The Liquid Recovery Unit contains a cryogenic plant with an improved overhead recycle (IOR) scheme. The cryogenic plant consists of two columns, an Absorber (7 theoretical stages) and a Demethanizer (Column A) of 32 theoretical stages. The top product from the Demethanizer is cooled and partially condensed, with the resulting liquids providing reflux for both columns. The cooling required to partially condense the upper vapor of the Demethanizer is provided by the top product of the Absorber. The two columns normally operate at approximately the same pressure, with pumps providing the energy necessary to transfer the liquids between the columns [6]. Subsequently, the bottom product is sent to the fractionation unit, which separates liquefied petroleum gas (LPG) from gasoline. The fractionation unit consists of 2 columns. A 27-stage debutanizer column produces LPG as its overhead product, and a 12-stage depentanizer column that separates stabilized gasoline at the top and a bottom product enriched in iso-pentanes.

While the lightest and cheapest product (ethane) is directly sent to a pipeline, the other three more valuable products are stored in tanks. Demand for these three products fluctuates significantly. In some cases, the fluctuations can be forecasted in advance, allowing for proactive measures. In other cases, when the changes cannot be predicted, a quick and effective response is necessary. This presents a significant challenge for operators, given the system's complexity and the limited time available to decide on the best countermeasures. If the latter scenario (with unpredicted changes) is relatively frequent during the operation, our proposed strategy becomes an interesting tool for improving the plant economic performance.

## INTEGRATING DECISION LAYERS

Traditionally, scheduling, production economic optimization, and control problems are considered individually and solved in a sequential way, each one representing a different decision layer. Scheduling problems usually set production targets to address the timing of actions for different manufacturing facilities. For example, avoiding storage overflow or shortage, timing production operating mode changes, etc. Scheduling decisions can be translated to targets, such as production sequences, that are sent to the production optimization layer. In this layer, real-time optimization (RTO) provides ideal economic setpoints for the control layer, which is responsible to implement these setpoints while handling plant disturbances [7]. Such sequential strategies result in upper-level decisions made with little knowledge of the production constraints at the lower levels of the decision-making hierarchy. The decisions are usually assumed to be inflexible, and lower-levels decision makers either achieve the targets at higher costs, or fail to achieve those targets [1].

Similar to the integration of continuous production optimization strategies and advanced control (e.g., economic model predictive control [8]), the scheduling layer and the continuous optimization layer can be integrated in cases where scheduling-relevant disturbances occur on a time scale relevant to the system dynamics [9]. The goal in this case is to improve overall performance by simultaneously optimizing all major continuous and discrete degrees of freedom that are influential at control and scheduling time scales. Apart from the time-scale overlap, there are other reasons for such an integration of advanced process control and scheduling: planning

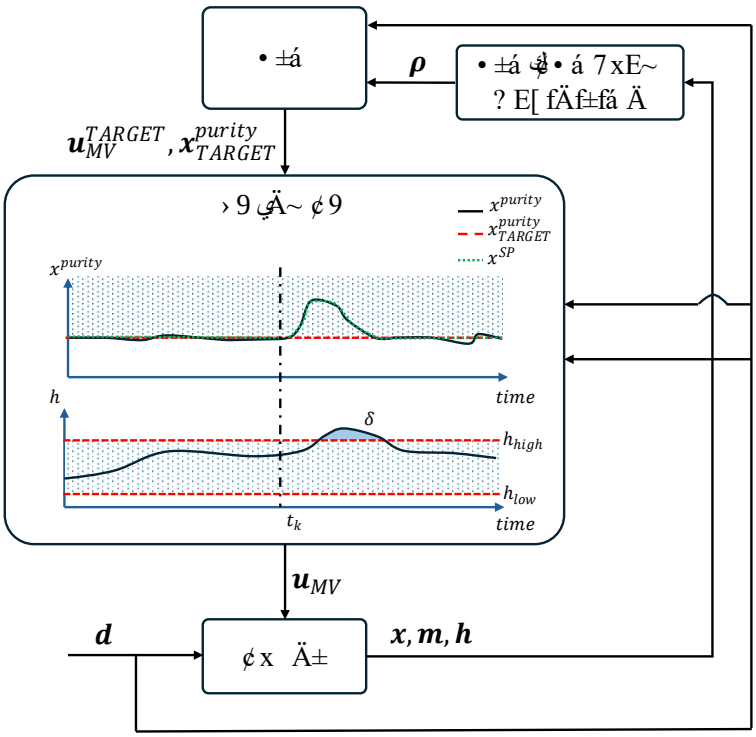

**Figure 2:** Block diagram of the proposed method. The variables that are sent between different blocks are indicated. The definition of the variables can be found in the Mathematical Formulation section. Inside the ZC-NMPC block, we illustrate an operating scenario and the action taken by the controller.

sequences that avoid costly set-ups and changeovers, reducing the duration and the lost product during transitions, avoiding schedules that lead to operational problems, using more precise and timely information in scheduling, etc. [1].

## Traditional Formulation

A range of problem formulations is used for solving scheduling problems. Typically, a mixed-integer linear program is formulated to determine when and how the operating conditions should be modified, taking into account the timing of actions as well their feasibility [1].

In contrast, RTO optimizes an economic objective function subject to a detailed first principle steady-state model that describes the plant behavior. At each RTO sampling time, key parameters of the steady state model are updated to reduce the plant-model mismatch, using plant measurements [10]. Then, the setpoint values, obtained by the economic model optimization, are fed to the control layer below, typically a model predictive controller (MPC) [7].

MPC predicts future system behavior and calculates a sequence of control actions that minimize the deviation from the setpoints defined at the RTO level. The literature is rich in diverse MPC formulations. Here, we use zone control (ZC) MPC. This strategy is interesting when maintaining outputs within defined zones is more important than achieving precise set point tracking. Therefore, while the outputs are within the pre-determined zone, the controller "gains" additional degrees of freedom that can be used to track other targets, such as input targets, giving the controller some flexibility [11].

## Proposed Strategy

Figure 2 depicts the proposed strategy and illustrates how it works. Within the controller block (ZC-NMPC), we show a specific operating condition and the corresponding controller actions. The top plot displays the purity trajectory of one of the column's products, while the bottom plot shows the level of the associated tank. The dotted pattern in both plots indicates the desired operating zone for the controller: the product purity should be larger than the target value, and the tank level must remain within the defined low-high level limits.

In this illustrative scenario, we assume a sudden unexpected decrease in product demand at time $t_k$. Consequently, the tank level $h$ begins to rise. The operator would typically respond by reducing the plant's overall feed rate to prevent tank overflow. While this action resolves the immediate issue, it can significantly impact plant profitability due to a decrease in the production of other products.

In contrast, when the proposed strategy is implemented, the controller takes two simultaneous actions.

Firstly, it increases the purity of the affected product. This higher purity typically leads to a reduced product flow rate, helping to stabilize the tank level. Secondly, the controller adjusts the operating conditions of the other columns within the plant based on the setpoints determined by the RTO level. This coordinated adjustment ensures that the tank level remains within safe operating limits while minimizing disruptions to the overall production process and maximizing plant profitability.

## MATHEMATICAL FORMULATION

Before presenting the mathematical formulation of the RTO and ZC-NMPC layers, we introduce some useful simplifications used to model the liquid recovery unit.

First, we consider only 4 generic components in the system $C_1$, $C_2$, $C_3$, and $C_4$ and assume constant relative volatility. The model keeps track of the fraction of the three lightest components in each tray of columns $A$, $B$, and $C$ (i.e., from tray 1 to $N_T$). The fractions are represented by $\boldsymbol{x}$. Note that the fraction of the heaviest component ($C_4$) can be easily obtained from the other three.

The system inputs are divided into freely manipulated variables (column's reflux and boil-up rates) $\boldsymbol{u}_{MV}$ and the remaining input variables (distillate and bottoms flow rates) $\boldsymbol{u}_{DV}$. We also defined the process measured disturbances $\boldsymbol{d}$ (feed flow rate and composition, as well as product demands)**.** We represent the system steady-state model as $\boldsymbol{f}$, which consists of mass balances and component mass balances, and the state and inputs feasible region as $\mathcal{X}$ and $\mathcal{U}$, respectively. Additionally, we define the operating constraints

$$\boldsymbol{g}(\boldsymbol{x}) = \begin{bmatrix} x_1^{purity} \\ x_2^{purity} \\ x_3^{purity} \\ x_4^{purity} \end{bmatrix} = \begin{bmatrix} x_{B,C1,N_T} - 0.07 \\ x_{B,C3,N_T} - 0.07 \\ \left(1 - \sum_{j=\{C1,C2,C3\}} x_{B,j,N_T}\right) - 0.002 \\ 0.95 - \left(1 - \sum_{j=\{C1,C2,C3\}} x_{C,j,1}\right) \end{bmatrix}, \quad (1)$$

where the first three algebraic equations from top to bottom represent the impurity constraints on the top product (tray $N_T$) of column $B$ whereas the remaining algebraic equations represents a constraint on the purity of the bottom product of the third column $C$. The calculation "$1 - \sum x$" is made in order to obtain the fraction of the lightest component $C_4$.

For the dynamic model, we need to define the holdup of all trays of the three columns, $\boldsymbol{m}$, as well as the levels in the tanks 1, 2, and 3, $\boldsymbol{h}$. The dynamic model $\boldsymbol{F}$ consists of (i) dynamic mass and component balances as well as, for each column, P-controllers relating the reboiler (stage 1) and condenser (stage $N_T$) with the respective variables in $\boldsymbol{u}_{DV}$; and (ii) dynamic mass balances of the tanks. The steady-state and dynamic models were based on [12].

### Real-time Optimization (RTO) Layer

The RTO problem is posed as follows:

$$\begin{aligned} \max_{\boldsymbol{x},\boldsymbol{u}_{MV},\boldsymbol{u}_{DV}} \quad & \varphi \\ s.t. \quad & \boldsymbol{f}(\boldsymbol{x},\boldsymbol{u}_{MV},\boldsymbol{u}_{DV};\boldsymbol{d}) = \boldsymbol{0} \\ & \boldsymbol{g}(\boldsymbol{x}) \le \boldsymbol{0} \\ & \boldsymbol{x} \in \mathcal{X} \\ & \boldsymbol{u}_{MV},\boldsymbol{u}_{DV} \in \mathcal{U} \end{aligned} \quad (2)$$

All variables have been previously defined, with the exception of the economic objective function

$$\varphi = (\rho_1 D_A + \rho_2 D_B + \rho_3 D_C + \rho_4 B_C) - \rho_5 \sum_{i=\{A,B,C\}} V_i, \quad (3)$$

where $D_i$ and $V_i$ are the distillate and boil-up rates of column $i$, which are contained in $\boldsymbol{u}_{DV}$ and $\boldsymbol{u}_{MV}$, respectively. The weight vector $\boldsymbol{\rho} := [\rho_1, \rho_2, \rho_3, \rho_4, \rho_5]$ is determined based on the operating condition:

$$\boldsymbol{\rho} := \begin{cases} if \quad h_{low} \le \boldsymbol{h} \le h_{high} & [0 \ +1 \ 0 \ 0 \ 0.01] \\ if \quad h_1 \ge h_{high} & [0 \ -1 \ 0 \ 0 \ 0.01] \\ if \quad h_2 \ge h_{high} & [0 \ 0 \ -1 \ 0 \ 0.01] \end{cases} \quad (4)$$

Each of these rules represent one desired operating scenario. The second rule, for example, indicates that in the case that the level of the tank storing the product of the second column reaches a high level condition, we want to minimize the second column distillate flow rate. Note that $\boldsymbol{\rho}$ is determined prior to the RTO execution based on the tank levels. Note also that the set of rules presented here is used only to illustrate how one can choose $\boldsymbol{\rho}$ based on the operating conditions. This set can be easily extended in order to encompass different operating scenarios depending on the practitioner needs.

### Zone Nonlinear Model Predictive Control Layer

After solving Equation (2), the RTO solution is sent to the ZC-NMPC layer as purity targets $\boldsymbol{x}_{TARGET}^{purity}$, calculated using the relations in Equation (1), and manipulated variables targets $\boldsymbol{u}_{MV}^{TARGET}$. The control problem is:

$$\begin{aligned} \min_{\boldsymbol{u}_{MV},\boldsymbol{x}_{i,k}^{SP}} \quad & \sum_{k=1}^{P_H} \Big( \sum_{i=1}^{4} \big(x_{i,k}^{purity} - x_{i,k}^{SP}\big)^2 \\ & + \gamma_1 \sum_{j=1}^{6} \big(u_{MV,j,k} - u_{MV,j}^{TARGET}\big)^2 \Big) \\ & + \gamma_2 \sum_{l=1}^{3} \delta_l{}^2 \\ s.t. \quad & \begin{bmatrix} \boldsymbol{x}_{k+1} \\ \boldsymbol{m}_{k+1} \\ \boldsymbol{h}_{k+1} \end{bmatrix} = \boldsymbol{F}\big(\boldsymbol{x}_k, \boldsymbol{m}_k, \boldsymbol{h}_k \boldsymbol{u}_{MV,k}, \boldsymbol{u}_{DV,k}; \boldsymbol{d}\big) \\ & \big|\boldsymbol{u}_{MV,k} - \boldsymbol{u}_{MV,k-1}\big| \le \Delta u_{max} \\ & h_{low} \le h_{l,\boldsymbol{k}} + \delta_l \le h_{high}, \quad l \in \{1,2,3\} \\ & 0 \le x_{1,k}^{SP} \le x_{1,TARGET}^{purity} \\ & 0 \le x_{2,k}^{SP} \le x_{2,TARGET}^{purity} \\ & 0 \le x_{3,k}^{SP} \le x_{3,TARGET}^{purity} \\ & x_{4,TARGET}^{purity} \le x_{4,k}^{SP} \le 1 \\ & \boldsymbol{x_k} \in \mathcal{X} \quad \boldsymbol{u}_{MV,k}, \boldsymbol{u}_{DV,k} \in \mathcal{U} \end{aligned} \quad (5)$$

where the subscript $k$ indicates time. The variables in Equation (5) have been already defined except: $x^{SP}$ that represents the setpoint of the purity targets that, due to zone control formulation, become variables in the problem. This means that $x^{SP}$can be freely changed by the controller given that the setpoints remain in the admissible zone purity; $\delta_{1,2,3}$ are slack variables for the tank level constraints. The plots ins Figure 2 visually demonstrate the effect of slack variables. The high-level constraint on the tank level is briefly violated (indicated by the blue area in the plot). However, this violation incurs a penalty within the objective function. As a result, the controller actively seeks to decrease the tank level as quickly as possible to minimize this penalty and return to within the acceptable operating range.

In addition to the variables above, the control formulation has the parameters $P_H$ that represents the controller prediction horizon, $\gamma_1$ and $\gamma_2$ that are weights of different terms in the objective function, and $\Delta u_{max}$ that represents the maximum allowable input change.

Plant profitability is significantly enhanced by the target tracking term in the objective function of Equation (5). Since the RTO layer determined these target values to maximize overall plant profitability (i.e., maximize $\varphi$), the controller prioritizes keeping the manipulated variables as close as possible to these targets due to the inclusion of this term. This ensures that controller actions not only address immediate operational issues, such as the tank level violation, but also contribute to maintaining optimal economic performance across the entire plant.

## CASE STUDY DESCRIPTION & RESULTS

As the case study, we chose a representative operation scenario where the demand of one of the tanks is suddenly interrupted at a given point in time as shown in Figure 3. The simulations start at a suboptimal point both from a steady-state economic perspective as well as from a product quality perspective, where the top product of the distillation column does not meet the purity constraint ($x_{B,C1,N_T} \leq 0.07$).

If the controller was not in place, the operator would first try to change the column operation to keep the product within the quality targets. After achieving the targets, they would handle the tank level problem. In the case of the demand decrease in Tank 2, they would monitor the level, and once it reaches a given threshold, they would decrease the unit load, significantly affecting the plant's profitability.

On the other hand, the controller reacts to both simultaneously. As the simulation begins, it immediately brings the fraction of $C_1$ at the top of column $B$ within the admissible bounds (Figure 4 - middle plot). However, since the level is decreasing rapidly before the demand change at $t = 100$ min, the controller decisions lead to purer distillate stream. The goal is to decrease the product flow rate. After the demand disturbance, we observe a short period where the top stream impurity increases, affecting the product quality.

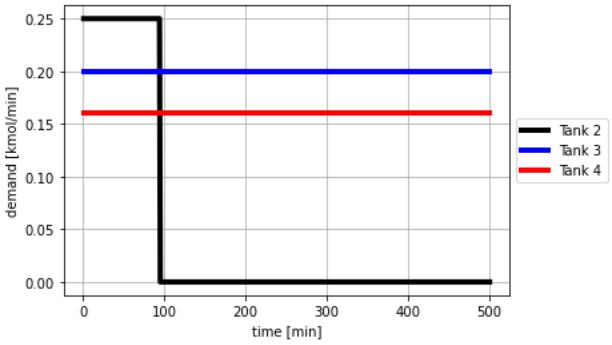

**Figure 3.** Change in the demand of Tank 2 at 99 minutes. Demands are in kmol/min

The proposed strategy then starts counteracting this effect immediately by increasing the reflux (Figure 4 - bottom plot). Next, the reflux rate is adjusted such that level constraint on Tank 2 is not violated. This effect can be seen in the slope change of the tank level trajectory (Figure 4 - top plot). Note that at time 500 minutes, the tank reaches the high-level threshold and the plant load will have to be decreased. However, this happens much later in comparison to the operator-based strategy, which can also give more time to the plant planning team to resolve the issue causing the demand problem.

## CONCLUSIONS

This work demonstrates the application of a hierarchical two-tier control strategy combining Real-Time Optimization (RTO) and Zone Control Nonlinear Model Predictive Control (ZC-NMPC) to a liquid recovery unit of an LPG production plant. Results indicate that this approach has the potential to effectively address production scheduling challenges, and significantly reduce excessive inventory fluctuations. By dynamically adjusting plant flow rates based on real-time economic objectives and uncertain demand scenarios, the proposed strategy significantly outperforms traditional operator-based decisions in terms of economic performance.

Future work will be divided in two stages. First, the proposed method will be compared to a single layer economic ZC-MPC as well as to the typical operator decisions. Both strategies will serve as a baseline for the performance proposed method. Second, we will further develop the method envisioning a practical implementation. For example, the RTO layer will be replaced by a look-up table and, since the optimal purity targets typically lie on the constraints to avoid product give-away, the possibility of replacing the nonlinear control structure by a linear

control one will also be studied. Furthermore, the controller performance will be analyzed in face of different operating scenarios to evaluate its robustness and potential economic benefits.

## ABSTRACT

Model-based control and optimisation strategies can play a key role in improving energy efficiency and reducing emissions into produced water re-injection facilities. However, building a model that adequately describes the plant is challenging and can also be used in online decision-making procedures. This work proposes a simple model based on a real water re-injection facility operating on the Norwegian continental shelf. The results demonstrate the model's flexibility, which could be fitted to different plant operating points while being fast to solve when embedded in optimisation problems. The developed model is expected to aid the implementation of strategies like self-optimising control and real-time optimisation on produced water re-injection facilities.

**Keywords**: Modelling, Water Injection, Subsea, Control, Optimisation.

## INTRODUCTION

Water injection (or water flooding) is an enhanced oil recovery technique that injects water into the reservoir to maintain pressure. The injected water can come either from the sea or the water separated from the oil and gas production (produced water). The reservoir engineers typically decide the amount of injected water in each well, and many methodologies have been proposed so far in the literature where reservoir models are usually applied [1]. Once the injection targets have been defined, the water injection network system can be optimised.

A relevant optimisation problem in this context may consist of the optimal operation of the pump system topside while ensuring the integrity of the subsea water injection system by maximising the lifetime of the equipment. Usually, the works in that phase are modelling the system at a macro-level where each unit is represented as a node in a network [2-3].

The use of simple and lower-level models where the manipulated variables and measured variables can be directly connected proved to be useful in the design of new control strategies [5-6] as well as in real-time optimisation formulations where the model parameters can be updated in real-time [4].

Several requirements should be fulfilled when a model-based control and optimisation strategy is developed: 1) The formulated model should adequately describe the target plant behaviour [5]; 2) The model should be able to be fitted to the plant available measurements considering the intrinsic uncertainty [7]; 3) A optimisation problem embedding the model should be able to be reliably solvable in the required time [4].

This work proposes a simplified mechanistic model of a produced water re-injection facility that aims to meet all those requirements. The model is shown to be capable of matching real industrial data. Furthermore, this work provides original insights into the challenge of training models with real operation data.

## BACKGROUND

### Oil and gas offshore production

Offshore oil and gas production has been used for over a century and is expected to still play a role in the next decades years. A typical offshore oil and gas production facility consists of a reservoir containing oil, gas and water. The reservoir's high pressure is the driving force to make the mixture flow through the production wells. A manifold connects all the wells through a riser that will transport the mixture to a separator that is

usually located topside, but subsea separators may also be applied [5]. A three-phase separator is used to separate the oil, which is then transported to the shore through the production lines or ships. The same is done with the produced gas.

After years of operation, the reservoir starts to decrease in natural pressure, resulting in production reduction. Production can be kept at a plateau using enhanced recovery (EOR) techniques. The gas-lift technique is one of the most common methods and consists of recirculating part of the produced gas using compressors and re-injecting it into the bottom of the well [7]. This reduces the hydrostatic pressure of the mixture in the well, and a higher production. Another technique commonly applied in addition to gas-lift, is to inject the water into the reservoir in separate injection wells. This keeps the reservoir pressure high, such that a high production can be maintained.

### Produced water (PW) re-injection facility

The outflow of water from the separator is called the produced water (PW). The destination of the PW has been the topic of many government regulations [8]. The simple solution would be to discharge the PW into the sea. However, since the separator is not 100 % efficient, drops of oil are carried into the PW. Therefore, the PW needs to be submitted to treatment before discharge, in a way that complies with the regulations [2,8].

Another possible destiny for the PW is to re-inject it into the reservoir. This strategy also has the advantage of being an enhanced oil recovery technique and can increase the revenues from the asset. However, the amount of water injected into each well must be carefully chosen. If too much water is injected into a well, the water cut (ratio of produced water compared to other liquids) will increase, potentially making oil production infeasible [9]. On the other hand, if insufficient water is injected, the reservoir pressure will decrease, lowering production [9]. As a complement, seawater can also be used for water injection.

### Produced water model-based optimal control and optimisation

Many tools were developed for subsea operations, multi-phase flow control [5], gas-lift optimal injection [7], electric submersible pump operation [10] and separator control [6]. Sometimes, the models were used to develop simple feedback solutions [10]. In other cases, the model was used to generate predictions in a Model Predictive Control structure [7].

The decision-making process in PW management is made on different layers [2,11]. On higher layers, decisions are made over the long horizon of many years, where the equipment's health condition should be considered, such as pump and valve degradation. A health-aware control strategy can be applied if a degradation model is available [12]. The injection targets are typically updated over months.

On a faster time scale, the production optimisation decisions are taken. Here the optimal flow rates and pump speeds are decided [2]. Those flow rates are typically sent to the lowest layer, the control and automation layer, where feedback loops and simple controllers are used to track the setpoints coming from the layer above.

## RELATED WORK

Many studies have been conducted to control and optimize PW facilities. Most use reservoir models to obtain the optimal injection flow rates based on reservoir dynamics [1,9]. Another set of works assumed that the injection targets were given and worked only on the production optimisation layer. The main goals of those works were to efficiently operate the pumping system and consider the seawater discharger regulation. The system is treated as a network, where the nodes can be pumping stations, tanks, valves or wells.

[9] proposed a mixed integer linear programming method to solve the PW system operating optimization problem. [2] proposed an economic model predictive control formulation for optimizing daily injection, with a strong focus on compliance with environmental regulation of PW sea discharging. As far as we are concerned, no work on lower-level layers of control and automation was developed.

### Motivation and contribution of the paper

We have two main motivatiors for building a new model for the PW re-injection facility: i) Obtaining a model that can be used on real-time control and optimization strategies; ii) To address the challenges of obtaining a model that can be easily fitted to real facility data. To address those goals, a static model for the PW was developed in this work.

The model is designed to be applied to operation and production strategies that are not fully explored and adapted yet in the industry. For example real-time optimisation Here, the optimal valve openings, pump speeds, and flows can be computed to minimize energy consumption while operating within the pump envelopes and reducing the risk of cavitation on the injection valves. The model is also suitable for obtaining insights on how a simple optimizing control structure may be implemented (e.g. self-optimizing control [14]).

## MATHEMATICAL MODEL

### System description

The system to be modelled is presented in Figure 1. It is based on a real reinjection facility operated on the

Norwegian continental shelf. The system in consideration has nine boundaries: three inflows and six outflows. The outflows consist of the reservoir injection wells placed in distinct locations. The inflows consist of a seawater return, and two produced water streams. Since the goal is to obtain a simple model, the focus was to include only the primary operations that can contribute to achieving the water injection targets or the energy efficient optimisation. Therefore, the PW treatment and the separators were excluded from the model development. The interested reader is referred to [6].

The overall water injection system is divided into two parts: the topside part (on a platform or a ship) and the subsea part. A topside tank is used to store the seawater inflow, which is mainly used to complement the PW streams. The tank guarantees a steadier flow and are connected to a fixed-speed pump C. Two variable-speed pumps A and B are used to pump water to the different injection wells of the reservoirs. The second part of the model is the subsea injection system, which uses flow modules and choke valves on top of the well to precisely control each well's injection flow rate.

## Main assumptions

The main assumption made was that a steady-state model can well describe the system. This decision was based on analysing past process data and the system's relative fast dynamics. Besides, it was discussed previously that static models suffice in most cases of daily production optimisation [11]. Model accuracy was another reason for building a steady-state model, as calibrating dynamic models can be challenging in real facilities [7] and requires state estimators. Besides, steady-state models can be more easily applied in real-time optimisation (RTO) approaches [4].

Another important assumption made is the description of the reservoir behaviour, which is considered to behave linearly based on the pressure gradient between the bottom hole pressure and the reservoir pressure. That assumption is commonly used since reservoir dynamics are much slower than pumping system dynamics, and the injection parameter can be obtained experimentally by operators through injectivity tests [2].

## Topside equations

The first part of the equations describes the topside of the water injection facility. The inlet flow on the tank is controlled by a valve. Since the goal was to obtain a steady-state model, we assumed a perfect control of the tank level ($h_{tank}$). Therefore, the ordinary differential equation originating from the mass balance in the tank was not included explicitly in the model.

The pump located downstream of the tank has a fixed speed (Pump C) and the outlet flow ($F_s$) can be computed using the pump equations, where the pressure in the bottom of the tank ($P_{out}^{tank}$) is computed using a static pressure equation. Another control valve is used for manipulating the flow ($P_{out}^{c}$) downstream Pump C. The Pump C head ($H_c$) is provided by the pump curve equation.

$$F_s = CV_s z_s \sqrt{P_{out}^{c} - P_{out}^{valve}} \tag{1}$$

$$P_{out}^{tank} = P_{tank} + \rho g h_{tank} \tag{2}$$

$$P_{out}^{c} = P_{out}^{tank} + \rho g H_1 \tag{3}$$

$$H_c = a_{10} + a_{11} F_s + a_{12} F_s^2 \tag{4}$$

Downstream the pump, the flow is split into two separate lines that will connect with the two PW streams. The

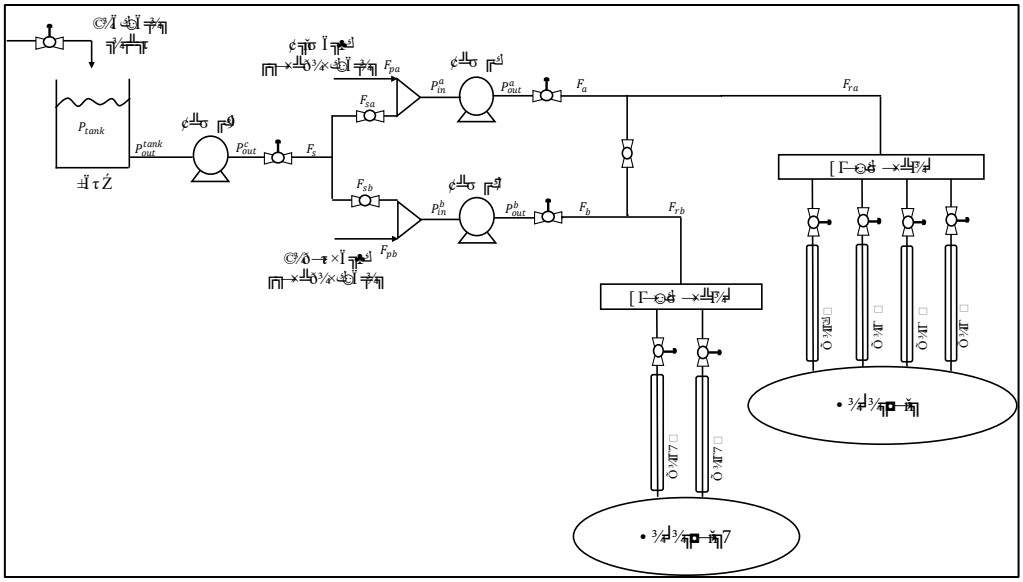

**Figure 1** – Illustration of the modelled produced water facility.

mass balances on those nodes are described as follows:

$$F_s = F_{sa} + F_{sb} \quad (5)$$

$$F_a = F_{sa} + F_{pa} \quad (6)$$

$$F_b = F_{sb} + F_{pb} \quad (7)$$

The two variable speed injection pumps are described using the pump equations, as well as the respective control valves.

$$H_a = a_{20}\omega_a^2 + a_{21}\omega_a F_a + a_{22}F_a^2 \quad (8)$$

$$H_b = a_{30}\omega_b^2 + a_{31}\omega_b F_b + a_{32}F_b^2 \quad (9)$$

$$F_a = CV_a z_a \sqrt{P_{out}^a - P_n^a} \quad (10)$$

$$F_b = CV_b z_b \sqrt{P_{out}^b - P_n^b} \quad (11)$$

$$P_a^{out} = P_a^{In} + \rho g H_1 \quad (12)$$

$$P_b^{out} = P_b^{In} + \rho g H_2 \quad (13)$$

## Subsea system equations

The second set of equations describes the flow modules, wells and reservoirs. The pressure on the flow modules as well as the mass balance are described as follow:

$$P_m^a = P_i^a + \rho g h_{riser}^a \quad (14)$$

$$F_{ra} = F_a + F_{an} \quad (15)$$

$$P_m^b = P_i^b + \rho g h_{riser}^b \quad (16)$$

$$F_{rb} = F_b + F_{bn} \quad (17)$$

Each well (i = B1, B2, A1, A2, A3 and A4) is described by the pressure in the top of the well ($P_{top}^i$) computed using the static valve equation, the bottom hole pressure ($P_{bhp}^i$) and the linear water injection on the reservoir's equation:

$$F_i^{valve} = CV_i z_i \sqrt{P_m^i - P_{top}^i} \quad (18)$$

$$P_{bhp}^i = P_{top}^i + \rho g h_i \quad (19)$$

$$F_i^{res} = (P_{bhp}^i - P_{res}^i) J_i \quad (20)$$

$$F_i^{res} = F_i^{valve} \quad (21)$$

## DATA GATHERING AND PARAMETER ESTIMATION

The industrial data was gathered from a PW facility operated on the Norwegian continental shelf. The available measurements were pressures, volumetric flow rates and pump and valve operating data. Outliers were removed, and all the data set was normalized. Figure 2 shows the water flow rate for pumps A and B during the collected period. Since the model to be fitted is static, five different steady-state operating points were selected to evaluate the model's capability of describing different scenarios.

The model comprises of 44 algebraic variables and nonlinear equations, 14 inputs and 31 parameters. Model parameters related to equipment dimensions and the valve's flow coefficient were fixed as in the real industrial system. The remaining 15 parameters were estimated using least squares regression from the field data ($P_{tank}$, $P_a^{In}$, $P_b^{In}$, $P_{res}^i$ and $J_i$).

A nonlinear weighted least-square problem was solved, where the weight used was the inverse of the variance of each measurement. Pump envelops and valve operation ranges were used to constrain the optimisation problem. The problem was implemented in MATLAB using the CasADi tool with automatic differentiation and the NLP solver IPOPT.

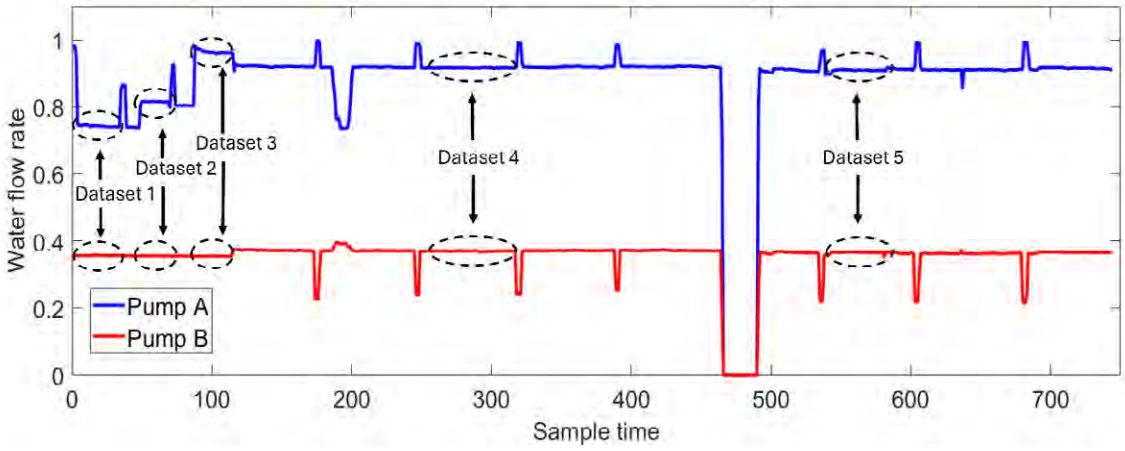

**Figure 2** – Five datasets used for parameter estimation.

## RESULTS

The fitted pump curves for pumps A and B are visualised in Figure 3, as well as the pumps operation envelopes that were used to constrain the problem feasible region. This is a crucial part of the model for future applications, because many optimal operation strategies try to optimise the pump performance [2].

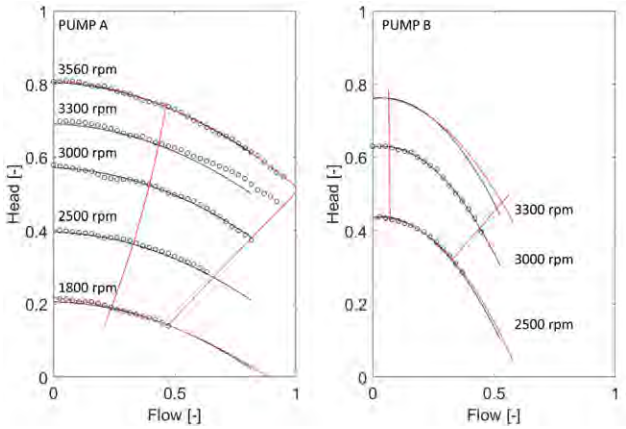

**Figure 3** –Normalized pump curves: Pump curves datapoints (circles), model predictions (black line) and operation envelopes (red line).

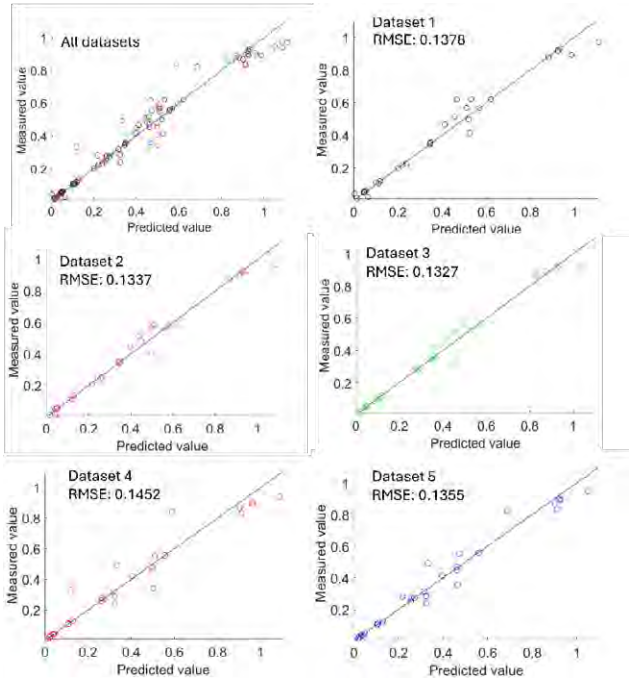

**Figure 4** – Scatter plot of the predicted and measured values for the five datasets.

A scatter plot comparing the model predictions and measurements for the five different steady state datasets can be visualized in Figure 4. All the five operating points could be described by the model with a relative equal root-mean square error (RMSE), with a slightly difference for dataset four.

The water injection rates for the different wells are the most relevant variables for optimizing water injection, since the rates should be driven to their respective targets provided by upper layers decision makers. Therefore, in Figure 5 a closer look on the predicted and measured water injection rates are shown.

Overall, the model could describe the injection rates satisfactorily, with a few exceptions. Operating points 1 and 2 have a distinct feature since either well A1 or A2 were shut down. However, the model predicted a low remnant injection rate on those wells. Furthermore, the model underpredicted wells B1 and B2 rates in almost all cases.

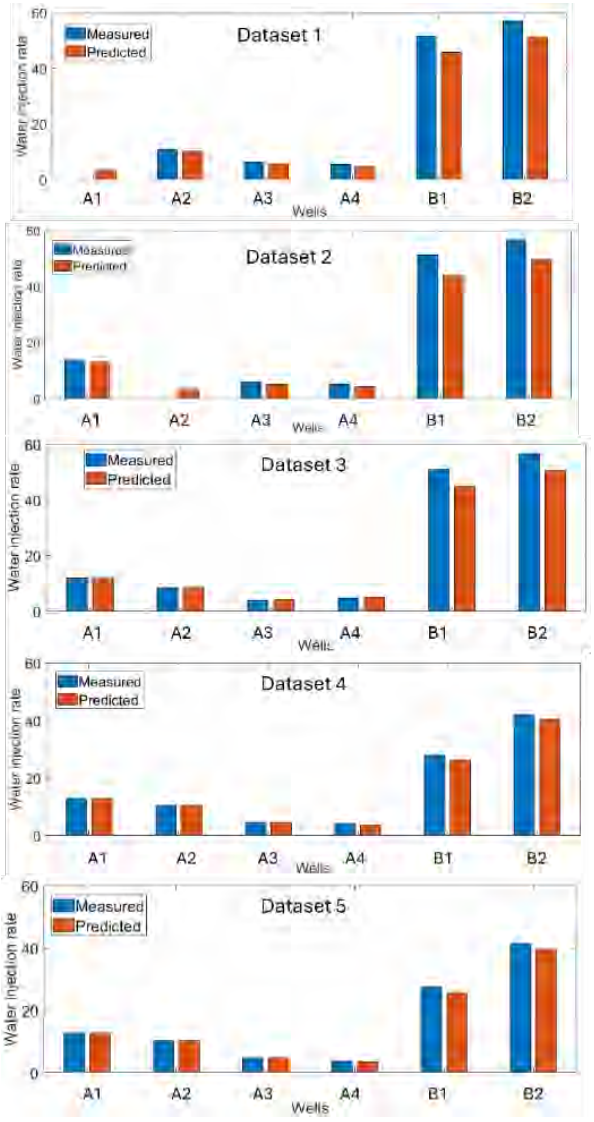

**Figure 5 –** Measured and predicted water injection rate of all the wells on the five different data-sets.

## CONCLUSIONS

A simple steady-state model could be fitted to

datasets from a real produced water re-injection facility. Overall, the model was flexible enough to fit different operating points with relatively small prediction errors.

Future work will focus on applying the developed model to applications such as real-time optimisation [4] and health-aware control by adding equipment degradation models [12]. Furthermore, an Economic Model Predictive Control strategy can also be explored. For that purpose, a dynamic model of the facility can be built based on the developed steady-state model.

## ABSTRACT

Process systems are negatively impacted by manufacturing uncertainties, and increasingly by unknown-unknown disruptive events. To this effect, systems need to be designed with the inherent flexibility and resilience to overcome the impacts of uncertainties and disruptions respectively as it is more challenging to retrofit existing systems with such capabilities. To this end, we propose a methodology based on flexibility analysis to systematically explore the feasibility of design alternatives under parameter uncertainty and discrete disruption scenarios simultaneously. Multi-parametric programming is utilized to generate explicit relationships between design decisions and the resulting system's ability to maintain feasible operations under uncertainty and disruptive events. We capture this ability by introducing the Combined Flexibility-Resilience Index (CFRI), which describes the likelihood that the system is feasible under the relevant uncertainty and disruption sets. With explicit functions for the CFRI, the flexibility and resilience objectives can be incorporated into a general superstructure design optimization problem alongside other objectives, allowing for the exploration of trade-offs among flexibility, cost and resilience. Our methodology provides the foundation of a holistic approach for design optimization for both flexibility and resilience. A case study involving a process plant with multiple sources of uncertainties and disruptive events is used to illustrate the application of the proposed methodology.

## INTRODUCTION

An important goal for process synthesis and design is hedging against future uncertainties. A realized design decision determines the range of operational strategies that can be deployed to respond to disruptions and uncertainties, which means that an overly restrictive or rigid design could be detrimental long-term even if it meets short-term objectives such as minimized investment cost. However, it is impossible to predict every fluctuation from nominal operating conditions and every disruption event with absolute certainty. Stress-testing with a set of highly probable scenarios is a commonly used method to assess the resilience of various design alternatives, but this may result in designs that are not adaptable to previously unseen disasters [1,2]. Methods that systematically evaluate process behavior within the entire range of possible realizations, such as the flexibility analysis framework, could bring additional insights into the expected performance of a particular design alternative under uncertainty. Furthermore, flexibility analysis can serve as a unifying framework for simultaneously considering resilience against specific disruption scenarios, reliability and availability of process equipment, and design under uncertainty.

Flexibility analysis in general, as initially formulated by Swaney and Grossmann [3], describes the range of uncertainty where a particular design configuration remains feasible. Variations of the flexibility analysis have introduced more complexities in the representation of

uncertainty, such as the stochastic flexibility analysis which considers the specific probability distribution of the uncertainty [4], flexibility-availability analysis which adds information about the likelihood that a specific design state will occur [5], and considerations of measured and unmeasured uncertainties [6]. This formulation has been used to generate designs for process systems as well as supply chains with a specific level of performance against uncertain parameters [7-9].

In this work, we showcase the use of an adapted stochastic flexibility analysis for optimizing the design of a process system under uncertainty and disruption scenarios. Specifically, the stochastic flexibility analysis is used to represent uncertain parameters and their probability distributions as well as discrete disruption scenarios. The combined flexibility-resilience index (CFRI) represents the probability that a particular design configuration will remain feasible under the given uncertainty and disruption scenarios. The CFRI can be expressed in terms of design variables, either through an analytical approach or numerical approximation. This function can then be incorporated into a superstructure optimization programming problem to assess trade-offs between prioritizing flexibility and resilience and other objectives such as cost minimization. The proposed methodology is demonstrated through a case study for retrofitting a process plant.

# METHODOLOGY

## Framework summary

In this work, a stochastic flexibility-based approach is used to represent how uncertainties and discrete disruption scenarios simultaneously affect the feasibility of a given design, which is taken as the representation of whether the design would be resilient under these disruption scenarios. From this approach, a Combined Flexibility-Resilience Index (CFRI) is generated which describes the likelihood that a design configuration is feasible under the set of uncertainties and disruption scenarios. This section describes the derivation of the CFRI as well as how it is utilized to explore trade-offs between resilience and other objectives in the design stage.

## Combined Flexibility-Resilience Index (CFRI) derivation

To derive the CFRI, a superstructure for the system at hand is first generated. At this initial stage, it is important to determine the allowable range for design variables and the desired performance goal (e.g. must meet 100% of demand). Additionally, the uncertainty set and discrete disruption scenario set are generated. These sets describe the full extent of uncertainties and disruptions that the optimal design should be feasible under.

## Calculating CFRI for one design realization

The stochastic flexibility index $SF$ represents the probability that a design configuration is feasible under the specific probability distribution for $\theta$ [4]. Mathematically, this is expressed as:

$$SF = \Pr(\psi \leq 0) \tag{1a}$$
$$s.t.\ \psi(d,\theta) = \max u \tag{1b}$$
$$s.t.\ f_j(d,\theta) \leq u \quad \forall j \in J \tag{1c}$$
$$h_m(d,\theta) = 0 \quad \forall m \in M \tag{1d}$$
$$\theta : P_d(\theta) \tag{1e}$$

For a given design configuration, the stochastic flexibility is expressed by the integral of the joint distribution function of $\theta$, $P_d(\theta)$ over the feasible region:

$$SF = \int_{\theta:\psi(d,\theta)\leq 0} P_D(\theta)\, d\theta \tag{2}$$

For cases where $\theta$ is normally distributed and $\psi(\theta)$ is linear, an exact value for the stochastic flexibility can be derived. For cases where $\theta$ has a non-standard distribution, numerical approaches such as the use of Gaussian quadratures or a sample average approximation approach can be used as an approximation [9, 10].

An assumption that is still implicit in the stochastic flexibility formulation is that the process constraints $f_j, h_m$ are fixed. However, discrete disruption scenarios realize as a modification on these constraints (e.g. loss of equipment capacity changes a constraint that caps the amount that can be produced). A change in process constraints means that the feasible region has changed, which would in turn change the value of the stochastic flexibility index for each scenario (see Figure 1). The Combined Flexibility-Resilience Index (CFRI), therefore, is the weighted sum of the stochastic flexibility index for all discrete scenarios given the probability of each scenario:

$$CFRI = \mathbb{E}(SF) \tag{3}$$

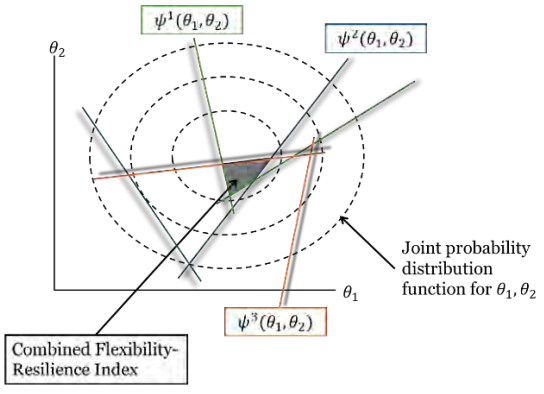

**Figure 1.** Graphical illustration of the CFRI for three potential discrete disruption scenarios and two independent, normally-distributed uncertain parameters

To efficiently calculate the CFRI for one design realization and a given set of uncertainties and disruption scenarios, the following steps can be performed:

1. Generate reduced subproblems based on each disruption scenario
2. For each subproblem, formulate the feasibility test problem
3. Solve the feasibility test problem via multi-parametric programming to yield explicit equations for $\psi(\theta)$
4. Use the $\psi(\theta)$ expression to calculate the stochastic flexibility for the given probability distribution of the uncertainty
5. Calculate the CFRI as the weighted sum of the stochastic flexibility for each disruption scenario (Equation 2)

### CFRI as a function of design variables

With the CFRI calculated for different design realizations, a correlation between the CFRI and design variables can then be derived. This correlation can then be used to express a flexibility-resilience goal in a design optimization problem. Numerical approximations such as using Gaussian quadratures and sample average approximation methods have been proposed for relating flexibility with design variables [7, 9, 10]. In this work, a sample average approximation approach is utilized to approximate CFRI as a function of design variables.

## Superstructure optimization to yield optimal design

For a problem where the objective is to minimize design and nominal operating costs, the design optimization problem can be constructed as follows:

$$\min CAPEX(d) + OPEX(d, \theta^{NOM}) \quad (4a)$$
$$s.t.\, f_j(d, \theta) \leq 0 \quad \forall j \in J \quad (4b)$$
$$h_m(d, \theta) = 0 \quad \forall m \in M \quad (4c)$$
$$CFRI(d) \geq CFRI^{target} \quad (4d)$$

Where Equations 4b, 4c describe the process constraints and Equation 4d describes the minimum desirable CFRI as a function of design variables. To obtain a Pareto front that describes trade-off between cost and CFRI, the simplest method is to solve Equation 4 repeatedly for different values of $CFRI^{target}$. If $CFRI(d)$ is a non-linear function, the optimization problem is a non-linear program (NLP) which might also be non-convex. This increases the difficulty in obtaining a continuous Pareto front parametrically, as the problem would then need to be reformulated as an mp-NLP (multi-parametric NLP). Several algorithms have been proposed in literature [11-14] to obtain either global solutions or approximations for mp-NLP problems which can be used to obtain explicit functions that describe trade-offs between objectives.

# CASE STUDY

## Setup

To demonstrate how the CFRI can be used as part of a design optimization problem, a case study is constructed based on the co-generation plant first described in Al-Fadhli, et al. [15]. The plant, pictured in Figure 2, consists of a steam power plant and a PV system for electricity generation as well as a reverse osmosis plant and a thermal desalination plant (based on multi-stage flash units) for water generation.

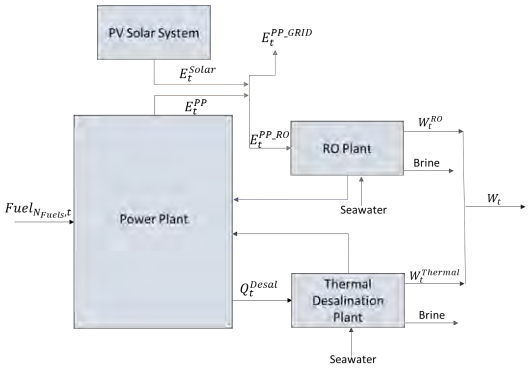

**Figure 2.** Simple process flowsheet for the co-generation plant case study. Adapted from Al-Fadhli, et al. [15].

The process constraints are given as follows:

$$E^{PP} = 0.13F_1 + 0.15F_2 + 0.82F_3 + 0.50F_4 - 0.43Q^{Desal} \quad (5a)$$
$$E^{PPGrid} = 0.85(E^{PP} + E^{Solar}) - E^{RO} \quad (5b)$$
$$W^{Thermal} = 9.95Q^{Desal} \quad (5c)$$
$$W^{RO} = 192E^{RO} \quad (5d)$$
$$W^{Thermal} + W^{RO} \geq W^{Demand} \quad (5e)$$
$$E^{PP} + E^{Solar} \geq E^{Demand} \quad (5f)$$
$$W^{Thermal} \leq cap_{MSF} d_{MSF} \quad (5g)$$
$$W^{RO} \leq cap_{RO} d_{RO} \quad (5h)$$
$$E^{Solar} \leq cap_{PV} d_{PV} \quad (5i)$$

Demand for both water and electricity are assumed to be normally distributed, as shown in Figure 3.

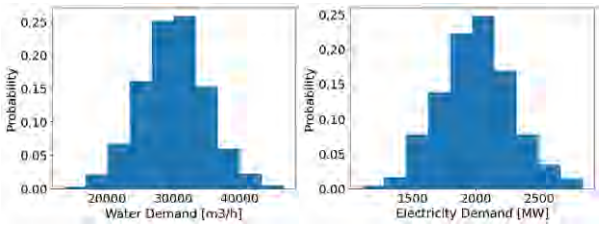

**Figure 3.** Probability distribution for water ($W^{Demand}$, left) and electricity ($E^{Demand}$, right) demand

Equipment failure scenarios are also generated for the PV, RO, and MSF units ($cap_{PV}, cap_{RO}, cap_{MSF}$ respectively), which includes both partial (25%, 50%, 75% capacity loss) and full (100% capacity loss) failures as represented in Figure 4. In total, 125 mutually exclusive scenarios are generated with different discrete probabilities. The goal of this case study is to retrofit the existing plant through expansion of the PV, RO, and MSF plants up to 2X their current capacities to maximize its resilience against uncertain demand and failure scenarios simultaneously while minimizing retrofit cost.

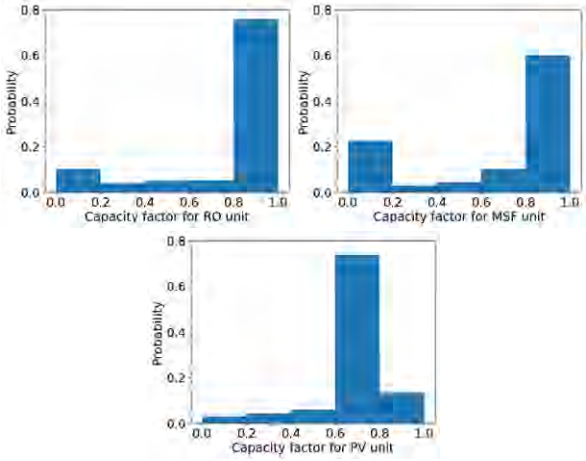

**Figure 4.** Discrete probability distribution for capacity loss disruption scenarios for RO (left), MSF (right), and PV (bottom) plants

With $W^{Demand}, E^{Demand}$ as the uncertain parameters and $d_{MSF}, d_{RO}, d_{PV}$ as the design variables, a multi-parametric reformulation can be constructed to derive the feasibility function $\psi(\theta, d)$ which is then used to derive the CFRI.

## Results and discussion

For the set of process constraints in Equation 4 and nominal design values of $d_{MSF} = 20836\frac{m^3}{h}, d_{RO} = 11364\frac{m^3}{h}, d_{PV} = 1000\ MW$, the feasibility regions that each represent a different expression for $\psi(\theta)$ are shown in Figure 5 below. This figure represents the feasibility region map, which provides information about how to evaluate the design feasibility depending on the realized water and electricity demand values. The stochastic flexibility for the nominal design values given the demand distributions is calculated to be $SF = 1$. To incorporate equipment failure scenarios, reduced subproblems are generated based on the discrete failure probabilities presented in Figure 4. Finally, the CFRI can be calculated as a weighted average of the stochastic flexibility across scenarios. For the nominal design values, $CFRI = 0.26$. Appendix A describes the derivation of the CFRI value in more detail.

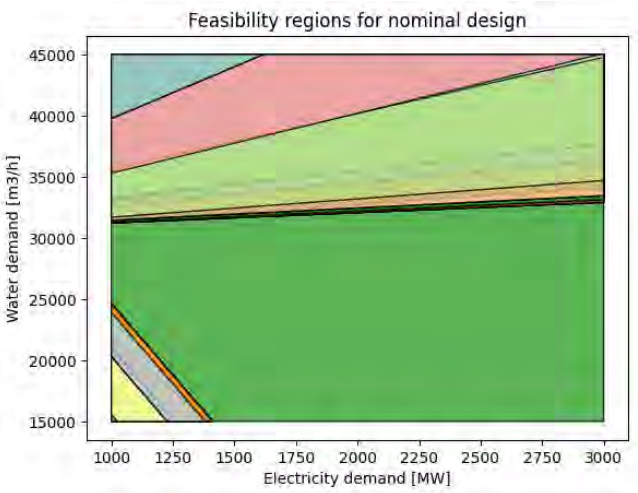

**Figure 5.** Feasible region map, where one color represents one feasibility region (a distinct $\psi(\theta)$ function), for the nominal design variables of $d_{MSF} = 20836\frac{m^3}{h}, d_{RO} = 11364\frac{m^3}{h}, d_{PV} = 1000\ MW$, under the scenario of 0% capacity loss. This figure was generated via PPOPT (Python Parametric Optimization Toolbox), a Python-based multi-parametric program solver [16].

To derive a function that describes how the three design variables affect system resilience under uncertainty and disruptions $CFRI(d_{RO}, d_{MSF}, d_{PV})$, a sample average approximation method is used. The CFRI value is calculated for 1000 random samples of design realizations that fall within the desired design variable range ($20836 \le d_{MSF} \le 41672\frac{m^3}{h}, 11364 \le d_{RO} \le 22728\frac{m^3}{h}, 1000 \le d_{PV} \le 2000\ MW$). The function is then fitted to a polynomial form in terms of normalized design capacity to yield the following expression:

$$\begin{aligned} CFRI = -1.93 &+ 1.37\widehat{d_{RO}} + 1.19\widehat{d_{MSF}} + 1.00\widehat{d_{PV}} - 0.17\widehat{d_{RO}}^2 \\ &- 0.62\widehat{d_{RO}}\widehat{d_{MSF}} - 0.39\widehat{d_{RO}}\widehat{d_{PV}} - 0.54\widehat{d_{MSF}}^2 \\ &+ 0.71\widehat{d_{MSF}}\widehat{d_{PV}} - 0.60\widehat{d_{PV}}^2 + 0.002\widehat{d_{RO}}^3 \\ &+ 0.05\widehat{d_{RO}}^2\widehat{d_{MSF}} + 0.02\widehat{d_{RO}}^2\widehat{d_{PV}} \\ &+ 0.16\widehat{d_{RO}}\widehat{d_{MSF}}^2 - 0.09\widehat{d_{RO}}\widehat{d_{MSF}}\widehat{d_{PV}} \\ &+ 0.12\widehat{d_{RO}}\widehat{d_{PV}}^2 + 0.05\widehat{d_{MSF}}^3 \\ &- 0.07\widehat{d_{MSF}}^2\widehat{d_{PV}} - 0.09\widehat{d_{MSF}}\widehat{d_{PV}}^2 \\ &+ 0.09\widehat{d_{PV}}^3 \end{aligned} \quad (5)$$

The general design optimization problem (Equation 3) is then constructed where Equation 4 describes the process constraints and Equation 5 describes the minimum desirable CFRI value based on how CFRI correlates with design variables. The optimization problem is then

solved with different $CFRI^{target}$ values to demonstrate the relationship between retrofit costs and achievable resilience and flexibility performance.

**Table 1**: Design retrofit alternatives with different CFRI values

| CFRI | Retrofit cost [$MM] | $d_{RO}[m^3/h]$ | $d_{MSF}[m^3/h]$ | $d_{PV}\ [MW]$ |
|---|---|---|---|---|
| 0.26 | 0 | 11,364 | 20,836 | 1,000 |
| 0.53 | 225 | 22.728 | 20,836 | 1,000 |
| 0.59 | 1,000 | 22,728 | 20,836 | 2,000 |
| 0.63 | 1,200 | 22,728 | 27,086 | 2,000 |

Table 1 shows the achievable gains in flexibility and resilience with retrofit of the RO, MSF, and PV units. Expanding the RO capacity is paramount to increasing the flexibility and resilience of the co-generation, leading to the conclusion that water production is the bottleneck which prevents the system from being more adaptable to the expected set of disruptions. It can also be observed that a large financial cost is required to invest in additional PV and MSF capacity, but the resulting flexibility and resilience gains are not as significant. This may represent a point where capacity expansion no longer serves as a cost-effective resilience measure, and strategies such as energy and/or water storage may be introduced.

## CONCLUSION

To design process systems that can adequately respond to a variety of disruptions and uncertainties, resilience needs to be an integral part of the conceptual design process alongside other critical objectives such as economic feasibility. By extending the stochastic flexibility analysis framework to also consider discrete disruption scenarios, we have formulated a Combined Flexibility-Resilience Index which accounts for the ability of a particular design alternative to handle uncertainties and disruptions simultaneously. Furthermore, we have demonstrated how the CFRI can be used within a superstructure optimization problem to uncover trade-offs between investment cost and flexibility-resilience goals. This provides a method for assessing the performance of a design alternative, as well as a method for synthesizing new alternatives that may uncover cost-competitive resilient design alternatives. Data from flowsheet simulations can be harnessed to construct the range of uncertainties that needs to be designed for. To apply this method for more complex systems, decomposition algorithms may be needed to reduce the computational burden involved in simulating a large number of disruption scenarios.

## APPENDIX A: CASE STUDY – DETAILED CFRI DERIVATION

The feasibility function problem for the case study presented is given as follows:

$$\psi = \min u \tag{A1}$$

$$s.t.\ E^{PP} = 0.13F_1 + 0.15F_2 + 0.82F_3 + 0.50F_4 - 0.43Q^{Desal} \tag{A2}$$

$$E^{PPGrid} = 0.85(E^{PP} + E^{Solar}) - E^{RO} \tag{A3}$$

$$W^{Thermal} = 9.95Q^{Desal} \tag{A4}$$

$$W^{RO} = 192E^{RO} \tag{A5}$$

$$W^{Demand} - (W^{Thermal} + W^{RO}) \le u \tag{A6}$$

$$E^{Demand} - (E^{PP} + E^{Solar}) \le u \tag{A7}$$

$$W^{Thermal} - cap_{MSF}d_{MSF} \le u \tag{A8}$$

$$W^{RO} - cap_{RO}d_{RO} \le u \tag{A9}$$

$$E^{Solar} - cap_{PV}d_{PV} \le u \tag{A10}$$

$$E_{LB}^{Demand} \leq E^{Demand} \leq E_{UB}^{Demand} \quad \text{(A11)}$$

$$W_{LB}^{Demand} \leq W^{Demand} \leq W_{UB}^{Demand} \quad \text{(A12)}$$

Where $W^{Demand}, E^{Demand}$ are uncertain parameters and $d_{RO}, d_{MSF}, d_{PV}$ are design variables. To derive the CFRI for one $d_{RO}, d_{MSF}, d_{PV}$ realization, the next steps are:

1. Reduced subproblems based on the disruption scenarios are generated. The disruption scenarios are represented as capacity factors $cap_{RO}, cap_{MSF}, cap_{PV}$ that represent a reduction of production capacity of the RO, MSF, and PV units (see Figure 4).
2. For each reduced subproblem, the actual production limit quantity can be substituted into Equations $A8, A9, A10$ to simplify those equations. The feasibility function problem is then be solved parametrically to obtain expressions for $\psi(W^{Demand}, E^{Demand})$.
3. Because the uncertain parameters are normally distributed and $\psi(W^{Demand}, E^{Demand})$ is a linear function, the stochastic flexibility for each reduced subproblem can be calculated analytically [4].
4. The CFRI for the $d_{RO}, d_{MSF}, d_{PV}$ realization is a weighted average of the stochastic flexibility index for all reduced subproblems (Equation 2).

## ABSTRACT

One market scope of bioindustries is the production of recombinant proteins for its application in serotherapy. However, its process's monitoring and optimization present limitations. There are different approaches to optimize bioprocess performance; one is using model-based control strategies such as Model Predictive Control (MPC). Another strategy is learning-based control, such as Reinforcement Learning (RL). In this work, an RL approach was applied to maximize the production of recombinant proteins in *E. coli* at the induction phase using as a control variable the substrate feed flow rate ($F_{in}$). The RL model was trained using the actor-critic Twin-Delayed Deep Deterministic (TD3) Policy Gradient agent. The reward corresponded to the maximum value of protein productivity. The environment was represented with a dynamic hybrid model. The optimization was evaluated by stages of two hours to check the protein productivity performance. Afterwards, the results were compared with an MPC approach. Finally, the control approaches were trained considering temperature disturbances. The results elucidate that the RL approach could be implemented as a control strategy, reaching values from 0.014 mg/h to 0.079 mg/h through all the optimization stages previously demonstrated to be the optimal ones. Despite exhibiting temperature disturbances, the RL approach demonstrated its robustness by adapting the control action to maintain similar protein productivity values.

## INTRODUCTION

Scorpion sting envenoming (scorpionism) is a severe public health issue in developing countries in North Africa, the Middle East, and Central and South America [1,2]. The symptoms associated with scorpion stings are intense local pain, sweating, tachypnea, tachycardia, agitation, pancreatitis, pulmonary edema, hemolysis, necrosis, and, in severe cases, leads to death. The use of antivenom is the only effective treatment against scorpion stings where different types of molecules can neutralize the venom. Those antivenom molecules were commonly obtained from animal origin [1,2].

Advances in serotherapy allowed for the production of recombinant proteins using species such as *E. coli*, becoming one of the critical market scopes of bioindustries [3,4]. Nevertheless, its process's monitoring, control, and optimization are challenging. Different approaches to optimize bioprocess performance exist: model-based control strategies, such as Model Predictive Control (MPC), and learning-based control, like Reinforcement Learning (RL). Dubencovs *et al.* [5] used an MPC to optimize the growth of *E. coli* BL21 (DE3) and the production of two different recombinant proteins, nerve growth factor (NGF) and coat protein of bacteriophage Qβ (Qβ-CP). In their paper, three experiments were conducted: the first focused on finding the optimal "Golden batch" states without any induction, the second considered induction for NGF protein production, and the third

considered induction of the bacteriophage Qβ coat protein (Qβ-CP). It was concluded that MPC demonstrates rapid adaptability to various systems, where a meticulous estimation of model parameters could significantly reduce the number of experiments required to optimize the model. The proposed methodology allowed satisfactory control of biomass growth, with deviations between 6-12% compared to the values calculated as the Golden batch. Bonanni *et al*. [6] proposed a deep-learning approach to optimize recombinant protein production using *E. coli*. The authors proposed ML approaches based on a recurrent Neural Network (NN) to predict the optical density (DO) from several process variables such as pH, dissolved oxygen, temperature, etc.

Although the results are prominent, the optimizations were focused on improving cell growth rather than directly maximizing protein production. Additionally, the MPC requires highly detailed knowledge of the process, which must be represented in the model; learning techniques require a large quantity of data [7]. RL appears to be an innovative approach to optimize and control biological processes.

RL refers to mapping situations to actions by maximizing a numerical reward signal. The goal of the RL agent is not to indicate which actions to take; it must discover which actions yield the most reward by associating them with the outcomes they produce [8]. In other words, the goal is to find the best sequence of control actions that generate the optimal outcome by interacting with its environment [9]. In RL, the agent interacts with the environment and learns which actions to take by trial and error. Each interaction implies executing an action over the environment. The agent receives a reward for its actions. In this manner, the agent learns the best control policy that maximizes the total accumulated reward [7,9]. The majority of the RL learners are based on policy gradient methods. This method directly obtains a policy by maximizing a desired performance index [10]. Petsagkourakis *et al*. [10] applied RL over three computational case studies. The first study is a "real" photo-production system; however, the exact model is unknown, and a simplified deterministic model is assumed. In the second case, however, it was assumed that the simplified model is supposed to follow a Wiener stochastic process. The last case was a photoproduction of phycocyanin synthesized by *cyanobacterium Arthrospira platensis*. The results highlight the possibility of obtaining a near-optimal policy for a stochastic system when true dynamics are unknown. However, RL has no applications for recombinant protein production in *E. coli*.

In this work, an actor-critic agent was selected due to the continuous actions space property. For a determinate observation action, the critic returns an approximation of the policy value. For a determinate observation, the actor returns the action that maximizes the policy value. Overall, the actor learns the best action to take using the feedback from the critic.

This work proposes a learning-based RL approach to optimize the glucose feed flow rate at the induction phase to maximize protein productivity. The contributions of this work are summarized as follows:

- A learning-based RL approach was designed to maximize protein productivity by manipulating the feed flow rate at the induction phase
- An actor-critic Twin-Delayed Deep Deterministic (TD3) policy gradient Agent was used for the first time over a protein production process using *E.coli*
- The impact of temperature disturbances was considered in the training of the TD3 agent
- The results demonstrated that the RL approach produced superior outcomes in comparison to the MPC approach

# MATERIALS AND METHODS

## Optimization problem statement

The process variables correspond to Glucose $(S)$, Biomass $(X)$, Protein $(P)$, and Volume $(V)$ of the liquid phase in the bioreactor; The Manipulated variables refers to the glucose feed flow rate $(F_{in})$. The aim is to maximize protein productivity $(Pprod = P \cdot V/t)$ through process simulation by finding the optimal $F_{in}$ profile at induction phase $(t \geq 8h)$. The optimization strategy was divided into six different control intervals "stages" from the beginning of the induction phase $(t \geq 8h)$ until the end of the process $(t = 20h)$, as shown in Figure 1.

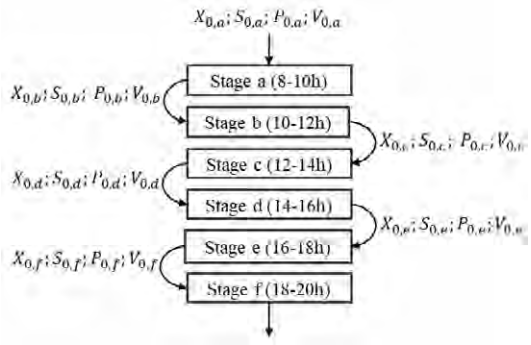

**Figure 1.** Stages of the optimization strategy. Protein production using *E. coli* CH10-12 with an induction temperature of 28°C.

The in-Silico experiment was conducted for protein production using *E. coli* CH10-12 with an induction temperature of 28°C. In this work, It was considered one of the specific conditions reported in Alonso Villela *et al*. [11]; The simulated conditions were conducted in batch phase at $2L$ and 37°C with an initial glucose concentration of $10g_{glucose}/L$ $(pO_2 > 15\%, pH = 6.8)$ for $3.4h$. Then,

in the fed-batch phase at 37°C the glucose feed was $300 g_{glucose}/L$ with a flowrate $1.0 \times 10^{-3} L/h$ for $8.0h$. Afterwards, the inductor ($1mM$ of isopropyl- thiogalactopyranoside IPTG) was added to start protein production, and temperature was lowered to 28°C.

It is assumed that the optimization stage "a" started at $8h$, considering as inputs the last point of the feed batch process, and successively the output of each optimization stage corresponds to the input of the next stage. This guarantees to check the $Pprod$ performance every two hours until the final process time ($t = 20h$).

## Dynamic hybrid model

Since the optimization will be conducted through process simulation, it is used the dynamic hybrid model (DHM) for the nanobody-based antivenom (protein) production process proposed by Corrales *et al.* [12]. The model is referred to as dynamic because the estates are represented by differential equations based on the first principles mass balances Eq. (1)-(4), and hybrid due to the integration of machine learning algorithms to estimate kinetics that are not easier to establish, such as the specific productivity of the protein production Eq. (5)-(4).

$$\frac{dX}{dt} = r_X - X\frac{F_{in}}{V} \quad (1)$$

$$\frac{dS}{dt} = \frac{F_{in}}{V}S_{in} - r_S - S\frac{F_{in}}{V} \quad (2)$$

$$\frac{dP}{dt} = r_P \quad (3)$$

$$\frac{dV}{dt} = F_{in} \quad (4)$$

with $X$ and $S$ in $g/L$; $P$ in $mg/L$; $V$ in $L$; $F_{in}$ $(L/h)$ is the glucose feed flow rate, with $S_{in}(g/L)$ as the concentration of glucose; $r_X$ $(g/L/h)$; and $r_S$ $(g/L/h)$ the production rate of biomass and glucose, respectively.

The production rate of proteins $r_P(mg/L/h)$ is defined as Eq. (5).

$$r_P = \begin{cases} 0 & if\ there\ is\ not\ induction \\ q_P X & if\ there\ is\ an\ induction \end{cases} \quad (5)$$

$q_P$ $\left(mg_{protein}/g_{CDW}/h\right)$ intended for the specific productivity of the protein production, which was modeled using a Radial Basis Function (RBF) Support Vector Machine (SVM) learner. The SVM was trained with experimental data provided by in Alonso Villela *et al.* [11] as Eq. (6).

$$q_P = SVM_{Model}(\mu, T) \quad (6)$$

with $\mu\,(1/h)$ and $T(°C)$ as the specific growth rate and process temperature. The algorithm was trained using a 5-fold cross-validation using the optimized hyperparameters: $C = 0.4165$, $\varepsilon = 0.0329$, and $\sigma = 0.0825$.

# RL DEVELOPMENT

## Reinforcement learning training

Figure 2 shows the structure of the learning-based RL training. The actor and critic networks are initialized with random parameters to obtain an initial value of $F_{in}$. Similarly, the dynamic model is initialized using the final conditions of the fed-batch process ($X_0, S_0, P_0, V_0$).

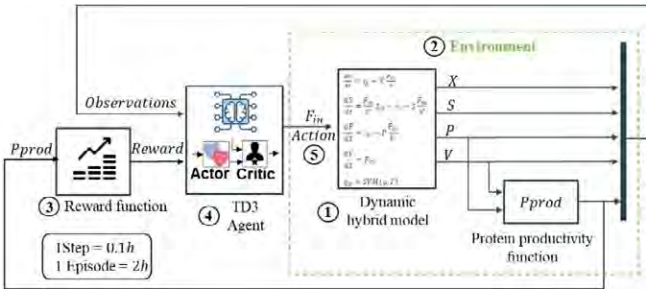

**Figure 2.** RL structure for protein productivity optimization. Numbers 1-5 in the Figure corresponds to the diagram workflow.

For each episode, *i.e.*, for the subsequent two hours of induction, the environment simulates a single fixed step (0.1h), the observations $(X, S, P, V + Pprod)$ are sent to the TD3 agent, and it is calculated the reward ($Reward$). Finally, the agent policy (actor-critic interaction) is updated and the new action (optimal $F_{in}$), subject to $0.001 \leq F_{in} \leq 0.020\ L/h$ and $1.5 \leq V \leq 5.0\ L$, is computed and sent back to the environment. This process is repeated until the maximum number of episodes is reached (max number of episodes=1000). An additionally restriction is imposed to the agent in case of achieve a physical constraint $1.5 \leq V \leq 5.0\ L$.

The workflow is summarized as follows [7]:

1. Initialize the environment $(X_0, S_0, P_0, V_0)$

**While** stop criterion not satisfied (max number of episodes):

  **for** each step in an episode:

2. Simulate the environment for a single step (0.1h)
3. Provide the observations $(X, S, P, V + Pprod)$ to the TD3 agent and calculate the reward ($Reward$)
4. Perform the policy iteration (actor-critic interaction)
5. Provide action to the environment ($F_{in}$)

  **end for**

**end while**

## Environment

In learning-based control, the DHM and the computation of $Pprod$ are considered the environment (representation of the process).

## Agent

The actor-critic Twin-Delayed Deep Deterministic (TD3) Policy Gradient Agent was used due to the continuous action-space property of the environment, and NN's were used as function approximators for the actor and

critic. The critic NN presented an Observation/Action path comprising three layers with 64/32/32 nodes per layer and 2 ReLU activation functions. The actor NN presented an Observation patch consisting of one layer with 32 nodes and a Tanh activation function. The training options are reported in Table 1.

**Table 1:** Training options for the TD3 RL agent.

| | |
|---|---|
| Optimizer | Adam |
| Max Episode Number | 1000 |
| Simulation time ($h$) | 2 |
| Agent sample time (h) | 0.1 |
| Episode Steps | 20 |
| Total Agent Steps | 20000 |
| Experience Buffer Length | $1\times10^{6}$ |
| Mini batch size | 100 |
| Standard deviation | 0.3 |
| Standard deviation decay rate | $1\times10^{-5}$ |
| TargetSmoothFactor | $1\times10^{-3}$ |
| DiscountFactor | 0.9 |
| LearnRate | Critic= $1\times10^{-3}$; Actor= $1\times10^{-4}$ |
| GradientThreshold | Critic= Actor= 1.0 |
| Total Agent Steps | 20000 |

## Reward Function

The TD3 RL agent learns the optimal policies by maximizing the reward function. In this case it corresponds to the final value of $Pprod$, which is calculated as in Eq (7)

## Model Predictive Control

The results of the learning-based control approach were compared with a model-based control approach in terms of an MPC; the open loop optimization problem is represented in Eq. (7).

$$\max_{\{F_{in}\}} (Pprod = P \cdot V/t) \tag{7}$$

$$Subject\ to \begin{cases} Equations\ 1-4 \\ 0.001 \le F_{in} \le 0.020\ L/h \\ 1.5 \le V \le 5.0\ L \end{cases} \tag{8}$$

To maintain conditions similar to the RL approach, in the MPC, the goal was to optimize the $Pprod$ every $2\ h$ with a prediction horizon of $2\ h$ as a manipulated variable the $F_{in}$ and subject to the constraints of Eq. (8). In this work, the time step (solver step) of the DHM was fixed at $0.1h$ to allow the comparison between the two approaches.

# RESULTS AND DISCUSSION

All simulations were run using a 13th Gen Intel® Core(TM) i7-13800H 2.50 GHz, 32 GB RAM computer. The *fmincon* function from MATLAB® was used to obtain optimal feed flow rate performance to develop the MPC control. The TD3 RL agent from the reinforcement learning toolbox from MATLAB® was used to develop the RF.

## RL training results

Figure 3 shows the results of the training using the TD3 RL agent. In the optimization stage "a" (Figure 3a), the episode reward ($Ep\ rew$) and the average reward ($Av\ rew$) started at approximately 0.13 until episode 280, where it converged to 0.14. In the following stages, the $Ep\ rew$ and $Av\ rew$ increased to 0.45 (stage b), 0.78 (stage c), 1.10 (stage d), 1.36 (stage e), and 1.57 (stage f). This is expected since $Pprod$ depends on protein concentration and process time, increasing $Av\ rew$. The average rewards showing the highest variability occurred in stage "a", while the other stages stabilized during the first episodes. This is due to the learning limitation given by the nature of the optimization; each starting point depends on the previous output conditions. A statistical evaluation ($Ev\ Stat$) was performed with a frequency of 100 episodes considering a number of 50 episodes. In all optimization stages, the $Ev\ Stat$ (red squares in Figure 3) fits with the average reward, indicating that the agent's training is appropriately done.

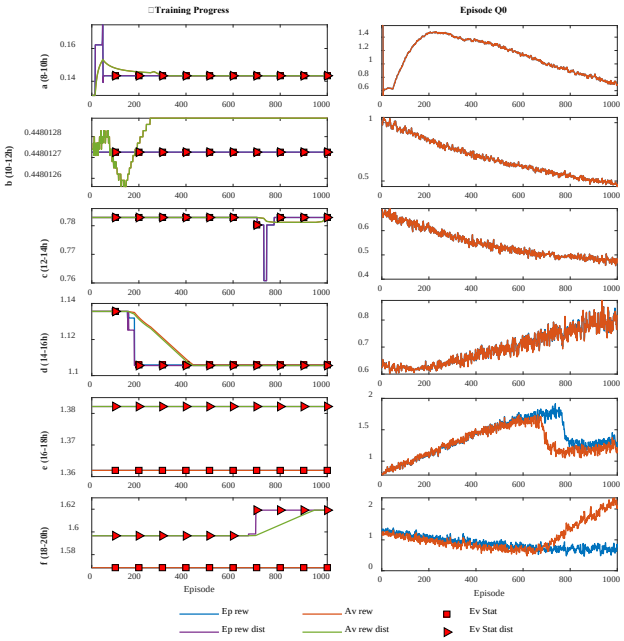

**Figure 3**. RL training progresses every 2 hours at the induction stage. The episode reward (Ep rew), Average reward (Av rew), and Statistical evaluation (Ev Stat). The variables with temperature disturbances are indicated as dist.

## RL and MPC test

Figure 4 displays the results of evaluating the MPC and RL optimizations. It is observed how the dynamics of variables $S$, $X$, and $V$ changes over the bath, fed-batch, and induction phases. Additionally, it is displayed the

optimized $F_{in}$ and the $Pprop$ respond to these actions. Temperature disturbance at induction phase is presented to relate it with the pair $F_{in}$ action – $Pprod$ response.

The dynamic variables $S$, $X$, $V$, and $P$ presents different behaviors with both approaches. Table 2 summarizes the main results. The RL approach suggests maintaining a $F_{in} = 0.02\ L/h$ in the optimization stages "a"-"c" and then changing to $F_{in} = 0.001$ L/h in optimization stages "d"-"f". In contrast, the MPC approach suggests maintaining a $F_{in} = 0.02\ L/h$ in stages "a", "d"- "f", and reducing to $F_{in} = 0.0014$ L/h and $F_{in} = 0.019\ L/h$ in stages "b" and "c", respectively. Those changes represent a $Pprod$ difference between the MPC and RL of $0.016 mg/h$, $0.009 mg/h$, $0.006 mg/h$, $0.009 mg/h$, and $0.012 mg/h$ thought stages "b", "c", "d", "e", and "f" (see Table 2).

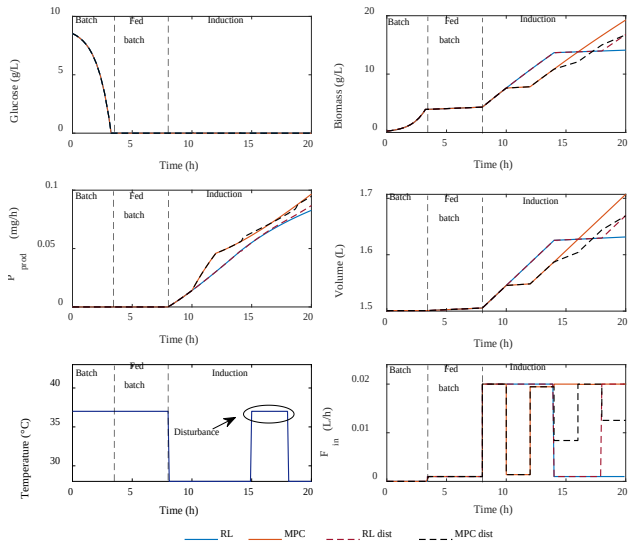

**Figure 4.** Dynamic behavior results with the MPC and TD3 RL at induction temperatures of 28°C. States: Glucose $(S)$, Biomass $(X)$, Protein $(P)$, and Volume $(V)$; Manipulated variable: glucose feed flow rate $(F_{in})$; Optimized variable: protein productivity $(Pprod)$.

Given the variability in the results obtained from both approaches, the protein yield $(Pyield)$ was calculated at the end of each optimization stage, Eq. (9). The $Pyield$ accounts for the relation between the protein produced and the quantity of substrate added in each optimization step.

$$Pyield = \frac{P \cdot V - P_0 \cdot V_0}{Glu_0 \cdot V_0 + Glu_{in} \cdot F_{in} \cdot t_{induction}} \quad (9)$$

$P_0$, $Glu_0$, and $V_0$ refers to the protein and glucose concentrations, and volume at the beginning of each optimization stage. $t_{induction}$ is the duration of the optimization stage.

The RL shows the highest $Pyield$ increase from stage "c" to "f" (Table 2), which indicates that the $F_{in}$ profile exhibited with the RL approach could be a better alternative to optimize the protein production, *i.e.*, the optimal control policy the training of the TD3 agent and the use of the DHM as environment permits to find the optimal $F_{in}$ actions to maximize the $Pprod$. In summary, it can be concluded that although MPC achieves higher $Pprod$ than RL, it requires significantly more $F_{in}$. RL can achieve competitive $Pprod$ with MPC while using less $F_{in}$.

**Table 2:** Optimization results with MPC and RL approaches.

| Stage | $Fin$ $(L/h)$ | $Pprod$ $(mg/h)$ | $Pyield$ $(mg/g)$ | Average optimization time (s)* |

*Without (first line) and with (second line) temperature disturbance. ⁺It corresponds to the difference MPC $Pprod$-RL $Pprod$.

## Temperature Disturbance analysis

A temperature disturbance is simulated between 15 and $18h$, *i.e.*, the temperature increased from 28 to 37°C between the optimization stages "d" and "e" (see temperature in Figure 4). Figure 3 displays the training results for optimization stages "a" to "d". The $Ep\ rew$ and $Av\ rew$ were the same as the process without disturbances. In the optimization stages "e"-"f", the $Ep\ rew$ and $Av\ rew$ differ, which is related to the citric episode $Q0$. This means the critic expected different cumulative $Q0$ values for

each step episode with and without temperature disturbance. Figure 4 presents the behavior of dynamic variables considering the temperature disturbances. Until $14h$, both control approaches followed the same behavior, with and without disturbance.

The RL follows the same behavior with and without temperature disturbance. In the subsequent optimization stages, both approaches optimized $F_{in}$ to maintain the $Pprod$ differences $< 0.016mg/h$, *e.g.*, the RL approach suggest to change $F_{in}$ from $0.001L/h$ to $0.02L/h$ in the last optimization stage "f" to maintain similar productivities with and without temperature disturbances. This implies that the optimal control policy can adapt the control actions (optimal $F_{in}$), including temperature disturbances. Although the MPC approach presented the lowest average optimization time (see Table 2) concerning the RL approach, the latest is preferred due to its performance.

## CONCLUSIONS

Model Predictive Control and Reinforcement Learning approaches were explored to optimize protein production in *E. coli*. The optimization was evaluated by stages of two hours to check the protein productivity performance at the induction phase. Protein productivity values of $0.091mg/h$ and $0.079mg/h$ were reached with the MPC and RL approaches after $20h$ of process. Nevertheless, the latest exhibited the highest $Pyield$ increase through the optimization stages "c" to "f", indicating that this approach produces a higher quantity of protein per hour by applying a lower $F_{in}$ concerning the MPC approach. The results suggest that the RL approach yields an optimal control policy by interacting with the environment (dynamic hybrid model) and can adapt the control action during the optimization process, accounting for temperature disturbances. In future work, rewards that include protein productivity and yield can be studied, enabling a better understanding of the process. Additionally, the integration of two Critic NNs in the training of the TD3 agent can be applied, allowing for enhanced process optimization through the learning-based strategy.

## ABSTRACT

Safe Bayesian Optimization (Safe BO) has demonstrated significant promise in enhancing data-driven optimization strategies in safety-critical settings, where model discrepancies, noisy measurements, and unknown safety constraints are prevalent. Despite these advancements, there still remains a limited understanding on the effectiveness and applicability of these Safe BO methods, particularly within process system engineering. Specifically, this study adapts and examines Safe Exploration for Optimization with Gaussian Processes (**SafeOpt**), Goal-oriented Safe Exploration (**GoOSE**), Gaussian Processes with Trust Region (**GPs-TR**) and Adversarially Robust Gaussian Processes (**StableOpt**). Methods such as **SafeOpt** and **GoOSE** face challenges in managing continuous systems due to their reliance on system discretization and together with **StableOpt**, lack the capability to manage multiple safety constraints. Thus, this work presents a comprehensive evaluation of state-of-the-art safe BO methods, with our own addition and enhancements, focusing on their performance in process system engineering. The performances of methods are assessed using a case study on the William Otto Reactor, focusing on convergence speed, unknown constraints mitigations, practicality, and robustness against adversarial perturbations. Overall, this study underscores the unique strengths and limitations of safe BO methods in process system engineering, advancing the field on data-driven approaches in safety-critical processes while also identifies areas where further improvements are necessary.

**Keywords**: Safe Bayesian Optimization, Data-Driven Optimization, Model Uncertainty

## INTRODUCTION

In the realm of Process Systems Engineering (PSE), performing optimization under safety-critical settings is paramount for enhancing process operational safety and efficiency [1]. Conventional optimization methods typically rely on detailed mathematical models of the system and the availability of derivative information for both objective function and constraints. However, developing precise models are frequently hindered by complexity of the process and computational burdens which leads to inherent model discrepancies. These challenges often result in treating objective and constraint functions as black-box functions without available derivative information.

To address these challenges, data-driven and derivative-free optimization methods have emerged as viable alternatives for handling black-box functions [2]. These methods include both direct and model-based methods, with model-based methods showing promise in presence of safe-critical constraints.

Among these, Bayesian Optimization (BO) has emerged as a powerful model-based approach for optimizing expensive black-box functions, particularly in presence of uncertainty and unknown safe constraints [3-6]. BO generally employs Gaussian Process (GP) as a probabilistic surrogate model to guide acquisition function and balance exploration and exploitation. Despite the successes of classical BO, ensuring safe exploration in the presence of unknown constraints remain a significant challenge. Consequently, various approaches have been proposed as safe BO methods, specifically designed to address the challenges inherent in safety-critical applications [7-10].

However, the current literature reveals a substantial gap in our understanding of how safe BO methods perform in complex process systems. Many existing approaches rely on system discretization and incapability to manage multiple safety constraints. These restrictions hinder the practical applicability in PSE.

Thus, in this paper, we bridge these gaps by providing an integrated review of the state-of-the-art safe BO methods alongside our own enhancements. Specifically, we introduce modifications to **SafeOpt**, **GoOSE**, and **StableOpt** to overcome discretization issues and improve their capability to manage multiple constraints, in addition to evaluating the algorithms including **GPs-TR**. Through a case study on the William Otto Reactor, we compare these methods in terms of conversion speed, unknown constraints management, practicality, and robustness against adversarial perturbations.

By combining a critical literature review with methodology advancements, our work aims to advance data-driven approaches in safety-critical process systems while highlighting areas for future improvements.

# PRELIMINARIES

## Problem Setup

Consider the constrained optimization problem defined by an unknown but measurable objective function $f : \mathcal{D} \subseteq \mathbb{R}^p \to \mathbb{R}$ and a set of unknown but measurable constraint functions $g_i : \mathcal{D} \subseteq \mathbb{R}^p \to \mathbb{R},$, where the goal is to:

$$\min_{\boldsymbol{x}\in\mathcal{D}} f(\boldsymbol{x}) \quad s.t.\, g_i(\boldsymbol{x}) \geq 0, \forall i \in \mathcal{I}_g \tag{1}$$

At iteration $t$, we query $f$ at a single input $\boldsymbol{x}_t \in \mathcal{D}$ and observe noisy samples $y_{f,t} = f(\boldsymbol{x}_t) + \epsilon_t$ and $y_{i,t} = g_i(\boldsymbol{x}_t) + \epsilon_{t,i}, \forall i \in \mathcal{I}_g$, where $\epsilon_t \sim \mathcal{N}(0, \sigma_\epsilon^2)$. **SafeOpt**, **GoOSE**, and **GPs-TR**, follow this problem setup, but **StableOpt**, on the other hand, extends the formulation by incorporating perturbation variable, which will be elaborated in Section 3.4.

## Introduction to Gaussian Processes

Gaussian Processes (GPs) are widely used in non-parametric Bayesian regression to model distributions over functions. GP is parameterized by a prior mean function $m_t(x)$ and a covariance function $k(\boldsymbol{x}, \boldsymbol{x}')$ as

$$f(\boldsymbol{x}) \sim \mathcal{GP}(\mathrm{m}(\boldsymbol{x}), \mathrm{k}(\boldsymbol{x}, \boldsymbol{x}')) \tag{2}$$

If we have $t$ previous observations of the objective $y_t = [y_1, \ldots, y_t]^T$ at inputs $\boldsymbol{X}_t = [x_1, \ldots, x_t]$ with the measurements being noisy as $y_t = f(\boldsymbol{x}_t) + \epsilon_t$ where $\epsilon_t \sim \mathcal{N}(0, \sigma_\epsilon^2)$, the posterior distributions are given by the mean $\mu_t$ and variance $\sigma_t^2$

$$\mu_t(\boldsymbol{x}) = \mathbf{k}_t^T(\boldsymbol{x})(\mathbf{K}_t + \sigma_\epsilon^2 \mathbf{I})^{-1}\mathbf{y}_t \tag{3}$$

$$\sigma_t^2(\boldsymbol{x}) = k(\boldsymbol{x}, \boldsymbol{x}') - \mathbf{k}_t^T(\boldsymbol{x})(\mathbf{K}_t + \sigma_\epsilon^2 \mathbf{I})^{-1}\mathbf{k}_t(\boldsymbol{x}') \tag{4}$$

where $\mathbf{k}_t(\boldsymbol{x}) = \left(k(\boldsymbol{x}_1, \boldsymbol{x}), \ldots, k(\boldsymbol{x}_t, \boldsymbol{x})\right)^T$ is a vector of covariances between input $\boldsymbol{x}$ and observed points $\boldsymbol{X}_t$, $\mathbf{K}_t$ is the positive definite kernel matrix $[\boldsymbol{K}_t]_{ij} = k(x_i, x_j)$ for all $i, j \in \{1, \ldots, t\}$, and $\mathbf{I} \in \mathbb{R}^{t\times t}$ denotes the identity matrix. In Bayesian Optimization, GP serve as a surrogate model for the objective and constraint functions, enabling the construction of acquisition functions $\mathcal{A}(\boldsymbol{x})$. A common choices for an acquisition function are Lower Confidence Bound (LCB), $l_t(\boldsymbol{x}) = \mu_{t-1}(\boldsymbol{x}) - \beta_t \sigma_{t-1}(\boldsymbol{x})$, and Expected Improvement, $EI(\boldsymbol{x}) = E[\max(0, f_{best} - f(\boldsymbol{x}))]$. $\beta_t$ represents a confidence level that balances the trade-off between exploration and exploitation when selecting the next query point using acquisition function. In this work, we primarily employ LCB as the acquisition function as shown in Equations (6), (7), (9), (12), (13) etc. Nonetheless, other acquisition functions are compatible to be used. Also, LCB is used to adopt a conservative approach on safety constraint predictions in this study for safe explorations as:

$$S = \{\boldsymbol{x} \in \mathcal{D} \,|\forall i \in \mathcal{I}_g : l_{i,t}(\boldsymbol{x}) \geq 0\} \tag{5}$$

# METHODOLOGY

## Safe Exploration for Optimization with Gaussian Processes (SafeOpt)

**SafeOpt**, first introduced by Sui et al. (2015) [7], is a Bayesian optimization algorithm tailored for safe exploration in constrained optimization problems. In each iteration, **SafeOpt** partitions the safe set $S_t$ into two subsets: a minimizer set within safe region that are likely to be minimal and an expander set that are likely to expand the safe set when observed, based on Lipschitz continuity. For each iteration, **SafeOpt** queries the most uncertain point of the objective function within the two subsets, where uncertainty is quantified as $w_t(x) = u_{f,t}(\boldsymbol{x}) - l_{f,t}(\boldsymbol{x})$. By querying the most uncertain point in minimizer, we gain a more accurate understanding of the minimal point within the safe set; by querying the most uncertain point in the expander, we expand the safe set and thus better characterizes its safe boundaries. The original **SafeOpt** algorithm relied on domain discretization, which is computationally prohibitive for large or high-dimensional domains. We address this limitation by modifying the algorithms to operate in continuous domain.

For each iteration, **SafeOpt** queries minimal points for each subset. The most uncertain point in the minimizer set is selected as:

$$\boldsymbol{x}_{M,t+1}^* \in \operatorname*{argmax}_{\boldsymbol{x}\in S_t} w_t(\boldsymbol{x}) \quad s.t\ l_{f,t}(\boldsymbol{x}) \leq \min_{\boldsymbol{z}\in S_t} u_{f,t}(\boldsymbol{z}) \tag{6}$$

The expander set focuses on expanding the boundaries of the safe region by leveraging Lipschitz continuity. This is achieved by identifying pairs of points $x$ (in the

safe set) and $z$ (in the unsafe set) such that Lipschitz $u_i(\boldsymbol{x}) - L_i \cdot d(\boldsymbol{x}, \boldsymbol{z}) \geq 0,\ \forall i \in \mathcal{I}_g$ is satisfied where $L_i$ is the Lipchitz constant for the $i$-th constraint, and $d$ represents distance function. Thus, the most uncertain point in the expander set is selected as:

$$\boldsymbol{x}^*_{G,t+1} \in \underset{\boldsymbol{x}\in S_t,\ \boldsymbol{z}\in D\setminus S_t}{\operatorname{argmax}}\ w_t(\boldsymbol{x}) \tag{7}$$

$$s.t\ u_{i,t}(\boldsymbol{x}) - \max \left|\left|\nabla\mu_{i,t}\right|\right|_\infty \cdot d(\boldsymbol{x}, \boldsymbol{z}) \geq 0, \qquad \exists i \in \mathcal{I}_g$$

Here, Lipchitz constant $L_i$ is replaced with $L_i \approx \max \left|\left|\nabla\mu_{i,t}\right|\right|_\infty$ as $L_i$ is assumed to be unknown.

**SafeOpt** selects the next query point $x^*_{t+1}$ by choosing the most uncertain point from both the minimizer and the expander sets as:

$$\boldsymbol{x}^*_{t+1} \in \arg\max(w_t(\boldsymbol{x}^*_{M,t+1}), w_t(\boldsymbol{x}^*_{G,t+1})) \tag{8}$$

This process ensures an efficient trade-off between refining the objective function in known safe regions and expanding the safe for further explorations.

## Goal Oriented Safe Exploration (GoOSE)

**GoOSE**, introduced by Turchetta et al. (2019) [8], enhances the safe exploration capabilities using an oracle during safe set expansion. **GoOSE** partitions the safe set into two subsets: pessimistic safe set and optimistic safe set. The pessimistic safe set corresponds to conventionally defined safe set in equation (2), while the optimistic safe set comprises points outside of the safe region, but that are likely to become safe based on Lipchitz continuity. During exploration, the objective function is set as LCB which encourages more exploration in finding the minimal point. The original **GoOSE** algorithm was formulated for discretized domains and single constraints. Our modifications extend **GoOSE** to operate over continuous domains and handle multiple constraints, analogous to our enhancements to **SafeOpt**.

For each iteration, **GoOSE** queries minimal points from each subset. The minimal point in pessimistic safe set is selected as:

$$\boldsymbol{x}^*_{P,t+1} \in \underset{\boldsymbol{x}\in S_t}{\operatorname{argmin}}\ \mathcal{A}_{f,t}(\boldsymbol{x}) \tag{9}$$

At optimistic set, **GoOSE** focuses on finding minimal point (oracle) by leveraging Lipschitz continuity similarly to **SafeOpt**. This involves identifying pairs of points $x$ (in the safe set) and $z$ (in the unsafe set) but focuses on finding the minimal point of $z$ rather than the most uncertain point in $x$, as **SafeOpt** does. Hence, the minimal point in in optimistic safe set is selected as:

$$\boldsymbol{z}^*_{O,t+1} \in \underset{\boldsymbol{z}\in D\setminus S_t,\ \boldsymbol{x}\in S_t}{\operatorname{argmin}}\ \mathcal{A}_{f,t}(\boldsymbol{z}) \tag{10}$$

$$s.t\ \mathrm{u}_{i,t}(\boldsymbol{x}) - max \left|\left|\nabla\mu_{i,t}\right|\right|_\infty \cdot d(\boldsymbol{x}, \boldsymbol{z}) \geq 0\ \exists i \in \mathcal{I}_g$$

Once the optimal points from both sets are determined, **GoOSE** compares them. If $\boldsymbol{x}^*_{P,t+1}$ has lower $l_{f,t}$, it is directly queried for exploration. If the point from the optimistic safe set ($\boldsymbol{z}^*_{O,t+1}$) is more promising, **GoOSE** queries the nearest points in the pessimistic safe set:

$$\boldsymbol{x}^*_{t+1} \in \underset{\boldsymbol{x}\in S_t}{\operatorname{argmin}}\ d\left(\boldsymbol{x}, \boldsymbol{z}^*_{O,t+1}\right) \tag{11}$$

## Gaussian Processes with Trust Region (GPs-TR)

**GPs-TR**, introduced by del Rio Chanona et al. (2019) [9], is a derivative-free optimization method designed to ensure robust and efficient exploration. As its core, **GPs-TR** restricts the search domain at each iteration to a trust region, where the prediction of the objective function and the constraints are considered to be reliable. The step $d_{t+1}$ is determined as follows:

$$\boldsymbol{d}_{t+1} \in \underset{\boldsymbol{d}\in\mathbb{R}^{\mathrm{p}}}{\arg\min}\ \mathcal{A}_{f,t}(\boldsymbol{x} + \boldsymbol{d}) \tag{12}$$

$$s.t\ ||\boldsymbol{d}|| \leq \Delta_{\mathrm{t}},\ \ \boldsymbol{x} + \boldsymbol{d} \in S_t \tag{13}$$

where $\Delta^t$ denotes the trust-region radius. The size and center of the trust region are adaptively updated based on the accuracy ratio $\rho_{t+1}$, which evaluates the improvement of GPs predictions relative to the observed improvement.

$$\rho_{t+1} := \frac{y_{f,t+1} - y_{f,t}}{\mu_{f,t+1}(\boldsymbol{x}_t + \boldsymbol{d}_{t+1}) - \mu_{f,t}(\boldsymbol{x}_t)} \tag{14}$$

The update rules for the trust region are governed by predefined trust region parameters $(\eta_1, \eta_2, \gamma_{\mathrm{inc}}, \gamma_{\mathrm{red}}, \Delta_{max}, \Delta_{min})$. If $\rho_{t+1} > \eta_2$ and constraints are satisfied at point $(\boldsymbol{x}_t + \boldsymbol{d}_{t+1})$, then trust region radius is expanded $\Delta_{t+1} = \gamma_{\mathrm{inc}}\Delta_{\mathrm{t}}$ and the center is updated to $\boldsymbol{x}_t = \boldsymbol{x}_t + \boldsymbol{d}_{t+1}$. If $\rho_{t+1} < \eta_1$ or constraints are violated, then trust region radius is contracted $\Delta_{t+1} = \gamma_{\mathrm{red}}\Delta_{\mathrm{t}}$ and trust region center remains unchanged. If $\eta_1 < \rho_{t+1} < \eta_2$, then both the radius and the center remain unchanged. To prevent trust region radius being excessively enlarged or diminished, maximal and minimal trust-region radius $\Delta_{max}, \Delta_{min}$ are imposed.

## Adversarially Robust Gaussian Processes (StableOpt)

**StableOpt**, proposed by Bogunovic et al. (2019) [10], addresses the challenge of optimizing functions under adversarial perturbations. **StableOpt** ensures robustness in GP-based optimization by explicitly accounting for worst-case scenarios of objective function in the presence of input perturbations. **StableOpt** operates with a robust optimization problem within an input domain $\mathcal{D} \subseteq \mathbb{R}^{p_x}$, subject to perturbations $\delta \in \mathcal{U} \subseteq \mathbb{R}^{p_\delta}$, where $\mathcal{U} = \{\delta \mid d(\delta) \leq \Gamma\}$. Here, $d$ represents a distance function, and $\Gamma$ represents a predefined maximum allowable perturbation magnitude, determined based on prior knowledge.

The original **StableOpt** algorithm did not support

handling single or multiple constraints. To addres this limitation, we have enhanced the algorithm so it can manage multiple constraints under adversarial perturbations, factoring in worst-case scenarios for both the objective functions and the constraints.

Thus, **StableOpt** finds the minimal point by solving the following robust optimization problem.

$$\boldsymbol{x}^*_{t+1} \in \arg\min_{\boldsymbol{x}\in\mathcal{D}} \max_{\boldsymbol{\delta}\in\mathcal{U}} \mathcal{A}_{f,t}(\boldsymbol{x}+\boldsymbol{\delta}) \quad (15)$$

$$\text{s.t} \min_{\boldsymbol{\delta}\in\mathcal{U}} l_{i,t}\,(\boldsymbol{x}+\boldsymbol{\delta}) \geq 0,\ \forall i \in \mathcal{I}_g$$

The worst-case scenario for the objective function corresponds to the maximum value within $\mathcal{U}$, as the goal is to minimize the objective function. Conversely, the worst-case scenario for the constraints corresponds to the minimum value within $\mathcal{U}$, as the objective is to ensure the constraints remain satisfied, i.e., above zero. To achieve robustness, **StableOpt** iteratively identifies the optimal point ($\boldsymbol{x}^*_{t+1}$) and the corresponding worst-case perturbation $\boldsymbol{\delta}_{t+1}$ selected as:

$$\boldsymbol{\delta}_{t+1} \in \arg\max_{\boldsymbol{\delta}\in\mathcal{U}} \mathcal{A}_{f,t}(\boldsymbol{x}^*_{t+1}+\delta) \quad (16)$$

The point $\boldsymbol{x}^*_{t+1}$ is then queried with the perturbation $\delta_{t+1}$, ensuring that the robustness of the solution under the maximum adversarial perturbation.

## Prior Mean of Constraints

Typically, a prior means of Gaussian Processes (GPs) are set to zero. This approach, however, permits exploration of unknown regions that may potentially violate the constraints as the prior means being zero allow the GPs to satisfy constraints where $g \geq 0$. To mitigate this, the prior means of the GPs for constraints can be set to a negative value. The degree of conservatism one applies in setting an unexplored area as unsafe depends on the magnitude of the negative value. Overall, the negative prior means were set in all the algorithms except **StableOpt** in this work. If the prior means for the constraints are set below zero for **StableOpt**, the algorithm may interpret the negative prior mean as part of the worst-case scenario, potentially leading to the entire search space being considered unsafe and preventing any explorations.

# RESULTS AND DISCUSSION

The performance of the algorithms was tested on a

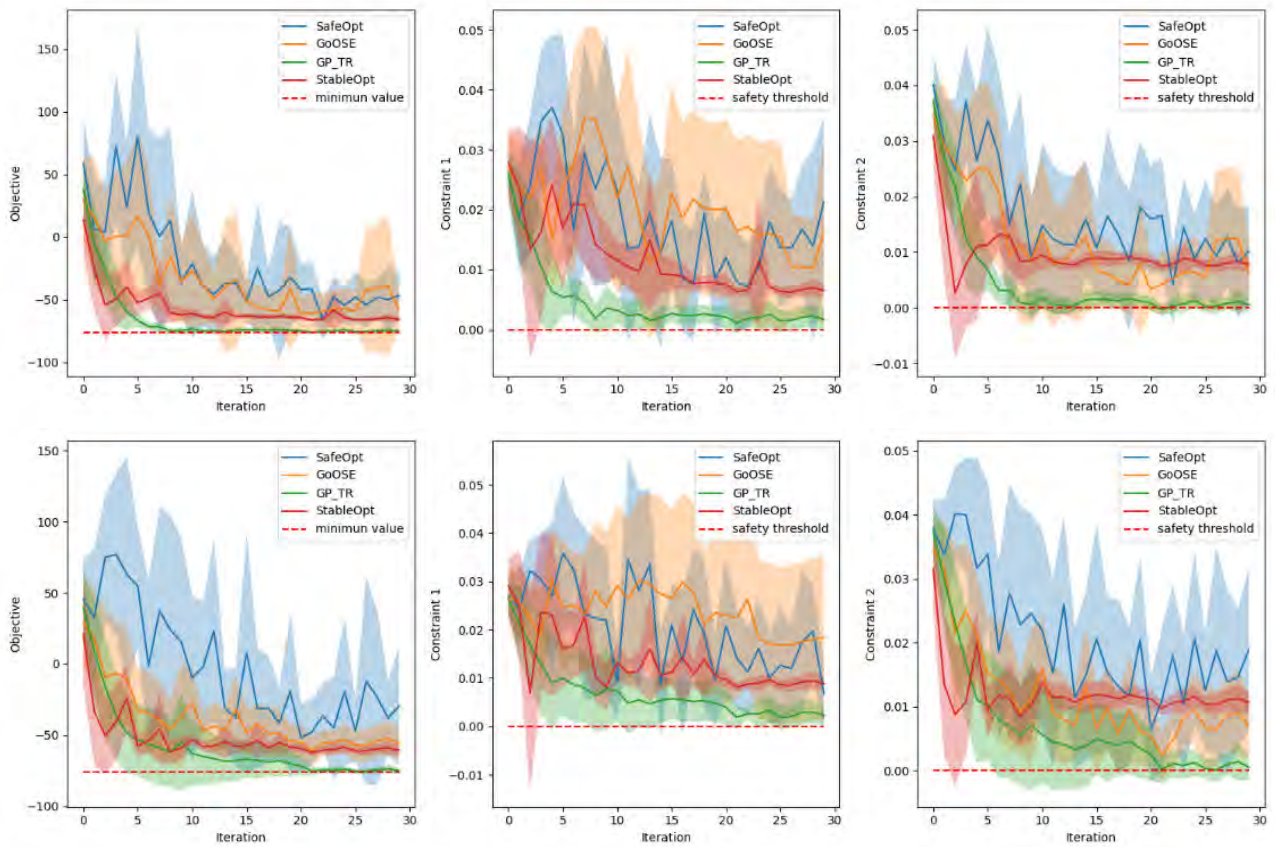

**Figure 1:** Average objective and two constraints under noise variance of inlet flowrate ($\sigma^2_{F_A}$) at (a) 0.005 and (b) 0.01

Williams Otto CSTR, which is frequently used to benchmark algorithms on process optimization. The objective is to minimize the economic cost by manipulating feed flowrate of component B, $F_B$, and the reactor temperature, $T_R$, with mass fraction of component $A$, $X_A$, and G, $X_G$, to be below 0.08 and 0.12. In this study we set two different scenarios where each has a Gaussian noise with variances $\sigma_{F_A}^2 = 0.005, 0.01$ exist as a perturbation in the feed flowrate of component A, $F_A$. In this case study, trust region parameters are set as $\eta_1 = 0.2, \eta_2 = 0.8, \gamma_{\text{inc}} = 1.2, \gamma_{\text{red}} = 0.8, \Delta_{max} = 1.5, \Delta_{min} = 0.1$. Confidence level is set as $\beta = 2$ for all algorithms. Also, differential evolution [11], a population-based stochastic optimization algorithm, has been used on all four algorithms while Sequential Least Squares Programming (SLSQP) [12] has been additionally used in **StableOpt** to find maximum and minimum value of objective function and constraints within $\delta \in \mathcal{U}$ to find the worst-case scenario. The objective (cost) of William Otto Reactor consistently declined towards minimal value across all algorithms.

**StableOpt** demonstrates a rapid and safe progress, approaching to an adversarially robust optimum value while not violating both constraints except during the early stages. Furthermore, its performance remains unaffected by varying levels of noise variance, which indicates a robustness to mitigate the effect of adversarial perturbations. This aligns with the findings of Paulson, Makrygiorgos, and Mesbah[13] where they demonstrated that ARBO(StableOpt) can significantly reduce constraint violations in a bioprocess while maintaining high product yields**.** Notable constraint violations at the early stages are attributed to the prior mean not being initialized below zero, allowing **StableOpt** to explore unsafe regions at the early phase.

**GPs-TR** emerges as the algorithm with fastest progress at smaller noise ($\sigma_{F_A}^2 = 0.005$) with slight violations on the constraints. However, the performance of the algorithm gets worse at the higher noise level ($\sigma_{F_A}^2 = 0.01$) where it exhibits significant variations and big violations of the constraints. These findings underscore the strengths and limitations of the trust region approach. While it enables accurate predictions within a reliable region and facilitates an efficient path toward optimal solutions, its vulnerability to noise is evident. Noise can introduce misleading values, causing the algorithm to temporarily stagnate in suboptimal regions due to restrictions imposed by the trust region. Additionally, the performance of **GPs-TR** is highly sensitive to the tuning of trust-region parameters, suggesting that optimized parameter settings could enhance its performance under higher noise conditions.

**SafeOpt** and **GoOSE** exhibit similar characteristics in the performances. They make slower progress with high fluctuations and variance on objective function and constraints. For **SafeOpt**, this variability arises from frequent alternations between selecting points between minimizer and expander. In contrast, **GoOSE** primarily selects points in the pessimistic safe set that are closest to the oracle within the optimistic safe set, but the oracles and the closest points are often varied for each simulation due to the noise in the system. Between the two, **GoOSE** typically converges faster by querying the points to minimize the objective function wheras SafeOpt selects the most uncertain point for its next query. This behaviour aligns with the findings of Turchetta et al.[8].

## CONCLUSION

This study introduces four Safe Bayesian Optimization algorithms, specifically tailored for applications in Process Systems Engineering. Our proposed modifications have successfully enabled these algorithms to handle multiple constraints and perform optimization within continuous systems. Their performance was demonstrated through the optimization of the William Otto Reactor, subject to perturbations in one of the flow rates. Among the algorithms, **StableOpt** exhibited notable robustness and rapid convergence, albeit with initial constraint violations attributed to its prior settings. **GPs-TR** outperformed others under low-noise conditions but showed vulnerability to higher noise levels. **SafeOpt** and **GoOSE** provided viable alternatives, though their persistent fluctuations and sensitivity to noise constrained their effectiveness. Given the significant dependence of algorithmic performance on problem characteristics, further studies are recommended across diverse applications in Process System Engineering. Additionally, future research should prioritize enhancements to **StableOpt**, focusing on mitigating early-stage constraint violations to improve its robustness in handling multiple constraints.

## ABSTRACT

Successful implementation of optimization-driven control techniques, such as model predictive control (MPC), is highly dependent on an accurate and detailed model of the process. As complexity in the system increases, linear approximation used in MPC may result in poor performance since a critical operating point is valid in only a small neighborhood of operation. To address this problem, this paper proposes a collaborative approach that combines linear and data-based models to predict state variables individually. The outputs of these models, along with constraints, are then incorporated into the MPC algorithm. For data-based process model, a multi-layered feedforward network is used. Additionally, the offset-free technique is applied to eliminate steady-state errors resulting from model-process mismatch. To demonstrate the results, a binary distillation column process which is multivariable and inherently nonlinear is chosen as testbed. We compare the performance of the proposed method to MPC using the full nonlinear model and also to single-model MPC methods for both the linear model and neural network model. We show that the proposed method is only slightly suboptimal with respect to the best available performance and greatly improves over individual methods. In addition, the computational load is reduced when compared to the full nonlinear MPC.

**Keywords**: Distillation column, Multiple Models, Model Predictive Control, Data-based Modeling

## INTRODUCTION

Distillation column process constitutes a reasonably proper benchmark for a designer aiming superior control which finds solution to strongly coupled nonlinear multi-input multi-output (MIMO) system that is prone to input disturbances [1,2]. MPC is among the leading methods that provide control solutions for the plants with aforementioned challenges [3-6]. Due to the increasing demand for performance and rising complexity of systems, classical model predictive control (MPC) techniques are often inadequate and new applications often requires some modifications in predictive control mechanism [7-9]. The modifications frequently include reformulation of optimal control in order to cope with system uncertainties, external perturbations and adverse effect of rapid changes in operating points [10]. As complexity in the system increases, successful implementation of this optimization-driven control technique is highly dependent on an accurate and detailed model of the process. However, the linear approximation at a critical point used in MPC may result in poor performance and remains valid in only a small neighborhood of operation. In such a case, nonlinear system model can be used for optimal control signal calculation but lack of reliable dynamic process model and high computational burden are major drawbacks in real time implementation of MPC schemes [11]. A multi model predictive controller (Multi-MPC) based on integration of linear system models may provide efficient control of nonlinear process with reduced computational complexity along with covering a large space of operating regions [12-15]. Alternatively, considering uncertainties in real-time operations, data-based models may complement linear approximation models for the prediction of MPC and enlarge the operational region of controller.

In this paper, we propose to employ multiple models that can describe the same process dynamics to a certain degree. In addition to the linear model, multi-layered feedforward network is used for data-based modeling

and constitutes an additional process model. A cost function formulation is proposed to enable both models to collaborate in predicting state variables individually, with their outputs and constraints incorporated into the MPC algorithm. The aim is to enhance efficiency and robustness in process control by compensating for the limitations of each individual model. Additionally, the offset-free technique is applied to eliminate steady-state errors resulting from model-process mismatch. To demonstrate the potential challenges addressed above, a binary distillation column process is chosen as testbed. The process is multivariable, inherently nonlinear and extremely sensitive to input uncertainty especially when LV configuration is selected [16]. We compare the performance of the proposed method to MPC using the full nonlinear model and also to single-model MPC methods for both the linear model and neural network model.

## PROCESS MODELING

A methanol-water binary distillation process schematic is depicted in Figure 1. Before giving the mathematical description of the system, the following assumptions are made:

- Heat losses are zero and temperature changes along the column are small.
- Constant liquid flow along the column.
- Liquid on every tray is well mixed.
- Each plate, which contains liquid and vapor leaving, is in equilibrium.
- There is no vapor holdup on trays.
- There is a constant liquid holdup on trays, reboiler, and condenser.
- The column operates at a constant pressure of 1 atm.
- Real liquid phase molar fraction equals the ideal liquid phase molar fraction, $x = x^*$.

Efficiency and vapor molar fractions are correlated with the following equation:

$$\eta_i = \frac{y_i - y_{i+1}}{y_i^* - y_{i+1}} \tag{1}$$

where $y_i$ is real concentration of vapor phase on $i$-th tray and $y^*$ is ideal concentration of vapor phase on $i$-th tray. The theoretical vapor and liquid molar fractions are correlated with the following empirical relation which is obtained by using a laboratory scale distillation column data:

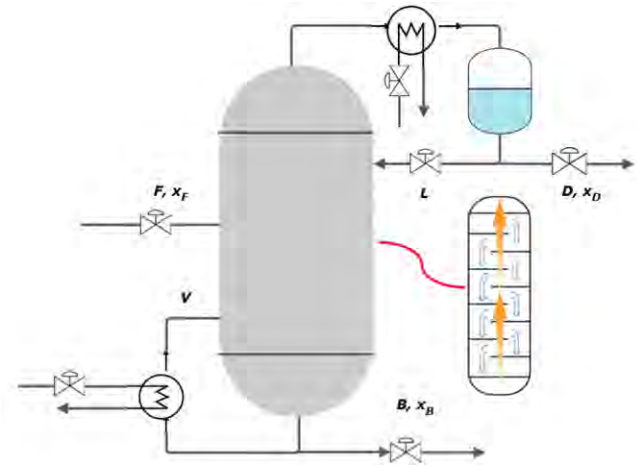

**Figure 1.** Distillation column schematic diagram.

$$y^* = -23.805x^6 + 82.142x^5 - 112.570x^4 + 78.529x^3 - 29.821x^2 + 6.524x + 0.003 \tag{2}$$

We consider 10 trays for the column, treating the condenser and reboiler as individual trays. Tray numbering starts from the top (tray 1) to the bottom (tray 10). The liquid mixture enters the column at tray 6. Considering mass balance for the entire column, the nonlinear state-space model is given by the following equations [17]:

$$\frac{dx_1}{dt} = -\frac{(D+L)}{N_1}x_1(t) + \frac{V}{N_1}y_2(t) \tag{3}$$

$$\frac{dx_i}{dt} = -\frac{L}{N_1}x_i(t) + \frac{L}{N_1}x_{i-1}(t) + \frac{V}{N_i}y_{i+1}(t) - \frac{V}{N_i}y_i(t), \quad i = 2,\dots,5 \tag{4}$$

$$\frac{dx_6}{dt} = -\frac{L+F}{N_6}x_6(t) + \frac{L}{N_6}x_5(t) + \frac{F}{N_6}x_F(t) + \frac{V}{N_6}y_7(t) - \frac{V}{N_6}y_6(t) \tag{5}$$

$$\frac{dx_i}{dt} = -\frac{L+F}{N_i}x_i(t) + \frac{L+F}{N_i}x_{i-1}(t) + \frac{V}{N_i}y_{i+1}(t) - \frac{V}{N_i}y_i(t), \quad i = 7,\dots,9 \tag{6}$$

$$\frac{dx_{10}}{dt} = -\frac{B}{N_{10}}x_{10}(t) + \frac{L+F}{N_{10}}x_9(t) - \frac{V}{N_{10}}y_{10}(t) \tag{7}$$

where $N_i$ is holdup in $i$-th tray, $x_F$ is the molar fraction of volatile component in feed, $F$ is the molar flow of feed, $D$ is the molar flow of distillate, $V$ is the molar flow of vapor, $L$ is the molar flow of reflux, $B$ is the molar flow of bottom, $x_i$ is the molar fraction of methanol in $i$-th tray in liquid phase, $x_i^*$ is the ideal molar fraction of methanol in $i$-th tray in liquid phase, $y_i$ is the molar fraction of methanol in $i$-th tray in vapor phase and $y_i^*$ is the ideal molar fraction of methanol in $i$-th tray in vapor phase. Table 1 shows the process parameters.

The above equations including theoretical vapor and liquid molar fractions correlation imply that high purity distillation process has strong nonlinearity and any realistic study should take this into account. It is important to start control design with properly selected manipulated variables for the system of concern due to the system

complexity. There are various control variable pairings in practice such as LV, LB, DV, and LD where LV configuration is the most commonly used in industrial practice and chooses liquid and vapor flows as manipulated variables. In this study we select LV configuration for the optimal control application.

