49.8 |
| Production-based rescheduling | 107.7 | 51.7 | 48.3 |
| EMX load shift | 107.7 | 51.5 | 48.3 |

An advantage of EMX's implementation of load shifting is that the impact of flexibility on investments on a longer timescale can be explored. In SEAC, the load shifting was coupled with investments in BESS and PV. Table 3 displays the results for the load shifting-coupled investment model compared to an investment model without the load shifting. Investments in PV and BESS investments increased by 1.7 % and 4.5 %, respectively, with load

shifting compared to without. While the difference between the two models is relatively small due to the limited magnitude of the load shifting in SEAC, the increased BESS investments are interesting. Typically, we expect that the load shifting reduces the investments into BESS systems since the consumption can be shifted according to the availability of the PV power.

**Table 3:** Optimal investments in SEAC in 2030 using energy systems modelling in EMX as set up in Figure 2 with and without load shifting.

| | PV (kWp) | BESS (kWh) | Flexibility (kWh/year) |
|---|---|---|---|
| EMX without load shift | 294.8 | 194.6 | 0 |
| EMX load shift | 299.8 | 203.3 | 12 480 |

The reason for this behavior in SEAC can be that the constraint on the duration and timing of the load shifting inhibits a perfect match between the shifted production and the PV energy generation. Figure 5 illustrates how making use of BESS therefore is necessary to exploit the full potential of the load shifting, and to increase the utilization of the renewable energy from the PV panels.

## CONCLUSIONS

The EnergyModelsX framework provides a high level of flexibility in modelling energy systems. Its primary strength lies in the exploitation of the multiple dispatch feature provided by the Julia programming language. New technologies can be introduced in the model by dispatching on existing implementations resulting in less complex code.

The application of EnergyModelsX to industrial settings has proven to provide the flexibility needed to model the goals of the analysis. The main challenge is to achieve the correct data and the implementation of these into constraints.

The present work has demonstrated that the implementation of load shifting can adequately represent the production flexibility of industrial settings. One of the major advantages with load shifting is the relative incomplexity compared to production-based rescheduling algorithms, which ultimately enable investigations into the impact of process and energy flexibility on a long timescale. In industries where the magnitude of the load shifting is larger than in SEAC, this can have a significant impact. This is, however, given that the load shifting represents the process flexibility of the industry, which may require extensive preprocessing of data and industry information and remains one of the key challenges with the representation of process flexibility through load shifting.

## ABSTRACT

Superstructure based approaches have long been employed for optimal process synthesis problems. Due to the difficulties of using rigorous process models and simultaneous solutions, shortcut calculations have been the preferred means of modeling unit operations within larger process network problems. However, even with the use of shortcut equations to model the behaviour of unit operations, the resulting mixed-integer programs can be challenging to solve. Furthermore, generating the problem superstructure has often been done manually, presenting issues for scaling to larger problems. We demonstrate the use of an algorithmic approach to generate network superstructures for synthesis problems coupled with equation reformulations to yield an MIQCP (Mixed-Integer Quadratically Constrained Program) for networks of thermally coupled distillation columns. The combination of rapid problem generation with the ability to leverage recent advances in the performance of QCP (Quadratically Constrained Program) solvers enables efficient and scalable solutions for these process synthesis applications.

**Keywords**: Optimization, Distillation

## INTRODUCTION

The design of systematic and algorithmic approaches for the synthesis of optimal separation systems is a highly developed research area within process systems [8,9]. While recent research has moved beyond previous heuristic-based approaches, finding global optimum through rigorous models and simultaneous solutions has still remained a difficult task [7].

Process synthesis problems for separation networks face two main challenges: combinatorial complexity and a high degree of nonlinearity. The combinatorial complexity of a separation network synthesis problem results from the need to determine an optimal sequence of separation tasks. As the number of components to be separated increases, the search space of possible separation cuts grows combinatorically, resulting in a large number of binary variables. Furthermore, rigorous modeling of individual separation unit operations is typically done with the MESH equations [5]. The resulting optimization model for the full space formulation of a separation network is a large-scale MINLP that is often intractable using off-the-shelf solvers.

Determining a suitable representation of the process superstructure is the first step in optimization-based process synthesis. State-task networks (STN) provide a formalism to construct the process topology that will define the search space of the optimization problem [12]. For the case of distillation networks, states are defined as mixtures of components and tasks are defined as a separation cuts between components. Figure 1 shows an STN representation for a separation network for a mixture of four components, ordered by decreasing relative volatility. The separation tasks shown do not necessarily have a one-to-one association with actual unit operation equipment.

In many process synthesis problems, the state-task network is generated by hand for the specific use case [2]. Manually writing out a superstructure can be tedious and error-prone. The network size, both the number of nodes and edges, will increase rapidly with the number of components to be separated. Thus, the manual generation of a process superstructure can become prohibitive for problems of even reasonably large size.

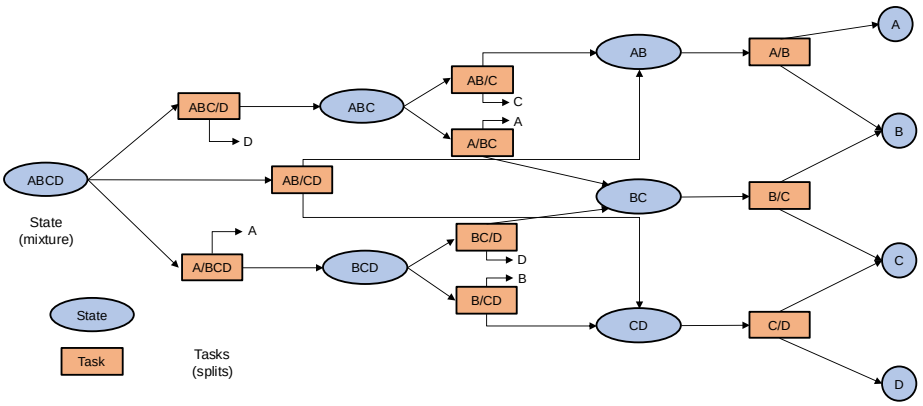

**Figure 1.** A state-task network for the separation of a 4-component mixture into pure components. The mixture components are ordered by decreasing relative volatility. The network uses splits between consecutive key components.

Many separation network synthesis approaches utilize shortcut equations, as opposed to the full set of MESH equations, to model unit operation behavior [9]. The Fenske-Underwood-Gilliland (FUG) equations are some of the most commonly used shortcut equations for modeling multicomponent separations. While the FUG equations are limited in their application based on their modeling assumptions (constant relative volatilities between components, non-azeotropic mixtures, etc.) they can still prove useful in initial system design applications.

Distillation network design places a large emphasis on reducing the utility consumption of a process. Distillation processes are costly to operate due to the high thermal requirements associated with heat exchangers. Thermal coupling of distillation columns can reduce the system operating expense by reducing both the number of heat exchangers needed and the overall heat load on the system [3]. Figure 2 shows an example of thermal coupling in which vapor and liquid streams are exchanged between separation tasks. A single reboiler and condenser provide the heating and cooling for the fully thermally coupled system.

Caballero & Grossmann [4] present a mathematical formulation for the synthesis of thermally coupled columns modeled as a generalized disjunctive program (GDP). Separation tasks are modeled with mass balances and shortcut equations in a set of disjuncts. Heat exchangers, reboiler and condensers associated with a distillation column, are modeled in a separate set of disjuncts. This formulation allows for the selection or absence of heat exchangers. The absence of a heat exchanger between tasks represents a thermal couple, in which separation tasks exchange liquid and vapor flows and the heat duty for a task is provided by a single heat exchanger.

Previous distillation modeling approaches had only used conventional columns, in which each column has an associated reboiler and condenser [1]. The thermally coupled model introduces significantly more complexity in the superstructure of the mathematical program. Solution algorithms not only have to determine the optimal selection of separation tasks, but also the selection of intermediate and final state heat exchangers, that are realized as reboiler and condensers associated with distillation columns. The disjuncts for separation tasks and heat exchangers can be written conceptually as:

$$\begin{bmatrix} Y_t \\ \text{Mass and component balance in each column} \\ \text{Product recovery specification} \\ \text{Shortcut equations (Underwood, Fenske)} \\ \text{Empirical cost and sizing correlations} \end{bmatrix} \vee \begin{bmatrix} \neg Y_t \\ \text{Material flows} = 0 \\ \text{Capital cost} = 0 \end{bmatrix} \quad \forall\, t \in Tasks \tag{1}$$

$$\begin{bmatrix} Z_s \\ \text{Heat duty calculations} \\ \text{Utility costing calculation} \\ \text{Empirical cost and sizing correlations} \end{bmatrix} \vee \begin{bmatrix} \neg Z_s \\ \text{Heat flows} = 0 \\ \text{Capital cost} = 0 \end{bmatrix} \quad \forall\, s \in States \tag{2}$$

The modeling of networks of thermally coupled columns as a GDP allows for a more conceptually understandable problem formulation. Each separation task disjunct can be understood to act as a separation column that is selected or not selected. While the FUG equations are used in this particular formulation, other shortcut equations could be substituted into the disjunctive formulation. Furthermore, Caballero & Grossmann use the Boolean variables associated with the separation task and heat exchanger disjuncts to construct logical relations that enforce the conceptual structure of the problem within the mathematical program. The GDP is

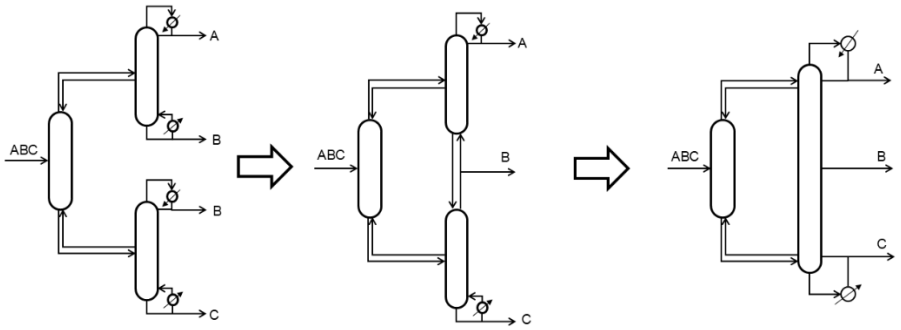

**Figure 2.** Separation of a three-component mixture using varying degrees of thermally coupled columns. The leftmost system uses a prefractionator units with two conventional columns. The right most system represent a fully thermally coupled configuration.

transformed into a mixed-integer nonlinear program and a heuristic decomposition algorithm is used to solve the problem.

In this work, we present a novel superstructure generation algorithm and an MIQCP (Mixed-Integer Quadratically Constrained Program) reformulation of the thermally coupled distillation superstructure optimization model developed by Caballero and Grossmann[4] that shows orders of magnitude improvement in solution times.

## METHODOLOGY

### Superstructure Generation

Generation of process superstructures has often been done manually. For smaller case studies or single problems, a manual approach is not prohibitive. However, for larger synthesis problems generating the superstructure and index sets manually is cumbersome and error prone. An algorithmic approach for automatically generating state-task network superstructures and their corresponding index sets allows for a much faster generation of problems. For the case of state-task networks as the process superstructure we can employ approaches from n-ary tree representations. N-ary trees are a generalization of binary trees that allow parent nodes to have at most *n* child nodes in a tree structure. State-task networks can be generated with recursive n-ary tree approaches using alternating state and task nodes with appropriately specified parent-child relations.

The difficulty that arises in naively applying n-ary data structure approaches to state-task networks is that the STNs are networks, not trees. The STN shown in Figure 1 has multiple parent nodes pointing to the same child node and the layers of the network cannot be easily decomposed into bipartite graphs. A key insight into how to algorithmically generate a problem superstructure is that we do not have to directly generate an STN as depicted in the network graph, shown in Figure 1. Constructing the actual mathematical program does not require a graph structure, only the index sets that arise from the STN.

Our algorithmic approach relies on generating an n-ary tree structure of alternating state and task nodes and then searching through the data structure to build up index sets that define relations between the nodes. Figure 3 shows a tree structure that can be easily constructed for a four-component separation. In the tree data structure, we build two distinct classes of nodes: state nodes and task nodes. State nodes can have an arbitrary number of child nodes, while task nodes are restricted to having exactly two child nodes: a distillate and a bottoms. The data structure is constructed recursively by alternating between these node types until the final state nodes, representing pure components, are produced. Once the tree structure is built, we perform a recursive search through the structure to construct the index sets for the problem, ensuring uniqueness during this search.

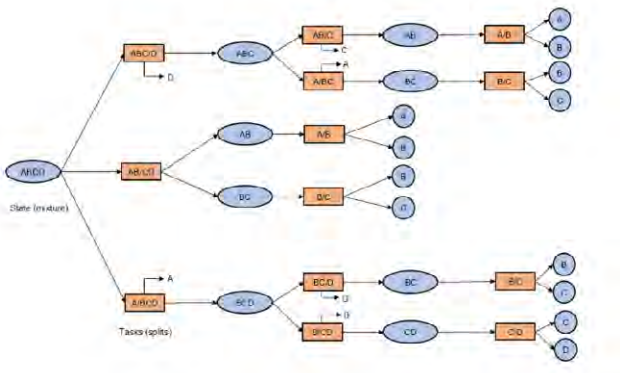

**Figure 3.** Tree representation of superstructure for the separation of a four component mixture. Note that, unlike in the network structre shown in Figure 1, there are duplicate state and task nodes.

For example, the index set for tasks that

can generate a state includes the entry: Tasks_to_statesBC: {A/BC, BC/D}. The process superstructure shown in Figure 1 has only one state node BC. A recursively generated tree, as shown in Figure 3, will have two state nodes BC, with parent task nodes *A/BC* and *BC/D*. In constructing the index sets for the optimization problem we recursively search through the generated tree and return all the tasks that are the parent for a given state node. This approach avoids generating a graph structure that becomes increasingly complex in its connections as the number of components in the system increases.

## MIQCP Reformulation

Using the formulation for thermally coupled columns from Caballero & Grossmann (2004), the separation tasks and heat exchangers for a network of distillation columns are modeled using generalized disjunctive programming. The FUG (Fenske-Underwood-Gilliland) are used to model column behavior. After the transformation of the GDP, commercial solvers can fail to find solutions for the resulting MINLP. In the original work, a heuristic solution approach is used that exploits knowledge about the structure of the problem. Because most of the nonlinearities present in the thermally coupled GDP model are bilinear, we develop a solution methodology that leverages recent advances in MIQCP solver performance to find globally optimal solutions.

Each separation task in the thermally coupled model is represented as a pair of disjunctive relations, as shown below. The left side disjunct is for an active separation task, *t*, and the right side disjunct is for an inactive separation task, in which associated variables are set to zero. The total molar flow mass balances, component summations, and recovery specifications are linear equations in terms of the decision variables of the problem. The Underwood equations are used to model internal vapor flows of each separation task and are the only modeling equations that have general nonlinear terms [11]. When a Big-M transformation is applied to the separation task disjuncts the Underwood equations yield general nonlinear terms in the MINLP.

Eqn. (3) shows one of the Underwood equations, in which $F_{i,t}$, $V_{r,t}$ and $V_{s,t}$ are molar flow rates. The relative volatility of a component *i*, $\alpha_i$, is assumed to be constant, and is thus a parameter. The other decision variable present in the equations is the Underwood root, $\phi_{r,t}$. By introducing an intermediate variable, $Z_{i,r,t}$, in Eqn. (4), we can reformulate the shortcut equations into two constraints, Eqns. (5) and (6) that are bilinear.

$$\sum_{i \in Components} \frac{\alpha_i F_{i,t}}{\alpha_i - \phi_{r,t}} - \left(V_{r,t} - V_{s,t}\right) = 0 \qquad (3)$$

$$z_{i,r,t} = \frac{1}{\alpha_i - \phi_{r,t}} \qquad (4)$$

$$z_{i,r,t}\left(\alpha_i - \phi_{r,t}\right) = 1 \qquad (5)$$

$$\sum_{i \in Components} \alpha_i F_{i,t}\, z_{i,r,t} - \left(V_{r,t} - V_{s,t}\right) = 0 \qquad (6)$$

After reformulating the shortcut equations, Big-M transformation of the GDP will yield a non-convex MIQCP. The transformation from a MINLP to a MIQCP is useful

Mass Balance

because of recent advancements in solver performance for MIQCPs. While solving large-scale MINLPs still remains a challenge, Gurobi has seen a 450 times speedup in solving large-scale non-convex MIQCPs between versions 8 and 11 [6]. Note that this reformulation of the shortcut equations is exact, i.e. solving the MIQCP with a global solver will yield a solution to the original MINLP formulation.

## RESULTS

To demonstrate the computational advantages of the problem reformulation we use an example problem for the separation of a mixture of linear hydrocarbons. The model for thermally coupled columns is formulated as a MINLP and a MIQCP. Computational times are shown in Table 1 for an increasing number of components in the feed mixture. The superstructure of each problem instance was generating using the approach described in the Methodology section. We solve the MINLP with BARON and solve the MIQCP with both BARON [10] and Gurobi [6]. We achieve optimal results for increasingly large instances of the MIQCP in short run times. In solving the MINLP, BARON is able to find an incumbent solution, but after several hours of run time fails to make progress at reducing the gap.

The computational results demonstrate that the MIQCP reformulation significantly improves performance, especially for larger problem instances where conventional MINLP approaches struggle. Notably, all problem instances were constructed using automated superstructure generation methods, making the time required to build each instance negligible.

We also present the solution of a case study problem for the separation of a mixture of hydrocarbons. Table 2 shows the system feed specifications and desired recoveries. The problem is built using the automated superstructure approach as an MIQCP and solved with Gurobi. Figure 4 shows an illustration of the separation network that results from the solution. The system includes thermal coupling between some, but not all tasks, and can have the final separation tasks B/C and C/D integrated into the same column shell.

**Table 2.** System feed specifications for the separation of a zeotropic mixture of linear hydrocarbons.

| **Feed** ($F_{T0}$) | | 250 [kmol/hr] |
|---|---|---|
| **Desired Recovery** | | 0.98 |
| **Species** | **Molar Fraction in System Feed** | **Relative Volatility** |
| Hexane (A) | 0.1 | 8.9 |
| Heptane (B) | 0.25 | 5.7 |
| Octane (C) | 0.4 | 3.2 |
| Nonane (D) | 0.25 | 1 |

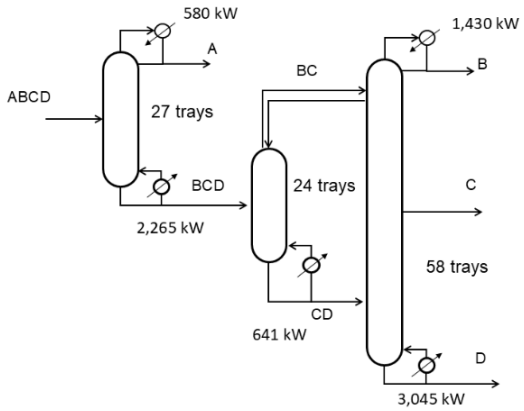

**Figure 4.** Illustration of the solution for the separation of a four component mixture of linear hydrocarbons. The second column, which is thermally coupled with the final column, acts as a prefractionator. The tasks B/C and C/D lack final product heat exchangers for C, so the component is taken off as a side draw.

It is worth noting that there are a variety of reasons for which the exact solution that results from the optimization problem may not be a good one to construct. Specifically, operability and control are some of the largest concerns with complex distillation arrangements. Since thermal couples have to exchange liquid and vapor stream between different separation tasks, maintaining precise control of column pressure is critical. Still, since the problems can be generated and solved quickly the solutions can be used to reduce the

**Table 1.** Computational results for the separation of a mixture of linear hydrocarbons with different formulations of the model for thermally coupled distillation columns.

| Problem Formulation | | MINLP | MIQCP | |
|---|---|---|---|---|
| # of components in feed mixture | # of separation tasks | BARON solve time (secs) | BARON solve time (secs) | Gurobi solve time (sec) |
| 3 | 4 | 171.7 | 899.66 | 0.51 |
| 4 | 10 | 7 hours (no progress) | 7 hours (no progress) | 2.8 |
| 5 | 20 | - | - | 105.96 |
| 6 | 35 | - | - | 1159.67 |

very high dimensional solution space of all column configurations to a few good initial designs as starting points. A modeler could alter the feed conditions or recovery fractions and quickly iterate through different solutions.

The computational speed-up presents an opportunity to solve much larger problems, such as non-sharp separation and divided wall column extensions [13].

## CONCLUSION

Despite decades of research, general process synthesis problems for separations remain challenging to formulate and solve. Traditional optimization approaches have often relied on heuristic algorithms tailored to specific problem instances, which limits their broader applicability and scalability. In this work, we demonstrated how automatic superstructure generation paired with state-of-the-art MIQCP solvers can provide an extensible and robust framework for process design. Our methodology facilitates the rapid design of thermally coupled distillation networks without the need for manual superstructure generation or heuristic decomposition methods. Our approach reduces the complexity of problem formulation and ensures that the solution process scales effectively to larger systems.

The success of this approach in distillation network synthesis highlights its potential to be extended to other process synthesis challenges, such as membrane separation systems. Many other separation systems, such as membrane systems, also involve separating N-pure components and the automated superstructure generation process can be adapted for those systems as well. If governing equations for membrane separations or other separation techniques can be expressed as quadratic constraints, advanced MIQCP solvers could be employed to find optimal solutions. Such extensions hold promise for applications such as a network for critical mineral recovery, where membrane systems are valued for their energy efficiency and selectivity.

## ABSTRACT

Olefins are essential precursors in producing a wide range of chemical products, including plastics, detergents, adhesives, rubber, and food packaging. Ethylene and propylene are the most ubiquitous olefin components and are predominantly produced through steam cracking. However, steam cracking is highly energy- and carbon-intensive, making its decarbonization a priority as the energy sector shifts toward clean, renewable electricity. Electrifying the steam cracking process is a promising pathway to reduce carbon emissions. However, this is challenged by the intrinsic conflict between the continuous operational nature of ethylene plants and the intermittent nature of renewable energy sources (e.g., solar and wind) in modern power systems. Massive energy storage systems or full plant reconfigurations to meet the power demand of electrified crackers are shown to be economically and practically infeasible. Thus, a more viable solution is to pursue a gradual electrification pathway and operate an ethylene plant as a microgrid that adopts diverse energy sources. To optimize the operational strategy of such a microgrid considering uncertainties in renewable energy generation and market prices, in this work, we introduce a stochastic multi-objective optimization approach that minimizes operating costs and carbon emissions of steam cracking. Results from a case study not only elucidate the trade-offs between economic and environmental objectives, but also provide insights into the optimal operating scheme in sustainable ethylene production.

**Keywords**: Steam cracking, Ethylene, Multi-objective Optimization, Renewable and Sustainable Energy, Decarbonization

## INTRODUCTION

The U.S. energy landscape is undergoing a fundamental transition as the proportion of clean, renewable electricity in total U.S. electricity generation will double to 44% between now and 2050 [1]. Thus, electrification is a promising pathway to decarbonize various energy-intensive chemical processes, including the steam cracking process for olefins production. Recently, there have been significant advancements in electrified cracking technology [2]. While conventional cracking furnaces transfer only 40-45% of firing energy to process fluids, electrified furnaces achieve efficiencies of at least 95% [2-4]. Most U.S. ethylene plants are large-scale, continuously operating facilities with capacities exceeding 1 million tons annually. Due to the intermittent nature of variable renewable electricity (VRE), energy storage solutions must be in place. However, the intermittent nature and seasonal variation in VAE generation will lead to a 1~2-order increase in battery storage requirements compared to the storage requirement based on the average daily power supply, making energy storage purely using battery an expensive option [5,6]. On the other hand, the use of byproduct hydrogen ($H_2$) as energy storage substantially reduces battery size. The combined use of solar and wind energy can significantly reduce storage requirements [5]. And low but continuing use of fossil fuels and a gradual transition from conventional crackers to electrified ones are feasible intermediate solutions toward long-term complete decarbonization [7].

In **Figure 1**, we propose a novel process scheme for steam cracking decarbonization that incorporate these important aspects. The envisioned process is a microgrid – a localized electric grid capable of independent

operation. Both electrified and conventional crackers are considered in this superstructure. Diverse energy sources, including on-site VRE, battery storage, electrolyzers, $H_2$ fuel cells as well as conventional natural gas and liquid fuel, can be adopted. Operating the cracking plant as a microgrid offers several advantages, including enhanced resilience, efficiency, and flexibility [8]. For example, a microgrid can operate in grid-connected mode to benefit from low electricity prices or in islanded mode to ensure continuous operation during grid outages or price spikes.

This study builds on our previous work [7] and explores the optimization of microgrid scheduling for clean ethylene production based on the superstructure shown in **Figure 1**. A hypothetical ethylene plant located on the Texas Gulf Coast is used as a case study, with ethane selected as the primary feedstock due to its prevalence in U.S. crackers [1]. A deterministic, steady-state, multi-objective MILP model will be developed to determine the optimal electrification level for our hypothetical plant, and uncertainties in VRE generation and market price predictions will be considered as different scenarios.

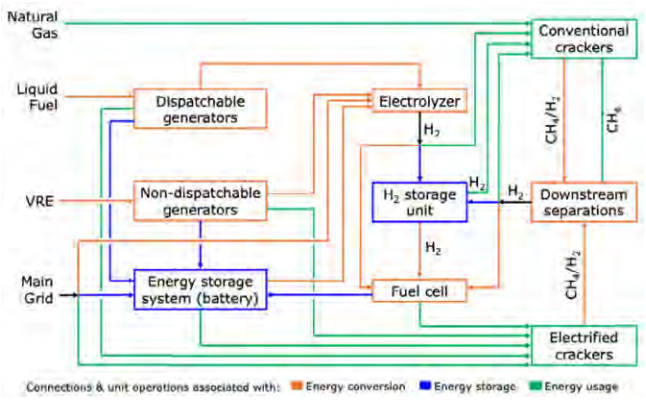

**Figure 1.** Our envisioned framework for using electricity to supply process heat for steam cracking [7]. Based on the context, the connections shown in the superstructure can represent either energy or mass flows.

## MULTI-OBJECTIVE SCENARIO-BASED OPTIMAL SCHEDULING FORMULATION

Before formulating the microgrid scheduling problem, a preliminary calculation [6] demonstrates the importance of incorporating diverse energy sources and energy storage systems for electrified cracking. In the case of a plant with an ethylene production capacity of 1 million tons/year, even if one ignores seasonal variation, since VRE is accessible for only 30% of the day on average, around 70% of the daily energy demand – equivalent to 3,356 MWh – must be stored to ensure uninterrupted operation of electrified crackers. Relying solely on battery would require an excessive amount of battery storage units. For example, if all the electricity is stored using Tesla Megapack, each with 3.9 MWh of energy capacity and 40.7 $m^3$ of storage volume [12], the resulting battery volume would occupy a massive structure of 32.7 m × 32.7 m × 32.7 m. Furthermore, this storage requirement could increase by one to two orders of magnitude due to variations in daily and seasonal weather patterns [5]. These findings highlight the need for a hybrid energy landscape, as illustrated in **Figure 1**, which integrates both dispatchable and non-dispatchable generators. Dispatchable generators, powered by fossil fuel (e.g., diesel) and controlled by microgrid master controllers, are subject to operational constraints such as generation limits, ramping rates, and minimum on/off times [13]. In contrast, non-dispatchable generators are driven solely by the availability and capacity of VRE sources and operate independently. Motivated by these results, we develop a multi-objective scenario-based mixed-integer linear programming (MILP) model to identify the optimal schedule for the microgrid and the optimal degree of electrification for ethane cracking.

### Mathematical Formulation

In this section, we describe MILP model in detail. First, the objective function (1) minimizes the expected daily operating cost, which includes fuel costs ($c^{NG}$), electricity costs from the main grid ($c^G$), local energy generation costs by dispatch units ($c^D$) and fuel cell units ($c^{FC}$), startup ($c^D_{SU}$) and shutdown costs ($c^D_{SD}$), and $H_2$ generation($c^{EL}$) and storage ($c^{HS}$) costs across all scenarios $\omega \in \Omega$. The maximization function in the startup and shutdown costs in the objective function can be easily linearized. Constraint (2) adopts the $\epsilon$-constraint approach for modeling the trade-off between operating costs and environmental impacts by ensuring that the expected total released $CO_2$-equivalent emissions in every hour generated by all cracker units do not exceed a specified level. Note that burning one ton of natural gas in conventional cracker releases approximately 2.95 ($E^{NG}$) tons of $CO_2$-equivalent emissions [14]. Meanwhile, based on current power generation technologies, each MWh of electricity from the power grid is associated with 0.434 ($E^G$) tons of $CO_2$-equivalent emissions [15]. Equations (3) and (4) are energy balance equations with respect to the amount of ethylene produced by conventional crackers (CC) and electrified (EC) ones, respectively. In our previous work [7], we developed a differential-algebraic equation (DAE) numerical model for ethane cracking based on detailed kinetics model [16] and solved the resulting dynamic optimization problem in pyomo.dae [17] to obtain that the minimum energy required to produce one ton of ethylene in a conventional cracker ($P^{CC}$) and electrified cracker ($P^{EC}$) are 4.27 MWh and 1.75 MWh, respectively (due to different thermal efficiencies). The RHS of Equations (3) and (4) uses the lower heating values of natural gas

($LHV^{NG}$) (13.826 MWh/ton) and $H_2$ ($LHV^{H_2}$) (33.320 MWh/ton). Assuming year-round continuous and steady-state operation of CCs and ECs, Equation (5) ensures that the hourly production rate of ethylene ($F^{C_2H_4}$) of all CCs and ECs must be 114.155 ton/h to achieve an annual production target of 1 million tons. After steam cracking, the product stream undergoes a series of downstream processing steps to obtain individual product streams, including $C_2H_4$, $C_3H_6$, $H_2$, and other value-added hydrocarbons. For $CH_4$ produced by ECs and CCs, it will be directly recycled to power the CCs, as shown in Equation (6). For byproduct $H_2$, it can either be stored in $H_2$ storage (HS) units, or be used to power the CCs or produce electricity in fuel cell (FC) units [18], as described in Equation (7). The mole fractions of $CH_4$ ($R^{Mix,CH_4}$) and $H_2$ ($R^{Mix,H_2}$) in the product mixture are 0.469 and 0.531, respectively [7]. Furthermore, we assume $CH_4$ and $H_2$ recovery rates in downstream separation units to be 99.7% ($r^{CH_4}$) and 99% ($r^{H_2}$), respectively [7]. Next, given that the ratio of product flow rates between $H_2$ and $C_2H_4$ ($R^{H_2}$) is 0.149 as determined from the DAE model [7], equations (8-9) indicate that not all $CH_4$ and $H_2$ produced have to be recycled. Equation (10) limits the amount of $H_2$ in a HS unit to its storage capacity ($HSC$) which is 15 tons. Equations (11-12) are hydrogen balances around the HS unit and electrolyzer (EL). The energy balance for the electrolyzer is shown in Equation (13) using the NREL-validated PEM stack efficiency ($\eta^{EL}$) of 73.6% [19] and the theoretical electrolysis energy requirement ($\dot{Q}^{H_2}$) of 40 MWh/ton. Equation (14) indicates the current $H_2$ production capacity ($F_{EL}^{H_2}$) from the electrolyzer (0.6 ton/h). The fuel cell energy balance, generation limit, and power distribution constraints are formulated in Equations (15-17), where we assume a 65% fuel cell efficiency ($\eta^{FC}$) and a power generation capacity ($\bar{P}^{FC}$) of 1 MW. Equations (18-22) show power distribution associated with the local non-dispatchable, dispatchable, energy storage system (both charging and discharging), and main grid. In Equation (23), we set the allowable power withdrawal from the main grid to the microgrid to be at most 50 MW ($\bar{P}^{G}$). Additional constraints related to local dispatchable generation, ramping, up/downtime, energy storage charging/discharging, and power storage are described in [9] and also included in the model [7].

## ILLUSTRATIVE CASE STUDY

In this section, we illustrate the proposed multi-objective scenario-based MILP model in a case study of a hypothetical plant designed with an ethylene production capacity of 1 million tons per year. Each cracking furnace in the U.S. typically can produce 100,000 to 250,000 tons of ethylene per year. Based on this, we assume the plant operates with five ethane crackers, each with a production capacity of 200,000 tons of $C_2H_4$ per year. The microgrid is equipped with 20 natural gas-powered local generators with minimum (resp. maximum) capacity of 1 (resp. 5) MW, a minimum up/downtime of 3 hr, a ramp-up/down rate of 2.5 MW/h, and an operating cost of $33.4/MWh. The battery storage units have a total capacity of 20 MWh with 5 hours of minimum charging/discharging time. The minimum and maximum capacities of charging/discharging power are 0.8 and 4 MW, respectively. Our planning horizon is 24 hours.

**Table 1:** Probability of generated scenarios for LMP, wind power, and PV.

| 5 | 1 | 3 | 5 | 22.19 |

Electricity market prices, along with solar and wind energy generation, are inherently intermittent. To account for these uncertainties in our model, we generate five scenarios for each uncertain parameter using Monte Carlo simulations based on a log-normal distribution, ensuring that no negative parameter values are produced [7]. These scenarios are derived using publicly available data from the Texas grid (ERCOT) for August 2024. For locational marginal pricing (LMP), we select Bus TC-KO arbitrarily as a representative case without loss of generality. **Table 1** summarizes the probabilities of scenarios for each uncertain parameter. Note that the combination of these scenarios results in $5^3 = 125$ possible outcomes. To manage this complexity, we apply a scenario reduction technique to identify 5 representative combinations. This is achieved using a probability distance algorithm based on the Kantorovich distance [9] (see **Table 2**). **Figures 2 through 4** illustrate the mean and average values for electricity market prices, wind power, and solar power across the 5 representative scenarios synthesized.

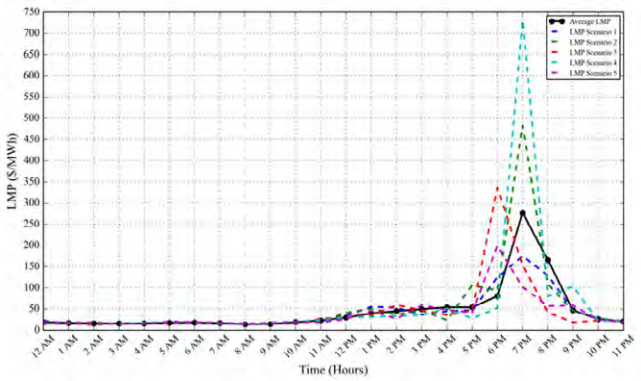

**Figure 2.** The electricity market prices (in $/MWh) of the five scenarios considered.

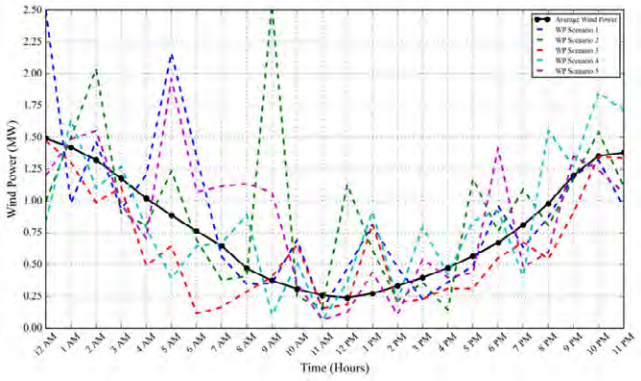

**Figure 3.** The generation output (in MW) of wind turbines of the five scenarios considered.

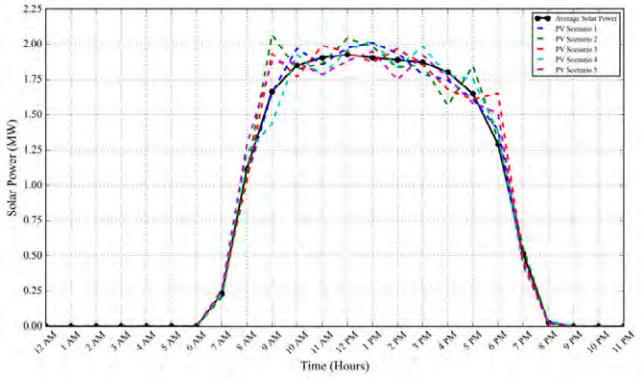

**Figure 4.** The output power (in MW) of solar panels of the five scenarios considered.

First, we solve the problem without incorporating the $\epsilon$ -constraint of Equation (2) to determine the

minimum operating cost and the corresponding degree of electrification (i.e., % of ethylene produced from ECs) required. The minimum expected daily operating cost is calculated to be $11,705.22, with 5.28% of the daily ethylene production coming from electrified crackers. The expected daily $CO_2$-equivalent emissions amounted to 919.42 tons, with the maximum hourly emissions reaching 39.43 tons (the first row in **Table 3**).

Next, we solve the problem for different values of $\epsilon \in [32,39]$ to evaluate the corresponding optimal operating and degree of electrification. It is important to note that the problem becomes infeasible when $\epsilon = 32$, indicating that reducing the hourly $CO_2$-equivalent emissions to less than 33 tons is not feasible with the current technology. The results, summarized in **Table 3**, show that the highest degree of electrification achievable is 19.25%, which corresponds to an operating cost of $33,884.81 – a 189.5% increase compared to the case without the $\epsilon$-constraint (the first row in **Table 3**). On the other hand, the expected daily $CO_2$-equivalent emissions are reduced by 13.86% (almost 130 tons).

**Table 3:** Summary of expected operating costs, degrees of electrification, and $CO_2$-equivalent emissions for different values of $\epsilon$, highlighting the trade-offs between emissions reduction and associated costs.

| # | $\epsilon$ (tons) | Expected $CO_2$-equiv emissions (tons) | Degree of electrification (%) | Expected operating cost ($) |
|---|---|---|---|---|
| 1 | 39 | 918.70 | 5.46 | 11,755.57 |
| 2 | 38 | 910.08 | 7.65 | 12,172.48 |
| 3 | 37 | 887.99 | 12.06 | 14,225.26 |
| 4 | 36 | 863.99 | 14.59 | 17,556.30 |
| 5 | 35 | 840.00 | 16.77 | 21,792.20 |
| 6 | 34 | 815.99 | 18.49 | 27,436.60 |
| 7 | 33 | 792.00 | 19.25 | 33,884.81 |

Here, we discuss some of the key findings and results. First, **Figures 5 and 6** illustrate the Pareto front and the operating cost-degree of the electrification relationship, respectively, providing quantitative insights into the trade-off between the two important measures. Meanwhile, **Figure 7 and 8** illustrate changes in the expected transferred power from the main grid to the microgrid and the charge/discharge status of local energy storage system (batteries). As one would expect, these fluctuations are partly driven by hourly variations in electricity market prices (as shown in **Figure 2**). During peak hours, there will be less power transferred from the main grid to the microgrid, thereby prompting the chemical plant to prioritize local power generation or stored energy to maintain continuous operation. During off-peak hours, the microgrid can rely more on the main grid power to reduce operating costs. Additionally, this figure highlights the environmental considerations affecting grid power usage. As stricter $CO_2$-equivalent emission constraint ($\epsilon$) is enforced, the microgrid reduces its reliance on the main grid and favors cleaner, locally generated energy sources. This is due to the relatively high carbon footprint associated with main grid electricity given the existing energy landscape. Therefore, decarbonization of chemical manufacturing should not be considered in silo. Instead, it must be synergistically coupled with decarbonization in power systems to achieve holistic decarbonization that is economically favorable.

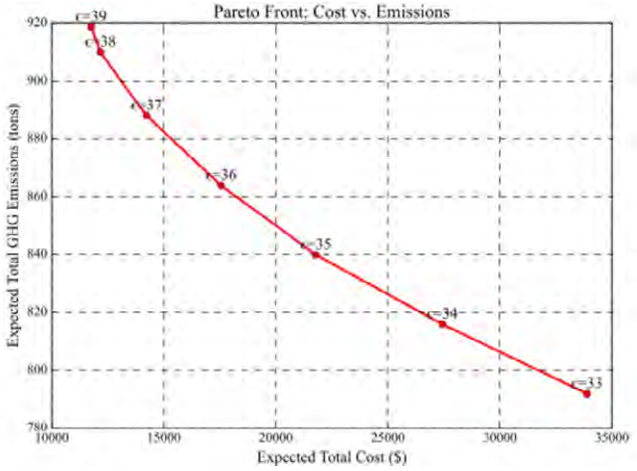

**Figure 5.** Pareto front showing the trade-off between expected daily operating cost and expected daily $CO_2$-equivalent emissions for different values of $\epsilon$. Each point represents an optimal solution for a specific $\epsilon$-value.

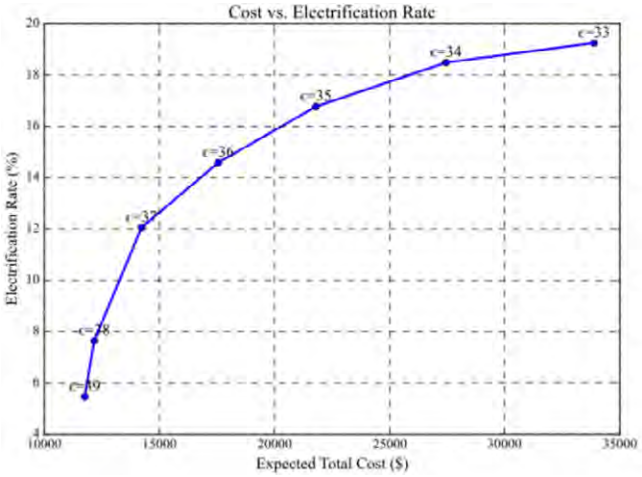

**Figure 6.** A concave relationship between expected operating cost and degree of electrification for different values of $\epsilon$. The plot highlights how the tightness of emission constraint affects of optimal degree of electrification and cost.

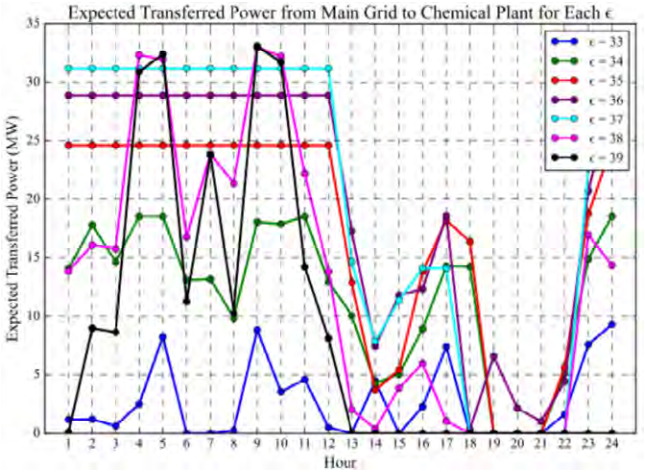

**Figure 7.** Expected transferred power from the main grid to the chemical plant.

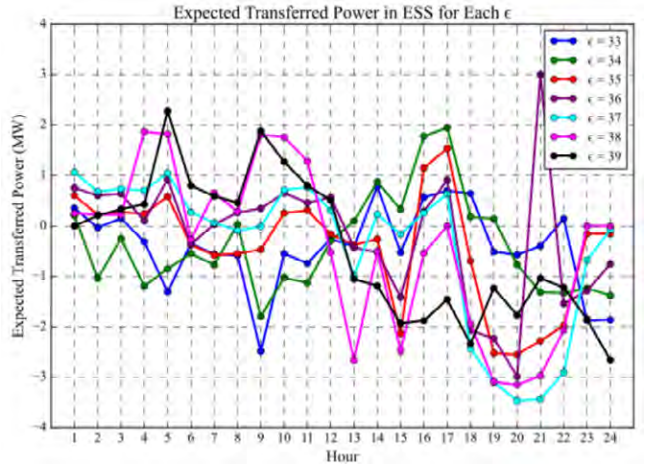

**Figure 8.** Expected charge/discharge power from ESS to ECs.

## CONCLUSION

This work presents an optimization framework for operating the microgrid that integrates electrified and conventional steam crackers along with renewable energy sources and diverse energy sources and storage systems. The proposed multi-objective scenario-based MILP model illustrates the feasibility of reducing CO2-equivalent emissions and the resulting process economics trade-off. The results suggest that, while higher degree of electrification leads to lower emissions, there is a lower limit to which electrification and decarbonization of steam cracking process can reach given 1) the limited capacities of energy storage systems and technology readiness of fuel cells and electrolyzers, and 2) the resulting increase in operating cost. Overall, operating the ethylene plant as a microgrid offers flexibility and resilience as it can better cope with the ongoing industrial decarbonization initiatives and the evolving U.S. energy landscape. Our proposed microgrid superstructure provides a viable solution for energy-intensive steam cracking process to transition toward being sustainable while economically competitive. Looking ahead, further research should explore the integration of emerging energy storage technologies, such as advanced batteries and thermal storage, to enhance the stability of electrified steam cracking. Additionally, policy incentives and carbon pricing mechanisms could play a critical role in making sustainable production pathways more economically viable. Future studies should also investigate the electrification of other key process units, such as distillation systems using heat pumps, and assess the feasibility of fully electrified cracking plant. Addressing these aspects will unlock the full decarbonization potential of clean olefins production while ensuring operational reliability and economic feasibility.

## ABSTRACT

In response to global efforts to reduce carbon emissions, the oil refining sector, a major source of industrial emissions, has set ambitious decarbonization targets. This study analyzes trade-offs between minimizing $CO_2$ emissions and costs through the use of Pareto optimal solutions. A superstructure optimization framework evaluates various technological pathways and timelines, employing a bi-criterion optimization approach using the $\epsilon$-constraint method. Results show that cost-effective, higher-emission solutions often involve natural gas-based technologies with carbon capture, while expensive, low-emission solutions favor electric power-based technologies. The analysis incorporates detailed assumptions about grid carbon intensity of varying degrees and accounts for varying national policies. Comparative case studies across locations highlight how grid carbon profiles influence optimal strategies, providing insights to inform local policies and incentivize technologies.

## INTRODUCTION

With each successive UN Climate Change Conference, the need for decisive climate action becomes increasingly evident. This year, for the first time, Earth is projected to exceed the 1.5°C of warming above pre-industrial levels, emphasizing the need for immediate action [1]. In response, nations worldwide have implemented stricter carbon pricing mechanisms, and set more ambitious net-zero targets to mitigate the accelerating climate crisis. The industrial sector is a major contributor to these global GHG emissions, with the key contributors in the US being oil refining (15%), cement production (7-8%), steel manufacturing (7-9%), and chemical production (4-6%) [2]. In particular, the oil refining sector faces increasing pressure to align with these climate objectives, while maintaining economic viability.

A conventional refinery processes various types of crude oil with variable compositions to produce various products, including liquified petroleum gas, gasoline, jet fuel, diesel, and paraffin through distillation and conversion units like hydrotreaters, crackers, and reformers. Burning of fossil fuels for heat, the Fluid Catalytic Cracker (FCC), and the Steam Methane Reformer (SMR), are identified as the main primary sources of scope 1 emissions accounting for 94% of total $CO_2$ emissions [4]. Recent studies have explored future refinery configurations and potential decarbonization pathways. Griffith et al. [3] highlight the dual role of refineries as both major contributors to greenhouse gas emissions, and critical actors in transitioning to sustainable energy systems in their critical review of socio-technical systems. They emphasize the importance of tailored strategies, including carbon pricing, stricter emissions controls, renewable technology investments, and subsidies. Bryum et al. [4] advocate for low-carbon hydrogen fuels, electrification, and Carbon Capture and Storage (CCS) as key measures,

proposing two conceptual designs for low-emission refineries. However, both studies offer qualitative insights without quantitative optimization strategies. Complementary analyses, such as those by Nixon et al. [5] evaluate the feasibility of CCS for oil refineries, and emphasize the need for combined approaches involving fuel substitution and emission offsets, while Li et al. [6] assess cost-effective $CO_2$ abatement technologies in China's refineries. These studies perform techno-economic assessments for different decarbonized technologies. Yáñez et al. [7] analyze $CO_2$ mitigation pathways for a Colombian oil refinery, while Sachs et al. [8] emphasize diverse technology mixes to meet climate targets, although their methodologies may not yield optimal solutions. Optimization-based approaches provide a more systematic perspective on refinery decarbonization. De Maigret et al. [9] employ a multiobjective optimization framework to minimize $CO_2$ emissions and costs for an Italian refinery, though their model focuses on short-term cost minimization without a transition timeline. Similarly, a paper by Zhang et al. [10] develops a multiperiod optimization model to obtain biomass-based retrofits, but omits options for scope-1 and scope-2 emission reductions. Beyond the refining sector, Sotiriou et al. [11] have developed a multi-objective optimization framework tailored to the dynamic policy context of EU member states, exploring trade-offs between stronger decarbonization ambitions and associated costs. This study has demonstrated the use of multi-objective optimization in planning problems involving longer time horizons.

Although techno-economic analyses are available for individual decarbonization initiatives, Chattopadhyay et al. [12][13] have highlighted the need for a specialized tool that can find decarbonization pathways for individual refineries based on specific factors such as production capacity, plant structure, and the cost of renewable energy sources. They have developed an optimization tool to address this problem. However, scope 2 emissions (stemming from the indirect consumption of purchased electricity) were not accounted for in their paper. The reality presents a complex landscape where scope 2 emissions significantly influence the economic viability, especially for electrification-based alternatives. This is relevant for multinational corporations whose refineries operate across different regions, each with unique regulatory frameworks and economic conditions. Our study addresses these limits and proposes a multi-objective optimization (MOO)-based framework for analysis. The rest of the paper is organized as follows; the various decarbonization pathways considered in the superstructure are presented, followed by the problem statement considered. A MOO problem modeling the superstructure by minimizing $CO_2$ emissions, and the present value of cost, are presented in the methodology section. Finally, in the results section, we compare the results obtained for Canada and the United States, subject to respective natural gas and electricity prices and carbon emission reduction policies.

The superstructure (Fig.1) consists of several decarbonized and current pathways for hydrogen production and steam generation. Alternatives for hydrogen production include traditional fossil-based processes, blue hydrogen production (involving steam methane reforming (SMR) augmented with post combustion or precombustion-based capture), and green hydrogen production via electrolysis, supported by technologies like proton exchange membrane electrolyzer (PEME) and alkaline electrolyzers (AE). Precombustion carbon capture requires less energy and is more cost-effective in terms of both capital and operational expenses. However, it is compatible only with gasification units that generate flue gas containing higher $CO_2$ concentrations. In contrast, post-combustion $CO_2$ capture, while demanding more energy, is capable of managing flue gas with lower $CO_2$ concentrations. Alkaline electrolyzers (AEs) are less energy efficient and have the drawback related to their shutdown current as they cannot operate at low current densities, but are cheaper than PEMEs. Process heating is achieved using high pressure steam (HPS), which is produced by natural gas boilers with or without carbon capture, or electric boilers. The superstructure also includes a pathway to capture $CO_2$ from flue gas emissions from other units such as FCC or furnaces, using post-combustion carbon capture. The problem involves strategic selection and timely implementation of the best set of initiatives for retrofitting the supply of HPS and hydrogen to the given refinery considering the operating data for a typical crude-based refinery, with a distillation capacity of 220 kbbl crude oil per day to minimize emissions and present value of cost.

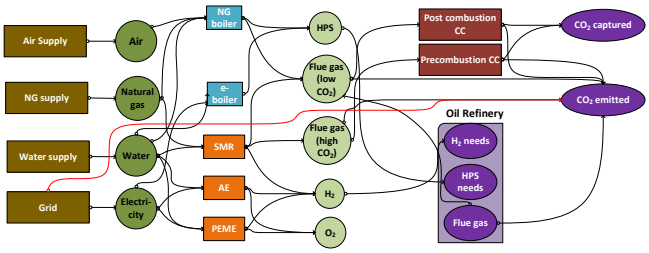

**Figure 1.** Superstructure showing options considered for decarbonization

## METHODOLOGY

The variables used in the model are, $F_{k,j,yr}$, a positive continuous variable representing the amount of component $k$ present in a stream flowing to or from a unit $j$ in year $yr$. $y_{j,yr}$ is a binary variable indicating whether the installation of a specific unit of technology $j$ (e.g. PEME, AE) takes place in the year $yr$. $Q_{j,yr}$; $(QE_{j,yr}/QD_{j,yr})$, a continuous variable indicating the total (expansion

in/decommissioned) capacity of a technology j in a given year $yr$. These constraints apply to all years in the entire time horizon i.e. 2022-2040 unless specified otherwise.

## Mass balance constraints

The proposed formulation requires specifying balances across the task nodes (or the technology units) and the resource nodes (or the components). The task balance involves Eqs. (1) and (2) relating the amount of components present in the inlet and outlet streams to a certain key component through simplified yield-based models. Eq. (1) represents a yield-based model where $\mu_{k,j}$ is the yield coefficient relating the flowrate of reactant $k$ to produce a certain flowrate of key component $k'_j$ in unit $j$. Similarly, in Eq. (2), $-\mu_{k,j}$ denotes the amount of by-product (e.g. $CO_2$) $k$ in the outlet stream of unit $j$, given a certain amount of key component $k'_j$ in the outlet stream. The total hydrogen and HPS produced across all pathways must match the refinery's overall hydrogen and HPS requirements. The $CO_2$ captured and emitted after passing through carbon capture units are proportional, determined by the efficiency of the respective CC equipment. Likewise, the steam generation and losses via the purge stream (blowdown) from boilers are proportional, governed by a constant factor.

$$F_{k,j,yr} = \mu_{k,j} F_{k_j',j,yr} \; if \; k \in \{In(j)\}, \mu_{k,j} \geq 0, \forall yr,$$

$$\forall \, j \in \{\text{AE, PEME, e-boiler, CC units, NG boiler, SMR}\} \quad (1)$$

$$F_{k,j,yr} = -\mu_{k,j} F_{k_j',j,yr} \; if \; k \in \{Out(j)\}, \mu_{k,j} \leq 0, \forall yr,$$

$$\forall \, j \in \{\text{AE, PEME, e-boiler, CC units, NG boiler, SMR}\} \quad (2)$$

Here, the notations $In(j)$ and $Out(j)$ represent the set of resource nodes connected at the inlet and outlet of node $j$ respectively. Additionally, mass balances are imposed across the resource nodes as shown in Eq. (3). Here $k$ denotes a particular component node and $In(k)$ and $Out(k)$ denote the set of task nodes connected at the inlet and outlet of resource node k. K denotes the set of all component nodes.

$$\sum_{l \varepsilon \, In(k)} F_{k,l,yr} = \sum_{j \varepsilon \, Out(k)} F_{k,j,yr} \quad \forall \, k \in \text{K}, \forall \, yr \quad (3)$$

## Energy balance and $CO_2$ intensity constraints

Energy balances for e-boilers, and electrolyzers are given by Eqs. (4) and (5) respectively where $P_{j,yr}$ denotes the power drawn from equipment j in a given year $yr$.

$$P_{\text{e-boiler, } yr} \eta_{\text{e-boiler}} = \Delta H_{vap} F_{H_2O,\text{e-boiler, } yr} \; \forall \; yr \quad (4)$$

$$F_{Hydrogen,j,yr} \Delta H_{electrolysis} = P_{j,yr} \, \eta_j, j \in \{PEME, AE\}, \forall \, yr \quad (5)$$

where $\eta_j$ denotes the energy efficiency of equipment $j$. The emissions from the grid are calculated using the Eq. (6) Here $CI_{yr}$ denotes the $CO_2$intensity of the grid.

$$CI_{yr} \sum_{j \varepsilon \, Out(Grid)} P_{j,yr} = \text{F}_{\text{grid,CO}_2,yr} \quad (6)$$

## Capacity expansion constraints

Eqs. (7) and (8) impose logical constraints on the capacity expansion/decommissioning capacity reduction in any year.

$$LB_j y_{j,yr} \leq QE_{yr} \leq UB_j y_{j,yr}$$

$$\forall \, \text{j} \in \{\text{AE, PEME, e- boiler, CC units}\} \quad (7)$$

$$LB_j y_{j,yr} \leq QD_{yr} \leq UB_j y_{j,yr} \; \forall \, \text{j} \in \{\text{SMR, NG-boiler}\} \quad (8)$$

Eqs. (9) and (10) evaluate the total capacity at the end of any year $yr$. [23, 19].

$$QE_{j,yr} + Q_{j,yr-1} = Q_{j,yr}$$

$$\forall \, \text{j} \in \{\text{AE, PEME, e-boiler, CC units}\} \quad (9)$$

$$-QD_{j,yr} + Q_{j,yr-1} = Q_{j,yr} \; \forall \, \text{j} \in \{\text{SMR, NG boiler}\} \quad (10)$$

Eqs. (11) and (12) state that the operating flow rate or power is less than the installed capacity and greater than a certain fraction (the minimum possible turn down $\chi_j$) of the installed capacities.

$$\chi_j Q_{j,yr} \leq P_{j,yr} \leq Q_{j,yr} \quad \text{j} \in \{\text{e-boiler, PEME, AE}\} \quad (11)$$

$$\chi_j Q_{j,yr} \leq F_{k'_j,yr} \leq Q_{j,yr} \; \text{j} \in \{\text{NG boiler, SMR, CC}\} \quad (12)$$

We assume that the capacity expansion for e-boilers and CC facilities can vary continuously, while the expansion of electrolyzer capacity is restricted to discrete increments corresponding to standard sizes. To handle this, we introduce non-negative integer variables $w_{j,s,yr}$ which denote how many electrolyzers, in year $yr$, of type $j \in \{\text{PEME, AE}\}$ are of size s, where $s \in [1, \text{Num. of available discrete sizes}]$, with $d_{j,s}$ denoting the available sizes for each type of electrolyzer. Eq. (13) adds the size of all installed electrolyzers to calculate the total capacity expansion in any given year [10].

$$\sum_s w_{j,s,yr} d_{j,s} = QE_{j,yr} \quad \text{j} \in \{\text{PEME, AE}\} \quad (13)$$

## Cost constraints and objective function

Eq. (14) expresses the total CAPEX for an expansion as $\alpha + \beta QE$, where $\alpha$ represents the fixed cost and $\beta QE$ represents the variable cost, $dur(j)$ represents the time taken to build a unit of tech. $j$. Eq. (15) enforces an upper limit on the annual capital expenditure (CAPEX) that can be allocated to these decarbonization initiatives.

$$CAPEX_{yr} = \Sigma_j \sum_{h=0}^{dur(j)-1} \frac{\alpha_{j,yr+h} y_{yr+h}}{dur(j)} + \sum_{h=0}^{dur(j)-1} \frac{\beta_{j,yr+h} \; QE_{j,yr+h}}{dur(j)} \quad (14)$$

$$CAPEX_{yr} \leq CAPEX \; CAP \quad (15)$$

The annual OPEX associated with decarbonization efforts, shown in Eq. (16), includes two key components: one arising from the use of natural gas and electricity, and the other, associated with the energy related to capture in CC units. The capture cost is directly proportional to the amount of emissions reduced via carbon capture.

$$OPEX_{yr} = \Big( \sum_{j \epsilon Out(NG)} \$_{\frac{NG}{unit\ mass}} F_{NG,j,yr} + \sum_{j \epsilon Out(Power)} \$_{\frac{electricity}{unit\ energy}} P_{j,yr} + \sum_{j \epsilon CCS\ Units} OPEX_j \, F_{Captured\ CO_2,j,yr} \Big) time \quad (16)$$

Finally, we formulate the objective functions as the present value of the cost of the decarbonization project (17), and the total emissions over the transition period

(18). The amount of $CO_2$ and other gases present in the flue-gas released from the rest of the operations in the refinery are specified additionally.

$$Minimize \sum_{yr=1}^{19}(CAPEX_{yr} + OPEX_{yr})/(1+i)^{yr} \quad (17)$$

$$Minimize \sum_{yr=1}^{19}\sum_{j\,\epsilon In(CO_2\ emission)} F_{CO_2 emission,\,j,yr} \quad (18)$$

The $\epsilon$-constraint method [14] is used to convert the second objective Eq. (18) into a constraint and the Pareto front is generated by plotting the ordered pair of objective values for the non-dominated solutions.

## RESULTS

The retrofit MILP model was implemented in Pyomo 6.6.1 with the Gurobi 10.0.1 solver [15] for a 19-year horizon, involving 1,160 variables (133 discrete, 1,027 continuous) and 1,197 constraints. Results are presented for two case studies, based on energy prices, policies, and grid carbon intensities for Canada and the USA. The Pareto fronts from the bi-criterion optimization highlight the effects of carbon mitigation policies, such as carbon taxes and tax credits, on the cost-emissions trade-off. The analysis also examines the role of scope-2 emissions on the non-dominated solutions. The CAPEX for carbon capture technologies was modeled as a linear function of the processed $CO_2$, with an intercept. Similarly, CAPEX for electrolyzers and e-boilers vary linearly with an intercept installed capacity, reflecting economies of scale. OPEX for carbon capture was tied to the amount of $CO_2$ captured.

### Canada

Electricity and natural gas prices for Canada, sourced from [16] [17] and shown in Figure 2 (a) and (b), were used to estimate the operational costs. While Canada aims for a net-zero electricity grid by 2035 [18], our scenarios project a 100% emissions reduction by 2040 (optimistic), 2043 (baseline), and 2045 (pessimistic), based on predicted greenhouse gas emissions from Annesley et al. [19] and grid mix forecasts from Canada's Energy Future 2021 [20] (shown in Fig. 2 (c)).

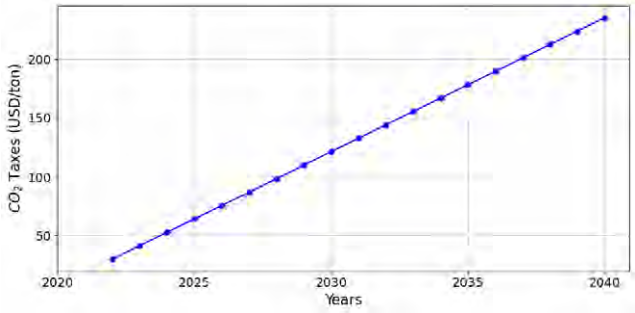

**Figure 3.** $CO_2$ taxes implemented as per Canadian rates

When $CO_2$ taxes are implemented as per the rates shown in Figure 3, we see that the Pareto front compresses towards low emission solutions as compared to the baseline solution (shown in Figure 4). Beyond a certain point, increasing the ε value does not reduce $CO_2$ emissions further, as the ε-constraint becomes inactive. Remaining within the ε limit is financially advantageous due to the penalties for exceeding it. Non-dominated solutions incur higher costs than the baseline due to the imposed penalties. Figure 5 shows that low-cost, non-dominated solutions obtained when $CO_2$ taxes are

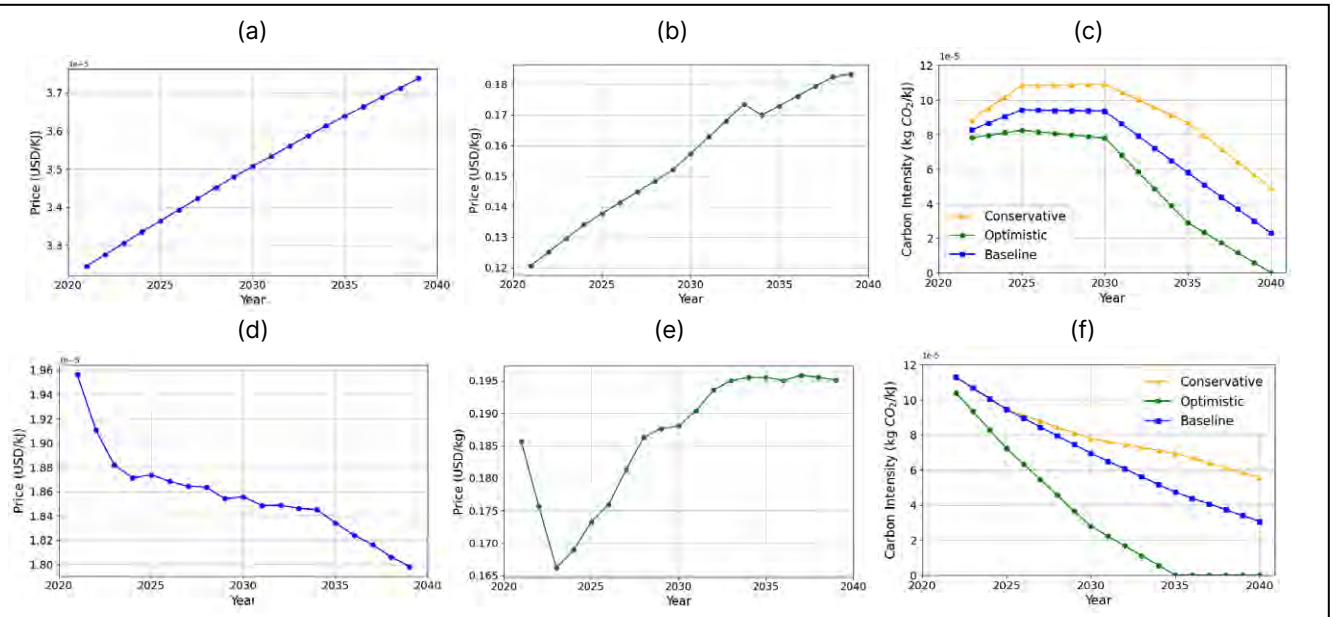

**Figure 2** (a) Canadian electricity price forecasts (b) Canadian natural gas price forecasts (c) Carbon intensity scenario forecasts for Canadian grid (d) US electricity price forecasts (e) US natural gas price forecasts (f) Carbon Intensity Scenarios for US grid

implemented. These favor carbon capture options. For higher cost and lower emission non-dominated solutions earlier, and higher adoption of both pre- and post-combustion carbon capture takes place. Since no cases include e-based options, variations in grid intensity profiles have no significant impact on the Pareto front.