**Table 1:** Distillation column operating parameters.

| Description | Variable | Unit | Value |
|---|---|---|---|
| Feed molar flow | $F$ | $\mathrm{kmolh}^{-1}$ | 0.300 |
| Vapor molar flow | $V$ | $\mathrm{kmolh}^{-1}$ | 0.264 |
| Reflux molar flow | $L$ | $\mathrm{kmolh}^{-1}$ | 0.104 |
| Distillate molar flow | $D$ | $\mathrm{kmolh}^{-1}$ | 0.160 |
| Feed molar fraction | $x_{\mathrm{F}}$ | - | 0.650 |
| Distillate molar fraction | $x_{\mathrm{D}}$ | - | 0.904 |
| Bottom molar fraction | $x_{\mathrm{B}}$ | - | 0.164 |
| Reboiler holdup | $N_{10}$ | kmol | 1 |
| Tray/condenser holdup | $N_i$ | kmol | 0.2 |
| Tray efficiency | $\eta_t$ | - | 0.8 |
| Reboiler efficiency | $\eta_b$ | - | 1 |

## Linear System Model

A linear state-space model is used as the first approximation of the distillation process. System state variables represent concentrations in liquid phase for each tray, $\boldsymbol{x} = (x_1, x_2, \dots, x_{10})^{\mathrm{T}}$, with initial conditions $x_i(0) = x_{i0}$ for $i = 1,2,\dots,10$. The concentrations of interest are distillate fraction $x_{\mathrm{D}} = x_1(t)$ and bottom product $x_{\mathrm{B}} = x_{10}(t)$ which are considered as outputs of the process to be controlled by manipulated variables reflux $L$ and boilup $V$. We assume that the process is in steady-state at $t = 0$ where we start the system from operating point such that $\boldsymbol{x}_{\mathrm{op}} = (x_1(0), x_2(0), \dots, x_{10}(0))^{\mathrm{T}}$ and $\boldsymbol{u}_{\mathrm{op}} = (u_1(0), u_2(0))^{\mathrm{T}} = (L(0), V(0))^{\mathrm{T}}$. Then, the process is linearized in the steady-state with the assumption of small the deviation from operating point in the form of $\boldsymbol{x}_{ss} = \boldsymbol{x}(t) - \boldsymbol{x}_{\mathrm{op}}$, $\boldsymbol{u}_{ss} = \boldsymbol{u}(t) - \boldsymbol{u}_{\mathrm{op}}$. The resulting multi-input multi-output (MIMO) state-space model in discrete time can be represented as follows:

$$\boldsymbol{x}_{ss}(k+1) = \boldsymbol{A}\boldsymbol{x}_{\mathrm{ss}}(k) + \boldsymbol{B}\boldsymbol{u}_{\mathrm{ss}}(k), \tag{8a}$$

$$\boldsymbol{y}_{ss}(k) = \boldsymbol{C}\boldsymbol{x}_{\mathrm{ss}}(k) + \boldsymbol{D}\boldsymbol{u}_{\mathrm{ss}}(k) \tag{8b}$$

## Neural Network Model

The second process model is created by acquiring system dynamics directly from data without using first principle models. A multi-layered feedforward neural network is used due to its effectiveness in process modeling and control. To construct data-driven model, datasets for training, testing, and validation are derived from a nonlinear simulation of a distillation process. Excitation signals are carefully designed to ensure the data encapsulates the system dynamic behavior across a wide range of operating conditions. Specifically, multilevel pseudorandom step (MLPRS) signals are applied to the manipulated variables with a sampling interval of 0.5 s. These signals feature varying frequencies and amplitudes, constrained within the operational limits of the manipulated variables (e.g., reflux flow L and vapor molar flow V), to excite the nonlinear dynamics sufficiently for accurate prediction and control. Since all system input/output variables change in range of (0, 1) preprocessing of raw data does not require scaling. The neural network (NN) model accepts current and previous values of system outputs plus current and previous values of manipulated variables as inputs and predicts two system outputs $\mathrm{x_D}$ and $\mathrm{x_B}$. The model has 8 inputs and gives one-step ahead prediction of 2 outputs. We can write the discrete input-output model of NN in the following form

$$\boldsymbol{y}(k+1) = \boldsymbol{f}_{\mathrm{nn}}(\boldsymbol{y}(k), \boldsymbol{y}(k+1), \boldsymbol{u}(k), \boldsymbol{u}(k-1)) \tag{9}$$

where $\boldsymbol{y}(k) = (x_{\mathrm{D}}(k), x_{\mathrm{B}}(k))^{\mathrm{T}}$ and $\boldsymbol{u}(k) = (L(k), V(k))^{\mathrm{T}}$. In the NN design we use tanh activation function for nodes in the hidden layer and a linear activation in output layer. The defined NN is trained by using Levenberg-Marquardt algorithm for error convergence between predicted and actual target values. The dataset is split into training (70%), validation (15%), and testing (15%) subsets, ensuring no overlap in operating conditions between splits. The final architecture (16-8-16-8) is selected based on the lowest validation mean squared error (MSE) and satisfactory performance on the test set, achieving MSE = $4.0 \times 10^{-7}$ for both outputs.

# MULTI-MODEL PREDICTIVE CONTROL

The control goal is to utilize linear system model and NN model to predict future states and maintain the system covering a broader space of operating points. Since the scenario is to use linear model in (8) and data-based model in (9) as MPC predictors, plant-model mismatch is likely to occur when a large deviation from operating point is started. In order to overcome this problem, the value of the state disturbance is estimated using the measurement of current process states and linear system states as follows [18]

$$\boldsymbol{d}_{\mathrm{ss}}(k) = \big(\boldsymbol{x}(k) - \boldsymbol{x}_{\mathrm{op}}\big) - (\boldsymbol{A}\boldsymbol{x}_{\mathrm{ss}}(k-1) + \boldsymbol{B}\boldsymbol{u}_{\mathrm{ss}}(k-1)) \tag{10}$$

Then the state and output predictions for linear MPC are calculated with the help of (10) and can be rewritten as

$$\boldsymbol{x}_{\mathrm{ss}}(k+i|k) = \boldsymbol{A}\boldsymbol{x}_{\boldsymbol{ss}}(k+i-1|k) + \boldsymbol{B}\boldsymbol{u}_{\mathrm{ss}}(k+i-1|k) + \boldsymbol{d}_{\mathrm{ss}}(k), \quad i = 1, \dots, p, \tag{11a}$$

$$\boldsymbol{y}_{\mathrm{ss}}(k+i|k) = (x_{\mathrm{ss,D}}(k+i|k), x_{\mathrm{ss,B}}(k+i|k))^{\mathrm{T}}, \quad i = 1, \dots, p. \tag{11b}$$

where $p$ is the length of the prediction horizon and the notation $\boldsymbol{x}_{\mathrm{ss}}(k+i|k)$ denotes variable x predicted for a

future sample $k+i$, but calculated at the current sample time $k$. The same mechanism for output disturbance estimation can be applied to the NN model. Off-set values between NN model outputs and actual process outputs are estimated with the following formulation

$$\boldsymbol{d}_{\mathrm{nn}}(k) = \boldsymbol{y}(k) - \boldsymbol{f}_{\mathrm{nn}}(\boldsymbol{y}(k-1), \boldsymbol{y}(k-2), \boldsymbol{u}(k-1), \boldsymbol{u}(k-2)) \quad (12)$$

Considering (12), the output predictions are then be calculated as follows

$$\boldsymbol{y}_{\mathrm{nn}}(k+i|k) = \boldsymbol{f}_{\mathrm{nn}}(\boldsymbol{y}_{\mathrm{nn}}(k+i-1|k), \boldsymbol{y}_{\mathrm{nn}}(k+i-2|k), \boldsymbol{u}\big((k+i-1|k)\big), \boldsymbol{u}\big((k+i-2|k)\big) + \boldsymbol{d}_{\mathrm{nn}}(k), \quad i = 1, \dots, p. \quad (13)$$

## Predictive Control Formulation

Control design aims to combine precision of each model over prediction horizon of MPC to obtain process outputs $\boldsymbol{y}(k+i|k) = (x_{\mathrm{D}}(k+i|k), x_{\mathrm{B}}(k+i|k))^{\mathrm{T}}$ using the calculated present and future control $\boldsymbol{u}(k+m-1|k) = L(k|k), \dots, L(k+m-1|k), V(k|k), \dots, V(k+m-1|k)^{\mathrm{T}}$ where $m$ is the control horizon. Subsequently, optimization problem for reference tracking with partial costs can be represented as

$$J_{\mathrm{ss}}(k) = \sum_{i=1}^{p} \boldsymbol{e}_{\mathrm{ss}}(k+i|k)^{\mathrm{T}} \boldsymbol{Q}_y \boldsymbol{e}_{\mathrm{ss}}(k+i|k) + \sum_{i=0}^{m-1} \boldsymbol{\Delta u}(k+i|k)^{\mathrm{T}} \boldsymbol{Q}_u \boldsymbol{\Delta u}(k+i|k) \quad (14a)$$

$$J_{\mathrm{nn}}(k) = \sum_{i=1}^{p} \boldsymbol{e}_{\mathrm{nn}}(k+i|k)^{\mathrm{T}} \boldsymbol{Q}_y \boldsymbol{e}_{\mathrm{nn}}(k+i|k) + \sum_{i=0}^{m-1} \boldsymbol{\Delta u}(k+i|k)^{\mathrm{T}} \boldsymbol{Q}_u \boldsymbol{\Delta u}(k+i|k) \quad (14b)$$

$$\text{s.t.} \quad \boldsymbol{e}_{\mathrm{ss}}(k+i|k) = \boldsymbol{y}_{\mathrm{ref}}(k+i|k) - \boldsymbol{y}_{\mathrm{ss}}(k+i|k) \quad (14c)$$

$$\boldsymbol{e}_{\mathrm{nn}}(k+i|k) = \boldsymbol{y}_{\mathrm{ref}}(k+i|k) - \boldsymbol{y}_{\mathrm{nn}}(k+i|k) \quad (14d)$$

$$\boldsymbol{y}_{\min} \le \boldsymbol{y}_{\mathrm{ss}}(k+i|k) \le \boldsymbol{y}_{\max}, \quad (14e)$$

$$\boldsymbol{y}_{\min} \le \boldsymbol{y}_{\mathrm{nn}}(k+i|k) \le \boldsymbol{y}_{\max}, \quad (14f)$$

$$\boldsymbol{u}_{\min} \le \boldsymbol{u}(k-1+i|k) \le \boldsymbol{u}_{\max}, \quad (14g)$$

$$i = 1, \dots . p,$$

where $\boldsymbol{y}_{\mathrm{ref}}(k+i|k)$ denotes the future reference, $\boldsymbol{Q}_y$ and $\boldsymbol{Q}_u$, are the penalizations on outputs and control increments, respectively. There are lower/upper constraints on the manipulated variables ($\boldsymbol{u}_{min}, \boldsymbol{u}_{max}$) and outputs ($\boldsymbol{y}_{min}, \boldsymbol{y}_{max}$). The state and output disturbance, $\boldsymbol{d}_{\mathrm{ss}}$ and $\boldsymbol{d}_{\mathrm{nn}}$, for each model plays a crucial role in multi-model MPC and the proposed control configuration uses weighted costs for optimization problem which is defined as:

$$\min_{\boldsymbol{u}(k)} \{\omega(k) J_{\mathrm{ss}}(k) + (1-\omega(k)) J_{\mathrm{nn}}(k)\}, \text{ s.t. (14)} \quad (15)$$

where $\omega(k)$ represents weighting parameter of performance functions at each sampling instant $k$, which depends on the values of modeling errors. Using the Euclidean norm for vectors of estimated off-set values of models, it can be calculated as follows:

$$\omega(k) = 1 - \frac{\|\boldsymbol{d}_{\mathrm{ss}}(k)\|}{\|\boldsymbol{d}_{\mathrm{ss}}(k)\| + \|\boldsymbol{d}_{\mathrm{ss}}(k)\|} \quad (16)$$

## RESULTS AND DISCUSSION

Nonlinear system simulations are conducted on a workstation equipped with an i7 10750H Intel 6-core CPU (base clock speed of 2.60 Ghz up to 4.8 GHz) and 16 GB of RAM. The simulations are performed in the MATLAB environment by utilizing ode15s solver with a relative tolerance of $1\,x\,10^{-6}$ and simulation step size of 0.5 s. The calculation of optimal control inputs for predictive control is performed using the `fmincon` function.

For MPC setup, all controllers run with $\boldsymbol{Q}_y = \mathrm{diag}(1,1)$ and $\boldsymbol{Q}_u = \mathrm{diag}(0.05,0.05)$, the prediction horizon and control horizon are set to $p = 10, m = 3$. The control inputs of the plant, $\boldsymbol{u}(k) = (L(k), V(k))^{\mathrm{T}}$ i.e, reflux liquid flow rate and vapor flow rate are constrained such that distillate flow rate must be kept in the interval of $0.01 < D < 0.200$ kmol/h as well as having the physical constraints. The controlled outputs $\boldsymbol{y}(k) = (x_{\mathrm{D}}(k), x_{\mathrm{B}}(k))^{\mathrm{T}}$ are constrained as well

$$\begin{bmatrix}0.01\\0.01\end{bmatrix} \le \boldsymbol{u}(k) \le \begin{bmatrix}0.3874\\0.5874\end{bmatrix}, \quad \begin{bmatrix}0.8973\\0.0600\end{bmatrix} \le \boldsymbol{y}(k) \le \begin{bmatrix}0.9663\\0.2261\end{bmatrix} \quad (17)$$

We also consider slack variables of outputs at constraints for SSMPC and NNMPC so as to ensure feasibility of the optimization problem in a case of unknown disturbances such that

$$\boldsymbol{y}_{\min} - \boldsymbol{\varepsilon}(i) \le \boldsymbol{y}_{\mathrm{ss}}(k+i|k) \le \boldsymbol{y}_{\max} + \boldsymbol{\varepsilon}(i) \quad (18a)$$

$$\boldsymbol{y}_{\min} - \boldsymbol{\varepsilon}(i) \le \boldsymbol{y}_{\mathrm{nn}}(k+i|k) \le \boldsymbol{y}_{\max} + \boldsymbol{\varepsilon}(i) \quad (18b)$$

where slack variable $\boldsymbol{\varepsilon}(i)$ is subject to the constraint $\boldsymbol{\varepsilon}(i) \ge 0$. Consequently, cost of optimization problem given in (14a) and (14b) is updated with slack variable as

$$J(k) = \sum_{i=1}^{p} \left[\boldsymbol{e}(k+i|k)^{\mathrm{T}} \boldsymbol{Q}_y \boldsymbol{e}(k+i|k) + \boldsymbol{\varepsilon}(i)^{\mathrm{T}} \boldsymbol{Q}_{\varepsilon} \boldsymbol{\varepsilon}(i)\right] + \sum_{i=0}^{m-1} \boldsymbol{\Delta u}(k+i|k)^{\mathrm{T}} \boldsymbol{Q}_u \boldsymbol{\Delta u}(k+i|k) \quad (19)$$

The penalization of new variable is set to $\boldsymbol{Q}_{\varepsilon} = \mathrm{diag}(0.5,0.5)$ for both NN-MPC and SS-MPC. The parameters listed in Table 1 are used to derive linear process model of distillation column. The operating point, for this steady state data, corresponds to a lower purity of compositions $x_{\mathrm{D}}$ and $x_{\mathrm{B}}$. Here, it is desired to drive the system to another operating point with high purity of top product, which implies that large perturbations from steady state are expected. Therefore, a linear state-space model may not be adequate to give sufficiently accurate predictions for MPC mechanism. It should be noted that the nonlinear process accepts $x_{\mathrm{F}}$ and $F$ as disturbance inputs in addition to manipulated variables $L$ and $V$ in the selected control setup, and they are assumed to be constant for all simulation scenarios. Simulations are started with an initial condition selected in the vicinity of steady-state data

which is used to linearize nonlinear column model. To evaluate the reference tracking performance of all controllers, the following four distinct step changes in the setpoints are applied to both outputs

$$\boldsymbol{y}_{\text{ref},1} = \begin{bmatrix} 0.928 \\ 0.190 \end{bmatrix}, \boldsymbol{y}_{\text{ref},2} = \begin{bmatrix} 0.897 \\ 0.226 \end{bmatrix}, \boldsymbol{y}_{\text{ref},3} = \begin{bmatrix} 0.941 \\ 0.126 \end{bmatrix}, \boldsymbol{y}_{\text{ref},4} = \begin{bmatrix} 0.966 \\ 0.060 \end{bmatrix}$$

A predictive control employing exact nonlinear process model, which is referred to as Nonlinear-MPC in this context, is selected as benchmark for time response performance evaluation. The optimization problem in (19) subject to the constraints given in (17) and (18) is also valid for Nonlinear-MPC case. Single-model approaches, including Nonlinear-MPC, NN-MPC, and SSMPC, are compared with Multi-MPC. Their reference tracking capabilities are demonstrated in Figure 2. It can be seen from the figure that both SS-MPC and NN-MPC approaches are prone to exhibit large overshoots especially when the plant is forced to run in a high purity point coinciding with output constraints. NN-MPC approach has slightly better time response whereas it generates more aggressive control inputs. On the other hand, controlled process using Multi-MPC formulations exhibits better reference tracking performance along with reduced control effort. Nonlinear-MPC, which is base control for simulations, exhibits the best performance among the controllers.

**Table 2:** Performance indicators of MPC methods

| Controller | $J$ (%) | Average CPU Time (sec) |
|---|---|---|
| NN-MPC | 107 | 4.802 |
| SS-MPC | 107 | 3.378 |
| Multi-MPC | 102 | 4.157 |
| Nonlinear-MPC | 100 | 5.106 |

For the purpose of better understanding of results, the performance of controllers are also evaluated by using closed-loop objective function with the following formulation

$$J = \sum_{i=1}^{N} \boldsymbol{e}(i)^{\mathrm{T}} \boldsymbol{Q}_x \boldsymbol{e}(i) + \Delta \boldsymbol{u}(i)^{\mathrm{T}} \boldsymbol{Q}_u \Delta \boldsymbol{u}(i) \qquad (20)$$

where $N$ is the number of sampling instants within the total simulation time. The closed-loop performance costs in Table 2 are normalized with respect to the benchmark Nonlinear-MPC. In the case of using approximate models as predictors, Multi-MPC achieves superior reference tracking for both process outputs while generating less aggressive control signals. It also performs better compared with SS-MPC and NN-MPC in terms of the performance cost. Multi-MPC requires slightly less computational effort compared to Nonlinear-MPC, as indicated by the average CPU time. Note that CPU time for SS-MPC was found using the default NLP solver and it would be significantly reduced using a QP solver.

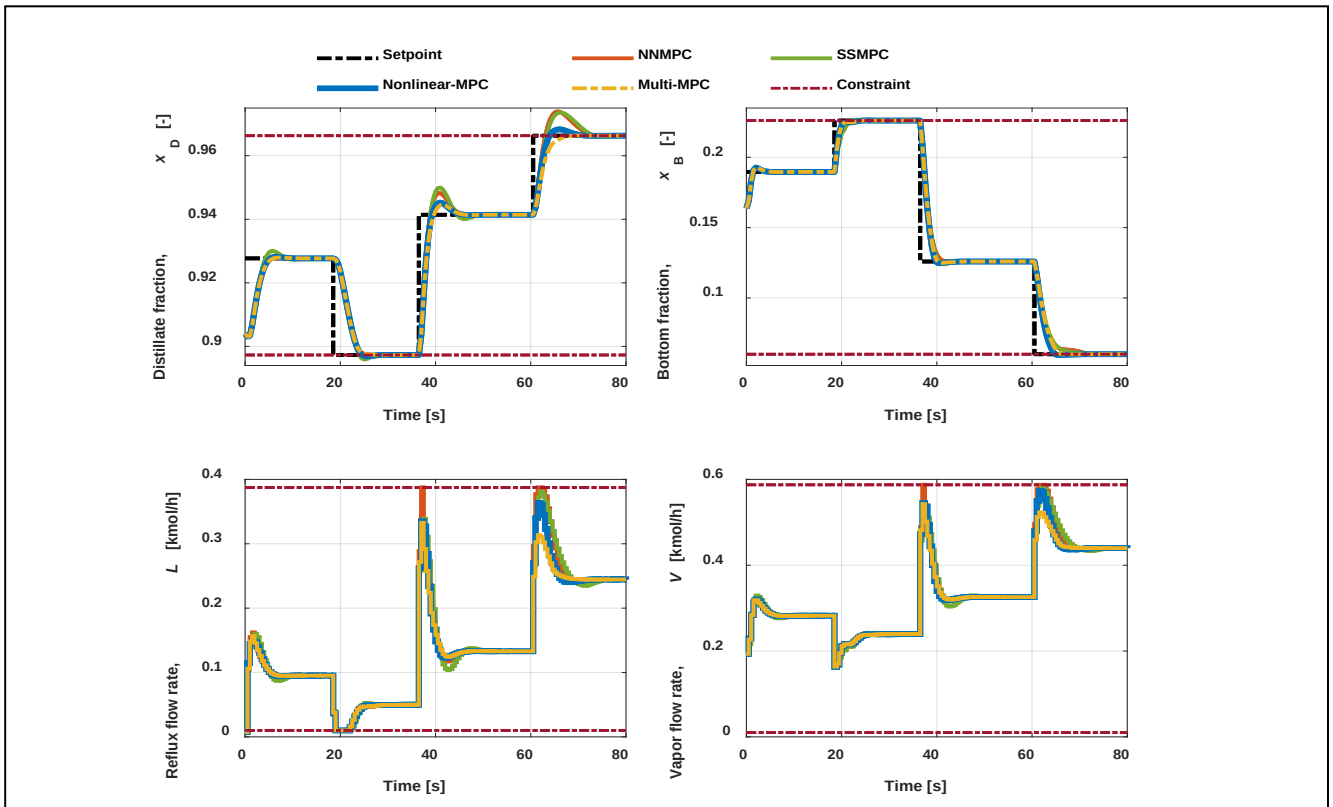

**Figure 2:** Setpoint tracking results of controlled system outputs (top two plots) and manipulated variables

## CONCLUSION

This study represents an implementation of multi-model predictive control to a distillation column process which constitutes a notably proper benchmark for multi-input interacting nonlinear MIMO systems. Time responses of both single-model and multi-model MPC formulations are demonstrated via computer simulations under various control scenarios including operational limits as well as input and output constraints. Running the system in a large space operating regions allows us to observe that multi-model MPC outperforms linear and data-based single model approaches. The results are validated with closed-loop performance cost values of all controllers. In addition, time response and performance indicators show that offset-free technique successfully eliminates steady state errors resulting from model-process mismatch for all control methods. The proposed multi-model MPC formulation demonstrates that collaboration of linear and data-based models might be an acceptable candidate instead of full nonlinear MPC with less computational time.

## ABSTRACT

Liquid-liquid extraction (LLX) is an essential technique for separating heat-sensitive, highly diluted, or azeotropic mixtures. However, the design and optimization of LLX processes can be challenging due to mass transfer limitations and complex fluid dynamics. While distillation can often be modeled using equilibrium-based (EQ-based) approaches with (constant) height equivalent to theoretical stage (HETS) values, these kinetic effects can limit the applicability of EQ-based LLX models for conceptual design. Non-equilibrium (NEQ) or rate-based modeling can account for detailed mass transfer and fluid dynamics but further increases the nonlinearity and complexity of the respective optimization problems, which should account for closed-loop solvent recovery. To successfully address these complexities, we propose an integrated methodology combining NEQ-based simulation with EQ-based superstructure optimization to design a hybrid extraction-distillation process. An NEQ model is first used to derive operation-dependent HETS correlations, which are then incorporated into an EQ-based superstructure model for techno-economic optimization targeting total annualized cost. This approach balances model fidelity and computational efficiency, providing more reliable solutions by capturing the solvent-specific mass transfer behavior. We illustrate the methodology for a dilute acetone-water system with different solvents.

**Keywords**: Hybrid Processes, Process Design, Superstructure Optimization

## INTRODUCTION

Liquid-liquid extraction (LLX) is a critical technique for separating mixtures that are sensitive to high temperatures, highly diluted, or exhibit azeotropic behavior [1]. The technique relies on the distribution of target components between two immiscible liquid phases, making it particularly effective when conventional distillation alone becomes impractical or even impossible. Despite its usefulness, LLX requires subsequent solvent recovery, which can be accomplished by distillation in many cases. As a result, hybrid extraction-distillation processes have emerged as a standard combination in the chemical and biochemical industries, integrating the strengths of both unit operations and offering potentially lower energy consumption and improved selectivity for challenging separations [2].

Despite its widespread industrial application, the design and optimization of LLX processes remain challenging, mainly due to the necessity of selecting a suitable solvent. In contrast to distillation, where equilibrium-based (EQ-based) models with constant values for the height equivalent to a theoretical stage (HETS) are mostly considered sufficient to yield accurate results, LLX is significantly affected by kinetic phenomena, e.g., fluid dynamics, due to the much lower density difference between the phases compared to vapor-liquid equilibria in distillation, and mass transfer limitations [3]. Therefore, it has been reported that an EQ model with constant stage efficiencies [4] or a constant HETS [5] can introduce considerable inaccuracies when designing LLX processes.

Non-equilibrium (NEQ) models, which incorporate a dedicated description of mass transport and fluid dynamics, offer a superior representation but are

associated with a substantial increase in model complexity [3,6], as well as additional requirements of system-specific transport property data and equipment-specific hydrodynamics and mass transfer kinetics. Additionally, the necessary consideration of solvent recovery in a closed-loop process further increases the challenges for an optimization-based design. This complexity represents a significant obstacle to the frequent use of NEQ models in process optimization, particularly in large-scale industrial applications [7].

In a previous study, Kampwerth et al. [3] employed a rate-based NEQ dispersion model of a counter-current LLX column based on population balance equations accounting for complex and interconnected kinetic phenomena. For the considered hybrid process, the rate-based LLX model is complemented by a shortcut model (Fenske-Underwood-Gilliland) for the distillation column for solvent recovery and product purification. By neglecting the mutual solubility of the carrier and the solvent and assuming a sharp split in the solvent recovery column, the process recycle comprises a pure solvent. Therefore, the recycle stream is not explicitly considered, which simplifies the model notably. Based on this model, Kampwerth et al. [3] perform a solvent selection by manually determining the optimal solvent-to-feed ratio based on a sensitivity analysis considering the total annualized costs (TAC) as their objective. Using the Kremser method [8] to estimate the minimum number of EQ stages in the LLX column, Kampwerth et al. [3] determined solvent-specific HETS values based on their optimal process conditions, reporting a broad range for the HETS values ranging from 0.26 m to 1.10 m. In a following study, Kampwerth et al. [6] extend their model by considering mutual solubility of the carrier and the solvent in the two-phase liquid system to include solvent loss in the raffinate and evaluate the impact of different alternatives for raffinate purification. Based on the results of the study, the authors highlight the importance of fluid dynamics and mass transfer phenomena when selecting solvents and designing LLX columns.

In order to expand the scope of the study to an increased solvent search space, Polte et al. [9] combined the developed NEQ model and the design procedure with a computer-aided molecular and process design method (CAMPD) introduced by Scheffczyk et al. [10]. The combination allows for generating new solvent candidates using a genetic algorithm. The NEQ model framework provides the TAC concerning the optimal solvent-to-feed ratio as a fitness function for the genetic algorithm. The approach successfully demonstrates the automatic evaluation and design of solvent candidates based on a rigorous rate-based LLX model with an enlarged solvent design space. However, the hybrid process was still evaluated based on a shortcut representation of the distillation column, assuming a perfect separation of the product and solvent recycle stream. Moreover, besides the solvent selection, all studies consider a single design degree of freedom (DDoF), namely the solvent-to-feed ratio, due to their chosen model types and assumptions.

In contrast to the latter approach that focuses on the detailed modeling of the LLX column, Kruber et al. [11] proposed an EQ-based superstructure model to optimize the closed-loop hybrid extraction-distillation process in the context of solvent screening. The resulting problem is effectively solved as a successively relaxed mixed-integer nonlinear programming (SR-MINLP) problem [12]. The polylithic solution strategy allows for an efficient optimization of multiple operational DDoF, e.g., the solvent-to-feed ratio as well as the reboiler and condenser duty in the distillation column, and structural DDoF, e.g., the column heights and diameters. Nonetheless, the model relies on pre-specified constant HETS values for the LLX and distillation column. The study did consider these fixed for all investigated solvents and operating conditions.

To overcome the limitations of the individual approaches, an integrated approach that combines the NEQ modeling by Kampwerth et al. [3,6] with an EQ-based superstructure optimization for a hybrid extraction-distillation process [11] is presented in this work. The objective is to develop a reliable method for process optimization that captures the essential features of mass transfer and fluid dynamics in the LLX column without the computational burden of full rate-based representation throughout the entire design process. In the initial phase, the NEQ representation of an LLX column is employed to calculate HETS values specific to the selected solvent and contingent on the operational conditions [6]. Based on the generated data, solvent-specific HETS correlations are generated and incorporated into an EQ-based extraction-distillation superstructure model [11], thereby enabling accurate incorporation of mass transport phenomena in combination with a rigorous closed-loop process optimization. The efficacy of the proposed design approach is illustrated through its application to the separation of a diluted acetone-water mixture. The cost-optimal process designs for a range of solvents are evaluated, with a particular focus on the specific HETS values. Furthermore, the results are compared to those derived for constant HETS values across all solvents and operating conditions. Finally, a conclusion and an outlook for future research opportunities are given.

## METHODOLOGY

By combining a rigorous superstructure optimization based on the assumption of EQ conditions with a detailed NEQ-based approach to determine solvent-specific

HETS values, the developed methodology partly preserves the accuracy of the rate-based approach while being computationally efficient for superstructure optimization. A schematic depiction of the methodology is shown in Figure 2. First, a database of HETS values for the LLX column is generated based on calculations for each selected solvent using the NEQ-based simulation at different ratios of continuous and dispersed phases. A polynomial regression is performed to generate solvent-specific surrogate models for the HETS values. Subsequently, an economic superstructure optimization is carried out, incorporating the gained correlation for the HETS value. The following subsections briefly explain the main parts of the procedure.

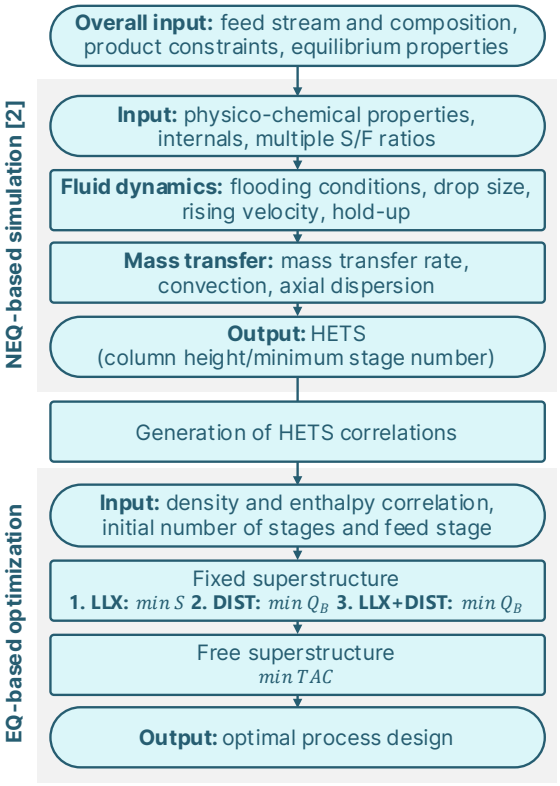

**Figure 1.** Conceptual framework for integrating HETS correlations derived by NEQ-based simulations into an EQ-based superstructure optimization.

## NEQ-based prediction of HETS values

A one-dimensional, rate-based dispersion model is employed to capture mass transfer effects in the extraction column. The primary output of interest is the column height, which reflects the extent of mass transfer required under specified conditions (e.g., temperature, phase ratio, column load). Physical property-based correlations (densities, viscosities, interfacial tension) are used to estimate key fluid dynamic parameters such as drop size distribution, sedimentation velocity, holdup, and dispersion coefficients. These parameters determine interfacial area and residence time available for mass transfer, eventually defining the necessary column height. Once the column height is determined for the required separation and operating condition, the method by Kremser [8] is applied to calculate the minimum number of EQ stages, thus enabling the estimation of HETS. Details on the underlying correlations and boundary conditions regarding the rate-based modeling approach can be found in Kampwerth et al. [3].

To achieve simple HETS-correlations, quadratic, cubic, and quartic polynomial models are investigated based on their corrected Akaike information criterion (AICc) [13]. The AICc enables a comparison of different models by considering the model's accuracy and simplicity, balancing the risks of under- and overfitting. It is generally recommended to use the corrected version of the AIC, which accounts for small sample sizes. Based on the insights gained, a cubic polynomial of the ratio of continuous and dispersed phases results in a sufficiently accurate and simple representation of the solvent-specific HETS values.

## EQ-based superstructure optimization

The superstructure model for the hybrid extraction-distillation process is illustrated in Figure 2. The process feed (F) and the lean solvent enter the column at the top and bottom, respectively, to form the countercurrent flow. While the depleted raffinate stream (R) leaves at the bottom, the enriched extract stream (E) is heated to boiling conditions before entering a distillation column. Depending on the mixture topology, the product (P) is either obtained as distillate or bottom product. Prior to the LLX column, the recycle stream is cooled to the operating condition of the extraction and fed to a decanter. The solvent-rich phase leaving the decanter and a solvent make-up stream (S) are recycled to the the LLX column. The solvent-lean phase from the decanter is mixed with the raffinate stream, leaving the process.

The overall structure of the process is predefined, while the height of each unit is introduced as a DDoF by a superstructure formulation with variable feed, reflux, and boil-up positions [11,14]. The superstructure model comprises continuous and discontinuous variables resulting in a mixed-integer nonlinear programming (MINLP) problem, which is efficiently solved as a series of successively penalized MINLP problems [12]. The solution strategy follows a polylithic approach to ensure a robust model and a high-quality local optimal solution based on profound starting values [11]. The second half of Figure 1 captures the core steps of the polylithic solution approach.

The robustness of the model is further increased by using external equations to calculate the equilibrium conditions and the necessary enthalpies. Using external equations notably reduces the number of variables and

equations in the process model. Furthermore, dedicated solution strategies can be employed inside the external equations to calculate the different phase equilibria efficiently, further improving robustness and reliability.

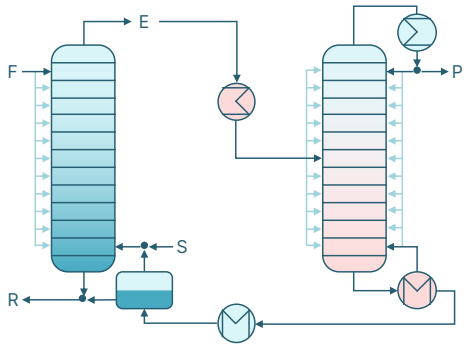

**Figure 2.** Extraction-distillation superstructure model.

## RESULTS

The separation of a diluted acetone-water mixture demonstrates the application of the developed approach. The acetone-water system forms a tangent pinch at high acetone compositions, resulting in high reflux ratios and low energy efficiency for conventional distillation [15]. Previous studies have already suggested the separation by LLX and highlighted the impact of fluid dynamics and mass transport [3,9]. In accordance with these studies, we use the same feed conditions of 76 mol·s$^{-1}$ (5 m$^3$·h$^{-1}$) with an acetone content of 2 mol% (5.5 wt%), representing a highly aqueous feed stream. The solvent make-up stream consists of pure solvent. A minimum product purity of 94 mol% acetone and a maximum impurity of 0.01 mol% acetone in the raffinate stream are set as inequality constraints. The necessary physico-chemical property data is taken from the DIPPR database. The non-random two-liquid model (NRTL) represents the EQ behavior, which is fitted to predicted activity coefficients using COSMO-RS [9].

Kampwerth et al. [3] investigated 14 frequently used solvent candidates, out of which five that provide a balanced distribution of the published HETS values are considered in the current study. Therefore, the two solvents with the lowest and highest HETS values are selected, n-butanol (BUT) and methyl isobutyl ketone (MIBK) (low HETS), as well as tetralin (TET) and cyclohexanol (CYC) (high HETS). Toluene (TOL) is also selected as a solvent with an intermediate HETS value close to the reference value of 0.5 m.

The LLX column and the decanter are operated at ambient conditions (25 °C, 1 atm), with a maximum of 15 stages in the LLX column and 50 stages in the distillation column (EQ model). The superstructure models are implemented in GAMS 34.3, and the local SQP solver SNOPT is employed. TAC are determined via the bare module method by Woods [14], using a CEPCI value of 567.5 (2017), a depreciation time of ten years, an interest rate of 6%, and an exchange rate of 0.87 €·$^{-1}$ [3]. The costs for fresh solvent make-up are initially considered with 1000 €·t$^{-1}$ for all investigated solvents.

### Correlation of HETS data

The calculation of solvent-specific HETS values is described in detail by Kampwerth et al. [3]. HETS data are generated for a range of volume ratios using the rate-based simulation model, to fit a cubic polynomial in MATLAB using the built-in “polyfit” function. TOL serves as the benchmark solvent and generally shows an increase in HETS with a rising volume ratio, reflecting changes in solvent flow rate. All solvents follow a similar trend except TET, for which an inversion in phase densities leads to distinct droplet behavior and deviations in the HETS values. The cubic correlations result in a sufficient representation of the data for all five solvents with a minimum $R^2$ of 0.90 and an average of 0.96.

### Superstructure optimization

Figure 3 illustrates the distribution of the capital expenditures (CAPEX) for the optimized flowsheets of all considered solvents for a constant HETS of 0.5 m (left bar) and the correlated HETS (right bar). As expected, TET and CYC exhibit the highest CAPEX, driven primarily by their large HETS values of, on average, 1.2 m and 1.5 m, respectively. The CAPEX of the LLX column for TET and CYC is approximately 50% higher compared to the other solvents. In contrast, TOL shows more moderate CAPEX due to a much lower overall HETS value close to the reference of 0.5 m. Although MIBK and BUT exhibit similar phase diagrams with acetone and water compared to CYC, considering the size of the miscibility gap and the slope of the tie lines, the CAPEX for the LLX column differ strongly.

Interestingly, when comparing the CAPEX based on a constant HETS of 0.5 m, CYC initially appears more cost-effective, but the investment costs increase substantially once volume-ratio-dependent HETS values are incorporated, making it less attractive than MIBK and BUT. Comparing the overall CAPEX, there are differences between the constant and correlated HETS of up to 29%, stressing the importance of considering mass transfer and fluid dynamics, even in a simplified form.

Figure 4 depicts the operating expenditures (OPEX), revealing the dominant influence of solvent make-up flow rates and associated utility requirements. For MIBK, CYC, and BUT, pronounced solvent losses into the raffinate inflate their solvent make-up and drive OPEX substantially above TOL and TET. Losses in the product stream can be tolerated since they account for less than 0.15% of the overall losses for MIBK, CYC, and BUT only.

TET not only shows high investment costs in the extraction column but also suffers elevated utility expenses for distillation due to its large heat of vaporization. As a result, despite differences in the LLX column size and design, the overall TAC across the various solvents primarily depend on the OPEX for the considered economic parameters.

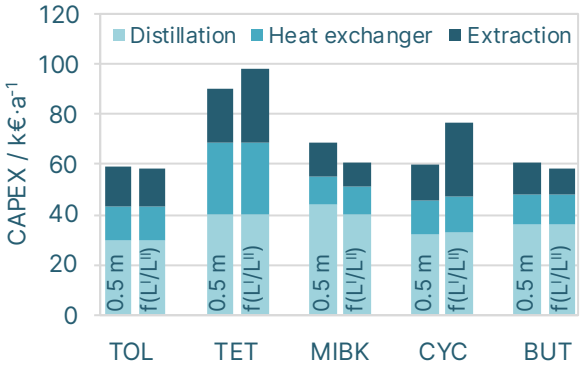

**Figure 3.** Capital expenditures (CAPEX) of the optimal process design for the solvents toluene (TOL), tetralin (TET), methyl isobutyl ketone (MIBK), cyclohexanol (CYC), and butanol (BUT) with constant and correlated HETS values.

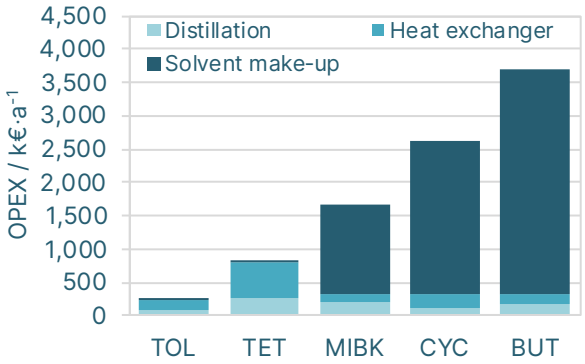

**Figure 4.** Operational expenditures (OPEX) of the optimized process design for the solvents toluene (TOL), tetralin (TET), methyl isobutyl ketone (MIBK), cyclohexanol (CYC), and butanol (BUT) with correlated HETS values.

The impact of the CAPEX on the TAC is comparably small, especially for those solvents that require large make-up streams, rendering the impact of the fluid-dynamics-related costs negligible. In order to evaluate the impact of the specific solvent costs, the cost for solvent recovery by raffinate treatment are evaluated based on the optimization of a heteroazeotropic distillation (HAD) superstructure model [17] for the solvents MIBK, CYC, and BUT, as these require large make-up streams. Based on the small acetone impurities, the solvent recovery from the raffinate is evaluated as a binary separation problem with a purity constraint of 99.99 mol% of water in the waste stream and a saturated solvent recycle, resulting in an average solvent recovery of 99%. Adjusting the assumed solvent make-up costs on the basis of these calculations, the TAC of the overall process can be reduced by approximately 80% on average. As this model is evaluated separately from the extraction–distillation framework, these corrections should be verified in a closed-loop process model.

In addition to solvent recovery, a straightforward estimation of potential savings through energy integration reveals further cost reduction possibilities. Since the preheater and cooler operate at comparable heat loads for all five solvents, heat integration by means of a heat pump is very attractive. The favorable temperature difference also supports direct integration for a large portion of the heat, saving the investment for a heat pump setup. As illustrated in Figure 5, these measures could yield overall savings of up to 92% of the TAC for the three solvents, making them competitive with TET. Besides improving economic viability, such strategies also shift the balance between capital and operating costs, making the LLX column design a more critical element in the overall process configuration.

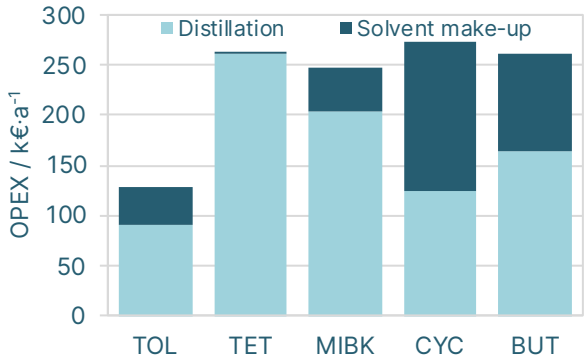

**Figure 5.** Adjusted operational expenditures (OPEX) with improved solvent recovery for the solvents methyl isobutyl ketone (MIBK), cyclohexanol (CYC), and butanol (BUT) and heat integration for all five solvents.

## CONCLUSION AND OUTLOOK

The current work introduces a novel approach that combines NEQ modeling with EQ-based superstructure optimization to design and evaluate LLX processes with integrated solvent recovery. The approach is successfully applied to the separation of a diluted acetone-water mixture, illustrating that solvent-specific HETS are of decisive importance for the accurate design of extraction columns and associated investment costs. If the investment costs are comparably small in respect to the operating costs, as is the case in the current study,

solvent recovery including losses in the raffinate, and proper heat integration are decisive for the choice of the best solvent. These results stress the importance of a holistic process design approach, in particular, the consideration of processes with closed recycle streams and heat integration.

Therefore, future research should expand the balance envelope for these processes and investigate a broader range of solvents and separation tasks. Regarding the incorporation of kinetic phenomena, the correlated HETS values should be expanded, e.g., towards a temperature dependency. This opens the opportunity to add the temperature as a DDoF rather than a predefined parameter. However, special care needs to be taken to ensure correct thermodynamic behavior with respect to the liquid-liquid equilibrium. Such extensions will require further refinement of the model formulation as well as improved initialization strategies to account for an increase in process complexity.

## ABSTRACT

Due to the intermittent nature of most renewable energy sources, developing good and flexible control structures for green electrolysis systems is crucial for maintaining efficient and safe plant operation. This work uses the "top-down" section of Skogestad's plantwide control procedure to propose a suitable control architecture for PEM electrolysis systems based on advanced regulatory control. Advanced regulatory control structures, such as active constraint control, may offer several advantages over MPC and AI-based control methods as they are computationally less expensive, less affected by model accuracy, easier to scale, and offer fast disturbance rejection. In our approach, we first mapped the constraint regions for the system. Then, we reduce the complexity by reformulating the optimization problem slightly, to remove some constraint regions to obtain a simpler solution structure that gives a negligible loss. Finally, we propose an active constraint control architecture using PI controllers and a selector for switching between the active constraint regions. We found that the system's fully constrained solution is close to the optimal solution, implying that our active constraint control approach may be used with little loss in efficiency. The proposed control structure was shown to perform well in dynamic simulations.

## INTRODUCTION

Global warming and climate change necessitate a transition from carbon-based energy sources to Renewable Energy Sources (RES) such as wind and solar power. Two significant challenges in this transition are the intermittent nature of these energy sources and their reliance on geographical factors. Carbon-free energy carriers like hydrogen can help address these challenges by facilitating efficient energy storage and transportation. Hydrogen is a promising candidate as it is already widely used in chemical industries, such as ammonia production, and can replace fossil fuels in processes that are difficult to electrify. However, successfully integrating hydrogen into the future energy economy depends on developing sustainable, efficient, and safe production methods. Currently, about 95% of the world's hydrogen is produced from fossil fuels, primarily grey hydrogen, through steam methane reforming [6].

A well-established method for producing green hydrogen is water electrolysis, in which an electric current separates water into hydrogen and oxygen gases. The two most prominent types of water electrolyzers used in industry are alkaline and Proton Exchange Membrane (PEM) electrolyzers. While alkaline electrolyzers are more mature and well-established, PEM electrolyzers are gaining popularity due to their greater flexibility, compact design, less corrosive electrolyte, and higher hydrogen purity compared to alkaline systems [6]. However, to fully take advantage of the benefits offered by PEM technology, it is essential to develop suitable control structures.

Most control architectures for PEM electrolysis systems primarily consist of relatively simple control structures of Proportional-Integral-Derivative (PID) and on-off controllers. Some works investigate more advanced control structures, such as model predictive control (MPC) and AI-based control methods [9]. However, few studies have been conducted on the viability of using Advanced Regulatory Control (ARC) structures [11], such as active constraint control and constraint switching strategies, for PEM systems. These control architectures offer several advantages: Being part of the regulatory control layer,

they provide fast local disturbance rejection, are easier to scale, less affected by model accuracy, and less computationally intensive than methods like MPC, while remaining relatively simple [2]. The main contribution of this paper is the application of ARC [11] to a PEM water electrolysis system. To the author's best knowledge, this type of control structure (with selectors for constraint switching) has not been reported for PEM systems before.

## METHODOLOGY

This section provides a brief overview of the PEM model and the development and implementation of our control structure. The model focuses on the system's electrochemical and gas crossover phenomena and is based on the PEM models developed by Afsari et al. [1] and Crespi et al. [3].

### Case study

We consider a 60 kW PEM electrolysis system, as presented in Figure 1. Deionized water is stored in a buffer tank and cooled by a heat exchanger before being fed to the electrolyzer stack. In the stack, an electric current splits the water into hydrogen and oxygen gases. The gases are separated from the water in separators, and the water is recycled back to the deionized water tank. The hydrogen gas is compressed to 30 barg for storage, while the oxygen is vented.

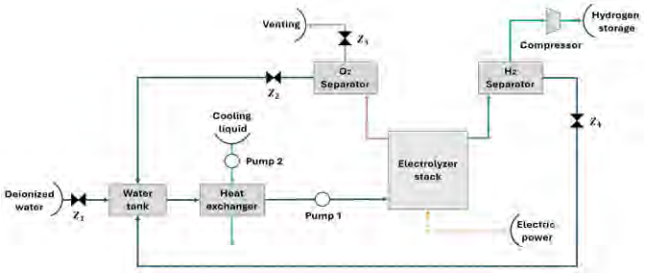

**Figure 1.** PEM water electrolysis system layout.

### PEM stack model

The PEM electrolyzer stack consists of multiple cells that are electrically connected in series. The PEM membrane, which acts as the electrolyte, divides each cell into an anode and cathode compartment. Water is fed to the anode, where it is oxidized to oxygen gas. The protons then cross the membrane to the cathode, where they are reduced to hydrogen gas.

### Electrochemical submodel

The voltage of each cell ($V_{cell}$) is the sum of the reversible cell voltage ($V_{rev}$), the ohmic overpotential ($V_{ohm}$), the activation overpotential ($V_{act}$), and the concentration overpotential ($V_{con}$):

$$V_{cell} = V_{rev} + V_{ohm} + V_{act} + V_{con} \quad (1)$$

The reversible cell voltage is the minimal theoretical voltage necessary to drive the reaction. It is estimated using the reaction's Gibbs free energy ($\Delta G_0(T)$) and the Nernst equation to account for pressure variations [3],

$$V_{rev} = \frac{\Delta G_0(T)}{zF} + \frac{RT}{zF} ln\left(\frac{P_{H_2} P_{O_2}^{0.5}}{P_0^{1.5}}\right). \quad (2)$$

Here, $z$ is the number of electrons participating in the reaction, $F$ is Faraday's constant, $R$ is the universal gas constant, $T$ is the stack temperature, $P_i$ is the partial pressure of species $i$, and $P_0$ is the reference pressure (1 bar).

The ohmic overpotential accounts for the electric and ionic resistance in the cells. It is found using an analytical expression for the membrane conductivity of the Nafion 117 membrane [3].

$$V_{ohm} = \left(\frac{\delta_{mem}}{(0.5139\lambda - 0.326)\, exp\left(1268\left(\frac{1}{303} - \frac{1}{T}\right)\right)} + R_{el}\right) i_{el} \quad (3)$$

$\delta_{mem}$ is the thickness of the membrane, $\lambda$ is the humidity factor, $R_{el}$ is the electric resistance of the electrodes, and $i_{el}$ is the current density.

The activation overpotential represents the energy required to initiate the reaction. It is approximated using Tafel kinetics [8],

$$V_{act} = \frac{RT}{\alpha_{an} zF} \ln\left(\frac{i_{el}}{i_{0,an}}\right) + \frac{RT}{\alpha_{cat} zF} \ln\left(\frac{i_{el}}{i_{0,cat}}\right), \quad (4)$$

where $\alpha_{an}$ and $\alpha_{cat}$ are the charge transfer coefficients and $i_{0,an}$ and $i_{0,cat}$ are the exchange current densities at the anode and cathode.

We also use Tafel kinetics to describe the concentration overpotential, which represents the resistance to mass transfer within the cells [10],

$$V_{con} = \frac{RT}{zF} \ln\left(\frac{C_{O_2}^{mem}}{C_{O_2}^{0}}\right) + \frac{RT}{zF} \ln\left(\frac{C_{H_2}^{mem}}{C_{H_2}^{0}}\right). \quad (5)$$

$C_{H_2}^{mem}$ and $C_{O_2}^{mem}$ are the concentration of hydrogen and oxygen at the membrane surface, which was found by applying Fick's law [1], and $C_{H_2}^{0}$ and $C_{O_2}^{0}$ are the concentration of hydrogen and oxygen in the flow channels.

### Thermal submodel

Due to the overpotentials in the stack, the stack produces heat, warming up the system. To calculate the temperature changes, we use the following reformulation of the general energy balance [8]:

$$\frac{dT}{dt} = \frac{1}{nC_p}\left(\sum \dot{n}_{in,i} C_{p,i} (T_{in} - T) + \left(V_{stack} - \frac{\Delta_r H}{zF}\right) i_{el} + Q\right) \quad (6)$$

Where $V_{stack}$ is the stack voltage, $\Delta_r H$ the heat of reaction, $T_{in}$ the feedwater temperature, $C_{p,i}$ the heat capacity of species $i$, $\dot{n}_{in,i}$ the molar inflow of species $i$, and $n$ the total amount of moles inside the stack. The heat transfer ($Q$) between the stack and the environment is given by,

$$Q = -\frac{1}{R_{th}} (T - T_{env}). \quad (7)$$

Where $R_{th}$ is the thermal resistance and $T_{env}$ is the temperature of the environment [8].

## Mass transport submodel

The inventories of the cathode and anode flow channels are lumped together, representing the stack as a large cell divided into one anode and one cathode compartment. The change in the molar inventories of hydrogen, oxygen, and water in each compartment is given by

$$\frac{dn_i}{dt} = \dot{n}_{in,i} - \dot{n}_{out,i} + \dot{n}_{gen,i} + \dot{n}_i^{cross}. \quad (8)$$

Here $\dot{n}_{in,i}$ is the molar inlet flow, $\dot{n}_{out,i}$ is the molar outlet flow, $\dot{n}_{gen,i}$ is the number of moles consumed or generated, and $\dot{n}_i^{cross}$ is the number of moles crossing the membrane of species $i$.

The crossover through the membrane is driven by diffusion ($\dot{n}_i^{diff}$), pressure gradients ($\dot{n}_i^{dp}$), and the electroosmotic drag ($\dot{n}_i^{eod}$),

$$\dot{n}_i^{cross} = \dot{n}_i^{diff} + \dot{n}_i^{dp} + \dot{n}_i^{eod}. \quad (9)$$

The diffusion is approximated by Fick's law [1],

$$\dot{n}_i^{diff} = D_{i,mem}^{diff} H_i \frac{P_{i,cat}^{mem} - P_{i,an}^{mem}}{\delta_{mem}} A_{stack}, \quad (10)$$

where $H_i$ is Henrys constant and $D_{i,mem}^{diff}$ is the diffusion coefficient of species $i$, and $A_{stack}$ is the surface area of the membrane. The subscripts $an$ and $cat$ is used to represent the anode and cathode section, respectively.

To reduce the oxygen contamination in the hydrogen, we usually have a higher cathode pressure than anode pressure, resulting in hydrogen being pushed from the cathode to the anode,

$$\dot{n}_i^{dp} = \epsilon_i^{dp} \frac{P_{i,cat} - P_{i,an}}{\delta_{mem}} A_{stack}. \quad (11)$$

$\epsilon_i^{dp}$ is the diffusion constant of $i$ due to pressure difference. The oxygen crossover due to the pressure gradient is neglected as it is very small [1].

As the protons cross the membrane, they drag with them water and gasses. The electroosmotic drag moves the hydrogen and oxygen from the anode to the cathode, thus working against the pressure and diffusion-driven hydrogen crossover [1],

$$\dot{n}_i^{eod} = \pm \frac{i_{el}}{F} \zeta \frac{P_i H_i}{C(H_2O)} A_{stack}, \quad (12)$$

where $\zeta$ is the drag coefficient, and $C(H_2O)$ is the concentration of water in the membrane.

## Separator models

The hydrogen and oxygen separators separate the gases from the liquid water using gravity. We assume that the holdup time in the separators is sufficiently large to separate all the gas bubbles from the water. However, some hydrogen and oxygen will remain dissolved in the water. This amount is approximated using Henry's law.

$$n_{i_{dissolved}} = H_i \left(\frac{n_{g,i}}{n_g}\right) \frac{n_{H_2O} M_{H_2O}}{\rho_{H_2O}} P. \quad (13)$$

Where $M_{H_2O}$ is the molar mass and $\rho_{H_2O}$ is the density of water and $n_g$ is the moles of gas in the system. Furthermore, we assume that the heat loss from the separators is negligible.

## Water tank model

The deionized water buffer tank is modeled as a simple adiabatic mixing tank. It collects the water recycled from the separators and new deionized water that is added to replace the water consumed in the reaction.

## Heat exchanger model

The heat exchanger is divided into three sections: a hot flow section, a cold flow section, and a dividing wall section. The sections are further divided into segments following the hot stream flow direction. This gives us temperature gradients inside the heat exchanger, which we use to calculate the heat transfer from the hot to the cold liquid [7].

## Compressor and pump work

The compressor and pumps consume some of the power supplied to the system, establishing a minimum power requirement to start hydrogen production. We can reduce the compressor work by raising the pressure in the cathode section of the electrolyzer stack; however, this will also decrease the stack's overall efficiency. We assume the compression happens in multiple stages with cooling, thus representing the compression as isothermal. The compression work ($W_c$) is given by,

$$W_c \, \eta_c = \dot{n}_{H_2} \cdot R \cdot T_{separator} \cdot \ln\left(\frac{P_{storage}}{P_{separator}}\right). \quad (14)$$

The pump work ($W_p$) is given by,

$$W_p \, \eta_p = \left(P_{final} - P_{initial}\right) \frac{\dot{n} M}{\rho}. \quad (15)$$

Where $\eta_p$ (75%) and $\eta_c$ (80%) are the efficiency factors of the pumps and compressor, respectively.

## Development of control structure

The control structure is developed inspired by the "top-down" section of Skogestad's plantwide control procedure [12]:

1. Identify constraints and a cost function that characterizes optimal operation.
2. Identify the degrees of freedom.
3. Analyze the optimal solution for various disturbances to find the primary control variables.
4. Determine where to place the production rate.

## Step 1: Cost function and constraints

Our objective is to maximize the plant's hydrogen production while minimizing the hydrogen loss due to crossover using the system's manipulated variables (MVs). The cost function is to maximize the hydrogen output from the cathode separator ($\dot{n}_{H_2}$).

$$\begin{aligned} \min_{\text{MVs}} \quad & -\dot{n}_{H_2} \\ s.t. \quad & \textit{Process model equations} \\ & \textit{Operational constraints} \end{aligned} \tag{16}$$

Maintaining the stack pressure, temperature, and hydrogen-to-oxygen ratio (HTO) within a specified operating range is essential to prevent damage to the PEM membrane and other system components. To establish the upper temperature and pressure bounds, we refer to the operating conditions provided by Crespi et al. [3]. The absolute upper bound of the HTO is given by the lower explosion limit of 4 vol% $H_2$. However, to incorporate a safety margin, we lower the upper bound of the HTO in the anode separator to 2 vol% [2, 4]. We do not limit the oxygen content in the cathode separator, as these values are neglectable and far from the explosion limit. The resulting operating constraints are presented in Table 1.

**Table 1.** Operational constraints for the system.

| Condition: | Upper bound: | Lower bound: |
|---|---|---|
| Anode pressure | 2.7 barg | 0.2 barg |
| Cathode pressure | 30 barg | 0.2 barg |
| Temperature | 60 °C | 10 °C |
| HTO | 2 vol% | 0 vol% |
| Cooling liquid | ~0.9 L/h | 0 L/h |

## Step 2: Degrees of freedom

The second step in the procedure is to identify the degrees of freedom. Our system consists of four valves, two pumps, and one compressor. However, we have three liquid inventories requiring control: the liquid level in the water tank and the anode and cathode separators. Additionally, we need to keep the amount of water fed to the electrolyzer stack constant. This results in three degrees of freedom that we use to optimize the operation.

## Step 3: Optimal solution

The input power is assumed to be our primary disturbance. This leads to an optimization problem in which power is distributed to the stack, pumps, and compressor to maximize hydrogen production. The resulting steady-state optimization problem, as expressed in Equation 16, was solved 120 times for power inputs ranging from 0 kW to 60 kW in Julia using JuMP with the interior point solver IPOPT and the linear solver Ma57 from HSL [5, 13]. IPOPT is a local solver; thus, it does not guarantee optimal global solutions. However, the solution is consistent with the behavior reported for PEM electrolysis systems [1, 8, 13].

Figure 2 presents the active constraint regions for the optimal solution as a function of the power input. Each region is defined by the constraints that are currently active. A constraint is active when it either reaches its upper ($g/g_{max} = 1$) or lower limit ($g/g_{max} = 0$). The system has five active constraint regions. In Region 1, both pressure constraints are active; in Region 2, only the anode pressure constraint is active; in Region 3, the cooling liquid constraint and anode pressure constraint are active; in Region 4, the anode pressure and stack temperature constraint are active, and in Region 5, only the stack temperature constraint is active. Thus, the system has one or two active constraints in each region.

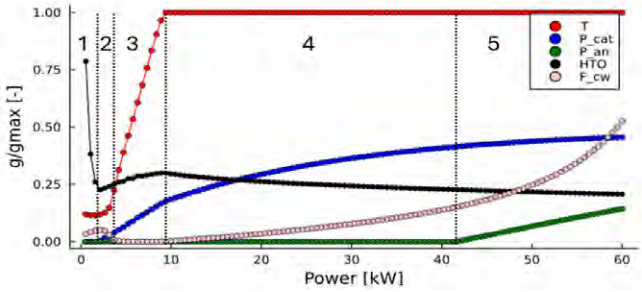

**Figure 2.** Constraint regions for optimal PEM operation.

## Altered solution:

Implementing the solution in Figure 2 is quite complicated. Thus, we propose slightly altering the optimization problem to achieve a different solution with fewer active constraint regions by adding terms to maximize the cathode and minimize the anode pressure to our cost function.

$$\min_{\text{MVs}} \quad -\dot{n}_{H_2} - 10^{-3}(P_{cat} - P_{an}). \tag{17}$$

The pressures were adjusted as they have a small impact on the overall stack efficiency and are not active constraints in several of the constraint regions in Figure 2.

The resulting fully constrained system presented in Figure 3 has three active constraint regions, which share several similarities with those found for alkaline systems by Cammann and Jäschke [2]. In Region 1, the system is heating up as the power increases, and the HTO is at its upper bound, limiting the rise of the cathode pressure.

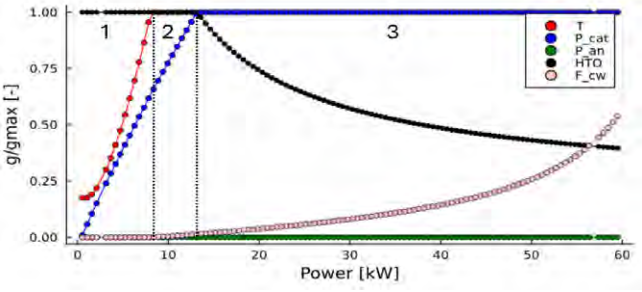

**Figure 3.** Constraint regions for fully constrained system.

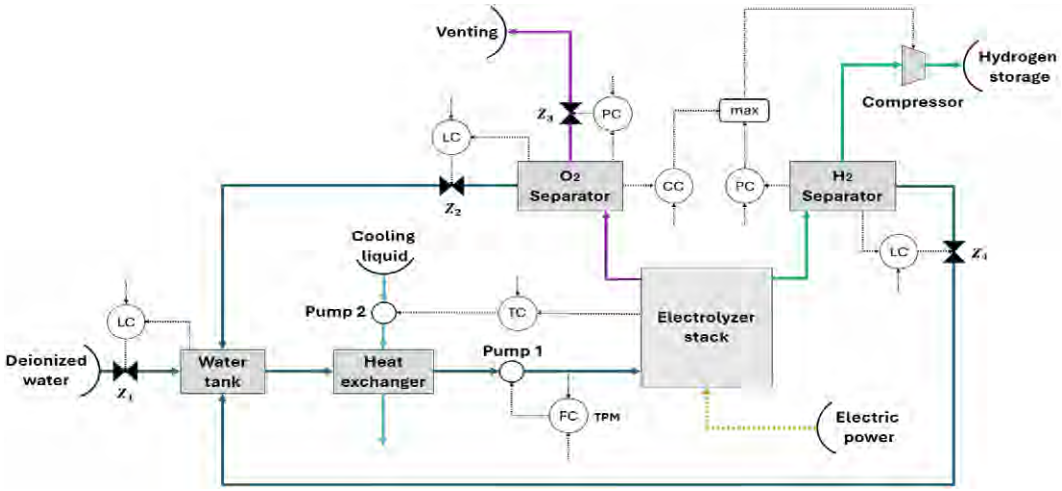

**Figure 4.** Block diagram of suggested control structure for PEM electrolysis system using active constraint control.

In Region 2, the system reaches its maximum temperature and starts using cooling liquid. When we cross from Region 2 to Region 3, the HTO constraint stops being active, and the cathode pressure reaches its upper bound. The four safety constraints - HTO, temperature, and anode and cathode pressures - are our control variables (CVs).

### Step 4: Production rate and control structure

We use decentralized control with single-loop PI controllers to design the control structure. We pair the CVs and MVs in the system using the "pair close" and "input saturation" pairing rules [11]. First, we pair the stack feedwater flow rate with the feedwater pump (Pump 1). Second, we close the inventory loops. That is, we pair the liquid inventories with the valves $z_1$, $z_2$, and $z_4$. The last valve $z_3$ is paired with the anode pressure, which is kept at its lower bound during the entire operational range.

We propose a simple MV-CV switch between active constraint Region 1 and 2. From Figure 3 we see that the temperature control can be given up when the cooling liquid saturates, we pair the stack temperature to the cooling liquid pump (Pump 2) and add anti-windup to the temperature controller [11].

Switching from Region 2 to 3, we have a CV-CV switch, as we stop controlling the anode separator HTO in favor of the cathode pressure. We introduce a maximum selector since both constraints can be satisfied by increasing the compressor work [11]. Thus, both the HTO and the cathode pressure are paired to the compressor through the selector. Figure 4 presents the resulting control structure.

## RESULTS AND DISCUSSION

By altering our cost function from Equation 16 to Equation 17, we have moved away from the original optimal point of operation. As a result, there is a slight loss in hydrogen production. The loss is a function of the power input and is highest at low power loads, see Figure 5. This will not make a big difference in practice, as we prefer to operate at high power because the stack is more efficient at high power loads. The loss is ca. 0.1 % of the total hydrogen production above 40 kW. The maximum loss is slightly above 0.5 % as we approach zero power input (no production).

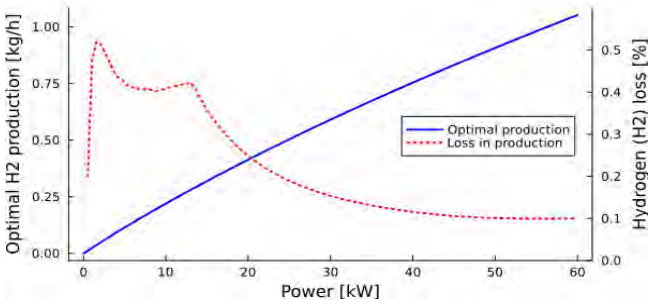

**Figure 5.** Loss in hydrogen output of the cathode separator by altering our objective function.

We conducted a dynamic simulation to test our control structure, focusing on the anode separator HTO and the cathode pressure, the CVs linked to the selector. After 2 minutes, we exposed the system to a power drop, decreasing the power input from 56 kW to 10 kW with a two-second ramp response. We then simulated the system for 30 minutes before increasing the power back to 56 kW and ran the simulation for another 20 minutes.

Figure 6 shows that the cathode pressure is reduced to counteract the rapid increase in the HTO within the anode separator. This occurs when the ratio controller takes over control of the compressor as the HTO rises. After approximately 20 minutes, the HTO stabilizes at the setpoint without significant overshoot or oscillations. As

power increases, the HTO decreases, and the pressure controller regains control of the compressor. The pressure in the cathode separator then returns to its setpoint. Overall, the controllers and the selector perform well.

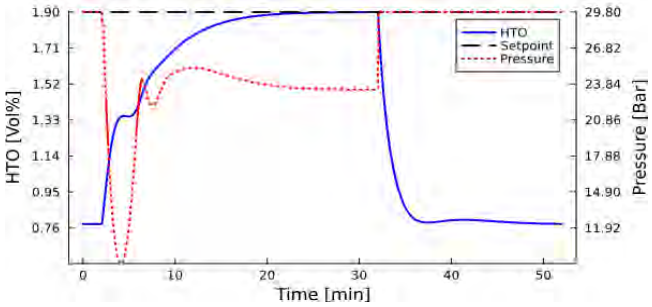

**Figure 6.** Control of HTO and cathode pressure.

## CONCLUSION AND FUTURE WORK

We have found that the optimal solution of the PEM electrolysis system is close to the fully constrained solution in all operating regions. This implies that active constraint control structures may be used to control the system with relatively little loss in hydrogen production. We implemented the active constraint control structure in our dynamic PEM electrolysis model using PI controllers and a selector. When exposed to power changes, the system controlled the HTO and cathode pressure well.

To simplify the model, we assumed that Henry's constant and the diffusion coefficients for hydrogen and oxygen are not temperature dependent. Introducing temperature dependencies might shift the active constraint regions somewhat, but we do not expect it to change the solution structure significantly. As such, we believe that the control structure will continue to work well.

For future work, the active constraint control structure should be compared to the performance of an MPC or AI-based control method.

## ABSTRACT

Microfluidic mixing has gained popularity in the Pharmaceutical Industry due to its application in the field of Nano-based Drug Delivery Systems (DDS). The flow conditions in Microfluidic mixers enable very efficient mixing conditions, which are crucial for the production of Nanoparticles by Flash Nanoprecipitation (FNP), as it enables reproducible production of particles with low-size variability. Mixer geometry is one of the most determinant factors, as it largely determines the flow patterns and the degree of contact between the two mixing streams. In this paper, a shape optimization methodology using Computational Fluid Dynamics (CFD) and Bayesian optimization is applied to the toroidal micromixer design, considering three different operating conditions. It consists of first defining a geometry solution space and then using Multi-Objective Bayesian optimization to explore the different designs. Mixer performance is evaluated with CFD simulations and two objective functions are considered: mixing time and pressure drop. Approximations of the Pareto front for each case study are obtained and the analysis of the best geometries enabled to derive some general geometric features of optimal mixer designs.

**Keywords**: Micromixing, Geometry Optimization, Multi-objective Optimization, Computational Fluid Dynamics.

## INTRODUCTION

Mixing and mass transfer are fundamental aspects of many chemical and biological processes. Microfluidic mixing has recently gained much traction as an advantageous technology in the field of Nano-based Drug Delivery Systems in the Pharmaceutical Industry [1]. Several Drug products, such as peptides and nucleic acids, must rely on specialized nanostructures to protect the Active Drug Ingredient (API), and are therefore able to achieve the desired Drug Pharmacokinetic and Pharmacodynamic properties [2]. These systems, usually Nanoparticles, are synthesized by Flash Nanoprecipitation (FNP), which consists in the rapid dilution of a solution containing amphipatic molecules with an anti-solvent. This sudden change of solubility results in the rearrangement of the solute molecules and consequent formation of Nanoparticles [3].

The reduced channel size of Microfluidic mixers entails a high mass-transfer area/ volume ratio, which enables the very fast mixing of the two solutions. This reduces the mass transfer resistance during the FNP process, allowing the formation of particles of controlled size and low polydispersity, both critical quality attributes (CQA) of these products. Consequently, Microfluidic mixing is generally a more fit process to reproducibly comply with the tight quality demands of the product, when compared with the traditional alternatives [4].

Conceptually, Microfluidic mixing is merely the passive mixing of two solutions. Process optimization is therefore limited to the tuning of two operating parameters (Total Flow Rate (TFR) and Flow Rate Ratio (FRR) of the two inlet streams) and of the mixer's geometry. Optimizing the flow rates for a given geometry can be done experimentally with general Quality by Design (QbD) procedures. In contrast, mixer geometry optimization presents some challenges. The limitless degrees of freedom in mixer design ensue a very large number of experiments to realistically cover the broad solution space. Furthermore, the experimental evaluation of each design is in itself a cumbersome and expensive task, as it would involve the iterative design, fabrication and testing of each device.

In this paper, we present a systematic approach for

the geometry optimization of the toroidal micromixer. The adopted methodology begins with the comprehensive parametrization of the mixer geometry solution space, using continuous and discrete geometric parameters with established bounds. Mixer performance evaluation is achieved through the simulation of the Villermaux-Dushman reaction system [5-6] inside the mixer, using Computational Fluid Dynamics (CFD). Two metrics, pressure drop and mixing time, are then considered in the multi-objective optimization problem. The solution space is subsequently navigated employing a Bayesian optimization framework, by iteratively selecting the solution point most likely to improve the Hypervolume indicator. Three case-studies are presented considering different operating conditions.

## METHODOLOGY

### Toroidal micromixer

The toroidal micromixer [7] has become a widely used system for the synthesis of nanoparticles, with applications mainly in the development of drug delivery systems. As shown in Figure 1, it consists of a Y-mixer with additional toroidal mixing elements. The curved geometry of the mixer's channels prompts the formation of Dean flows, which effectively increases the area of contact between the two mixing fluids. As also depicted in Figure 1, the mixer's geometry can be described by the following parameters: channel width and height, number of toroids and their radii, neck angle and length, and Y-mixer entry angle. An additional parameter was considered regarding the smoothness of the geometry's corners ("Corner Length").

### Problem formulation

This mixer shape optimization problem aims to maximize the mixing performance for three operating conditions. The TFR value is 10 ml/min for all cases and the FRR values are 1, 2 and 4. The goal is to find the optimal micromixer design for each operating condition and investigate the differences between the obtained geometries. To achieve this, two objectives were considered: minimizing pressure drop, with the goal of minimizing energy consumption but more importantly reducing the risk of device breakage; and minimizing mixing time, which is defined as the characteristic time constant of mixing described as a process of exponential decay of system heterogeneity. Mixing time is used to describe the rate in which the solutions are homogenized, inferring mass-transfer resistance. The mixing time can be estimated from the selectivity analysis of the Villermaux-Dushman competing reactions[5-6].

The evaluations of the two objective functions require the simulation of the system using CFD. This implies the automation of the non-trivial steps of geometry and mesh generation in the CFD simulation workflow. This was done using in-house Python™ code to describe the channel geometries as sets of hexahedral blocks, which were subsequently discretized, using the `blockMesh` utility of OpenFOAM®, to produce the system's mesh.

The complex and expensive nature of the objective functions evaluation calls for the use of efficient optimization algorithms able to locate great performing geometries with minimal number of function evaluations. This is achieved using a Bayesian optimization methodology, as illustrated in Figure 2. In this case, the first 30 system evaluation points were defined using SOBOL sampling. The subsequent 170 points were chosen in a sequential matter by fitting the previously attained data into a Gaussian Process and subsequently maximizing the Expected Hypervolume Improvement function (qEHVI method) [8], totaling 200 function evaluations. The optimization loop was carried out using the Adaptive Experimentation Platform package (Ax-platform) for Python™ [9].

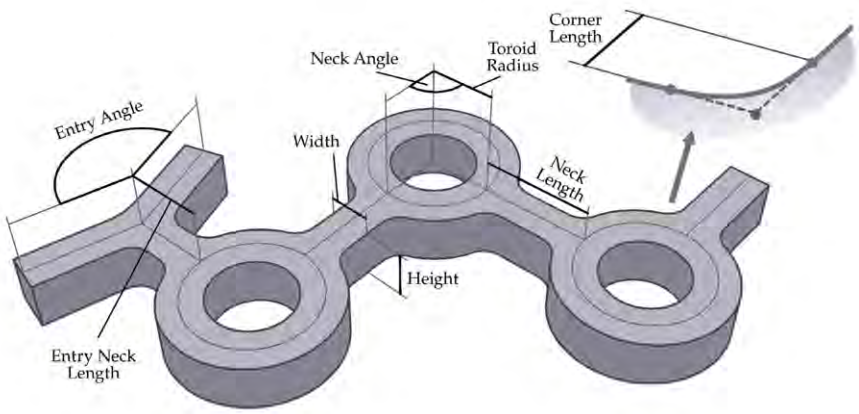

**Figure 1.** Geometry of the toroidal micromixer and respective parametrization.

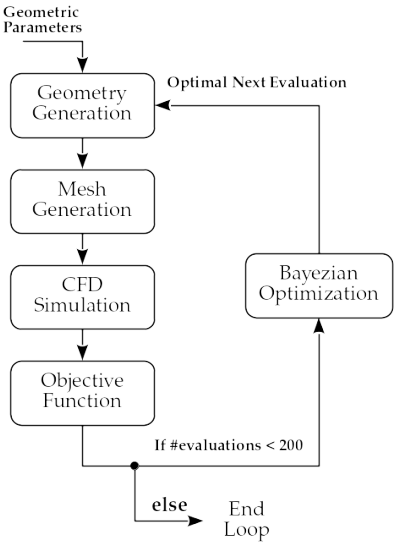

**Figure 2.** Illustration of the shape optimization loop.

The geometric domain was defined using the aforementioned geometry parametrization of the toroidal mixer and assigning bounds for each parameter, as presented in Table 1. Additional constraints were also implemented in order to avoid the generation of invalid geometries.

**Table 1.** List of the geometry parameters and additional constraints.

| Parameter | Value Range | Units |
|---|---|---|
| Entry Angle | [45, 180] | ° |
| Entry Neck Length | [200, 500] | μm |
| Width | [100, 400] | μm |
| Height | [0.1, 0.3] | μm |
| Neck Angle | [90, 270] | ° |
| Neck Length | [200, 700] | μm |
| Toroid Radius | [100, 600] | μm |
| # Toroids | [1, 5] | - |
| Corner Length | [10, 150] | μm |
| **Constraints** | | |
| 1.5 Width ≤ Toroid Radius | | |
| 1.5 Width ≤ Neck Length | | |
| 2.2 Corner Length + Width ≤ Neck Length | | |
| 2.2 Corner Length + Width ≤ Entry Neck Length | | |

## CFD simulation

In order to evaluate mixer performance, CFD simulations were carried out for each mixer design, considering single-phase, incompressible steady-state flow. Considering the mentioned geometry space, the Reynolds number ($Re$) range is ≈ [476, 1666], which approaches the upper limit of laminar flow in internal flows. Moreover, the toroidal mixer's geometry is conducive to flow separation and the formation of eddies. A RANS modelling approach was therefore applied using the SST k-ω turbulence model, which is appropriate for lower-Reynolds flows. For boundary conditions, fixed values for velocity and all scalar fields (except pressure) were considered at the inlets. No backflow was allowed at the outlet, and no-slip conditions were considered at the walls. The remaining boundary conditions were modeled as zero gradient conditions. The Villermaux-Dushman reaction is modeled by considering both reactants and reaction products as passive scalars and including the reaction terms in the corresponding transport equations. The reaction kinetics are taken from the literature [6].

The simulations were carried out using OpenFOAM® v2312 and post-processing was done in Python™ using the PyVista package [10].

## Villermaux-Dushman Reaction and IEM model

The Villermaux-Dushman competing reaction (Figure 3) consists of a quasi-instantaneous neutralization reaction (R1) and a fast redox reaction (R2) competing for hydrogen ions. The rate of R1 is highly dependent on the mass transfer process and, as such, some hydrogen ions are left to be consumed by the slower reaction (R2). As a result, the selectivity of the Villermaux-Dushman reaction is directly related to mass transfer resistance.

The concept of mixing time ($t_m$) arises from the Interaction by Exchange with the Mean (IEM) micromixing model, in which mixing time appears as a measure of mass transfer resistance. The model considers two separate volumes of fluid which exchange mass with each other. The mass transfer rate is proportional to the difference in concentration between each volume and the weighted average of both, as written in Equation 1:

$$\begin{cases} \frac{dC_{k,1}}{dt} = \frac{\overline{C_k} - C_{k,1}}{t_m} + R_{k,1} \\ \frac{dC_{k,2}}{dt} = \frac{\overline{C_k} - C_{k,2}}{t_m} + R_{k,2} \\ \overline{C_k} = \alpha C_{k,1} - (1-\alpha) C_{k,2} \end{cases} \quad (1)$$

where $C_{k,1}$, $C_{k,2}$, and $\overline{C_k}$ are the concentrations of species $k$ in volume 1, volume 2, and the weighted average of both, respectively. $R_{k,1}$ and $R_{k,2}$ are the source/sink terms for each species k in volume 1 and 2. Lastly, $\alpha$ and $(1-\alpha)$ correspond to the fractions of volumes 1 and 2 with respect to the total volume.

A calibration curve between mixing time and concentration of the R2 reaction product ($I_2$) in equilibrium can be obtained by solving the IEM model for a range of mixing time values. Since the relationship between both values is linear, a simple linear regression model can be used. This method is extensively used in literature to experimentally characterize the performance of micromixers [5]. This methodology is implemented here to relate the CFD-simulated $I_2$ concentration data, at the outlet, with a mixing time value.

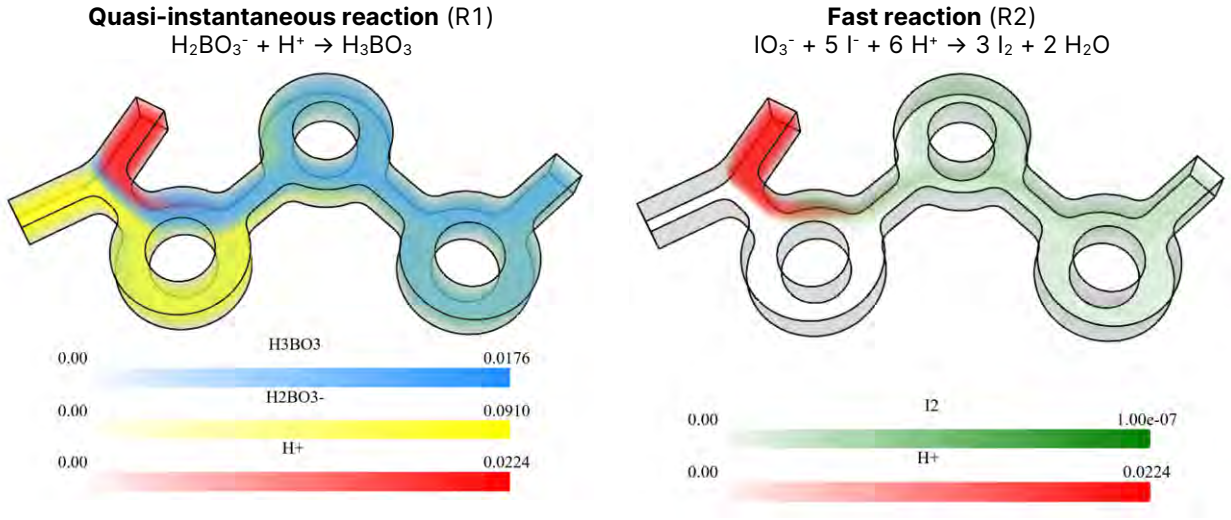

**Figure 3.** Representation of the CFD simulation of Villermaux-Dushman reaction system. Concentrations of the reactants and product of both reactions are presented in mol.dm$^{-3}$, using volume rendering of the CFD data of one of the simulations.

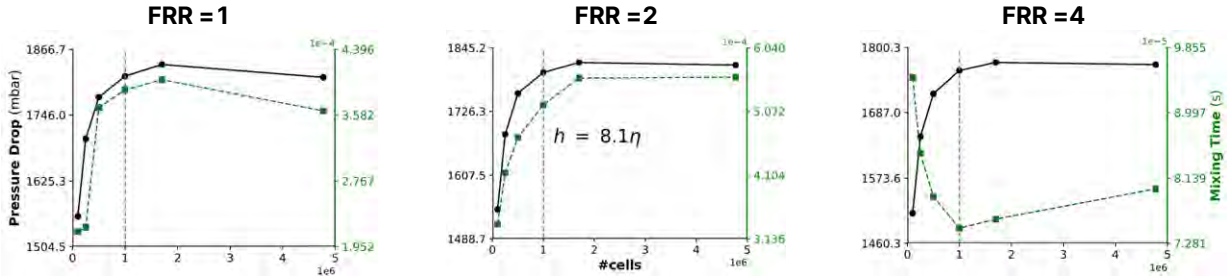

**Figure 4.** Results of the mesh convergence test. Plot of both objective functions (pressure drop in black and mixing time in green) as a function of the mesh number of cells. The vertical dotted line corresponds to the mesh parameter used in the optimization loop.

## Mesh Convergence

The choice of an appropriate mesh is a crucial factor for building faithful CFD models. A grid convergence test was therefore carried out for each operating condition, considering the geometry of the commercially available NanoAssemblr™ Ignite™ cartridge. In Figure 4, both objective functions (ΔP and $t_m$) are plotted against the number of cells of the respective mesh. Unlike for pressure drop, mixing time convergence was not fully reached. The relation between mixing time and grid size ($h$) was also not monotonic, likely due to the highly non-linear reaction terms of the Villermaux-Dushman system.

Establishing an appropriate mesh size criteria for all the geometries generated by the optimization algorithm is a non trivial task. It must be robust enough to provide accurate simulations throughout the whole solution space, without producing any type of numerical bias towards any kind of solutions. The criteria should also not be overly conservative to avoid the inefficient use of computational resources in prohibitively expensive meshes. In this case, the Kolmogorov turbulent length scale ($\eta$) was used as a reference to determine the appropriate mesh size. From the mesh convergence test, a mesh size of 5.78 µm was chosen as good compromise between model accuracy and computational cost. This corresponded to a grid size 8.1 times larger than the turbulent length scale. This factor was kept constant for the mesh generation throughout the optimization cycles. The turbulent length scale could be estimated prior to mesh generation using Equation 2 [11]:

$$\eta \approx D_h Re^{-3/4} \quad (2)$$

which considers the channel's hydraulic diameter ($D_h$), calculated with the geometry's height and width values, and the Reynolds number ($Re$), estimated with the TFR.

## RESULTS AND DISCUSSION

The optimization cycle for each value of FRR produces a set of geometry solutions and respective objective function values. These results are illustrated in Figure

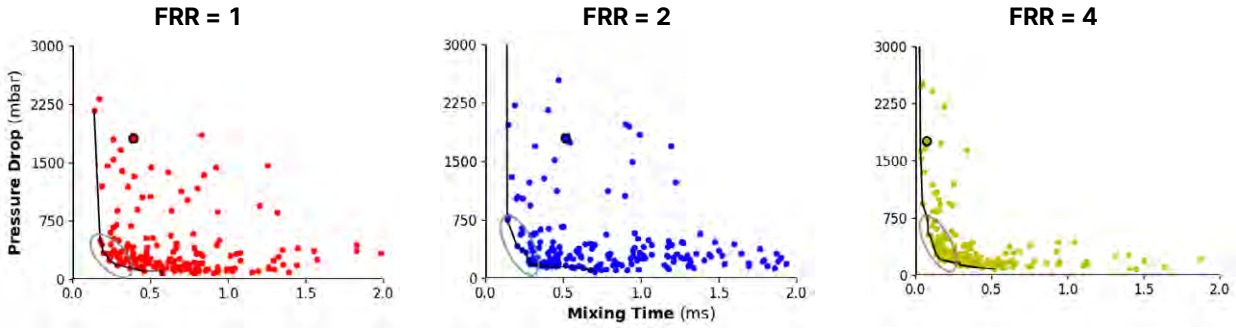

**Figure 5.** Scatter plot of each solution's objective functions, for each considered FRR. The Pareto front approximation is plotted as black line. The knee fraction of the Pareto front is circled in gray. The point circled in black represents the simulated performance of the reference geometry.

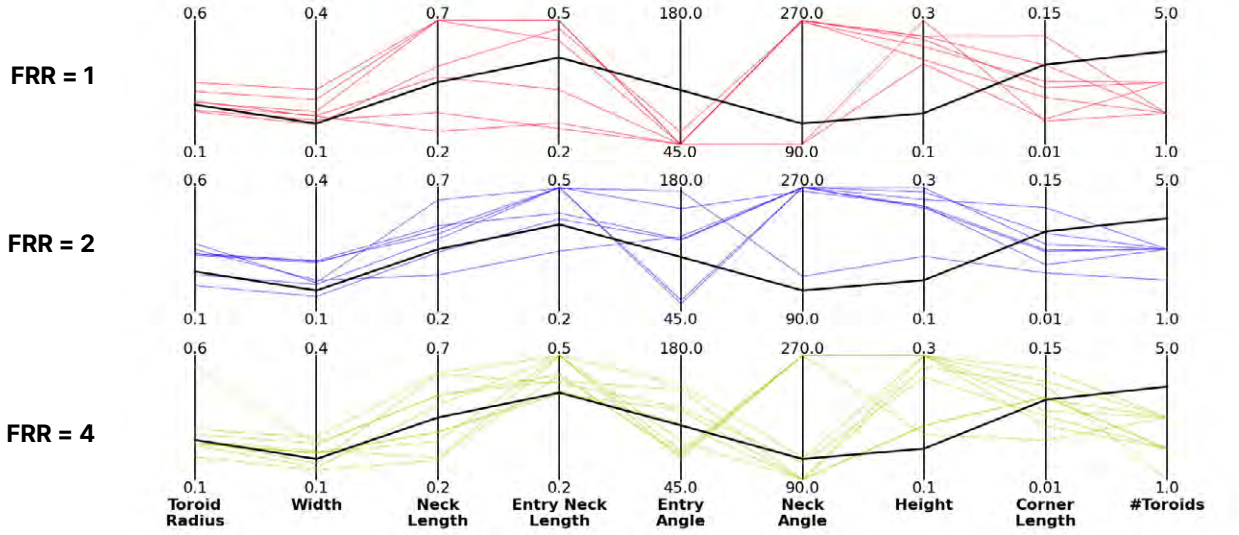

**Figure 6.** Geometric parameters of the nondominated solutions inside the knee fraction area, for each FRR. The reference geometry parameters are plotted in black.

5, in which the values of the solution's objective functions are compared to the NanoAssemblr™ Ignite™ geometry as a reference. Generally, this reference geometry performed suboptimally when compared to the respective obtained approximation of the Pareto front, in particular for low values of FRR. The main shortcoming being the elevated values of pressure drop.

In Figure 5, the knee fraction of each Pareto front is highlighted within a gray circle. The geometric parameters of the nondominated points of these subsets are presented and compared with the benchmark geometry in Figure 6 for each case study. From these results, it is clear that there is some solution redundancy, as considerably different mixers have similar performance values. This is not surprising, as many engineering problems present the same problem. For this reason, it is difficult to pinpoint how and which geometric parameters are affected by the change in FRR. The clearest exception is the "Entry Angle" parameter which is clearly minimized when FRR = 1 to reduce pressure drop. This is not the case with larger values of FRRs, where the lower flow rate stream is enveloped by the largest one at the inlet junction. This engulfment phenomenon contributes to faster mixing times and is likely enhanced with a wider angle of entry.

Moreover, when comparing the best obtained geometries with the benchmark, the biggest differentiating factor is the increased "Height" of the channels. This has two main effects: first, the cross-sectional area of the channel is increased, reducing pressure drop; second, since the inlets meet laterally, the increase in channel height results in a larger contact area between the flows, promoting mixing. Other significant differences include the reduced number of toroids and the maximization of the "Neck Angle" (90° and 270° produce symmetrical geometries).

Figure 7 illustrates the geometry of good solutions for each FRR value and the reference mixer. Values of the

respective objective function values are also presented. The methodology was able produce improved geometries with a ≈75% reduction of pressure drop in the mixer and a ≈50% reduction in mixing time (except for FRR=4).

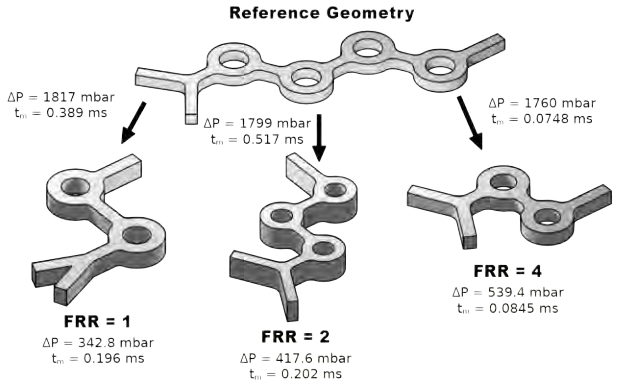

**Figure 7.** Illustration of the reference geometry and selected solutions for each FRR, and respective objective function values.

## CONCLUSION AND PERSPECTIVES

In this work, a shape optimization methodology, using Multi-Objective Bayezian Optimization, was presented and applied to the micromixer design problem. A set of improved geometries were presented and compared to a commercially available reference geometry for three different operating conditions. The most significant geometrical features to mixing performance were identified by analysing the geometrical parameters of the best-found solutions.

The results indicate some discrepancies in the ideal geometry for each operating condition. Thus, future work will consider the formulation of a robust Bayesian optimization framework to optimize the micromixer geometry design for a given range of operating conditions.

## ABSTRACT

Recent advancements in machine learning and time series analysis have opened new avenues for improving predictive control in complex systems such as mineral flotation. Techniques leveraging multivariate predictive control in mineral flotation have seen significant progress in recent years. However, challenges in developing an accurate dynamic model that encapsulates both the pulp and froth phases have hindered further advancements. Now, with a readily available model containing equations that describe the physics of flotation froths, an opportunity for novel control strategies presents itself. In this study, a Gaussian Process (GP) Model Predictive Control (MPC) strategy is proposed to integrate uncertainty quantification directly into the control framework. By leveraging the probabilistic nature of GP models, this approach captures process variability and adapts dynamically to new data, ensuring continuous refinement of the GP model within the MPC strategy. Unlike previous implementations where model parameters remained static, this methodology updates the GP model in real time, allowing for improved decision-making in the face of process uncertainty. The GP model was trained, optimized with JAX, evaluated using relevant metrics, and implemented as a surrogate within the MPC framework. The results demonstrate the capability of the GP model to accurately represent process dynamics while minimising prediction errors. Moreover, incorporating uncertainty reduction through standard deviation minimisation in the objective function enhances both control performance and system robustness. This paper sets the basis for the potential of using GP-MPC to enhance both the accuracy and robustness of mineral froth flotation control.

**Keywords**: Mineral Flotation, Model Predictive Control, Gaussian Processes, Machine Learning

## INTRODUCTION

Machine learning has rapidly become one of the most exciting and revolutionary tools in modern industrial processes [1]. Leveraging data-driven models, such as Gaussian Processes (GPs), offers sophisticated methods to tackle the inherent complexity and nonlinearity of chemical processes. Mineral flotation is recognised as a critical separation technique in the mining industry, playing a vital role in extracting value from low-grade and complex ore bodies [2]. This process utilises differences in surface properties to selectively separate valuable minerals from the gangue. The process can be fine-tuned by adjusting various parameters such as air flow rate, chemical dosages, and pulp level to optimise recovery and grade (purity) of the desired minerals. However, the introduction of non-linear dynamics, complex interactions, and instability arising from multi-phase operation introduce challenges to achieving effective control [3]. GPs are particularly valuable in these contexts because they provide a flexible, probabilistic approach to modelling complex systems, allowing for both accurate predictions and uncertainty quantification. This makes them well-suited for optimising and controlling industrial processes where uncertainty and variability are significant challenges. Optimal control and optimisation in mineral froth flotation processes have made significant progress in recent times [5,6]. In mineral froth flotation, key control variables, such as air flow rate and pulp level, play a crucial role in maintaining process stability and optimising

performance. These parameters directly influence the dynamics of both the pulp and froth phases, affecting the efficiency of the separation process. The process is of particular interest to researchers due to marginal improvements in efficacy yielding substantial economic benefits as well as helping with global efforts of meeting increasing demand effectively.

### Problem Description

A common control strategy in flotation is Model Predictive Control (MPC), widely recognised as one of the most efficient for multi-variable processes. Its development for mineral flotation was previously limited by the lack of a dynamic model accurately representing the complex froth flotation interactions [3]. Earlier MPC implementations relied on empirical models capturing only the pulp phase, neglecting the froth phase, which significantly impacts flotation performance [5]. However, due to the contributions made by Quintanilla et al. [5,6], a physics-based model has been proposed, developed, and calibrated. This opens the possibility of applying state-of-the-art probabilistic modelling to a control strategy for this mineral flotation process. Building on the success of using this process model to implement an economic-model predictive controller [4], this paper aims to design a novel GP-MPC control strategy for the optimal operation of a mineral froth flotation process. By integrating GPs into the MPC framework, this strategy aims to achieve higher recovery rates and better product quality, ultimately contributing to more sustainable and economically viable mineral processing practices.

## BACKGROUND

### Gaussian Processes

Gaussian Processes (GPs) have become a powerful tool in various fields, including process control [16]. A key advantage is their ability to capture residual uncertainty from plant-model mismatches, useful in control systems where understanding the confidence of predictions is crucial. Unlike traditional mathematical optimisation, which assumes exact function evaluations, GPs model observations as stochastic, providing a probabilistic system representation. Although GPs in control for a mineral flotation process are not well documented, the use of GP as a surrogate model are present in the control community. GPs alongside MPC first started appearing in the early 2000's with Murray Smith et al [7]. The inclusion of information about the trust in the model depending on the region, enabled a more nuanced exploration of the control space. Overall, this departure from the traditional deterministic view creates a novel opportunity for optimal control by leveraging uncertainty to refine dynamic models, improving robustness. Given the process's inherent nonlinearities [6], GP-based probabilistic modeling holds strong potential for mineral flotation.

### Model Predictive Control for Mineral Flotation

Flotation is a key recovery process in the mineral industry. Studying this process is crucial due to its versatility and efficiency in processing large ore volumes, where even small improvements can yield significant economic benefits [3]. Attempts to introduce a robust and effective control strategy for the mineral flotation process have been made [8,9]. However, in previous work, modelling for control purposes was challenging. Most models have only focused on the pulp phase rather than the froth phase [5]. A comprehensive phenomenological model has been created by Quintanilla et al [5,6]. The model involves several innovative features, encompassing not only the representation of the pulp phase but also the inclusion of variables pertinent to the froth phase, such as froth stability, bursting rate, and air recovery. The equations in the model facilitate the estimation of critical variables associated with the key performance indicators: grade (product purity) and recovery. Such variables could then be seamlessly integrated into a dynamic optimisation objective function formulation for an MPC strategy. The availability of this dynamic model enables novel control strategies to be attempted. While success in stochastic data-driven MPC using GPs and froth flotation MPC is documented, applying GPs and MPC to mineral flotation will be, to the best of the authors' knowledge, the first of its kind.

## METHODOLOGY

### Gaussian Process Training and Implementation

As previously outlined, GP's offer a flexible and nonparametric approach to modelling processes. In the context of MPC, this GP will serve as a surrogate model that predicts the future states of the process given current and past inputs. The structure of the GP model is designed to handle the multi-input, multi-output nature of the froth flotation process with multiple training datasets provided by the synthetic flotation model. This training data consisted of 9 state variables and 2 control variables. Before training the GP model, all input data were standardised to have zero mean and unit variance. This preprocessing step prevents any one input feature from dominating the prediction due to scale differences. A negative-log-likelihood (NLL) objective function was deployed in the training process to optimise the hyperparameters of the GP model. The negative log likelihood is given by:

$$NLL(\boldsymbol{\theta}) = -\log P\left(\boldsymbol{Y} \mid \boldsymbol{\theta}\right) \quad (1)$$

NLL is a standard objective function employed in hyper-parameter optimisation for GP's due to its versatility and being directly related to the model's predictive performance. In this GP formulation, a radial basis function (RBF) kernel was selected with respective hyper-parameters acquired through the maximisation of the marginal likelihood for each parameter (or equivalently, the minimisation of the negative log likelihood). With an 11-dimensional input space, a multi-start strategy improved exploration. These samples were passed to a stochastic gradient-based optimisation algorithm, specifically the Adam algorithm, to generate optimal hyperparameters, as seen in Algorithm 1. The selection of this solver was due to its computational efficiency as well as its capabilities in handling noisy and large volumes of data. An area of concern for this iterative process was the length of time taken to arrive at a suitable solution due to the computational complexity, nonconvexity, and taxing matrix operations conducted in the GP formulation procedure. To speed up this hyper-parameter optimisation procedure, the JAX python library was deployed. Notable advantages such as vectorised mapping, just-in-time compilation through XLA [10] and automatic differentiation allows for efficient computation of gradients in regard to the GP log-likelihood objective function. Due to the repeated nature of complicated matrix operations such as the inversion of the optimal covariance matrix, JAX's GPU acceleration capabilities can dramatically speed up the central matrix calculations in the GP computations.

**Algorithm 1.** JAX GP – Creation & Inference

1. **Input**: Xdat, Ydat, Kernel, multi_hyper, var_out
2. **Initialise**: Normalise Xdat and Ydat
3. Set bounds for optmisation procedure
4. Generate initial points using Sobol sequences
5. **For** i in initial points & GP output:
    a. **Define:** $-\log p(X \mid \theta)$ ***where*** $\boldsymbol{\theta} = \{\boldsymbol{\iota_{opt}}, \boldsymbol{\sigma^2_{f,opt}}, \boldsymbol{\sigma^2_{n,opt}}\}$
    b. Compute $\nabla_\theta NLL(\theta \mid X)$
    c. Update parameters using SGD: $\theta_{t+1} = \theta_t - \eta \nabla_\theta Loss(\theta_t)$
    d. **If** Max iterations or convergence criteria met **Then:**
        i. Select optimal solution $\theta_i^*$ with smallest $-\log p(X_i^* \mid \theta^*_i)$ value **end if**
    e. **End for**
6. Computer optimal coveriance matrix: $cov_{ij} = \sigma_f^2(-\frac{1}{2} dist_{ij})$
7. Computer inverse of covariance matrix: $K^{-1}$
8. Computer covariance between the test and training points: $k$
9. Computer predicted mean: $\mu_* = k^T K^{-1} Y$
10. Compute predicted variance: $\sigma_*^2 = max(0, \sigma_f^2 - k^T K^{-1} Y)$
11. **Output:** $\theta_{opt} = \{\boldsymbol{\iota_{opt}}, \boldsymbol{\sigma^2_{f,opt}}, \boldsymbol{\sigma^2_{n,opt}}\}$, $\mu_*$, : $\sigma_*^2$

## Gaussian Process Model Predictive Control

The objective function contains 3 objectives. The first is related to the concentration of valuable materials lost in the tailings (Equation 2) due to the primary goal of flotation being to optimise the separation of valuable minerals. Secondly, the control effort (Equation 3) explicitly incorporates the cost of actuator movements, which is important due to controls such as pulp height ($h_p$) being controlled via a valve. Finally, the standard deviation penalty is introduced to discourage the MPC from making decisions on uncertain estimates and rather to guide it towards more reliable and robust control strategies (Equation 4).

$$J_{loss} = \sum_{k=0}^{N-1} Loss_k \tag{2}$$

$$J_{control} = \sum_{k=1}^{N-1} (u_k - u_{k-1})^2 \tag{3}$$

$$J_{std} = \sum_{k=0}^{N-1} \sigma^2_{GP_k} \tag{4}$$

The three equations are then put altogether with weighting constant values of 50,1 and 10 respectively to form a multi-objective function to be minimised by an SLSQP method.

The GP-MPC approach leverages the predictive capabilities of GP models to enhance the performance of MPC by providing more accurate and probabilistic forecasts of the system's behaviour. The combination of both should enable better adaptation to dynamic conditions and improve overall system robustness. The use of a surrogate model involves the creation of simplified models that approximate the behaviour of complex systems. This approach reduces the computational burden typically associated with solving the optimisation problem at each MPC iteration, as it allows for faster evaluations of the system's future states without sacrificing accuracy. This efficiency is crucial in this mineral froth flotation application where computational resources and time are limited. In the context of this mineral froth flotation process MPC framework, the trained GP model will be employed at each time step to predict the future states of the system for the entire prediction horizon, allowing the MPC to evaluate the impact of different control actions over this horizon. These GP-generated predictions, which include

both mean estimates and associated uncertainties, are fed into the MPC's objective function. The MPC then optimises the control inputs based on these predictions to achieve desired future outcomes while considering uncertainties. The GP can be updated online as new data becomes available. As the system evolves, the updated models are then used to predict the next set of future states, ensuring that the control strategy remains relevant and effective as the system dynamics change. The overall process of training the GP, simulating the surrogate within the MPC framework, calculating the optimal control and finally updating with the relevant process model states as depicted in Figure 1.

## RESULTS AND DISCUSSIONS

### GP Training and Validation

Evaluating the effectiveness of the GP surrogate implementation was done with a training and validation dataset. It is important to note that this is a state-space GP model, where the states are: mineral ($M_{min}$), gangue masses ($M_{gangue}$), gas holdup classes ($\varepsilon_1 - \varepsilon_5$), pulp level ($h_p$) and tailings flow rate ($Q_{tails}$). Both datasets were generated using the physics-based process model from [5,6]. Various statistical measures were used to evaluate the performance of the GP surrogate model, including negative log predictive density (NLPD), mean absolute percentage (MAPE), and root mean squared percentage error (RMSPE). Before the calculations of these statistical parameters, the states were normalised to avoid problems due to differences in the order of magnitude of the different states. Figure 2 displays the GP predictions closely following the underlying system data. It was observed that the testing results show slightly higher error rates than the training data, which is expected. The $\epsilon$'s are slightly less accurate and confident, with the GP predictions deviating slightly from the real data and a wider confidence region. Confidence regions remain consistent from training to testing, with estimations related to Qtails, $h_p$, $M_{gangue}$ and $M_{min}$ showing the highest confidence in estimations due to a tighter standard deviation. Overall, from graphical interpretation, the model seems to fit the training data well, with predictions closely following the experimental data points. Tables 1 and 2 reflect a similar conclusion drawn from the graphs, with a low RMSPE and MAPE.

**Table 1:** GP Without JAX Testing Metric Results

| Experiment No. | RMSPE | NLPD | MAPE |
|---|---|---|---|
| Experiment 1 | 0.15% | -5.47 | 0.09% |
| Experiment 2 | 0.24% | -5.29 | 0.14% |
| Experiment 3 | 0.36% | -4.91 | 0.20% |

A low NLPD is also seen, portraying good probabilistic predictions and uncertainty quantification. The metrics show consistent performance across all three testing experiments, with little variation, suggesting robustness in the GP model. Results from the JAX-enhanced GP formation are seen in Figure 2 which also illustrates similar prediction patterns and confidence intervals across the training and testing dataset. Quantitatively, the performance metrics for the JAX-GP in Table 2 demonstrates comparability with the non-JAX GP. Some differences can be observed from the JAX-GP and non-JAX GP, such as estimation of the states $M_{min}$ and $Q_{tails}$ in the testing data, which are slightly less accurate in the JAX-GP, with a smoother mean being estimated. The estimations of states $M_{min}$, $h_p$ and $\epsilon$'s are confident with an observable tight standard deviation. The most notable improvement was observed in compilation time, with a reduction of 33% when run on an Apple M2 chip running on macOS 14.4.1. This speedup in compilation, coupled with the preservation of model accuracy, underscores the potential of JAX to enhance the efficiency of GP implementations.

**Table 2:** GP with JAX testing metric results

| Experiment No. | RMSPE | NLPD | MAPE |
|---|---|---|---|
| Experiment 4 | 0.40% | -4.78 | 0.26% |
| Experiment 5 | 0.40% | -4.79 | 0.28% |
| Experiment 6 | 0.63% | -4.17 | 0.44% |

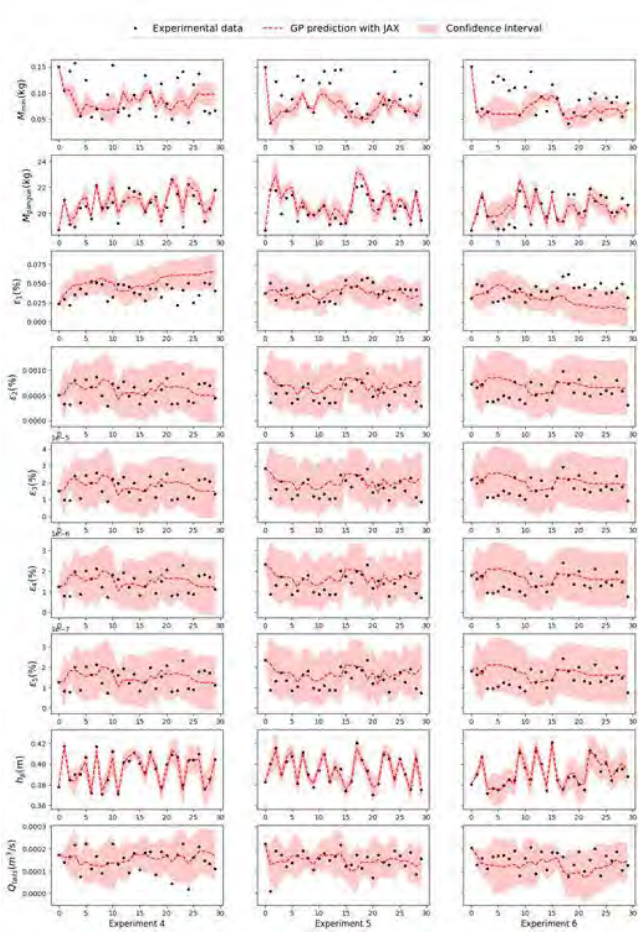

**Figure 2** – GP with JAX results illustrating the evolution of system states and predictions. The black dots represent the experimental data from the process, the red lines indicate the GP predictions, and the red shadows depict two standard deviations from the GP model. These states are assumed to be observable within the MPC framework.

## GP-MPC Control Performance

The effectiveness of the overall control strategy was assessed using MAE, RMSE, and ISE metrics, comparing the desired setpoint with the actual control actions. Table 3 depicts these metrics, showing that the control mechanism appears to be effective in maintaining the desired levels for both $h_p$ and $Q_{air}$. Additionally, the evaluation considered the average concentration of valuable material lost in the tails. The dataset fed was unseen by the GP and MPC. Figure 3 demonstrates the GP estimates for the $h_p$ (pulp height) state evolution with associated confidence intervals as well as the resulting optimal control action for $h_p$ control. The GP predictions follow closely the process, with tight uncertainty region suggesting a well-calibrated surrogate model for the process. Moreover, Figure 4 visualises the air flow rate ($Q_{air}$) control strategy derived by the MPC strategy with an overall trend of increasing air flow over time, which typically promotes increased bubble production and mineral recovery in froth flotation.

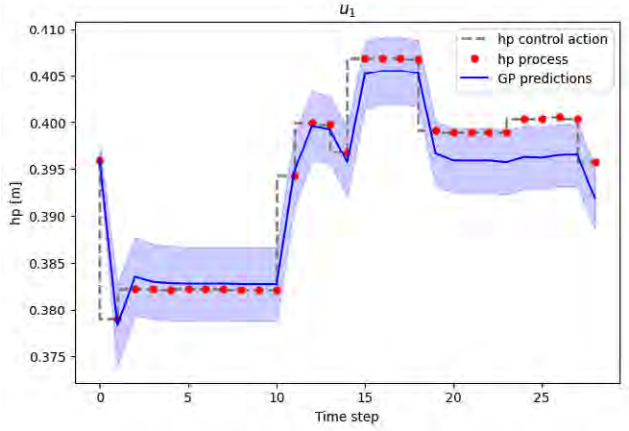

**Figure 3 –** Pulp height ($h_p$) control output from GP-MPC

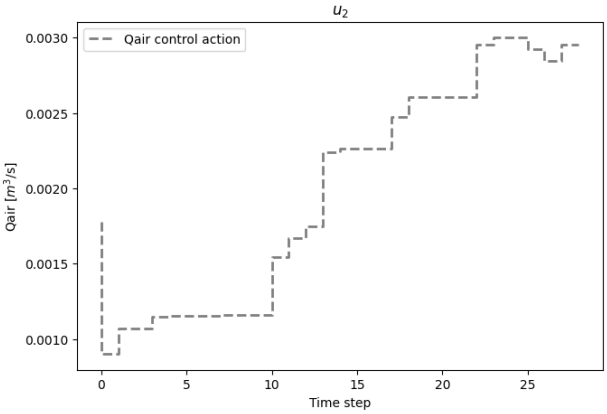

**Figure 4** - $Q_{air}$ control output from GP-MPC

**Table 3:** Non-JAX GP with MPC metric values

| Metric | $h_p$ [m] | $Q_{air}$ [$m^3/s$] |
|---|---|---|
| MAE | 0.012431 | 0.000758 |
| RMSE | 0.015232 | 0.000957 |
| ISE | 0.006728 | 0.000027 |
| Mean Loss in Tails ($kg/m^3$) | 0.630612 | |

Overall, the control strategy balances stability and responsiveness, initially maintaining constant action (time steps 2-10) and introducing significant adjustments around steps 12 and 20 to manage the trade-off between metallurgical recovery and grade. Lower pulp heights, which yield higher grades but reduce recovery, are dynamically adjusted alongside air flowrate $Q_{air}$ to optimise flotation performance. This aligns with findings on peak air recovery and froth stability from prior studies [5], highlighting the importance of $Q_{air}$ in achieving optimal recovery. Furthermore, Figure 4 demonstrates a stepped approach rather than continuous increase, suggesting the controller is allowing the flotation system to stabilise at each air flow level before making further adjustments. The strategy demonstrated efficiency, with low mean material loss in tailings (0.630612 kg/m³). Control metrics, including low MAE, RMSE, and ISE values, confirm precise and robust system performance, validating the effectiveness of the GP-MPC approach.

## CONCLUSION

MPC strategies have proven effective in mineral froth flotation, improving recovery and grade. However, many models focus on the pulp phase and struggle with the froth phase. With a more accurate process model for both phases now available, an opportunity arises for GPs to be applied, leveraging confident decisions. MPC with GPs for mineral froth flotation has not been widely explored. The findings from the implemented models demonstrated that the surrogate model generates accurate and certain inferences on unseen datasets with low amounts of associated error. Moreover, the possibility of accelerating the surrogate model creation was outlined with the implementation of JAX. The MPC strategy utilised the GP surrogate to generate an optimal control trajectory. Most notably, the mean loss in tails was measured at a low 0.630612 kg/m³. The performance is further evidenced by examining the control accuracy, with both $h_p$ and $Q_{air}$ parameters exhibiting low MAE and RMSE values, indicating precise control overall. These findings reinforce the benefits of leveraging the uncertainty quantification and probabilistic attributes of the GP model alongside an MPC control strategy. Being the first of its kind to apply GP-MPC to a mineral froth flotation process, this work drives forward the objective of multivariate predictive control of flotation processes, providing an alternative probabilistic approach to enhancing mineral recovery and grade. In addition, the improvements noted in this study related to reduced compilation outline the possibility for an accurate and fast control strategy.

## ABSTRACT

Recently, the focus on increasing process efficiency to reduce energy consumption has driven the adoption of alternative systems, such as Petlyuk distillation columns. It has been proven that, when compared to conventional distillation columns, these systems offer significant energy and cost savings. From an economic standpoint, achieving high-purity products alone does not ensure the feasibility of a process. Instead, balancing the trade-off between product purity and cost necessitates multi-objective optimization. While conventional optimization methods are effective, novel strategies like Bayesian optimization offer distinct advantages for handling complex systems. Bayesian optimization requires no explicit mathematical model and can efficiently optimize even when starting from a single initial point. However, as a black-box method, it demands a detailed analysis of hyperparameters, such as the acquisition function and the number of initial points, to ensure optimal performance. This work presents a case study of a Petlyuk distillation column, focusing on the influence of key hyperparameters in Bayesian optimization. Additionally, the role of uncertainty in the optimization process is explored, as it is a critical factor in real-world applications. By simulating uncertainty, this study provides insights into its impact on the optimization process.

## INTRODUCTION

In chemical engineering, complex systems such as Petlyuk distillation columns have been analyzed to achieve considerable energy savings compared to traditional distillation columns, due to its configuration, a Petlyuk column consists of a prefractionator and a main column, where vapor and liquid streams are thermally coupled, thus, unlike conventional sidestream columns, it uses a single reboiler and a single condenser. Therefore, various methodologies have been employed for the operation and design of Petlyuk columns, including nonlinear programming (NLP) [5] and mixed-integer nonlinear programming (MINLP) [10]. Traditional solvers for NLP and MINLP problems frequently face convergence challenges. In practice, these solvers often fail to identify the global optimum due to the non-convex nature of the problem. Alternative solution approaches, such as genetic algorithms, have been explored. However, their performance improvements over the past two decades have been limited [9], highlight the need to explore alternative methods, such as data-driven optimization. In this manner, Bayesian optimization (BO), a black-box method, does not require an explicit mathematical model

of the problem suited to this problem. The core of this method is the construction of a surrogate probabilistic model, most commonly a Gaussian process (GP), which efficiently guides the sequential acquisition of new data through an acquisition function. Whose role is to balance the trade-off between exploration and exploitation. In practical terms, exploration targets points where the surrogate model variance is high, while exploitation focuses on points with a high surrogate model mean. This balance allows BO to intelligently select evaluation points for the objective function, thereby guiding the search toward the optimal value effectively. Moreover, the optimal solution is reached either after a specified number of iterations or when a stopping condition based on the objective function is achieved. This method is especially suited for handling expensive objective functions, where “expensive” refers to high computational or experimental costs. Additionally, the objective function can be expressed as a multi-objective function [4]. The problem to be addressed can be formally stated as follows: "Given an initial set of potentially noisy process measurements of system outputs, determine the optimal operational policy that maximizes a defined operational target. In this context, the process outputs may include stream compositions, such as mole fractions, or other composition metrics. Achieving the specified operational target requires selecting a set of input variables to enforce optimal operation. As evident from this definition, the problem falls within the domain of dynamic optimization. However, it is important to note that dynamic process calculations are not involved. Instead, it is assumed that the application of input variables drives the system to a new steady state, where calculations are repeated iteratively until the target conditions are satisfied. BO emerges as a robust alternative to the reinforcement learning methodologies commonly utilized in modern artificial intelligence systems, offering a structured and efficient approach to address such optimization challenges. This work proposes a data-driven optimization strategy tailored for complex process systems, such as the Petlyuk column, where traditional optimization methods are computationally expensive. The approach utilizes a multi-objective function that aims to minimize cost while maximizing the desirable component purities in each output stream of the Petlyuk column. Furthermore, the impact of random noise on the BO process is investigated to assess the feasibility of the proposed strategy in real-world applications

## METHODOLOGY

The use of BO that can be used to evaluate expensive objective functions, as mentioned before the term “expensive” can be used for both economic or computational cost to evaluate a process or an experiment. In the absence of a Petlyuk column to realize the experiments, the commercial simulator Aspen plus was used to mimic the behavior to obtain the results of the expensive objective function. Moreover, in the figure 1 explains the Bayesian optimization process, where the core are two steps [2]: First, the estimation of the black-box function from data through a probabilistic surrogate model, the most common a GP and secondly, maximizing an acquisition function that trade off the parameters of exploration and exploitation. Therefore, the criteria of the convergence test can be in different ways as a stop criterion for a condition in the objective function or a defined number of iterations, the last one was selected for a more balanced comparative of the hyperparameters; by stop the optimization process after 50 iterations in all cases.

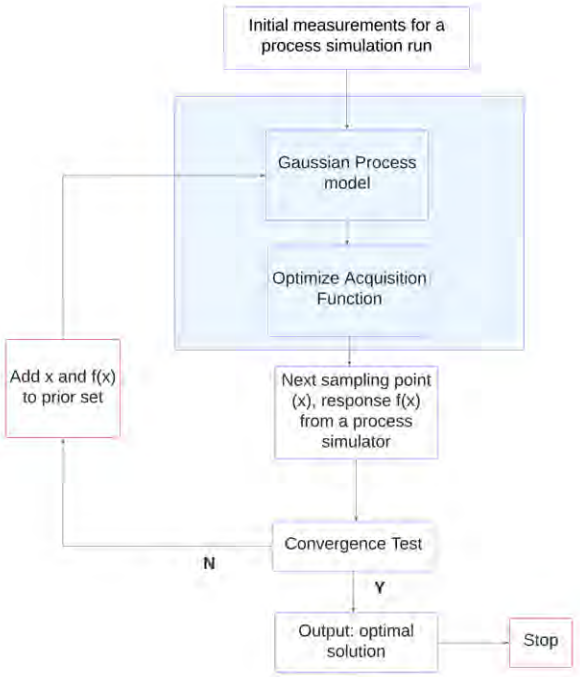

**Figure 1.** Flow chart for the BO process. Key steps, such as GP and the acquisition function, are denoted in blue. The optimization loop begins with the IP obtained from the simulation and adapted to the GP, and then the next sample is determined by the Acquisition Function. Furthermore, the loop terminates when the user objective function criteria are met for the convergence test.

To analyses the Petlyuk column, the involve mixture consists of feed flow (F=800 kmol/h) of benzene(A), toluene(B), and xylene(C) (figure 2) also known as a BTX mixture [3]. Therefore, the selected manipulated variables are the Distillate flow rate of the main column(D), reflux ratio (R), liquid flow rate (LR) and vapor flow rate(VR) to the pre-fractionator column, the interval of the manipulated variables in the same order are: $D \in [5–100]$ kmol/h, $R \in [2–35]$, $LR \in [20–150]$ kmol/h and $VR \in [20–150]$ kmol/h. The BO process is computing using the

Scikit-Optimize library [6], in Python and establish a connection with the ASPEN Plus simulator through Windows Component Object Model (COM) access. Additionally, all manipulable variables are normalized in the GP and denormalized for use in the Aspen Plus simulator.

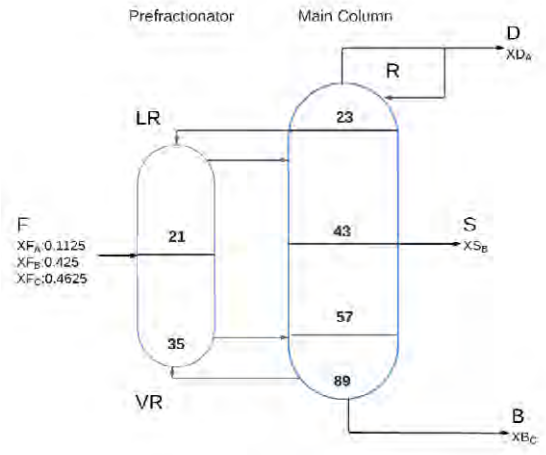

**Figure 2.** Flowsheet of a Petlyuk column system, consisting of a main column and a prefractionator, the locations of streams and stages are illustrated.

The multi-objective function, defined in Equation 1, is formulated as a minimization function, where we aim to maximize the desired composition of the component of interest in each stream: the distillate ($XD_A$), the lateral side ($XS_B$), and the bottoms ($XB_C$). In this case study, the function also seeks to improve economic performance by maximizing the desirable components in each stream while minimizing the total operational cost (TOC), which is calculated based on the costs of cooling water and steam incorporated into the ASPEN simulation. Moreover, the composition variables obtained from the Aspen Plus simulation are already normalized to values between 0 and 1. However, in the case of TOC, two preliminary BO runs are conducted, using default values Matern for the kernel and LCB for the acquisition function. These runs define the upper (UB) and lower (LB) bounds of TOC values by minimizing and maximizing TOC as an objective function. The resulting bounds are then used to perform a min-max normalization, as defined in Equation 2 [8]. This normalization ensures that the multi-objective function maintains an equitable trade-off among all decision variables.

$$\Omega_i = \left(XD_{B,i} + XD_{C,i} - XD_{A,i}\right) + \left(XS_{A,i} - XS_{C,i} - XS_{B,i}\right) + \left(XB_{A,i} + XB_{B,i} - XB_{C,i}\right) + \phi_{TOC,i} \quad (1)$$

$$\phi_{cost,i} = \frac{cost_i - LB_{cost}}{UB_{cost} - LB_{cost}} \quad (2)$$

Some aspects are analyzed: First, the number of initial points is varied. Instead of providing random information, these initial points are designed to generate insights into the possible optimal zone using an initial BO run with default values. This initial run starts with a single point at the center of the search space for all manipulated variables. The optimal result obtained from this run is then used to generate initial points (IPs) by varying the optimal manipulated variables within a random range of ±5%, creating new initial points. This approach aims to provide high-quality information to the Gaussian Process (GP) rather than relying on arbitrary random points in a non-optimal region. Second, this process is executed using different acquisition functions, including Expected Improvement (EI), Lower Confidence Bound (LCB), and Probability of Improvement (PI). Additionally, uncertainty is analyzed by incorporating noise into the results. This is done by introducing cumulative noise (ε) into the objective function value (Ω), adding random variations at a level of ±5% of the value of Ω, as shown in Equation 3.

$$\Gamma_i = \Omega_i + \varepsilon \quad (3)$$

## RESULTS

As is denoted in tables (1-6), each of the different acquisition functions with the variation of the initial points was computed, with the iteration at which the optimal value is reached also counting the initial points added. First, in the case of EI (tables 1-2), there is no notable difference in the objective value of the optimal solution achieved with an increase in the number of initial points. Even with 30 initial points, the objective value does not show a significant increase compared to using 20 initial points; instead, it decreases to the level observed with 5 initial points. Moreover, this minimal change in the objective function indicates that when the purity product fractions are analyzed across all optimal solutions, there is no sharp difference. The purities achieved are 0.99, 0.96, and 0.96 for $XD_A$, $XS_B$, and $XB_C$, respectively, for all cases. On the other hand, only the flow of VR is the manipulable variable that shows a notable change from 150 kmol/h (1 initial point) to 110.02 kmol/h (5 initial points). Therefore, regarding the economic aspect, the solutions related to the R value fall within the same interval, which is directly related to operational costs. In this manner, the trend of no notable difference continues.

Secondly, for the LCB acquisition function (tables 3-4), there is a slight increase in the optimal value of the objective function. This results in a slight improvement in the achieved purity of the products, allowing the purity of the intermediate component $X_{SB}$ to reach up to 0.96 and the bottom component $X_{BC}$ to reach 0.98. However, in the trade-off with TOC, there is an increase of more than 0.47x $10^6$ USD/year, and this occurs only when using more than 10 initial points. Only the case with 30 initial points can achieve a trade-off with similar economic performance to EI, while also achieving better purity values for the components ($XS_B$ = 0.964; $XB_C$ = 0.986).

| 10 | 78.04 | 17.59 | 136.92 | 150.00 |
| 20 | 77.45 | 17.03 | 123.92 | 129.88 |
| 30 | 78.78 | 16.27 | 132.33 | 150.00 |

**Table 6:** Results BO PI.

| IP | Description | | | TOC | Ω | Iter. |
|---|---|---|---|---|---|---|
| | $XD_A$ | $XS_B$ | $XB_C$ | x $10^6$ | | |
| 1 | 0.999 | 0.964 | 0.968 | 5.26 | -2.479 | 42 |
| 5 | 0.999 | 0.964 | 0.968 | 5.06 | -2.493 | 36 |
| 10 | 0.999 | 0.965 | 0.980 | 5.26 | -2.505 | 52 |
| 20 | 0.999 | 0.962 | 0.962 | 5.06 | -2.476 | 42 |
| 30 | 0.999 | 0.961 | 0.965 | 4.93 | -2.489 | 45 |

Finally, in the case of PI (tables 5-6), the performance shows the trend of EI, with achieved purities of 0.99 ($XD_A$), 0.96 ($XS_B$), and 0.96 ($XB_C$). The results are very similar, with the difference in the objective function between the cases of 1 and 10 initial points being just 0.001. In this manner, the economic aspect also shows only slight differences. Additionally, when comparing the different acquisition functions, the differences are minimal.

Similarly to the previous results, when noise is added to the objective function, as shown in Tables 7–12, the trend of achieving a high-purity distillate product ($XD_A$ = 0.999) continues, except for an outlier in the LCB acquisition function with 30 IPs. Additionally, both $XS_B$ and $XB_C$ maintain purities of ≥0.95, showing no significant difference compared to the noise-free case.

On the economic side, TOC results remain in the range of 4.63 to 6.85 × $10^6$ USD, with an exception for an outlier in the EI acquisition function with 1 IP. Thus, no improvements are observed in relation to any acquisition function, and increasing the number of IPs does not lead to better performance in the objective functions. It is important to highlight, as in the previous case, that adding noise does not negatively impact the BO process, and good results can still be achieved even with just one IP. Moreover, when comparing the different acquisition functions with and without uncertainty, the differences between the results are minimal. Therefore, the number of IPs providing quality information is not necessarily associated with better objective function performance, regardless of the acquisition function. Additionally, the multi-objective function ensures that the trade-off between purities and TOC remains balanced. However, as mentioned before, although TOC stays within a narrow range, its scale ($10^6$ USD) means that even a slight change, especially in the reflux ratio (R), can significantly impact TOC, either increasing or decreasing it by a considerable amount.

## CONCLUSIONS

In this work, we present a practical methodology for solving multi-objective problems. The results obtained demonstrate a favorable trade-off between objectives for the Petlyuk distillation column, which serves as an energy-saving alternative to traditional sequences. This approach allows for analyzing the feasibility of the process without specifying a particular conversion fraction, as is typically required in distillation optimization problems. The solutions indicate that the achieved trade-off demonstrates the possibility of equilibrium between cost and product purity, with all cases achieving high purity fractions (≥0.96). Furthermore, as mentioned earlier, in low-dimensional Bayesian optimization problems like the one presented, there is no significant difference in performance based on the number of initial points or the acquisition function used. Additionally, despite variations in the number of initial points (IPs), the acquisition function, and the influence of noise in the process, no notable differences were observed, and all results remained within the same range of manipulable variable settings. However, even a slight change in the normalized cost represents a relatively significant change in the total operational cost (TOC) due to its magnitude ($10^6$ USD/year). While these differences are noticeable, increasing the number of initial points does not necessarily lead to better performance in the objective function. This work highlights the potential of Bayesian Optimization (BO) for process simulation, demonstrating that, when combined with modern computing power, it can achieve an optimal design in just a few fast iterations unlike traditional techniques that rely on explicit mathematical models, which often require simplifications. Thus, regardless of the number of initial points or the acquisition function selected, in cases with a low number of manipulated variables and system uncertainties, a multi-objective function can still provide a good trade-off for the Petlyuk column. Moreover, the procedure is easily extendable to other problems, not only those that are complex due to model structure but also large-scale or stochastic problems where computational costs are significant. These types of approaches will be explored in future work.

## ABSTRACT

Asserting the phase stability of multi-component mixtures is an important task in computer-aided mixture/blend design (CAM$^b$D), but it is often hindered by the lack of reliable and tractable models. In this paper, we propose a group-contribution machine-learning (GC-ML) method to predict phase coexistence for a large set of ternary mixtures consisting of two solvents and one (fixed) solute. Each solvent is represented by a vector of functional group numbers, encoded by integer values. The solvent vectors are combined with mixture composition and temperature to form the input features to a GC-ML surrogate classifier, which distinguishes between four types of stable phase configurations as possible outputs: liquid (L), solid-liquid (SL), liquid-liquid (LL) or solid-liquid-liquid (SLL). To explore the performance of the trained GC-ML multi-classifier, it is embedded as a surrogate phase-stability constraint in the optimisation of an ibuprofen crystallisation process. A two-step solution strategy is proposed, iterating between a surrogate-based subproblem and a rigorous UNIFAC-based subproblem, to design binary solvent mixtures that improve the yield of ibuprofen. A high classification accuracy score of over 0.96 is achieved in identifying the correct phase configurations with the surrogate model, making it possible to accurately predict whole phase diagrams for numerous mixtures. Moreover, reliable solutions to the crystallisation design problem are generated with the two-step strategy, yielding objective function values close to those with the UNIFAC-based model at a lower computational cost. These results reveal the value of the proposed surrogate model in guiding the search for better solvent mixtures in CAM$^b$D applications.

## INTRODUCTION

Identifying optimal multicomponent mixtures is critical in process design, e.g., extraction, absorption and crystallisation [1]. In the past few decades, the computer-aided mixture/blend design (CAM$^b$D) formalism has been widely used to guide the design of solvent mixtures as part of process optimisation efforts. The CAM$^b$D problem is often formulated as a mixed-integer nonlinear programming (MINLP) model, which includes process constraints and property prediction constraints [2]. In addition, ensuring the phase stability of the designed blends is important to avoid undesirable demixing behaviour of the mixture during operation. Given a mixture at a specific temperature, pressure, and composition, phase stability is achieved at the global minimum of the Gibbs free energy of the mixture. It can be enforced by ensuring the sign of the minimum tangent plane distance (TPD) is non-negative [3]. However, the need to use nonlinear thermodynamic models to model complex mixtures makes TPD minimisation a nonconvex optimisation problem. Embedding this nonconvex problem within the CAM$^b$D results in a bilevel problem that is highly challenging and expensive to solve within reasonable runtime in practice. Although tailored optimisation strategies and algorithms have been developed to address the phase stability problem [4,5] or to embed heuristic phase stability checks within CAM$^b$D [6], this remains a hurdle to designing stable mixtures.

Recently, the idea of replacing the lower-level phase stability constraint in the CAM$^b$D problem with a data-

**Figure 1:** Overview of the main steps, namely data generation, model training and optimisation in proposed framework to develop a surrogate ANN multi classifier and implement it in the solvent design optimisation problem.

driven machine learning model has been gaining attention. The use of artificial neural networks (ANNs) as surrogate models has been investigated due to their ability to achieve high accuracy and the potential to embed them as linear constraints, which are preferable in optimisation [7]. In principle, this approach provides a way to simplify nonconvex problems and to reduce computational cost. ANNs [8,9] and support vector machines (SVMs) [10] have previously been trained to predict the phase stability of a specific mixture and have been found to reduce computational cost. However, these mixture-specific models have limited potential for use in CAM$^b$D when many mixture candidates are considered in the design space. To address this, Karia et al. [11] trained an ANN classifier to predict the phase stability of all binary mixtures for a set of predefined solvent candidates, using parameters that describe the solvent identities along with composition and temperature as inputs. The classifier model was used to replace the phase stability criterion and was found to lead to improvements in optimisation efficiency and solution quality. This work was extended by considering SVM classifiers and introducing an additional surrogate model to replace the phase equilibrium (solubility) constraints [12], demonstrating further the potential of data-driven models in CAM$^b$D.

Although these studies revealed that training surrogate models for phase stability prediction can lower computational cost, the exploration of solvent mixtures beyond the dataset is restricted as the solvent identities are linked to a subset of the UNIFAC parameters [13], namely surface and volume. Furthermore, the need to train different surrogate models for solubility and phase stability prediction increases model complexity. To overcome these limitations, a group-contribution machine learning (GC-ML) ANN is developed in this work to predict the phase behaviour of ternary mixtures. In GC-ML, the number and identity of functional groups in a molecule are used as inputs to an ML model to predict a target property. It has been used for pure component properties [14,15], but, to the best of our knowledge, not for mixture properties. Here, each solvent is represented by a vector of functional groups, resulting in a more general surrogate model than that in [11,12]. In addition, a multi-class classifier is developed to determine phase coexistence, instead of relying on a binary classifier for phase stability; this gives the ability to generate entire phase diagrams. The framework for constructing the GC-ML model is described in detail in the next section. The design of a binary solvent mixture for ibuprofen crystallisation is next presented as a case study. Conclusions are developed in the final section.

## METHODOLOGY

The model construction is described in the context of a binary solvent mixture and a solute at conditions where the solute may crystallise and/or the ternary mixture may exhibit one or more liquid phases. It is assumed that the pressure $p$ is fixed but the temperature $T$ is variable. The approach can be extended to other mixtures or phase equilibria. Figure 1 illustrates the steps required to construct the surrogate model, including data generation and model training, and to use it in optimisation.

### Data generation

A set of $N_S$ common solvent candidates is collected from [16]. Each solvent is decomposed into $N_G$ groups by GCIdentifier.jl [17] in Julia. The groups can either be UNIFAC functional groups [13] or SAFT-$\gamma$ Mie [18] functional groups. The input features for the GC-ML model are two $N_G$ -dimensional vectors of group numbers describing each solvent, a 2-dimensional mole fraction vector and the temperature. To obtain a diverse dataset that includes all the solvent candidates, each component is paired with $N_p$ other solvents to create $N_s \times N_p$ solvent mixtures. Notice that not all possible mixtures within the design space are selected. A dataset with $N$ points is generated by adding the solute (e.g., ibuprofen) to each solvent pair and sampling the space of compositions via a Sobol' sequence [19] and the space of temperatures at

regular intervals. A $pT$ flash calculation is executed for each sample with the rigorous model (phasepy [20] with UNIFAC), to identify the stable phase configuration. There are four possible outcomes or categories: liquid ($L$), solid-liquid ($SL$), liquid-liquid ($LL$) or solid-liquid-liquid ($SLL$). The resulting dataset is split into a training dataset (80%$N$) and a test dataset (20%$N$). The sampled mixtures are distributed across both datasets to ensure that the model effectively learns from each functional group.

## Model training

The ANN classifier is developed in Pytorch [21]. The classifier structure, including the number of layers, the number of neurons per layer and the activation function, is defined before training. For the $i^{th}$ input, the ANN yields four real output values, $z_{i,k}$, where $k \in K = \{L, SL, LL, SLL\}$ represents the category. These outputs are normalised into the likelihood $\hat{y}_{i,k}$ via a softmax function:

$$\hat{y}_{i,k} = \frac{\exp(-z_{i,k})}{\sum_{kk \in K} \exp(-z_{i,kk})} \quad \forall k \in K, i = 1, \dots, N \tag{1}$$

The binary label $y_{i,k}$ is then set to 1 for $k = \underset{k \in K}{\operatorname{argmax}}\, \hat{y}_{i,k}$ and to 0 for other values of $k$ and the cross-entropy loss function $L$ is given by:

$$L = -\frac{1}{N} \sum_{i=1}^{N} \sum_{k \in K} y_{i,k} \log(\hat{y}_{i,k}) \tag{2}$$

Once the loss function has been minimized, the chosen architecture is assessed. Given that the dataset is extremely imbalanced since data points in categories LL and SLL are rare, the Matthews Correlation Coefficient (MCC) [22] is applied as a metric to evaluate model performance instead of the more usual accuracy metrics. The MCC score is defined as follows:

$$MCC = \frac{\sum_k \sum_l \sum_m C_{kk} C_{lm} - C_{kl} C_{mk}}{\sqrt{(\sum_k \sum_l C_{kl})(\sum_k \sum_l C_{lk})(\sum_k \sum_m C_{km})(\sum_l \sum_m C_{lm})}} \tag{3}$$

Here $C_{lm}$ refers to the number of samples in the confusion matrix which are predicted as belonging to category $m$ while the true category is $l$. The MCC score takes into account all the prediction results and varies from -1 (a totally wrong prediction) to 1 (a perfect prediction). The MCC score for the test dataset is compared to a threshold $MCC_{min}$ and the model architecture is modified by either adding hidden layers or increasing the number of neurons until the threshold is reached.

## Optimisation strategy

To use the surrogate within an optimisation problem, it is converted into a set of algebraic constraints via the OMLT [23] and embedded into the solvent design optimisation problem in Pyomo [24]. To solve the overall design problem, a two-step approach is implemented. First, the surrogate-based model is formulated by replacing all equations related to phase equilibrium or stability calculations, including the thermodynamic model, with the trained ANN classifier. The surrogate-based model involves binary and continuous variables and may be linear or nonlinear depending on the activation function. Additionally, process constraints may also be nonlinear. With the surrogate model, the phase stability and phase equilibria are replaced by constraints based on the predicted probability values $\hat{y}_k, k \in K,$. To ensure a stable liquid phase, the following constraints are used to ensure $k = L$ has the highest probability:

$$\hat{y}_L \geq \hat{y}_k \quad \forall k \in \{SLL, SL, LL\} \tag{4}$$

To approximate the phase equilibrium constraint, such as SL equilibrium (solubility), the difference between the likelihoods of the two relevant categories, $\hat{y}_{SL}$ and $\hat{y}_L$, should be within a predefined error $\varepsilon$:

$$|\hat{y}_L - \hat{y}_{SL}| \leq \varepsilon \tag{5}$$

The resulting surrogate-based MILP or MINLP is then solved to obtain optimal solvent identities, compositions, and process conditions. Only the optimal solvent identities are retained for the second step. The second optimisation subproblem is an NLP (fixed solvent identities) which includes the rigorous phase equilibrium constraints and a surrogate phase stability check, formulated as the following constraint [11]:

$$\hat{y}_L + \hat{y}_{SL} \geq \hat{y}_{LL} + \hat{y}_{SLL} \tag{6}$$

This constraint ensures that the probability of having one stable liquid phase is larger than that of having two stable liquid phases. If desired, the process of generating candidate solvent mixtures can be repeated by adding integer cuts to eliminate previous solutions.

# CASE STUDY

## Problem description

The proposed framework is demonstrated on an ibuprofen crystallisation process [25]. At the initial state, the ibuprofen is dissolved in a binary solvent mixture consisting of solvents $s_1$ and $s_2$ at temperature $T_0$. There are no crystals in this state. During the crystallisation, more solvent $s_2$ can be added to the mixture as an antisolvent and the mixture can be cooled to temperature $T$. In the present case study, the ranges of $T_0$ and $T$ are taken to be $[293.15\,K,\ 313.15\,K]$ and $N_S = 48$ solvent candidates are considered. The goal of the optimisation is to select the binary solvent mixture from the $N_s$ solvent candidates (2,256 possible mixtures), as well as the mixture composition and temperature, that maximise the yield of ibuprofen. The solvents combine any of $N_G = 33$ UNIFAC functional groups and the predicted mixture properties are compared against UNIFAC [13] as the rigorous thermodynamic model. More details on this case study can be found in [11,25].

All models are trained and optimised on Windows11 using Intel(R) Xeon(R) Gold 6226R CPU @ 2.90GHz with 64GB RAM and NVIDIA RTX A4000 GPU with 16GB RAM.

## Performance of multi-class classifier

A parametric study is carried out for the given number of solvent candidates and temperature ranges to

determine the appropriate size of the dataset for training. As a result, $N_p$=30 is applied, leading to $N_s \times N_p$=1,440 randomly generated solvent mixtures. The temperature range is sampled every 2 K, leading to 11 temperature values. For each solvent mixture at each temperature, 400 mole fraction vectors are sampled, leading to a large set of inputs that consists of 6,336,000 data points. The phasepy calculations are conducted in parallel and require nearly 3 hours of wall time. An overview of the dataset is presented in Table 1.

**Table 1:** Overview of the dataset.

| Category | # input vectors | % category |
|---|---|---|
| LLS | 371,350 | 5.86% |
| LL | 183,962 | 2.90% |
| LS | 3,428,021 | 54.10% |
| L | 2,333,993 | 36.84% |
| E | 18,674 | 0.30% |
| # inputs | 6,336,000 | 100.00% |
| # valid inputs | 6,317,326 | 99.70% |

Category E refers to input vectors for which phasepy does not converge. This small subset is discarded. As expected, the LS and L categories are most abundant in the dataset, making up 90% of the data.

Since 33 functional groups are used to define one solvent, the input vector has 69 elements consisting of the two solvents, the temperature as well the mole fraction of each solvent. As shown in Table 2, the final ANN includes a first hidden layer of 80 neurons and a second layer with 30 neurons. The number of epochs is set to 30, and the batch size is set to 2,056 with a learning rate of 0.005. The tanh activation function is used based on previous experience to avoid introducing redundant binary variables that can slow down convergence [12]. The training time is mostly determined by the large dataset.

**Table 2:** Training statistics for the final ANN model.

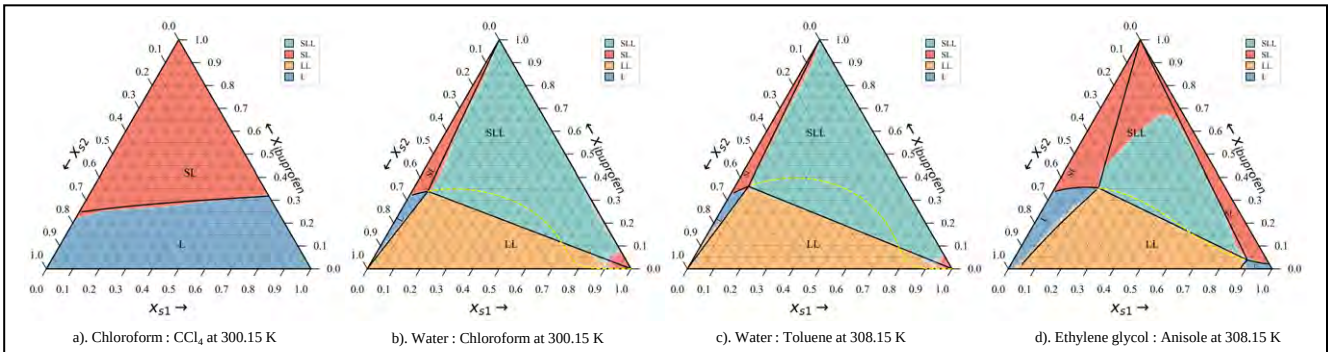
| Parameters | Values |
|---|---|
| Activation function | tanh |
| Model complexity | [69,80,30,4] |
| Epochs | 30 |
| Batch size | 2,056 |
| Learning rate | 0.005 |
| Training time /s | 14,032 |
| MCC for training dataset | 0.9771 |
| MCC for test dataset | 0.9698 |

Encouragingly, for a value of $MCC_{min} = 0.96$, a surrogate model that achieves a high MCC score for both the training dataset (0.9771) and the test dataset (0.9698) is obtained. This indicates that the surrogate model captures the nature of the phase coexistence at different temperatures and for different mixtures. To investigate the performance of the trained ANN multi-class classifier, the model is used to generate phase diagrams for four combinations of solvent 1/solvent 2/temperature that do not appear in the dataset: chloroform-tetrachloromethane (CCl4) at T=300.15 K, water-chloroform at T=300.15 K, water-toluene at T=308.15 K and ethylene glycol-anisole at T=308.15 K. These are shown in Fig. 2, where the predictions from the classifier are marked with different colours. The true phase boundaries are also obtained with the rigorous UNIFAC model and are denoted by black solid curves. The yellow dashed curves represent metastable solid-liquid equilibrium points in a region of solid-liquid-liquid equilibrium. The predicted phase boundaries are in good agreement between the two models. For example, the chloroform-$CCl_4$ mixture (Fig. 2a) only displays SL and L, indicating that no liquid-liquid demixing occurs. The solubility of ibuprofen, denoted by the black solid line, is described well by the classifier. For the remaining mixtures, which all exhibit two liquid phases, SLL and LL regions are indeed identified. For water-chloroform and water-toluene (Figs. 2b-c), misclassification occurs when the composition is close to pure $s_1$, predicting SL instead of the true LL and SLL regions. This probably arises from the presence of other mixtures in the dataset that exhibit this behaviour. For ethylene glycol-anisole (Fig. 2d), the surrogate model does not capture the extent of the SLL region very well. There are 254,808 data points that involve anisole, only 4.69% of which are labelled as SLL. The model tends to predict ethylene glycol-anisole mixtures forming a single liquid (SL or L), leading to an underestimation of the SLL region but accurate identification of a tiny L region of pure $s1$ between L and LS, which is most important in solvent design for crystallisation. Overall, the data-driven model captures the phase coexistence of multi-component mixtures well. Finally, parts of the solid-liquid equilibrium boundary that correspond to a metastable equilibrium are shown with yellow curves in Fig. 2. If the phase stability constraint were not included in the solvent design, solutions that fall on these undesirable parts of the curve would likely be identified.

## Optimisation performance

The problem is solved with the proposed two-step approach. Details on the process can be found in [11]. Here a summary of the surrogate-based model is given:

$$\max \text{ yield of ibuprofen} \tag{7}$$



$$\text{s. t. process constraints} \tag{8}$$

$$\text{mixture formulation constraints} \tag{9}$$

$$\hat{y}_{k,st} = f_{ANN}(x_{in,st}) \; \forall k \in K, st \in \{\text{initial, final}\} \tag{10}$$

$$\left|\hat{y}_{L,st} - \hat{y}_{LS,st}\right| \leq \varepsilon \; \forall st \in \{\text{initial, final}\} \tag{11}$$

$$\hat{y}_{L,st} \geq \hat{y}_{k,st} \; \forall k \in K \backslash \{L\}, st \in \{\text{initial}\} \tag{12}$$

a). Chloroform : $CCl_4$ at 300.15 K b). Water : Chloroform at 300.15 K c). Water : Toluene at 308.15 K d). Ethylene glycol : Anisole at 308.15 K

**Figure 2:** Phase diagrams generated by the surrogate model and the rigorous model for four solvent mixtures at 300.15 K or 308.15 K. The mixture is shown as $s_1{:}\,s_2$ in each figure caption. The colours denote the prediction from the surrogate model. The solid curves are the phase boundaries generated by $pT$ flash calculations with UNIFAC. The yellow curves denote parts of the solid-liquid equilibrium boundaries that are metastable, as computed with UNIFAC. The regions are labelled L, LL, SL and SLL based on the results of the rigorous model.

$$\hat{y}_{SL,st} \geq \hat{y}_{k,st}\ \forall k \in K\backslash\{SL\}, st \in \{\text{final}\} \quad (13)$$

Equation (10) represents the ANN with $x_{in,st}$ referring to the input vector at state $st \in \{\text{initial}, \text{final}\}$. A value of $\varepsilon = 0.1$ is used in Equation (11). Equation (12) ensures the mixture at the initial state is in region L. It is not necessary to impose that the mixture be saturated at the initial temperature, although it is desirable as it leads to lower solvent consumption. Equation (13) ensures the final mixtures is in the SL region after crystallisation, while Equation (11) ensures it is close to equilibrium solubility.

Neither of the models can be solved within 3 hours with global solvers. Instead, sBB [26] is used to solve the surrogate-based MINLP and CONOPT [27] is used for the UNIFAC-based NLP. Five solutions are listed in Table 3, including the runtime needed to generate each solution, the yield of ibuprofen from each step, and the outcome of the phase stability check in phasepy. All the solutions have the same optimal temperature range, from 313.15 K to 293.15 K, except for the first solution whose final temperature is 302.06 K. Every subproblem can be solved within 3 minutes. This small runtime makes a more extensive search of the design space possible. Ibuprofen yields of around 0.77 are obtained from all instances of step 1. In all cases apart from iteration 3, good agreement between the yields from the two subproblems is found. In iteration 3, a deviation of 0.051 is observed, arising from misclassifications for the benzene-p-cymene mixture. All the solvent mixtures designed only present one liquid phase at both the initial and final states, which satisfies the stability check. This is in contrast to approaches in which this constraint is only enforced *a posteriori* [25]. Applying data-driven surrogates of phase stability to assist solvent design in CAM$^b$D results not only in lower computational cost but, more importantly, in more reliable solutions.

## CONCLUSIONS AND FUTURE WORK

We proposed a multi-class classifier for predicting phase coexistence and stability. The group contribution concept was adopted to represent solvent candidates with a vector of functional groups, leading to a GC-ML ANN that can predict a whole phase diagram. This framework was tested on a crystallisation optimisation problem with ibuprofen as the target compound. The results showed that the trained classifier can generate phase diagrams for unseen mixtures with sufficient accuracy for use in CAM$^b$D. A two-stage strategy was proposed to obtain solutions to the crystallisation process optimisation problem. High-quality designs were obtained, exhibiting a homogeneous liquid phase as desired. The proposed classifier surrogate offers a promising alternative for the formulation of CAM$^b$D problems. However, misclassifications arising from the data-driven model can occasionally misdirect the search to a suboptimal or infeasible solution. Future work will thus focus on developing strategies such as active learning to improve model accuracy.

**Table 3:** Optimal binary solvent mixtures for the ibuprofen crystallisation process via the optimisation.

| Iter. | Runtime /s | Solvent A: Solvent B | **Yield** (Step 1) | **Yield** (Step 2) | Phase stability (initial: final) |
|---|---|---|---|---|---|
| 1 | 137.20 | DMSO: Formic acid | 0.784 | 0.799 | L: L |
| 2 | 74.14 | Formic acid: Anisole | 0.779 | 0.770 | L: L |
| 3 | 112.72 | Benzene: p-Cymene | 0.779 | 0.728 | L: L |
| 4 | 145.23 | Anisole: Formic acid | 0.766 | 0.770 | L: L |
| 5 | 124.84 | Chloroform: Hexane | 0.764 | 0.752 | L: L |

## ABSTRACT

Process optimisation and quality control are crucial in process industries for minimising product waste and improving plant economics. Identifying robust operational regions that ensure both product quality and performance is particularly valued in industries. However, this task is complicated by operational uncertainties, which can lead to violations of product quality constraints and significant batch discards. We propose a novel robust optimisation strategy that integrates advanced machine learning and process systems engineering to systematically identify optimal operational regions under uncertainty. Our approach begins by using a process model to screen a broad operational space across various uncertainty scenarios, pinpointing promising control trajectories to satisfy process constraints and product quality. Machine learning is then employed to cluster these trajectories into sub-regions. Finally, a two-layer dynamic optimisation framework is employed to determine the optimal control trajectory and corresponding operable space within each promising sub-region. To demonstrate the efficiency of our approach, we used a case study focusing on the quality control of a dynamic batch process for formulation product manufacturing. The resulting operational regions were shown to meet product quality demands and offer a significant improvement in optimality over the current operation, highlighting the advantage and industrial potential of our strategy.

**Keywords**: Operational regions, Machine learning, Optimisation under uncertainty, Process control, Dynamic optimisation

## INTRODUCTION

Product quality control is a critical concern in industries such as pharmaceuticals, speciality chemicals, and formulation processes, where strict regulatory standards are enforced to ensure safety, efficacy, and economic viability [1]. As a result, manufacturers face growing pressure to minimise product waste, a challenge particularly pronounced in pharmaceutical production, where batch rejections due to variability and quality deviations can result in significant economic and environmental consequences. To maintain a competitive edge while adhering to sustainability goals, there is a strong need for process optimisation strategies that enhance efficiency, reduce waste, and improve operational flexibility. Traditionally, process control has relied on rigid set-point strategies, where specific operating conditions are predetermined and maintained through fixed state profiles [2]. While effective in ensuring stable operations, such approaches lack adaptability in the face of uncertainty, making them prone to inefficiencies. Furthermore, the rigid nature of set-point control often results in excessive energy consumption, as significant resources are required to maintain precise operational conditions [3]. Even in cases where real-time closed loop feedback control is implemented to account for variability, the reliance on extensive sensor networks and rapid data processing can introduce prohibitive costs and practical limitations. Furthermore, unaccounted uncertainties can lead to deviations in key performance indicators (KPIs), increasing the likelihood of batch failures and product inconsistencies.

To address these challenges, robust optimisation techniques have been widely explored in the literature. One commonly employed approach is stochastic optimisation, which leverages probability distributions to model uncertainties and has been successfully applied in

complex, non-linear systems [4]. A particularly effective subset of stochastic optimisation is scenario tree optimisation, which transforms probabilistic problems into a structured deterministic framework by propagating uncertainty across different realisations of a process [5].

An emerging alternative to traditional set-point-based control is operational space control, which shifts the focus from maintaining rigid state profiles to defining feasible operational spaces within which a process can be adjusted [6]. This approach has found use in the chemical and pharmaceutical sectors, where it is often referred to as design space identification. For instance, [6] demonstrated the effectiveness of operational space methodologies in the temperature control of a fed-batch bioreactor under uncertainty, ensuring ethanol production constraints were met despite process variability. Such methodologies provide greater flexibility and adaptability than conventional set-point control, making them well-suited for processes characterised by uncertainty and dynamic variability [7].

Despite its advantages, current operational space methodologies still face notable challenges. Existing approaches often limit the consideration of uncertainty to parameter variations alone, overlook optimality in favour of robustness, and rely on computationally expensive sampling techniques. Moreover, there has been little research into the systematic identification of multiple feasible operational spaces for a given process, despite the potential benefits of having multiple viable operating regions. Notably, operational space control has yet to be applied in formulation industries, where the need for flexible quality control and real-time process monitoring is particularly pronounced.

In this paper, we address these gaps by proposing a novel scenario tree optimisation framework that integrates flexible operational spaces with dynamic optimisation. This framework not only enables the identification of multiple optimal and flexible operational regions but also enhances product quality control in a manner that is useful to real-world manufacturing constraints. Additionally, we present the first case study applying operational space methodologies to formulation processes, demonstrating the practical benefits of this approach in an industrial setting.

## METHODOLOGY

Operational spaces can generally be categorised into three key classifications. The feasible space represents the multidimensional range of operating conditions that satisfy all process constraints. Within this, the flexible space forms a subset that is not only feasible but also resilient to uncertainties. Lastly, the optimal space is another subset of the feasible space where operating conditions are selected to maximise performance according to a predefined objective. In this study, we introduce a novel methodology to systematically identify the intersection of the flexible and optimal spaces, ensuring that the resulting solution space consists exclusively of operating conditions that are both robust to uncertainty and optimal in performance.

Additionally, as multiple distinct optimal operating conditions may exist, we seek to distinguish and characterise separate optimal regions within the identified design space. Each region is defined by a unique optimal state profile—or a set of profiles if multiple state variables are involved—along with its corresponding operational boundaries. In this work, we utilise an interval-based representation, where operating spaces are defined by upper and lower limits on the identified optimal state profiles. The overall methodology can be summarised into 4 steps, which are shown in Figure 1.

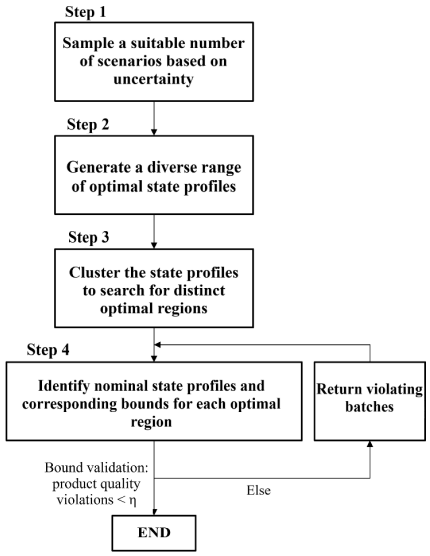

**Figure 1.** Schematic showing the general framework proposed in this study.

### General Problem Formulation

We consider a mathematical model that captures the dynamics of the process, where state variables are categorised into two distinct groups: (i) Flexible state variables, denoted as $\dot{\boldsymbol{x}}_{flexible}(t_j) \in \mathbb{R}^{n_{flexible}}$, represent variables that can be directly adjusted through control inputs. Here, $t_j$ indicates a specific time point within the operational time horizon. (ii) Dependent state variables, represented as $\dot{\boldsymbol{x}}_{dept}(t_j) \in \mathbb{R}^{n_{dept}}$, are those influenced by both control inputs and flexible state variables but cannot be directly regulated. The process dynamics are described by the following system of differential equations:

$$\dot{\boldsymbol{x}}_{flexible}(t) = \boldsymbol{F}_{flexible}(t, \boldsymbol{x}_{flexible}(t), \boldsymbol{\theta}, \boldsymbol{\xi}, \boldsymbol{u}(t)) \quad (1a)$$

$$\dot{\boldsymbol{x}}_{dept}(t) = \boldsymbol{F}_{dept}(t, \boldsymbol{x}_{dept}(t), \boldsymbol{x}_{flexible}(t), \boldsymbol{\theta}, \boldsymbol{\xi}) \quad (1b)$$

Where $\boldsymbol{u}(t_j) \in \mathbb{R}^m$ represents the vector of control inputs, $\boldsymbol{\theta} \in \mathbb{R}^p$ is the vector of fixed parameters, and $\boldsymbol{\xi} \in \mathbb{R}^r$ denotes the vector of uncertain parameters. Each source of uncertainty, $\xi_i$ for $i = 1 \cdots r$, is modelled as a Gaussian-distributed random variable, with its mean set to the nominal parameter value, and its variance reflecting expected variability. Both parameters are assumed to be known.

The goal of this study is to determine a flexible, optimal, and practical operational space for $\boldsymbol{x}_{flexible}(t_j)$ ensuring that key performance indicators (KPIs), such as product quality, are consistently met while maximising process efficiency despite the presence of uncertainties. Herein, the term operational space will be used to refer specifically to the identified flexible state space of $\boldsymbol{x}_{flexible}(t_j)$.

## Step 1: Sampling Uncertainty

We utilise scenario tree analysis, as discussed in Section 1, to capture the potential range of uncertainties encountered during processing. The full scenario tree is constructed by sampling each uncertainty source from its respective distribution, with a detailed description available in [8]. It is crucial to ensure that uncertainty is well-represented to develop a robust control strategy. Therefore, selecting a sufficient number of uncertainty samples is needed. However, this must be balanced against the increased computational cost associated with expanding the scenario tree. Once the scenario tree is established, all optimisation strategies are executed across the entire tree, ensuring that any imposed constraints are met under all considered uncertainty scenarios. An important note to consider is the computational expense of the methodology, which is largely dependent on the system under study. For high dimensional and complex systems, it should be encouraged to explore parallelisation, high performance computing alongside scenario reduction methods.

## Step 2: Filling out the Optimal Region

Since multiple optimal state profiles of $\boldsymbol{x}_{flexible}(t)$ can satisfy process constraints while ensuring KPIs remain within specification, Step 2 (illustrated in Figure 1) focuses on refining the broad process design space. The goal is to identify promising operational regions that likely contain the majority of optimal state profiles of $\boldsymbol{x}_{flexible}(t)$. When successfully designed, these optimal operational regions should consist primarily—if not entirely—of state trajectories that adhere to a predefined standard of process efficiency while respecting constraints under all uncertainties represented in the scenario tree. Specifically, for each set of optimal state profiles, the objective is to minimise a process cost $C_{avg}$, which is computed as the average cost across all scenarios in the scenario tree, while ensuring that the calculated KPI remains within the specified range and close to its target value as defined in the PFD.

The operational time horizon is discretised into $N$ intervals. To simplify control efforts, we assume that $\boldsymbol{x}_{flexible}(t)$ remains constant within each interval, meaning it follows a piecewise constant representation ($\boldsymbol{x}_{flexible}(t) = \boldsymbol{x}_k^{flexible}$, for $t \in [t_k, t_{k+1})$ and $k = 0 \cdots N-1$), where $t_k = k\Delta t$ and $\Delta t = {}^{t_f}/_{N}$. Furthermore, due to physical constraints on control actions $\boldsymbol{u}(t)$, the flexible state variables are also bounded within a predefined range, $[\underline{\boldsymbol{x}}_k^{flexible}, \overline{\boldsymbol{x}}_k^{flexible}]$ for $k = 0 \cdots N-1$. The process is also subject to constraints, $\boldsymbol{g}(\boldsymbol{x}_{k,s}^{dept}, \boldsymbol{x}_k^{flexible})$ for $s = 1 \cdots S$, where $S$ represents the number of uncertain scenarios in the scenario tree. Additionally, it is assumed that the initial state $\boldsymbol{x}_0^{dept}$ is known. With these considerations, the optimisation problem is defined to determine the optimal state trajectories of $\boldsymbol{x}_{flexible}$.

$$min_{x_k^{flexible}, k=0,\dots,N-1} \lambda_1 \cdot obj_1 + \lambda_2 \cdot C_{avg} \quad (2)$$

$$s.t.$$

$$for\ k = 0, \dots, N-1, s = 1, \dots, S,$$

$$obj_1 = (1/S) \sum_{s=1}^{S} \left(y_{KPI,s} - y_{KPI,T}\right)^2$$

$$C_{avg} = (1/S) \sum_{s=1}^{S} C_s$$

$$y_{KPI,s} = h\left(\boldsymbol{x}_{k,s}^{dept}, \boldsymbol{x}_k^{flexible}\right)$$

$$\boldsymbol{x}_{k+1,s}^{dept} = \boldsymbol{f}_{dept}\left(\Delta t, \boldsymbol{x}_k^{dept,s}, \boldsymbol{x}_k^{flexible}, \boldsymbol{\theta}, \boldsymbol{\xi}_s\right)$$

$$\boldsymbol{g}\left(\boldsymbol{x}_k^{dept,s}, \boldsymbol{x}_k^{flexible}\right) \leq 0$$

$$\boldsymbol{x}_0^{dept} = \boldsymbol{x}^{dept}(0)$$

$$\underline{\boldsymbol{x}}_k^{flexible} \leq \boldsymbol{x}_k^{flexible} \leq \overline{\boldsymbol{x}}_k^{flexible}, \underline{y}_{KPI} \leq y_{KPI,s} \leq \overline{y}_{KPI}$$

Here, $\lambda_1$ and $\lambda_2$ are weighting parameters assigned to each objective. $obj_1$ represents the average sum-of-squared deviations from the target KPIs across all scenarios, while $C_s$ denotes the process cost for each scenario. The function $h(\cdot)$ describes the transformation between process states and their corresponding KPIs, where $y_{KPI,s}$ and $y_{KPI,T}$ represent the KPI value for Scenario $s$ and the target KPI value, respectively. The term $\boldsymbol{f}_{dept}(\cdot)$ accounts for the numerical integration of the dependent state variables. $\boldsymbol{g}(\cdot)$ is the process inequality constraints.

To obtain a diverse set of optimal state trajectories and explore a broader operational space, the optimisation of Problem 2 is initially performed. Once this is complete, additional optimal state profiles can be identified by re-optimising the problem with an additional penalty function, $p$, introduced into the objective function. The penalty used may be:

$$p = \lambda_3 \cdot \sum_{d=1}^{D_{curr}} \sum_{j=1}^{n_{flexible}} \sum_{k=0}^{N-1} \left( \frac{\left(x_{flexible,j,k} - x^*_{flexible,j,k,d}\right)}{\Delta \bar{x}_{flexible,j,k}} \right) \quad (3)$$

Here, $\boldsymbol{\lambda_3}$ serves as the weighting parameter that regulates the strength of the penalty function. Higher values encourage greater variation among solutions, thereby facilitating the identification of more distinct optimal regions. The term $D_{curr}$ denotes the number of previous optimisation iterations, which increases as the number of iterations does. Within this framework, $x^*_{flexible,j,k,d}$ represents the discretised optimal state value from an already identified trajectory, whereas $x_{flexible,j,k}$ corresponds to the state value in the current optimisation. To ensure comparability across variables with different scales, the term $\Delta\bar{x}_{flexible,j,k}$ represents the maximum range of $x_{flexible,j,k}$ across previously identified trajectories. By applying this iterative approach, and with a sufficiently large number of iterations $D_{max}$ , one can systematically explore the entire design space to uncover a broad set of high-quality optimal state profiles that remain feasible under uncertainty.

## Step 3: Clustering Optimal Regions

After completing Step 2, multiple operational spaces may emerge. To systematically identify and characterise these spaces, clustering algorithms are employed. Given that clustering is an unsupervised learning approach, it is crucial to validate the results by applying different clustering methods and analysing the resulting cluster characteristics. This ensures a clear distinction between solutions and assists to assess variations in their behaviours. In this work, several algorithms were used and compared in order to ensure consistent results for the recommended number of clusters. These are k-means, DBSCAN, and spectral clustering [9].

## Step 4: Nominal State and Bound Estimation Strategy

In Steps 2 and 3 (as shown in Figure 1), estimations for a set of distinct optimal operational regions are made. The next step involves refining these regions by determining the nominal state profiles for each region, as well as the upper and lower bounds for each flexible state variable. An optimal operational region for a particular flexible state variable is characterised by its nominal profile and associated bounds, where staying within these bounds provides feasibility under the given uncertainties.

The nominal profiles, which represent the optimised state variable set-points at various stages of the process, are identified through a dynamic optimisation approach, as described in Problem 2. At this point, the search space is limited to the clustered region defined in Step 3. This ensures the solution remains within the appropriate cluster. Consequently, the bounds in Problem 2, $\underline{\boldsymbol{x}}_k^{flexible}$ and $\overline{\boldsymbol{x}}_{\mathrm{k}}^{flexible}$, are adjusted to reflect the specific characteristics of the cluster. Once the nominal profiles are determined, a two-step algorithm is proposed to independently find the upper and lower bounds, maximising the distance between them while still adhering to process constraints. The optimisation strategy for determining the lower bound is shown in Equation 4.

$$\max_{\substack{x_k^{flexible,lb} \\ k=0\cdots N-1}} \min_{j=1}^{(n_{flexible})} \min_{k=1}^{(N-1)} \underline{w}_{j,k} \cdot \left(x_{j,k}^{flexible,nominal} - x_{j,k}^{flexible,lb}\right)$$

$$s.t. \tag{4}$$

$$\underline{w}_{j,k} = \frac{1}{x_{j,k}^{flexible,nominal} - \underline{x}_{j,k}^{flexible}}$$

$$y_{KPI,s} = h\left(\boldsymbol{x}_{k,s}^{dept}, \boldsymbol{x}_k^{flexible}\right)$$

$$\boldsymbol{x}_{k+1,s}^{dept} = \boldsymbol{f}_{dept}\left(\Delta t, \boldsymbol{x}_{k,s}^{dept}, \boldsymbol{x}_k^{flexible,lb}, \boldsymbol{\theta}, \boldsymbol{\xi}_s\right)$$

$$\boldsymbol{g}\left(\boldsymbol{x}_{k,s}^{dept}, \boldsymbol{x}_k^{flexible,lb}\right) \leq 0$$

$$\boldsymbol{x}_0^{dept} = \boldsymbol{x}^{dept}(0)$$

$$\underline{\boldsymbol{x}}_k^{flexible} \leq \boldsymbol{x}_k^{flexible,lb} \leq \boldsymbol{x}_k^{flexible,nominal}, \underline{y}_{KPI} \leq y_{KPI,s} \leq \overline{y}_{KPI}$$

Problem 4 is designed to maximise the minimum distance between the nominal flexible state, $x_{j,k}^{flexible,nominal}$, and the lower bound of the flexible state, $x_{j,k}^{flexible,lb}$, across all flexible state variables and time steps. The normalisation parameter, $\underline{w}_{j,k}$, is used to standardise the influence of different flexible states on the objective function. By formulating the objective this way, the goal is to spread the bounds as evenly as possible across the entire trajectory for each flexible state variable. This reduces the need for highly precise set-point control at any given time step.

This optimisation strategy can be repeated for the upper bound to provide the full operational region where control of the design variables can be relaxed but achieve good process performance and required specifications. As the two-step algorithm determines the upper and lower bounds independently, each bound is ensured to meet the constraints on its own. However, this does not guarantee that all state profiles sampled within these bounds will adhere to the constraints. Therefore, it is crucial to validate these bounds by randomly sampling state profiles within them and identifying instances where constraints are violated. Once these violating samples are recorded, they are reintroduced into the framework by incorporating a penalty function into the objective functions of Equations (4) and (5). This penalty function serves to narrow the bounds, ensuring that future state profiles do not violate the constraints. The penalty function may take many forms dependant on the study, but one must consider its practicality against its conservativeness.

# CASE STUDY

To illustrate the effectiveness of the proposed framework, an in-silico case study has been developed using a dynamic model designed to simulate a real-world industrial formulation process. A simplified schematic of the primary mixing unit is presented in Figure 2. This case study focuses on the production of a multiphase, non-Newtonian liquid formulation via a batch mixing process where the process flow diagram (PFD) is characterised by a sequence of ingredient additions, alongside key processing such as temperature and shear rate. Due to the complex nature of multiphase mixing mechanisms, the product KPI is inherently challenging to control and cannot be measured in real-time. As a result, defining a robust operational space that ensures both process flexibility and consistent product quality is essential. Furthermore, it is desired to reduce operational expense and improve the sustainability of the process through reducing the batch cycle time (i.e., the process cost).

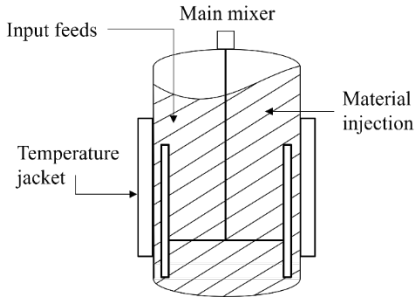

**Figure 2.** Diagram of the batch mixing unit for which the case study is based on.

Within this study, both the sequence of ingredient additions and the final ingredient ratio and mass are predefined by established protocols. As a result, the selection of flexible state variables is limited to standard processing parameters such as shear rate, pressure, temperature, and flowrate. For this investigation, two process parameters are chosen, along with an additional variable representing the timing of ingredient additions, leading to a total of three distinct types of flexible state variables. A mechanistic model exists to describe the dynamic mixing process with high accuracy, a full description of which can be found in [10]. In this model, there exists a set of 5 key ingredient concentrations (dependent states), determined dynamically through 3 material transformation equations, which influence the product quality. Furthermore, there are 3 flexible state variables used to control the process, and in total, there are 14 model parameters which were parameterised. The 3 flexible state variables were each discretised into 5 decision variables for the purpose of solving the optimal control problem (i.e., a total of 15 decision variables). The 3 flexible state variables will henceforth be referred to as Process Parameters 1, 2 and 3.

The primary challenges in this case study stems from the difficulty in achieving the desired end-product quality, which is influenced by various process uncertainties typically encountered in standard operations. These uncertainties were categorised into three sources. The first being variations in the input feed composition, which are reflected in the estimated model parameters. The second source is human error, primarily introduced through inconsistencies in precisely following the scheduled timing for ingredient additions. The third source is system control error, which involves deviations in state variables from their set-point values. The uncertainty levels for these variables were assumed to be 10%, 20%, and 5%, respectively. Additionally, 100 uncertain scenarios were considered in the assembly of the scenario tree.

## RESULTS AND DISCUSSION

The methodology outlined in Section 2 was fully implemented, resulting in the identification of 40 optimal set-points during step 2. In Step 3, the analysis revealed the presence of two distinct clusters, each associated with separate state profiles which were both carried forth for Step 4. From application of Step 4, the initial nominal state profiles and corresponding bounds for Process Parameters 1 and 2 in each cluster were determined as shown in Figures 3 (initial bounds) and 4 (refined bounds).

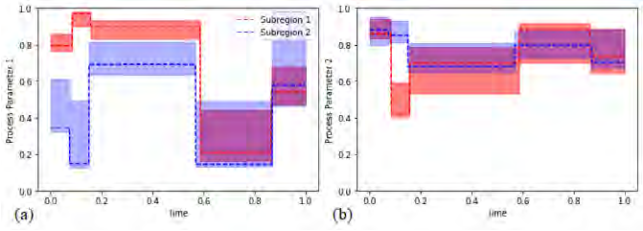

**Figure 3.** Normalised state profiles and operational region for Process Parameters 1(a) and 2(b) for each of the clusters identified before bound refinement

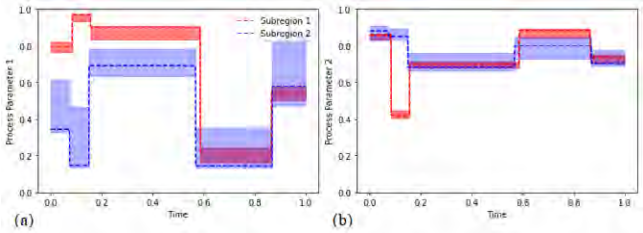

**Figure 4.** Normalised state profiles and operational region for Process Parameters 1(a) and 2(b) for each of the clusters identified after bound refinement.

To validate the initial bounds for both clusters, 1000 state trajectories were randomly sampled from within the optimal operational regions, across 100 unseen uncertain scenarios (i.e., $10^5$ tests). To compare the performance, the batch failure rate is defined: this is the fraction of the

test batches that encounter a product quality violation. After validation of the initial bounds (Figure 3), the results showed that Cluster 1 and 2 had a batch failure rate of 0.9% and 0.1%, respectively, suggesting that the initial bounds are reasonably robust to uncertainties.

When the bounds were refined (Figure 4), the batch failure rates dropped significantly to 0% and 0.009% for Clusters 1 and 2, respectively. However, it is immediately noticed that the refined operational area of Cluster 2 is much greater than that of Cluster 1. Specifically, Cluster 1's refined operational areas are 67.1% and 59.2% smaller for Process Parameters 1 and 2, respectively. Using these results, we can conclude that although it may be possible to achieve a 0% batch failure rate, it may be more practical to permit a small batch failure rate in order to largely improve flexibility in the operational area.

Overall, this case study demonstrates the framework's capacity to identify multiple distinct optimal regions, each offering operational areas that are practically resilient to uncertainties. Additionally, both identified regions led to a significant reduction in batch time compared to the existing set-point control approach used for the system, achieving a 38.6% decrease in both cases. After a thorough evaluation of each operational region's performance, it is likely that Region 2 would be recommended for execution, given its greater operational flexibility to Region 1.

## CONCLUSION

In conclusion, operational space design provides an innovative approach for integrating uncertainties into the development of robust control strategies, ensuring that key process constraints are reliably met. By combining flexibility with optimality, this approach enables the creation of control strategies that are both reliable and high-performing. A significant advantage over traditional set-point control is the increased operability, which allows processes to operate within broader ranges instead of being constrained to strict set-point conditions. Additionally, the systematic identification of various operating regions within the entire optimal space offers a major benefit over traditional set-point control, which may overlook the existence of such regions. This methodology not only aids in designing robust controls but also provides valuable insights into how processes can be operated, helping operators identify areas where the process may be more stable and easier to control.

## ABSTRACT

The Reverse Osmosis (RO) system has the potential as a vibrant technology to generate high-quality water from brackish water sources. Nevertheless, the progressive growth in water and electricity demands necessitates the development of a sustainable desalination technology. This can be achieved by reducing the specific energy consumption of the process, which would also reduce the environmental footprint. This study proposes the concept of reducing the overall energy consumption of a multistage multi-pass RO system of Arab Potash Company (APC) in Jordan via heating the feed brackish water. The utilisation of waste heat generated from different units of production plant of APC such as steam condensate supplied to a heat exchanger is a feasible technique to heat brackish water entering the RO system. To systematically assess the contribution of water temperature on the performance metrics including specific energy use, a generic model of RO system is developed. Model based simulation is used to evaluate the effect of water temperature. The results indicate a clear enhancement of specific energy consumption while using water temperatures close to the maximum recommended temperature of the manufacture. It has been noticed that an increase in water temperature from 25 ºC to 40 ºC can result an overall energy saving of more than 27%.

## 1. INTRODUCTION

Due to limited sources of freshwater and progressive increase of global population, there is a rapid engineering pace to produce freshwater from seawater and brackish water. This would interpret the global capacity of water production, which exceeds 100 million $m^3$ per day (Jones et al., 2019). In this regard, the utilisation of Reverse Osmosis desalination process is remarkably increased beyond the thermo-driven distillation. Zotalis et al. (2014) ascertained that the RO technology is dominated the global water desalination technologies by more than 70%. This can be ascribed to the simplicity and compact design of RO process with consuming less energy if compared to thermal ones. Wang et al. (2020) elaborated that the conventional thermal desalination plants requires 3 kWh/$m^3$ of specific energy consumption compared to 0.8 kWh/$m^3$ of RO process. Also, the RO process can be easily scaled up or down to meet variable water demands (Al-Obaidi et al., 2022). Interestingly, the freshwater production cost of RO process based seawater and brackish water ranges between 0.5 to 1.5 USD$/$m^3$ compared to 0.7 to 2.0 USD$/$m^3$ for thermal distillation units (Al-Hotmani et al., 2020). Furthermore, the continuous improvement in RO membrane technology and pre-treatment approaches has upgraded the effectiveness of RO systems, making them more attractive than conventional thermal processes.

Despite the fact that the RO process generally offers lower freshwater production cost and reduced specific energy consumption compared to thermal distillation methods, there is still a vital need for further minimising the energy requirements of RO process. Thus, several researchers are clearly focused on exploring advanced practices to ensuring sustainable and low specific energy consumption of cost-effective process.

A number of studies were conducted to examine the effect of water temperature on the performance indicators of RO process. For instance, Koutsou et al. (2020) analysed the impacts of feed-water temperature on the specific energy consumption in RO desalination processes, concentrating on both seawater and brackish treatment. The researchers systematically examined the itemized contributions to specific energy consumption, bearing in mind both positive belongings from increased permeate flux and mitigated viscosity, and negative belonging of reduced salt rejection. For brackish water, an increase in water temperature generally causes a significant reduction in specific energy consumption. However, these advantages were diminished for seawater beyond 25 °C as a result to elevated osmotic pressure. This research has ascertained the need for careful water temperature management in RO system design and operation.

The current research attempts to alleviate the overall energy consumption of the multistage multi pass medium-sized spiral wound brackish water RO desalination plant of Arab Potash Company (APC) located in Jordan with a capacity 1200 m³/day. Specifically, the pre-heating of feed water of RO process is the main objective of this research while investigating its impact on the overall specific energy consumption. To conduct this aim, the concept of waste heat recovery is utilised here via exploiting the generated heat of the potash production process or other nearby industrial operations. More specifically, this can be achieved through using heat exchangers that transfer heat from exhaust gases or hot fluids to the feed water. The simulation of the RO process is achieved using a developed model of the multistage RO process of APC while considering the effect of a selected range of water temperature on the specific energy consumption at a fixed set of feed salinity of brackish water, feed flowrate and pump pressure of RO process. Expectedly, this research would therefore aid to introduce a practicable solution to enhance the overall economic feasibility of RO process desalination of Arab Potash Company. This in turn would be in line of meeting the growing demand for a high-quality (low-salinity) water, which is delivered to ion exchangers and then used in the boilers of APC. Also, this research would address environmental concerns associated with energy use in brackish water desalination.

## 2. BRACKISH WATER RO DESALINATION SYSTEM OF APC

The BWRO desalination plant of APC was designed with a nominal low-salinity water capacity of 1200 m³/day with a product salinity of around 2 ppm. The brackish water is fed into the treatment plant at 100 ppm and (pH = 7.45-7.59) to a set of treatment stages including pre-treatment of three multi-media filters and three cartridge filters, two high-pressure pumps and one standby pump, two passes of 20 pressure vessels with 120 RO membrane modules, post treatment to re-mineralize product water. Two parallel stages of six pressure vessels with arrangement (4:2) constitute the 1st pass while the 2nd pass comprises four pressure vessels with arrangement (2:1:1). Figure 1 depicts a schematic diagram of two passes multi-stage RO process. Six series polyamide thin-film composite spiral wound membranes of 37.2 m² (TMG20D-400, Toray Membrane USA Inc.) are included in each pressure vessel.

The membrane features are provided in Table 3.

## 3. MODELLING OF RO SYSTEM AND VALIDATION

A comprehensive model was established by Al-Obaidi et al. (2018) to predict the performance indicators of the APC. The model consists of a number of algebraic equations. Some of these equations are presented in Table 1. The model was validated against experimental data of the first pass of APC and showed a good consistency as depicted in Table 2 with insignificant errors.

**Table 1:** Model equations (Al-Obaidi et al., 2018).

## 4. PERFORMANCE ANALYSIS OF SPECIFIC ENERGY CONSUMPTION. IMPACT OF WATER TEMPERATURE

SEC is specifically representing the required energy to generate a unit volume of fresh water. Determining the specific energy consumption of RO process is vital to optimise the overall performance and associated water production cost. In other words, analysing SEC can help to elevate water productivity, and product water quality besides improving the RO membrane configurations. Indeed, lessening SEC can therefore enhance the sustainability of the entire desalination process by reducing the carbon footprint associated with energy use. Utilising heat waste of APC, this section emphasis on demonstrating the simulation results of variable water temperatures' effect on the specific energy consumption of RO process of APC. In this aspect, the water temperature varies between 25 °C to 45 °C. The maximum value of 45 °C is taken based on the maximum allowed temperature recommended by the membrane's supplier (Toray Membrane USA Inc.). It is also important to declare that the present simulation is carried out using the following operating conditions of 1098.62 ppm of brackish water salinity, 74 $m^3/h$ of feed flowrate, 9.22 atm of pump pressure.

Figure 2 introduces the consequence of increasing water temperature from 25 °C to 45 °C on the specific energy consumption considering a fixed inlet conditions. Clearly, a decrease of specific energy consumption can be seen as a response to increasing water temperature. Statistically, the reduction of 27% can be accomplished as a response to this action. This behaviour can be ascribed to a number of plausible reasons. First of all, an increase of water temperature can decrease water density and viscosity of water. This in turn can facilitate easier flow through the feed channel of RO module. Also, the decrease of viscosity property can result in lower resistance to flow, permitting for greater water flux through the membrane pores. second, using an elevated temperature can improve the water diffusion rate, which is related to improving the driving force of water from the feed channel to the permeate channel as a result to limiting the concentration polarization and osmotic pressure and therefore improving the pressure gradient across the membrane. Third, warmer water can make changes on membrane structure with increasing pore size, which would exhibit a greater water permeability constant and enhanced water flux.

Eq. 2 of Table 1 specifies the increase of water permeability constant as a result to increasing water temperature. Referring to the above mentioned reasons, it can be said that water permeation is improved due to increasing water temperature, which finally shows an increase of water productivity. Eqs. 9 and 11 introduce the fact that both water density and viscosity can be decreased with increasing water temperature. This would positively affect the mobility of water molecules to pass through the membrane pores. Eq. 17 of Table 1 introduces the fact of reduced specific energy consumption with increasing permeate flowrate. Furthermore, it has been ascertained that the increase of water temperature from 25 °C to 45 °C has resulted in a growth in water productivity from 1.99 ppm to 25 ppm, respectively. This behavior can be attributed to increasing membrane pore size, which allows for more solute to pass through the membrane texture. This has resulted in an increase of product water salinity. Although this rise in product water salinity, it is crucial to mention that the resulted water remains within tolerable limits for high-quality water standards.

On top of this, the overall advantage of having higher water productivity at elevated temperatures and reduced specific energy consumption would outweigh the concern of increased product water salinity to 25 ppm at 45 °C, as long as water quality keeps within an acceptable range.

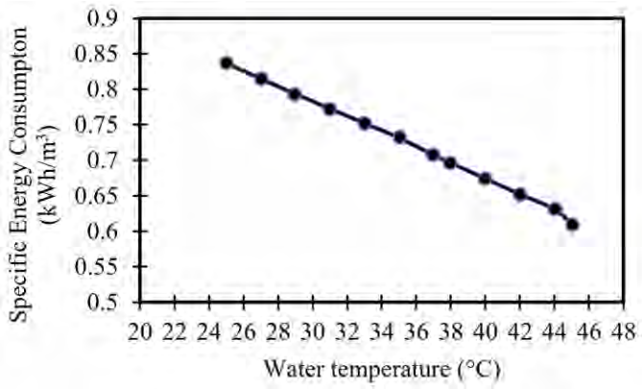

**Figure 2:** Influence of water temperature on specific energy consumption.

The above results come to an agreement with the findings of Yagnambhatt et al. (2024) who appraised the potential of thermally enhanced RO seawater desalination on the overall energy consumption and water permeation. The researchers looked for discussing the trade-off between pump energy savings and the thermal energy input required to heat the seawater. The associated results indicated that an increase of feed water from 20 °C to 50 °C can result in reductions of specific energy consumption of 24% and 33% for seawater and brackish water, respectively. Also, Ghourejili et al. (2022) examined the impacts of water temperature and pH on the specific energy consumption, and outlet water quality of different configurations of RO systems, including simple single-stage, single-stage hybrid, simple two-stage, and two-stage hybrid designs. The researchers specified that a higher water temperature can reduce the energy consumption. In this regard, the configuration of two-stage

hybrid system has shown the lowest specific energy consumption in a comparison to other configurations.

## 5. CONCEPTUAL IDEAS TO RAISE FEED WATER TEMPERATURE OF RO SYSTEM

Section four elucidates the prosperity of elevated brackish water temperature on the specific energy consumption of RO process of APC. This section defines conceptual approaches to increase the water temperature as represented below;

- Waste heat can be provided from a heat exchanger from a nearby industrial process or power generation facility. Successfully, the heat exchanger can transfer thermal energy to the brackish water before entering the RO system, which would increase the temperature and improving performance.
- The integration of heat and power systems which produce both electricity and heat can be exploited to preheat water temperature of the brackish water via the excess heat generated.
- Utilising a solar thermal collector is another possible option to harness solar energy and heating brackish water. Indeed, this option can meaningfully increase water temperature especially in sunny regions besides reducing the dependence on conventional energy sources.
- Heat pumps is another feasible option to preheat brackish water. The heat pump can extract heat from the environment and easily transfer it to the brackish water.

## 6. CONCLUSIONS

The current research intended to evaluate the utilisation of waste heat to increase brackish water temperature and consequently assessing its impact on the specific energy consumption of multi-stage RO process of APC. The simulation results were conducted using a developed validated model. The simulation results introduced a reduction of 27% in specific energy consumption due to increasing water temperature from 25 °C to 45 °C (within the maximum water temperature). This improvement was ascribed to the possible changes of the membrane structure, water transport parameter in addition to physical properties. A number of possible techniques to exploit waste heat from nearby industrial processes and preheating brackish water were illustrated at the end.

## NOMENCLATURE

$Q_p$ : Permeate flow rate (m³/s)

$A_{w(T)}$ : Water permeability constant (m/atm s)

$A_m$ : Effective membrane area (m²)

$B_{s(T)}$ : Solute permeability constant (m/s)

$C_b$ : Bulk solute concentration (ppm)

$k$ : Mass transfer coefficient (m/s)

$T$ : Brackish water temperature (°C)

$L$ : The membrane length (m)

$d_h$ : The hydraulic diameter (m)

$SEC$: Specific energy consumption (kWh/m³)

$Rec$: Recovery rate (-)

$k_{dc}$ : Constant (-)

$D_b$ : Solute diffusion coefficient (m²/s)

$Ff$: Fouling factor (1/s)

$\mathrm{P_{fb}}$ : Bulk pressure (atm)

$P_p$ : Permeate pressure (atm)

$P_r$ : Retentate pressure (atm)

$\pi_b$ : Bulk osmotic pressure at the feed channel (atm)

$\pi_p$ : Permeate osmotic pressure (atm)

$Q_f$ : Feed flowrate (m³/s)

$Q_b$ : Bulk flowrate (m³/s)

$Q_r$ : Retentate flowrate (m³/s)

$Q_s$ : Solute flux (kg/m² s)

$C_w$ : Solute concentration on the membrane wall (ppm)

$C_p$ : Permeate solute concentration (ppm)

$Re_b$ : Reynolds number (-)

$Sc$ : Schmidt number (-)

$\rho_b$ : Density (kg/m³)

## ABSTRACT

Seawater desalination is considered as the only available solution that can cope with the increasing demand for freshwater around the world. Improving the desalination techniques may help to cut off the cost and increase sustainability. In this paper, a mathematical model describing the MED process is developed within gPROMs software. The model includes all the necessary mass and energy balance equations together with thermodynamic and physical properties equations. The model predictions are validated against the actual plant data before using the model for optimizing the process to achieve minimum heat transfer area. For two different operating conditions (summer and winter) and a fixed production demand, the heat transfer area is minimised while optimising different parameters of the MED process. The results showed that a 10.4% reduction in the heat transfer area can be achieved under summer operating conditions and around 26% decrease in the heat transfer area can be met under winter operating conditions.

**Keywords**: gProms, Modelling and Simulations, Optimization, MED Desalination, Heat Transfer Area

## INTRODUCTION

The improvement in the living standard and increasing abstraction of available freshwater put more stress on the desalination industries to cope with the increasing demand for freshwater. Unfortunately, seawater desalination is the last and maybe the only available option to produce freshwater by removing the salt from the seawater. However, with the increasing world population and improved standard of living, freshwater production processes face the challenge of producing freshwater at higher quality and lower cost. The most known techniques for water desalination are thermal techniques such as Multistage Flash desalination (MSF) and Multiple Effect desalination (MED) and membrane techniques such as Reverse Osmosis (RO). Although the installed capacity of (RO) remarkably surpasses the MSF and MED [1], the MED process, operating considerably at a much lower temperature, is more preferred option for new construction plants in different locations around the world where waste heat is available [2]. However, the MED desalination technology is highly energy intensive (ranging from 5.5 to 20 kW h/m3) [3]. In addition, the product cost of freshwater from the MED process may vary between 0.27 and 1.49 USD/m3 [4]. It is still quite expensive and hence, it is believed that more work is required to cut off the costs and increase the profitability by operating the plant at minimal energy consumption. Some previous studies in the literature have been carried out to reduce the cost of freshwater by hybrid MED process with other desalination techniques. Al-hotmani et al. [5] integrated the MED process with the RO process to find more room for improvement. With a slight reduction of the consumed energy, the results showed that 9% increase in production rate and a 5% reduction in the brine flow rate. Others attempt to reduce the cost by powering the MED process with renewable sources of energy such as wind and solar energy. Kaabinejadian et al. [6] investigated the advantages of integration of MED with a humidification-dehumidification (HDH) unit powered by solar energy. The optimised total cost is found to be 0.548 $/s. Moreover, integrating the HDH unit with the MED process resulted in an increase in the freshwater production and the cost by 0.5% and 0.1%, respectively. However, the main drawbacks of renewable energies are their dependencies on climate conditions (available sunshine, wind power). The

optimization of a single MED process can be classified into two categories; finding the optimal operating conditions that result in minimum energy consumption and maximum production rate and/or finding the optimum design configuration that results in minimum fixed cost of the plant. Al-Mutaz and Wazeer [7] optimized the number of effects that result in minimum capital cost and steam cost. The results showed that increasing the number of effects from 11 to 15 would result in a reduction of water cost by 0.029 $/m3. With the aid of solar energy as supplied heat, Talebbeydokhti, et al. [8] carried out a performance analysis to investigate the feasibility of finding the optimum operating conditions at different numbers of effects and different heat sources. Processes with different number of effects (7, 9 and 11 effects) were investigated and obtained optimum operating conditions for each case. Sadri et al. [9] conducted multi-objective optimization to increase the gain output ratio (GOR) and minimise the heat transfer area. For the fixed mass flow rate of the seawater, the results showed an increase of 11.32 % in the GOR and a 17.29 % reduction in the heat transfer area. Harandi et al. [10] performed multi-objective optimization for the MED process integrated with a gas power plant using nondominated sorting genetic algorithm II. Considering GOR and annual cost as objective functions, it was found that higher GOR can be obtained for 9 effects MED and lower annual cost can be obtained for 4 effects MED. Rivera et al. [11] carried out multi-objective optimization for two different-sized MED plants one with 9 effects and the second with 12 effects. The objective of the study was to find optimum operating conditions that minimise the thermal energy and the cost of produced water and maximize the production rate. The authors claimed that different optimal solutions can be found depending on the objectives of the optimization.

Most of the previous studies consider the MED process in one single mode (Summer/Winter) and a typical MED configuration. In this paper, a mathematical model for MED is developed and solved using gPROMs software. For a fixed production rate, several operating parameters are optimized to minimise the heat transfer area of the MED process. Unlike most of the previous works, the optimization procedure is conducted for two different seasons (summer and winter). Further, the MED plant under investigation interestingly has a different design configuration with two large effects and two small effects combined together in a single MED process which makes it unique to other types of MED plants around the world.

## MED PROCESS DESCRIPTION

The MED process, as presented in Figure 1, consists of two large effects, two small effects and a condenser. The heating steam coming from the ejector flows inside the tubes of the first effect while a portion of the feed seawater is sprayed around the outside surface of the tubes of the first effect. The other seawater portion is divided over the rest of the effect based on the size of each effect. The release of the latent heat of the steam causes an increase in the temperature of the seawater resulting in the evaporation of some water. The evaporated water then flows through the channel into the tubes of the second effect and the process is repeated until the fourth effect. In most configurations of the MED, part of the low-pressure entrained vapour is taken from the last effect and introduced to high-pressure motive steam through the ejector. However, in the MED process considered here, the part of the low-pressure-entrained vapour is taken from the second effect leading to a smaller amount of vapour entering the third and fourth effects. As a result, the installed third and the fourth effects have a smaller area. More details of the process can be found in the literature.

## MATHEMATICAL MODEL OF MED PROCESS

A steady-state mathematical model is developed to simulate the MED process. The model is built based on mass and energy balance equations, and it is supported with physical and thermodynamic properties correlations. The developed model is divided into three parts: evaporators, a steam ejector and a down condenser. The two plate heat exchangers are also modelled as a simple heat exchanger, but their model equations are not included here. More details of the model equations and physical properties correlations can be obtained from Al-Mutaz and Wazeer [12]. For the sake of simplicity and to obtain reasonable results from the model, the following assumptions are made:

1. The distillate product is salt-free.
2. There are no heat losses to the surroundings as the equipment is well insulated.
3. The release of non-condensable gases is neglected.
4. The heat of mixing is neglected.

The following are the governing equations of the process including the physical properties correlations.

### Evaporator

$$\Delta T = \left[T_{b_out(1)} - T_{b_out(n)}\right]/[n-1] \quad (1)$$

$$T_{b_out(1)} = T_s - \Delta T \quad (2)$$

$$T_{b_out} = T_{b_in} - \Delta T \quad (3)$$

$$T_{v_out(1)} = T_{b_out(1)} - BPE \quad (4)$$

$$F + B_{in} = V_{vapour} + V_{brine} + V_{dist} + B_{out} \quad (5)$$

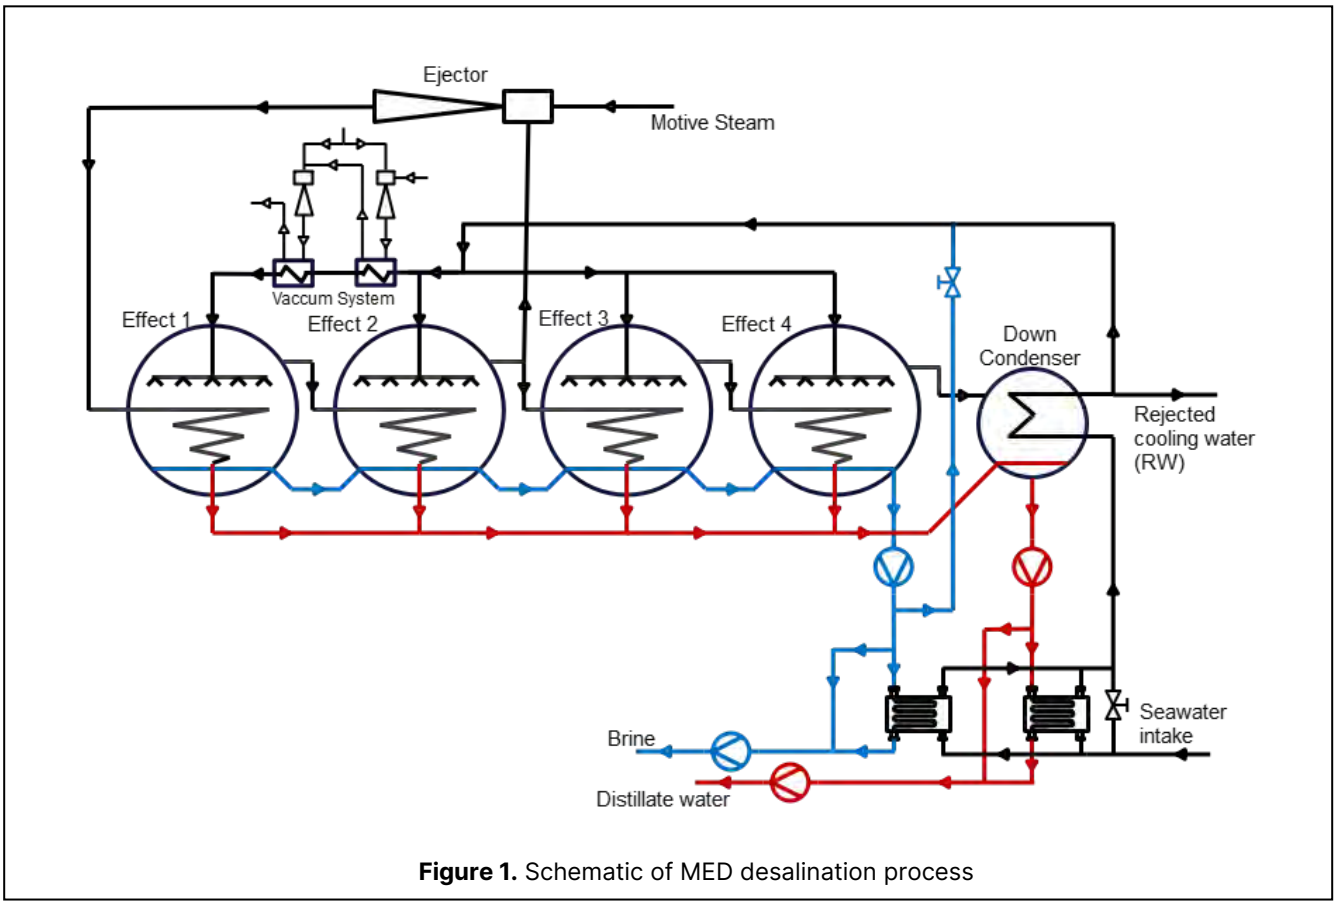

**Figure 1.** Schematic of MED desalination process

$$X_F\,F + X_{b_in}B_{in} = X_{b_out}B_{out} \quad (6)$$

$$V_{_in}\lambda_{in} = F\,Cp_w\left(T_{b_out} - T_f\right) + V_{vapour}\lambda_{out} \quad (7)$$

$$V_{_in}\,\lambda_{in} = A_e\,U\,(T_{v-in} - T_{v-out}) \quad (8)$$

$$V_{brine} = \left[B_{in}Cp_{brine}(T_{b_{in}} - T^{'})\right]/[\lambda_{in}] \quad (9)$$

$$T^{'} = T_{b_out} - NEA \quad (10)$$

$$NEA = \left[33\left(T_{b_{in}} - T_{b_{_out}}\right)^{0.55}\right]/\left[T_{v_out}\right] \quad (11)$$

$$V_{dist} = \left[D_{in}Cp_{dist}\,(T_{cond} - T^{'})\right]/[\lambda_{out}] \quad (12)$$

$$T^{"} = T_{v_out} + NEA' \quad (13)$$

$$NEA' = \left[33\left(T_{C_{in}} - T_{v_{_out}}\right)^{0.55}\right]/\left[T_{v_out}\right] \quad (14)$$

$$T_{cond} = T_{v-in} - \Delta T_{loses} \quad (15)$$

$$V_{out} = V_{vapor} + V_{brine} + V_{dist} \quad (16)$$

## Down Condenser

$$V_{out(n)}\lambda_{out(n)} = F\,Cp_{cw}\,(T_F - T_{cw}) \quad (17)$$

$$V_{out(n)}\lambda_{out(n)} = A_cU_cLMTD_C \quad (18)$$

$$LMTD_C = \left[(T_f - T_{cw})\right]/\left[\ln\left(\frac{T_{v-out} - T_{cw}}{T_{v-out} - T_f}\right)\right] \quad (19)$$

## Steam Injector

$$M_s = M_{ev} + M_u \quad (20)$$

$$R_a = 0.296\,\frac{{P_S}^{1.19}}{{P_{ev}}^{1.04}}\left(\frac{P_m}{P_{ev}}\right)^{0.015}\left(\frac{PCF}{TCF}\right) \quad (21)$$

$$PCF = 3\times10^{-7}\left({P_m}^2\right) - 0.0009\,P_m + 1.6101 \quad (22)$$

$$TCF = 2\times10^{-8}({T_{ev}}^2) - 0.0009\,T_{ev} + 1.0047 \quad (23)$$

$$CR = P_s/P_{ev} \quad (24)$$

$$P_s = 1000\times\exp\left(\frac{-3892.7}{T_s+273.15-42.6776} + 9.5\right) \quad (25)$$

$$P_{ev} = 1000\times\exp\left(\frac{-3892.7}{T_{ev}+273.15-42.6776} + 9.5\right) \quad (26)$$

$$GOR = D_{total}/M_S \quad (27)$$

## Physical properties correlations

### Specific Heat Capacity (Cp)

$$\mathrm{Cp} = (\mathrm{a} + \mathrm{bT} + \mathrm{cT}^2 + \mathrm{dT}^3)\times10^{-3}$$

Where:

$$\mathrm{a} = 4206.8 - 6.6197\,\mathrm{S} + 1.2288\times10^{-2}\mathrm{S}^2$$

$$\mathrm{b} = -1.1262 + 5.4178\times10^{-2}\,\mathrm{S} - 2.2719\times10^{-4}\mathrm{S}^2$$

$$\mathrm{c} = 1.2026\times10^{-2} - 5.3566\times10^{-4}\,\mathrm{S} - 1.8906\times10^{-6}\mathrm{S}^2$$

$$\mathrm{d} = 6.877\times10^{-7} + 10517\times10^{-6}\,\mathrm{S} - 404268\times10^{-9}\mathrm{S}^2$$

## Boiling Point Elevation

$$BPE = Xb \times ((A + B \times Xb) + (C \times Xb^2))$$

$$A = 8.325 \times 10^{-2} + 1.883 \times 10^{-4} T_{b-out} + 4.02 \times 10^{-6} T_{b-out}^{\ 2}$$

$$B = -7.625 \times 10^{-4} + 9.02 \times 10^{-5} T_{b-out} - 5.02 \times 10^{-7} T_{b-out}^{\ 2}$$

$$C = 1.522 \times 10^{-4} - 3 \times 10^{-6} T_{b-out} - 3 \times 10^{-8} (T_{b-out})^2$$

## Boiling Point Elevation

$$\lambda_{in} = 2499.5689 - 2.20486\, T_s - 0.00176\, T_s^{\ 2}$$

$$\lambda_{out} = 2499.5689 - 2.20486\, T_{v-out} - 0.00176\, T_{v-out}^{\ 2}$$

In the above two equations, the temperature is in °C, and latent heat is in kJ/kg.

## Simulation and Validation

The MED plant under this investigation is located in Sirte, Libya. It was installed in 2010 and got into actual operation after 2016. Table 1 presents input operating parameters for two different modes: summer mode and winter mode. The accuracy of the model predictions is very important in any simulation. Hence, the model is validated against actual data for the summer mode. The actual plant data and the simulation results are shown in Table 2. As can be seen, good agreement against actual data has been obtained. Normally in winter mode, the plant operates in different conditions. However, due to the lack of full actual winter operating data from the plant, the validation is carried out only against summer operating data.

**Table 1:** Input parameters of 4 effects MED process for summer and winter modes

| Parameters | Summer mode | Winter mode |
|---|---|---|
| Motive steam pressure (bar) | 11.4 | 11.4 |
| Motive steam flowrate (kg/s) | 5.85 | 5.85 |
| Inlet steam temperature to the first effect (°C) | 68.5 | 68.5 |
| Mass flow of the seawater to the effects (kg/s) | 144.444 | 144.444 |
| Intake seawater temperature (°C) | 27 | 14 |
| Recycle brine flowrate (kg/s) | 0.0 | 60.444 |
| Last stage brine outlet temperature (°C) | 52 | 50 |

## Optimization Problem

To obtain the optimal operating conditions that result in a minimum heat transfer area, an optimization approach is carried out to minimize the heat transfer area at a fixed demand of freshwater. Motive steam flowrate, entrained vapour to the ejector, last effect's brine temperature, feed flowrate and intake seawater flowrate are optimized to achieve the objective. For winter mode, the recycle brine flow rate is also optimized. To maintain the feasible operating conditions, the optimised parameters are controlled by introducing equality and inequality constraints including lower and upper desalination plant limits.

**Table 2:** Validation of the simulation results against actual operating parameters.

| Parameters | Values | | |
|---|---|---|---|
| | Actual | Model | Error |
| Top Boiling Temp. (°C) | 64 | 64.38 | 0.6% |
| Distillate flowrate (kg/s) | 47.91 | 45.89 | -4.2% |
| Distillate water temp. (°C) | 52 | 51.45 | -1% |
| The feed seawater temp. (°C) | 46.41 | 46.72 | 0.7% |
| **Heat transfer area, Ae ($m^2$)** | | | |
| First effect | 3760 | 3674.2 | -2.3% |
| Second effect | 3760 | 3673.2 | -2.3% |
| Third effect | 810 | 775.8 | -4.2% |
| Fourth effect | 810 | 779.6 | -3.7% |
| Gain Output Ratio (GOR) | 8.19 | 7.82 | -4.5% |

The optimization problem can be described as follows:

Optimization Problem

| Minimize | Optimize |
|---|---|
| Ae | Mev, Mu, Tb(n), F, seawater intake and brine recycle for winter mode only |

Subject to:

Equality constraints: the fixed demand for freshwater ($D_{TOTAL}$ = 45.89 kg/s)

Inequality constraints: the lower and upper limits of some constraints are different between summer and winter.

**Table 2**

| Summer conditions | | | | Winter conditions | | | |
|---|---|---|---|---|---|---|---|
| Lower | | Parameter | upper | Lower | | Parameter | upper |

** Temperature of the brine leaving the brine plate heat exchanger

Table 3 shows the new values of the optimized parameters for summer and winter conditions. The flow rate of the main source of energy which is the motive steam slightly decreased by 1.5 % in summer and increased by 3.6 % in winter. In addition, table 4 depicts the results of the optimization process. As can be seen, the values of the constraints in the optimization problem did not violate the constraints' limits. Table 5 shows the results of the optimization process. Interestingly, the total heat transfer area for the 4 effects has been reduced by 10.4% in summer and by 26% in winter. Hence, the new design of the MED process should be based on summer conditions which require more available area. If the MED process is designed based on winter conditions, the available area can not meet the demand for freshwater in the summer season. Other parameters are in the feasible values and the MED process can operate at the new conditions comfortably.

**Table 3:** Optimized parameters and the optimization results for the two seasons

| **Optimized parameters** | | |
|---|---|---|
| Parameters | Summer | Winter |
| Motive steam flowrate, (kg/s) | 5.76 | 6.06 |
| Entrained vapour flowrate, kg/s | 13.68 | 10.97 |
| Last effect temperature $^{o}$C | 49.67 | 43.0 |
| Feed flowrate, kg/s | 150.95 | 170 |
| Seawater intake flowrate, kg/s | 170 | 135 |
| Brine recycle flowrate, kg/s | - | 40.32 |

**Table 4:** optimization results for the two seasons.

| **Optimization results** | | |
|---|---|---|
| Parameters | Summer | Winter |
| Rejected water (RW) (kg/s) | 19.04 | 6.01 |
| CR | 1.569 | 1.83 |
| Tf ($^{o}$C) | 44.75 | 46.67 |
| Td* ($^{o}$C) | 35.2 | 25.14 |
| Tb** ($^{o}$C) | 36.1 | 26.09 |

**Table 5:** Objective function of the optimization process.

| Summer | Winter |
|---|---|
| 1$^{st}$ effect = 3426.2 m$^2$ | 1$^{st}$ effect = 2338.1 m$^2$ |
| 2$^{nd}$ effect = 3343.7 m$^2$ | 2$^{nd}$ effect = 2230.1 m$^2$ |
| 3$^{rd}$ effect = 589.10 m$^2$ | 3$^{rd}$ effect = 638.60 m$^2$ |
| 4$^{th}$ effect = 620.20 m$^2$ | 4$^{th}$ effect = 732.10 m$^2$ |
| Total area = 7979.2 m$^2$ | Total area = 5938.9 m$^2$ |

Total area reduction is 10.4% in summer mode and 26% in winter mode.

## CONCLUSIONS

The optimization problem to minimize the heat transfer area has been solved and the minimum required heat transfer area has been achieved. To accomplish this goal, a detailed mathematical model for the MED process was developed and validated against actual plant data. For a fixed freshwater demand, the results showed the possibility of designing the MED process with less heat transfer area. Moreover, the results depicted that the MED process should be designed based on the summer conditions due to a higher available area and lower motive steam. Moreover, the demand for the freshwater is higher in the summer than in the winter.

## ABSTRACT

Enhanced weathering (EW) of alkaline minerals in chemical reactors with a controlled environment is recognized as a promising approach for gigaton-level carbon dioxide removal. However, reactor configuration and operating conditions must be optimized to balance the interfacial areas between gas, liquid and solid phases prior to industrial application. We developed a physics-based and data-driven hybrid modelling approach, coupled with multi-objective optimization, to study and compare three typical chemical reactors, i.e., trickle bed, packed bubbling columns, and stirred slurry reactors, and the optimal design to improve $CO_2$ capture rate and reduce energy and water consumptions. Then an adaptive optimization is proposed to dynamically adjust the operating of the reactors in response to intermittent $CO_2$ emission and renewable energy supply. Results indicated that forced stirring enhances $CO_2$ capture rates by accelerating mass transport but increases energy consumption. Trickle bed reactor achieves the highest capture rate and lowest energy and water consumption. The AI-enabled, multi-objective, and adaptive optimization developed in response to intermittent $CO_2$ and energy supplies shows considerable potential for industrial applications, advancing progress towards achieving SDG #13.

**Keywords**: $CO_2$ capture, Enhanced weathering, Chemical reactors, Data-driven, Optimization

## 1. INTRODUCTION

Enhanced weathering (EW) of minerals is considered as a promising method for large-scale sequestering atmospheric $CO_2$, with the potential to absorb approximately a billion tonnes annually [1]. This process primarily occurs in specific natural environments where $CO_2$ interacts with water and minerals and converts to bicarbonate [2]. Despite its potential, the inherently slow rate of natural weathering raises critical questions about its capacity to scale up effectively to meet the ambitious goal of limiting global warming to 1.5°C by the end of the century [3]. Recent studies have shown that deploying crushed minerals in controlled engineering reactors rather than natural settings can significantly enhance $CO_2$ capture efficiencies [4]. EW has undergone validation through various scales of testing, including laboratory experiments, small-scale field trials, and idealized land ecosystem simulations [5]. However, the transition to larger operational scales presents substantial challenges, primarily due to the significant resources and energy consumption involved. This includes substantial quantities of water, energy for crushing minerals, and the transport and circulation of liquid and gas reactants during EW-based $CO_2$ capture reactions.

Trickle bed reactors (TBR), packed bubble columns (PBC), and stirred slurry reactors (SSR) are three common types of multi-phase reactors utilized in the chemical industry. To investigate their potential in EW-based $CO_2$ capture, we developed detailed mechanistic models that describe the unique mass transport characteristics of each reactor type. These models were rigorously validated using experimental data. Following validation, we developed data-driven models employing machine learning algorithms, which were further enhanced with multivariable and multi-objective optimization approaches. This methodology allows for the identification of trade-off solutions between $CO_2$ capture rate, and water and

energy consumption. Ultimately, these reactors were integrated into renewable energy systems with intermittent energy and $CO_2$ supplies. Dynamic adaptive optimization was conducted, enabling the autonomy of the system to respond effectively to fluctuations in energy and $CO_2$ availability. This integration facilitates the effective model predictive control of $CO_2$ capture systems and offers significant performance enhancement, cost reduction and environmental benefits.

## 2. PHYSICS-BASED MODELLING AND MODEL VALIDATION

Physics-based mechanistic models for the three reactor types were developed by integrating reaction kinetics with mass transport processes. For $CO_{2(g)}$, the following equation is used to describe the mass balance:

$$\varepsilon_G \frac{\partial}{\partial t} c_{CO_2(g)} + \nabla \cdot (u_G c_{CO_2(g)}) = -r_{G-L} \quad (1)$$

The mass balance for aqueous species *i* is described by:

$$\varepsilon_L \frac{\partial}{\partial t} c_i - \varepsilon_L E_L \nabla^2 c_i + u_L \nabla \cdot c_i = r_i \quad (2)$$

where $\varepsilon_G$ and $\varepsilon_L$ are the gas holdup, $r_{G-L}$ and $r_i$ are the source terms for gas and aqueous species, $u_G$ and $u_L$ are the gas and liquid superficial velocities, $c$ is the concentration, $E_L$ is the dispersion coefficient.

More details for model development can be found elsewhere [4,6-9]. The following assumptions are used:

- Mineral particles are loaded at the start of the operation without further replenishment.
- Isothermal operations at 20 °C without considering the reaction heat.
- Radial gradients of concentration or velocity are omitted.
- An average particle-shrinking rate was applied to all calcite particles, independent of the location inside the packed bed.
- No gas impurities influencing reaction kinetics.

In each model, a counter-current flow of gas and liquid is applied, allowing the rising $CO_2$-rich gas to make thorough contact with the mineral particles and the liquid phase within the reactor. At the gas-liquid interface, $CO_2$ dissolves into the aqueous environment, and at the solid-liquid interface, chemical reactions occur as mineral particles dissolve. Consequently, $CO_2$ in the gas phase is converted and sequestered as bicarbonates and carbonates in the liquid phase, enabling long-term storage. As shown in Figure 1, the solid particles in the TBR are only partially wetted by the liquid, necessitating a packed bed of several meters to ensure sufficiently long residence times for the reactants to reach equilibrium [4]. The PBC contactor provides the three-phase environment necessary for EW-based $CO_2$ capture, benefiting from the stagnant packed bed and controllable volume ratios between solid, liquid, and gas, which are expected to reduce energy consumption. However, due to the lack of agitation, the random kinetics of bubble coalescence and breakup could lead to the formation of large bubbles. These larger bubbles have a lower surface area-to-volume ratio, subsequently reducing the gas-liquid interfacial area essential for effective $CO_2$ dissolution into the liquid [6]. The SSR also facilitates a three-phase solid-liquid-gas environment essential for EW reaction. The SSR benefits from stirring, which permits the use of smaller packing particle sizes and generates smaller bubbles, thereby increasing the solid-liquid contact area and enhancing mass transfer through improved gas-liquid interfacial area. However, the agitation required in this setup consumes more energy [10].

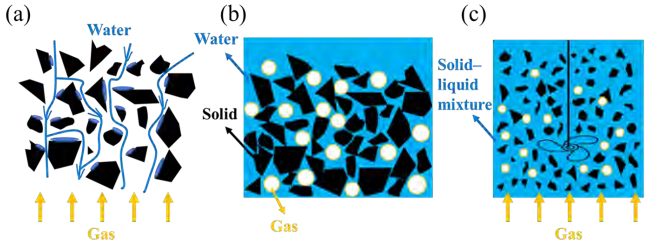

**Figure 1.** Sketch of (a) TBR, (b) PBC, (c) SSR.

In summary, there are notable differences in component representation across three reactor types. In the TBR, the gas phase is continuous, eliminating the need to consider bubbles. The liquid forms a thin, discontinuous film on the solid particles, resulting in partial wetting and a relatively high gas-liquid interface area, with mass transfer occurring across this liquid film. In contrast, the PBC and SSR feature solid particles fully immersed in the liquid phase, with bubbles forming the discontinuous phase. The interfacial area in these reactors depends on the sizes of the bubbles and particles. Additionally, the TBR experiences a lower pressure drop due to less liquid filling the void spaces, unlike the PBC and SSR. In the PBC, where the volume of liquid typically exceeds that of the solid, a two-layer bed usually forms, in which one layer at the bottom is a three-phase packed bed, while the other layer at the top consists only of gas and liquid without solid. Conversely, in the SSR, agitation creates a well-mixed three-phase mixture.

Although the chemical reactions remain consistent across the models, the governing equations for mass transport vary slightly to accommodate differences in fluid dynamics and mass transfer behaviors among the different reactors. These variations include the interfacial areas of gas-liquid and solid-liquid as well as the mass transport coefficients. The specific expressions used for calculating these areas and coefficients are summarized in Table 1. Other expressions could be found elsewhere

**Table 1:** Specific expressions for the areas and coefficients of different reactors.

| Reactors | Gas-liquid mass transfer interface area, $a_{G-L}$ ($m^{-1}$) | Reference |
|---|---|---|
| TBR | $a_{G-L} = [6(1-\varepsilon)/d_p]\left\{1 - exp\left[-1.45\left(\frac{\sigma_C}{\sigma_L}\right)^{0.75} Re_L^{0.1}\, F\, r_L^{-0.05} We_L^{0.2}\right]\right\}$ | [11, 12] |
| PBC | $a_{G-L} = 6\varepsilon_G/d_b$ | Calculated |
| SSR | $a_{G-L} = 6\varepsilon_G/d_b$ | Calculated |
| | **Solid-liquid mass transfer interface area, $a_{S-L}$ ($m^{-1}$)** | |
| TBR | $a_{S-L} = [6(1-\varepsilon)/d_p]\{1 - exp[-1.986 Fr_L^{0.139} Mo_L^{0.0195} \varepsilon_M^{-1.55}]\}$ | [13] |
| PBC | $a_{S-L} = 6(1-\varepsilon)/d_p$ | [14] |
| SSR | $a_{S-L} = 6(1-\varepsilon)/d_p$ | [14] |
| | **Mass-transfer coefficients on the liquid side, $k_L$ (m $s^{-1}$)** | |
| TBR | $k_L = 0.0051(\frac{\rho_L u_L}{a_{G-L}\mu_L})^{2/3}(\frac{\mu_L}{\rho_L D_{Lm}})^{-0.5}(a_t d_p)^{0.4}\left(\frac{\rho_L}{\mu_L g}\right)^{-1/3}$ | [12] |
| PBC | $k_L = \sqrt{D_L u_S/d_b}$ | [15] |
| SSR | $k_L = 0.5 g^{5/8}(d_b E_L)^{1/2}(\sigma/\rho_c)^{-3/8}$ | [16] |

| PBC | $d_b = 26 d_R Bo_L^{-0.50} Ga_L^{-0.12} Fr_G^{-0.12}$ | [16] |
| SSR | $d_b = 0.72(\mu_B/\rho_B)^{0.22} U_g^{0.33}$ | [17] |

[4, 6-9].

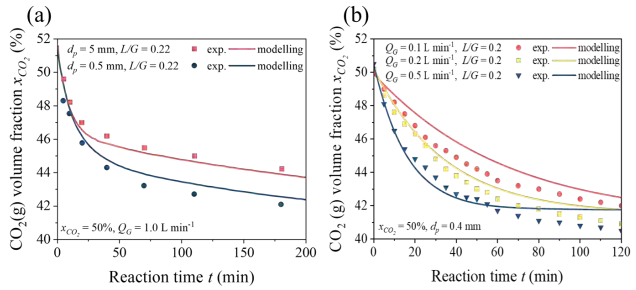

**Figure 2.** Results of model validation (a) PBC (b) SSR.

We developed laboratory-scale setups specifically designed to meet the unique requirements of various reactor types, e.g., a volume of 18 L and an internal diameter of 12 cm. $CO_2$ concentrations ranging from 4% to 20% were applied to simulate typical flue gas emissions from power plants. We conducted experiments under a range of conditions including varying $CO_2$ concentrations, gas and liquid flow rates, liquid-to-gas volume ratios, particle sizes, and temperatures. Figure 2 illustrates the progression of $CO_2$ pressure above the liquid phase within the PBC and SSR over time. This pattern indicates that equilibrium was reached when the reaction time was sufficiently long. In most cases, the predicted results closely aligned with the experimental data, demonstrating the acceptable accuracy of the developed mechanistic models. The discrepancies between the experimental and modeling results are likely attributable to imperfect sealing of the reactor. It is worth noting that no experiments were conducted on the TBR because all the governing equations are from well-validated previous work [18, 19]. However, we developed a set of equations to determine the maximum allowable operating superficial gas and liquid flow rates as functions of particle size, which are designed to prevent flooding when gas flows counter currently upward from the bottom.

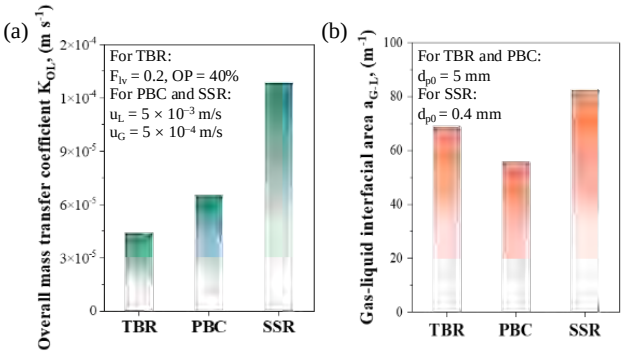

**Figure 3.** Gas-liquid mass transfer coefficient (a) and interfacial area (b) in reactors. $x_{CO2}$ = 10%, $H_{bed0}$ = 5 m.

The mass transfer coefficients and gas-liquid interfacial areas were compared between TBC, PBC and SSR. As illustrated in Figure 3, the SSR achieves the highest mass transfer coefficient, attributed to its smaller particle size and the enhanced agitation effect. Additionally, the TBR maintains a slightly higher gas-liquid contact area than PBC due to continuous airflow. Under agitation conditions, the SSR produces smaller gas bubbles, resulting in a greater gas-liquid contact area compared to both PBC and TBR. Our research further reveals that in both the PBC and SSR systems, $CO_2$ capture rates can be

significantly enhanced by increasing the $CO_2$ concentration in the feed air. Even modest enrichment of $CO_2$ in the inlet air can lead to substantial enhancement of capture rate and savings in energy and water.

## 3. DATA-DRIVEN SURROGATE MODELLING AND MULTI-VARIABLE OPTIMIZATION

After validating our models on a laboratory scale, we scaled them up to explore the impact of design variables on key performance indicators, including $CO_2$ capture rate (CR), operational energy consumption (EC), and water consumption (WC). Identifying optimal solutions through exhaustive enumeration and search is often cumbersome. While complex Multiphysics simulations can reduce time and resource demands, more efficient methods are still required for analyzing the Pareto fronts across different reactor types for optimization purposes. To address this, leveraging physics-based simulation data to develop data-driven surrogate models presents a viable approach for tackling multivariable optimization challenges effectively. In our work, machine learning algorithms, e.g., RSM, RBF, SVR and E-AHF, and optimization approaches, e.g., GA and NSGA-II, were employed [11]. The established data-driven surrogate models significantly reduce simulation computation time and enable rapid prediction of reactor performance metrics. The R2 values for RSM and E-AHF predictions of CR and WC exceed 0.84. Notably, for the TBR, the calculated R2 value surpasses 0.96. Using the RSM model to predict SSR performance yields $R^2$ values for WC and CR above 0.99, while the $R^2$ for EC is 0.87, exceeding the prediction accuracy for EC in both TBR and PBC systems (approximately 0.79). Further improvements in prediction accuracy are observed when outliers are excluded or the E-AHF model is applied, with $R^2$ increasing to 0.89. Figure 4 presents the optimal outcomes of the three reactors under different objectives. In terms of energy consumption, SSR requires higher energy due to continuous stirring. However, when aiming for minimal water consumption (WC) or maximal carbon capture rate (CR), SSR exhibits comparable or even lower energy usage. Notably, PBC achieves substantial energy savings while minimizing water consumption.

Figure 4 shows the optimal performance of three different reactors under various objectives. SSR requires higher energy for continuous stirring, yet it shows comparable or lower energy consumption when optimizing for minimal WC or maximum CR. Notably, PBC achieves significant energy savings, particularly when reducing WC is prioritized. Meanwhile, TBR excels in scenarios that focus on water reduction due to its discrete liquid flow. SSR, operating in batch mode, utilizes the least water overall. Optimization with surrogate models significantly enhanced performance metrics for continuous systems: CR increased by 37.8% for TBR and 13.1% for the PBC. EC decreased by 37.4% in TBR and 23.8% in PBC, while WC dropped by 12.5% and 40.7%, respectively. Comparatively, SSR reduced water requirements to 0.9045 $m^3$, which is about 60% of that required by TBR (1.4928 $m^3$) and PBC (1.4966 $m^3$), achieving a CR of 1.11 kg $h^{-1}$, comparable to TBR's 0.73 kg $h^{-1}$ and lower than PBC's 1.91 kg $h^{-1}$. The CR of SSR reached 2.93 kg $h^{-1}$, surpassing PBC's 2.01 kg $h^{-1}$. Although SSR's EC (1.2567 MJ) and WC (3.6675 $m^3$) per kg of $CO_2$ captured were lower than PBC's (1.7331 MJ and 14.142 $m^3$), they were slightly higher than that of TBR due to increased energy for stirring and higher material processing energy from the smaller packing material. Despite the higher energy input, SSR's efficient mixing and the buoyant forces from upward flow reduced operational energy, leading to a CR of 2.44 kg $h^{-1}$ with an EC of 0.9853 MJ and a WC of 2.9167 $m^3$ per kg $CO_2$ captured.

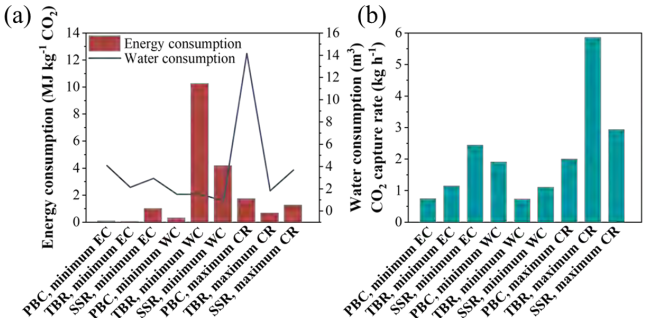

**Figure 4.** Comparison of optimization results for EC, WC and CR across different systems with minimum energy consumption, water consumption (a) and maximum $CO_2$ capture rate (b).

## 4. RESPONSIVE $CO_2$ CAPTURE FOR MANAGING VARIABLE FLUE GAS

Due to the intermittent nature of $CO_2$ emissions and renewable energy sources such as wind and solar, the availability of $CO_2$ and energy dynamically changes over time. To enhance the efficiency of EW-based $CO_2$ capture systems, developing an adaptive optimization strategy is crucial. This strategy could predict the availability of $CO_2$ and energy for the upcoming hour, enabling the determination of optimal operating conditions. Adaptive multi-objective optimization integrates process modeling with optimization algorithms to enable dynamic system optimization [20]. By leveraging adaptive optimization, optimal solutions can be forecasted before optimization actions are executed. By developing machine learning surrogate models from existing physics-based models, we can achieve more accurate chemical system modeling. This approach is particularly effective for handling time-dependent data and evolving patterns, enabling the

model to learn from historical process data, adapt to real-time changes, and predict reactor behavior. Such advancements will significantly enhance the flexibility and robustness of the EW-based $CO_2$ capture systems in response to fluctuations in external environments.

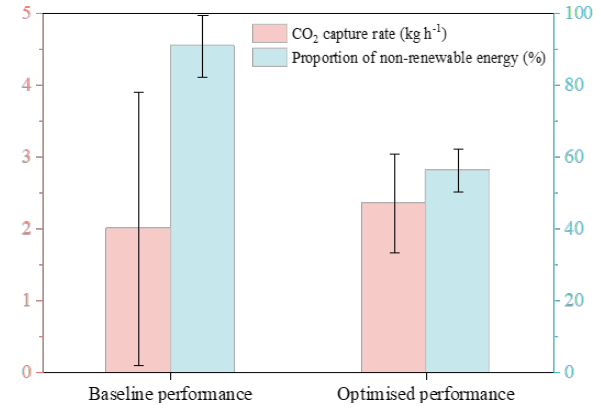

**Figure 5.** Improvement of EW-based $CO_2$ capture system after adaptive optimization.

In our study, we initially developed two deep learning models, a two-stage multilayer perceptron (2-stage MLP), and a long short-term memory (LSTM) network, for the prediction of the dynamic performance of the reactor and $CO_2$ emissions and wind energy forecasts. We then trained these models using data on $CO_2$ emissions from a coal-based power plant in China and wind energy data from the UK, collected over a period of 500 hours. We assessed the predictive accuracy of our data-driven surrogate models by comparing their predictions with those from mechanistic models. The surrogate models demonstrated superior accuracy over traditional LSTM techniques, achieving $R^2$ values of 0.99 for $CO_2$ capture rate and 0.98 for energy consumption predictions, compared to 0.99 and 0.92, respectively, for the LSTM models. Additionally, the adaptive optimization framework, enhanced by these machine learning models, aids in predicting external system variables, thereby improving system performance. The LSTM-based model for the prediction of wind energy and $CO_2$ concentration achieved $R^2$ values of 0.908 and 0.981, respectively. By using the NSGA-II algorithm to adaptively optimize the reactor in response to fluctuations in $CO_2$ concentrations and wind energy, and by equally weighting both objectives, we achieved a 16.7% increase in the capture rate and a 36.3% reduction in non-renewable energy consumption over a month of continuous operation, as shown in Fig. 5.

## 5. CONCLUSION

EW-based $CO_2$ capture accelerates natural processes to potentially achieve Gt atmospheric carbon sequestration in ocean. To reveal the potential of various chemical reactors for EW-based $CO_2$ capture, we developed physics-based mechanistic models of these reactors by coupling reaction kinetics and mass transport processes. The models were experimentally validated under laboratory conditions before scaling up to industrial scales. Then data-driven surrogate modeling and multivariable optimization were employed to significantly save computational resources, enabling efficient identification of optimal operating conditions with respect to various scenarios. Our finding revealed the importance of gas-to-liquid mass transport that could be considered as the main rate-limiting process in most cases. Operated at 4%-20% $CO_2$, after optimization, the EC, WC and CR are: SSR-0.9853 MJ per kg $CO_2$, 0.9045 $m^3$, and a $CO_2$ capture rate of 2.93 kg $CO_2$ $h^{-1}$, TBR-0.04368 MJ per kg $CO_2$, 1.4928 $m^3$, and 5.8568 kg $CO_2$ $h^{-1}$, PBC-0.07115 MJ per kg $CO_2$, 1.4966 $m^3$, and 2.0013 kg $CO_2$ $h^{-1}$.

The minimum WC is about 1.5 $m^3$ per $CO_2$ captured for all reactors. Compared to packed bubble column (PBC), the stirred slurry reactor (SSR) improves the capture rate, but at the cost of a significant increase in energy consumption. Additionally, under batch operation conditions, the water consumption of the SSR is nearly half that of the PBC. In summary, TBR holds the greatest potential for EW-based $CO_2$ capture.

Our findings also underscore the importance of enhancing $CO_2$ capture efficiency while reducing energy and water consumption. This can be achieved by using $CO_2$-rich feedstocks, such as flue gas from power plants (which is more effective than atmospheric capture), and by generating smaller bubbles to further accelerate gas-to-liquid mass transfer. Leveraging the advancements in AI and model predictive control, the adaptive optimization of the EW-based $CO_2$ capture system could be further optimized to mitigate the fluctuation of intermittent $CO_2$ supply and renewable energy. The models and methodologies developed in our work are poised to contribute to the broader adoption of EW-based $CO_2$ capture technology across the industry, serving as a reference for sustainable and large-scale $CO_2$ capture at an industrial level.

## ABSTRACT

Maintaining operational efficiency while ensuring safety is a longstanding challenge in industrial process control, particularly in high-risk environments. This paper presents a novel Dynamic Risk-Informed Explicit Model Predictive Control (R-eMPC) framework that integrates safety and operational objectives using probabilistic constraints and real-time risk assessments. Unlike traditional approaches, this framework dynamically adjusts safety thresholds based on Bayesian updates, ensuring a balanced trade-off between reliability and efficiency. The validation of this approach is illustrated through a case study on tank level control, a safety-critical process where maintaining the liquid level within predefined safety limits is paramount. The results demonstrate the framework's capability to optimize performance while maintaining robust safety margins. By emphasizing adaptability and computational efficiency, this research provides a scalable solution for integrating safety into real-time control strategies for similar process systems.

**Keywords**: Model predictive control, Bayesian risk analysis, Dynamic risk assessment, Safety-aware control, Multi-parametric programming, Chance-constrained programming

## INTRODUCTION

Industrial operations, particularly in chemical plants, carry an inherent risk of catastrophic incidents, posing threats to both human safety and the environment [1]. These risks have driven extensive research and the development of systematic methods to enhance process functional safety [2]. While traditional safety measures, such as Hazards and Operability analysis and fault tree analysis [3], have significantly contributed to accident prevention, the increasing complexity of industrial processes necessitates advanced optimization, control, and machine learning techniques capable of integrating safety and performance objectives seamlessly [4,5].

Traditional Model Predictive Control (MPC) frameworks, though widely adopted, rely on rigid constraints to enforce safety, often leading to overly conservative operations [6]. Recent efforts have explored merging safety principles with MPC through adaptive, learning-based [7], and probabilistic approaches [8,9]. However, these methods often fall short in dynamically quantifying and updating risk parameters in real time, limiting their applicability in highly dynamic and uncertain environments [10].

This paper addresses these gaps by introducing the Dynamic Risk-Informed Model Predictive Control (R-eMPC) framework. Inspired by dynamic risk-based design and optimization principles [11], R-eMPC incorporates Bayesian updates and chance-constrained programming to dynamically adjust safety thresholds along a receding horizon [12]. This integration ensures a robust balance between safety and operational efficiency while responding to real-time process variations. The proposed framework is systematically applied to a tank-level control case study, demonstrating its potential for scalable and adaptive safety-critical applications.

The remainder of this paper is organized as follows: Section 2 introduces the case study, providing the context and system dynamics for evaluating the proposed framework. Section 3 details the R-eMPC methodology

and demonstrates its sole application to the case study of tank level control. Section 4 present results and discusses the implications of the framework, while Section 5 concludes with key findings and outlines potential future research directions.

## TANK-LEVEL CONTROL CASE STUDY

The tank level control system serves as a representative case study to evaluate the proposed R-eMPC framework (Figure 1). In industrial operations, precise regulation of the liquid level within a storage tank is crucial to prevent safety-critical incidents. Overflow scenarios may result in hazardous spills with severe environmental and operational consequences, while underflow conditions can disrupt downstream processes, leading to inefficiencies and potential system failures. The inherent dynamics and uncertainty associated with this system make it an ideal testbed for assessing the efficacy of the proposed methodology.

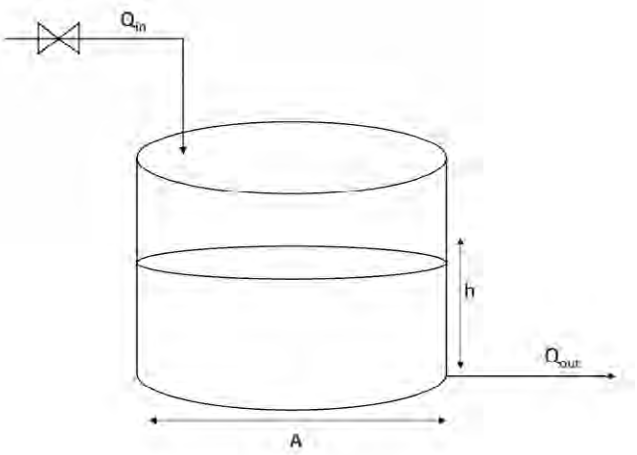

**Figure 1.** The schematic of the tank-filling system

The control system is designed to manage the liquid level by regulating the inflow, while the outflow is governed by the tank's current level and outlet characteristics. The system dynamics are mathematically described as:

$$\frac{dh(t)}{dt} = \frac{Q_{in}(t) - Q_{out}(t)}{A} + \frac{w(t)}{A} \quad (1)$$

where
$h(t)$ represents the liquid level
$Q_{in}(t)$ represents the inflow
$Q_{out}(t)$ represents the outflow
$A$ represents the cross-sectional area of the tank

$w(t)$ captures external disturbances that influence the system. The primary control objective is to maintain $h(t)$ within predefined safety limits while optimizing operational performance, even in the presence of uncertainties and dynamic variations.

The choice of the tank level control system as a case study is motivated by its direct relevance to the challenges of managing safety-critical processes under dynamic and uncertain conditions. This system exemplifies the interplay between operational constraints and safety requirements, where deviations in liquid levels can result in hazardous overflows or disruptive underflows. Traditional control strategies, which often rely on static constraints, struggle to accommodate real-time disturbances, leading to conservative or infeasible operations. By applying the R-eMPC framework, this study aims to bridge this gap by integrating dynamic risk assessment and probabilistic constraints into the control process. The framework's ability to adaptively balance safety and efficiency under varying conditions underscores its potential for broader applications in safety-critical process control.

## RISK- INFORMED EXPLICIT MPC FRAMEWORK

In this section, we introduce a stochastic control framework as an extension to 'Dynamic Risk-based Design and Control Optimization framework' developed in [11]. This framework serves as a comprehensive approach for the seamless integration of safety and control elements, achieved through the dynamic inclusion of risk factors within a controller optimization framework. This unique approach facilitates real-time monitoring of risk levels and the implementation of adaptive control strategies. The ensuing section provides a step-by-step elucidation of the procedural aspects of this framework.

The R-eMPC framework under discussion represents a nuanced and adaptive approach to address the complexities inherent in managing uncertain systems. This innovative paradigm seamlessly blends several pivotal elements. Firstly, it employs a Receding Horizon MPC strategy, continuously optimizing control inputs while considering the dynamics of the evolving system. Secondly, it introduces a dynamic probabilistic constraint, strategically integrating real-time risk management into the control framework to maintain system operation within predefined risk thresholds. Complementing this, a Bayesian update mechanism is seamlessly incorporated, allowing for the dynamic adaptation of these risk thresholds based on live system observations. This integrated approach represents a comprehensive strategy that not only prioritizes safety but also enables the system to adaptively optimize its performance within the realm of uncertainties—a pragmatic and adaptable solution for contemporary engineering challenges. The implementation of the framework is given below:
R-eMPC:

$$min_u\ J = x_N^T P x_N + \sum_{k=1}^{OH-1} \Big( (y_k - y_k^R)^T Q R_k (y_k - y_k^R) \Big) \quad (2a)$$

$$+ \sum_{k=0}^{CH-1} (\Delta u_k - \Delta u_k^R)^T R_k (\Delta u_k - \Delta u_k^R) + f(x_k)$$

s.t. $$x_{k+1} = Ax_k + Bu_k + C[d_k, De] \quad (2b)$$

$$y_k = Dx_k \quad (2c)$$

$$P[Event|x(t)] \le \epsilon_t \quad (2d)$$

$$\bar{x} \le x \le \underline{x} \qquad \bar{u} \le u \le \underline{u} \qquad \bar{y} \le y \le \underline{y} \quad (2e)$$

Bayesian update (time step t out of prediction horizon k)

$$P[Event|x(t+1)] = L(x(t)) * P[Event|x(t)] \quad (2f)$$

where $P$ is terminal weight, $QR$ and $R$ are controller weights, $OH$ and $CH$ are output and control horizons, $N$ represents the terminal step of the prediction horizon, superscript $R$ is setpoint, $t$ represents the time step for the entire operation of the controller, where at each step, the Bayesian update is applied to refine risk estimates dynamically. The function $f(x_k)$ represents the loss function for safety, which penalizes unsafe behaviors and is formulated based on the specific system under consideration. The details of its selection and impact are discussed in the subsequent section [17] (in (7a)). $L$ is the likelihood function (detailed by [18]). $x$, $y$, $u$ represent the state, output and input vectors respectively. Here, $x_k$ corresponds to the system state at prediction horizon $k$, while $x(t)$ denotes the state at each time step $t$ within the receding horizon framework. The index $k$ represents the prediction step within the optimization window of the receding horizon MPC. At each time step $t$, the controller solves an optimization problem over the prediction horizon, updating the control inputs accordingly.