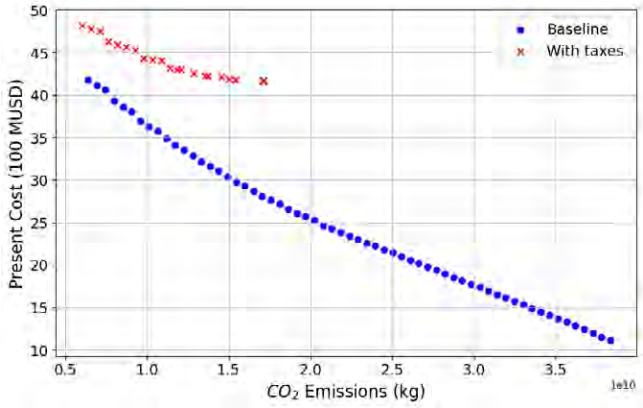

**Figure 4.** Pareto front with $CO_2$ taxes implemented

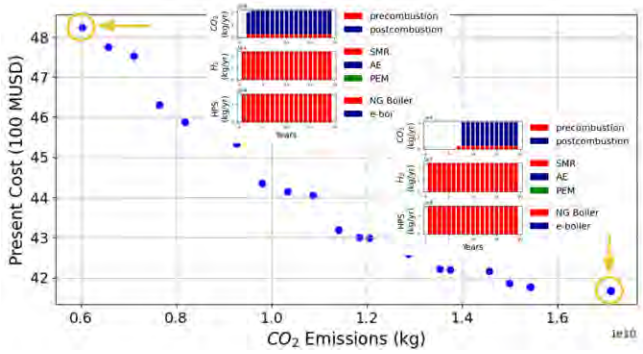

**Figure 5.** Canada with $CO_2$ taxes: Pareto front with the solutions shown for a few points.

## United States

The electricity and natural gas price projections, based on EIA data (Figure 2 (d) and 2 (e)), were used to estimate the operational cost estimates. Carbon intensity scenarios for the electricity grid included 3 cases with the optimistic case, predicting a 100% reduction in emissions by 2035, baseline 95% by 2050, and the pessimistic case 65% by 2050, informed by Leard et al [21]. Evaluating the effect of scope-2 emissions for different carbon intensity profiles of the grid (as shown in Figure 2 (f)) on the non-dominated solutions, we see in Figure 6 that with higher grid $CO_2$ intensities, carbon capture (CC)-based solutions were favored over e-based alternatives. The point on the Pareto-front with the lowest $CO_2$ emissions involve e-based solutions but was feasibly obtained only with the optimistic grid intensity predictions as shown in Figure 6. As per the 45Q tax credit rates under the Inflation Reduction Act USD [22], $ 85 are provided per metric ton of $CO_2$ captured and stored securely underground. It is assumed that the 45 Q credits increase at the same rate as the carbon taxes. Additionally, according to the 45 V tax credits, at least 0.6 USD tax credits are provided per kg of green $H_2$ produced. With the imposition of these incentives, as shown in Figure 7, the Pareto front shifts towards low-emission solutions, though the NPV values are lower than the base case due to the received credits. As shown in Figure 8, the non-dominated solutions resemble those in Figure 3, but the highest-cost, lowest-emission solution includes partial adoption of e-boilers.

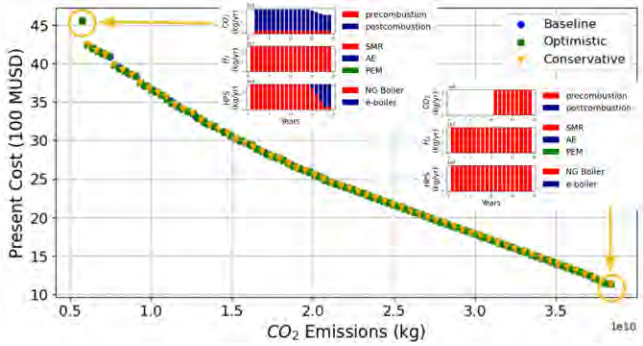

**Figure 6.** US : Pareto front under changing grid intensity profiles.

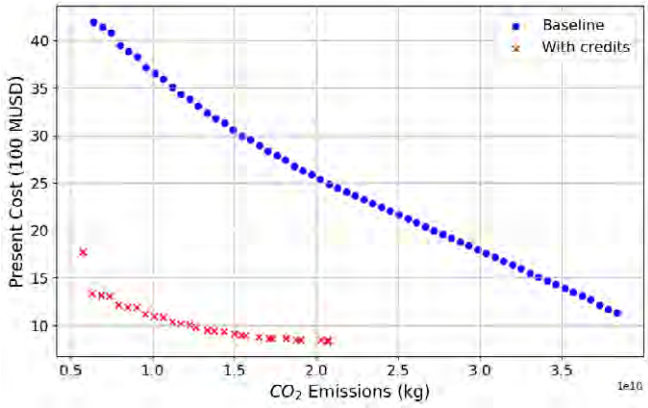

**Figure 7.** Pareto front with $CO_2$ credits implemented

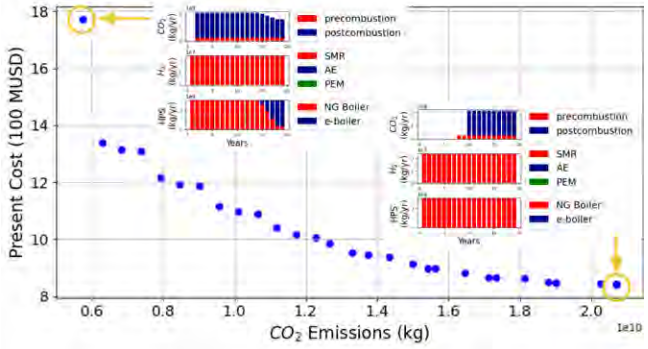

**Figure 8.** US with carbon credits: Pareto front with the solutions shown for a few points

## CONCLUSIONS

The multi-objective optimization framework developed in this paper, minimizes retrofit decarbonization costs and $CO_2$ emissions, providing insights into the trade-offs between cost and emissions under various scenarios. Solutions incorporating carbon capture (CC)

equipment were unaffected by changes in grid intensity, with several non-dominated solutions favoring earlier adoption of CC. E-based technologies are chosen exclusively when $CO_2$ emissions reach their minimum on the Pareto front, assuming the grid's $CO_2$ intensity decreases in line with optimistic projections. Carbon mitigation policies, such as carbon taxes and 45Q/V tax credits. compress the Pareto frontier toward low-emission, high-cost solutions, demonstrating their effectiveness in incentivizing aggressive emission reductions.

## ABSTRACT

Green hydrogen is widely recognized as a key player in the decarbonization of the energy system. To transport it efficiently, hydrogen must be converted into a carrier, such as liquefied hydrogen or ammonia, to increase its volumetric density. The supply chain of these carriers includes hydrogen conversion into the carrier, overseas transport, and carrier reconversion back to hydrogen. A case study involving hydrogen transportation across the Mediterranean Sea is used to evaluate the carrier efficiency. The processes involved in the supply chain are simulated in Aspen Plus® V11 to determine material and energy balances, and the "net equivalent hydrogen" method is applied to calculate the equivalent amount of hydrogen needed to supply thermal or electric power. The efficiency, defined as the ratio of net hydrogen delivered (after accounting for consumption and boil-off losses) to the initial hydrogen input, is higher for ammonia than for liquefied hydrogen (73% vs 60%, respectively). This advantage lies in the lower overall hydrogen consumption for ammonia synthesis and cracking compared to liquefaction.

**Keywords**: green hydrogen, green ammonia, liquefied hydrogen, hydrogen carrier, energy efficiency

## INTRODUCTION

Green hydrogen is commonly regarded as a key player in the transition towards a low-carbon future [1]. It can be efficiently produced in regions with abundant renewable resources, which are often remote and distant from major consumption centers. Therefore, the efficient and cost-effective transportation of $H_2$ from production hubs to end users is essential. However, $H_2$ has an extremely low volumetric density at ambient conditions. To overcome this issue, hydrogen carriers, such as liquefied hydrogen ($LH_2$) and ammonia ($NH_3$), are being explored for its transportation on a large-scale [1].

This study assesses the energy consumption involved in the supply chain of these carriers, focusing on the processes of converting hydrogen into the carrier and reconverting it back to hydrogen. For $LH_2$, these processes involve hydrogen liquefaction and regasification, while for $NH_3$, they include ammonia synthesis and cracking. The simulations are conducted using Aspen Plus® V11 [2] to determine the material and energy balances. The analysis adopts the "net equivalent hydrogen" method, which is analogous to the widely used "net equivalent methane" method [3]. This approach assesses the equivalent amount of hydrogen that would need to be burned to power specific equipment. By using this unified energy basis, the method allows for a fair comparison between different processes.

## METHODS

The case study considered is for green hydrogen transportation across the Mediterranean Sea [1]. The feed hydrogen conditions are assigned in terms of temperature ($T_{in}$ = 25 °C), pressure ($P_{in}$ = 20 bar) and flowrate ($F_{in}$ = 1,800 kg/h), which resemble the conditions at the outlet of an alkaline electrolyzer. The $H_2$ is converted into the considered carrier, transported overseas covering a distance of 2,500 km, and finally reconverted to $H_2$ at the utilization site. The conditions of the delivered hydrogen

are selected based on the requirements for industrial application. Therefore, the $H_2$ purity is 99.9 mol% and the pressure is 30 bar.

The energy analysis is based on the "net equivalent hydrogen" (NEH) method, which evaluates the equivalent amount of hydrogen that would need to be burned to power specific equipment. The Net Equivalent Hydrogen Delivered (*NEHD*) is then calculated by subtracting both the Net Equivalent Hydrogen Consumed (*NEHC*) and the hydrogen lost due to the boil-off phenomenon during shipping ($F_{lost}$) from the total hydrogen fed into the plant:

$$NEHD = F_{in} - NEHC - F_{lost} \quad (1)$$

The energy interactions can be categorized in:

- heating below ambient temperature,
- cooling above ambient temperature,
- heating above ambient temperature,
- cooling below ambient temperature,
- supplying of electrical power.

According to the methodology described by Pellegrini et al. [3], heating below ambient temperature (< 25 °C) and cooling above ambient temperature (> 25 °C) do not consume hydrogen since service water can be used to provide or remove heat, respectively. In the studied processes, heating above ambient temperature is achieved, where feasible, by coupling process streams. When this is not possible, heating is supplied by burning the hydrogen carrier (hydrogen, ammonia, and their mixtures) as a fuel with air in a furnace. In this case the Net Equivalent Hydrogen Consumed for heating ($NEHC_{he}$) is related to the hydrogen content of the fuel mixture and is computed as:

$$NEHC_{he} = F_{fuel} \cdot w_{hydrogen} \quad (2)$$

where $F_{fuel}$ is the flowrate of the carrier used as fuel, and $w_{hydrogen}$ is the weight fraction of hydrogen in the fuel. Cooling below ambient temperature is accomplished through heat exchange with fluids flowing in refrigeration cycles. Therefore, the hydrogen consumed is indirectly linked to the electric power required to operate the compressors in these cycles. The Net Equivalent Hydrogen Consumed for supplying electric power ($NEHC_{el}$), used for driving compressors and pumps, is computed assuming hydrogen utilization in fuel cells with an efficiency $\eta_{FC}$ of 60%:

$$NEHC_{el} = \frac{W}{\eta_{FC} \cdot LHV} \quad (3)$$

where *W* is the electric power consumption, and *LHV* is the lower heating value of hydrogen.

The efficiency of the value chain ($\eta$) is then computed as the ratio between the *NEHD* and the hydrogen feed flow rate:

$$\eta = \frac{NEHD}{F_{in}} \quad (4)$$

A schematic of the hydrogen carrier supply chain is depicted in Figure 1.

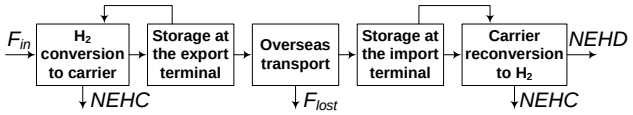

**Figure 1.** Schematic of the hydrogen carrier supply chain.

## PROCESS SIMULATION

The processes involved in the $LH_2$ and $NH_3$ value chains are simulated using Aspen Plus® V11 [2] to obtain material and energy balances, necessary for the NEH assessment. It is supposed that the impurities in the hydrogen feed have been removed before the hydrogen enters the processes. Heat exchangers' pressure drops are neglected. An isentropic efficiency of 0.8 is assumed for pumps, compressors and turbine expanders, unless otherwise stated.

### Liquefied hydrogen supply chain

#### Hydrogen liquefaction process

The hydrogen liquefaction process involves cooling hydrogen gas to extremely low temperatures until it transitions from gas to liquid. This happens at about -250 °C at atmospheric pressure. The process typically includes a precooling section, where nitrogen or other refrigerants are used to remove heat, and a cryogenic section, where further cooling happens using Joule-Thomson expansion or other cryogenic methods until hydrogen reaches its liquefaction point. Various process configurations have been explored in the literature. Among them, the process described by Cardella [4], which employs a mixed refrigerant Joule-Thomson cycle for precooling and a dual-pressure hydrogen Claude cycle for cryogenic cooling, stands out as the most balanced in terms of complexity and specific electricity consumption for the small-capacity plant under consideration [5]. For simulating this process, the Peng-Robinson thermodynamic package, modified as detailed in [6], is used to account for the behavior of equilibrium hydrogen and to model continuous ortho-para hydrogen conversion, which is achieved by packing a suitable catalyst within the tubes carrying the processed hydrogen. The Process Flow Diagram (PFD) is depicted in Figure 2a. The hydrogen stream (H2 in Figure 2a) undergoes precooling to -173 °C in the multi-stream heat exchanger HX-1, where it flows counter-currently to a mixed refrigerant. The composition of this refrigerant, optimized by Cardella [4] to minimize temperature differences between the cold and hot composite curves in HX-1, is 14 mol% nitrogen, 30 mol% methane, 31 mol% ethane and 25 mol% iso-butane. The mixed refrigerant is

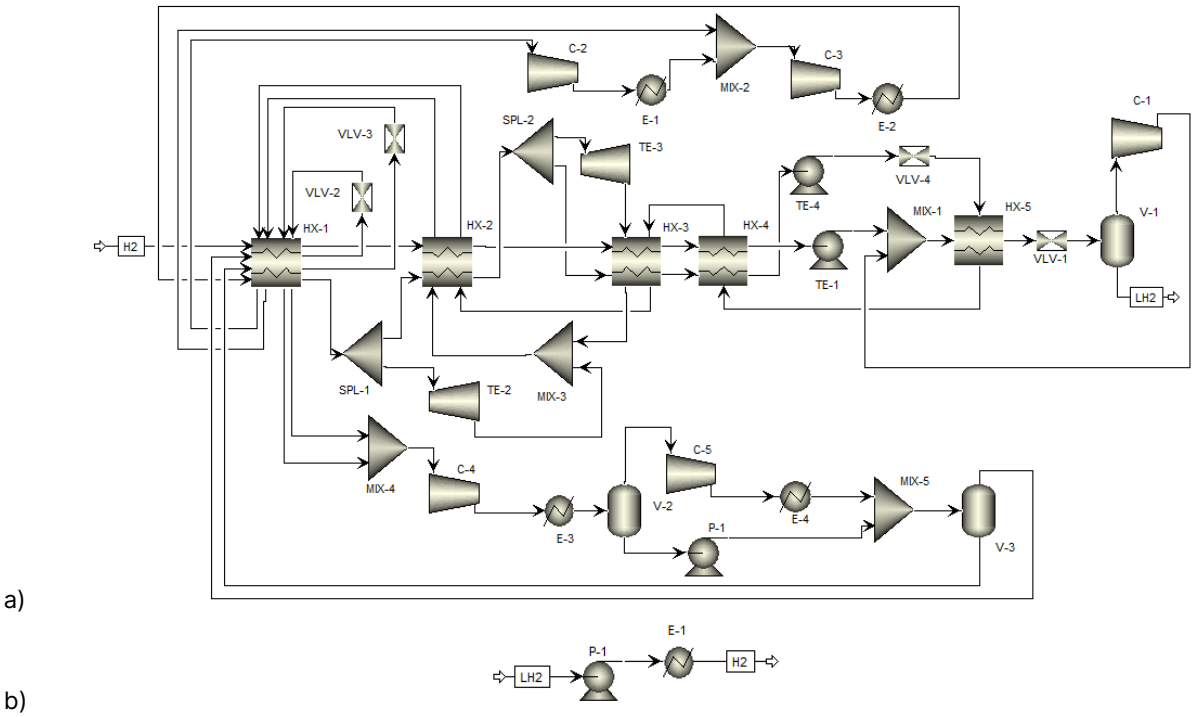

**Figure 2.** PFD of the processes involved in the $LH_2$ supply chain: a) $H_2$ liquefaction and b) $LH_2$ regasification.

compressed to 25 bar in compressor C-4, cooled to 30 °C in heat exchanger E-3 using service water, and separated in flash vessel V-2 to avoid the presence of liquid at the inlet of the second compressor. The separated vapor is compressed to 50 bar in C-5, cooled to 25 °C in E-4, and mixed with the liquid from V-2 after it is pumped to 50 bar in pump P-1. This mixture is separated in V-3, with liquid and vapor streams sent to the hot side of HX-1. The former is precooled to -110 °C and expanded to 2.9 bar through Joule-Thomson valve VLV-2. The latter is precooled to -193 °C and expanded to 2.9 bar through VLV-3. These low-pressure streams are directed to the cold side of HX-1 and are mixed at its outlet in mixer MIX-4. The design of the dual-pressure $H_2$ Claude cycle has been optimized by Cardella [4] to reduce temperature differences in the heat-exchangers HX-2, HX-3, HX-4, and HX-5. The low-pressure $H_2$ refrigerant is compressed to 8.3 bar in C-2, cooled to 30 °C in E-1 using service water, and mixed with the intermediate-pressure $H_2$ refrigerant in MIX-2. The mixture is compressed to 49.9 bar in C-3, and cooled to 25 °C in E-2. The resulting high-pressure $H_2$ refrigerant is precooled to -173°C in HX-1 and then split in splitter SPL-1, directing 38.8 % of the flow to turbine expander TE-2, where it is expanded to an intermediate pressure of 8.3 bar. This stream is mixed with a recycle stream in MIX-3 and routed to the cold side of HX-2. The remaining flow from SPL-1 passes at the hot side of HX-2, reaching an outlet temperature of -213 °C, and is then split in SPL-2. Of this, 73.8 % is directed to TE-3, where it expands to 8.3 bar, then passes at the cold side of HX-3 to cool the processed hydrogen stream. The remaining flow from SPL-2 passes at the hot side of HX-3, reaching -237 °C at the outlet. The processed hydrogen and the high-pressure hydrogen refrigerant are further cooled in HX-4 to -249 °C. At the outlet of HX-4, the processed hydrogen is expanded in TE-1 to 5 bar, then mixed with the vapor from the flash separator V-1 and cooled in HX-5 to -251 °C. The high-pressure refrigerant is expanded to 3 bar in TE-4 and then to 1.4 bar in VLV-4, then passes as cold stream through HX-5, HX-4, HX-3, HX-2, and HX-1. The processed hydrogen is finally throttled to the storage pressure (1.3 bar) in VLV-1. A minimum approach temperature of 3 °C is maintained in all heat exchangers, except for the exchanger where hydrogen undergoes a phase change (HX-5), where the minimum approach temperature is set to 1 °C.

## Liquefied hydrogen storage and transport

The produced liquid hydrogen is stored in properly insulated tanks. The boil-off gas is assumed to be reliquefied at the export terminal and sent to the regasification process at the import terminal. During overseas transport, the boil-off gas is lost with a rate of 0.2 % per day [1]. The total hydrogen loss during transport is calculated based on the travel distance and an average shipping speed of 30 km/h [1].

## Liquefied hydrogen regasification process

Regasification involves converting liquid hydrogen back into its gaseous state. This process is relatively straightforward, involving the pumping of liquefied hydrogen followed by heating it to ambient temperature.

The PFD of the process is depicted in Figure 2b. The discharge pressure of the pump (P-1) is set to 30 bar to meet the pressure requirements for industrial application. The pump is assumed to have an efficiency of 0.6, and service water is used as the heating medium in the vaporizer (E-1).

## Ammonia supply chain

### Ammonia synthesis process

$NH_3$ is synthesized from nitrogen and hydrogen, according to the reaction:

$$3H_2 + N_2 \rightarrow 2NH_3 \quad (5)$$

The simulation utilizes the Redlich-Kwong-Soave equation of state with the alpha function modification proposed by Boston and Mathias (RKS-BM). The PFD of the process is shown in Figure 3a. The nitrogen required for the synthesis is determined by the stoichiometric ratio given in Eq. (5). Nitrogen is produced from air using the process scheme proposed in [7]. Air (AIR in Figure 2a) is compressed to 9.9 bar and then precooled to its dew point in the multi-stream heat exchanger HX-6. The resulting stream is sent to the high-pressure rectification column T-1, which consists of 50 theoretical stages. This column separates the air into two streams: a nitrogen-rich vapor (residual oxygen content of 2 ppm) as the top product and a bottom product comprising an approximately equimolar mixture of oxygen and nitrogen. The bottom stream is expanded to 3.3 bar and fed into the low-pressure stripping column T-2, which separates the feed into a top stream resembling the composition of air and an oxygen-enriched bottom stream. The oxygen-

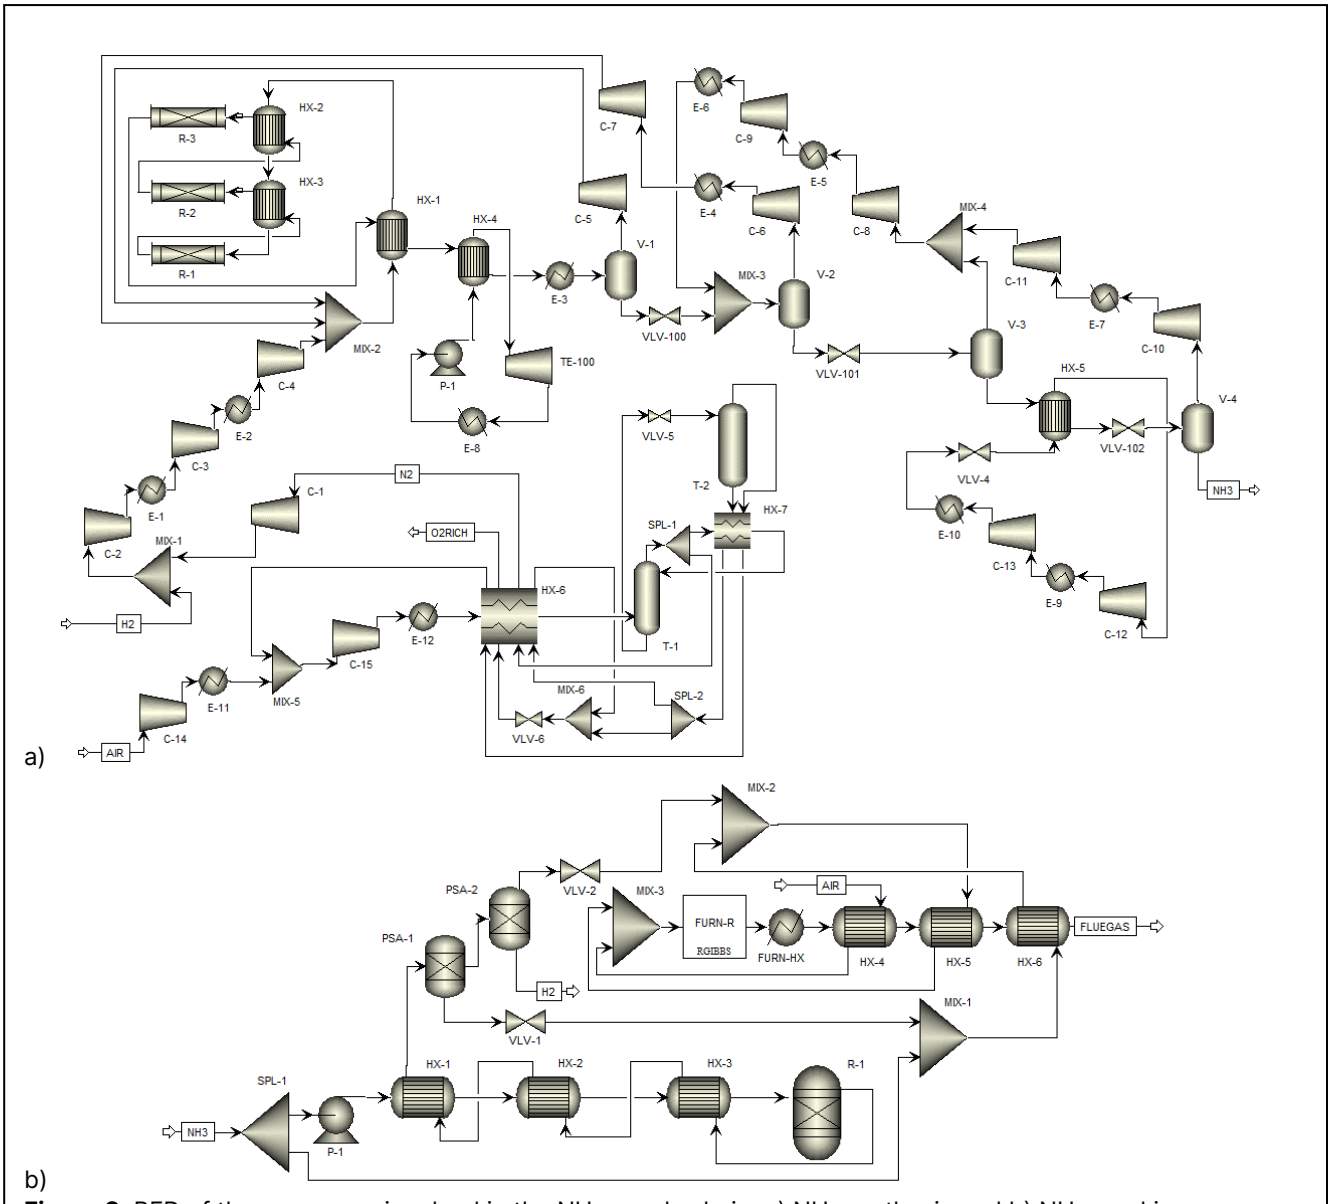

**Figure 3.** PFD of the processes involved in the $NH_3$ supply chain: a) $NH_3$ synthesis and b) $NH_3$ cracking.

enriched stream is routed through process exchangers HX-7 and HX-6 and exits as a product (O2RICH in Figure 3a). The top stream also passes as a cold stream in HX-7 and HX-6 and is then recycled to mixer MIX-5, where it mixes with the incoming air feed. The cooling required to condense part of the nitrogen-rich vapor from the high-pressure column, providing reflux, is achieved by evaporating the bottom product of the low-pressure column. HX-7 operates with an approach temperature difference of 1 °C. The produced nitrogen stream (N2 in Figure 3a) feeds the ammonia synthesis section. The hydrogen stream (H2 in Figure 3a) is mixed with N2, after being compressed to 20 bar, and then compressed to 200 bar in a three-stage compressor with intercooling. The resulting stream is mixed with the recycle streams, the vapors exiting the V-1 and V-2 separators, suitably compressed, and heated to 347 °C using a series of process-process heat exchangers (HX-1, HX-2, HX-3), which recovers heat from the streams exiting the reactor beds, before being sent to the first catalytic stage R-1. The reaction section comprises three adiabatic catalytic beds (R-1, R-2, R-3) with intermediate cooling. Iron-based catalysts are used to enhance the conversion (Haber-Bosch process). The stream exiting the last reactor stage R-3 contains ammonia along with hydrogen and nitrogen. The unconverted reagents must be separated and recycled to the reactor. The goal is to produce liquid ammonia at near-ambient pressure (1.3 bar), with a purity exceeding 99.95%, as defined by legislation [8]. To achieve this, the stream is first cooled to 50 °C in HX-4, transferring heat to a steam Rankine cycle, and further cooled to 30 °C in heat exchanger E-3 using service water. The resulting biphasic stream is separated in the V-1 separator: the vapor phase is recycled to the reaction section, while the liquid phase undergoes further purification through downstream expansion and cooling stages. Specifically, flash vessels V-2, V-3, and V-4 operate at pressures of 40 bar, 7 bar, and 1.3 bar, respectively. Cooling is achieved in HX-5 using an ammonia refrigeration cycle.

### Ammonia storage and transport

Liquefied ammonia storage takes place in properly insulated tanks. The boil-off gas is assumed to be reliquefied at the export terminal and directed to the cracking process at the import terminal. During overseas transport, a boil-off gas loss rate of 0.024 % per day is considered [1].

### Ammonia cracking process

The dissociation of ammonia is a highly endothermic process, described by the following reaction:

$$2NH_3 \rightarrow 3H_2 + N_2 \quad (6)$$

Commercially, small-scale ammonia cracking reactors (capacities ranging from 1 $Nm^3/h$ and 1,000 $Nm^3/h$), operating at temperatures between 800 and 1,000 °C with Ni-based catalysts are available. The endothermic reaction is supported by electricity.

The simulation of the ammonia cracking process assumes the use of the thermocatalytic technology with Ni-based catalysts, as this is the most mature technology. Figure 3b illustrates the PFD of the process. Upon reaching the utilization site, ammonia (NH3 in Figure 3b) is pumped to 30 bar, preheated through a series of heat exchangers (HX-1, HX-2 and HX-3) that recover heat from the reaction products, and fed into the cracking reactor (R-1). The reactor is modeled using Aspen Plus's RGibbs module due to the lack of sufficiently detailed kinetic data. As a result, the ammonia conversion is assumed to follow thermodynamic equilibrium at the reactor's operating conditions of 30 bar and 900 °C. The heat required for the endothermic cracking reaction is supplied by burning a portion of the ammonia, which is mixed with hydrogen-rich waste streams from the purification section. Air (AIR in Figure 3b), used as the oxidizer, is added slightly above the stoichiometric ratio to ensure complete combustion. Following the reaction stage, hydrogen is separated from the unconverted ammonia and nitrogen via pressure swing adsorption units (PSA-1 and PSA-2).

## RESULTS AND DISCUSSION

The Net Equivalent Hydrogen Consumed is calculated from the material end energy balances obtained from process simulations using Eqs. (2)-(3), then the Net Equivalent Hydrogen Delivered is computed using Eq. (1). Figure 4 presents the results through Sankey diagrams, which are particularly effective for visualizing where hydrogen is consumed or lost within the supply chain. Processes characterized by a low efficiency must be the primary targets for future research efforts. The *NEHD* for $LH_2$ is 1,072 kg/h, reflecting an overall efficiency of 60% for the supply chain. Among the processes, hydrogen liquefaction exhibits the highest equivalent hydrogen consumption, with approximately one-third of the hydrogen input being consumed during the process. This highlights the need to focus research on optimizing the process to minimize electricity consumption. One potential solution is the use of refrigerant mixtures in both the precooling and cryogenic cooling stages, with their composition optimized to achieve a close match between the hot and cold composite curves of the heat exchangers, while ensuring that no components precipitate as solid at the operating temperature of the refrigeration cycle. Another approach is to explore energy integration opportunities with processes that require low-temperature heat, such as liquefied natural gas regasification. The *NEHD* for $NH_3$ is 1,323 kg/h, corresponding to an overall $\eta$ of 73% for the supply chain. Ammonia cracking accounts for the highest equivalent hydrogen consumption, utilizing approximately one-fifth of the total hydrogen input during the

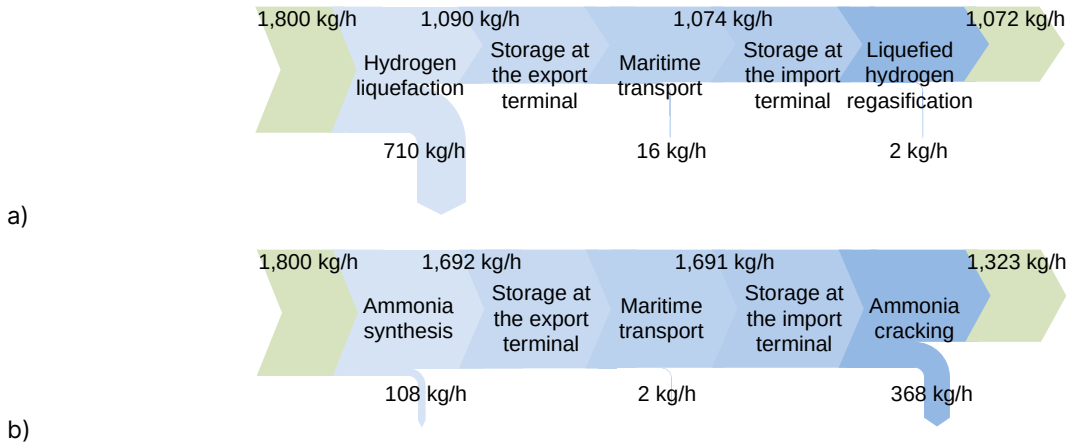

**Figure 4.** NEH assessment for the a) $LH_2$ and b) $NH_3$ supply chains.

process. Therefore, research efforts should focus on improving this process by exploring alternative and sustainable methods for supplying the heat of reaction.

The *NEHD* is higher for $NH_3$ than $LH_2$ because the combined hydrogen consumption for ammonia synthesis and cracking is lower than that required for the liquefaction process. The difference in *NEHD* between the two carriers is 251 kg/h, meaning that hydrogen liquefaction would need to consume 459 kg/h, equivalent to one-fourth of the total hydrogen input, to break even with $NH_3$. In addition, hydrogen losses due to boil-off during maritime transport are smaller for $NH_3$, even if their contribution does not significantly impact the overall results. Therefore, $NH_3$ is the most efficient hydrogen carrier for hydrogen delivery considering the final hydrogen application to the industrial sector.

## CONCLUSIONS

The processes involved in the liquefied hydrogen and ammonia supply chains for hydrogen overseas transportation have been analyzed from an energy consumption perspective. The ammonia supply chain is more efficient than the liquefied hydrogen supply chain, with efficiencies of 73% and 60%, respectively. This is because the combined equivalent hydrogen consumption for ammonia synthesis and cracking is lower than that required for the liquefaction process. Ammonia would become even more attractive if it could be used directly by end consumers, eliminating the inefficiency associated with its reconversion back to hydrogen.

## ABSTRACT

The urgent need to mitigate climate change and reduce reliance on fossil fuels highlights green hydrogen as a key component of the global energy transition. This study assesses the feasibility of producing hydrogen offshore using wind energy, focusing on economic and environmental aspects. Offshore wind energy offers several advantages: access to water for electrolysis, potentially lower hydrogen export costs compared to electricity, and storage systems that stabilize wind energy output. However, significant challenges remain, including the high costs of storage solutions, capital expenditures (CAPEX), and operational costs (OPEX). A Mixed-Integer Linear Programming (MILP) model optimizes the production units, storage, and distribution processes. A case study in southern France examines hydrogen production from a 150 MW floating wind farm. While hydrogen produced from offshore wind ranks among the most environmentally friendly, its costs remain high, and production volumes fall short of meeting regional demand. The findings emphasize the need to optimize power capacities and explore hybrid renewable systems to better balance economic and environmental trade-offs, enhancing offshore wind's competitiveness in hydrogen production and its role in the global energy transition.

**Keywords**: offshore wind, hydrogen, supply chain, optimization, mixed-integer linear programming

## INTRODUCTION

The urgent need to mitigate climate change and reduce dependence on fossil fuels has led to the exploration of alternative energy solutions, with green hydrogen emerging as a key player in the global energy transition [1].

France's National Hydrogen Strategy aims to achieve 6.5 GW of renewable hydrogen production capacity by 2030 [2]. Leveraging its extensive maritime zone, France is advancing the deployment of floating offshore wind farms and exploring the integration of wind energy into hydrogen production systems. Floating offshore wind farms (OWFs) offer a compelling array of benefits: an access to high-capacity wind resources in deep waters, proximity to water for the electrolysis process, and the elimination of land-use constraints that onshore systems face. Such characteristics position offshore wind energy as a promising enabler of hydrogen production [3]. However, the integration of such systems presents significant challenges such as high capital (CAPEX) and operational (OPEX) costs [4]. Existing literature on supply chain modeling for offshore wind and hydrogen systems identifies two major gaps [[5], [6]]:

1. **Limited integration of offshore wind and electrolyzer constraints**: Most studies lack an explicit consideration of the constraints and challenges associated with coupling offshore wind farms and electrolyzers for hydrogen production. This oversight limits the ability to develop realistic and comprehensive models for supply chain optimization.
2. **Narrow focus on deployment optimization**: Current research tends to prioritize electrical aspects or specific system-level developments rather than addressing the broader optimization of deploying

these sectors. While system design and performance evaluations are valuable, they often neglect the strategic deployment of offshore wind and hydrogen production systems within a supply chain framework.

For instance, studies analyzing the performance and energy output of autonomous wind-hydrogen hybrid systems often focus on technical performance without incorporating optimization considerations [7]. This study addresses these gaps by focusing on systems-level modeling that explicitly incorporates the constraints of coupling offshore wind and hydrogen production while optimizing their deployment at the supply chain level.

The scientific research question is formulated as follows: How can spatial energy planning in maritime areas anticipate and address the challenges and opportunities associated with developing future hydrogen networks?

Therefore, the specific objectives of this study are:

- To assess the potential of floating offshore wind farms as an energy source for hydrogen production in a regional context.
- To optimize the design and operation of hydrogen supply chains, including production units, storage systems and distribution networks.
- To analyze two optimization scenarios: one focusing on cost minimization, and the other on greenhouse gas emissions reduction.

# METHODOLOGICAL FRAMEWORK

## Modeling concepts

This study's model builds upon the foundational work of [8], the main innovation is the integration of floating offshore wind farms as a primary energy source within a previously established framework. The optimization problem is formulated as a multi-period mono-objective model, divided into five-years periods. The problem is formulated as a linear programming problem, and the optimizer used is of Mixed-Integer Linear Programming (MILP) type, the model is implemented using the GAMS® modeling language with the CPLEX 12 solver. More details regarding the parameters, formulas and constraints are documented in [8].

## Assumptions

The assumptions of the model can be summarized by:

- The components of the hydrogen supply chain considered are as follows: primary energy sourcing, production, storage, transport, and refueling stations.
- The territory is divided into cells, each characterized by a specific hydrogen demand.
- Two production methods are evaluated: electrolysis powered by renewable electricity or nuclear energy, and steam methane reforming (SMR). Note that nuclear energy was included to represent an alternative, as it constitutes a major share of the French electricity mix (approximately 65% of the national grid).
- Three electrolyzer sizes are available: small, medium, and large. Production units can only be installed on designated cells.
- The offshore cell is modelled by being directly connected to onshore cell n°2 (the closest) to simplify its representation.
- The offshore components - electrolyzers, desalination, pipeline, floating platform – are incorporated into the model through a cost parameter, as a part of the total CAPEX of the offshore system.
- The produced hydrogen is dedicated to transport applications and distributed via refueling stations.

## Optimization criteria

Two optimization scenarios are analyzed, based on two different criteria. The first aims to minimize the total daily cost (TDC) of the hydrogen network, which is an important criterion to ensure the economic feasibility and deployment of the technology. The second focuses on minimizing the global warming potential (GWP) of the supply chain to progress towards the zero emissions goal.

1. **Total Daily Cost:** The TDC (in $) ensures that both operational and capital expenses are optimized over the project's lifespan. It is defined as follows:

$$TDC = \sum_p Cost(p) \quad (1)$$

Where $Cost(p)$ represents the discounted cost for each period $p$, calculated as:

$$Cost(p) = \frac{CAPEX(p)}{(1+r)^{nn(p)}} + [OPEX(p) + ESC(p)] * \sum_{m=1}^{5} \frac{1}{(1+r)^{YEAR(p,m)}} \quad (2)$$

In this formula, $ESC(p)$ is the primary energy source cost and the sum term accounts for discounted values over time using a discount rate r. The number of years in a period is denoted by $m$ and ranges from 1 to 5 years, and capital costs are discounted over the lifespan of the project $nn(p)$.

2. **Global warming potential:**

$$GWPtot = \sum_p [PGWP(p) + SGWP(p) + TGWP(p)] \quad (3)$$

The total GWP of the hydrogen supply chain represents the combined environmental impact of production $PGWP(p)$, storage $SGWP(p)$ and transport activities $TGWP(p)$, expressed in $CO_2$-equivalent emissions.

## Case study

The Occitanie region in southern France is chosen as a first case study for offshore wind integration into hydrogen production. The imagined floating wind farm is located 30 km from the coast and has a capacity of 150 MW, consisting of 10 floating turbines, each with a capacity of 15 MW. As part of the offshore cell, the setup includes a centralized hydrogen production unit on a dedicated offshore platform directly connected to the wind farm. This fictitious scenario examines the potential impact on the regional hydrogen production mix if 150 MW of offshore wind energy were allocated to hydrogen production.

The region has been discretized into 13 cells, corresponding to its departmental boundaries. In this case study, the offshore cell acts fully as a hydrogen producer, with zero local hydrogen demand. We considered an offshore hydrogen production in this study as it seems to be one of the efficient configurations for offshore wind-to-hydrogen systems, as it allows for a direct coupling with the wind farm while minimizing transmission losses [5]. More configurations will be explored in future works. The produced hydrogen is transported through an undersea pipeline to the connected onshore cell, where it is stored and distributed to meet regional demand. Other energy sources onshore may complement offshore wind energy to meet hydrogen supply demands, either locally or through transport via tanker trucks. A simplified version of the previously explained territorial discretization of the case study is illustrated in **Figure 1**. Cost parameters for the onshore and offshore subsystems of the supply chain were extracted from [6], [9], and [10], as shown in **Table 1**.

**Table 1:** Cost parameters of key subsystems of the hydrogen supply chain

| Subsystem | CAPEX | OPEX (%/yr) |
|---|---|---|
| Onshore Electrolyzer (AEL) [6] | 866 $/kW | 2.2 |
| Offshore Electrolyzer (PEM) [6] | 1 543 $/kW | 4.4 |
| Desalination [9] | 6 687 $/kW | 3.0 |
| Compression/Liquefaction [10] | 3 000 $/kgH2/d | 4.0 |
| Offshore platform [6] | 250 000 $/kgH2/d | 1.0 |
| Pipeline [6] | 4 873 $/kW | 3.0 |

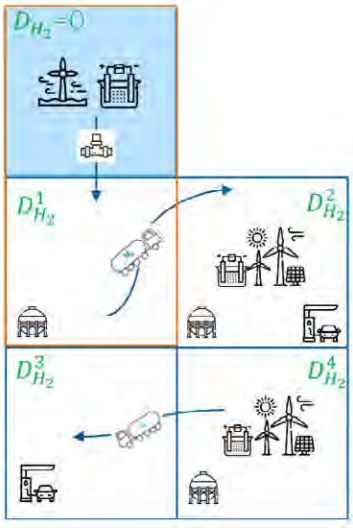

**Figure 1:** Simplified territorial discretization

The region's renewable energy availability – including the contribution from the offshore cell – is represented in **Figure 2** to provide a better visualization on resource allocation and distribution. An important assumption is the inclusion of nuclear energy, available in large volumes across all nodes through the power grid, which allows hydrogen production to benefit from both renewable and nuclear sources. **Figure 3** illustrates the combined energy availability of the interconnected offshore and onshore cell n°2.

The main parameters related to the primary energy sources considered in this study are summarized in **Table 2**: Levelized Cost of Energy (LCOE), Capacity Factor (Cap. Factor), and GWP. The capacity factor of each source is considered in the model through the calculation of energy availability, which reflects the actual amount of energy that can be generated over time based on the source's operational characteristics(Cap. Factor), and GWP. The capacity factor of each source is considered in the model through the calculation of energy availability, which reflects the actual amount of energy that can be generated over time based on the source's operational characteristics.

**Table 2:** Primary energy source parameters

| Energy source | LCOE ($/kWh) | Cap.Factor (%) | GWP ($kgCO_2eq/kgH_2$) |
|---|---|---|---|
| PV | 0.071 | 24 | 1.82 |
| Onshore wind | 0.055 | 38 | 1.08 |
| Offshore wind | 0.078 | 45 | 0.90 |
| Hydro | 0.085 | 51 | 1.68 |
| Nuclear | 0.060 | 85 | 1.24 |
| SMR | 0.160 | - | 10.3 |

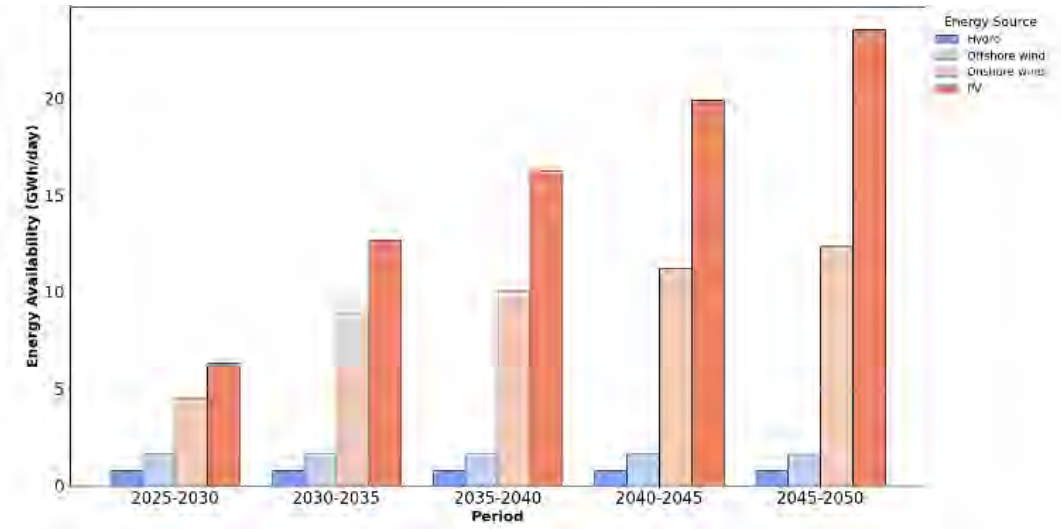

**Figure 2:** Availability of renewable energy sources in Occitanie [11],[12]

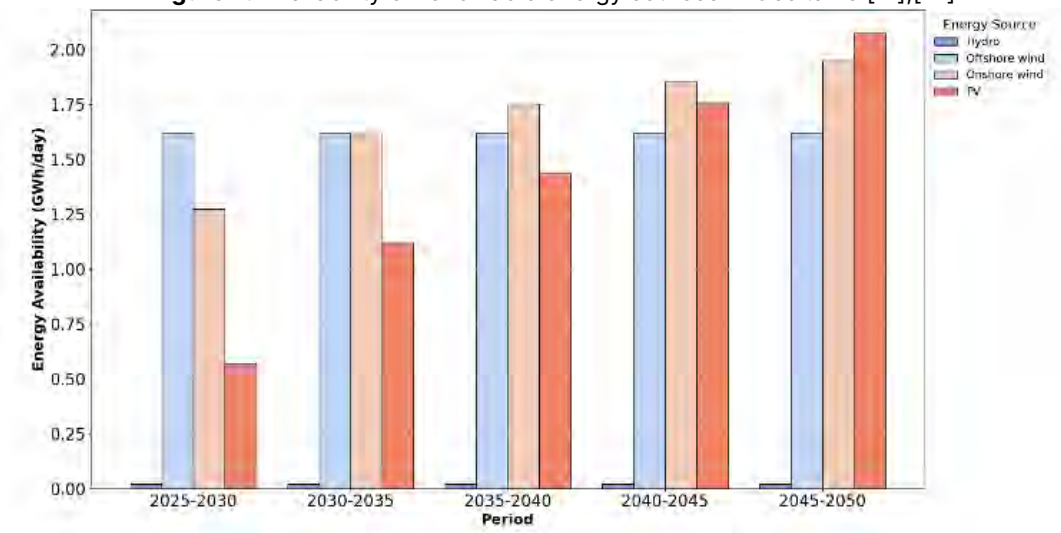

**Figure 3:** Availability of renewable energy sources in cell n°2 [11],[12]

## RESULTS

In this study, two single-objective optimization scenarios – minimizing cost and global warming potential – were evaluated to assess the competitiveness of hydrogen production from offshore wind energy. In a similar manner to the LCOE, a LCOH (Levelized Cost of Hydrogen) is calculated for hydrogen.

Using a multi-period approach, the LCOH is weighted by hydrogen demand across all periods. This method accounts for the varying significance of each period in the total hydrogen demand, as periods with lower demand have less influence on the overall LCOH. The LCOH is calculated as follows:

$$LCOH = \sum_p \frac{DT(p) * LCOH(p)}{\sum_p DT(p)} \quad (4)$$

where $DT(p)$ represents the hydrogen demand in period p.

With TDC minimization, a LCOH of 2.4 \$/kg$H_2$ is obtained. However, this economic optimization results in a trade-off with environmental sustainability, as evidenced by a GWP value of 8.84 kg$CO_2$eq/kg$H_2$. This outcome is directly linked to the resulting energy mix, as illustrated in **Figure 4**. During the initial period, the mix is mainly composed of renewable sources (78% onshore wind and 22% PV), driven by relatively low hydrogen demand, which does not justify the activation of a SMR plant. As demand increases in subsequent periods, SMR is introduced into the energy mix and plays a dominant role in this cost-driven configuration due to its lower capital costs and its ability to meet demand efficiently.

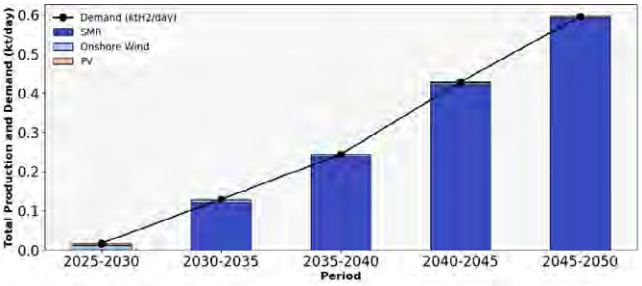

**Figure 4:** Total production and hydrogen demand for the TDC scenario

In contrast, the environmental approach results in a significantly lower GWP value of 1.24 $kgCO_2eq/kgH_2$, which, however, leads to an increase in the LCOH to 8.93 $/kgH_2$, as offshore wind is integrated into the mix with onshore wind and nuclear energy (**Figure 5**), given the higher CAPEX associated with these technologies. Offshore wind, being the least carbon-intensive option, emerges as one of the primary energy sources. As time progresses, offshore capacity is fully utilized, prompting the integration of onshore wind to meet additional hydrogen demand as it increases over time. This shift reflects a progressive reliance on renewable sources.

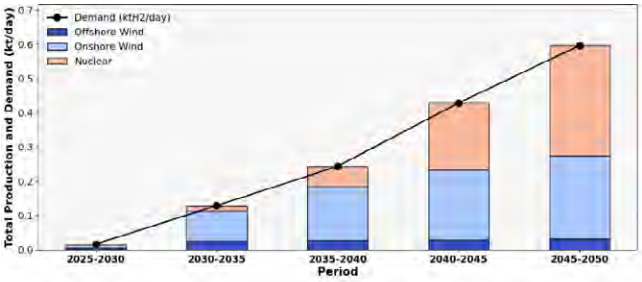

**Figure 5:** Total production and hydrogen demand for the GWP scenario

In this scenario, hydrogen produced offshore is transported via an undersea pipeline to cell n°2, the closest onshore cell. While offshore wind energy is the least carbon-intensive source, one might expect its hydrogen to be prioritized; however, the transport of hydrogen to other cells is constrained. Specifically, offshore hydrogen is primarily routed to cell n°5, due to its proximity to cell n°2, to meet the local hydrogen demand. This configuration is a direct consequence of the scenario's objective to minimize greenhouse gas emissions. Transporting hydrogen over long distances via tanker trucks would increase the carbon footprint. The hydrogen demand in other cells is met using alternative energy sources which are locally available in the cell such as onshore wind and nuclear, which have higher carbon emissions but do not require onshore transport. **Figure 6** illustrates the deployment of the hydrogen supply in the Occitanie region from the first period to the final one, for both optimization scenarios. The different technologies are represented by colored shapes with the numbers inside indicating the quantity of production plants implemented for each source. An important limitation of the current analysis is the assumption that existing electricity sources are fully mobilized for hydrogen production. In practice, only the surplus electricity—available after meeting direct regional demands—would be realistically allocated for hydrogen production. This simplification may overestimate the available energy and influence both cost and environmental outcomes. Future work should refine the model by incorporating detailed regional electricity consumption data, ensuring that only the remaining, truly available electricity is used in the hydrogen production calculations.

Under TDC minimization, electrolysis is the dominant production mode, driven by the low demand during the first period, with a single hydrogen flow from cell n°9. As demand increases, however, the scenario shifts significantly, with SMR becoming the leading technology, resulting in a centralized supply chain and hydrogen transport across cells. In the GWP minimization scenario, electrolysis dominates again, but with a decentralized supply chain. The analysis confirmed the antagonism between the criteria observed in previous studies like [8] and highlights the importance of adopting a multi-objective optimization approach. This is particularly evident when considering the significant disparities between the results of single-objective optimizations. The range obtained for GWP includes the value of 3.38 $kgCO_2eq/kgH_2$, which represents the emission threshold for hydrogen to be considered low-carbon, as defined by European Regulation 2023/1185, further reinforcing the need to balance environmental and economic criteria in the optimization process [13].

## CONCLUSION

The model developed for this study aimed to assess the feasibility and competitiveness of hydrogen production from offshore wind energy. The Occitanie region serves as a case study.

The TDC scenario showed the economic benefits of carbon-intensive methods like SMR, though at significant environmental costs. In contrast, the GWP scenario showcased offshore wind's capacity to lower emissions but required higher economic investment due to offshore infrastructure.

The methodology can be further improved with a multi-objective analysis, which is essential to balance these competing priorities. Future work should explore alternative configurations for integrating offshore wind into hydrogen systems, deepen the understanding of offshore modeling to yield more specific results, and account for wind intermittency to achieve a more refined

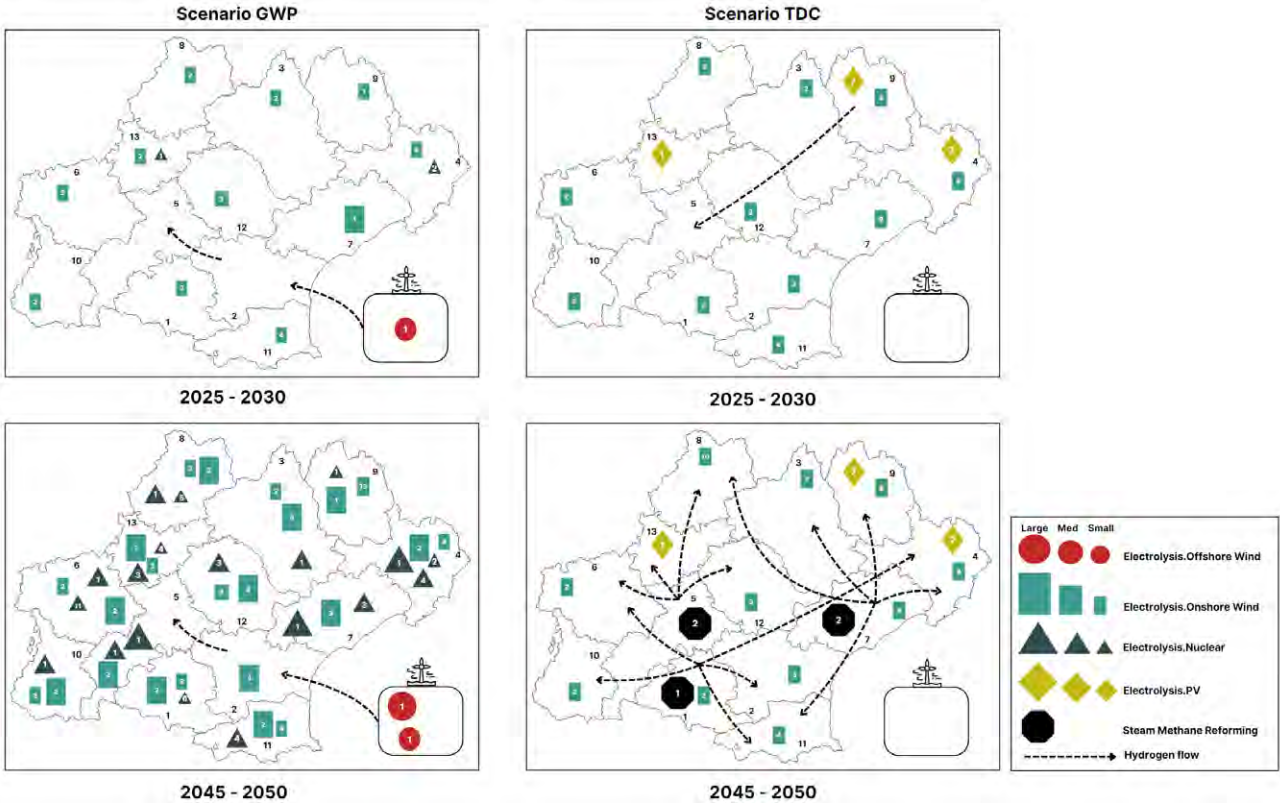

**Figure 6:** Evolution of hydrogen production plants distribution in Occitanie from period 1 to 5

temporal scale. For this study, tanker trucks are selected as the onshore transport option due to their practicality for short-distance distribution and the flexibility they offer in early deployment phases, where hydrogen supply routes remain adaptable. However, to enhance the realism of the model, future work will revisit transport assumptions and consider pipeline-based hydrogen transport at longer time horizons for a more accurate representation. Additionally, it is important to improve the realism of electricity availability for hydrogen production, by considering the remaining electricity after direct regional demands are met, rather than assuming full mobilization of existing sources for hydrogen production.

## ABSTRACT

Deriving accurate cost projections associated with producing hydrogen within the context of an energy-export paradigm is a challenging feat due to non-deterministic nature of weather systems. Many research efforts employ deterministic models to estimate costs, which could be biased by the innate ability of these models to 'see the future'. To this end we present the findings of a multistage stochastic model of hydrogen production for energy export (using liquid hydrogen or ammonia as energy vectors), the findings of which are compared to that of a deterministic programme. Our modelling found that the deterministic model consistently underestimated the price relative to the non-deterministic approach by \$ 0.08 – 0.10 $kg^{-1}(H_2)$ (when exposed to the exact same amount of weather data) and saw a standard deviation 40% higher when modelling the same time horizon. In addition to comparing modelling paradigms, different grid-operating strategies were explored in their ability to mitigate three critical co-sensitive factors of the production facility: high-cost hydrogen storage, uncertainty in weather forecasting and sluggish production processes. We found that a 'grid-wheeling' strategy substantially reduces the production cost for a solar system (by 16% and 21% for $LH_2$ and $NH_3$, respectively) due to its ability to guarantee the return of energy borrowed overnight during the day, but was not effective for the wind system, due to the non-periodic nature of aeolian weather patterns.

**Keywords**: Hydrogen, Non-Deterministic Programming, Non-Convex Optimisation, Stochastic Modelling.

## INTRODUCTION

The fervent interest in hydrogen's use as a decarbonisation tool has begun to show early signs of stagnation, primarily due to challenges associated with bridging its high production cost to that necessary to support its use in industry. However, in a net zero paradigm, many projections still see the deployment of the hydrogen economy as unavoidable, due to challenges associated with decarbonising specific 'hard-to-abate' sectors such as aviation, heavy industry and ammonia production.

Whilst technological innovations will substantially influence the prospects of the hydrogen economy, there is still a significant opportunity to reduce costs through optimal supply chain planning and design. This has led to hydrogen production within an export paradigm being a very active research area within the field of process systems engineering.

In order to design supply chains which operate at minimal cost, many research efforts employ deterministic optimisation with cost-minimising objectives. These supply chain models are unavoidably complex, due to the need to account for the dynamic nature of weather systems. There are numerous approaches available to account for the influence of weather system dynamics on the design of the hydrogen value chain. Some research efforts elect to use fixed capacity factors [1,2], a strategy which significantly simplifies the computational load, but is known to underpredict the cost of production by approximately 60% [3].

Other research efforts employ time-indexed Mixed-Integer-Programming, taking meteorological data at hourly intervals for a representative years' operation [4,5]. This modelling approach is, naturally, significantly more computationally demanding than employing fixed capacity factors, but in return cost estimates are more

realistic. In order to mitigate this increase in complexity, some of these papers elect to cluster the meteorological time-series [5,6], employing different strategies to ensure time-critical decisions are still made accurately.

Stochastic optimisation allows for decisions to be made in stages, reflecting the influence of uncertainty on the optimal planning and operation of stochastic processes. This methodology offers numerous benefits as it is able to limit the foresight the optimisation model has, but does so with increased computational load. A further benefit of this methodology is that it allows for a better quantification of the cost-benefit yielded by operational strategies which aim to mitigate the cost of uncertainty in weather (such as having a grid connection).

Whilst some studies have used similar methodologies (i.e., those which quantify the influence of uncertainty) on liquid hydrogen or ammonia production systems [7,8,9], they have yet been used in a comparative context and to evaluate the cost-benefit yielded by specific operational strategies. As such, this research aims to do the following:

- Compare the cost estimates of a multistage stochastic model for hydrogen production, against those of a deterministic model.
- Quantify the cost-benefit of different grid operational strategies, such as grid wheeling (a strategy where energy can be 'borrowed' from the grid if it is returned within a fixed time period) and compare this benefit between $LH_2$ and $NH_3$.