$Event$ represents the occurrence of a failure scenario or an undesirable event within the system. It can be defined using mathematical expressions or conditions that capture the event of concern. For instance, in engineering, the event might relate to a variable exceeding a certain threshold. $\epsilon_t$ is the threshold value denotes the acceptable level of risk associated with the event. It quantifies the maximum probability at which the event can occur without exceeding acceptable risk levels. The choice of $\epsilon_t$ reflects the trade-off between safety and system performance, with lower values indicating a lower tolerance for risk. The probability constraint is handled via chance-constrained programming by obtaining its deterministic approximation [14] (more description in Eqs (5) and (6)).

## TANK-LEVEL CONTROL: IMPLEMENTATION, RESULTS & DISCUSSIONS

The proposed R-eMPC framework was applied to the tank-level control system to validate its efficacy in maintaining safety-critical constraints while optimizing performance.

### Step 1: High Fidelity Dynamic Modeling

The system dynamics were modeled using mass balance equations, where the liquid level $h(t)$ was regulated by controlling the inlet flow rate $Q_{in}(t)$. The outlet flow rate $Q_{out}(t)$ was assumed proportional to the current liquid level, modeled as $Q_{out}(t) = k\ h(t)$, with $k$ as the proportionality constant. External disturbances $w(t) \sim \mathcal{N}(0,0.5)$, were introduced to simulate uncertainties, making the control problem more realistic. The resulting high-fidelity model from Eq. (1) is expressed as follows:

$$\frac{dh(t)}{dt} = \frac{-kh(t)}{A} + \frac{Q_{in}(t)}{A} + \frac{w(t)}{A} \quad (3)$$

### Step 2: Model Reduction

To facilitate the design of an optimal control strategy, the high-fidelity dynamic model was simplified into a linear state-space representation. This reduction is typically performed using system identification tools for nonlinear systems to derive an approximate representation that facilitates control design. However, since our system is inherently linear, we can directly express the linear state-space model as:

$$h(i+1) = \left(1 - \frac{k}{A}\right) h(i) + \frac{1}{A} Q_{in}(i) + \frac{1}{A} w(i) \quad (4)$$

### Step 3: Risk Modeling via Safety Constraints

Risk modeling was incorporated via probabilistic constraint.

$$P[h(t) > h_{max}] \le \epsilon_t \quad (5)$$

The probabilistic constraint ensured that the liquid level remained below the maximum allowable height ($h_{max} = 8\ m$) with a predefined risk tolerance ($\epsilon_t$). To ensure computational feasibility, the probabilistic constraint was converted to a deterministic equivalent using chance-constrained programming. Assuming $h(t)$ follows a normal distribution with mean $\mu_t$ and standard deviation $\sigma_t$, the reformulation yielded:

$$h(t) \leq h_{max} + (z_t \sigma_t) \quad (6)$$

where $z_t = \varphi^{-1}(\epsilon_t)$ represents the z-score corresponding to the risk tolerance, and $\varphi^{-1}$ is the inverse cumulative distribution function of the standard normal distribution. This deterministic form simplifies the inclusion of the constraint in the optimization problem [14].

## Step 4: Risk Informed Explicit Model Predictive Controller

The control objective was to minimize deviations from the setpoint $h_{sp} = 6.4\ m$ while penalizing safety violations using an inverted normal loss function (INLF) [17]. The optimization problem was expressed as:

$$min_u\ J = \sum_{i=1}^{OH-1} \left( \left( (h_i - h_{sp})^2 \right) + INLF(h_i, h_{sp}) \right) \quad (7a)$$

s.t.

$$h(i+1) = \left(1 - \frac{k}{A}\right) h(i) + \left(\frac{1}{A}\right) Q_{in}(i) + \left(\frac{1}{A}\right) w(i) \quad (7b)$$

$$0 \leq h(i) \leq h_{max} \quad (7c)$$

$$P(\Delta h > 0|t) \leq \epsilon_t \quad (7d)$$

Bayesian Update:

$$P[\Delta h > 0|t+1] = L(h(t)) * P[\Delta h > 0|t] \quad (7e)$$

Bayesian update is calculated out of the optimization problem before rolling into the next time step in the horizon. The likelihood function being used in Bayesian update is of the functional form that supports the probabilities in the direction of minimal difference between the instantaneous state and the set-point.

$$L(h(t)) = \frac{1}{\sqrt{2\pi}\sigma} \exp\left( -\frac{(h(t) - h_{sp})^2}{2\sigma^2} \right) \quad (7f)$$

The deterministic reformulation of the risk-informed problem is solved using multi-parametric programming, with the initial state $h_0$ and the parameter $(z_t \sigma_t)$ varying within the range of -3 to +3. This approach enables the explicit computation of control laws as functions of the varying parameters, facilitating efficient real-time implementation while ensuring robust performance under the prescribed risk tolerance. The resulting explicit control map (Figure 2) provide a precomputed map, which can be efficiently used to calculate the optimal solutions for the entire parameter space, ensuring real-time applicability and robust performance under the prescribed risk tolerance [15,16].

The results obtained from the proposed framework provide valuable insights into the behavior and limitations of the control strategies under varying scenarios. Initially, the system was tested with a standard hard-constrained MPC, enforcing the liquid level to strictly adhere to $h(t) \leq h_{max}$. For the first seven-time steps $t = 7$, the controller maintained the liquid level within the permissible range, effectively keeping the system stable. However, as shown in Figure 2, the strict nature of the constraint led to infeasibility at $t = 7$, causing the MPC to fail. Upon failure, the system reverted to an open-loop response, resulting in uncontrolled deviations where the liquid level rapidly exceeded $h_{max}$. This behavior illustrates the rigidity of hard constraints, which, while effective in maintaining safety under ideal conditions, lack the robustness to handle uncertainty and disturbances effectively.

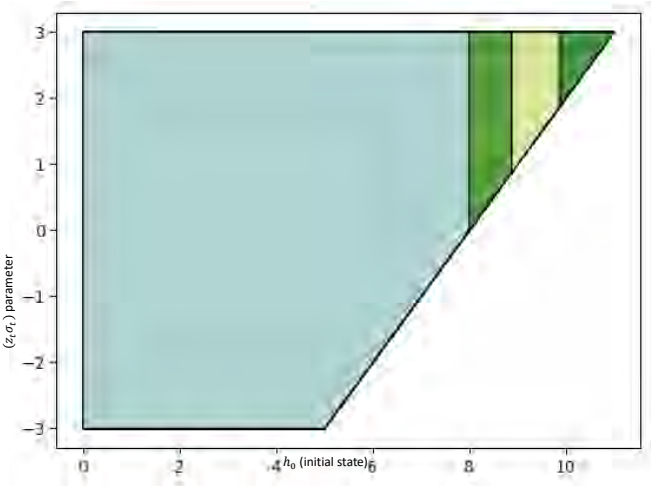

**Figure 2**. Explicit Control law map of Tank level control

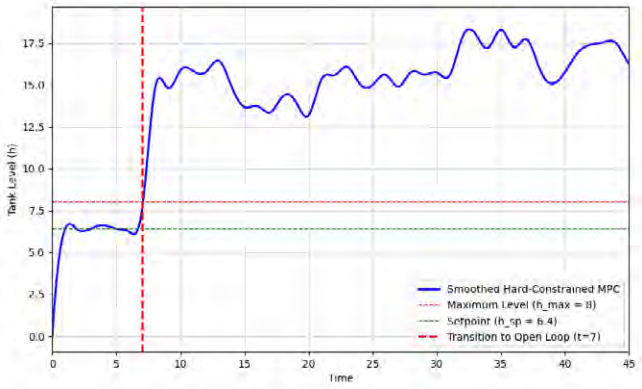

**Figure 3.** Liquid level evolution under hard-constrained MPC

Recognizing the limitations of a hard-constrained approach, the framework was extended to include probabilistic constraints. By introducing a predefined risk tolerance ($\epsilon_t$), the system gained the ability to handle uncertainties more flexibly. Probabilistic constraints allowed for occasional controlled violations of $h_{max}$ within the acceptable bounds of risk. As depicted in Figure 3, this approach alleviated the infeasibility issues observed with hard constraints, enabling the controller to operate continuously. However, while the liquid level was better

regulated, noticeable excursions beyond $h_{max}$ occurred. These excursions highlight the trade-off inherent in probabilistic constraints: a reduction in controller infeasibility at the expense of occasional deviations beyond safety limits. This raised the need for further refinements to address these excursions effectively.

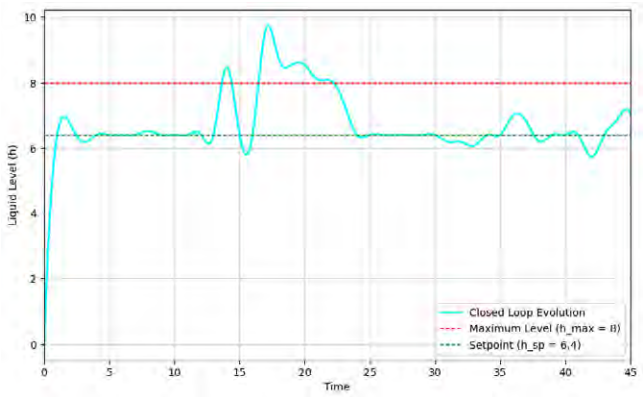

**Figure 4.** Liquid level evolution under probabilistic constraints

To mitigate the deviations observed in the probabilistic MPC, Bayesian updates and safety-aware objectives were incorporated into the control strategy. Bayesian updates dynamically adapted the risk tolerance ($\epsilon_t$) based on real-time deviations from the setpoint $h_{sp} = 6.4\ m$. The likelihood of deviations was quantified using a functional form that penalized large deviations while favoring adherence to the setpoint. Simultaneously, safety losses were added to the objective function to ensure a direct penalty for violations of $h_{max}$, effectively steering the system toward safer operation.

The effectiveness of this enhanced framework is evident in Figure 4, where the liquid level remained closer to $h_{sp}$, with significant reductions in excursions beyond $h_{max}$. Notably, when deviations beyond $h_{max}$ did occur, the system rapidly adapted its behavior, a capability driven by the dynamic nature of the Bayesian updates. This is further supported by the risk tolerance evolution shown in Figure 5, where $\epsilon_t$ sharply decreased during periods of significant deviations, indicating increased caution, and subsequently recovered as the system stabilized. This adaptive response underscores the robustness of the framework in balancing performance and safety under uncertainty.

The comparison of the control strategies highlights the progressive improvement offered by each enhancement. The transition from hard-constrained MPC to probabilistic constraints reduced infeasibility but introduced the challenge of controlling safety violations. The integration of Bayesian updates and safety-aware objectives addressed these challenges by dynamically adapting risk tolerance and penalizing safety violations, ensuring compliance with safety requirements while optimizing system performance. Together, these results demonstrate the proposed R-eMPC framework's ability to provide a robust, adaptive, and computationally efficient solution for managing safety-critical systems under uncertain environments.

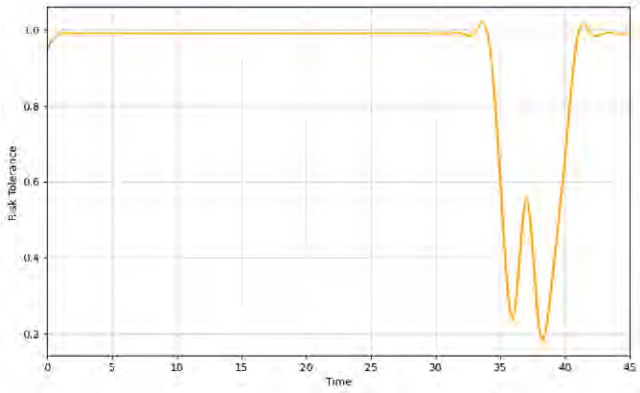

**Figure 6.** Risk tolerance evolution under Bayesian updates

## CONCLUDING REMARKS

In conclusion, the proposed R-eMPC framework demonstrated its efficacy in addressing the critical challenges associated with balancing safety and performance in a safety-critical system under uncertainty. Through a structured progression of enhancements, starting with a conventional hard-constrained MPC, we identified its inherent limitations in handling disturbances and uncertainties, which resulted in system infeasibility and subsequent failure.

By introducing probabilistic constraints, the framework gained flexibility, allowing for controlled risk while maintaining continuous operation. However, the excursions beyond the safety limit highlighted the need for further refinement. The incorporation of Bayesian updates and safety-aware objectives marked a significant step forward, dynamically adapting risk tolerance in real time and penalizing safety violations directly in the objective function. This adaptive capability resulted in substantial

improvements, as the system successfully managed uncertainties while keeping safety-critical constraints in check.

The results underline the importance of incorporating probabilistic considerations and adaptive mechanisms in modern control frameworks. The R-eMPC approach not only mitigated infeasibility but also demonstrated robustness and resilience in handling uncertain conditions, ultimately maintaining safety and improving operational efficiency. These findings highlight the potential of the proposed framework as a powerful tool for safety-critical applications, paving the way for future advancements in adaptive and uncertainty-aware control methodologies.

## ABSTRACT

The evaluation of control properties in industrial processes is essential to achieve sustainability, a very relevant topic today. This study emphasizes the importance of control studies to ensure that processes are efficient, operable and safe. While strategies such as process intensification can reduce the size, cost, and consumption of energy, it can present challenges in control and operability. This work focuses on the evaluation of the control properties of schemes with different degrees of intensification for the purification of levulinic acid, with the aim of identifying designs with the best control properties and the best economic and environmental indicators. The schemes were designed under a systematic synthesis strategy and optimized using the hybrid method of differential evolution with a tabu list, considering the total annual cost and Eco-indicator 99. An open-loop study analyzed the relationship between manipulable variables and output variables using total condition number, sensitivity index, and relative gain matrix analysis. The dynamic behavior in a closed loop was subsequently analyzed using the minimization of the absolute error integral as a criterion. The results showed that the design, which includes a liquid-liquid extraction column, three distillation columns, and thermal coupling, presented the best dynamic performance. This design had a low total condition number, a below-average sensitivity index, a stable control structure, and low values of the absolute error integral. In addition, it stood out for its excellent cost and environmental impact indicators, which makes it the most favorable option among the proposed designs.

**Keywords**: Stochastic optimization, Control, Distillation, Bioproducts.

## INTRODUCTION

The obtaining of bioproducts from lignocellulosic biomass as a sustainable alternative has gained strength in recent years. However, the processes for obtaining these bioproducts generate very dilute product streams, which represents a challenge due to the high energy consumption that their purification entails [1].

An alternative to guarantee the viability of obtaining bioproducts is the use of Process Intensification (PI). PI is an ideology that is born from the need to increase the efficiency of processes, saving energy, and maximizing production and profits, while at the same time reducing emissions of $CO_2$ and other by-products or polluting wastes [2]. The PI has been implemented in distillation, obtaining hybrid schemes, such as reactive distillation that combines reaction and separation, as well as HiGee columns that have external assistance [3]. Furthermore, if non-reactive hybrid separation PI is considered, there are schemes such as dividing wall columns (DWC), Petlyuk columns and thermally coupled columns present significant energy savings, obtaining savings of more than 25%.

PI is a powerful strategy for creating more efficient, economical, safe, and environmentally friendly processes. However, the industrial operability of these intensified processes can be challenging due to their complexity and the need for sophisticated control structures [4]. Some studies show that intensified designs may have better control properties, while others suggest that

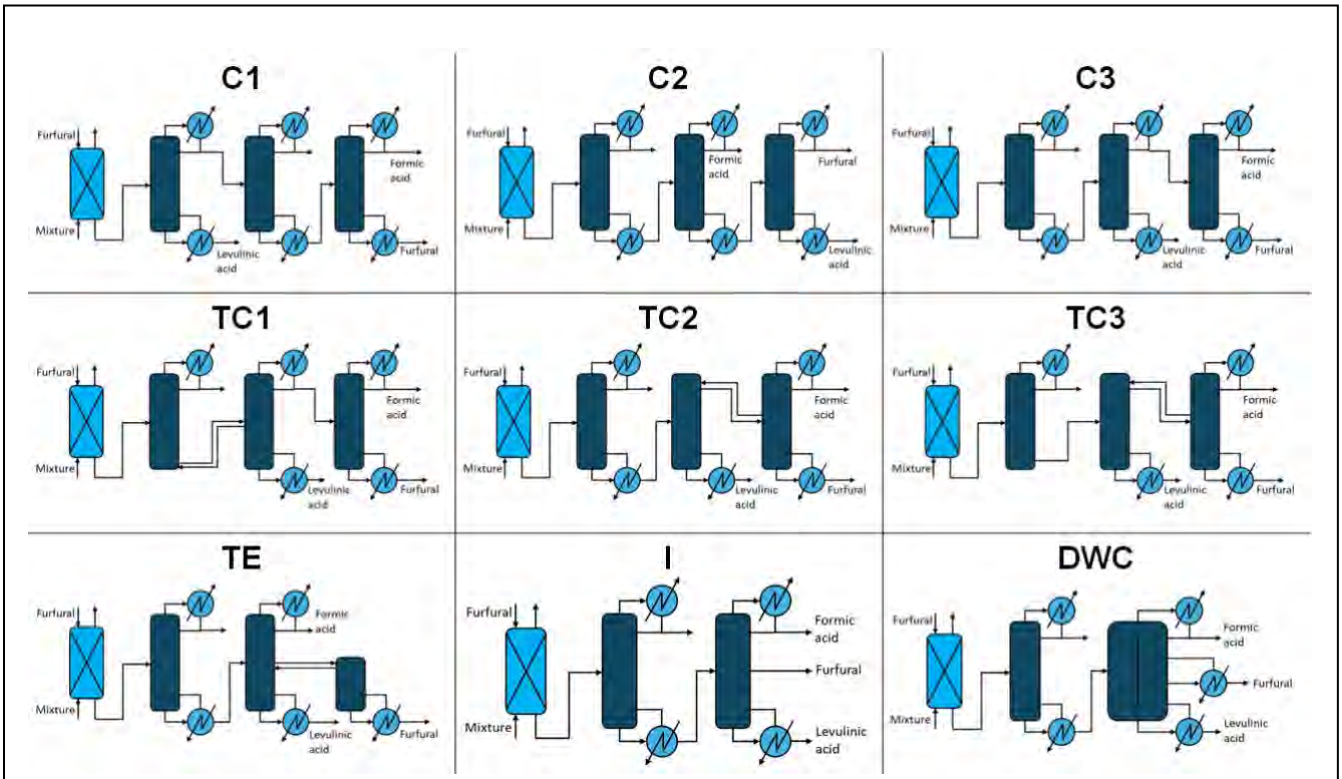

**Figure 1:** Schemes analyzed in the study, proposed by Alcocer-García et al. [12]

increased complexity does not always improve control. An in-depth analysis of control properties is essential to develop effective strategies and contribute to more sustainable and efficient processes. Specific challenges include modeling and parameter tuning, complex dynamic behavior, and reduced degrees of freedom. Addressing these challenges allows progress toward the Sustainable Development Goals (SDGs) and the transition to Industry 4.0, promoting more precise and sustainable production.

Incorporating process operability indices during design allows for the development of efficient, economically viable, and dynamically stable chemical processes. To analyze the control of distillation systems and other industrial systems, techniques and indices have been developed that help to understand their dynamic behavior. Molina-Guerrero et al. [5] performed an open-loop control analysis of an extractive distillation system, while Li et al. [6] focused on minimizing the IAE for systems with thermally coupled columns. Pushkala et al. [7] studied the optimal control structure for a reactive distillation column using the RGA. Alcocer-García et al. [8] found that schemes with greater intensification do not always have the best control properties. Therefore, dynamic analyses are essential to understand the behavior of processes and build effective control strategies.

On the other hand, levulinic acid (LA), considered one of the twelve main bioproducts through biomass, presents a bottleneck in its separation process. This is because the current resulting from thermal pretreatment and acid hydrolysis generates a very dilute current, causing the formation of azeotropes and increasing the cost of their separation, and consequently the production cost [9]. Recently, Alcocer et al. [10] developed schemes with varying degrees of intensification for the purification of levulinic acid, demonstrating significant economic and environmental savings. However, these schemes lack a comprehensive analysis of control properties. Consequently, this study undertakes an in-depth analysis of the control properties for the systems proposed by Alcocer et al. [10], thereby contributing to the understanding and enhancement of operability in intensified systems and to obtain safer and more sustainable designs.

The schemes studied consist of conventional sequences (C1, C2, C3), thermally coupled (TA1, TA2, TA3), thermally equivalent (TE), intensified with n-1 columns (I) and with dividing wall (DWC) were obtained, all with a previous liquid-liquid extraction process, shown in Figure 1. These schemes were optimized using the hybrid method of differential evolution with a tabu list, taking as a multi-objective function the total annual cost (TAC) Eco-Indicator 99 (EI99). The analysis of the control properties was carried out using two approaches: open loop and closed loop. In the open-loop analysis, the indices of total condition number, RGA and power sensitivity were incorporated as indicators, as well as a closed-loop analysis seeking to minimize the IAE by tuning the gain and integral time of the controllers. The objective is to determine the dynamic properties of the schemes to predict

and resolve control problems. The collected information on TAC, environmental impact using the EI99, and control properties provides a comprehensive understanding of the schemes and their industrial viability.

## METODOLOGY

An open-loop analysis was performed using three indicators: γ, which measures directionality in multiple-input, multiple-output (MIMO) systems; the RGA, which evaluates the interactions between the output variables and the manipulable variables; and the SI, which assesses the sensitivity of the system to disturbances in feeding. The schemas were simulated in Aspen Plus and exported to Aspen Dynamics to obtain dynamic responses to disturbances, using the NRTL-HO thermodynamic model. The NRTL-HOC thermodynamic model, suitable for highly non-ideal chemical systems, was employed to calculate liquid-vapor equilibrium and the thermodynamic properties of the vapor phase of organic acids.

For the open loop, 0.5% perturbations were applied to the manipulable variables to calculate the following indices: Total Condition Number (TCN), Relative Gain Matrix (RGA), and Sensitivity Index (SI). The responses obtained were fitted to a transfer function in MATLAB and transformed into the frequency domain to calculate γ and RGA. The open loop methodology is shown in Figure 2.

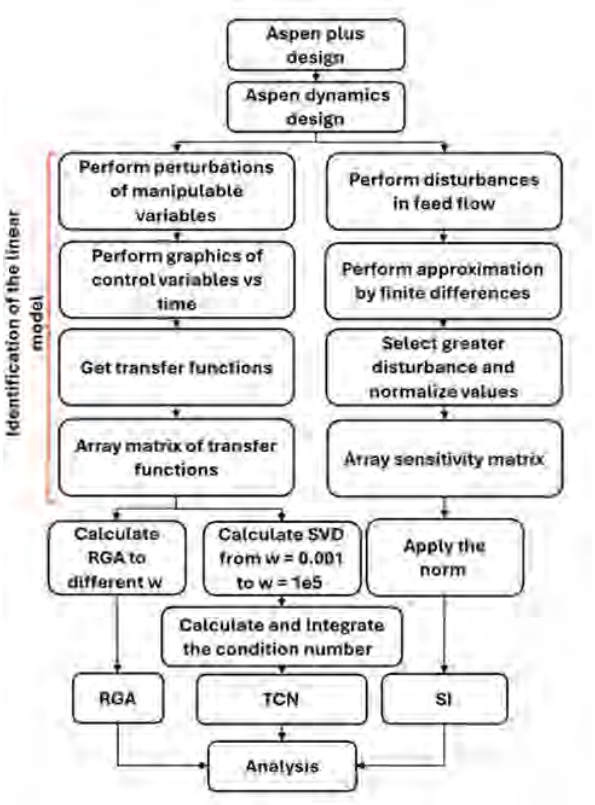

**Figure 2.** Open-loop methodology.

TCN will allow us to identify the input-output control relationship of the system. This will be calculated using the method of Santaella et al. [11], where the integral of the crow generated by the condition number γ and the frequency ω is calculated.

$$TCN = \int_{\omega_1}^{\omega_2} \gamma d\omega \quad (1)$$

A high γ suggests that the system is sensitive to input uncertainties, but it does not always imply greater sensitivity in practice. Systems with a lower γ are expected to have better dynamic performance and be easier to control, as they are less sensitive to disturbances. This facilitates the implementation of simple and straightforward control strategies, such as Proportional-Integral-Derivative control.

The RGA analysis shows how the manipulable variables affect the system's outputs. In distillation columns, the most used control structure is the LV configuration, which controls the distillate composition with the reflux ratio (RR) and the bottom composition with the reboiler heat duty (RHD). However, in intensified schemes, different structures can be identified at LV (DLV), where a different manipulable variable than the one established in the LV configuration has a greater influence on the output variable. In addition, it is possible that some configurations at different frequencies have a changing control structure (CCS) entre la LV y DLV. The RGA on the other hand will allow us to find the best control pairing, calculated as follows:

$$\mathrm{RGA(G)} = \Lambda(G) \triangleq G \otimes (G^{-1})^T \quad (2)$$

In this study evaluated the consistency of the control structure by calculating the RGA at three frequencies: steady state (0 rad/h), near steady state (0.001 rad/h), and high frequency (1e5 rad/h). The variation in the control structure at different frequencies indicates frequency dependence, suggesting nonlinearity and variations in interactions between process variables, which can affect control effectiveness and require adaptive or robust control strategies.

The SI allows us to observe the sensitivity of the output variables according to the input perturbations, which was calculated using the method of Prado-Rubio et al. [12] through finite differences:

$$SI(t) \approx \frac{X[F_{in}(t)+\Delta F_{in}(t)]-X(F_{in})}{\Delta F_{in}} \frac{F_{in}(0)}{X(0)} \quad (3)$$

A high SI value suggests that the system is very sensitive to disturbances in the feed, which requires the implementation of robust control strategies. This can include predictive control to anticipate and correct disturbances, as well as adaptive control to adjust parameters in real-time and maintain process stability and efficiency.

For the closed loop, perturbations were performed at the output of the LA at 5% and 30%, varying and tuning

the gain (Kc) and the integral time (τi) to find the minimum IAE using PI proportional-integral composition controllers. This with the objective of exploring dynamic behavior to a small disturbance and another of greater magnitude.

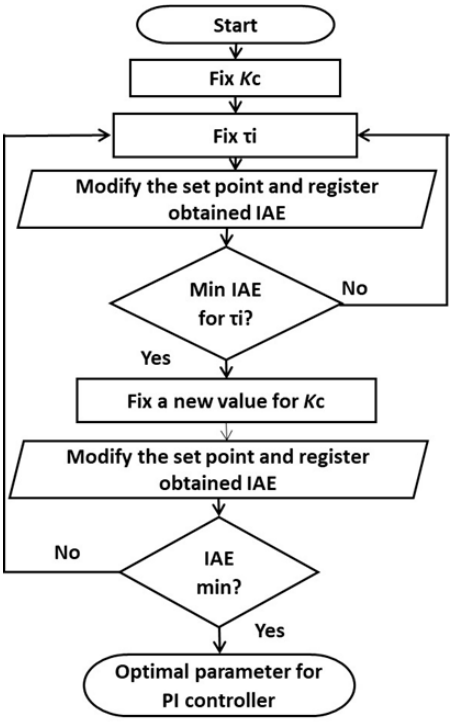

**Figure 3**. Process diagram for tuning PIC.

## RESULTS

The open-loop analysis, shown in Table 1, revealed that the C2, TA1 and TA2 designs have an LV configuration at all frequencies, which translates into systems that can be controlled with direct and less complex strategies, reducing the need for advanced and expensive control systems. In particular, the TA2 design is distinguished by the lower TAC and IAE values, making it the most economical option with the lowest environmental impact. Therefore, considering that it presents a stable control structure, it is positioned as one of the best alternatives of the schemes studied.

On the other hand, the C3, TE, and DWC designs have a DLV configuration, which is stable, but may need more specific control. In these cases, a more specific control refers to the need to adjust and tune the manipulable variables more precisely to maintain the desired performance of the system. This could include the use of advanced control techniques such as predictive control, which anticipates future changes and adjusts control variables accordingly, or adaptive control, which adjusts controller parameters in real-time to respond to variations in process behavior. Although the TAC and EI99 values are slightly higher, they are still good alternatives. However, the C1, TA3 and TE designs, with CCS structure, are unstable and require advanced control strategies. Advanced control strategies are necessary for these designs because of the added complexity and nonlinear interaction between process variables. These strategies can include the use of nonlinear control, which handles the complex, nonlinear relationships between variables, and robust control, which is designed to maintain system performance under a wide range of uncertainty and disturbance conditions. It may also be necessary to implement multivariable control systems, which coordinate multiple inputs and outputs simultaneously to optimize the overall performance of the system.

Due to the increase in interconnection flows in the generated recycles, the TA3 design, which has two thermal couplings, has a greater sensitivity to disturbances in the power supply, generating an increase in SI. And also negatively impacting the TAC and HAI, being the design with the worst values in these indicators and presenting an unstable control structure, which positions it as the worst alternative of those studied.

Design factors such as column diameter and location of thermal couplings significantly impact TCN, with smaller diameter columns facilitating more effective control and reduced operating costs. In summary, systems with low TCN and SI values are more stable and less sensitive to disturbances, while systems with high values require more sophisticated and costly control strategies.

**Table 1:** Open-loop results analisis

| Design | TAC | EI99 | TCN | SI | RGA |
|---|---|---|---|---|---|
| C1 | 1.85E+07 | 5.35E+09 | 5.87E+09 | 13.37 | CCS |
| C2 | 1.56E+07 | 4.70E+09 | 1.04E+07 | 6.68 | LV |
| C3 | 1.49E+07 | 4.60E+09 | 1.95E+08 | 12.37 | DLV |
| TA1 | 1.64E+07 | 4.56E+09 | 4.68E+09 | 0.50 | LV |
| TA2 | 1.39E+07 | 4.21E+09 | 6.44E+06 | 11.28 | LV |
| TA3 | 1.90E+07 | 5.16E+09 | 1.78E+07 | 33.15 | CCS |
| TE | 1.43E+07 | 4.35E+09 | 1.18E+07 | 11.50 | DLV |
| I | 1.77E+07 | 5.22E+09 | 6.30E+07 | 7.56 | CCS |
| DWC | 1.43E+07 | 4.34E+09 | 1.23E+07 | 11.49 | DLV |

The results of the closed-loop analysis are shown in Figure 4. Design TA1 presented the lowest IAE values in all perturbations due to the recycling between the first two distillation columns, which helps dampen disturbances. Additionally, this design shows the smallest Kc values, which improves stability and reduces oscillations. On the other hand, design C1 has the highest IAE values because it recovers levulinic acid in the first distillation column, complicating thermodynamic stability. Designs C2, C3, TA2, TA3, TE, I, and DWC stand out for having similar IAE values in all perturbations, revealing homogeneous dynamic behavior. This suggests that despite differences in configurations, their response to disturbances is uniformly balanced, facilitating a more

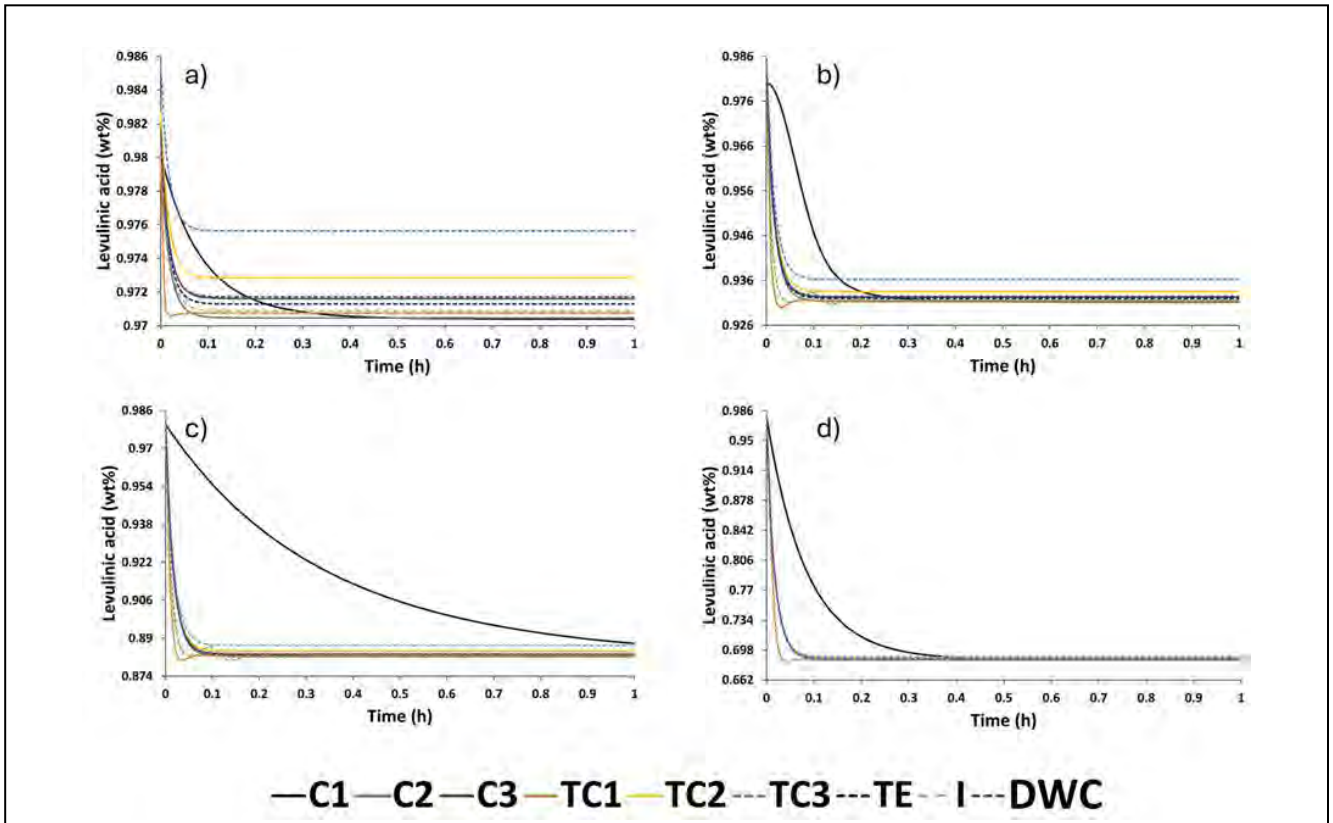

**Figure 4:** Closed-loop responses 1% (a), 5%(b), 10%(c) and 30%(d).

predictable implementation of control strategies.

These findings not only contribute to the understanding of operability in intensified systems but also highlight the importance of selecting appropriate configurations and optimizing specific factors to achieve effective control. The incorporation of additional thermal couplings, as in the TA3 design, improves the distribution of disturbances and the stability of the System in the face of disturbances in the manipulable variables, but makes it unstable in the face of disturbances in the feed.

In addition, sensitivity analysis and interactions between manipulable and output variables underscores the need for robust and adaptive control strategies, especially in designs with higher TCN and SI values. Finally, the economic and environmental benefits derived from the optimization and control of these systems underscore the relevance of these approaches to move towards a more sustainable and efficient industry. In particular, the TA2 design is positioned as the most balanced choice in terms of stability, control efficiency, and costs, which is crucial for the successful implementation of intensified processes in industrial practice. Design TA2 is low TAC and EI99 not only reflect its economic efficiency, but also its lower environmental footprint, standing out as a model for future sustainable designs in the industry.

## CONCLUSIONS

The analyses conducted on open and closed loops revealed significant differences in the dynamic performance and control requirements of the various designs evaluated. Notably, the C2, TA1, and TA2 designs, which exhibit LV configurations at all frequencies, stand out for their superior dynamic performance and stability, obtaining the best values in RGA and IAE analyses and showing a homogeneous response to disturbances.

In contrast, designs such as C3, TE, and DWC, while stable in DLV configurations, may require more specific control techniques like predictive or adaptive control to maintain desired performance. Although the TAC and EI99 values are slightly higher, they remain good alternatives. However, C1, TA3, and TE designs with CCS structures proved unstable and necessitate advanced control strategies like nonlinear and robust control to handle complex interactions.

Factors such as column diameter and the location of thermal couplings significantly impact TCN, with smaller diameter columns facilitating more effective control and reduced operating costs. The TA2 design is particularly noteworthy, presenting the best TAC and EI99 values, making it the most economical option with the least environmental impact. The results underscore that systems with low TCN and SI values are more stable and less

sensitive to disturbances, allowing for more predictable and efficient control, while systems with high values require sophisticated control strategies.

The economic and sustainability benefits from optimizing and controlling these systems highlight their relevance to a more sustainable and efficient industry. The TA2 design stands out as the most balanced option in terms of stability, control efficiency, and costs, with its LV RGA configuration ensuring a stable and predictable control structure. These findings emphasize the importance of selecting suitable configurations and optimizing specific factors like column diameters and thermal couplings to achieve effective control, lower environmental impact, and reduced operational costs. This study provides a clear path toward optimizing the stability and efficiency of control systems in distillation column design.

## ABSTRACT

Distillation is not only a widely-used but also an energy-intensive separation process, in which internals such as structured packings play an important role. Increasing mass transfer efficiency by designing improved structured packings in order to provide a large interfacial area while enabling low pressure drop is one promising approach to quickly reduce the energy requirements of vacuum distillation where low pressure drop is important for separation efficiency and thermal stability of the processed media. The current work presents an innovative method to optimize structured packings by means of constrained shape optimization on the basis of computational fluid dynamics simulations to minimize the pressure drop while maintaining a constant specific surface area. To solve the fluid dynamic optimization problem, a gradient-based local optimization algorithm in a continuous adjoint formulation is utilized. The shape optimization is applied for a commonly used Rombobak packing, and tested as a refinement method for an initial structure derived by topology optimization. The results demonstrate a successful reduction of the pressure drop in both cases, which can be attributed to several factors, including the refinement of the edges and the mending of the dead zones.

**Keywords**: structured packings, CFD simulation, optimization-based design

## INTRODUCTION

The design of structured packings for thermal separation columns has been the subject of extensive research for 60 years [1]. Despite the profound expertise and considerable advances that have already been gained in this field, it remains a challenging but promising task. This is due to the fact that the packing performance depends on a variety of fluid dynamic and mass transfer-related parameters, which exert a mutual and not necessarily beneficial influence on one another. The systematic development of improved packings by means of computational fluid dynamics (CFD) simulations is a promising approach to yield improved designs that can be manufactured on the basis of the derived computer aided design (CAD) models.

Various research groups conducted parameter variations of specific structured packings based on CFD simulations to systematically generate new improved designs [2,3]. However, only a limited number of studies have employed mathematical optimization for this purpose. While Lange and Fieg [4] focused on the optimization of novel structures by means of topology optimization based on CFD simulations, Blauth et al. [5] performed shape optimization of a specific structured packing that was initially derived from the Rombopak 9M packing [6]. In the topology optimization approach [4], the material distribution is varied in a predefined grid structure making use of an evolutionary algorithm. While this approach provides high potential for innovation, it can only produce rough design drafts for tractable grid sizes. In contrast, shape optimization modifies a given structure gradually based on gradient information of the objective function, as obtained through adjoint simulations [7]. This approach does not allow for the generation of new structures, but can be beneficial as a refinement tool for further improvement of existing packing designs or initial course structures. As demonstrated and experimentally validated by Blauth et al. [5], the shape optimization has been proven to be successful, resulting in an increased separation efficiency of 20%.

In this contribution, shape optimization coupled with

single-phase CFD simulations of the gas phase is used to improve two initial packing structures. By starting from a topology-optimized packing structure, the sequential integration of both optimization methods is evaluated, while the shape optimization approach is further tested for an established structured packings on the basis of an initial Rombopak packing.

## METHODOLOGY

The initial structures of the two different packing elements are depicted in Figure 1, showing the topology-optimized packing [4] and the Rombopak packing. The individual structural elements of the topology-optimized packing (left) consist of cubes. Due to the sharp edges, they exert a detrimental impact on the overall flow such that vortex formation can occur here, which are associated with increased pressure drop. The Rombopak packing (right) consists of thin, x-shaped structural elements, which are already significantly more conducive to the flow. The size of the packings to be optimized is a single packing element at laboratory scale with a diameter of 54 mm diameter and a height of 100 mm selected based on the dimensions of an available experimental setup to measure the fluid dynamics.

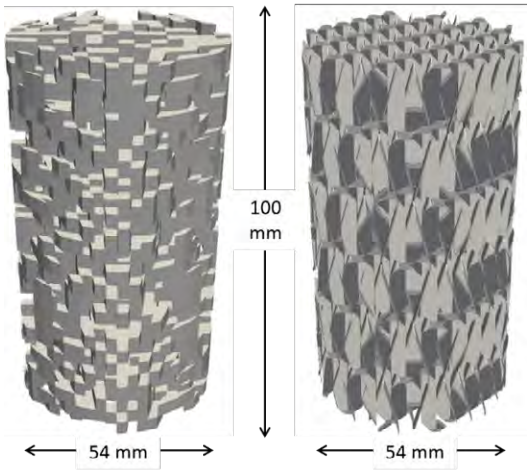

**Figure 1.** Initial packings for shape optimization: topology-optimized packing (left) and Rombopak packing (right).

### CFD simulations

To evaluate the pressure drop of the different packings generated during shape optimization, CFD simulations are performed using the software OpenFOAM. The fluid flow through the packings is modelled based on the continuity equation and the Navier Stokes equations. Whereas the primary focus of this study is on the fluid dynamics, the specific surface area serves as a simplified metric for the potential interfacial area for mass transfer, assuming a completely wetted packing surface. While this assumption is certainly optimistic it allows to use simple single-phase simulations instead of a complex multiphase model, which is important for the complex optimization task. The air flow is entered at the bottom of the packing with a velocity of 0.2 m/s, corresponding to an F-factor of 0.22 $Pa^{0.5}$. At these conditions, the flow can be assumed as incompressible. Further assumptions for the CFD simulations include steady state and laminar flow. Newtonian fluid behavior is be assumed and the flow is modeled at ambient pressure and temperature. The domain includes the packing element surrounded by a hollow cylinder representing the column wall. For convergence reasons, the cylinder is enlarged to a diameter of 63.5 mm. Furthermore, the length of the cylinder exceeds that of the packing on both sides to effectively simulate the inlet and outlet areas of the fluid. To solve the CFD simulations, the SIMPLE algorithm is used. The pressure drop is evaluated over the inlet and outlet of the computational domain. Furthermore, post-processing tools are employed to calculate the specific surface area of the structured packing, which is defined as the ratio of the surface area to the volume. To execute shape optimization, an additional solver is used, which is described in the following section.

### Adjoint-based shape optimization

The shape optimization problem can be stated as

$$\min J(\boldsymbol{u}, p, \boldsymbol{\beta}) \; s.t. \, \boldsymbol{h}(\boldsymbol{u}, p, \boldsymbol{\beta}) = 0 \wedge g(\boldsymbol{\beta}) = 0 \qquad (1)$$

with the objective function J describing the pressure drop Δp, $\boldsymbol{h}$ corresponding to the mathematical model of the fluid dynamics problem, consisting of the continuity and the Navier Stokes equations, as well as a geometric constraint $g$, which keeps the specific surface area a constant. The design variables $\boldsymbol{\beta}$ of the optimization algorithm are defined as the surface points of the packing, which form the faces and thereby the shape of the packing. The surface points can be moved along the surface normal during the optimization in order to deform the packing in a targeted manner for minimizing the objective function.

A gradient-based local optimization algorithm in a continuous adjoint formulation is used to solve the fluid dynamic optimization problem [7]. An overview of the iterative process of shape optimization is depicted in Figure 2. The initial geometry is provided in the form of a $stl$ file and is meshed before the optimization of the current iteration starts.

To obtain information about the extent for shifting the surface points, the gradients are necessary, which are also referred to as sensitivities in this context. An effective method for calculating the sensitivities with a large number of design variables, as in this case, is the adjoint method. In addition to the conventional system of equations based on the continuity equation and the

Navier Stokes equations, referred to as primal equation system, a similarly structured adjoint equation system is set up. This second system is a purely mathematical construct. To solve the constrained optimization problem of equation 1, the Lagrange method is applied. The resulting Lagrange function is shown in equation 2, where $\Omega$ corresponds to the solution domain of the fluid dynamic problem and the Lagrange multipliers are represented by the adjoint velocity $\boldsymbol{u_a}$ and the adjoint pressure $p_a$.

$$L = J + \int (\boldsymbol{u_a}, p_a) \boldsymbol{h} d\Omega \tag{2}$$

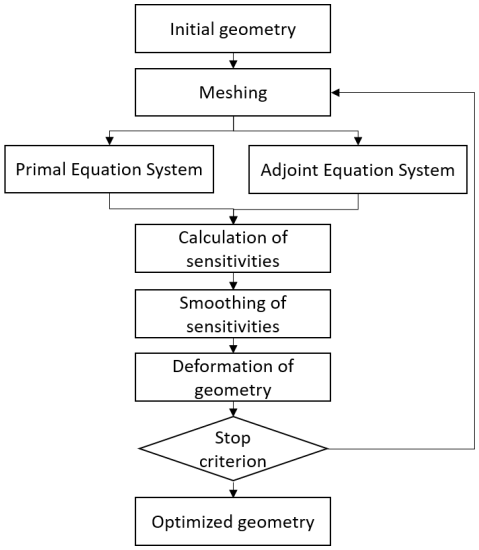

**Figure 2.** Schematic visualization of the iterative process of shape optimization.

The sensitivity field with respect to the design variables can then be calculated from the scalar product of the wall-normal gradients of the primary and adjoint velocities:

$$\frac{\partial L}{\partial \boldsymbol{\beta}} = -\nu (\boldsymbol{n} \cdot \nabla) \boldsymbol{u_a} \cdot (\boldsymbol{n} \cdot \nabla) \boldsymbol{u} \tag{3}$$

The geometrical constraint of a constant specific surface area is implemented using a penalty method whereby a penalty term weighted with a penalty parameter γ is added to the sensitivity values as illustrated in equation 4. The specific surface area of the initial packing is denoted by $a_0$ and the lower limit for the specific surface area $a_{min}$ is defined as $a_0$ subtracted by a tolerance value of 1.5 m²/m³ for both packing types. In order to prevent uncontrolled expansion of the structural elements, which leads to a decrease in the free cross-sectional area and thus to an increase in pressure drop, all negative sensitivities are set to zero once the geometric constraint is violated. Consequently, the correction of the sensitivity field is constrained to positive sensitivities.

$$\frac{\partial L}{\partial \boldsymbol{\beta}_{corrected}} = \frac{\partial L}{\partial \boldsymbol{\beta}_{>0}} + \gamma \frac{a_{min} - a}{a_0} \tag{4}$$

Subsequent to the calculation of the sensitivity values, a smoothing equation with a specified number of iterations can be used in order to reduce the scatter of the sensitivity field. Depending on the specific application, the magnitude of the sensitivity field varies, which can result in complications, such as overlapping faces when using the deformation tool. To address this, the sensitivities are normalized to the largest value. For the deformation of the surface points, the method of steepest descent with a specified step size α is applied. As indicated by equation 5, the surface normal displacement of the packings' surface points is obtained by multiplying the step size by the negative gradient of the surface sensitivities, which indicates the search direction.

$$\boldsymbol{\beta}^{i+1} = \boldsymbol{\beta}^{i} + \alpha \left( -\frac{\partial L}{\partial \boldsymbol{\beta}}^{i} \right) \tag{5}$$

The iterative shape optimization continues as the deformed geometry is used as a new initial packing in the next iteration step. The process continues until a specified stop criterion is reached.

In order to ensure that the cylindrical shape of the structured packing is retained and that it can be stacked in height without gaps, a maximum volume is introduced and sensitivities on the outer surfaces of the packing in this volume are set to zero. This approach also provides a constant cylindrical reference volume for the calculation of the specific surface area, thereby ensuring the comparability of the packings across different iterations of shape optimization.

The success of shape optimization is subject to the selection of the previously outlined hyperparameters, for which the values selected on the basis of preceding preliminary studies are shown in Table 1. For both structured packings, a step size of $10^{-4}$ is used whereas a higher penalty parameter and no smoothing iterations are used for the Rombopak packing compared to the topology-optimized packing for ensuring the specific surface area to remain above the prescribed lower limit.

**Table 1**. Selected parameters for the shape optimization algorithm

| Parameter | Topology-optimized packing | Rombopak packing |
|---|---|---|
| Step size | $10^{-4}$ | $10^{-4}$ |
| Penalty parameter | 10,000 | 100,000 |
| Smoothing iterations | 10 | 0 |

## RESULTS

The shape optimization results are first discussed for the topology-optimized packing and subsequently for the Rombopak packing, analyzing the development of the pressure drop and specific surface area, as well as the deformation of the packings induced by shape

optimization and the respective velocity plots and streamlines.

## Topology-optimized packing

Figure 3 shows the progression of shape optimization regarding pressure drop and specific surface area over the course of the iterations. For the initial packing, the pressure drop is 0.063 mbar/m and the specific surface area of the packing is 375.3 $m^2/m^3$. It should be noted that the pressure drop is relatively low, which is a consequence of the low F-factor. As the number of iterations increases, the pressure drop decreases continuously. In the first 20 iterations, the decline is precipitous, followed by a more modest decrease that is almost stagnating in the last 10 iterations. The specific surface area is characterized by a fluctuating course over the iterations. It decreases until the defined lower limit of 373.8 $m^2/m^3$, is attained, at which point the geometric constraint becomes effective. After the 136th iteration, the minimum limit for the specific surface area is permanently undercut, so that the optimum is found at this point. The pressure drop of this packing is 0.053 mbar/m and the specific surface area 374.0 $m^2/m^3$. Overall, the pressure drop is reduced by 16% during the process of shape optimization while the specific surface area is kept constant with minor deviations of 0.3%

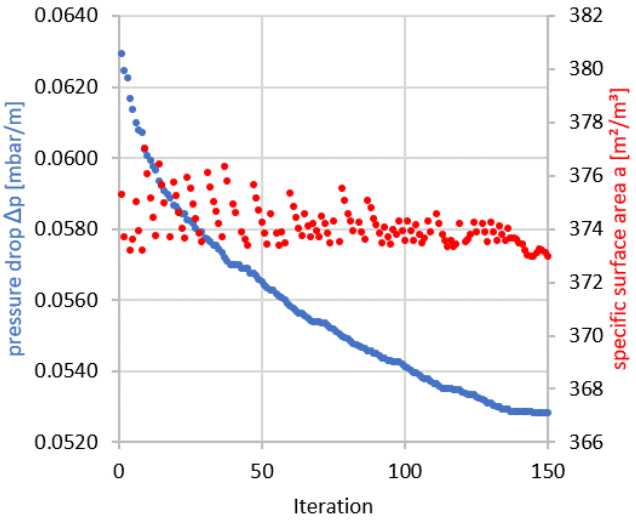

**Figure 3.** Shape optimization results of the pressure drop and specific surface area for the topology-optimized packing.

In order to conduct a more thorough examination of the effect of shape optimization, a comparison is made between the initial packing and the optimized packing shown in Figure 4. It becomes evident that the initially cubic structural elements are rounded, as expected, and extended in the direction of the flow. This results in a reduction in pressure drop, attributable to the gentler deflection of the fluid flow. Moreover, a reduction in horizontal surfaces is evident subsequent to shape optimization. In a distillation column, this phenomenon is anticipated to result in diminished stagnant liquid and a more frequent renewal of the liquid film, thereby enhancing mass transfer. A more detailed analysis of the two zoomed-in sections in Figure 4 offers additional insights. The section is situated at the bottom of the packing, with the cube in the center representing a dead zone since it is only open at the bottom. The figure demonstrates that this zone is filled with material during shape optimization, a factor that exerts a positive influence on both the pressure drop and the distribution of the fluid.

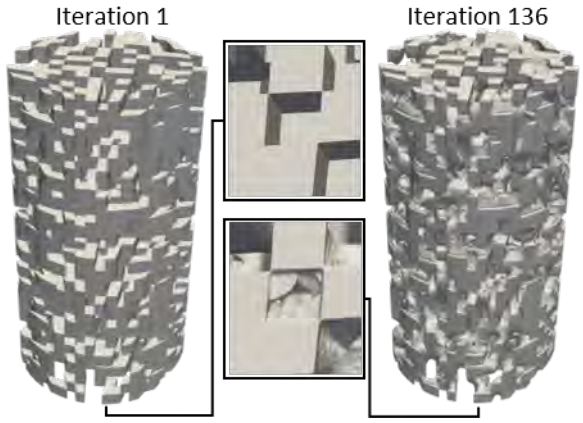

**Figure 4.** Packing element of the initial topology-optimized packing and after 136 shape optimization iteration steps including zoomed-in sections at the bottom of the packing.

To analyze the effects of the deformations on the fluid dynamics, sections of the velocity plots and the streamlines in Figure 5 are considered, where the initial packing and the optimized packing of iteration 100 are compared. For both cases, it is evident that subsequent to entering the packing from the bottom at 0.2 m/s, substantial variations in velocity occur, with velocities reaching up to 0.7 m/s in the constricted segments. These velocity differences contribute substantially to the formation of vortex structures, which are particularly evident in the outlet area, on top of the packing section. However, the flow stabilizes further downstream, which is not depicted in the section shown. Smaller vortices can also be observed within the packing. Furthermore, a considerable part of the fluid flows past the exterior of the packing between the packing and the cylindrical wall. The augmentation of the cylinder diameter, which is imperative for convergence reasons of the adjoint equation system, exerts a substantial influence on the flow behavior. However, it is noteworthy that the optimization process remains effective. Despite the general resemblance of the structure and velocity fields, it is evident that initial regions exhibiting minimal velocity are being replenished

with material (see black ellipsoid) fostering a more homogeneous fluid distribution in the cross-section. Furthermore, a discernible weakening of the vortex structures is apparent following the shape optimization, accompanied by a reduction in dissipation and, consequently, a decrease in pressure drop. This phenomenon is primarily attributable to the rounding of the structural elements, which deflects the fluid flow more gently. Yet it needs to be noted that the obvious bypassing close to the wall is merely affected by the improvements.

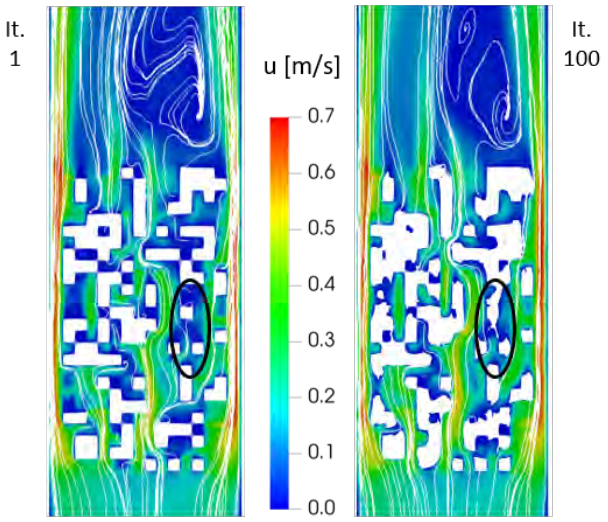

**Figure 5.** Section of velocity profiles of the initial topology-optimized packing (left) and after 100 shape optimization iterations (right) in central 2D section with streamlines; sections of the cylinder above and below the packing have been removed.

## Rombopak packing

The result of the shape optimization of the Rombopak packing is depicted in Figure 5. The development of the pressure drop and the specific surface area over the course of the iterations exhibits a resemblance to the previously studied packing. The specific surface area shows less fluctuation since the geometric constraint is undercut more frequently for this packing. At iteration 49, the specific surface area ceased to exceed the minimum defined value of 499.4 $m^2/m^3$ and therefore marks the optimum for this packing. The initial pressure drop of 0.036 mbar/m is reduced by 3% whereas the specific surface area remains constant with a negligible deviation of 0.3%.

The initial Rombopak packing and the resulting deformation after 49 shape optimization iterations, depicted in Figure 6, appear rather identical. However, a more thorough examination of the zoomed-in section reveals the deformations of shape optimization. It can be observed that the introduction of new material, particularly in the middle of the structural element and at the joints between different structural elements has been incorporated. Furthermore, as with the topology-optimized packing, the presence of rounded edges is evident. These rounded edges serve to prevent an abrupt change in the direction of fluid flow, thereby preventing flow separation and reducing pressure drop.

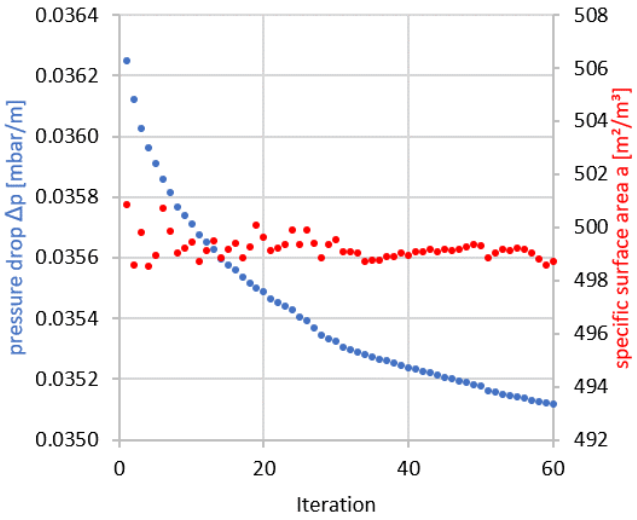

**Figure 6.** Shape optimization results of the pressure drop and specific surface area for the Rombopak packing.

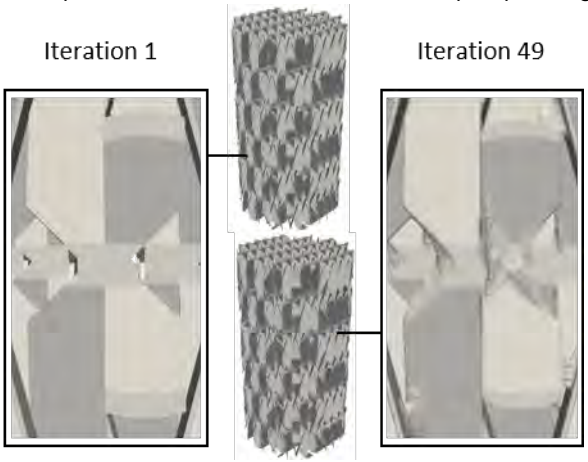

**Figure 7.** Packing element of the initial Rombopak packing and after 49 shape optimization iteration steps including zoomed-in sections.

An analysis of the velocity profiles and streamlines of the Rombopak packing before and after shape optimization, as shown in Figure 7, reveals more linear streamlines and a more uniform fluid distribution along the cross section compared to the topology-optimized packings, which has a positive effect on the pressure drop. While shape optimization does not significantly affect the velocity plots and streamlines in this case, zoomed-in sections highlight the deformations of the packings. As illustrated in Figure 6, the bottom right ellipse indicates the process of material addition at the joints of structural elements. Furthermore, the top left ellipse demonstrates

that there is an extension of the structural elements in the direction of the flow. An examination of the overall longitudinal section yields the finding that the deformations occur primarily on the outer elements.

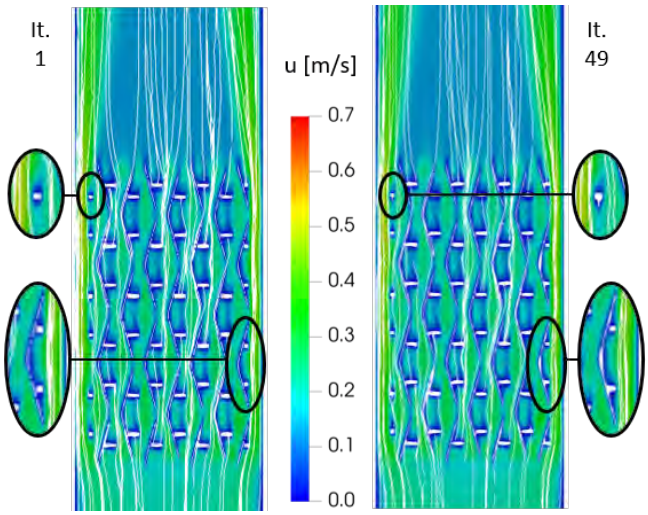

**Figure 7.** Section of velocity profiles of the initial Rombopak packing (left) and after 49 shape optimization iterations (right) in central 2D section with streamlines with zoomed-in sections; sections of the cylinder above and below the packing have been removed.

## CONCLUSION & OUTLOOK

The two optimization studies indicate the successful application of the shape optimization with reduced pressure drop at constant specific surface area. The initial pressure drop of the coarse topology-optimized packing is effectively reduced by 16%, while the pressure drop of the Rombopak packing is reduced only slightly by 3%, and the optimal result was attained after 49 iterations. These differences are however expected due to the coarser structure of the topology-optimized packing, which provides significantly larger potential for improvement. Overall, it can be concluded that shape optimization provides an effective tool for the refinement of existing packing structures.

To further improve the optimization, it is essential to systematically vary the parameterization of the optimization algorithm for every packing considered. A particular emphasis should be placed on the tolerance value for the lower limit of the geometric constraint, as an increase in this value may contribute to a higher freedom for deformation. In order to ascertain the impact of shape deformation on the separation efficiency, experiments of the optimized packings in a distillation column are imperative.

## ABSTRACT

Circular economy is recognized as one of the most effective strategies for promoting plastic sustainability. However, its implementation requires to enhance consumer engagement, which remains a primary target of regulatory initiatives designed to promote plastic circular economy. To ensure sustained consumer participation, it is essential to evaluate and optimize various incentives, including regulatory policies, voluntary programs, and market-related mechanisms. This study applies Stackelberg Game Approach to quantitatively capture the strategic interactions between the authorities (as the leader) and consumers (as followers). The model incorporates key consumer behaviors, i.e., "use less," "use longer," and "recycling", to reflect their role in advancing plastic circular economy goals. By integrating factors such as governmental utility (gains of benefits), consumer utility (welfare), and plastic waste reduction, the model identifies the optimal intensities of various public initiatives, which represent the quantitative levels of policy intervention necessary to maximize desired outcomes. A case study based on EU-27 data demonstrates the model's applicability, revealing optimal intensities of 0.91, 0.41 and 0.8 for regulatory, voluntary, and market-related initiatives. At these optimal intensities, regulatory measures achieve the highest governmental utility (benefits) and plastic waste reduction, while market-related mechanisms yield more favorable outcomes for consumer welfare. The findings highlight the need for a balanced policy mix that effectively aligns government objectives with consumer incentives.

**Keywords**: Circular Economy, Plastic Waste Reduction, Government initiatives Consumer behavior, Stackelberg Game

## INTRODUCTION

The conventional plastic consumption model, characterized by a linear "use-and-dispose" pattern, is gradually being replaced by a more sustainable approach known as the plastic circular economy [1]. This model emphasizes behaviors such as "use less", "use longer", and "recycling", which collectively aim to minimize plastic waste and maximize resource efficiency [2]. Howe-er, the transition to a circular economy presents significant challenges, particularly in influencing and sustaining changes in consumer behavior.

Governments play a pivotal role in this transition by implementing a range of initiatives designed to either incentivize or regulate consumer behavior. These measures include regulatory policies, voluntary programs, and market-related mechanisms such as taxes or subsidies [3]. While these initiatives are essential, their effectiveness largely depends on how consumers respond [4], making the dynamic interaction between government interventions and consumer behaviors a key issue.

Previous research has extensively explored this relationship, primarily through qualitative methods, such as consumer surveys and behavioral assessments [5]. Although these studies provided valuable insights into

consumer preferences and policy acceptance, they often lack quantitative evaluation of how different policy intensities affect consumer behavior and plastic waste reduction. Most existing literature tends to focus on broad initiative evaluations, such as the overall impact of policies on waste reduction, rather than exploring the strategic interactions between policymakers and consumers in a structured, decision-theoretic manner [5].

To address this gap, this study employs a Stackelberg game model, a well-established framework for analyzing hierarchical decision-making processes where one player (the leader) makes decisions anticipating the responses of another player (the follower) [6]. In the context of the plastic circular economy, the government acts as the leader, setting initiatives to influence consumer behaviors, while consumers act as followers, adjusting their actions to maximize their utility in response to these initiatives. This approach allows for the quantitative evaluation of interactions between the government and consumers, providing insights into how different measure intensities affect not only plastic waste reduction but also the benefits of both parties.

The contributions of this work are outlined as follows,

1) The establishment of a Stackelberg Game model to quantitatively capture the interaction between the government and consumers, addressing the lack of quantitative focus in the existing literature.

2) Assessment of the interactions between government initiatives, i.e., regulatory, voluntary, and market-related, and consumer behaviors such as "use less," "use longer," and "recycling," providing a quantitative evaluation of how these factors influence the plastic circular economy.

3) Optimization of the intensities of various government initiatives, considering the balance between government utility, consumer welfare, and plastic waste reduction, providing a decision- making framework for government initiatives.

The remainder of this work is organized as follows: Section 2 proposes the developed Stackelberg game model for capturing the interactions between government and consumer. Section 3 introduces a numerical case study based on the EU-27. The numerical results are presented and discussed in Section 4. This work is concluded in Section 5. All symbols used in this work are illustrated in Table 1.

**Table 1:** Symbols.

| | |
|---|---|
| **Sets** | |
| $I$ | Types of government initiatives and/or policies implemented to promote a circular economy in plastics |
| $J$ | Types of consumer behaviors relevant to fostering a circular economy for plastics |
| **Indices** | |
| $i$ | Index for initiatives aimed at promoting the circular use of plastics, $i$ = {Regulatory measure, Voluntary measure, Market-based measure} |
| $j$ | Index for consumer behavior supporting the adoption of a circular economy for plastics, $j$ = {Reduce plastic use (Use less), Extend plastic product lifespan (Use longer), Recycling plastics} |
| **Parameters** | |
| $\alpha_i$ | Consumer sensitivity or resistance to $i$-th government initiative. ($\alpha_i \leq 0$) |
| $B$ | The total budget for voluntary measures, measured in € |
| $C_c$ | The cost of carbon price for consumer (€/kg) |
| $C_d$ | The charges of consumer plastic disposal, i.e., landfill (€/kg) |
| $C_e$ | The cost of government education investment (€/kg) |
| $C_r$ | The cost of consumer plastic recycling (€/kg) |
| $C_v$ | The cost of plastic virgin raw material consumption (€/kg) |
| $C_w$ | The cost of plastic waste management (€/kg) |
| $F_r$ | The consumer refundable fees of plastic recycling (€/kg) |
| $P_p$ | The price of plastics (€/kg) |
| $P_s$ | The prices of plastic substitutes (€/kg) |
| $T_c$ | The tax paid by consumer on plastic consumption (€/kg) |
| $W_0$ | The total amount of plastic waste generated (kg) |
| **Decision Variables** | |
| $\delta_{ij}$ | The impact of the $i$-th government initiative on the $j$-th consumer behaviour, where a value of 0 indicates no impact and a value of 1 indicates full impact. |
| $S_i$ | Government measure intensity, where $S_i \in [0,1]$. |
| **Functions** | |
| $R(S_i)$ | The response rate of the consumer behavior under the $i$-th government initiative and/or policy |
| $U_{ci}$ | Consumer utility under the $i$-th government initiative (€) |
| $U_{gi}$ | Government utility under the $i$-th government initiative (€) |
| $W_{di}$ | Reduction in plastic waste achieved under the $i$-th government initiative (kg) |

## STACKELBERG GAME MODEL

The Stackelberg Model is a framework designed to

describe strategic decision-making processes between hierarchical players under conditions of incomplete information [7]. In this work, the two-stage framework of government and consumer is illustrated in Figure 1. In the first stage, the government acts as the leader, selecting a measure from set $I$ and anticipates the corresponding consumer response. In the second stage, consumers, as followers, adjust their behaviors by choosing a strategy from set $J$ based on the selected government measure $i$ to maximise their benefits in response to these initiatives, primarily through actions such as using less, extending plastic product lifespan (use longer), and promoting plastic recycling.

Note that stage 2 captures the aggregated response of a heterogeneous consumer population, considering variations in overall consumer behavior under different government interventions. $\delta_{ij}$ is introduced to represent the impact of various government initiatives on corresponding consumer behaviours, while it equals 0 if there is no impact on consumer behaviours, as shown in Table 2. For instance, if the government adopts a regulatory measure, the consumer's strategy set includes only "Use less", while there is no impact on "Use longer" and "Recycling".

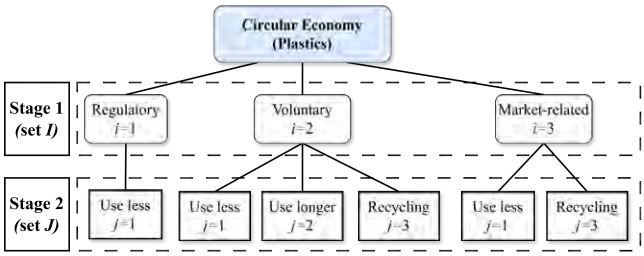

**Figure 1.** Two-stage Stackelberg Game model for plastic circular economy.

**Table 2:** The impact of government initiatives on consumer behaviors.

| | Regulatory | Voluntary | Market-based |
|---|---|---|---|
| Use less | $\delta_{11}=1$ | $\delta_{21}=1/3$ | $\delta_{31}=2/3$ |
| Use longer | $\delta_{12}=0$ | $\delta_{22}=1/3$ | $\delta_{32}=0$ |
| Recycling | $\delta_{13}=0$ | $\delta_{23}=1/3$ | $\delta_{33}=1/3$ |

Building upon the two-stage Stackelberg framework, the mathematical models are elaborated. As followers, consumers adjust their behaviors in response to the government's initiatives based on the intensity of initiative implementation, denoted by $S_i$. These intensities correspond to specific policy measures, such as the extent of regulatory enforcement, financial support for voluntary programs, and subsidies or market-based instruments promoting recycling. While consumers generally exhibit certain responsiveness (i.e., $R(S_i)$ ) to different government measures, new initiatives often trigger resistance [8]. This resistance constrains the sensitivity of consumer responses, causing the reaction function to exhibit saturation effects rather than continuous linear growth as the intensity of the government's measures increases. The parameter $\alpha_i$ is introduced to represent the resistance constrains, as shown in Eq. (1).

$$R(S_i)=\frac{\alpha_i {S_i}^3}{1+\alpha_i(S_i+{S_i}^2)} \quad (1)$$

The total reduction in plastic waste under the $i$-th government initiative, i.e., $W_{di}$, is determined by the combined effects of consumer responses to the employed government initiative. Specifically, it is the weighted sum of the impacts of each consumer behaviours, multiplied by the initial amount of plastic waste $W_0$. This relationship is expressed in Eq. (2) as follows:

$$W_{di}=\sum_{j=1}^{3}\delta_{ij}R(S_i)W_0 \quad (2)$$

The $i$-th government's utility function, $U_{gi}$, as shown in Eq. (3), consists of two main components: (1) the benefits derived from the implementation of measures, such as the reduction in waste disposal costs and the avoidance of raw material consumption due to waste reduction, tax revenue generated by market-related measures, and charges collected from the disposed plastic waste; and (2) the costs associated with the implementation of these measures, including the costs from the introduction of substitutes, the costs of voluntary measures, and the recycling deposits to be refunded to consumers. It is noted that only under market-related measures does the 'use less' behavior of consumers get influenced by the tax, $T_c$.

$$U_{gi}=(C_w+C_v)W_{di}-\left(P_p-P_s\right)\delta_{i1}R(S_i)W_0-\delta_{i2}S_iC_eW_0-F_r\delta_{i3}R(S_i)W_0+T_c\delta_{31}R(S_3)W_0+(W_0-W_{di})C_d \quad (3)$$

The function of consumer welfare under the $i$-th government initiative, $U_{ci}$, as shown in Eq. (4), also consists of two components: (1) the benefit component, which includes the reduction in carbon costs due to decreased plastic waste and the net benefit from plastic recycling (recycling revenue minus recycling costs); and (2) the cost component, which includes the additional expenses required for using plastic substitutes and the charges incurred for disposing of plastic waste.

$$U_{ci}=C_cW_{di}-(P_s-P_p)\delta_{i1}R(S_i)W_0+(F_r-C_r)\delta_{i3}R(S_i)W_0-(W_0-W_{di})C_d \quad (4)$$

The model's constraints are shown in Eqs. (5)–(8). The intensity of government measures ($S_i$) and the range of the consumer response function $R(S_i)$ are both within [0,1] (see Eqs. (5) and (6) ). The reduction in waste $W_{di}$ under the $i$-th government initiative should not exceed the total amount of waste $W_0$ (see Eq. (7) ). Voluntary measures, such as education, are primarily aimed at all

plastic waste, and their total cost should equal the total budget allocated for voluntary measures, as shown in Eq. (8).

$$0 \le S_i \le 1, \forall i \in \{1,2,3\} \quad (5)$$

$$0 \le R(S_i) \le 1, \forall i \in \{1,2,3\} \quad (6)$$

$$W_{di} \le W_0 \quad (7)$$

$$C_e \times W_0 = B \quad (8)$$

## CASE STUDY

A case study based on the EU-27 is conducted using the proposed Stackelberg model to quantitatively assess the interactions between government initiatives and consumer behaviors, aiming to promote a circular economy for plastic sectors. The case study utilizes data from official EU reports, industry surveys, and relevant literature data to numerical analyze the effects of varying intensities of regulatory, voluntary, and market-based interventions on consumer responses. This allows for an assessment of how various measure intensities and consumer reactions influence both government and consumer welfare, as well as the effectiveness of the strategies for plastic circular economy. All relevant parameters, including their descriptions, numerical values and data sources, are presented in Table 3.

**Table 3:** Collected data for proposed Stackelberg Game model in the EU-27.

| Parameters | Description | Values | Ref. |
|---|---|---|---|
| $\alpha_1$ | Consumer sensitivity to regulatory initiative. | -1.125 | [9] [10] [11] |
| $\alpha_2$ | Consumer sensitivity to voluntary initiative. | -3 | |
| $\alpha_3$ | Consumer sensitivity to market-related initiative. | -1.33 | |
| $B$ | The total budget for voluntary measures. | 13,850,000 € | [12] |
| $C_c$ | The cost of carbon price for consumer. | 0.16 €/kg | [13] |
| $C_d$ | The charges of consumer plastic disposal. | 0.8 €/kg | [14] |
| $C_e$ | The cost of government education investment. | 0.0021 €/kg | [15] |
| $C_r$ | The cost of consumer plastic recycling. | 0.73 €/kg | [16] |
| $C_v$ | The cost of plastic virgin raw material consumption. | 2.7€/kg | [17] |
| $C_w$ | The cost of plastic waste management. | 0.116 €/kg | [18] |
| $F_r$ | The consumer refundable fees of plastic recycling. | 1.2 €/kg | [19] |
| $P_p$ | The price of plastics. | 1.154 €/kg | [20] |
| $P_s$ | The prices of plastic substitutes. | 1.546 €/kg | [21] |
| $T_c$ | The tax paid by consumer on plastic consumption. | 0.8035 €/kg | [22] |
| $W_0$ | The total amount of plastic waste generated | 32·109 kg | [23] |

The collected numerical values are substituted into Eqs. (1)-(4) and calculated using backward induction. The specific steps are as follows:

**(1)** Under the given government $i$-th strategy, the objective of consumer is to maximize their benefits:

$$\max U_{ci} \quad (9)$$

This involves determining the optimal consumer response that yields the highest benefits based on the given government initiative.

**(2)** Take the first derivative of $U_{ci}$ with respect to $S_i$ and set it equal to zero to identify the optimal policy intensity that maximizes consumer's benefits:

$$\frac{dU_{ci}}{dS_i} = 0 \quad (10)$$

This condition helps determine the critical points where consumer utility reaches its maximum under the given government initiative.

**(3)** Substitute the optimal $S_i$, constrained by Eq. (5) within the range [0,1], into the government utility function $U_{gi}$ (Eq. (3)), the consumer utility function $U_{ci}$ (Eq. (4)), and the plastic waste reduction equation $W_{di}$ (Eq. (2)). This allows for the calculation of maximum benefits for government and consumer, and the plastic waste reduction under the optimal policy intensity $S_i$.

## RESULTS AND DISSCUSSION

The case study is conducted using the proposed Stackelberg Game model, calculated in Mathematica 14.0 software [24]. Figure 2 presents the optimal benefits for both the government and consumer, and plastic waste reduction under the optimal government strategy intensity.

As shown in Figure 2, the government initiative intensities are as follows: regulatory measure: 0.91, voluntary measure: 0.41, and market-related measures: 0.8, For each optimal strategy intensity, the government utility (represented by the blue bars in Figure 2) and waste reduction (represented by the green bars in Figure 2) resulting from the regulatory measure outperform those of the voluntary and market-related measures. This suggests that, within the context of the given case study, regulatory measures are the most effective in maximizing

government utility and reducing plastic waste, provided that the intensity reaches 0.91. These findings underscore the importance of carefully calibrating the strength of government interventions when formulating policies aimed at advancing a circular economy in the plastic sector [25].

**Figure 2.** The results under different initiative intensities for government utility ($U_{gi}$), consumer utility ($U_{ci}$), and plastic waste reduction ($W_{di}$): S1: Regulatory intensity; S2: Voluntary intensity; S3: Market-related intensity.

With the optimal intensities for government interventions, all consumer utilities are negative (represented by the orange bars in Figure. 2), whereas market-related measures, at an intensity of 0.8, exhibit the highest consumer utility. This suggests that while regulatory measures may achieve significant government utility and plastic waste reduction, they come at the expense of consumer welfare. On the other hand, market-related measures seem to strike a better balance, offering more favorable outcomes for consumers [3]. This indicates that when designing effective policies, it is crucial to consider not only the environmental and economic goals of the government but also the potential impacts on consumer behavior and utility. Striking this balance can help ensure more sustainable and effective strategies for promoting a circular economy in the plastic sector.

## CONCLUSION

This study develops a Stackelberg game model to quantitatively capture the interactions between the government (as the leader) and consumers (as the followers) in promoting the circular economy of plastics. By considering both the benefits and costs of the government and consumer within the plastic circular economy, a case study of the EU-27 is implemented. The optimal intensities of various government initiatives are captured: regulatory measures at 0.91, voluntary measures at 0.41, and recycling measures at 0.8.

The proposed Stackelberg Game model provides valuable insights into the strategic decision-making process between government interventions and consumer behaviour. By utilising this framework, policymakers can better assess the potential outcomes of different intervention strategies and determine the most effective measure intensities to promote sustainability in the plastic sector. The model highlights the trade-offs between government utility, consumer welfare, and environmental goals, offering a more comprehensive approach to policy design in the context of a circular economy in plastic sector.

The limitation of this study lies in not considering the combined effects of the various government initiatives, as well as the detailed consumer responses to each measure. Future research will address this by incorporating the synergistic impacts of the three initiatives and refining the model to capture more nuanced consumer behavior in response to government initiatives.

## ABSTRACT

Anthropogenic carbon-dioxide emissions, exceeding 51 billion tons annually, are a major driver of global climate impacts. Aqueous amine scrubbing offers an effective carbon-capture solution, but the energy-intensive thermal regeneration step of the process significantly increases costs, limiting large-scale adoption. To address these challenges, computational optimization of process and molecular design is promising but often too resource-intensive, emphasizing the need for efficient surrogate models. Specifically, we develop a surrogate model based on an artificial neural network (ANN) that is employed to replace rigorous phase-equilibrium computations performed with the SAFT-γ Mie group contribution method within a steady-state aqueous amine carbon-capture process model. Our ANN is trained on 32,768 vapour–liquid equilibrium data points of a quaternary mixture of water, monoethanolamine, carbon dioxide, and nitrogen over industrially relevant temperature, pressure, and composition ranges, achieving mean-relative errors below 2% for most variables. The ANN is integrated into a computer aided process design (CAPD) framework and evaluated via mathematical optimization, with the total annualized cost (TAC) as the objective function. Compared to the rigorous process model, the model with the ANN surrogate exhibits reduced computational times of up to 81% while converging to near-identical optima within 1% of the TAC. With a robustness analysis across the lean-loading and desorber-pressure design space we show that the ANN effectively captures 90% of the investigated design space, vs. 77% for the rigorous model. In a multi-start optimization ensuring global optimality, the surrogate converges to the same point as the rigorous model, taking 10 h less. This demonstrates that carefully trained surrogate models can significantly accelerate process optimization and enable larger-scale applications, paving the way for future solvent and process co-design efforts.

**Keywords**: Carbon Capture, Machine Learning, Phase equilibria, Process Design, gPROMS

## INTRODUCTION

Annual anthropogenic carbon dioxide ($CO_2$) equivalent emissions total approximately 51 billion tons, contributing to measurable climate change, manifested as droughts, storms, and floods [1]. Carbon capture is widely recognized as a key technology to reduce or even reverse these emissions by separating $CO_2$ from exhaust gases in power, cement, and steel plants for storage or utilization. A commonly considered approach is amine scrubbing, in which $CO_2$ is absorbed in an aqueous amine solution via the equilibrium formation of bicarbonate and carbamate species and subsequently released through a thermally driven process. This second step requires considerable energy, increasing costs and diminishing incentives for large-scale implementation [2].

Mathematical optimization can address cost and efficiency challenges by identifying optimal process designs [3]. The solvent choice presents a significant optimization problem, greatly increasing complexity and computational cost. In a recent study, Lee *et al.* [4] introduced an algorithm to solve the integrated solvent and process design problem reliably. However, the associated computational costs remain prohibitively high,

necessitating significant model simplifications, such as employing equilibrium-stage models instead of more detailed rate-based models. Surrogate models have historically been used to mitigate the burden of high computational costs [5], and the emergence of accessible machine-learning (ML) packages has further enhanced their utility, enabling tractable solutions to problems previously limited by rigorous thermodynamic models [6].

A notable example is the study by Zhang *et al.* [7], in which an ANN surrogate was employed to compute the solubility of $CO_2$ in ionic liquids in a carbon-capture process. The use of the surrogate made the global optimization of the integrated solvent and process design possible. In recent studies, Karia *et al.* [8] and Zhang *et al.* [9] evaluated various surrogate models for predicting the phase stability of liquid mixtures in a solvent design problem, showing that the integration of surrogates within optimization could be used to achieve much greater tractability. Nentwich *et al.* [10] tested several surrogate models – ANNs, Gaussian Processes (GPs), and Support Vector Machines (SVMs) – to calculate the distribution coefficient for the hydroformylation of 1-dodecane, replacing a rigorous PC-SAFT thermodynamic model. Using these ML surrogates successfully transformed an intractable rigorous model into a tractable one. In another study by Forster *et al.* [11], symbolic regression surrogates were investigated for use in optimization. These authors concluded that, with the currently available training methods, the surrogates were too inaccurate and required excessive training time to be practical. There is yet no consensus on when it is possible to achieve a satisfactory balance between accuracy and computational cost with surrogate models, and model development for a new application usually requires extensive trial and error. The most promising areas appear to be the use of surrogate models to replace models with no closed algebraic form (e.g., phase stability [8, 9]) or to replace expensive components of the model to facilitate solutions with local or global solvers.

Phase-equilibrium calculations, due to their expense and nonlinearity-induced numerical issues, are ideal for surrogate substitution. We aim to eliminate these costly computations in aqueous amine carbon-capture design by replacing the SAFT-$\gamma$ Mie GC equation of state calculations [12, 13] with an ANN model. We consider a quaternary mixture of water ($H_2O$), monoethanolamine (MEA), $CO_2$, and nitrogen ($N_2$). MEA is chosen as the solvent as it is widely utilized, making it an ideal benchmark for evaluation.

In this article, we first introduce the process model and detail the ANN architecture and training. Next, we incorporate the ANN surrogate into our process design and optimization framework, focusing on lean loading and desorber pressure as decision variables, and compare its performance against the rigorous thermodynamic model, evaluating computational efficiency, robustness, and convergence to thoroughly assess accuracy and reliability.

# METHODS

## Process Model

The process model used in our study (see Figure 1) is a steady-state, two-column aqueous amine capture system implemented in the process simulation software gPROMS Process 2023.1.0. It comprises an absorber, heat exchanger, desorber, condenser, reboiler, and mixer, with equipment dimensions calculated from stream properties and process requirements (e.g., capture rate). The model is derived from our previous work [14, 15], considering a 400 MWe combined-cycle gas-turbine plant [14], but where a rate-based model [15] replaces the equilibrium-stage absorber model in [14]. All thermodynamic properties are computed with the SAFT-$\gamma$ Mie GC method [12]. The total annualized cost (TAC) is obtained as given by Lee *et al.* [14] assuming a lifespan of 25 years and fixing the capture rate to 90%.

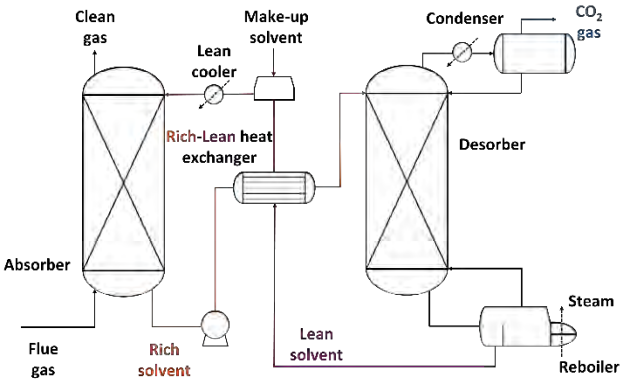

**Figure 1.** Flowsheet representation of the modelled aqueous amine carbon-capture process in our current work adapted from [14] licensed under CC BY 4.0.

## Artificial Neural Network (ANN) – Architecture, Training and Results

The ANN features are the inputs of a standard $Tp$-flash algorithm, namely temperature $T$, pressure $p$, and the global composition vector $\boldsymbol{z}$. After performing a hyperparameter study using OPTUNA [16], we found that two hidden layers with 50 nodes each adequately reproduce the fluid-phase behaviour, as more layers or nodes yielded diminishing returns. The hidden layers employ the ELU activation function, chosen for its smoothness and suitability in gradient-based optimization. The output of the ANN passes through a sigmoid function, bounded between 0 and 1. The elementwise multiplication of the resulting output vector $\boldsymbol{w}$, and the global composition vector $\boldsymbol{z}$, are used to obtain the liquid-phase mole amounts,

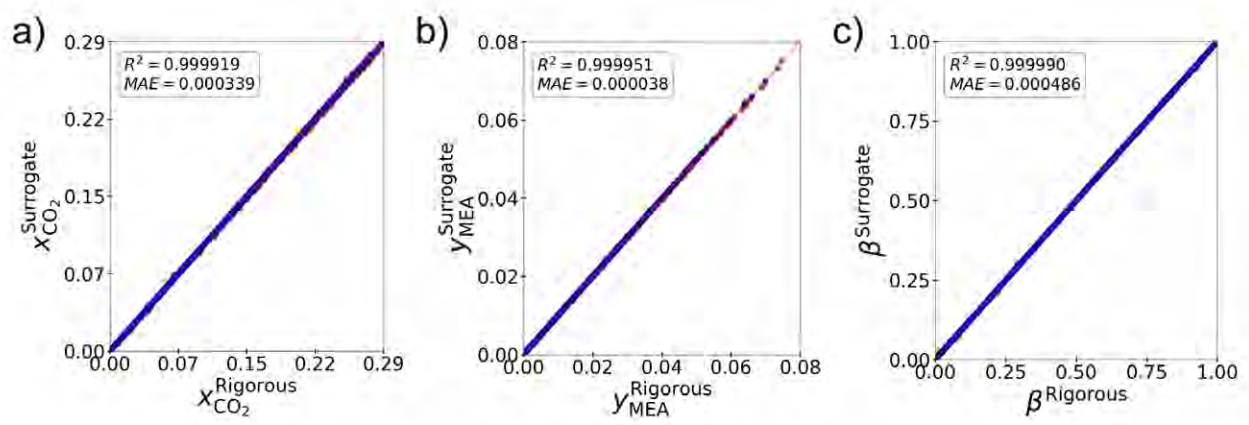

**Figure 2:** Parity plots comparing the description of the phase equilibria with rigorous thermodynamic model and phase-equilibria calculations against predictions of the the trained surrogate for all points in the test set for a) the liquid molar fraction of $CO_2$, b) the vapour molar fraction of MEA, and c) the vapour phase fraction.

vector $\boldsymbol{n_x}$:

$$n_{x,i} = z_i w_i, i \in \mathcal{C} = \{H_2O, MEA, CO_2, N_2\}. \quad (1)$$

The vector $\boldsymbol{n_y}$ of vapour-phase amounts is computed by

$$\boldsymbol{n_y} = \boldsymbol{z} - \boldsymbol{n_x}, \quad (2)$$

the vectors of mole fractions in the liquid and vapour phases, $\boldsymbol{x}$ and $\boldsymbol{y}$, respectively, follow as

$$\boldsymbol{x} = \boldsymbol{n_x}\left(\sum_{i\in\mathcal{C}} n_{x,i}\right)^{-1}, \ \boldsymbol{y} = \boldsymbol{n_y}\left(\sum_{i\in\mathcal{C}} n_{y,i}\right)^{-1}, \quad (3)$$

and the vapour-phase fraction β is given by

$$\beta = \left(\sum_{i\in\mathcal{C}} z_i - \sum_{i\in\mathcal{C}} n_{x,i}\right)\left(\sum_{i\in\mathcal{C}} z_i\right)^{-1} \quad (4)$$

In training the ANN, we used 32,768 vapour-liquid equilibrium (VLE) data points for the chosen $H_2O$-MEA-$CO_2$-$N_2$ mixture within the input domains of $T = [298.15, 420]$ K, $p = [0.1, 0.25]$ MPa, $z_{H_2O} = [0.43,\ 0.984]$, $z_{MEA} = [0.001,\ 0.15]$, $z_{CO_2} = [0.015,\ 0.25]$, and $z_{N_2} = [0,\ 0.4]$, based on typical process ranges established from previous work [15]. The data points are sampled using a Sobol sequence and generated using the gSAFT $Tp$-flash algorithm with the SAFT-γ Mie equation of state [12] and the relevant model parameters [13]. The data are split into training, validation, and test sets using an 8:1:1 split. Both labels and features are normalized using a mean-variance standardization. A learning rate $\alpha = 0.001$ is identified as suitable with the OPTUNA framework. The model is trained for 3000 epochs, tracking training and validation losses saving all parameter sets that achieved a lower validation loss than the lowest loss recorded so far. Twelve parallel pieces of training are performed with different seeds to mitigate initialization bias, and the best-performing model parameter set is implemented in the process model. The setup and training of the ANN are performed using the Pytorch 2.21 and CUDA 11.8 framework in Python 3.8. Data sampling and training takes 7 h on a Z8 HP workstation with 32 GB working memory, an Intel Xeon 5416S processor, and an NVIDIA T1000 graphics card.

### ANN Implementation and Process Optimization

The ANN is incorporated into gPROMS via its ForeignObject (FO) framework. The ANN code is first translated into C++ using the Libtorch library and then compiled into a custom FO file. This setup provides direct access to all custom functions and their analytical derivatives, computed through backpropagation, facilitating efficient gradient-based optimization.

Process optimization is executed using a Control Vector Parameterization Single Shooting algorithm. The objective function is the TAC. The primary decision variables are lean loading $\theta_{CO_2}$ and desorber pressure $p_{des}$. Optimization runs employ either the rigorous phase-equilibrium model or the ANN surrogate. Subsequently, the results of these two models are compared in terms of speed, robustness, and consistency in finding optima from different initial conditions.

## RESULTS AND DISCUSSION

### ANN Training Results

Our ANN is found to be highly accurate. For the given quaternary mixture of $H_2O$-MEA-$CO_2$-$N_2$, the ANN allows the successful prediction of the molar amounts in both phases and the phase fractions. Due to space constraints, presenting all 17 parity plots is beyond the scope of this publication. Instead, we include the parity plots of

the liquid molar fraction of $CO_2$, the vapour molar fraction of MEA, and the vapour phase fraction as representative results of the test set between the rigorous and the surrogate model shown in Figure 2 a), b), and c), respectively. Excellent agreement is apparent from these plots, with most points lying on the 45-degree line and the few deviations remaining very close. The maximum mean-relative error is 2% for the vapour mole amount of the MEA, whereas the minimum mean-relative error of 0.15% is reported for the liquid fraction of MEA. Following these promising results, we integrate the ANN into the process model and conduct optimizations.

## Process Design and Trajectories Comparison

We conduct a process design optimization, evaluating both the rigorous and surrogate models. Starting at two distinct initial points, one closer to the best known optimal solution (Initial point 1, IP1: desorber pressure of $p_{\mathrm{des}} = 0.181$ MPa and lean loading of $\theta_{\mathrm{CO_2}} = 0.250$), and one further away (Initial point 2, IP2: desorber pressure $p_{\mathrm{des}} = 0.181$ MPa, lean loading $\theta_{\mathrm{CO_2}} = 0.030$). The results of these runs are reported in Table 1. For IP1, both models are in good agreement on the TAC (36.02 M$/year for the rigorous model vs. 36.51 M$/year for the surrogate model), while for IP2, there is a more significant deviation (99.51 M$/year for the rigorous model and 132.21 M$/year for the surrogate). This is caused by minor inaccuracies in the predicted phase compositions that influence properties such as heat and flow, which in turn lead to a higher TAC, indicating the high degree of sensitivity of the model near IP2.

As shown in Table 1, for IP1, the solutions obtained following optimization are in good agreement, with a 1% deviation in TAC and less than 2% deviation in the design variables. Regarding computational efficiency, the total optimization time is reduced by 71% using the surrogate model, requiring 52 s compared to 182 s. The surrogate took 32 iterations to converge, whereas the rigorous model took 41. Model evaluation times are, similarly, reduced by 63%.

For IP2, despite the initial difference in TAC, the optimizer converges to very similar values. The surrogate model deviates slightly from the previous optimal point with respect to the optimal pressure. This, however, can be explained by the fact that the value of the objective function is relatively insensitive to the desorber pressure in this region of the design space, see Figure 3 b). Regarding the computational efficiency, the total optimization time is reduced by 82% when using the surrogate model. The surrogate took 89 iterations to converge, whereas the rigorous model took 104. Model evaluation times are, reduced to a lesser extent (38%). Using the surrogate model within optimization brings additional benefits by increasing the speed of gradient evaluations and reducing the number of iterations needed for convergence. The surrogate maintains an accuracy within 1% for the objective function and less than 5% deviation in the design space.

Finally, a comparison between the optimization trajectories taken by both models is performed and presented using the contours of the TAC of the rigorous and surrogate model as a background, see Figure 3 a) and b), respectively. When comparing the trajectories taken for IP1, it is evident that both models follow the same path, and the speed advantage of the ML model stems purely from the faster evaluation of the model and gradients at each iteration. However, when comparing the trajectories for IP2, the rigorous model requires more iterations, resulting in the 82% speedup compared to the 71% speedup achieved for the optimization performed starting from the closer initial point. These results exemplify the possible benefits of using an ML surrogate in optimization. One can observe slow progress near the final point, as the line search does not lead to improved points. Successful convergence is achieved after reinitialization at the optimal solution for both models, suggesting that the optimization tolerance is most likely not met due to corruption of the Hessian caused by quasi-Newton updates, indicating there is scope for further acceleration.

## Robustness and Multi-start Optimization

To compare the robustness of both models, a sampling of the design space within the bounds of $p_{\mathrm{des}} = [0.1, 0.35]$ MPa and $\theta_{\mathrm{CO_2}} = [0.02, 0.5]$ is conducted. The results are summarized in Figures 3 a) and b), where the coverages for both models are shown as a contour plot showing the TAC values. The surrogate model covers approximately 90% of the sampled space, whereas the rigorous model covers 77%.

When analyzing the relative deviation between the

**Table 1:** Comparison of optimization results starting from two different initial points for the rigorous and the surrogate models, in terms of speed and accuracy.

| | Initial point 1 | Rigorous | Surrogate | Initial point 2 | Rigorous | Surrogate |
|---|---|---|---|---|---|---|
| $\theta_{lean}$ / - | 0.250 | 0.314 | 0.315 | 0.030 | 0.317 | 0.314 |
| $p_{des}$ / MPa | 0.181 | 0.206 | 0.199 | 0.181 | 0.203 | 0.194 |
| TAC / (M$/year) | 36.08/36.52 | 32.09 | 32.33 | 99.05/132.13 | 32.09 | 32.34 |
| Time / s | - | 182 | 52 | - | 454 | 80 |
| Time per model eval. / s | - | 0.082 | 0.031 | - | 0.042 | 0.026 |

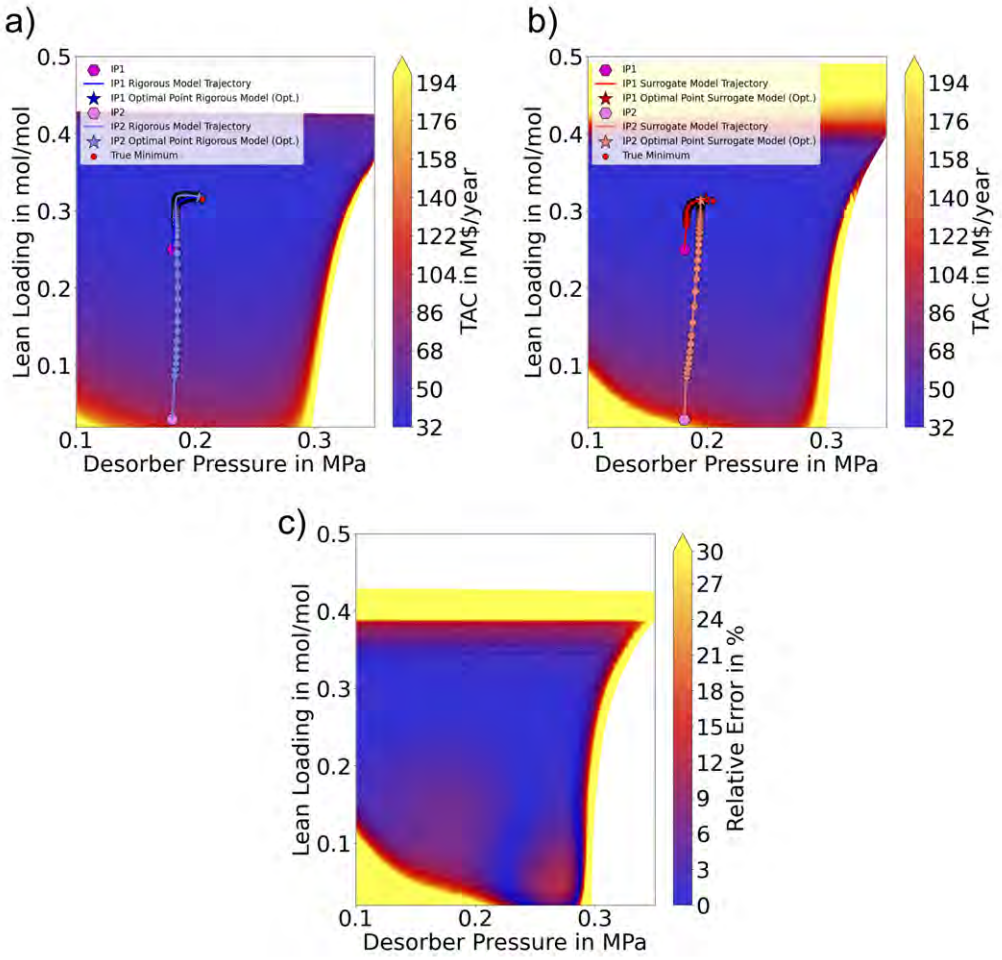

**Figure 3:** Feasible region of a) the rigorous model and b) the surrogate model with the objective function as a contour plot, including the trajectories for both optimizations performed from initials points IP1 and IP2. In c) the relative error between both models is shown as a contour plot. The contour plots are clipped at a TAC of 200 M$/year and 30% relative deviation, respectively.

values of the objective function in the overlapping areas, as presented in Figure 3 c), the deviation is below 10% in most of the space and close to 0% in proximity to the optimal region. However, at the edges, the deviation rises to a maximum of several million percentage points.

Lastly, we perform a global search based on multi-start optimization. We initialize the optimization at 128 points within the given design space using a Sobol' sequence. In the case of the surrogate, the ten best solutions are re-optimized with the rigorous model to improve accuracy. The average time to converge to the optimal point is 672 s for the rigorous model, whereas the surrogate requires just 175 s, a time reduction of 74%. This amounts to a total time of 23.91 h for the rigorous model compared to 6.8 h for the surrogate, including the re-optimization, which in turn equates to a ~10 h total time advantage for the surrogate model, considering the 7 h sampling and training time. The ten best solutions for the surrogate after re-optimization converge to the point $p_{\mathrm{des}} = 0.202995 \pm 0.000242$ MPa, $\theta_{\mathrm{CO_2}} = 0.317342 \pm 0.000058$ with a $\mathrm{TAC} = 32.0914 \pm 0.000082$ M$/year. The values for the rigorous model are $p_{\mathrm{des}} = 0.203184 \pm 0.000783$ MPa, $\theta_{\mathrm{CO_2}} = 0.317355 \pm 0.000003$ with a $\mathrm{TAC} = 32.09132 \pm 0.000092$ M$/year. It is apparent that using this approach, both methods effectively converge to the same optimal solution.

## CONCLUSIONS

We have demonstrated how integrating an ANN into the model of an aqueous amine carbon-capture plant, to replace rigorous phase-equilibrium calculations, can reduce the optimization time by up to 82%. We have also conducted a detailed analysis comparing the ANN to the rigorous model, which makes use of the SAFT-γ Mie GC approach in terms of optimization paths and robustness

across the design space as well as in a multi-start optimization. We show that a well-trained surrogate can converge to the solution with a time reduction between 70% and 80% compared to the rigorous model. The ANN surrogate successfully represents 90% of the investigated design space compared with 77% for the rigorous model. Additionally, the surrogate model successfully converged to the same point in a multi-start optimization taking 74% less time than the rigorous model

Our work demonstrates that ANN-based surrogates for phase-equilibrium calculations can be significantly faster and more robust than rigorous thermodynamic models, making them ideal for complex optimization tasks with a high number of decision variables or dynamic conditions. A transfer learning approach could further mitigate lengthy sampling and training challenges. In future work, we plan to extend this framework to tackle coupled process and molecular design problems.

## ACKNOWLEDGEMENTS

We acknowledge the UK Research and Innovation grant for funding the ECO-AI project under the AI4Net-Zero program (EP/Y006143/1, EP/Y005732/1).

## ABSTRACT

Intensified schemes, such as reactive distillation, have been proposed to produce silane ($SiH_4$). Several studies have been carried out around this intensified scheme focusing directly on its improvement in energy or economic criteria. However, these mentioned criteria do not ensure that the scheme is also optimal from the control point of view. There is a direct compromise between the economic criterion and the control criterion. Thus, the best controllable scheme is not necessarily the most economical and vice versa. Analyses have been proposed to evaluate the controllability of steady-state processes using open-loop with Singular Value Decomposition (SVD) under quantitative a criterion such as $A_\gamma + \gamma_{sm}$ with simplified first-order transfer functions. This work considers four feasible designs with multiple reactive zones and evaluates their controllability from their open-loop dynamic responses obtained from Aspen Dynamics® by calculating the condition number for different frequency ranges analyzing qualitative aspects and the $A_\gamma + \gamma_{sm}$ criterion evaluating the controllability of each scheme and the conditions of the simplification of their dynamic responses. For this, simplifications of first and second order transfer function models are compared with the models that robustly predict their behavior. The results of this study show that first order functions, despite their simplicity, can predict well the complex model of these distillation schemes. However, for low frequencies (i.e. $\omega < 10$ rad/h) second order functions are better options because they capture the overshooting (damping) effect. The proposed methodology can be applied in global optimization with controllability as an additional criterion in the objective function.

**Keywords**: Silane, Reactive Distillation, Singular Value Decomposition, Process Control, Dynamic Behaviour

## INTRODUCTION

Various energy alternatives to fossil fuels have been proposed; one option for generating electricity in homes and industries is silicon-based solar photovoltaics (PV). Huang et al., [1] proposed the production of silane ($SiH_4$) from the disproportionation process of trichlorosilane in a reactive distillation column ($RD$). The studies of Zang et al., [2] for this $RD$, based on parametric studies, found that partitioning the reactive zone into three reactive zones improves the energy consumption being lower than the energy consumption used in the scheme proposed in the previous reference. Alcántara-Maciel et al., [3] took the three reactive zone scheme and optimized this problem through the Total Annual Cost ($TAC$) minimization using dynamic boundaries allowing to analyze in a single optimization the three cases for reactive zones finding that the optimal scheme tends to be a single reactive zone.

The best solution evaluated under an economic criterion does not ensure that it is the best design in terms of controllability. In a study carried out on a $RD$ for silane production [4] the trade-off between economic and controllability criteria was observed. Generally, the review of the process control is carried out after the optimization [5].

Aspen Dynamics solves the MESH equation system in a dynamic state to provide responses to perturbations that occur on the system. They are represented in a transfer function matrix after an adjustment of known transfer functions to model their behavior. Eq. 1 shows the case of a binary distillation column where the reflux ratio and reboiler load are perturbed for two components.

$$G(s) = \begin{bmatrix} g_{C1,RR}(s) & g_{C1,Q_H}(s) \\ g_{C2,RR}(s) & g_{C2,Q_H}(s) \end{bmatrix} \quad (1)$$

Where $C_1$ and $C_2$ refer to component 1 and 2 respectively, $RR$ to the reflux ratio perturbation and $Q_H$ to the reboiler duty perturbation. A small perturbation was performed ($\approx \pm 0.5\%$). The SVD technique has been used to evaluate the dynamic controllability of industrial processes [6,7] and particularly for distillation columns [8]. The systems controllability can be known by calculating their maximum ($\sigma^*$) and minimum ($\sigma_*$) singular values.

The calculation of the SVD is carried out with Eq. 2, where $\mathbb{A} \in \mathbb{R}_r^{m \times n}$ is the matrix finding singular values, in this case $G(s)$ in the frequency domain (i.e., $s = \omega j$), $\mathbb{U} \in \mathbb{R}_r^{m \times n}$ and $\mathbb{V} \in \mathbb{R}_r^{m \times n}$ are orthogonal matrices and $\Sigma$ is a matrix where the diagonal have the singular values [7].

$$\begin{aligned} &\mathbb{A} = \mathbb{U}\Sigma\mathbb{V}^T \\ &\Sigma = \mathrm{diag}(\sigma^*, \cdots, \sigma_*) \end{aligned} \quad (2)$$

A large value of the $\sigma^*$ suggests good invertibility of the system, while a small value of the $\sigma_*$ suggests bad invertibility of the system [6,9]. For a distillation column, the $\sigma^*$ corresponds to the change in the composition or temperature of the products depending on the setting of a vapor or liquid valve; a large value of $\sigma^*$ implies that the composition or temperature of products can be controlled with a change in that liquid or vapor flow. If $\sigma_*$ is small, it is related to a change in the vapor or liquid valve, it means that a small change in that flow does not have a large effect on the compositions or temperatures of the products. A measure that relates the $\sigma^*$ and $\sigma_*$ is the condition number ($\gamma^*$) shown in Eq. 3

$$\gamma^* = \sigma^*/\sigma_* \quad (3)$$

$\gamma^*$ indicate the sensitivity of the system to small changes or perturbations in its inputs and gives information of the system from four aspects [10]:

- **Sensitivity:** A large $\gamma^*$ indicates that the system is sensitive to small perturbations in the inputs. It will be impractical or impossible to satisfy the entire set of control objectives (regardless of the control strategy used).
- **Controllability:** If $\gamma^*$ is low (close to 1), the system is well conditioned, and the inputs uniformly affect the outputs. A high $\gamma^*$ indicates that the system is poorly conditioned (some variables are easily controlled, others cannot even be influenced).
- **Stability:** A large $\gamma^*$ can be related to the instability of the system and an unpredictable behavior. A low $\gamma^*$ indicates that the system is stable and predictable to variations in the inputs.
- **Dimensions and optimal control:** If $\gamma^*$ is large it may be an indication that the system is considering variables that do not significantly affect the system. A small $\gamma^*$ allows for simpler controllers to be designed [11].

Evaluating the $\gamma^*$ over a range of frequencies allows identifying critical ranges where the system may become more unstable or where a more robust control needs to be designed to handle certain input frequencies. It is recommended to do this type of analysis for frequency ranges of $0 < \omega \leq 100\ rad/h$, larger ranges are physically meaningless [12].

The criterion to determine if a scheme is better or worse in terms of controllability with the described technique has been defined qualitatively by comparing the $\gamma^*$ vs frequency graphs resulting from applying the SVD technique [5,8,13]. Cabrera Ruiz et al. [14] propose the following: *"it can be inferred that the best solution will have the minimum area below $\gamma^*$ in the frequency domain. That area of the condition number can be used as the controllability index $A_\gamma$"*. However, $\gamma^*$ values sometimes show sharp peaks in some frequency ranges, such a rapid change of these values is not suitable from the control and stability point of view (model singularities). Cabrera Ruiz et al. [15] complements the criterion $A_\gamma$ adding the term $\gamma_{sm}$ that allows to quantify the presence of such peaks in the area under the curve of $\gamma^*$evaluated in the frequency range.

$\gamma_{sm}$ acts as a "punishment" factor, since the presence of peaks in the curve will increase the total value of the area. The complete criterion $A_\gamma + \gamma_{sm}$ that qualitatively evaluates the controllability of an open-loop analysis via the SVD technique is the Eq. 4

$$\begin{aligned} A_\gamma + \gamma_{sm} &= \frac{\int_{\log a}^{\log b} \log(\gamma^*)\, d(\log \omega)}{\log b - \log a} \\ &+ \int_{\log a}^{\log b} \Delta log(\omega)\, |\gamma'_{i+1} - \gamma'_i|\, d(\log \omega) \end{aligned} \quad (4)$$

Where:

$$\gamma'_{i+1} - \gamma'_i = \frac{log[\gamma^*(\omega_{i+1})] - log[\gamma^*(\omega_i)]}{log(\omega_{i+1}) - log(\omega_i)} - \frac{log[\gamma^*(\omega_i)] - log[\gamma^*(\omega_{i-1})]}{log(\omega_i) - log(\omega_{i-1})}$$

where the logarithm of the $\gamma^*$ values for the frequency $\omega$

is taken by numerically integrating the data resulting from the SVD analysis to calculate the area. $b$ is the upper limit and $a$ is the lower limit of the evaluated frequency range.

Eq. 4 has been used to evaluate the controllability of an open-loop system in steady state via multi-objective optimization by approximating first-order transfer functions [4,15,16]. It has been shown that for some intensified schemes this approximation works well for frequencies lower than $100\ rad/h$ [14,15]. However, this has not been tested for reactive distillation schemes with multiple reactive zones.

In this work, three designs are taken of a previous multi-objective optimization where the objective functions are the $TAC$ and the $Q_H$, and the solution of Zang et al. [2] is also taken considering three reactive zones. These designs were evaluated with the criterion $A_\gamma + \gamma_{sm}$ of Eq. 4 for the adjustment of transfer function matrices $G(s)$ in four ways: best possible fit using the most suitable transfer function for each scheme (i.e., Robust fit), approximation using only first order transfer functions (FO), using only second order transfer functions with dumpling (SO), using only second order transfer functions without dumpling (SOL). The robust fit (RF) was done by adjusting dynamic responses to not only first or second order functions, but to other functions such as first and second order in competence, death time, etc. prioritizing that overshoot and damping effects are depicted by the functions while minimizing the error in Eq. 5. The Robust fit adjustment considered first order with and without deadtime $\theta$ ($\theta > 0$ and $\theta = 0$, respectively), second order with $0 < \zeta < 1$ with and without dead time and second order with $\zeta = 1$ with and without deadtime.

## METHODOLOGY

### Case Study

The processes described in Figure 1 were simulated using Aspen Plus V12® software and the Peng-Robinson

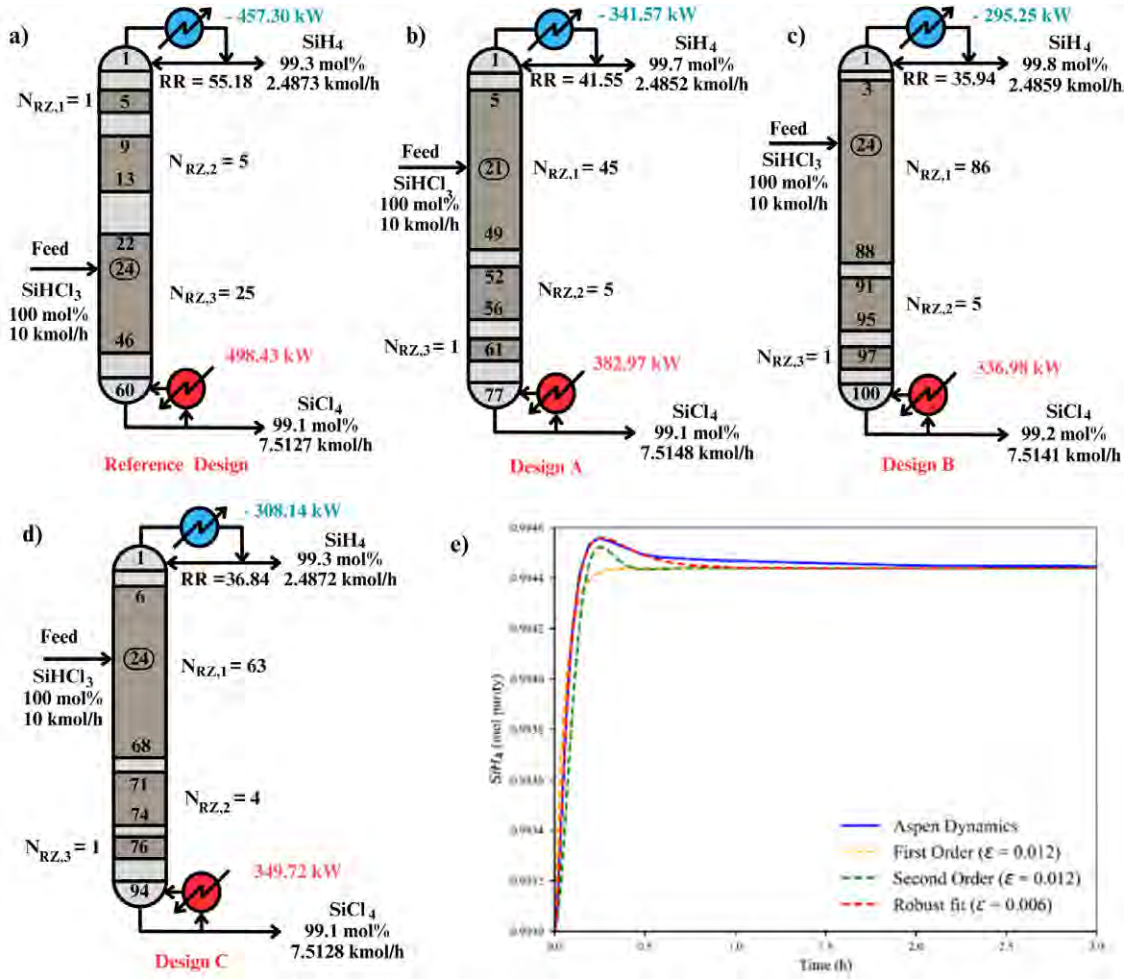

**Figure 1:** a) Reference design, b) Design with minimum $TAC$, c) Design with minimum $Q_H$, d) Design with 50/50 balance for $TAC$ and $Q_H$ and e) Positive perturbation response of $SiH_4$ of Design A for $RR$ considering different fit.

thermodynamic model was used. Figure 1a corresponds to the design proposed by Zang et al. [2] (Reference Design), Figure 1b is the design with the minimum $TAC$ (Design A), Figure 1c is the design with the minimum $Q_H$ (Design B) and Figure 1d is the design that has a 50/50 balance between $TAC$ and $Q_H$ [17]. Figure 1e, shows a dynamic response using Aspen Dynamics V12® with a $+0.5\%$ disturbance in the reflux flow. The solid blue line represents the response obtained from Aspen dynamics, the FO adjustment corresponds to the yellow dotted line, the SO adjustment corresponds to the green dotted line, and the Robust fit adjustment corresponds to the red dotted line.

## Dynamic Responses: Model Adjustment

For the FO, SO, and SOL adjustments, all the transfer functions in the matrix $G(s)$ are the same type, while for the Robust fit adjustment, the transfer functions of the matrix $G(s)$ can be of different type.

To fit all the models, a minimization of the error $\varepsilon$ between the Aspen Dynamics responses $X_i$ (simulation data) in the time domain and $Y_i$ (adjusted response) as shown in Eq. 5.

$$\min \varepsilon = \min \sum_i |X_i - Y_i| \qquad s.t. \quad \theta \geq 0, \ \ \tau > 0, \ \ 0 < \zeta \leq 1 \tag{5}$$

It is worth mentioning that minimizing Eq. 5 can fail to reach the damping/overshooting values, which can be misleading in the sense of having a low error value but not completely representing the trajectory of the disturbance response. The transfer functions shown in Figure 1e are presented below: Eq. 6, 7 and 8 for first order, second order and robust fit respectively.

$$g_{SiH_4,RR}(s) = \frac{0.5748}{1 + 0.0564\, s} \tag{6}$$

$$g_{SiH_4,RR}(s) = \frac{0.5748}{3.6000x10^{-3}\, s^2 + 0.0804\, s + 1} \tag{7}$$

$$g_{SiH_4,RR}(s) = -\frac{0.2045}{1 + 0.1715\, s} + \frac{0.7793}{(1 + 0.0771\, s)(1 + 0.0144\, s)} \tag{8}$$

Figure 1e shows that the first and second orders have the same error $(\varepsilon = 0.012)$ but the second order transfer function fits better the real trajectory of the dynamic response. It is imperative to review various types of simplified adjustments to determine their final impact on the application of the SVD and verify which is the best option.

## RESULTS AND DISCUSSION

Tables 1, 2, 3 and 4 present the results of $A_\gamma + \gamma_{sm}$ for each case. The area that comes closest to the robust fit is highlighted in bold. In addition, number 1 refers to the design with $\theta = 0$ and 2 to $\theta > 0$.

Figure 2 shows the $\gamma^*$ for the robust fit and its transfer function matrix (shaded area), as well as the estimates by the proposed models for each of the designs. Table 5 shows a summary of results.

**Table 1:** Values of $A_\gamma + \gamma_{sm}$ for different frequencies $(rad/h)$ for the reference design (Figure 1a).

**Table 5:** Summary of the frequency of occurrence of the best fit according to $A_\gamma + \gamma_{sm}$ of all designs and all models at different frequencies

| Model | | $10^0$ | $10^1$ | $10^2$ | $10^3$ | $10^4$ | Total |
|---|---|---|---|---|---|---|---|
| $FO$ | $\theta = 0$ | 1 | 1 | 1 | 1 | 1 | 5 |
| | $\theta > 0$ | 0 | 1 | 1 | 2 | 2 | 6 |
| $SO$ | $\theta = 0$ | 3 | 0 | 0 | 0 | 0 | 3 |
| | $\theta > 0$ | 0 | 1 | 2 | 0 | 0 | 3 |
| $SOL$ | $\theta = 0$ | 0 | 0 | 0 | 0 | 0 | 0 |
| | $\theta > 0$ | 0 | 1 | 0 | 1 | 1 | 3 |

By comparing the results for RF at $100\ rad/h$, the controllability improves in the following order: Reference design < Design A< Design B < Design C. In addition, Design A and Design B have similar values. For FO-1 the order is: Reference design < Design B < Design A < Design C. However, Design A and Design B are very similar. FO-2 has the same order as RF. For the second order adjustments (i.e., SO-1, SO-2, SOL-1, SOL-2): Reference design < Design B < Design A < Design C. However, the difference between Design A and Design B is higher than that for FO-1

## CONCLUSIONS

For $100\ rad/h$, the FO-2 adjustments showed the same order as in RF in terms of controllability. Therefore, first-order transfer functions can reliably be used as approximations to dynamic responses in stochastic optimization to assess design and controllability simultaneously. By increasing the complexity in adjustments by using second-order transfer functions, the order of controllability improvement differs from that in RF. Moreover, the controllability index difference

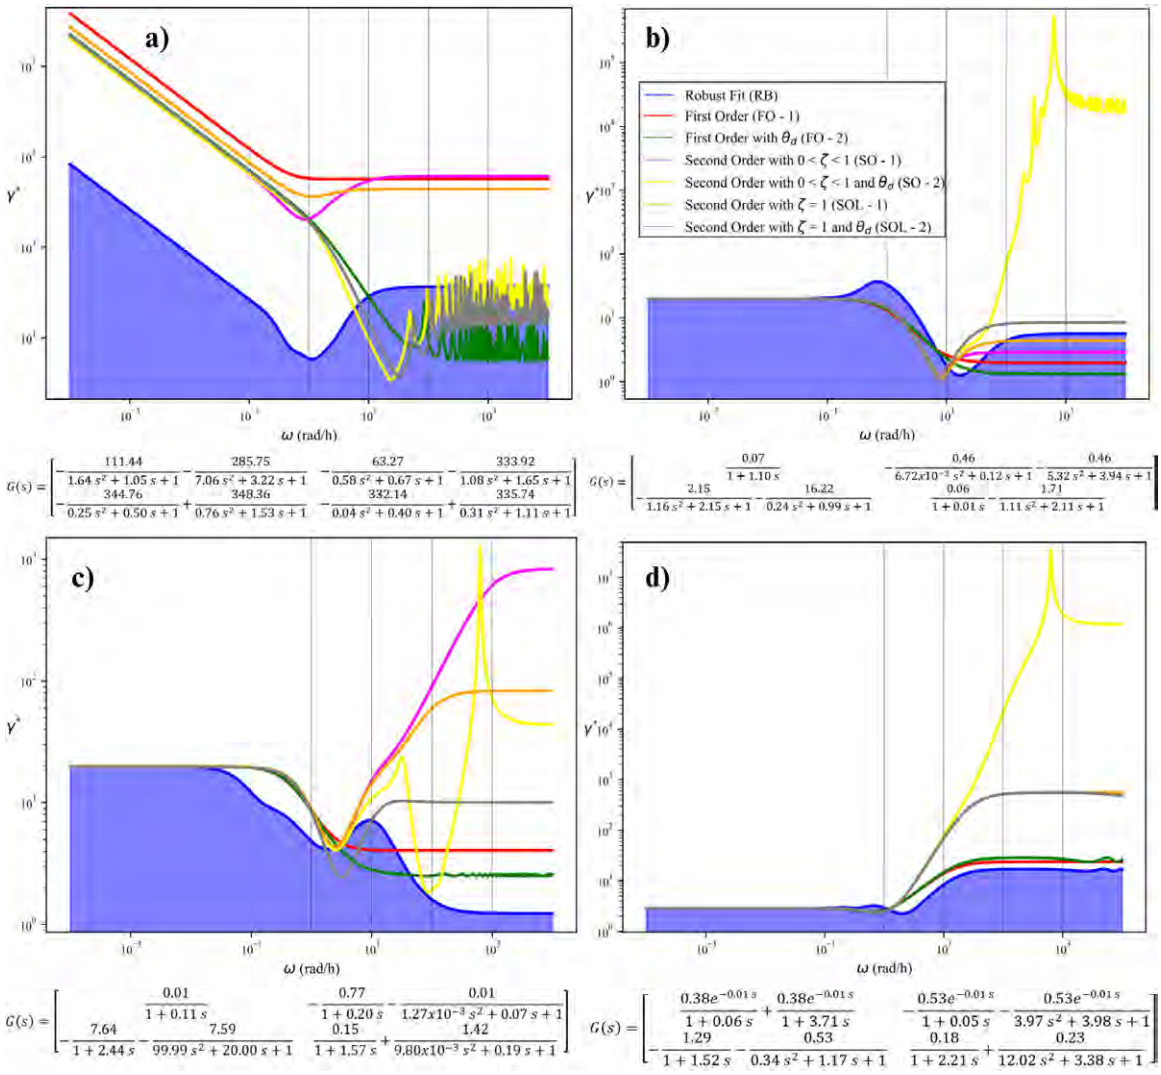

**Figure 2:** Condition number ($\gamma^*$) for different frequencies and models for the response of a positive disturbance ($\pm 0.05$) for a) Reference design, b) Design A, c) Design B and d) Design C.

between Design A and Design B was little (0.02) for FO-1, but one order of magnitude for SO-1 (0.15), and SOL-1 (0.2). Therefore, using more complex transfer functions can be counterproductive in assessing controllability properties.

## ABSTRACT

Solar Thermal Power Plants (STPPs) use solar energy for large-scale electricity production but face significant operational challenges. These include variations in solar radiation, cloud cover, electricity demand fluctuations, and the need for frequent shutdowns if energy storage is inadequate. Deciding an optimal STPP operating conditions is challenging due to these factors. While revenue maximization has been used as an objective in existing literature, current models are often static and fail to capture the dynamic nature of STPPs. In contrast, this work proposes a dynamic model-based revenue optimization approach that accounts for plant dynamics and operational constraints, such as solar radiation variability and changing electricity demand. The objective function is designed to maximize revenue while considering power generation and fluctuating electricity prices. A simulation model of 1 MWe hybrid solar thermal power plant in Gurgaon, India, featuring two solar fields—Parabolic Trough Collector (PTC) and Linear Fresnel Reflector (LFR), is chosen as a case study. The optimization focuses on the oil mass flow rate through the PTC, which influences steam production. The mass flow rate of oil side is optimized at discrete time intervals, forming the decision variables in a nonlinear programming problem (NLP). The results demonstrate the effectiveness of this approach in significantly enhancing the STPP's revenue.

**Keywords**: Optimization, Dynamic Modelling, Parabolic Trough Collector, Linear Fresnel Reflector

## INTRODUCTION

In recent years, there has been a global push to commercialize renewable energy sources as an alternative to fossil fuels. Among these alternatives, solar energy has gained considerable attention due to its abundance, widespread availability, and minimal carbon emissions. Solar energy is a key source for generating electricity, harnessed through photovoltaic (PV) systems and solar thermal power plants (STPPs). PV Systems convert sunlight directly into electricity, while STPP use mirrors or lenses to concentrate sunlight, generating heat that drives turbines to produce power [1]. Specifically, STPP captures the direct normal irradiation (DNI) of the sun, concentrates it onto a receiving surface, converts the absorbed heat into mechanical work, and subsequently produces electricity, typically through advanced thermodynamic power cycles. STPP is an environmentally friendly technology that offers significant potential for energy conservation and environmental protection [2].

To unlock the full potential of an STPP, several studies have focused on optimizing the operation of STPP from various perspectives. Simon et al. [3] explored the techno-economic optimization of low-temperature solar thermal plants ($< 100^\circ C$). Alix et al. [4] introduced dynamic real-time optimization (DRTO) with an emphasis on improving storage management and reducing operating costs and excess energy delivery. Antonio et al. [5] proposed solutions to boost sales revenue by optimizing turbine inlet temperature and prioritizing energy production during high sales price hours, particularly in low solar radiation months. Luigi et al. [6] focused on maximizing revenue in solar thermal plants with limited storage capacity through optimal control. Sun [7] developed a self operation and low-carbon scheduling optimization model, demonstrating that thermal storage improves power generation capacity and revenue. However, no previous work has specifically addressed revenue optimization based on electricity cost fluctuations in an STPP while incorporating dynamic nature of plantwide operations.

This paper presents a revenue optimization strategy for a dynamic plantwide solar thermal plant, focusing on electricity production in response to time varying electricity demand and solar radiation variability. Thus, unlike traditional methods that focus solely on performance optimization, this approach considers both supply-side factors (solar energy availability) and demand-side factors (market prices) to determine the optimal electricity production levels. Since the operation of STPP is highly complex and nonlinear, finding an optimal operating strategy in presence of the different kind of variations in these factors can be challenging. Therefore, in the current work, an optimization approach is proposed for the same.

In this study, we focus on a 1 MWe (or 5 MW thermal) Hybrid STPP (HSTPP) located at the National Institute of Solar Energy (NISE), affiliated with the Ministry of New and Renewable Energy (MNRE), Government of India (GoI), situated in Gwalpahari, Gurgaon (28°25′N, 77°09′E), India [7, 8, 9]. The HSTPP system employs parabolic trough collectors (PTC) and linear Fresnel reflectors (LFR) as its main energy concentrators, contributing to its hybrid nature. No previous reports on an optimization study exist for this system. However, dynamic models of various components of this HSTPP are available in literature [10], and hence we have selected this plant for our study.

The rest of the paper is organized as follows: PLANT OVERVIEW section provides a description of the various components of the (HSTPP). METHODOLOGY outlines the approach and techniques used to address the problem formulation. RESULTS AND DISCUSSIONS presents the outcomes from the case study, followed by CONCLUSIONS AND FUTURE SCOPE.

## PLANT OVERVIEW

### Plant components

Figure 1 illustrates the schematic of the Gurgaon HSTPP [9, 11]. This plant has five primary components. These components along with the corresponding dynamic model as available in literature [10] are briefly discussed below:

- Concentrator: Parabolic Trough Collectors (PTCs) are efficient and reliable collectors in STPP systems, utilizing an absorber tube with heat transfer fluid (HTF) flowing through it. The absorber tube is enclosed by a glass envelope to minimize heat losses, while solar radiation is focused by a parabolic reflector [9, 11, 12]. In contrast, Linear Fresnel Reflectors (LFRs) use fixed ground-based mirrors and a water-steam mixture, lowering costs and simplifying maintenance [13]. The PTC model includes three partial differential equations (PDEs) for temperature profiles, whereas the LFR model involves five PDEs for mass, momentum, and energy balances [13].
- Energy storage: Thermal energy storage is crucial for STPPs, enabling power generation during cloudy periods or nighttime by storing heat in fluids such as molten salts or thermal oil [15, 16]. The HSTPP in Gurgaon uses two relatively low-capacity oil storage units namely high temperature (HT) and low temperature (LT) tanks to enable plant operation for 10-15 minutes during low solar availability [9]. Both the tanks are modeled by two ordinary differential equations (ODEs) each.
- Heat Exchanger: The heat exchanger in an STPP transfers thermal energy between fluids, enabling steam generation for turbine and electricity production [17]. The HSTPP at Gurgaon uses multiple heat exchangers such as pre-heater (PH), steam generator (SG) and super-heater (SH), with the PH and SH modeled by two ODEs each for fluid outlet temperatures and the SG described by five ODEs considering various system variables [9].
- Steam Drum: The steam drum (SD) separates the two-phase flow from LFR tubes into liquid water and vapor, with the liquid recirculated and reheated in the LFR receiver, while the steam is pressurized and sent to the SH for turbine operation [7, 9]. The drum dynamics are modeled using five ODEs [9].
- Turbine & Generator: The turbine generates power by utilizing the pressure difference between high-pressure steam from the SG and the low-pressure condenser, driving the turbine blades and generating electricity through the connected generator [8]. The power output is calculated using Willan's line equation, as described in the literature [7, 9].

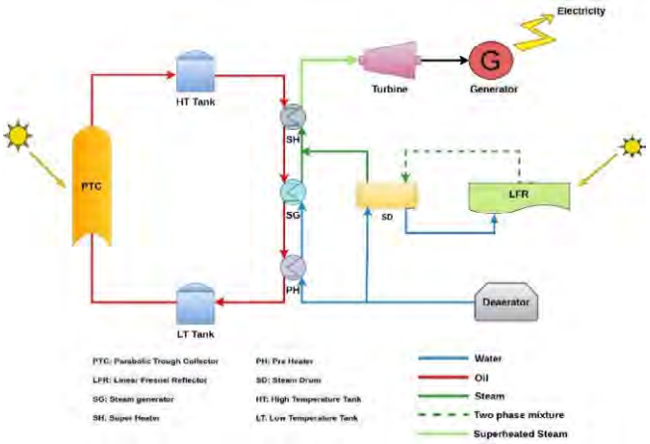

**Figure 1.** HSTPP block diagram.

The overall HSTPP model is comprised of a total of 58 ODEs (without LFR and SD) after conversion of PDEs to ODEs via spatial discretization. The LFR side (LFR+SD) is modeled by a total of 1,20,005 ODEs but is decoupled from the PTC loop. The dynamic model has been preliminarily validated using field data [10] and is considered in the current work.

### HSTPP standard operating procedure

Apart from the differential equations representing the dynamic behaviour, the HSTPP operations also involves discrete decisions corresponding to connections between various components. These are necessitated due to the daily startup and shutdown requirement of the plant. For example, at startup, when the PTC oil outlet temperature is lower than the HT oil temperature, the HT is bypassed, and the oil flow path follows LT-PTC-LT. However, when the PTC oil outlet temperature reaches or exceeds the HT oil temperature, the HT is integrated into the loop, and the flow path shifts to LT-PTC-HT-LT. Similarly, the various heat exchangers (SG, SH, PH) are brought inline when appropriate conditions are met [10].

## METHODOLOGY

### Proposed approach

The electricity price fluctuates throughout the day based on various factors, particularly market demand, thereby opening up the possibility of increasing revenue by intelligently varying the plant operation. In this context, the oil flow rate through the PTC in an HSTPP emerges as a critical decision variable since it ultimately affects revenue generation as shown in Figure 2.

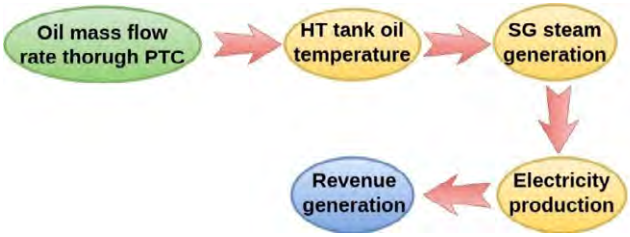

**Figure 2.** HSTPP block diagram.

This work focuses on developing a strategy to maximize revenue by dynamically adjusting the oil flow rate in response to market price fluctuations and solar radiation variations. For the current study, plant operation in a 10-hour window (8 AM - 6 PM) is considered. The corresponding electricity price is assumed to be proportional to the reported electricity demand [16] on a typical day, and is depicted in Figure 3(a). It is seen that the price varies across 15 minute intervals. Also, the real-time solar insolation data has been taken from a typical summer day at the plant site in Gurgaon, India, specifically from May 14th, 2014 [12] for our simulation as shown in Figure 3(b).

### Proposed formulation

The objective in our work is to determine the optimal oil mass flow rate through the PTC loop during daytime operation of HSTPP, so to ensure maximum revenue from electricity generation while adhering to the operational constraints of the HSTPP. This revenue optimization

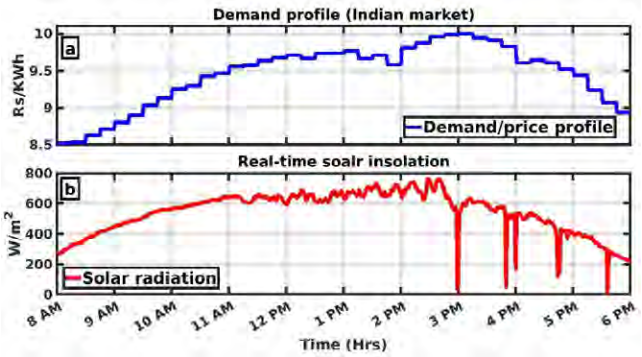

**Figure 3. (a)** Realtime electricity demand profile [16]. **(b)** Realtime solar insolation profile [10].

problem is defined as Formulation 1:

**Formulation 1:**

$$\max_{u(t),\ t_0 \le t < t_f} \int_{t_0}^{t_f} W_{PB}(t) P(t)\ d(t) \tag{1a}$$

$$\text{s.t.} \quad \dot{\tilde{x}} = \tilde{f}\big(\tilde{x}(t), u(t), s(t)\big) \tag{1b}$$

$$u_L \le u(t) \le u_U, \quad \forall\ t_0 \le t < t_f \tag{1c}$$

where the objective function (Equation (1a)) represents revenue generated by HSTPP in a day, and Equation (1b) represents the dynamic model of the HSTPP. Further, $W_{PB}$: Power generation from turbine (MW), $P$: Price per unit of electricity generation (Rs/MWh), $\tilde{x}$: State variables of HSTPP, $u$: Decision variables (manipulated inputs), namely PTC oil flow rate ($\dot{m}_{oil,PTC}$) that can be adjusted to influence the states in the optimization problem with upper and lower bound $u_L$ and $u_U$, $s$: Solar radiation profile, and $t_0$ and $t_f$ correspond to the period over which optimization is performed. Since $u(t)$ is a continuous variable, this is an infinite dimensional optimization problem. Further, the plant model involves a large number of nonlinear differential equations coupled with discrete connection operations. This makes Formulation 1 computationally tough to solve. Thus, we make the following simplifications to make the problem tractable:

- **Control Vector Parametrization:** We approximate the decision variable (DV) profile $u(t)$ by discretizing it over time, such that: $\mathrm{u}(t) = u(t_p)$, for $t_p \le t < t_{p+1}, p = 0,1,..,P-1$, where $P$ is the number of discretization intervals. Thus, the manipulated variable trajectory is approximated as a piecewise constant function over each time

interval.

- **Decoupling of LFR+SD Loop:** The LFR+SD operation is not affected by the PTC oil flowrate. Hence, we precompute the profile of steam ($r\ (t)$) generated by LFR+SD loop for the given solar insolation profile (Figure 3(b)). The dynamic equations corresponding to LFR+SD are then excluded from the model and instead $r(t)$ profile is used. The resulting dynamic model thus comprises of 58 ODEs with states represented as vector $x$.
- **Numerical Integration of Model Equations:** The dynamic model equations cannot be solved analytically. Hence, they are integrated numerically within the optimization formulation.

With these simplifications, Formulation 1 is reformulated as follows:

**Formulation 2:**

$$\max_{u(t_p),\ p=0,1,..,P-1} \sum_{j=1}^{N} W_{PB}(t_j)P(t_j)\Delta t \qquad (2a)$$

$$\text{s.t.} \quad x(t_{j+1}) = \int_{t_j}^{t_{j+1}} f(x(t), u(t_j), s(t_j), r(t_j))\ dt + x(t_j) \qquad (2b)$$

$$u(t_j) = u(t_p), \quad for \quad (p-1)M \le t_j < pM \qquad (2c)$$

$$u_L \le u(t_p) \le u_U, \quad p = 0,1,\dots,P-1 \qquad (2d)$$

Equations (2b,2c) are written for $j = 0,1,\dots,N-1$. Equation (2b) corresponds to numerical integration of the HSTPP model other than the LFR+SD component, with step size $\Delta t = 1$ minute. Model-equation integration and objective function evaluation is done at 1 minute interval to capture the significant dynamic variations in the plant. However, if the DV $u$ were to be determined at each 1 minute of time interval, the dimensionality of the problem would increase significantly, making it computationally very complex to solve. To mitigate this issue, the DV $u$ is held constant using zero-order hold over a time period $M = \frac{t_f - t_0}{P}$. Specifically, for each interval of $M$ minutes, $u(t_j)$ remains the same. This approach reduces the dimensionality of the problem while still capturing the dynamic variation of the system over the given simulation period.

## Solution strategy

Formulation 2 is a nonlinear programming (NLP) optimization problem. Further, the constraints are not explicit due to the need for numerical integration of model equations within the optimizer. The model equations are nonlinear, and non-differentiable at finite time instants, due to presence of discrete variables within model equations. Genetic Algorithm (GA), a popular meta-heuristic approach, are suited for solving such problems and are used in the current work.

# RESULT AND DISCUSSION

## Case Study

We consider three cases, each focusing on the revenue optimization problem but with varying number of DVs. These cases aim to explore the impact of adjusting key operational parameter, namely PTC oil mass flow rate ($\dot{m}_{oil,PTC}$) on the overall revenue generation in presence of varying electricity prices (Figure 3(a)) and solar radiation (Figure 3(b)). The study aims to identify optimal strategies for maximizing the HSTPP plant revenue under different levels of operational complexity.

The HSTPP stops electricity generation if the HT tank oil temperature drops below $300^{\circ}C$ for 5 minutes which leads to plant shutdown [9]. As solar radiation decreases at the end of the day, the temperature of the HT tank begins to fall. Consequently, the total plant runtime will vary for different oil mass flow rates.

The GA relevant parameters are listed in Table 1.

**Table 1:** GA-relevant parameters for case study.

| Parameter | Value |
|---|---|
| Population size | 100 |
| Number of generations | 50 |
| Elite count | 2 |
| Lower ($u_L$) and upper ($u_U$) bound | 2,5 kg/sec |

## Case-1 ($P = 1$):

In this optimization problem, a single DV is used, i.e., representing a simplified scenario for analysis. Throughout the 10-hours simulation period, the oil mass flow rate through the PTC loop is kept constant, regardless of the varying electricity demand. The optimizer determines the optimal mass flow rate as $\dot{m}_{oil,PTC} = 2.7\ kg/sec$, with corresponding revenue being $Rs.25{,}636$ for the $8.8\ hrs$ of plant run. In contrast, the designed oil mass flow rate $\dot{m}_{oil,PTC} = 3\ kg/sec$ as reported in literature [9], would correspond to revenue of $Rs.24{,}462.5$ for $7.2\ hrs$ of plant run (results not shown here). This revenue value is taken as the base case for comparison.

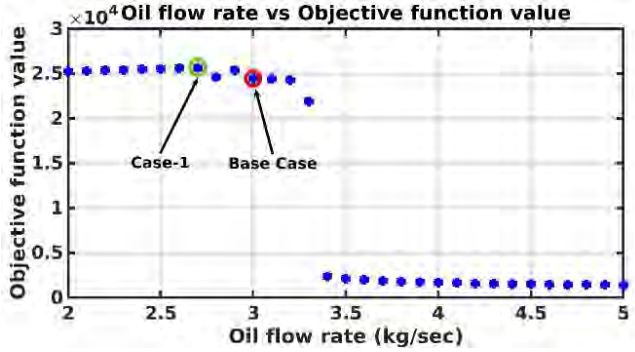

**Figure 4.** The validation of optimal value for Case-1

### Validation of Case-1:

To validate the optimizer results, we computed revenue for 30 different constant mass flow rate values in the range $2-5\ kg/sec$ (Figure 4). The Figure demonstrates the optimality of the GA obtained solution, despite the highly nonlinear and non-differentiable nature of the model equations.

### Case-2 ($P = 10$):

This case considers 10 DVs, offering more degrees of freedom. Here, while the mass flow rate is held constant for each hour starting from 8 AM to 6 PM for the 10 hrs of simulation, the flow rates across different hours can be different. The optimizer generated mass flow rate profile for this case is shown in Figure 5. The corresponding generated one-day revenue amounts to $Rs.25730.2$ for the daytime plant run of $8.76\ hrs$.

### Comparison of Case-1 and Case-2:

The power generated for these cases are depicted in Figure 6(a). It is seen that power generation profile for Case-2 is marginally higher (see Figure 6(a) inset) during the day. However, it is significantly higher during the beginning (9-9.30 AM) which leads to larger revenue. To understand this difference, consider Figures 6(b), 6(c).

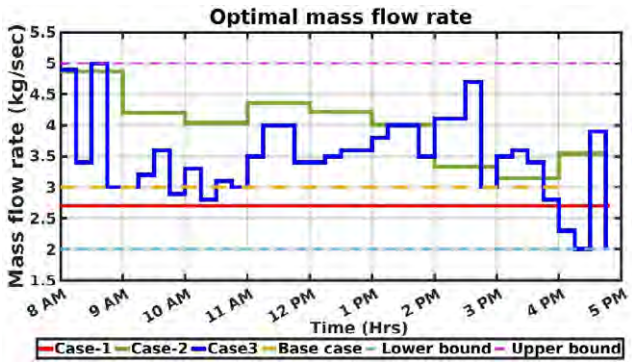

**Figure 5.** Optimal mass flow rate of oil for the three cases

The plant operation for both cases corresponds to warm startup where the plant has been operating for several days prior to the simulation. The corresponding starting temperatures are: HT tank: $306^{\circ}C$, LT tank: $240^{\circ}C$, and the PTC oil temperature: $30^{\circ}C$. During the initial start-up phase, only the PTC and LT tanks are connected since PTC oil outlet temperature is lower than HT tank oil temperature. In Case-1, the mass flow rate of the oil is $2.7\ kg/sec$ while it is $4.9\ kg/sec$ for Case-2 in the initial period. This leads to faster rise of PTC oil temperature in Case-2 due to injection of higher flowrate from the LT tank which is at higher temperature than the PTC oil temperature. This way of operation, namely injecting higher flowrate in the beginning, is non-intuitive but has been discovered by the optimizer to result in higher revenue generation. Further examination of Figure 6(b) and Figure 6(c) reveals that Case-2 maintains a lower HT oil outlet temperature ($T_{(o,o,HT)}$) throughout the 10-hours simulation but exhibits a higher oil mass flow rate (Figure 5) compared to Case-1. This increased flow rate results in a higher steam flow rate from the SH to the turbine in Case-2 compared to Case-1 leading to higher power generation. This demonstrates that optimizing the DVs can enhance the performance of HSTPP.

### Case-3 ($P = 40$):

We also considered a case with 40 DVs where oil flow rate change is allowed every 15 minutes. This led to revenue of $Rs.25895.7$ ($8.75$ hrs of plant operation) which is higher than that obtained in Case-1 and Case-2. Thus, an increase in the number of DVs offers greater opportunity to increase revenue generation. However, optimizing this case is considerably more complex. For the sake of brevity, detailed results for Case-3 are not presented here.

For our problem we also tried the gradient-based method 'fmincon' (MATLAB inbuilt function). However, the results were inferior to those obtained by GA.

## Performance metrics

Various performance metrics for the three cases are listed in Table 2. From this Table, it is seen that Case-3, with larger number of DVs, demonstrates the best performance in terms of both energy output and economic benefit. Specifically, considering a single, 10, and 40 DVs optimization strategy yields a revenue increase of $4.80\%, 5.18\%,$ and $5.86\%$ compared to the base case. These findings highlight the critical role of optimizing key operational variables to enhance the revenue generation of STPPs. Also, the significant computation times for the three cases indicate that the problem is computationally intensive to solve.

**Table 2:** Performance metrics for case study.

| Parameters | Base Case | Case-1 | Case-2 | Case-3 |
|---|---|---|---|---|
| Steam generation from SG (kg) | 9548.5 | 9989.4 | 10134 | 10488 |
| Steam Generation from LFR (kg) | 17535 | 18660 | 18645 | 18632 |
| Total steam produced (kg) | 27083 | 28649 | 28778 | 29120 |
| Electric energy produced (MWe) | 2.54 | 2.66 | 2.68 | 2.69 |
| Duration of power generation (hrs) | 7.2 | 8.8 | 8.76 | 8.75 |
| Revenue (Rs.) | 24462 | 25636 | 25730 | 25895 |
| % revenue increase (over base case) | - | 4.80 | 5.18 | 5.86 |
| Computation time (days) | - | 6 | 6.5 | 7 |

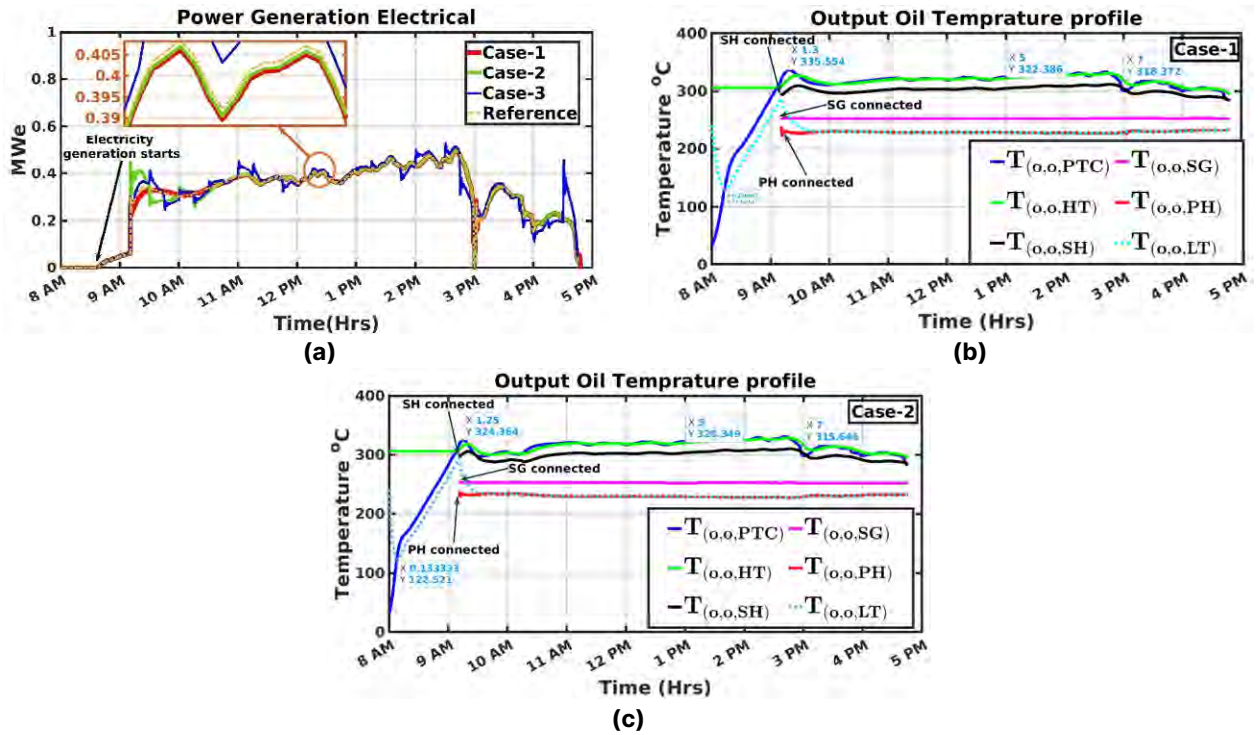

**Figure 6.** (a) Electricity generation profile for various cases, (b) Case-1 HSTPP oil profile, (c) Case-2 HSTPP oil profile. Here $T_{(o,o,K)}$ is represent the oil outlet temperature (°C) of component K, K ∈ {PTC,HT,SH,SG,PH,LT}.

## CONCLUSION AND FUTURE SCOPE

This paper presents an NLP revenue optimization approach that accounts for plant complexities such as solar radiation variability, fluctuating electricity demand, and process dynamics. The results demonstrate that increasing the number of decision variables (PTC oil flowrate variations) offers greater flexibility in plant operation, which in turn enhances performance and revenue for the HSTPP. The results underscore the importance of integrating dynamic models and optimization techniques to increase profitability of HSTPP by improved operation without any capital investment. In future, other operating variables such as mass flow rates from the HT tank and SD, can also be optimized to further increase revenue generation. Further, the current optimization approach servers as proof-of-concept and can be scaled up by applying it to STPPs with much larger production ratings.

## ABSTRACT

Wastewater treatment and resources recovery from large wastewater flowrates of the municipalities and circular bio-based economy ask for efficient control solutions. The paper presents solutions for operating the wastewater treatment plant, based on advanced process control methods aimed to merge the benefits of the cooperation between the lower-level regulatory control loops and the upper-level model predictive control strategy. The lower-level is designed to regulate the nitrification in the aerated bioreactors by controlling the Dissolved Oxygen or the ammonia concentration and to control the denitrification in the anoxic reactor by controlling the nitrates concentration. The model predictive controller either sets the setpoints of the regulatory layer or directly manipulates the air and nitrate recycle flow rates. The plant performance results obtained using the regulatory Proportional and Integral control are compared to the direct or the supervisory model predictive control outcomes. Both feedback and feedforward control configurations were considered, with the influent ammonia concentration as a representative disturbance. The WWTP control results were assessed using the Pumping and Aeration Energy, Effluent Quality, and Green House Gases emissions performance indices. They showed the advantage of the two-level control system for ammonia and nitrates concentration control with setpoints driven by the constrained model predictive controller, in association with the feedforward control.

**Keywords**: Wastewater, Model Predictive Control, Supervisory Control, Energy, Effluent Quality, and Green House Gas Emissions.

## INTRODUCTION

Driven by increasing urbanization and industrialization, the demand for clean water has firmly become one of humanity's top problems. The restoration of wastewater quality and recovery of wastewater resources have emerged as topics of high interest for researchers and practitioners of the wastewater industry. As the typical drinking water and wastewater treatment plants (WWTP) account for 30% to 40% of the total urban energy consumption and greenhouse gas (GHG) of the WWTP sector account for 1% to 2 % of the global GHG emissions, the importance of economic and sustainable operation of the WWTP constantly increases. The recovery of resources from the wastewater adds tempting opportunities and raises challenges. As biomass is a carbon-neutral resource and biowaste enzymatic transformations use water as a solvent, they became a high-potential resource to obtain bio-based valuable products, such as 5-hydroxymethylfurfural (HMF) [1]. Emerged wastewater has to be processed for water quality and resource recovery, and the WWTP has the main responsibility for performing these tasks. Modelling and process control have the remarkable potential to support the tough energy and GHG emissions restrictions and cope with continuously stricter regulations for clean water quality.

Modelling the complex biochemical processes specific to this technology has been greatly achieved by the family of the Activated Sludge Models no. 1, 2, 2d and 3 [2], in association with the Benchmark Simulation Models 1 and 2 [3]. Their benefits have emerged as invaluable

support for improving the wastewater treatment plant operation via traditional and advanced solutions [4,5].

The rapidly growing perspective and need for resource recovery from wastewater is asking for complex control solutions [6]. The present work contributes to this challenge by investigating new WWTP control system configurations. The novelty also consists in finding the control structure to satisfy the comprehensive assessment of plant performance by the triplet of the effluent quality, spent energy, and GHG emissions indices. Model Predictive Control (MPC) was used in either a single control layer or at the top of a supervisory control configuration with PI control loops at the regulatory layer. Investigations were carried out to find the most favourable combination of controlled variables for the nitrification and denitrification processes, to improve the performance indices. Candidates considered as potential controlled variables were the ammonia concentration ($S_{NH}$) and Dissolved Oxygen (DO) in the aerated bioreactor, and nitrates and nitrites ($S_{NO}$) concentration in the anoxic reactor. MPC with feedback and feedforward control configurations were studied. The results assessed the way MPC supervisory control with the regulatory PI loops for the $S_{NH}$ and $S_{NO}$, augmented with feedforward control, enhanced the WWTP performance indices.

# METHODS

## WWTP description

This study considered the WWTP with an Anaerobic-Anoxic-Oxic configuration, as shown in Figure 1.

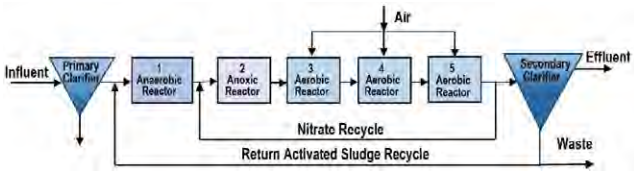

**Figure 1.** Layout of the A$^2$O WWTP.

**Table 1:** Main WWTP equipment parameters.

| WWTP Unit | Parameter | Value | Unit |
|---|---|---|---|
| Primary settler | Area | 2,125 | $m^2$ |
| | Height | 3.5 | m |
| Anaerobic bioreactor | Volume | 9,015 | $m^3$ |
| Anoxic bioreactor | Volume | 12,678 | $m^3$ |
| Aerobic bioreactors | Volume | 33,066 | $m^3$ |
| | Area | 6,012 | $m^2$ |
| Secondary settler | Area | 11,304 | $m^2$ |
| | Height | 3.0 | m |

The main design parameters of the Cluj-Napoca municipal WWTP, used as a case study, are presented in Table 1.

The software simulator of the plant was built using the mathematical models of the primary settler, the five ASM1 biological reactors [1] and the secondary settler. The simulator of the WWTP was calibrated with process data from the Cluj-Napoca municipal WWTP, designed for 420,000 PE and a typical wastewater influent flowrate of 120,000 $m^3$/day.

The calibrated simulator for the municipal WWTP was implemented in Simulink™ software environment. S-functions in the dynamic simulator were written as C-files and compiled into executable forms to reduce the simulation time.

## Control structures

The continuously changing influent variables of the WWTP (flowrate, concentration of pollutants, temperature), with values ranging in a ratio of up to four times, represent the main challenge for the control system.

Model Predictive Control was used as main control approach, in either direct control layer or at the top of a supervisory control configuration with PI control loops at the regulatory layer. It is aimed to cope with the challenges and bring expected new control solutions. The investigated control system configurations are PI control, presented in Figure 2; Direct MPC control, shown in Figure 3; Supervisory MPC Control, displayed in Figure 4.

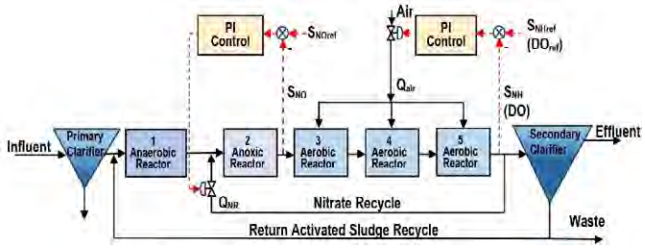

**Figure 2.** PI control structure.

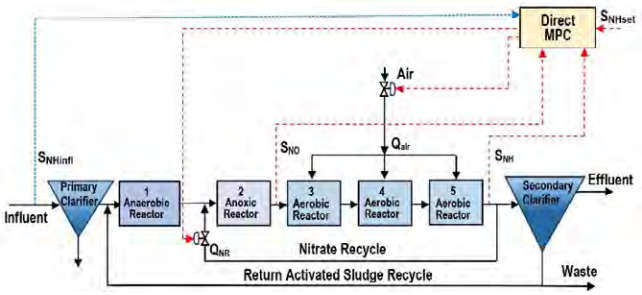

**Figure 3.** Direct MPC control structure.

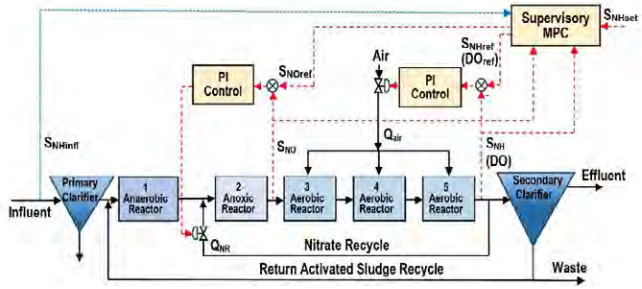

**Figure 4.** Supervisory MPC control structure.

## Controlled variables

To ensure the efficiency of the nitrification process two candidates were considered as controlled variables. They were DO (measured by the LDO sc sensor), and $S_{NH}$ in the effluent of the aerated bioreactors (measured by the Amtax sc sensor). The $S_{NO}$ in the anoxic reactor (measured by the Nitratax clear sc sensor) was the controlled variable, aiming to keep the denitrification process at a suitable rate. However, considering the importance of the nitrification process on the energy, effluent quality and GHG emissions, the control was mostly directed to the $S_{NH}$ control, as a more straightforward solution when compared to the DO control. The $S_{NO}$ control was used to assist this main control target.

## Manipulated variables

The manipulated variables for the PI control structures and for the Direct MPC control structures were the air flowrate ($Q_{air}$) entering the aerobic reactors, alone or together with the Nitrate Recycle ($Q_{NR}$) flowrate. The manipulated variables for the Supervisory MPC control structures consist in the setpoints to the regulatory layer of the PI control loops, with either the $DO_{ref}$ and $S_{NOref}$ pair or the $S_{NHref}$ and $S_{NOref}$ pair. The regulatory control loops use $Q_{air}$ and $Q_{NR}$ flowrates as manipulated variables. They are the most effective manipulated variables acting on the controlled ones and are typically available in WWTPs.

The study also included feedforward control, together with the feedback one, by considering as representative disturbance the influent concentration of ammonia ($S_{NHinfl}$).

The control cases and their associated control structure are presented in Table 2.

**Table 2:** Investigated control structures

| No. | Control Structure | Controlled variables | Manipulated variables | Feed-forwd. |
|---|---|---|---|---|
| 1 | PI | DO<br>$S_{NO}$ | $Q_{air}$<br>$Q_{NR}$ | - |
| 2 | PI | $S_{NH}$<br>$S_{NO}$ | $Q_{air}$<br>$Q_{NR}$ | - |
| 3 | PI | $S_{NH}$ | $Q_{air}$ | - |
| 4 | Direct MPC | $S_{NH}$ | $Q_{air}$<br>$Q_{NR}$ | - |
| 5 | Direct MPC | $S_{NH}$ | $Q_{air}$<br>$Q_{NR}$ | + |
| 6 | Supervisory MPC | $S_{NH}$ | $DO_{ref}$<br>$S_{NOref}$ | - |
| 7 | Supervisory MPC | $S_{NH}$ | $DO_{ref}$<br>$S_{NOref}$ | + |
| 8 | Supervisory MPC | $S_{NH}$ | $S_{NHref}$<br>$S_{NOref}$ | - |
| 9 | Supervisory MPC | $S_{NH}$ | $S_{NHref}$<br>$S_{NOref}$ | + |

## Design and tuning the controllers

Due to its straightforwardness and lower requirements for computing resources, linear MPC was used in this study. The transfer function models employed by the MPC controllers for making predictions were developed using a specific model identification methodology. It first consisted of finding the plant's nominal steady-state operating point, followed by simulating the plant's response to an appropriate sequence of model input changes. The acquired input and plant response time series were subsequently used to identify the model's form and parameters that best fit the time series data. The regulatory control loops were chosen to have a Proportional Integral (PI) form.

Tuning the MPC controllers was achieved using the following parameters, mentioned in the order of their importance: weighting factors for the control (manipulated) variable moves and for the controlled (output) variables, prediction horizon, control horizon, constraints on the controlled and manipulated variables (for the feasibility of preserving the last ones to positive values). The tuning parameters were set by a two-step procedure. The MPC controller was first tuned against the control of the linearized model of the plant and then tuning was refined by simulations implying the nonlinear WWTP behaviour.

The regulatory PI controllers were tuned based on balancing the open-loop crossover frequency and targeting a phase margin of 60°. Again, simulations with control of the nonlinear plant were used to refine the PI tuning.

Simulations and controllers' tuning were performed in Matlab and Simulink® software in association with the System Identification™, MPC and Control System Toolboxes.

## Controlled WWTP performance assessment

The performance of the different control structures, presented as cases in Table 2, was primarily evaluated by the conventional offset from the setpoint value and by the overshoot. Additionally, the operation benefits brought by control to the WWTP were evaluated according to the following four performance indices.

Aeration Energy (AE):

$$AE = \frac{SO_{sat}}{T \cdot 1.8 \cdot 1000} \cdot \int_0^T (\sum_3^5 Bioreact_i \cdot Vol_i \cdot K_L a_i(t))dt \quad (1)$$

Pumping Energy (PE):

$$PE = \frac{1}{T} \cdot \int_0^T [0.004 \cdot Q_{NR}(t) + 0.08 \cdot Q_{RAS}(t) + 0.05 \cdot Q_{waste}(t)]dt \quad (2)$$

Effluent Quality (EQ):

$$EQ = \frac{1}{T \cdot 1000} \cdot \int_0^T [PU_{TSS}(t) + PU_{COD}(t) + PU_{BOD}(t) + PU_{TKN}(t) + PU_{NO}(t)] \cdot Q_{effluent}(t)d \quad (3)$$

Detailed descriptions of the notations and values of

the parameters of equations (1) to (3) can be found in [3].

The GHG emissions index includes the sum of the on-site and off-site emissions of the $CO_2$ and $N_2O$ gases, computed according to the following relationships [7].

Onsite $CO_2$ gas emissions:

$$P_{CO_2,on-site} = Q_{influent} \cdot 0.99 \cdot (1 - Y_H) \cdot \eta_{ASP} \cdot bCOD + Q_{influent} \cdot 1.03 \cdot Y_H \cdot \eta_{ASP} \cdot bCOD \cdot \frac{k_{d,H} \cdot MCRT}{1 + k_{d,H} \cdot MCRT} \quad (4)$$

Offsite $CO_2$ gas emissions:

$$P_{CO_2,off-site} = k_{PG} \cdot e_D \quad (5)$$

Onsite $N_2O$ gas emissions:

$$P_{N_2O,on-site} = Q_{influent} \cdot (TN_{in} - TN_{out}) \cdot r_{N_2O} \quad (6)$$

Offsite $N_2O$ gas emissions:

$$P_{N_2O,off-site} = N_{effluent} \cdot EF_{effluent} \quad (7)$$

Reaching reduced values of the key performance indices Total Energy (Pumping and Aeration), Effluent Quality and GHG emissions were targeted by the control system.

## RESULTS AND DISCUSSION

The investigated control structures were proposed with the assumption that effluent ammonia concentration is the most important variable to be targeted by the aeration control. Besides direct MPC, the supervisory MPC control structure was considered for its potential to combine incentives of centralized control with the regulatory layer and for the capability of systematically handling constraints. Simulations were performed for 22 days. The PI controllers worked on a continuous-time basis, while the MPC was implemented in a discrete-time framework, using a sample time of 10 min. Due to its minimal form, Case 3 was considered the reference case to the other control structure cases. Best case is highlighted in red.

Aeration energy index results are shown in Figure 5.

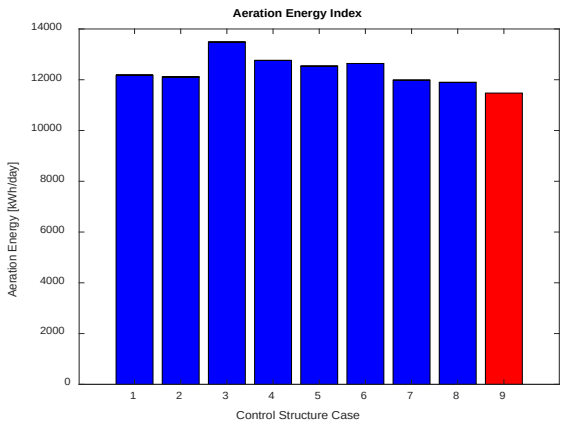

**Figure 5.** Aeration Energy Performance Index.

They reveal the advantages of the feedforward Supervisory MPC control structure of Case 9. Compared to the reference case, the reduction of AE is about 15%. Figure 5 shows the advantages of the Supervisory MPC over the Direct MPC. Additionally, the superiority of the $S_{NHref}$ manipulated variable over the $DO_{ref}$ one is confirmed.

Figure 6 presents the control results of the Pumping Energy index.

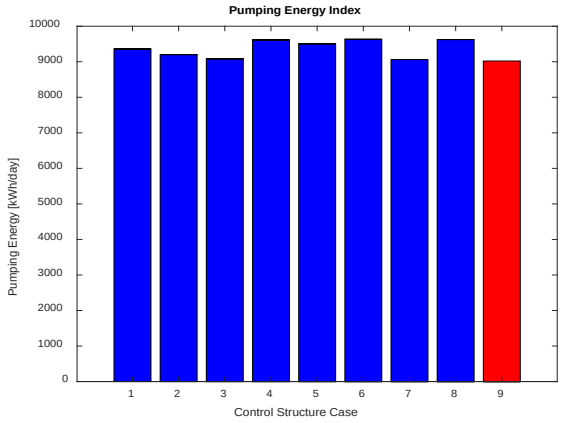

**Figure 6.** Pumping Energy Performance Index.

The pumping energy spent by WWTP for the investigated control structure cases shows again that feedforward Supervisory MPC control structure of Case 9 is the best, with the PE index value very close to those of Cases 7 and 3. When compared to Case 3, a slightly lower value of 0.7% was reported. However, the sum of the AE and PE energy indices consolidates the Total Energy advantage of the Case 9 control design by the diminished value of about 9% with respect to the reference case.

Figure 7 shows the results obtained for the Effluent Quality Index.

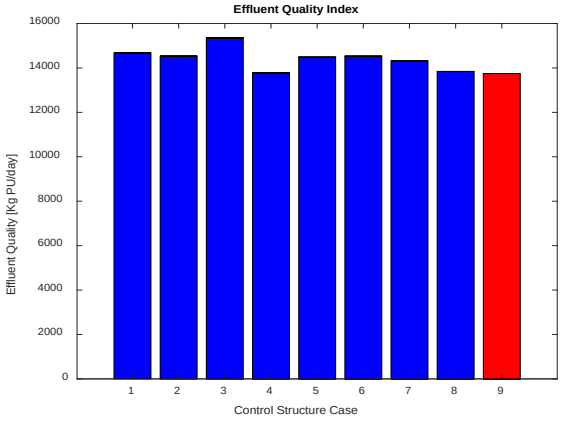

**Figure 7.** Effluent Quality Performance Index.

Evaluated by a weighted sum of discharged effluent pollutants mass flowrates, the WWTP effluent quality indices computed for the considered cases confirm the

control superiority of the feedforward Supervisory MPC Case 9. The reduction of the EQ index value is 10% with reference to Case 3. It may be noted that Direct MPC Case 4 showed marginally lower performance than Case 9.

Figure 8 presents the GHG emissions results.

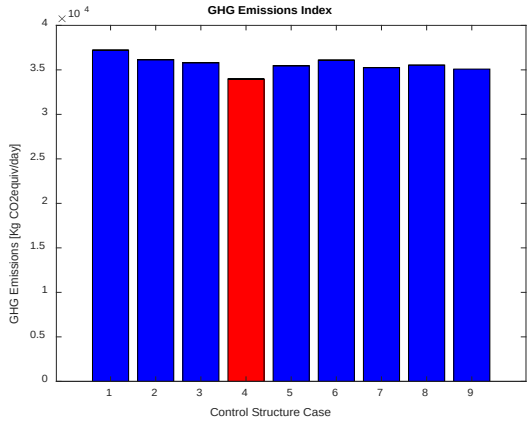

**Figure 8.** GHG Emissions Performance Index.

The best performance was demonstrated by the Direct MPC control of Case 4, followed by the feedforward Supervisory MPC of Case 9. The latter case showed lower performance than Case 4 by about 3%. When compared to the reference case, the improvement of Case 9 was evaluated at around 2%. All values reported for the performance Indices were computed as daily mean values over the considered period.

A set of results emerged from the detailed examination of each of the effluent pollutant mean concentration values, over the simulated period.

The effluent Total COD mean values showed reduced differences between the investigated cases. Cases 3 to 9, which present the lowest values of the effluent Total COD, differ by less than 1% when they are referred to the typical value of 21 g COD/$m^3$.

Figure 9. presents effluent ammonia concentration.

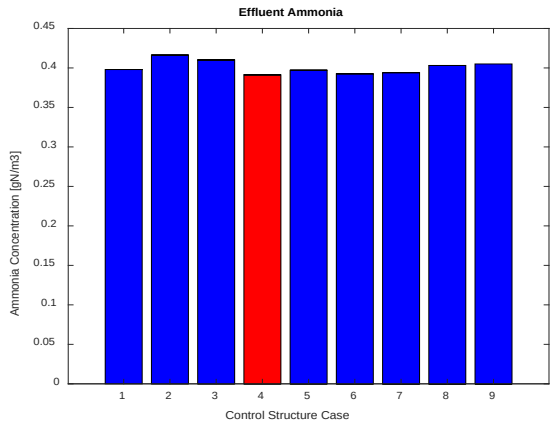

**Figure 9.** WWTP effluent $S_{NH}$ mean concentration.

For the majority of the cases, the mean value of the effluent ammonia concentration shows a higher value when compared to the $S_{NH}$ setpoint value of 0.39 gN/$m^3$. The largest difference from setpoint was +6%, for Case 2, and the lowest difference was -0.002%, for Case 4. Case 9 $S_{NH}$ mean value differs from setpoint by +3%.

The WWTP effluent mean concentration of nitrates and nitrites presents large differences among the control cases. These results are presented in Figure 10.

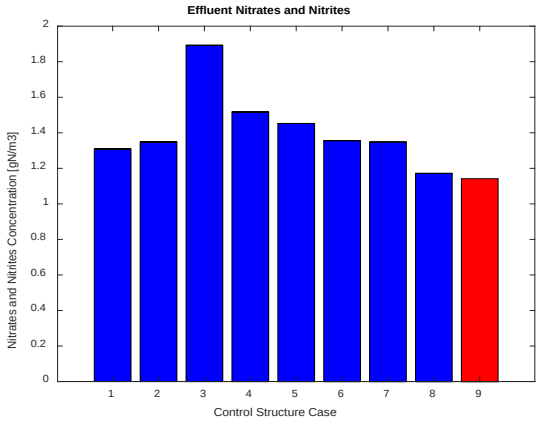

**Figure 10.** WWTP effluent $S_{NO}$ mean concentration.

The lowest $S_{NO}$ value was obtained for the feedforward Supervisory MPC control structure of Case 9. It reveals a considerable reduction of the concentration by roughly 65% when it is compared to the reference Case 3.

The WWTP effluent mean Total Nitrogen concentration, presented in Figure 11, reveals the superiority of Cases 8 and 9, i.e. the Supervisory MPC structure. This is partially induced by their lower $S_{NO}$ concentration values.

**Figure 11.** WWTP Total Nitrogen mean concentration.

When the comparison is made to the reference Case 3, the Total Nitrogen reduction was 17.5% for Case 8 and 17% for Case 9.

Given the high amplitude changes of the WWTP

influent variables, the overshoot of the $S_{NH}$ controlled variable of Case 9 was also considered to be good. Figure 12 shows the comparative control results between Cases 3 and 9, for the period between the 15th and the 20th day of controlled operation.

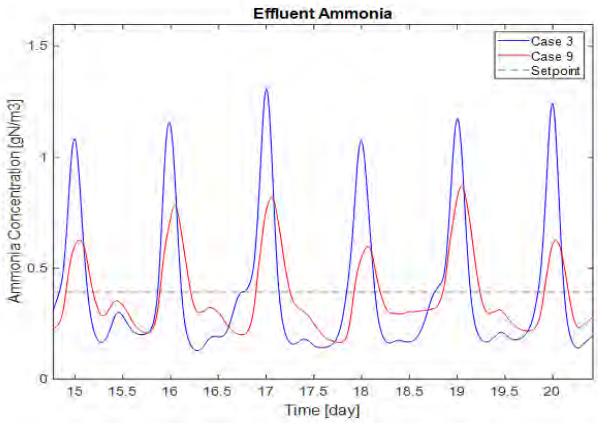

**Figure 12.** $S_{NH}$ control results for Case 3 and Case 9, as detailed plot for the period between days 15 and 20.

Figure 12 shows that overshoot is considerably smaller in Case 9 than in the reference Case 3. Further reduction of the overshoot may be obtained to the detriment of robustness and leads to the deterioration of the WWTP performance indices.

In comparison with literature results, the best-proposed control structure is based on a more comprehensive GHG-based approach and shows improvements (the effluent quality was improved, for e.g. by 17% for the effluent total nitrogen, versus 8.1 % reported in [4]).

## CONCLUSIONS

The four performance indices and WWTP effluent concentrations were analysed to find which of the investigated control structure candidates globally demonstrates the dominant incentives. The study concluded that feedforward Supervisory MPC with $S_{NH}$ and $S_{NO}$ manipulated variables is the first-ranked candidate, as it prevails in being best for most of the performance indices. Additionally, it succeeds in keeping effluent total nitrogen at the lowest values, without significantly increasing the effluent total COD. Compared to the reference case of the $S_{NH}$ PI control, this control structure improves the performance indices of Total Energy, EQ and GHG emissions, assessed to range between 2 and 10%.

The study also revealed that MPC performs better in the supervisory than in the direct control structure. For the Supervisory MPC the combination of $S_{NH}$ and $S_{NO}$ manipulated variables showed better results than the DO and $S_{NO}$ pair.

## ABSTRACT

The optimization of the power conversion system, responsible for thermal-to-electrical energy conversion, for a pulsed fusion power plant is presented. A spherical tokamak is modelled as three heat sources, all pulsed, with different stream temperatures and available amounts of heat. A thermal energy storage system is considered in the design to compensate for the lack of thermal power during a dwell. Thermal storage enables continued power generation during a dwell and can avoid thermal transients in sensitive components like turbomachines. Multiple lower grade heat sources are integrated into the process through parallel preheating trains. The evaluation of a dynamic model of the power conversion system is used to define an objective function with multiple criteria. A bi-objective optimization problem is defined to investigate the trade-off between the size of the thermal energy storage system and the variability in turbine power output during a dwell. The set of non-dominated designs demonstrates the trade-off, with designs covering the range from steady state turbine power output to a design that reduces the turbine power output by 46.3% during a dwell. The dynamics of three non-dominated designs demonstrate the power conversion system can maintain relatively stable conditions at the turbine inlet under different operating conditions, but molten salt temperature control is an issue.

## INTRODUCTION

The United Kingdom Atomic Energy Authority (UKAEA) is leading the Spherical Tokamak for Energy Production (STEP) programme to design and build a fusion power plant that demonstrates net electricity generation [1,9]. Fusion is an appealing prospect for clean and abundant energy but faces several engineering challenges. Two of these challenges are addressed here:

- Pulsed tokamak operation - the steady state nature of early fusion power demonstrators, notably tokamaks, will be challenging due to operational uncertainty and, as for conventional tokamaks, pulsed operation may be required. Rapid dynamics of the plasma compound this issue
- Multiple heat sources - generated thermal power is distributed to multiple tokamak components, and will be extracted via multiple coolant streams at different temperatures and flow rates

A power conversion system design for a pulsed fusion tokamak is presented, featuring a thermal energy storage system, using molten salts as is common in solar thermal power plants, and two parallel feed water trains to integrate multiple lower grade heat sources.

The pulsed heat generation requires the use of dynamic models to evaluate the performance of the power conversion system. The dynamic models are used within an optimization framework such that each objective

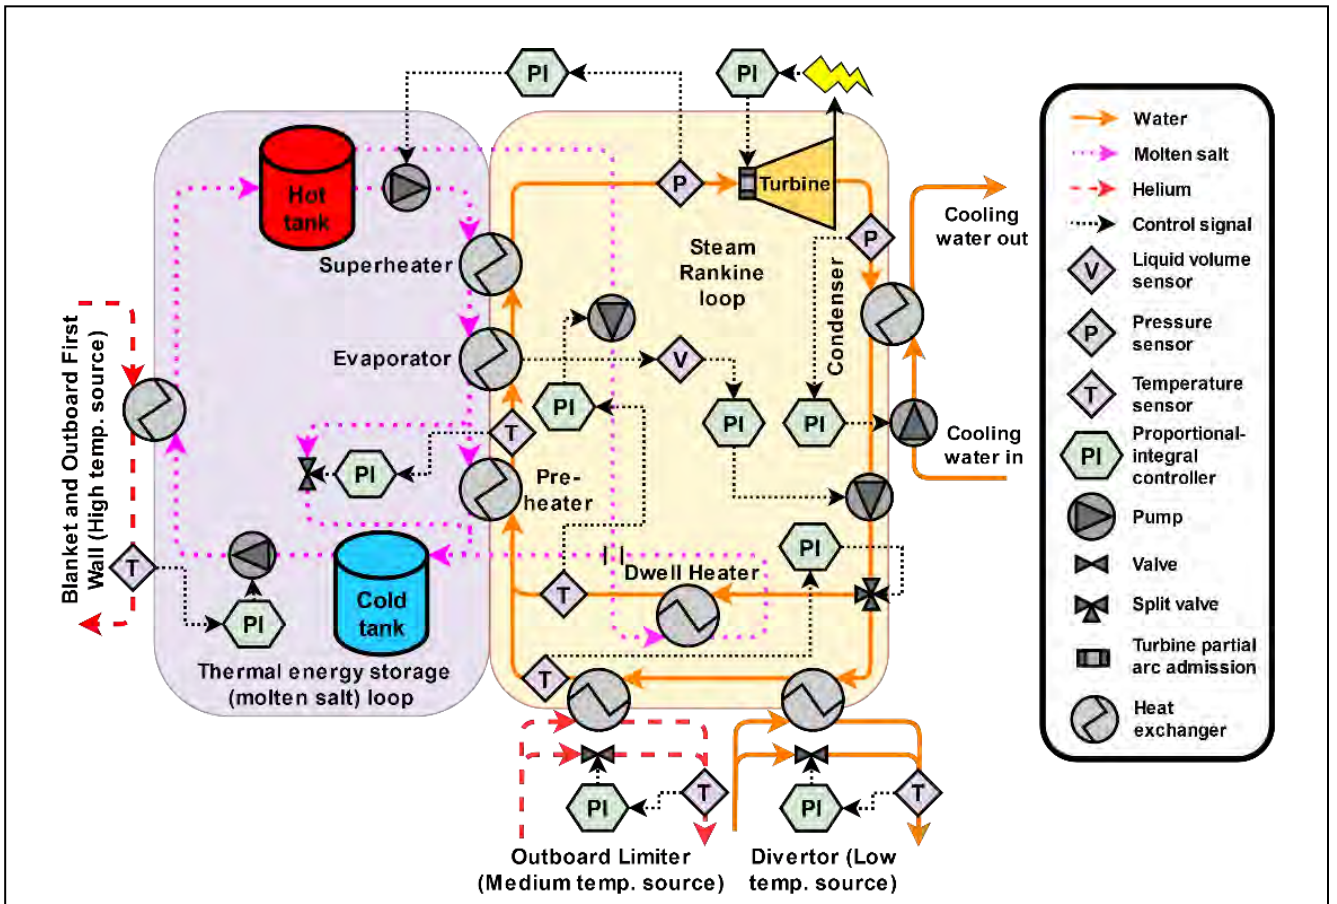

**Figure 1:** Power conversion system layout for a fusion tokamak with three pulsed sources. The high temperature source is used to heat and store molten salt for use during a dwell. The other two sources are used to heat feed water during a pulse. Their heat duty is replaced by a dwell heater, fed by molten salt, during a dwell. Note that all heat exchangers are counter current.

function evaluation involves a dynamic simulation of the designs identified by the optimization procedure.

## DYNAMIC POWER CONVERSION SYSTEM MODEL

Figure 1 shows the proposed power conversion system layout. There are three heat sources available from the fusion tokamak, with pulse and dwell values summarized in Table 1. While the tokamak outlet temperatures are fixed as the model boundary conditions, the temperature of the coolant returning to the tokamak is not fixed. Each source follows a $C^1$-continuous pulsed profile with an initial 2 h pulse period, a 5 min ramp down, a 15 min dwell period followed by a 5 min ramp up back to pulse.

The high temperature source exchanges heat with the molten salt in the thermal energy storage loop (left side of the process diagram in Figure 1) via the high temperature heat exchanger. The hot molten salt is stored in an insulated tank, at a target temperature of 550°C, where it can be pumped on demand to provide heat to the steam Rankine cycle (the right side of the process diagram in Figure 1). The cooled molten salt is stored in another insulated tank, at a target temperature of 350°C, for pumping and reheating by the high temperature heat source.

**Table 1:** Parameters of the available heat sources from the tokamak during a pulse, with values during a dwell given in brackets. These are early estimate values.

| Source grade | Coolant | Outlet temperature (°C) | Target return temperature (°C) | Thermal power (MWth) |
|---|---|---|---|---|
| High | Helium | 600 (450) | 450 (450) | 1,350 (0) |
| Medium | Helium | 450 (225) | 225 (225) | 215 (0) |
| Low | Water | 300 (275) | 275 (275) | 270 (0) |

A steam Rankine cycle is used to generate electrical power. Feed water is pumped through two parallel heating trains: the low and medium temperature heat exchangers that heat the feed water from their respective

heat sources during a pulse; and a dwell heater that heats the feed water using molten salt from the hot tank. The feed water then passes through a preheater, an evaporator and a superheater, with heat provided by the hot molten salt in counter current exchanges. The water exits as superheated steam. The steam then drives a turbine to generate electrical power before being condensed back to the liquid phase by the condenser, exchanging heat with cooling water, closing the loop for the steam cycle.

There are ten proportional-integral controllers in Figure 1. Two controllers regulate the feed water temperature at the outlet of the parallel heating trains by controlling the flow rate of molten salt to the dwell heater and the split fraction of feed water between the two trains. This allows the plant control to switch between the two heating modes when the tokamak switches between pulse and dwell.

The condenser pressure is regulated by a controller manipulating the flow of cooling water. A controller manipulates the mass flow rate of feed water in the Rankine cycle to ensure the evaporator doesn't flood or dry out due to a lack or excess of evaporation respectively. The turbine power output and inlet pressure are regulated by two controllers manipulating the turbine's partial arc admission and the mass flow rate of hot molten salt to the superheater respectively.

There is a bypass for the molten salt around the preheater, where the bypass valve opening is manipulated by a controller regulating the temperature of feed water leaving the preheater. This is to avoid the feed water boiling before the evaporator. Each of the heat sources has a controller regulating the temperature of coolant returning to the tokamak.

For the high temperature source, the mass flow rate of cold molten salt is manipulated. For the other two sources, the openings of bypass valves for the coolants are manipulated. The controllers are all hand tuned by repeated simulations here to reduce the dimension of the optimization problem. Previous work has looked at the controller parameters as decision variables [10].

The model has been implemented in the Modelica language [6] and solved numerically using OpenModelica [8]. Full descriptions of the dynamic models will be published in a future paper that is currently under review.

## OPTIMIZATION OF THE POWER CONVERSION SYSTEM FOR REDUCED DWELL POWER

Based on industry experience with thermal energy storage for solar thermal power plants, thermal energy storage systems are a significant fraction of total investment. For a 50MWel concentrating solar power plant, a cost of 33M€ was predicted [7]. With STEP expected to be generating ~500MWel (before parasitic loads like the tokamak itself), significant thermal storage would be required to generate a steady amount of power for fusion tokamaks [1]. The size of the storage system could be reduced by reducing the power generation during a dwell; stopping power generation entirely is infeasible due to the thermal stresses this would place on the components.

To investigate this, we propose an optimization problem to find the trade-off between the size of the thermal storage system, quantified as the volume of each tank $V_{tank}$ and the dwell power fraction $\varphi$, the fraction by which the turbine power setpoint is reduced during dwell relative to pulse. The bi-objective optimization problem is stated as:

$$\begin{aligned} &\min_{\boldsymbol{x}} \begin{bmatrix} V_{tank} \\ -\varphi \end{bmatrix} \\ &s.t.\ \boldsymbol{g}(\boldsymbol{x}) \leq \boldsymbol{0} \\ &\boldsymbol{h}(\boldsymbol{x}) = \boldsymbol{0} \end{aligned} \tag{1}$$

where the decision vector $\boldsymbol{x} = [V_{tank}, \varphi, P_{pulse}]^T$ includes the turbine power setpoint during a pulse $P_{pulse}$. This is necessary as designs that reduce the power generated during a dwell will necessarily generate more power during the pulse to satisfy energy balances in the overall process over time. Between a pulse and dwell periods, the setpoint smoothly transitions between $P_{pulse}$ and $\varphi P_{pulse}$ by following a sinusoidal curve. The equality constraints $\boldsymbol{h}(\boldsymbol{x})$ represent the dynamic model. The inequality constraints $\boldsymbol{g}(\boldsymbol{x})$ include requirements for long term operability of the plant. For a simulation to be completed, the volume of molten salt in either tank $V_{MS}$ must stay in the range $0.05 \leq V_{MS}/V_{tank} \leq 0.95$ for the $T_{sim} = 15900s$ of simulated time. The simulated time covers an initial pulse period $T_{pulse} = 7200s$, a dwell period $T_{dwell} = 900s$ and another pulse period, with a ramp down and ramp up between them of $T_{ramp} = 300s$. These are estimated from the DEMO pre-concept design [2]. The simulation covers the period of interest, namely the ramp-dwell-ramp dynamics. The bounds on the decision variables are $2000m^3 \leq V_{tank} \leq 8000m^3$, $0.25 \leq \varphi \leq 1$ and $500MW \leq P_{pulse} \leq 750MW$.

To evaluate the inequality constraints, a simulation must be performed using the dynamic model of the power conversion system presented in section 2. A multi-objective plant propagation optimization algorithm, as implemented by the Fresa.jl package [5], is used to solve the optimization problem. Fresa is a black-box optimization algorithm that does not require gradients which would be computationally costly to estimate using finite differences. Fresa is also population-based, allowing for many simulations to be run in parallel, making effective use of multi-core desktop computers. The OMJulia.jl

**Table 2:** Parameters used for the *solve* function of Fresa. For more detailed explanations, please refer to the documentation at ucl.ac.uk/~ucecesf/fresa.html.

| Description | Parameter | Value |
|---|---|---|
| Number of objective evaluations before stopping | $nfmax$ | $100$ |
| Number of solutions to propagate each generation | $np$ | $(20,40)$ |
| Parameter for similarity function | $\epsilon$ | $0.01$ |
| Multi-objective solutions ranked based on [2] | $fitnesstype$ | $:nondominated$ |
| Solutions are compared based on their values of $\boldsymbol{x}$ | $issimilar$ | $Fresa.similarx$ |
| The non-dominated solutions are automatically included in the next generation | $elite$ | $true$ |
| Any pruned non-dominated solutions are added back to the population at the end of the run | $archiveelite$ | $true$ |

**Table 3:** Infeasibility $g$ of different simulation outcomes, favoring designs that are expected to be closer to being feasible. $t_{failure}$ is the internal simulation time at the failure. $\Delta V_{MS}$ is the change in stored hot molten salt at the end of the simulation relative to one full cycle earlier in the simulation.

| Simulation Outcome | Reasoning | $g$ |
|---|---|---|
| Simulation takes longer than $1{,}800s$ | Undesirable behaviour, like oscillations, are slowing the simulation | $1e6$ |
| Simulation fails before initialization | Unknown error | $1e3$ |
| Simulation fails after initialization | Molten salt is being greatly over/under-utilized in the design, so $P_{pulse}$ needs to be adjusted | $1+(1-\frac{t_{failure}}{T_{sim}})$ |
| Simulation completes successfully | Designs that underutilize molten salt will be feasible but outcompeted by propagated designs that balance molten salt better and have smaller tanks – useful to keep in the population | $-\frac{\Delta V_{MS}}{V_{tank}}-0.01$ |

package is used to run the Modelica model within Julia. The Fresa parameters used are presented in Table 2. With these parameters, 126 calls of Fresa.solve are made, each one being initialized with the final population of the previous run. This is necessary to clear simulation processes from memory periodically.

The simulation based objective function assigns an infeasibility value, g, to every design. Designs with g≤0 are considered feasible and other values indicate infeasible designs. This indication of feasible and infeasible is used by Fresa in the selection of solutions to propagate during the search. To help the algorithm search, different simulation outcomes are identified for calculating g, shown in Table 3.

## NON-DOMINATED DESIGNS OF THE POWER CONVERSION SYSTEM

The set of non-dominated designs found by the optimization algorithm is presented in Figure 2. The flexibility in turbine operation during a dwell can allow for the volume of the molten salt tanks to be reduced by up to 40.5% at the cost of a 46.3% reduction in the dwell turbine power output relative to pulse values.

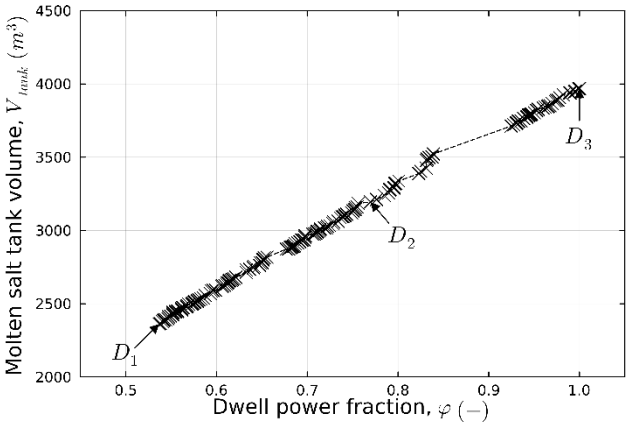

**Figure 2:** Non-dominated designs showing the trade-off between the size of the thermal energy storage and the fraction of pulse turbine power produced during dwells. Three designs $D_1$, $D_2$, $D_3$ are selected for later discussion.

To investigate the effectiveness of the power conversion system designs, three designs are selected evenly across the range of φ to show their different dynamics. These are shown in Figure 2, and their decision variables are given in Table 4. The dynamics at the turbine are presented in Figure 3, as it is identified as being one of the most sensitive components to large transients.

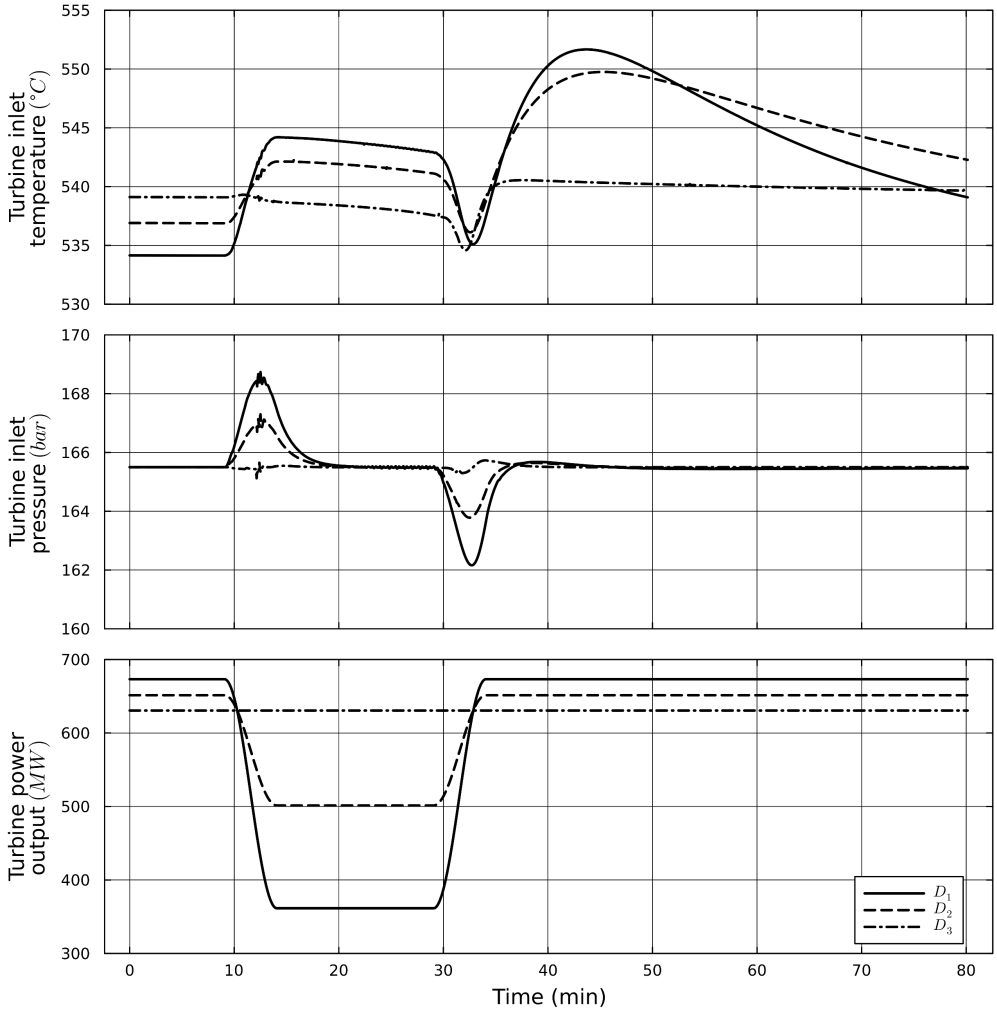

**Figure 3:** Dynamics of the turbine inlet temperature, inlet pressure and power output of three non-dominated designs from the final population. The time covers a dwell period and part of a subsequent pulse period, when process transients are most significant. Note that the turbine inlet temperature is not directly controlled by a proportional-integral controller, unlike the other two variables.

**Table 4:** Decision variables of the three highlighted designs in Figure 2.

| | $V_{tank}$ (m$^3$) | $\varphi$ (-) | $P_{pulse}$ (MW) |
|---|---|---|---|
| $D_1$ | 2,363 | 0.5369 | 673.2 |
| $D_2$ | 3,195 | 0.7697 | 651.4 |
| $D_3$ | 3,969 | 1 | 630.6 |

Turbine inlet temperature is not directly controlled by any of the controllers and is largely driven by the temperature of molten salt in the hot tank and the flow rate of hot molten salt and steam through the superheater. Design $D_3$ shows the smallest fluctuation in turbine inlet temperature, which is due to the steam mass flow rate being approximately constant to maintain a constant power output in that design. Designs $D_1$, $D_2$ show larger fluctuations due to the decreasing mass flow rate of steam during a dwell. The slower decay of the temperature in design $D_2$ relative to $D_1$ is attributed to the increased thermal inertia of molten salt in the hot tank due to the larger tank size, and hence larger mass of 'residual' molten salt that will always be present in valid designs due to the constraints on tank levels discussed in section 3. For all three designs, the temperature change is small enough, and over long enough time periods, that thermal stresses should be acceptable [3].

The turbine inlet pressure is controlled by manipulating the mass flow rate of hot molten salt to the superheater, and the ramp periods can be seen to cause a pressure fluctuation in all the designs. As with the inlet temperature, the magnitude of the changes is larger for designs with larger changes in dwell power, with design

$D_3$ showing the smallest changes. During the ramp down, all three designs show a small period of small, higher frequency oscillations. This could be due to feedback between multiple controllers or poorly tuned controllers. This could be solved by using more advanced control methods, such as model predictive control, or by including key controller parameters as decision variables.

The turbine power output is well controlled by the controller manipulating the partial arc admission of steam to the turbine, with all designs following the set points well. As expected, designs that produce less power during the dwell produce more power during the pulse, as the total energy input to the system is the same for all designs and hence the total energy output will be the same too, neglecting small differences in efficiency.

Molten salt temperatures below freezing point occur at the preheater and dwell heater outlets for lower values of φ. For every design, heat exchangers are currently sized the same. Resizing the dwell heater for each design, based on its dwell power set point, or adjusting the control system to better regulate molten salt temperatures, such as via electric heaters, could address this.

## CONCLUSION

The use of a dynamic process model of a power conversion system for a pulsed fusion power plant in an optimization-based design procedure is presented. The process features the integration of multiple pulsed heat sources of different grades into a single power cycle. Simulations demonstrate this configuration is capable of effectively utilizing the lower grade heat, while maintaining stable operation of the steam Rankine cycle. The dynamic model is developed to minimize simulation time and support automated simulations, allowing for its use within an objective function of an optimization problem.

By using the dynamic model in an optimization framework, the flexibility of the power conversion system design to different dwell operating conditions was investigated. A set of non-dominated designs showed that the size of the molten salt tanks could be reduced by 40.5% by reducing the turbine power output during a dwell by 46.3% relative to during pulse. The dynamics of three non-dominated designs are presented, showing good control of the turbine inlet conditions in all three designs, even for designs with large changes in turbine power output. The control system caused small pressure oscillations in all three designs. Future work could be to include control system parameters as decision variables alongside the process variables considered here and to improve molten salt temperature control. Another interesting direction is to consider plant design for load following.

The optimization methodology can easily be extended to any process model developed in OpenModelica, which is a multi-domain simulation environment. Integration with Julia allows complex analysis to be performed with the design simulation results, giving great flexibility in the objective functions.

## ABSTRACT

In the steam power system for the centralized heat supply in an industrial park, heat demands of all consumers are satisfied by the energy station, leading to the high steam delivery costs caused by the several distant enterprises. Additionally, the number of steam levels is limited due to the trade-off between distance-related costs and heat cascaded utilization, thus some consumers are supplied with heat at higher temperature than that of required, resulting in the low energy efficiency. To deal with the above problems, this work proposes an optimization model for steam power systems (SPSs) in industrial parks, which incorporates the distributed heat supply and auxiliary steam turbines (ASTs). Field erected boilers (FEBs) can independently supply heat to consumers, thereby avoiding the excessive pipeline costs. ASTs are used for the re-depressurization of steam received by consumers, which can increase the electricity generation capacity and improve the temperature matching of heat supply and demand. A mathematical model is established for the problem, in which the influence of different numbers of steam levels is considered, and the SPSs are optimized by the objective function of minimizing the total annual cost (*TAC*). A case study illustrates that the optimal number of steam levels, and the selective installation of FEBs and ASTs for consumers, can effectively reduce the cost of pipeline network, increase the income of electricity generation, and minimize the *TAC* of the system.

**Keywords**: Steam power systems, Steam turbines, Distributed heat supply

## 1. INTRODUCTION

The optimization of steam power systems (SPSs) has been extensively studied since the 1980s. In previous studies, SPSs of individual plants were optimized mainly in terms of the equipment structure and operating conditions for the minimum total costs. Papoulias and Grossmann [1] were the first to adopt mathematical programming method to optimize stream flowrates and sizes of units in SPSs. The equipment efficiency and the steam physical properties were given as parameters in their work. Bruno et al. [2] used second order polynomial correlations to calculate steam physical properties, and added the constraints related to steam physical properties in the model. Aguilar et al. [3] developed the equipment models, so that the variations in equipment efficiency were described. Sun et al. [4] noted the unsaturated steam conditions and obtained more realistic energy targets. Recently, Jiménez-Romero et al. [5] were the first to consider the effects of different numbers of steam levels in SPSs. However, in their study, the spatial scale of the SPSs was still limited to a single plant, thus the distance-related costs were neglected. At the spatial scale of industrial parks, there is a trade-off between energy cascaded utilization and distance-related costs in SPSs. As a remedy, we previously proposed a distributed steam turbine system model for optimizing the SPSs in industrial parks [6], aiming to balance the energy cascaded utilization and distance-related costs. Nevertheless, in Ref. [6], all consumers were supplied by a centralized energy station, leading to the high steam delivery costs caused by the several distant enterprises. Therefore, based on our previous research, this work provides consumers with the option of distributed heat

supply in an effort to further reduce the distance-related costs and the total cost of the system.

## 2. PROBLEM STATEMENT

In an industrial park, enterprises and the energy station have been built at fixed locations. Enterprises are the heat consumers with different required temperatures and heat loads, and are denoted as $i$, $i \in I$, $I = \{I_1, I_2, \ldots, I_m\}$. The energy station supplies heat to enterprises using steam as the medium. In the energy station, very high pressure steam (VHPS) is produced in a large package boiler (LPB) with fuel consumed, and then is depressurized through main steam turbines (MSTs) into lower-pressure steam for heat supply, while electricity is generated, so that energy is utilized in cascade. Steam levels are denoted as $s$, $s \in S$, $S = \{S_1, S_2, \ldots, S_n\}$. Nonetheless, extremely high cost of the pipeline network is incurred when each required temperature is corresponded with a level of steam. Therefore, the number of steam levels is limited, and some consumers are supplied with heat at higher temperature than that is required. In this situation, auxiliary steam turbines (ASTs) are selectively installed for consumers, by which the received steam is re-depressurized, thereby increasing the electricity generation capacity. In addition, each consumer can choose to install a field erected boiler (FEB) for the distributed heat supply, so that the cost of steam pipeline network (SPN) is reduced. In the SPS, the costs include the capital cost of LPB ($C^{LPB,cap}$), the cost of fuel consumed by LPB ($C^{LPB,fuel}$), the cost of FEBs ($C^{FEB}$), the cost of steam turbines ($C^{turb}$), and the cost of SPN ($C^{pipe}$), while the income from electricity generation ($I^{elec}$) is obtained. In this study, the mathematical model is established and solved to determine the optimal number of steam levels, the operating conditions (such as saturation temperature and mass flow rate) and supply scheme of each steam level, and the configuration of FEBs and ASTs, aiming to design the SPS with the minimum total annual cost (*TAC*). The objective function is expressed by Eq. (1). The superstructure for the SPSs is expressed in Figure 1.

$$min\{TAC = C^{LPB,cap} + C^{LPB,fuel} + C^{FEB} + C^{turb} + C^{pipe} - I^{elec}\} \quad (1)$$

## 3. MODEL FORMULATION

### 3.1. Centralized steam production model

The pressure and temperature of VHPS are set as 4.5 MPa and 400 °C, respectively. The corresponding saturation temperature ($T^{VHPS,sat}$) and specific enthalpy ($h^{VHPS}$) are 257.4 °C and 3207 kJ.kg$^{-1}$, respectively. The physical properties of steam levels are calculated by fitting formulas Eqs. (2)-(5), with saturation temperature of steam levels $T_s^{MST,sat}$ as the independent variable.

$$h_s^{l,MST,sat} = 4.431 \cdot T_s^{MST,sat} - 29.89 \quad (2)$$

$$\Delta h_s^{is,MST} = -4.876 \cdot T_s^{MST,sat} + 1251 \quad (3)$$

$$\rho_s^v = 0.0005078 \cdot \left(T_s^{MST,sat}\right)^2 - 0.1053 \cdot T_s^{MST,sat} + 6.148 \quad (4)$$

$$\rho_s^l = -1.053 \cdot T_s^{MST,sat} + 1071 \quad (5)$$

where $h_s^{v,MST,sat}$ and $h_s^{l,MST,sat}$ are the specific enthalpies of saturated vapor and liquid of steam level $s$, respectively. $\Delta h_s^{is,MST}$ is the specific isentropic enthalpy difference of steam across the MST. $\rho_s^v$ and $\rho_s^l$ are the densities of vapor and condensate of steam level $s$.

The performance of MSTs is formulated by the

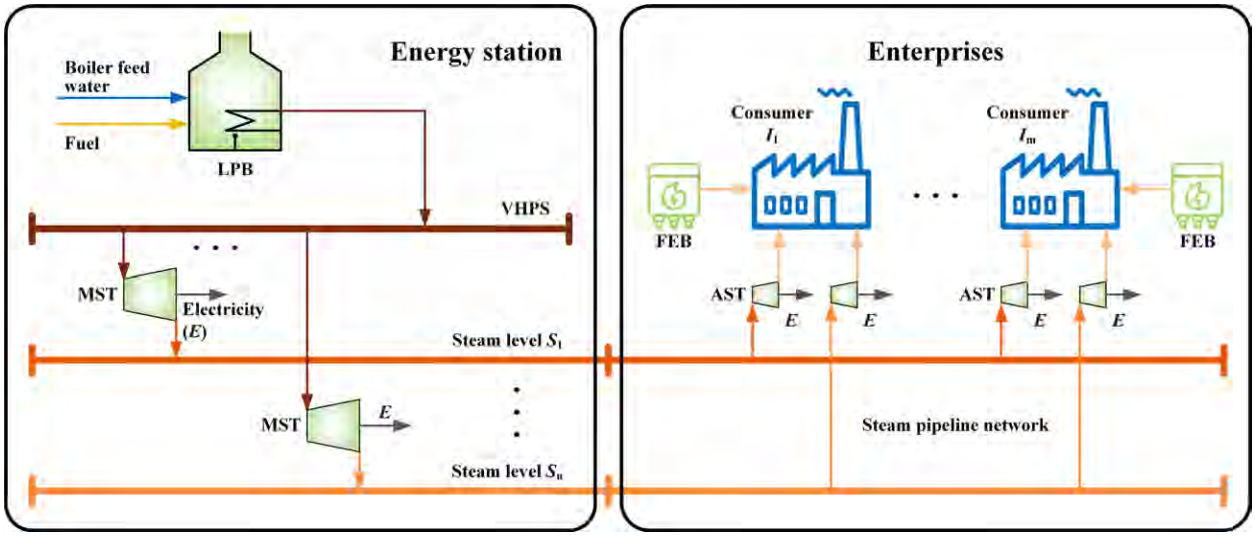

**Figure 1:** Superstructure of SPSs in industrial parks with FEBs and ASTs

model developed by Aguilar et al. [3], as expressed by Eqs. (6)-(8).

$$W_s^{MST} = \frac{m_s^{level} \cdot \Delta h_s^{is,MST} - [a_0 + a_1 \cdot (T^{VHPS} - T_s^{MST,sat})]}{a_2 + a_3 \cdot (T^{VHPS} - T_s^{MST,sat})} \quad (6)$$

$$h_s^{v,MST,out} = \frac{m_s^{level} \cdot h^{VHPS} - W_s^{MST}}{m_s^{level}} \quad (7)$$

$$h_s^{HV,MST} = h_s^{v,MST,out} - h_s^{l,MST,sat} \quad (8)$$

where $W_s^{MST}$ is the shaft work of the MST for steam level $s$. $a_0$, $a_1$, $a_2$ and $a_3$ are the parameters. $h_s^{v,MST,out}$ and $h_s^{HV,MST}$ are the specific enthalpy and specific heat value of steam out from the MST, respectively.

The mass balance of steam levels is represented by Eq. (9).

$$m^{VHPS} = \sum_s m_s^{level} \quad (9)$$

## 3.2. Centralized steam supply model

In this work, the steam pipeline network is simply formulated. Consumers are divided into four directions, and are connected to the energy station by main and branch pipelines. Directions are denoted as $d$, $d \in D$, $D$ = {East, West, North, South}. Consumers in each direction are denoted as $j$, $j \in J$, $J = \{J_1, J_2, \ldots, J_k\}$. The lengths of main pipeline segments $L_{d,j}^{main,seg}$ is calculated by Eq. (10) and Eq. (11), and the lengths of branch pipeline segments $L_{d,j}^{bran}$ is calculated by Eq. (12).

$$L_{d,j}^{main} = \begin{cases} X_i, & d = \text{East}(\,|X_i| \geq |Y_i|, X_i > 0) \\ |X_i|, & d = \text{West}(\,|X_i| \geq |Y_i|, X_i < 0) \\ Y_i, & d = \text{North}(\,|X_i| < |Y_i|, Y_i > 0) \\ |Y_i|, & d = \text{South}(\,|X_i| < |Y_i|, Y_i < 0) \end{cases} \quad (10)$$

$$L_{d,j}^{main,seg} = \begin{cases} L_{d,j}^{main} & (j = J_1) \\ L_{d,j}^{main} - L_{d,j-1}^{main} & (j \neq J_1) \end{cases} \quad (11)$$

$$L_{d,j}^{bran} = \begin{cases} |Y_i|, & d = \text{East} \\ |Y_i|, & d = \text{West} \\ |X_i|, & d = \text{North} \\ |X_i|, & d = \text{South} \end{cases} \quad (12)$$

where $L_{d,j}^{main}$ is the distance of consumer $j$ in direction $d$ from the energy station in the main direction. $X_i$, $Y_i$ are the coordinates of consumer $i$ while the location of the energy station is set as the original coordinate.

The binary variable $y_{s,d,j}^{sup}$ is used to determine the supply scheme of steam levels, as expressed by the Big-M constraint Eq. (13).

$$m_{s,d,j}^{sup} \leq y_{s,d,j}^{sup} \cdot M^{sup,max} \quad (13)$$

where $m_{s,d,j}^{sup}$ is the mass flow rate of steam level $s$ supplied to consumer $j$ in direction $d$. Parameter $M^{sup,max}$ is the upper bound of $m_{s,d,j}^{sup}$.

The temperature constraint of steam supply is represented by Eq. (14).

$$T_s^{MST,sat} \geq y_{s,d,j}^{sup} \cdot T_{d,j}^{need} \quad (14)$$

where $T_{d,j}^{need}$ is the required temperature of each heat consumer.

The mass balance of steam in the pipeline network is formulated by Eqs. (15)-(17).

$$m_s^{level} = \sum_d m_{s,d}^{dire} \quad (15)$$

$$m_{s,d}^{dire} = \sum_j m_{s,d,j}^{sup} \quad (16)$$

$$m_{s,d,j}^{main,seg} = \begin{cases} m_{s,d}^{dire} & (j = J_1) \\ m_{s,d,j-1}^{main,seg} - m_{s,d,j-1}^{sup} & (j \neq J_1) \end{cases} \quad (17)$$

where $m_{s,d,j}^{sup}$ is the mass flow rate of steam level $s$ supplied to direction $d$. $m_{s,d,j}^{main,seg}$ is the mass flow rate of steam in each main pipeline segment.

The inner diameters of steam main and branch pipeline segments ($D_{s,d,j}^{in,v,main,seg}$ and $D_{s,d,j}^{in,v,bran}$) are calculated by Eq. (18) and Eq. (19), respectively. The inner diameters of condensate main and branch pipeline segments ($D_{s,d,j}^{in,l,main,seg}$ and $D_{s,d,j}^{in,l,bran}$) are calculated by Eq. (20) and Eq. (21), respectively. The above inner diameters of pipelines are used to calculate the capital cost of the pipeline network $C^{pipe}$.

$$D_{s,d,j}^{in,v,main,seg} = \sqrt{\frac{4 \cdot m_{s,d,j}^{main,seg}}{\pi \cdot u^v \cdot \rho_s^v}} \quad (18)$$

$$D_{s,d,j}^{in,v,bran} = \sqrt{\frac{4 \cdot m_{s,d,j}^{sup}}{\pi \cdot u^v \cdot \rho_s^v}} \quad (19)$$

$$D_{s,d,j}^{in,l,main,seg} = \sqrt{\frac{4 \cdot m_{s,d,j}^{main,seg}}{\pi \cdot u^l \cdot \rho_s^l}} \quad (20)$$

$$D_{s,d,j}^{in,l,bran} = \sqrt{\frac{4 \cdot m_{s,d,j}^{sup}}{\pi \cdot u^l \cdot \rho_s^l}} \quad (21)$$

## 3.3. Consumer side model

The conditions of steam received by each consumer, including the saturation temperature $T_{d,j}^{rece}$, the mass flow rate $m_{d,j}^{rece}$, the specific enthalpy $h_{d,j}^{v,rece}$, the specific heat value $h_{d,j}^{HV,rece}$, are calculated by Eqs. (22)-(25).

$$T_{d,j}^{rece} = \sum_s \left( y_{s,d,j}^{sup} \cdot T_s^{MST,sat} \right) \quad (22)$$

$$m_{d,j}^{rece} = \sum_s \left( y_{s,d,j}^{sup} \cdot m_{s,d,j}^{sup} \right) \quad (23)$$

$$h_{d,j}^{v,rece} = \sum_s \left( y_{s,d,j}^{sup} \cdot h_s^{v,MST,out} \right) \quad (24)$$

$$h_{d,j}^{HV,rece} = \sum_s \left( y_{s,d,j}^{sup} \cdot h_s^{HV,MST} \right) \quad (25)$$

The existence of AST for each consumer is determined by the binary variable $z_{d,j}^{AST}$, and it is related to the

saturation temperature drop $\Delta T_{d,j}^{sat,AST}$, as expressed by Eq. (26).

$$\Delta T_{d,j}^{sat,AST} \le z_{d,j}^{AST} \cdot \Delta T^{sat,AST,max} \quad (26)$$

where parameter $\Delta T^{sat,AST,max}$ is the upper bound of $\Delta T_{d,j}^{sat,AST}$.

The performance of ASTs is formulated by Eqs. (27)-(31).

$$\Delta h_{d,j}^{is,AST} = \frac{\Delta T_{d,j}^{sat,AST}}{1854-1931 \cdot h_{d,j}^{HV,rece}} \quad (27)$$

$$W_{d,j}^{AST} = \frac{m_{d,j}^{rece} \cdot \Delta h_{d,j}^{is,AST} - \left(z_{d,j}^{AST} \cdot a_0 + a_1 \cdot \Delta T_{d,j}^{sat,AST}\right)}{a_2 + a_3 \cdot \Delta T_{d,j}^{sat,AST}} \quad (28)$$

$$h_{d,j}^{v,AST,out} = \frac{m_{d,j}^{rece} \cdot h_{d,j}^{v,rece} - W_{d,j}^{AST}}{m_{d,j}^{rece}} \quad (29)$$

$$h_{d,j}^{l,AST,sat} = 4.431 \cdot \left(T_{d,j}^{rece} - \Delta T_{d,j}^{sat,AST}\right) - 29.89 \quad (30)$$

$$h_{d,j}^{HV,AST} = h_{d,j}^{v,AST,out} - h_{d,j}^{l,AST,sat} \quad (31)$$

where $\Delta h_{d,j}^{is,AST}$ is the specific isentropic enthalpy difference of steam across the AST, and it is calculated by Singh's model [7]. $W_{d,j}^{AST}$ is the shaft work of the AST. $h_{d,j}^{v,AST,out}$ and $h_{d,j}^{HV,AST}$ are the specific enthalpy and specific heat value of steam out from the AST, respectively. $h_{d,j}^{l,AST,sat}$ is the specific enthalpy of saturated liquid of steam out from the AST.

The existence of FEB for each consumer is determined by the binary variable $z_{d,j}^{FEB}$. The relations among the centralized steam supply, AST, and FEB for each consumer are represented by Eq. (32) and Eq. (33).

In this work, it is assumed that the FEBs produce saturated steam at the required temperature of consumers, thus no electricity is generated at the same time. The saturation temperature of steam and the heat load actually used by each consumer ($T_{d,j}^{use}$ and $Q_{d,j}^{use}$) are expressed by Eq. (34) and Eq. (35), respectively. The former is constrained by Eq. (36), and the latter satisfies the energy balance, as expressed by Eq. (37).

$$\sum_s y_{s,d,j}^{sup} + z_{d,j}^{FEB} = 1 \quad (32)$$

$$z_{d,j}^{AST} \le \sum_s y_{s,d,j}^{sup} \quad (33)$$

$$T_{d,j}^{use} = \left(T_{d,j}^{rece} - \Delta T_{d,j}^{sat,AST}\right) + z_{d,j}^{FEB} \cdot T_{d,j}^{need} \quad (34)$$

$$Q_{d,j}^{use} = m_{d,j}^{rece} \cdot h_{d,j}^{HV,AST} + z_{d,j}^{FEB} \cdot Q_{d,j}^{need} \quad (35)$$

$$T_{d,j}^{use} \ge T_{d,j}^{need} \quad (36)$$

$$Q_{d,j}^{use} = Q_{d,j}^{need} \quad (37)$$

where $Q_{d,j}^{need}$ is the required heat load of each heat consumer.

## 3.4. Objective function calculation

The economic terms $C^{LPB,cap}$, $C^{LPB,fuel}$, $C^{FEB}$, and $C^{turb}$ in Eq. (1) are calculated by the formulas presented by Bruno et al. [2]. $C^{pipe}$ and $I^{elec}$ are calculated according to the methods in Ref. [8] and Ref. [9], respectively. The above calculations are not shown in detail here.

In this mathematical programming model, there are non-linear constraints for the steam physical properties, the equipment performance, and the energy balance. Furthermore, binary variables are used for the steam supply selectivity and the existence of equipment. Therefore, the model is formulated as a mixed-integer nonlinear programming (MINLP) model.

# 4. CASE STUDY

## 4.1. Data

As shown in Table 1, this case includes fourteen consumers. Different numbers of steam levels (*n*) are considered, ranging from one to five.

## 4.2. Model solution and results

The model is solved by a two-layer algorithm to deal with the solution difficulty, as shown in Figure 2. In the outer layer, the particle swarm optimization (PSO) algorithm transforms the variable $T_s^{MST,sat}$ into a parameter, and assigns it to the inner MINLP model. Once the saturation temperature of each steam level is determined, the supply selectivity of some consumers is eliminated due to the temperature constraint Eq. (14). Therefore, the feasible region is reduced and the inner model is much easier to be solved. In this work, the inner MINLP model is solved using Gurobi 11.0.1 as the solver.

**Table 1:** Data of consumers.

| i | $X_i$ (m) | $Y_i$ (m) | $T_i^{need}$ (°C) | $Q_i^{need}$ (MW) |
|---|---|---|---|---|
| $I_1$ | 850 | 250 | 180 | 4.3 |
| $I_2$ | 1450 | 400 | 125 | 4.8 |
| $I_3$ | 1700 | -650 | 135 | 3.1 |
| $I_4$ | 1900 | 550 | 200 | 5.2 |
| $I_5$ | -600 | 500 | 160 | 3.4 |
| $I_6$ | -900 | -150 | 175 | 2.9 |
| $I_7$ | -1500 | 300 | 190 | 4.0 |
| $I_8$ | -1800 | -800 | 200 | 6.0 |
| $I_9$ | -250 | 700 | 175 | 4.2 |
| $I_{10}$ | 650 | 1200 | 140 | 5.6 |
| $I_{11}$ | 650 | 1200 | 225 | 2.3 |
| $I_{12}$ | -500 | 1700 | 240 | 5.7 |
| $I_{13}$ | 950 | -1300 | 210 | 4.1 |
| $I_{14}$ | -550 | -1650 | 150 | 6.5 |

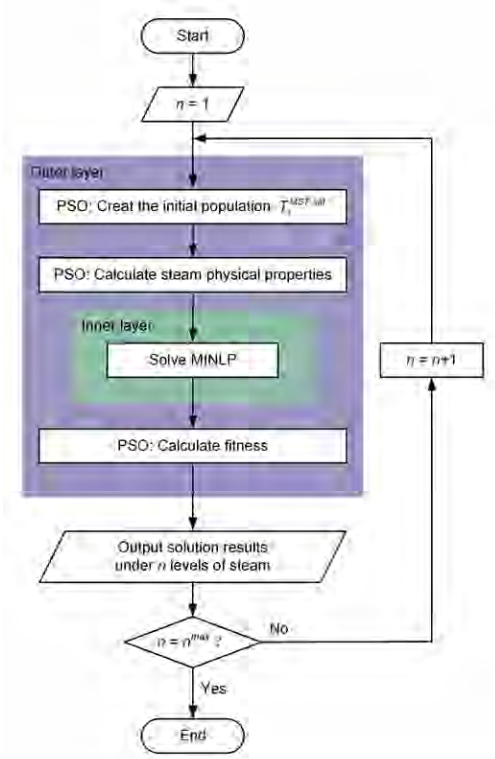

**Figure 2. Solution algorithm.**

The economic performance of the SPS under different numbers of steam levels is shown in Figure 3. It is indicated that the *TAC* of the SPS is minimized when the number of steam levels is two. The corresponding optimal scheme is presented in Figure 4.

## 4.3. Discussion

Figure 3 illustrates that among the different numbers of steam levels, the scheme with two steam levels has the second-lowest $C^{LPB,fuel}$, the second-lowest $C^{pipe}$, and the third-highest $I^{elec}$. The economic items of the system are well balanced, thus the lowest *TAC* is achieved. In this case, three consumers (J3, J4 in the North direction, and J1 in the South direction) require heat at temperatures higher than the saturation temperature of the two steam levels. Their required temperatures are 225 °C, 240 °C, and 210 °C, respectively. Therefore, FEBs are needed by them for distributed heat supply. As a consequence, the total length of the SPN decreases, thus $C^{pipe}$ is reduced. On the other hand, the configuration of FEBs for the three consumers with high required temperature also allows the lower outlet saturation temperature of MSTs in the energy station, leading to the rise of the isentropic enthalpy change of MSTs. Therefore, a substantial electricity generation capacity is obtained, despite the reduction in the mass flow of VHPS. Besides, the combined electricity generation capacity of the three ASTs accounts for 8.5% of the total electricity generation capacity, also contributing to the reduction of *TAC*.

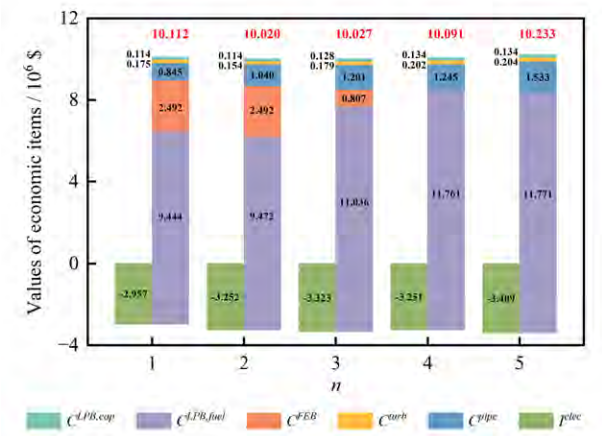

**Figure 3.** Economic results of the SPS.

## 5. CONCLUSIONS

An optimization model including the distributed heat supply and ASTs has been established for the SPSs in industrial parks. A case study demonstrates that the economic items of the SPSs vary with the number of steam levels. In this case, the optimal number of steam levels is two. With the arrangement of three FEBs and three ASTs, $C^{pipe}$ decreases and $I^{elec}$ increases, ultimately leading to the optimal design of the SPS with the minimum *TAC*.

## ABSTRACT

This work presents a plantwide model of a Haber-Bosch ammonia synthesis loop (HB-loop) in a PtA plant, consisting of heat exchangers, compressors, steam turbines, flash separators and catalytic reactor beds. The total electrical power utility of the HB-loop is a combination of compressor power, refrigeration power, and steam turbine power. We optimise the HB-loop operating parameters, subject to constraints for maximum reactor temperatures, compressor choke and stall, minimum steam temperature, and maximum loop pressure. The loop features six degrees of freedom (DOFs) for the optimisation: three reactor temperatures, reactor $N_2/H_2$-ratio, separator temperature, and loop pressure. The optimisation minimises the total loop power utility for a given hydrogen make-up feed flow, with the PtA load varied by ranging the hydrogen make-up feed flow from 10 % to 120 % of the nominal. Across this load range, different constraints become active, with the compressor surge limit being particularly critical at low loads, significantly increasing HB-loop power consumption. To address this, we investigate configurations with two, three, and four compressor trains operating in parallel. Reductions in total power of 55%, 74%, and 84% are achieved at reduced plant loads, with two, three, and four parallel trains, respectively. In terms of total compressor capital and operating cost, we demonstrated savings of 8.06%, 8.29%, and 7.11% in total cost after ten years of operation with two, three, and four parallel compressor trains compared to a single train configuration.

**Keywords**: Power-to-Ammonia, Synthesis loop model, Optimisation, Parallel compressors.

## 1 INTRODUCTION

Power-to-X (PtX) is one of the most promising solutions for long-term storage of renewable energy such as wind and solar power [1]. Among the various PtX technologies, Power-to-Ammonia (PtA) receives significant attention due to its ability to store and recover energy without carbon dioxide emissions. PtA employs the traditional Haber-Bosch synthesis loop but with hydrogen produced via electrolysis rather than steam-methane reforming and nitrogen from air separation. The hydrogen production consumes around 90 % of the total plant electricity and hence highly depends on the available renewable energy. Due to the intermittent nature of renewable power sources, the synthesis loop is required to operate across a broad operating envelope from 10 % to 120 % of the nominal synthesis feed flow [2]. In [3], we developed dynamic models for three general ammonia reactor types: adiabatic quench-cooled (AQCR), adiabatic indirect-cooled (AICR), and internal direct-cooled reactors (IDCR). These reactors were optimised across a wide range of feed flow rates and evaluated for flexibility and robustness in a PtA plant, with the AICR and IDCR identified as the most suitable options.

In this work, we expand the scope by introducing a model for the entire HB synthesis loop, including an AICR reactor. The study focuses on optimising the HB-loop across the operating range from 10 % to 120 % of the nominal hydrogen make-up feed flow. We evaluate different loop designs with multiple parallel compressors to identify the most economical configuration.

## 2 SYNTHESIS LOOP MODEL AND OPTIMISATION

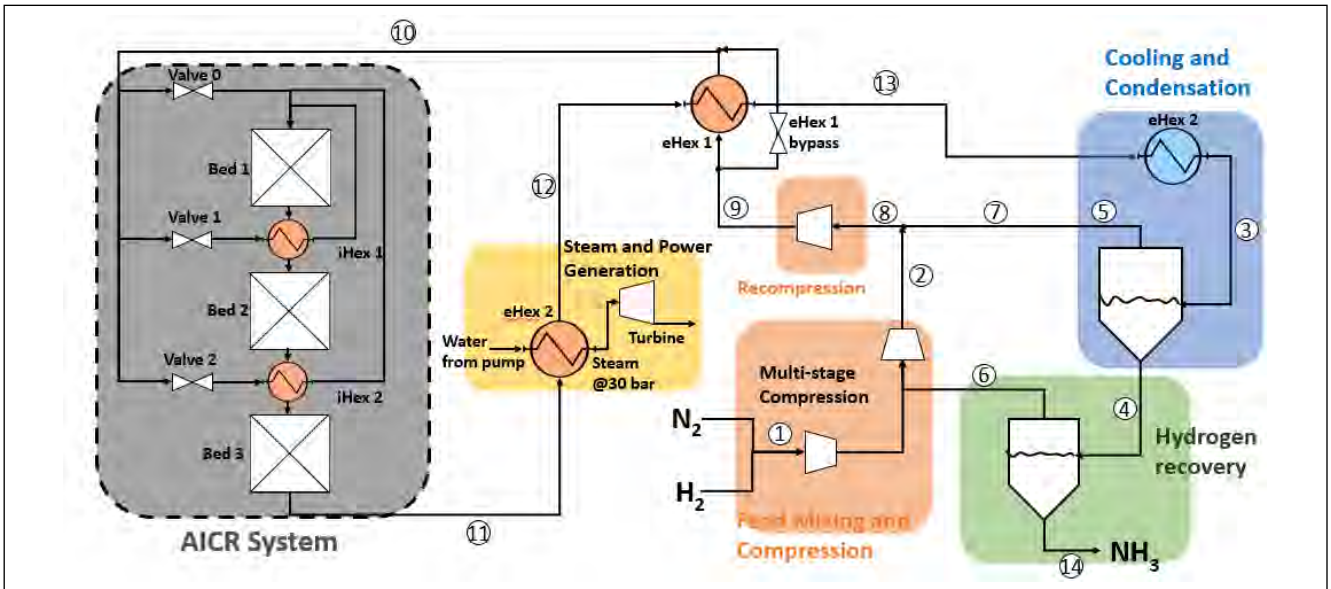

**Figure 1:** Schematic illustration of the Haber Bosch synthesis loop with an adiabatic indirect cooled reactor (AICR). Streams connecting the operating units are numbered as indicated in the diagram.

Figure 1 shows the Haber-Bosch ammonia synthesis loop. The make-up gas of hydrogen and nitrogen is compressed to the high synthesis loop pressure (>80 bar) and preheated before entering the reactor. The nitrogen feed, produced via air separation, contains 0.1% argon, significantly lower than the 1.2% found in conventional ammonia plants, where the nitrogen is supplied directly from combustion air. This eliminates the need for a purge stream in the synthesis loop as the solubility in the liquid ammonia product stream balances the argon build-up.

## 2.1 Reactor and heat exchanger model

The AICR consists of a combination of catalytic fixed beds and counter-current heat exchanges. The catalytic beds are assumed to be adiabatic and modelled in one dimension along the axial direction. Furthermore, we assume no transport limitations within the catalytic particles, which implies isothermal catalytic particle phase and gas phase. The reactor model is extensively described in [3]. The pressure drop across the catalytic bed is determined using Ergun's equation,

$$\frac{\mathrm{d}P}{\mathrm{d}l} = \frac{180\mu^g}{d_p^2}\frac{(1-\epsilon)^2}{\epsilon^3}v_s + \frac{1.75\rho^g}{d_p}\frac{(1-\epsilon)}{\epsilon^3}v_s^2, \qquad (1)$$

in which $P$ is the pressure, $\mu^g$ is the gas viscosity, $\rho^g$ is the gas density, $d_p$ is the hydraulic diameter of the catalyst particles and $v_s$ is the superficial gas velocity.

## 2.2 Compressor model

Centrifugal compressors are employed in the ammonia synthesis loop to compress the make-up feed gas and re-compress the recycle stream. The compressors are modelled based on isentropic compression from inlet pressure, $P_1$, to outlet pressure $P_2$,

$$S(T_1, P_1, F_{comp.}) = S(T_s, P_2, F_{comp.}), \qquad (2a)$$

$$W_{s,\ comp.} = H(P_{out}, T_s, N) - H(P_{in}, T_{in}, N), \qquad (2b)$$

with $W_{s,\ comp.}$ being the work of the isentropic compression. The real outlet temperature, $T_2$, and work, $W_{comp.}$, are found by solving,

$$\eta_s W_{comp.} = W_{s,\ comp.}, \qquad (2c)$$

$$W_{comp.} = H(T_2, P_2, F_{comp.}) - H(T_1, P_1, F_{comp.}), \qquad (2d)$$

where $\eta_s$ is the isentropic efficiency. The compressor efficiency is assumed to follow a polynomial expression as a function of the corrected flow, $F_{cor.}$,

$$\eta_s(F_{cor.}) = -0.44\left(\frac{F_{cor.}}{F_{n,\ comp.}}\right)^2 + 0.85\left(\frac{F_{cor.}}{F_{n,\ comp.}}\right) + 0.35, \qquad (2e)$$

where $F_{n,\ comp.}$ is the nominal compressor flow. The corrected flow is given by, $F_{cor} = F_{comp.}\frac{P_1}{P_{1n}}$, with $P_1$ being the compressor inlet pressure and $P_{1n}$ the inlet pressure at the design point. The coefficients of the polynomial ($a = -0.44, b = 0.85, c = 0.35$) are determined from a qualitative fit of a compressor map generated with Concept NREC® design software for the relevant [$N_2$,$H_2$,Ar,$NH_3$] gas mixture [4]. Furthermore, to prevent compressor surge and choke, the operating range of the compressors is restricted between 65 % and 130 % of the nominal compressor flow. Below 65 % corrected compressor flow, anti-surge recycle control is activated. The feed gas compression is performed using multistage compressors with a maximum compression ratio of 3.5 per stage.

## 2.3 Separator model

Due to the large difference in boiling points between ammonia and the synthesis gas, the product separation

**Table 1:** Optimal operating parameters and power distribution at nominal load.

| Optimal parameters | | Power distribution | |
|---|---|---|---|
| Bed inlet temperatures [K] | [724, 704, 694] | Feed compression | 5.50 MW |
| Reactor inlet pressure | 206.8 bar | Recycle compression | 0.18 MW |
| Separator temperature | 25 °C | Steam generator | 3.60 MW |
| Reactor $H_2/N_2$-ratio | 2.71 | Refrigeration power | 0 MW |
| | | **HB-loop power** | **2.11 MW** |

is achieved via a flash tank. The material balance over the flash tank is,

$$0 = F^{l}_{sep.} + F^{g}_{sep.} - F_{f,\ sep.}, \tag{3a}$$

where $F_{f,\ sep.}$ is the separator inlet flow, and $F^{l}_{sep.}$ and $F^{g}_{sep.}$ are respectively the liquid and gas flow exiting the separator. At vapour-liquid equilibrium the component chemical potentials of the phases are identical,

$$0 = \mu^{g}_{i}\left(T_{sep.}, P_{sep.}, x^{g}\right) - \mu^{l}_{i}\left(T_{sep.}, P_{sep.}, \mathrm{x}^{l}\right), \tag{3}$$

in which the chemical potential, $\mu_i$, of component $i$ is a function of the separator temperature, $T_{sep}$, pressure, $P_{sep}$, and composition, $x_{sep}$. The chemical potential of the gas and liquid mixtures are calculated with the thermodynamic tool `Thermolib` [5].

## 2.4 Cooling and Refrigeration

Cooling is performed before the separator and between stages for make-up feed compression. We assume cooling water is available at 15 °C and the heat exchangers are designed based on a 10 °C minimum temperature approach. Therefore, cooling below 25 °C requires a refrigeration cycle. Assuming a coefficient of performance of three ($COP = 3$), typical for refrigeration around 0 °C [6], the refrigeration power for cooling before the flash tank is,

$$W_{refrigiation} = \frac{\left(\dot{H}(25.0\ ^{\circ}\mathrm{C}, P_{sep.}, F_{sep.}) - \dot{H}(T_{sep.}, P_{sep.}, F_{sep.})\right)}{COP} \tag{4}$$

in which $\dot{H}$ is the enthalpy flow of the stream at the temperature, $T$, pressure, $P$, and flow $F$. The enthalpy flows in Eq. 4 are for two-phase flows.

## 2.5 Rankine cycle

The hot outlet stream from the reactor is around 750-820 K. This temperature facilitates the generation of superheated steam at 30 bar ($T^{@30\mathrm{bar}}_{sat} = 507.0\ ^{\circ}\mathrm{C}$), driving a turbine in a Rankine cycle. We assume a heat-to-electric power efficiency of, $\eta_{rankine} = 40\ \%$, representing a high-efficiency cycle with superheated steam [6]. Thus, the generated electrical power is given by,

$$W_{rankine} = \eta_{rankine}\begin{pmatrix}\dot{H}(T^{out}_{reac.}, P^{out}_{reac.}, F^{out}_{reac.}) \\ -\dot{H}(T_{S12}, P^{out}_{reac.}, F^{out}_{reac.})\end{pmatrix} \tag{5}$$

where $\dot{H}$ is the enthalpy flow of the stream at the temperature, $T$, pressure, $P$, and flow, $F$. $T_{S12}$ is the temperature of stream 12 (see Figure 1) given by $T_{S12} = T_{S10} + 10\ ^{\circ}\mathrm{C}$, where $T_{S10}$ is reactor feed temperature. The addition of $10\ ^{\circ}\mathrm{C}$ ensures sufficient temperature driving force in the pre-reactor external heat exchanger (Figure 1: eHex 1).

## 2.6 Optimisation problem

The electrical power consumption of the Harber-Bosch process consists of compressor and refrigeration power, while the steam turbine generates electricity. The total external electrical utility of the HB-loop, $W_{HB}$, is,

$$W_{HB} = W^{feed}_{comp} + W^{recycle}_{comp} + W_{refrigiation} - W_{rankine}. \tag{6}$$

We assume cooling water is a negligible operational cost. Hence, the total electrical power utility, $W_{HB}$, represents the cost function for the synthesis loop. As no purge stream figures in the PtA synthesis loop (see Figure 1), all hydrogen and nitrogen leave the synthesis loop by conversion to ammonia. This entails that hydrogen and nitrogen are fed at the stoichiometric ratio. Thus, for a given hydrogen make-up feed flow, minimising $W_{HB}$ represent the optimal solution. The optimisation involves six degrees of freedom (DOF): three reactor temperatures, $N_2/H_2$-ratio, separator temperature, and loop pressure. We define the DOFs in a vector, $\nu$,

$$\nu = \left[T^{in,1}_{reac.},\ T^{in,2}_{reac.},\ T^{in,3}_{reac.}, P^{in}_{reac.}, T_{sep.}, S_{\mathrm{H_2/N_2}}\right] \tag{7}$$

The optimal solution is found minimising the objective function across the six DOFs,

$$\min_{\nu} \quad W_{HB}, \tag{8a}$$

$$\text{s.t.} \quad f\left(x, y, F_{S1,\mathrm{H_2}}\right) = 0,\ g(x, y) = 0, \tag{8b}$$

$$0.65 \leq \frac{F_{cor.}}{F_{n,\ comp.}} \leq 1.3 \tag{8c}$$

where Eq. 8b represents the steady-state solution for a given hydrogen make-up flow, $F_{S1,\mathrm{H_2}}$, with $f$ and $g$ denoting the rate function and the algebraic equations as described in [3]. The optimisation problem is solved using the Matlab minimisation function `fmincon`. We define the specific HB-power cost for producing ammonia as,

$$E_{\mathrm{NH_3}} = \frac{W_{HB}}{\dot{m}_{\mathrm{NH_3}}}, \tag{9}$$

Where $\dot{m}_{\mathrm{NH_3}}$ is the mass flow of produced ammonia from the separator.

# 3 RESULTS

## 3.1 Optimisation at nominal load

The nominal load of the HB-loop is defined relative to a hydrogen make-up flow of 1.98 ton/h, corresponding to the 100 MW PtA plant presented in [7]. Table 1 summarises the optimal operating parameters and the corresponding power distribution when solving the optimisation in Eq. 8 at nominal load. The feed compression consumes most of the electrical utility with 5.50 MW, while the recycle compression only constitutes 0.18 MW. The optimal separator temperature of 25 °C is at the lower bound for water cooling, avoiding refrigeration power. A relatively big fraction of the electrical utility for compression is regained through the Rankine cycle delivering 3.6 MW. This sums to a total of 2.11 MW of external electrical utility required to power the HB-loop.

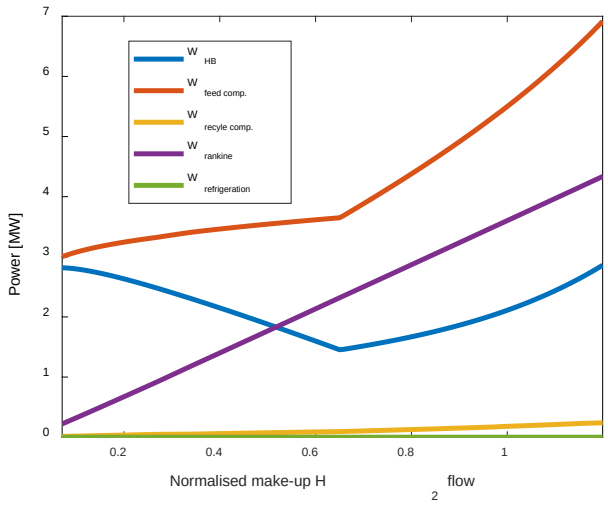

**Figure 2.** Distribution of power in the HB-loop across the operating envelope.

## 3.1 Optimisation across the operating window

We define the hydrogen load, $HL$, as the normalised make-up feed flow relative to the nominal flow,

$$HL = \frac{F_{S1,\mathrm{H_2}}}{F_{S1n,\mathrm{H_2}}}, \tag{10}$$

The optimisation problem in Eq. 8 is solved across the hydrogen load range from 10 % to 120 % of nominal flow. Figure 2 shows the optimal solution for the power utilities of the operating units across the operating window. The feed compressor power naturally decreases with the hydrogen load as less make-up feed gas is supplied. However, at 65 % of nominal hydrogen feed, the reduction in compressor power with hydrogen load is significantly restricted. This can be explained from Figure 3, showing the normalised corrected make-up feed and recycle flow along with the compressor surge limit across the operating envelope. The corrected feed flow intersects the surge line corresponding with the discontinuity in the feed compressor power in Figure 2. Reaching the surge line initiates the anti-surge recycling, limiting the decrease in compressor power. Figure 3 reveals that the recycle compressor reaches the surge line at a significantly lower load than the feed flow; however, its relatively smaller contribution to the total compressor power (see Figure 2) makes this effect negligible.