# METHODOLOGY

## Model Description

This model is of a hydrogen production facility, for export and thus employs either liquefaction or Haber-Bosch synthesis to convert the hydrogen to a form that is suitable for long distance transportation. For the solar system, the facility is located in the north of Chile and the south of Chile for the wind system. A brief overview of the 'production model' is given, diagrammatically, in the centre of figure 1. The objective of this model was to minimise the levelised cost of hydrogen, the equation for which is shown below in equation 1.

$$\mathrm{LCOH} = \frac{\sum_{t=0}^{T_f}\left[\frac{C_{op}}{(1+r)^n}\right]+C_{cap}}{\sum_{t=0}^{T_f}\left[\frac{8760}{h_f(1+r)^n}\sum_{h=0}^{h_f}\dot{m}_{H_2}(h)\right]} \quad (1)$$

Where $C_{op}$ is the annual operating cost of all equipment, $r$ is the discount factor, $C_{cap}$ is the capital cost of all equipment, $h_f$ is the number of hours modelled (serially), $T_f$ is the lifetime of the plant, $\dot{m}_{H_2}(h)$ is the hourly (mass) production of $H_2$.

The scale factor for this system is the number of parallel trains employed for the Haber-Bosch or Liquefaction process, with 5 and 12 trains used for each respectively. This enabled the hydrogen production to be a free variable, meaning the influence of weather variations manifested in the weekly production quantities of hydrogen.

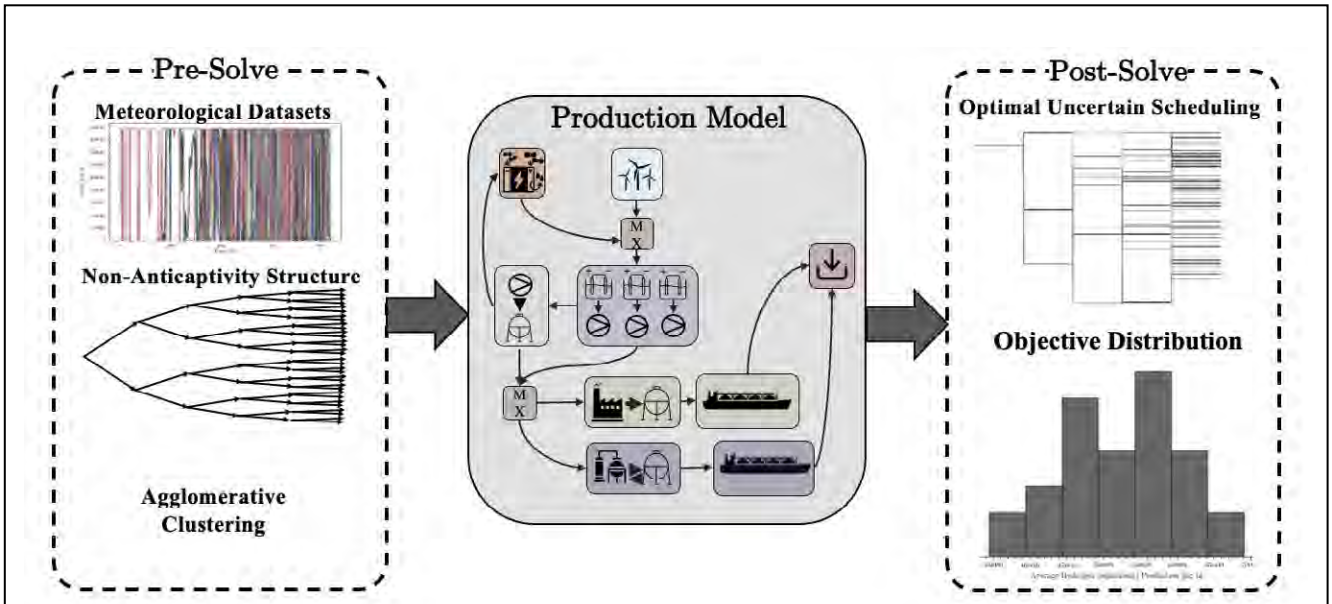

**Figure 1:** Diagram showing the modelling work flow for the stochastic systems modelling. During the pre-solve stages of the modelling, meteorological datasets are sampled and subsequently agglomeratively clustered using Ward's method [10]. Then, a non-anticipativity structure is produced using indexing rules in order to generate a contiguous time-series, which is sampled from the clustered weather dataset.

This, unavoidably so, results in the system being non-linear as both the system Net-Present-Cost (analogous the numerator of the LCOH quotient) and discounted lifetime hydrogen production (the denominator) were endogenous optimisation variables. The strategies involved in simplifying and solving this formulation are discussed in the forthcoming section.

## Mathematical Formulation

The optimisation problem is formulated as a non-convex mixed integer quadratic programme, of structure that is shown below:

$$\min_{x,y} \; f(x,y)\cdot[g(x,y)]^{-1}$$

$$\text{s.t.} \quad B\boldsymbol{x} + C\boldsymbol{y} \le \boldsymbol{a}$$

$$0 \le x \le \boldsymbol{x^u}$$

$$0 \le \boldsymbol{y} \le \boldsymbol{y^U}$$

$$\boldsymbol{x} \in \mathbb{R}^n, y \in \mathbb{Z}^m$$

Where: B $\in \mathbb{R}^{n\times l}$, C $\in \mathbb{R}^{m\times l}$, $\boldsymbol{a} \in \mathbb{R}^l, \boldsymbol{x^u} \in \mathbb{R}^n, \boldsymbol{y^U} \in \mathbb{Z}^m$. This form of model can be solved iteratively using the Dinkelbach algorithm for fractional programming problems [10]. The solution approach involves replacing the objective with a linearised form (equation 2).

$$\lambda g(x,y) - f(x,y) \tag{2}$$

This modified sub-problem is subsequently solved iteratively, updating the value of $\lambda(\tilde{x},\tilde{y})$ in accordance with equation 3 after each iteration.

$$\lambda(\tilde{x},\tilde{y}) = f(\tilde{x},\tilde{y})\cdot\ [g(\tilde{x},\tilde{y})]^{-1} \tag{3}$$

Where $\tilde{x}, \tilde{y}$ correspond to the optimal values from the previous solution. This means, given sufficient iterations, the value of the subproblem's objective will converge to 0 at $\tilde{x} = x^*$.

$$\lim_{(x,y)\to(x,y)^*} [f(x,y) - \lambda^* g(x,y)] \to 0 \tag{4}$$

In this case, this is iterated subject to the convergence condition shown in equation 5 (with $\varepsilon = 0.05$ used in these studies).

$$\lambda g(x^*,y^*) - f(x^*,y^*) \le \varepsilon\,\lambda \tag{5}$$

Casting context to the system model at hand, the linearised equation is the Net-Present-Value (NPV) of the system, where $\lambda$ is the sale price per kg of hydrogen. The LCOH is minimised when the NPV = 0, i.e. the sale price is equal to the unit production cost.

In order to simplify the computational complexity of this programme, as shown in figure 1, the model employs agglomerative clustering for the aeolian time series. This reduces the number of variables and equations in the model by clustering together identical values, thus improving tractability whilst minimising accuracy loss. For this model, Ward's method of agglomerative clustering was employed [11], with hierarchical grids to ensure key time-dependent decisions could still be made.

This clustering is performed as the initial pre-solve stage and influences the indexing of the stochastic programme's formulation. This is all handled by a standalone python module, called PyStochOpt, for which more information is given in the digital supplementary information.

## Multistage Stochastic Programme

The objective of the stochastic programme was to model a months' operation of a hydrogen production facility (for export), using a *multistage* stochastic model in order to manifest the influence of non-deterministic weather forecasting on the optimal planning and operation of the facility. For this model, we take our meteorological system to be a stochastic process, $\{Z_n\}_{n\in N_s}$, defined on the probability space $(\Omega, \mathcal{F}, \mathbb{P})$. Here, for each $n$, $Z_n$ is defined to be a random vector consisting of 168 random variables.

In context of the above problem description, each random vector consists of a weeks' renewable energy production, with the index $h \in (1,2,\dots,168)$ enumerating a contiguous set of data. To reduce model complexity and size, this programme employs an inheritance-based indexing structure, rather than traditional non-anticaptivity constraints.

Specifically, for each $n \in (1,\dots,4)$, let $\mathcal{F}_n := \sigma(Z_1,\dots Z_n)$ denote the $\sigma$-algebra generated by the random variables up until week $n$. Subsequently, the set of time-dependent decision variables: $\{x_t, y_t\}$ are enforced to be $\mathcal{F}_n$-measurable, where $n$ is the current week of operation given hour $t$, and is determined in accordance with equation 6.

$$n := \left\lfloor \frac{t}{168} \right\rfloor \tag{6}$$

This ensures that the model is not able to anticipate the future perfectly and can only make decisions based on the realised values of the stochastic process, up to week $n$. Regarding the equations used to model the system, equations 1-34 and 49-55 were taken from [5] and used in this study.

## Single-Stage Deterministic Programme

For the counterfactual analysis, a deterministic analogue to the abovementioned stochastic programme was developed. In order to give consistency and comparability between the studies, the deterministic model uses the same formulation as the stochastic programme, but with a single stage.

The stochastic programme with three stages and three branches requires 40 distinct weeks weather data (27 + 9 + 3 + 1), in order to model the four weeks' operation. As such, in accordance with the first aim of this research, two deterministic models were developed: one with 4 weeks' data, and one with 40 weeks data.

## Modelling Scenarios

In order to achieve the second and third aim of this research, a series of modelling scenarios in the form of Pareto optimal fronts, were developed. For each front, the analyses were repeated for both liquid-hydrogen and ammonia producing facilities, each employing both Solar and Wind power respectively (i.e., four different scenarios per front). These fronts studied the following operational strategies:

- Variations in hydrogen price. This was employed to study the behaviour of the abovementioned Dinkelbach algorithm. These price variations will also be used to study the behaviour of the deterministic model.
- Cost of employing a grid connection. Here, the grid energy cost, as a fraction of the levelised cost of power (for the wind or solar farm), was varied.
- The period at which the model may 'grid wheel'. As aforementioned, grid wheeling is an operational strategy allowed by some grid operators, such as in South Africa and Egypt.

# RESULTS AND DISCUSSION

## Dinkelbach Algorithm

Figure 2, below, shows the findings of employing the Dinkelbach algorithm for the wind production model. The findings of the solar model showed similar results and as such are not repeated here (but can be found in the digital supplementary information).

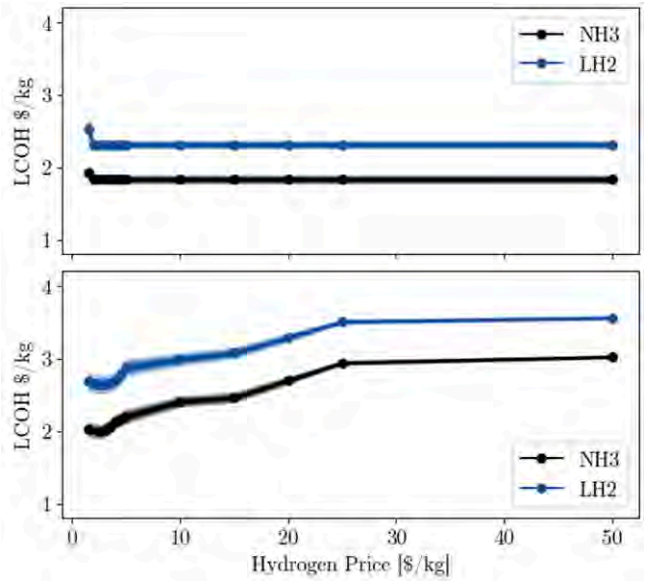

**Figure 2:** Pareto front for the grid connected (top) and islanded (bottom) Dinklebach algorithms. The shaded region represents the spread in LCOH from each of the leaf-nodes of the multistage stochastic model (27 total).

It is clear to see that the presence of the grid connection has a significant influence on the capacity of the production process to 'adapt' to different hydrogen prices. This manifests through varied investments in hydrogen storage. As such, when the hydrogen price is low, the model will elect to curtail excess energy.

In figure 3, below, we see the influence of employing the stochastic programme as opposed to the deterministic. In general, there is more 'noise' in the predictions as opposed to those shown in figure 2, and the deterministic model consistently *underpredicts* the cost of hydrogen production by an average of $ 0.08 $kg^{-1}(H_2)$ for $LH_2$. The case is similar for the $NH_3$ production model, but with a greater average under-prediction of $ 0.10 $kg^{-1}(H_2)$, which is proportionally more significant given the lower average production cost of $NH_3$. It is of note that both models are given the same amount of weather data and, as such, the difference in cost observed is due to the *overoptimised* nature of deterministic models.

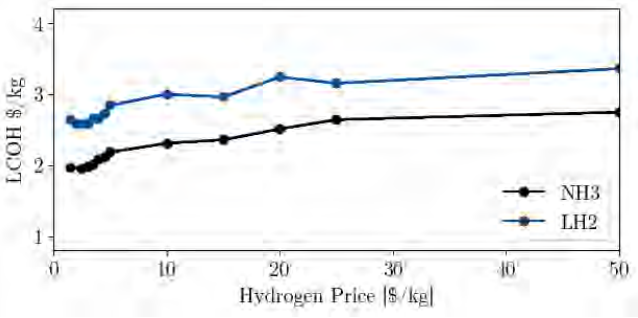

**Figure 3**: Pareto front showing an islanded Dinkelbach algorithm for a wind-powered deterministic model. This is for comparison to the bottom Pareto front of figure 2. This model employs a continuous series of 40 weeks weather data.

To understand the consistency of these models when modelling the same period (4 weeks), the models were solved numerous times whilst varying the random seed used in sampling the meteorological dataset. The deterministic model saw an average cost of $2.80 $kg^{-1}(H_2)$ with a standard deviation of $ 0.25 $kg^{-1}(H_2)$ for $LH_2$ and $2.23 $kg^{-1}(H_2)$ with a standard deviation of $ 0.21 $kg^{-1}(H_2)$ for $NH_3$ (for the islanded, wind powered systems). However, the stochastic model saw average production costs of $2.92 $kg^{-1}(H_2)$ with a lower standard deviation of $ 0.16 $kg^{-1}(H_2)$ for $LH_2$ and $2.26 $kg^{-1}(H_2)$ with a standard deviation of $ 0.16 $kg^{-1}(H_2)$ for $NH_3$. This finding serves to evidence the benefit of including non-determinism in cost estimates when modelling a short time period, as it enables much greater exposure of the model to a variety of weather patterns.

## Grid Energy Cost

Figure 5 shows the influence of varying the cost of

grid energy on the LCOH. An interesting observation is how the grid-energy 'buffers out' any uncertainty in weather energy, when it is available at a low cost. When the cost is high, the model elects to curtail more energy, meaning variations in weather have a more significant influence on the profitability of operation.

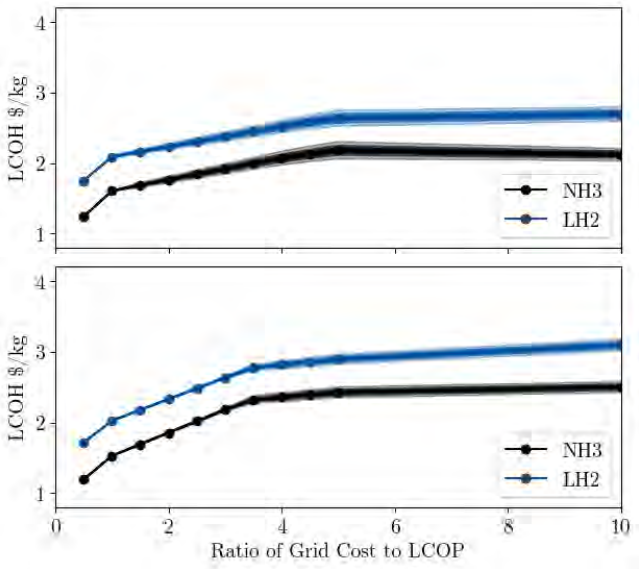

**Figure 5:** Pareto fronts for a grid-connected wind-powered system (top) and a grid-connected solar powered system (bottom). LCOP stands for levelised cost of power, referring to the cost of energy from the wind and solar farm, respectively.

Below a cost ratio of 1, the model will elect to not build a solar or wind farm as it is cheaper to use the grid energy directly. Above this ratio, the solar model uses the grid energy in lieu of storing or curtailing excess energy. The wind model, however, will use some grid energy, but will also begin curtailing energy and investing in storage (evidenced by the increased spread in LCOH values). This is because the capacity factor for the solar farm is lower than that of the wind, meaning the increase in output begotten when using grid energy warrants paying a high price for it, rather than using a curtailment strategy.

When the grid cost becomes excessively high, both models elect to employ storage and curtailment and do not use any grid energy. When not using grid energy the model is less able to 'buffer out' the variations in wind output and, as such, directly influences production quantities of hydrogen.

## Grid Wheeling

The analysis of grid wheeling allowed for unlimited energy to be 'borrowed' within a given period (again, contingent on it being returned within the same period). The pareto fronts demonstrating the results of these analysis are shown in figure 6.

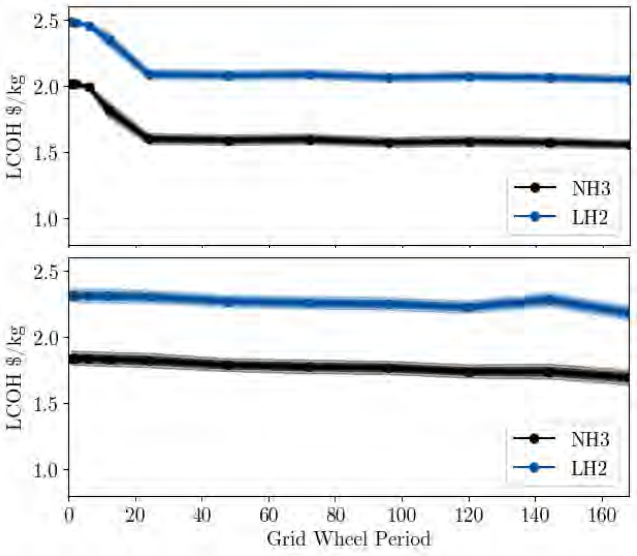

**Figure 6:** Pareto front for variations in the greed wheeling 'period' for the solar (top) and wind (bottom) system.

It is clear to see from figure 6 that enabling the system to grid-wheel offers a substantial benefit for the solar powered system when the wheeling period is above 24 hours, at which the model will wheel up to 42% of the solar farm's capacity. This makes sense given the diurnality of solar production. For the wind system, the benefit is much less significant, which we hypothesise to be due to the more stochastic nature of aeolian weather patterns, meaning it is difficult to guarantee that any 'borrowed energy' can be returned in a singular fixed interval.

## CONCLUSIONS

This research aimed to study the potential benefit yielded by employing a multistage deterministic model for hydrogen export systems and use it to study the cost-benefit yielded by different operational strategies. The stochastic model yielded some benefit over the deterministic system including highlighting the slight underestimation of the cost of hydrogen when compared to the deterministic model and the reduced standard deviation of LCOH prediction when modelling the same time period.

Another key benefit of the stochastic system is in its ability to model a solar system for a short time period. This is important as it is more challenging to cluster a solar time series than an aeolian, due to it being more continuously dynamic in nature. This challenge leads to many researchers using 'representative days' in order to model the solar time series, which assists in reducing computational load. Here, without clustering, the solar model was able to process 27 distinct 4-week weather patterns, giving a large exposure to different weather patterns whilst still solving in a reasonable time-frame.

Although the stochastic model offers slight improvements to the accuracy and repeatability of cost

estimation, it is more computationally intense and scales geometrically with the number of decision-making stages, hence this analysis was limited to studying a months' operation. Whilst a month is a functional period to study in this context, it is insufficient when studying a full value chain which would include shipping between supply and demand regions.

Grid wheeling was found to be very effective in a solar system due to its ability to guarantee the return of energy in a given time period. There is a natural question as to the 'greenness' of wheeled energy, given on balance green energy is contributed to the grid and green energy is removed; but the energy used to produce the hydrogen when 'borrowing' may not be green itself.

Whilst the infrastructural requirements of endorsing a grid-wheeling approach would be significant, the potential economic remuneration associated with cutting hydrogen export costs by up to 20% would serve to stimulate interest in such strategies. As such, it is not untenable given the broad political interest in hydrogen export with certain nations. However, whilst this strategy shows promise, some nations have set limits on the amount of energy that can be wheeled, which could serve to limit the economic benefit of such an approach.

## ABSTRACT

Fossil fuel reliance in the transportation sector remains a leading contributor to global greenhouse gas emissions, underscoring the urgent need for renewable alternatives like biodiesel. Derived from renewable feedstocks, biodiesel can reduce emissions, enhance energy independence, and support rural economies. However, its production faces challenges such as low energy efficiency, process optimization barriers, and the limited utilization of byproducts like glycerol, which elevate costs and hinder large-scale adoption. This study addresses these challenges by developing an integrated framework for biodiesel production and byproduct valorization, supporting the long-term decarbonization of biofuel production. Three key feedstocks—refined palm oil, rapeseed oil, and soybean oil—are evaluated for biodiesel yield. The single-step transesterification process is enhanced through a two-stage approach, optimizing fatty acid methyl ester conversion under varying methanol and NaOH catalyst split ratios. Glycerol valorization strategies, including combustion, purification, and anaerobic digestion, are analyzed to improve economic and environmental sustainability. Using mixed-integer linear programming (MILP), the study minimizes total costs by balancing operational and capital expenditures while incorporating process integration constraints. The findings provide actionable insights into cost-effective and sustainable biodiesel production pathways, promoting the broader adoption of biofuels in the transition toward net-zero emissions.

**Keywords**: Process Design, Alternative Fuels, Energy Efficiency, Techno-economic optimization, Mixed Integer Linear Programming (MILP)

## INTRODUCTION

The extensive reliance on fossil fuels as an energy source is a primary contributor to greenhouse gas emissions, driving global warming and environmental degradation. The combustion of fossil fuels disrupts the carbon cycle by releasing carbon that has been long sequestered underground into the atmosphere. In contrast, biomass represents the fourth largest energy source after coal, oil, and natural gas, making it a crucial renewable alternative. Biomass-derived fuels can contribute to a net-zero carbon cycle, as the carbon released during combustion is offset by the carbon absorbed during feedstock growth. Biodiesel has emerged as a promising alternative to fossil-based diesel for use in compression ignition engines due to its significant environmental benefits. It can be produced from a variety of renewable feedstocks, including vegetable oils, animal fats, and waste cooking oils. The production of biodiesel typically involves a transesterification reaction, in which triglycerides react with an alcohol—predominantly methanol—in the presence of an acid or alkali catalyst. Alkali-catalyzed transesterification, commonly using sodium hydroxide (NaOH), is highly efficient but requires feedstocks with a free fatty acid (FFA) content below 1%. Degummed and neutralized vegetable oils are ideal feedstocks, achieving high biodiesel yields (>98%). Figure 1 shows the reaction mechanism where a triglyceride molecule undergoes three reversible steps to form three fatty acid methyl ester (FAME) molecules and one molecule of glycerol.

Excess of methanol is added to shift the reaction to the product side (Le Chatelier's principle of chemical equilibrium) [1]. The fatty acid composition varies among different vegetable oils. For instance, palm oil primarily consists of palmitic acid (C16:0) and oleic acid (C18:1), soybean oil contains more than 50% linoleic acid (C18:2) along with oleic acid, and rapeseed oil is rich in oleic acid (>60%).

The choice of feedstock significantly impacts the energy efficiency and economic feasibility of biodiesel production. This is often assessed using the Net Energy Ratio (NER), which is calculated by dividing the energy content of the produced biodiesel by the total energy consumed throughout its life cycle, including crop cultivation, oil extraction, and biodiesel production. A study in Thailand estimated the NER of palm oil biodiesel at 2.42, with an annual biodiesel energy output of 94.7 GJ per hectare and a total life cycle energy consumption of 39.16 GJ/ha·y [2]. Similarly, rapeseed biodiesel was found to have an NER of 1.69 when accounting for the energy contribution of two by-products—rape meal and glycerol [3]. In comparison, soybean biodiesel had an estimated NER of 1.97 after mass allocation of all by-products [4]. Both rapeseed and soybean biodiesel exhibit lower energy yields than palm oil, with output of 26.7 GJ/ha·y and 17 GJ/ha·y, respectively. Additionally, these studies highlight the substantial fossil energy requirements associated with biodiesel production, particularly the energy consumed in methanol synthesis, which is a crucial component of the transesterification process.

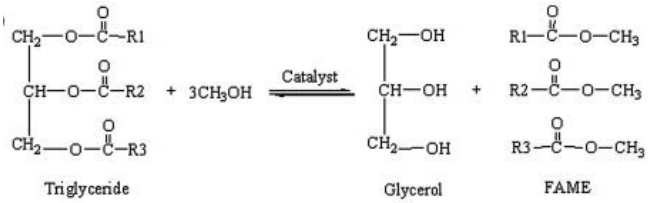

**Figure 1.** Trans-esterification reaction mechanism. R1, R2, and R3 are long chains of fatty acids and vary with the source of Triglyceride (feedstock).

This study focuses on the biodiesel production process from the extracted vegetable oil and aims to model the production process of trans-esterification of Palm, Rapeseed, and Soybean oil along with the further conversion steps to get pure biodiesel. The model is then used to optimize the process design to maximize yield while minimizing reaction time and methanol consumption. The heat and mass streams are characterized, and process integration strategies are explored to improve the economic and environmental performance. In addition, every ton of biodiesel production generates approximately 100 kg of crude glycerol as a by-product. Due to the presence of impurities such as methanol, catalysts, and water, crude glycerol has limited economic value and is classified as a hazardous material, restricting its disposal. To enhance its utilization, this study explores valorization pathways, including purification to pharmaceutical-grade glycerol (>99.5% purity) and anaerobic digestion for energy recovery. Although glycerol has a lower heating value (LHV) of 16.2 MJ/kg, as reported in [5], its high auto-ignition temperature and viscosity at room temperature create challenges for combustion, necessitating specialized burners for co-combustion with other fuels. Due to these technical constraints, crude glycerol combustion has not been considered in this process integration study.

## METHODOLOGY

The biodiesel production process was modeled in ASPEN Plus, using a reference flowsheet from Zhang et al. [6]. The model includes a transesterification reactor, methanol recovery column, water washing, glycerol purification, catalyst removal, and biodiesel purification. The reactor operates with a kinetic reaction model, while catalyst removal is modeled as a fixed conversion neutralization reaction. Water washing is simulated using a liquid-liquid extractor, and methanol recovery, glycerol purification, and biodiesel purification are carried out using RadFrac distillation columns. The composition profile of palm oil was taken from Che Man [7], and the reaction kinetic parameters were based on Narvaez et al. [8]. The reference model was adapted to simulate biodiesel production from rapeseed and soybean oils, with their triglyceride compositions sourced from the literature [9]. The triglyceride composition for rapeseed oil includes 36% OOO, 16% LiLnO, 15% OOLI, 13% POLi, 10% OOLn, 7% LiOLi, and 3% OPO, whereas soybean oil consists of 27% LiLiLi, 25% OLiLi, 19% PLiLi, 15% OOLi, and 13% PliO [10]. Here, "PLiO" represents a triglyceride with one palmitic acid (R1), one linoleic acid (R2), and one oleic acid (R3) chain, while "Ln" denotes linolenic acid. The reaction parameters were modeled similarly to the reference case using palm oil. All relevant components, including diglycerides and monoglycerides as reaction intermediates, were available in the ASPEN APV110 Biodiesel Database.

The model was used to evaluate biodiesel yields for palm, rapeseed, and soybean oils under varying reaction temperatures and residence times. As shown in Fig. 1, triglycerides and FAME molecules share the same chemical constituents, meaning that, theoretically, 1 ton of oil should yield approximately 1 ton of biodiesel. This serves as an indicator of the completeness of the transesterification reaction. The reaction yield was calculated using Eq. 1, and a summary of the feedstock compositions is provided in Table 1.

$$Yield = \frac{Pure\ biodiesel\ produced, FAME\ (\frac{ton}{hr})}{Input\ vegetable\ oil(\frac{ton}{hr})} \quad (1)$$

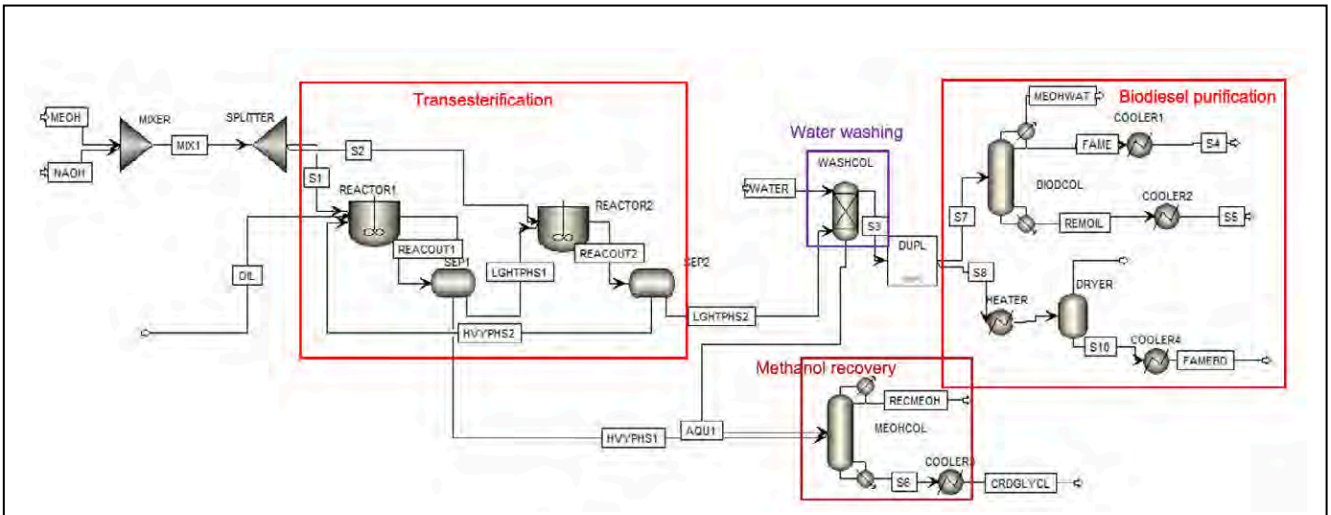

**Figure 2:** ASPEN Plus Model of the Biodiesel production considered. The two-step reaction is introduced to the reference model along with decanters. The heavier phase separated after the second reactor is sent back to the first reactor to reduce the methanol and Alkali catalyst consumption. This is as per the Lurgi process described in [12].

## Two-step Transesterification reaction

To reduce the reaction time for mass production and increase the biodiesel yield, the trans-esterification reaction is modeled in two steps. Previous studies have shown increased conversion yield when doing the reaction in two steps compared to the single-step reactions[11].

**Table 1:** Fatty acid constituents in three vegetable oil feedstocks considered for biodiesel production. They have been calculated based on individual triglyceride constituents in previous studies [7], [9], [10].

| Constituent | Percentage in Input Feedstock (%) | | |
|---|---|---|---|
| | Palm Oil | Soybean Oil | Rapeseed Oil |
| Oleic Acid | 40 | 22 | 67 |
| Linolenic Acid | 10 | 67 | 19 |
| Palmitic Acid | 45 | 11 | 5 |
| Linolenic Acid | - | - | 9 |
| Stearic Acid | 4 | - | - |
| Myristic Acid | 1 | - | - |

Figure 2 shows the ASPEN model with two reactors and gravity-based phase separators. The heavier phase from separator two is recirculated to Reactor 1, following the patented Lurgi process outlined in [12]. This modification reduces methanol and catalyst consumption while enhancing the reaction yield. The heavier phase from separator one, along with the water from biodiesel washing, is directed to the methanol recovery column, where excess unreacted methanol is recovered and returned to the reactors. The impact of varying methanol and catalyst split fractions on the two reaction steps is evaluated by comparing reaction yields for different values. The results are presented both with and without the implementation of the Lurgi process for rapeseed oil.

## Process Integration and Crude Glycerol Valorization

After methanol separation from glycerol, the remaining steam contains water and catalyst (NaOH). The catalyst is separated by adding phosphoric acid, with a neutralization reaction and a filter to precipitate out the salts. The resulting crude glycerol, though suitable for market sale, has a lower value. For pharmaceutical or food applications, high-purity glycerol is required, which is achieved through distillation columns. Given the high-water content (40-60%) in crude glycerol, mechanical vapor recompression (MVR) is employed to recover heat during the separation process. In ASPEN Plus, the mixture is heated to 110°C and expanded under a vacuum pressure of 0.5 bar. The separated vapors are directed to a two-stage compression process to generate steam at 2.5 bar, with an intercooler placed between stages to prevent the vapor temperature from exceeding 210°C, under steam compressor design constraints. The condensed water vapor, now substituting for fossil-based steam, is recycled back into the biodiesel water washing process, offering additional operational cost benefits. The model of these two options is depicted in Figure 3. After water evaporation, the resulting glycerol can also be directed to anaerobic digestion instead of the distillation column. Due to its high chemical oxygen demand (COD) and substantial volatile solids content, it is an ideal substrate for co-digestion, enhancing methane production as demonstrated in previous studies [13]

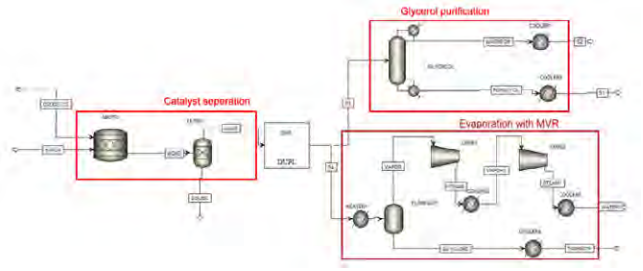

**Figure 3.** The crude glycerol valorization model considered in the process integration study.

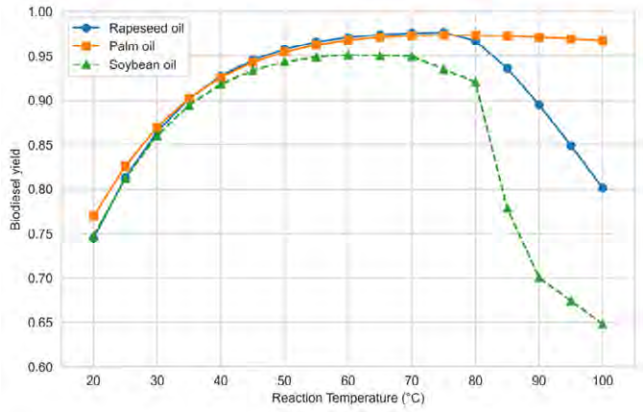
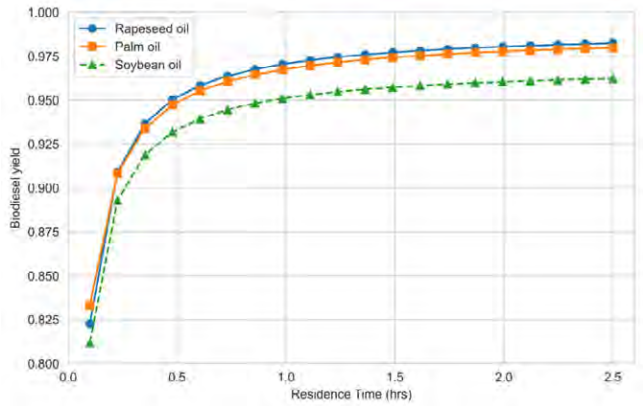
All mass and heat streams from ASPEN for the various models are integrated into the OSMOSE software. OSMOSE, developed as a system integration platform for multi-objective optimization at IPESE Lab, EPFL [14], allows for the integration of glycerol valorization routes and utilities into the biodiesel production process. The system is solved as a Mixed-Integer Linear Programming (MILP) problem to minimize total costs. Additionally, carbon emissions resulting from electricity and natural gas use are incorporated, with constraints placed on the total emission value to generate a list of decarbonization solutions for the biodiesel production process. The digestion of crude glycerol is modeled with a total solids content of 1000.8 g/L, and a volatile solids content of 947.8 g/L [13]. The Biomethane Potential (BMP) is 408 $Nm^3$ $CH_4$/kg glycerol, based on the composition of the resulting stream after glycerol-water evaporation, consistent with findings from previous studies [15][16].



## RESULTS AND DISCUSSION

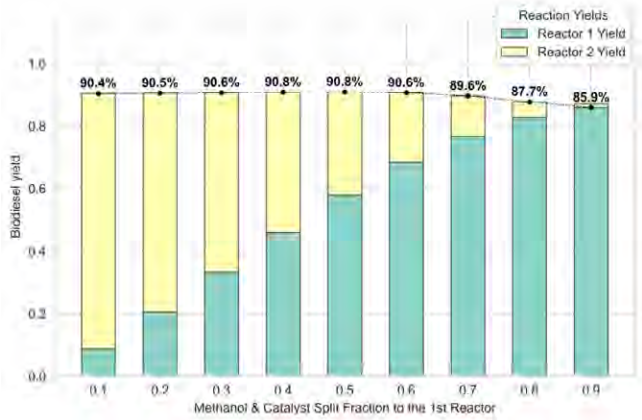
The biodiesel yield variation for three feedstocks is compared based on a single-step trans-esterification reaction model. Then, the results of the two-step reaction process for Rapeseed oil are shown, followed by the process integration part.



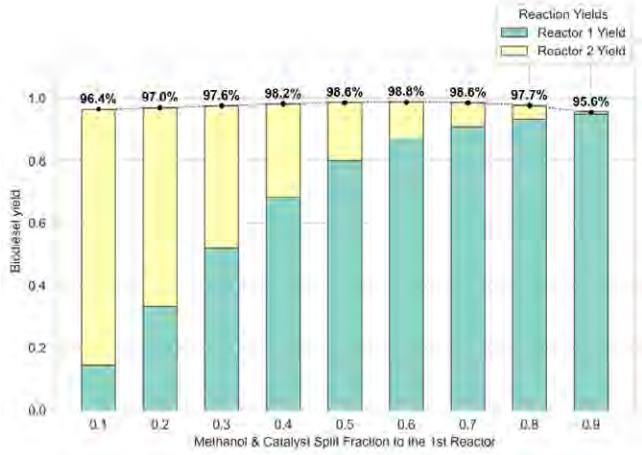
### Influence of Reaction parameters

Figure 4 illustrates the variation in reaction yield for Soybean, Rapeseed, and Palm oils at different operating temperatures and residence times in the reactor. These simulations were conducted using a 6:1 molar ratio of methanol to oil. Palm and Rapeseed oils achieve higher biodiesel conversion yields compared to Soybean oil. The optimal reaction temperatures are 80°C for Palm oil, 75°C for Rapeseed oil, and 60°C for Soybean oil. The yield increases steadily with residence time for all three feedstocks. For a 10-minute residence time at 60°C, more than 80% of the triglyceride content is converted to FAME molecules. The yield continues to increase non-linearly, with Soybean oil requiring over 1 hour to reach a 95% conversion yield.

As shown in Figure 4, even after a reaction time of 2.5 hours, Rapeseed oil achieved the highest yield of 98.2% at an operating temperature of 60°C. However, this is not optimal for mass production, and implementing a multi-step reaction could reduce the residence time while maintaining high yields. Figure 5 illustrates the yield variation in two reactors with different split fractions of methanol and NaOH. Without using the Lurgi process—i.e., sending the heavier phase from both separators back for methanol recovery while maintaining a 6:1 molar ratio—the conversion yields are lower. For a residence time of 12 minutes and a temperature of 60°C in both reactors, the total yield was only 90.8% for the 6:1 methanol-to-oil ratio (as shown in Figure 5a). This yield increased to 98.8% when the ratio was adjusted to 9:1, as shown in Figure 5b. The optimal split ratio was found to be 60% to Reactor 1. However, when the Lurgi process is used, reaction yields are higher and are at lower split ratios. Figure 5c demonstrates that a 99% yield can be achieved at lower operating temperatures and residence times with a 6:1 molar ratio. Recycling the heavier phase back to the first reactor significantly improves yields while reducing methanol consumption.



(a) Residence time is 1 hour for all the simulations



(b) The operating temperature is 60°C for all the simulations.

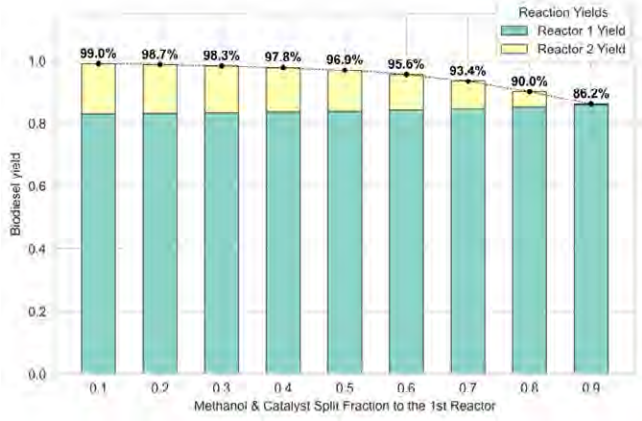


**Figure 4.** Reaction yield variation for different residence times and operating temperatures for three feedstocks. Influence of Two-step trans-esterification reaction

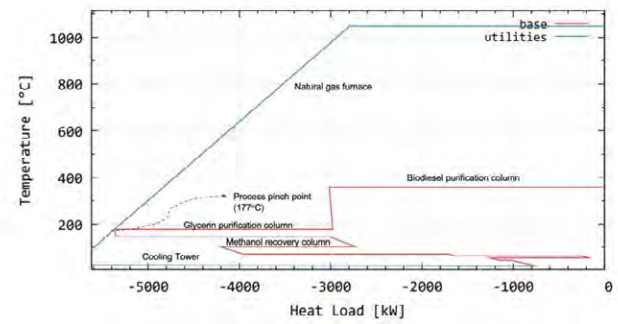
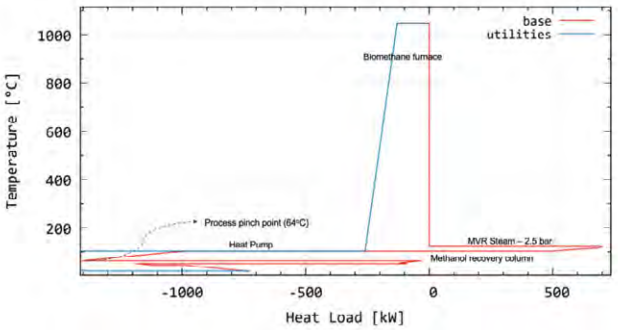
(a) Residence time is 12 min and operating temperature of 60°C for both reactors without the Lurgi process (Methanol ratio 6:1)



(b) Residence time is 12 min and operating temperature of 60°C for both reactors without the Lurgi process (Methanol ratio 9:1)



(c) Residence time is 10 min, and the operating temperature of 50°C for both reactors with the Lurgi process (Methanol ratio 6:1)

**Figure 5.** Reaction yield variation for different methanol-catalyst split fractions in the two reactors for Rapeseed oil

(a) With biodiesel and glycerol purification columns and all the heat coming from fossils resulting in minimal total cost.

(b) With biodiesel drying, crude glycerol anaerobic digestion, and MVR cycle with water recycling. A heat pump is also integrated to improve the exergy efficiency.

**Figure 6.** Integrated composite curves for two different configurations of the biodiesel production process.

## Process Integration

The streams from the two-step Lurgi reaction model for Rapeseed oil were integrated with a list of options. The heat cascade incorporates pinch analysis to maximize internal heat recovery, thereby minimizing the heating and cooling requirements of the biodiesel production process. Figure 6a presents the integrated composite curve (ICC) for the minimum total cost configuration, which includes biodiesel and glycerol purification columns, a natural gas furnace, and a cooling tower. This configuration results in the highest carbon emissions and low exergy efficiency. International standards specify a minimum of 96.5% FAME content in biodiesel. If the reaction yield falls below this threshold, the unconverted oil fraction in the stream after water washing must be separated, requiring a distillation column. However, with a yield exceeding 98% using the Lurgi process, the biodiesel drying process is employed instead of the purification column. The stream is heated to 115°C and expanded in a tank at 0.2 bar vacuum pressure. The dry biodiesel is then cooled to ambient temperature to maximize heat recovery. Unlike crude glycerol evaporation, integrating MVR is not cost-effective due to the lower water content (<0.2%). Figure 6b displays the ICC without the biodiesel and glycerol purification columns. The crude glycerol produced after evaporation is sent for anaerobic

digestion, and the methane generated from the purified biogas is partially used to supply process heat. The excess methane is injected into the gas grid, resulting in negative carbon emissions. Additionally, the steam generated from the integrated MVR cycle during glycerol water evaporation is used to supply process heat, reducing the size of the required gas furnace. The process pinch temperature of 64°C makes the methanol recovery distillation column's reflux condenser an ideal source for the heat pump. The heat pump extracts heat from below the pinch and supplies heat above the pinch to the column's reboiler at 100°C. This not only reduces heating requirements but also decreases the load on the cooling tower. In regions with a low-carbon electricity mix, the biodiesel production process can even become carbon-negative, as a result of the biomethane production from crude glycerol.

## CONCLUSION

The biodiesel production process from three feedstocks—palm, rapeseed, and soybean oil—was modeled in Aspen Plus, and reaction yields were compared under different operating temperatures and residence times. Palm and rapeseed oils exhibited similar yield values, while soybean oil had the lowest yield. A two-step transesterification reaction resulted in significantly higher biodiesel conversion (98.9%) at a much lower residence time compared to a single-step process (82.1% yield at 10 min residence time and 50°C). However, the two-step reaction required a higher methanol-to-oil ratio, increasing the energy demand for methanol recovery. The Lurgi process, which recirculates the heavier phase from the second reactor, reduced methanol and catalyst consumption, improving overall process efficiency. The optimal split ratio for the methanol-catalyst mixture was 10% to the first reactor.

Process integration strategies, such as heat recovery, heat pumps in methanol recovery distillation, and mechanical vapor recompression (MVR) for crude glycerol evaporation, improved exergy efficiency and reduced fossil steam consumption. Further sustainability gains can be achieved by valorizing crude glycerol, either through purification to pharmaceutical-grade glycerol or anaerobic digestion for biogas production. The developed methodology can be extended to optimize biodiesel production from second-generation feedstocks, including waste cooking oils and animal fats, enhancing both economic and environmental sustainability. The $CO_2$ generated from biogas purification can also be integrated with solid oxide fuel cells, enabling negative emissions and additional chemical production.

## ABSTRACT

This study aims to develop an optimization-based approach to design the carbon capture, utilization, and storage (CCUS) supply chain and analyze the optimal configuration and investment strategies. To achieve this goal, we develop an optimization model that determines the logistic decision-making to maximize the net present value (NPV) and minimize the net $CO_2$ emissions (NCE) of the strategies of the CCUS supply chain under logical and practical constraints. We estimate the technical (production scale and energy consumption), economic (capital and operating expenditure), and carbon-related ($CO_2$ emissions) parameters based on the literature. By adjusting major cost drivers and economic bottlenecks, we determined major decision-making problems in the CCUS framework, such as sequestration vs. utilization. As a real case study, the future CCUS system of South Korea was evaluated, which includes three major $CO_2$ emitting industries in South Korea (power plants, steel, and chemicals), as well as transportation modes and sequestration sites. As a result, we analyzed different design and operation strategies based on various objectives. We provided a strategic solution for national-level planning of the CCUS supply chain. The major finding of this study can support industry stakeholders and government policymakers by providing a practical guideline for investing in the deployment of CCUS.

**Keywords**: Carbon capture, utilization, and storage (CCUS), optimization, South Korea, MILP, supply chain

## 1. INTRODUCTION

Global warming is one of the most important issues for humanity, receiving significant attention from the scientific community. Carbon dioxide ($CO_2$) is one of the major greenhouse gases that can affect global warming. $CO_2$ emissions are mainly generated through three key areas: fuel combustion, industrial processes, and natural gas processing [1]. According to recent estimates, global $CO_2$ emissions from fossil fuel combustion have exceeded 37.1 Gt, marking a notable increase of over 2.7% compared to 2017. [2]. To achieve the 1.5°C target set by the Paris Agreement, substantial reductions in $CO_2$ emissions are required, amounting to 24 Gt of $CO_2$ per year by 2030, 14 Gt of $CO_2$ per year by 2040, and 5 Gt of $CO_2$ per year by 2050 [2, 3]. Achieving these reductions necessitates implementing advanced technological solutions, among which Carbon capture, utilization, and storage (CCUS) has emerged as a promising solution.

In the CCUS process, $CO_2$ is captured from air or industrial sources using carbon capture technology. Captured $CO_2$ is then transported to its destination into two main technological pathways. The first pathway is carbon capture and storage (CCS), where $CO_2$ is delivered to a designated storage site and permanently sequestered in geological formations, such as depleted oil and gas reservoirs or deep saline aquifers. The second pathway is carbon capture and utilization (CCU), which utilizes $CO_2$ as a key carbon feedstock for producing value-added products. CCUS technologies can reduce $CO_2$ effectively. For example, gasoline production can reduce more than 5 kg of $CO_2$ eq per unit of fuel [4]. However, the implementation of associated technologies within the industrial sector is challenging. The limitations are caused by the lack of a supply chain, including CCU and CCS with existing energy and industrial infrastructures.

Recently, a few studies have focused on addressing the CCUS supply chain design. Huang et al. examined the CCUS supply chain utilizing $CO_2$-enhanced coal bed methane ($CO_2$-ECBM) recovery [5]. Leonzio et al.

incorporated methanol (MeOH) production via dry reforming for CCU and developed the CCUS supply chain for Germany [6]. A few studies about the economic optimization of CCS are reported for distinct geographical characteristics: Klokk et al. for Norway, and Zhang et al. for China [7,8]. The preceding studies highlight the necessity of developing region-specific CCUS supply chain optimization models, for unique characteristics and constraints specific to each region. These models emphasize the significance of multi-stage planning in achieving efficient carbon management systems. Nevertheless, the expansion of the scope of research is imperative, integrating approaches that address multi-objective and multi-period scenarios. These approaches are essential for capturing the dynamic nature of $CO_2$ supply and demand, technological advancements, and fluctuating economic and regulatory landscapes.

In this study, we develop an optimization-based framework for the CCUS supply chain to integrate the overall CCUS infrastructure into the supply chain to maximize net present value (NPV). $CO_2$ is captured, compressed, and transported from $CO_2$ emission sources. After transporting captured $CO_2$, we consider the $CO_2$ utilization technologies, which involve the production of MeOH, and the $CO_2$ storage option, which includes the $CO_2$ intermediate storage terminals and offshore storages to sequester $CO_2$. Then, two distinct scenarios with different criteria (social cost of $CO_2$, and $CO_2$ capture rate) are analyzed over a multi-period framework. The proposed model presents strategies that incorporate economic and environmental considerations while addressing future scenarios.

## 2. METHODOLOGY

### 2.1. Problem statement

The main objective of this study is to develop an optimization-based approach to design a supply chain incorporating both CCS and CCU. The proposed CCUS supply chain optimization model comprises the following components: $CO_2$ sources, $CO_2$ capture processes, transportation infrastructure, $CO_2$ storage facilities, and $CO_2$ utilization systems. $CO_2$ storage facilities include intermediate storage terminals and offshore storage sites, while $CO_2$ utilization focuses on the MeOH production process via direct hydrogenation. The system boundary of the model is illustrated in Figure 1.

In the proposed model, carbon-related data ($CO_2$ emission sources, location, and annual emissions), transportation data (loading/unloading times and transportation capacities), and technical data (production scales, and raw material consumption) are utilized as basic elements for decision-making [9]. The model determines the optimal number and location of $CO_2$ storage terminals and MeOH production facilities.

To simplify the model, the following assumptions are made:

- Each $CO_2$ emission source is linked to a single $CO_2$ intermediate storage terminal or MeOH production facility.
- MeOH prices are assumed to increase due to inflationary trends, while hydrogen prices are projected to decrease in a multi-period context, reflecting expected technological advancements and market dynamics [9].

### 2.2. Optimization model

The objective function of the optimization model is to maximize the NPV of the CCUS supply chain. The optimization is formulated using a mixed integer linear programming (MILP) model. The NPV is calculated as the total revenue minus the total cost and is defined as follows:

$$\max NPV = Revenue + TSC - TPC \quad (1)$$

TPC (total production cost) consists of PCC (production capital cost), SCC (storage capital cost), TCC (transportation capital cost), POC (production operating cost), SOC (storage operating cost), and TOC (transportation operating cost).

$$TPC = PCC + SCC + TCC + POC + SOC + TOC \quad (2)$$

PCC & POC quantify the capital expenditures and operating expenditures of MeOH production facilities. TCC &

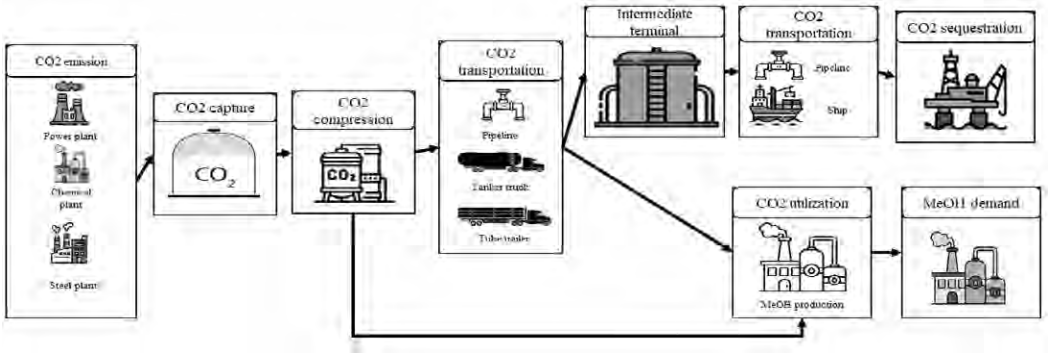

**Figure 1:** System boundary of CCUS supply chain

TOC quantify the capital expenditures and operating expenditures of transporting $CO_2$ from its emission sources to MeOH production facilities/$CO_2$ intermediate storage terminals and from $CO_2$ intermediate storage terminals to offshore storage facilities. SCC & SOC quantify the capital expenditures and operating expenditures of $CO_2$ intermediate storage terminals. Revenue quantifies the profit from MeOH sales in CCU. TSC (total salvage cost) quantifies the total salvage cost of MeOH production facilities and $CO_2$ intermediate storage terminals.

For the mass balance constraints at the $CO_2$ capture and transportation, Eq (3) indicates that the amount of captured $CO_2$ is equal to the total amount of $CO_2$ transported to intermediate terminals of MeOH production facilities.

$$CC_{rt} = \sum_{r'} Q^{T}_{trr'} + \sum_{s} Q^{T}_{trs} + F_{jrt} \quad (3)$$

Where $CC_{rt}$ and $F_{jrt}$ indicate amount of captured $CO_2$ and utilized $CO_2$. $Q^{T}_{trr'}$ and $Q^{T}_{trs}$ denote the amount of $CO_2$ transported to MeOH production facility and $CO_2$ storage terminals.

For $CO_2$ storage, Eq (4) indicates the amount of $CO_2$ transported to storage terminals is equal to the amount of $CO_2$ sequestered.

$$\sum_{s} CT^{T}_{ts} = \sum_{q} S^{T}_{tq} \quad (4)$$

$CT^{T}_{ts}$ and $S^{T}_{tq}$ present the amount of $CO_2$ stored in $CO_2$ intermediate storage terminals and sequestered in offshore storage.

Regarding transportation capacity constraints, Eq (5) the amount of $CO_2$ does not exceed the capacity of the respective transportations.

$$N^{T}_{trr}\vartheta_p \le Q^{T}_{trr'} \le N^{T}_{trr}\theta_p \quad (5)$$

Where $\vartheta_p$ and $\theta_p$ indicate minimum capacity and maximum capacity of $CO_2$ transportation. $N^{T}_{trr'}$ presents the number of transportation unit. $Q^{T}_{trr'}$ indicates the amount of $CO_2$ from $CO_2$ source to MeOH production facility.

## 3. CASE STUDY: APPLICATION TO SOUTH KOREA

To demonstrate the effectiveness of the optimization model, we present a case study on the supply chain in South Korea. With annual $CO_2$ emissions amounting to approximately 600 million tons, representing 1.6% of global emissions, South Korea's major contributors include fossil fuel combustion and industrial activities such as power generation, steel production, and chemical manufacturing. To align with the government's 2050 net-zero target, substantial reductions in industrial sector emissions are projected, aiming to cut up to 80% of current levels through the implementation of CCUS technologies. A comprehensive survey was conducted involving 157 facilities across the country, encompassing 25 power plants, 46 steel facilities, and 86 chemical plants. The annual $CO_2$ emissions of these facilities were assessed, with the data summarized in Table 1.

**Table 1:** Category of $CO_2$ emission sources

| $CO_2$ source | Number of factories | Total $CO_2$ emissions |
|---|---|---|
| Power plant | 25 | 49.96 Mt |
| Steel plant | 46 | 123.53 Mt |
| Chemical plant | 86 | 300.78 Mt |
| Total | 157 | 474.27 Mt |

These facilities were identified as potential MeOH production sites, using captured $CO_2$ as a feedstock. For $CO_2$ sequestration, two depleted gas reservoirs located in the East Sea and West Sea were selected as storage sites. Additionally, $CO_2$ intermediate storage terminals were strategically proposed for each province. Coastal areas favored terminals at ports, while inland areas selected locations in plains over mountainous regions to minimize infrastructure and transport costs. To facilitate offshore sequestration, the transport network links $CO_2$ intermediate storage terminals to the selected ports. To visualize the $CO_2$ flow from emission sources to MeOH production facilities or $CO_2$ intermediate storage terminals, $CO_2$ emissions were evaluated at the provincial level, as depicted in Figure 2.

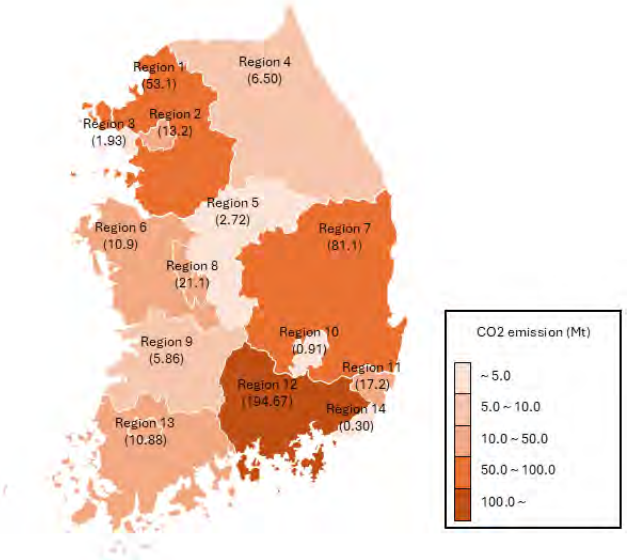

**Figure 2.** $CO_2$ emissions map in Korea in 2030

## 4. RESULTS AND DISCUSSION

This section presents the results of the optimized CCUS supply chain applied to South Korea, demonstrating the efficacy of the developed model. The optimization problem formulated as a MILP model and solved using

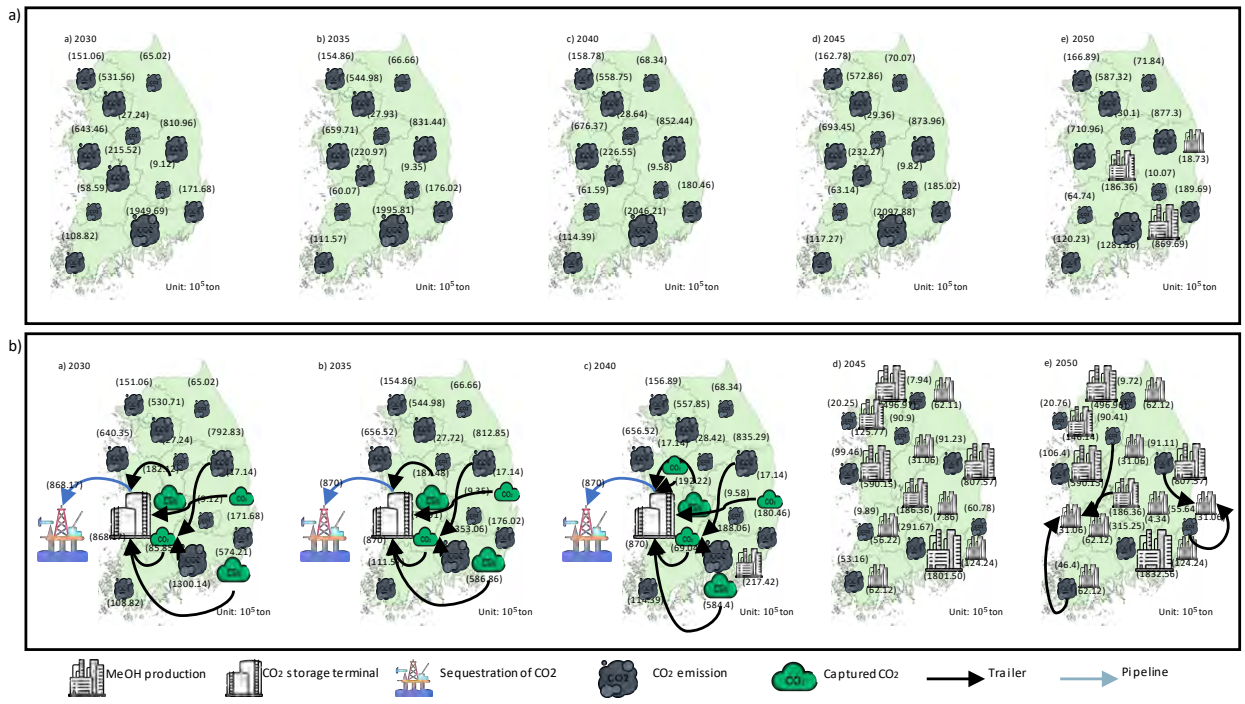

**Figure 3:** Topology of the optimized CCUS supply chain with (a) \$40 and (b) \$170 of social cost in South Korea from 2030 to 2050

CPLEX, aimed to maximize the NPV of the system. The analysis was conducted under two scenarios: (1) incorporating social costs of $CO_2$ emissions which is the monetary value of the environmental damage of each additional ton of $CO_2$ emitted, and 2) varying $CO_2$ capture rates for emission sources [10]. The social cost of $CO_2$ is evaluated from a baseline of \$0 per ton of $CO_2$, representing no economic impact, up to a maximum of \$185 per ton of $CO_2$ reflecting the potential role of the social cost of $CO_2$ emissions as a financial penalty [11]. Additionally, the CO2 capture rates for emission sources are assessed up to maximum efficiency of $CO_2$ capture technology.

## 4.1 Results for CCUS supply chain with social costs

In scenarios with low social costs for $CO_2$ emissions, the optimization results reveal that deploying CCUS facilities is not economically viable. Instead, the atmospheric emission of $CO_2$ continues to be economically favorable. However, as the social cost increased to \$40 per ton, the CCUS supply chain model suggests the deployment of CCU technologies to produce MeOH as a viable strategy by 2050. The graphical topology of this supply chain at \$40 and \$170 of social cost is shown in Figure 3. At this price point, the model suggested that regional $CO_2$ emissions from regions 7, 8, and 12 are captured and utilized directly at local MeOH production sites, eliminating transportation costs. Regions 7, 8, and 12 are primarily associated with steel production facilities, where the relatively low cost of carbon capture serves as a key driver for $CO_2$ capture implementation. When the social cost reaches \$170 per ton, the model predicts the construction of $CO_2$ intermediate storage terminals in selected regions such as region 9, by 2030. This cost level facilitates the sequestration of 86.8 million tons of $CO_2$, reflecting the increased feasibility of CCS under higher social costs.

A multi-period analysis demonstrates that declining hydrogen prices, from \$4.21 per kg in 2030 to \$3.21 per kg in 2040, and rising MeOH prices influenced by inflationary trends enhance the attractiveness of CCU technologies. Consequently, $CO_2$ initially allocated for storage is reallocated for utilization, underscoring the dynamic adaptability of the supply chain to economic fluctuations.

## 4.2 Results for CCUS supply chain with capture rates

This study systematically evaluates the performance of the CCUS supply chain under varying $CO_2$ capture rates, focusing on $CO_2$ allocation, infrastructure development, and the economic and operational performance of the network.

At a capture rate of 10%, all captured $CO_2$ amounting to 47.4 million tons by 2030 is directed to offshore storage. The graphical topology of this supply chain at 10% and 30% of the capture rate is shown in Figure 4. Infrastructure development in this scenario required constructing intermediate storage terminals in region 9 and

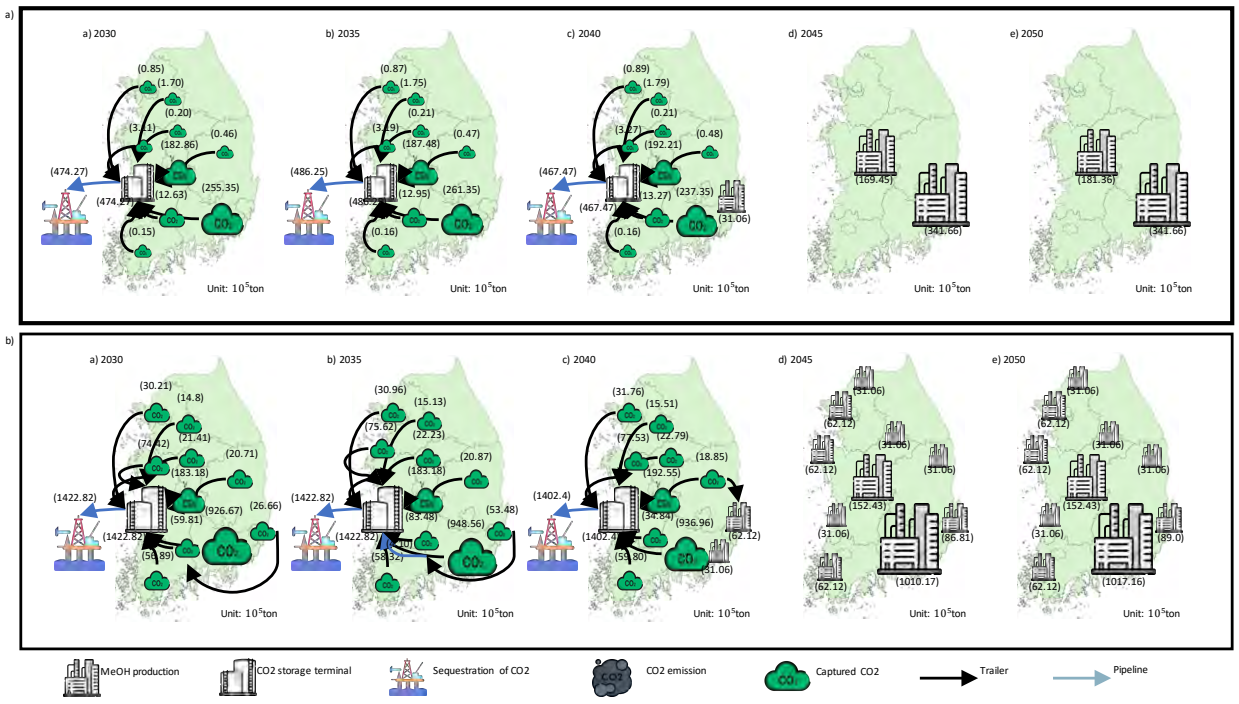

**Figure 4:** Topology of the optimized CCUS supply chain with (a) 10% and (b) 30% of capture rate in South Korea from 2030 to 2050

deploying pipelines to transport $CO_2$ to the West Sea. In a multi-period analysis, CCU facilities emerge in regions 8 and 12, enabling MeOH production from captured $CO_2$ by 2040. Capture rates of 30% or higher facilitate the establishment of additional $CO_2$ intermediate storage terminals and production facilities.

## 5. CONCLUSION

The CCUS supply chain plays a critical role in South Korea's efforts to achieve its carbon neutrality target by 2050. This study presents a CCUS supply chain model incorporating two distinct scenario criteria (the social cost of $CO_2$ and $CO_2$ capture rate) over a multi-period framework. The result demonstrated that 1) $CO_2$ utilization holds an economic priority over $CO_2$ storage due to the significant costs associated with injecting $CO_2$ into offshore storage sites, and 2) higher social costs and capture rates act as drivers for promoting carbon capture. This study confirms the effectiveness of implementing an optimization strategy for multi-objective, multi-period CCUS supply chains to address the uncertainties in strategic planning. By applying a systematic approach that adapts multi-period and multi-objective scenarios, the proposed model facilitates comprehensive planning that incorporates economic and environmental considerations. The proposed model successfully demonstrates the potential to achieve such integration and optimization, providing valuable insights for future CCUS applications. By utilizing the optimization model from this study, stakeholders and policymakers can develop deployment strategies that effectively balance economic and environmental objectives.

## ABSTRACT

Perishable consumer products like food, cosmetics, and household chemicals face challenges in supply chain management due to limited shelf life and uncertainties in demand and transportation. To address some of these issues, this work proposes a robust optimization framework for jointly optimizing facility allocation and inventory management. The framework determines optimal locations for distribution centers and their assigned customers, as well as inventory policies that minimize the total costs related to transportation, distribution, and storage under uncertain demand in a robust setting. Specifically, we develop a two-stage mixed-integer linear programming (MILP) model is that incorporates First-In-First-Out (FIFO) inventory policy to reduce spoilage. The bilinear FIFO constraints are linearized to improve computational efficiency. Social equity is integrated by defining a fairness index and incorporating it in facility allocation. Demand uncertainty is tackled using a robust optimization approach with affine demand functions to handle multiple scenarios. The model is solved using row and column generation techniques for scalability. Overall, this robust optimization framework is expected to enhance supply chain resilience, reduce waste, and improve cost-effectiveness in managing perishable products.

**Keywords**: Optimization, Supply Chain, Facility Allocation, Perishable Products

## INTRODUCTION

The optimization of facility location and inventory management is a critical area in operations research, with applications spanning healthcare, telecommunications, and supply chain logistics. For perishable consumer products like food, cosmetics, and household chemicals, the challenges are further intensified by their limited shelf life and uncertain demand. For instance, every year in the U.S., 38% of all food goes unsold or uneaten, which translates to almost 145 billion meals' worth of food, or roughly 1.8% of U.S. GDP [1]. Overestimating demand can lead to excessive holding costs and spoilage, while underestimating it results in unmet demand, penalties, and delays. These challenges necessitate robust optimization frameworks that account for perishability, uncertainty, and the dynamic nature of supply chain operations [2].

Facility location problems, particularly the Uncapacitated Facility Location (UFL) problem, aim to identify optimal facility placements that minimize allocation costs via optimization approaches [3,4]. Despite significant advancements in areas such as mixed-integer programming (MIP), large-scale problems often require advanced computational techniques like Lagrangian relaxation and decomposition methods such as row and column generation algorithms for efficient solutions [5,6].

Meanwhile, by introducing ethical and social aspects along with efficiency and cost-effectiveness, fairness has emerged as an important consideration in facility allocation. Metrics such as Rawlsian maximin, leximax criteria [7], group parity measures [8], and proportional fairness [9] address equitable resource allocation. In this work, a state-level social fairness is contextualized by prioritizing disadvantaged communities based on poverty and unemployment rates, thereby ensuring equitable access to consumer products being distributed. We remark that, in this work, we define the social fairness index by simply calculating the weighted sum of state-level poverty rate and unemployment rate obtained from the most recent U.S. Census as proof of concept. A more refined definition of social fairness will be developed in future studies.

This study proposes a joint optimization framework that integrates fair facility allocation with robust inventory management for perishable products. Adopting the robust inventory management framework proposed in [10], a linearized FIFO inventory policy is incorporated to minimize spoilage and maintain product shelf life. We also incorporate robust optimization techniques such as affine demand functions to model demand uncertainty and ensure resilience of the optimal solution found. The problem is decomposed and solved using row and column generation technique [5] to ensure scalability and computational efficiency.

## PROBLEM STATEMENT

Perishable goods, such as food, cosmetics, and household chemicals (e.g., detergents and pesticides), represent a significant portion of consumer products, creating stringent requirements for supply chain network design and inventory management. The perishable nature of these products, combined with uncertainties in product transportation and demand, requires us to holistically consider facility allocation and inventory management within a joint optimization framework. In this study, we consider a hypothetical U.S. nation-wide perishable food (including dairy, meat, fruits, and vegetables) supply chain network that needs to be jointly optimized for facility allocation and inventory management subject to demand uncertainty at a state level.

The objective is to identify the optimal locations for food distribution centers, assign customers to these centers, and determine inventory management strategies that effectively meet uncertain demand. The problem is formulated as a two-stage mixed-integer linear programming (MILP) model and is solved using row and column generation technique. The master problem determines the optimal facility locations, customer assignments, and initial inventory decisions for a finite set of demand scenarios, whereas the subproblem iteratively identifies new worst-case demand scenarios that could increase costs. These scenarios are incorporated into the master problem until no further costly scenarios are found, thereby ensuring the solution is robust against demand uncertainty.

## FORMULATION

As mentioned earlier, in the first stage of our proposed two-stage multi-objective robust optimization framework, we determine the optimal locations for food distribution centers, their capacities, customer allocations, and the amount of perishable products to be purchased from the supplier. Then, in the second stage, optimal inventory management is carried out based on the FIFO policy. Note that our inventory management and bilinear FIFO policy extend the original framework of [10] by incorporating linking constraints between facility allocation in the first stage and inventory management in the second stage, which leads to a nonconvex MINLP model in the first place. Nevertheless, by implementing the reformulation strategy introduced in [10], we can reformulate the second-stage problem as a scenario-based linear programming (LP) problem, thus making the joint problem a MILP with significantly improved computational efficiency and tractability.

### First stage: Fair capacitated facility allocation

In the first stage, the here-and-now decisions are made, which include selecting locations/states $i \in I$ for establishing food distribution centers, determining their capacities, and assigning customers. The objective is to minimize the total opening cost, which consists of land acquisition and construction costs ($\$313/\text{ft}^2$), permit costs ($\$2.75/\text{ft}^2$), labor costs ($\$0.3/\text{ft}^2$), energy costs ($\$0.00134$ kWh/$\text{ft}^2$.day), shipping costs ($3.19/mile), and the cost of purchasing products from the supplier (dairy: $0.88/lb, meat: $2.25/lb, fruits: $0.75/lb, and vegetables: $0.75/lb). Equation (1a) represents the objective function of the here-and-now stage. Considering an annual hurdle rate of 12% and a distribution center lifespan of 39 years, the corresponding 15-day discount factor is 0.005. To formulate the trade-off between economic and social fairness objectives, we use the $\epsilon$-constraint in Equation (2a), which ensures that the overall social fairness index does not fall below a specified level. Equations (3a-5a) are standard integer constraints for facility location problems. Equation (6a) ensures that the size of a food distribution center ranges from $50{,}000\ \text{ft}^2 \times 30\ \text{ft}$ to $800{,}000\ \text{ft}^2 \times 30\ \text{ft}$. Generally, at most 85% of the warehouse capacity can be utilized for inventory purposes, while the remaining space is allocated for other functions such as office use. Therefore, Equation (7a) ensures that the amount of products purchased from the supplier does not exceed the effective storage capacity. Furthermore, the average volume per pound ($v_p$) for dairy products, meat, fruits, and vegetables are given by 0.025, 0.025, 0.033, and 0.036 ($\text{ft}^3$/lb), respectively.

$$F^{H\&N} = \min \sum_{i \in I} \left[ 0.005\left(313 + 2.75 + c_i^{land}\right) + \sum_{t \in T} \left(0.3 + 0.00134\, c_t^{energy}\right) \right] \frac{q_i}{30} + \sum_{i \in I} \sum_{t \in T} \sum_{p \in P} c_p^{supply} u_{i,t,p}^{supply}, \quad (1a)$$

$$\sum_{i \in I} r_i^{fairness} y_i \geq \sum_{i \in I} r_i^{fairness} \epsilon, \quad (2a)$$

$$\sum_{i \in I} x_{i,j} = 1, \forall j \in J, \quad (3a)$$

$$x_{i,j} \le y_i, \forall i \in I, j \in J, (4a)$$

$$\sum_{j \in J} x_{i,j} \ge y_i, \forall i \in I, (5a)$$

$$1.5 \times 10^6 y_i \le q_i \le 24 \times 10^6 y_i, \forall i \in I, (6a)$$

$$\sum_{p \in P} v_p u_{i,t,p}^{supply} \le 0.85 q_i, \forall i \in I, t \in T, (7a)$$

## Second stage: Robust inventory management

In the second stage, the wait-and-see (W&S) decisions are made and must reflect the robust inventory management policy. Since our inventory management model is similar to that in [10], we only present its reformulation here. The objective is to minimize holding, backlog, and spoilage costs across all possible scenarios while considering the specified level of conservatism (Γ). Equation (1b) is the objective function associated with the second stage. Equation (2b) ensures that the total cost minimized in (1b) corresponds to the worst-case scenario, which is a standard formulation technique in robust optimization. In Equation (2b), the holding cost is assumed to be 15% of the supply cost, and the backlog cost is equal to the supply cost, and the spoilage cost factor $\beta^{spoil}$ can take difference values and is a user-defined parameter. Constraint (3b) ensures that under every possible scenario, the total amount of stored products in the inventory does not exceed the effective storage capacity ($0.85q_i$). Constraints (4b) and (5b) respectively represent the amount of stored and backlogged products subject to demand uncertainty, which consists of infinite number of scenarios ξ that belong to an uncertainty set Ξ. Equations (6b) and (7b) implements the FIFO policy in calculating spoilage [10].

$$F^{W\&S} = \min z, (1b)$$

$$z \ge \sum_{i \in I} \sum_{t \in T} \sum_{p \in P} \left(0.15 c_p^{supply} u_{i,t,p,\xi}^{inv} + c_p^{supply} u_{i,t,p,\xi}^{backlog} + \beta^{spoil} c_p^{supply} u_{i,t,p,\xi}^{spoil}\right), \forall \xi \in \Xi, (2b)$$

$$\sum_{p \in P} v_p u_{i,t,p,\xi}^{inv} \le 0.85 q_i, \forall \xi \in \Xi, i \in I, t \in T, (3b)$$

$$u_{i,t,p,\xi}^{inv} \ge \sum_{k=1}^{t} \left(u_{i,t,p}^{supply} - \sum_{j \in J} D_{p,j,k}(\xi) x_{i,j} - u_{i,k,p,\xi}^{spoil}\right), \forall \xi \in \Xi, i \in I, t \in T, (4b)$$

$$u_{i,t,p,\xi}^{backlog} \ge \sum_{k=1}^{t} \left(\sum_{j \in J} D_{p,j,k}(\xi) x_{i,j} + u_{i,k,p,\xi}^{spoil} - u_{i,t,p}^{supply}\right), \forall \xi \in \Xi, i \in I, t \in T, (5b)$$

$$u_{i,t,p,\xi}^{spoil} = 0, \forall \xi \in \Xi, i \in I, t \le m, (6b)$$

$$u_{i,t+m,p,\xi}^{spoil} = \max\left\{0, \sum_{k=1}^{t} u_{i,t,p}^{supply} - \sum_{k=1}^{t+m} \sum_{j \in J} D_{p,j,k}(\xi) x_{i,j} - \sum_{k=m+1}^{t+m-1} u_{i,k,p,\xi}^{spoil}\right\}, \forall \xi \in \Xi, i \in I, t \le |T| - m, (7b)$$

## Row and column generation

The proposed problem contains an infinite number of variables and constraints, making it inherently intractable. To address this, we employ an iterative approach that alternates between solving a relaxed master problem and separation problems. While the master problem is still nonlinear (due to Equation (7a)) for now, it can be easily linearized using standard techniques and it is a finite optimization problem, unlike the infinite optimization formulations discussed above. Consider $S \subset \Xi$ be a finite set of scenarios generated by the separation problem. The restricted master problem (RMP) is defined as follows.

$$(RMP): \min F^{H\&N} + F^{W\&S}, (1c)$$

$$(2a) - (7a),$$

$$z \ge \sum_{i \in I} \sum_{t \in T} \sum_{p \in P} \left(0.15 c_p^{supply} u_{i,t,p,\xi}^{inv} + c_p^{supply} u_{i,t,p,\xi}^{backlog} + \beta^{spoil} c_p^{supply} u_{i,t,p,\xi}^{spoil}\right), \forall \xi \in S, (2c)$$

$$\sum_{p \in P} v_p u_{i,t,p,\xi}^{inv} \le 0.85 q_i, \forall \xi \in S, i \in I, t \in T, (3c)$$

$$u_{i,t,p,\xi}^{inv} \ge \sum_{k=1}^{t} \left(u_{i,t,p}^{supply} - \sum_{j \in J} D_{p,j,k}(\xi) x_{i,j} - u_{i,k,p,\xi}^{spoil}\right), \forall \xi \in S, i \in I, t \in T, (4c)$$

$$u_{i,t,p,\xi}^{backlog} \ge \sum_{k=1}^{t} \left(\sum_{j \in J} D_{p,j,k}(\xi) x_{i,j} + u_{i,k,p,\xi}^{spoil} - u_{i,t,p}^{supply}\right), \forall \xi \in S, i \in I, t \in T, (5c)$$

$$u_{i,t,p,\xi}^{spoil} = 0, \forall \xi \in S, i \in I, t \le m, (6c)$$

$$u_{i,t+m,p,\xi}^{spoil} = \max\left\{0, \sum_{k=1}^{t} u_{i,t,p}^{supply} - \sum_{k=1}^{t+m} \sum_{j \in J} D_{p,j,k}(\xi) x_{i,j} - \sum_{k=m+1}^{t+m-1} u_{i,k,p,\xi}^{spoil}\right\}, \forall \xi \in S, i \in I, t \le |T| - m, (7c)$$

After solving the (RMP), the optimal facility locations, their capacities, customer assignments, the amount of products purchased from the supplier, and the worst-case scenario inventory management cost ($z^*$) for the current scenarios can be determined. The separation problem (SP) is proposed to find a new scenario with a higher inventory management cost.

$$(SP): w = \max \sum_{i \in I} \sum_{t \in T} \sum_{p \in P} \left(0.15 c_p^{supply} u_{i,t,p}^{inv} + c_p^{supply} u_{i,t,p}^{backlog} + \beta^{spoil} c_p^{supply} u_{i,t,p}^{spoil}\right), (1d)$$

$$\xi \in \Xi, (2d)$$

$$\sum_{p\in P} v_p u^{inv}_{i,t,p} \le \eta q^*_i,\ \forall i \in I^*,\ t \in T, (3d)$$

$$u^{inv}_{i,t,p} = \max\left\{0, \sum_{k=1}^{t}\left(u^{supply*}_{i,t,p} - \sum_{j\in J^*_i} D_{p,j,k}(\xi) - u^{spoil}_{i,k,p}\right)\right\},\ \forall i \in I^*,\ t \in T, (4d)$$

$$u^{backlog}_{i,t,p} = \max\left\{0, \sum_{k=1}^{t}\left(\sum_{j\in J^*_i} D_{p,j,k}(\xi) + u^{spoil}_{i,k,p} - u^{supply*}_{i,t,p}\right)\right\},\ \forall i \in I^*,\ t \in T, (5d)$$

$$u^{spoil}_{i,t,p} = 0, \forall i \in I^*,\ t \le m, (6d)$$

$$u^{spoil}_{i,t+m,p} = \max\left\{0, \sum_{k=1}^{t} u^{supply*}_{i,t,p} - \sum_{k=1}^{t+m}\sum_{j\in J^*_i} D_{p,j,k}(\xi) - \sum_{k=m+1}^{t+m-1} u^{spoil}_{i,k,p}\right\}, \forall i \in I^*,\ t \le |T| - m, (7d)$$

If there exists a $\xi^*$ such that $w^*(\xi^*) > z^*$, then $\xi^*$ is added to $S$, and the (RMP) is solved again with the updated set of scenarios. This iterative approach continues until no new scenario with a higher inventory management cost is found. By implementing this row and column generation method, the problem can be solved with a finite number of variables and constraints. Note that the linearization technique for (SP) is discussed in [10].

## ILLUSTRATIVE CASE STUDIES

To evaluate the effectiveness of our proposed framework, we conduct a hypothetical case study featuring the national supply chain of perishable food products. This case study illustrates the trade-offs among total cost, fairness, and inventory efficiency for perishable consumer products.

By incorporating the poverty and unemployment rates of all 50 states in 2023 [11], we develop a social fairness index that assigns equal weight to these socioeconomic factors. And the overall social fairness $\sum_{i\in I} r^{fairness}_i \epsilon$ can vary from $\epsilon = 0$ (excluding the fairness) to $\epsilon = 1$ (maximum fairness). **Figure 1** shows the average daily demand (in Mlbs) for these products per state in 2023 [12,13]. In our study, we investigate a planning horizon of 15 days, and the storage duration is $m = \{2,5\}$ days. Furthermore, we consider the spoilage cost factor $\beta^{spoil} \in \{0.5,1,1.5,2\}$ and the uncertainty parameter $\Gamma \in \{1,3,5\}$ Mlbs, where $\Gamma = 1$ represents the least conservative case, and $\Gamma = 5$ represents the most conservative case.

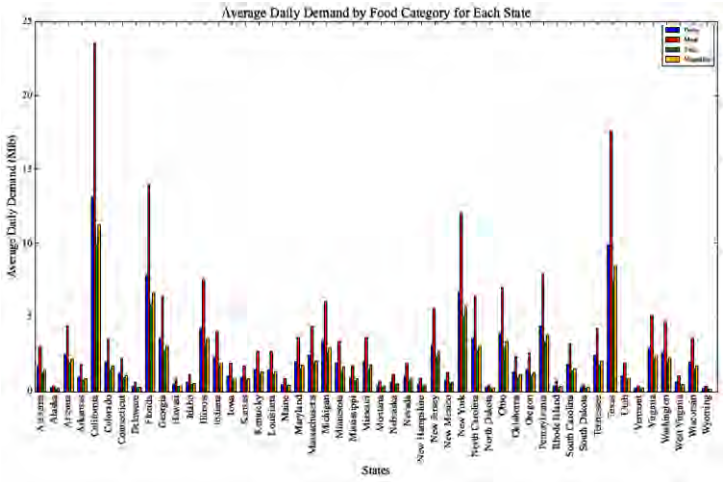

**Figure 1.** Average daily demand of dairy products, meat, fruits, and vegetables per state.

**Figures 2**, **3**, **4**, and **5** illustrate the Pareto front between social fairness and total costs, the percentage of spoilage for all products, the total amount of backlogged products, and the total amount of stored products for various $\epsilon$ levels for the case when $m = 5$, $\Gamma = 3$, and $\beta^{spoil} = 1$. First, as $\epsilon$ increases, the total costs would continuously increase. Additionally, lower $\epsilon$ values, which indicate that fewer facilities will be chosen, are associated with higher spoilage percentage and higher backlogging. However, the trend for the total inventory level behaves exactly the opposite way. This suggests that, when fewer facilities are established, which leads to higher backlogs, the inventory level decreases as if the supply chain system transfers its weight from stored inventory to unmet demand. This opposite trend illustrates the trade-off and delicate interplay between storage and shortages in the supply chain.

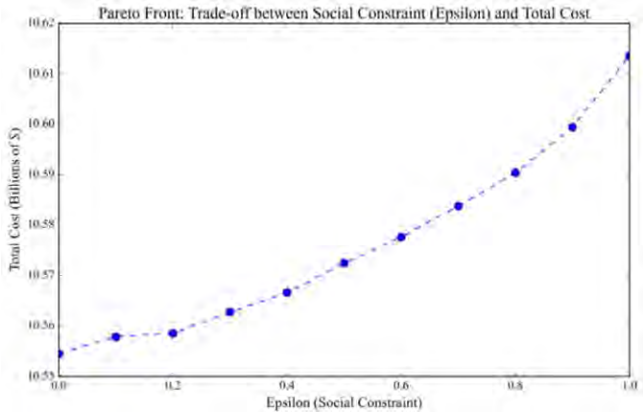

**Figure 2.** Pareto front showing the trade-off between social fairness and the total cost for the case where $m = 5, \Gamma = 3, \beta^{spoil} = 1$.

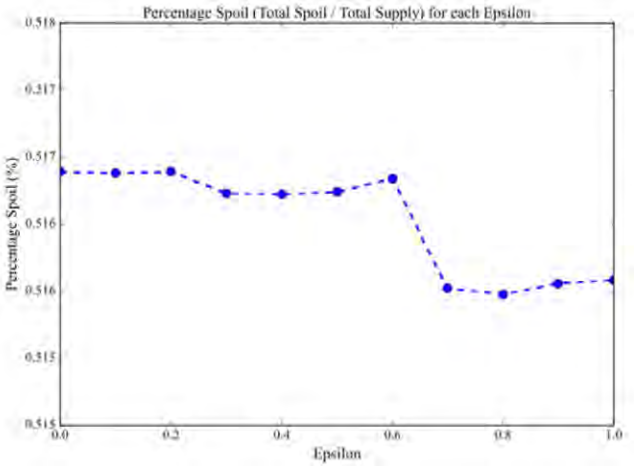

**Figure 3.** The percentage of total spoiled products for different levels of social fairness when $\mathrm{m} = 5, \Gamma = 3, \beta^{\mathrm{spoil}} = 1$.

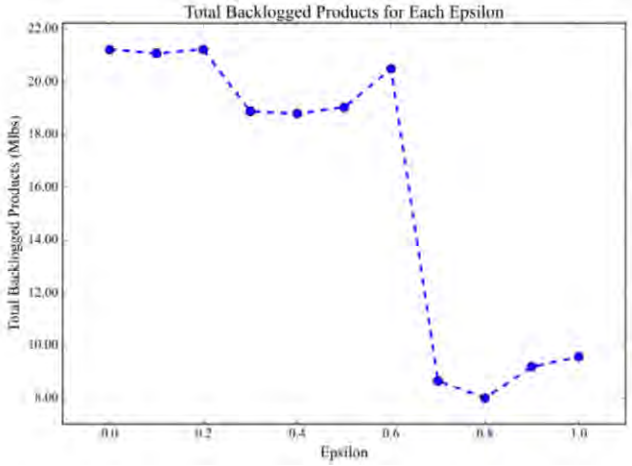

**Figure 4.** The percentage of total backlogged products for different levels of social fairness when $\mathrm{m} = 5$, $\Gamma = 3, \beta^{\mathrm{spoil}} = 1$.

Next, we conduct a sensitivity analysis to understand how spoilage changes under different levels of conservatism and social fairness. **Figures 6** presents the results for the total amount of spoiled products under various scenarios. As the uncertainty level $\Gamma$ increases, in most of the cases, the amount of spoiled products also increases. However, increasing the number of days that products can be stored in inventory and raising the spoilage cost factor help reduce the total amount of spoilage by making spoiled products more expensive. For instance, when the cost of spoiled products is doubled compared to the supply cost, spoilage is completely eliminated across all levels of conservatism.

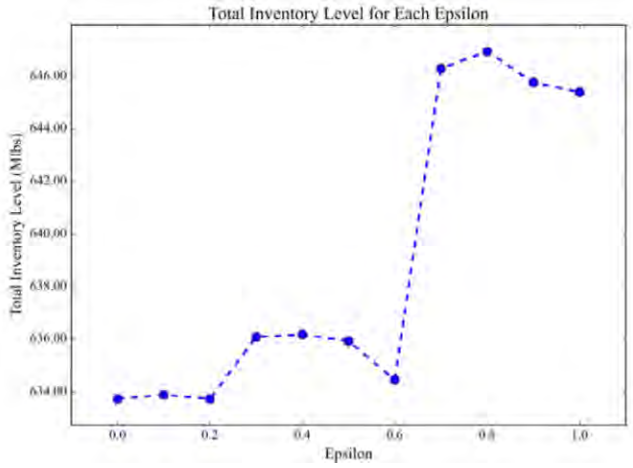

**Figure 5.** The percentage of total stored products for different levels of social fairness by varying $\epsilon$ for $\mathrm{m} = 5$, $\Gamma = 3, \beta^{\mathrm{spoil}} = 1$.

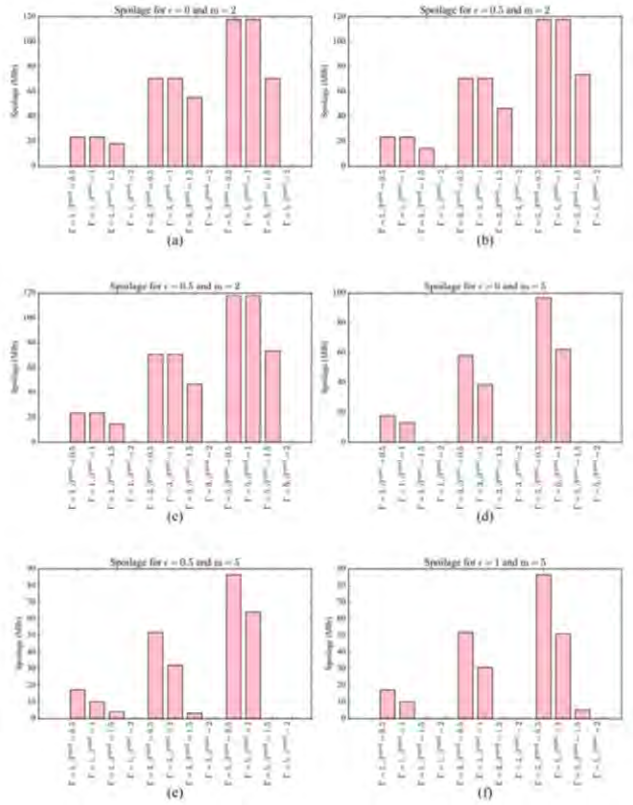

**Figure 6.** Total amount of spoiled products under different levels of fairness level $\epsilon$, uncertainty level, and cost factors. (a-c) correspond to $\mathrm{m} = 2$, while (d-f) represent $\mathrm{m} = 5$.

On the other hand, when the spoilage cost factor is half of the supply cost, the highest amount of waste is generated across all levels of conservatism. For example, when the storage duration $\mathrm{m} = 2$ days, $\Gamma = 5$ Mlbs, and $\beta^{\mathrm{spoil}} = 0.5$, the total amount of waste for all three levels of fairness is almost 120 Mlbs, which represents the

highest recorded spoilage.

## CONCLUSION

In this study, we develop a robust mixed-integer linear programming (MILP) model to jointly optimize facility allocation and inventory management for perishable consumer products. Our approach incorporates a FIFO inventory policy, leveraging prior results for constraint linearization [10], and employs row and column generation techniques to improve scalability. To account for social equity, we introduce a fairness index based on poverty and unemployment rates across U.S. states [11], allowing for trade-off analysis between fairness, cost, and inventory efficiency. Through a national case study, we examine how factors such as demand uncertainty, storage duration, and spoilage cost sensitivity influence supply chain outcomes. Our results reveal that higher levels of conservatism in demand forecasting lead to increased spoilage, while higher fairness levels result in rising total costs. Additionally, storage duration and spoilage cost penalties significantly impact waste levels, with severe penalties eliminating spoilage altogether. These findings underscore the need for systematic optimization approaches to balance supply chain resilience, cost efficiency, and waste mitigation, consistent with our previous research [14,15]. In terms of future research, we will primarily focus on three main aspects: 1) refine social fairness characterization backed by rigorous, comprehensive prior research in game theory and regional economics; 2) investigate novel approaches (e.g., political districting) to model and solve facility allocation while ensuring fairness; and 3) accelerate the computational efficiency by developing more effective decomposition and/or distributed optimization techniques.

# A two-level model to assess the economic feasibility of renewable urea production from agricultural waste

**Diego C. Lopes[a], Moisés Teles dos Santos[a]**

## ABSTRACT

This work proposes a two-level model, combining process and supply chain models, and an optimization framework for an integrated biorefinery system to convert agricultural residues into renewable urea via gasification routes. The process model of the gasification, ammonia and urea synthesis was developed in Aspen Plus® to identify key performance indicators such as energy consumption and relative yields for urea for different biomasses and operating conditions; then, these key process data were used in a mixed-integer linear programming (MILP) model, designed to identify the optimal combination of energy source, technological route of urea production and plant location that maximizes the net present value of the system. The model was applied to the whole Brazilian territory, divided into 5569 cities and 558 micro-regions. Each region's agricultural production was evaluated to estimate biomass supply and urea demand. The Assis microregion, in close proximity with sugarcane and soybean crops, was found to be an optimal location for the plant, with an NPV of 110 MMUSD. Urea demand was found to be the main limiting factor, with more than 30 microregions needed to consume the plant's production. The results indicate the feasibility of producing renewable urea from agricultural waste and the importance of considering a two-level approach to assess the economic performance of the entire system.

**Keywords**: fertilizer, renewability, optimization

## INTRODUCTION

Since 1961, worldwide food supply per capita has raised by 30%, in large part because of the increase of use of nitrogen fertilizers to improve agricultural productivity [1]. The importance of fertilizers on agriculture cannot be overstated, with research indicating that half of the world's population is sustained by mineral fertilizers [2]. Fertilizers account for a fifth of the producer's costs on the US [3], while on Brazil, the financial impact on cultures such as soya is between 30% and 40% [4]. The agricultural sector is also responsible for approximately 11% and 15% of all greenhouse gas (GHG) emissions worldwide [5], with fertilizers accounting for 2% to 3% of emissions [6]. Production of mineral fertilizers is dependent on fossil fuels and raw materials, including mineral extraction, transportation, manufacturing, and power supply. In this scenario, decarbonizing the fertilizer sector is equally important to the industry's expansion [7], considering the GHG emissions reduction preconized in the 2015 Paris agreement.

The mineral fertilizers divide themselves into three main categories, each one corresponding to the main macronutrient present in its composition: nitrogen (N), phosphorus (P) and potassium (K). Although none of the macronutrients can be considered more or less important than the other, nitrogen is the one consumed at higher volumes, and also the one with the more energetically intensive manufacturing process and heavily reliant on fossil fuels throughout its manufacturing process, both as energy input and as a direct feedstock [2]. Out of all nitrogen fertilizers, urea is the main commercial product, produced by the synthesis of ammonia with carbon dioxide via the Basarov reaction [8]. Since both ammonia and urea synthesis are energetically intensive, efforts were made throughout the 20th century to improve its energy efficiency, involving equipment changes, process control and residual heat utilization. With these efforts, current

ammonia production is very close to the theoretical minimum energy consumption [2] . Considering the small efficiency improvements still possible, a natural future step is to search for sustainable replacements for the process' feedstocks and energy usages.

In this scenario, biomass is a promising feedstock replacement. Although biomass presents a polymeric structure, divided in cellulose, hemicellulose and lignin as its main polymers, it can be represented in a simplified way as a mixture of carbon (C), hydrogen (H), oxygen (O) and nitrogen (N) [9]. Most of the chemicals produced with oil or natural gas can be produced with biomass, by resorting to either thermochemical routes such as gasification or pyrolysis, or biological routes such as fermentation [10].

Urea production using biomass gasification as a feedstock has also been the object of recent studies [11-13] focused on process modeling and obtaining ideal operational parameters and technological routes. There is an obvious synergy in producing urea with agricultural waste, as the regions with high biomass supplies will necessarily have high urea demand. However, none of these studies consider supply-chain and location specific aspects, which can be critical at the planning stage [14]. This highlights the need to combine both a traditional process modeling approach with a robust optimization framework that takes spatial data, local biomass supply and urea demand into account. The present work proposes such a model to fill this literature gap.

# METHODOLOGY

## Process models

A process model of the full biomass gasification, ammonia and urea synthesis was developed in Aspen Plus v8.8 [13]. A simplified process topology is presented on Figure 1.

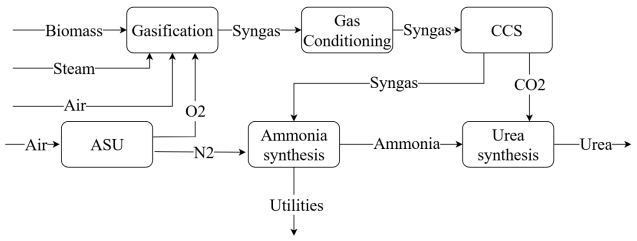

**Figure 1.** Process flow diagram

Biomass is firstly dried to 15% moisture and sent to a gasification unit, modeled with a non-stoichiometric equilibrium approach [15]. A global gasification reaction can be described as:

$$CH_aO_bN_c + wH_2O_l + sH_2O_g + e(O_2 + \rho N_2) + dCO_2 \rightleftharpoons n_{CH_4}CH_4 + n_{CO_2}CO_2 + n_{CO}CO + n_{H_2}H_2 + n_{H_2O}H_2O + n_{O_2}O_2 + n_{N_2} \quad (1)$$

With a, b and c being derived from the biomass composition; w, s, e, $\rho$ and d representing the gasifying agent mixture, and n being the number of moles of each component in the syngas. At equilibrium, the Gibbs energy of the mixture (G) must be at minimum:

$$G = \sum_{i=1}^{M} n_i G_i^0 + \sum_{i=1}^{M} n_i RTln(\frac{n_i}{n_{tot}}) \quad (2)$$

The number of moles of each component, $n_i$, are constrained by the mole balance of each atom C, H, O and N on the biomass. Tar formation is not considered in this model. The minimization of Gibbs energy is obtained on the Gibbs reactor block (RGibbs) in Aspen Plus. Syngas properties were calculated using the Peng-Robinson equation of state, with Boston-Mathias modifications.

The gasification agents are a mixture of air, steam and pure oxygen, produced in an air separation unit (ASU), with an optional $CO_2$ intake. The syngas composition is adjusted to improve $H_2$ concentration in a gas conditioning unit, consisting of two water-gas shift reactors and a methanation unit. The $CO_2$ present is the syngas is captured at a physical solvent carbon capture unit using DEPG (Dimethyl Ether of Polyethylene Glycol) as a solvent [16]. The purified syngas is mixed with nitrogen and sent to an ammonia synthesis unit, modeled with three catalytic beds and intermediate intercooling, based on a state of the art design [17]. The ammonia and captured $CO_2$ are sent to the urea synthesis plant, modeled as a $CO_2$ stripping process based on the commercial Stamicarbon® technology [8]. The final urea is concentrated to 99 wt. % in a double effect evaporator and sent to a granulation or prilling unit. A utility plant was designed to recover heat from the gasification, ammonia and urea synthesis. High pressure steam is generated in the syngas cooling stages and expanded into a multi-stage turbine to be used by the main steam consumers of the plant. The remaining steam generated is condensed at 0.1 bar, generating power. The purpose of the process model was to obtain the conversion of biomass to urea and the utilities consumption for any combination of operational parameters.

## Supply-chain

The whole Brazilian territory was divided into 5569 cities, grouped in 558 micro-regions and 137 macro-regions. The open database PAM [18] from IBGE (Instituto Brasileiro de Geografia e Estatística) was used to obtain the total agricultural production for each location. Based on this, 5 crops were chosen as the most representative of the Brazilian agricultural scenario. Each crop's residue production was estimated using fixed ratios [19] to obtain an individual biomass supply for each location. Individual urea demand was also estimated using published data for mineral fertilizer usage by crop [20] and planted area.

Table 1 summarizes the chosen crops, biomass it produces and urea demand.

**Table 1:** Biomass supply and urea demand per crop

| Crop | Biomass production (kg/ kg crop) | Urea demand (kg N / ha) |
|---|---|---|
| Rice | 0.620 | 83 |
| Coffee | 0.295 | 161 |
| Corn | 0.672 | 68 |
| Soy | 0.690 | 16 |
| Sugarcane | 0.185 | 76 |

Sugarcane residue production is divided between straw and bagasse. Distances and travel times between all locations were obtained from geographical data [21]. Power prices were also individually considered using published tariffs [22].

## Economical model

The capital costs for all subunits of the process were estimated by using the scale factor methodology [23], with an estimation of 368.7 MMUSD for a reference 35 t/h process. The CAPEX for other capacities ranging from 0 to 80 t/h was estimated using piecewise linearization.

Net present value is defined as:

$$NPV = \sum_{t=1}^{n} \frac{F_t}{(1+r)^t} - CAPEX \quad (3)$$

With $F_t$ being the net cash flow at year $t$, $r$ being the discount rate (by default at 10%) and $CAPEX$ being the total capital costs of the plant. Net cash flow is defined as:

$$F_t = -CAPEX_t + R + C_b + C_{tb} + \mathrm{C_{tu}} + C_u \quad (4)$$

With $R$ being urea revenue, $C_b$ being biomass costs, $C_{tb}$ being biomass transport costs, $C_{tu}$ being urea transport costs, and $C_u$ being utility costs.

Table 2 summarizes the main economical assumptions for the model.

**Table 2:** Economical assumptions

| Parameter | Unit | Value |
|---|---|---|
| Urea price | USD/t | 310.0 |
| Biomass price | USD/GJ | 4.50 |
| Transport price | USD/km/t | 0.058 |

Power prices are considered in a city-by-city basis using published tariffs.

## Optimization model

A mixed-integer linear programming (MILP) optimization model was built using the Pyomo open-source software suite, to obtain the ideal location and capacity of a renewable urea plant, based on the process model performance. The model can be divided into 4 layers, best represented in Fig. 2.

The model consists of 3 main sets:

$L$: set of possible locations ($l$)

$B$: set of biomasses ($b$)

$R$: set of technological routes for urea production (e.g.: pure oxygen gasification vs. air mixed gasification).

With:

$CV_{br}$: conversion of biomass $b$ to urea at route $r$, in $t\ urea/t\ biomass$

$D_l$: urea demand at location $l$.

$S_{bl}$: Supply of biomass $b$ at location $l$.

The decision variables of the model are:

$W_l$: binary variable corresponding to the installation of the plant at location $l$

$BS_{bll'}$: biomass $b$ sold from location $l$ to location $l'$

$BU_{brl}$: biomass $b$ used to produce urea via route $r$ at location $l$

$UP_{rl}$: urea produced via route $r$ at location $l$

$US_{ll'}$: urea sold from location $l$ to location $l'$

$C$: capacity of the plant in tons urea/h

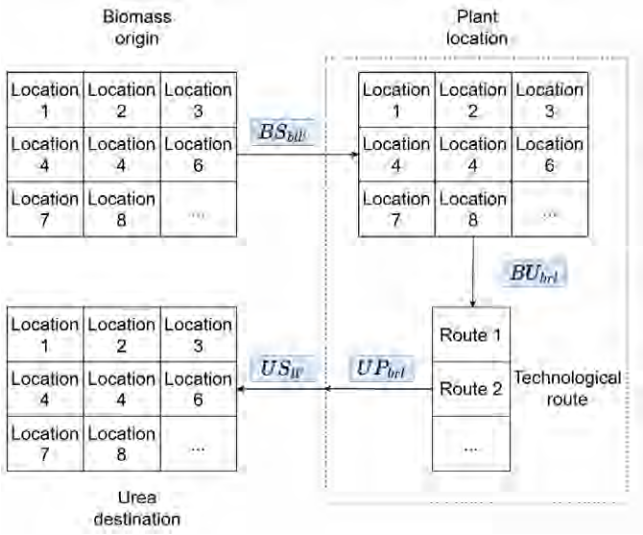

**Figure 2** – Layers of decision

The objective function of the model is to maximize the NPV of the plant. Biomass consumption and utility usage for each technological route is given by the process model. Transport costs are calculated by using the distance from location $l$ to location $l'$. The main constraints of the model, connecting the decision variables, are:

$$\sum_{l \in L} W_l = 1 \quad (5)$$

$$\sum_{b \in B} \sum_{r \in R} \sum_{l \in L} UP_{brl} = \mathrm{C} \cdot 8300 \quad (6)$$

# RESULTS

## Process model

The plant's performance was evaluated using the process model for all 6 types of biomasses and 2 technological routes, totaling 14 runs. Gasification temperature was set to 1200 °C, controlled by the oxygen intake. Two technological routes were chosen for this study: pure oxygen gasification, and air mixed gasification. In pure oxygen gasification, the only gasifying agent used is oxygen, while the nitrogen required by the ammonia synthesis is separated at the air separation unit and directly mixed before the syngas compression stage, controlling the $N_2/H_2$ ratio in the ammonia synthesis at 3.0. Meanwhile, in air mixed gasification, the air intake controls the $N_2/H_2$ ratio and oxygen is complemented to keep the gasification temperature at the desired setpoint. Table 3 summarizes the results. The informed utility consumption already takes into account internal power production; overall, oxygen gasification is more efficient in converting biomass into urea, but power generation is also smaller in comparison. Sugarcane bagasse has high average moisture, which explains the large difference between this biomass and all the others. Also, higher moisture increases steam consumption in the drying stage but reduces the need of steam injection at the gas conditioning phase to adjust the gas composition.

## Optimization model

The commercial solver Gurobi was used to solve the MILP model, taking 19.11 mins on average on a Ryzen 7 CPU at the largest simulation. The database used in the simulations, as well as the full results, are provided in the supplementary material. Table 4 provides the summary of the results.

The optimization model was initially applied to the whole country at the micro-region level (558 locations). In this scenario, it was found that the Assis microregion in the state of São Paulo is the optimal location for the installation of the renewable urea plant. Pure oxygen gasification was the route chosen, and the biomasses used are a 50/50 mix of soybean straw and sugarcane straw, leveraging the large sugarcane crops in the São Paulo state. The plant capacity was constrained to a maximum

of 80 t/h to limit the errors on capital costs estimation. The total urea produced (663,000 tons/year) is enough to supply 50% of the state demand and 9.2% of the national urea demand.

The Assis microregion has enough biomass available to provide 99% of the required biomass of the plant. However, the urea produced needs to be sold 30 different microregions, crossing state borders and navigating more than 250 km. Figure **4** shows the plant location and all optimal markets for the urea product destination.

The model was constrained to other regions of Brazil to evaluate local feasibility. In the south region, the microregion of Cianorte presented the best NPV results, using a mixture of rice husks and sugarcane straw as biomasses. In this case, the local supply of biomass is not enough to satisfy the plant's demands, so biomass needs to be imported from close regions, which raises transport costs. The Midwest region consists of a large agricultural belt in Brazil, and the optimal location in this region was found to be the "Sudoeste de Goiás" microregion. At this scenario the plant uses 100% soybean residues, which forms much of the biomass available in the Midwest. In both scenarios, the urea must also be sold to more than 20locations as the local markets cannot accommodate the total plant production.

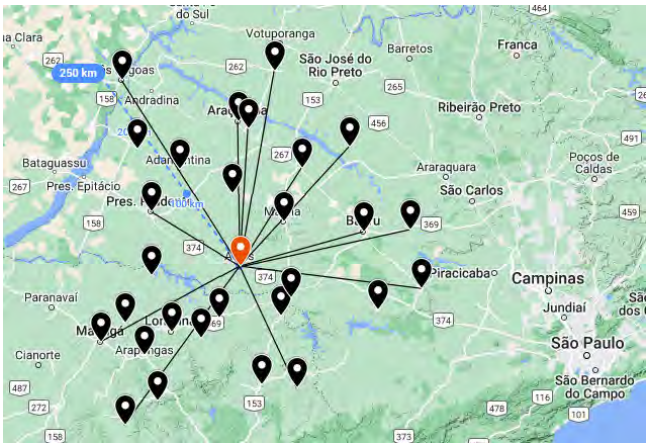

**Figure 4** – Plant location and urea consumers for main scenario.

The model's results for the other two regions of Brazil (North and Northeast) show that a large-scale renewable urea plant is not feasible, with optimal capacities of 2.01 and 2.83 t/h respectively. Despite large biomass supplies in these regions, the distance between urea markets is too large and local urea demand is too small, to the point where the logistical costs of transporting urea become the main limiting factor. To illustrate this, an additional scenario, called "Northeast – Max." was modeled constraining the possible locations to the Northeast region but also fixing the plant's capacity to the maximum (80 t/h). In this scenario, the NPV is -91 MMUSD, with the urea transport costs increasing to 36 MMUSD.

## CONCLUSIONS

A two-level model for the production of renewable urea was developed, combining a traditional process model with a supply-chain and optimization framework. The process model was applied to 6 different biomasses and 2 technological routes, obtaining the key performance indicators (KPIs) for all 14 scenarios. These KPIs were used in the supply-chain model to obtain the optimal combination of plant location, biomass used and technological routes considering local biomass supplies, urea demands and distance between regions. It was found that the optimal location for a renewable plant in Brazil is in the São Paulo state, given the high urea demand and short distances between markets. When constraining the model to different regions, it was found that the logistical costs of urea distribution bottlenecks the feasibility of the plant. This highlights the need for a robust supply chain model coupled with a traditional process modeling approach.

## ABSTRACT

Production scheduling in the process industry is an area of significant activity in research and of great practical importance for the performance of industrial companies. In the vast majority of research papers, the scheduling problem is formulated as an off-line problem where a number of jobs is scheduled on a number of resources and the efficiency of the formulation and the solution algorithms is discussed. In reality, however, scheduling is a continuous activity that has to react to the arrival of new orders, to variations in processing times, breakdowns, lack of resources etc. This is termed real-time (or online) scheduling. Available commercial solutions usually provide solutions with relatively long update intervals due to the necessary computation times and a delayed flow of information from the manufacturing execution systems where the data on the current state of the production is collected. Thus the computed schedules are outdated quickly, if not already at the point in time when they become available, and new orders and all kinds of variations and disturbances are handled by the operators and plant supervisors. There has been little concern for systematic solutions for real-time scheduling that continuously react to the changing situation in the plant. In this contribution we present a simulation-optimization approach to real-time scheduling where a detailed discrete-event simulation of the plant is coupled with an evolutionary algorithm. The simulation model is continuously updated with the latest plant data, and the optimization algorithm continuously improves the schedule based on the currently available information. We validate our approach using an example of a multiproduct, multistage batch plant in the pharmaceutical industry from the literature, demonstrating that the proposed approach can generate high-quality solutions quickly. We compare the results with those of an ideal (clairvoyant) scheduler, demonstrating that our method effectively manages unforeseen disturbances.

## INTRODUCTION

Production scheduling is a decision-making process that determines the optimal allocation to resources and sequence of operations in production processes. This improves plant efficiency, reduces operational costs, and improves customer satisfaction by meeting the promised delivery dates. Scheduling in the scientific literature is typically considered in an offline setting where a static problem for a given production environment, given jobs and timing constraints, and a given cost function is solved. In industrial practice, scheduling is usually done periodically with relatively long intervals between the computations or manual generations of updated schedules due to the complexity and required computation time as well as the lack of fast feedback from the shop floor.

Real-world production environments however are subject to frequent unforeseen events such as machine breakdowns, new order arrivals, varying processing times and changes of the availability of resources. Such events may render the available schedules inefficient or even infeasible so that adaptations are needed.

Real-time scheduling systems have the task to generate updates of the production plans based on a continuous exchange of information with the shop floor systems. These plans should be executable by the real plant

because otherwise time-consuming modifications or refinements are necessary. So there are two, contradictory requirements: The computation of the schedules must be fast, where sufficiently fast is defined by the execution times of the production plant. When an operation is finished, the next executable operation must be started with a delay that should not be larger than a small fraction of the average execution time. On the other hand, for a schedule to be executable, the scheduling system should be based on a detailed model of the plant that includes all relevant conditions and constraints for the execution of the production plans. This excludes the use of simplified models which consider only basic constraints as e.g. the sequence of operations within jobs, exclusivity of the use of resources and changeover times. Many existing approaches fall short to deliver timely responses and to generate schedules that are interpretable and executable by plant operators [1]. One possible way of solving the real-time or online scheduling problem is to see the scheduler as a controller that continuously monitors the current state and applies corrective actions to keep the system on track toward the reference trajectory [2]. Then offline scheduling is analogous to providing the reference trajectory or setpoint of a dynamic system. However, while this is a convincing analogy, there are fundamental differences, in particular regarding what "tracking" means for schedules. Our approach here therefore is similar to the "all in one" optimizing control approach [3]. Specifically, we employ simulation-optimization to realize this idea.

In [4], MILP-based methods using state-space formulations were introduced for online scheduling in a feedback loop. However, as noted in [4], these approaches require advanced solution techniques to handle high-complexity and high-fidelity problems to maintain computational feasibility.

Simulation-optimization (SO) is well suited for this task as high-fidelity simulation models that represent the production process in detail can be used and therefore the scheduler will generate production plans that the plant operators can implement without modification. Simulation models can easily be adapted to changes of the structure (e.g. available resources) and the parameters (e.g. predicted execution times) of the production system and to new jobs and re-computed schedules. For scheduling on the basis of detailed complex stimulation models, rigorous scheduling methods usually are not well suited because the transformation of the simulation model into the underlying formalism leads to very complex models and excessive computation times. Therefore in SO generally metaheuristics as e.g. evolutionary algorithms are applied. Such algorithms are less performing than rigorous algorithms for the solution of MILPs or constraint satisfaction problems as long as the solution times of the rigorous algorithms are acceptable, but have the advantage of being more generally applicable and leading to acceptable solutions early in the solution process, however without guarantees for the closeness of the solution to the true optimum. In [5], a successful application of SO with evolutionary algorithms to a complex real-world industrial scheduling problem was reported. It was also shown in [6] for general video game playing (GVGA) that evolutionary algorithms (EA) with simulation models compete well in environments where changes of the decision space are frequent and fast responses are crucial.

Our proposed simulation-optimization approach provides greater flexibility and adaptability for handling complex scheduling problem and the results are easier to interpret, thereby facilitating practical adoption in industrial settings. In [7], we presented the idea of a reactive real-time scheduling approach based on SO. In this paper, we extend our previous work by providing a more detailed explanation of the interaction between the real plant and the scheduling system, by exploring the influence of critical parameters and by discussion a case study of a complex pharmaceutical batch production [8], simulating a typical 8-hour production shift with major disruptions.

## APPROACH

Our online scheduling framework uses simulation-optimization with real-time feedback from the production process that is used to update the simulation model to align with the state of the production. The framework contains two components, the scheduling system and the production system. Figure 1 shows the components and their interactions.

### Scheduling System

The evolutionary algorithm runs continuously and improves the schedules gradually based on the currently available information. The simulation system (a detailed commercial discrete-event simulator) uses heuristics and logic constraints to generate the detailed schedules, i.e. it acts as the schedule builder. The model in the scheduler is updated continuously with the latest information from the plant. The detailed schedule that is passed to the production management system is executable on the shop floor. This is achieved by the execution logic and, if needed repair mechanisms that are implemented in the simulator. E.g., no new operation can be started on a resource which has become unavailable. Transferring schedules that are generated fast after changes in the plant or in the structure of the orders provide an immediate response to disturbances. As this happens after few iterations of the EA, their quality will be lower, but in the following iterations of the EA they are further improved.

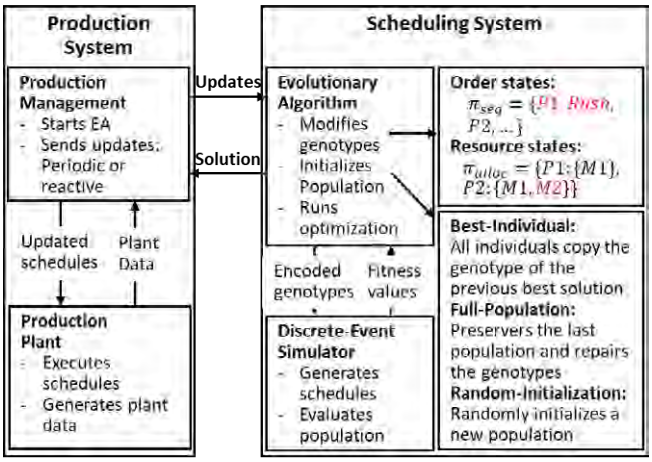

**Figure 1.** The reactive real-time scheduling framework integrates a scheduling system with an evolutionary algorithm and discrete event simulator and a production system with data access to the plant to dynamically adapt to changes and disruptions in the plant. The scheduling system modifies genotypes representing order sequences and resource allocations and uses a discrete-event simulation to evaluate schedules. The evolutionary algorithm iteratively updates and refines schedules for the current model of the production system. The production system provides data from the plant and triggers updates in response to events such as delays, rush orders, and maintenance tasks, ensuring continuous alignment between schedules and the current plant state.

In the case investigated here, the scheduling solutions are encoded as genotypes which contain a global sequence of orders, e.g. $\pi_{seq} = \{P1, P2, P3, \dots\}$, and the allocation of orders to resources, e.g., $\pi_{alloc} = \{P1:\{M1\}, P2:\{M1, M2\}, \dots\}$. In more complex examples, further degrees of freedom can be encoded, e.g. the splitting of customer orders into production jobs (see [4]). The EA explores the space of feasible schedules through selection, recombination, and mutation. The repeated execution of the EA starts with the modification (if needed) and initialization of the genotypes. In each iteration, the algorithm evaluates the fitness of each genome in the population by the execution on the updated simulation model, selects the most promising candidates, and applies recombination and mutation to generate new solutions. A survivor selection process ensures which solutions are carried forward. During the evaluation of the genomes, the simulator builds a detailed schedule that complies with all known constraints. The best available detailed schedule is transferred to the plant when an update is requested.

## Production System

The production system provides real-time information to the scheduling system. It consists of the production management system and the production plant itself. The production management system initiates and parametrizes the evolutionary algorithm and monitors the real-time data from the production plant for deviations that require updates of the scheduling model or of the genotypes and of the genomes of the solutions in the population. Updates are performed either periodically, updating the current state of the execution of the schedule and parameters as e.g. expected execution times, or reactively in response to significant disruptive events, such as rush orders, breakdowns, large delays in the execution of operations or maintenance requirements.

## Information Exchange

Figure 2 illustrates the information exchange between the production system and the scheduling system.

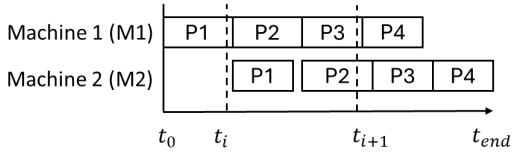

**Figure 2.** Gantt Chart with update events. M1 and M2 process the orders sequentially (first on M1, then on M2).

At each update instance $t_i$, the production system provides the scheduling system with real-time operational data, including the current status of ongoing tasks, estimated remaining processing times, and details of disruptions such as machine breakdowns, maintenance tasks, or urgent new orders. At the same time, the scheduling system sends an updated detailed schedule for the next period starting at $t_{i+1}$.

After the exchange at $t_i$, the scheduling system updates its simulation model and configures the evolutionary algorithm by adjusting decision variables if needed. It then continues optimizing the schedule for the next period (starting at $t_{i+1}$). Operations that are already in progress (e.g., P2 on M1) remain fixed.

Disruptive events, such as maintenance activities or new order arrivals, trigger immediate reactive updates. The scheduling system instantly integrates this new information, modifies the simulation model and reconfigures the evolutionary algorithm. After a predefined interval after such disruptive events, a revised schedule is generated and sent to the production system after which the evolutionary algorithm continues its optimization for the rest of the regular update interval.

## Reinitialization of the population

A key element in designing the scheduling system is how the population is managed between updates, as this can be used to preserve information between updates and to control the balance between exploiting current solutions and exploring new ones. We investigated three options:

**Best-Individual:** The best individual from the previous population (i.e., the best schedule found before $t_i$) is copied into the new population, and only the parts affected by the changed conditions are adjusted randomly.

**Full-Population:** The entire population is carried over to the next generation, and the solutions are only repaired to fit the updated constraints (e.g., new tasks or changed machine availability). The balance of exploration and exploitation largely depends on the diversity of the previous population.

**Random-Initialization:** The entire population is reinitialized randomly, producing a new and diverse population. This enhances the exploration and may help avoid local minima that arise when solutions become too similar.

The three strategies can be mixed, e.g. by updating a fraction of the population with random solutions after a disruptive event. Another option is to modify the strategy parameters of the EA, e.g. the mutation strength, at disruptive events and then including them in the optimization process (Co-evolution, [9]).

## EXPERIMENTS

The case study addressed in this work is taken from Kopanos, et al., [8]. It is a multiproduct batch plant with 17 units (machines) that are organized in 6 stages (Figure 3). The problem, which is a variant of a hybrid flow shop problem, comprises 12 instances that vary in the number of orders, the objectives, and in the storage policy. The features of the problem include limited product-unit flexibility, machine-dependent processing times, sequence-dependent changeover times, and product-specific recipes, meaning that certain jobs are not processed on some of the available stages.

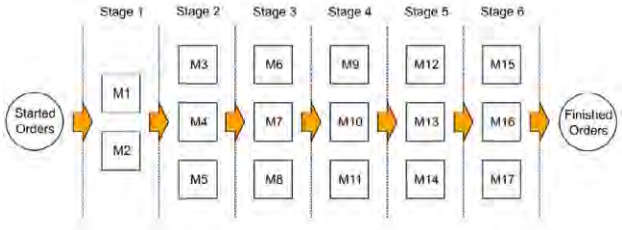

**Figure 3:** Plant layout of the case study.

A series of experiments were executed to evaluate the performance of the proposed real-time scheduling system and to show the effects of the length of the update intervals, the time required to evaluate one generation, and of the initialization strategy. The experiments simulate one production shift in the multiproduct batch plant and include disruptive events. The results are compared to the outcomes from using a clairvoyant scheduler that anticipates all disruptive events. This solution was computed by optimizing the full schedule over the full time horizon with the disruptive events taken into account. The same evolutionary algorithms was used and run over 1000 generations.

In total, 20 combinations of parameters were evaluated, with each case being repeated 20 times to account for the inherent randomness of the evolutionary algorithm. The experiments differ in the length of the update intervals of the production system, the time before the immediate response must be provided, the time to evaluate one generation of the scheduling system, and the initialization strategy after update events.

### Fixed Parameters

The following parameters were used across all experiments to ensure comparability:

**Problem setting:** Initially 30 orders have to be fulfilled within a time horizon of 32 hours. For each order there is a due date. All orders are released at time 0. The prime objective (Equation (1)) is the minimization of the maximum tardiness T. If the tardiness is below 0, the objective shifts to the largest negative earliness. This pushes the completion times $C_i$ of the orders $i$ further away from their due dates $d_i$ if all due dates can be met.

$$F = \max_i \ (C_i - d_i) \tag{1}$$

**Simulation Horizon**: Each simulation run consists of 8 hours (28,800 seconds) of production, representing a typical production shift. Note that this is only a fraction of the execution time of a schedule. The schedules are evaluated over the full execution time, i.e. using the completion times of the orders that finish in the simulation horizon and the predicted (simulated) completion times of the remaining orders.

**Initial Solution:** The simulation was initialized with a high-quality scheduling solution that was computed in a separate run with the same objective and 1000 generations, serving as a reference schedule. The initial solution has an objective value of -1.34 (i.e. all orders finish early). The total time to complete the full production schedule is 30 hours and 23 minutes.

**Disruptive Events:** Table 1 lists the eight disruptive events that were introduced during each simulation to represent real-world disturbances.

**Table 1:** Disruptive events and their arrival times.

| Event | Time (sec) | Info |

| Maintenance of M19 | 12000 | 1h duration |
| Release of P05_Rush | 13800 | Due in 12h |
| Maintenance of M13 | 18000 | 1h duration |
| Maintenance of M16 | 21600 | 0.5h duration |

All maintenance orders were non-preemptive,

meaning they had to be executed after the current operation on the respective machine had completed.