From Figure 2 we observe that the total HB-power, somewhat counterintuitively, increases with decreasing load when compressor anti-surge recycle is activated. This occurs because the power generated by the steam turbine decreases linearly with the hydrogen load, while the compressor power experiences only a slight reduction. Figure 4 illustrates that this dramatically impacts the specific ammonia production cost shown on the left y-axis. At reduced loads, the specific ammonia cost is up to twenty times higher relative to the nominal load. Additionally, Figure 4 displays the optimal reactor pressure across the operating envelope on the right y-axis. The optimal pressure decreases at reduced loads, explaining the slight decrease in feed compressor power seen in Figure 2 after reaching the surge limit.

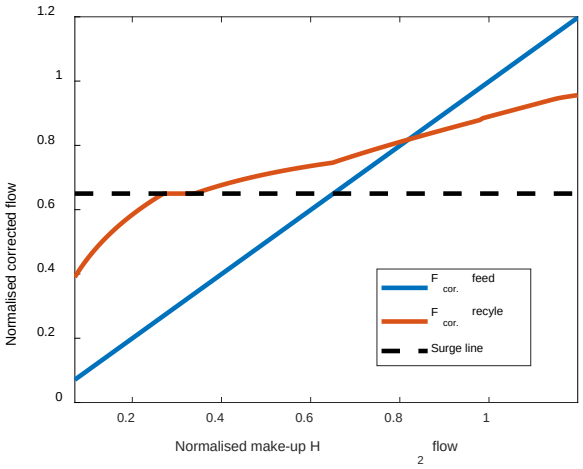

**Figure 3.** Normalised corrected flow for the feed and recycle compressors across the operating envelope.

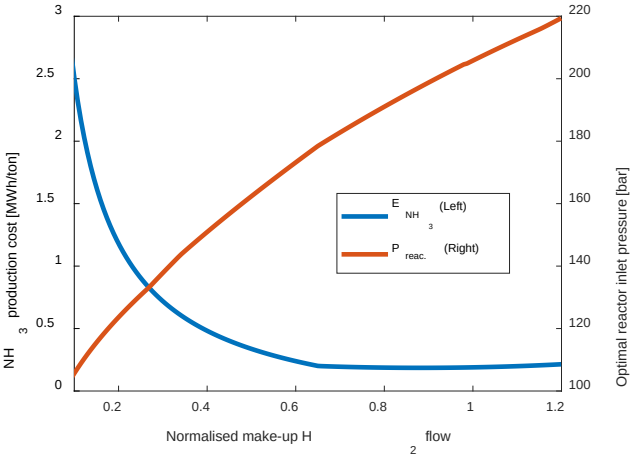

**Figure 4.** Left y-axis: Specific ammonia production cost.

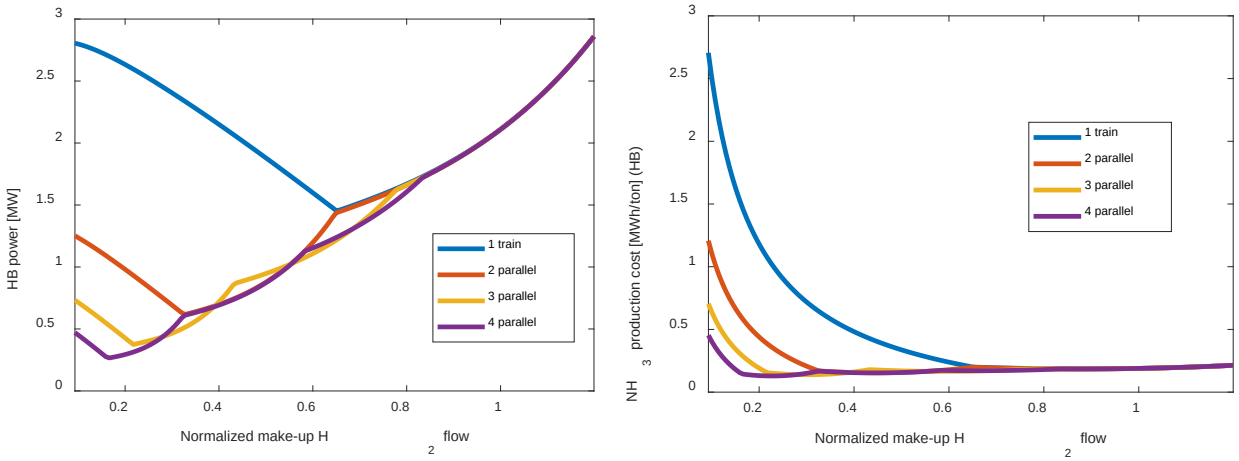

**Figure 4:** a) HB-power requirement and b) Specific ammonia production cost across the operating envelope with one, two, three and four parallel compressor trains.

Right y-axis: Optimal reactor pressure across the operating window.

## 3.1 Compressors in parallel

Figure 4 illustrates the drastic increase in ammonia production cost at low loads, caused by compressor anti-surge recycling. To reduce this loss, we investigate operating with multiple compressor trains in parallel. Parallel compressor trains extend the combined operational range of the compressors as one train can be stopped when the surge limit is reached. Additionally, multiple parallel compressors can facilitate higher compressor efficiency as the compressor flow can be distributed closer to the optimal operating flow. We solve the optimisation problem in Eq. 8 across the operating window with two, three, and four parallel compressor trains. Figure 5a displays the optimal HB-loop power for different compressor configurations, showcasing a significant reduction in HB-power by operating with multiple parallel compressor trains. At around 80 % hydrogen feed load, the configurations with 3 and 4 parallel compressor trains reduce the HB-power due to improved compressor efficiency achieved by pausing one compressor. However, the substantial reduction in HB-power occurs below the compressor surge limit, as the anti-surge recycling is shifted to 32.5 %, 21.7 % and 16.3 % of nominal hydrogen load for two, three and four parallel compressor trains, respectively.

Figure 5b shows the specific ammonia production cost across the operating envelope. Clearly, multiple parallel compressors significantly decrease production costs. At 10 % load, the ammonia production cost is reduced by 55 %, 74 % and 84 % for two, three and four parallel compressor trains, respectively.

# 5 ECONOMIC COMPARISON

Figures 4a and 4b illustrate that operating with multiple parallel compressor trains significantly reduces the HB-loop power during part-load operation. However, to evaluate the economic benefits, it is essential to consider the distribution of operating hours across the hydrogen loads. This is an extensive optimisation problem depending on factors such as the local wind and solar power distribution, the relative size of renewable power to the electrolyser and synthesis loop capacity, hydrogen storage size and electricity price. Performing this optimisation is not the scope of this paper, but was assessed by [2] and [8] . They concluded that wind and solar-powered PtA plants optimally operate mainly at minimum load, during periods of limited renewable power, or nominal load and above, during periods of surplus renewable energy. Complete reactor shutdown should be avoided as start-up times are extensive and frequent shutdowns damage the reactor catalyst [2,8]. Based on this, we assume an HB-loop capacity factor of 70 % with the hydrogen load distribution in Figure 5. The mean power consumption of the HB-loop is found from the probability density function, $p$, via,

$$\overline{W_{HB}} = \int_{0.1}^{1.2} W_{HB}(HL)p(HL)\,\mathrm{d}HL \tag{11}$$

Note $p$ is a piecewise function from the distribution in Figure 5. Table 2 summarises the mean HB-loop power for the four parallel compressor configurations. Approximately 25 % reduction in mean HB-power is achieved by operating with two parallel compressors, while further power savings are less significant for three and four parallel compressors.

**Table 2:** Mean HB-power with one, two, three or four compressor trains in parallel.

| **Par. compressors** | **1** | **2** | **3** | **4** |
|---|---|---|---|---|
| Mean HB-power [MW] | 2.14 | 1.60 | 1.45 | 1.37 |

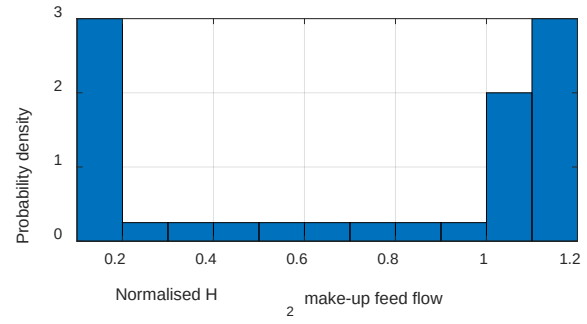

**Figure 5.** Probability density distribution of the synthesis loop load.

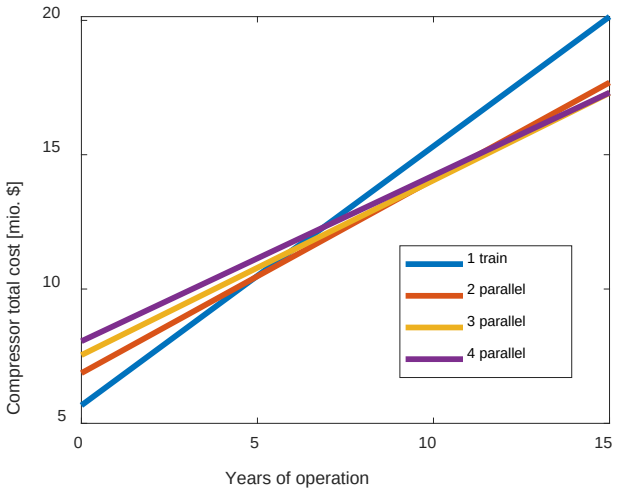

**Figure 6.** Total compressor cost (CAPEX + OPEX) for 15 years of operation with one, two, three or four compressor trains in parallel.

The compressor capital costs are assessed using the bare module cost (BMC) method described in [9]. Electricity is the only operational cost differentiating the parallel compressor configurations. We assume a relatively conservative electricity price of 0.045 $/kWh. Figure 7 displays the compressor systems' total cost (CAPEX + OPEX) as a function of years of operation. Naturally, the initial capital cost increases with the number of parallel compressors. However, the reduced electrical utility cost relatively quickly outweighs the additional capital costs. After ten years, operating with two, three, and four parallel compressor trains saves 8.06%, 8.29% and 7.11% of total costs, compared to a single train configuration. Additionally, from the redundancy principle, the reliability of the synthesis loop is significantly enhanced with more parallel compressors. Specifically, with three parallel trains, near full-load operation can be maintained using the remaining two compressor trains if one is out of function. Therefore, considering economic and reliability factors, we recommend the configurations with two or three parallel compressors for operation in a PtA plant.

## 5 CONCLUSION

In this work, we have introduced a static model of an ammonia synthesis loop to evaluate the total synthesis loop power. The power function was minimised to identify the optimal operating parameters for reactor bed inlet temperatures, reactor inlet pressure, separator temperature and reactor $N_2/H_2$-ratio. The optimisation was performed across the operating window from 10 % to 120% of nominal make-up feed hydrogen flow. This demonstrated that the compressor anti-surge limit strongly impacted the synthesis loop power at reduced loads. The surge boundary constrained the reduction in compressor power, resulting in an increase in total HB-loop power at low loads. To mitigate losses from anti-surge recycling, we evaluated configurations with multiple compressors operating in parallel. Optimisation results showed substantial reductions in HB-loop power at reduced loads: 55%, 74%, and 84% for two, three, and four compressor trains, respectively. This corresponded to total cost savings of 8.06%, 8.29% and 7.11%, respectively, compared to a single train configuration. Additionally, considering the enhanced reliability of configurations with parallel compressors, we recommended the configurations with two or three parallel compressor trains.

## ABSTRACT

Efficient temperature control in greenhouses is essential for optimal plant growth, especially in arid regions where the harsh environment poses significant challenges to maintaining a stable microclimate. Maintaining the optimum temperature range directly influences healthy plant development and overall agricultural productivity, impacting crop yields and financial outcomes. However, the greenhouse in the present case study fails to maintain the optimum temperature as it operates based on predefined settings, limiting its ability to adapt to dynamic climate conditions. To maintain an ideal temperature range within the greenhouse while dynamically adapting to fluctuating external conditions, this study introduces a control framework using Deep Deterministic Policy Gradient, a model-free deep reinforcement learning algorithm, to optimize temperature control in the closed greenhouse. A deep neural network is trained using historical data collected from the greenhouse to accurately represent the nonlinear behavior of the greenhouse system under varying conditions. The deep deterministic policy gradient algorithm learns optimal control policy by interacting with a simulated greenhouse environment, continuously adapting without needing an explicit system dynamics model. Results from the study demonstrated that, over a five-day simulation period, the deep deterministic policy gradient control system outperformed the existing greenhouse climate system in temperature regulation. It achieved a mean squared error of 0.01°C and a mean absolute error of 0.13°C. Additionally, the deep deterministic policy gradient algorithm demonstrated a significant improvement in energy efficiency, reducing total energy consumption by 6.80% compared to the current system.

**Keywords**: Reinforcement learning, Greenhouse temperature control, Closed environment agriculture

## INTRODUCTION

By 2050, the global population is projected to rise to about 9.7 billion, significantly increasing the need for water, energy, and food. To satisfy this growing food demand, agricultural production must be increased by nearly 70% from current levels. However, the persistent effects of climate change create significant challenges for increasing crop yields via conventional open-field farming (1). More frequent extreme weather events, higher temperatures, and changing rainfall patterns compromise these traditional methods. These environmental challenges make traditional farming methods more vulnerable. Therefore, it's essential to develop innovative, high-efficiency agricultural practices that preserve land and resources while providing greater yields (2).

Controlled Environment Agriculture (CEA) represents a viable solution, as it offers a regulated environment that mitigates climate-related risks (3). Among the various CEA technologies, greenhouses effectively optimize crop production by regulating environmental variables such as temperature, humidity, and $CO_2$ levels. However, efficiently managing greenhouse microclimates still poses challenges, necessitating a careful balance of various factors to promote plant growth while minimizing energy and water consumption. To address these challenges, various control strategies have been developed to regulate greenhouse environments, ranging from traditional rule-based methods to advanced model-based approaches. However, the complexity and variability of greenhouse conditions require more adaptive and data-driven solutions.

Reinforcement learning (RL) is a data-driven method that can optimize greenhouse climate control without depending on explicit system models (4). Unlike traditional controllers, RL dynamically adjusts to changing conditions, making it well-suited for complex and uncertain greenhouse environments. Deep reinforcement learning (DRL) methods, such as deep deterministic policy gradient (DDPG) and proximal policy optimization (PPO), have demonstrated significant potential in managing greenhouse operations. These methods use neural networks to learn optimal control policies from data, allowing for real-time adaptation to disturbances such as solar radiation fluctuations and external temperature changes.

Several studies have explored RL-based greenhouse control strategies, demonstrating promising results in improving energy efficiency and climate stability. For instance, a DRL-based controller integrated with robust optimization reduced energy consumption by up to 57% while maintaining stable temperature regulation (5). Multi-agent reinforcement learning approaches have also been applied to coordinate multiple greenhouse subsystems—such as heating, ventilation, and cooling—leading to improved operational efficiency (6). While RL-based strategies have demonstrated significant potential, their implementation still encounters significant challenges.

Despite the advancements, multiple challenges persist in RL-based greenhouse control systems. Training RL agents requires a considerable volume of high-quality data, and inadequate exploration strategies may result in unstable learning behaviors. Furthermore, ensuring safety constraints and interpretability in RL-based controllers continues to represent a significant research area. Additionally, a significant obstacle in RL deployment is the reliance on precise greenhouse models for training and evaluation.

Many researchers use physics-based models to simulate greenhouse dynamics; however, these models often include simplifying assumptions that may not accurately reflect real-world conditions. For instance, they often oversimplify thermal behaviors and may overlook difficult-to-measure factors, such as air leakage through greenhouse walls, heat exchange with the ground, or variations in moisture levels. Such omissions can lead to less accurate predictions about temperature variations and energy consumption, limiting the effectiveness of control strategies. Furthermore, greenhouses present unique challenges compared to traditional structures because of their specific design requirements. They are designed to maximize sunlight for plant growth while also maintaining a stable internal environment. This dual objective complicates thermal and energy management, making traditional control methods less effective when environmental conditions change rapidly. Given these limitations, a data-driven approach can offer a more precise representation of greenhouse dynamics, allowing RL agents to make better-informed decisions.

To address the challenges associated with greenhouse management, this study introduces a deep deterministic policy gradient approach based on data-driven modeling. Operational data has been collected from an actual greenhouse to train a deep neural network (DNN) surrogate model, which captures the intricate relationships among various environmental variables. Utilizing the developed DNN, a DRL agent using the DDPG algorithm was developed to maintain optimal temperature levels within the greenhouse while simultaneously minimizing energy consumption. The performance of the DDPG controller was evaluated in comparison to the existing greenhouse control system under deterministic conditions.

## METHODOLOGY

This study introduces a DRL approach that utilizes the DDPG algorithm to optimize greenhouse temperature control while minimizing energy consumption. The framework integrates two essential components: a DNN surrogate model and a DRL-DDPG architecture. The DNN model, trained using real-world greenhouse data, captures the dynamics of the greenhouse system, including weather conditions, internal temperature, fan operation, HVAC temperature (HT) settings, and energy usage. This surrogate model was integrated into a DRL environment to simulate greenhouse behavior, allowing the DDPG agent to learn an optimal control policy.

### Greenhouse system

The greenhouse, located in Qatar, utilizes glass as its covering material to enhance the penetration of photosynthetically active radiation into the plant canopy, ensuring optimal light for crop growth. To regulate cooling, the facility is equipped with an HVAC system alongside a hydroponic setup that efficiently supplies water, nutrients, and fertilizers to the plants. Figure 1 demonstrates the closed greenhouse.

The greenhouse operates as a closed-loop system that captures hot, humid air from the plant canopy. Instead of releasing this air into the atmosphere, it is redirected to an air-to-water chiller, where its temperature is reduced below the dew point (12-13°C). This cooling mechanism enhances the condensation of water vapor present in the air, enabling the collection of the resulting water for reuse in irrigation, significantly reducing water loss. The cooled air is subsequently reheated to an optimal temperature by the HVAC system prior to its recirculation back into the greenhouse. To meet irrigation requirements, additional water is supplemented from groundwater sources and treated through a reverse osmosis process. The climate control system is calibrated to maintain optimal growth temperatures for crops,

sustaining 18°C during the night and 23°C throughout the day.

**Figure 1:** Closed greenhouse located in Qatar.

## Data collection

Data was collected every 5 min over a one-year period, from September 2023 to September 2024, utilizing a network of sensors installed at the greenhouse. These sensors continuously monitored environmental variables, with solar irradiance and external temperature recorded by devices mounted on the greenhouse roof. The internal temperature within the greenhouse was measured through a sensor box located inside the unit. During the summer months, solar irradiance reached a peak value of 1060 W.m$^{-2}$, and external temperatures to as high as 45.2 °C. A summary of the ranges for all measured variables is detailed in Table 1.

**Table 1:** Range of measured variables.

| Parameter | Value and unit |
|---|---|
| Solar radiation | 0 – 1060 W.m$^{-2}$ |
| Outside temperature | 7.5 – 45.2 °C |
| Fan speed | 25 – 100 % |
| HVAC control | 17 – 22 °C |
| Greenhouse temperature | 12.1 – 25.2 °C |

## Deep reinforcement learning

The DDPG algorithm is a model-free, off-policy actor-critic approach in DRL. It builds upon the deterministic policy gradient method and is appropriate for dynamic environments with large, continuous action spaces (7). DDPG learns an optimal policy through the interaction of two primary components: the actor and critic networks.

The actor network, denoted as $\mu(s \mid \theta^{\mu})$, maps states to deterministic actions. Its goal is to identify the best possible action for a given state by selecting actions that maximize the Q-value predicted by the critic network. The critic network, represented as $Q(s,a \mid \theta^{Q})$, evaluates the quality of actions by estimating the expected cumulative future rewards for each state-action pair. The actor network is trained to improve its policy by maximizing the Q-value, while the critic network is updated using temporal difference learning to refine its predictions based on immediate rewards and estimated future values.

The DDPG algorithm incorporates several techniques to enhance learning stability and efficiency. A replay buffer stores past experiences, which include the current state, the action taken, the resulting reward, the next state, and whether the episode has terminated. By sampling and learning from these experiences, the agent breaks the temporal correlation between consecutive samples, improving the quality and efficiency of the training process.

Separate target networks are used for both the actor and critic. These networks provide stable reference values during training, especially when calculating the temporal difference error. To further enhance stability, DDPG employs a soft update strategy, where the target networks' parameters are gradually updated, preventing abrupt changes that could destabilize the learning process. The weight updates for the actor and critic networks are guided by mathematical equations. The actor's weights are updated to maximize the Q-value of the policy's actions(8):

$$\Delta\theta = \eta_\theta \nabla_\theta \left( \frac{1}{N} \sum_{k \in \mathcal{B}} Q\big(s(k), \pi(s(k) \mid \theta_\pi) \mid \phi_Q\big) \right) \quad (1)$$

Here, $\Delta\theta$ represents the change in the actor's parameters, $\eta_\theta$is the learning rate, $\nabla_\theta$ is a minibatch sampled from the replay buffer, and $N$ is the number of samples in the minibatch. The critic's weights are updated to minimize the difference between the predicted Q-value and the target Q-value (8):

$$\Delta\phi = \eta_\phi \nabla_\phi \left( \frac{1}{N} \sum_{k \in \mathcal{B}} \Big( Q\big(s(k), u(k) \mid \phi_Q\big) - v(k) \Big) \right) \quad (2)$$

Here, $\Delta\phi$ is the change in the critic's parameters, $u(k)$ is the action at time step $k$. Target Q-value is calculated as:

$$v(k) = r(k) + \gamma Q'\big(s(k+1), \pi'(s(k+1) \mid \theta_{\pi'}) \mid \phi_{Q'}\big) \quad (3)$$

where $r(k)$ is the immediate reward, $\gamma$ is the discount factor, $Q'$ is the target critic network, and $\pi'$ is the target policy network. By iteratively refining the actor and critic networks, DDPG efficiently learns optimal control policies without requiring an explicit model of the environment, making it highly suitable for control tasks in complex, continuous systems.

## System model

The surrogate model's accuracy in predicting future states is critical for an effective control strategy.

Traditional analytical models for greenhouses often rely on estimated parameters, introducing errors that compromise predictive reliability. To overcome this, a DNN was developed using PyTorch (9) to accurately represent the greenhouse system, capturing the nonlinear relationships among variables like solar irradiance, ambient temperature, HT, and fan speed.

The architecture of the DNN includes an input layer that processes 12 input features as illustrated in **Figure 2**. The model is trained using the Adam optimizer, which efficiently handles parameter updates, and the MSE loss function, which quantifies the prediction error. Training is conducted over 50 epochs to ensure the model converges to a solution that accurately captures the system's dynamics. By using this DNN-based surrogate model, the greenhouse system's behavior can be predicted with greater precision, providing a robust foundation for the control strategy.

**Figure 2:** DNN model for the greenhouse system.

### Reward function

The reward function for the DDPG agent is designed to achieve two main goals: minimizing the difference between the greenhouse temperature and the desired set point and reducing energy consumption. By penalizing both temperature deviations and energy usage, the reward function ensures the agent prioritizes maintaining optimal conditions while being energy efficient. The function assigns specific weights to each component, allowing for flexibility in emphasizing either precise temperature control or energy savings, depending on the desired objectives. The reward function is expressed as:

$$R(k) = -\left(\alpha \cdot |T(k) - T_{\text{set}}(k)| + \beta \cdot E(k)\right) \quad (4)$$

### Training

The critic network in the DDPG framework processes both state and action inputs through two fully connected layers, each containing 256 neurons. These layers use ReLU activation functions and include batch normalization to stabilize and improve the learning process. The network outputs a single Q-value, representing the expected cumulative reward for the given state-action pair. Similarly, the actor network processes the state inputs through two fully connected layers with 256 neurons each. These layers also use ReLU activation functions, along with batch normalization, to ensure stable and efficient learning. The network concludes with a Tanh activation function, which outputs the control actions within the required range. The training phase for the DRL agent spaned 500 epochs, with each epoch representing one day of operation, divided into 288 steps corresponding to 5-minute intervals. This high-resolution sampling enabled the agent to respond effectively to rapid changes in the greenhouse environment, which was crucial for maintaining optimal growing conditions.

The training process used a learning rate of $1\times10^{-4}$ to ensure steady weight updates. A soft update coefficient $\tau$ of 0.005 was employed for gradual updates to the target networks, enhancing stability during learning. The discount factor $\gamma$ was set to 0.99, balancing the importance of immediate rewards with long-term gains.

## RESULTS AND DISCUSSION

### Model performance

The DNN model, developed using historical data, was evaluated for its ability to predict greenhouse temperatures over a five day period from March 27th to April 1st, 2024. The model was trained on a dataset of 24,480 samples, with predictions generated at 5 min intervals. It demonstrated high accuracy, achieving an $R^2$ score of 0.94 and an MSE of 0.676 °C, as illustrated in Figure 3. While the model slightly underestimated greenhouse temperatures during peak solar irradiance hours on the last two days, it successfully captured the overall diurnal trend.

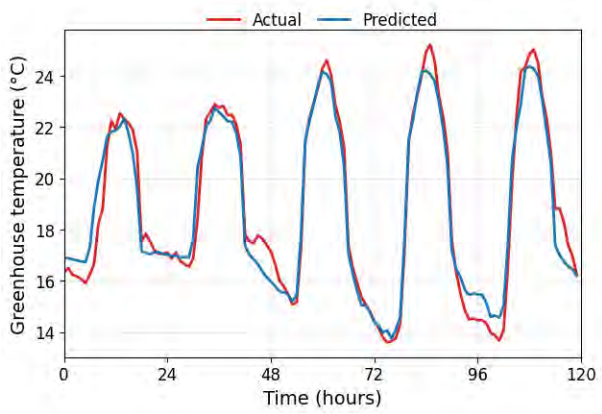

**Figure 3:** DNN greenhouse temperature prediction performance.

### Deep deterministic policy gradient performance

The performance of the DDPG controller in regulating greenhouse temperatures was assessed over a five-

day simulation, comparing its performance to the existing greenhouse control system for fixed setpoints of 23°C during the daytime and 18 °C at night. As illustrated in Figure 4, the DDPG controller outperformed the GCS in achieving temperature control. The DDPG controller (represented by the blue line) maintained temperatures within ±0.1°C of the setpoints (green line), ensuring smooth adjustments with minimal overshooting or undershooting. In contrast, the GCS experienced significant temperature variability, with actual temperatures (red line) often significantly deviating from the setpoints, reaching peaks of 24.3°C during the day and dropping to lows of 13.8°C at night. The GCS resulted in an MSE of 3.89 °C and an RMSE of 1.97 °C, while the DDPG controller achieved a lower MSE of 0.01 °C and an RMSE of 0.13 °C, demonstrating its superior performance in temperature regulation.

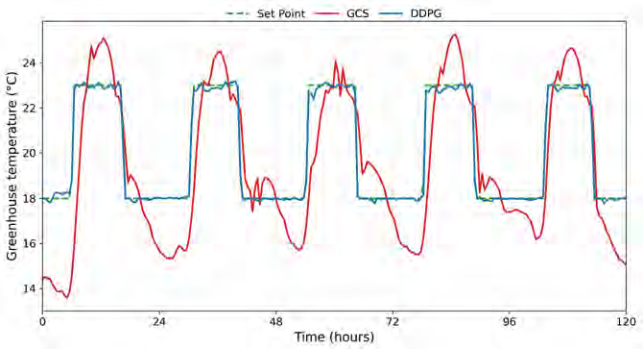

**Figure 4:** Temperature control performance comparison between GCS and DDPG.

The control actions of the DDPG controller were compared to the actual control actions implemented by the GCS, as demonstrated in Figure 5. The DDPG controller operated the fan at relatively lower speeds than the GCS, ensuring smoother transitions in operation. Additionally, the fan speed was always operated above 25%, maintaining consistent $CO_2$ circulation within the greenhouse. For HVAC control, the GCS operated on fixed temperature setpoints of 17°C at night and 22°C during the day. In contrast, the DDPG controller adopted a more dynamic approach, adjusting the temperature in response to changing environmental conditions. This adaptive behavior resulted in improved temperature regulation and overall greenhouse climate control.

Figure 6 illustrates the energy consumption over five days, demonstrating that the DDPG controller consistently resulted in lower energy consumption compared to the GCS. The DDPG controller accounted for a total energy usage of 7,789 kWh, while the GCS utilized 8,357 kWh. This led to an overall reduction of 6.80% in energy consumption with the DDPG compared to the GCS.

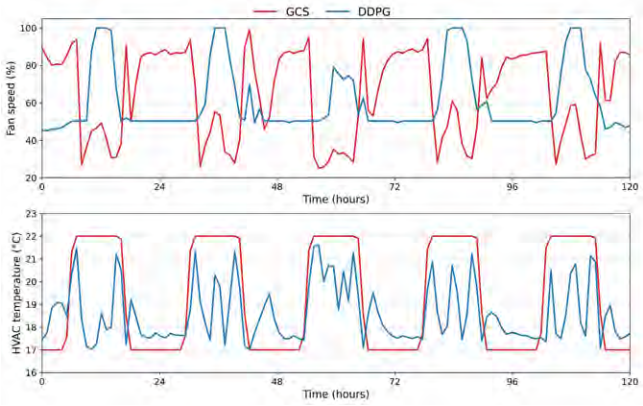

**Figure 5:** Control action comparison of GCS and DDPG.

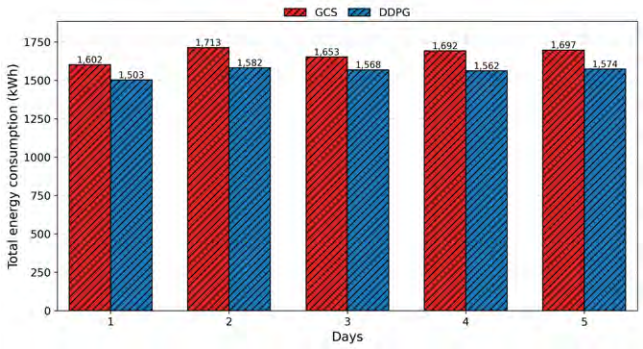

**Figure 6:** Energy utilization comparison of GCS and DDPG.

## CONCLUSION

This study demonstrated the effectiveness of a deep reinforcement learning approach using DDPG for greenhouse temperature control. The developed control system significantly outperformed the existing greenhouse control system, achieving superior temperature regulation with a mean squared error of 0.01°C and root mean squared error of 0.13°C, compared to 3.89°C and 1.97°C respectively, for the existing greenhouse system. The DDPG controller maintained temperatures within ±0.1°C of the setpoints while implementing smoother control actions, particularly in fan speed transitions. Furthermore, the controller achieved a 6.80% reduction in energy consumption, utilizing 7,789 kWh compared to the existing greenhouse system's 8,357 kWh over the five-day testing period.

## ABSTRACT

This work explores Aotearoa-New Zealand's potential to fully electrify and source industrial process heat demands from renewable energy for 286 industrial sites while exploring the feasibility of green methanol production using excess electricity. Most energy models rely on spatially aggregated supply and demand, which limits the accurate representation of energy value chains. To address this limitation, the model incorporates industrial sites with varied temperature profiles, enabling the use of diverse heating technologies such as heat pumps, electrode boilers, bubbling fluidised bed reactors and biomass boilers. The proposed Mixed-Integer Linear Programming energy model uses the Accelerated Branch-and-Bound (ABB) algorithm, which is implemented within the P-graph framework to optimise the system. The model considers different energy transportation modes, including road transport for biomass and grid infrastructure for electricity. The multi-period design determines optimal heating technology capacities for each unique industrial site while accounting for renewable energy variability, spot electricity prices, and sectoral energy demand fluctuations. The optimisation results reveal the most effective configurations of heat technologies for industrial sites and projected 1.03 Mt/y of green methanol production in New Zealand when the selling price exceeds NZD1050 /ton (EUR 569 /ton). The findings demonstrate a 41.3% reduction in total process energy supply from 25.9 TWh/year to 18.8 TWh/year, driven by the higher coefficients of performance (COP) and efficiencies of electrification.

## INTRODUCTION

Aotearoa-New Zealand is transitioning toward a net zero, climate resilient future where total energy supply is generated by renewable resources. The government has set aims to eliminate greenhouse gas emissions before the year 2050, with the exception of biogenic methane from agriculture and waste. The Climate Change Commission's demonstration pathway envisions a large-scale transition away from coal and fossil fuels. Under the current plans, the use of coal will be phased out by 2037 and similarly fossil gasses by 2050 [1].

In terms of direct renewable energy use in New Zealand, only 30% of primary energy consumption is supplied by renewables [2]. The hard to abate sectors namely industrial processes are primarily reliant on fossil fuels such as natural gas and coal. Industries such as dairy, meat, chemical, pulp, wood and paper sectors require larger amounts of high temperature heating where it might be prohibitively expensive or infrastructure lacking to be supplied by electrification.

Electricity consumption in New Zealand's industrial sector holds a significant share of the country's total usage. In 2022, New Zealand's industrial sector accounted for approximately 13.7 TWh or 34% of the nation's total electricity consumption. Industrial process heat which encompasses systems such as hot water, direct heat, process steam is responsible for 8.3 Mt of carbon dioxide equivalent emissions annually, where 35% of the nation's total energy use is consumed for process heat [3]. Energy efficiency and switching to low-carbon fuels help reduce the energy needed to provide useful heating. This, in turn, lowers the carbon footprint associated with meeting the heating demand.

A utility system delivers the heating, cooling, and power essential for industrial processes. Renewable energy resources have the potential for the generation of process heat namely direct combustion (e.g. bioenergy) and indirect heating via electrification. Wood energy industrial symbiosis is particularly important to create a circular economy in the forestry and wood processing sector and potentially solving energy problems in industries. Wood processing regions have substantial forestry resources which could potentially alleviate the infrastructure cost of full electrification reducing the need for capacity upgrades and grid reliance [4].

Optimisation models have been generally accepted as the most applied methodology for energy system analysis since 2010 [5]. It is also a robust method due to the inclusion of techno-economic structure and the capability to simulate numerous scenario-based projections which would inherently be important for policy makers to undergo decision making processes. These energy system optimization models (ESOMs) determine the cost-optimal mix of fuels and conversion technologies required to meet energy demand efficiently. Among them, the most prominent ESOMs frameworks are Long-range Energy Alternatives Planning (LEAP), MARKet and Allocation (MARKAL), The Integrated MARKAL-EFOM System (TIMES), Model for Energy Supply Strategy Alternatives and their General Environmental Impact (MESSAGEix) [5].

Geographic information system (GIS) has been partially addressed in studies to deal with spatial-related difficulties [6]. Spatial tools are often used to conduct analysis and geographic data processing. GIS is combined with energy system modelling tools such as The Integrated MARKAL-EFOM System [7]. The integration effort demands a variety of parameters and datasets, and increased analytical effort which amplifies the model's complexity, resulting in longer computational run-time.

An alternative approach is to build an energy systems model from a generic modelling framework, such as P-graph connected with ArcPy. The P-graph framework is introduced along with the systematic creation of defined mathematical optimisation models for process synthesis [8]. P-graph has been employed as an energy modelling tool. For example, Aviso et al. have extended the scope of P-graph into macroscale energy systems modelling [9]. Xu et al. investigated the technoeconomic feasibility of converting electricity generated from renewable sources into hydrogen using P-graph [10]. P-graph framework has been popularised in solving large models with low computational power which leads to many hybrid uses of P-graph being carried out. The efficiency of P-graph solvers has encouraged the development of an open-sourced Python library which allows P-graph models to be scaled more seamlessly to build and solve large scale problems more efficiently [11].

The implementation of ArcPy automates the analysis for one or a series of spatial tools for each row of the dataset [12]. For example, Wang has applied ArcPy within the Python environment to process qualitative and quantitative descriptions in the urban building energy model [13]. ArcPy is also used to assess solar generation output for the electrification of transportation [14]. The benefit of ArcPy lies in its extensive range of spatial tools. As such, ArcPy is used to estimate distances across various levels or layers in each successive step. Additionally, ArcPy is used to identify the points of connection assigned to specific generation and factory sites by defining electricity transmission and distribution lines as barrier boundaries.

As noted, existing energy models tend to aggregate industrial heat loads without distinguishing temperature demand profiles resulting in poor resolution and the selection of non-optimal solutions (e.g. boilers instead of heat pumps) [15]. Separating temperature profiles by sector would provide better resolution for evaluating different heating technologies or implementing heat cascading in energy models [16]. However, this also elicits the need to build a new model using a generic framework and packages.

The aim of this research is to develop a national energy transition model, applying the P-graph approach, to assess Aotearoa-New Zealand's potential to achieve net zero in the industrial sector in the future. This includes exploring opportunities to produce high-value, hydrogen-rich compounds, all within the country's resource constraints.

The content of the paper is structured as follows. The context and the scope of the model introduce the extent of the research. In the methods section, it outlines the software implementation and model structure which introduce the application of modelling tools and the approaches which are used to design the structure. The results section presents the configurations of heat technologies in the optimisation model while the conclusions summarise the key findings.

## SCOPE OF THE MODEL

The purpose of this model is to identify the most suitable heating technologies which run on renewables resources for every industrial site nationwide using more than 1 GWh/y. These include various classes of industrial heat pumps (HPs) designed for specific thermal profiles, electrode boilers for high-temperature applications, and biomass boilers for using biomass fuels.

Given the research aim involves heat cascading across different plants in Aotearoa-New Zealand, a high level of detail in spatial resolution is essential. Temporal dynamics of industry energy demand is accessed in a monthly time series. The time period is important to take account the intermittent renewable generation which

affects the capacity factor of electricity output, monthly average electricity spot price for each point of connection, heat and power demand profiles for industrial, residential and commercial consumption. The analysis covers one year to capture seasonal changes in heating capacity and green methanol production capacity.

# METHODS

## Software Implementation and Tools

The national energy transition model (NET-Mod) is implemented as Python. Python is a high-level programming language equipped with an extensive range of libraries which is suitable for data analysis and mathematical optimisation. The Python-based model utilised the following libraries: Pgraph, ArcPy and RenewablesNinja.

## P-graph Optimisation Model

P-graph is a directed bi-partite graph which consists of two types of vertices: operating units, ($O$) and material nodes ($M^*$). The P-graph superstructural model, $S$ comprises three main sets, expressed as $S = (P, R, O)$ where $P$ and $R$ are the subset of set of materials $M^*$, representing the products and raw materials respectively [8]. Additionally, operating units ($O$) generate subgraphs $(M^*, O)$ and $(O, M^*)$ to represent the interconnections between two material nodes, incorporating transformation coefficients that define the flow conversion between the connected nodes [9]. The sets and indices in the model are stated in **Table 1**.

**Table 1.** Sets and indices in the model.

| | |
|---|---|
| $i, u \in I$: Point of Connections | $t \in T$: Monthly Periods |
| $j \in J$: Electricity Generation Sites | $(i, u) \in V$: Edges between POCs |
| $k \in K$: Biomass Supply Sites | $n \in N$: Heating Technologies |
| $q \in Q$: Temperature Profiles | $l \in L$: Factory Sites |
| $p \in P$: Electricity Generation Technologies | |

In the model, the "raw material" nodes represent the resources supplied to the energy system. These include the electricity generated using technology $p$ at site $j$ at time $t$, denoted as $E_{j,p,t}$ and biomass resource available at site $k$ at time $t$, represented by $B_{k,t}$. The "product" nodes define the targets for the energy model, which must be fulfilled for a feasible process network synthesis problem (PNS) solution. The product set includes the temperature profile demand $q$ at site $l$ at time $t$ ($D^{in}_{l,q,t}$), green methanol production at site $j$ ($G_j$), residential and commercial demand at POC $i$ at time $t$ ($D^{re}_{i,t}$) and electricity curtailment at site $j$ at time $t$ ($H_{j,t}$). The "operating unit" nodes are critical components of the model, influencing costs as well as endogenous and exogenous flows within the system. The elements include electricity generation capacity using technology $p$ at site $j$ ($Cap^{e}_{j,p}$), methanol plant capacity at site $j$ ($Cap^{g}_{j}$), and heat technology capacity $n$ at industrial site $l$ ($Cap^{ht}_{l,n}$). Additionally, transmission and distribution charges in POC $i$ at time $t$ ,($T^{e}_{i,t}$), biomass transport costs from site $k$ to industrial site $l$ at time $t$($T^{b}_{k,l,t}$) and biomass transport costs from site $k$ to electricity generation site $j$ at time $t$, ($T^{b}_{k,j,t}$) are included within the set of "operating unit" nodes. The equations defining the sets are:

$$R = \{E_{j,p,t}, B_{k,t}\} \quad (1)$$

$$P = \{D^{in}_{l,q,t}, G_{j,t}, D^{re}_{i,t}, H_{j,t}\} \quad (2)$$

$$O = \{Cap^{e}_{j,p}, Cap^{g}_{j}, Cap^{ht}_{l,n}, T^{e}_{i,t}, T^{b}_{k,l,t}, T^{b}_{k,j,t}\} \cup O' \quad (3)$$

In this work, time step is a crucial factor in the optimisation model, as it determines the sizing of operations.
The optimisation model is formulated in **Equation 4**:

$$\min CC_R + CC_O - CC_P \quad (4)$$

where the total annualised cost is the sum of resource costs ($CC_R$) and operating units costs ($CC_O$), subtracting the total revenue or product costs ($CC_P$).
The detailed cost formulation for $CC_R$, $CC_O$ and $CC_P$ are outlined in **Equation 5-7**. The symbol $C$ represents a cost function, where the respective subscript and superscript specify costs for different components.
The resource cost is formulated as:

$$CC_R = \sum_{j\in J}\sum_{t\in T}\sum_{p\in P} C^{e}_{j,p,t} \cdot E_{j,p,t} + \sum_{t\in T}\sum_{k\in K} C^{b}_{k} \cdot B_{k,t} \quad (5)$$

The operating cost is outlined as:

$$CC_O = \sum_{j\in J}\sum_{p\in P} C^{cap^e}_{j,p}\, Cap^{e}_{j,p} + \sum_{j\in J} C^{cap^g}_{j}\, Cap^{g}_{j} + \sum_{l\in L}\sum_{n\in N} C^{ht}_{n}\, Cap^{ht}_{l,n} + \sum_{t\in T}\sum_{i\in I} C^{e}\, T^{e}_{i,t} + \sum_{t\in T}\sum_{k\in K}\sum_{l\in L} C^{b}\, T^{b}_{k,l,t} + \sum_{t\in T}\sum_{k\in K}\sum_{j\in J} C^{b}\, T^{b}_{k,j,t} \quad (6)$$

The product cost is given by:

$$CC_P = \sum_{t\in T}\sum_{l\in L}\sum_{q\in Q} C^{in}_{q} D^{in}_{l,q,t} + \sum_{t\in T}\sum_{j\in J} C^{g} G_{j,t} + \sum_{t\in T}\sum_{i\in I} C^{re} D^{re}_{i,t} + \sum_{t\in T}\sum_{j\in J} C^{H} H_{j,t} \quad (7)$$

## Model Structure

The model comprises five parts: utility generation, transmission, local generation, biomass resources, factory sites, and green methanol plants. **Figure 1** provides a simplified model structure, showing utility-scale generation and green methanol production for a single time step. For local generation, the structure is similar, but the electricity node bypasses transmission and connects directly after distribution charges.

Electricity is generated either at the utility scale or local scale, with the capacity and utilisation factor (or capacity factor) specified. Electricity generated from utility power stations can be delivered to the National Grid by injecting it into the designated points of connection.

Additionally, both utility-scale and local-scale electricity have the option to convert excess electricity into green hydrogen, which serves as a raw ingredient to produce green methanol.

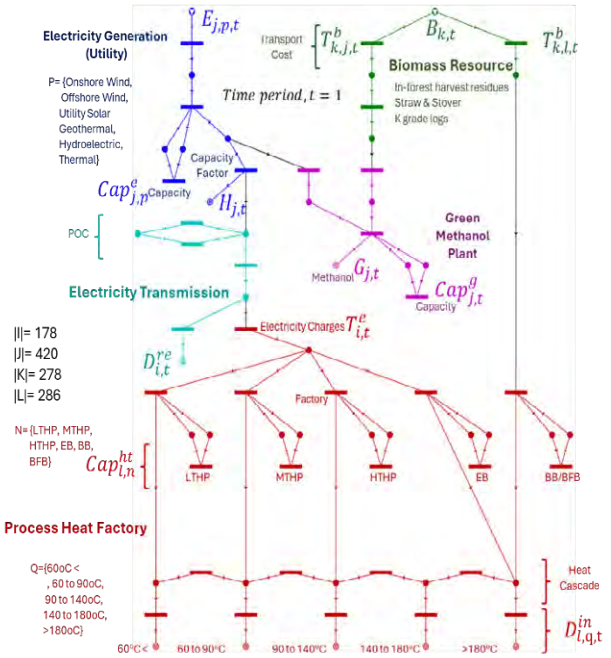

**Figure 1**. Example of the P-graph structure for the energy model for a single time period, t=1, for one generic industrial site, existing electricity demand at the POC, and one new green methanol plant, all supplied by renewable electricity generation and/or biomass.

Note. POC=point of connection, LTHP=low temperature heat pump, MTHP=medium temperature heat pump, HTHP=high temperature heat pump, EB=electrode boiler, BFB=bubbling fluidised bed reactor, BB=biomass boiler.

The National Grid is interconnected through a network of transmission infrastructure, primarily a series of points of connection. Electricity can flow in two directions but only one direction at a time, necessitating the application of mutual exclusion for each connection. The electricity is then supplied to meet the residual demand of industrial, commercial, and residential consumers. The aggregate electricity demand includes the current industrial electricity demand behind POC nodes, which distinguishes electricity demand from energy demand met by non-renewable fuels. Subsequently, the electrical flow is directed to the respective factories and distributed among four operating units, each representing a different heating technology tailored to specific temperature profiles. Consequently, there will be multiple configurations for each factory across New Zealand.

On the biomass side, three different biomass types are specified, none of which exhibit intermittent characteristics or serve as intermediate commodities for further processing. The biomass resources used in this study are k-grade log wood, in-forest harvest residues as well as straw and stover. Biomass can be directly supplied to factories for high-temperature heating or delivered to prospective green methanol plants as a source of carbon and hydrogen. Since biomass is transported by trailers, there is a direct relationship between transport distance and associated transportation costs. The transport cost is estimated at 0.3 NZD per ton-km.

The NET-Mod comprises 420 electricity generation power stations, which include commissioned, consented, proposed, or under appeal facilities (342 utility-scale and 78 local-scale); 286 industrial sites with an annual process heat demand exceeding 1 GWh; 178 points of connection; 278 biomass sites; 14,956 connections between factories and biomass sites; and 18,980 connections between biomass sites and generation facilities. In total, there are 202031 variables (117021 material nodes and 85010 operating units) and 104210 equations.

**Table 2** presents the efficiencies or coefficient of performance (COP) of each heating technology and its respective specifications. It is particularly important for the introduction of heat pumps in industries as it has a higher COP and efficiency when operating in lower temperature, meaning useful energy is supplied to fulfil the load demand in the processes.

**Table 2.** Specifications of proposed industrial heating technologies.

| Tech | Fuel | Temperature (°C) | COP | Cost (NZD /MW·y) |
|---|---|---|---|---|
| **LTHP** | Electricity | 60< | 4.57 | 342,933 |
| **MTHP** | Electricity | 60-90 | 2.69 | 201,399 |
| **HTHP** | Electricity | 90-140 | 1.73 | 129,983 |
| **EB** | Electricity | >180 | 0.99 | 7,920 |
| **BB** | K-log wood, In-forest residue | >140 | 0.80 | 83,333 |
| **BFB** | Straw and Stover | >140 | 0.70 | 53,333 |

## RESULTS

The Accelerated Branch and Bound (ABB) solver was executed on an Intel CPU 2.30 GHz i7-12700H processor with 32 GB of RAM. The solver required 60 mins to find the optimal solution. In the solution, 15.9% of process heat energy is sourced from biomass, as indicated by the energy model. This significant share highlights the diverse dependence on various energy sources. The reliance on biomass varies significantly across regions, reflecting disparities in energy resource availability and industrial demand (**Figure 2**). For example, industrial sites in the central and southern part of the South Island

heavily rely on bioenergy for process heat, with 55% of the process heat met locally by abundant biomass resources. **Figure 2** illustrates that the Central North Island regions such as Waikato and the Bay of Plenty region also benefit from biomass resource due to their high concentrations of forest plantation-based pulp and paper mills. In contrast, regions such as Northland, Auckland, Taranaki and Wellington region face limited biomass mass availability, resulting in a high dependence on electricity for industrial heat demands, exceeding 95%.

In process heat sectors, **Figure 3** illustrates the heat technologies used in different types of industrial sectors. High-temperature heating technologies not only supply heat to their intended temperature profiles but cascade residual heat to lower-temperature processes, maximising energy utilisation. Although highly efficient heat pumps offer notable benefits, the economic feasibility of biomass boilers, especially in regions with abundant biomass resources, makes them a more practical choice for industrial heating. For instance, the high utilisation of electrode boilers in the Taranaki Region is largely attributed to Methanex, a grey methanol plant. According to the model, a proposed scenario for its future operation involves replacing all heating with electricity while retaining natural gas as a raw material for chemical processes.

**Table 3.** The energy requirements for industrial process heat by proposed heating technologies.

| Heating Technologies | Energy required (TWh/y) |
|---|---|
| **Electricity Total** | **15.85** |
| **- LTHP** | 0.36 |
| **- MTHP** | 1.12 |
| **- HTHP** | 3.29 |
| **- EB** | 11.01 |
| **Biomass Total** | **2.99** |
| **- BB** | 2.97 |
| **- BFB** | 0.02 |

**Table 4.** Projected green methanol production by region and power generation type (at NZD 1050/tonne).

| Zone | Region | Type | Production (kt/y) |
|---|---|---|---|
| **UNI** | Northland | Geothermal, Wind | 839.29 |
| **CNI** | Waikato | Geothermal, Wind | 36.34 |
| **LNI** | Manawatu-Wanganui | Wind | 6.66 |
| **CSI** | Canterbury | Hydroelectric | 152.09 |
| **Total Production** | | | **1034.37** |

The shift towards combined electrification and increased biomass utilisation has reduced the total process heat demand across industrial sites in New Zealand. Advanced energy technologies, such as heat pumps and electrode boilers, have significantly enhanced energy efficiency. These technologies operate with much higher efficiency, requiring lower input power to deliver the same amount of process heating compared to conventional systems. **Table 3** illustrates the end-user demand fulfilled by each heating technologies. The transition has contributed to a 41.3% reduction in total end-use heating demand, from 25.9 TWh/year to 18.8 TWh/year.

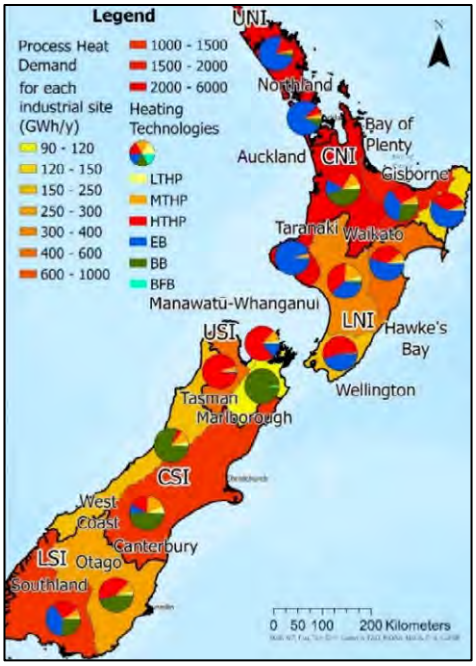

**Figure 2.** Process heat demand and its respective heating technologies across New Zealand.

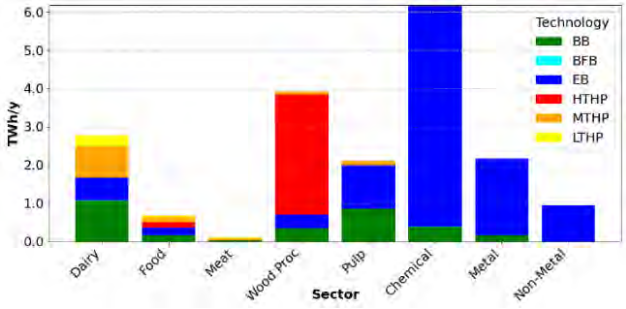

**Figure 3.** The amount of energy required from heating technologies across industrial sections in New Zealand.

As the model incorporates a new green methanol industry to showcase the potential for sustainable industrial practices in New Zealand, the economic feasibility of this production is influenced by the total capital and fixed operating cost of 180 NZD/tonne whereas the variable operating cost such as electricity and biomass are based on their respective distances and locations [17]. According to the modelling simulation, green methanol becomes profitable when the selling price exceeds NZD 1050/ton. **Table 4** outlines the potential off-grid production of green methanol and its respective power generation

type. To produce one tonne of green methanol, the process requires 3.44 MWh of electricity for electrolysis and 4.38 MWh of biomass as carbon and hydrogen sources.

Given the promising path of power-to-fuel technologies, it is vital to access other green hydrogen-based chemical compounds, such as ammonia, urea and sustainable aviation fuel, to meet New Zealand goals to achieve net-zero carbon emissions by 2050.

## CONCLUSIONS

The nationwide modelling approach offers an outlook on decarbonising industrial process heat demand with a good firming capacity from biomass and electricity supply. The results indicate a reduction in industrial energy supply from 25.9 TWh/year to 18.8 TWh/year within national resource constraints. Additionally, a green methanol economy is feasible in specific regions of New Zealand where surplus electricity and biomass resources are available, provided the selling price exceeds NZD1050/tonne. The utilisation of the open-source P-graph framework enables users to conduct custom analysis on site specific modelling studies by modifying and customising key parameters.

## ACKNOWLEDGEMENTS

## ABSTRACT

The oil production in wells using electric submersible pumps (ESPs) demands precise control of parameters within safety and efficiency constraints to minimise failures, extend equipment lifespan, and reduce costs. This study proposes a non-linear model predictive control (NMPC) system designed for ESP-lifted wells, leveraging pump frequency and choke valve adjustments to maximise production while adhering to operational limits. Tested on a simulated pilot plant using a first-principles model to predict key variables like flow and liquid column height, the NMPC demonstrated offset-free performance, effective disturbance rejection, and ensured stable, safe, and optimised operations, addressing challenges in nonlinear, constraint-intensive environments.

**Keywords:** Nonlinear Predictive Control, ESP, Oil Wells, Operating envelope

## INTRODUCTION

Oil production using electric submersible pumps (ESPs) is common in artificial lift systems due to their versatility, high flow capacity, and efficiency under demanding conditions [1,2,3]. ESPs adapt to vertical, deviated, and horizontal wells and handle diverse fluid compositions like high water-cut, viscous, or low-gravity crude oil [4,5]. Their compact design suits space-limited wells, while advances in materials and sealing technology improve reliability in high-temperature and high-pressure environments [6].

On the other hand, stable and safe operation is important, as it minimises equipment failures, prolongs the lifespan of components, and significantly reduces costs associated with repairs, maintenance, and production downtime [7]. Additionally, ensuring operational stability helps mitigate revenue losses caused by unexpected equipment failures or suboptimal production processes [8].

In this sense, the effectiveness of these systems depends heavily on the precise control of operational parameters while strictly adhering to safety and efficiency constraints. Indeed, advanced process control has emerged as a tool for reducing constraint violations and optimising production [9,10,11]. By maintaining operations within a well-defined operational envelope, control strategies help avoid common issues such as excessive vibrations, which can lead to premature wear and tear of the pump.

The growing demand for advanced control techniques for nonlinear systems, such as oil wells assisted by ESPs, has driven extensive research into applying nonlinear model predictive control (NMPC) strategies.

While PI/PID controllers are common in industrial applications, they face limitations in managing multivariable systems with strong interactions and operational constraints. NMPC offers a key advantage by predicting future behaviour, coordinating multiple variables, and incorporating constraints directly into the control strategy. Studies such as Sharma & Glemmestad (2013) [12] and Mejía et al. (2018) [13] demonstrate that NMPC outperforms PI/PID in ESP systems, particularly in disturbance rejection and constraint handling

Recently, Mirzaie Harsini et al. (2022) [14] introduced an NMPC designed explicitly for oil wells with ESPs, emphasising its effectiveness in tracking setpoints and managing the complex dynamic interactions between the pump and the reservoir while adhering to the system's operational constraints. This work highlights the importance of robust modelling for optimisation and efficient control.

In earlier studies, Sharma and Glemmestad (2013) [15] explored the optimisation and control of ESP-lifted systems using nonlinear techniques to maximise production and ensure operational stability. Subsequently, the authors expanded this work (Sharma and Glemmestad, 2014 [16]) by applying NMPC to the optimal operation of oil fields with ESPs, demonstrating significant improvements in system performance through detailed simulations.

Mejía et al. (2018) [17] advanced the development of control strategies for ESP-assisted wells by implementing model-based NMPC techniques. Their work underscored the NMPC's ability to handle the complex dynamics of wells and meet the operational demands under strict safety and efficiency constraints.

More recently, Santana et al. (2023) [18] investigated embedded MPC strategies for ESP-lifted wells, evaluating the performance of nonlinear techniques through hardware-in-the-loop (HIL) analyses. This study provided valuable insights into the practical implementation of NMPC strategies, highlighting their feasibility in industrial systems.

This work aims to develop an NMPC system specifically designed for a well-equipped ESP. This NMPC framework integrates the pump's operational constraints while efficiently leveraging the available degrees of freedom to optimise performance. Its primary goal is to maximise oil production while ensuring strict compliance with physical and safety-related system constraints. Compared to traditional PID-based control methods, this approach offers a more advanced and structured solution, making it particularly effective in managing the nonlinear dynamics and constraint-intensive nature of oil well operations.

# METHODOLOGY

## ESP pilot plant

This study involves a pilot plant located at the Industrial Automation Technological Training Center (CTAI) at the Federal University of Bahia (UFBA). The system features a vertical oil well with a 32-meter column and a multistage electric submersible pump (ESP) at 22.8 meters. The pump, a 15-stage model driven by an 18-horsepower motor, circulates mineral-based lubricating oil (API gravity 10) through a closed-loop system with a storage tank (T-101).

The setup includes sensors for pressure, flow rate, motor speed, and auxiliary components such as compressors and chokes.

Figure 1 illustrates the pilot plant's instrumentation and layout, providing an overview of the key components and their arrangement.

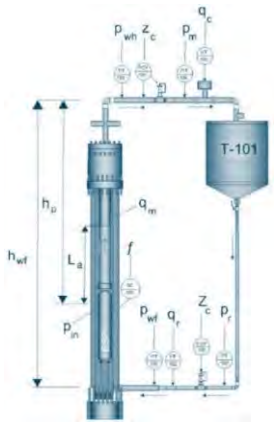

**Figure 1.** Schematic representation of the ESP pilot plant with key variables and components.

In Figure 1, the system inputs are the ESP motor frequency ($f$) and choke valve opening ($Z_c$), with the liquid level in the well ring ($L_a$) as the pump intake reference. Key pressures include reservoir ($p_r$), bottom-hole ($p_{bh}$), intake ($p_{in}$), choke ($p_c$), and manifold ($p_m$). Distances are measured from the choke valve reference ($h_c = 0\,;\, m$), with $h_p$ as the distance to the pump inlet and $h_{bh}$ to the well bottom. Flow rates include reservoir inflow ($q_r$), average well flow ($q_m$), and production flow ($q_c$).

## ESP model

The experimental pilot plant is represented by a virtual plant (Table 1) based on the validated model proposed by Costa et al. (2021) [19].

The phenomenological model of the ESP system is based on the principles of mass and momentum conservation, assuming an isothermal system with incompressible and monophasic fluid, and constant physical and thermal properties. The key variables describing the system include the ESP intake pressure $(p_{in})$, choke pressure $(p_c)$, and the average flow rate in the column $(q_m)$.

Table 2 summarises the parameters employed in the model, encompassing geometric configurations, fluid attributes, and key pump specifications.

**Table 1:** Mathematical representation of ESP system dynamics and flow characteristics.

| Description | Equation |
|---|---|
| Dynamics of intake pressure ($\boldsymbol{p_{in}}$) | $\frac{dp_{in}}{dt} = \left(\frac{g}{A}\right)(q_r - q_m)$ |
| Dynamics of choke pressure ($\boldsymbol{p_c}$) | $\frac{dp_c}{dt} = \left(\frac{1}{V}\right)(q_m - q_c)$ |
| Momentum balance for flow ($\boldsymbol{q_m}$) | $\frac{dq_m}{dt} = \left(\frac{1}{l}\right)(p_{wf} - p_c - \Delta P_p - \Delta P_h - \Delta P_f)$ |
| Hydrostatic pressure loss ($\boldsymbol{\Delta P_h}$) | $\Delta P_h = \Delta P_{h1} + \Delta P_{h2}$, $\Delta P_{h1} = \rho g\,(h_{wf} - h_p)$, $\Delta P_{h2} = \rho g(h_p - h_c)$ |
| Average pressure ($\boldsymbol{\rho_{bar}}$) | $\rho_{bar} = \frac{(\rho_1 V_1 + \rho_2 V_2)}{(V_1 + V_2)}$ |
| Pressure increment by ESP ($\boldsymbol{\Delta P_p}$) | $\Delta P_p = H(f, q_b)\, g, H(f, q_b) = H_0(q_b, f_0)\,(f/f_0)\text{^}2$ |
| Pump polynomial for freshwater ($\boldsymbol{H_0}$) | $H_0 = x_2\, q_m^2 + x_1\, q_m + x_0$ |
| Frictional pressure loss ($\boldsymbol{\Delta P_f}$) | $\Delta P_f = F_1 + F_2$, $F_i = f_i\left(\rho\, L_i\, \frac{D_i}{4}\right)\left(\frac{q_i}{A_i}\right)^2$ |
| Average system length ($\boldsymbol{l_{bar}}$) | $l_{bar} = \frac{(l_1 + l_2)}{2}$ |
| Flow rates through valves ($\boldsymbol{q_r, q_c}$) | $q_r = K_r\, Z_r \sqrt{(p_r - p_{wf})}$, $q_c = K_c\, Z_c \sqrt{(p_c - p_{wf})}$ |

**Table 2:** Parameters and physical properties of the ESP pilot plant system.

| Parameter | Value |
|---|---|
| Gravity constant, g (m/s²) | 9.81 |
| Fluid density, ρ (kg/m³) | 855 |
| Fluid viscosity, μ (Pa·s) | 0.00889 |
| Bulk modulus, $\beta_e$ (Pa) | $1.8\times10^9$ |
| Cross-section area of the annulus, A (m²) | 0.033059 |
| Average cross-section area, Â (m²) | 0.0108 |
| Pipe radius below ESP, $r_1$ (m) | 0.110 |
| Pipe radius above ESP, $r_2$ (m) | 0.0375 |
| Length from the pump intake to choke, $l_2$ (m) | 22.7 |
| Length from the reservoir to choke, $l_1$ (m) | 9.3 |
| Average length, l (m) | 16 |
| Pipe volume below ESP, $V_1$ (m³) | 0.3286 |
| Pipe volume above ESP, $V_2$ (m³) | 0.103 |
| Head's polynomial coefficient, $x_2$ (s²/m³) | -75.397 |
| Head's polynomial coefficient, $x_1$ (s/m³) | 7.8962 |
| Head's polynomial coefficient, $x_0$ (m) | 180.7986 |
| Reservoir valve constant, $K_a$ (m³/s·Pa) | 0.7221 |
| Choke valve constant, $K_e$ (m³/s·Pa$^{0.5}$) | 0.2283 |
| Minimum flow rate, $q_{min}$ (m³/s) | $1\times10^{-3}$ |
| Maximum flow rate, $q_{max}$ (m³/s) | 0.1 |
| ESP characteristic ref freq, $f_0$ (Hz) | 60 |
| Height from the pump intake to choke, $h_p$ (m) | 22.7 |
| Height from the reservoir to choke, $h_{\beta h}$ (m) | 32 |

## Nonlinear MPC

The NMPC is formulated to optimise the system performance by minimising a cost function $J_k$, which consists of three terms: the tracking error term, the error correction term, and the movement suppression term. This approach ensures that the controlled system achieves its desired objectives while maintaining adherence to operational and safety constraints. The cost function is expressed as:

$$J_k = \sum_{j=1}^{H_p} \left\| y_{k+j|k} - y_{sp} + e_{k|k} \right\|_Q^2 + \sum_{j=0}^{H_c-1} \left\| \Delta \mathrm{u}_{\mathrm{k+j|k}} \right\|_R^2 \quad (1)$$

subject to:

$$-\Delta u_{max} \le \Delta \mathrm{u}_{\mathrm{k+j|k}} \le \Delta u_{max}$$

$$u_{min} \le \mathrm{u}_{\mathrm{k+j|k}} \le u_{max}$$

$$j = 0, \ldots, m-1, \Delta u_{k+j|k} = 0, \forall j \ge m$$

$$y_{min} \le y_{k+j|k} \le y_{max}$$

$$\Delta \mathrm{u}_{\mathrm{k+j|k}} = \mathrm{u}_{\mathrm{k+j|k}} - \mathrm{u}_{\mathrm{k+j-1|k}}$$

where $H_p$ is the prediction horizon, $H_c$ is the control horizon, and $Q$ and $R$ are tuning parameters that adjust the weights of the respective terms.

The first term, the tracking error term, represents the deviation between the predicted outputs $y_{k+j|k}$ and the reference setpoints $y_{sp}$, ensuring that the system tracks the desired trajectory effectively over the prediction horizon. The second term, the error correction term, accounts for the initial deviation $e_{k|k}$ at the start of the horizon, enhancing the system's ability to address pre-existing errors. The third term, the movement suppression term, penalises excessive changes in the manipulated variables $\Delta \mathrm{u}_{\mathrm{k+j|k}}$, promoting smoother control actions that minimise wear and energy consumption.

To maintain operational feasibility, the NMPC framework incorporates constraints such as limits on the rate of change of the manipulated variables ($-\Delta u_{max} \le \Delta \mathrm{u}_{\mathrm{k+j|k}} \le \Delta u_{max}$) control input bounds ($u_{min} \le \mathrm{u}_{\mathrm{k+j|k}} \le u_{max}$), and output constraints ($y_{min} \le y_{k+j|k} \le y_{max}$). Additionally, adjustments to the control inputs are limited to the control horizon , ($\Delta u_{k+j|k} = 0, \forall j \ge m$ ).

In this formulation, the controlled variables are the liquid column height (head) and the production flow, while the manipulated variables are the ESP motor frequency and the choke valve opening. The NMPC balances accurate tracking, operational stability, and smooth control actions, providing an advanced solution for managing nonlinear systems with dynamic and constraint-intensive behaviour.

The NMPC's nonlinear optimization problem was solved using FMINCON, MATLAB's optimization toolbox, providing a reliable benchmark for simulations.

## RESULTS

The NMPC performance was evaluated in two distinct scenarios: a servo case focused on setpoint tracking and a regulatory case involving two situations with unmeasured disturbances, one with noise and the other without noise, as is shown in Figure 2 and 3. The results highlight the controller's ability to manage monitoring and regulatory tasks while respecting operational constraints effectively. The NMPC was configured with a prediction horizon of 10 and a control horizon of 6. The tuning parameters were set as Q = [1000, 100] and R = [1, 1], ensuring a balance between accurate tracking and smooth control actions.

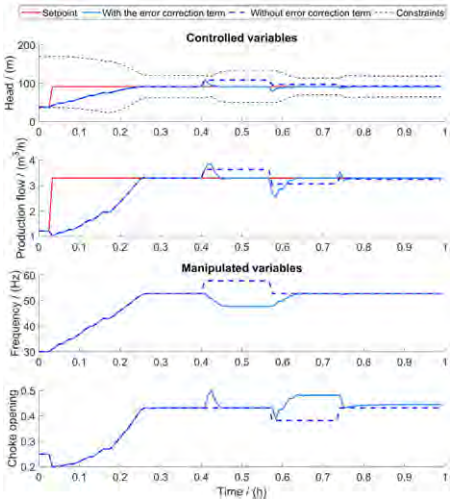

**Figure 2.** NMPC performance in servo and regulatory scenarios with noise disturbance.

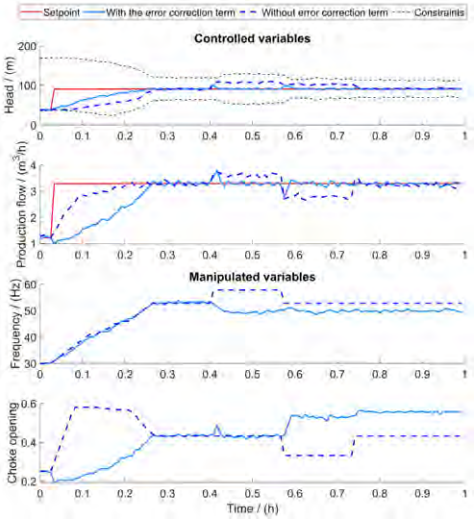

**Figure 3.** NMPC performance in servo and regulatory scenarios without noise disturbance.

In the servo case, the NMPC precisely tracked the reference setpoints for the controlled variables, namely head and production flow. The inclusion of the error correction significantly improved the tracking performance, resulting in smoother transitions and reduced oscillations, particularly in the production flow. The manipulated variables, represented by the ESP motor frequency and choke opening, gradually adjusted to achieve the desired setpoints without causing abrupt changes. This smooth behaviour underscores the controller's ability to optimise performance while avoiding unnecessary stress on the system.

The regulatory case demonstrated the NMPC in rejecting unmeasured disturbances. Without noise, the controller effectively maintained the controlled variables within their constraints and close to their setpoints. The manipulated variables responded predictably, adapting smoothly to compensate for disturbances. When noise was introduced, the NMPC continued to perform well, with only minor fluctuations observed in the controlled variables due to the noise. The error correction term's presence further mitigated the noise's impact, ensuring stable operation and minimising deviations from the setpoints. The manipulated variables remained within acceptable operational ranges, highlighting the controller's ability to handle noisy environments.

Comparing the scenarios with and without the error correction term revealed its significant impact on system performance. The error correction term reduced tracking errors during setpoint transitions and enhanced disturbance rejection capabilities. It also contributed to smoother adjustments of the manipulated variables, promoting stable and efficient operation. Across all scenarios, the NMPC maintained the controlled variables within predefined constraints, demonstrating its ability to manage nonlinear dynamics and constraint-intensive processes effectively.

Figure 4 illustrates the convergence of the objective function during the optimisation process in the regulatory and servo scenarios without noise. The curve shows a sharp initial decrease, indicating rapid minimisation of the objective function in the early iterations. This behaviour reflects the NMPC's ability to quickly adjust the manipulated variables to align the controlled variables with the desired setpoints. After approximately 20 iterations, the objective function stabilises, demonstrating the controller's efficiency in achieving a steady-state solution with minimal computational effort without noise.

Figure 5 depicts the convergence of the objective function in the presence of noise for both regulatory and servo scenarios. Similar to the noise-free case, the objective function exhibits a rapid initial decrease, signifying effective adjustments by the NMPC. However, the curve is less smooth compared to the noise-free case, with slight fluctuations observed during the optimisation process. These fluctuations are attributable to the noise disturbance, which introduces variability in the system's

responses. Despite this, the objective function stabilises after approximately 25 iterations, highlighting the effectiveness of the NMPC in handling noisy environments and maintaining convergence toward an optimal solution.

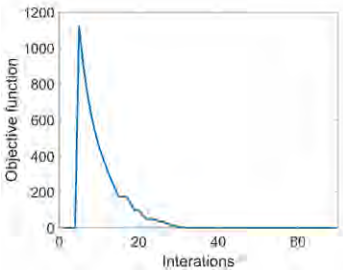

**Figure 4.** Convergence of the objective function in the regulatory and servo scenarios without noise disturbance.

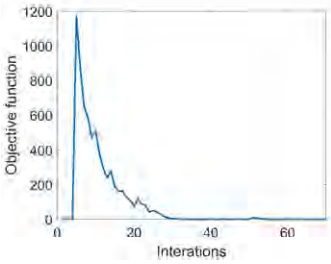

**Figure 5.** Convergence of the objective function in the regulatory and servo scenarios with noise disturbance.

The results validate the NMPC's effectiveness in both servo and regulatory cases. The controller achieved accurate setpoint tracking, disturbance rejection, and stable operation, even under the influence of noise.

To assess the NMPC's robustness, a new simulation was conducted with plant-model mismatch and measurement noise. A 5% uncertainty in the pump's maximum head simulated performance variations, while stochastic noise modelled sensor inaccuracies. Figure 6 shows that the NMPC adapts well, maintaining constraints and stability. The error correction term improves setpoint tracking by mitigating steady-state offsets. Despite minor fluctuations in the manipulated variables due to noise, the controller ensures smooth adjustments, demonstrating its feasibility for real-world ESP applications. Figure 7 presents the convergence of the objective function under noise disturbances in regulatory and servo scenarios.

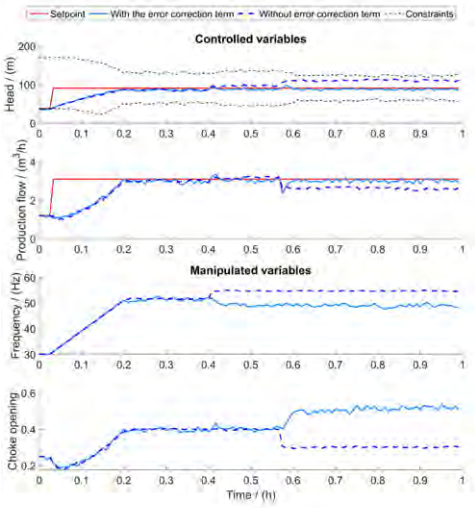

**Figure 6.** NMPC performance under plant-model mismatch and measurement noise: comparison with and without the error correction term.

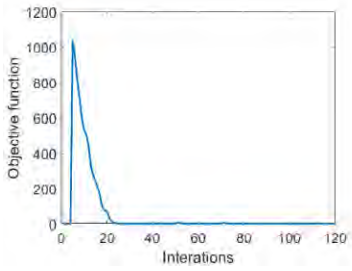

**Figure 7.** Convergence of the objective function in the regulatory and servo scenarios with plant-model mismatch and measurement noise.

## CONCLUSIONS

The results demonstrate that the NMPC effectively handles ESP-lifted oil wells' nonlinear dynamics and constraints, ensuring stable operation and improved setpoint tracking. The controller adapts well to plant-model mismatch and noise, highlighting its capability for real-world applications. In future work, the NMPC will be implemented in the pilot plant to validate its experimental performance and compare it with conventional PI/PID controllers under real operating conditions.

## ABSTRACT

In chemical process control, decision-making often involves balancing multiple conflicting objectives, such as maximizing production, minimizing energy consumption, and ensuring process safety. Traditional approaches for multi-objective optimization, such as linear programming and evolutionary algorithms, have proven effective but struggle to adapt in real-time to the dynamic and nonlinear nature of chemical processes. In this paper, we propose a framework that combines Reinforcement Learning (RL) with Multi-Objective Evolutionary Algorithms (MOEAs) to address these challenges. Specifically, we utilize MOEAs, such as NSGA-II, to optimize the parameter space of policy neural networks, resulting in a Pareto front of policies. This Pareto front provides a diverse set of policies that enable operators to dynamically switch control strategies based on real-time system conditions and prioritized objectives. Our proposed methodology is applied to a Controlled Stirred Tank Reactor (CSTR) case study, focusing on balancing the objectives of minimizing set point error and operational costs. The case studies highlight the adaptability of the method in dynamic environments, including scenarios involving fouling, showcasing its resilience and flexibility in complex, nonlinear systems. This work demonstrates the potential of combining RL and MOEAs to advance decision-making in chemical process control, providing a robust and adaptable framework for navigating environments with changing objectives. The methodology can also be extended to other industrial applications with similarly challenging multi-objective requirements.

**Keywords**: Process Control, Machine Learning, Industry 4.0, Reinforcement Learning

## INTRODUCTION

In recent years, the field of Process Systems Engineering (PSE) has experienced a significant shift towards advanced optimization techniques that can handle the inherent complexities of modern systems, whether in process control, sustainable supply chains, or other industrial operations. A key challenge in these systems is optimizing multiple, often conflicting objectives —such as minimizing operational costs, ensuring process safety, improving product quality, and reducing environmental impact. This challenge has been amplified by a growing emphasis on sustainability and efficiency in industrial operations which highlights the need to develop decision-making frameworks that can handle dynamic environments with shifting priorities.

In industrial process control, balancing multiple objectives, such as optimizing productivity, reducing energy consumption, minimizing environmental impact, whilst maintaining safety is crucial. However, traditional control methods struggle to handle these competing goals, especially when unexpected disruptions occur, leading to emergency shutdowns and costly downtime.

Traditionally, industrial control problems have been addressed using model-based techniques, such as proportional-integral-derivative (PID) controllers, model predictive control (MPC), and multi-objective optimization (MOO) methods. These methods rely on mathematical models of system dynamics and predefined performance criteria to achieve optimal control. While effective in many industrial settings, they often struggle to manage the complexities of nonlinear, high-dimensional, and

dynamically changing environments.

For instance, PID controllers are limited in their ability to handle multi-variable interactions and time-varying dynamics. MPC, although more robust, can become computationally expensive and less effective when confronted with nonlinear stochastic systems or unexpected disturbances. Similarly, traditional MOO techniques rely on explicit trade-offs between objectives and are often static. These approaches can be inflexible, failing to adapt to evolving priorities in real-world decision-making where conflicting or shifting objectives are common.

Reinforcement Learning (RL) has emerged as a promising alternative to overcome these limitations. As a data-driven, model-free approach, RL enables agents to learn optimal control policies by interacting with the environment, making it well-suited for dynamic and nonlinear stochastic systems [1]. By framing control tasks as sequential decision-making problems, RL offers a natural framework for optimizing processes over time. This adaptability makes it particularly effective for applications such as chemical reactors, power grids, and supply chains, where system behavior can be complex and difficult to model explicitly.

Despite its advantages, standard RL algorithms are typically designed to optimize a single objective, which limits their effectiveness in scenarios requiring trade-offs among multiple competing goals. This limitation has driven the development of multi-objective reinforcement learning (MORL), an extension of RL tailored to handle multiple objectives simultaneously.

MORL methods can be broadly categorized into scalarization-based, Pareto-based, and decomposition-based approaches. Scalarization converts multiple objectives into a single reward function, often requiring prior knowledge of preference weights [2]. Pareto-based methods, such as Pareto Q-learning [3], maintain a set of non-dominated solutions, by learning a set of Pareto-optimal policies, enabling agents to explore multiple trade-offs without explicit weighting. Decomposition-based approaches, including MORL/D [4], break multi-objective problems into smaller subproblems and leverage reinforcement learning to solve them iteratively. Recent advances, such as deep reinforcement learning for multi-objective optimization (DRL-MOA) have further improved the scalability and generalization of MORL methods.

Multi-Objective Evolutionary Algorithms (MOEAs), for instance, offer a robust way to search across a broad solution space without requiring differentiable objective functions. Their ability to maintain a population of solutions, each addressing different trade-offs between objectives, makes them a natural fit for tackling multi-objective problems in dynamic environments. In this paper, we combine the adaptive decision-making capabilities of RL with MOEAs' ability to balance diversity and proximity to the Pareto front. Specifically, we use MOEAs to search the parameter space of neural network policies, resulting in a Pareto front of policies. This equips the decision-maker with a swarm of policies, allowing for dynamic switching between policies based on the current system objectives and dynamics. This strategy ensures flexibility in real-time decision-making under uncertainty, allowing the system to adapt quickly to changing conditions without the need to evolve policies continuously.

The rest of the paper is organized as follows: the preliminaries section provides the background on reinforcement learning and evolutionary strategies, the methodology section describes the proposed multi-objective evolutionary algorithm-based reinforcement learning framework in more detail. The case study section discusses the simulation and experimental results and finally, we summarize the paper and provide an outlook for future work.

## PRELIMINARIES

### Introduction to Reinforcement Learning

In single agent reinforcement learning, the agent aims to learn an optimal policy by interacting with the environment and learning through trial-and-error. In RL, the agent observes the current state $x_t \in X \subseteq \mathbb{R}^{n_x}$, chooses an action $u \in U \subseteq \mathbb{R}^{n_u}$ with probability given by the policy $\pi(u|x)$ and transitions into the next state, $x_{t+1} \in X \subseteq R^{n_x}$ with probability given by the state transition probability function $P(x_{t+1}|x_t,u_t)$ and receives a reward $r_{t+1} = \mathcal{R}(x_t,u_t,x_{t+1}) \in \mathbb{R}$. The agent finds an optimal policy $\pi^*$ by maximizing the expected sum of rewards over a time horizon defined as:

$$J(\pi) = \mathbb{E}_{(x_t,u_t)\sim\pi}\left[\sum_{t=0}^{T-1}\gamma^t r_{t+1}(x_t,\, u_t = \pi(x_t))|\right]$$

$$\pi^* \in \arg\max_{\pi} J(\pi)$$

Where $\gamma \in [0,1]$. In practice, the policy is parameterized such that $\pi^* \approx \pi^*(u|x;\theta)$, where $\theta \in \Theta \subseteq \mathbb{R}^{n_\theta}$ represents the weights of the neural network and $\Theta$ is the parameter space. The aim is to optimize parameters $\theta$ to maximize the cumulative rewards, learning an effective mapping from states $x$ to actions $u$.

To achieve this, policy-gradient methods optimize parameters $\theta$ by estimating gradients of the expected reward with respect to parameters $\theta$. This approach contrasts to value-based methods, as they directly update the policy, making it suitable for continuous action spaces and high dimensions. Algorithms like REINFORCE, Proximal Policy Optimization (PPO), and Trust Region Policy Optimization (TRPO) are popular choices here, as they leverage policy gradients and surrogate objectives to improve stability and performance [5,6]. However, policy gradient methods rely on sampling rollouts to

estimate gradients. These samples can exhibit large variance due to the stochastic nature of the environment and policy, leading to noisy gradient estimates.

An alternative approach is using Evolutionary Strategies (ES). ES methods optimize parameters $\theta$ by exploring the parameter space $\Theta$ through simulating an evolutionary process. Rather than relying on gradient-based updates, ES methods employ population-based search techniques to evolve policies. In each iteration, a population of candidate policies is evaluated based on a reward metric, with the most successful candidates selected to "reproduce" via mutation and recombination, guiding the search toward high-performing areas of the parameter space.

Evolutionary strategies for reinforcement learning (ES-RL) have shown promising results in optimizing policy parameters due to their lack of need for backpropagation. Instead of relying on gradient information, ES-RL evaluate policy performance by sampling multiple trajectories and directly update the parameters towards those that lead to higher performance. This method enhances scalability in distributed settings as its easier to parallelize. There's also fewer hyperparameters to tune compared to gradient-based methods and they are less likely to get stuck in local optima as they are population-based methods so search "globally" rather than relying on stochastic estimates of gradients to optimize the parameters. Although ES-RL has demonstrated competitive performance, as highlighted in OpenAI's work [7], where it showed comparable results to other policy gradient methods on environments like MuJoCo and Atari, it is important to note that ES-RL does not universally outperform policy gradient methods. Rather, ES-RL is particularly advantageous in specific contexts, especially when extended to multi-objective evolutionary reinforcement learning (MOEA-RL). The population-based search techniques of ES-RL can be leveraged to handle multiple, conflicting objectives in complex, dynamic environments providing a framework for optimization problems where traditional RL methods may face limitations.

## METHODOLOGY

This section presents the proposed multi-objective reinforcement learning framework which integrates traditional reinforcement learning with multi-objective evolutionary strategies.

### MORSE - Multi-Objective Reinforcement learning via Strategy Evolution

Due to the aforementioned benefits of evolutionary strategies, the proposed methodology leverages multi-objective evolutionary strategies (MOEA) for multi-objective reinforcement learning (MORL). In this work, we leverage NSGAA-II [8] to directly optimize the parameter space of the policies, building a Pareto set of policies rather than a Pareto set of solutions, as is common in traditional multi-objective optimization methods. This approach provides the decision maker with a diverse set of adaptable and dynamic policies, facilitating rapid decision-making in complex environments. The proposed methodology is shown in Algorithm 1 and Figure 1.

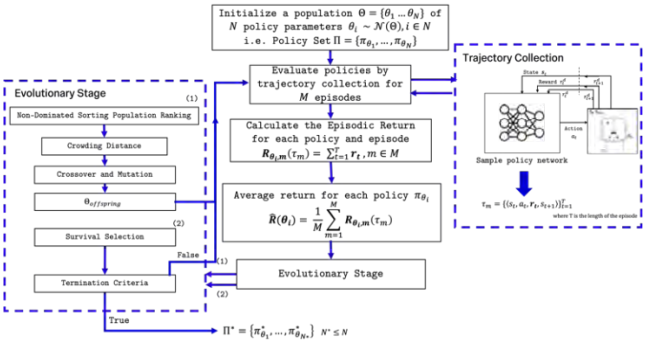

**Figure 1.** Schematic overview of our MORSE framework.

This results in a Pareto front of policies rather than a single policy. This allows decision-makers to have the flexibility to switch between policies and choose one that gives the best trade-off according to the needs in real-time. This is valuable in dynamic environments where priorities may shift due to external disruptions to the system [3,5,9].

### Multi-Objective Markov Decision Process

The sequential decision-making problem is formulated as a Multi-Objective Markov Decision Process, which can be defined as a tuple $\langle X, U, \mathcal{T}, \gamma, \mu, \mathbf{R} \rangle$ where $X$ is the state space, $U$ is the action space, $\mathcal{T}$ is the probability transition function where $\mathcal{T} : X \times U \times X \to [0,1]$, $\mu : X \to [0,1]$ is a probability distribution over initial states and $R : X \times U \times X \to R^d$ is a vector valued reward function where $d \geq 2$ is the number of objectives. The vector-valued reward function $R$ is one of the differences between single-objective RL and multi-objective RL. Finally, a policy $\pi : X \to U \in \Pi$, maps states to actions where $\Pi$ is a set of all the possible policies. Another notable difference between multi-objective and single-objective MDPs is the vector valued value function, $V^\pi \in R^d$ which is conditioned on the number of objectives and is defined as $V^\pi(x) = \mathbb{E}_\pi \sum_{t=0}^{T-1} \gamma^t r_{t+1}$ where $r_{t+1} = R(x_t, u_t, x_{t+1})$.

A note that due to the multi-objective nature of the definition, it is possible to encounter a situation where for objectives $j$ and $k$ where $j, k \in \{1, 2, \dots, d\}$ and policies $\pi$ and $\pi'$ where $\pi, \pi' \in$, both of the following inequalities can hold true:

$$V_j^\pi(x) > V_j^{\pi'}(x) \text{ Policy } \pi \text{ is better for objective } j$$

$$V_k^\pi(x) < V_k^{\pi'}(x) \text{ Policy } \pi' \text{ is better for objective } k$$

This indicates that while policy $\pi$ outperforms policy $\pi'$ in

objective $j$, it underperforms in terms of objective $k$. This illustrates the concept of trade-offs in multi-objective reinforcement learning, where optimizing for one objective can lead to suboptimal performance in another. Therefore, the agent must make decisions based on the relative importance of each objective.

## Computational Case Study

The modelled system is a Controlled Stirred Tank Reactor (CSTR), a complex and nonlinear dynamical system which can be modelled using two ordinary differential equations. A schematic is also shown in Figure 2.

$$\frac{\mathrm{d}C_A}{\mathrm{d}t} = \frac{q}{V}\left(C_{A_f} - C_A\right) - kC_A e^{\frac{-E_A}{RT}}$$

$$\frac{\mathrm{d}T}{\mathrm{d}t} = \frac{q}{V}\left(T_f - T\right) - \frac{\Delta H_R}{\rho C_p} kC_A e^{\frac{-E_A}{RT}} + \frac{UA}{\rho C_p V}\left(T_c - T\right)$$

The equations above describe a CSTR where an irreversible chemical reaction occurs which converts species A to B with cooling provided by water flowing through a coiled tube

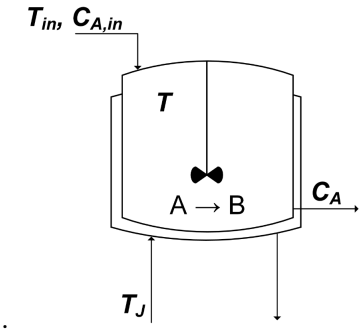

**Figure 2.** Schematic overview of Controlled Stirred Tank Reactor (CSTR)

The state variables are the concentration of species A, $C_A$ and the reactor temperature T, which constitute the state representation in our RL framework. At any given time step, the state can be expressed as a vector $x_t = [C_A, T]$, which provides the agent with the necessary information about the system's current conditions. The state variables evolve dynamically according to the system's governing equations.

Our system features one input control variable, the cooling water temperature $T_c$, modelled as a continuous variable.

Due to the non-linear dynamics, evident in the exponential term which includes the reactor temperature $T$, strong coupling between state variables, and potential for instability, the control of the CSTR presents significant challenges [10]. These difficulties are further exacerbated in systems with multiple conflicting objectives and when objectives change over time depending on the dynamics of the system. For instance, optimizing reactor performance might involve simultaneously maintaining a desired product concentration, minimizing energy consumption, and ensuring safe operating conditions, which often conflict with one another.

**Algorithm 1** MORSE

**Input:** Number of policies $N$, Maximum generations $G$, Evaluation episodes $E$
**Output:** Pareto front set of policies $\mathcal{F}_{\text{Pareto}}$

**Step 1: Initialization**
Generate a population of policies $\Pi = \{\pi_1, \pi_2, \ldots, \pi_N\}$, where each policy $\pi_i$ is parameterized by $\theta_i$
**Step 2: Policy Evaluation**
**for** each policy $\pi_i \in \Pi$ **do**
  **for** each episode $e = 1, 2, \ldots, E$ **do**
    Initialize state $s_0$ from the environment
    **for** each time step $t = 0, 1, \ldots, T$ **do**
      Select action $a_t \sim \pi_{\theta_i}(s_t)$ based on the policy
      Execute action $a_t$, observe reward $r_t$, next state $s_{t+1}$
      Accumulate discounted reward for each objective
    **end for**
  **end for**
  Compute average objective values over $E$ episodes
**end for**
**Step 3: Non-dominated Sorting**
Sort policies into fronts based on dominance relationships: $\mathcal{F}_1, \mathcal{F}_2, \ldots$
**Step 4: Crowding Distance Calculation**
**for** each front $\mathcal{F}_j$ **do**
  Compute crowding distance $d(\pi_i)$ for each policy $\pi_i$
**end for**
**Step 5: Selection and Reproduction**
Binary tournament selection, then crossover & mutation:
$\theta_{\text{offspring}} = \text{Crossover}(\theta_i, \theta_j) + \text{Mutation}(\theta_k)$
**Step 6: Survival Selection**
Combine parent population $\mathcal{P}$ and offspring $\mathcal{P}_{\text{offspring}}$. Select top $N$ policies based on non-domination rank and crowding distance:
$\mathcal{P}' = \text{Top-}N(\mathcal{P} \cup \mathcal{P}_{\text{offspring}})$
**Step 7: Termination Criteria**
**if** Termination criteria met **then**
  **break**
**end if**
**Step 8: Pareto Front Identification**
Identify non-dominated solutions in the final population:
**return** Pareto front set $\mathcal{F}_{\text{Pareto}}$ ; $\Pi = \{\pi_1^*, \pi_2^*, \ldots, \pi_{n*}^*\}$

In this study, our CSTR model integrates two cumulative objective functions throughout the time horizon: Minimize the set point error and minimize the costs (composed of heat costs and emergency shutdown costs). The reward function therefore is a vector-valued function at each time step:

$$\boldsymbol{R}_t = \left[\left(C_A(t) - C_A^*(t)\right)^2, \alpha\left(T_c - T(t)\right)^2 + \beta\mathbb{I}(shutdown)\right]$$

The first term represents the squared error between the actual concentration of species A and the desired set point concentration, $C_A^*(t)$. The second term captures the heat costs related to the deviation between the cooling temperature $T_c$ and reactor temperature $T(t)$ where $\alpha$ is a constant; the term $\beta\mathbb{I}(shutdown)$ accounts for emergency shutdown costs where $\mathbb{I}(shutdown)$ is an indicator function that takes value 1 if an emergency shutdown takes place and 0 otherwise. The cost coefficient $\beta$ reflects the severity of this event.

The goal is to ascertain the optimal control action during each time period $t$ spanning over a total of $T$ time periods within a discrete-time setup. The environment is implemented by adapting PC-Gym [10].

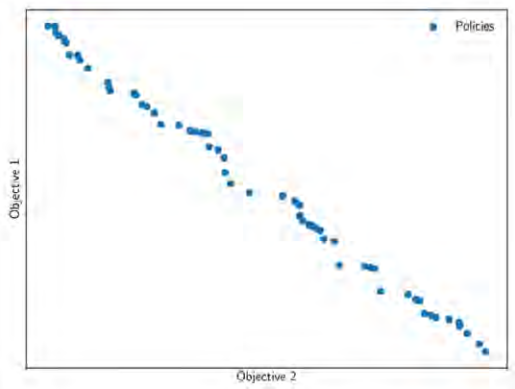

Figure 3. The resulting Pareto front showing the set of non-dominated policies, illustrating the trade-off between two competing objectives.

## SCENARIOS

In this section, we examine the adaptability of our methodology through several case studies. Using our approach, we derive a Pareto set of policies, as shown in Figure 3, that optimally balance competing objectives. When a disruption affects the system, this Pareto set allows for swift policy switching, enabling us to select a policy that best meets the real-time needs and constraints. By dynamically adjusting to changing conditions, we demonstrate how our method offers resilience and flexibility in complex environments.

### Scenario 1: Fouling

Fouling is a common issue in chemical processes, particularly in CSTRs, where unwanted material accumulates on the reactor walls or heat exchanger surfaces. This buildup can significantly reduce heat transfer efficiency, alter reaction rates, and increase operating costs due to the need for additional energy to maintain the desired temperature.

In this case study, we simulate fouling by introducing a time-dependent reduction in the heat transfer coefficient. As fouling progresses, maintaining optimal product concentrations and minimizing energy costs become increasingly challenging. Using our methodology, we analyze how the Pareto set of policies adapts to these conditions. For instance:

- Policies that prioritize minimizing set-point error may involve increasing the heat input to compensate for the reduced heat transfer efficiency.
- Policies that that prioritize cost minimization may tolerate larger deviations from the desired set-point to avoid excessive energy consumption.

The results shown in Figure 4 demonstrate that the proposed approach can dynamically adjust control actions to balance competing objectives under fouling conditions, ensuring safe and efficient reactor operation. The dynamic policy significantly outperforms the constant policy in minimizing set point error (Objective 1), showcasing its ability to respond quickly to disturbances and maintain the system closer to the desired operating range. However, the difference in costs (Objective 2) between the dynamic and constant policies is relatively small, indicating that both approaches manage costs effectively under normal fouling conditions.

This small difference in costs suggests that cost optimization may not be as sensitive to dynamic control under routine disruptions. However, costs could become a much more prominent factor in scenarios where fouling leads to severe disruptions, such as an emergency shutdown or significant system failure.

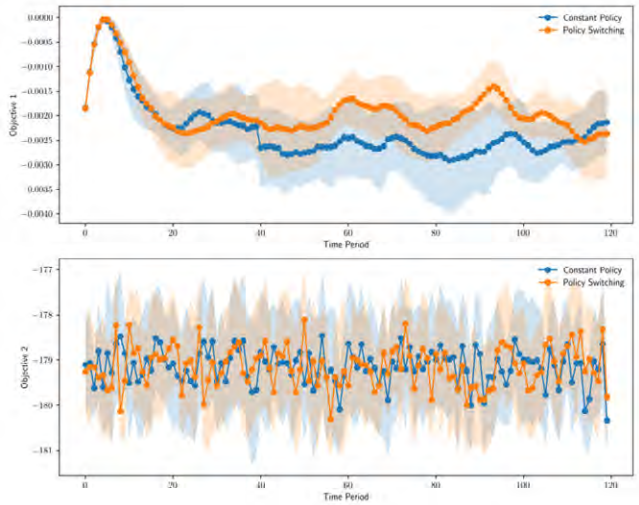

**Figure 4.** Execution profiles of the fouling case study, showing objective 1 (set point error) and objective 2 (costs) with shaded variance.

## CONCLUSIONS AND FUTURE WORK

In conclusion, we have proposed a methodology which leverages reinforcement learning (RL) and multi-objective evolutionary algorithms (MOEAs) to address the challenges of controlling a CSTR with competing objectives. By leveraging a Pareto-based approach, by using MOEAs to search the parameter space of the neural network policies, we successfully derive a set of non-dominated policies that balance objectives such as minimizing set-point error and operational costs. The case studies highlight the adaptability of the method in dynamic environments, including scenarios involving fouling showcasing its resilience and flexibility in complex

systems.

Future work will focus on improving the efficiency of the evolutionary search process by integrating domain-specific knowledge and operator expertise. Additionally, we will investigate collaborative decision-making strategies across interconnected processes by extending this work to multi-unit reactor systems. We also plan to adapt our method to handle partially observable environments, which are often encountered in industrial settings with incomplete measurements. Finally, the incorporation of additional objectives such as emissions control, stability and long-term maintenance costs, will further enhance its relevance to real-world applications. Source code for this study is available on GitHub.

# Extremum seeking control applied to operation of dividing wall column – DWC

**Ivar J. Halvorsen[a,c*], Leontine I.M. Aarnoudse[b], Mark A.M. Haring[a], Sigurd Skogestad[c]**

## ABSTRACT

The dividing wall column (DWC) has significant energy saving potential compared to conventional column sequences. However, to reach these savings in practice, it is essential that the control structures can track the optimal operation point despite inevitable changes in feed properties, performance characteristics and other uncertainties. Otherwise, the energy consumption may rise significantly or, more commonly, the DWC becomes unable to produce pure products even at its maximum reboiler duty. Extremum seeking control (ESC) is a model-free optimisation technique that may mitigate off-optimal operation in this environment. By active perturbation of selected manipulative variables, the algorithm infers gradient properties of the measured cost function and, by that, enables tracking of a moving optimum. Extremum seeking control can be used also in combination with other approaches, e.g. self-optimising control. Applied to the DWC, the presented perturb-and-observe algorithm, which can be classified as ESC, appears to be able to track changes in the optimal values of the manipulated variables and setpoints.

## INTRODUCTION

The dividing wall column (DWC) is an attractive integrated distillation arrangement, since there are significant saving potentials in energy and capital cost compared to conventional column sequences [1, 2]. Despite that challenges in operation and design have been listed in the literature as a key obstacle, there are developments in this area that can enable more widespread industrial usage [3]. In a conventional column sequence, e.g., the direct split configuration, controlling the purities of each column to their specifications implicitly gives the lowest overall energy consumption [4]. In DWC operation, there are some pitfalls that may lead to either higher energy consumption and/or failure to produce the designed product purities [5]. Thus, it is of great interest to develop operating strategies that can handle real-world uncertainties and enable the DWC to operate such that it always maintains its designed capabilities in low energy consumption and simultaneous high product purity.

The characteristics of optimal operation have been described in detail for ideal mixtures and infinite number of stages [6] and also for finite stages [7], but the practical challenge is to use these insights to devise a control structure that can implement the optimal moves of the key manipulative variables as unmeasured disturbances affect the optimum process characteristics. This kind of on-line optimisation is needed in addition to the regulatory control that is required for maintaining the products inside the given purity specifications.

Herein, the focus is on perturbation-based optimisation of the available manipulators. Perturbation-based optimization methods such as extremum seeking control (ESC) are capable of optimizing many types of processes, even when these processes vary in time and model knowledge is limited [8–10]. In this paper, we consider the application of perturb-and-observe, a type of ESC, to approach optimal operation points for the dividing wall column. The main idea of this method is to iteratively perturb the available manipulative variables, observe the outcome and move in the direction of improvement. This leads to fast convergence to the optimal

operation point, as well as fast tracking if the optimal operation point changes over time.

## PERTURB AND OBSERVE

In this section, the perturb-and-observe method for model-free adaptive optimization is introduced. Consider the problem of minimizing an unknown, time-varying function $f(k,u(k))$ with input $u(k)$, where $k = 1,2,\ldots$ denotes the time index. We make the following assumptions:

1. The function $f$ is unknown at any time $k$, but we can obtain noisy measurements of the form
2. $$y(k) = f\big(k,u(k)\big) + \varepsilon(k). \quad (1)$$
3. The magnitude of the measurement disturbance $\varepsilon(k)$ is small compared to the range of possible function values.
4. At any time $k$, function $f$ has a unique minimum.
5. The rate of change of $f$ is small compared to the sampling frequency.
6. The function $f\big(k,u(k)\big)$ is static. If the underlying process contains dynamics, $f\big(k,u(k)\big)$ represents the steady-state behavior.

Function $f\big(k,u(k)\big)$ can represent many different processes. In the context of the dividing wall distillation column considered in this paper, a typical choice is the energy consumption $V$ of the reboiler as a function of the liquid split $R_l$ , i.e., $f\big(k,u(k)\big) = V\big(k,R_l(k)\big)$ with $u(k) = R_l(k)$. The corresponding measurement $y(k)$ could be a direct, noisy measurement of the reboiler energy consumption, or an estimate based on, e.g., temperature measurements.

The aim is to find the input $u(k)$ that minimizes $f\big(k,u(k)\big)$ and tracks this minimum while it changes over time. To this end, a perturb-and-observe method is employed. The main idea is to perturb the input variable $u$ and determine the direction of improvement from the corresponding measurements $y$. Consider an initial input $u(1)$, for which output $y(1)$ is measured. The next input is chosen as

$$u(2) = u(1) + \Delta_u, \quad (2)$$

for some step size $\Delta_u$. For $k = 2,3,\ldots$, the corresponding measurement $y(k)$ is compared to the previous measurement $y(k-1)$ to obtain the direction of improvement $g(k+1) \in \{-1,1\}$ as follows:

$$g(k+1) = \begin{cases} g(k), & if\ \ y(k) \le y(k-1), \\ -g(k), & if\ \ y(k) > y(k-1). \end{cases} \quad (3)$$

Next, the direction of improvement is used to determine the next input by taking

$$u(k+1) = u(k) + g(k+1)\Delta_u. \quad (4)$$

Thus, if input $u(k)$ leads to a smaller measured output $y(k)$ compared to the previous input $u(k-1)$, we are moving towards the minimum and the direction of movement remains unchanged. If $y(k) > y(k-1)$, we are moving away from the minimum and need to reverse the direction of movement. The iterative method is summarized in the flowchart in Figure 1.

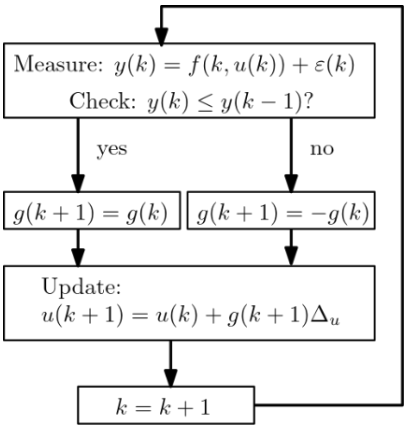

**Figure 1.** Flowchart for perturb and observe.

### Implementation of perturb and observe

The implementation of the perturb-and-observe method described here is straightforward, as it consists only of updating an input parameter and observing the resulting outcome. Still, there are some implementation aspects that need to be considered. First, it is noted that the method can be applied to maximization instead of minimization of a function by changing the update rule for the direction of improvement to

$$g(k+1) = \begin{cases} g(k), & if\ \ y(k) \ge y(k-1), \\ -g(k), & if\ \ y(k) < y(k-1). \end{cases} \quad (5)$$

In this case, $y(k)$ being smaller than $y(k-1)$ leads to a change in direction.

A second consideration when implementing perturb and observe is that this method continues perturbing the input after the minimum has been found. In case of time-varying processes, this behavior is desired as it enables tracking of the time-varying optimal operating point. However, if the optimal operating point can be assumed to be time-invariant, it is in general preferred to reduce the step size $\Delta_u$ over time to limit the amount of unnecessary perturbation. Possible extensions also include resetting the automatic reduction of $\Delta_u$ once a change in the process is detected through additional sensors, see, e.g., [10] for ideas in this direction.

Third, the influence of the measurement disturbances $\varepsilon(k)$ needs to be considered. If $\varepsilon(k)$ is stochastic in nature and its magnitude is similar to the absolute difference between $y(k)$ and $y(k-1)$, one measurement might

not be sufficient to determine the direction of improvement. In this case, it is recommended to keep the input $u(k)$ constant for several time steps and average the resulting measurements to obtain more accurate estimates of $f(k,u(k))$.

## DWC CASE DESCRIPTION

We consider the "standard" ternary dividing wall column (DWC) as illustrated in Figure 2. It is operated at constant pressure. The feed (F) enters the prefractionator sections (1,2) at the left side of the wall and is described by its molar fractions (z) of pure components (A,B,C) and its liquid fraction (q). There are three product specifications, given by the main component purities in each product stream (D,S,B). There are five manipulated variables (MVs): 1) boilup vapor rate (V), 2) reflux rate (L), 3) side product draw rate (S), 4) the liquid split ratio ($R_l$) above the wall and 5) the vapor split ratio ($R_v$) below the dividing wall.

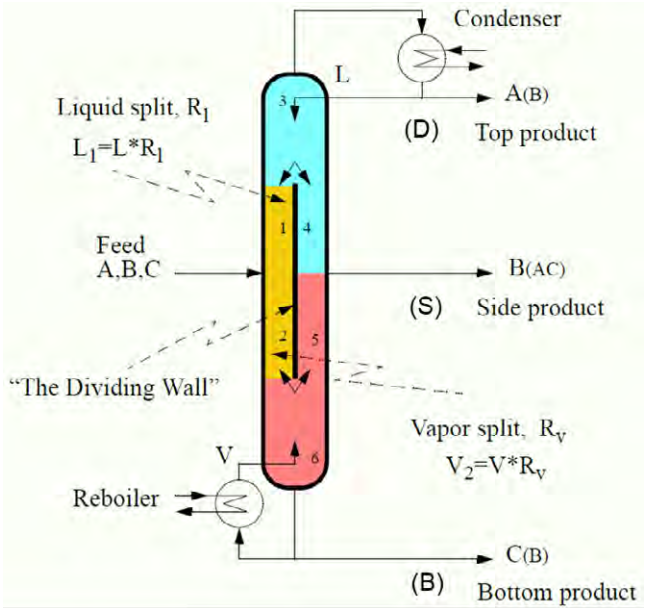

**Figure 2.** The ternary Dividing Wall Column (DWC). Section 1,2 is the prefractionator and 3,4,5,6 is denoted main column.

For the virtual infinite stage case and ideal feed mixture components, the minimum energy condition is precisely described by the Vmin-diagram [6]. Figure 3 shows this for the ideal case with equimolar feed, liquid fraction q=0.5 and relative volatilities $\alpha = [4,2,1]$ referred to the heavy component (C). The two peaks represent minimum vapor (in the top) for the sharp A/BC and AB/C splits. Point P is the so-called preferred split, which is minimum vapor for the AB/BC split. In a DWC, the highest peak sets the overall minimum reboiler vapor requirement. However, this minimum is only reachable when the prefractionator is operated at a point exactly on the (bold) line from the preferred split (P) on the boundary line to a balance point (B) (where all sections in the main column are at their minimum vapor simultaneously).

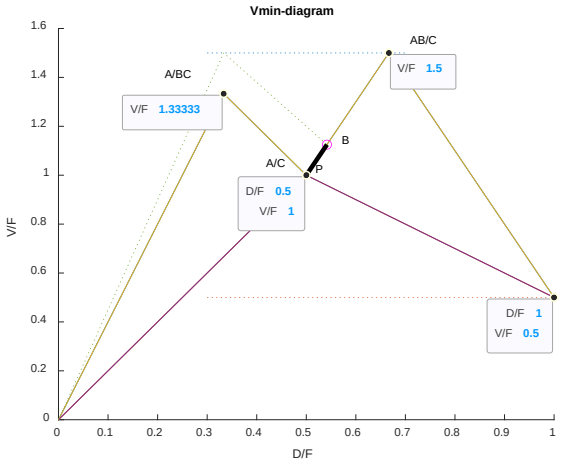

**Figure 3.** Vmin-diagram for the equimolar feed showing the optimality region for prefractinator operation at (bold) line from the so-called preferred split to the balance point (P to B).

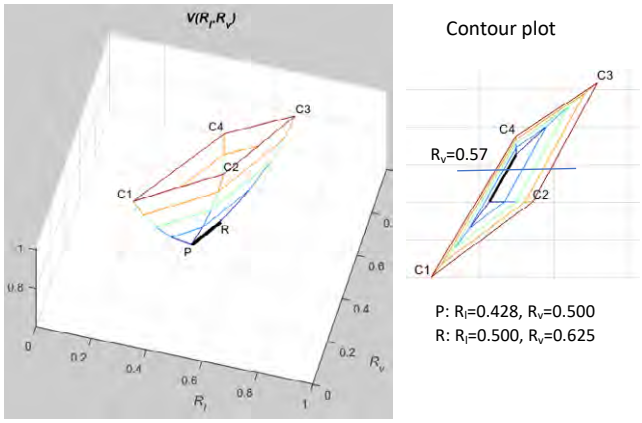

**Figure 4.** Perspective and contour view of the reboiler vapor solution surface V($R_l$,$R_v$ ) for a sharp product split and an infinite number of stages. The optimality region PR maps directly from the Vmin-diagram to the $R_l$,$R_v$ space. Each contour represents a 10% increase in V. The maximum reboiler saving for this case is as high as 39% (compared to conventional "direct split" and 30% in the condenser).

Most industrial DWC-implementations set the vapor split by design of the wall placement and tray/packing pressure drop characteristics. It is crucial that the obtained vapor split is properly checked to cover the expected feed property variation range, since the Vmin-diagram and solution surface will move whenever feed properties change. A constant, properly designed $R_v$=0.57 is illustrated in the contour plot in Figure 4 as a line that hits approximately the middle of the PR-line.

Then, it will usually be sufficient to adjust only the liquid split $R_l$ to track the optimum on a moving solution surface.

In the simulation case considered here, the number of stages has been set to 16 in each of the 6 sub-sections. This leads to the real minimum boilup being about 6-7% above Vmin. In practice, this corresponds to about 2.3 times the minimum stage number for a product purity of 99%. A rigorous stage design should evaluate the pareto curve that balances capital and operational costs [3], but this level of detail is not required for this study.

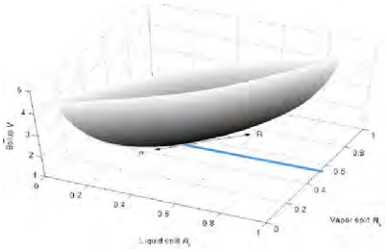

**Figure 5.** Finite stage solution surface, cf. Figure 4.

The impact to the finite stage solution surface, see Figure 5, is that it will be more rounded and not have the sharp edges shown in Figure 4. The optimality region will not be completely flat like the PR-line, but clearly much steeper perpendicular to the PR direction than along PR.

## Temperature profiles

For each disturbance, a set of grid points $V(R_l)$ have been calculated as illustrated below in Figure 6.

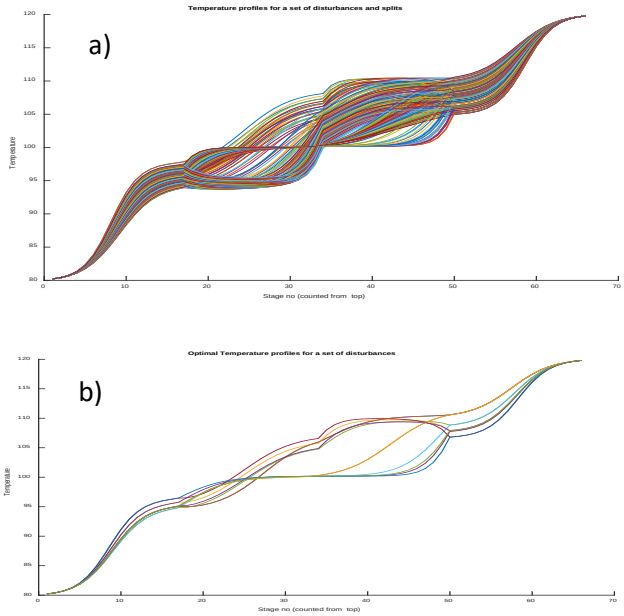

**Figure 6.** a) Temperature profiles for a set of disturbances and liquid split values, while the product composition is controlled, and b) The profiles where liquid split is optimised for each disturbance.

Figure 6 shows the all the executed runs in the upper plot but only the optimal profiles for each disturbance in the lower plot. The profiles may look a bit crowded, but a certain symmetry in the optimised plots can be observed, and that symmetry changes in different ways depending on which side of the optimum the DWC is operated. This gave rise to propose the so-called "Difference Temperature Symmetry" (DTS) described in more detail in [7], which is the sum of differences across the wall in the middle of sections 1,2,4,5 (see Figure 2): DTS=(T1-T4)-(T2-T5).

## Self optimising control of the DWC

In self optimising control (SOC), the idea is to find a variable that contains some gradient-like information for a given cost function such that when this controlled variable (CV) is regulated to a setpoint by applying the available MV for optimisation as a regulatory controller MV, the deviation from the optimum upon disturbances is reduced compared to keeping the MV constant.

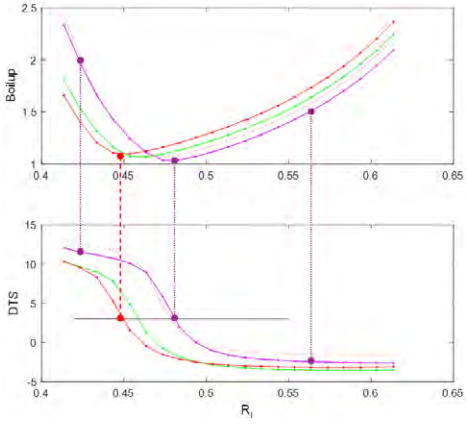

**Figure 7.** The relation between the SOC CV=DTS, the primary manipulated variable $R_l$ and the boilup $V(R_l)$

Figure 7 indicates qualitatively that the DTS as a self optimising controlled variable has close to ideal properties; namely, that for low values the operation is at one side of the optimum and for high values on the other side. And by controlling to the setpoint, e.g. DTS=3, as for the nominal optimum, this value ensures close to optimum operation for the considered disturbances too.

But still, the optimal setpoint value for any given case cannot be assumed to be known, and this calls for a smart procedure for adjusting the setpoint. And here is where the perturb-and-observe algorithm is handy.

# SIMULATION RESULTS

The relations between the MVs and the column state have been obtained by simulating the DWC with the products controlled to meet specifications by use of simple PI controllers for a range of grid-points for the

optimisation MV around the calculated optimum for each disturbance scenario. The perturb-and-observe algorithm has no information about the active disturbance acting on a system and is just given a suitable (feasible) initial value for the MV. The perturb-and-observe algorithm considers basically the structure illustrated in Figure 8.

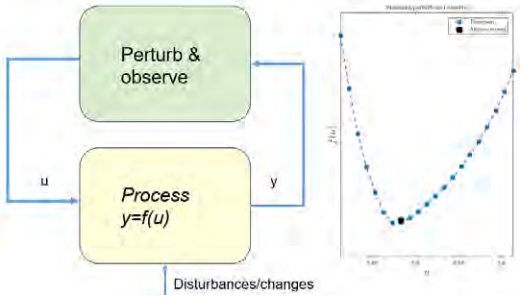

**Figure 8.** The general structure for the perturb-and-observe algorithm during extremum search.

## Manipulating liquid split ratio

The first scenario is a case where some changes are applied to the feed composition and liquid fraction. The vapor split is set constant (as in most industrial cases).

Applied to the DWC, the structure of y=f(u) is illustrated in Figure 9 where u is the liquid split ($R_l$) and y is the reboiler vapor (V) which in this case is used as energy measure. It is an "output" in this context since its value is manipulated by the product purity controls to maintain the CVs at specification setpoints. The challenge is that the cost function is influenced by unknown disturbances and the actual optimum needs to be tracked by the perturb-and-observe algorithm.

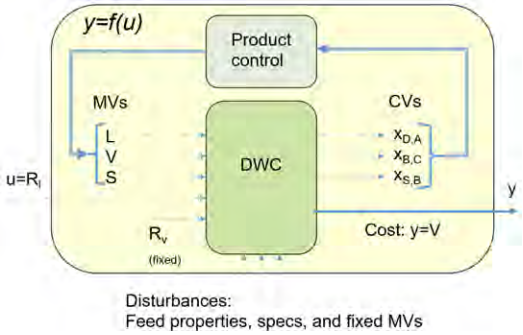

**Figure 9.** The cost function y=f(u) for the DWC is on top the basic regulatory product purity control. The optimisation MV is the liquid split u=$R_l$.

Figure 10 illustrates the minimisation search when the set of disturbances are applied. For each disturbance the cost function is moved as illustrated in the left graph. Noise is added to the measurement (y) and it can be observed in the upper right graph that the applied manipulated (perturbed) u-value (green) very soon after a change tracks the current optimal value (black) which is of course unknown to the algorithm. The feed composition and liquid fraction are changed at k=30,60,90,120. Note that white noise is added to the measurements to simulate measurement noise.

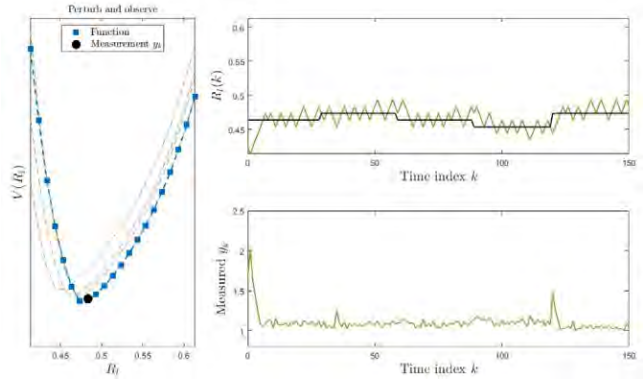

**Figure 10.** The resulting tracking of the optimal liquid split obtained by the perturb-and-observe algorithm.

## Manipulating SOC setpoint

The structure of the basic regulatory control, including a self optimising control loop is shown in Figure 11. The perturb-and-observe algorithm will work with the SOC setpoint as its manipulative variable "u".

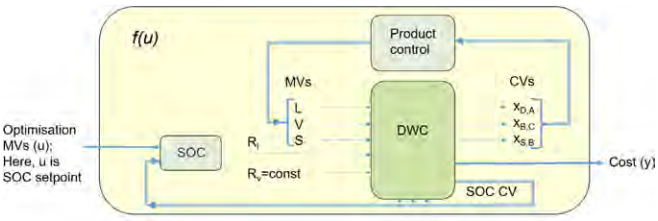

**Figure 11.** The cost y=f(u) when the perturb-and-observe is manipulating the SOC setpoint.

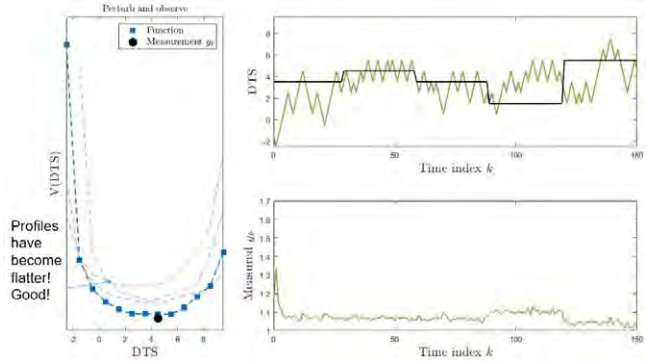

**Figure 12.** The tracking of y=f(u=DTS) for the same disturbance scenario as in Figure 7. Observe that the solution surface is "flattened" cf. Figure 7, thus being more robust for the exact setpoint.

A key advantage with use of the SOC is that it will

reject fast disturbances in the regulatory layer. A disturbance may have some impact to the optimal setpoint, and then the perturb-and-observe algorithm can do the search for the best setpoint on the slower time scale. This configuration ensures less off-optimal operation time in the case with frequent variations in the disturbances.

## DISCUSSION

The first question to be raised is how the perturb-and-observe method will perform in a true dynamic plant environment. The presented procedure is basically a steady-state method intended to be used on a process that is stabilised by its regulatory control system, and such that changes in the optimisation MVs do not interfere and degrade process transient performance and stability properties. This can typically be done by time-scale separation, e.g. by using a sample period in the ballpark of the typical closed-loop settling time for the regulatory control level. It is not required to have complete steady-state conditions (which in practice never occur perfectly in a plant) since the algorithm is robust against somewhat noisy measurements.

In distillation in general, including for the DWC, inferential product composition control is usually based on temperature measurements, and often on-line measurements of compositions are not available. Temperature based product purity control has been simulated too. The corresponding results are similar to the results for perturb-and-observe as shown in this work.

For products that are being quality controlled in a lab, it is possible to update the correlation between temperature setpoints and product composition. For temperature points in the profiles in the prefractionator, these kinds of correlations are not available, so some kind of tweaking of the setpoints will always be required. For this case, the perturb-and-observe algorithm fits perfectly since there is no alternative to pre-calculate the optimal setpoints exactly based on product data. Another desirable function for industrial practice is to gracefully handle a scenario where the optimal solution becomes constrained and to include some kind of safety supervision to prevent malfunction.

## CONCLUSION

The simulation study indicates that extremum seeking control by the perturb-and-observe algorithm can track the moving optimum value of the available manipulated optimisation variable when the DWC is exposed to some unknown disturbances that alter the optimal operating point. The algorithm can also be used in combination with self optimising control on the regulatory layer by using that controller's setpoint as the manipulative optimisation variable.

## ABSTRACT

By capturing carbon dioxide from biomass flue gases, energy processes with negative carbon footprint are achieved. Among carbon capture methods, the fluidized temperature swing adsorption (TSA) column is a promising low-pressure alternative, but it has been developed on small scales. This work aims to model, simulate and optimize a fluidized TSA multi-stage equilibrium system to obtain a cost estimate and a conceptual design for future process scale up. A mathematical model described adsorption in multiple stages, each with a heat exchanger, coupled to the desorption operation. The model was based on elementary macroscopic molar and energy balances, coupled to pressure drops in a fluidized bed designed to operate close to the minimum fluidization velocity, and coupled to thermodynamics of adsorption equilibrium of a mixture of carbon dioxide and nitrogen in solid sorbents (the Toth equilibrium isotherm was used). The complete fluidized TSA process has been optimized to minimize costs, considering equilibrium in each stage. The optimal configuration for heat exchangers was determined and a unit cost for carbon dioxide capture was estimated. It was found that a small number of stages is required to meet captured carbon specification at 95% molar purity, while process cost per metric ton of $CO_2$ was within range of other capture technologies. These findings show that the methodology developed here is useful for guiding the conceptual design of fluidized TSA process for carbon capture.

## INTRODUCTION

### Motivation

The Paris Agreement is a legally binding international treaty adopted in 2015 by 196 countries. Its goal is to limit global warming to below 1.5°C, by reducing greenhouse gas emissions [1]. In the context of global decarbonization efforts, carbon capture and storage (CCS) technologies are often emphasized as a necessary pathway to limit global warming [2]. Bioenergy CCS (BECCS) is particularly promising due to its potential for achieving negative emissions, as it captures and permanently stores $CO_2$ that was originally removed from the atmosphere during biomass growth.

However, most optimization studies to date on the BECCS field focus on linear spatial and temporal analysis of networks of plants, farms and transportations, instead of diving into operational details and process variables in each site [3,4]. Process simulations and optimizations could provide key insights into relatively new $CO_2$ capture technologies in order to scale up processes and make them more mature.

Among recently developed $CO_2$ capture technologies that could benefit from such insights is the fluidized temperature swing adsorption (TSA) column, where a solid adsorbent flows countercurrent to an upward $CO_2$-rich gas [5,6]. Some works in the literature have already explored packed-beds TSA simulations [7,8], but fluidized TSA process optimization works remain scarce and limited to small scales [9,10]. This process is a suitable $CO_2$ capture method due to its high selectivity, reusability of solid adsorbents, and lower energy consumption

compared to conventional absorption-based methods. Adsorption-based methods using solid sorbents, such as zeolite 13X binder free, offer higher $CO_2$ selectivity and lower regeneration energy requirements [6].

## Objective

The study aims an optimization-based design of fluidized TSA systems for large scale $CO_2$ capture from biomass-derived flue gases. This simulation study integrates process modeling and optimization techniques to improve fluidized TSA performance under realistic operating conditions, to develop basic guidelines to process scale up, in order to enhance process efficiency and minimize operational costs. This objective aligns with the need (highlighted in a previous study) to obtain a cost estimate for $CO_2$ capture through fluidized TSA process [5]. It also aligns with the Sustainable Development Goals set by the United Nations for 2030, including 7: Affordable and Clean Energy; 9: Industry, Innovation and Infrastructure; and 13: Climate Action [11].

# MATERIALS AND METHODS

## Hypothesis and parameters

The fluidized TSA system consists of two fluidized columns—one for adsorption and another for desorption—with continuous adsorbent recirculation. Each column has a heat exchanger at the gas inlet in the bottom, and each bed in each column also has a heat exchanger to optimize temperature. The recirculating solid adsorbent also passes through a heat exchanger between the columns. The number of adsorption stages should be optimized based on $CO_2$ purity targets and energy efficiency considerations. Our initial simplified simulations indicated that a small number of adsorption stages (as low as 3-5) suffices to obtain $CO_2$ at over 90%v/v purity [12]. Table 1 presents the hypothesis for the process modeling, while Table 2 presents the values and units for several parameters assumed for the optimization.

**Table 1:** Fluidized TSA modeling hypothesis.

| |
|---|
| No chemical reactions |
| No flue gas contaminants, only $N_2$ and $CO_2$ |
| Ideal gases |
| No phase changes |
| Part of solid adsorbent replaced monthly |
| Equilibrium reached within each stage |
| No gradients within each stage |
| Spheric solid adsorbent particles |
| Air viscosity independent with respect to pressure |
| Startup cost is 10% of fixed capital investment [13] |
| Pressure drop due to stage heat exchangers neglected |
| Steady state |

**Table 2:** Parameter values used in the GAMS code for modeling the fluidized TSA column.

| Parameter description | Value |
|---|---|
| Flue gas molar flow | 413 $mol.s^{-1}$ |
| Flue gas molar composition | 15%v/v $CO_2$ and 85%v/v $N_2$ |
| Flue gas temperature | 328 K |
| Flue gas pressure | 1 bar |
| $CO_2$ max concentration after adsorption | 0.5%v/v |
| Stage height *H* | 1 m |
| Captured $CO_2$ min concentration | 95%v/v |

| Adsorbent monthly losses | 10% |

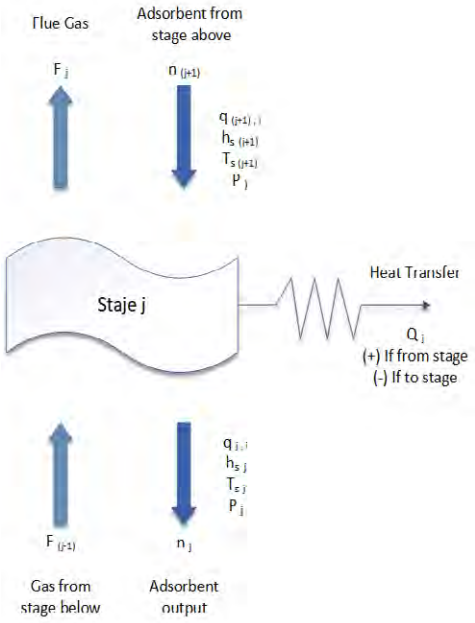

**Figure 1.** Modelling scheme of a generic equilibrium stage in the fluidized TSA column [6].

## Modeling

A multistage fluidized bed receives an adsorbent stream from the upper side (solid phase inlet) and a biomass post-combustion flue gas stream at atmospheric pressure (1.01325 bar) from the lower side (flue gas inlet). The bed interior is subdivided into various stages; each stage receives the adsorbent and the flue gas from the neighboring stages. As each stage depends on the solution of other stages, an iterative solution is required. Figure 1 presents a sketch for a generic stage. A compressor is used at the bottom of the adsorption column to increase the flue gas pressure so it flows upwards.

The model is based on molar and energy balances of each gas component in each stage and in each external heat exchanger, coupled with thermodynamics of adsorption heat, according to previous studies where further details can be found [5,6] The Toth equation describes adsorption equilibrium within each stage, with model parameters from previous empirical results. For this study, based on our previous experimental results [6], we consider the heterogeneity parameter for $N_2$ to equal unity and not change with temperature.

Since particles in the present simulation are of Geldart group B and the system fluidizes readily (since minimum fluidization velocity and minimum bubbling velocity are similar) [19], air velocity was limited to twice the minimum fluidization velocity, which was calculated according to Equation 1 [20] where $U_{mf}$ is the minimum fluidization velocity; $g$ is gravity (9.80665 m.s$^{-2}$); $\mu$ is air viscosity; and $\rho_g$ and $\rho_p$ are respectively the gas and particle densities. The void fraction was calculated according to the semi empirical Ergun equation, which covers the entire range of flow rates as shown in Equation 2 [21], where $\Delta P$ is stage pressure drop; $U$ is superficial air velocity; and $\varepsilon$ is the bed void fraction. The pressure drop in each stage at the point of incipient fluidization was calculated according to the traditional Equation 3 [21], where $\varepsilon_{mf}$ is the minimum fluidization void fraction.

$$U_{mf} = 0.0008g(\rho_p - \rho_g)D_p^2/\mu \quad (1)$$

$$\frac{\Delta P}{H} = \frac{150U\mu(1-\varepsilon)^2}{D_p^2\varepsilon^3} + \frac{1.75U^2\rho_g(1-\varepsilon)}{\varepsilon^3 D_p} \quad (2)$$

$$\Delta \mathrm{P} = gH(\rho_p - \rho_g)(1 - \varepsilon_{mf}) \quad (3)$$

The fixed capital investment (FCI) for the plant consisted in equipment, freight and installation cost for columns, heat exchangers and compressors. Correlations taken from the literature were generally in the form of Equation 4 [22], where $K$ is an equipment constant; $C$ is equipment capacity; $n \leq 1$ is a dimensionless scale factor; and $F$ is a shape and material factor. The FCI was then annualized and then added to the yearly cost of utilities and startup cost according to Equation 5 [15]. The Marshall & Swift (*M&S*) index in Equation 4, which adjusts prices for inflation, was estimated as 2500 for late 2024 from values reported in the literature [16]. The utilities costs (cold water and high-pressure steam) were obtained from the literature for 2012 [17] and corrected for inflation [18] as shown in Table 2. Labor costs, taxes, depreciation, storage and transport costs, and revenues were not considered in this study, neither were carbon credits or other forms of subsidy.

$$FCI = \sum_{eqpts.} \frac{M\&S}{280} K(C)^n(F + 2.2) \quad (4)$$

$$\text{annualized cost} = \text{utilities yearly cost} + (FCI + \text{startup cost} + \text{cost of land}) \times \frac{i}{1-(1+i)^{-t}} \quad (5)$$

The balance, thermodynamic and Toth equations, along with equations for pressure drops, velocity, void fraction and costs (constraints), were implemented and solved in an environment within GAMS software (GAMS Software GmbH), release 48.2.0, using the non-linear programming solver CONOPT4 [23]. The model has 320 constraints (including inequalities) and 305 variables, with 95 definitional constraints. The objective function was to minimize the annualized cost defined in Equation 5 divided by yearly $CO_2$ capture (in mass units).

## RESULTS AND DISCUSSION

As expected for a non-linear formulation, the problem convergence was heavily dependent on initial guesses and variable bounds. Pressure, temperature and Toth equilibrium parameters were therefore bound at the maximum and minimum theoretical values, and strictly positive initial guesses were applied to variables that would have cause undefinition errors if set to zero.

Low particle Reynolds numbers in each stage in adsorption and desorption, between 4 and 7, indicate the system readily fluidizes. It also indicates that viscous and kinetic energy losses during air flow past the particles are of similar order of magnitude, thus the use of both terms of the Ergun equation in Equation 2 is justified [21]. Calculated minimum fluidization porosity by the Ergun semi-empirical equation was about 0.42, similar to the 0.43 value reported in a previous study [6] and within the usual 0.40-0.45 range for spherical particles [21]. Stage pressure at the adsorption column was initially fixed at 1.8 bar in preliminary simulations, then set as a variable. Optimized results set the pressure between 1.42 bar (bottom stage) and 1.17 bar (top stage). It is worth mentioning that the simulated bed height had a conservative estimate (1 m, as shown in Table 2).

An initial assessment of the influence of stage numbers in adsorption and desorption columns resulted in a small number of stages reaching the specified project constraints on separation and purity of Table 2. In fact, only 5 adsorption stages and a single desorption stage were enough to extract $CO_2$ from a 15%v/v composition

flue gas into a 0.5%v/v composition stream, while $CO_2$ captured and recovered was 95%v/v. This supports claims that capturing $CO_2$ at purities greater than 90% is physically as well as economically feasible [12]. This also confirms previous results from the authors [5,6], indicating that fluidized TSA column size is probably not an impediment for scaling up this $CO_2$ capture technology. Additionally, increasing the flue gas molar flow from 1.556 $mol.s^{-1}$ [5,6] to 413 $mol.s^{-1}$ showed economies of scale effects on the $CO_2$ capture cost per mass unit.

Figure 2 shows the optimized setup with five adsorption stages, indicating temperatures and process streams. It was also possible to confirm that not all stages in the columns needed heat exchangers, with some heat loads being set at zero during the optimization [5]. Figure 3 shows the heat load per heat exchanger for the entire process, and the heat exchanger between columns removes most of the heat applied in the desorption column.

Utilities are the main cost drivers, as shown in Figure 4, which highlights the importance of adequate energy efficiency management. Future studies might simulate a fluidized TSA process with a heat pump between the adsorption and desorption columns, which could render the heat exchanger for the recirculating solid obsolete. Figure 4 also shows that, from all equipment costs comprising the FCI, the compressor at the bottom of the adsorption column is the most expensive. In most conventional setups, flue gas is delivered at atmospheric pressure because its thermal and kinetic energy is largely expended during upstream processes. However, if these processes are optimized or even omitted, the inherent pressure drop in the system preceding the column can be minimized. Consequently, the flue gas could maintain a higher pressure from the combustion process to the TSA column. This elevated pressure at the column inlet would reduce or eliminate the necessity for a compressor, decreasing costs.

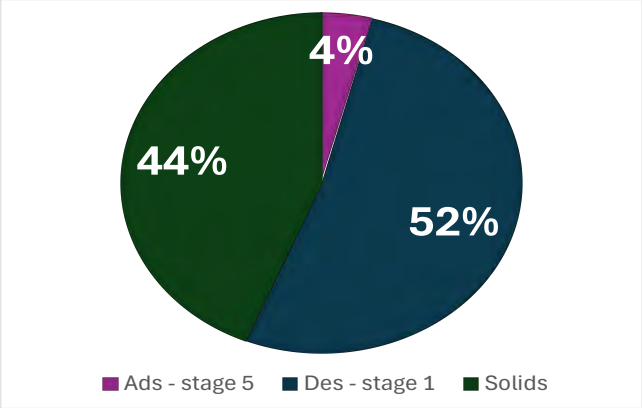

**Figure 3.** Heat loads per heat exchanger in an optimized fluidized TSA process.

The objective function value, the $CO_2$ capture cost per mass unit, was optimized at 84.6 $USD.t^{-1}$. This value falls within ranges reported in the literature for some technologies, and is significantly smaller than costs for direct air capture [2,30], as shown in Table 3. It is still, however, larger than amine-based absorption technologies [31], which are more mature despite their shortcomings. However, there is still room for fluidized TSA processes improvement before scale-up, such as development of new adsorbents as well as even greater economies of scale. For reference, the estimated market price of $CO_2$ at 96%v/v in Brazil is about 100 $USD.t^{-1}$, and

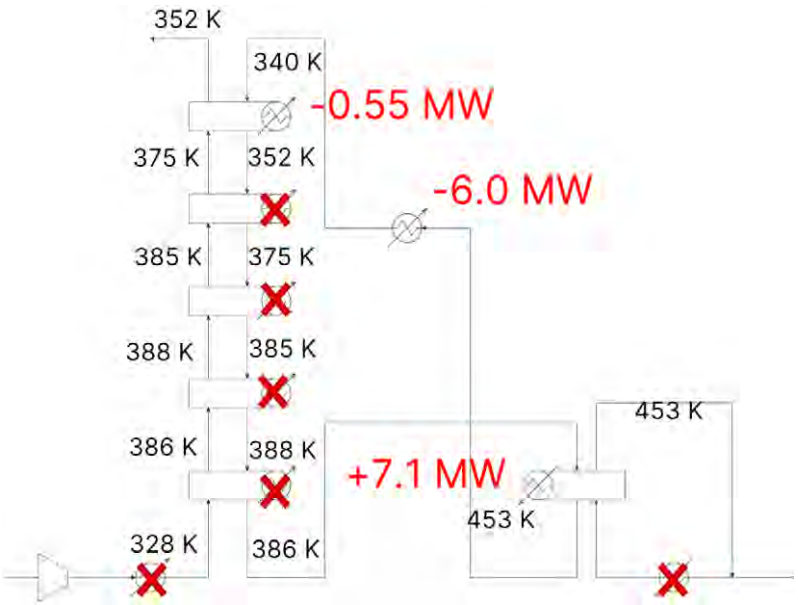

**Figure 2:** Fluidized TSA process schematics.

carbon credits for compliant industries sell as high as 50 USD.t$^{-1}$ in some countries.

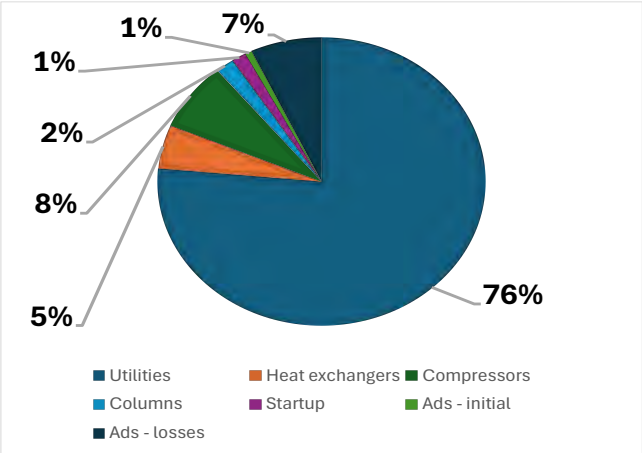

**Figure 4.** Main annualized cost drivers in an optimized fluidized TSA process.

**Table 3:** $CO_2$ capture costs reported in the literature.

| Reference | $CO_2$ capture cost (USD.t$^{-1}$) | $CO_2$ source |
|---|---|---|
| [2] | 40-120 | Industrial processes with diluted $CO_2$ streams |
| [2] | 134-342 | Direct air capture |
| [24] | 25-190 | BECCS |
| [25] | 20-290 | Several industrial processes |
| [26] | 36-107 | Industrial processes with diluted $CO_2$ streams |
| [27] | 84-129 | 5-20%v/v $CO_2$ |
| [28] | 104-147 | Wet flue gas, 15%v/v $CO_2$ |

| [30] | 177-399 | Direct air capture |
| [31] | 31-45 | Blast furnace gas |

## CONCLUSION

These findings show that the methodology developed here is useful for guiding the conceptual design of fluidized TSA processes for carbon capture. This study draws key conclusions based on modeling and optimization of a fluidized TSA process to capture $CO_2$ from biomass flue gases. Process-wide optimization is crucial for balancing $CO_2$ capture efficiency and energy consumption, particularly in large-scale implementations. The study identifies key design parameters, such as heat exchanger placements, that significantly impact process efficiency. The research establishes guidelines for scaling up TSA systems, emphasizing computational tools for process design refinement. This study thus contributes to the development of fluidized TSA systems for biomass-based $CO_2$ capture, supporting the bioenergy sector and global decarbonization efforts. Multi-scale integrated modeling approaches should be integrated into future process optimization studies to further assess residence time distribution, assist in temperature control, and improve energy efficiency.

## ABSTRACT

This work presents a Lyapunov-based framework for safe reinforcement learning (RL) applied to the control of an unstable reactor. The proposed method imposes stability constraints on the value and Q-functions through a Lyapunov candidate function defined as the negative of these functions, $L(s)=-V(s)$ and $L(s,a)=-Q(s,a)$. Constraints enforce positivity of the Lyapunov candidate function and non-positive time derivatives, promoting monotonic behavior aligned with Lyapunov stability conditions. The framework was tested on both on-policy (PPO) and off-policy (SAC, TD3, and DDPG) RL algorithms, with performance evaluated against their baseline versions and a nonlinear Model Predictive Controller (NMPC). Results showed that stability constraints significantly improved control performance across all tested algorithms, yielding consistently higher cumulative rewards, reduced overshoot, and decreased variability. Derivative-based constraints successfully mitigated abrupt changes and oscillatory behavior in the Q and value functions, especially evident in PPO, DDPG, and TD3. This work demonstrates that Lyapunov-based constraints are an effective tool for improving the safety and stability of RL algorithms in safety-critical applications. The proposed approach avoids the complexity of auxiliary optimization and offers a computationally efficient solution for enhancing the safety and stability of RL algorithms in safety-critical control applications.

**Keywords**: Lyapunov functions, process control, safety-critical systems, unstable dynamics

## INTRODUCTION

Reinforcement Learning (RL) has shown great potential for solving complex control tasks. However, its application in safety-critical systems, such as unstable reactors, remains limited due to the absence of closed-loop stability guarantees and inherent mechanisms for enforcing hard constraints, unlike traditional Model Predictive Control (MPC) formulations [1]. These limitations pose significant challenges in process control, where stability and constraint satisfaction are of prime importance.

Safe RL aims to address these challenges by incorporating mechanisms that enforce stability and safety constraints during both training and deployment. Unlike conventional control methods, which explicitly encode these properties, RL optimizes policies directly from data, often without structured guarantees of stability, particularly in model-free RL approaches. To overcome these challenges, this work introduces a Lyapunov-based framework to enforce closed-loop stability by directly constraining the value function, without relying on explicit system models.

It is important to distinguish between safety constraint enforcement, which ensures the system operates within predefined safety bounds, and closed-loop stability guarantees, which ensure that the system converges to a stable/stabilized operating point over time. While both aspects are critical for safe control, our approach focuses on the latter by leveraging Lyapunov functions to directly enforce stability during policy learning.

Lyapunov functions provide a mathematical framework for enforcing stability by ensuring that the system's "energy" decreases over time. However, designing such functions for RL controllers is challenging and often requires detailed system-specific knowledge [2]. For instance, Brunke et al. [3] emphasized the importance of

developing RL algorithms that maintain safety during training and deployment, especially in uncertain environments where modelling errors or disturbances can compromise stability. Moreover, Gu et al. [4] highlighted that constructing Lyapunov constraints that remain valid across varying conditions remains an open challenge, particularly in high-dimensional and stochastic settings.

Recent advancements in safe RL have highlighted the potential of integrating stability guarantees directly into the learning process. For example, methods leveraging Lyapunov functions [5] define invariant state domains that ensure stability under neural network control policies. This approach provides a framework for guaranteeing system convergence to an equilibrium point while managing nonlinearities and disturbances. Similarly, Osinenko et al. [6] proposed an RL framework incorporating Lyapunov-like constraints, which utilize a control Lyapunov function (CLF) as a basis to establish semi-global stability guarantees through an online sample-and-hold optimization scheme, demonstrating its efficacy in maintaining closed-loop stability during learning. Another notable advancement involves using control invariant sets (CIS) [7], which streamline training by embedding stability guarantees into the learning process through invariant set constraints.

Despite these advancements, significant gaps remain. Lyapunov-based methods often require identifying suitable Lyapunov functions or barrier functions, which can be computationally expensive and challenging for highly nonlinear systems. Furthermore, these approaches frequently rely on predefined invariant domains or approximations that may lack generalization across diverse operational conditions. CIS-based methods, while efficient in improving sample efficiency and providing robust stability guarantees, require precise state reset mechanisms and careful integration of invariant constraints into both offline and online phases, which may not always translate effectively to complex control environments.

Building on these foundations, this work introduces a Lyapunov-based framework that simplifies the enforcement of closed-loop stability by directly constraining the value function. Unlike existing methods that rely on auxiliary cost objectives, this approach integrates stability constraints into the reinforcement learning process, reducing computational overhead and improving scalability.

Conventional RL implementations typically fall into two main categories: on-policy and off-policy algorithms. On-policy methods, such as Proximal Policy Optimization (PPO), update the policy using data sampled sequentially from the current policy, allowing for consistent tracking of changes in the value function over time. This sequential sampling simplifies the computation of time derivatives, making on-policy algorithms more stable under policy updates. However, these methods require significant amounts of data due to the need for fresh samples in each update cycle. Conversely, off-policy methods, such as Soft Actor-Critic (SAC), Twin Delayed Deep Deterministic Policy Gradient (TD3), and Deep Deterministic Policy Gradient (DDPG), use experience replay buffers that enable random sampling of past experiences. This improves sample efficiency but complicates the estimation of time derivatives due to the lack of temporal ordering in the samples, making the learning process more prone to instability.

This work proposes to enforce closed-loop stability across on-policy and off-policy RL algorithms using Lyapunov-based constraints. Specifically, the Lyapunov candidate functions were defined explicitly as the negatives of the value (on-policy) and Q-functions (off-policy), $L(s) = -V(s)$ and $L(s,a) = -Q(s,a)$. Stability is enforced by penalizing positive values of the original functions, thus ensuring $V(s), Q(s,a) < 0$. Additionally, penalties on time derivatives encourage monotonic increases in these original functions, which translates directly to monotonic decreases in the Lyapunov functions, satisfying the Lyapunov stability condition ($dL/dt \leq 0$). These constraints promote that the resulting learned policies consistently meet stability requirements. The main contributions of this work are as follows:

- A unified Lyapunov-based stability constraint framework applicable to both on-policy and off-policy RL algorithms.
- A comparative analysis of time derivative-based and positivity constraints and their impact on training stability.
- An evaluation of the proposed approach to control an unstable reactor, demonstrating improved safety and performance compared to baseline methods.

The remainder of this paper is structured as follows: Section 2 presents the framework and implementation details. Section 3 provides experimental results and discussion. Section 4 concludes with a summary and future research directions.

## METHODOLOGY

### Framework and Environment Design

This work utilizes PC-Gym [8], an open-source framework for developing RL environments in chemical process control systems, for implementing the environment. PC-Gym provides robust tools for simulating process control problems, including customizable constraints, disturbance generation, and reward function design. It offers compatibility with RL algorithms like PPO, SAC, DDPG, and TD3, enabling standardized

benchmarking for process systems engineering problems.

The environment was constructed to simulate the dynamics of a Continuous Stirred Tank Reactor (CSTR), a nonlinear system often used as a benchmark in process systems engineering due to its complex dynamics and control challenges. The CSTR involves an irreversible reaction that converts species A into species B, with cooling provided by water circulating through a coiled tube. Two coupled nonlinear ordinary differential equations govern the dynamics:

$$\frac{dC_A}{dt} = \frac{q}{V}(C_{A,f} - C_A) - kC_A e^{\frac{-E_A}{RT}} \quad (1)$$

$$\frac{dT}{dt} = \frac{q}{V}(T_f - T) - \frac{\Delta H_R}{\rho C_p} kC_A e^{\frac{-E_A}{RT}} + \frac{UA}{\rho C_p V}(T_c - T) \quad (2)$$

Here, $C_A$ and T represent the concentration of reactant A and reactor temperature, respectively, while $T_c$ is the cooling water temperature, serving as the control input. Additional model parameters include feed concentration ($C_{A,f}$), feed temperature ($T_f$), volumetric flow rate (q), reactor volume (V), reaction rate constant (k), activation energy ($E_A$), universal gas constant (R), reaction enthalpy ($\Delta H_R$), fluid density (ρ), heat capacity ($C_p$), and heat transfer coefficient-area product (UA). The nonlinearities, particularly the exponential dependence of reaction rate on temperature, pose significant control challenges, including potential instability and multiple steady states. Simulation parameters and constraints were designed to realistically represent process control challenges:

**Action Space:** The manipulated variable $T_c$ was defined as a continuous range between 250 K and 350 K, normalized to [0, 1] during training.

**Observation Space:** The state variables $C_A$, T, and setpoint temperature $T_{SP}$ were normalized to [0,1] based on their physical bounds ([0.0, 200 K, 300 K] to [1.0, 600 K, 400 K]). Additionally, Gaussian measurement noise proportional to 0.1% of each observed state value was introduced during training.

**Reward Function:** Negative squared error between normalized T and $T_{SP}$.

**Dynamic Setpoint Strategy:** The setpoint dynamically transitioned midway through the episode to evaluate the RL algorithms' adaptability.

**Disturbance Generation:** Time-indexed disturbances in feed concentration ($C_{A,f}$) and inlet temperature ($T_f$) were dynamically generated to emulate real-world variability. These disturbances were sampled from predefined bounds and applied over multiple episodes to test robustness.

The implementation includes a steady-state solver to initialize the system state variables, ensuring valid initial conditions under varying disturbances. The reward function was designed so that the difference between the normalized reactor temperature and the setpoint temperature was squared and scaled, ensuring that the reward signal directly incentivized accurate tracking of the setpoint while maintaining interpretability.

The setpoint strategy was implemented dynamically, splitting the episode into two phases. During the first half of each episode, the setpoint was initialized to the steady-state temperature derived from the system's initial conditions. In the second half, the setpoint transitioned to a fixed value (e.g., 340 K). This approach tests the RL agent's ability to adapt to changing operational goals while maintaining system stability.

## Safe RL Implementation

The proposed stability enforcement mechanism is inspired by Lyapunov principles, focusing explicitly on the positive definiteness and monotonic decrease conditions required for stability. Given our reward function defined as the negative squared difference between the current state and desired setpoint, we define Lyapunov candidate functions as L(s) = −V(s) and L(s,a) = −Q(s,a) to maintain a consistent formulation where L > 0 and dL/dt ≤ 0 indicate stable behavior. The stability constraints, consistently applied across PPO, SAC, DDPG, and TD3 algorithms, are:

**Positive Definiteness Constraint:** Penalizing positive values of the original value/Q-functions (V, Q) to promote them remains negative, thereby enforcing L > 0.

**Time Derivative Constraint:** Penalizing decreases in the original value/Q-functions between consecutive time steps, ensuring their monotonic increase. This promotes a non-positive time derivative (dL/dt ≤ 0), satisfying the Lyapunov stability criteria.

These constraints were applied dynamically during training, with penalties weighted by hyperparameters $\lambda_{pos}$ (positive definiteness) and $\lambda_{der}$ (time derivative constraint) —additionally, the algorithms logged mean values and time derivatives of value/Q functions for interpretability and transparency.

### Safe RL Algorithm Implementations

#### 1. DDPG and TD3:

These off-policy methods relied on replay buffers for experience sampling. The critic loss incorporated stability constraints as follows:

$$\text{critic_loss} = \text{MSE_loss}(\text{curr_Q}, \text{target_Q}) + \lambda_{pos} \cdot \max(0, \text{curr_Q}) + \lambda_{der} \cdot \max(0, \text{prev_Q} - \text{curr_Q}) \quad (3)$$

where $\lambda_{pos}$ and $\lambda_{der}$ are penalty weights. Here:

$\text{curr_Q}$: The instantaneous Q-values estimated by the critic for the current batch of samples.

$\text{prev_Q}$: The Q-values for the same batch are computed during the previous gradient step in the current training iteration.

TD3 further used twin critics and applied constraints

to the minimum of the critics' Q-values for robustness. Noise models for exploration were algorithm-specific:

**DDPG:** Ornstein-Uhlenbeck noise was used, introducing temporal correlations in action exploration.

**TD3:** Normal noise was employed along with target policy noise and noise clipping for stable updates.

### 2. SAC:

The entropy-regularized objective was preserved in the SAC implementation to balance exploration and exploitation while incorporating stability constraints into the Q-function updates. The critic loss was computed as:

$$\text{critic_loss} = 0.5 \sum_i \text{MSE_loss}(\text{curr_Q}_i, \text{target_Q}) + \lambda_{pos} \cdot \max(0, \text{curr_Q}) + \lambda_{der} \cdot \max(0, \text{prev_Q} - \text{curr_Q}) \quad (4)$$

where $i$ indexes over multiple critics.

The actor loss was computed using the minimum Q-value across critics and included the entropy regularization term:

$$\text{actor_loss} = \mathbb{E}[\alpha \ \log \pi(a|s) - \text{minQ(s, a)}] \quad (5)$$

where $\alpha$ is the entropy coefficient, and $\pi(a|s)$) is the stochastic policy. This promotes safe exploration while optimizing the policy.

### 3. PPO:

PPO, an on-policy method, inherently stabilizes training using a clipped surrogate objective. Additional constraints on the value function $V(s)$ were introduced:

$$\text{loss} = \text{policy_loss} + \beta_{vf} \cdot \text{value_loss} + \lambda_{ent} \cdot \text{entropy_loss} + \lambda_{pos} \cdot \max(0, -\text{V(s)}) + \lambda_{der} \cdot \max(0, \text{V(s)} - \text{prev_V}) \quad (6)$$

where $\beta_{vf}$ and $\lambda_{ent}$ are coefficients for the value and entropy losses. Value functions were dynamically monitored for compliance with these constraints.

## Hyperparameter Optimization

This work employed Optuna [9], a hyperparameter optimization framework, to tune both common and algorithm-specific hyperparameters across all reinforcement learning (RL) algorithms. Optuna utilizes the Tree-structured Parzen Estimator (TPE) as its default optimization algorithm, enabling efficient exploration of the hyperparameter space.

A unified approach was used for tuning common hyperparameters across all algorithms, including:

- Learning rate ($\alpha$),
- Discount factor ($\gamma$),
- Replay buffer size (off-policy only),
- Batch size,
- Start step for training,
- Target network update factor ($\tau$).

Algorithm-specific optimizations included:

**DDPG:** Ornstein-Uhlenbeck action noise parameters ($\mu, \sigma, \theta, dt$).

**TD3:** Target policy noise parameters ($\sigma$, noise clip).

**PPO:** Epoch count, Generalized Advantage Estimation (GAE) parameters ($\lambda$), clip range, and entropy coefficient.

**SAC:** Entropy coefficient and seed for reproducibility.

For all Safe RL implementations, additional stability-specific hyperparameters were tuned:

- $\lambda_{pos}$: Weight for the positive definiteness penalty.
- $\lambda_{der}$: Weight for the time derivative penalty.

## Evaluation

To establish a performance benchmark, the baseline RL cases and a nonlinear Model Predictive Controller (NMPC) were implemented [8]. This controller leveraged full knowledge of the system dynamics and perfect state estimation to solve the optimal control problem at each time step. The NMPC formulation incorporated features absent in the RL-based controllers, such as state tracking and normalized control effort terms for consistent scaling across variables. Additionally, the system dynamics were discretized using orthogonal collocation to achieve high accuracy. This oracle served as the performance ceiling, representing near-optimal control strategies under perfect conditions, allowing us to quantitatively assess the efficacy of the RL algorithms.

Each RL policy (PPO, SAC, DDPG, and TD3) was evaluated across 20 episodes, each initialized with identical initial conditions and setpoint profiles that differed from those encountered during training. The primary variation among these episodes was introduced through progressively increasing levels of state measurement noise, linearly scaled from 0.0% to 0.5%. Performance metrics, including cumulative rewards and control effort, were collected to assess each policy's robustness to measurement noise. The collected data were aggregated to compute median cumulative rewards and mean value/Q functions. Since the reward was defined as the negative squared difference between the controlled states and setpoints, it offers a meaningful comparison to the NMPC oracle. Additionally, the evaluation tracked the evolution of the value/Q functions and their time derivatives for each policy. Reward distributions were visualized using histograms computed from cumulative rewards across evaluation episodes.

# RESULTS AND DISCUSSION

Figures 1 and 2 present the median performance of RL algorithms (SAC, PPO, DDPG, and TD3) compared to the NMPC oracle across 20 unseen evaluation episodes.

Figure 1 corresponds to the algorithms without stability constraints, while Figure 2 shows their performance under stability constraints.

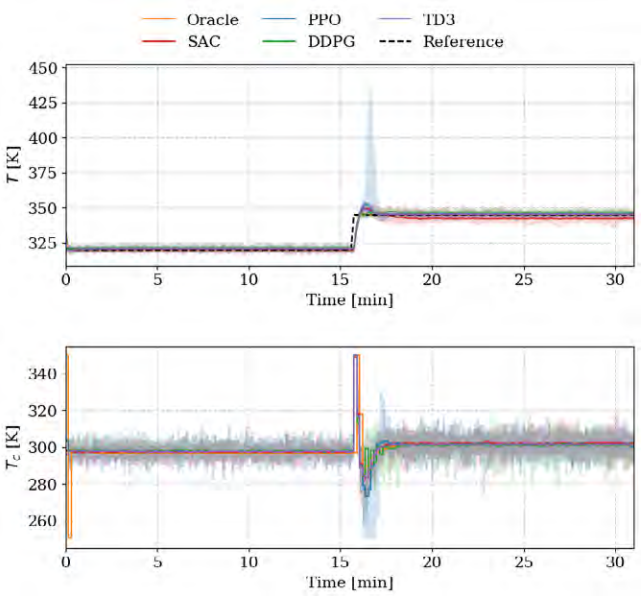

**Figure 1.** Performance of RL algorithms without stability constraints compared to the NMPC oracle (shaded areas: min-max, solid lines: median). Plots show (top) reactor temperature (T) and (bottom) control input $T_c$.

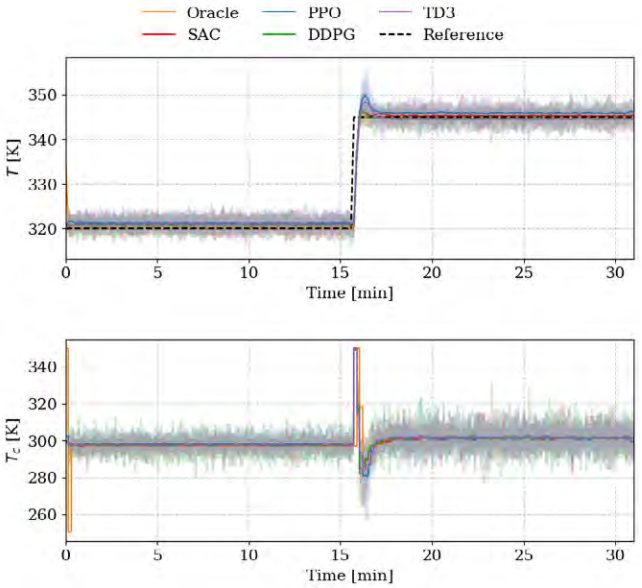

**Figure 2.** Performance of RL algorithms with stability constraints compared to the NMPC oracle (shaded areas: min-max, solid lines: median). Plots show (top) reactor temperature (T) and (bottom) control input $T_c$.

Under the baseline scenario (Figure 1), PPO and SAC exhibit significant overshoot and oscillations in reactor temperature following the setpoint change at 15 min, with PPO showing the largest transient deviation, indicating less stability. Coolant temperature ($T_c$) shows significant fluctuations, particularly for PPO.

In contrast, the safe RL scenario (Figure 2) demonstrates improved stability across all RL algorithms tested. Overshoot and variability are significantly reduced, while manipulated variable responses ($T_c$) also present smaller transient fluctuations, especially PPO.

The reward distribution (Figure 3) highlights the performance differences between safe and baseline RL algorithms. The safe RL strategies (SAC, PPO, and DDPG) generally achieve cumulative rewards that are more concentrated and shifted towards higher values compared to their baseline counterparts. Baseline methods such as SAC and DDPG display wider distributions with lower reward values, indicating greater variability and less consistent performance.

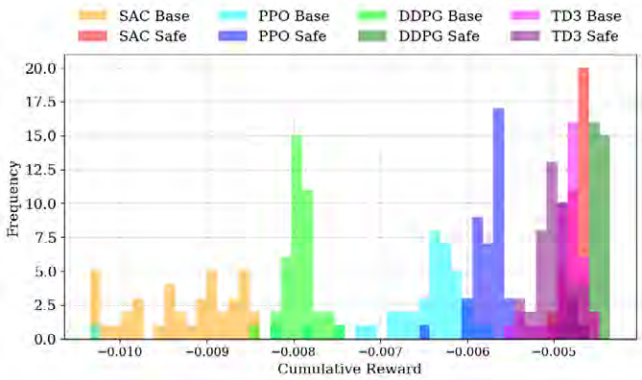

**Figure 3.** Distribution of cumulative rewards comparing baseline and safe RL strategies (SAC, PPO, DDPG, and TD3).

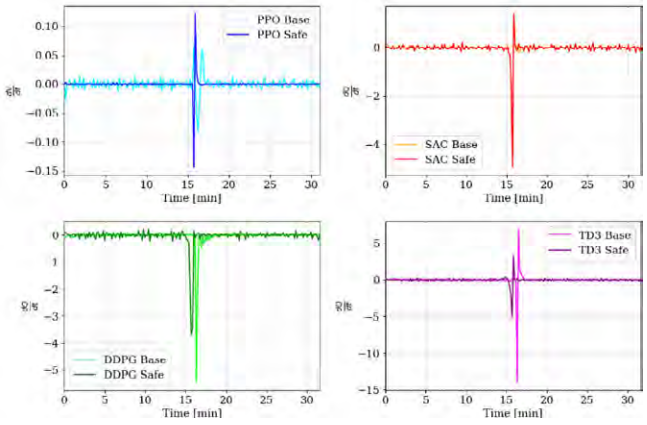

**Figure 4.** Comparison of time derivatives of Q-function (SAC, DDPG, TD3) or value function (PPO) for baseline and safe RL implementations.

Figure 4 shows the time derivatives of the Q/value functions for SAC, TD3, DDPG, and PPO, comparing baseline and safe implementations. Standard deviations are omitted for clarity. Safe PPO exhibits the most significant reduction in fluctuations, with near-zero oscillations. Safe implementations for DDPG and TD3 demonstrate reduced spikes, indicating improved stability.

However, safe PPO and SAC display larger transition spikes, likely due to value/Q function penalization on the setpoint change.

The spikes during setpoint transitions could be softened by "freezing" or temporarily relaxing constraint penalties during these events. Increasing training episodes or fine-tuning constraints may also further enhance stability across all algorithms.

## CONCLUSION

This work introduced a Lyapunov-based framework for stabilizing RL algorithms by directly constraining value and Q-functions. The proposed approach significantly improved the control performance of an unstable reactor when compared to baseline methods. Results demonstrated consistently higher cumulative rewards across all tested algorithms, indicating a reduction in setpoint tracking errors. Furthermore, safe RL substantially reduced overshoot and control variability, especially in SAC, PPO, and DDPG.

Time derivative-based penalties were critical for achieving monotonic decreases in the defined Lyapunov functions (L=−V and L=−Q), thereby promoting Lyapunov stability criteria. This improvement was particularly evident in DDPG and TD3, with reduced transient spikes. In contrast, PPO showed the lowest overall oscillations but still displayed higher transient spikes, which could be due to the value function penalization on the setpoint change.

The results demonstrate that the proposed Lyapunov-based framework effectively enhances stability in RL-based control of unstable systems. Future work should explore dynamic penalty tuning, mechanisms to reduce transient spikes during disturbances (e.g., freezing penalties), and application to more complex environments to broaden its applicability.

## ABSTRACT

Industrial decarbonization is considered one of the key objectives in mitigating global climate change. To achieve a net-zero industry requires actively transitioning from fossil fuel-based energy sources to renewable alternatives. However, the intermittent nature of renewable energy sources poses challenges to a reliable and robust supply of energy for industrial sites. Therefore, the integration of renewable energy systems with existing industrial processes, subject to energy storage solutions and main grid interconnections, is essential to enhance operational reliability and overall energy resilience. This study proposes a novel framework for the design and optimization of industrial utility systems integrated with renewable energy sources. A monthly-based analysis is adopted to consider variable demand and non-constant availability in renewable energy supply. Moreover, carbon capture is considered in this work as a viable decarbonization measure, which can be strategically combined with renewable-based electrification. The proposed optimization model evaluates the economic trade-offs of integrating carbon capture, renewable energy, and energy storage. By applying this approach, systematic design guidelines are developed for the transition of a conventional steady-state utility system toward renewable energy integration, ensuring economically viable and sustainable energy management in process industries.

**Keywords**: Renewable energy, CO2 capture, Industrial utility operation, Cost optimization, Process integration

## INTRODUCTION

The International Energy Agency (IEA) estimates that the industrial sector, including power generation, accounts for a major portion of overall $CO_2$ emission [1]. Therefore, the 2030 targets for industrial energy consumption focus on increasing the share of electricity while reducing reliance on fossil fuels. In particular, electricity generated from renewable sources is identified as a key solution to achieve environmental improvements in the industrial sector.

In South Korea, where most energy supply systems rely on fossil fuel-based facilities, the integration of renewable energy systems with existing infrastructure for process utility enhances system operational stability by addressing the intermittency of renewable energy sources. Additionally, carbon capture technology, as the additional solution of industrial decarbonization, can complement existing fossil fuel-based utilities by reducing environmental burdens [2], while helping to resolve potential challenges that may occur during the transitional period to complete process integration. However, previous studies on the optimization of integrated energy supply systems often fail to fully account for the flexibility and/or constraints associated with renewable energy production. In many cases, the power demand of the utility systems is met through electricity imported from external plants for renewable electricity, rather than reflecting the complexity of direct integration [3]. Furthermore, the impact of $CO_2$ emitted from fossil fuels in the integrated process is often oversimplified as a carbon tax without considering the potential role and benefits of incorporating carbon capture processes.

This study proposes integrating conventional utility

systems with $CO_2$ capture processes and renewable energy systems, including electricity storage, as a practical approach for industrial decarbonization. A cost-based optimization framework is developed as a monthly-based analysis to evaluate strategies for the economically efficient operation of the integrated process. Monthly minimum costs are determined using weather data specific to South Korea, allowing for more accurate cost predictions in renewable electricity generation and enhancing the reliability of the optimization model.

## METHODOLOGY

To achieve an environmentally upgraded utility system, the integration of renewable energy and carbon capture processes is optimized with the objective function, as given in Eq. (1), of minimizing overall system costs while meeting practical energy demands as outlined in **Table 1**.

$$f_{Total,Min} = f_{Utility,Min} + f_{Renewable,Min} \quad (1)$$

Steam demand is supplied exclusively by fossil fuel-based systems, with the low-pressure (LP) steam demand allowed to vary during process optimization, while steam requirements for other pressure levels remain fixed at constant values. Electricity demand can be met either through the integrated system or by purchasing it from external sources, depending on the specific scenario evaluated. The process flow diagram illustrating the overall system in this study is described in **Figure 1**.

**Table 1:** Energy demand of a Total site.

| Energy | Unit | Values |
|---|---|---|
| Electricity | $MW_e$ | Min. 68.0 |
| VHP steam | t/h | 20.0 |
| HP steam | t/h | 54.5 |
| MP steam | t/h | 55.9 |
| LP steam | t/h | 128.0+$\alpha$* |

The costing parameters used to calculate the annualized cost of each system are based on previous studies [3, 5]. For renewable facilities, the cost references were adjusted by scaling down costs according to the GDP ratio to account for the differences in economic contexts between South Korea and the UK, from which the original data was derived. The cost-related values applied in this study are summarized in **Table 2**.

### Utility Process

The fossil fuel-based utility system uses a traditional configuration with boilers and gas turbines (GT) paired with heat recovery steam generators (HRSG), followed by electricity generation via steam turbines (ST). In line with current industrial trends, coal and natural gas are selected as the primary fuel sources for steam and electricity production. The system meets four different steam demands at varying pressure levels, as outlined in **Table 1**. Residual steam is used to generate electricity via back-pressure steam turbines. For simplicity, the fossil fuel-based facility is represented using a streamlined model developed in UniSim®, as referenced previously in [3].

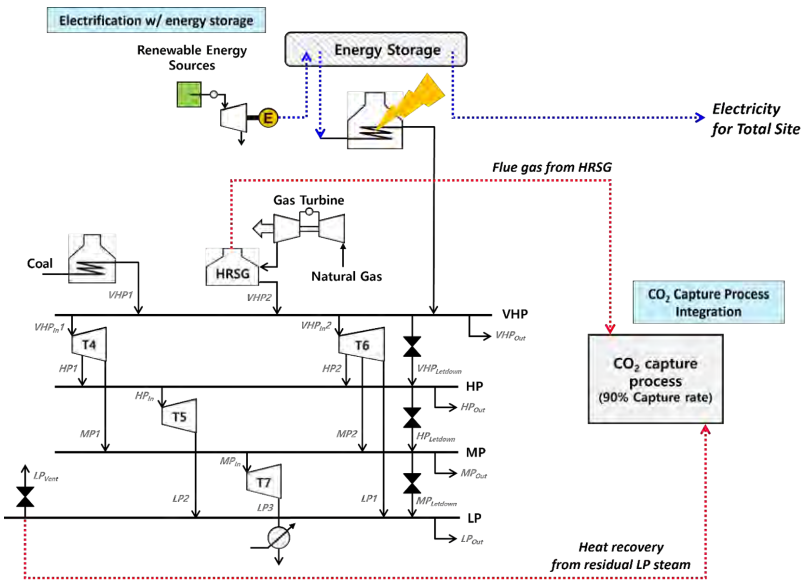

**Figure 1:** Simplified process flow diagram of the utility system integrated with renewable energy supply and carbon capture.

**Table 2:** Costing parameters considering the site location for the integrated utility process.

| Parameters | Unit | Description | Values |
|---|---|---|---|
| $C_{coal}$ | \$/t | Coal price | 65 |
| $C_{NG}$ | \$/t | Natural gas price | 220 |
| $NHV_{coal}$ | kJ/kg | Net heating value of coal | 28,000 |
| $NHV_{NG}$ | kJ/kg | Net heating value of Natural gas | 47,206 |
| $C_{elec,ex}$ | \$/kWh | Electricity price (Export) | 0.067 |
| $C_{elec,im}$ | \$/kWh | Electricity price (Import) | 0.081 |
| $C_{water}$ | \$/t | Water price | 0.005 |
| $CP_{PV}$ | \$/kW | PV capital cost | 781.3 |
| $OP_{variable,PV}$ | \$/kWh | PV variable O&M cost | 0.004 |
| $OP_{fixed,PV}$ | \$/kW/yr | PV fixed O&M cost | 9.8 |
| $CP_{WT}$ | \$/kW | WT capital cost | 3156.4 |
| $OP_{variable,WT}$ | \$/kWh | WT variable O&M cost | 0.5 |
| $OP_{fixed,WT}$ | \$/kW/yr | WT fixed O&M cost | 23.4 |
| $CP_{EST}$ | \$/kW | EST capital cost | 421.9 |
| $OP_{variable,EST}$ | \$/kWh | EST variable O&M cost | 0.004 |
| $n$ | yr | Plant lifetime | 30 |
| $r$ | % | Interest rate | 12 |
| $CR$ | kg$CO_2$/kWh | $CO_2$ emission from renewable system | 0.254 |
| $CT$ | \$/t$CO_2$ | Carbon tax | 20 |

The optimization framework of the utility steady-state operation is formulated with the objective function of minimizing system costs. This includes the operating costs from fuel consumptions, capital costs for conventional equipment, and carbon tax, and is described by:

$$f_{Utility,Min} = f_{OP,Utility} + f_{CP,Utility} + f_{CT,Utility} \quad (2)$$

$$f_{OP,Utility} = C_{coal} f_{coal}(m_{coal}) + C_{NG} f_{NG}(m_{NG}) + C_{water} Q_{condensor\ for\ BFW} \quad (3)$$

$$f_{CP,Utility} = f_{Boiler} + f_{GT} + f_{HRSG} + f_{ST} \quad (4)$$

$$f_{CT,Utility} = CT f_{coal}(m_{coal}) NHV_{coal} + 10^{-3} CT f_{NG}(m_{NG}) NHV_{NG} \quad (5)$$

Each term in the objective function is determined based on the optimized fuel consumption which can be calculated as a function of VHP steam mass flowrate ($m_{coal}$, $m_{NG}$) generated from each fuel. Specifically, the capital cost function is calculated using the capacity of each piece of equipment, which also reflects fuel consumption. As a result, major variables for minimizing fossil fuel-based processes are the quantities of coal and natural gas consumed. This optimization is carried out using the UniSim® optimization tool, incorporating the parameters, constraints, and boundaries outlined in [3].

For the flue gas emitted from the HRSG by natural gas, a conventional Monoethanolamine (MEA)-based $CO_2$ capture process, commonly used for post-combustion capture, is considered as referenced for capturing $CO_2$ from the NGCC plant [5]. A percentage of 90% of $CO_2$ is captured, with the remaining $CO_2$, including the flue gas from a coal-fired boiler, subject to a carbon tax penalty.

The primary optimization variable for the capture process is the thermal energy consumed by the stripper reboiler, typically supplied as LP steam generated by the utility. The LP steam demand for the capture process varies depending on the optimization of natural gas consumption. Therefore, the fluctuation in LP steam demand by the capture process is also considered in the optimization of the integrated utility as $\alpha$* in **Table 1**, although the operating and capital costs of the capture process are not reflected. The thermal energy demands of each month for the capture process are optimized in UniSim®.

## Renewable Process

Renewable electricity is generated using weather data of South Korea, solar irradiation ($I_{solar}$) for the photovoltaic (PV) system and wind speed ($v_{WT}$) for the wind turbine (WT) system. Monthly generated power is calculated from the accumulated observational data and system operating time ($T_{PV}$, $T_{WT}$), followed by calculating the system costs, including the carbon tax. Cost minimization of renewable energy is carried out by optimizing the capacity of each system. For PV and WT systems, the plant area ($A_{PV}$, $A_{WT}$) is considered for the optimization to determine the cost-based electricity production.

To address the irregular nature of renewable energy sources, an electricity storage (EST) system is introduced to supply power as needed. Hence, storage utilization for the overall site demand depends on the renewable energy available each month. The maximum storage capacity is limited to 5 $MW_e$ to reduce uncertainty during the optimization process, helping to identify the most cost-efficient operating conditions. When electricity exceeds this capacity, the surplus can be sold to the main grid connected to the site, generating additional revenue. Based on the costing parameters outlined in **Table 2**, the objective function considers all the costing elements of the renewable system from Eq. (6) to (11). In Eq. (9) and (10), $i$ which can be PV, WT, and EST is used to simplify the costing equations.

$$f_{Renewable,Min} = f_{OP,Ren} + f_{CP,Ren} + f_{CT,Ren} \quad (6)$$

$$P_{PV} = \frac{\sum_t 0.5\eta_{PV}A_{PV}I_{solar}(1-COS(34.5))}{T_{PV}} \quad (7)$$

$$P_{WT} = \frac{\sum_t 0.5\eta_{WT}A_{WT}v_{WT}^3}{T_{WT}} \quad (8)$$

$$f_{OP,Ren} = \sum_i (P_i OP_{fixed,i}/8760 + P_i OP_{variable,i}) - \begin{cases} C_{elec,im}P_{Grid}, & P_{Grid} < 0 \\ C_{elec,ex}P_{Grid}, & P_{Grid} > 0 \end{cases} \quad (9)$$

$$f_{CP,Ren} = \sum_i P_i CP_i \frac{r(1+r)^n}{(1+r)^n - 1} \quad (10)$$

$$f_{CT,Ren} = 10^{-3} CRCT(P_{PV} + P_{WT}) \quad (11)$$

The modeling and optimization of the renewable process are conducted using MATLAB® due to the data-driven nature of the process, which is more challenging to visualize compared to the fossil fuel-based process. A mathematical approach facilitates system cost optimization, providing valuable support for comprehensive strategic decision-making, particularly in complex, interdependent processes. This approach also has the advantage of being easily integrated with existing simulation software.

The optimization methodology for the integrated utility system is illustrated in **Figure 2**, which explains the overall applicable scenarios, including electricity generation, storage, and selling beyond the site through the main grid linked with the processes. This utility management can be explained by Eq. (12) and (13), which represents the key energy balance, including electricity storage, by adjusting the equations in previous studies [3, 4]. Moreover, inequality constraints required for the cost minimization are shown in **Table 3**. Especially, the boundaries of PV and WT system capacity serve to ensure that each system is optimized within an industrially feasible range based on the weather conditions.

$$P_{Utility} + P_{Renewable} - P_{Grid} - 68 = 0 \quad (12)$$

$$P_{Renewable} - (P_{PV} + P_{WT} - P_{EST}) = 0 \quad (13)$$

**Table 3:** Inequality constraints for the Integrated utility process optimization.

| Variable | Unit | Low bound | Upper bound |
|---|---|---|---|
| HP1 | t/h | 15 | - |
| MP2 | t/h | 30 | - |
| LP2 | t/h | 0 | - |
| $LP_{out}$ | t/h | 128+$\alpha$ | - |
| Steam letdown | t/h | 0 | - |
| PV system capacity ($A_{PV}$) | $m^2$ | 0 | 100,000 |
| WT system capacity ($A_{WT}$) | $m^2$ | 0 | 100,000 |
| Renewable electricity to Total site ($P_{Renewable}$) | $MW_e$ | 0 | 68 |
| Grid electricity ($P_{Grid}$) | $MW_e$ | - | 68 |
| EST capacity ($P_{EST}$) | $MW_e$ | 0 | 5 |

## RESULTS AND DISCUSSION

The variations in renewable resources is analyzed from weather data to ensure that only available renewable energy applicable within the operating range allowed is utilized. Therefore, PV system considers its operating time to be limited to daylight hours, and WT system considers cut-in and cut-out speed for the feasible system operation according to the reference [4]. Considering these constraints, **Figure 3** presents the monthly cumulative solar irradiation and wind speed, along with the operating hours of each system.

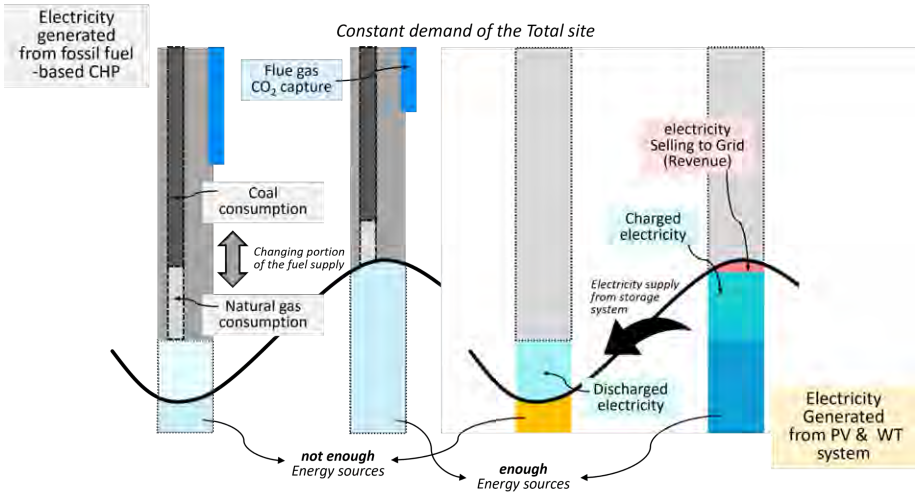

**Figure 2:** Research methodology for modeling and optimization of the integrated processes with a monthly basis.

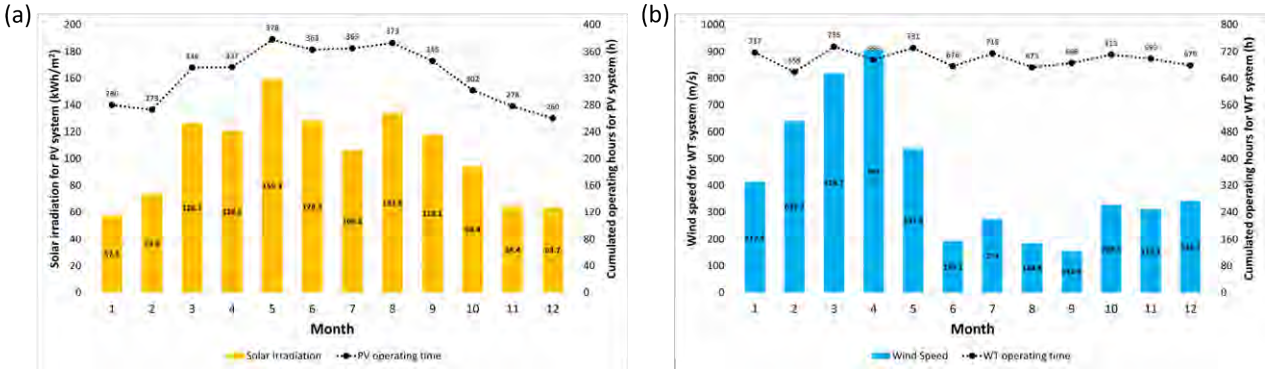

**Figure 3:** Monthly weather data for the analysis of (a) Solar irradiation and operating hours for PV system and (b) Wind speed and operating hours for WT system.

**Figure 4** illustrates the monthly optimized results of the integrated process under \$20/t$CO_2$ of carbon tax. Each month fully meets the Total site electricity demand of 68 MW, with fossil fuel-based systems contributing a significantly larger share than renewable systems. This is due to the lower costs associated with fuels and equipment in fossil fuel-based systems compared to the costs of renewable systems. In particular, during March and April, the higher electricity generation from the WT system leads to a substantial increase in the overall cost of the integrated utility. Therefore, it is observed that the fossil fuel-based system is chosen as the only operating system. Compared to the WT system, the PV system generates less electricity for the same plant area. Consequently, the contribution of the PV system to the site demand remains relatively small.

Although renewable electricity does not make up a large portion of the total power supply, the results in **Figure 4** (a) highlight the contribution of the integrated processes optimization. Renewable electricity can replace between 4.78% and 34.32% of the total site electricity demand each month, confirming the effective validation of the preliminary stage of the integrated utility process design and supporting the goal of establishing renewable energy-based electrification. This variation trend directly influences the system cost, as shown in **Figure 4** (b). The annualized cost of the utility process serves as the base case for comparison with the monthly optimized results. The cost reduction is primarily attributed to the WT system within the renewable energy system, which plays a dominant role in the optimization. The annualized cost in May shows the largest decrease of 5.53%, driven by peak renewable electricity generation, compared to the base case. The optimization also contributes to a 2.67% reduction in the annual cost of the integrated overall processes, with the price portion of the fossil fuel-based system decreasing by 6.15%.

The $CO_2$ emissions from fossil fuels account for the majority of the carbon tax, as shown in **Figure 4** (b). This is because the smaller emission per unit of electricity generated by renewables, along with the lower energy output from the renewable systems, leads to different optimization results concerning the ratio of renewable energy to fossil fuel-based systems. **Figure 5** shows the impact of carbon tax on integrated process optimization through sensitivity analysis. As carbon tax increases, the

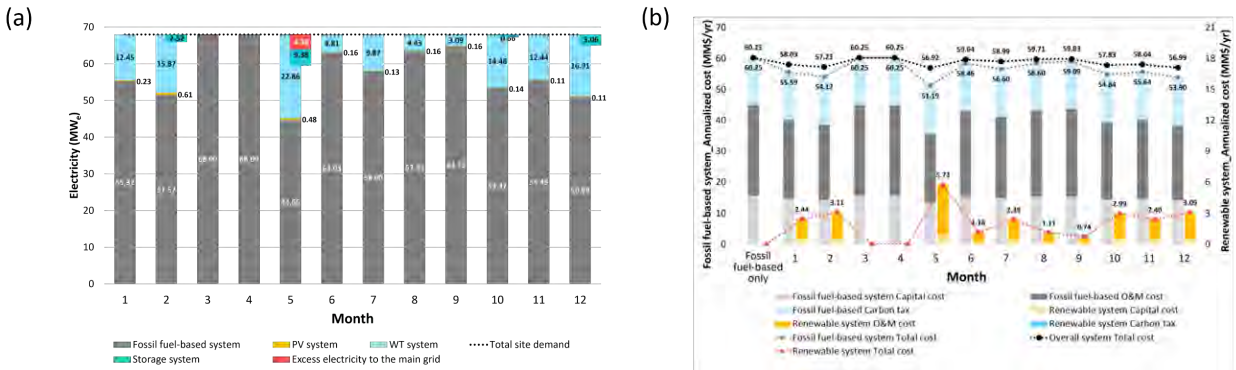

**Figure 4:** Monthly optimized results of integrated utility processes under \$20/t$CO_2$ of carbon tax. (a) Electricity generated from each system (b) Annualized cost breakdown.

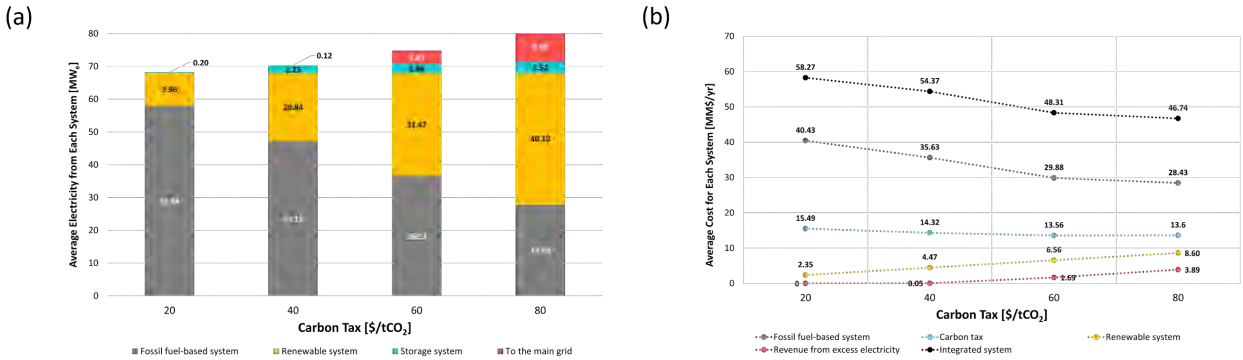

**Figure 5:** Average optimization results for the sensitivity analysis in carbon tax. (a) Electricity breakdown for each system and (b) Average annualized cost for each system.

portion of renewable electricity in the overall system grows due to the increased penalty for fossil fuel consumption. Accordingly, the cost of each system also changes in the same trend with electricity breakdown, and the cost of integrated processes ultimately decreases, as shown in **Figure 5** (b). At a 4 times increase in carbon tax, average overall system cost is reduced about 19.7%, highly affected by about 29.7% decrease of fossil fuel-based system.

## CONCLUSION

This study demonstrates the successful integration of renewable and $CO_2$ capture processes with conventional utility processes as an industrial decarbonization strategy. The optimization framework effectively addresses efficient management in process industries, providing a practical method for balancing economic sustainability with environmental improvement during the transition toward a fully renewable-based system.

If renewable systems with improved cost competitiveness are considered in the future, their increased contribution to the system's power demand could reduce fossil fuel consumption and the additional energy required for the carbon capture process, leading to lower $CO_2$ emissions across the overall processes. Furthermore, this approach mitigates the vulnerability to price fluctuations of fossil fuels on the international market, enhancing the cost stability of process operation through renewable energy integration.

Future work will focus on expanding the current framework to incorporate other renewable technologies. In particular, introducing the CSP system from the perspective of heat integration could add complexity, making it challenging to optimize steam demand across renewable energy with thermal energy storage and existing utilities. Moreover, sensitivity analysis on various costing parameters would provide valuable insights for planning decarbonized industries.

## ABSTRACT

This work addresses a practical challenge in batch process optimization: the need for sample efficient learning methods due to the high cost and time-intensive nature of running physical batch processes. While reinforcement learning (RL) offers a promising framework for optimizing batch processes, traditional approaches require numerous experimental runs to converge to optimal policies. A novel sample efficient RL method that leverages Gaussian Processes (GPs) to accelerate learning from limited batch data is proposed. However, the direct application of GPs becomes computationally intractable as data accumulates batch-to-batch, and their performance degrades when training distributions shift during policy improvement. To address these challenges, an integrated framework that combines Q-learning with GPs was developed and a strategic subset selection mechanism using determinantal point processes is introduced to maintain computational efficiency while preserving diverse, high-performing samples. The method exploits problem structure and backward induction to further maximize sample efficiency and incorporates both aleatoric and epistemic uncertainty for robust policy improvements. The approach is demonstrated on a non-isothermal semi-batch reactor case study, showing significantly improved learning efficiency compared to exact GP strategies while maintaining computational tractability. The results highlight the method's practical applicability to industrial batch process optimization where experimental data is limited and costly to obtain.

**Keywords**: Reinforcement Learning, Gaussian Processes, Batch Process Control

## INTRODUCTION

Fed-batch process control and online optimization is an area of focus within the process systems engineering community. This is a problem well described by finite horizon stochastic optimal control; however, identification of optimal policies is inherently challenging. This is in part due to the difficulty in identifying systems models and their uncertainty and then propagating that uncertainty over the decision horizon. This latter element is a primary focus within the stochastic model predictive control (sMPC) community [1], [2]. This has led to interest in the development of batch-to-batch learning schemes.

For example, [3] demonstrated the use of policy gradients and transfer learning to improve an initial parametric policy function approximation directly from batch process data. Similar ideas were exploited in [4] and [5] using Gaussian process (GP) models that were iteratively updated with new batch process data and then exploited to improve the operational strategy.

All the works detailed above exploit methods common to Reinforcement Learning and bandit strategies. State-action value learning is a subset of Reinforcement Learning algorithms that aim to solve Markov decision process formulations of the online batch process optimization problem, through concepts broadly termed approximate dynamic programing (ADP). ADP aims to identify an optimal state-value function approximation through function approximation, and sampling-based policy evaluation and policy improvement steps to approximate the workings of exact dynamic programming (DP) solvers. It is worth noting that DP is not applicable in

this problem setting due to computational intractability. From this optimal function approximation, one can derive the optimal policy by acting greedily with respect to it in each state.

In chemical engineering applications, the high cost and time-intensive nature of running physical batch processes makes it crucial to develop sample efficient methods for reinforcement learning. Traditional RL approaches often require numerous iterations to converge to optimal policies, which becomes prohibitively expensive when each episode represents a complete batch process. This motivates our focus on combining Gaussian Process (GP) models with Bayesian Optimization (BO) principles to create more sample efficient RL methods that can learn effective control policies with significantly fewer experimental runs. This approach is particularly valuable in chemical engineering contexts where each experiment may involve substantial material costs, energy usage, and time investment.

State-action value learning algorithms typically exploit function approximations to provide point estimates of the expected state-action value function, rather than modelling it explicitly a conditional random variable. This has led to uncertainty aware approaches to state-action value learning. Perhaps the most common approach to integrating uncertainty within policy learning is GP approximations to process dynamics. This then enables identification of the state-action value function through formulation of a nonlinear program. However, this requires that the process be well described by a GP model [6].

An alternative means is to use the GP for approximating the state-action value function directly. For example, the GP Temporal Difference (GPTD) framework aims to identify a value function approximation under a given control policy and leverages the SARSA algorithm for approximate policy improvement steps [7]. Bayesian neural network approaches have also been explored for approximating the state-action value function, which enabled the use of Thompson sampling rollout policies – effectively balancing exploration and exploitation of the decision space [8].

In this work, a sample efficient reinforcement learning strategy for process control based on Gaussian processes and Bayesian optimization principles is proposed. To address the poor scaling of Gaussian processes with data, and the well-known distributional shift challenge in reinforcement learning a subset selection strategy is introduced. Finally, it is shown how the exploitation of problem structure and backward induction can maximize sample efficiency in this context.

This paper is structured as follows. The methodology section presents the foundations of Q-learning and Gaussian Process function approximation, followed by our approaches to Thompson sampling policies and uncertainty-aware Q-learning. The method for maintaining computational tractability with GPs is introduced and then the complete algorithmic implementation is detailed. A computational case study of a non-isothermal semi-batch reactor demonstrates the practical application of our approach. Finally, results are presented that compare our GP-based Q-learning method to an exact GP strategy, followed by conclusions.

# METHODOLOGY

## Q-Learning

Reinforcement learning (RL) describes a set of sampling-based algorithms for solving Markov decision process (MDP). Finite MDP formulations of batch process optimization may be defined as a six tuple $< \mathcal{X}, \mathcal{U}, p, \phi, \gamma, T >$; with $\boldsymbol{x} \in \mathcal{X}$ denoting a state space, $\boldsymbol{u} \in \boldsymbol{\mathcal{U}}$ a set of controls, $X_{t+1} \sim p(\boldsymbol{x}_{t+1} \mid \boldsymbol{x}_t, \boldsymbol{u}_t)$ a state transition probability density function, $\phi: \mathcal{X} \times \mathcal{U} \rightarrow \mathbb{R}$ a cost function, $\gamma \in [0,1]$ a discount factor, and $T$ the finite time horizon over which the MDP evolves, after which the process terminates. In finite horizon MDPs, the aim is to identify a state feedback policy, $\boldsymbol{u}_t = \pi(\boldsymbol{x}_t)$, to minimize the expected sum of costs over a discrete time horizon of length $T$ from any given state. This quantity is otherwise known as the state-action value function, $Q(\mathbf{x}_t, \mathbf{u}_t)$. Dynamic programming (via backward induction) is known to find optimal solutions to MDPs; however, its use becomes intractable in large discrete or continuous state and control spaces.

Q-Learning is a model-free reinforcement learning algorithm that estimates the optimal state-action value function, $Q^*(\mathbf{x}, \mathbf{u})$, which may be defined recursively as:

$$Q^*(\mathbf{x}_t, \mathbf{u}_t) = \mathbb{E}_{\pi^*}\left[\phi(\mathbf{x}_t, \mathbf{u}_t) + Q\left(\boldsymbol{x}_{t+1}, \pi^*(\boldsymbol{x}_{t+1})\right)\right] \quad (1)$$

subject to,

$$\pi^*(\mathbf{x}_{t+1}) = \underset{\mathbf{u}_{t+1}}{\operatorname{argmin}} Q^*(\mathbf{x}_{t+1}, \mathbf{u}_{t+1}). \quad (2)$$

In practice, one does not have access to the actual Q-function and must estimate and learn it from interactions with the samples of the underlying MDP. Q-learning may be thought as an approximate dynamic programming (DP) strategy, which is constituted by iterative application of an approximate policy evaluation step, and a policy improvement step. The policy evaluation step used by Q-learning is inspired by stochastic approximation,

$$Q(\mathbf{x}_t, \mathbf{u}_t) \leftarrow Q(\mathbf{x}_t, \mathbf{u}_t) + \alpha_k \delta_t, \quad (3)$$

where $\alpha_k$ is the learning rate at update step $k$ and $\delta_t$ is the TD error,

$$\delta_t = \phi(\boldsymbol{x}_t, \boldsymbol{u}_t) + \gamma \min_{\mathbf{u}_{t+1}} Q(\mathbf{x}_{t+1}, \mathbf{u}_{t+1}) - Q(\mathbf{x}_t, \mathbf{u}_t). \quad (4)$$

The TD error is a bootstrapped estimate of the error in the state-action value approximation of the optimal policy, and under some conditions the update ensures convergence to the optimal policy. One condition is that there must be sufficient coverage of the state-control space through learning iterations. This is enabled by a rollout policy which balances exploration and exploitation. Such a rollout policy is usually defined through the application of a bandit strategy with respect to the state-action value function, such as the $\epsilon$-greedy strategy.

In continuous state and control, one becomes interested in constructing an approximation to the state-action value function, typically through a parametric function. These approaches tend to be sample inefficient. In this work, the utility of constructing Gaussian process approximations is explored, which are a class of Bayesian non-parametric models.

## Gaussian Process Function Approximation

A Gaussian process (GP) is a probability model defined on a collection of random variables, such that every finite subset is described by a multivariate Gaussian distribution. Specifically, it is assumed that given some dataset, $\mathcal{D}_t = \{\boldsymbol{v}_{t,i}, Q_{t,i}\}_{i=1:N}$ with $\boldsymbol{v}_t = [\boldsymbol{x}_t, \boldsymbol{u}_t]^T$, and a test point $\boldsymbol{v}_{t,*}$, the joint multivariate prior distribution may be defined,

$$\begin{bmatrix} Q_{t,1} \\ \vdots \\ Q_{t,N} \\ Q_{t,*} \end{bmatrix} \sim \mathcal{N}\left( \begin{bmatrix} m(\boldsymbol{v}_{t,1}) \\ \vdots \\ m(\boldsymbol{v}_{t,N}) \\ m(\boldsymbol{v}_{t,*}) \end{bmatrix}, \begin{bmatrix} K(V_t, V_t) & k(\boldsymbol{v}_{t,*}, V_t)^T \\ k(\boldsymbol{v}_{t,*}, V_t) & k(\boldsymbol{v}_{t,*}, \boldsymbol{v}_{t,*}) \end{bmatrix} \right), \quad (5)$$

where $k(\cdot,\cdot)$ is the kernel function that evaluates the covariance of the random variables, $K(V_t, V_t)$ is the gram matrix which evaluates covariance of the data $V_t = [\boldsymbol{v}_{t,1}, \ldots, \boldsymbol{v}_{t,N}]^T$, and $m(\cdot)$ is a prior mean function. Since the joint prior distribution is a multivariate Gaussian one can obtain conditional and marginal distributions as Gaussian distributions also. This enables one to exploit Bayes' rule to make predictions about a test point, given data via a Gaussian posterior distribution,

$$Q_{t,*} \mid \boldsymbol{v}_{t,*}, \mathcal{D}_t \sim \mathcal{N}\left(m(\boldsymbol{v}_{t,*} \mid \boldsymbol{\mathcal{D}}_t), \sigma^2(\boldsymbol{v}_{t,*} \mid \boldsymbol{\mathcal{D}}_t)\right), \quad (6)$$

with $m(\boldsymbol{v}_{t,*} \mid \boldsymbol{\mathcal{D}}_t)$ and $\sigma^2(\boldsymbol{v}_{t,*} \mid \boldsymbol{\mathcal{D}}_t)$ provided in closed form through the conditioning equations. The posterior prediction provides means to estimate the state-action value of a new state and control pair $\boldsymbol{v}_{t,*}$ given access to a discrete dataset.

## Thompson Sampling Policies

In this work, it is assumed that such a dataset is built iteratively in a batch-to-batch fashion by rolling out a policy that leverages the GP state-action value function approximation and its uncertainty. Specifically, the method takes advantage of the explicit uncertainty quantification of GPs to define a Thompson Sampling (TS) rollout policy. This policy makes use of an approximated sample $\tilde{Q}_t$ of the posterior distribution using a decoupled sampling method, described by [9], which is minimized to select the next control input:

$$\tilde{Q}_t \sim Q_t \mid \mathcal{D}_t \quad (7)$$

$$\pi_{TS}(x_t) = \arg\min_{u_t} \tilde{Q}_t(x_t, u_t) \quad (8)$$

This behavioral policy naturally balances exploration and exploitation - areas of high uncertainty can be targeted for exploration, while areas of low uncertainty and high predicted value can be exploited. Furthermore, the minimization of the Q-function follows the standard Q-learning paradigm.

## Uncertainty Aware Q-Learning

Our approach implements an adaptive learning rate mechanism that automatically adjusts based on the model's predictive uncertainty. While traditional Q-learning employs a fixed learning rate $\alpha_k$ in the update equation ((9). Instead, the method uses the analytical uncertainty estimates from the GPs to adapt to this learning rate as follows:

$$Q_t(\mathbf{x}_t, \mathbf{u}_t) \leftarrow \alpha_k * Q_t(\mathbf{x}_t, \mathbf{u}_t) + \cdots (1 - \alpha_k) * (r_t + \gamma \arg\min_{u'} Q_{t+1}(\mathbf{x}_{t+1}, \mathbf{u}_{t+1})), \quad (9)$$

$$\text{where } \alpha_k = \frac{1}{1+\sigma_t^2}. \quad (10)$$

Here, $\sigma_t^2$ represents the GP for timestep $t$ predictive normalized variance at the current state-action pair. When the model exhibits high uncertainty in its Q-value predictions, $\alpha_k$ approaches zero, causing the update to rely more heavily on the observed returns. Conversely, when the model is confident in its predictions (low variance), $\alpha_k$ approaches unity, giving more weight to the current Q-value estimates. This mechanism (Equation 10) ensures that the learning process naturally adapts to the model's confidence, leading to more conservative updates in regions of high uncertainty while maintaining efficient learning in well-understood parts of the state-action space.

### Subset Selection Strategy

To handle the computational expense of GPs with large datasets while maintaining accurate modeling of promising regions, a reparametrized determinantal point processes (DPPs) was employed, which can be sampled to give diverse and high performing subsets of our original datasets [10].

These subsets are constructed of points, $\boldsymbol{v} \in V$, which are sampled with the probability proportional to the determinant of the gram matrix of the DPP $|K_V|$ and the quality function $q: \mathcal{X} \times \mathcal{U} \rightarrow \mathbb{R}$:

$$\mathbb{P}(V) \propto |K_V| \star \prod_{v \in V} q(v)^2, \tag{11}$$

where the quality function is larger for higher performing subsets. This formulation is particularly valuable for Q-learning as it allows us to naturally forget poor-performing historical data while maintaining a diverse set of high-value state-action pairs, effectively focusing our modeling capacity on regions of the Q-function that are most relevant for policy improvement.

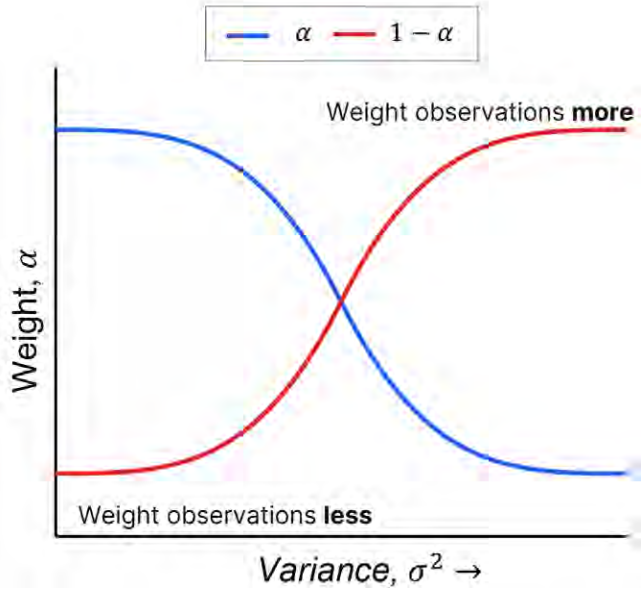

**Figure 1.** Uncertainty-aware learning rate

## Algorithmic Implementation

Our GP-Based Q-learning algorithm combines GP function approximation with temporal difference learning. The outer loop iterates over batches, where each batch collects new trajectories through policy rollouts in the process. It is assumed that the process dynamics do not change between batches. The inner loop is over timesteps in reverse order, from $T-1$ to 0, to allow information from the end of the episode to flow to the initial state-action pairs for correct credit assignment. All Q-values in the dataset for the current timestep are updated with the current model estimate via. a TD update as an approximate policy iteration step. A subset selection strategy preserves a subset of data points for training using the method described in the previous section. An overview of the Q-learning algorithm is described below.

**Algorithm 1:** GP-Based Q-learning

**Data:** Initial Data, $\mathcal{D}_{0,j,t} = \{(\mathbf{x}_t, \mathbf{u}_t, q_t)_i\}_{i=1:N}$

**Inputs:** Total number of batch runs $B$, Batch process operation $\mathcal{P}(\cdot)$, Subset selection strategy $\mathcal{M}(\cdot)$, Data collection strategy $\pi(\cdot)$, Q-learning algorithm, $\mathcal{Q}(\cdot)$.

**Outputs:** GP models, $\mathcal{F}_*(\mathcal{D}_*) = \{f_{*,t}(\cdot; \mathcal{D}_{*,t})\}_{\{t=0:T-1\}}$

Initialize GP models $\mathcal{F}_0(\mathcal{D}_0)$

**For Each** $b \in \{0, \dots, B-1\}$ **do**

  Rollout policy in process, $\{\mathcal{D}_{new,t}\}_t = \mathcal{P}(\pi(\mathcal{F}_b))$

  Append $\mathcal{D}_{b+1,t} = \mathcal{D}_{b,t} \cup \mathcal{D}_{new,t} \quad \forall\, t$

  **For Each** $t \in \{T-1 \dots 0\}$ **do**

    Update data $\mathcal{D}_{b+1,t} = \mathcal{Q}\left(\mathcal{D}_{b+1,t}, f_{b,t:t+1}(\cdot)\right)$

    Select data for training, $\mathcal{D}^{\mathcal{T}}_{b+1} = \mathcal{M}\left(\mathcal{D}_{b+1,t}, f_{b,t}(\cdot)\right)$

    Train GP model independently, $f_{b+1,t}(\cdot, \mathcal{D}^{\mathcal{T}}_{b+1,t})$

**Return** $\mathcal{F}_*(\mathcal{D}_*) = \mathcal{F}_B(\mathcal{D}_*)$

## COMPUTATIONAL CASE STUDY

The case study used to demonstrate the control algorithm described in previous sections is a non-isothermal semi-batch reactor [11]. The aim of the case study is to assess how the proposed algorithm performs again other GP-based methods and whether it approaches the optimum. The reactor carries out the following reactions:

$$\mathrm{A} \longrightarrow B \longrightarrow 3\mathrm{C} \tag{12}$$

Where both reactions are catalysed and are first-order reactions. The first step is exothermic and the second is endothermic which are both characterised by rate constants $k_{1A}(T)$ and $k_{2B}(T)$ that are functions of temperature. A cooling jacket is used to manipulate the reactor temperature. The state of the system $\mathbf{x}$ contains the concentration of all three species, the temperature, and volume of the reactor:

$$\mathbf{x} = [C_A, C_B, C_C, T, V].$$

The two control inputs are the temperature of the cooling jacket and the feed flow rate of A:

$$\mathbf{u} = [T_a, F].$$

The dynamics of the reactor are defined as follows:

$$\frac{\mathrm{d}C_A}{\mathrm{d}t} = -k_{1A}C_A + (C_{A0} - C_A)\frac{F}{V} \tag{13}$$

$$\frac{\mathrm{d}C_B}{dt} = \frac{1}{2}k_{1A}C_A - k_{2B}C_B - C_B\frac{F}{V} \tag{14}$$

$$\frac{\mathrm{d}C_C}{\mathrm{d}t} = 3k_2C_B - C_C\frac{F}{V} \tag{15}$$

$$\frac{\mathrm{d}V}{\mathrm{d}t} = F \tag{16}$$

$$\frac{\mathrm{d}T}{\mathrm{d}t} = \frac{\mathrm{UA}(\mathrm{T_a} - T) - F_{A0}C_{P_A}(T - T_0) + \cdots}{[C_AC_{P_A} + C_BC_{P_B} + C_CC_{P_C}]V + N_{H_2SO_4}C_{P_{H_2SO_4}}} \\ \frac{[(\Delta H_{R1A})(-k_{1A}C_A) + (\Delta \mathrm{H_{R2B}})(-k_{2B}C_B)]V}{[C_AC_{P_A} + C_BC_{P_B} + C_CC_{P_C}]V + N_{H_2SO_4}C_{P_{H_2SO_4}}}. \tag{17}$$

The case study is implemented using the PC-Gym Python package [12]. The episode length is defined as four hours

with timesteps of 24 minutes where control inputs are applied. The objective is to maximize the final amount of the desired product (species C) this results in the following reward function of:

$$\phi_t = \begin{cases} C_C V \; if \; t = \; T-1 \\ 0 \; otherwise \end{cases} \tag{18}$$

## RESULTS

The GP-based Q-learning algorithm presented in Algorithm 1 was trained with an initial dataset $\mathcal{D}_0$ size of 10, 20 and 30 trajectories then trained for a further 25 batches of training. This training was repeated 5 times to ensure repeatability of the algorithm. The resulting policy is rolled out for 20 repetitions to measure the final objective value. When rolling out the policy in testing the actions are selected by maximizing over the mean function of the resulting GPs from training. This algorithm is compared to work by Savage et. al (2021) [13] which differs mainly by using expected-improvement as its behavioural policy, follows the Monte-Carlo learning scheme and having no subset selection scheme The algorithms are also compared to an oracle which is a Nonlinear Model Predictive Controller (NMPC) with a perfect model as implemented by the PC-Gym [12] which acts as a ceiling to performance on this case study.

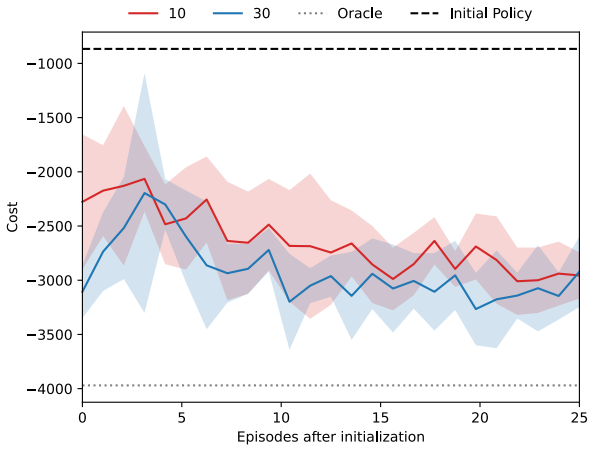

**Figure 2.** Learning Curve of GP-based Q-learning for initial dataset size of 10 and 30 compared to the average initial policy (dashed) and oracle (dotted).

Figure 2 shows the learning curve of our algorithm when using an initial dataset size of 10 and 30 trajectories. The oracle is shown with a dotted line, and the average performance of the initial dataset is shown as a dashed line. The initial performance is higher when using 30 trajectories compared to 10 trajectories, as the larger dataset provides more information for constructing the models of the Q-function. Over the first 5 training episodes, a decrease in performance for both dataset sizes is observed due to the exploration behavior induced by the Thompson sampling rollout policy.

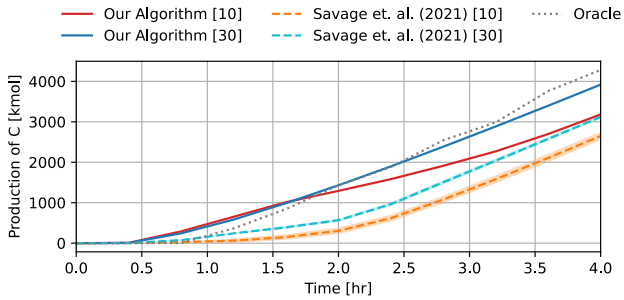

**Figure 3.** Objective value over the test episode for different sized intial datasets compared to the oracle and Savage et.. al. (2021) [13].

The mean objective value for over the test episode is shown in Figure 3. Higher performance is obtained with our algorithm for both initial dataset sizes compared to Savage et. al. (2021)'s [13] algorithm, and with the 30-trajectory dataset our algorithm approaches the oracle's performance. The variance in performance across repetitions is larger for Savage et. al.'s [13] algorithm, as indicated by the wider shaded areas.

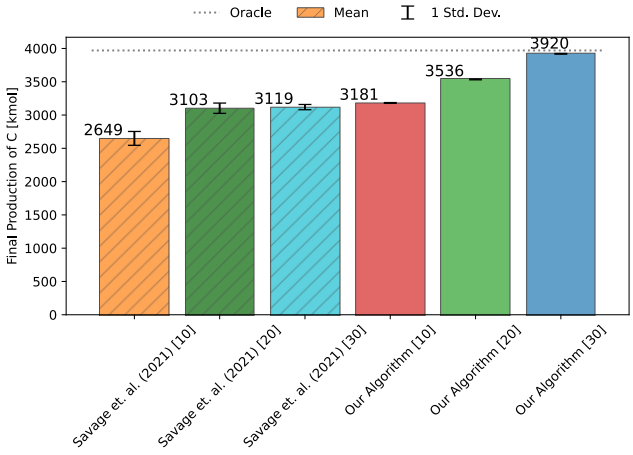

**Figure 4**. Comparison of final objective values for different initial dataset sizes.

A comparison of final objective values for all initial dataset sizes is presented in Figure 4. Our algorithm's performance approaches the oracle's as the dataset size increases. A significant portion of this performance difference can be attributed to our use of TD learning updates, enabling the method to learn about the optimal greedy policy when following a non-greedy rollout policy.

## CONCLUSION

This work compared a Gaussian Process Q-learning

approach with subset selection against prior methods on a non-isothermal semi-batch reactor. With 30 initial trajectories, our approach nearly matched the performance of an oracle NMPC controller demonstrating the effectiveness of our TD learning updates over Monte Carlo for learning optimal policies from non-greedy rollouts.

## ABSTRACT

Middle vessel batch distillation (MVBD) is an alternative configuration of the conventional batch distillation with improved sustainability index. This article presents a comparison of model-based control approaches for MVBD column. Specifically, two control approaches - sequential (open-loop optimization followed by closed-loop control) and simultaneous (closed-loop optimization and control) are pursued. These two approaches are compared in terms of their effectiveness, overall performance, and robustness to plant-model mismatch. The effectiveness of these control strategies is illustrated using a simulation case study of a ternary mixture separation consisting of benzene, toluene and o-xylene.

**Keywords**: Batch distillation, model-based control, economic model predictive control

## INTRODUCTION

Batch distillation is a preferred separation process for small-scale production, multi-product and high-purity separations because of its operational flexibility and cost-effectiveness. However, it also encounters challenges like long batch time and low thermodynamic efficiency. Multi-vessel (also known as multi-effect) batch distillation is an alternative configuration of the conventional batch distillation with reduced energy consumption for multicomponent separation. Middle vessel batch distillation (MVBD), as shown in Figure 1, is a special case of multi-effect distillation with a single intermediate vessel. It allows for simultaneous separation of a ternary mixture wherein relatively pure products are collected in the three holdup vessels.

Several studies have focused on optimization and control of the MVBD configuration. Hasebe et al. (1995) used vessel holdups as manipulated variables to control composition of the products in multi-effect batch distillation [1]. Wittgens et al. (1996) proposed a temperature-based feedback control structure for multi vessel column. The temperature at a particular location in each column section is controlled using reflux flows which allows for indirect adjustment of the vessel holdup [2-3]. Further, this control strategy was examined by Furlonge et al. (1999) using dynamic optimization to determine the controller gains and set points. They demonstrated existence of a trade-off between quality of temperature control and minimum energy consumption for the separation [4]. Zhu et al. (2016) investigated composition and temperature control structures for MVBD. It was found that composition control structure was unable to control the process stably [5]. Krishna et al. (2021) showed that a cascade control structure provided more effective control than a single layer feedback control for the MVBD column [6].

The MVBD is a highly interactive system with nonlinear dynamics and requires coordinated manipulation of heat input and reflux flows to achieve desired separation. The studies mentioned above underline challenges associated with implementation of traditional linear feedback controllers. For energy integrated batch distillation, Vibhute et al. (2020) demonstrated performance improvement with model-based feedback control strategies [7]. Along similar lines, model-based control configurations can be employed to MVBD to achieve desired separation and address stability and optimality of the operation.

In this paper, two types of model-based control approaches are explored for efficient operation of a MVBD column. Firstly, in a sequential approach, optimal set-point trajectory generated with offline optimization is

tracked using a model predictive control (MPC). Alternatively, in the simultaneous approach, performance optimization and control are integrated using an economic MPC.

The rest of the paper is organized as follows. A brief overview of the MVBD configuration and operating principles is presented in the next section. The following section presents design of model-based control strategies for a MVBD column. Comparison of closed-loop performance of the MVBD column with these control strategies is presented using a simulation case study of benzene, toluene and o-xylene separation.

## MIDDLE VESSEL BATCH DISTILLATION

As shown in Figure 1, middle vessel batch distillation consists of two column sections separated by a vessel for the separation of a ternary mixture. It works on the principle of multi-effect operation wherein vapour from one column section is used to drive the subsequent effects, thus reducing the overall energy consumption. The entire system is operated under total reflux and at the end of the batch, the three products are accumulated in the three vessels (distillate, middle and bottom vessels).

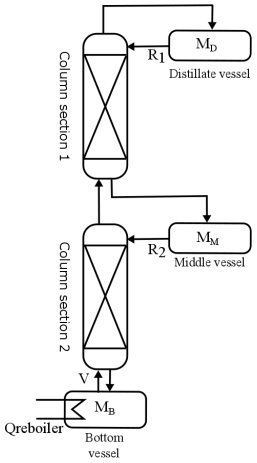

Figure 1. Middle vessel batch distillation configuration.

The mathematical model to capture the dynamics of MVBD configuration, with the assumptions of constant molar overflow and constant tray holdup, is given in Eq. (1).

### Distillate vessel:

$$\frac{dM_D}{dt} = V - R_1, \qquad \frac{d(M_D x_{D,j})}{dt} = V y_{1,j} - R_1 x_{D,j}$$

### Column section 1:

$$\frac{d(M_t x_{i,j})}{dt} = R_1\left(x_{(i-1),j} - x_{i,j}\right) + V\left(y_{(i+1),j} - y_{i,j}\right)$$

Middle vessel:

$$\frac{dM_M}{dt} = R_1 - R_2, \qquad \frac{d(M_M x_{M,j})}{dt} = R_1 x_{N_{T1},j} - R_2 x_{M,j}$$

### Column section 2:

$$\frac{d(M_t x_{i,j})}{dt} = R_2\left(x_{(i-1),j} - x_{i,j}\right) + V\left(y_{(i+1),j} - y_{i,j}\right)$$

### Bottom vessel:

$$\frac{dM_B}{dt} = R_2 - V, \qquad \frac{d(M_B x_{B,j})}{dt} = R_2 x_{N_{T2},j} - V y_{B,j} \qquad (1)$$

Here $M$, $x$, and $y$ represent molar holdup, liquid phase mol fraction, and vapor phase mol fraction, respectively. V, $R_1$, and $R_2$ represent the vapor flow rate and reflux flow rates from the distillate and middle vessel, respectively. Subscripts $D$, $M$, and $B$ refer to the distillate vessel, middle vessel, and bottom vessel, respectively. Subscripts $t$, $i$, and $j$ denote tray, stage number (from the top of the column), and component j, respectively. Subscripts $N_{T1}$ and $N_{T2}$ refer to the last stage of column section 1 and 2, respectively.

### Performance quantification

In MVBD, a ternary mixture is separated into valuable products using thermal energy. Therefore, the performance of MVBD can be effectively evaluated with the inclusion of separation and energy efficiency. Motivated by this, overall performance index (OPI) was previously defined to incorporate both production and energy consumption [9]. The OPI is defined as the ratio of the value of products obtained to the cost of energy supplied to distillation. It can be computed using the following expression:

$$OPI = \frac{\sum_{i=1}^{3}(C_i * M_i(t_{batch}))}{\int_0^{t_{batch}}[C_Q * Q_{reboiler}]dt} \qquad (2)$$

Here $M_i$, $C_Q$, and $t_{batch}$ represent $i^{th}$ vessel holdup, cost of the reboiler duty, and batch processing time, respectively.

## MODEL BASED CONTROL STRATEGIES

In previous work, the OPI was maximized to generate optimal operation policy (initial feed distribution, vessel holdup profile, and input variable profile) for the MVBD by redistributing holdup in the three vessels [9]. Specifically, it was shown that material holdup in the column can be dynamically redistributed among the three vessels to maximize OPI for the entire batch. This optimal operation policy obtained with open-loop optimization can be directly implemented in the MVBD column. However, in the presence of external disturbances and plant-model mismatch (primarily due to simplifying modeling assumptions and vapor liquid equilibrium), a feedback

control is required to maintain product purity and operational optimality.

To this end, model-based feedback control strategies can be formulated using two different approaches. In a sequential approach, offline optimization is used to derive dynamic trajectory for key process variables (vessel holdup, product purity, material and energy flows) to maximize OPI for the entire batch. Subsequently, a feedback controller is used to track this trajectory in an online manner. In the case of MVBD operation, as shown in Figure 2, this can be achieved by tracking optimal vessel holdup or product composition profiles by manipulating the reflux and vapor flows. Alternatively, in the simultaneous approach, optimization is combined with feedback control into a single step, similar to the framework of an economic model predictive control. Specifically, the typical regulatory control objective is replaced by OPI maximization and the corresponding optimal input trajectory is sent to the column in a receding horizon manner. For the MVBD operation, as shown in Figure 3, the MPC uses OPI maximization over the prediction horizon ($N_p$) to estimate vapor and reflux flow profile over the control horizon.

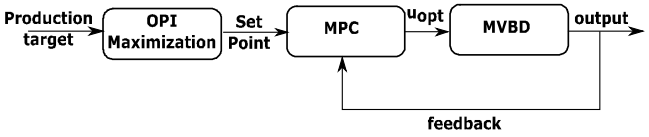

**Figure 2.** Sequential approach.

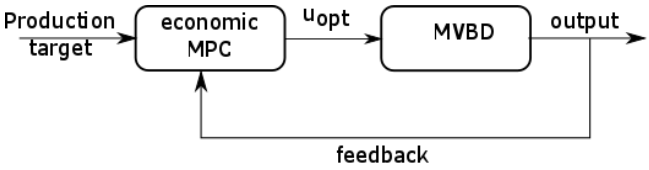

**Figure 3.** Simultaneous approach.

Under normal operating scenario, the sequential approach results in optimal performance. However, it meets challenges in achieving the desired product purity and/or maintain optimality in presence of significant disturbances and plant-model mismatch, since the optimal trajectory is obtained in the absence these factors. On the other hand, the simultaneous approach can effectively handle disturbances and plant-model mismatch due to active feedback. However, it can result in comparatively lower OPI since it considers a smaller prediction horizon ($N_p \ll t_{batch}$) for optimization than the sequential approach. Both these approaches are explored for MVBD column.

Let us now set up the corresponding controller formulations. At every instant, the MPC solve the following optimization problem.

$$\min_{u(t)} \quad J$$

Subject to:

Dynamic model for MVBD (Eq. (1))

Input bounds: $u_{min} \leq u(t) \leq u_{max}$

Input move constraints: $\Delta u_{min} \leq \Delta u(t) \leq \Delta u_{max}$

Vessel holdup constraints: $M_{min} \leq M(t) \leq M_{max}$

Feasible composition constraints:

$$0 \leq x(t) \leq 1,\ 0 \leq y(t) \leq 1 \qquad (3)$$

The sequential and simultaneous approaches differ only in terms of their objective function.

## Sequential approach

Here, optimal set-point trajectory generated with offline optimization (OPI maximization) is tracked using a model predictive control (MPC). The dynamics of the MVBD column, as shown in Eq. (1), is nonlinear; therefore a nonlinear model predictive controller (NMPC) is designed. The key variable to be tracked are composition of the products or holdup of the vessels. The corresponding objective functions are given in Eq. (4) and Eq. (5).

Vessel holdup tracking:

$$J = \sum_{i=1}^{N_p} (M_{set}(i) - M(i)) Q1 (M_{set}(i) - M(i))^T \qquad (4)$$

Product composition tacking:

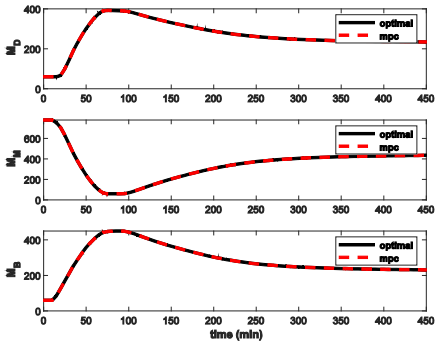
$$J = \sum_{i=1}^{N_p} (x_{set}(i) - x(i)) Q2 (x_{set}(i) - x(i))^T \qquad (5)$$

Here the subscript $set$ refers to the optimal offline trajectory, Q1 and Q2 are positive definite weighting matrices and $N_P$ is the prediction horizon. Tracking holdup trajectory has the benefits of faster response and low sensor cost requirement but it relies on indirect control of product composition. On the other hand, tracking composition profile ensures product quality but suffers from slower response due to measurement delays and increased sensing cost (costly composition sensor or need for state estimator).

## Simultaneous approach

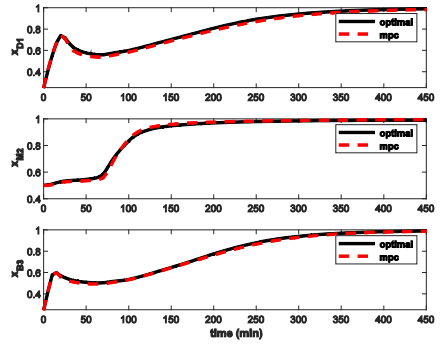
The primary objective of the controller is to maximize OPI. However, due to the absence of any penalty term on product purity, the controller would rarely achieve the desired purity at the end of the batch. Therefore, the controller objective consists of two parts, maximization of OPI for the time window of prediction horizon and minimization of difference between desired product purity and product composition in the vessels, as shown in Eq. (6).

$$J = -w_1 * OPI(N_p) + w_2 \left(x_{D1,desired} - x_{D1}(N_p)\right) + w_3 \left(x_{M2,desired} - x_{M2}(N_p)\right) + w_4 (x_{B3,desired} - x_{B3}(N_p)) \qquad (6)$$



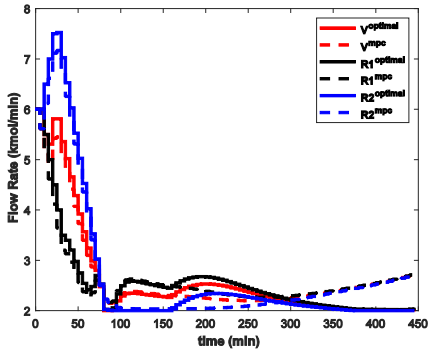
Here, the OPI is computed for the prediction horizon by replacing $t_{batch}$ in Eq. (2) by $N_p$. This formulation is similar to the economic MPC as the prediction horizon for this controller is much smaller than the batch time. The tuning parameters $w_1, w_2, w_3$ and $w_4$ are adjusted to attain desired product purity with optimal performance. They also provide a trade off between quality (achieving product purity) and efficiency (optimal operation).

## SIMULATION CASE STUDY



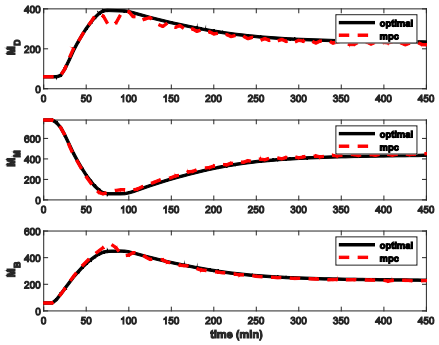
Let us now evaluate and compare the performance of these proposed control approaches with a case study of benzene, toluene, and o-xylene separation in MVBD column. The MVBD column consists of total 65 trays ($N_{T1} = 36$, $N_{T2} = 29$) to process 1000 kmol fresh feed ($F$) with a composition of (0.25, 0.5, 0.25). The modified Raoult's law is used to capture the vapor liquid equilibrium relationship. The activity coefficients and vapor pressure are computed using the NRTL model and Antoine equation, respectively [9]. Implicit Euler scheme with a time step of 5 min is used for the discretization of MVBD dynamics. The optimization problem is solved using the CasADi framework in MATLAB version R2022a [8]. The maximum and minimum value for each input variable is taken as 10 kmol/min and 2 kmol/min, respectively. Their rate of change across the time steps is bounded to ±0.5 kmol/min. The vessel holdups are constrained between 60 kmol and 900 kmol, respectively. Lastly, cost of each product and hot utility are taken as 15 rcu/mol and 2.3 rcu/MJ, respectively (rcu refers to relative cost unit). The OPI value of base case operation without optimization is 12.88.

In our previous work [9], we had generated optimal operation policy for the separation of above ternary mixture in MVBD column, by solving open loop optimization problem for OPI maximization. It was determined that feeding the system through the middle vessel results in optimal performance. The corresponding optimal OPI value and batch time are 26.8 and 450 minutes, respectively.

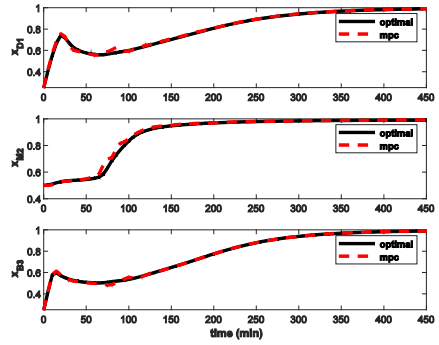


Let us first consider the sequential approach to track this optimal profile in the absence of any disturbances. Figure 4(a) shows the tracking of vessel holdup trajectory using Eq. (3) and (4). It can be observed that the nonlinear MPC is able to track the optimal trajectory of vessel holdup and desired product purity (Figure 4(b)) is achieved as well. Since the controller objective does not incorporate OPI, the optimal trajectory of vessel holdup can be achieved with various combinations of input variables. The vapour flow rate, shown in Figure 4(c), is comparatively higher than the optimal trajectory. Consequently, the OPI value with the holdup controller is 25.6, a drop of 4.5% from the openloop optimal value.

(a) Vessel holdup (M)

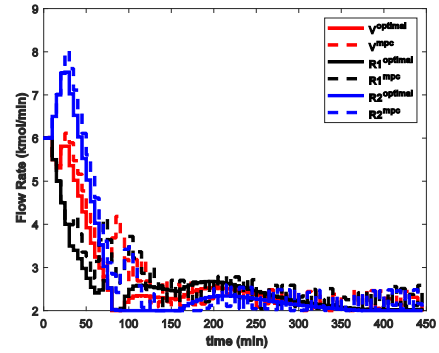


(b) Product composition



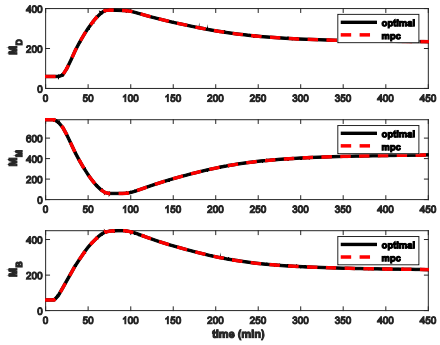
(c) Input variables

**Figure 4.** Dynamic response for the sequential approach with vessel holdup tracking in the absence of disturbance

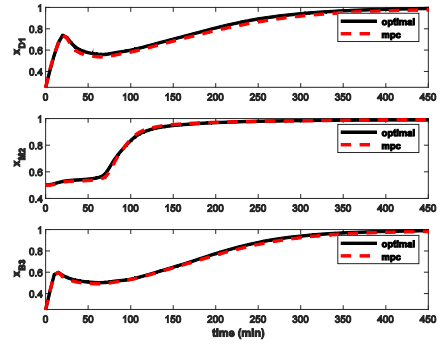


Similarly, product composition tracking using Eq. (3) and (5) is shown in Figure 5. In this case as well, the controller is able to track the optimal trajectory and reach the desired product purity. The corresponding OPI value is 24.40, a drop of 9% as compared to the openloop optimal value, due to higher vapour flow rate.

(a) Vessel holdup (M)



(b) Product composition

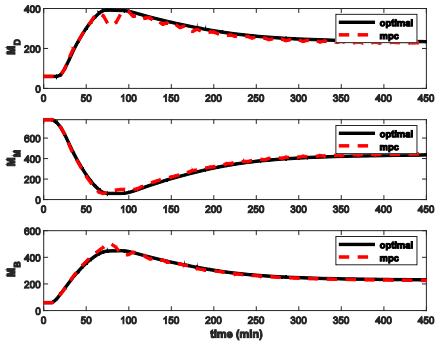


(c) Input variables

**Figure 5.** Dynamic response for the sequential approach with composition tracking in the absence of disturbance

Let us now consider a disturbance scenario (plant-model mismatch) in implementation of the sequential approach. It is considered that after 50 min of operation, tray efficiency for all the trays in the MVBD column is dropped by 10% due to an undetected fault. As the openloop optimization does not incorporate this disturbance, the MPC set point trajectory remains the same. In the case of vessel holdup tracking, even though the holdup tracking is done effectively, it fails to meet desired purity. The corresponding dynamic responses are as shown in Figure 6. On the other hand, in the case of product composition tracking, continuous feedback from plant ensures that at the end of the operation, desired product purity of all the components is attained. However, as the original composition trajectory is not longer optimal in this disturbance scenario, the OPI value decreases from 24.4 to 22.4, reduction of 8.2% due to presence of plant-model mismatch. The corresponding dynamic responses are depicted in Figure 7.

(a) Vessel holdup (M)



(b) Product composition

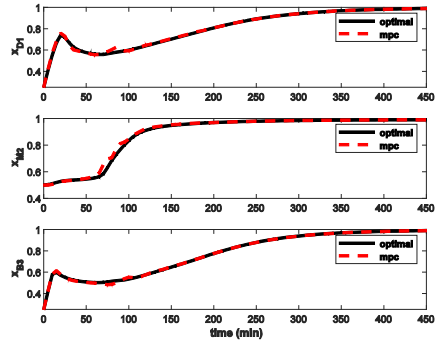


**Figure 6.** Dynamic response for the sequential approach with vessel holdup tracking in the presence of disturbance

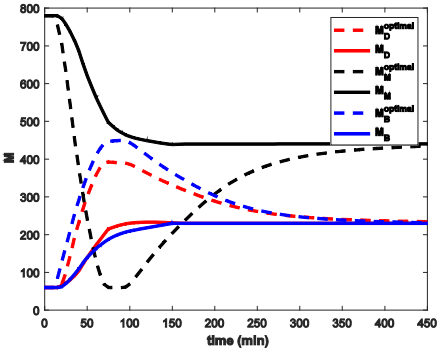
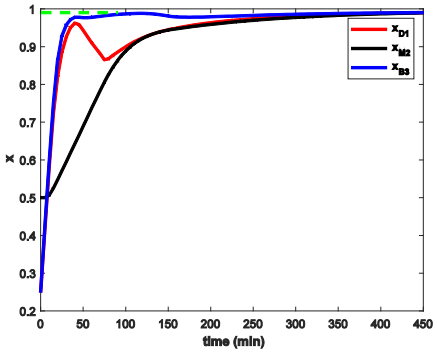
Let us now assess the performance of the simultaneous approach. A nonlinear MPC is implemented using Eq. (3) and (6). Tuning parameter values are selected as $w_1 = 9 * 10^{-4}$, $w_2 = 44 * 10^{-4}$, $w_3 = 7.55$, $w_4 = 13.2$ to achieve good balance between purity attainment and performance optimization. The dynamic response of the controller in the absence of any disturbance is shown in Figure 8. Similar to the sequential approach, this controller is also able to achieve the desired product purity at the end of the batch. However, it can be observed from Figure 8(a) that the simultaneous approach is not able to capture the holdup distribution profiles obtained with open loop optimization. Previously [9], it was shown that OPI maximization requires two phases of vessel holdup redistribution for the optimal performance. During the first phase (up to 90 min), the material from the middle vessel is redistributed between the top and bottom vessel such that the composition of the heaviest component in the top vessel and lightest component in the bottom

vessel is negligible. This requires top and bottom compositions to drop during the first phase (see Figure 4(b)). These purities are subsequently recovered during the second phase. As the simultaneous approach has a smaller prediction (and thus optimization) window, it cannot exploit this vessel holdup redistribution effectively, resulting in a smaller OPI value of 17.92.

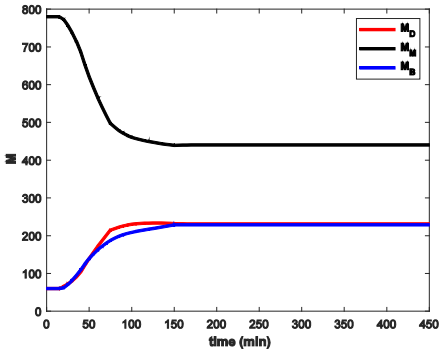


(a) Vessel holdup (M)

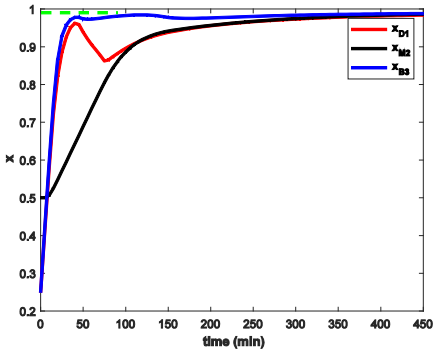


(b) Product composition

**Figure 7.** Dynamic response for the sequential approach with composition tracking in the presence of disturbance



(a) Vessel holdup (M)



(b) Product composition

**Figure 8.** Dynamic response for the simultaneous approach in the absence of disturbance

In the next simulation, the performance of simultaneous approach is analysed for plant-model mismatch. The same disturbance scenario of 10% drop in the tray efficiency after 50 min of operation is considered. Figure 9 shows the corresponding vessel holdup and product composition profiles. It can be seen that the controller is still able to achieve the desired product purity at the end of the batch. Furthermore, the OPI value in this case is again 17.92. Due to runtime optimization of OPI, this controller is robust to plant-model mismatch.

(a) Vessel holdup (M)

(b) Product composition

**Figure 9.** Dynamic response for the simultaneous approach in the presence of disturbance

Overall, it can be concluded that, in the absence of any plant-model mismatch, all the controllers are able to meet the desired product purity. The sequential approach exhibits better performance (OPI) than the simultaneous approach due to its longer optimization horizon. However, in the presence of significant plant-model mismatch, it shows substantial decline in performance. Furthermore, the holdup tracking approach can also fail to achieve the desired end of the batch purity. On the other hand, the simultaneous approach cannot match the openloop optimal performance in terms of OPI due to its shorter optimization window. However, it is quite robust in terms of maintaining this performance and product purity even in the presence of significant plant-model mismatch.

## CONCLUSION

In this paper, a comparison of two model-based control strategies, sequential (two-step) approach and simultaneous (one-step) approach, is presented for middle vessel batch distillation. The objective of optimal control is to produce products at the desired purity with optimal performance. An economic performance index (OPI) is used to evaluate the performance of MVBD column. For the case study of benzene, toluene and o-xylene separation, the proposed approaches are compared in terms of the effectiveness, overall performance and robustness to plant-model mismatch. In the absence of any disturbance, both the approaches effectively track the optimal trajectory. However, in presence of significant plant-model mismatch, the sequential approach results in substantial performance deterioration. The simultaneous approach shows robustness to plant-model mismatch, but at the cost of sub-optimal performance. Thus a trade-off between performance and robustness is observed through the sequential and simultaneous approaches.

## ABSTRACT

Real-time optimization (RTO) is a model-based technique that drives plants to optimal operating conditions. Modifier Adaptation (MA) is a class of methods that adjusts the optimization problem using gradient information. This enables the plant to reach the optimum operating point or batch trajectory without the need of a precise model which reduces the necessary modeling efforts. However, computing the gradients of the cost function or of the plant outputs with respect to the inputs online is a challenging task. Modifier Adaptation with Quadratic Approximation (MAWQA) integrates MA with Quadratic Approximation (QA), which helps mitigate the challenges of estimating gradients from noisy measurements by utilizing historical operating data. However, the distribution of these past operating points significantly affects the effectiveness of the MAWQA strategy. To address this issue in this contribution, new methods to compute probing points which lead to fast convergence to the optimum are proposed. The effectiveness of these methods is validated using the Williams-Otto reactor benchmark.

**Keywords**: Modifier Adaptation, Real-time Optimization, Derivative Free Optimization, Probing.

## INTRODUCTION

In recent years, the field of real-time optimization (RTO) has gained significant attention. This is due to the increasing pressure to operate processing plants optimally from both economic and emissions perspectives. A key challenge in RTO is ensuring that plant models are accurate enough to determine feasible and optimal operating inputs or batch trajectories. While re-estimating model parameters online can enhance the performance when the plant model is structurally correct, Modifier Adaptation (MA) addresses both parametric and structural plant-model mismatch without updating the model [1, 2]. This iterative method adjusts the gradients of the cost function and the constraints based on measurement information, so that the first-order optimality conditions are satisfied upon convergence.

In this contribution, we investigate Modifier Adaptation with Quadratic Approximation (MAWQA). This algorithm combines MA with a Quadratic Approximation (QA) approach that was adapted from derivative-free optimization, thereby alleviating the problem of estimating the gradients from noisy measurements [3]. However, the distribution of the points that are used for the approximation significantly influences the QA. If the prior operating data points are not well-distributed, the optimization process may become trapped in a region away from the true optimum. In such cases, additional trials are necessary. For gradients computed via finite differences, it was proposed in [1] to solve an optimization problem to determine a trial input that improves the geometry of the set of past data points. While this strategy is effective for simplex gradients, it is less suited for QA.