**Population Size:** The population consists of 32 individuals, which are evaluated in parallel using 32 threads on a machine with 16 cores (Intel Core i9-14900K). The offspring size was set to 32, with an elitist size of 16.

**Mutation Operator:** We used a permutation mutation, which selects a subsection of the gene and shuffles it randomly. The mutation rate was set to 1, meaning every individual underwent mutation.

**Crossover Operator:** The cycle crossover operator was applied to preserve as much information as possible about the absolute position of the elements [10]. The crossover rate was set to 1.

**Parent Selection:** Rank-based selection was used to choose parent individuals for the next generation.

**Survivor Selection:** Random survivor selection was employed, with an elitist fraction of 50%. The top 50% of the individuals from the previous generation were retained, while the remaining individuals were selected randomly from the remaining population.

**Decision Variables of the EA:** Only the sequence of orders, e.g., $\pi_{seq} = \{P1, P2, P3, \dots\}$, was encoded in the genomes of the individuals of the EA. The allocation of orders to machines was performed by the simulator using a greedy FIFO rule. Each operation is executed on the machine where it finishes the earliest.

## Variable Parameters

To study their effect on the performance of the scheduling system, the following parameters were varied:

**Update Interval:** The length of the periodic update interval was set to 60 and to 300 seconds.

**Simulation time:** This parameter is a fictitious time for the evaluation of one generation of solutions. It determines the number of generations that are evaluated. Simulations times of 3s and 12s were tested.

**Immediate Response Time:** This is the time when after a disruptive event a new solution is sent to the production system. The minimum time is the time needed to evaluate on generation of solutions. The second value that was tested is 60 seconds.

**Initialization:** The modes *Full-Population*, *Best-Individual* and *Random* were tested.

# RESULTS

Figure 4 shows the distribution of the mean fitness values for the three different initialization modes. The mean fitness values for all experiments at the minimum time needed to evaluate the generation of solutions after each disruptive event in Table 1.

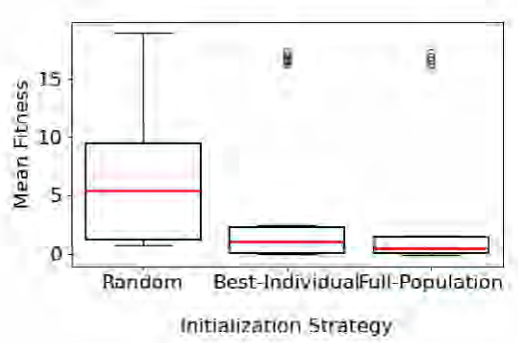

**Figure 4:** Distribution of the schedule quality for different initialization strategies after the disruptive events.

The Random initialization is clearly inferior. There are only small differences between the *Best-Individual* and *Full-Population* strategies. As the latter performs slightly better, only results for this strategy are shown in the sequel.

Figure 5 shows the evolution of the mean fitness over all 20 runs and of the best 25% of the runs at the end of the simulation horizon over the simulated 8 hours of production with the disruptive events listed in Table 1 for different configurations (300 s periodic update interval, 3 and 12 s/gen, immediate response after one generation (0) and after 60 seconds). Additionally, the performance without replanning is indicated by the solid black line.

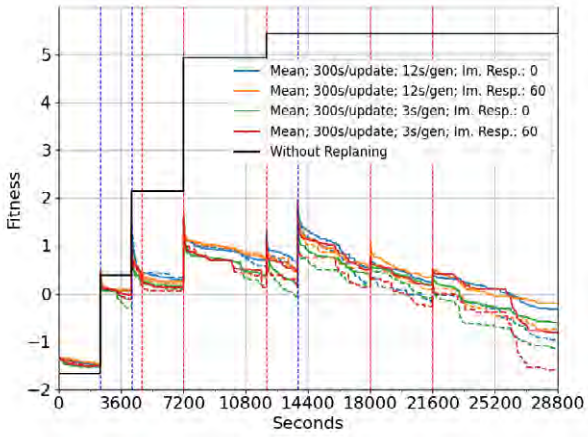

**Figure 5:** Mean (colored solid line) and mean of best 25% (colored dashed line) fitness values of 20 experimental runs for different configurations (300 s/update, 3 and 12 s/gen, im. Resp after one generation and 60 seconds). The disruptive events are marked as dashed vertical lines (blue for maintenances and red for new order arrivals).

Table 2 shows the results for all configurations. The clairvoyant scheduler uses the same algorithm but has the a priori information about all disruptive events. This provides a lower bound that cannot be achieved by a real-time scheduler.

**Table 2:** Best, mean, mean of best 25% of fitness values for the different configurations (formatted as "seconds per update, seconds per generation, immediate response time"), for the clairvoyant scheduler, and for the case without replanning.

| Configurations | Best | Mean | Mean Best 25% |
|---|---|---|---|
| 300, 12, 60 | -1.30 | -0.20 | -0.74 |
| 300, 12, 0 | -1.67 | -0.32 | -0.96 |
| 300, 3, 60 | -1.76 | -0.81 | -1.60 |
| 300, 3, 0 | -2.10 | -0.61 | -1.14 |
| 60, 12, 0 | -1.68 | -0.52 | -1.08 |
| 60, 12, 60 | -1.61 | -0.23 | -0.74 |
| 60, 3, 0 | -2.10 | -0.68 | -1.34 |
| 60, 3, 60 | -1.53 | -0.24 | -0.83 |
| Clairvoyant | -4.37 | | |
| W/o replan | 5.44 | | |

The differences between the configurations are relatively small when the results at the end of the simulation horizon are compared. The best configuration realizes 75 – 80% of the possible improvement. The simulation time has a negative influence but due to the long optimization interval at the end it is not very pronounced. Between disruptive events the shorter simulation time leads to significantly faster improvements. The influence of the immediate response time is small and nonuniform.

For the disruptive events considered here, the deterioration of the performance of the production system with rescheduling is relatively small, pointing to the system not being operated under full load.

## SUMMARY

We proposed an approach to real-time scheduling which is based on simulation-optimization using a detailed discrete-event simulator with schedule building heuristics and an evolutionary algorithm that handles the key decision variables. The main idea is to run the evolutionary algorithm continuously with updates of the simulation model and of the decision vector being performed periodically and in response to disruptive events. Maintaining the previous population except for changes required by changes of the decision parameters is preferable over other possible initializations. The resulting performance is good even for low numbers of generations that are evaluated during the update interval.

We characterized the performance by comparison with the execution of the schedule without changes due to the disruptive events and with the results obtained with a fictitious clairvoyant scheduler which cannot be achieved in a situation where these events are not known before.

We considered the influence of simulation time on the performance. Other cases with demanding simulation times may require additional simplifications or algorithmic optimizations to meet the time constraints. This aspect will be further studied.

In this paper we only reported results for a small number of relatively infrequent disruptive events for lack of space. It will be studied in the future which influence the parameters of the algorithm have in situations where the plant operates at the capacity limit.

## ABSTRACT

By 2050 around 12% of cumulative emissions reductions will come from Carbon Capture, Utilisation and Storage (CCUS) making it an essential component in the path towards net zero [1]. Focus will initially be on the retrofitting of fossil fuel power plants, which will shift to hard-to-decarbonise industries such as iron, steel, and concrete [1]. Such industries are often grouped together in industrial clusters. Comprising both large and small point sources concentrated over a defined geographical area, industrial clusters offer an opportunity to maximise the impact of CCUS whilst also improving economic feasibility [2]. The North Sea Port (NSP) cluster an example of this. Within the NSP cluster an initial set of five emitters are to join a capture, conditioning, and transport network by 2030. From there other emitters within the area will be able to join incrementally to 2050 [3]. However, the emitters who join and the timing of their connection will have a significant effect on the evolution the network. The pipeline network design will balance design requirements for initial emitters in a backbone network, with requirements for encouraging and enabling expansion. This study builds on scenarios defined between 2030 and 2050 [3] and applies a multi-period evolutionary-based approach (Steiner tree with Obstacles Genetic Algorithm (StObGA)) to predict pipeline year-on-year network growth in the NSP cluster. This provides a novel approach to the problem. The results are used in an examination of the potential growth of the pipeline network and an investigation of trade-offs necessary in the infrastructure design.

**Keywords**: Carbon Dioxide Capture, Genetic Algorithm, Modelling and Simulations, Energy, Carbon Capture.

## BACKGROUND

Carbon Capture, Utilisation and Storage (CCUS) is a key technology in the pathway to meaningful CO2 abatement. If the application of CCUS is to be successful, the planning of the infrastructure required must be comprehensive and consider several factors. Technical, geographical, political, and social factors all require extensive planning/research if any CCUS infrastructure is to be successfully deployed. If improperly planned and risks/uncertainties are not accounted for there could be serious economic repercussions for emitters, thus dissuading any further uptake [4,5,6].

One way to make CCUS more enticing to emitters is the formation of industrial clusters. Here emitters within a set geographical area are grouped and can share infrastructure, thus increasing the potential for economy of scale and reducing the cost to individual entities [4,5]. However, the cost is influenced by many factors including number and size of emitters, availability of potential transport methods, distance from utilisation/storage sites, upcoming policies and regulations, and social acceptance of CCUS within the area. Subsequently, despite the benefits that industrial clusters offer, the infrastructure must still be properly planned [7].

Figure 1 outlines the major infrastructure elements of the CCUS supply chain. Starting with CO2 sources, the gas is captured and conditioned (usually compressed and purified) then it is transported onward for either utilisation or storage.

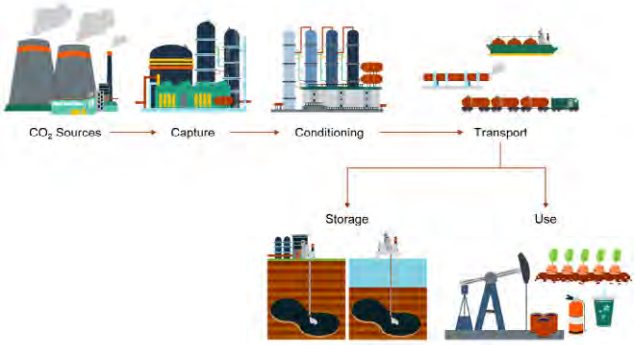

**Figure 1.** Diagram of the key stages in the CCUS supply chain.

In general, capture occurs at the site of large stationary emitters. The vast majority of which are from power plants, and other industries such as concrete, steel and chemical production [8]. Once captured, CO2 must be conditioned to ensure safe and efficient transport. Whilst often sited with capture, it can be considered as a distinct and vital stage in the CCUS supply chain. Conditioning encompasses several processes including dehydration, purification, and compression.

There are several options when considering CO2 transport infrastructure, each with their own advantages and disadvantages.

For smaller, discontinuous volumes of gas, rail and road are valid options. Shipping, however, is a candidate that can be scaled up to meet these demands, and, geography depending, can also be implemented with minimal infrastructure capital expenditure [4,5]. This is particularly evident in locations of well-established industrial clusters along coastlines and canal networks. As CCUS projects become established, shipping is seen as a viable option for the initial timeframe when pipeline infrastructure has yet to be established, and/or fewer emitters have joined the network.

Pipeline transport is anticipated to be the most economically efficient transportation option for large stationary emitters over industrial clusters [9-11] Pipelines also have the advantage of being able to efficiently transport CO2 over large distances and multiple terrains.

Whilst pipelines do have the potential to be an effective mode of transport, they require extensive infrastructure investment. This can be involved, requiring knowledge on pipeline sizing; locations of emitters and storage sites; specifications for transport and storage; network expansion over time [12]. Fortunately, gaseous phase pipeline infrastructure technologies for are well established, so existing standards on sizing and material can be drawn on when designing networks [12, 13]. However liquid phase pipeline transport requires additional considerations [6].

Extra complexity is added when considering network expansion, as geographic information needs to be combined with predictive models to create the most future-proof network.

Generally, pipeline network designs are modelled using graphs with emitters and offtake sites are taken as nodes with the pipelines themselves as arcs between them. To model both the topology and pipeline sizing simultaneously is computationally expensive so the two are generally modelled separately [14].

For length minimisation, Minimum Spanning Tree algorithms, such as Kruskal's are commonly used. This allows for generalised cost minimisation [15].

However, for any simulation to be truly representative, real-world constraints must be considered. In some cases, this can be circumvented, by utilising existing infrastructure such as road, or gas networks to provide predefined routes [16].

However, these methods are inflexible and do not consider novel routes, thus eliminating many possible optimal solutions.

Graph-based methods, such as Steiner points can also be used to enhance design flexibility, however this can also be limiting due to high computational expense, and inability to consider different geographic obstacles [14].

A more recently developed methodology by Rosenberg et al. (2021), displayed the viability of combining the Steiner tree method with a genetic algorithm to design networks that consider such obstacles [17]. This methodology is built on here, by applying it to CCS networks within an industrial cluster.

## Methodology

The methodology used in this work produces an optimised pipeline route for CCUS pipeline networks that connects point sources with offtake locations. Also taken into consideration, is a set of real-world constraints such as urban areas and waterways. These may be regions in which construction cannot occur, or in which a higher cost will be incurred to traverse them, known and solid and soft obstacles respectively. Such obstacles are represented as a graph consisting of polygons, each is assigned a crossing weight representative of the ease of traversal, with those that are un-traversable given an infinite value. An obstacle's crossing weight is multiplied with the length of the pipeline that crosses it.

## Topology

To separate the topology from sizing, the necessary assumption that the shortest route will be the most cost-effective is made. To find the minimum length between emitters and offtake, the Euclidean Steiner tree problem with soft and solid obstacles (ESTPO) is applied. To solve this for a set of given constraints, a genetic algorithm for Steiner trees with obstacles (StObGA) can be used. This was developed by Rosenberg et al. (2021) [17].

The genetic algorithm utilises the following chromosome type structure:

$$\{(x_1, y_1), (x_2, y_2), (x_3, y_3), \dots, (x_s, y_s)\} + \{1|0|1|0|0|0|1|1|0|0\} \quad (1)$$

This is split into two distinct parts, the first being the x-y coordinates of s number of Steiner points of variable length, and the second is a fixed length binary list which determines four obstacle corners to be used in the network.

To connect the terminals, Steiner points and obstacle nodes, weighted edges are created using Kruskal's minimum spanning tree [18]. The weighting depends on edge length and whether is traverses any obstacles.

The nodes and edges found this way are then subject to an optimisation regarding given emission and offtake values, with all edges assumed to be unidirectional.

## Sizing

Pipeline sizing is determined using a mixed integer nonlinear programming (MINLP) optimisation. With constraints being hydraulic, structural, and commercial. The following objective function minimised the total cost in $, C, for a defined set of arcs A:

$$C = (1 + 0.03) \sum_{i|(i,j)\in A} C_{ij}^{C} \quad (2)$$

Where the total cost is the sum of the capital costs ($C^C$ in the equation below) and the operating costs (assumed to be 3% of $C^C$.

The capital cost is a function of pipeline length L, outer diameters $D^{po}$, and considers the material, labour, right-of-way and other miscellaneous costs:

$$C^C = [674(dia)^2 + 11754(dia) + 234085](length) + 405000 \quad (3)$$

Where diameter (*dia*) is in inches, length is in miles, and cost is in dollars.

Additional constraints are material balance, discrete sizing, and erosion velocity as described by Ejeh et al 2023b, and Hammond et al 2025 [19, 20].

An overview of the methodology can be found in Figure 2.

# CASE STUDY

The method described above has been applied to the case study illustrated in Figure 3. Here an industrial cluster spread over the North Sea Port region which spans Belgium and The Netherlands.

The emitters have been selected as a selection of the largest in the region with respect to their 2023 verified emissions data [21]. The planned base route is as described in Ejeh et al 2023a. This is predicated to start working in 2030, and will include Zeeland Refinery, Sloe Centrale, DOW Benelux, Yara Sluiskil B.V., and ArcelorMittal. From there the network can then expand to encompass more and more emitters in the cluster.

This will then expand over successive years to 2050 in increments shown in Table 1.

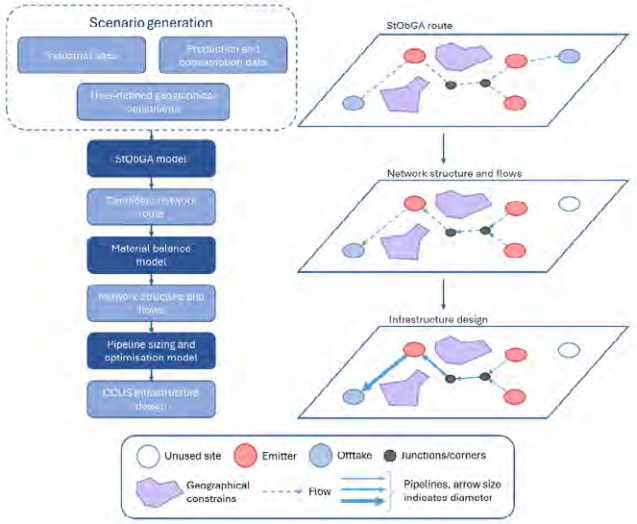

**Figure 2.** The worflow of the model showing consectutive steps and the final output.

**Table 1.** The list of point sources within the NSP cluster with the assumed year that they will join the network.

| Number of emitters | Assumed Addition year |
|---|---|
| 5 | 2030 |
| 11 | 2035 |
| 17 | 2040 |
| 23 | 2045 |
| 29 | 2050 |

A diagram displaying all emitters, obstacles, and the currently planned 2030 route is shown in Figure 3. The route shown in Figure 3 is based work previously conducted by C4U [3].

Compared with previous work [20, 22], the network developed here spans across a much smaller area with a higher density of emitters and industrial/urban areas. Providing a set of scenarios to further refine the network expansion methodology.

The network expansion was divided into Graded increases, with predetermined additions at 5-year intervals. This was further split into two distinct scenarios. The first (Graded Perfect), where the final network was simulated, and the intermediates were then built to match it. The second (Graded), was build piecewise with no knowledge of the final network. This allowed for a comparison of the two levels of implied knowledge.

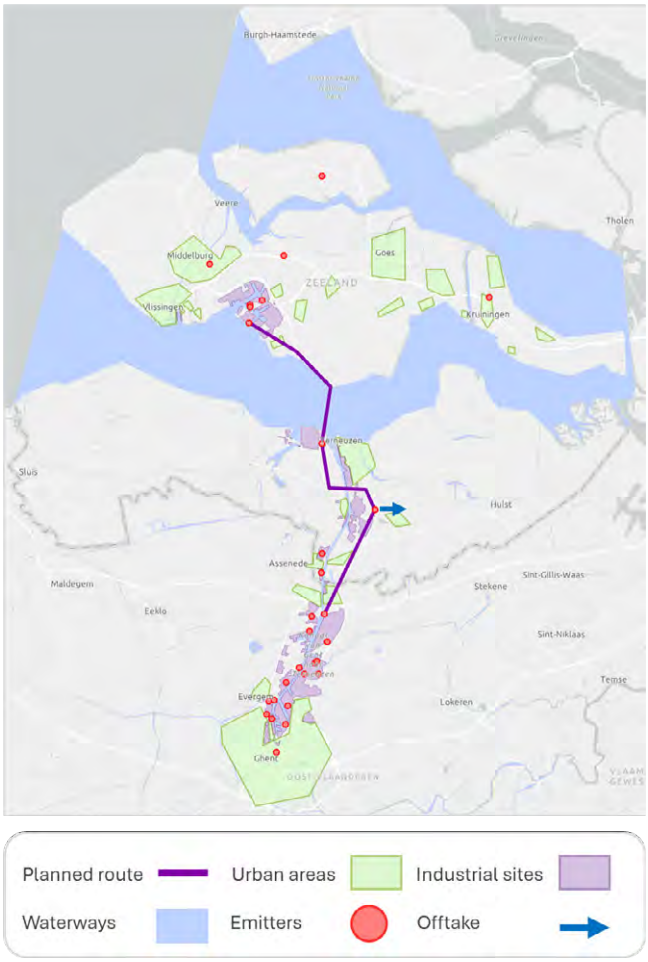

**Figure 3.** The NSP cluster showing the location of all point source emitters, built up areas, and the currently planned pipeline route.

## RESULTS AND DISCUSSION

A numerical summary of the results is shown in Table 2, with topological results presented in Figure 4. It can be seen in Table 2 Graded Perfect is longer than Graded but is cheaper, this indicates that it routed around areas with higher weighting when compared to the Graded system (Table 2 and Figure 4). The difference in length is 0.71% whereas the difference in costs is 7.9%. Indicating the importance of routing around areas with higher cost weightings. Highlighting the advantages of a predetermined final network when considering known, phased additions.

The difference in routing is clearly visible Figure 4, where the Graded Perfect method has deviated from the original set out in Figure 3. Providing an interesting contrast between partially fixed sections of the infrastructure with that of a fully variable one. The difference between the two networks is most likely due to the prioritisation of cost reduction over pipeline length.

The difference also highlights the potential for many possible routes across the same geographical area.

Here, the cost weightings of the urban and industrial areas have dictated the shape of the routes, specifically the Graded Perfect (Figure 4a) where no pre-existing initial route was enforced. This left the algorithm to find the most cost-effective route across the cluster, leading to a different final network to the Graded results (Figure 4b). To fully assess the impact of the cost weightings on the final network may be altered to bring the Graded Perfect network in line with that of the Graded.

This emphasises inherent uncertainties in pipeline network design, as small changes in decision-making can affect the final network. Such changes can have an impact on overall costs due to differing infrastructure requirements needed to counter pressure drops and cross certain obstacles, so require fully assessing before construction can begin.

Further work will be required to understand the effect of predetermined infrastructures fully.

**Table 2.** Summary of simulated pipelines, with calculated costs based on pipeline lengths, diameters, and operating costs

| Scenario | Total Length (km) | Total cost ($million) |
|---|---|---|
| Graded Perfect | 115.04 | 162.20 |
| Graded | 114.23 | 174.94 |
| % Difference | 0.71 | 7.9 |

## CONCLUSIONS

This work has provided an extension to previous work on pipeline network design that considers topological constraints. Here, the decreased length scale and increased density of point source emitters has provided a unique view of this method.

The Authors have successfully demonstrated its applicability in this case, thus increasing the scope of the method to shorter distances and more densely populated areas. The effect of cost weighting on soft obstacles was presented. The Authors also believe that the consideration of known and unknown final infrastructures will facilitate more informed decision making by allowing for consideration of a wide array of possible arrangements.

Future work should focus on further quantifying the impact of the addition of point source emitters over varying time periods. With particular emphasis on prior knowledge of the final infrastructure. The impact of predetermined sections of infrastructure on final outcomes should also be investigated.

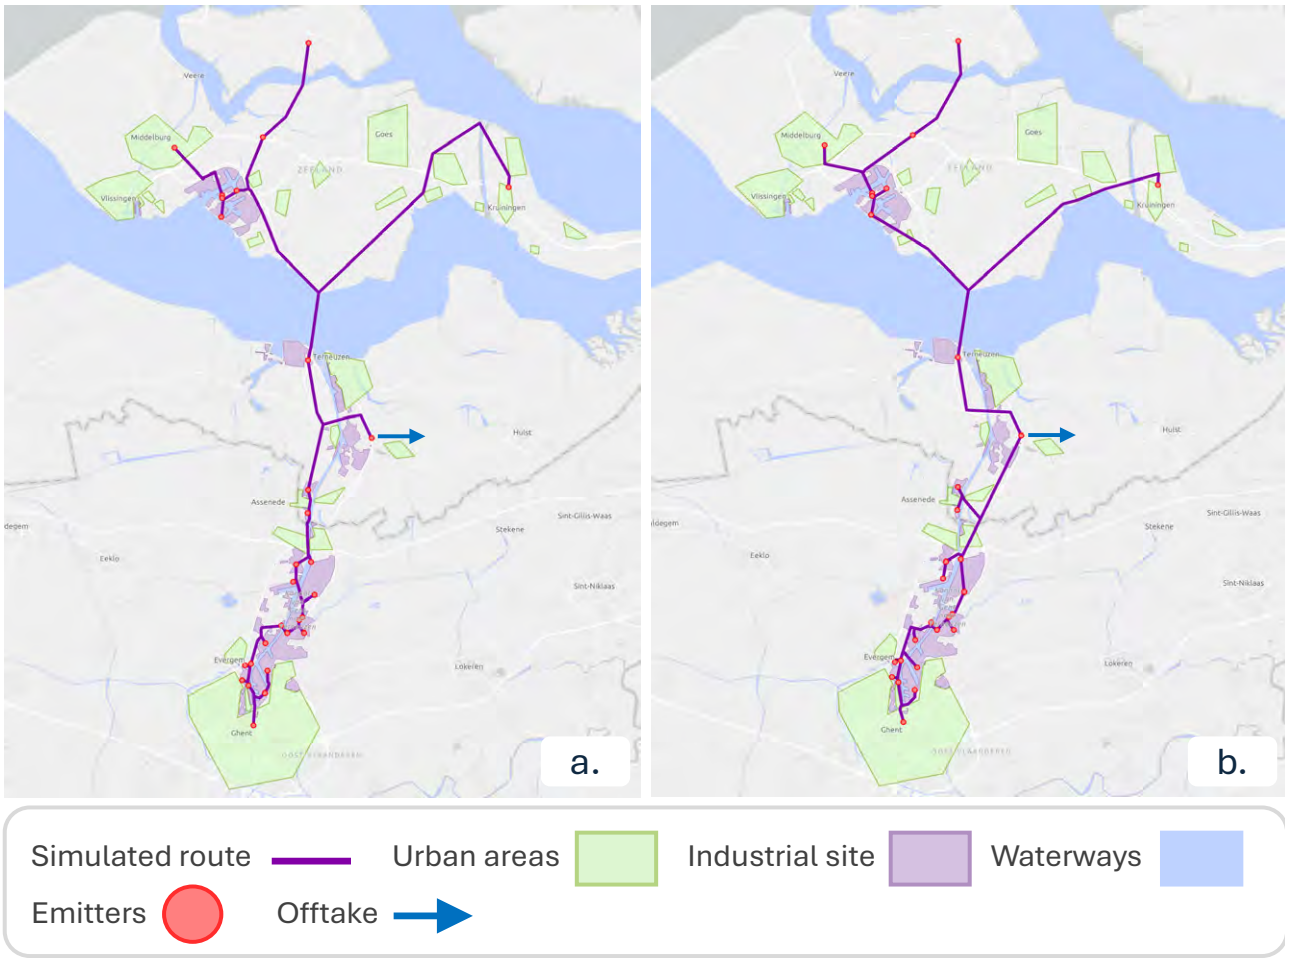

**Figure 4:** The NSP cluster showing the simulated pipeline infracstructure routes with a. Graded Perfect, and b. Graded.

# Flow Simulation of Plastic Life Cycle Considering Carbon Renewability and Environmental Impact

**Kota Chida[a], Heng Yi Teah[b], Yuichiro Kanematsu[b], Yasunori Kikuchi[a,b,c]***

[a] Department of Chemical System Engineering, The University of Tokyo, Bunkyo-ku, Tokyo, Japan
[b] Presidential Endowed Chair for "Platinum Society", The University of Tokyo, Bunkyo-ku, Tokyo, Japan
[c] Institute for Future Initiatives, The University of Tokyo, Bunkyo-ku, Tokyo, Japan

## ABSTRACT

Renewable carbon sources, such as biomass and waste, are being explored as alternatives for sustainable plastic production. However, the significant uncertainties surrounding the environmental impact of biomass supply processes raise questions about whether these plastics positively contribute to society. Furthermore, the lack of systematic knowledge about plastics and incomplete understanding among stakeholders pose challenges to conducting comprehensive assessments and designing effective plastic life cycle systems. This study aims to clarify the carbon flow within the life cycle of biomass- and recycled-derived plastics and to design a plastic life cycle that enables the introduction of renewable carbon sources. To this end, the study analyzed the structure of plastics containing renewable carbon and conducted a flow analysis of packaging plastics in Japan. The flow analysis was conducted in the form of an optimization problem. Greenhouse gas (GHG) emissions and the proportion of renewable carbon were selected as assessment indicators and objective functions. Constraints for optimization included the availability of biomass supply, the demand for product resins, and the processing capacity of various End-of-Life (EoL) methods. As a result, it was revealed that the priority of resin types to be produced and recycled shifts in response to changes in constraints such as biomass input and recycling capacity. Furthermore, a trade-off between reducing environmental impact and increasing the renewability of carbon was identified, highlighting the necessity of designing systems that balance these factors. This research provides valuable insights for designing sustainable plastic life cycles in the future.

**Keywords**: Life Cycle Analysis, Flow analysis, Biomass-derived plastic, Recycling, Carbon renewability

## INTRODUCTION

Fossil-based plastics, owing to their convenience, are materials that contribute significantly to modern societal benefits. However, their production and disposal are accompanied by substantial environmental challenges, including GHG emissions [1] and the issue of marine plastic pollution [2], making it clear that urgent countermeasures are required. Plastics derived from biomass or recycled materials utilize sustainable carbon sources and are considered to emit lower GHG levels across their life cycles. As such, their broader adoption is being explored as an alternative to conventional fossil-based plastics. Research on the environmental impacts of these plastics has been vigorous. For instance, case studies employing life cycle assessment (LCA) have assessed the environmental and economic impacts of specific plastics, such as PHBH (Poly(3-hydroxybutyrate-co-3-hydroxyhexanoate)) and Bio-PE, comparing them to traditional fossil-derived plastics [3, 4]. Nevertheless, it remains unclear whether the adoption of these materials will genuinely yield positive environmental and societal outcomes. Variations in environmental assessments arise due to differences in factors such as the type of biomass used as feedstock, resin production processes, and geographic boundaries. Moreover, comprehensive and quantitative assessments of the environmental impacts that arise from introducing multiple resins into existing societal systems remain scarce. A further complication is the incomplete understanding of the carbon flow pathways within the plastic life cycle. This lack of clarity weakens the connections between stakeholders involved

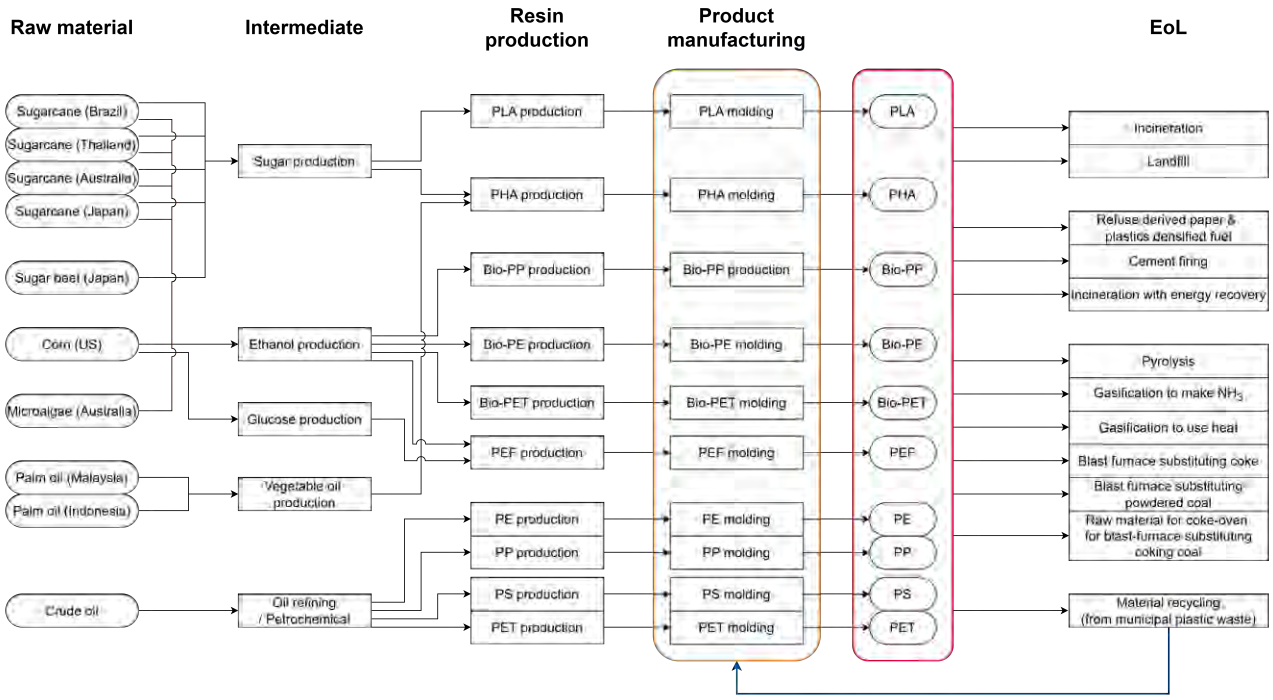

**Figure 1:** The life cycle of plastics considered in the flow analysis.

in various stages of the plastic life cycle, creating challenges in designing flexible, sustainable life cycles aligned with a sustainable society.

This study first aims to elucidate the potential changes in the overall carbon life cycle brought about by the introduction of plastics derived from biomass and recycled carbon sources. Building on this understanding, it aims to conduct a flow analysis from the perspectives of environmental impact and carbon renewability. Ultimately, the study aspires to design more sustainable life cycles that facilitate the adoption of biomass- and recycled-derived plastics.

# METHOD

## Assessment targets / indicators

In this study, a case analysis was conducted, focusing exclusively on plastics used for packaging applications in Japan. The resins selected for assessment included conventional fossil-derived plastics commonly used in packaging (PE, PP, PS, PET) as well as biomass-derived plastics such as Bio-PE, Bio-PP, Bio-PET, PEF (Polyethylene Furanoate), PHA (Polyhydroxyalkanoates), and PLA (Poly-Lactic Acid). PHA, PLA, and PEF were chosen as examples of biomass-derived plastics with either significant current production volumes or well-established manufacturing technologies [5]. Meanwhile, Bio-PE, Bio-PP, and Bio-PET were selected to explore the feasibility of substituting existing fossil-based plastics with biomass-derived counterparts that possess identical physical properties. Additionally, recycled resins produced through material recycling of these plastics were also included in the assessment.

The assessment criteria were established based on challenges identified in the current plastic life cycle. Climate change, measured through GHG emissions, was selected as the key indicator for assessing environmental impacts. To quantify the renewability of carbon within the life cycle, the amount of renewable carbon (sourced from biomass or recycling) within the system was adopted as a supplementary indicator.

## System boundaries

To establish the system boundary, a bibliometric analysis was first conducted to cluster relevant literature, extracting key terms associated with the resins and technologies under assessment. Subsequently, based on these keywords, an extensive review of existing literature on plastics was carried out. Information on raw materials, manufacturing methods, applications, and EoL strategies—including those not yet commercialized—was collected for various plastics. This data facilitated the creation of a superstructure for the plastic lifecycle [6]. The superstructure revealed that the introduction of renewable carbon into the plastic system creates numerous combinations of technologies at both the raw material and EoL stages [7, 8]. The choice of raw material, the resulting resin, and the selection and combination of EoL

strategies significantly influence the environmental impact and carbon renewability across the entire lifecycle. The system boundary for analyzing the flow of plastic packaging materials was constructed based on this superstructure, as illustrated in **Figure 1**. In this study, sugarcane, sugar beet, corn, microalgae, and palm oil were considered as biomass feedstock options. The geographic boundaries for each raw material were also taken into account. The raw materials are processed into plastics via intermediate products such as sugar, bioethanol, starch, and vegetable oils. For waste plastics, the EoL options examined included no-recovery methods like incineration and landfilling, as well as energy recovery, non-closed-loop chemical recycling, and closed-loop material recycling.

## Model construction

A linear programming approach was employed to optimize the flow. The objective functions for environmental impact and carbon renewability were defined as shown in equations (1) and (2), respectively, and calculations were performed for each.

$$\text{Min. } G_{total} = \sum_{mat}^{all}\sum_{tech}^{all}\sum_{resin}^{all} M_{mat,tech,resin}E_{mat,tech,resin} + \sum_{resin}^{all}\sum_{EoL}^{all} M_{resin,EoL}E_{resin,EoL} \quad (1)$$

$$\text{Min. } W_{total} = \sum_{\text{mat}}^{fossil}\sum_{tech}^{all}\sum_{resin}^{all} M_{mat,tech,resin} + w \cdot G_{total} \left(w \cdot G_{total} \ll M_{mat,tech,resin}\right) \quad (2)$$

Here, M [t] represents the mass of product resin in the equation, E [t-$CO_2$ eq/t-product] denotes the GHG emission factor, and w [–] signifies the weighting coefficient in the weighted sum method. The second term in equation (2) is provided to manage the flows at the product's EoL stage, excluding material recycling processes that do not affect carbon renewability. GHG emission factors and inventory data for each process in the equations were primarily sourced from the literature. The details of the data sources are provided in the supplementary information. The constraints considered include technological feasibility, the supply availability of various biomass feedstocks, the demand for product resins, and the processing capacities of each EoL method. Technological feasibility was defined such that M = 0 t for flows deemed infeasible or excluded under specific cases. The upper limits for biomass supply were set based on the current production ratios for each raw material and were assumed to vary proportionally while maintaining these ratios. The demand for product resins was estimated from the current consumption volumes (assumed equal to production volumes) of PE, PP, PS, and PET in packaging applications [9], representing the functional requirements plastics must fulfill in society. It was assumed that these functional requirements would remain unchanged even if replaced with renewable carbon-derived plastics. For substitution with other resin types, calculations were based on prior studies comparing the environmental impacts of bio-based and fossil-based plastics [10-12], assuming resins of the same volume have equivalent functionality. The upper limits for the processing capacities of EoL methods were determined using data on the current processing volumes for each method in Japan.

In this study, three cases, as shown in **Table 1**, were examined to visualize changes in the life cycle due to variations in constraint conditions. Case I and Case II represent cases in which the availability of biomass supply improves, while Case III alters the values of constraint conditions related to both the biomass supply and the capacity for material recycling processing. In Case I, the production of all resins shown in **Figure 1** is considered. In contrast, Case II excludes PHA from the target resins, reflecting the fact that the life cycle of PHA is not yet well established. All other constraint conditions and parameters are set identically.

# RESULTS AND DISCUSSIONS

**Figure 2** presents the results of GHG emission optimization in Case I based on Equation (1). The horizontal

**Table 1:** Cases of Future Changes in Plastic Life Cycles Considered in the Flow Analysis

| | Case I | Case II | Case III |
|---|---|---|---|
| **Assessment targets** | All plastics shown in Figure 1 | Excluding PHA from Case I | All plastics shown in Figure 1 |
| **Biomass Supply Potential** | Variable | Variable | Constant (1% of the production volume of each biomass material is available for use) |
| **Recycling capacity** | Constant (equivalent to current capacity) | Constant (equivalent to current capacity) | Variable |

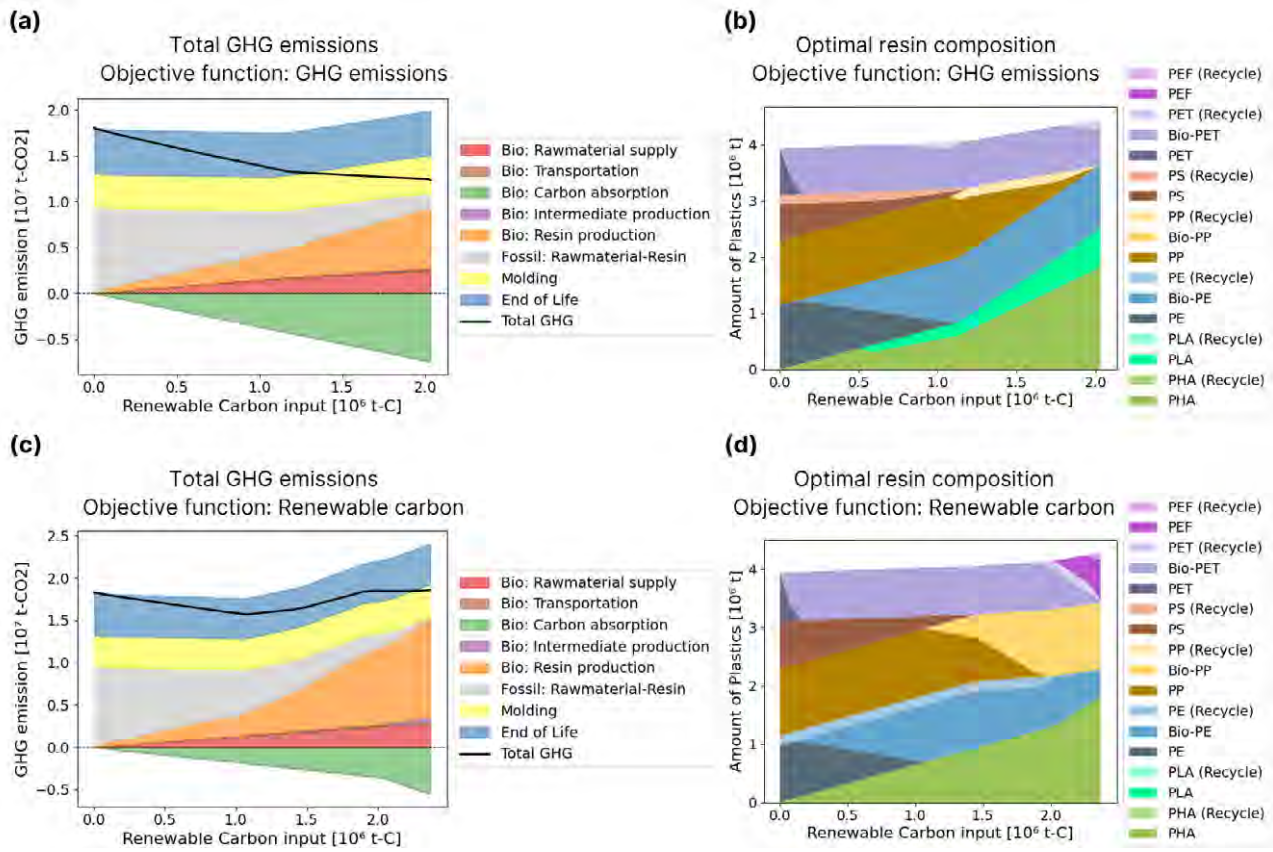

**Figure 2:** Flow analysis results for Case I. (a, c) Objective function: GHG emissions (b, d) Objective function: Renewable carbon within the system. The left-hand diagram shows the changes in the contribution of GHG emissions from each life cycle stage within the system, corresponding to variations in the amount of renewable carbon introduced. The right-hand diagram illustrates the changes in the types of resin products as the amount. of renewable carbon introduced varies.

axis represents the amount of renewable carbon introduced into the system. The points at which the slope of total GHG emissions changes in **Figures 2(a) and 2(c)** correspond to shifts in the types of resins prioritized for production or recycling, as well as transitions in the raw materials used for production, as shown in **Figures 2(b) and 2(d)**. As shown in **Figure 2(a)**, GHG emissions decrease with increasing biomass input, demonstrating the superiority of biomass from the perspective of GHG emission reduction. This reduction is primarily attributed to carbon sequestration during biomass cultivation. Additionally, regardless of the level of biomass input, various life cycle stages—such as raw material supply, carbon absorption by biomass, resin production, and EoL processes—significantly contribute to the total GHG emissions of container and packaging plastics. This highlights the necessity of designing the system across the entire life cycle. **Figure 2(b)** reveals that PET should be replaced with Bio-PET and PS should be substituted with PHA or recycled alternatives as a priority. This indicates that considering the environmental burdens of biomass feedstock and the avoided impacts of recycling, these substitutions achieve significant reductions in GHG emissions. **Figures 2(c) and 2(d)** illustrates the results when minimizing the amount of fossil-derived carbon within the system in Case I. By introducing approximately 2.3 Mt of renewable carbon, defossilization within the system was achieved. Compared to the GHG-optimized result, as seen in **Figure 2(d)**, the types and order of resins prioritized for introduction or recycling differ, with Bio-PP introduction and PE recycling taking precedence. However, as shown in **Figure 2(c)**, a trade-off was observed in which the total net GHG emissions increased with biomass introduction. This suggests that balancing environmental impacts and renewability must be carefully considered when designing a sustainable system reliant on biomass.

In the GHG optimization results for Case II, PLA and PEF were selected as biomass applications instead of PHA, which was prioritized for introduction in Case I but was absent in Case II. However, as PLA and PEF are less advantageous than PHA in terms of environmental impact, the system's total GHG emissions increased by up to 4% during the renewable carbon introduction process.

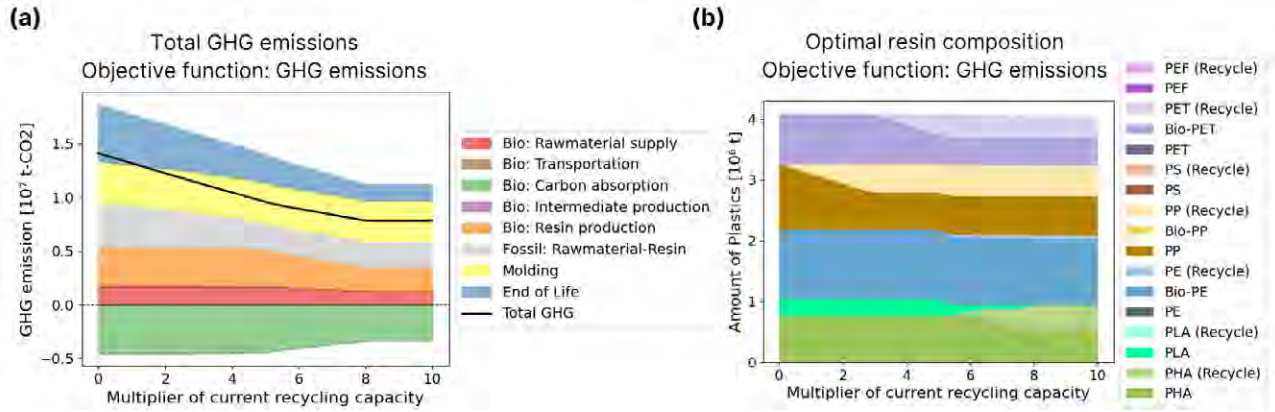

**Figure 3:** Flow analysis results for Case III (Objective function: GHG emissions) Figure 3(a) shows the changes in the contribution of GHG emissions from each life cycle stage within the system, corresponding to variations in the recycling capacity. Figure 3(b) illustrates the changes in the types of resin products resulting from variations in recycling capacity.

**Figure 3** presents the results of GHG emission optimization in Case III, based on Equation (1). The horizontal axis represents the multiplier relative to the current material recycling capacity. From the results in **Figure 3(b)**, it is evident that material recycling is prioritized in the order of PP, PET, and PHA. This prioritization reflects the combined environmental impact of recycling itself and the avoided environmental burden of raw material supply, favoring resins with the greatest reduction potential. As shown in **Figure 3(a)**, an increase in the upper limit of recycling capacity leads to a monotonic decrease in the system's overall GHG emissions, supporting the effectiveness of recycling. However, when the input of biomass feedstock is low, increasing recycling capacity beyond a certain point no longer impacts the objective function value, and complete defossilization remains unachieved. At this stage, the proportion of carbon derived from recycling is approximately 30-40%. This limitation arises from incorporating the substitution rate into the model to account for the degradation in quality of recycled materials. These findings suggest that, while recycling is effective, achieving greater system renewability requires the continued expansion of biomass feedstock introduction. Furthermore, closed-loop chemical recycling methods, such as repolymerization, which were not considered in this study, have the potential to reintegrate plastics into their life cycle while maintaining high quality. Such methods may offer advantages over the currently considered EoL processes in terms of both environmental impact and resource renewability [13, 14]. Therefore, incorporating these advanced recycling methods into flow analysis is essential for designing a more sustainable life cycle.

## CONCLUSIONS

In this study, a flow analysis methodology was developed to assess the plastic life cycle in Japan's packaging sector, focusing on the introduction of biomass-derived and recycled carbon. The assessment was conducted from the perspectives of environmental impact and carbon renewability. The findings revealed the types of resins that should be prioritized for production and recycling under constrained conditions, such as limited biomass supply and recycling capacity, as well as the effects of such prioritization. Furthermore, it was demonstrated that a trade-off may exist between reducing GHG emissions and improving carbon renewability. Achieving a low-GHG, decarbonized system requires the dual advancement of biomass utilization and recycling expansion.

The developed flow analysis framework is adaptable to changes in assessment targets, technologies, and variables. Future expansions of the model should incorporate additional applications, resin types, and processes, including chemical recycling, to enable more comprehensive flow analyses. Moreover, sustainability discussions should assess additional environmental indicators, such as eutrophication—which may be significantly affected by the introduction of biomass—and the potential for introducing biodegradable plastics, taking into account plastic leakage into the environment. Taking these considerations into account, a sustainable life cycle should be carefully designed through scenario analysis that takes into account future system changes.

## DIGITAL SUPPLEMENTARY MATERIAL

For a detailed explanation of the methodology for system boundary construction and the data sources

used for flow analysis model construction, including GHG emission intensities, please refer to the supplementary material available at https://psecommunity.org/LAPSE:2025.0040.

## ABSTRACT

To address the dynamic operational demands of the gas processing sector, which is continuously evolving due to gas market opening, increase in natural gas production, and the growing challenge of upstream-midstream integration in a competitive environment, this work presents the Integrated-Gas-Scheduling-System, IntegraGAS. The proposed methodology innovates by using first principles rigorous process simulation coupled with a scheduling tool for short/medium/long-term, enabling gas plants to swiftly adapt to varying operational conditions and meet the requirements of this new market. IntegraGAS was implemented in Petrobras and has significantly enhanced scheduling efficiency, reducing execution time by up to 99.2% and avoiding approx. US$ 2.3 million in annual labor costs, optimizing resource utilization. By integrating Excel for the frontend, Aspen HYSYS for process simulation, VBA for automation, and Microsoft PowerBI for real-time data visualization, IntegraGAS improves decision-making, regulatory compliance, and operational agility. Its key functionalities include alerts for operational limit violations, automated mass and energy balance calculations, optimized gas allocation, integration with maintenance shutdown plans and KPI monitoring. With an intuitive interface and a robust architecture driven by digital transformation, IntegraGAS eliminates manual inefficiencies, ensures seamless coordination among stakeholders, and enables rapid responses to market dynamics.

## INTRODUCTION AND OBJECTIVES

Natural gas processing plays a pivotal role in the oil and gas production chain, being responsible for treating the raw gas and separating impurities that can impair product quality [1]. This process not only ensures that gas meets the standards for end-use, but also maximizes production efficiency and resource value. Furthermore, in the context of global energy transition, natural gas is gaining increasing relevance due to its ability to function as an intermediary energy source — cleaner than oil and coal, yet still essential to meet global energy demand while renewable alternatives are not fully viable [1, 2].

In Brazil, the importance of natural gas processing has been further accentuated by the development of pre-salt reserves, where the high gas-oil ratio is a challenge, creating a need for advanced infrastructure for its processing and commercialization. This gas must be separated and appropriately treated before being transported or utilized. Therefore, the increase in natural gas production demands efficient and innovative solutions, both to optimize industrial operations and to ensure competitiveness in the global energy market.

The opening of the gas market in Brazil, driven by recent regulatory reforms, has marked a significant change in the country's energy sector [3]. With the approval of Law 11.909/2009, all companies gained access to gas transportation and processing infrastructure, previously restricted to the owner of the processing facility. This move aims to increase competitiveness, reduce gas

costs, stimulate investments in new infrastructure and contribute to the diversification of supply sources, which is essential for national energy security [3, 4]. This new framework thus yielded a more dynamic, fast-paced and complex multi-party environment.

Gas market opening has introduced new operational and logistic challenges, particularly regarding management and scheduling of gas processing and its products. Previously centralized within a single player, scheduling now involves a multitude of stakeholders with varying demands and priorities. The complexity has increased as each economic actor requires dynamic and efficient management to handle its products, ensure contract compliance, transport optimization, cost management and adherence to regulatory standards [3, 4].

In this context, scheduling of natural gas processing plants has become a critical process, as production planning needs to be frequently adjusted to meet variable demand while simultaneously optimizing resources. The need to perform detailed and accurate simulations to manage multiple scenarios, involving variables such as gas flowrates, processing capacity and contractual requirements, calls for more elaborated tools [3, 4].

Whereas traditional works on chemical production scheduling rely on simplified models (linearized versions of highly nonlinear systems and/or recovery factors) [7] and do not consider key process variables such as flows, compositions and temperatures [7], this is no longer sufficient to address the complexity of this new context. This work intends to fill this gap by proposing an innovative integrated first principles scheduling methodology and applying it into a digital-based tool for industrial application. Throughout this article, the details of IntegraGAS implementation at Petrobras, observed benefits, and its contributions to the digital transformation of the natural gas sector will be explored.

## METHODOLOGY

To reach the objective of this work, a practical case study was chosen for proof of concept and industrial application: Petrobras integrated natural gas processing assets. IntegraGAS was developed, tested and applied at each gas asset for: plant modeling, automation, integration and management of the scheduling processes. The next subsections will cover details on the case-study system, plant modeling and computational aspects that yielded IntegraGAS.

### System Description

The system in study consists of four industrial gas processing assets: UTGC, UTGCA, UTGCAB and UTGITB. They are part of Petrobras natural gas processing area, which is illustrated in Figure 1. In each of those midstream assets, three main scheduling processes are carried out; they vary in time-horizon, level of detail required from planning and frequency, as detailed in Table 1.

**Figure 1.** Illustration of Petrobras integrated natural gas processing system, showing the connections between upstream and midstream (UTGC, UTGCA, UTGCAB, UTGITB) facilities along Brazil coast.

**Table 1:** The three scheduling processes that are considered in this work. Details include the number of simulation scenarios, time basis and frequency of each of them.

| Time horizon | Simulation scenarios | Time basis | Frequency |
|---|---|---|---|
| Short | 30 | days | daily |
| | 92 | days | monthly |
| Medium | 15 | months | monthly |
| Long | 12 | months | annually |
| | 15 | years | annually |

### Plant Modeling

Unlike most scheduling tools [7], this work chose a first principles rigorous approach for plant modeling. This decision was based on business evaluation, considering that the requirements of this new dynamic market scenario are not anymore satisfied by classic simplified approaches, such as recovery factors and linear models.

Aspen HYSYS was the commercial simulator chosen for all plant modeling, due to its widespread usage and peer-recognition for natural gas processing simulation. Every asset had its specific first-principles process model, as illustrated in Figure 2. Each model was developed in the light of the current official plant Process Flow Diagrams (PFDs), allowing for rigorous and accurate representation of the industrial asset as well as for easy verification and third-party auditing of the model and its results. Proper model validation was then carried out along with the plant Operations team, by comparing product flowrate outputs, per model, against actual data.

The simulations were specifically tailored for scheduling application, ensuring appropriate compromise between model fit, execution time and open-market transparency requirements. Also, an extensive engineering work was carried out on mapping key process plant variables, i.e. the ones to which production scheduling was

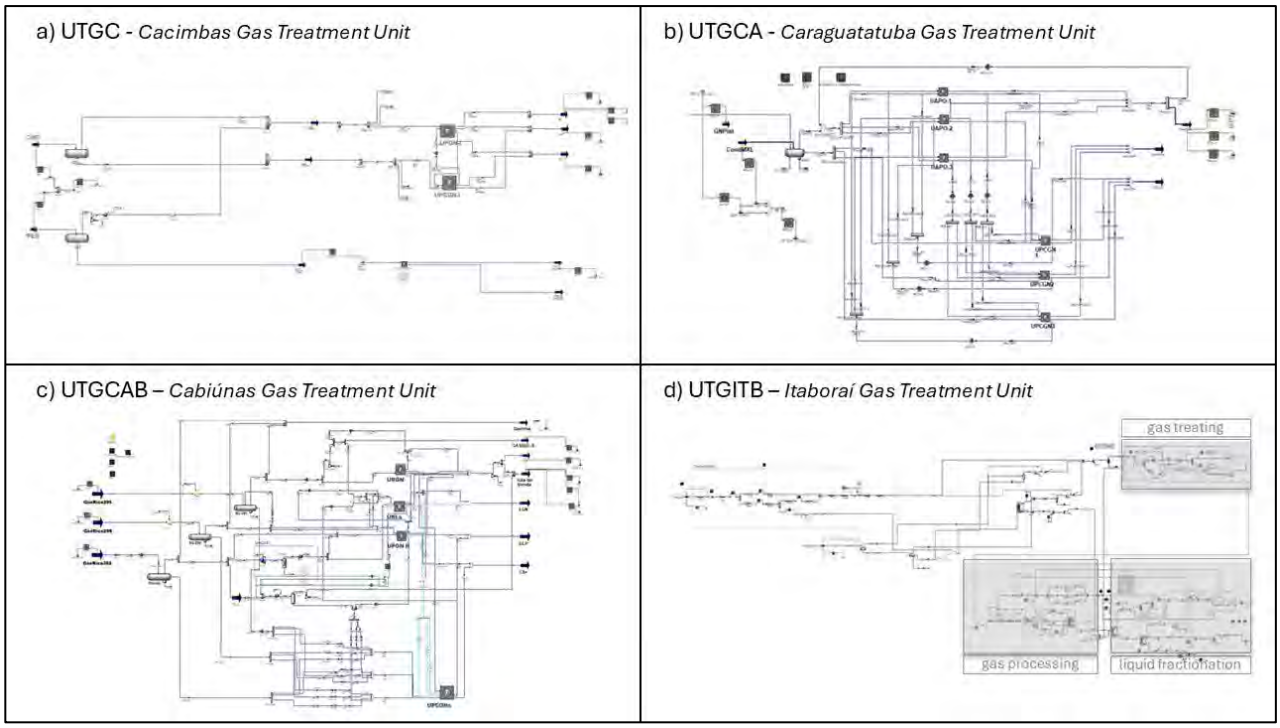

**Figure 2.** Representation of the main flowsheet from Aspen HYSYS simulation model of UTGC (a), UTGCA (b), UTGCAB (c) and UTGITB (d).

the most sensitive and adding them as frontend user inputs (manipulated variables at IntegraGAS) in two levels: a) main and b) specific.

## Computational aspects

### Architecture

IntegraGAS architecture was conceived based on the following business goals: (1) plant modeling should be rigorous and executed on recognized commercial process simulator; (2) interface and usability should be user-friendly and easy for Process Engineers to adapt, thus increasing software adoption; (3) software maintainability and improvement should be easy and fast to implement, in accordance with business dynamics.

Based on these criteria, IntegraGAS architecture used Microsoft Excel for the frontend, VBA (Visual Basic for Applications) for engine calculations and an OLE connection between VBA and Aspen HYSYS to enable automated rigorous process simulation, as seen in Figure 3.

From Figure 3, it is important to emphasize that IntegraGAS connection with plant modeling was such that HYSYS simulation files stay totally transparent to the end user, who interacts only with the application frontend (Excel). Thus, while IntegraGAS robustly guarantees accurate and rigorous process simulation results, it is not necessary for the end user to be familiar with HYSYS, keeping the access to IntegraGAS simple and easy to use throughout a wide range of users from the gas plants. This is especially important for this application, since the short-time scheduling process is required by contract to be executed every day, even on weekends; this means that different shifts will be working to meet this process.

**Figure 3.** IntegraGAS architecture made in this work.

### Features

IntegraGAS is organized into three main sections, designed to address the scheduling processes detailed in Table 1. Each section incorporates functionalities that enhance user efficiency and ensure seamless integration with operational workflows:

1. **Data input:** streamlines the collection and consolidation of raw gas data by integrating information from various processes, systems, and departments through standardized Excel spreadsheets. This feature reduces manual data handling errors and ensures consistency across dataflow.
2. **Simulation environment:** offers an intuitive and dynamic workspace to: a) configure multiple scenarios by adjusting key manipulated variables, enabling flexible *what-if* analyses; b) execute rigorous process simulations with speed and accuracy; c) analyze detailed results and turn them into actionable

insights for business planning and decision-making.

3. **Scheduling export**: automates the generation and export of production planning results tailored to short-, medium-, and long-term needs, facilitating seamless interaction between teams and systems.

### User Interface and Engine

IntegraGAS frontend uses Microsoft Excel due to its familiarity among process engineers, enabling smooth adoption and seamless integration into daily workflows. Excel's intuitive interface simplifies data input, scenario configuration and result analysis without requiring additional training or specialized software expertise.

The engine, built in VBA, connects directly to Aspen HYSYS simulations, offering:

1. **Flexibility:** Custom functionalities tailored to plant-specific needs.
2. **Dynamic Updates:** Easy fit to plant modifications, business demands, and new scheduling methods.
3. **Automation:** Streamlined calculations and integration with first-principles HYSYS models, ensuring accuracy with minimal manual effort.

The interface is designed for simplicity and efficiency, featuring well-structured Excel worksheets with drop-down menus, conditional formatting, and automated alerts. This reduces cognitive load and allows engineers to focus on optimizing production plans and evaluating scenarios.

### Information Security

In all sections of IntegraGAS the appropriate information security measures are applied. This means that the user does not manipulate the input/output data at any time nor has editing privileges to alter any of these numbers after the input/output procedure is complete, since the tool is password protected and only the development team has admin privileges. This guarantees a secure and reliable dataflow, a primary requirement for this application in case of auditing or questioning by third parties.

## Operation aspects

To further enhance usability and reliability, IntegraGAS included a suite of advanced features focusing on operation performance:

1. **Automatic Alerts:** Notifications for operational limit violations and convergence status, ensuring compliance with safety and performance standards.
2. **Data Consistency Checks:** Built-in validation mechanisms to identify and correct inconsistencies in input data before simulation.
3. **Mass and Energy Balance Calculations:** Automated balances ensure all simulations maintain physical accuracy and adhere to process constraints.
4. **Integration with Shutdown Plans:** Synchronizes scheduling with planned maintenance activities to minimize downtime and operational disruptions.
5. **Automated Gas Allocation:** Streamlines the distribution of processed gas, including calculations for flaring and fuel gas, to optimize resource utilization.
6. **KPIs:** Calculation and graphical display of the main business key performance indicators of each asset.

Moreover, by combining advanced modeling capabilities with a user-friendly interface, IntegraGAS not only simplifies complex scheduling tasks but also empowers process engineers to focus on strategic decision-making. The robust architecture and automation reduce manual effort, enhance operational accuracy and support plants in achieving optimal performance with minimal downtime.

# RESULTS AND DISCUSSION

## Plant Modeling

Plant simulations were carried out in Aspen HYSYS v11/v14. Each model was validated against actual plant history data and showed good fit, with deviations under 10 % – the validation results and methodology followed previous literature works from the same research group [5, 6], where further details can be found on the model.

## Computational aspects

### Features: development and gains

The main features that were created specifically for IntegraGAS are shown in Figure 4, which gather multiple screenshots from the tool Main Dashboard (a) and Simulation Environment (b). This structure aimed to fulfill the requirements mapped in Table 1 besides making the scheduling process easy to be conducted. They are reflected in the three sections of the Main Dashboard (Figure 4.a): short-term (a.1), medium-term (a.2) and long-term (a.3). For each, the main features are:

1. **Data input:** Represented by the yellow buttons in Figure 4a. Collects data via VBA code. Data refers to the plant inlet gas stream, per entry point, at 20 °C and 1 atm, mole composition, temperature and pressure. IntegraGAS collects information from those files, manipulates them and presents to the user in a friendly and easy-to-interpret layout (shown in Figure 4b.2).
2. **Simulation environment (Figure 4b):** The process engineering core of IntegraGAS. It is the main hub from where user defines the main manipulated variables (Figure 4b.3), configures and executes simulations (Figure 4b.1), and analyzes input/output data (Figure 4b.1/b.4). Allows for automatized multi-case execution of simulation scenarios (Figure 4b.1) and performs input data checking (Figure 4b.1).
3. **Scheduling export:** Represented by the yellow buttons in Figure 4a. Generates structured planning output, fitted to the scheduling process under execution. Exports the results as an Excel file and saves

it in a user-selected folder.

Those implemented features yielded several gains. The main were, per feature: (1) secure and seamless data flow; information integrity and consistency between gas plants, (2) centralized information from different sources in one environment, reducing manual data handling; easy manipulation of plant simulation from Excel frontend, even for users without HYSYS experience; multi-case execution of simulations in one go; easy data checking and error identification, (3) automatic file generation in standard layout, reducing labor expense and human errors.

## Execution time

By automatizing the process, one of the major gains was on the reduction of total execution time to generate planning results. The manual approach required several data handling, manipulation and one-by-one input in the HYSYS simulation files. This process was extremely laborious and inefficient – IntegraGAS approach was up to 125 times faster, as seen in the numbers from Table 2.

## Performance Gains: Business aspects

The expressive reduction in execution time, discussed in the previous section, yielded a direct gain for business: lower labour cost and resource optimization. With this time saving, plant Process Engineers can focus on more specialized tasks, such as results analysis, process investigation and plant optimization.

For instance, considering only the short-term scheduling, a total of 992 process simulations are executed per month, per gas asset – or 11'904 per year. Considering the reduction in execution time (Table 2) and a reference labour cost of US$ 53.9 per working hour (Bureau of Labor Statistics), IntegraGAS is returning a total savings of US$ 2.3 million per year for Petrobras natural gas processing sector. Still adds to this number the potential gains for medium- and long-term scheduling.

## Petrobras Natural Gas Strategic Plan

IntegraGAS did also cover the main scheduling process in Petrobras: Annual Strategic Plan. This process is key for being highly strategic for long-term business decisions – and consequently demands a high level of interaction and flow of information with other systems and business departments, such as: Strategy, Performance, Logistics, Marketing, Commercialization and Upstream/Midstream Operations.

IntegraGAS was successfully used in Petrobras Natural Gas Strategic Planning 2025-2029, conveying a

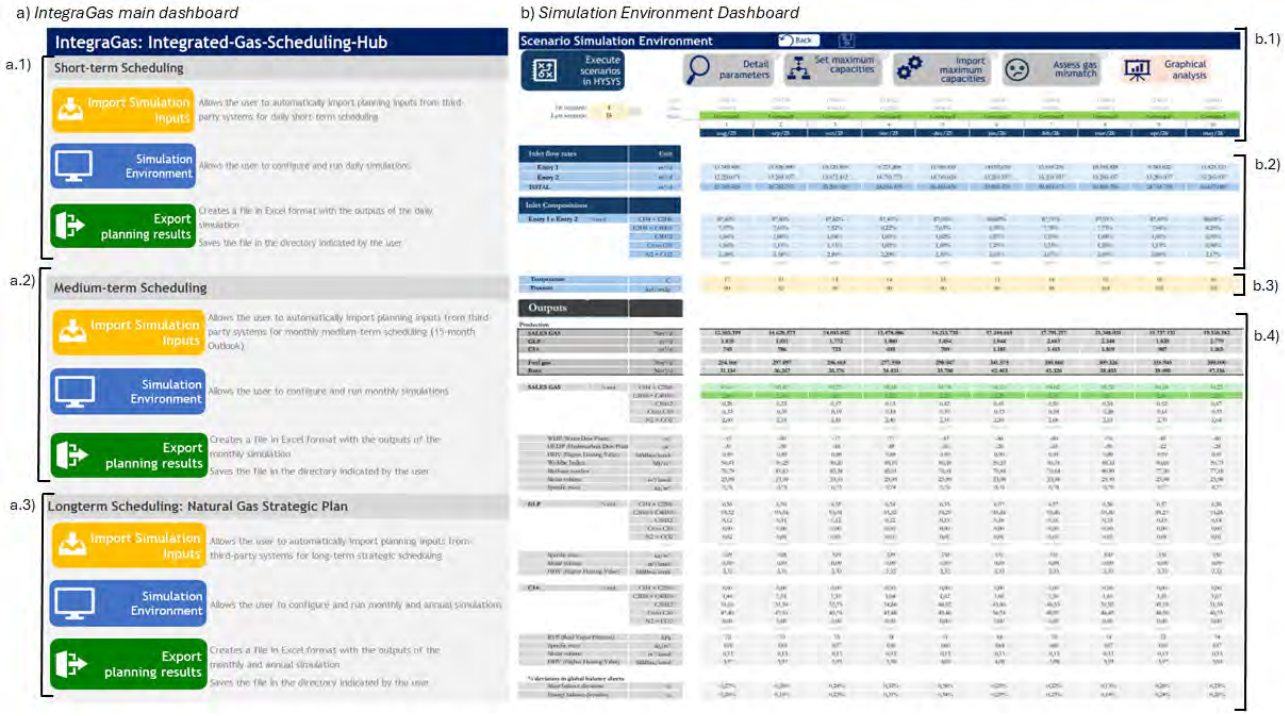

**Figure 4. a)** Main dashboard in Excel, where desired planning is chosen: **a.1)** short-, **a.2**) medium-, or **a.3)** long-term. Each has three features (buttons): input data import (yellow), access to the Simulation Environment Dashboard (blue) and export of simulated results (green). **b)** Simulation Environment Dashboard, where users can analyze and simulate data: **b.1)** Dedicated buttons to additional functionalities. Displays simulation times and convergence status. **b.2)** Input data such as flowrates and compositions, marked in blue. **b.3)** User-manipulated variables, marked in yellow. **b.4**) Simulation results, marked in gray, including mass and energy balances.

seamless functionality that integrated all this scattered information and yielded consistent and reliable results for proper decision-making on investment analysis and strategic planning. Also, by providing structured input and output results, IntegraGAS enabled the development of a Business Intelligence (BI) layer for data visualization, making strategic data readily available online across departments, thus reducing time spent on data handling and information sharing, as well as ensuring proper information security, access control and data levelling.

**Table 2:** Comparison between planning execution time with manual and IntegraGAS approaches, by gas asset.

| Asset | Execution time (min) | |
|---|---|---|
| | manual | IntegraGAS |
| UTGC | 50 | 0.8 |
| UTGCA | 50 | 0.4 |
| UTGCAB | 50 | 2 |
| UTGITB | 50 | 1 |

### Visual Identity

A logo (Figure 5) was created to strengthen IntegraGAS identity and symbolize departmental integration for optimizing gas processing.

**Figure 5.** IntegraGAS logo created by this work.

## CONCLUSIONS AND FUTURE WORKS

This work intended to propose a novel approach for production scheduling, utilizing the implementation of a digital-based tool (IntegraGAS) in four assets of Petrobras natural gas processing sector as case study. IntegraGAS architecture used Excel for frontend, VBA for engine and direct OLE communication between VBA and Aspen HYSYS – this facilitated software retention by end users, who are familiar with Excel applications. The most distinguishing and innovative feature of this approach is the transparent use of first principles rigorous simulation for plant modeling, what guarantees consistent, verifiable and reliable simulation results – key requirements of the multi-party open gas market scenario – while being transparent to the end user. The implementation of IntegraGAS was successful and it has been in use in the industry since 2022, with hundreds of thousands of simulations successfully executed so far, considering short-, medium-, and long-term planning.

This work contributed to the literature by successfully developing, implementing and testing a novel first-principles integrated scheduling tool, with industrial application, that delivered rigorously accurate yet fast, auditable and reliable automated results. For future works, the suggestion is to develop a higher-level decision layer, by integrating upstream and midstream planning as a single system (Figure 1), thus opening the path for unified planning and optimization studies.

## ABSTRACT

The battle against climate change and the search for innovative solutions to mitigate its effects have become the focus of the researchers' attention. One potential approach to reduce the impacts of the global warming could be the design of a Carbon Capture and Storage Supply Chain (CCS SC). However, the high complexity of the model requires exploring alternative ways to optimise it. In this work, a CCS multi-period supply chain for Europe is designed. Data on $CO_2$ emissions have been sourced from the EDGAR database, which includes information spanning the last 50 years. Since this problem involves optimising the cost and operation decisions over a 10-year time horizon, it would be advisable to forecast carbon dioxide emissions to enhance the reliability of the data used. For this purpose, a neural network-based model is implemented for forecasting N-Beats. Furthermore, a temporal decomposition scheme is used to address the intractability issues of the model. The selected method is Lagrangean decomposition, which has been employed in other high complexity works, demonstrating strong performance and significant computational savings.

**Keywords**: Mathematical Programming, Generalized Disjunctive Programming, Supply chain, Mixed Integer Linear Programming, Lagrangean Decomposition, Time Series Forecasting, Deep learning.

## 1. INTRODUCTION

Over the last decades, climate change has become one of the main challenges that society must address. Consequently, many recent breakthroughs have focused on this issue. This is the case with $CO_2$ capture and storage supply chains, which have emerged as one of the most promising possible options to decarbonize the industrial sector. D'Amore, for example, proposes a European Carbon Capture and Storage Supply Chain (CCS SC) [1,2]. To achieve this, a Mixed Integer Linear Program (MILP) is implemented. As a result, the problem becomes computationally intractable for $CO_2$ reduction targets exceeding 70% due to its high complexity. A possible solution to overcome this difficulty might be the use of decomposition methods, such as the Lagrangean Decomposition [3]. Similarly, Jackson and Grossmann propose a temporal decomposition scheme based on this Lagrangean approach to solve a multiperiod nonlinear programming optimization model, obtaining satisfactory results [4]. Additionally, designing a supply chain over a time horizon involves inherent uncertainties, such as future $CO_2$ emissions. Therefore, it is crucial to explore methods to enhance data reliability.

Altogether, this paper implements a temporal decomposition technique based on Lagrangean Decomposition to design a CCS SC in the Iberian Peninsula. The model is optimized over a 10-year time horizon. As a result, the suitability of applying this resolution method to solve such complex problems is analyzed. Furthermore, a neural network-based model (N-BEATS) is implemented to forecast $CO_2$ emissions over the same 10-year time horizon [5].

## 2. PROBLEM STATEMENT

As mentioned earlier, this paper proposes a temporal decomposition technique based on Lagrangean decomposition to optimize a CCS SC within the Spanish and Portuguese territory over a 10-year time horizon.

The model is formulated as a grid-based, spatially explicit Mixed Integer Linear Program (MILP). Consequently, the territory is divided into smaller regions *g*. The $CO_2$ emissions for each region are sourced from the Emissions Database for Global Atmospheric Research (EDGAR) [6], which is a global database of anthropogenic emissions of greenhouse gases and air pollution on Earth. Additionally, potential $CO_2$ storage sites are obtained from the $CO_2$Stop Project database [7], which provides information on the locations and capacities of underground geological formations in Europe that could be suitable to store $CO_2$.

It is now necessary to define how the $CO_2$ is captured and transported. On the one hand, three different possible technologies *k* are considered regarding the $CO_2$ capture: post-combustion, pre-combustion and oxy-fuel combustion. On the other hand, they can be transported by onshore or offshore pipelines *L* depending on the region's location.

## 3. NOMENCLATURE

### Sets

| | |
|---|---|
| $g$ | regions |
| $k$ | capture technology {post$^{comb}$, pre$^{comb}$, oxy$^{fuel}$} |
| $l$ | pipelines {onshore, offshore} |
| $t$ | time period {1,2,…,10} |
| $CR_{g,g'}$ | It is possible to connect *g* to *g'* by a pipeline |

### Parameters

| | |
|---|---|
| $\alpha$ | $CO_2$ reduction target |
| $E_{g,t}$ | Region g $CO_2$ emissions at time period t [$10^7$ tons] |
| $S_g$ | Storage capacity in region g [$10^9$ tons] |
| $UC_k$ | Capture technology k unitary cost [€/ton] |
| $FC_{g,g'}$ | Pipeline between g and g' construction cost [€] |
| $OC_{g,g'}$ | Pipeline between g and g' operational cost [€/year] |
| $D_{g,g'}$ | Distance between g and g' [km] |
| $C^{IR}$ | Intra-regional transport cost [€/(ton·km)] |
| $SIZE_g$ | Region g size [km] |
| $\eta_k$ | Capture technology k efficiency |
| $\gamma_{g,k}$ | Technology k feasibility in region g according to fuels contribution to emission |
| $Q^{MAX}$ | Transport capacity of the pipelines [$10^7$ tons/year] |
| $C^{MAX}$ | Upper limit for the construction rate of pipelines [km/year] |
| $CAP^{INJ}$ | Maximum injection well capacity [tons/year] |
| $depth_g$ | Injection depth in region [km] |
| $CCR$ | Capital cost rate for injection well |
| $OM$ | Mainteneance rate for injection well |

### Continuous Variables

| | |
|---|---|
| $p_{k,g,t}$ | Processed $CO_2$ through technology k in region g at time period t [$10^7$ tons] |
| $c_{k,g,t}$ | Captured $CO_2$ through technology k in region g at time period t [$10^7$ tons] |
| $q_{g,g',t}$ | $CO_2$ transported from g to g' at time period t [$10^7$ tons] |
| $s_{g,t}$ | $CO_2$ sequestred in region g at time period t [$10^9$ tons] |

### Binary Variables

| | |
|---|---|
| $y_{g,g',t}$ | Takes a value of 1 if a pipeline from g to g' is built |
| $\widehat{y_{g,g',t}}$ | Duplicate of binary variable $y_{g,g',t}$ |

### Integer Variables

| | |
|---|---|
| $n_{g,t}^{wells}$ | Number of injections well constructed in region g at time period t |

In this model It is possible to identify three different problems:

- Capture Problem.
- Transport Problem.
- Sequestration Problem.

The capture problem is modeled using Eqs. (1-4). First, Eq. (1) defines that the total processed $CO_2$ in region g at time t cannot exceed its emissions $E_{g,t}$. Next, Eq. (2) sets the maximum $CO_2$ that can be processed by each technology k. Then, Eq. (3) specifies the minimum total $CO_2$ that must be processed across all regions g over the 10-year time horizon. Finally, Eq. (4) establishes the relationship between $c_{k,g,t}$ and $p_{k,g,t}$.

$$\sum_k p_{k,g,t} \leq E_{g,t}, \quad \forall g, \forall t \tag{1}$$

$$p_{k,g,t} \leq \gamma_{g,k} E_{g,t}, \quad \forall k, \forall g, \forall t \tag{2}$$

$$\sum_{k,g,t} \eta_k \, p_{k,g,t} \geq \alpha \sum_{g,t} E_{g,t} \tag{3}$$

$$c_{k,g,t} = \eta_k p_{k,g,t}, \quad \forall k, \forall g, \forall t \tag{4}$$

Regarding the transport problem, the mass balance is established in Eq. (5).

$$\sum_c c_{c,g,t} + \sum_{g' \in SR_{g,g'}} q_{g',g,t} = 100 s_{c,g,t} + \sum_{g' \in SR_{g,g'}} q_{g,g',t} \quad \forall g, \forall t \tag{5}$$

Additionally, as $CO_2$ transport from region g to

region g' at time t depends on if the pipelines that connects both regions is built at that time, the Boolean variable $Y_{g,g',t}$ is defined. This Boolean variable is true if the pipeline to transport $CO_2$ from region g to region g' is built at time t.

The disjunctive model is formulated as follows:

$$\underset{(g,g'\in CR_{g,g'})}{\vee} \begin{bmatrix} Y_{g,g',t} \\ q_{g,g',t} \le Q^{MAX} \end{bmatrix}, \quad t \in T \tag{6}$$

It is now necessary to establish that if a pipeline between a region g and a region g' is built at time t-1, then the pipeline will remain there at time t. The logical relationship which defines it is shown in Eq. (7).

$$Y_{g,g',t-1} \Rightarrow Y_{g,g',t}, \ \forall g \in CR_{g,g'}, \forall g' \in CR_{g,g'}, \forall t \tag{7}$$

Eqs. (6) and (7) reformulated in terms of binary variables are shown below in Eqs. (8) and (9).

$$q_{g,g',t} \le Q^{MAX} y_{g,g',t}, \ \forall g, g' \in CR_{g,g'}, \forall t \tag{8}$$

$$y_{g,g',t} - y_{g,g',t-1} \ge 0, \ \forall g, g' \in CR_{g,g'}, \forall t \tag{9}$$

Furthermore, Eqs.(10) and (11) establish an upper limit to the total length of pipelines built throughout a year.

$$\sum_{g,g'} D_{g,g'} \left(y_{g,g',t} - y_{g,g',t-1}\right) \le C^{\text{MAX}}, \quad \forall t > 1 \tag{10}$$

$$\sum_{g,g'} D_{g,g'} y_{g,g',t} \le C^{MAX}, \quad t = 1 \tag{11}$$

Next, the sequestration problem is defined below:

$$\sum_t s_{g,t} = S_g, \quad \forall g \tag{12}$$

$$n_{g,t}^{wells} = \frac{s_{g,t}}{CAP^{INJ}}, \quad \forall g, \forall t \tag{13}$$

Eq. (12) sets the maximum $CO_2$ which can be store at each region as its storage capacity, and Eq. (13) defines the number of wells built at region g at time t.

Lastly, the objective function shown in Eq. 14 minimizes the total cost of the supply chain given by the cost of capturing the $CO_2$ plus the pipeline's construction and operational cost, the shipping cost and the storage cost.

$$\begin{aligned} min\ \Phi = {} & 10^{-1} \sum_{k,g,t} UC_k \eta_k p_{k,g,t} + \\ & 10^{-8} \sum_{g,g' \in SR_{g,g'}} FC_{g,g'} y_{g,g',T} + \\ & 10^{-8} \sum_{g,g',t \in SR_{g,g'}} OC_{g,g'} y_{g,g',t} + \\ & 10^{-1} \sum_{g,g',t \in SR_{g,g'}} \mathrm{D}_{g,g'} \mathrm{q}_{g,g',t} + \\ & 10^{-1} C^{IR} \sum_{\mathrm{k},g,t} \mathrm{SIZE}_g \gamma_k p_{k,g,t} + \\ & 10^{-8} \sum_{g,t} (CCR + OM)\left(m_1 depth_g + m2\right) n_{g,t}^{wells} \end{aligned} \tag{14}$$

Notice that the model has been scaled in order to improve the numerical stability and efficiency of the solver.

## 4. SOLUTION STRATEGY

The Mixed Integer Linear Programming (MILP) described by Eqs. (1)-(14) can easily become an intractable problem as the number of regions g, the reduction target, or the time horizon increase. Therefore, given the model's structure, a decomposition method could be suitable to overcome these issues. The decomposition algorithm, outlined in Figure 1, follows the approach by Jackson and Grossmann [4].

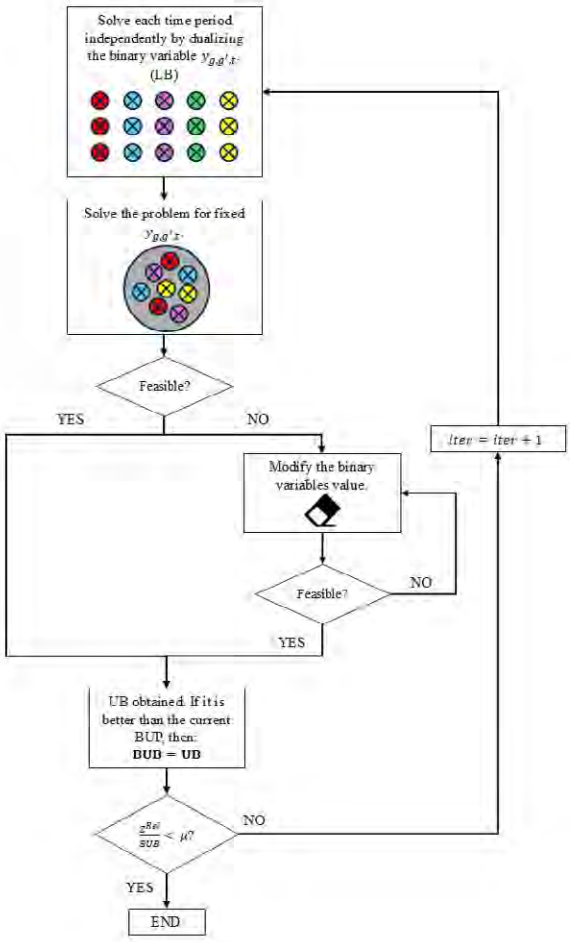

**Figure 1.** Decomposition algorithm steps.

We adopt a temporal decomposition scheme. To implement it, we first identify the constraints which couple the time periods. In this case, these constraints are Eqs. (9) and (10). Thus, the binary variables $y_{g,g',t}$ must be duplicated, as formulated in Eq. (15).

$$y_{g,g',t} = \widehat{y_{g,g',t}}, \quad \forall g \in CR_{g,g'}, \forall g' \in CR_{g,g'}, \forall t \tag{15}$$

Now, Eqs. (16) and (17) are obtained after rewriting the affected equations.

$$y_{g,g',t} - \widehat{y_{g,g',t-1}} \ge 0, \quad \forall g, \forall g', \forall t > 1 \tag{16}$$

$$\sum_{g,g'} \left[D_{g,g'} \left(y_{g,g',t} - \widehat{y_{g,g',t-1}}\right)\right] \le C^{\text{MAX}} \tag{17}$$

Eq. (15), which is called interconnection constraint, is dualized so that the Lagrangean Decomposition is applied. After dualizing, Eq. (15) transforms into Eq. (18).

$$min\ \Phi_{\mathrm{LR}} = \Phi + \sum_{g,g',t\in SR} \lambda_{g,g',t}\left(y_{g,g',t} - \widehat{y_{g,g',t}}\right) \quad (18)$$

As indicated in Figure 1, a lower bound is obtained once each subproblem is optimized. Then, the binary variables are fixed to the values given by the decomposed model and the original problem, comprising Eqs. (1)-(14) is solved. If the problem is infeasible, which is more likely due to the high number of variables, a strategy must be designed to modify the binary variables. The following algorithm is proposed to guarantee that a solution is achieved:

$If \quad \sum_t y^k_{g,g',t} \geq 2,$

Being $Y$ the first time period $t$ with $y^k_{g,g',t} = 1$, for all $t > Y$:

$$y^k_{g,g',t} = 1, \quad \forall t > Y$$

Else

$$y^k_{g,g',t} = 0, \quad \forall t$$

**Figure 2.** Binary variables modification algorithm

Lastly, Eqs. (19) and (20) update the Lagrange multipliers $\lambda_{g,g',t}$, ensuring convergence across iterations.

$$step^k = 0.5\frac{LB_k - UB}{\sum_{g,g',t}\left(y^k_{g,g',t} - \widehat{y^k_{g,g',t}}\right)^2} \quad (19)$$

$$y^{k+1}_{g,g',t} = y^k_{g,g',t} - step^k\left(y^k_{g,g',t} - \widehat{y^k_{g,g',t}}\right) \quad (20)$$

# 5. $CO_2$ EMISSIONS FORECAST

As mentioned earlier, N-BEATS is the neural network-based model selected for forecasting $CO_2$ emissions. This section explains the methodology implemented to select the most suitable model.

## 5.1 Exploratory Data Analysis

Given a dataset containing multiple series, Exploratory Data Analysis is conducted to identify potential correlation between the series and exploit this knowledge to enhance the training process.

In this regard, cross-correlation is a widespread tool to assess the degree of correlation between two time series. We compare series pairwise by computing its Pearson correlation coefficient and visualize the results with the aid of heatmaps. The Pearson correlation coefficient is shown in Eq. (21).

$$\rho_{x,y} = \frac{cov(X,Y)}{\sigma_x \sigma_y} \quad (21)$$

Where X and Y represent two different time series.

As this metric might be affected by the autocorrelation among preceding lags, this within-series dependence must be first removed. This is achieved by recursively differencing each series until the ADF test proofs its stationarity.

## 5.2 Data preprocessing

Before training forecasting models, historical data was normalized for convenience using min-max normalization

$$x_{scaled} = \frac{x - x_{min}}{x_{max} - x_{min}} \quad (22)$$

Then, data was also split into train (80%), validation (10%) and test (10%) sets.

## 5.2 Model Selection

The model architectures studied are shown in Figure 3.

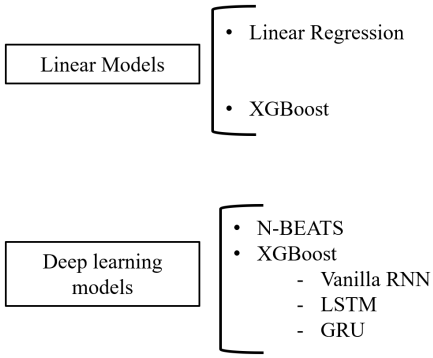

**Figure 3.** Model architectures studied.

Their performance was benchmarked against a baseline model, namely, the moving average of the last two preceding values.

For each model type, the best hyperparameter configuration (BHC) was search inside a predefined search space. While a grid search approach was preferred for regression models, the tuning process of deep learning models was carried out using the open-source library Optuna [5]. The BHC was found by training different models varying the hyperparameter values, evaluating its mean absolute percentage error (MAPE) on the validation set and using the minimum MAPE as selection criteria.

For neural network-based models, the learning rate of the model with the BHC was further refined given the impact of this hyperparameter on model performance. This was achieved by running the training process again, this time increasing the learning rate after each batch is processed. The evolution of the loss function is logged, and loss vs. learning rate plots are used as guidance for choosing a good value of this hyperparameter.

Next, the model with the BHC found so far was retrained on the whole training set (concatenation of test and validation sets), and its performance was evaluated on the test set.

Finally, the model reporting the lowest MAPE in the test set will be the one selected to generate future forecasts.

### 5.3 Results

The heatmap in Figure 4 represents the cross-correlation between the $CO_2$ emissions in the regions considered for this case study. It evidences strong correlations among the $CO_2$ emissions in regions, as is the case of regions 26 and 14.

The results of the model selection process are shown in Table 1. For comparison purposes, all models were trained for 200 epochs, using a batch size of 32, and the forecasts are obtained one year at a time.

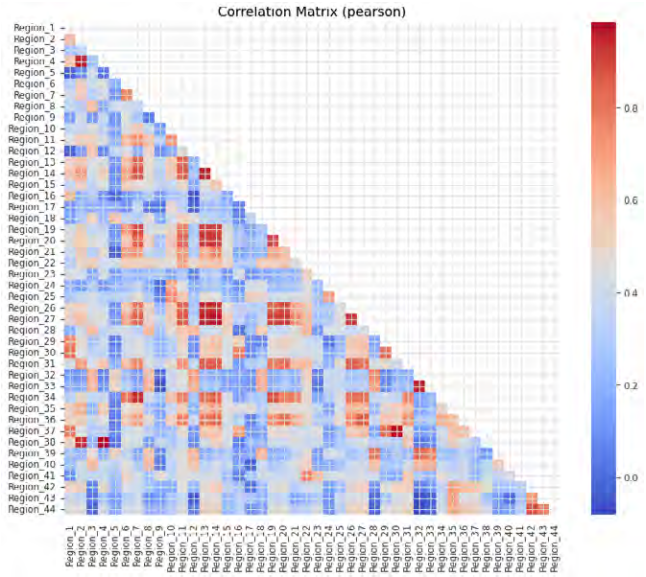

**Figure 4.** Heatmap of Pearson correlation coefficient.

**Table 1**: Results of tuning process and performance on the test set.

| | $MAPE_{test}$ | BHC |
|---|---|---|
| **Moving average** | 14.31% | window size = 2 |
| **Linear Regression** | 14.63% | lags = 4 |
| **XGB** | 14.96% | lags = 2 |
| **N-BEATS** | 14.16% | input_chunk 3<br>num_blocks = 2<br>num_layers = 4<br>num_stacks = 2<br>layer_width = 256<br>batch_size = 32<br>learning_rate = $10^{-4}$ |
| **RNNs** | 15.13% | Model type: LSTM<br>num_layers = 4<br>input_chunk = 4<br>batch_size = 32<br>learning_rate=$2{\cdot}10^{-3}$<br>optimizer = ADAM |

In light of the results shown in Table 1, N-BEATS model was selected to forecast $CO_2$ emissions for a 10-year time horizon.

## 6. RESULTS AND DISCUSSION

The model was implemented in GAMS 46.5.0 and solved using Gurobi 11.0.1 solver. All code was executed on an Intel® Core™ i7-4790 CPU (3.60 GHz) with 8.00 GB RAM. The results are presented in Table 2.

**Table 2**. Optimization results.

| | No. of iterations | Solution time (s) | Solution obtained | Gap (%) |
|---|---|---|---|---|
| Full-Space | - | 8’26 | 1180.74 | - |
| Lag. Dec. | 47 | 13’ 44” | 1257.13 | 6.47 |

As observed, the Lagrangean decomposition algorithm provides a good solution to this problem. However, it requires a significant amount of computational time to close the gap between the lower and upper bounds. Since this method is intended to be applied to problems of higher complexity, the proposed algorithm shown in Figures 1 and 2 needs to be improved. The supply chain obtained at the end of the 10-year time horizon is displayed in Figure 5.

## 7. CONCLUSION

The decomposition algorithm has demonstrated its effectiveness. However, further research is needed to improve the algorithm shown in Figure 2 and enhance the proposed resolution method, as it requires many iterations to close the gap.

Regarding the time series forecast, although N-BEATS proved to be the best model (Table 1), it performed only slightly better than a simple linear regression when applied to this case. This is due to the small size of the dataset used for forecasting. If a larger dataset had been used, the difference between the two methods would have been considerably greater.

## ABSTRACT

Despite the potential benefits of decision-level integration for process and energy supply chains (SCs), these systems are traditionally assessed and optimised by incorporating simplified unit operation models within a spatially distributed network. The desired organisational-level integration cannot be achieved without leveraging complex computational tools and concepts. This work proposes a multi-scale agent-based model to facilitate the transition from traditional practices to coordinated SCs. The proposed multi-agent system framework incorporates different enterprise dimensions of the process and energy SCs, including raw material suppliers, rigorous processing plants, and consumers. The behaviour of each agent type and its interactions are implemented, and their impact on the overall system is investigated. This approach allows for the simultaneous assessment and optimisation of process and SC decisions. By integrating each decision level into the operation, the devised framework goes beyond existing studies in which the impacts of lower decision levels are neglected. A biofuel SC example comprising farmers, biorefineries, and end-users is presented to demonstrate the application of the proposed multi-agent system. The involved actors seek to increase their payoffs given their interdependencies, intra-organisational variables, and the underlying dynamics of the network. The aggregated payoff of the supply network is optimised under different scenarios, and fractions of capacity allocated to biofuel production and consumption are obtained. The results indicate that integrated decision-making significantly influences SC performance. The proposed research expounds a more realistic view of multi-scale coordination schemes in process and energy SCs.

**Keywords**: Process and energy systems, Decision level integration, Agent-based models, Biofuel supply chains, Payoff optimisation

## INTRODUCTION

Effective coordination between supply chain (SC) levels from operational to strategic areas is an essential tool for improving the comprehensiveness of process and energy system models [1]. Such a decision-level integration notion is true for models encompassing changing policy decisions and technological innovations, such as those in biofuel SCs [1]. Biofuels can provide an essential alternative to fossil fuels as they utilise renewable feedstocks whilst allowing for lower net carbon dioxide emissions [2]. Although the further adoption of biofuels has been touted as a possible key contributor to meeting the climate objectives, the complex interactions between stakeholders, such as raw material suppliers, processing plants, and consumers, and the impact of government policies, such as subsidies, result in unclear or oversimplified outcomes from conventional biofuel SC models.

Several studies have explored the optimisation of biofuel SCs to meet sustainability objectives [3-5]. Whilst some explore the impact of technology options on SCs, none were found to investigate the effects of biorefinery process details on biofuel adoption. In this context, computational approaches such as agent-based modelling have been used to handle the complexities and uncertainties associated with biofuel SCs, specifically the feedback relationships between agents [1]. The most rigorous studies [1, 6], proposed agent-based models to simulate the adoption of biofuels by stakeholders in response to government policies such as differing subsidy

levels and products' social and environmental impacts. The current investigation utilises a multi-scale agent-based model to capture the organisational structure of integrated SCs. Such multi-faceted features allow for simultaneous assessment and optimisation problems, particularly exploring the optimal adoption in biofuel-driven processes and energy systems. The framework extends decision-making beyond that from prior studies by including decisions at the firm level, through adjustments to intra-organisational planning options, as well as at lower levels, through the incorporation of biorefinery process variables.

# METHODOLOGY

## Biofuel Adoption Problem Formulation

In this work, a biofuel SC is modelled as an interrelated system of computational ecosystems featuring distributed and asynchronous decision-making, and incomplete information.The conceptual structure of the system is shown in Figure 1.

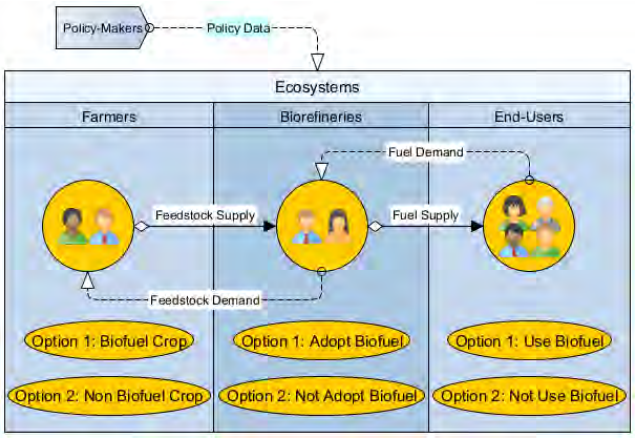

**Figure 1.** Conceptual model of the biofuel SC [1].

The system comprises multiple actors, including farmers, biorefinery facilities, and end-users, each with binary options regarding biofuel adoption. The biofuel adoption problem is formulated as follows.

$$max_{P,O}\ \mathcal{U}_T = \sum_{e\in SCE}\sum_{t_m\in T_m}\mathcal{U}_t(P,O) \tag{1a}$$

$$s.t.\ P \in \Theta_P, O \in \Theta_O \tag{1b}$$

Where $\mathcal{U}_T$ is the total utility of all involved ecosystems ($SCE$) in all sample periods ($T_m$), which is calculated by the individual payoff functions ($\mathcal{U}_t(P,O)$). The planning decision variables ($P$) include re-evaluation frequencies, while the operational-level decisions ($O$) entail adjusting biorefining facility process parameters. Additionally, the feasible regions of both levels confined by equality, inequality, and implicit constraints are denoted by sets $\Theta_P$ and $\Theta_O$.

## Supply Chain Dynamic Behaviour

The SC behaviour at the aggregate level is driven by actors alternating between adopting or not adopting biofuels and changing the ecosystem's payoff. The following constraints determine the rate at which actors choose the former at the ecosystem level [1].

$$\frac{df_e}{dt} = \alpha_e\left(\rho_e\left(f_i(t-\tau_e)\right) - f_e(t)\right), \forall e,i \in SCE \tag{2}$$

$$\rho_e = \frac{1}{2}\left(1+\text{erf}\left(\frac{G_{e1}(f_i)-G_{e2}(f_i)}{2\sigma_e}\right)\right), \forall e,i \in SCE \tag{3}$$

$$\alpha_e \in (\alpha_{e,min}, \alpha_{e,max}) \tag{4}$$

Where $f_e$ is the fraction of actors in an ecosystem adopting biofuels and $\alpha_e$ $[\frac{1}{month}]$ is the re-evaluation frequency for each ecosystem, bounded by minimum and maximum values ($\alpha_{e,min}, \alpha_{e,max}$). The preference probability of biofuel adoption ($\rho_e$) depends on the payoff of selecting said option. As a result, two utility functions, represented as $G_{e1}$ and $G_{e2}$ are defined for adopting or not adopting biofuels, respectively, influenced by same-tier and neighbouring ecosystem adoption fractions. $\tau_e$ denotes the delay parameter and accounts for the asynchronous information flows between ecosystems and the inherent inertia to respond to external changes. Finally, the uncertainties are introduced through measurement errors of utility functions, characterised by $\sigma_e$ [1].

## Biorefinery Model

The production process behaviour is reflected via a nonlinear model of a biodiesel plant described elsewhere [7]. The closed form of the process model is described below.

$$\mathcal{F}(\mathcal{X}) = 0 \tag{5}$$

$$x \in (x_{min}, x_{max}), \forall x \in \mathcal{X} \tag{6}$$

Where $\mathcal{X}$ refers to the process variables and parameters, including feed and solvent flow rates and temperatures along with water mass flow and the boiler pressure. The set $\mathcal{F}$ relates the final product flow rate, purity, temperature, and heat duty requirement to the input parameters [7].

The plant's overall profit is calculated based on the following equation.

$$Profit = Sale_{Biodiesel} - TAC \tag{7}$$

Where $Sale_{Biodiesel}$ represents the final product sale, and $TAC$ refers to the total annual costs, which include the operational and annualised capital costs discounted by a given factor.

## Multi-Scale Agent-Based Model

A multi-agent system encompasses various actors carrying out numerous tasks. These agents can select from multiple resources to complete their assignments.

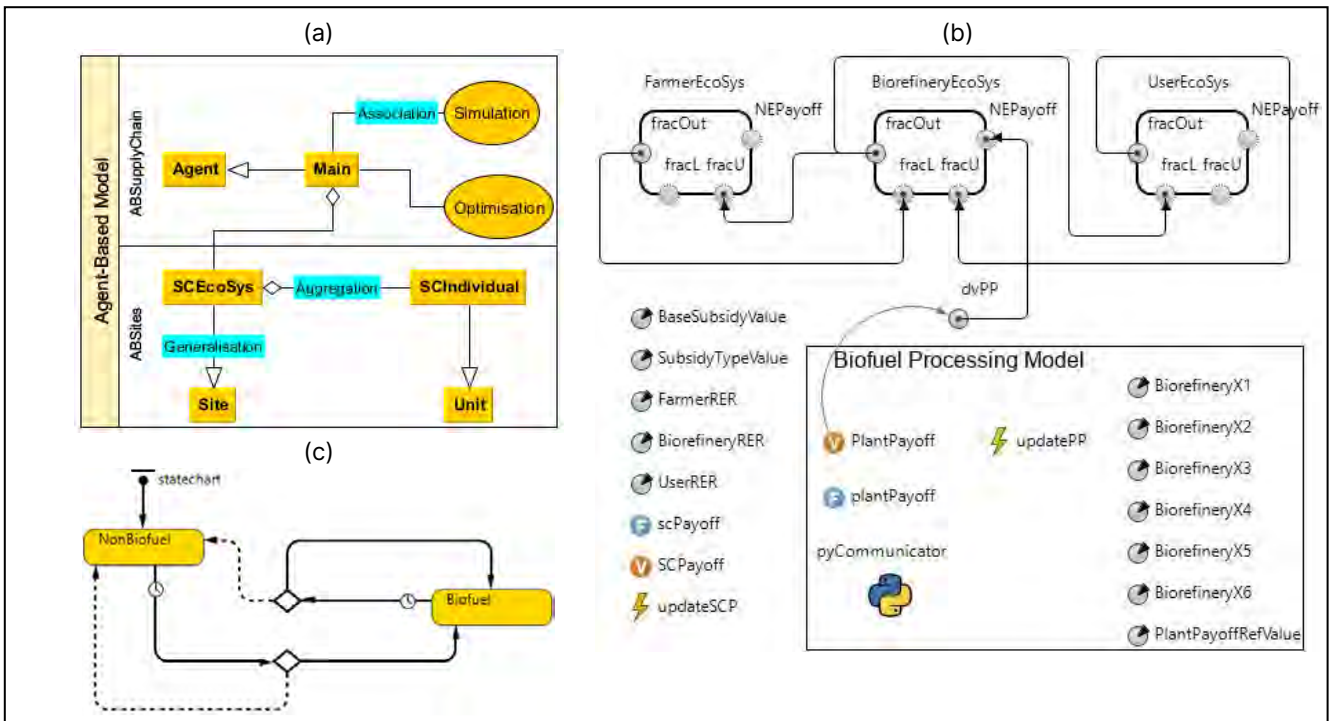

**Figure 2:** Schematic representation of the agent-based model employed. (a) shows the higher abstraction levels, (b) gives a representation of the biofuel SC at the planning level, and (c) illustrates an entity behaviour at the individual level.

Their choices are based on the perceived benefits of each resource. While these decisions are rational, they may not always result in the best overall performance for the system. Due to these similarities, the agent-based modelling approach is selected to reflect the complex process and energy systems. The framework materialises a two-level hierarchy by conceptualising and abstracting specific supply networks [1, 8]. For implementation purposes, the AnyLogic software (ver. 8.7.9) [9] is employed due to its ease of use in incorporating different intricacy levels.

## Supply Chain Domain Model

Figure 2(a) shows the domain model, in which connections of two broad modules are established. The supply chain module offers the main functionality to represent the overall structure of supply networks. At the same time, the site module involves elements comprising Unit and Site to capture the details of an individual or ecosystem in a network.

## Application-Level Model

The specialised model, as illustrated in Figure 2(b), supports the high-abstraction model for the biofuel adoption problem and encompasses three interconnected agents to represent partners of the SC. The framework reflects the two-option behaviour of each component in the system, as demonstrated in Figure 2(c). A linear realisation of coupled payoff functions is used, similar to the case discussed in the previous investigation [1]. The process model is deployed in Python using Pyomo (ver. 6.8.0 ) [10] and connected to the main platform via the Pypeline interface.

## Solution Strategy

The solution strategy is depicted in Figure 3.

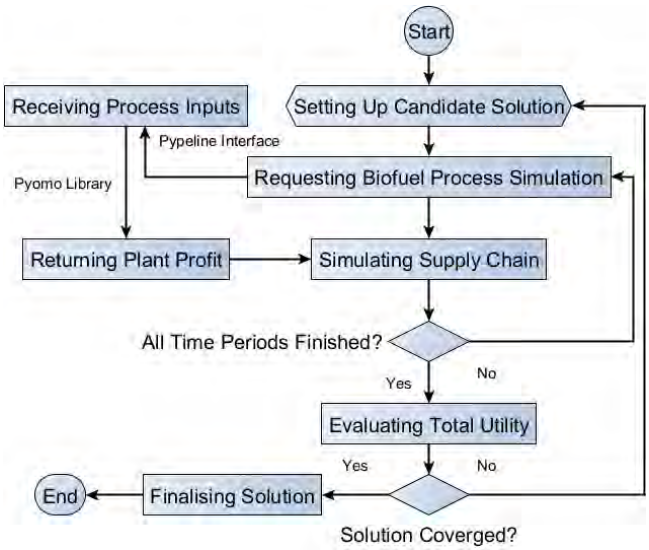

**Figure 3.** The solution workflow.

As seen in the figure, the optimisation engine creates a candidate solution comprising the re-evaluation

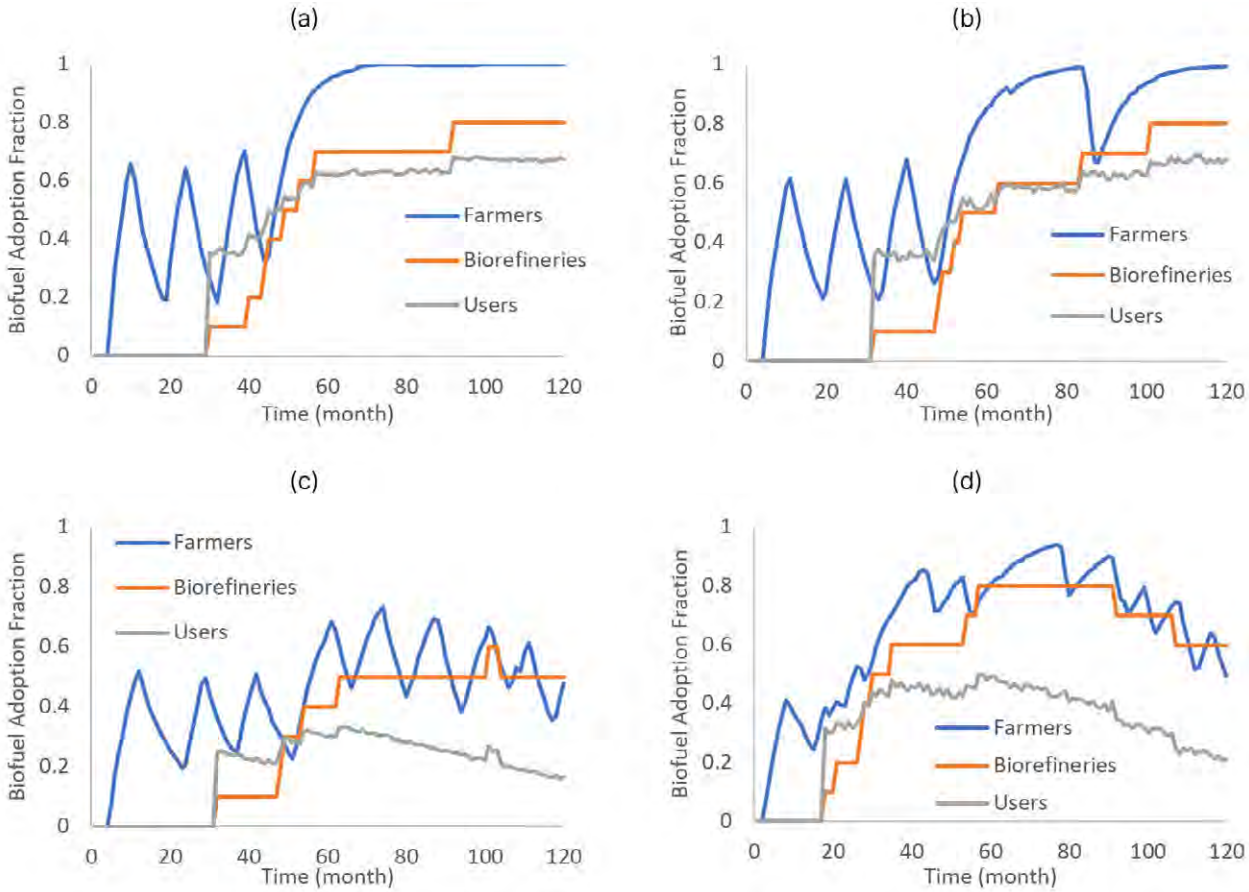

**Figure 4:** The variation of adoption fraction over time for (a) Scenario 1, (b) Scenario 2, (c) Scenario 3, and (d) Scenario 4.

rates and biofuel process variables and sends it to the corresponding ecosystems. Each ecosystem computes its contribution to the total utility and sends the information to the main agent. For the biorefinery optimisation, process variables are sent to the external Python model, and the obtained profit value is used to scale the respective ecosystem payoff. In this context, the process model is an implicit constraint of the optimal adoption problem. The aggregated utilities are then calculated, and if required, a new candidate solution is generated to be utilised for the next iteration. Notably, without the biorefinery's implicit constraints and under specific conditions with no delays and uncertainties, the optimisation and agent interactions may lead to an equilibrium point (See [1]).

## CASE STUDY

A biofuel SC case study is adopted from the prior study [1]. The specific model and parameters for biofuel plants [7] are also incorporated into the optimisation problem. Four scenarios are considered, details of which are summarised in Table 1. As seen in the table, the considered cases are characterised by different subsidy levels or delay parameters (scaled against default values), and the inclusion or absence of the biorefinery considerations (Equations 5-7). Notably, two subsidy types, constant and phased-out policies, are considered. The subsidy values positively affect the payoff of adopting biofuels in each ecosystem. While both types have a similar base value, the latter is in full effect at the start and linearly decreases to zero at the final period [1].

**Table 1:** Implemented scenarios.

| No. | Process Constraints | Subsidy (Base Value) | Delay Scale Factor |
|---|---|---|---|
| 1 | No | Constant (5) | 1 |
| 2 | Yes | Constant (5) | 1 |
| 3 | Yes | Phased-Out (5) | 1 |
| 4 | Yes | Phased-Out (5) | 1/2 |

The dynamic adoption problem (Equations 1-7), implemented in the AnyLogic environment, is optimised using OptQuest solver across 10 years with monthly sample periods. Ecosystem populations of farmers, biorefineries,

and users are 1000, 10, and 30000, respectively. A maximum of 1000 generations is used as the convergence measure to improve performance, compared to the default criteria. Other considerations, such as raw material and biodiesel prices and bounds for the ecosystem parameters, remain the same as in the prior works [1, 7]. Notably, the existence of delay and uncertain parameters and process constraints pose a serious challenge in reaching and identifying equilibria in discussed scenarios. The implemented scenarios intend to evidence the impacts of decision-level integrations and intricate considerations (delays and uncertainties) on the SC's overall performance. All experiments are performed on an Intel(R) Xeon(R) CPU E5-2620 processor and 128GB RAM.

## RESULTS AND DISCUSSION

Figure 4 presents the predicted adoption fraction over time for the different scenarios. In addition, the supply chain decision variables and utility function values are listed in Table 2. In the following sections, the study results are discussed.

**Table 2:** Scenario results.

| No. | $\alpha_{Farmers}$ | $\alpha_{Biorefineries}$ | $\alpha_{Users}$ | $u_T$ |
|---|---|---|---|---|
| 1 | 0.165 | 0.009 | 12.68 | 540.31 |
| 2 | 0.13 | 0.008 | 26.81 | 536.15 |
| 3 | 0.089 | 0.008 | 7.33 | 823.24 |
| 4 | 0.083 | 0.014 | 18.11 | 731.63 |

### Influences of The Biofuel Process Model

As seen in Figures 4(a) and 4(b), there is a significant difference in the adoption fraction of actors in the system, particularly in the later time horizons. This comparison indicates the impacts of the biofuel process on SC behaviour. While biorefineries attain similar adoption fractions in both cases, a late accelerated adoption and a subsequent drop (particularly for farmers) can be seen in the second scenario. This observation can be attributed to the fact that processing plant integration enhances the whole environment's visibility, slightly downgrading the actors' participation. In addition, the second scenario features the coupling of raw material supply from farmers and biofuel demand from users. At later planning stages, the increased potential supply of feedstocks creates local competition among farmers, adversely influencing their adoption. The resulting drop has cascading effects on downstream actors, as shown in Figure 4(b).

The same conclusion can be drawn by comparing the objective function values in Table 2, in which incorporating plant constraints leads to a more accurate estimation of the total utility. Here, the changes in SC decision variables are more noticeable, particularly the re-evaluation rates of users. Based on Table 2, due to the introduction of process constraints, users re-evaluate their decisions more frequently. At the same time, other ecosystems assess their decisions less regularly, so emergent and asymmetrical effects on farmers and users can be observed.

### Subsidy and Delay Effects

Figures 4(b) and 4(c) show that a constant subsidy leads to higher overall adoption fractions, indicating its effectiveness in promoting consistent adoption. However, the declining subsidy leads to a higher total utility value, owing to the regular changes in the adoption patterns. Therefore, a trade-off between subsidy types and values exists, potentially guaranteeing a less oscillating adoption and higher payoffs.

Scenario 4 has a reduced delay factor compared to Scenario 3. Figures 4(c) and 4(d) reveal that a smaller delay factor results in faster adoption rates, highlighting the importance of information flow and responsiveness in the SC. The reduced information delay also translates to higher adoption fractions across all parties. In contrast, increased information flows lead to a lower utility and a less stable adoption pattern, specifically for biorefineries and end-users.

Overall, Figure 4 and Table 2 provide evidence supporting the argument that biofuel SC models should consider process details, policy types, and information delays to represent system behaviour accurately. These factors directly impact the adoption patterns of different actors, ultimately influencing the success of policy implementation.

## CONCLUSION

This work proposes an agent-based framework to explore the multi-scale integration of process plant constraints and the dynamic interactions of multiple actors in the context of process and energy SCs. The developed model implements a bilevel structure to reflect the general and specialised cases such as biofuel SCs. The agent technology effectively captures the interdependencies and feedback relationships among different actors. By accounting for these actors' individual decisions and behaviours, the model provides a more comprehensive representation of the SC dynamics and reveals the potential for emergent system-level behaviours that may not be apparent in simpler models and conventional research works.

The capability of the framework is evidenced via a biofuel SC case study. The SC actors, namely farmers, biorefineries, and end-users, interact in a dynamic network. The case study aims to find an optimal collective adoption pattern based on a two-option strategy at individual levels. Multiple optimisation scenarios featuring

different parameter values and subsidy types are implemented to evaluate the SC aggregated payoff and adoption behaviours. The results show that integrated decision-making leads to a more realistic and insightful biofuel SC model. Integrating process constraints results in a more accurate estimation of the total utility function compared to models that rely on simplified unit operation representations. The findings also underscore the importance of moving beyond the traditional assumption that biorefineries are the sole decision-makers in the SC.

The advantages that arise from this framework extend beyond those mentioned in this study. In this regard, future research should include a better representation of individual payoff functions to capture the intricacies and interactions in biofuel SCs. Furthermore, policy efforts should focus on implementing more complex subsidy types and environmental sustainability measures. By embracing a more holistic and dynamic modelling approach, researchers and decision-makers can better understand the biofuel SC and develop more effective strategies to address the challenges and opportunities associated with this emerging industry.

## ABSTRACT

In the last decades, the growing awareness of climate change and the high political sensitivity of critical resources such as energy have emphasized a need for local, renewable and optimized energy mixes at various scales. Several studies have therefore aimed to optimize renewable energy technologies and plant locations to develop more renewable and efficient Energy Mixes. Following this trend, this paper applies and compares Goal Programming, Branch-and-Cut and NSGA-II to a multi-objective combinatorial optimization problem focused on the energy mix of Oise, France. Results show more optimality for Goal Programming and Branch-and-Cut, accompanied by a high sensitivity to constraints, while NSGA-II provides more technological diversity in the computed solutions.

**Keywords**: Energy Systems, Optimization, Genetic Algorithm, Stochastic Optimization, Goal Programming, Branch-and-Cut, Energy Mix

## 1. INTRODUCTION

The global rise of climate change awareness and its urgency has prompted governmental and intergovernmental organisations to update their policies in several areas. Environmental considerations have become paramount in the design of energy mixes, and renewable energy sources are now widely preferred to fossil fuels. The latter have also become highly sensitive to geopolitical issues and conflicts, making energy a critical resource more than ever. These environmental and economic incentives have led economic regions at different scales to improve their energy mixes and achieve energy independence [1]. The development of optimized, renewable and local energy mixes is therefore strongly supported by both environmental and economic situations globally [2].

The optimization of renewable energy technologies, plant locations and energy mixes has been the objective of several studies in the last decades, aiming to develop more renewable and efficient energy mixes [3]. Most of these optimization problems are solved using Mixed-Integer Linear Programming (MILP), Mixed-Integer Non-Linear Programming (MINLP) or heuristic algorithms [3].

This study aims to compare three optimization methods in their application to the optimization of the energy mix of Oise, France, focused on the Paris-Beauvais Airport, from environmental and economic perspectives.

The focus is put on annual production potential at a regional scale and therefore does not consider decomposition optimization methods, better suited to problems involving temporal variation or multiple time periods. For this study, Goal Programming, Branch-and-Cut and Non-dominated Sorting Genetic Algorithm II (NSGA-II) were selected for their wide use and coverage of problem formulations The first two can easily handle MILP and MINLP problems but require the problem to be expressed as a single objective function. On the other hand, NSGA-II can handle both objectives separately [4,5].

After census of energy resources already present in the target area, the available energy mix undergoes a

carbon footprint evaluation that serves as the environmental component of the problem [6]. The economic component is based on the Levelized Cost of Energy (LCOE), an aggregation of operating, maintenance and installation costs. These two components constitute the objectives of the problem, either treated separately or weighted in a single objective function depending on the optimization method. The three selected methods are applied to the problem, and the results provided by each are gathered and assessed based on criteria such as optimality of solutions, sensitivity to constraints and parameters, execution time and diversity of solutions. The evaluated methods are then compared against these criteria, to identify their strengths and weaknesses of each method regarding the studied problem.

The aim of the study is to assess not only optimality but also diversity of solutions and to identify acceptable trade-offs between the two. This could lead to the development of a hybrid method ideally fitted to this energy mix optimization problem.

# 2. METHODS

## 2.1 Choice of optimization methods

The methods compared in this study are Goal Programming, Branch-and-Cut and NSGA-II. They approach problems very differently but are all recognized and widely used for multi-objective combinatorial optimization problems. Each of these methods has its own strengths and weaknesses, but all three are suitable for the energy mix optimization problem studied and described later in this paper [7,8].

### 2.1.1 Goal Programming

Goal Programming is known for being ideal in multi-criteria decision-making problems, especially with conflicting objectives. Computationally, it is the simplest method of the three, essentially defining an ideal solution from given objectives and calculating deviations between possible solutions and the ideal one. In this way, it can handle multiple conflicting objectives, allowing the decision-makers to prioritize one objective over others, addressing trade-offs explicitly. In the case of energy-related problems, it has been applied to several energy-planning issues, especially to handle the conflict between financial costs and greenhouse gases emissions [7,9]. Its simplicity and its ease in dealing with conflicting objectives make Goal Programming fitted to the energy mix optimization problem later described in this paper.

### 2.1.2 Branch-and-Cut

The Branch-and-Cut optimization method combines Branch-and-Bound and Cutting-Planes, two algorithmic approaches, to solve mixed-integer linear programming (MILP) problems. Branch-and-Cut explores the space of feasible solutions by creating branches of decision variables, then refines the solution space with cutting planes to remove identified non-optimal solutions. While it can find guaranteed global optima for MILP problems, its computation times can rise quickly depending on problem size. However, Branch-and-Cut is well suited to problems involving discrete variables, which is often the case with Energy-related scenarios [10]. Despite it being a combinatorial optimization problem, the studied optimization problem is rather small and can be optimized using the Branch-and-Cut method.

### 2.1.3 Non-dominated Sorting Genetic Algorithm (NSGA-II)

Unlike previous methods, NSGA-II uses a stochastic approach to solve more complex, non-linear problems. It is widely used for multi-objective optimization problems, including energy mix optimization problems. It generates successive populations of candidate solutions before ranking them according to Pareto dominance. Although it is computationally intensive, it provides flexibility in handling non-linear, non-convex problems, making it a widely used method in a variety of fields, including energy problems for energy development and greenhouse gases (GHG) emission reduction [8,11]. In the case of the studied energy mix optimization problem, the key asset it provides is the Pareto-front solutions which, while not guaranteeing global optimality, allows to test trade-offs without having to implement weights. A comparison of optimality between NSGA-II solutions and deterministic algorithms will allow to assess the acceptability of solutions regarding optimality, while still exploring technological diversity in the computed energy mix optimizations.

## 2.2 Studied optimization problem

The case study for this work is a combinatorial optimization problem for the energy mix of Oise, France. The problem consists in the selection of energy sources from a given dataset [12–15], presenting as a list of potential installations. The optimization algorithms then combine multiple of these installations to build an energy mix. To do so, the objective function is based on two criteria, an environmental criterion and a economic criterion. The first is derived from the energy mix evaluation method proposed in [6]. It consists of three emission components, expressed in tons of expressed in tons of CO2eq per year. The first component is a product of energy production and an energy source emission factor, the second represents emissions due to urbanization, and the third translate the emissions depending on the distance between the energy source and the consuming infrastructure.

The economic criterion is based on the Levelized Cost Of Energy (LCOE) data from [16]. It also depends on

the annual production and is expressed in euros per year. The problem is therefore expressed in Equations (1), (2) and (3).

$$minf_{env}(P) = \sum_{i=1}^{n}(P_i * EES_i + CFU_i + CFD_i) \quad (1)$$

$$minf_{eco}(P) = \sum_{i=1}^{n}(P_i * LCOE_i) \quad (2)$$

$$\sum_{i=1}^{n}(P_i) \geq PMin \quad (3)$$

With EES the GHG emission factor assigned to production, CFU the emissions of urbanization and CFD the emissions assigned to distance [6,12,13]. PMin is the target annual production to reach and varies between 0 and the total annual production for the dataset.

## 2.3 Python Implementation

The optimization of the problem with Goal Programming, Branch-and-Cut and NSGA-II was implemented using the Python programming language, chosen for its versatility and wide number of libraries. Moreover, Python offers accessibility and is ideal for open-source applications.

### 2.3.1 Goal Programming

The solving of the optimization problem by Goal Programming was implemented using PuIP, an open-source Python library. To guide the algorithm in decisions between the conflicting objectives, weights $\alpha$ and $\beta$ were introduced, summing to 1 and weighting the environmental and economic criteria respectively. Both components were then added up in a single objective function and therefore needed to be comparable. The LCOE value, expressed in €/y, was converted to $tCO_{2eq}$/y using the Social Cost of Carbon (SCC) as the average of calculations in the literature from 2018 to 2022 [17]. The final objective function for Goal Programming application is expressed in Equation (4).

$$minf_{env}(P) = \alpha \sum_{i=1}^{n}(P_i * EES_i + CFU_i + CFD_i) + \beta \sum_{i=1}^{n}(P_i * LCOE_i * SCC) \quad (4)$$

Using the PuIP library, a Linear Programming problem was specified. The decision variable for each item was defined as a binary value: each item is either included or not included in the final solution. Deviations were defined from zero for objectives to minimize, and from PMin for the target production constraint.

### 2.3.2 Branch-and-Cut

The solving of the optimization problem with Branch-and-Cut was also implemented using PuIP. The weights implemented in the Goal Programming method were retained to allow comparison between the two approaches. Similarly, both objectives were combined into a single objective function, and the LCOE value was also converted to $tCO_{2eq}$/y using the SCC. The PuIP library-implementation also uses the *LpProblem* function and a binary decision variable. The cutting plane methods used for this optimization were Gomory cuts, Knapsack cuts, suitable for combinatorial problems, and Probing cuts, which are suited to problems with binary variables.

### 2.3.3 Non-dominated Sorting Genetic Algorithm (NSGA-II)

The solving of the optimization problem with NSGA-II was implemented using the DEAP Python library. Unlike previous methods, both objectives can be evaluated together without having to sum them or implement weights. The algorithm was initially run with a population of 100 at generation 0, a crossover probability of 75% and a mutation probability of 20%, for a duration of 300 generations. To ensure that the production constraint is met, an infinite penalty is applied to both minimization objectives for all individuals that do not reach the production objective.

# 3. RESULTS

## 3.1 Goal Programming

Goal Programming was applied to the problem with a weight of 0.65 for the $\alpha$ parameter and 0.35 for $\beta$, while the minimum energy production (PMin) was set at 1422 GWh/y, representing 60% of the maximum possible production. Results showed a significant dominance of wind energy, with 53 out of the 66 selected installations being wind turbines, accounting for approximately 81% of the total production (**Table 1**).

**Table 1:** Summed results for the Goal Programming optimization, with PMin=1422, $\alpha$=0.65, $\beta$ =0.35. P_Tot is the total production, in GWh/y. T_Env is the environmental component of the objective function and T_Eco the economic component of the objective function, both in $tCO_{2eq}$/y.

| Energy | Count | P_Tot | T_Env | T_Eco |
|---|---|---|---|---|
| Wind | 53 | 1153.2 | 25112 | 20373 |
| Solar | 2 | 0.1 | 5 | 4 |
| Biomethane | 11 | 268.7 | 6290 | 8508 |
| Total | 66 | 1422.0 | 31408 | 28885 |

Further computations were performed with weight values varying between 0.05 and 0.95, and target production varying between 40% and 60% of total production. PMin is the most influential parameter on results,

and the algorithm is less sensitive to weighting when PMin is lower, resulting in fewer optimal solutions and more convergence (**Figure 1**).

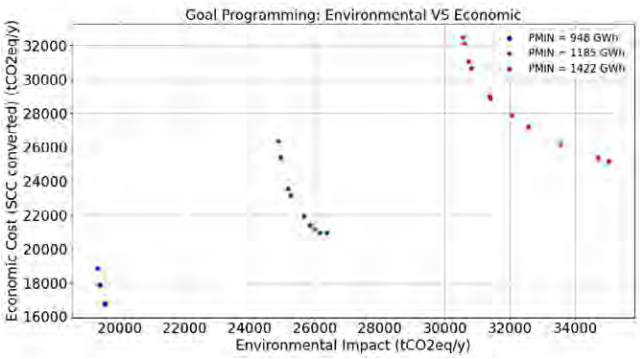

**Figure 1:** Compared results of the optimization with the Goal Programming approach, with varying PMin, $\alpha$ and $\beta$

## 3.2 Branch-and-Cut

The Branch-and-Cut method was applied to the optimization problem, with the same values of PMin, $\alpha$, and $\beta$, and with the same variations as with Goal Programming. The results obtained were identical: the total values were the same, as the exact same elements were selected by both approaches. The trends observed based on the variables therefore remain consistent for Branch-and-Cut. The only difference observed between the methods is a variation in execution time, with Branch-and-Cut being 8% faster than Goal Programming.

## 3.3 NSGA-II

Unlike previous methods, no weights were applied in the NSGA-II optimization. As a stochastic approach, the algorithm was run multiple times with the same PMin value and could inherently explore different trade-offs. Different iterations with identical parameters therefore resulted in slightly different Pareto-fronts. The computed results differ significantly from those produced by Goal Programming and Branch-and-Cut (**Figure 2**).

NSGA-II computed results are globally less optimal for both criteria, and tend to exceed the production constraint more than necessary, often by more than 1 GWh/y. They also tend to return higher values for the environmental objective and favour minimizing the economic component of the problem. Computation times for the NSGA-II optimizations were about 15 times faster than Goal Programming or Branch-and-Cut and rarely lasting more than a dozen seconds. The initial population size was therefore increased to 2000 and 5000, which showed a positive impact and partially resolves the optimality problem, with results much closer to Goal Programming and Branch-and-Cut, although still less optimal. However, computation times were raised significantly (circa 500 times longer for a population of 5000).

The population size increase mitigated the excess production in solutions, although solutions provided still exceed the threshold production constraint. On the other hand, NSGA-II solutions appear to provide more diversity in the technologies used to reach that threshold (**Table**

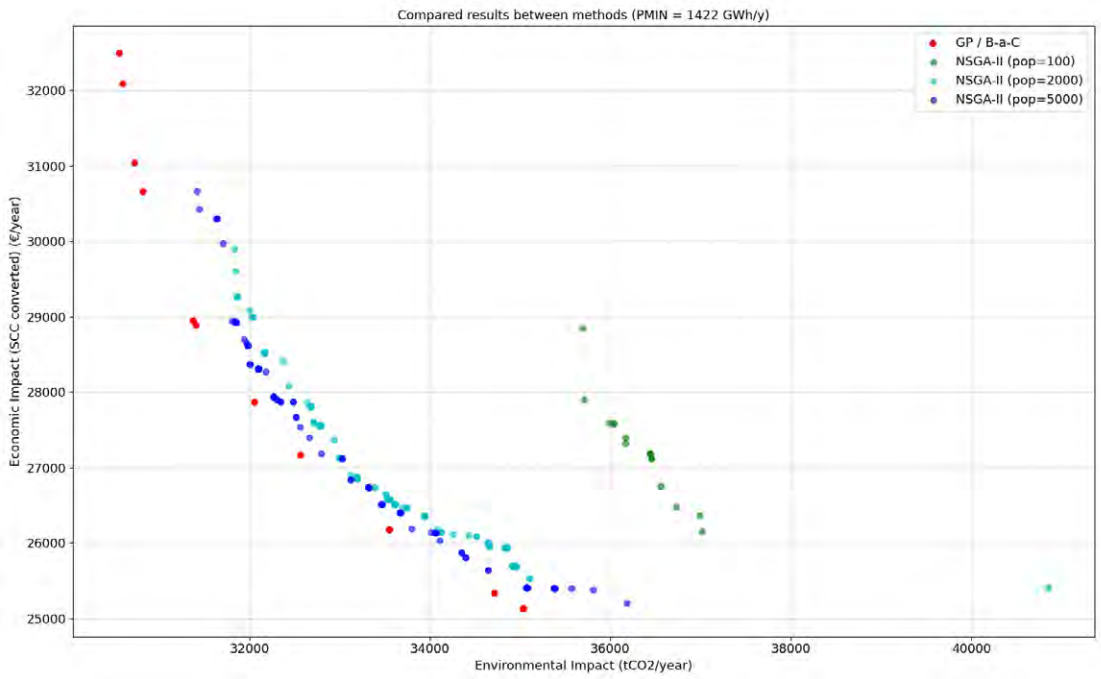

**Figure 2:** Comparison of optimization results for three NSGA-II runs with results for Goal Programming / Branch-and-Cut. Production target value is fixed to 1422 GWh/y.

**2**), using more solar plants than Goal Programming or Branch-and-Cut methods. Upscaling tests were performed, and results suggest that the optimality difference between NSGA-II and deterministic methods increases with the number of selectable items, as well as the computation times, while maintaining technological diversity.

**Table 2:** Mean results for NSGA-II optimization computation with PMin=1422. P_Tot is the reached production, in GWh/y.

| Energy | Count | P_Tot |
|---|---|---|
| Wind | 54.79 | 1231.59 |
| Solar | 111.22 | 10.58 |
| Biomethane | 8.88 | 181.03 |
| Bioenergy | 0.32 | 0.53 |
| Total | 175.22 | 1423.74 |

## 4. DISCUSSION

The Goal Programming results show an over-representation of wind energy installations compared to the original dataset. This can be explained by the evaluation methods, which both favor wind power installation. Moreover, wind turbines are individually some of the most productive installations, so the reward for incorporating them in the mix is high. This bias could be controlled and limited by adding a third objective, possibly regarding the flexibility or controllability of the production, or social acceptance of the project.

The high similarity between Goal Programming and Branch-and-Cut results confirms the optimality of found solutions. These two computational approaches, both deterministic, are therefore computationally closer to each other than to NSGA-II, thus explaining the observed disparities with the latter's results. Though they provide optimality in this study, further work may introduce additional objectives and constraints that may be too complex for deterministic approaches and require an evolution of the method. In addition, the algorithms require weights to explore the solution space, which induces a high dependency between the results and the $\alpha$ and $\beta$ parameters, especially with high PMin values. This could mean that a small number of items in the dataset are significantly better than others in regard to both criteria and would therefore be systematically preferred in cases with low PMin, resulting in a weight dependence increasing with target production. On the other hand, NSGA-II can explore different regions of the solution space and find trade-offs without these weights.

Concern is raised regarding NSGA-II, since the pareto fronts produced were not as optimal as the results of previous methods. The efficiency of the method on this problem can be doubted, although some explanation can also be provided by the strong penalties implemented in the computation. The algorithm is so strongly encouraged to reach the production constraint, that it seems reluctant to slightly reduce production to find more optimal solutions in terms of the environmental and economic objectives. Although increasing the population size partially solved this issue, upscaling the problem could prove difficult, with a larger dataset implying even longer computation times. However, the technological diversity provided by NSGA-II is significantly better than that of deterministic approaches, which supports interest in pursuing the research of trade-offs between optimality and technological diversity, as long as computational times remain acceptable. To pursue this goal, a hybrid approach could be considered, incorporating portions of the deterministic approaches to reduce the solution space and thus guide the NSGA-II towards more optimized results.

## 5. CONCLUSION

The comparative analysis of Goal Programming, Branch-and-Cut, and NSGA-II for a combinatorial energy mix optimization problem in Oise, France, shows nuanced insights. Goal Programming and Branch-and-Cut produced remarkably similar results, demonstrating good solution optimality and computational efficiency with a strong dependence to the input dataset, translating to a distinct preference for wind energy installations. This underlines an interesting development opportunity for introducing additional objectives like production flexibility or social acceptance to create more fitted optimization approaches.

NSGA-II provided less optimal solutions than deterministic methods across both environmental and economic criteria, which correlates with existing literature. However, the optimality difference reduces with the population size used for NSGA-II computation, with an increase in computational time. The method's performance was constrained by strict production penalties, which may have limited its ability to find optimal solutions and explore more nuanced trade-offs. However, its overperformance regarding the production threshold criteria and the greater technological diversity it provides in its solutions suggest that an acceptable trade-off between optimality, computation time and technological diversity can be found.

Future research should focus on refining penalty mechanisms, implementing additional objectives and constraints to progress towards better suited optimization algorithms, both in terms of computational methodology and parameter definition. Opportunities for hybrid methods should not be ignored and will be considered in future works.

## ABSTRACT

Real-world flowshop problems which are very common in the chemical industry are often difficult to solve in a reasonable time with allocation, sequencing, and lot-sizing decisions. Although great progress has been made in the last 20 years regarding MILP model formulations and solution algorithms, realistically-sized flowshop problems with resource and buffer constraints are still difficult to solve. On the other hand, discrete-event simulation (DES) allows for very detailed modelling of process plants, but lacking of optimization capabilities. Simulation Optimization (SO) combines the high-detail DES with mathematical optimization. We show that is possible to integrate MILP and DES using Benders decomposition. We explain the Benders-DES (BDES) approach with a small motivation example with makespan minimization objective and apply it to a real-world case study of a formulation plant with seven formulation and filling lines with sequencing, allocation, and lot-sizing decisions. We show that the BDES approach performs comparably to the original monolithic-sequential MILP-DES approach. However, the key advantage of this method is the ability to leverage MILP optimization power without requiring a detailed model description.

## INTRODUCTION

### General Motivation

In the chemical process industry, optimization-based scheduling is a critical advantage in today's fast-paced and interconnected world. However, the complexity when optimizing chemical processes is high: A chemical process that requires personnel and processing equipment, consumes raw materials and utilities, and is linked to a complex supply chain, is naturally subject to many constraints and objectives [1]. Discrete Event Simulation (DES) models can describe complex real-world processes to a great level of detail, have relatively short computation times, and allow to include uncertain parameters. However, since DES models have limited optimization capabilities, the solutions of DES models may be far away from the optimum. While MILP models enable global optimization, they quickly grow to intractable size, when trying to include all relevant constraints. In addition, MILP models can be difficult to set up, validate, and maintain for real-world applications.

### Simulation Optimization

Simulation Optimization (SO) combines the high-detail DES with mathematical optimization. SO has repeatedly shown success in solving process design and operations problems [2]. The interested reader is referred to the review [3] on DES-based optimization methods for industrial engineering problems.

However, SO approaches struggle with complex real-world models that contain many discrete and continuous decision variables and constraints. For example, in [2] the same hybrid flowshop as in this paper is solved with a genetic algorithm (GA). The authors use a detailed DES model of the plant and include lot-sizing decisions. The GA requires 200 generations with a population size of 20, which leads to several hours of solution time on large computer resources.

In [4], a simulation-optimization approach for adaptive manufacturing capacity planning in small and medium-sized enterprises is developed. An artificial neural

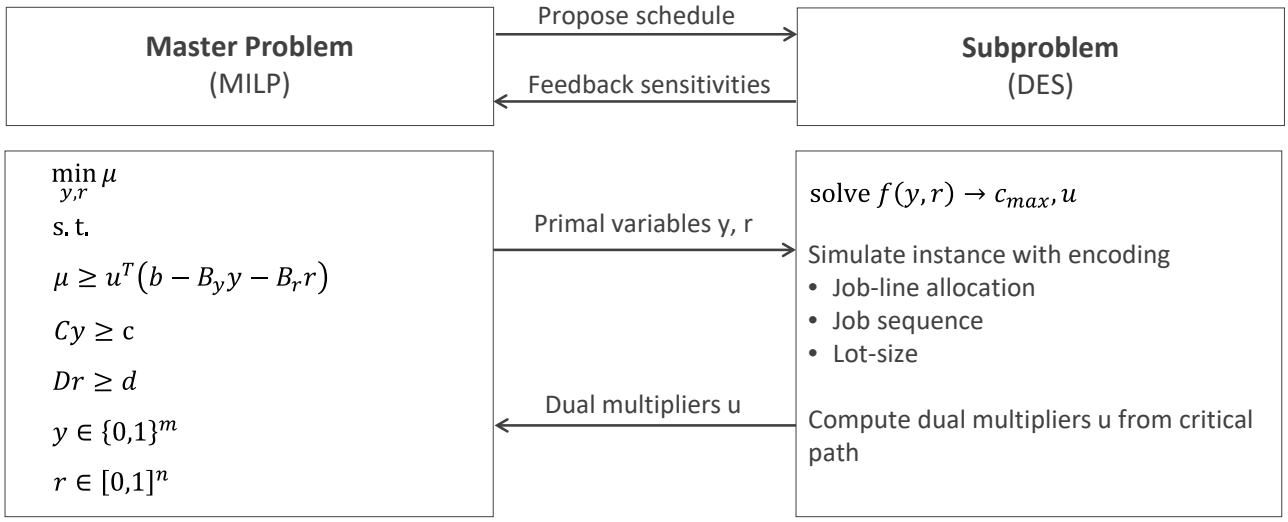

**Figure 1:** Benders-DES algorithm for hybrid flowshops. $y$ represents the discrete allocation and sequence decision variables; $r$ the continuous lot-sizing variables as split factors, which indicate what percentage of the job is covered by the lot. The objective is to minimize the makespan $c_{max}$.

network (ANN) is trained on production data of an industrial case study of pastry production and a GA is used to optimize the ANN. While this is a practical solution approach for complex problems it is concluded that the GA can be a limiting factor when exact solutions with guaranteed optimality are required.

In [5], a Digital Twin-driven dynamic scheduling approach is presented featuring a MILP model and a 3D shop floor simulation model to address a hybrid flow shop problem in perfume manufacturing. While the approach is effective and practical, it requires a "human-in-the-loop" to assess the results of the simulation model. Similarly to [6], there is no automatic feedback from the simulation to the optimization model which is a disadvantage compared to the aforementioned SO approaches.

### Contribution of this Work

This work presents a novel SO approach that integrates DES and Benders Decomposition. Sequencing, allocation, and lot-sizing are included in the Benders master problem, while important real-world constraints such as sequence-dependent changeover times, limited personnel resources, and limited intermediate buffer capacities are considered in the Benders subproblem. It is shown that the BDES can be applied to a real-world hybrid flowshop as presented in [6] and that good schedules in a reasonable amount of time can be obtained.

## METHODOLGY

### Benders Decomposition Framework

The Benders decomposition framework is shown in Figure 1. This master MILP problem proposes a new schedule (job sequence) as well as job-line allocation and lot-sizing decisions if required. Based on this information, the DES subproblem calculates the resulting schedule and returns an upper bound of the makespan and sensitivities (dual multipliers) using the concept of critical path mapping, which is explained in the next section. The dual multipliers are used to set up the Benders cuts. For every DES schedule, one Benders cut is added to the MILP master problem leading a new lower bound for the makespan. If the lower bound reaches the upper bound or the upper bound is not improving any more, the algorithm will stop. Further details can be found in [7].

### Motivating Example

The BDES approach is explained with a small flowshop problem with no intermediate storage, processing only 3 jobs (see Figure 2). The objective is to find the job sequence which minimizes the makespan. For the sake of simplicity, allocation and lot-sizing decisions play no role here. It can be shown by enumeration that *Schedule 2* of Figure 2 is the optimal one with a makespan of 6 h.

For the above mentioned flowshop, a MILP problem (1) – (6) is set up. The model formulation is based on precedence variables. The precedence variable $y_{ij}$ is one, if a job $i \in I = \{1,2,3\}$ is processed before job $j \in I = \{1,2,3\}$. $s_{il}$ is the start time variable of a job $i$ on stage $l \in L = \{1,2\}$. $p_{il}$ are the processing time parameters which can be read from Figure 2. $T$ is the Big-M constant. A valid (but weak) estimate for this value can be the summation of all processing times.

The objective (1) is to minimize the makespan $c_{max}$. Constraint (2) is the makespan constraint. Constraint (3) ensures that a job on a stage only starts after the processing of the previous stage concluded. The constraint

(4) ensures that only one job is processed at a given time on a given stage. (5) is a logical constraint.

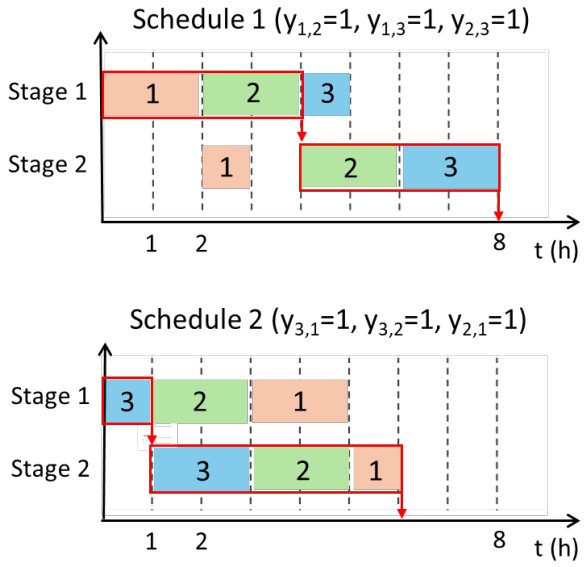

**Figure 2.** Small flowshop problem with 3 jobs and no intermediate storage (numbers in the Gantt bars indicate the job number, not the processing time). The critical paths are are indicated by the red boxes.

$$\min c_{max} \tag{1}$$

$$\text{s.t.} \quad c_{max} \geq s_{i2} + p_{i2} \; \forall \, i \in I \tag{2}$$

$$s_{il} + p_{il} - s_{il+1} \leq 0 \; \forall \, i \in I, l \in L \backslash \{2\} \tag{3}$$

$$s_{jl} + p_{jl} - T y_{ij} - s_{il} \leq 0 \; \forall \, l \in L, i, j \in I : i \neq j \tag{4}$$

$$y_{ij} + y_{ji} = 1 \quad \forall \, i, j \in I : i \neq j \tag{5}$$

When fixing the precedence variables $y_{ij}$, the MILP reduces to a LP. Defining $y_{ij}$ as complicated variables, the LP becomes the Benders subproblem in the classical Benders decomposition approach [8]. In the BDES approach, the subproblem corresponds to one DES simulation.

The LP solution returns the information of the binding constraints. For example, for *Schedule 1* in Figure 2, the following sequencing constraints are active:

$$s_{32} + p_{32} - c_{max} \leq 0 \tag{6}$$

$$s_{21} + p_{21} - s_{22} \leq 0 \tag{7}$$

$$s_{11} + p_{11} - T y_{21} - s_{21} \leq 0 \tag{8}$$

$$s_{22} + p_{22} - T y_{32} - s_{32} \leq 0 \tag{9}$$

All active constraints are associated with a non-zero dual multiplier $u$ which is -1 in case of makespan minimization, and the Benders cut can then be set up accordingly:

$$\mu \geq -u \cdot (p_{32} + p_{21} + p_{11} - T y_{21} + p_{22} - T y_{32}) \tag{10}$$

This dual information can also be obtained from the critical path of the Gantt diagram of the DES simulation (see Figure 2). The makespan is obtained by summing over all lot processing times on the critical path. For *Schedule 1* ($y_{21} = 0$ and $y_{32} = 0$), the makespan can be derived from the Benders cut (11): $p_{11} + p_{21} + p_{22} + p_{32} = 8$. For every DES simulation, a new Benders cut is generated and added to the MILP, as shown in Figure 1.

## CASE STUDY

As a case study, a hybrid flowshop problem of a agrochemical formulation plant as presented in [6] is considered. The process is a two-stage formulation and filling process that takes place in a multi-product batch plant, as shown in Figure 3. In the formulation stage, raw materials are milled, mixed, and brought to reaction. In the filling stage, the intermediate products are filled into final containers of different sizes. The plant has seven parallel production lines (machines) per stage, each with different run rates per product and sequence-dependent changeover times. There are seven optional buffer tanks to decouple formulation and filling between the two stages. In addition, shift personnel is limited and organized into two different schedules. The process is exposed to 50 raw materials on the input side and a highly fragmented demand for 83 finished products on the output side. The goal is to process various products (jobs) in the shortest possible makespan, which results in a complex flowshop optimization problem.

## PROBLEM FORMULATION

### MILP Core Problem

The core problem of the presented case study is a hybrid flowshop MILP problem. The model formulation is based on assignment and precedence variables as suggested in [8]. Binary assignment variables $a_{biml}$ indicate whether lot $b \in \{1, \ldots, B\}$ of job $i \in \{1, \ldots, N\}$ is processed on machine $m \in \{1, \ldots, M\}$ in process stage $l \in \{1, \ldots, L\}$. Binary indicator variables $h_{bb'ijml}$ indicate whether lot $b \in \{1, \ldots, B\}$ of job $i \in \{1, \ldots, N\}$ and lot $b' \in \{1, \ldots, B\}$ of job $j \in \{1, \ldots, N\}$ are both processed on the same machine $m \in \{1, \ldots, M\}$ in process stage $l \in \{1, \ldots, L\}$. Binary precedence variables $y_{bb'ijml}$ indicate whether lot $b$ of job $i$ is processed before lot $b'$ of job $j$ on machine $m$ in process stage $l$. Continuous lot-sizing variables $r_{bi} \in [0,1]$ represent the split factors, which indicate what percentage of job $i$ is covered by lot $b$. Start time variables $s_{biml}$, completion time variables $c_{biml}$, and processing time parameters $t_{iml}$ define the resulting schedule. $T$ is the Big-M constant.

The objective (11) is to minimize the makespan $c_{max}$.

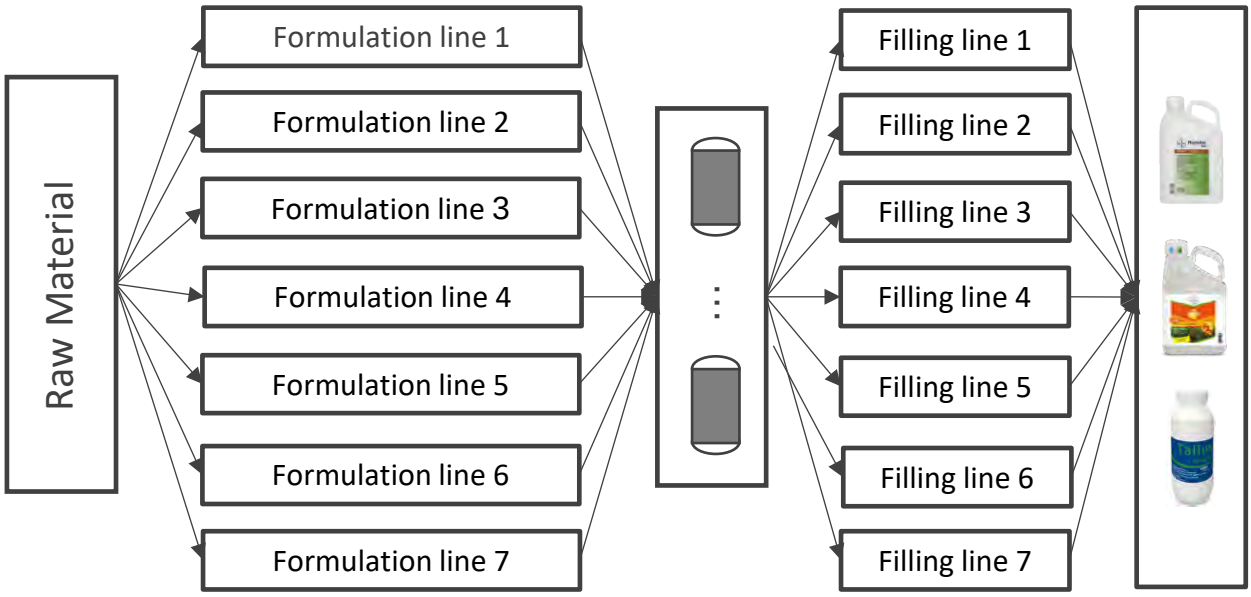

**Figure 3:** Equipment layout of the agrochemical formation plant treated in the case study. The case study is a two-stage flexible flowshop problem with seven formulation lines (stage 1) and seven filling lines (stage 2). The intermediated (formulated) product can be stored in seven buffer tanks before being processed in the filling lines.

(12) is the makespan constraint. Constraint (13) sets the start and completion times according to the processing times, (14) enforces the lot sequence on each machine, (15) ensures valid start times of lots when switching from one stage to the next, (16) forces each lot to be processed on exactly one machine in each stage, and (17) defines for each machine the precedence relation between lots which are assigned to that machine. Constraints (18) to (20) build the binary indicator variables $h_{bb'ijml}$ and (21) enforces valid lot sizes.

$$\min c_{max} \tag{11}$$

$$\text{s.t.} \quad c_{max} \geq c_{bimL} \; \forall \, b \in B, i \in N, m \in M \tag{12}$$

$$s_{biml} + r_{bi} t_{iml} \leq c_{biml} + T(1 - a_{biml}) \; \forall \, b \in B, i \in N, m \in M, \mathrm{l} \in L \tag{13}$$

$$c_{biml} + r_{b'j} t_{jml} \leq c_{b'jml} + T\left(1 - y_{bb'ijml}\right) \; \forall \, b, b' \in B, i, j \in N : i \neq j, m \in M, l \in L \tag{14}$$

$$T(a_{biml} - 1) + s_{biml} + r_{bi} t_{iml} \leq s_{binl+1} + T(1 - a_{binl+1}) \; \forall \, b \in B, i \in N, m, n \in M, l \in L \backslash \{Lmax\} \tag{15}$$

$$\sum_{m=1}^{M} a_{biml} = 1 \; \forall \, b \in B, i \in N, l \in L \backslash \{Lmax\} \tag{16}$$

$$y_{bb'ijml} + y_{b'bjiml} = h_{bb'ijml} \; \forall \, b, b' \in B, i, j \in N : i \neq j, m \in M, l \in L \tag{17}$$

$$h_{bb'ijml} \leq a_{biml} \; \forall \, b, b' \in B, i, j \in N : i \neq j, m \in M, l \in L \tag{18}$$

$$h_{bb'ijml} \leq a_{b'jml} \; \forall \, b, b' \in B, i, j \in N : i \neq j, m \in M, l \in L \tag{19}$$

$$h_{bb'ijml} \geq a_{biml} + a_{b'jml} - 1 \; \forall \, b, b' \in B, i, j \in N : i \neq j, m \in M, l \in L \tag{20}$$

$$\sum_{b=1}^{B} r_{bi} = 1 \quad \forall \, i \in N \tag{21}$$

## Benders Master Problem

From the MILP core problem, the Benders master problem (22) to (29) is derived. The Benders cuts in (23) are based on the dual variables $u_{biml}$ which assume a value of -1 if lot $b$ of job $i$ on machine $m$ in stage $l$ is on the critical path, and 0 otherwise. Constraints (24) to (27) ensure valid lot-machine assignments and lot sequencing. Constraint (29) enforce valid lot sizes.

$$\min \mu \tag{22}$$

$$s.t. \quad \mu \geq \sum_{b=1}^{B} \sum_{b'=1}^{B} \sum_{i=1}^{N} \sum_{j=1}^{N} \sum_{m=1}^{M} \sum_{l=1}^{L} -u_{biml} \left( r_{bi} t_{iml} - T\left(1 - y_{bb'ijml}\right)\right) \tag{23}$$

$$\sum_{m=1}^{M} a_{biml} = 1 \; \forall \, b \in B, i \in N, l \in L \tag{24}$$

$$y_{bb'ijml} + y_{b'bjiml} = h_{bb'ijml} \; \forall \, b, b' \in B, i, j \in N : i \neq j, m \in M, l \in L \tag{25}$$

$$h_{bb'ijml} \leq a_{biml} \; \forall \, b, b' \in B, i, j \in N : i \neq j, m \in M, l \in L \tag{26}$$

$$h_{bb'ijml} \leq a_{b'jml} \; \forall \, b, b' \in B, i, j \in N : i \neq j, m \in M, l \in L \tag{27}$$

$$h_{bb'ijml} \geq a_{biml} + a_{b'jml} - 1 \; \forall \, b, b' \in B, i, j \in N : i \neq j, m \in M, l \in L \tag{28}$$

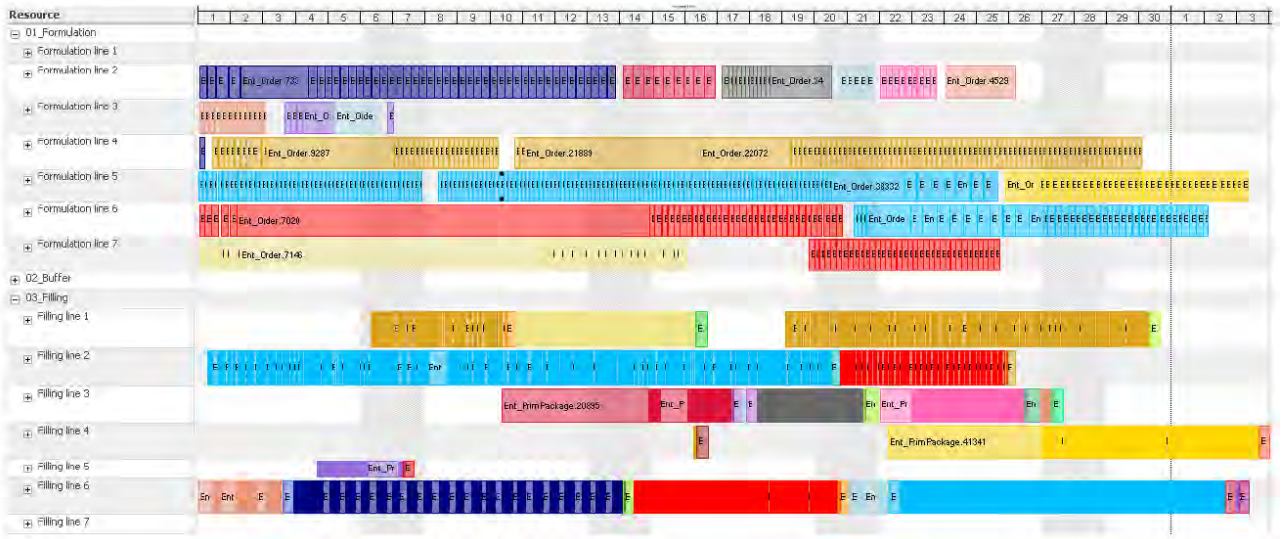

**Figure 4:** Gantt chart of best solution after solving one-month production dataset with BDES for 360 seconds.

$$\sum_{b=1}^{B} r_{bi} = 1 \quad \forall\, i \in N \tag{29}$$

Note that the cuts (23) only include the processing times as contributors to the critical path because they were derived from the core flow shop problem. If these cuts are applied to the detailed DES model of the case study, they remain valid inequalities as discussed in [7], but omit certain features of the problem such as secondary resources and changeover times. In this case, the cuts represent valid underestimators to the DES makespan with a gap $\delta \geq c_{max} - \mu^* \geq 0$.

## Benders Subproblem

For the Benders subproblem, a DES model of the case study flow shop is assumed. In contrast to the MILP, the DES does not suffer from the curse of dimensionality, and computation times do not increase exponentially with problem size. This makes it possible to accurately model, simulate, and analyze complex systems. The DES model is considered as a black box function $f: y_{bb'ijml}, a_{biml}, r_{bi} \rightarrow s_{biml}, c_{biml}, c_{max}$ that computes a solution for the non-complicating variables and dual multipliers, given an input solution of the complicating variables. In the case study, the input contains the lot sequences, lot-line assignments, and lot sizes. The output includes the starting and completion times of all lots. In addition, the dual multipliers are calculated from the critical path.

# RESULTS

BDES is applied to the one-month production dataset 2 of the case study in [6, Table 4]. As DES Python-based SimPy 4.1.1 is used, and for MILP gurobipy 11.0.1 with Gurobi 9.5.2. Similar to the monolithic-sequential MILP-DES approach of [6], BDES can compute an optimized one-month production schedule for the formulation and filling plant. This schedule is found after approximately one minute of solution time, which is faster than the monolithic MILP model, which required approximately ten minutes for the first optimization step to schedule the production within the month without backlog. However, a shortcut DES model was used, and the makespan in the same full-space DES model as used in [6] is 33 days (see Figure 4). This result is comparable to the manually generated DES schedule and implies that some backlog quantities occur.

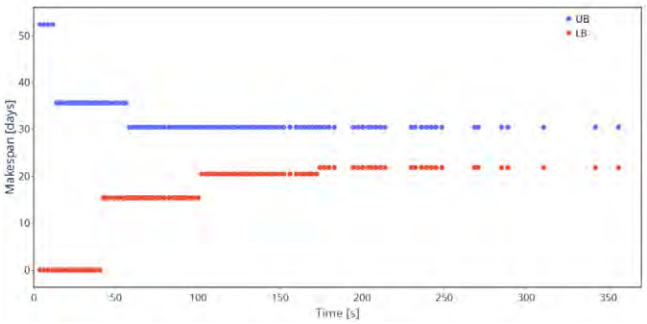

**Figure 5.** Makespan bounds progression when solving a one-month production dataset with BDES for 360 seconds.

Figure 5 shows that the lower bounds on the makespan increase after a solution with a makespan of 30.5 days has already been found. This information can be helpful in practice to terminate the search process prematurely, as it can be assured that no better solutions than with a makespan of 20 days can be found. Meaningful lower bounds can be computed for the one-month case study dataset because eligibility constraints are

added to the master problem. These constraints rule out many lot-line assignments, reducing the search space a priori.

Lot-sizing is an important degree of freedom that enables efficient scheduling with minimal makespan. However, BDES only exploits splitting for some products. For example, the first products on formulation lines 5 and 6 exploited the split factor of two (see Figure 4). Therefore, a split factor of two already supports a high utilization of formulation and filling lines. An unlimited split factor as implemented in [6] may lead to further makespan improvements but also increases the model complexity. In this work, experiments with higher split factors indicated that the complexity can be prohibitive for BDES because the search space for the Benders master problem grows exponentially.

Furthermore, Figure 4 shows that fewer changeovers in the filling stage occur compared to the result in [6]. This is because the objective function in this work is not to minimize changeover costs but the makespan. In [6], many changeovers occurred due to favorable changeover cycles in the filling stage that minimized the overall changeover costs.

The application of BDES to the one-month production dataset shows that the performance of BDES is generally comparable to the manual-DES approach in [6] for real-world scheduling tasks. Furthermore, BDES requires similar solution times as the MILP-DES approach in [6] but yields slightly worse results. However, building the complex, monolithic MILP model and manually reconciling the MILP results with the DES model is not necessary. Instead, a Benders master model of a generic, hybrid flowshop (see Section "Problem Formulation") is used to guide the search process in the DES subproblem.

## CONCLUSIONS

This work presents a novel BDES algorithm to minimize the makespan of hybrid flowshop with allocation, sequencing, and lot-sizing decisions as well as secondary resource constraints. BDES performs similarly to the sequential monolithic MILP-DES approach of [6]. Although BDES yields slightly worse results compared to the approach of [6], the setup of BDES is less complex compared to a monolithic MILP approach.

The main advantage of BDES is that it can apply MILP in the form of simple Benders cuts to highly detailed DES models. It is not necessary to build a complex MILP model, but a MILP Benders master model of a generic hybrid flowshop with precedence variables is used while the real-world constraints being moved to the DES subproblem. This work shows that combining the strengths of rigorous optimization and detailed modeling can be attractive from a practical perspective since it allows for fast model development and implementation.

Future research will focus on the investigation of the generality of the approach, i.e., the influence of different problem instances on the solution quality as well as strengthening the Benders cuts and generation of robust schedules.

## ACKNOWLEDGEMENTS

We thank the Bayer AG, Leverkusen, Germany for providing the case study.

## ABSTRACT

Sustainable industrial development depends on optimizing resource and energy integration within Eco-industrial parks (EIPs), combined with stringent carbon emissions reduction policies. The main challenge is ensuring transparency, accountability, and data privacy while optimizing the conversion of raw materials and energy into valuable products and controlling emissions within EIPs. This research introduces an innovative framework to design optimized EIPs and deploy a blockchain-enabled trading platform for resources and emissions management, tackling these key issues. The proposed framework integrates EIPs with emission control policies, supported by two distinct smart contracts: one dedicated to blockchain-based resource trading and another handling financial transactions related to emission control policies, including other regulations such as income tax. The resource trading platform fosters transparency, enabling accurate tracking of material and energy flows. Furthermore, the framework integrates an off-chain Mixed-Integer linear Programming model (MILP) to optimize EIP design and operations, which is seamlessly integrated with smart contracts on the Ethereum blockchain (BC) to ensure data privacy and traceability among processes to meet environmental targets. The model also determines emission reductions and investments in carbon capture technology, promoting operational efficiency. By incorporating identity verification and external entities for compliance, the framework ensures secure and regulated operations. Offering a powerful tool to decision-makers and authorities, this framework enhances comprehension of resource and emissions tracking, paving the way for the development of innovative policies and fostering regulatory compliance. This development promotes sustainable industrial activities and supports environmental goals.

## INTRODUCTION

The global push for sustainable development, spearheaded by the United Nations' Sustainable Development Goals (SDGs), highlights the importance of integrated resource management to balance environmental and economic sustainability. While progress has been made in SDG monitoring, critical data gaps remain, hindering comprehensive assessments and the formulation of effective policies [1]. The efficient and transparent management of material and energy resources is essential for mitigating environmental impacts and promoting the long-term sustainability and adaptability of industrial ecosystems [2]. However, assessments of EIPs have revealed persistent challenges, such as low compliance in resource management and environmental performance, underscoring the urgent need for technological solutions [3]. Addressing these challenges requires innovative strategies that integrate transparent resource management, strict adherence to sustainability standards, and robust compliance with regulatory frameworks.

Significant research has focused on optimizing resource integration to enhance sustainability in industrial systems. A two-step MILP approach was developed to

design cost-effective carbon dioxide ($CO_2$) reduction networks, integrating renewable energy to reduce mitigation costs [4]. Multi-objective frameworks for $CO_2$ Capture, Utilization, and Storage (CCUS) supply chains have been proposed, balancing economic, environmental, and safety objectives through Pareto optimization [5]. $CO_2$ and heat integration approaches have also been explored to minimize net energy demand and emissions, leveraging synergies such as process heat recovery to reduce $CO_2$ capture costs [6]. Additionally, a MILP-based optimization for CCUS supply chains in the UK demonstrated the economic viability of emissions reduction strategies under $CO_2$ tax policies, highlighting the role of site selection in minimizing costs and maximizing net present value [7].

For water and energy integration, an extended pinch analysis was used to design water recycling networks [8], while seasonal variations in water-energy systems were addressed using a mixed-integer non-linear optimization framework (MINLP) to ensure robust designs under peak demand [9]. Multi-objective optimization has also been applied to minimize $CO_2$ and water footprints while maximizing economic returns in industrial clusters [10]. Lastly, integrating renewable energy with $CO_2$ capture and utilization has been shown to enable net-zero emissions in energy systems through dynamic optimization [11].

While previous research has advanced resource integration strategies in EIPs, a critical challenge remains - the lack of transparency in resource management, emissions tracking, and regulatory compliance. Studies indicate that industrial parks often struggle with inadequate transparency in environmental practices, leading to inefficient resource utilization and unchecked pollution emissions [12]. Additionally, the absence of reliable data-sharing mechanisms hinders effective industrial symbiosis, as firms face barriers such as data inaccessibility, lack of trust, and inconsistent byproduct supply [13]. Policy inconsistencies further exacerbate these challenges, as gaps in the adherence to EIP guidelines and misinterpretations of sustainability principles reduce the effectiveness of implementation strategies [14]. These transparency-related inefficiencies not only limit the potential for industrial collaboration but also weaken the environmental and economic benefits that EIPs aim to achieve.

To address these transparency gaps, emerging technologies such as BC have been proposed to enhance data integrity, traceability, and regulatory enforcement in industrial ecosystems. Permissioned BC frameworks have been explored for $CO_2$ emission trading, aiming to reduce fraud, improve monitoring, and facilitate secure, automated transactions [15]. In the context of CCUS supply chains, BC-based smart contracts have been shown to enhance tracking, compliance, and cost efficiency by reducing reliance on third-party verifiers [16]. Beyond emissions management, BC is increasingly recognized as a solution for data governance in EIPs, offering decentralized platforms that enable peer-to-peer resource exchange, transparent record-keeping, and enhanced industrial collaboration [17] [18]. These developments highlight the potential of integrating optimization models with BC-based smart contracts to create a secure, transparent, and efficient framework for managing resource flows and emissions within EIPs.

Despite advancements in resource integration and the application of BC for transparency, existing frameworks still exhibit significant limitations. Most models focus either on optimization-based resource integration or BC-enabled trading mechanisms but rarely synthesize both in a way that ensures simultaneous economic, environmental, and operational efficiency. Additionally, while BC applications have been explored for $CO_2$ markets and CCUS supply chains, they often lack comprehensive integration with broader EIP resource flows, including water, energy, and materials. Furthermore, transparency challenges persist in data tracking, regulatory compliance, and secure material, energy, and financial resource exchanges, as many frameworks do not incorporate accurate monitoring of industrial symbiosis. This research addresses these gaps by introducing a hybrid optimization-BC framework that integrates a MILP model for EIP design with smart contract-based resource exchange. By leveraging BC's architecture, the proposed framework ensures secure, transparent, and efficient management of resource flows, emissions, and financial transactions. This approach not only enhances trust and compliance within EIPs but also establishes a scalable and adaptable solution for industrial ecosystems aiming to meet sustainability targets while maintaining operational resilience.

## FUNDAMENTALS OF BLOCKCHAIN AND SMART CONTRACTS

BC is a decentralized digital ledger that enables secure, transparent, and tamper-proof transactions across various industries, including finance, healthcare, supply chains, and energy systems [19]. Unlike centralized databases, it eliminates intermediaries, reducing fraud and enhancing security through cryptographic hashing and consensus mechanisms such as Proof of Work (PoW) and Proof of Stake (PoS) [20]. Transactions, once validated, are stored in linked blocks, ensuring immutability and trust, making BC ideal for applications requiring secure financial transactions, identity verification, and supply chain tracking [21].

Key BC features include decentralization, which prevents system failures and reduces fraud [20]; immutability, ensuring a tamper-proof and auditable record of transactions [19]; and transparency, allowing participants

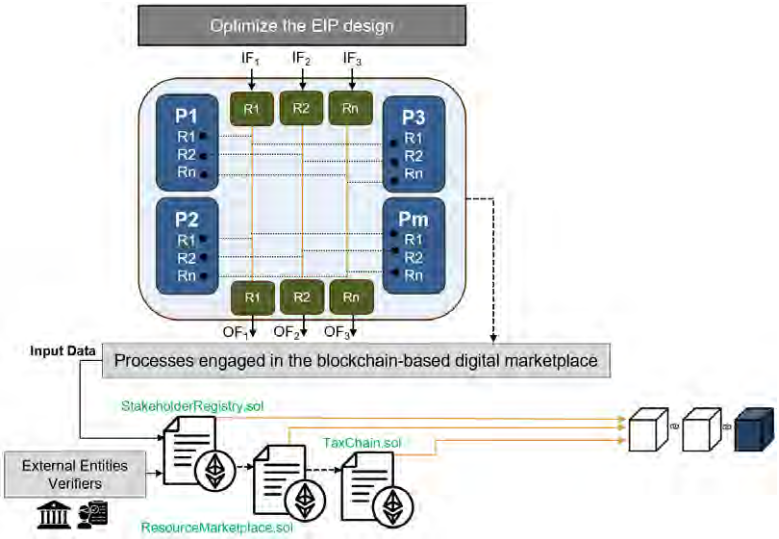

**Figure 1:** Proposed Blockchain-Integrated Framework for EIP Optimization and Operation.

to access synchronized data, promoting accountability [21]. Security is reinforced through cryptographic encryption, protecting data from cyber threats [22], while smart contracts automate transactions, streamlining operations and reducing the need for intermediaries [23].

These features drive BC adoption across multiple sectors. In healthcare, it ensures secure patient data management and prevents counterfeit pharmaceuticals [24]. Supply chain management benefits from BC's immutable records, enhancing product traceability and fraud prevention [25]. In energy systems, BC facilitates peer-to-peer energy trading, reducing dependency on centralized grids and supporting renewable energy adoption [26]. It also enhances electoral security in government systems [23], and secures machine-to-machine transactions in smart manufacturing [27]. Furthermore, BC optimizes financial transactions by supporting cryptocurrencies, decentralized finance and automated smart contracts [28]. With its secure and transparent architecture, BC transforms industries by enhancing data security, fraud prevention, and operational efficiency, driving digital innovation and sustainable development.

## PROPOSED FRAMEWORK AND METHODOLOGY

This study presents a multi-stage optimization and BC-based framework to enhance resource integration, transparency, and emissions management within an EIP. The methodology comprises two primary components: (1) Optimization of the EIP design using
an extended MILP model which was initially proposed by [10], and (2) BC-enabled smart contracts for transparent resource trading and financial transactions. Figure 1 illustrates the architecture of the proposed system.

### 1. Optimization of the EIP Design

The first stage of the methodology involves optimizing the selection and capacity of industrial processes within the EIP. A MILP model is employed to identify the optimal set of processes, ensuring maximum economic profitability while adhering to environmental constraints, including $CO_2$ emissions cap and zero untreated wastewater discharge. The objective function is defined as:

$$\text{Max Profit} = \text{TR} - (\text{CC} + \text{OC} - \text{Taxes}) \quad (1)$$

where TR, CC, and OC represent the total revenue, capital cost, and operating cost, respectively. Total Revenue is generated from resource exchanges, and Capital/Operating Costs are associated with process operation. Taxes include $CO_2$ tax for excess $CO_2$ emissions and income tax, incentivizing industries that collaborate within the EIP. The mass balances for resource exchanges among processes is defined using:

$$\text{IF} - \text{RE} - \text{OF} = 0 \quad (2)$$

where IF, RE, and OF represents the input flow of the resource, resource exchange, and outlet flow respectively. For each process, mass balance constraints ensure:

$$\text{REP} - (\text{FP} \times \text{PC}) = 0 \quad (3)$$

where REP, FP, and PC represent the resource exchange with processes, flow parameter, and process capacity, respectively. Process capacities and resource imports/exports are bounded by upper and lower limits, ensuring realistic operational feasibility. Additionally, a constraint is imposed to eliminate untreated wastewater discharge, forcing all generated wastewater to be treated before release. $CO_2$ emissions are constrained based on a predefined $CO_2$ cap. If the emissions exceed the limit, a $CO_2$ tax is applied to the excess amount:

$$\mathrm{CE} - (\mathrm{CCA} + \mathrm{TCA}) \leq \mathrm{CAcap} \quad (4)$$

where CE, CCA, TCA, and CAcap represent the $CO_2$ emissions, captured $CO_2$ emissions, taxed $CO_2$ emissions, and the predefined $CO_2$ cap, respectively. The model dynamically adjusts process operations to optimize the costs of $CO_2$ taxation and $CO_2$ capture units.

## 2. Blockchain-Based Resource Exchange and Taxation

Once the optimal EIP configuration is determined, the activated processes participate in a BC-based digital marketplace for secure and transparent resource transactions. Ethereum is chosen as the BC platform due to its robust smart contract functionality and wide adoption.

### 2.2 Blockchain Transaction Process

The BC-based resource exchange mechanism follows a structured process to ensure secure and transparent transactions within the EIP. Initially, processes register through the StakeholderRegistry.sol smart contract, which verifies and maintains the identity of each participant. Once registered, industries list their available resources on the ResourceMarketplace.sol contract, specifying key attributes such as flow rate, quality, pressure, temperature, and price. When a process initiates a trade, the smart contract verifies resource availability, compliance with EIP constraints, and pricing conditions. Upon successful validation, the trade is executed, and the transaction is recorded on the BC, ensuring an immutable record of resource exchanges. Additionally, financial transactions, such as $CO_2$ tax and income tax payments, are automated through TaxChain.sol, which deducts applicable taxes from the EIP and transfers the payment to the regulatory authority. This decentralized mechanism eliminates manual oversight, reducing delays and ensuring compliance with environmental and financial regulations. By integrating BC into resource exchange and taxation, the system fosters trust, efficiency, and automated enforcement of sustainability policies within the EIP.

### 2.3 Advantages, Considerations, and Challenges

Ensuring trust, traceability, and regulatory compliance in industrial symbiosis is a major challenge. The proposed BC-enabled system enhances transparency by maintaining immutable records, minimizing fraud and data manipulation. Smart contracts automate verification, ensuring only registered processes participate in trades while meeting environmental and economic criteria. By requiring complete resource data before execution, the system prevents omissions, duplicates, and unauthorized transactions. The decentralized ledger allows external audits without intermediaries, while automated compliance checks enforce emission limits, wastewater treatment, and taxation policies, reducing administrative burdens. This framework ensures regulatory adherence and incentivizes industries to adopt sustainable practices.

The proposed MILP-BC framework enhances EIP efficiency by integrating process optimization with smart contract-based resource trading, ensuring optimal resource allocation, cost reduction, and emissions control. Automated $CO_2$ and income tax enforcement simplifies compliance, while BC's immutable ledger strengthens data security, transparency, and fraud prevention. Additionally, decentralization fosters accountability, promoting sustainable industrial practices while improving financial performance. However, several challenges must be addressed. Balancing data privacy and transparency is critical, as BC's immutability could expose sensitive information. The high computational cost of smart contracts and the lack of clear regulatory frameworks pose further obstacles. Additionally, industry adoption may be hindered by technical complexity and resistance to change. Overcoming these barriers requires scalability improvements, privacy-preserving techniques, and regulatory collaboration to ensure effective deployment and widespread adoption of the framework.

## ILLUSTRATIVE EXAMPLE

To evaluate the proposed system, a case study was conducted on an EIP integrating both product-based processes and emissions mitigation strategies. The industrial processes include Air Separation Unit (ASU), Ammonia Plant (AP), Cement Plant (CP), Methanol Plant (MP), Natural Gas Power Plant (NGPP), Seawater Reverse Osmosis (SWRO), Steam Methane Reforming Unit (SMR), Urea Plant (UP), and Wastewater Treatment Unit (WWTU). Emissions mitigation strategies incorporate $CO_2$ capture technologies (CC), utilization pathways (methanol, urea), enhanced oil recovery (EOR), direct air capture (DAC), and sequestration. The EIP aims to maximize net profit by optimizing resource exchanges and $CO_2$ capture, while adhering to a $CO_2$ cap of 250,000 tons $CO_2$/year, a $CO_2$ tax of \$40/ton $CO_2$, and an income tax of 15%. Process data for DAC, sequestration, EOR, NGPP, and its capture unit were sourced from [11], while data for other processes were obtained from [10]. The project lifespan is 20 years, with required inputs including capital and operating costs, as well as resource flow parameters expressed in tons per ton of the main product (t/t Ref).

Capacity limits were defined for each unit, with ASU, AP, MP, SMR, UP, and EOR capped at 200,000 t/y, CP and CP CC at 1,000,000 t/y and 500,000 t/y, respectively, NGPP at 600,000 MWh/y, and NGPP CC, SMR CC, and DAC at 1,500,000 t/y. SWRO and WWTU capacities were set at 8,000,000 t/y and 300,000 t/y, respectively, while sequestration was limited to 500,000 t/y. The $CO_2$ composition in emissions varies across processes, with

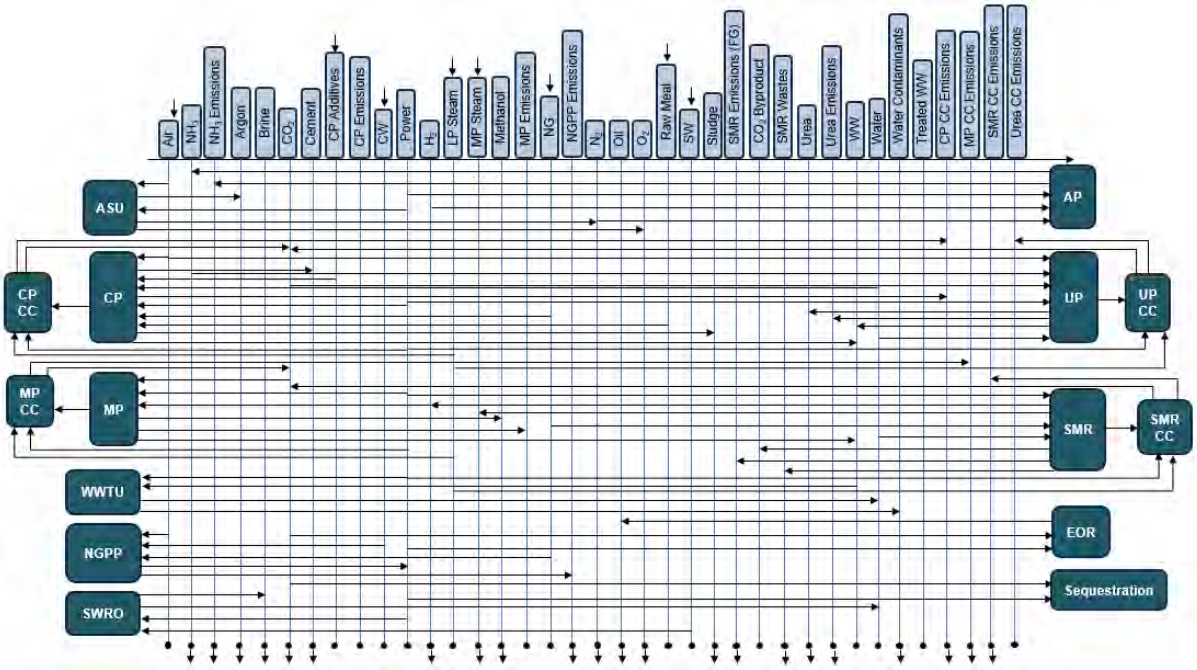

**Figure 2:** Resource Flow Network in the Optimized EIP.

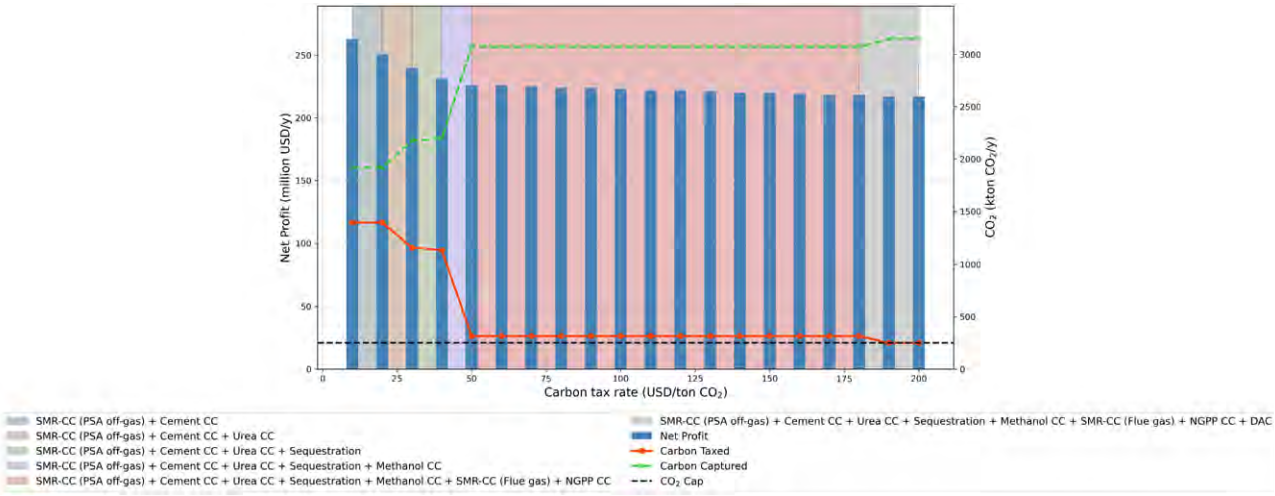

**Figure 3:** Impact of Carbon Tax Rate on Net Profit and $CO_2$ Emissions.

values ranging from 0.7% to 82%, depending on the emission source. This case study demonstrates the feasibility of resource optimization and emissions control within an EIP under regulatory and economic constraints.

The results show that the activated product-based processes include ASU, AP, CP, MP, SMR, UP, WWTU, and EOR, with NGPP and SWRO serving as utility plants. Emissions control strategies incorporate $CO_2$ capture from SMR-PSA off-gas, cement, and urea production, alongside sequestration and $CO_2$ taxation. The system successfully captured 1,945,930 tons of $CO_2$ per year, while 882,628 tons were taxed, demonstrating effective $CO_2$ management and regulatory compliance. Figure 2 presents the optimized EIP configuration, highlighting resource flows, activated processes, and emissions control measures.

The sensitivity analysis on the $CO_2$ tax rate, shown in Figure 3, explores its impact on net profit, $CO_2$ taxed, and $CO_2$ captured across a range of 10 to 200 \$/ton $CO_2$ with a step size of 10. The activated processes include ASU, AP, CP, MP, NGPP, SWRO, SMR, UP, WWTU, and EOR. The $CO_2$ cap was set at 250 kton $CO_2$/year, requiring any excess $CO_2$ to be either captured or taxed. As the $CO_2$ tax rate rises, the system shifts toward greater $CO_2$ capture and lower $CO_2$ taxation to minimize costs. The net profit decreases as $CO_2$ mitigation strategies become

more expensive, with higher tax rates making sequestration and capture more viable than direct taxation. The analysis identifies six regions of $CO_2$ mitigation progression: (1) at 10-20 \$/ton $CO_2$, capture is limited to SMR-PSA off-gas and cement, with the highest taxed $CO_2$; (2) from 20-30 \$/ton $CO_2$, urea capture begins; (3) from 30-40 \$/ton $CO_2$, sequestration is activated; (4) from 40-50 \$/ton $CO_2$, methanol capture is added; (5) from 50-180 \$/ton $CO_2$, capture extends to SMR flue gas and NGPP; and (6) at 180-200 \$/ton $CO_2$, DAC is introduced, reducing taxed $CO_2$ to zero at 190 \$/ton $CO_2$. This transition demonstrates how a rising $CO_2$ tax incentivizes a shift toward more extensive $CO_2$ capture, ultimately reducing emissions but at the cost of declining net profit.

The integration of BC in this EIP framework enhances transparency, efficiency, and regulatory compliance, particularly by automating the transition from MILP-optimized process capacities to real-world applications. Smart contracts ensure seamless execution of resource exchanges, taxation, and emissions management, maintaining adherence to optimized parameters while recording immutable, auditable transactions. This approach bridges the gap between theoretical optimization models and practical implementation, providing industries and policymakers with insights into resource utilization and emissions tracking. By ensuring accurate $CO_2$ taxation and automated compliance verification, BC fosters sustainable industrial operations and could enable incentive mechanisms, such as tax benefits or tradable environmental credits. The secure, transparent nature of BC further supports the development of standardized $CO_2$ credit trading, promoting a circular economy and data-based policies. This approach is adaptable to other energy-intensive industries such as steel production, chemical manufacturing, and renewable energy systems. In these sectors, the ability to optimize resource use, reduce emissions, and enhance operational transparency is crucial. Digitalization plays a pivotal role by enabling real-time data access, improving decision-making, and ensuring compliance with environmental standards. Thus, our methodology is well-suited to address similar challenges across various industrial contexts, promoting sustainable and efficient practices and supporting broader sustainability goals.

## CONCLUSIONS

This study presents a BC-integrated framework for optimizing EIP operations, combining MILP-based optimization with smart contract automation to enhance resource management, transparency, and regulatory compliance. By seamlessly linking optimized resource flows to smart contracts, the system ensures efficient trading, automated taxation, and emissions tracking, reducing $CO_2$ emissions while maintaining economic viability. The immutable ledger enables secure, auditable transactions, supporting policy enforcement and sustainability monitoring. This approach improves industrial efficiency and provides a scalable model for broader applications in decarbonization and circular economy initiatives. The integration of BC into EIP management paves the way for data-driven policymaking and enhanced environmental governance, fostering sustainable industrial development.

## ABSTRACT

This work presents an approach to implement and assess fractional controllers in an extractive distillation system. The experimental dynamic data for an extractive distillation column is used as a case study. A strategy is developed to fit the operation data to fractional-order transfer functions. Then, the fractional controllers are designed in the Simulink environment in Matlab, tuning the controllers through a hybrid optimization approach. First, the approach uses a genetic algorithm to find an initial point, and then the solution is improved through the fmincon algorithm. According to the results of the design of fractional controllers, the sum of the square of errors is below $2.9 \times 10^{-6}$ for perturbations in heat duty, and $1.2 \times 10^{-5}$ for perturbations in the reflux ratio. Moreover, after controller tuning, a minimal value for ISE of 1,278.12 is obtained, which is approximately 8% lower than the value obtained for an integer-order controller.

**Keywords**: Fractional calculus, fractional controllers, extractive distillation

## INTRODUCTION

Process intensification is a strategy applied to chemical engineering which is devoted to the development of technologies that enhance the performance of the operations in a chemical process. The philosophy of process intensification can be summarized through its four principles: (i) maximizing the effectiveness of intra and intermolecular events, (ii) giving each molecule the same processing experience, (iii) optimizing the driving forces at every scale, and (iv) maximizing the synergistic effects from partial processes [1]. This is achieved through the implementation of modified equipment and/or multi-tasking equipment, among other approaches. Among the common operations in chemical processes, distillation is a candidate for intensification, since it is a separation process with high energy requirements and, consequently, high operational costs and high environmental impact. Diverse approaches have been proposed to intensify distillation structures, such as thermally coupled distillation schemes, where modified configurations are used to make a proper use of the heat of the internal streams and the composition profiles to reduce the energy requirements (e.g. [2]); or reactive distillation, where the operations of reaction and distillation are performed in a single unit [3]. Extractive distillation is another example of an intensified distillation operation, where an entrainer is employed to allow the separation of azeotropic mixtures [4]. Further enhancements can be obtained by using advanced entrainers [5] or with the implementation of thermal couplings to the extractive distillation system [6].

Various studies have demonstrated that the dynamic properties of intensified systems can be, for some cases, better than those of conventional configurations (e.g. [7]). In the case of extractive distillation, there are various aspects that may affect the performance of the control structure, such as the kind of solvent employed [8], the solvent flow rate [9], and the pressure [10]. In a study presented by Yi and Chien [11], a modification of the steady-state design is proposed to enhance the performance of the control system. This indicates that the

development of better control structures is still necessary [12]. The use of fractional controllers can be an alternative to achieve this target.

Fractional PID controllers (or $PI^{\lambda}D^{\mu}$ controllers) take advantage of the concepts of fractional calculus, increasing the flexibility and robustness of the controller by allowing fractional orders for the derivative and the integral actions. These characteristics make fractional controllers adequate to be implemented in systems with complex dynamics, which may be difficult to control with classical PID controllers [13]. However, the additional flexibility implies a higher complexity to perform the tuning of the controller, since additional parameters must be included in the analysis. Fractional order controls have been widely implemented to process units like reactors [14,15]. Only few works have reported the implementation of fractional controllers for distillation systems. Mishra et al. [16] assessed the performance of a fractional order fuzzy PID controller for a binary distillation column, reporting a superior performance when compared to a fuzzy PID controller. Haji Haji and Monje [17] used a dynamic version of the metaheuristic bat algorithm to perform the tuning of a fractional-order PID controller in a distillation column. Marques de Almeida et al. [18] reported the implementation of a decentralized fractional-order PI controller on a TITO distillation column, reporting a superior performance of the fractional system in comparison with integer-order controllers and model predictive control structures. In the case of intensified distillation systems, to the authors knowledge, the only antecedent is given by the work of Edet [19], who reported the implementation of a fractional PI controller to a reactive distillation system. However, the implementation of $PI^{\lambda}D^{\mu}$ controllers for intensified distillation systems has not been reported. Thus, in this work a fractional-order model, based on transfer functions, is developed for an extractive distillation system. The model is obtained through experimental data to ensure that the proposed fractional approach properly represents actual operational data. A fractional controller is implemented in the model, developing a tuning strategy based on rigorous optimization. The performance of the fractional controller is compared with that of an integer order controller.

## METHODOLOGY

The experimental dynamic data reported by Kumar et al. [20] for an extractive distillation column has been used as a case study. The column is used to separate the mixture acetone-methanol, employing water as solvent. In this study, changes in the measured variables reported for perturbations in the reflux rate and the steam pressure on the reboiler are used to perform the analysis. Since the experimental data had been reported in graphical form, the tool *WebPlotDigitalizer4.6* has been used to extract the numerical data.

The experimental data has been fitted to fractional order functions. The general form of the transfer function is given by Equation (1).

$$G(s) = \frac{Ke^{-\theta s}}{As^{\alpha}+Bs^{\beta}} \quad (1)$$

Where $0 < \alpha < 1$ for a pseudo-first order model, and $1 < \alpha < 2$ for a pseudo-second order model. The numerical fitting has been performed in the *FOMCON* toolbox of Matlab, using the Grünwald-Letnikov definition of the fractional derivative [21]. The parameters of the model are adjusted, aiming to minimize the deviation of the predictions of the model in comparison to the experimental data. The effect of the step size *h* over the fitting is also analyzed.

The implementation of the fractional controllers is performed in the Simulink environment of Matlab. The response of the fractional controller, $u(t)$, is given by Equation (2).

$$u(t) = K_p e(t) + K_i D^{-\lambda} e(t) + K_d D^{\mu} e(t) \quad (2)$$

Where $K_p$, $K_i$ and $K_d$ are the gains for the proportional, integral and derivative actions, respectively. On the other hand, $\lambda$ and $\mu$ are the orders for the fractional integral and derivative operators.

An LV configuration is employed, using the reflux rate and the steam pressure in the reboiler as the manipulated variables. The measured variables are the compositions on the distillate and the bottoms. Decoupling elements are added to the control structure to reduce the interactions among the input and output variables of the control loops. The implementation of the fractional elements is performed through the interaction between Simulink and *FOMCON*. The controllers are tuned using a hybrid optimization approach. First, a genetic algorithm is used to find an initial guess. Then, the solution is refined with the *fmincon* algorithm. The objective in the optimization procedure is to minimize the total value for the integral square error (ISE). A penalization term *F* is incorporated to avoid solutions with high overshooting. Thus, the objective function *f* is given by Equation (3).

$$f = F \sum_{i=1}^{n} ISE_i \quad (3)$$

Where *i* represents the number of the corresponding product stream. For the distillate, $i = 1$. On the other hand, for the bottoms, $i = 2$.

## RESULTS

For fitting the experimental data to a fractional order function, a strong dependence of the fitting over the step size *h* has been observed. Figure 1.a shows that, based on the experimental data available, the fitting is adequate only for a relatively large step size. As the step size is reduced, the predictions of the model have a higher

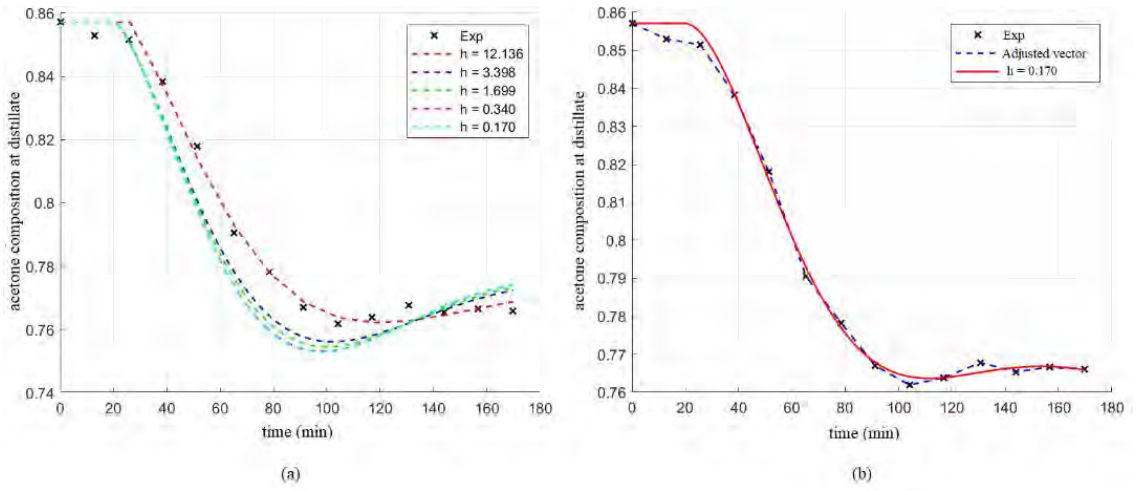

**Figure 1:** Effect of the step size in the adjustment of experimental data to fractional order transfer functions, (a) adjustment with the original data, (b) adjustment with the interpolation of data.

deviation from the experimental data. For *h* = 12.136, an acceptable fit is obtained, but there are still experimental points out of the trend. To further enhance the prediction, 1000 additional points have been generated by interpolating the experimental data. Using this approach, the prediction produced with low step sizes is considerably enhanced, as shown in Figure 1.b.

Tables 1 and 2 show the parameters obtained for the fractional transfer functions and the deviation for each fitting, where θ is given in minutes. It is important to notice that the delay time considers the period before the first experimental response is reported, which causes apparently large values for this parameter.

In general terms, low deviations are obtained through the fitting to fractional order transfer functions. It is also observed that, for all the cases, the values of α indicate pseudo-second order models. However, the values of that parameter for most cases are far from being integer. A similar trend is observed for the values of β. Thus, the relaxation of the order for the denominator in the transfer function allows flexibility in the data fitting. Although small deviations are obtained, it is important to mention that the error obtained when using integer-order transfer functions is similar to that obtained with the fractional functions. Thus, the studied system does not show a significant fractional response.

Table 3 shows the parameters of the fractional controllers after the optimization of the objective function given by Equation (2). It is observed that the integral and derivative actions are both relevant for the controller of the acetone composition in the distillate, with orders relatively close to unity. However, for the control of methanol composition in the bottoms, the derivative action has a low order, relatively close to zero. The controller in the distillate has a higher proportional gain, showing an oscillatory response.

**Table 1:** Results for the fitting of experimental data to fractional-order transfer functions when a perturbation in reflux rate occurs.

| | **Acetone composition at distillate** | **Methanol composition at bottoms** |
|---|---|---|
| K | 0.00080453 | 0.00014573 |
| A | 267.27 | 43.855 |
| B | 1 | 1 |
| θ | 415.444 | 434.55 |
| α | 1.7388 | 1.5568 |
| β | 0.11565 | 0.29164 |
| Deviation | $3.2015 \times 10^{-5}$ | $1.2120 \times 10^{-5}$ |

**Table 2:** Results for the fitting of experimental data to fractional-order transfer functions when a perturbation in steam pressure occurs.

| | **Acetone composition at distillate** | **Methanol composition at bottoms** |
|---|---|---|
| K | -0.0074095 | -0.00069622 |
| A | 121.14 | 23.576 |
| B | 1 | 1 |
| θ | 206.69 | 196.69 |
| α | 1.8119 | 1.6776 |
| β | 0.2643 | 0.41674 |
| Deviation | $5.2494 \times 10^{-5}$ | $2.9317 \times 10^{-6}$ |

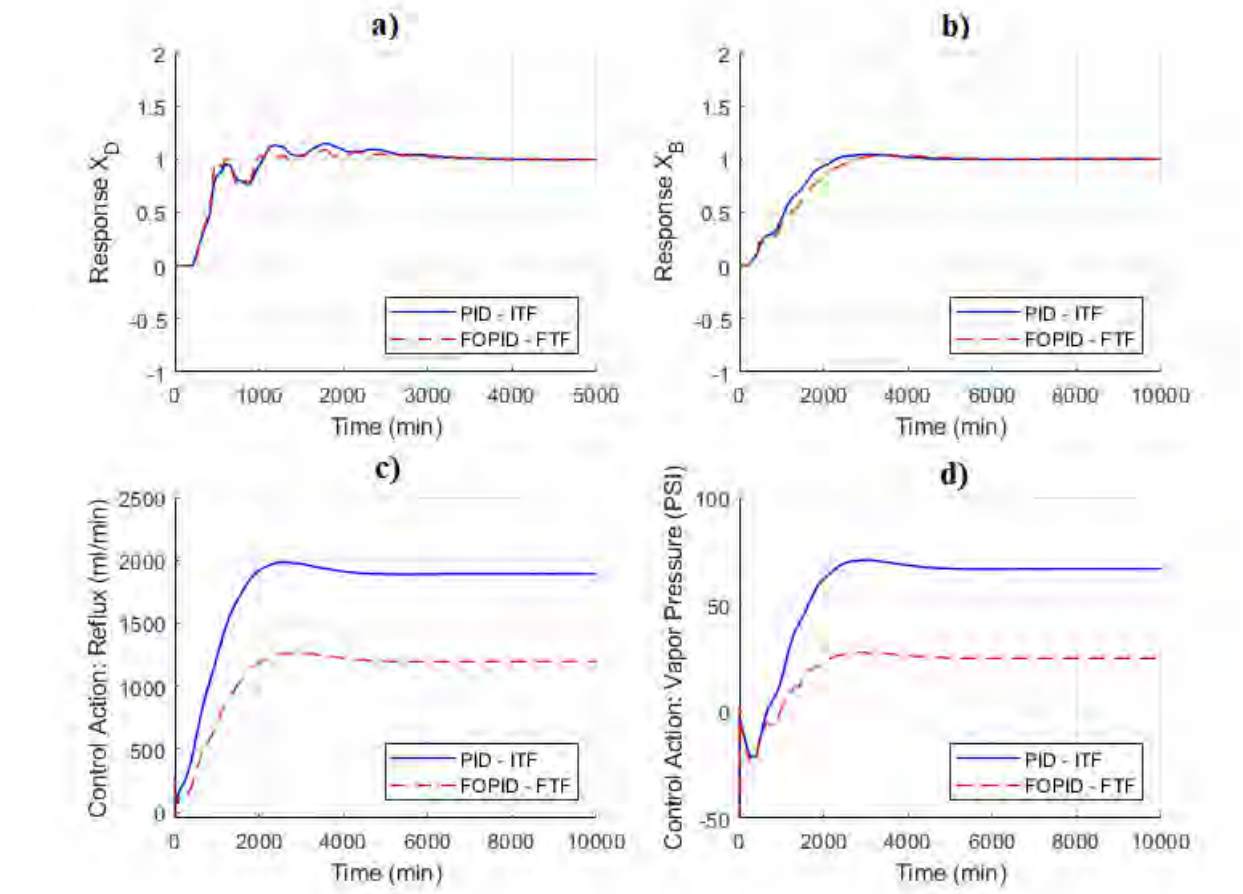

**Figure 2:** Responses and control actions for the PI$^{\lambda}$D$^{\mu}$ controller, compared with a PID controller, (a) response for the composition of acetone in the distillate, (b) response for the composition of methanol in the bottoms, (c) control action over the reflux rate, (d) control action over the steam pressure on the reboiler.

**Table 3:** Optimized parameters for the fractional controllers.

| Parameter | Distillate controller | Bottoms controller |
|---|---|---|
| $K_p$ | -128.0115 | 18.6006 |
| $K_i$ | -3.2562 | 0.2160 |
| $K_d$ | -0.7867 | -9.2389 |
| $\lambda$ | 0.8587 | 0.8229 |
| $\mu$ | 0.7091 | 0.1674 |

With the objective function used in the analysis, an overshooting percentage of 9.622 and 0% for the controllers in the distillate and the bottoms has been obtained, respectively. This is a lower percentage compared to that obtained if an integer-order controller is used, where the optimized parameters lead to overshooting values of 14.593 and 4.502% for the distillate and the bottoms, respectively. The objective function for the fractional controller has a value of 1278.12, which is approximately 8% lower than the value obtained for an integer-order controller.

Figure 2 presents the responses of the compositions when the fractional-order controller is used. The responses are compared with those obtained with an integer-order PID controller, where an integer-order transfer function is used to represent the dynamic performance of the column. Both cases use the optimized parameters of each controller. The optimized parameters for the integer-order controllers are presented in Table 4. Figure 2 also shows the corresponding control action.

**Table 4:** Optimized parameters for integer-order controllers.

| Parameter | Distillate controller | Bottoms controller |
|---|---|---|
| $K_p$ | -120.1442 | 12.9061 |
| $K_i$ | -1.8031 | 0.1253 |
| $K_d$ | -2.3642 | -6.3010 |

A similar performance is observed for the responses

of the measured variables for both kinds of controllers. The time required to reach a new steady state is similar for both kinds of controllers, with approximately 3,000 minutes needed for the stabilization of the response for both, the acetone and the methanol compositions. However, a higher over-shooting is observed for the integer-order controller, which is consistent with the over-shooting percentages described in the previous lines. The reduction on the over-shoot is highly desirable for the control of a chemical process [22,23]. Additionally, the fractional controllers allow reaching the new steady state with a lower increase in the control variables, as can be observed in Figures 2.c and 2.d. Whereas the integer controller requires increasing the reflux to a maximum value of 2,000 ml/min, the fractional controller only requires increasing the variable to approximately 1,300 ml/min. Similarly, the steam pressure in the reboiler changes to a maximum of approximately 30 psi with the fractional controller, whereas the integer controller requires increasing the manipulated variable to a value of approximately 70 psi. However, it is important to notice that this may be associated with multiplicity, which is a common situation in distillation systems [24]. Thus, the comparison in terms of the control action must be carefully verified.

## CONCLUSIONS

In this work, the use of fractional controllers in an intensified distillation system has been proposed. The studied system is an extractive distillation column. Experimental data has been used to ensure that the model fits actual operating trends. The data is successfully fitted to fractional-order transfer functions, obtaining low deviations after the fitting of parameters. However, to obtain a better fitting, it is necessary to generate additional data points. Although the fitting is adequate, the improvement achieved with fractional control is not significant when compared to that resulting from the use of an integer-order transfer function; such result indicates that the dynamic response may not have significant memory effects. In fact, for the controllers, the dynamic responses are not considerably different between the integer and the fractional-order controllers. On the other hand, the fractional controllers have been successfully designed, showing that the use of such controllers allows reducing the overshooting while obtaining responses with a lower change in the control variables. Moreover, the changes performed by the controller over the control variables to achieve the new steady-state have lower magnitudes than those required when the integer-order controller is used.

## ABSTRACT

This paper focuses on the control and dynamics of an oil refinery process on an intermediate level - the flows, masses and compositions of and between units within the refining operation. It aims to elucidate optimal strategies for the routing of streams during upset events imposed on the process. A general flowsheet simulation technique including tunable controllers for flows, compositions, levels and reaction extents is incorporated in a Linear Programming model. A standard node represents a mixed receiving tank, with exit streams which can be split, converted and separated. These nodes can be inter-connected arbitrarily in the flowsheet. The method is demonstrated for the case of a planned 3-day shutdown of the catalytic cracker.

**Keywords**: flowsheet, control, horizon, profit, maximisation, constrained

## 1. INTRODUCTION

A number of authors report work on the optimization of the journey of “parcels” of crude oil through a refinery complex. Examples of this type of MILP/MINLP production planning (or “inventory planning”) are presented in the work of [1-4]. In [5], tank levels are tracked throughout, from crude supply to customer dispatch, allowing for service disruptions. In the work of [6], model predictive control is used up to a moving horizon, taking cognisance of the present status of crude parcel storage and processing, and anticipated deliveries. The approach in [7] was to use a genetic algorithm to optimize crude oil movements, allowing for uncertainty of tank availability.

The present work focuses instead on the actual control dynamics of the refining process, within and between the flowsheet units. Intermediate storages may be provided to ease startups and upsets, so the optimization becomes a type of supply-chain problem. The authors in [8] considered how the locations and sizes of intermediate storage could be economically optimized taking into account capital costs, operating costs and product specifications and values. Their refinery representation was based on data from [9] and [10]. The present work uses the same data to construct a linear programming model of the refinery, with the purpose of examining the sequence of dynamic changes and flow re-routings required to maximise profitability during planned and unplanned upsets.

## 2. MODEL

With the aim of representing a range of process flowsheets, a systematic method of creating the linear programming equations was sought. This was based on a multi-purpose “node” consisting of a mixed storage tank which received inflows, with optional configurable reactors, separators and splitters on its outflows (Fig. 1). Here stream flows $\boldsymbol{f}$, stream compositions $\boldsymbol{x}$, tank compositions $\boldsymbol{X}$, component masses $\boldsymbol{m}$ and tank masses $\boldsymbol{M}$ are used to define the mass balances. Such nodes could be interconnected arbitrarily, even allowing recycles.

In the basic mass balance, the compositions of the streams leaving the storage are expected to equate to the composition of the tank inventory, resulting in non-linear terms $f_j\boldsymbol{m}_k/M_k$ in the mass balance. In the present work, this problem was dealt with using estimates of the tank compositions $\boldsymbol{X}_k=\boldsymbol{m}_k/M_k$ based on the previous solution of the linear program, and updating on each iteration until convergence. The inclusion of conversion, separation and stream splitting for multiple streams leaving a “tank” meant that final departing stream compositions $\boldsymbol{x}_j$ were ultimately fixed on the basis of the tank composition $\boldsymbol{X}_k$, determined in the preceding LP solution.

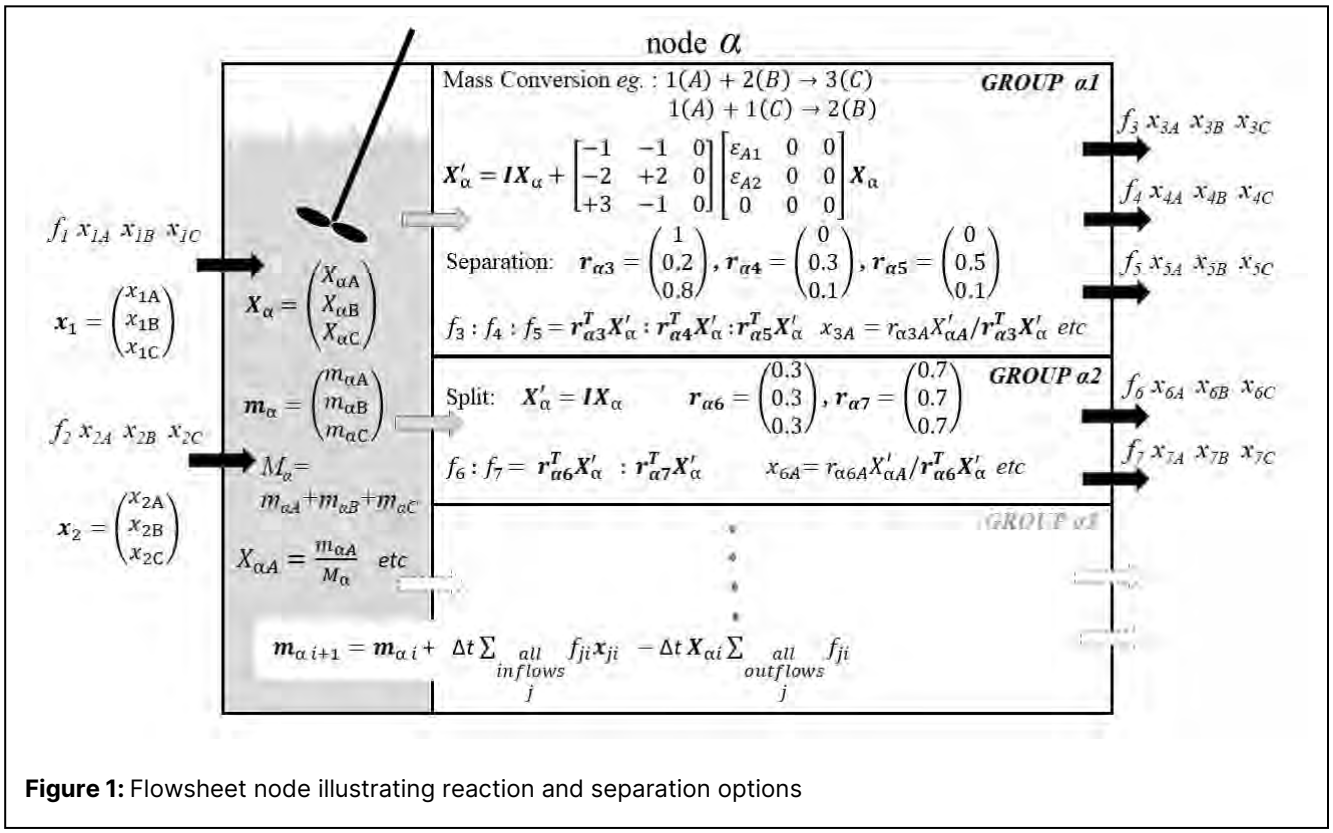

**Figure 1:** Flowsheet node illustrating reaction and separation options

Fig. 1 shows how conversion of an exit stream is handled according to the mass-stoichiometry and set reaction extents. Set-points for the extents ($\varepsilon_{A1}$, $\varepsilon_{A2}$, $\varepsilon_{B3}$, etc) are specified for each such reactor, and secondary linear programming solutions are performed for each reactor on each iteration in order to get as close as possible to these extents by minimizing the sum of weighted absolute deviations. After conversion, components may be split according to the ratios $\boldsymbol{r}_{\alpha k}$, resulting in different stream sizes as shown.

Tank levels (masses), tank compositions, reaction extents, and stream flow rates may all be controlled to specified setpoints. In linear programming, this is done by equating setpoint deviations as $\Delta=\delta_P-\delta_M$ where $\delta_P$ and $\delta_M$ are specified as non-negative, and minimising the weighted sum of these $\delta$'s. as part of the objective function.

Features of the optimisation of the time-varying flowsheet over the specified time-horizon include:

- Setpoint control of flows, storage masses & compositions, and reaction extents
- High and Low constraints for flows, storage masses & compositions
- All setpoints and setpoint weights, as well as constraints, can vary in time
- A weight (marginal value) can be set on the total mass in a tank for the objective function
- Move suppression for steady control, by penalty weights on absolute flow changes in the objective function
- Rate-of-change (ramp) limits for flows
- Exit streams from a tank can undergo reaction, fractional component separation, or total flow splitting
- A small storage volume simulates a pipe junction

## 3. FLOWSHEET REPRESENTATION AND OPERATING CONDITIONS

The simplified oil refinery flow diagram in Fig. 2 is adequate to represent the main features of transition dynamics that are investigated. This diagram and the operating conditions are based on the data of [8] shown in Tables A2 and A3 with constraints as in Table 1. In Fig. 1, AD is the atmospheric crude distiller, CC the catalytic cracker and RF the catalytic reformer. Four main Straight Run crude fraction streams: gas, naphtha, diesel and fuel oil (3-SRG, 4-SRN, 5-SRDS, 6-SRFO) move from left to right on the diagram, partially passing through the two main reaction units (RF and CC).

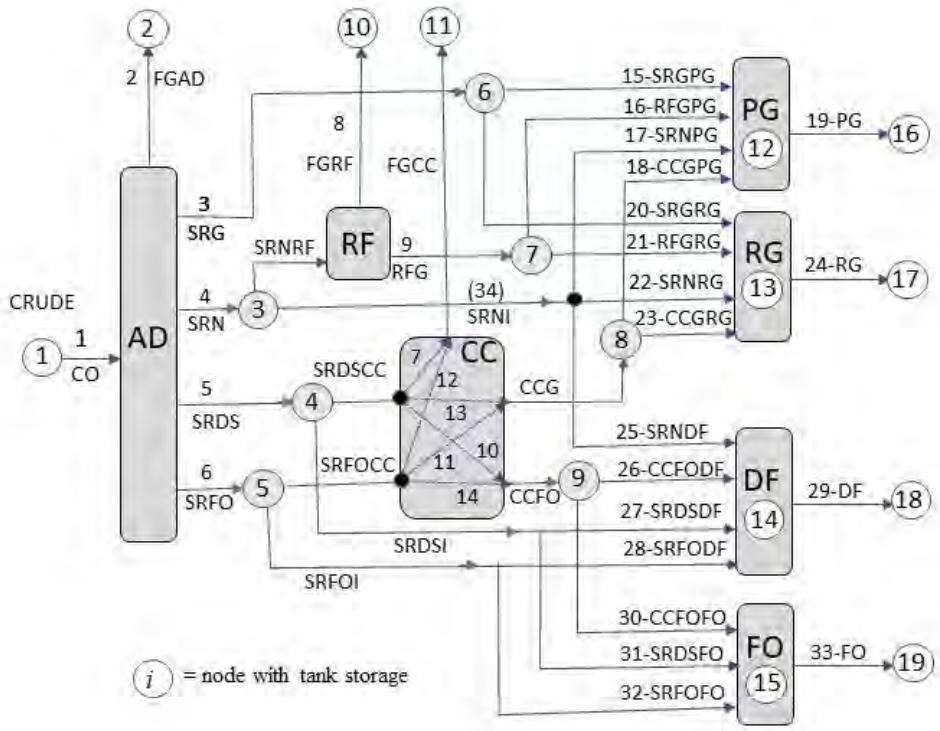

**Figure 2:** Simplified oil refinery flow diagram following [8]

**Table 1:** Economically optimal steady-state daily rates accounting for crude oil and product marginal values and associated processing costs, but excluding depreciation.

| **Stream** [bbl/day] | **Constraint** | **Optimal SS** |
|---|---|---|
| 1-COCrude Oil | ≤ 100000 | (max) 100000 |
| 19-PG Premium Gasol. | ≥ 23557 | 52645 |
| 24-RG Regular Gasol. | ≥ 11260 | 21942 |
| 29-DF Diesel Fuel | ≥ 8419 | 14058 |
| 33-FO Fuel Oil | ≥ 2826 | (min) 2826 |
| (8,9) SRN to Reformer | | (all) 23700 |
| (7,10,13) 5-SRDS to CC | | 0 |
| (12,11,14) 6-SRFO to CC | | (all) 37200 |
| (2,7,8,12) Total off-gas | | 8528 |
| OCT-PG 19-PG octane | ≥ 93 | (min) 93.0 |
| OCT-RG 24-RG octane | ≥ 87 | (min) 87.0 |
| VP-PG 19-PG vap pres | ≤ 12.7 | 8.88 mmHg |
| VP-RG 24-RG vap pres | ≤ 12.7 | 11.97 mmHg |
| DENS-DF 29-DF density | ≤ 306 | 293.3 lb/bbl |
| DENS-FO FO density | ≤ 352 | 293.4 lb/bbl |
| SULPH-DF 29-DF sulphr | ≤ 0.5 | 0.430 lb/bbl |
| SULPH-FO 33-FO sulphr | ≤ 3.0 | 0.726 lb/bbl |

**Net profit / day** (after material & operating costs, excluding capital depreciation) **$1.918\times10^6$ $/day**

**Return on USED crude oil value** **32.92%**

These create additional streams which, together with direct streams from the crude distiller, are combined in various ways to achieve the requirements of four main product streams: Premium Gasoline, Regular Gasoline, Diesel Fuel and Fuel Oil (19-PG, 24-RG, 29-DF, 33-FO) which are drawn from the finished product tanks marked PG, RG, DF and FO. The PG and RG are required to exceed minimum octane levels, and to be below a maximum vapour pressure level. The DF and FO must be below maximum density and sulphur levels (Table 1).

Around the outside of the diagram are nodes 1,2,10,11 and 16-19 – which are accumulators representing a supplier (crude oil) and customers (off-gas, premium & regular gasoline, diesel, fuel oil) for accounting purposes. "Off-gas" here refers to the byproduct gas discarded from the distillation, reforming and catalytic cracking. The objective in a 20-day case study was to maximise the value of the total inventory of the plant – including the accumulators. The marginal values and processing costs are given in tables A1 and A4. The internal nodes in the process have level setpoints of 67%, representing 2 days of operation at optimal conditions. These will reveal which storage best contributes in the event of an upset. Level setpoint weights are sufficient to prevent internal inventory emptying out to more valuable product.

## 4. STEADY-STATE OPTIMAL OPERATION

- Table 1 and Fig. 4a: Operation is stretched between minimizing octane for PG and RG at the top end (to spread available octane as far as possible), and minimizing FO production at the bottom end (which is a loss against the crude oil value – see Table A1)
- Straight Run Diesel (SRDS) bypasses the Catalytic Cracker to make up the entire Fuel Oil output (FO), and part of the Diesel Fuel (DF), where the sulphur is diluted using cracked Fuel Oil
- Cracked Fuel Oil, with its moderate octane, also becomes a major contributor to PG and RG where it helps to lower vapour pressure.
- All Straight Run Naphtha is reformed to 104 octane and sent to PG

## 5. PLANNED 3-DAY SHUTDOWN OF THE CATALYTIC CRACKER

The plant is initially running at its steady-state economic optimum. With all setpoints satisfied, only the economic terms (marginal values Table A1 and processing costs Table A4) influence the objective function. A planned 3-day shutdown of the catalytic cracker starts on day 6, so some evasive actions start in the first 5 days of the simulation. These include pre-shutdown surges of CCG to the PG product (Fig. 3a), and of CCFO to the DF product, followed by similar brief recovery surges just after the shutdown. There are surges of the SRFO to both the DF (Fig. 3b) and FO (Fig. 3c) products near the end of the shutdown, with the FO product struggling to maintain is minimum flow by draining both its storage vessel 15 (Fig. 3d) and SRFO storage 5 (Fig. 3e). The surge in SRFO to the DF product causes the DF product to reach its maximum sulphur content briefly (Fig. 3f). Extra SRG re-routed from PG to the RG product (Fig. 3g) during the shutdown causes RG to briefly reach its maximum vapour pressure (Fig. 3h). Although the crude feed rate manages to remain steady at is maximum, production rates of PG (Fig. 3i) and DF (Fig. 3j) fluctuate, reaching their minima.

In Fig. 4a a visual impression is given of the sequence of events at times before and during the shutdown. In Fig. 4b storage of SRFO is being drained whilst catalytically cracked fractions are rapidly dispatched to PG in advance of the shutdown.

The average net profit per day (over the 20 days) decreases marginally from 1.918 to 1.914 × $10^6$ $/day, as a result of the shutdown. Likewise there is a slight decrease in the profit per barrel of crude oil used, from 32.92 to 32.84%. This remarkably small impact during a major upset is largely due to the use of the Straight Run Fuel Oil storage at node 5 during the transition (Fig. 3e). The case of an *unplanned* shutdown (not presented here) is simulated with a shutdown start at steady-state on day 1, and shows similar but more radical recovery actions thereafter.

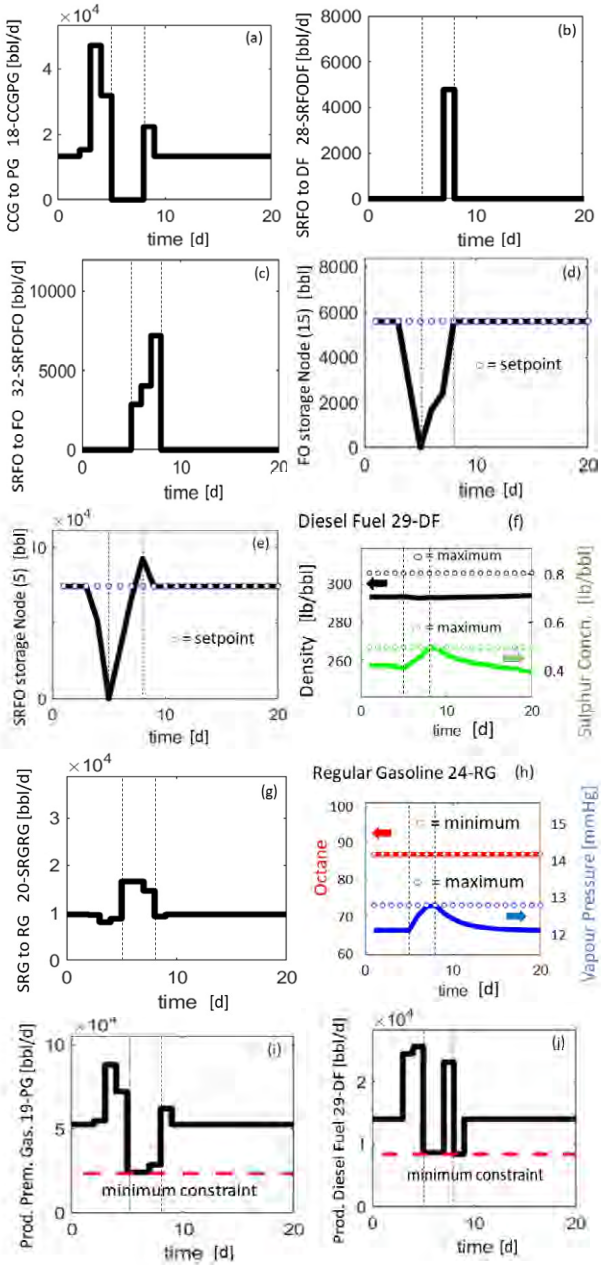

**Figure 3.** Planned 3-day shutdown of the catalytic cracker.

## 6. CONCLUSION

In this work a method is presented for dynamic optimisation of a process flowsheet, accounting for storage responses where necessary, and synchronizing transfers between units. The iteration of the LP solver provides an opportunity to update stream compositions, facilitating conversions, separations and stream splits.

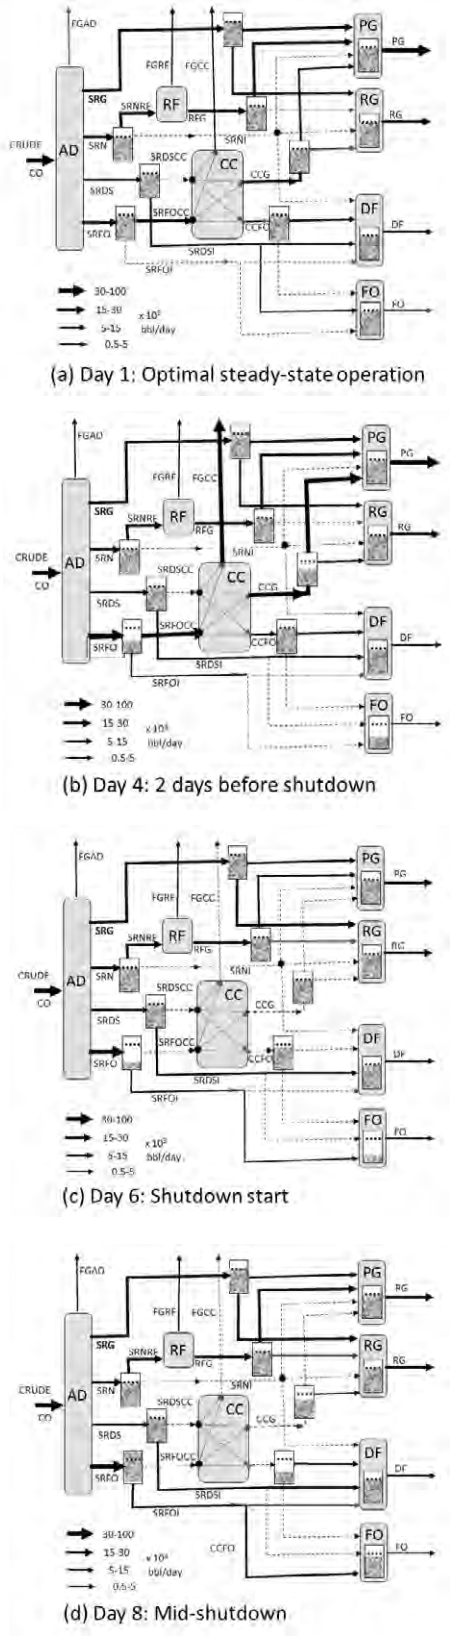

**Figure 4.** Stream flows and storage during a 3-day planned shutdown of the catalytic cracker

The method is effective for dealing with the inherent non-linearity of the mass-balance, allowing use of the robust features of linear programming. Between LP solutions, stream compositions are calculated on the basis of the recent solution, and then frozen as fixed variables for the next LP solution. At convergence, the original non-linear mass balances are all satisfied. Instability is avoided by smoothing the composition update.

A feature of the work which eased the loading of the LP variables and equations was the idea of the standard node which could provide mixing, splitting, conversion and component separation based on specified fractions and desired reaction extents. Configured to represent the operating conditions of [8], as shown in Tables A2 and A3, the steady-state economic optimum operating point was found, and subjected to upsets such as a crude change, reformer shutdown, and catalytic cracker shutdown. As seen in the latter case presented here, the process is rapidly returned to its steady-state economic optimuml operating point. The generous provisions of inter-unit storage served to reveal those storages which particularly helped minimize loss.

In this refinery simulation, the key free variables were obviously the flows $\boldsymbol{f}$. Like all other free variables these were subject to range inequality constraints as noted in Table 1. Additionally, flows were subject to flow ratio equality constraints as detailed in Fig. 1, as well as rate-of-change ramp constraints. Other free variables were tank total masses $\boldsymbol{M}$, compositions $\boldsymbol{X}$ and conversion extents $\boldsymbol{\varepsilon}$. These variables could all be controlled to setpoints (though flow setpoints and composition setpoints were unweighted in this solution). So that requires two more free variables in each case – non-negative plus and minus deviations $\boldsymbol{\delta_P}$, $\boldsymbol{\delta_M}$ from setpoint. The objective function penalised these deviations, rewarded tank inventory values, and penalised a similar absolute value of flow steps for move suppression.

In the present study all utilised setpoints were achievable at steady-state – therefore the steady-state yielded the economic optimum. One notes that the "optimality" of a transition requires prior knowledge of the future – eg. the length of a shutdown. Future work will consider placing the solution in an updated ("best guess") predictive control loop.

With the above variables individually represented at each time over the simulation horizon (20 steps), the total number of free variables amounted to 7700. These were constrained by 2120 inequality equations and 5180 equality equations. All solutions converged within 9 iterations taking a maximum of 50 seconds. Programming was done in MATLAB under Windows 10 E with a PC specification: Core 17-10510U @ 1.80 GHz with 4 cores, 8 Logical Processors and 16 GB RAM.

## APPENDIX

## ABSTRACT

The optimization of shell-and-tube heat exchangers (STHEs) is critical for improving energy efficiency, reducing operational costs, and mitigating environmental impacts in industrial applications. This study evaluates the performance of the Success-Based Optimization Algorithm (SBOA), a novel metaheuristic strategy inspired by behavioral patterns in success perception, against seven established algorithms—Cuckoo Search, Differential Evolution (DE), Grey Wolf Optimization (GWO), Jaya Algorithm, Particle Swarm Optimization, Teaching-Learning Based Optimization, and Whale Optimization Algorithm—for minimizing the total annual cost (TAC) of STHE designs. Using the Bell-Delaware method, the optimization framework incorporates eleven decision variables, including geometric and operational parameters, subject to thermo-hydraulic constraints. A penalty function method enforces feasibility by dynamically adjusting constraint weights. Statistical analysis of 30 independent runs reveals that DE achieves the lowest mean TAC (6,090 USD/year) with minimal variability (SD = 22.57), while GWO attains the best median TAC (6,076 USD/year). Although SBOA identifies competitive solutions (minimum TAC = 6,074 USD/year), its high standard deviation (270.66) underscores inconsistency in convergence.

**Keywords:** metaheuristic optimization, Success-Based Optimization algorithm, shell-and-tube heat exchangers, Bell-Delaware method.

## INTRODUCTION

The optimization of shell-and-tube heat exchangers (STHEs) plays a significant role in enhancing energy efficiency, reducing operational costs, and minimizing environmental impacts across various industries, including petrochemicals, power generation, and HVAC systems. STHEs are favored for handling high pressures and temperatures while maintaining an effective balance between heat transfer area and spatial footprint. However, designing an optimal STHE involves managing a set of thermo-hydraulic equations and multiple decision variables, such as tube diameter, baffle spacing, deflector configuration, and the number of tube passes [1, 2].

Traditional deterministic optimization methods, including MINLP and algorithms like BARON and DICOPT, have been widely employed to address these design challenges. These methods rely on mathematical programming and gradient-based techniques to provide precise solutions with rapid convergence for convex problems. Despite their effectiveness, deterministic approaches encounter limitations when applied to real-world scenarios characterized by non-linearity, multiple local optima, and mixed discrete-continuous variables. Additionally, the dependency on explicit mathematical models difficult their applicability when utilizing commercial simulators like Aspen Plus® or HYSYS®, which do not always offer direct mathematical formulations of the

design problems.

Although this study employs an explicit model based on established thermo-hydraulic equations (e.g., Bell–Delaware method, pressure-drop correlations), the complexity arises from (a) mixed discrete-continuous decision variables and (b) non-convex behavior that can lead to multiple local optima. While deterministic solvers, in principle, handle nonlinear mixed-integer problems, preliminary attempts indicated considerable computational effort and occasional convergence to suboptimal solutions, depending on initial guesses.

Metaheuristic optimization algorithms present an alternative approach capable of handling the inherent complexities of STHE design. Algorithms such as Genetic Algorithms (GAs), Particle Swarm Optimization (PSO), Grey Wolf Optimization (GWO), and Differential Evolution (DE) have been applied to optimize STHE configurations by balancing exploration and exploitation within complex, high-dimensional search spaces [3]. These algorithms effectively avoid local optima and adapt to various problem landscapes without the need for gradient information, making them suitable for practical optimization tasks where traditional methods fall short.

The wide variety of metaheuristic algorithms introduces opportunities and challenges in selecting the most appropriate method for specific STHE optimization problems. The NFL Theorem's [4] implications extend to practical engineering challenges, where algorithm performance hinges on problem-specific features such as dimensionality, constraint types, and the balance between discrete and continuous variables. Recent advances in metaheuristics have introduced hybrid and adaptive strategies to address these challenges, yet a systematic comparison of their efficacy in STHE optimization remains underexplored. This study bridges this gap by rigorously testing SBOA, a behaviorally inspired algorithm, against seven benchmark methods. By integrating dynamic sub-populations and probabilistic exploration-exploitation mechanisms, SBOA aims to balance global search capabilities with local refinement—a critical requirement for complex STHE design problems.

This study focuses on applying and comparing the performance of the Success-Based Optimization Algorithm (SBOA) with several established metaheuristic algorithms—Cuckoo Search (CS), Differential Evolution (DE), Grey Wolf Optimization (GWO), Jaya Algorithm (JAYA), Particle Swarm Optimization (PSO), Teaching-Learning Based Optimization (TLBO), and Whale Optimization Algorithm (WOA)—in the optimization of STHE designs. The research aims to identify effective strategies for minimizing the total annual cost (TAC) while adhering to operative and geometrical constraints. The comparative analysis seeks to provide insights into the strengths and limitations of each algorithm, thereby assisting practitioners in selecting the most suitable optimization tool for their specific heat exchanger design needs.

# METODOLOGY

## The Success-Based Optimization Algorithm

The SBOA was developed with initial inspiration drawn from psychological studies on human perceptions of success and failure [5]. According to Frieze and Weiner [6], an individual's success in performing an activity is influenced by personal ability, applied effort, task difficulty, and luck. Building on these insights, SBOA integrates behavioral patterns that prioritize successful solutions while maintaining diversity within the population to prevent premature convergence.

SBOA begins by generating an initial population of candidate solutions. Each candidate solution $x_{i,j}$ is represented within a matrix $\mathrm{X}$ of size $\mathrm{n} \times \mathrm{m}$, where $\mathrm{n}$ is the number of candidate solutions and $\mathrm{m}$ is the number of decision variables. The initial candidate solutions are generated randomly within the defined lower (lb) and upper (ub) bounds for each decision variable using the equation 1.

$$x_{i,j} = lb_j + \mathrm{rand}(0,1) \cdot (ub_j - lb_j), \quad i = 1, \ldots, n; \quad j = 1, \ldots, m \tag{1}$$

Each candidate solution is evaluated using the objective function $f_{obj}$, resulting in a fitness vector $F$, shown in equation 2.

$$\mathrm{F} = \left[f_{\mathrm{obj}}(X_1), f_{\mathrm{obj}}(X_2), \ldots, f_{\mathrm{obj}}(X_n)\right] \tag{2}$$

The SBOA utilizes two sub-populations of influence, spA and spB, to guide the search process.

- Sub-population *spA***:** This sub-population consists of the top three candidate solutions based on fitness, shown in equation 3.

$$spA = \begin{bmatrix} x_{spA1,1}, & \cdots & x_{spA1,j}, & \cdots & x_{spA1,m} \\ x_{spA2,1}, & \cdots & x_{spA2,j}, & \cdots & x_{spA2,m} \\ x_{spA3,1}, & \cdots & x_{spA3,j}, & \cdots & x_{spA3,m} \end{bmatrix} \tag{3}$$

- Sub-population *spB*: The composition of *spB* varies dynamically. Initially, it includes candidates ranked between the best solution and those near the population mean. As the algorithm progresses and diversity decreases, a fixed number of individuals are assigned to *spB* to maintain exploration capabilities.

A probability criterion $r \leq C_{p1}$ determines whether new candidate solutions are influenced by *spA* or *spB*, where r is a random number between 0 and 1.

When $r \leq 1C_{p1}$, new candidate solutions are

generated using *spA* as in equation 4:

$$G_j = spA_{1,j} + D_1 \cdot (2r2_j - 1) \cdot \left|(2r3_j - j) \cdot (spA_{\text{rand},j} - X_{i,j})\right| \quad (4)$$

Here, $D_1$ decreases linearly from 1 to 0 over the iterations, facilitating the transition from exploration to exploitation. The new candidate solution GG replaces the current solution $X_i$ only if $f_{obj}(G) \leq f_{obj}(X_i)$.

When $r > 1C_{p1}$, the updating process leverages *spB* to enhance exploration. Two strategies are employed based on another probability criterion $r \leq 1C_{p2}$, if it is satisfied equation 5 is used, otherwise equation 6 is employed.

$$X_{i,j}^{t+1} = X_{i,j}^{t} + D_2 \cdot (2r4_j - 1) \cdot (2r5_j) \cdot (spB_{\text{rand},j} - X_{i,j}^{t}) \quad (5)$$

$$X_{i,j}^{t+1} = X_{i,j}^{t} + D_2 \cdot (2r4_j - 1) \cdot (2r5_j) \cdot (spB_{\text{avg},j} - X_{i,j}^{t}) \quad (6)$$

In both cases, $D_2$ decreases linearly from 1 to 0, promoting finer search as iterations proceed.

## Application to STHE Optimization

The SBOA was applied to optimize the design of shell-and-tube heat exchangers using the Bell-Delaware method. The optimization problem involves eleven decision variables:

### Continuous Variables:

- Shell Internal Diameter ($D_s$).
- Outer Tube Diameter ($d_o$).
- Central Baffle Spacing ($L_{b,c}$).
- Inlet and Outlet Baffle Spacing ($L_{b,i}$, $L_{b,i}$).
- Diametral Gap between Shell and Baffles ($\delta_{sb}$).
- Diametral Gap between Tubes and Baffles ($\delta_{tb}$).
- Outer Diameter of Tube Bundle ($D_{otl}$).

### Discrete Variables:

- Tube Pitch ($P_t$):
- Tube Layout Angle (TL)
- Baffle Cut Percentage ($B_c$)
- Number of Tube Passes ($N_p$)

The objective is to minimize the Total Annual Cost (TAC), which comprises the annualized fixed cost ($C_{fix}$) and the operating cost ($C_{op}$), as shown in equation 7.

$$TAC = C_{\text{fix}} + C_{\text{op}} \quad (7)$$

The optimization problem is subject to constraints ensuring operational and geometrical feasibility, including limits on pressure drops, fluid velocities, and tube length, as described in equations 8-13.

$$\min_x \quad \text{TAC}(x) \quad (8)$$

subject to:

$$\Delta P_t \leq \Delta P_{\text{max},t} \quad (9)$$

$$\Delta P_s \leq \Delta P_{\text{max},s} \quad (10)$$

$$v_{\text{min},t} \leq v_t \leq v_{\text{max},t} \quad (11)$$

$$\frac{L}{D_s} \leq 15 \quad (12)$$

$$lb_i \leq x_i \leq ub_i \quad (13)$$

Where $\Delta P_t$ and $\Delta P_s$ are the pressure drops on the tube and shell sides, $v_t$ is the fluid velocity in the tubes, $L$ is the tube length, $D_s$ is the shell diameter, $lb_i$ and $ub_i$ are the lower and upper bounds for the decision variables, and $x$ is the vector containing the eleven decision variables shown in Tables 1 and 2, where their limits and allowed values are displayed.

**Table 1.** Limits for continuous design variables.

| Design Variable | Symbol | Lower Limit | Upper Limit |
|---|---|---|---|
| Shell Internal Diameter | $D_s$ | 300 mm | 1,500 mm |
| Outer Tube Diameter | $d_o$ | 6.35 mm | 50.8 mm |
| Central Baffle Spacing | $L_{b,c}$ | $0.2D_s$ | $0.55D_s$ |
| Inlet and Outlet Baffle Spacing | $L_{b,i}$, $L_{b,o}$ | $L_{b,c}$ | $1.6L_{b,c}$ |
| Diametral Gap between Shell and Baffles | $\delta_{sb}$ | $0.01D_s$ | $0.1D_s$ |
| Diametral Gap between Tubes and Baffles | $\delta_{tb}$ | $0.01d_o$ | $0.1d_o$ |
| Outer Diameter of Tube Bundle | $D_{otl}$ | $0.8(D_s - \delta_{sb})$ | $0.95(D_s - \delta_{sb})$ |

**Table 2.** Allowed values for discrete design variables.

| Design Variable | Symbol | Allowed Values |
|---|---|---|
| Tube Pitch | $P_t$ | $1.25d_o, 1.5d_o$ |
| Tube Layout Angle | $TL$ | $30°, 45°, 90°$ |
| Baffle Cut Percentage | $B_c$ | 25%, 30%, 40%, 45% |
| Number of Tube Passes | $N_p$ | 1, 2, 4 |

To manage constraints during the optimization process, a penalty function method is applied. This approach incorporates penalty terms into the objective function to account for any constraint violations. The modified objective function is expressed as equation 14.

$$\begin{aligned} min \quad & \text{TAC}(x) + \lambda_1 \, max\left(0, \Delta P_t - \Delta P_{\max,t}\right) \\ & + \lambda_2 \, max\left(0, \Delta P_s - \Delta P_{\max,s}\right) \\ & + \lambda_3 \, max\left(0, v_t - v_{\max,t}\right) \\ & + \lambda_3 \, max\left(0, v_{\min,t} - v_t\right) \\ & + \lambda_4 \, max\left(0, \frac{L}{D_s} - 15\right) \end{aligned} \tag{14}$$

To handle the constraints (Eqs. 9–13), it was implemented a dynamic penalty approach. The penalty coefficients ($\lambda$) initially take moderate values and increase linearly up to 50,000 over the course of the iterations. This strategy allows exploration in the early stages, while ensuring that near the final steps all constraints are strictly enforced. Although penalty methods may cause steep cost surfaces, we mitigated potential numerical issues by careful parameter tuning and by gradually escalating the penalty values until the stablished value.

**Table 3.** Parameter setting for optimization algorithms.

| CS | DE | GWO | JAYA |
|---|---|---|---|
| Yang and Deb [7[ | Storn [8] | Mirjalili et al. [9] | Rao [10] |
| n = 50 | n = 50 | n = 50 | n = 50 |
| $\alpha = 1$ | $C_r = 0.7$ | | |
| $p_a = 0.25$ | $F = 0.6$ | | |
| **PSO** | **TLBO** | **WOA** | |
| Kennedy and Eberhart [11] | Rao et al. [12] | Mirjalili and Lewis [13] | |
| n = 50 | n = 50 | n = 50 | |
| w - linearly decreasing from 0.9 to 0.2 | | | |
| $v_{max} = 6$ | | | |
| $c_1 = 2$ | | | |
| $c_2 = 2$ | | | |

Several optimization algorithms were included in this comparison to evaluate their effectiveness in solving the presented problem. The participating algorithms are Cuckoo Search (CS), Differential Evolution (DE), Grey Wolf Optimization (GWO), Jaya Algorithm (JAYA), Particle Swarm Optimization (PSO), Teaching-Learning Based Optimization (TLBO), and Whale Optimization Algorithm (WOA). For each algorithm, 30 independent experiments were conducted, each comprising 100 iterations with 50 candidate solutions per iteration. This rigorous experimental framework ensures the statistical validity and reliability of the comparative results. The parameters used for the different employed optimization algorithms are reported in Table 3.

## Case studies

The case study involves distilled water located on the shell side with a mass flow rate of 22.07 kg/s. The inlet and outlet temperatures for the distilled water are 33.9°C and 29.4°C, respectively. The cold fluid is hard water situated on the tube side, exhibiting a mass flow rate of 35.31 kg/s with inlet and outlet temperatures of 23.9°C and 26.7°C, respectively.

Carbon steel is utilized as the construction material for both the shell and the tubes. The correction factors applied for calculating the installation cost are Cm=1.7, Ct=1.0, and Cp=1.0.

# RESULTS

Table 4 displays the statistical outcomes for the third case study's TAC. GW achieves a consistently small standard deviation (SD) across multiple experiments, indicating uniform solutions. Although DE only manages to reduce its SD after iteration 35, it ultimately attains a stable convergence with the lowest mean TAC and smallest SD overall. The SBOA finds the best solution in at least one experiment, but the final SD remains high. This outcome suggests a lack of consistency among the solutions generated by SBOA, similar to the performance observed in PSO and TLBO. GWO's median TAC is slightly lower than DE's, whereas SBO's median is 6,154 USD/year, indicating that at least half of SBO's solutions deviate considerably from its best result.

**Table 4.** Statistical Results for Case Study

| | CS | DE | GWO | JA |
|---|---|---|---|---|
| Median | 6213.14 | 6079.54 | 6076.45 | 6392.31 |
| Mean | 6214.27 | 6090.73 | 6115.13 | 6385.67 |
| SD | 97.25 | 22.57 | 109.93 | 194.52 |
| Minimum | 6080.67 | 6074.89 | 6075.18 | 6107.79 |
| | **PSO** | **SBOA** | **TLBO** | **WOA** |
| Median | 6225.49 | 6154.87 | 6284.85 | 6859.73 |
| Mean | 6246.88 | 6273.03 | 6343.07 | 6871.36 |
| SD | 165.56 | 270.66 | 193.23 | 467.50 |
| Minimum | 6077.77 | 6074.83 | 6153.98 | 6228.60 |

Comparisons indicate that GWO records the lowest median TAC, while DE provides the smallest average TAC and standard deviation. SBOA's single best solution is on par with the top-performing algorithms, but its overall variability is notable.

The SBOA-derived design (Table 5) features a

compact shell diameter (0.30 m) and high tube count (900), achieving a heat transfer area of 42 m². The 90° tube arrangement and single-pass configuration minimize pressure drops (14,100 Pa tube-side, 5,180 Pa shell-side), aligning with efficiency goals. However, the 18 baffles and narrow central spacing (0.113 m) may pose maintenance challenges, underscoring the trade-offs between cost minimization and practicality.

**Table 5.** Values for the different variables for the best STHE design found.

| Variable | Value |
|---|---|
| Shell diameter (m) | 0.3000 |
| Outer tube diameter (mm) | 6.3500 |
| Number of tubes | 900 |
| Heat transfer area (m²) | 42.0000 |
| Tube length (m) | 2.3400 |
| Tube pitch (mm) | 7.9400 |
| Tube arrangement angle (°) | 90 |
| Number of tube passes | 1 |
| Central baffle spacing (m) | 0.1130 |
| End baffle spacing (m) | 0.1810 |
| Baffle cut (%) | 45 |
| Baffle-tube diametrical gap (mm) | 0.0635 |
| Baffle-shell diametrical gap (mm) | 3.0000 |
| Bundle outer diameter (m) | 0.2750 |
| Number of baffles | 18 |
| Tube velocity (m/s) | 1.8300 |
| L/D ratio | 7.8000 |
| Tube-side pressure drop (Pa) | 14100.0 |
| Shell-side pressure drop (Pa) | 5180.0 |
| Shell mass flow rate (kg/s) | 22.1000 |
| Tube mass flow rate (kg/s) | 35.5000 |

The dynamic penalty coefficients effectively enforced constraints, with final designs satisfying all pressure drop and velocity limits. However, the aggressive penalty escalation (to 50,000) risks overshadowing the primary objective in early iterations, potentially discarding promising infeasible solutions. Future work could explore adaptive penalty strategies that weigh constraint violations relative to TAC reductions.

A one-way ANOVA (Table 6) was done to compare the mean cost across eight different optimization algorithms. The results indicate a statistically significant difference among these means, as shown by the relatively large F-value (29.8160) and the very small p-value ($7.010874 \times 10^{-33}$). In other words, the variation in cost between the algorithm groups is unlikely to be due to chance alone, and we can reject the null hypothesis that all algorithms have the same mean cost. This finding suggests that at least one of the algorithms demonstrates a different average performance compared to the others.

Table 6. One-way ANOVA analysis.

| | Sum of Squares | df | F-value | p-value |
|---|---|---|---|---|
| Algorithm | $4.4402X10^{+6}$ | 8.0 | 29.81 | $7.0108 X10^{-3}$ |
| Residual | $4.8585 X10^{+6}$ | 261.0 | - | - |

Table 7 shows the average runtime for each algorithm per experiment. DE requires only 0.2987 seconds on average, while GWO and JAYA follow closely, also maintaining sub-second times. SBOA takes slightly longer. The runtime differences may be attributed to the simpler operator structure of DE, which involves fewer internal loops and parameters compared to algorithms like SBO (which employs dual sub-populations). All tested methods remain computationally feasible in practical engineering contexts according to the computational time.

**Table 7.** Computational time per experiment.

| | CS | DE | GWO | JA |
|---|---|---|---|---|
| Time (s) | 0.7795 | 0.2987 | 0.3423 | 0.3044 |
| | **PSO** | **SBOA** | **TLBO** | **WOA** |
| Time (s) | 0.3261 | 0.5205 | 0.7926 | 0.4523 |

## CONCLUSION

This study underscores the effectiveness of metaheuristic algorithms in optimizing STHE, with DE and GWO as particularly robust options for minimizing total annual cost under operational constraints. DE is distinguished by its consistency and computational efficiency, making it well-suited for routine optimization tasks, while GWO excels in searching in complex, non-linear search spaces due to its hierarchical search mechanism. The SBOA also demonstrates significant potential, achieving competitive solutions in terms of cost minimization. However, its performance exhibits higher variability across independent runs compared to DE and GWO, which may require additional refinement for applications demanding strict reproducibility.

The selection of an appropriate algorithm remains a critical consideration, as highlighted by the No-Free-Lunch Theorem, which asserts that no single method outperforms others across all problem types. DE's strength lies in its ability to handle mixed-variable problems through a balanced mutation-recombination process, while GWO's structured approach effectively avoids local optima. SBOA, inspired by behavioral patterns in success perception, introduces a unique dual-subpopulation strategy that balances exploration and exploitation. Although this approach yields highly

competitive solutions in certain runs, its variability suggests that further tuning or hybridization with deterministic methods could enhance its consistency.

In terms of constraint management, the dynamic penalty functions employed in this study effectively enforce feasibility by progressively increasing penalty weights. This approach ensures that final solutions adhere to operational and geometric constraints, though the aggressive scaling of penalties in early iterations may occasionally hinder the exploration of promising regions in the search space. Future work could explore adaptive penalty strategies that more flexibly balance constraint satisfaction and objective optimization.

From a practical perspective, the optimal designs generated by SBOA, such as its compact shell diameter and high tube count, demonstrate its ability to identify cost-effective configurations. However, certain design features, like the narrow baffle spacing, may pose maintenance challenges, underscoring the need to balance cost savings with operational practicality.

## ABSTRACT

The motivation of this work is an application of a production scheduling based on Real-Time Optimization and Zone Control Nonlinear Model Predictive Controller on a liquid recovery unit of an LPG production plant. In this unit, the scheduling-relevant disturbances occur on a time scale relevant to the system dynamics; thus, we propose a novel combination of a well-known control strategies leading to a hierarchical two-layered strategy, where the lower layer employs a zone control nonlinear model predictive controller (NMPC) to define inventory setpoints while the upper layer uses real-time optimization (RTO) to determine optimal plant-wide flow rates from an economic perspective. Unlike a traditional RTO, the proposed upper-layer problem is parameterized by product demands, with a distinct optimization problem formulated for each demand scenario. Our novel approach allows for proactive mitigation of potential inventory issues by dynamically recalculating the distribution of plant products. This approach addresses the challenges of storage bottlenecks and inventory fluctuations, and it is more effective than the typical operator decisions from an economic perspective in the system of interest.

## INTRODUCTION

Chemical industry has a high demand for process optimization methods and tools that enhance profitability while operating near the nominal capacity. The implementation of such methods can lead to significant productivity gains, particularly when the used strategy adopts a holistic perspective considering inventory [1,2].

Products inventory, both in-process and end-of-process, serve as buffers to mitigate fluctuations in operation and demand while maintaining consistent and predictable production. Efficient product inventory management is crucial for the profitable operation of chemical plants. To ensure optimal operation, various strategies have been proposed that consider in-process storage and aim to satisfy mass balances while avoiding bottlenecks [3].

When final product demand is highly oscillatory with unexpected stoppages, end-of-process inventories must be carefully controlled within minimum and maximum bounds. This prevents plant shutdowns and ensures compliance with legal product supply requirements. In both cases, a plant-wide perspective should be considered when making in- and end-of-process product inventory level decisions to improve overall profitability [4].

To address this problem, we propose a holistic hierarchical two-layered strategy. The upper layer uses real-time optimization (RTO) to determine optimal plantwide flow rates from an economic perspective. The lower layer employs a zone control nonlinear model predictive controller (NMPC) to define inventory setpoints. The idea is that RTO defines setpoints for flow rates that manipulate plant throughput, while NMPC maintains inventory levels within desired bounds while keeping flow rates as close as possible to the RTO-defined setpoints.

Despite the fact that the individual strategies used here have been widely studied, the use of this two-layered holistic approach is novel for this specific problem and our main contribution; however, a secondary contribution is the introduction of an ensemble of optimization problems at the RTO level. Each RTO problem is associ-

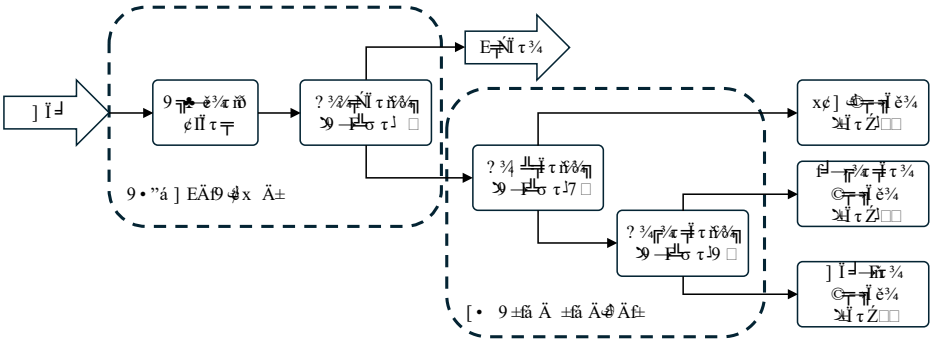

**Figure 1.** Liquid recovery unit block diagram. Only columns A, B and C will be considered in the optimization model.

ated with a different product demand scenario, which enables us to recompute optimal throughput plant manipulator setpoints using a steady-state method whereas inventory disturbances are inherently dynamic. In addition to the numerical results, we carried out a qualitative comparison between the decisions of the proposed strategy and typical actions taken by plant operators.

## LIQUID RECOVERY UNIT

The motivating case study for the development of our strategy is a three-stage distillation column system that separates a mixture of four products, inspired by a LPG production plant with recycle split vapor invented by Ortloff Ltd [5], which is illustrated in Figure 1.