In this paper, we discuss different methods to compute additional probing points, which improve the quality of the fitted quadratic surrogate model. The first method extends the approach introduced in [3] in which the input is computed by averaging with distant points. The second method uses the perturbation method from [1] to improve the distribution by solving an optimization problem. This method is then modified such that it is better suited for QA. By solving an optimization problem, it is ensured that the data matrix used in the QA is invertible and well-conditioned. This is based on optimizing the condition

number, which is a computationally expensive problem. This motivates the next approach, which simplifies the computations by using LU decomposition of the data matrix and transforming the polynomial basis such that the additional input can be computed by solving a scalar quadratic optimization problem [4]. Finally, we extend this approach to a completely model-free optimization by introducing well distributed trial points to compute an initial QA, followed by the application of the MAWQA algorithm. We compare these methods using the Williams-Otto reactor benchmark.

## MODIFIER ADAPTATION

We consider a real process with the objective function $J_p(\boldsymbol{u})$, where $\boldsymbol{u}$ is a vector of $n_u$ inputs of the stationary or periodic operation of the plant. The operation is subject to $n_c$ constraints $G_p(\boldsymbol{u})$. The optimal set of inputs $\boldsymbol{u}_p^*$ is defined by (1).

$$\boldsymbol{u}_p^* = \operatorname{argmin}_u J_p(\boldsymbol{u}) \quad \text{s.t. } G_p(\boldsymbol{u}) \leq 0. \tag{1}$$

However, in practice, the mappings $J_p(\boldsymbol{u})$ and $G_p(\boldsymbol{u})$ are not exactly known. We assume that an approximation of these mapping is available, and we denote these models by $J_m(\boldsymbol{u})$ and $G_m(\boldsymbol{u})$. The optimum of the optimization model $\boldsymbol{u}_m^*$ due to plant-model mismatch is not equal to the actual optimum $\boldsymbol{u}_p^*$. In MA, the optimization problem is adapted with modifiers to ensure that the KKT conditions of the plant are satisfied upon convergence [1, 2]. The inputs $\boldsymbol{u}_{ad|\,k}$ in the $k^{th}$ iteration that result from the adapted model are computed from (2), where $\boldsymbol{u}_k$ is the input applied at iteration $k$.

$$\boldsymbol{u}_{ad|\,k} := \operatorname{argmin}_{\boldsymbol{u}} \left( J_m(\boldsymbol{u}) + \epsilon_k^J + \left(\psi_k^J\right)^T (\boldsymbol{u} - \boldsymbol{u}_k) \right), \tag{2a}$$

$$\text{s.t. } G_m(\boldsymbol{u}) + \epsilon_k^G + \left(\psi_k^G\right)^T (\boldsymbol{u} - \boldsymbol{u}_k) \leq 0. \tag{2b}$$

$\epsilon_k^J$, $\epsilon_k^G$, $\psi_k^J$, and $\psi_k^G$ represent the cost function and constraints modifiers. The modifiers can be computed using at least $n_l := n_u + 1$ measurements. To reduce the impact of the estimation errors in the gradients of the actual plant, the inputs can be filtered by

$$\boldsymbol{u}_{ad|k+1}^* = K \cdot \boldsymbol{u}_{ad|\,k+1} + (I - K) \cdot \boldsymbol{u}_k^*, \tag{3}$$

where $K$ is a gain matrix [2]. The computation of the gradients in the MA algorithm is based on finite difference approximations using the past data points [1]. The decision to apply additional perturbations is based on the value of the condition number of past data points. Should the condition number drop below a certain threshold, a probing input is computed from (4).

$$\boldsymbol{u}_\tau = \operatorname{argmax}_{\boldsymbol{u}} \operatorname{cond}(\mathcal{S}_k^{-1}), \tag{4a}$$

$$\text{s.t. } G_m(\boldsymbol{u}) + \epsilon_k^G + \left(\psi_k^G\right)^T (\boldsymbol{u} - \boldsymbol{u}_k) \leq 0, \tag{4b}$$

$$\mathcal{S}_k = \left[\boldsymbol{u}_k - \boldsymbol{u}, \ldots, \boldsymbol{u}_k - \boldsymbol{u}_{k-n_u}\right]^T. \tag{4c}$$

## Modifier adaptation with quadratic approximation (MAWQA)

MAWQA combines MA with elements from derivative-free optimization (DFO) [4]. In the MAWQA framework, when enough data points are available, the modifiers in equation (2) are calculated by analytically differentiating the fitted quadratic functions corresponding to the measurements of $J_p$ and $G_p$ and evaluating them at $\boldsymbol{u}_k$. This works well if the regression set is well-poised. Poisedness refers to the quality of the regression set in terms of its ability to accurately represent the underlying function [4]. To achieve a well-poised regression set, a screening algorithm is employed. The regression set $\boldsymbol{\mathcal{U}}_k$ should include well-distributed distant data points $\boldsymbol{\mathcal{U}}_k^{dist}$, which serve as anchors, alongside neighboring points $\boldsymbol{\mathcal{U}}_k^{nb}$ near the current best iterate $\boldsymbol{u}_k^*$ within a radius of $\Delta$, which reduces the effects of the measurement noise [3]. The regression set contains $n_m$ data points, each data point is an $n_u$ input vector $\boldsymbol{u}$; $\boldsymbol{\mathcal{U}}_k = \{\boldsymbol{u}_k^*, \boldsymbol{\mathcal{U}}_k^{dist}, \boldsymbol{\mathcal{U}}_k^{nb}\}$. The quadratic polynomial used for this fit is defined by

$$\mathcal{P}(\boldsymbol{u}, \boldsymbol{\beta}) = c + \sum_{i=1}^{n_u} \left(b_i u(i)\right) + \sum_{i=1}^{n_u} \sum_{j=1}^{i} \left(a_{i,j} u(i) u(j)\right), \tag{5}$$

where $\boldsymbol{\beta} = \left[c,\ b_1, \ldots, b_{n_u}, a_{1,1}, \ldots, a_{n_u,n_u}\right]^T$ and $u(i)$ denotes the $i^{th}$ element in the vector $\boldsymbol{u}$. The polynomial basis, which correspond to the polynomials in (5), is defined by

$$\begin{aligned} \boldsymbol{\Gamma}(\boldsymbol{u}) = \{&1, u(1), \cdots, u(n_u), u(1)^2, u(1)\,u(2), \cdots, \\ &u(n_u - 1) u(n_u), u(n_u)^2\}. \end{aligned} \tag{6}$$

To fit the cost function $J_p(\boldsymbol{u})$, at least $n_Q := |\boldsymbol{\beta}| = (n_u + 1)(n_u + 2)/2$ observations of the function must be available, which are in stored in $\boldsymbol{\mathcal{U}}_k$ in the MAWQA algorithm. To determine the values of $\boldsymbol{\beta}$, the linear system of equations (7) is solved if $n_m = n_Q$ and in least squares sense if $n_m > n_Q$ .

$$\begin{bmatrix} \Gamma_1(\mathcal{U}_{1|k}) & \Gamma_2(\mathcal{U}_{1|k}) & \cdots & \Gamma_{n_q}(\mathcal{U}_{1|k}) \\ \Gamma_1(\mathcal{U}_{2|k}) & \Gamma_2(\mathcal{U}_{2|k}) & \cdots & \Gamma_{n_q}(\mathcal{U}_{2|k}) \\ \vdots & \vdots & \vdots & \vdots \\ \Gamma_1(\mathcal{U}_{n_m|k}) & \Gamma_2(\mathcal{U}_{n_m|k}) & \cdots & \Gamma_{n_q}(\mathcal{U}_{n_m|k}) \end{bmatrix} \begin{bmatrix} \beta_1 \\ \beta_2 \\ \vdots \\ \beta_{n_q} \end{bmatrix} = \begin{bmatrix} J_p(\mathcal{U}_{1|k}) \\ J_p(\mathcal{U}_{2|k}) \\ \vdots \\ J_p(\mathcal{U}_{n_m|k}) \end{bmatrix}$$

$$\mathcal{M}(\boldsymbol{\Gamma}(\boldsymbol{u}), \boldsymbol{\mathcal{U}}_k)\beta = J_p(\boldsymbol{\mathcal{U}}_k) \tag{7}$$

The notation $\mathcal{U}_{j|k}$ means the data point with index $j$ in the regression set $\boldsymbol{\mathcal{U}}$ in the $k^{th}$ iteration. The constraints are also fitted in the same way as the cost function. To ensure the adequacy of the fitted model, the method proposed in [5] can be employed when fitting the parameters $\boldsymbol{\beta}$. This involves employing the General Quadratic Convex Under-estimator (GQCU) to ensure that the fitted surrogate model remains convex by enforcing the Hessian matrix to be positive semi-definite. Since the fitted model is only a local approximation of the original function around $\boldsymbol{u}_k^*$, a trust region is employed while searching

for $\boldsymbol{u}_{k+1}$. In the MAWQA algorithm, the trust region depends on the regression set $\mathcal{U}_k$.

$$\boldsymbol{u}^*_{\phi|k+1} := \operatorname{argmin}_{\boldsymbol{u}} J_\phi(\boldsymbol{u}), \tag{8a}$$
$$\text{s.t. } G_\phi(\boldsymbol{u}) \leq 0, \tag{8b}$$
$$(\boldsymbol{u}-\boldsymbol{u}_k)^T \operatorname{cov}(\mathcal{U}_k)\,(\boldsymbol{u}-\boldsymbol{u}_k) \leq \gamma^2, \tag{8c}$$

where $J_\phi$ and $G_\phi$ are the fitted quadratic functions of $J_p$ and $G_p$. A tuning factor, denoted by $\gamma$, is used to scale the trust-region. The quality of the surrogate model is compared to that of the adapted process model. MAWQA solves either $(2a, b)$ with $(8c)$ or $(8a-c)$ depending on which model predicts the last $J_p$ and $G_p$ better [3].

**Algorithm** 1. MAWQA

**Step 1.** Collect $n_l$ measurements by applying feasible and well distributed data points.

**Step 2.** Apply MA until $n_Q$ measurements are collected. **If** $\operatorname{cond}(\mathcal{S}_k^{-1}) < \epsilon$, compute $\boldsymbol{u}_{k+1}$ from $(4)$.

**Step 3.** Construct the regression set $\mathcal{U}_k$ and compute $u_{k+1}$ from $(2)$ or $(8)$.

**Step 4.** If $\boldsymbol{u}_{k+1}$ lies near $\boldsymbol{u}^*_k$; $\|\boldsymbol{u}_{k+1}-\boldsymbol{u}^*_k\| < \Delta$, where $\Delta$ is a tuning parameter, then apply an explorative input $\boldsymbol{u}_{k+1} = \boldsymbol{u}_\alpha$, to improve the quadratic models.

**Step 5.** Apply $\boldsymbol{u}_{k+1}$ to the plant and check the improvement in the cost function.

**Step 6.** Successful iteration: **If** $J_p(\boldsymbol{u}_{k+1}) < J_p(\boldsymbol{u}^*_k)$, and $G_p(\boldsymbol{u}_{k+1}) \leq 0$ **then** set $\boldsymbol{u}^*_{k+1} = \boldsymbol{u}_{k+1}$, and increase $k$ by one then return to **Step 3**.

**Step 7.** **Otherwise** Add $\boldsymbol{u}_{k+1}$ to the regression set $\mathcal{U}_k$ and return to **Step 3**.

In [3], it is suggested to compute $\boldsymbol{u}_\alpha$ by applying two steps. First a data point is chosen from the distant points that are included in the regression set.

$$\boldsymbol{u}_i \in \mathcal{U}_k, \|\boldsymbol{u}_i - \boldsymbol{u}^*_k\| \geq 2\Delta, \tag{9a}$$
$$\boldsymbol{u}_\alpha = (\boldsymbol{u}_i + \boldsymbol{u}^*_k)/2. \tag{9b}$$

This approach has the same goal as the criticality step of the derivative free algorithm introduced in [4], which is a model improvement step. Experience however shows that this step often is inefficient in this form. In addition, MAWQA also relies on the explorative nature of the algorithm, that leads to improving the poisedness [6].

## PERTURBATION METHODS FOR MAWQA

In this section, we investigate four different options to improve the poisedness of the data points that are visited by the MAWQA algorithm. This improves the quality of the locally fitted quadratic models.

### Method I: Averaging with Distant Points

Here the original approach is adjusted to ensure that $u_\alpha$ adheres to the estimated process constraints. The initial input $u_i$ for starting Algorithm 2 can be chosen based on various criteria, such as prioritizing the best cost, or selecting the furthest point from $\boldsymbol{u}^*_k$ first, or ensuring a good geometric distribution.

**Algorithm** 2. Averaging with distant points

**Select** $\boldsymbol{u}_i$ and **compute** $\boldsymbol{u}_\alpha$ from $(9)$.
**If** $G_\phi(\boldsymbol{u}_\alpha) \leq 0$ **then** $\boldsymbol{u}_{k+1} = \boldsymbol{u}_\alpha$ **otherwise** choose a different $\boldsymbol{u}_i$.

### Method II: Simplex Gradients

The second method is the same as the perturbation method used in [1]. This means solving $(10)$ and replacing $\boldsymbol{u}_\alpha$ by $\boldsymbol{u}_\varepsilon$.

$$\boldsymbol{u}_\varepsilon = \operatorname{argmax}_{\boldsymbol{u}\in B} \operatorname{cond}(\mathcal{S}_k^{-1}), \tag{10a}$$
$$\text{s.t. } G_{\phi|k}(\boldsymbol{u}) \leq 0, \tag{10b}$$

where $B$ is a sphere with radius $r$.

### Method III: QA Matrix Conditioning

In the context of the MAWQA, it is crucial for the matrix $\mathcal{M}$ from $(7)$ to be well conditioned to avoid numerical instability and unreliable results. It is established in [4] that well-poisedness is related to the condition number of the matrix $\mathcal{M}(\boldsymbol{\Gamma}(\boldsymbol{u}), \widehat{\boldsymbol{\mathcal{U}}}_k)$, where $\widehat{\boldsymbol{\mathcal{U}}}_k := \boldsymbol{\mathcal{U}}_k - \boldsymbol{u}^*_k$ is a shifted version of $\boldsymbol{\mathcal{U}}_k$ with respect to $\boldsymbol{u}^*_k$. In Method III, the condition number of $\mathcal{M}(\boldsymbol{\Gamma}(\boldsymbol{u}), \widehat{\boldsymbol{\mathcal{U}}}_k)$ is optimized for the given set $\widehat{\boldsymbol{\mathcal{U}}}_k$ augmented with $\boldsymbol{u}_\omega$, the additional perturbation input.

$$\boldsymbol{u}_\omega = \operatorname{argmin}_{\boldsymbol{u}\in B} \operatorname{cond}\left(\mathcal{M}(\boldsymbol{\Gamma}(\boldsymbol{u}), \{\widehat{\boldsymbol{\mathcal{U}}}_k, (\boldsymbol{u}-\boldsymbol{u}^*_k)\})\right),$$
$$\text{s.t. } G_{\phi|k}(\boldsymbol{u}) \leq 0, \tag{11}$$

where $B$ is a sphere with radius $r$. The optimization problem computes a probing input $\boldsymbol{u}_\omega$ that improves the poisedness of $\widehat{\boldsymbol{\mathcal{U}}}_k$ and the surrogate quadratic model quality.

### Method IV: Pivot Polynomials

This method simplifies the computations by avoiding the need to solve the complex optimization problem $(11)$. It is a variant of the algorithms introduced in [4, Chapter 6]. The algorithm performs an LU decomposition of $\mathcal{M}(\boldsymbol{\Gamma}(\boldsymbol{u}), \widehat{\boldsymbol{\mathcal{U}}}_k)$ through Gaussian elimination. The matrix $\mathcal{M}(\boldsymbol{\Gamma}(\boldsymbol{u}), \widehat{\boldsymbol{\mathcal{U}}}_k)$ is factored into a lower triangular matrix $L$ and an upper triangular matrix $U$; $\mathcal{M}(\boldsymbol{\Gamma}(\boldsymbol{u}), \widehat{\boldsymbol{\mathcal{U}}}_k) = L \cdot U$. To enhance the numerical stability during this decomposition, pivoting is employed. Pivoting involves the selection of pivot elements prior to executing the Gaussian elimination process, thereby mitigating risks associated with division by small numbers and minimizing numerical inaccuracies. The algorithm decomposes $\mathcal{M}(\boldsymbol{\Gamma}(\boldsymbol{u}), \widehat{\boldsymbol{\mathcal{U}}}_k)$ into $L$ and $U$ such that $L$ contains ones along its diagonal, while $U$ contains pivot values along the diagonal. The symbolic functions yielding these pivot values are the output of the algorithm, these functions are referred to as the pivot polynomials $\boldsymbol{\Phi}(\boldsymbol{u})$. By this operation we obtain symbolic

functions in the diagonal of the computed upper triangular matrix. The condition number of the upper triangular matrix is improved by maximizing $|\Phi_i(\boldsymbol{u})|$, the $i^{th}$ polynomial in the set $\boldsymbol{\Phi}(\boldsymbol{u})$. The condition number of the matrix $\mathcal{M}(\boldsymbol{\Gamma}(\boldsymbol{u}), \widehat{\boldsymbol{\mathcal{U}}}_k)$ is improved indirectly by optimizing the pivots of the matrix $U$. In Algorithm 3 presented below, we differentiate between $\Phi_i(\hat{\mathcal{U}}_{j|k})$, which is a numerical scalar value that is computed from the $j^{th}$ data point in $\widehat{\boldsymbol{\mathcal{U}}}_k$, and $\Phi_i(\boldsymbol{u})$ which is a symbolic function of $\boldsymbol{u}$ (see **Steps e-f**). The algorithm starts under the assumption that $\widehat{\boldsymbol{\mathcal{U}}}_k$ is initiated with $\boldsymbol{u}_k^*$ as its first element; $\hat{\mathcal{U}}_{1|k} = \boldsymbol{u}_k^*$. In the $i^{th}$ iteration, the data point $\hat{\mathcal{U}}_{j|k}$ that maximizes the pivot polynomial $\Phi_i$ is identified in **Step b**. The data points $\hat{\mathcal{U}}_{j|k}$ and $\hat{\mathcal{U}}_{i|k}$ are then swapped in $\widehat{\boldsymbol{\mathcal{U}}}_k$ in **Step c**. Afterwards Gaussian elimination is applied to all subsequent rows to update the pivot polynomials as shown in the loop **Steps e-f**. The algorithm starts with the basis $\boldsymbol{\Phi}(\boldsymbol{u}) = \boldsymbol{\Gamma}(\boldsymbol{u})$ and progressively updates its entries using the row operations derived from Gaussian elimination.

**Algorithm** 3. Perturbation using pivot polynomials

**Require:** $\widehat{\boldsymbol{\mathcal{U}}}_k$; $|\widehat{\boldsymbol{\mathcal{U}}}_k| := n_m \geq 1$, $\boldsymbol{u}_k^*, \nu > 0$ a tuning factor.
**Initialization:** set $\boldsymbol{\Phi}(\boldsymbol{u}) = \boldsymbol{\Gamma}(\boldsymbol{u})$.
**LU decomposition using Gaussian elimination:**
**Step a**. **For** $i = 1, \dots, \min(m, n_Q)$
**Step b**. find $j = \underset{i \leq j \leq p}{\mathbf{argmax}} |\Phi_i(\hat{\mathcal{U}}_{j|k})|$
**Step c**. **If** $|\Phi_i(\hat{\mathcal{U}}_{j|k})| > \nu$ **then** swap the data points $\hat{\mathcal{U}}_{i|k}$ and $\hat{\mathcal{U}}_{j|k}$ in the regression set $\widehat{\boldsymbol{\mathcal{U}}}_k$
**Step d**. **Else** compute the $\boldsymbol{u}_{k+1}$ using (12) and terminate.
**Step e**. **For** $l = i + 1, \dots, n_Q$
**Step f**. $$\Phi_l(\boldsymbol{u}) \longleftarrow \Phi_l(\boldsymbol{u}) - \frac{\Phi_l(\hat{\mathcal{U}}_{i|k})}{\Phi_i(\hat{\mathcal{U}}_{i|k})} \Phi_i(\boldsymbol{u}).$$

$$\boldsymbol{u}_\xi = \operatorname{argmax}_{\boldsymbol{u} \in B} |\Phi_i(\boldsymbol{u})|, \tag{12a}$$
$$\text{s.t. } G_\phi(\boldsymbol{u}) \leq 0, \tag{12b}$$

where $B$ is a sphere with radius $r$.

In scenarios where $p < n_Q$, the regression set $\widehat{\boldsymbol{\mathcal{U}}}_k$ is completed by solving (12). To ensure numerical stability, a threshold $\nu$ is selected to mitigate the risk of division by small numbers in **Step f**. In instances where a data point cannot be identified such that $|\Phi_i(\hat{\mathcal{U}}_{j|k})| > \nu$, the algorithm computes a new input using (12). The algorithm continues until it computes the final pivot polynomial, then (12) is solved, to compute $\boldsymbol{u}_\xi$. The algorithm can be started with just one data point or less than $n_Q$ data points, however the constraint (12b) must be replaced by (2b) or (4b) depending on availability of data points.

As in the case of Method III, we apply Algorithm 3 in **Steps 2** and **4** of the MAWQA algorithm. The optimization problem (12) is significantly less computationally demanding than solving (10) or (11) because it solely involves optimizing a second-order polynomial.

## Model-Free Optimization (MFO)

As Algorithm 3 does not require $n_Q$ initial points, it can be used to formulate a completely model-free iterative optimization algorithm. First $n_Q$ data points are generated using Algorithm 3 and then iterative quadratic optimization is applied.

**Algorithm** 4. Model-free optimization

**Require:** $\boldsymbol{u}_0^*$, $\Delta$, $\nu$ and $\gamma$.
**Step i.** Apply Algorithm 3. until $n_Q$ points are available. Select the admissible point with the best objective value $\boldsymbol{u}_k^*$ as the first entry of $\boldsymbol{\mathcal{U}}_k$.
**Step ii.** Once $n_Q$ points are available, the optimization problem (8) is solved to compute the $u_{k+1}$.
**Step iii.** If $\boldsymbol{u}_{k+1}$ lies near $\boldsymbol{u}_k^*$; $\|\boldsymbol{u}_{k+1} - \boldsymbol{u}_k^*\| < \Delta$, then apply Algorithm 3.
**Step iv.** Apply $\boldsymbol{u}_{k+1}$ to the plant.
**Step v.** **If** $J_p(\boldsymbol{u}_{k+1}) < J_p(\boldsymbol{u}_k^*)$, $G_p(\boldsymbol{u}_{k+1}) \leq 0$,
Successful iteration: **then** set $\boldsymbol{u}_{k+1}^* = \boldsymbol{u}_{k+1}$, and increase $k$ by one then return to **Step ii**.
Unsuccessful iteration: **Otherwise** add $\boldsymbol{u}_{k+1}$ to the regression set $\boldsymbol{\mathcal{U}}_k$ and return to **Step ii**.

At each iteration, the first element of $\boldsymbol{\mathcal{U}}_k$ can change, which updates the center in Algorithm 3, resulting in exploration of the surrounding of current best iterate $\boldsymbol{u}_k^*$.

# RESULTS

In this section, we perform a comparative numerical study of the proposed methods for the generation of probing points. For this purpose, we have selected the Williams-Otto plant, which serves as a benchmark problem for evaluating RTO schemes [3, 7]. The variable definitions and parameter values originate from [7]. The core is a CSTR with chemical reactions:

$$A + B \xrightarrow{k_1} C, \qquad k_1 = 1.66 \times 10^6 e^{\frac{-6666.7}{(\theta + 273.15)}}$$
$$C + B \xrightarrow{k_2} P + E, \qquad k_2 = 7.212 \times 10^8 e^{\frac{-8333.3}{(\theta + 273.15)}}$$
$$P + C \xrightarrow{k_3} G, \qquad k_3 = 2.675 \times 10^{12} e^{\frac{-11111}{(\theta + 273.15)}}$$

where $k_1, k_2$ and $k_3$ are the reaction constants of the plant. Reactants $A$ and $B$ are continuously added to the reactor with mass flow rates denoted as $F_A$ and $F_B$. The primary objective is to synthesize the desired products $P$ and $E$, while $C$ serves as an intermediate product and $G$ is considered an undesired byproduct. The reactor operates under isothermal, maintaining a constant temperature $\theta$, with a constant mass holdup of $2105\text{kg}$. $F_A$ is kept at a constant value of $1.8275\ \text{kg/s}$, while $F_B$ and the reactor temperature are treated as decision variables; $\boldsymbol{u} = [F_B\ \ \theta]^T$. These decision variables are normalized by their operating intervals ($F_B$: 3 – 6 kg/s, $\theta$: 70 – 100 C°). The main goal of this operational setup is to maximize the profit,

which results from calculating the differences in price between the products and the consumed reactants.

$$\mathcal{V}(F_B,\theta) = 1143.38(F_A + F_B)\,X_P + 25.92\,X_E - 76.23\,F_A - 114.34\,F_B,$$

where $X_P$ and $X_E$ signify the mass fraction of products $P$ and $E$. $\mathcal{V}(F_B,\theta)$ is corrupted with noise, which follows a Gaussian distribution with a standard deviation $\sigma$. It is assumed that the process is not well understood. The optimization model contains only two reactions:

$$A + 2B \xrightarrow{\hat{k}_1} P + E, \qquad \hat{k}_1 = 2.189 \times 10^8 e^{\frac{-8077.6}{(\theta+273.15)}},$$
$$A + B + P \xrightarrow{\hat{k}_2} G + E, \; \hat{k}_2 = 4.31 \times 10^{13} e^{\frac{-12438}{(\theta+273.15)}},$$

where $\hat{k}_1$ and $\hat{k}_2$ denote the reaction constants of the optimization model. The tuning parameters for the MAWQA algorithm are set to $\Delta = r = 0.1$ and $\gamma = 3$. We used the furthest admissible point from $\boldsymbol{u}_k^*$ as $\boldsymbol{u}_i$ in (9). As for the matrix $\mathcal{S}_k$ in (10), we used the most recent $n_u$ data points chosen by the screening algorithm to construct $\boldsymbol{\mathcal{U}}_k$. In Algorithm 3, the tuning parameter is chosen to be $\nu = 0.25$, which is also used in the model-free optimization. Figures 1-5 demonstrate the results of applying the methods.

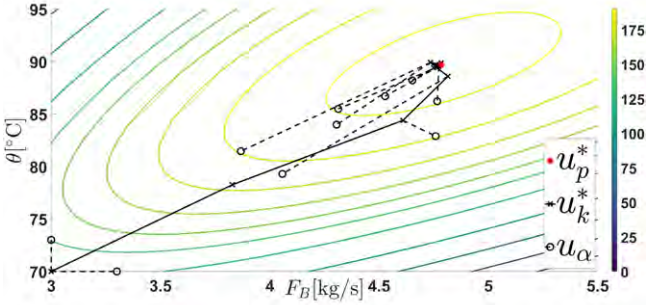

**Figure 1.** Results of applying the MAWQA Algorithm with Method I to the Williams-Otto reactor for $\sigma = 0.5$.

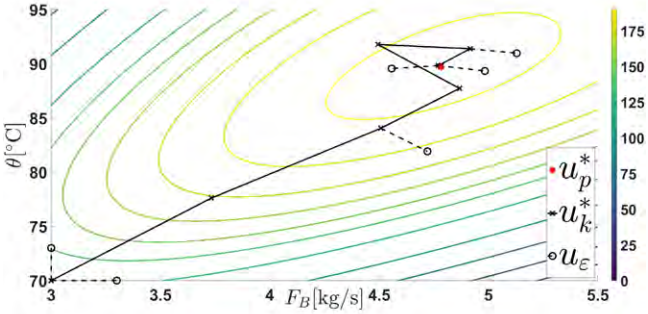

**Figure 2.** Results of applying the MAWQA Algorithm with Method II to the Williams-Otto reactor for $\sigma = 0.5$.

All the methods succeeded in finding $\boldsymbol{u}_p^*$ in a few iterations with good accuracy. From the results, Method I exhibits limitations in achieving good distribution of data points near the optimum. This is mainly due to its reliance on previously visited data points when calculating explorative moves, leading to a concentration of points on one side of the optimum. As for the remaining methods, well poisedness is reached at $\boldsymbol{u}_k^*$.

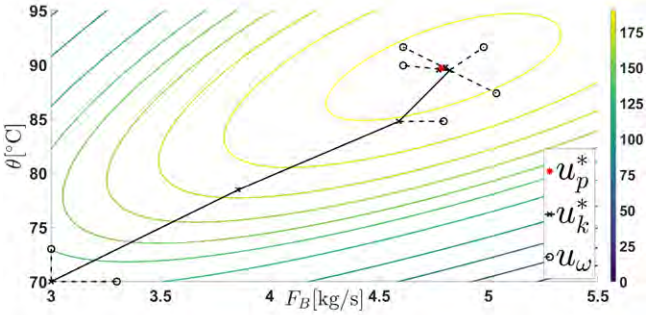

**Figure 3.** Results of applying the MAWQA Algorithm with Method III to the Williams-Otto reactor for $\sigma = 0.5$.

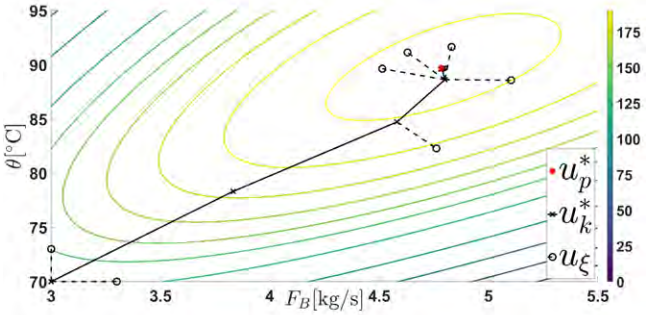

**Figure 4.** Results of applying the MAWQA Algorithm with Method IV to the Williams-Otto reactor for $\sigma = 0.5$.

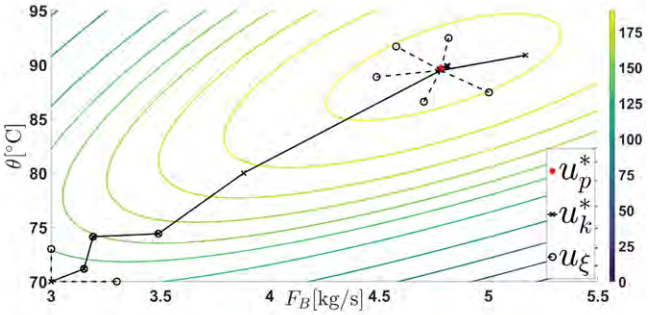

**Figure 5.** Results of applying model-free optimization (Algorithm 4) to the Williams-Otto reactor for $\sigma = 0.5$.

The proposed methods are compared against the performance of the original MA without QA [1] for 3 different levels of noise. As there are no constraints in this case study, Method I is the same as the method introduced in [3]. Each method was tested with 200 simulation runs. To avoid excessive probing, inputs that are at least $\Delta/2$ away from already visited data points are probed. Three key performance indicators (KPIs) were calculated.

1. **Optimum Proximity KPI**: This KPI assesses the distance between the $\boldsymbol{u}_k^*$ after 30 iterations and $\boldsymbol{u}_p^*$.
2. **Average steps KPI**: This indicator provides the average number of iterations needed to reach

the vicinity of the plant optimum, defined as $\left\|\boldsymbol{u}_p^* - \boldsymbol{u}_k^*\right\| \leq 0.05$.

3. **Poisedness KPI**: This KPI reflects the value of the $\Lambda$- Poisedness after 30 iterations, following the definition from [4]. $\Lambda \geq \max_{0\leq i\leq n_Q} \max_{\boldsymbol{u}} |\ell_i(\boldsymbol{u})|$ ,

where $\ell_i(\boldsymbol{u})$ are the Lagrange polynomials associated with $\mathcal{U}_k$. A lower value indicates a more favorable distribution. The best achievable $\Lambda$-poisedness is 1.

**Table 1:** Results of the 200 simulation runs for $\sigma = 0.5$.

| Method | Opt. Proximity | Av. steps | Poisedness |
|---|---|---|---|
| MA [1] | $0.0786 \pm 0.060$ | $16.1 \pm 4.0$ | 3.51 |
| I | $0.0164 \pm 0.010$ | $10.0 \pm 1.6$ | 5.07 |
| II | $0.0201 \pm 0.013$ | $9.3 \pm 1.6$ | 3.2 |
| III | $0.0130 \pm 0.010$ | $9.1 \pm 1.5$ | 2.02 |
| IV | $0.0107 \pm 0.009$ | $9.8 \pm 1.6$ | 1.75 |
| MFO | $0.0106 \pm 0.009$ | $11.9 \pm 2.1$ | 1.82 |

**Table 2:** Results of the 200 simulation runs for $\sigma = 1$.

| Method | Opt. Proximity | Av. steps | Poisedness |
|---|---|---|---|
| MA [1] | $0.0891 \pm 0.059$ | $17.2 \pm 4.4$ | 3.25 |
| I | $0.0264 \pm 0.017$ | $10.9 \pm 2.8$ | 5.31 |
| II | $0.0260 \pm 0.016$ | $10.5 \pm 3.6$ | 2.95 |
| III | $0.0203 \pm 0.016$ | $10.3 \pm 2.4$ | 1.98 |
| IV | $0.0187 \pm 0.013$ | $10.0 \pm 2.0$ | 1.66 |
| MFO | $0.0193 \pm 0.014$ | $12.3 \pm 2.4$ | 1.75 |

**Table 3:** Results of the 200 simulation runs for $\sigma = 2$.

| Method | Opt. Proximity | Av. steps | Poisedness |
|---|---|---|---|
| MA [1] | $0.1033 \pm 0.066$ | $19.0 \pm 6.1$ | 2.81 |
| I | $0.0380 \pm 0.025$ | $11.9 \pm 4.4$ | 5.16 |
| II | $0.0388 \pm 0.026$ | $12.7 \pm 6.0$ | 2.90 |
| III | $0.0330 \pm 0.024$ | $11.9 \pm 4.4$ | 1.99 |
| IV | $0.0337 \pm 0.021$ | $11.4 \pm 3.7$ | 1.81 |
| MFO | $0.0325 \pm 0.023$ | $13.5 \pm 3.5$ | 1.84 |

As the level of noise increases, both the accuracy and speed of convergence of all methods to the optimum decreases. The MA approach from [1] demonstrated the lowest accuracy and the slowest convergence across all levels of noise. This reduced accuracy can be attributed to the noise interference, which causes the MA to oscillate around $\boldsymbol{u}_p^*$. However, this continuous oscillation contributes to a good poisedness. Method I exhibited poor poisedness in the three noise levels, followed by MA without QA and Method II. This outcome aligns with our expectations, as these methods do not adequately address the poisedness required for QA. In contrast, Methods III and IV demonstrated robust and similar poisedness across varying noise levels, with Method IV consistently achieving slightly better results. Maintaining good poisedness improves the accuracy of the gradient estimation, which is crucial for tackling more complex problems. MFO achieved a level of accuracy comparable to Method IV, however with slightly more test points (20% more) than the model-based methods. On the other hand, the method does not need any plant model and is purely based on data collected at the plant. Moreover, the optimization problems (10) and (11) are significantly more computationally demanding than the other methods. The average computation time for (10) was recorded at 1.38s, while the average for (11) was 1.87s. Conversely, the optimization problem (12) has an average computation time of 7ms, which is ~200 times faster than solving (10), (11).

## CONCLUSION

In this paper, we investigated improvements of the MAWQA algorithm, with focus on the criticality step. Our proposed methods improve the distribution of the data points, which is vital for finding true plant optimum fast and reliably. We demonstrated their potential using the Williams-Otto reactor benchmark. The results show that these methods significantly improve the poisedness of the regression set, resulting in more reliable and accurate gradient estimations, as well as increased robustness against noise. Moreover, we presented an effective model-free optimization strategy that converges to the true plant optimum but requires more probing steps in the initial phase. Future work will address cases with higher dimensions of the input vector and complex constraints.

## ABSTRACT

Optimal energy scheduling for sector-coupled multi-energy systems is becoming increasingly important as renewable energies such as wind and photovoltaics continue to expand. They are very volatile and difficult to predict. This creates a deviation between generation and demand that can be compensated for by energy storage technologies. For these, rule-based control is well established in industry, and mixed-integer model predictive control (MPC) is an area of research that promises the best results, usually regarding minimal costs. Drawbacks of MPC include the need for an adequate system model, often associated with high modeling effort, high computational effort for larger prediction horizons, and complications with stochastic variables. In this work, Reinforcement Learning is used in an attempt to overcome these difficulties without applying elaborate mixed-integer linear programming. The self-learning algorithm, which requires no explicit knowledge of the system behavior, can learn a control policy and uncertainties of the variables just by interaction with the (simulated) system model. It is demonstrated that Reinforcement Learning (exchange factor = 36.8 %) can learn complex system behavior with comparable quality to model predictive control (ex. = 32.4 %) and outperforms rule-based control (ex. = 41.8 %). This is done in a case study with the goal of minimizing the exchange of energy with the grid, with a battery and hydrogen system providing storage flexibility. These results were achieved in the context that the Reinforcement Learning agent only has instantaneous rather than predictive information, i.e., a very limited state of information compared to the MPC. The trained policy is then deployed while significantly decreasing the computational effort.

**Keywords**: Optimal Energy Scheduling, Reinforcement Learning (RL), Model-Predictive-Control (MPC)

## INTRODUCTION

Due to the energy transition, the share of renewable sources of energy, such as wind and photovoltaic, is steadily increasing [1-3]. These are highly volatile, resulting in a discrepancy between generation and demand, which must be balanced by storage at any time but which is difficult to predict [2]. To accomplish this balancing efficiently and reliably, sector-coupled multi-energy systems (MES) combined with battery and hydrogen storage systems are deployed. These include batteries for daily fluctuations and electrolyzers, fuel cells and hydrogen storage systems for weekly volatility, for example. [1,2] As wind energy and photovoltaics, in particular, are decentralized and distributed, the electricity grid can be strained by uneven feed-in. More flexibility is therefore required at the place of power supply, whereby the energy exchange between production and load and the grid should be minimized. [1]

The optimal and safe operation of such MES requires operational planning, typically done by rule-based controllers (RBC) in industry [3]. In contrast, more elaborate model predictive control (MPC) strategies are the subject of current research. This form of optimal control is generally seen as delivering the best possible performance, usually aiming for minimum operating costs in compliance with the system-relevant constraints. [2,3]

However, the main obstacle to realizing MPC is that the optimization depends on an adequate model of the system dynamics. In addition, the uncertain prediction of

stochastic fluctuating quantities such as renewable energy generation, demand, and electricity prices significantly affect the control performance. Moreover, in scenarios that require long prediction horizons and detailed models, the arising mixed-integer optimization problems may require excessive computational effort. [2]

For these reasons, a control system that delivers optimal online performance without major computing effort is required. This can, for example, be achieved through Reinforcement Learning (RL), a form of machine learning that requires no explicit prior knowledge of the system dynamics. It can learn a control policy and the uncertainties of the input variables on the system only through repetitive interaction with the system model. RL has achieved excellent results in various disciplines, such as robotics and operational planning in industrial energy systems. [4]

Key contributions of this work are a consistent comparison between RBC, MPC and RL and an RL-based controller with comparable performance to MPC. It is demonstrated that this is possible with limited, instantaneous state information.

## THEORETICAL BACKGROUND

The basic control methods of MPC [5] and RL [4], as well as their corresponding advantages and disadvantages with regard to industrial energy systems, are described below.

### Model Predictive Control

In model predictive control, a mathematical model of the system dynamics called the design model hereafter is used to predict the system's future behavior based on the current state and a sequence of future control input values. The controlled system's response is optimized over a specific prediction horizon $\Delta T_{\text{pred}}$. The schematic control loop is shown in Figure 1.

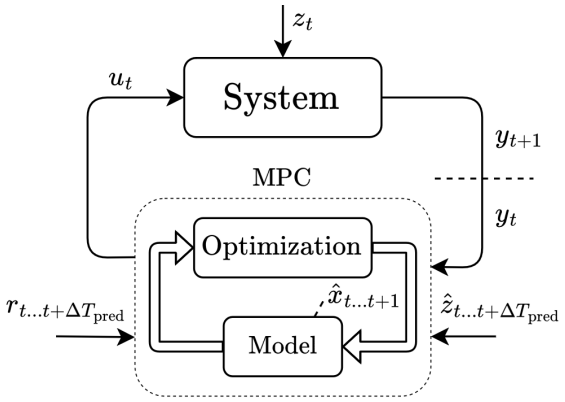

**Figure 1.** Model predictive control loop with control variables $u_t$, system state prediction $\hat{x}_{t\ldots t+T_{\text{pred}}}$ output $y_t$, disturbance $z_t$ and reference $r_t$ for timestep $t$ and prediction horizon $\Delta T_{\text{pred}}$ adapted from [5].

For simplicity of time discrete notation, index $t$ refers to the current sample, $t+1$ to the next, and $t+\Delta T_{\text{pred}}$ to the last sample in the current prediction horizon where the full trajectory $o_{t\ldots t+\Delta T_{\text{pred}}}$ is denoted hereafter with only the basis $o$. The sequence of the control variables $u$, is determined so that a predefined objective $J$, a cost function, is minimized, see Equation 1. These can be, for example, minimal costs, minimal deviations from a reference trajectory $r$ or minimal energy consumption. Constraints are imposed on the system's input variables $u$ and design model state estimates $\hat{x}$ via equality $(h(\cdot)=0)$ and inequality $(g(\cdot)\leq 0)$ constraints to ensure safe and physically feasible operation. The set $\mathrm{X}$ contains both real and integer-valued variables.

$$\begin{aligned} &\underset{u}{\operatorname{argmin}} \;\; J(\hat{x},u,\hat{z},r) \\ &\text{s.t.} \quad h(x,u)=0 \\ &g(x,u)\leq 0 \\ &x\in X, u\in U \end{aligned} \tag{1}$$

Only the control variables $u_t$ of the first-time step $t$ are applied to the system; all others are discarded. At the next time step, $t+1$, this iterative optimization process is repeated, using new predictions and measured values of the output $y_{t+1}$ and associated, updated system state estimate $\hat{x}_{t+1}$, also known as *receding horizon control*. It is particularly suitable for multivariable systems that contain complex relationships, relevant constraints and well-predictable inputs.

When both continuous and discrete variables are involved, as is often the case with energy systems, the optimal control problem (1) is usually formulated as a mixed-integer linear program (MILP) and solved using branch and bound algorithms [12]. Since the variables are typically linked across several time steps and constraints, it is difficult to decompose the problem. Binary variable formulations lead to combinatorial complexity, which becomes intractable as problem size increases. However, for practical applications, a large prediction horizon is often required, increasing the number of decision variables with each discrete time step and, therefore, the computational effort significantly. Although the MILP problem can be solved, it may be too complex for the necessary sampling time step size.

### Reinforcement Learning

In Reinforcement Learning, an entity called *agent* interacts with its environment with the purpose of learning to make sequential decisions. It receives a state observation $s_t$ and prior reward $r_t$ signal and performs an action $a_t$ that influences the environment, which evolves according to the internal system dynamics. The successor state $s_{t+1}$ and reward $r_{t+1}$ are the result. This process is sketched in Figure 2 and is understood in a stochastic sense as a Markov Decision Process (MDP).

Here, the agent learns by trial and error, guided by a reward function. Its goal is to maximize the discounted, cumulative reward over the considered period (episode)

$$\max \sum_{t=1}^{T} r(s_t, a_t, s_{t+1}) \cdot \gamma^{t-1}, \qquad (2)$$

with discount factor $\gamma$. While deriving a control law $a_t = \pi(s_t)$, which maps states to actions. Striking a good balance between exploration, i.e., visiting new state-action combinations, and exploitation, i.e., taking the actions with the highest cumulative reward expectation, is essential to the training process.

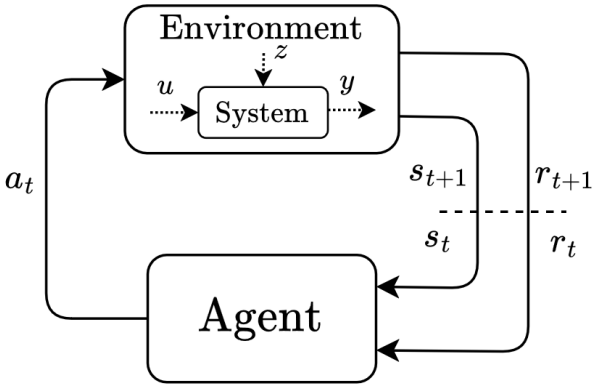

**Figure 2.** Reinforcement Learning control loop with control variables $u$, output $y$ and disturbance $z$, as well as, state observation $s_t$, action $a_t$ and reward $r_t$ for timestep $t$ adapted from [4].

In deep RL, the internal relationships in the agent are represented by deep neural networks (NN), which endows it with the ability to model any non-linear, high-dimensional function. Another advantage is that RL does not depend on modeling using first principles but learns from direct experience, allowing it to adapt to changing system dynamics even after the training process. This allows the performance to improve over time and can help reduce the prediction's uncertainty.

However, this method has difficulties with performance and stability guarantees, as it is challenging to provide for neural networks. In addition, the learning process is very sample-inefficient and a convergent learning process is not guaranteed in general. These topics are highly active fields of research. [6]

## METHODS

This chapter first outlines the use case and the underlying modeling adapted from [3]. It then links to the control methods and discusses the parameterization and implementation.

### Use Case

RL's potential is demonstrated through a representative use case, a MES providing storage flexibility. It consists of a battery (BSS) and a hydrogen storage system (HSS) comprising an electrolyzer, a fuel cell and a hydrogen storage unit. This MES, shown in Figure 3, is influenced, on the one hand, by generation $p_{\text{gen}}$ and consumption $p_{\text{de}}$ and, on the other hand, by the energy exchange not compensated for by the storage systems with the grid ($p_{\text{gr}}^{\text{in}}$,$p_{\text{gr}}^{\text{out}}$). All quantities are non-negative.

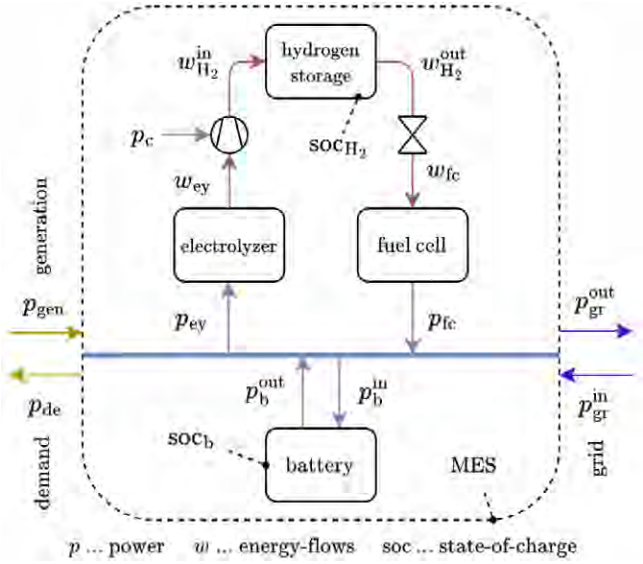

**Figure 3.** Multi-energy system (MES) with battery (b) and hydrogen storage systems, comprising electrolyzer (ey), storage ($H_2$) and fuel cell (fc).

The components can be modeled using the following relationships for the battery

$$\text{soc}_{\text{b,t+1}} = \text{soc}_{\text{b,t}} + \frac{\Delta t_{\text{sim}}}{C_{\text{b}}} \begin{cases} p_{\text{b},t}^{\text{in}} \cdot \eta_{\text{b}}, \text{ charge} \\ -p_{\text{b},t}^{\text{out}} / \eta_{\text{b}}, \text{ discharge} \end{cases} \qquad (3)$$

where $\text{soc}_{\text{b}}$ is the state-of-charge, $\eta$ the efficiency and $C_{\text{b}}$ the battery's capacity. The battery can either be charged by $p_{\text{b}}^{\text{in}}$ or discharged by $p_{\text{b}}^{\text{out}}$. The hydrogen storage is modeled using

$$\text{soc}_{\text{H}_2,\text{t+1}} = \text{soc}_{\text{H}_2,\text{t}} + \frac{\Delta t_{\text{sim}} \cdot \eta_{\text{H}_2}}{C_{\text{H}_2}} \left( w_{\text{H}_2,t}^{\text{in}} - w_{\text{H}_2,t}^{out} \right), \qquad (4)$$

and analogously $\text{soc}_{\text{H}_2}$ is the state-of-charge and $C_{\text{H}_2}$ is the capacity of the hydrogen storage. The energy level is increased when hydrogen is fed in ($w_{\text{H}_2}^{in}$) and decreased by $w_{\text{H}_2}^{\text{out}}$. The electrolyzer and the fuel cell are modeled using non-linear equations $w_{\text{ey}} = f_{\text{ey}}(p_{\text{ey}})$ and $w_{\text{fc}} = f_{\text{fc}}(p_{\text{fc}})$, respectively. An isentropic compressor, used to increase the pressure $pr$, using power $p_{\text{c}} = f_{\text{c}}(w_{\text{ey}}, pr)$, is located upstream of the storage tank, whereby the following applies, $w_{\text{H}_2}^{in} = w_{\text{ey}}$. Downstream of the hydrogen storage there is a valve for which $w_{\text{H}_2}^{\text{out}} = w_{\text{fc}}$ applies. For the MPC

design model all non-linear equations are piecewise linearized.

The energy equation

$$p_{\text{gen}} - p_{\text{de}} + p_{\text{fc}} - p_{\text{ey}} + p_{\text{b}}^{\text{out}} - p_{\text{b}}^{\text{in}} - p_{\text{c}} + p_{\text{gr}}^{\text{in}} - p_{\text{gr}}^{\text{out}} = 0 \quad (5)$$

links the various components' powers. The performance indicator, the exchange factor $\epsilon_t$, is defined as the ratio between the energy exchange with the grid and the difference of generation and demand sampled with $\Delta t_{sim}$

$$\epsilon_t = \frac{\sum_{\tau=0}^{\tau=t} p_{\text{gr},\tau}^{\text{in}} + p_{\text{gr},\tau}^{\text{out}}}{\sum_{\tau=0}^{\tau=t} |p_{\text{gen},\tau} - p_{\text{de},\tau}|}. \quad (6)$$

Here, $\epsilon_t = 0$ means that storage flexibility can compensate for any difference between generation and consumption. If $\epsilon_t = 1$, the entire difference is passed through to the grid.

## Control Engineering

In the control engineering sense, the process variables for the MPC can be divided up as follows. The control variable $u_t$ consists of the power flows into and out of the battery, the electrolyzer and the fuel cell

$$u_t = \left[p_{\text{b}}^{\text{in}} \quad p_{\text{b}}^{\text{out}} \quad p_{\text{ey}} \quad p_{\text{fc}}\right]_t^T. \quad (7)$$

The system's output $y_t$ comprises the state-of-charge for battery and hydrogen storage and the power exchange with the grid:

$$y_t = \left[\text{soc}_{\text{b}} \quad \text{soc}_{\text{H}_2} \quad p_{\text{gr}}^{\text{in}} \quad p_{\text{gr}}^{\text{out}}\right]_t^T. \quad (8)$$

The disturbance forecast $\hat{z}$, sampled with $\Delta t_{\text{opt}}$, consists of the generation and demand prediction from timestep $t$ to the prognosis horizon $t + \Delta T_{\text{pred}}$ acting on the system

$$\hat{z} = \begin{bmatrix} p_{\text{gen},t} & p_{\text{de},t} \\ \vdots & \vdots \\ p_{\text{gen},t+\Delta T_{\text{pred}}} & p_{\text{de},t+\Delta T_{\text{pred}}} \end{bmatrix}^T. \quad (9)$$

The objective of the MPC is to minimize the exchange of energy with the grid, i.e., the area under the absolute value of the power curve using a sampling time of $\Delta t_{\text{opt}}$,

$$\underset{u}{\text{argmin}} \sum_t^{t+\Delta T_{\text{pred}}} \left(p_{\text{gr},t}^{\text{in}} + p_{\text{gr},t}^{\text{out}}\right) \cdot \Delta t_{\text{opt}}. \quad (10)$$

The action $a_t$ of the RL agent is equivalent to the control variable $u_t$. The observation state $s_t$ consists in part of the system output $y_t$ and the disturbance $\hat{z}_t$ and can be written as

$$s_t = \left[\text{soc}_{\text{b}} \quad \text{soc}_{\text{H}_2} \quad p_{\text{gen}} \quad p_{\text{de}}\right]_t^T \quad (11)$$

and reward information comprises

$$r_t = \left[p_{\text{gr}}^{\text{in}} \quad p_{\text{gr}}^{\text{out}}\right]_t^T. \quad (12)$$

The reward function of the RL agent, sampled with $\Delta t_{\text{opt}}$, and chosen discount factor as $\gamma = 0.99$ can be written as

$$\max \sum_t^{t+\Delta T_{\text{pred}}} -\left(p_{\text{gr},t}^{\text{in}} + p_{\text{gr},t}^{\text{out}}\right) \cdot \Delta t_{\text{opt}} \cdot \gamma^{t-1}, \quad (13)$$

and a sampling time of $\Delta t_{\text{opt}}$ is used. All system-specific constraints are represented in the design model for the MPC and inherently in the simulation model for RL training and for the method comparison.

## Parameters & Data

Generation and demand data for Austria for 2023 were used as the data basis [7]. Five representative weeks according to their distribution were calculated, and one exemplary week (Figure 4, 19.6 - 26.6.2023) was used to test the use case. Energy production comprises 75 % photovoltaics and 25 % wind power. The data was normalized and scaled so that, on average, the demand is $\overline{P_{\text{de}}} = 250\,kW$ and generation $\overline{P_{\text{gen}}} = 300\,kW$, respectively. The data was subjected to white noise, whereby the signal-to-noise ratio is a factor of 20. The non-noisy data is used for the prediction of the MPC and for training the RL agent, while the noisy curves are declared as ground truth in the simulation.

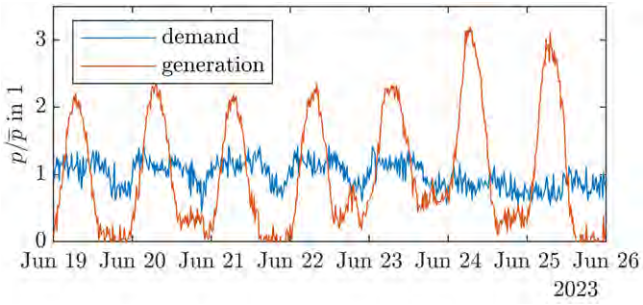

**Figure 4.** Demand and generation for a representative summer week of Austria, 2023 [7].

The MES components' parameters are listed in Table 1, and the simulation data in Table 2.

**Table 1.** MES Properties

| Battery System | | Hydrogen System | | |
|---|---|---|---|---|
| Property | Value | Property | Value | Unit |
| $C_{\text{b}}$ | 500 | $C_{\text{H}_2}$ | 3000 | kWh |
| $p_{\text{b}}^{max}$ | 100 | $p_{ey}^{max}$ | 400 | kW |
| | | $p_{fc}^{max}$ | 100 | kW |
| $\text{soc}_{\text{b}}^{min}$ | 0.2 | $\text{soc}_{\text{H}_2}^{min}$ | 0.1 | - |
| $\text{soc}_{\text{b}}^{max}$ | 0.8 | $\text{soc}_{\text{H}_2}^{max}$ | 0.9 | - |
| $\eta_{\text{b}}$ | 0.9 | $\eta_{\text{H}_2}$ | 1 | - |

## Simulation & Training

In the simulation environment, the system equations are solved with a time step size of $\Delta t_{\text{sim}}$. After $\Delta t_{\text{opt}}$, either the optimization for the MPC is solved or the trained neural network for RL is evaluated. For the MPC, the

prediction horizon $\Delta T_{\text{pred}}$ is divided into 96 time-steps with size $\Delta t_{\text{opt}}$. The RL agent is trained with a sampling time of $\Delta t_{\text{opt}}$. Proximal Policy Optimization (PPO) [8] is used as the RL algorithm, where it is trained for ~$10^4$ episodes.

**Table 2.** Simulation Properties

| Property | Value | Unit |
|---|---|---|
| $\Delta t_{\text{sim}}$ | 1 | min |
| $\Delta t_{\text{opt}}$ | 15 | min |
| $\Delta T_{\text{pred}}$ | 24 | h |
| $\Delta T_{\text{sim}}$ | 168 | h |

The neural network architecture used for the value-function critic is a fully connected, feedforward NN with ~1200 degrees of freedom. A stochastic Gaussian actor is implemented with ~3500 degrees of freedom.

## Implementation

The simulation environment was programmed in MatLab [9], whereby the optimization problem (MPC) was set up with YALMIP [10] and solved with Gurobi [11]. The PPO agent was trained with the MatLab Reinforcement Learning Toolbox [12] and 64 parallel workers. These were simulated on a system with 128 cores and 256 GB RAM (AMD EPYC 7702P).

## RESULTS & DISCUSSION

The results of the simulation are the process variables of the use case, whereby the control variables resulting from the optimization (MPC, NN-RL) and the state-of-charges are shown in Figure 6. Two tiles are used for the MPC (top) and two for the RL (bottom). These, in turn, are divided into hydrogen-related variables of the electrolyzer $p_{\text{ey}}$, the fuel cell $p_{\text{fc}}$ and the storage tank $p_{\text{H}_2}$ as well as battery-related variables charge $p_{\text{b}}^{\text{in}}$, discharge $p_{\text{b}}^{\text{out}}$ and state of charge $\text{soc}_{\text{b}}$. The powers are normalized, i.e. divided by the maximum power, because of $p_{\text{min}} = 0$. Without loss of relevant information aspects, three days were chosen from the test week and

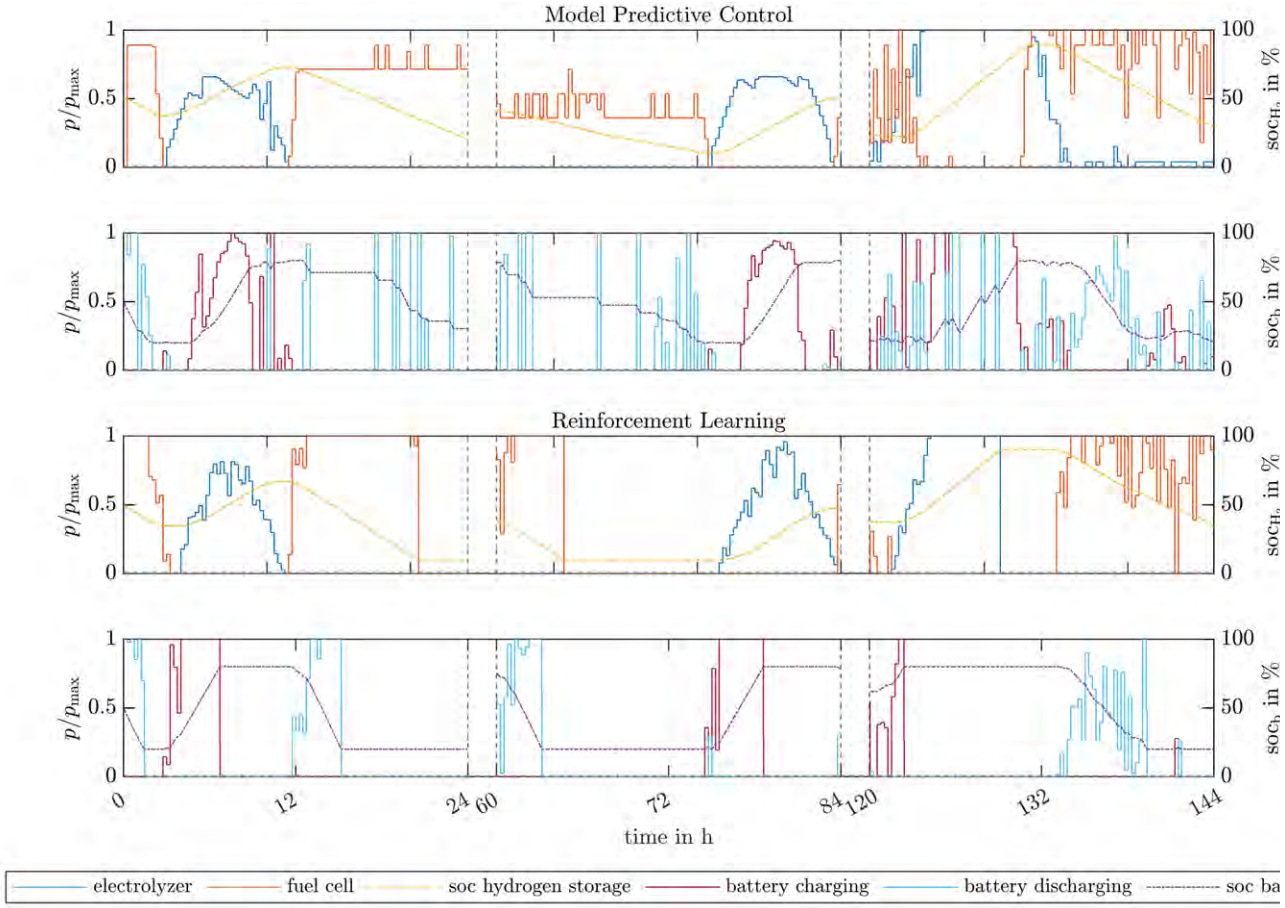

**Figure 5.** Setpoints electrolyzer power $p_{\text{ey}}$, fuel cell power $p_{\text{fc}}$ and fill level of storage tank $\text{soc}_{\text{H}_2}$ as well as battery-related variables charging power $p_{\text{b}}^{\text{in}}$, discharging power $p_{\text{b}}^{\text{out}}$and state-of-charge $\text{soc}_{\text{b}}$ for multi-energy system use case for model predictive control and Reinforcement Learning.

displayed for better visualization. In principle, as can be seen in Figure 5, two different operating modes can be identified: If more energy is generated than consumed, battery charging and electrolyzer are activated, and if there is a negative residual load, the battery is discharged, and the fuel cell is used. This only works as long as the storage units are not at their limits. Therefore, Predictive information is required on how the externally imposed energy flows will adjust to provide optimal flexibility. However, only the MPC has access to the inherent forecast information $\hat{z}_{t\ldots t+\Delta T_{\text{pred}}}$. The RL agent, which only has access to instantaneous observations, can only learn an implicit average prediction for future states through the sequence of observed states (trajectory). However, this assumes a similarity between the trained and tested generation and demand curves, which has been fulfilled in the tested scenario. Figure 6 shows the exchange factor $\varepsilon_t$ for MPC and RL, whereby the first 24 h can be regarded as a run-in effect, as the MPC has a forecast horizon of 1 day. The performance is comparable in the first 5 days; a difference can only be seen when a lot of renewable energy is produced and little is consumed.

In these situations, it is optimal to use a discontinuous switching behavior of the storage. It can be concluded that the lack of predictive information hinders the RL agent from performing better. After a one-week test phase, there is a difference in exchange factor of approx. 4 %.

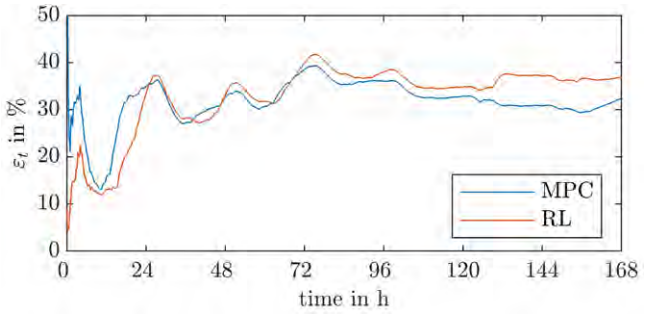

**Figure 6.** Energy exchange factor $\varepsilon_t$ with grid for 1 week.

## CONCLUSION & OUTLOOK

In this study, the performance of a Reinforcement Learning-based control strategy for sector-coupled multi-energy systems providing storage flexibility was evaluated. With Reinforcement Learning, a performance comparable to that of model predictive control can be achieved, which can be regarded as the upper limit in the nominal case. The Reinforcement Learning agent can outperform the industry standard rule-based control. With only instantaneous observations and without complex mixed-integer linear program modeling, the system can be controlled by a self-learning algorithm. The following questions are to be answered in a further study:

Can the Reinforcement Learning agent achieve better control quality if the same predictive information is provided for complete comparability? Can the self-learning system accomplish the same performance as model predictive control if unpredictable errors can be learned better than represented by a deterministic MPC?

## ABSTRACT

Predicting processes' future behavior based on past data is vital for automatic control and dynamic optimization in engineering. Recent advances in deep learning, particularly Artificial Neural Networks, have improved predictions in various engineering fields. Recurrent Neural Networks (RNNs) are well-suited for time series data, as they naturally evolve through dynamic systems with recurrent updates. Despite their high predictive power, RNNs may underperform if their training ignores the model's future application. In Model Predictive Control, for example, the model evolves over time using only current information, relying on its own predictions at later steps. A model trained for one-step-ahead predictions may fail when tasked with multi-step-ahead forecasting in autoregressive mode. This study explores deep recurrent neural network models for predicting critical operational time series of a large-scale Electric Submersible Pump system. We present an innovative training approach, framing the task as a multi-step-ahead prediction problem. Results show that aligning model training with its future use is crucial to ensure real-time performance.

## INTRODUCTION

Models play an important role in chemical and industrial engineering practice. First-principles models describe the energy and mass transport in unit operations through continuous conservation laws, rate, and equilibrium expressions. They are usually capable of providing reliable predictions in a broad range of conditions and have parameters with physical meaning. On the other hand, dynamic high-fidelity models can be tricky to frame correctly and identify, especially for highly nonlinear systems with few observable states [1].

Black-box or data-driven models are often used to circumvent such a problem. In this sense, Artificial Neural Networks (ANNs) are essential for identifying nonlinear dynamic systems in chemical engineering. ANNs have been widely used since the 1980s for nonlinear dynamic system identification, mainly as the nonlinear function for systems identification in the Nonlinear AutoRegressive with Exogenous inputs (NARX) formulation [2], [3]. It is well-known that the NARX formulation is suitable for prediction tasks (short-term horizons) but may perform poorly recursively for long-term predictions (simulation mode).

In contrast, the Nonlinear Output Error (NOE) representation is more appropriate for engineering systems and long-term predictions (simulation) as noise is assumed to be an output additive, i.e., there is a deterministic dynamic of states, and noise is placed only at observables [2], [4]. When the NOE nonlinearity is framed with a neural network, its resemblance with recurrent neural networks (RNNs) is evident [5]. NOE is one of the most important representations for simulation in engineering systems, but it is often misused and comprehended in practice.

In real-time applications requiring multi-step-ahead

predictions and sensor feedback, such as predictive control, choosing the appropriate formulation for a data-driven model plays an essential role in the final predictive capacity and it can be a significant source of confusion. To address these questions, this study assesses the performance of a multi-step ahead predictor designed explicitly for model predictive control (MPC) applications. The predictor employs deep recurrent neural networks (RNNs) and is evaluated using real operating data from an Electrical Submersible Pump (ESP) system deployed in an offshore oil field.

Electric Submersible Pumps (ESPs) are a vital technology in the oil and gas industry, enabling the efficient lifting of fluids from subsea reservoirs to the surface. Their effective operation and control require a comprehensive understanding of the complex interactions between the reservoir, pump, and surface conditions. While models are instrumental for understanding these dynamics, first-principles modeling is particularly challenging due to the complexity of the governing equations. This makes data-driven approaches an appealing alternative for modeling ESP system dynamics.

Several studies have investigated data-driven methods for modeling ESP behavior. For example, Jordanou et al. (2022) developed an Echo State Network (ESN) as a surrogate nonlinear dynamic model using training data from a rigorous mechanistic model [6]. Similarly, Abreu et al. (2024) applied ESNs for zone-based Nonlinear Model Predictive Control (NMPC) of an ESP-lifted oil well to maximize oil production using data from a mechanistic model [7]. In another study, Costa et al. (2024) proposed a deep neural network for system identification and uncertainty quantification, leveraging mechanistic model data [8].

However, to our knowledge, no prior work has demonstrated the predictive capabilities of deep-learning-based, data-driven models using real operational data from ESP systems. The remainder of this text is organized as follows:

The Methodology details the model representation, data collection, model training and hyperparameter tuning strategies. In the Results, the test set performance is evaluated. The conclusions summarize the main findings and points to future research directions.

# METHODOLOGY

## Recurrent Neural Networks

A recurrent neural network (RNN) is an artificial neural network designed to process sequential information, such as time series data. It has a deterministic $h$ state, and an evolution rule defines how the state changes based on its computed values and input data. This rule is typically a parameterized function $\mathcal{F}(\mathcal{W}_u, \mathcal{W}_x, b_u)$, such as a multilayer perceptron in a standard RNN or a more sophisticated structure in long-short-term memory (LSTM) architectures [9].

Training an RNN involves evolving the states according to the update rule and the current parameters. These states are mapped to outputs matching the dimensions of the observed data through a readout layer ($\mathcal{G}$). The prediction error is computed and used to adjust the parameters, often through gradient descent. This process is illustrated in Figure 1.

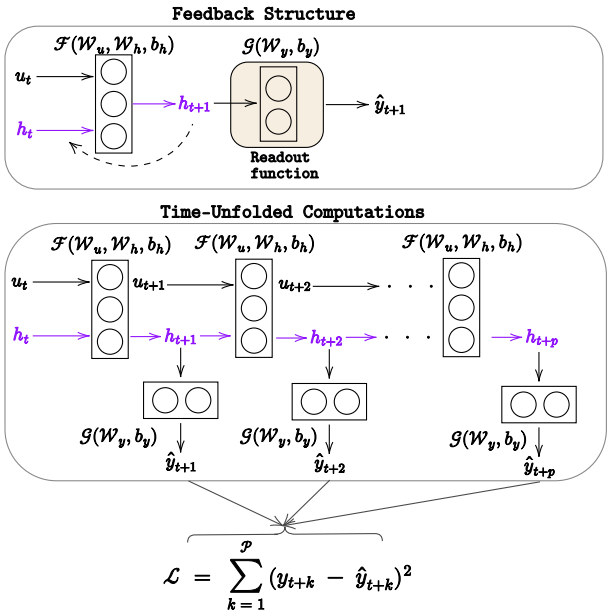

**Figure 1.** Diagrammatic representation of RNNs computations

However, practical implementations raise several questions: How many times should the states evolve? How many state observations should be used to calculate the error? There is no definitive answer to these questions. The training approach should align with the model's intended application [10]. In this work, we frame the model training as the closest to match a potential final application of model predictive control, as in [10].

## Data collection and processing

Identifying nonlinear dynamic models from real process data presents significant challenges. Industrial processes typically operate at fixed set points, and shifting these points to gather dynamic data involves safety and financial risks. Consequently, many studies develop and validate mechanistic models to be later used as a data source instead - a strategy called simulation-assisted identification [10]. However, identifying mechanistic models for industrial-scale ESP systems is particularly challenging.

In this work, real operational data was used to train the models. Only a small subset of the total operational

data - usually during startup and shutdown - proves useful for dynamic model identification. The Figure 2 and the the Figure 3 highlight these regions for the two normalized target variables – TV1, TV2 and the two manipulated variables – MV1, MV2. The variables and time have been normalized to avoid disclosing sensitive information about the data source. The two variables have different levels of noise in the process and were selected to evaluate how robust to noise is the used methodology.

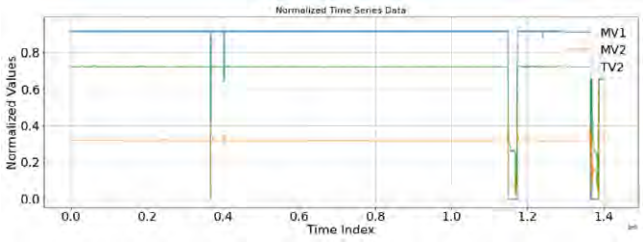

**Figure 2.** ESP real operational data history for MV1, MV2 and TV2.

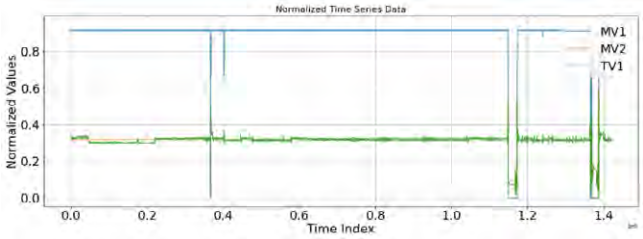

**Figure 3.** ESP real operational data history for MV1, MV2 and TV1.

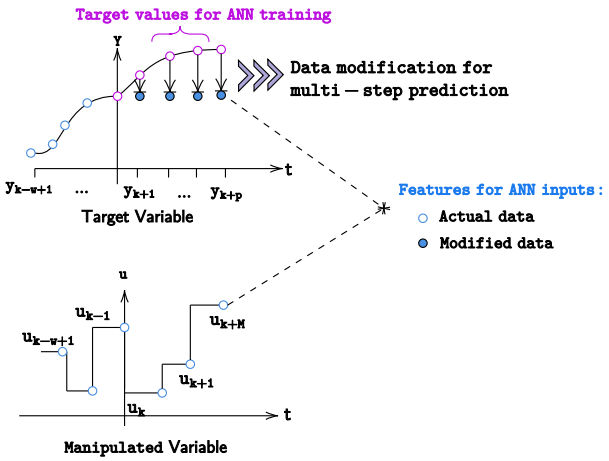

**Figure 4.** Illustration of the data preprocessing and organization for RNN training targeted at an MPC application. Adpated from [10].

The process data needs to be prepared differently to accommodate the particularities of each representation (NARX, NOE) and the final application for parameter identification (training) and inference. For this work, we are adopting a multi-step ahead prediction strategy that requires a unique data organization and follows the structure proposed in [10] and is depicted in **Figure 4**. The proposed data organization aligns well with the computations required in predictive control strategies, which should favor the model's predictive accuracy when handling this task. In contrast, **Figure 5** illustrates the traditional approach for preparing the data for single-step-ahead predictions. In this setting, the target output is a one-dimensional sequence of points. Multi-step-ahead predictions at inference time require a set of input distributions the model was not trained for.

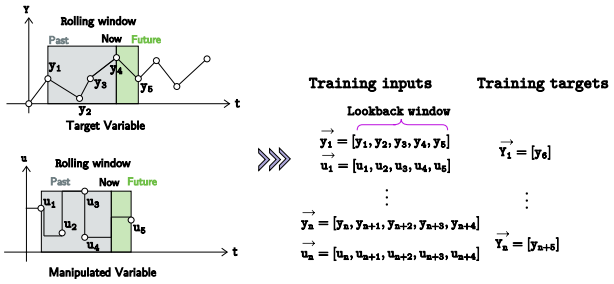

**Figure 5.** Illustration of the traditional data processing for single-step ahead prediction for training an RNN.

The dataset was split into training, validation, and test sets, ensuring no time overlap. Time series data was processed using a sliding window with a stride of 1, moving forward in time. The total window size was 12-time steps, including features and labels.

For the target variable to be used as features (predictors), 8 of the 12-time steps were actual past observations (white circles with blue contours). At the same time, the remaining 4 were repeated from the last valid observation (filled blue circles). For the manipulated variables (MV1 and MV2), all 12 points were actual observations (white circles with blue contours on the manipulated variable). The target consisted of 4 future actual observations (white circles with pink contours), as illustrated in the **Figure 4**.

This process resulted in a 3-dimensional feature tensor $X \in \mathbb{R}^{n_b \times 12 \times 3}$ where $n_b$ is the number of sequences of size 12 and 3 corresponding to the two MVs and the target variable being predicted. The target is also a 3D tensor $Y \in \mathbb{R}^{n_b \times 4 \times 1}$.

## Model Training and Hyperparameter Tunning

The estimation of the predictor's parameters constitutes the model training. One model was trained for each target variable (TVs), forming two multiple-input single-output (MISO) models. The mean squared error is the most common cost function for continuous numerical variables such as those used here.

For the proposed predictor, the cost function to be minimized is here proposed to be written as:

$$J(W,b) = \frac{1}{2m}\sum_{i=1}^{m}\sum_{k=1}^{4}\left(\hat{y}_{i,k},(W,b) - y_{i,k}\right)^2 \qquad (1)$$

$i$ varies from 1 to the number of training sequences $m$. $k$ varies from 1 to the number of time-steps 4. W and $b$ are the trainable weights and biases. Typically, the number of sequences is chucked into smaller data sets, forming batch sequences for updating the parameters.

In RNN parameter identification, layer-wise gradients are typically computed using Backpropagation Through Time (BPTT) to solve the optimization problem. However, this method often leads to convergence problems in recurrent neural networks due to vanishing or exploding gradients. Over the years, various RNN variants have been proposed to address these issues. Among them, the Long Short-Term Memory (LSTM) variant has been widely adopted to extract long-range patterns in time series data [9]. Therefore, this architecture was used in this work.

Model selection entails defining its architecture before parameter estimation, including the number of layers, neurons, activation functions, and optimizer parameters such as learning rate, momentum (for momentum-based optimizers), decay, epochs, and mini-batch size. The hyperparameter space comprises a set of discrete and continuous variables, making their selection a complex task. One recent approach to select them efficiently is wrapping another learning algorithm (hyper-learner) around the original learning problem to select hyperparameters by monitoring a cost function from a separated dataset (validation data set). The hyper-learner may also have more parameters, but it is simpler to choose than the hyperparameters.

Machine learning practitioners often employ exploratory random and grid search for hyperparameter tuning [11]. However, they are very time-consuming as they allocate the same resources for all sampled hyperparameters. Most recently, it has been possible to find a method called HYPERBAND [12], which has the advantage of being up to 30 times faster in search speed than random grid search. HYPERBAND formulates hyperparameter optimization as a pure-exploration problem where a predefined resource is allocated to randomly sampled configurations.

The neural network's initialization, the training process, and the hyperparameter tuning were implemented using TensorFlow 2.10.1 [13] and Keras [14] tuner version 1.4.7, respectively.

## Inference and state initialization

RNNs have a deterministic state variable that evolves according to the update rule (parameterized function $\mathcal{F}(\mathcal{W}_u, \mathcal{W}_x, b_u)$) in **Figure 6**. The initialization of this variable defaults to the null vector in many deep learning frameworks, including TensorFlow. During training with gradient descent, the default policy is that the states are restarted to zero for each batch. It has been shown that this is an effective way of learning the patterns in time series. However, this policy must be modified during real-time inference in a predictive control environment to accommodate the incoming data stream. In this sense, we propose the following state update policy for inference:

**Algorithm 1** Neural Network Inference Policy

**Input:** Time-series data $\mathbf{X} \in \mathbb{R}^{T \times F}$, LSTM model $M$, warm-up steps $W$, step size $S$.
**Output:** Predictions $\hat{\mathbf{Y}}$, True Values $\mathbf{Y}_{\text{true}}$.
**Step 1: Preprocessing**
Normalize each feature $f$:

$$\mathbf{X}_f = \frac{\mathbf{X}_f - \min(\mathbf{X}_f)}{\max(\mathbf{X}_f) - \min(\mathbf{X}_f)}.$$

Reshape data to 3D:

$$\mathbf{X}_{3D} \in \mathbb{R}^{1 \times T \times F}.$$

**Step 2: Warm-up**
Extract the first $W$ time steps:

$$\mathbf{X}_W = \mathbf{X}_{3D}[:, : W, :].$$

Reset the LSTM model's $M$ state.
Pass $\mathbf{X}_W$ through $M$ to initialize the state:

$$M(\mathbf{X}_W).$$

Save the updated state $\mathbf{S}_W$.
**Step 3: Forecasting Loop**
Initialize empty sets $\hat{\mathbf{Y}}, \mathbf{Y}_{\text{true}}$.
**for** $i = 0$ to $\lfloor \frac{T-W}{S} \rfloor - 1$ **do**
  Define start and end indices:

$$\text{start} = W + i \cdot S, \quad \text{end} = W + (i+1) \cdot S.$$

  Extract future data:

$$\mathbf{X}_S = \mathbf{X}_{3D}[:, \text{start} : \text{end}, :].$$

  Apply zero-order hold (ZOH) to the Target Variable with index 3:

$$\mathbf{X}_S[:, t, 2] = \mathbf{X}_{3D}[:, \text{start} + t - 1, 2], \quad \forall t \in \{1, \ldots, S\}.$$

  Predict outputs:

$$\hat{\mathbf{Y}} = M(\mathbf{X}_S).$$

  Save predictions $\hat{\mathbf{Y}}$ and true values:

$$\mathbf{Y}_{\text{true}} = \mathbf{X}_{3D}[:, \text{start} : \text{end}, 3].$$

  Restore the state $\mathbf{S}_W$:

$$\text{set_lstm_states}(M, \mathbf{S}_W).$$

  Perform one additional step to update the state:

$$\mathbf{X}_1 = \mathbf{X}_{3D}[:, \text{end} : \text{end} + 1, :].$$

  **if** $\mathbf{X}_1 \neq \emptyset$ **then**
    Use $M(\mathbf{X}_1)$ to update the state $\mathbf{S}_W$.
  **end if**
**end for**
**Output:** Predictions $\hat{\mathbf{Y}}$, True Values $\mathbf{Y}_{\text{true}}$.

**Figure 6.** Algorithm for inference and state initialization.

The algorithm operates in two alternating phases to emulate real-time application behavior. The first phase updates the internal states of the LSTM model using the most recent incoming data, ensuring that the model updates its states based on the latest observation. The second phase performs a 4-time-step-ahead prediction based on the updated state. These two phases are executed alternately across the test set, simulating a real-time scenario where the model continuously processes

new data while concurrently making multi-step future predictions based on the last observation and MV's actual inputs.

## Results and Discussion

The hyperparameter search space was limited to the numbers of neurons in the LSTM layer between 60 and 160 and step of 20, the activation function between hyperbolic tangent and rectified linear unit and minibatch size between 16 and 256 with step of 32. The ADAptive Moment estimation (ADAM) optimizer was used with a fixed learning rate of 0.001. The validation data set error was used to determine the best architecture during the search. The hyperband was parametrized with a factor of maximum allocated epochs of 100 and 1 iteration. The best configurations for TV1 and TV2 are displayed in the tables.

**Table 1.** Hyperparameters for TV1 and TV2 RNNs.

| Neurons | Activation | Batch size | Variable |
|---|---|---|---|
| 60 | tanh | 16 | TV1 |
| 160 | tanh | 16 | TV2 |

After finding the best hyperparameters, the model was retrained with the selected architecture for 1000 epochs, with early stopping and 100-step patience, by monitoring the validation set to avoid overfitting.

By applying the algorithm in **Figure 6**, a test set mean absolute error of $1.22 \times 10^{-3}$ for TV1 and $2.3 \times 10^{-3}$ for TV2.

The **Figure 7** and **Figure 8** show the parity plot and history for TV1. In the parity plot, predictions and actual values seem to be randomly distributed along the diagonal line in Figure. Still, there is a considerable variance due to the noise in the data. In **Figure 8**, it is possible to observe that the predictions follow the observations satisfactorily.

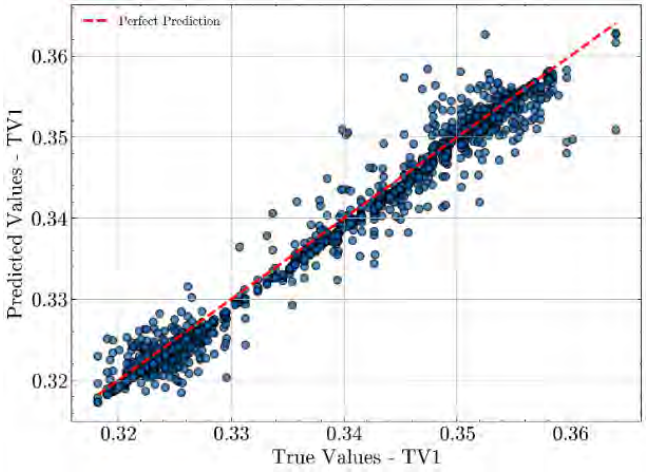

**Figure 7.** Parity plot for TV1.

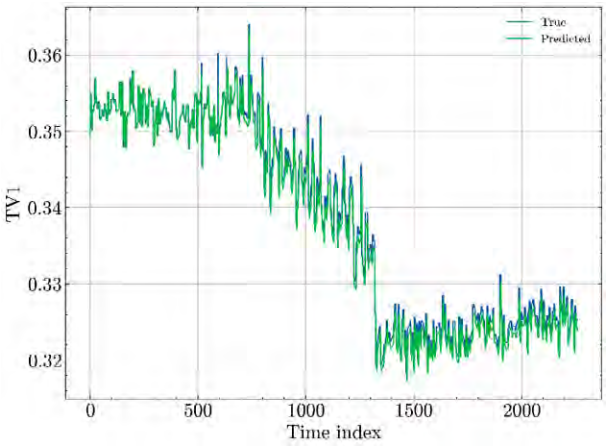

**Figure 8.** History of actual values and predictions for TV1.

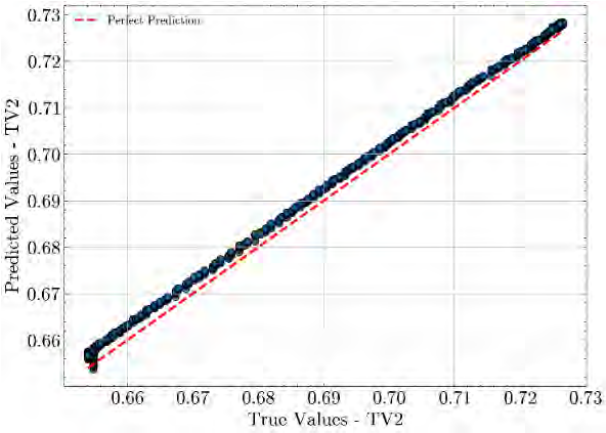

**Figure 9.** Parity plot for TV2.

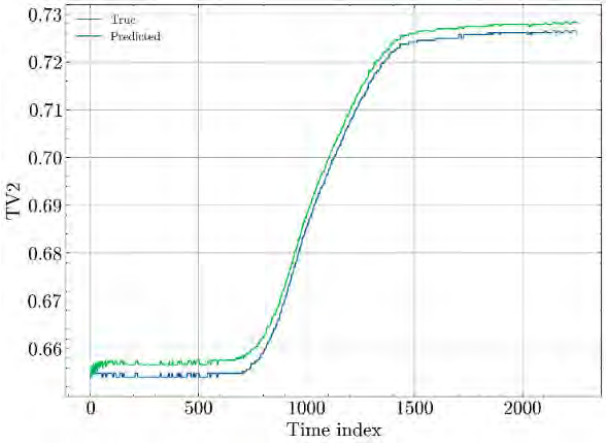

**Figure 10.** History of actual values and predictions for TV2.

The **Figure 9** and **Figure 10** show the parity plot and history for TV2 for the test set data set. They show that the predictions' dynamic behavior is close to that of the actual values. However, a slight bias prevents a better prediction. The prediction bias is more evident in **Figure 10** where the target variable 2 is displayed over time. However, for a real-time model-based application such as MPC, this mismatch would fit into the minimum requirements, and the additional modeling efforts and data

requirements would be beneficial, but the improvement in control performance may become marginal [15].

## CONCLUSIONS

This works investigates the formulation of dynamic system identification for an industrial size electrical submersible pump system using a multi-step ahead predictor targeted at model predictive control. The data processing considers how information is processed in real-time and formulate the model architecture and parameter identification accordingly. It has been shown the strategy provides a satisfactory predictive capacity and further attempts of improving may become marginal in a possible control strategy implementation. Future works might explore the use of new deep learning architectures for processing sequenced information such as Transformers and the introduction of physics constraints of the observed variables for enhanced extrapolation power.

## ABSTRACT

Vacuum (pressure) swing adsorption (V(P)SA) has received considerable attention in the past decades. Existing studies typically estimate vacuum pump energy consumption using an approximate constant energy efficiency or an empirical energy efficiency correlation, leading to inaccurate representation of realistic vacuum pump performance. In this paper an enhanced computational approach is proposed for simulation and optimisation of V(P)SA through simultaneous integration of realistic vacuum pump data and adsorption bed fluidisation limits. The computational results show that the developed prediction models accurately represent the actual performance curves of the vacuum pump. Incorporation of the vacuum pump prediction models and fluidisation constraints in V(P)SA optimisation leads to significantly different optimal solutions compared to when these factors are not considered.

**Keywords**: Pressure swing adsorption, Process simulation, Optimization, Vacuum pump modelling, bed fluidization

## INTRODUCTION

Vacuum (pressure) swing adsorption (V(P)SA) has received considerable attention for gas separation and purification in the past decades [1]. Mathematical modelling of V(P)SA involves description of the spatial and temporal evolution of mass, momentum and energy, resulting in coupled stiff hyperbolic/parabolic partial differential equations (PDEs). Auxiliary nonlinear equations including gas adsorption isotherms and pressure drop correlations are also included to complement process dynamics [2].

In most existing V(P)SA models, a time-dependent pressure profile or a fixed flow rate is used in the boundary conditions (BCs) at the vacuum pump end of the adsorption bed to estimate the performance of a real vacuum pump. With these predefined BCs, the total energy consumption of the vacuum pump is then determined by dividing the isentropic gas compression work by an estimated energy efficiency. It is reported that the vacuum pump can contribute at least 60% to the overall energy consumption in a VSA cycle for $CO_2$ capture [3]. Hence, accurate estimation of the vacuum pump efficiency and quantification of its energy consumption are crucial for the economic analysis of the V(P)SA processes.

Most existing computational studies on V(P)SA have assumed constant vacuum pump efficiency ranging from 60% to 100% where the vacuum pump efficiency of 72% was most used [4]. However, 72% is a typical efficiency value for compressors, instead of vacuum pumps [5]. A low efficiency of 30% was reported [5]. All these have indicated that the energy consumption of the vacuum pump could have been underestimated by at least a factor of two in many existing computational studies.

Instead of assuming a constant vacuum pump efficiency, an efficiency correlation has been developed to more accurately evaluate the vacuum pump performance. It has been observed that the efficiency tends to remain constant around 80% when the inlet pressure of the vacuum pump approaches 1 atm, whilst decreasing sharply to a very low value (e.g., below 20%) at lower pressures [6]. An empirical correlation was thus derived to relate the vacuum pump efficiency to the inlet pressure. However, their correlation fails to conform to the trend suggested by the data points at higher pressures due to significant deviations between data points and model predictions at high pressures.

The adsorption bed fluidisation is another key factor that must be accounted for in designing and operating

the V(P)SA process. This is because bed fluidisation incurs rapid adsorbent attrition and eventually results in a substantial decrease in the separation performance [7]. Nevertheless, only a few have considered the impact of bed fluidisation. They considered the effects of bed fluidisation at specific stages in PSA simulation. However, bed fluidisation can occur at any point along the bed during any step [8]. In other words, fluidisation may be experienced at certain points along the bed during certain steps in the above studies.

To address the above research gaps, in this work we first employ the data-driven modelling approach [9,10] to develop prediction models for the pumping speed and power of the vacuum pump based on real performance curves. This approach enables accurate predictions of the vacuum pump's flow rate and energy consumption. We then develop a new, comprehensive V(P)SA mathematical formulation with incorporation of the proposed vacuum pump performance models. This allows for an accurate evaluation of the V(P)SA process performance without relying on estimated vacuum pump energy efficiency or pressure/flow rate BCs at the vacuum pump end of the adsorption bed. To determine the optimal operating conditions and prevent bed fluidisation, we then construct a new optimisation problem that simultaneously incorporates the proposed V(P)SA model and the bed fluidisation constraints. To the best of our knowledge, this is the first work that considers simultaneously real vacuum pump performance data and bed fluidisation in V(P)SA optimisation. The capability of the developed V(P)SA model is illustrated through a case study.

## PROBLEM STATEMENT

A PSA process operates cyclically with three fundamental steps, including pressurisation, high-pressure adsorption, low-pressure regeneration. Some complementary steps such as pressure equalisation, rinse and purge are included to enhance process performance. An example of the 4-step PSA cycle is illustrated in Figure 1. This cycle involves adsorption, blowdown, evacuation and feed pressurisation. The problem can be stated below:

Given:

1. The number of adsorption bed, and bed configuration.
2. Feed conditions such as flow rate, composition, temperature, and pressure.
3. Adsorbent layers, physical properties of the adsorbent and the corresponding adsorption isotherms.
4. Product purity and recovery requirements.

Determine:

1. The time for each step.
2. Operating conditions, such as operating pressures and feed flow velocity.

For the illustrative example of the 4-step PSA cycle, the decision variables would be the time required for pressurisation, high-pressure adsorption, blowdown, and evaluation, the high adsorption pressure, the intermediate pressure, and the low pressure and the interstitial feed velocity. The degree of freedom is 8.

Assumptions:

- Gas phase follows ideal gas law.
- Non-isothermal adsorption process.
- The bulk flow pattern follows a plug flow model.
- The adsorption equilibrium is described by a dual-site Langmuir model with pure component isotherms dependent on gas phase concentration.
- The mass transfer is described by a linear driving force (LDF) model where the mass transfer resistance is controlled by the molecular diffusion in the macropores.
- The heat of adsorption of each gas component is constant.
- Instantaneous heat transfer between bulk fluid and adsorbent.
- Uniform bed with constant bed void fraction, particle porosity and particle size.
- No radial gradients in concentration, temperature, or pressure.

The objective is to minimise the energy penalty or cost. Other objectives such as minimize total annualised cost can also be employed.

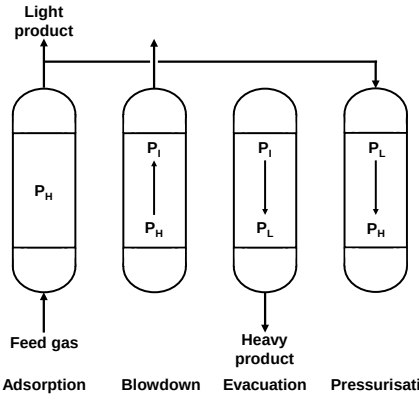

**Figure 1.** Example of a 4-step V(P)SA cycle.

## MATHEMATICAL FORMULATION FOR V(P)SA SIMULATION AND OPTIMISATION

## Rigorous PSA model

The dimensionless model equations for a general PSA process are provided as follows,

$$\frac{\partial y_i}{\partial \tau} = -\frac{\bar{T}}{\bar{P}}\frac{\partial}{\partial Z}\left(\frac{y_i \bar{P}}{\bar{T}}\bar{v}\right) - \psi\frac{\bar{T}}{\bar{P}}\frac{\partial x_i}{\partial \tau} - \frac{y_i}{\bar{P}}\frac{\partial \bar{P}}{\partial \tau} + \frac{y_i}{\bar{T}}\frac{\partial \bar{T}}{\partial \tau} \quad (1)$$

$$\frac{\partial \bar{P}}{\partial \tau} = -\bar{T}\frac{\partial}{\partial Z}\left(\frac{\bar{P}}{\bar{T}}\bar{v}\right) - \psi\bar{T}\sum_i^{n_{comp}}\frac{\partial x_i}{\partial \tau} + \frac{\bar{P}}{\bar{T}}\frac{\partial \bar{T}}{\partial \tau} \quad (2)$$

$$\frac{\partial \bar{T}}{\partial \tau} = -\Omega_1\frac{\partial}{\partial Z}(\bar{v}\bar{P}) - \Omega_2\bar{T}\sum_i^{n_{comp}}\frac{\partial x_i}{\partial \tau} + \sum_i^{n_{comp}}\left(\sigma_i\frac{\partial x_i}{\partial \tau}\right) - \Omega_3(\bar{T} - \bar{T}_w) - \Omega_1\frac{\partial \bar{P}}{\partial \tau} \quad (3)$$

$$\frac{\partial x_i}{\partial \tau} = \alpha_i(x_i^* - x_i) \quad (4)$$

$$q_i^* = \frac{q_{sb,i}b_i c_i}{1+\sum_{i=1}^{n_{comp}} b_i c_i} + \frac{q_{sd,i}d_i c_i}{1+\sum_{i=1}^{n_{comp}} d_i c_i} \quad (5)$$

$$-\frac{\partial \bar{P}}{\partial Z} = \frac{150}{4}\frac{1}{r_p^2}\left(\frac{1-\varepsilon}{\varepsilon}\right)^2\frac{v_0 z_0}{P_0}\mu\bar{v} + \frac{1.75}{2}\frac{1}{r_p}\left(\frac{1-\varepsilon}{\varepsilon}\right)\rho_g|\bar{v}|\bar{v} \quad (6)$$

Equation (1) is mass balance for each component. (2) is momentum balance equation. (3) is bed energy balance equation. (4) is linear driving force. (5) is adsorption isotherm equation. (6) is the Ergun equation for pressure drop. The boundary conditions for each cycle will be referred to [4].

We assume that the adsorption bed is connected directly to the vacuum pump with no pressure drop between them (see Figure 2). Given the same temperature, the outlet volumetric flow rate and pressure of the adsorption bed are equal to the inlet volumetric flow rate and pressure of the vacuum pump, respectively, as specified by Eqs. (7) and (8). In Figure 4, $Z = 0$ represents the vacuum pump end of the adsorption bed, $P_{out,B}$ and $V_{out,B}$ are the outlet pressure and volumetric flow rate of the bed, $P_{in,VP}$ and $V_{in,VP}$ are the inlet pressure and volumetric flow rate of the vacuum pump, and $P_{dis}$ is the discharge pressure of the vacuum pump, which is assumed to be equal to the atmospheric pressure, $P_{atm} = 1$ bar.

$$P_{out,B} = P_{in,VP} \quad (7)$$

$$V_{out,B} = V_{in,VP} \quad (8)$$

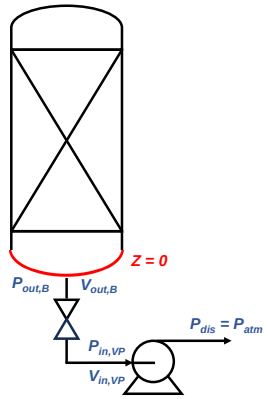

**Figure 2.** Direct connection between the adsorption bed and a vacuum pump

The inlet volumetric flow rate of the vacuum pump ($V_{in,VP}$) must satisfy the vacuum pump pumping speed prediction model, as shown by Eq. (10), where $f_1(P_{in,VP})$ represents the best model developed.

$$V_{in,VP} = f_1(P_{in,VP}) \quad (9)$$

At the vacuum pump end, the outlet flow rate of the bed needs to satisfy the pressure drop correlation $f_2(P_{out,B})$, as shown by Eq. (9), which is usually the Ergun equation [Eq. (6)] or Darcy's law.

$$V_{out,B} = f_2(P_{out,B}) \quad (10)$$

$V_{out,B}$ and $P_{in,VP}$ can be computed by combining Eqs. (7)-(10). It should be noted that the pumping speed curves are normally measured at 298.15 K and 1 atm. Therefore, the volumetric flow rate must be converted to match the corresponding operating conditions.

Given $V_{out,B}$, the outlet interstitial velocity of the adsorption bed $V_{out,B}$ can be computed:

$$v_{out,\,B} = \frac{V_{out,B}}{\varepsilon A} \quad (11)$$

where $\varepsilon$ is the adsorption bed void fraction, and A is the cross-section area of the column.

We define $PW_{tot,VP}$ as the total power required by the vacuum pump, which can be evaluated by the power prediction model, $f_3(P_{in,VP})$, as shown by Eq. (12).

$$PW_{tot,VP} = f_3(P_{in,VP}) \quad (12)$$

The instantaneous isentropic gas compression power ($PW_{isen,VP}$) can be evaluated using Eq. (13).

$$PW_{isen,VP} = \frac{\kappa}{\kappa-1}P_{in,VP}\cdot\varepsilon\cdot\pi\cdot r_{in}^2\cdot v_{out,B}\left[\left(\frac{P_{dis}}{P_{in,VP}}\right)^{\frac{\kappa-1}{\kappa}} - 1\right] \quad (13)$$

where $\kappa$ represents the gas isentropic constant, and $r_{in}$ is the inner radius of the column.

The instantaneous vacuum pump efficiency, $\eta_{VP}$, is therefore defined as the ratio of the isentropic gas compression power to the total vacuum pump power.

$$\eta_{VP}(\%) = \frac{PW_{isen,VP}}{PW_{tot,VP}} \times 100\% \quad (14)$$

Based on the instantaneous values from Eqs. (13) and (14), Eqs. (15) and (16) are used to compute the total energy consumption and the time-averaged efficiency of the vacuum pump:

$$E_{tot,VP} = \int_{t_{ini}}^{t_f} PW_{tot,VP}\,dt \quad (15)$$

$$\eta_{ave,VP}(\%) = \frac{1}{t_f - t_{ini}}\int_{t_{ini}}^{t_f}\eta_{VP}\,dt \quad (16)$$

where $t_{ini}$ and $t_f$ represent the initial and final time points between which the vacuum pump operates, $E_{tot,VP}$ is the total vacuum pump energy consumption, and $\eta_{ave,VP}$ is

the time-averaged efficiency of the vacuum pump over the period between $t_{ini}$ and $t_f$, respectively.

## Adsorption Bed Fluidisation

The adsorption bed fluidisation is characterised by the approach to fluidisation (ATF):

$$ATF = \frac{\frac{\partial P}{\partial Z}\big|_{local}}{\frac{\partial P}{\partial Z}\big|_{min.fluid}} \tag{17}$$

where $\frac{\partial P}{\partial Z}\big|_{local}$ denotes the pressure gradient at a specific location in the bed, and $\frac{\partial P}{\partial Z}\big|_{min.fluid}$ is the minimum fluidisation pressure gradient in the upflow direction.

$$-\frac{\partial P}{\partial Z}\big|_{min.fluid} = (\rho_g - \rho_s) \cdot (1 - \varepsilon) \cdot g \tag{18}$$

where $\rho_g$ and $\rho_s$are the density of gas and adsorbent, respectively; $\varepsilon$ is the bed void fraction; $g$ is the gravitational constant. Eq. (18) essentially states that bed fluidisation occurs when the upward force exerted on a section of the bed offsets its gravity due to the pressure drop.

To prevent the onset of fluidisation, the ATF value should be limited within some values in the upflow and downflow operations, respectively.

$$ATF_{up} \leq \theta_{up} \tag{19}$$

$$ATF_{down} \leq \theta_{down} \tag{20}$$

where $ATF_{up}$ and $ATF_{down}$ represent the ATF value in the upflow and downflow directions, respectively.

## Additional constraints

The following constraints are imposed in addition to the V(P)SA model. First, the required product purity and recovery must be satisfied.

$$Purity \geq Purity_{req}^{tar} \tag{21}$$

$$Recovery \geq Recovery_{req}^{tar} \tag{22}$$

$$Purity = \frac{Moles\ of\ target\ gas\ in\ product}{Total\ moles\ of\ product} = \frac{\frac{\varepsilon A}{R}\int_0^{t_p} \frac{v_{out} \cdot y_{out,i} \cdot P_{out}}{T_{out}} dt}{\frac{\varepsilon A}{R}\int_0^{t_p} \frac{v_{out} \cdot P_{out}}{T_{out}} dt} \tag{23}$$

$$Recovery = \frac{Moles\ of\ target\ gas\ in\ product}{Total\ moles\ of\ target\ gas\ fed} = \frac{\frac{\varepsilon A}{R}\int_0^{t_p} \frac{v_{out} \cdot y_i \cdot P_{out}}{T_{out}} dt}{\frac{\varepsilon A}{R}\sum_{j=1}^{n_{step}} \int_0^{t_f} \frac{v_f^j \cdot y_{f,i}^j \cdot P_f^j}{T_f^j} dt} \tag{24}$$

where $Purity^{tar}$ and $Recovery^{tar}$ are are the purity and recovery of the target gas, and $Purity_{req}^{tar}$ and $Recovery_{req}^{tar}$ denote the required purity and recovery.

We also constrain the bed length-to-diameter ratio ($L/D$) to either a fixed value or within specified bounds.

The lower and upper bounds are imposed for all decision variables, generally represented by a vector $\mathbf{x}$.

$$\mathbf{x}^{lb} \leq \mathbf{x} \leq \mathbf{x}^{ub} \tag{25}$$

where $\mathbf{x}$ is a vector of all decision variables, $\mathbf{x}^{lb}$ and $\mathbf{x}^{ub}$ are the lower and upper bounds. The V(P)SA optimisation problem (denoted as **P**) is defined as follows:

$$\begin{aligned} &min \quad obj \\ &s.t. \quad \text{PSA model equations } 1-6 \\ &\quad\quad \text{Eqs. } 7-11, \text{or estimated vacuum pump efficiency} \\ &\quad\quad \text{Equations } 12-24 \\ &\quad\quad L/D = R_{fixed} \text{ or } R^{lb} \leq L/D \leq R^{ub} \\ &\quad\quad \text{Boundary conditions in [4]} \\ &\quad\quad \mathbf{x}^{lb} \leq \mathbf{x} \leq \mathbf{x}^{ub} \end{aligned}$$

where $obj$ is the objective function, which usually denotes the total cost. Genetic algorithm (GA) in MATLAB is used to solve the optimisation problem **P** with a population size of 24 times of the number of decision variables and a maximum generation of 50 [3].

It should be noted that the V(P)SA model **P** enables computation of the instantaneous outlet gas velocity and pressure of the adsorption bed on the vacuum pump end. As a result, an estimated boundary condition, such as a constant flow rate or a predefined pressure profile, is not required. It enables accurate evaluation of the vacuum pump pumping speed and energy consumption, from which the vacuum pump efficiency is determined post-simulation. This contrasts with the common approaches where predefined estimations of the necessary BCs and vacuum pump efficiency are required in previous studies.

# RESULTS AND DISCUSSION

## Performance Prediction Models of Vacuum Pumps

After reviewing a large number of vacuum pump vendor manuals, ten vacuum pump performance curves are identified, which account for a broad range of the pumping speed. The ten vacuum pumps are given below,

- Leybold DRYVAC DV 800 screw vacuum pump
- Leybold LEYVAC LV 140 screw vacuum pump (50 Hz)
- Leybold LEYVAC LV 140 screw vacuum pump (60 Hz)
- Zhaohan 2BE1 202 liquid ring pump (790 RPM)
- Zhaohan 2BE1 202 liquid ring pump (880 RPM)
- Edwards EDS 300 dry screw vacuum pump
- Edwards EDS 480 dry screw vacuum pump

- Edwards nXDS20i dry scroll vacuum pump
- Edwards nXDS15i dry scroll vacuum pump
- Edwards nXDS10i dry scroll vacuum pump

Data points are extracted from each performance curve using WebPlotDigitizer to establish the prediction models of vacuum pump pumping speed and power (i.e., eqs. 10 and 12) using the data-driven approach [9,10]. The training and test results for pumping speed are provided in Table 1. It is quantitatively shown that each performance model demonstrates close agreement with the data, as indicated by the low RMSE values and coefficient of determination ($R^2$) values near 1.

**Table 1.** Training and test results

| Pump | Pumping speed | | | |
|---|---|---|---|---|
| | Training | | Test | |
| | $R^2$ | RMSE | $R^2$ | RMSE |
| **DV 800** | 0.9998 | 3.18 | 0.9985 | 9.0900 |
| **50 Hz** | 1.0000 | 0.14 | 0.9998 | 0.4866 |
| **60Hz** | 1.0000 | 0.09 | 1.0000 | 0.2588 |
| **790 RPM** | 0.9997 | 4.1074 | 0.9965 | 4.1737 |
| **880 RPM** | 0.9992 | 1.5844 | 0.9992 | 1.7538 |
| **EDS 300** | 0.9999 | 0.5709 | 0.9996 | 1.5020 |
| **EDS 480** | 0.9999 | 1.0752 | 0.9995 | 2.7210 |
| **nXDS20i** | 0.9998 | 0.0774 | 0.9995 | 0.1294 |
| **nXDS15i** | 0.9999 | 0.0414 | 0.9998 | 0.0658 |
| **nXDS10i** | 0.9999 | 0.0348 | 0.9997 | 0.0550 |

## VPSA Optimization Results

We take the VSA cycle from [3] to illustrate the process optimisation results by simultaneously considering the vacuum pump performance prediction models and the fluidisation constraints. The VSA cycle is illustrated in Figure 1. The feed gas mixture, consisting of 20% $CO_2$ and 80% $N_2$, enters the bed at 313.15 K. Parameters such as the adsorbent physical properties, adsorption isotherms, column configuration are adapted from [3]. The objective function is $CO_2$ capture cost from [3].

We compare the optimisation results by using a constant efficiency of 72%, the efficiency correlation from [6], and the developed V(P)SA model involving vacuum pump performance models, respectively. The constant efficiency of 72% is used in case 1, whilst the correlation from [6] is used in case 2. The developed V(P)SA model is used in case 3. The objective is to minimise the $CO_2$ capture cost [3]. The purity and recovery of product $CO_2$ are required to be at least 0.95 and 0.90, respectively. The length-to-diameter ratio is fixed at 3 [3].

| Overall power consumption ($MW_e$) | 36.43 | 57.56 | 43.84 | 58.67 |
| Overall time-averaged efficiency (%) | – | 42.12 | 36.14 | – |
| Approach to fluidisation (ATF) | | | | |
| Upflow | | | | |
| Maximum adsorption ATF | 0.35 | 0.44 | 0.60 | 0.56 |
| Maximum blowdown ATF | 0.73 | 0.74 | 0.35 | 0.55 |
| Downflow | | | | |
| Maximum evacuation ATF | 0.86 | 0.80 | 0.20 | 0.69 |
| Maximum pressurisation ATF | 1.48 | 1.51 | 1.31 | 1.35 |
| $CO_2$ capture cost (€/$t_{CO2,\ avoided}$) | 60.93 | 69.56 | 131.23 | 74.86 |

The optimisation results for cases 1-3 are provided in Table 2. When the constant efficiency of 72% and the efficiency correlation from [6] are used (i.e., cases 1-2),

the resulting vacuum pressure $P_L$ is 0.02 bar and the evacuation time is significantly longer than the blowdown time. These results correspond to the fact that deep vacuum and long evacuation are necessary to satisfy purity and recovery requirements. the lowest $CO_2$ capture cost of 60.93 €/t$CO_2$, avoided is achieved in case 1 with the constant efficiency of 72%. The cost in case 2 is 69.56 €/t$CO_2$, avoided, which is 14% higher than that in case 1. The $CO_2$ capture cost in case 3 is 131.23 €/t$CO_2$, avoided, which is the highest cost among these three cases. This is primarily due to the low outlet interstitial velocity in the blowdown and evacuation steps when using the DV 800 vacuum pump. The low flow rate eventually leads to longer blowdown and evacuation, which greatly increases the number of columns required to process the same amount of feed gas, resulting in a higher column cost and fixed operating cost.

We use the time-averaged efficiency of 36% obtained from case 3 as a constant efficiency to further illustrate the importance and effectiveness of incorporating the proposed vacuum pump performance models. The illustration is created as case 4. The optimisation results for case 4 are also provided in Table 2. The $CO_2$ capture cost is 74.86 €/t$CO_2$, avoided in case 4, which is 43% lower than 131.23 €/t$CO_2$, avoided in case 3. This indicates that the $CO_2$ capture cost can be significantly underestimated even when a well-estimated efficiency value is used. From Table 2, it is shown that the maximal ATF values in all cases have been constrained within the critical thresholds (i.e., 0.8 in the upflow and 1.8 in the downflow) at the final optimal solutions. The maximal ATF values in the pressurisation step remain the highest, as a sufficiently low $P_L$ is essential for satisfying both purity and recovery requirements.

We also compare the optimisation results without consideration of adsorption bed fluidisation, which are presented in Table 3. By comparing results in Tables 2 and 3, the duration of each step has been significantly extended to achieve lower ATF values. Notably, the adsorption time is 350, 348, 356 and 364 s for cases 1-4, respectively, which has been increased by 130% for case 3, and at least 160% for cases 1-2 and 4. The pressurisation time, which is an additional decision variable, increases less significantly from a fixed value of 30 s in Table 3 to ~60 s in Table 2, due to a slightly larger difference between $P_I$ and $P_L$. To maintain a small pressure drop across the bed and reduce the fluidisation level during the adsorption step, the feed velocity in Table 2 becomes almost half of that in Table 3 (i.e., 0.48 vs. 1.08 m $s^{-1}$ for case 1, 0.50 vs. 1.04 m $s^{-1}$ for case 2, 0.50 vs. 1.05 m $s^{-1}$ for case 3 and 0.50 vs. 0.99 m $s^{-1}$ for case 4), which in turn increases the number of parallel trains and the amount of the adsorbent required, leading to higher column and adsorbent costs. As a result, the optimal CO2 capture costs for cases 1-4 are increased by at least 16% compared those in Table 3. These results show that incorporating fluidisation constraints into PSA optimisation leads to substantial differences in the optimal solution, indicating a significant impact on PSA design.

## CONCLUSION

In this work, we developed an enhanced computational approach for simulation and optimisation of the vacuum (pressure) swing adsorption (V(P)SA) by incorporating both the realistic vacuum pump performance prediction models and adsorption bed fluidisation constraints. The computational results demonstrated that the predictions from the developed performance prediction models closely matched the vacuum pump data. The

developed V(P)SA model did not assume an estimated energy efficiency or predefined pressure/flow rate boundary conditions for the vacuum pump. The vacuum pump efficiency typically falls in the range of 20% to 40%. This is consistent with the efficiency of 30% reported in a pilot study. When an estimated vacuum pump efficiency was applied, the optimal $CO_2$ capture cost was underestimated by at least 42%. It was found that bed fluidisation occurs when using a large rate of change in the pressure boundary conditions, or a vacuum pump with an excessively high pumping speed. Incorporating the vacuum pump performance prediction models and accounting for bed fluidisation constraints have a significant impact on V(P)SA optimisation outcomes, with the optimal solution varying considerably under different conditions. Future research will integrate vacuum pump performance prediction models into industrial-scale V(P)SA simulations to further evaluate the effectiveness of the proposed computational approach.

## ABSTRACT

This study presents a deterministic optimization methodology for the design of shell-and-tube heat exchangers with twisted tape turbulence promoters, focusing on minimizing the total annualized cost (TAC) while balancing thermal performance and energy consumption. A sensitivity analysis was carried out as Case I (Methanol-Water), it reveals that increasing the twist ratio (TR) reduces flow turbulence, resulting in lower fluid velocity, pressure drop ($\Delta P_i$), and overall heat transfer coefficient (U). Among the turbulence promoters evaluated, twisted tapes with V-cuts achieved a 21.1% increase in U with a 52.27% increase in pressure drop, demonstrating an optimal balance between thermal enhancement and energy cost. In contrast, promoters with circular rings and multiple perforations showed the highest U improvements (26.7% and 25.8%, respectively) but incurred significant pressure drops (93.5% and 97.9%). The optimization problem has been stated as a nonlinear programming (NLP) problem and solved with the CONOPT solver. Results from two case studies emphasize the importance of operating with similar mass flows, directing the smaller flow through the tubes to maximize promoter effectiveness and achieve balanced heat transfer and pressure drop. For Case II (Residue-Water), the TAC was estimated at 11,467 USD/year, with the equipment cost as the major contributor. Case III (Water-Water) demonstrated improved balance in convective coefficients due to lower thermal effectiveness and similar mass flow rates, highlighting the positive impact of turbulence promoters on performance. This work demonstrates the potential of turbulence promoters for enhancing heat exchangers while emphasizing the importance of careful design to optimize performance and cost.

## INTRODUCTION

Techniques for enhancing heat transfer in existing designs are frequently utilized in heat recovery systems. One of the most common methods is the incorporation of twisted tape turbulence promoters, which increase thermal efficiency but simultaneously induce flow disturbances that result in higher pressure drops [1]. When designing shell-and-tube (SH&T) heat exchangers with twisted tape turbulence promoters, the design varies depending on the type of promoter used, and it is determined by several geometric variables, including the internal diameter [2]. Among the types of twisted tape inserts, plain twisted tape, perforated tape, tape with circular rings, tape with three centered perforations, and V-cut tape, can be mentioned [3,4,5,6]. The use of these promoters has been reported to enhance the thermo-hydraulic performance of the equipment from 6.3% to 360%, compared to smooth-tube exchangers [7].

Detailed methodologies for designing SH&T heat exchangers are widely available in the literature [8, 9], making their design straightforward. However, when designing with twisted tape turbulence promoter inserts, the calculation of the free-flow cross-sectional area remains an underexplored area, Figure 1 [1].

This study presents a retrofit case (***CASE I:***

***Methanol-Water***) where a sensitivity analysis is conducted to observe the behavior of heat exchanger design variables as the twist ratio (TR) varies, the twist ratio (TR) is a key geometric parameter in the design of heat exchangers with twisted tapes. It is defined as the ratio between the twist pitch length and the tube diameter. A high TR implies less twisting per unit length, reducing flow turbulence and pressure drop, while a low TR generates higher turbulence, enhancing heat transfer but increasing flow resistance. In heat exchanger design, finding a balance between thermal transfer and pressure drop is crucial for system efficiency. A retrofit case refers to the improvement of an existing design.

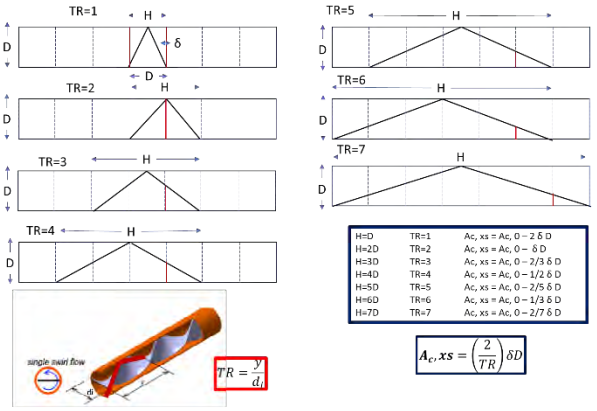

**Figure 1.** Calculation of the free-flow cross-sectional area with the turbulence promoters.

Additionally, a comparative study among different types of promoters is carried out, evaluating the increase in the overall heat transfer coefficient (U) and the pressure drop within the tubes.

Identifying the best alternative for design and process intensification involves selecting the optimal combination of geometric variables. In literature, optimization techniques have generally been employed to evaluate factors or performance correlations that do not involve costs or a complete equipment design [10, 11].

The primary objective in designing these systems is to minimize total cost, which entails enhancing heat transfer while reducing pumping power. Therefore, determining the optimal combination of parameters for calculating flow velocities, overall heat transfer coefficient (U), and pressure drops within the tubes becomes critical [12].

This work develops a deterministic optimization methodology for solving a nonlinear programming (NLP) problem, where the objective function is to minimize the total annualized cost (TAC) of the equipment and identify the optimal design variables, hence, two cases are studied, ***CASE II: Residue - Water*** and ***CASE III: Water-Water*** [13]. The variables of each case are presented in Table 1.

## METHODOLOGY

To carry out the optimization process of the design of heat exchanger with twisted tape inserts, the design methodology followed is shown in Figure 2.

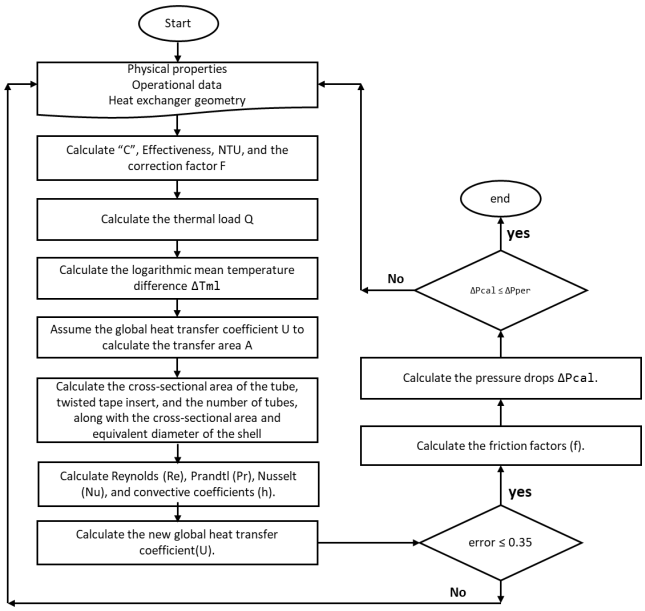

**Figure 2.** Methodology of design for a T&Sh heat exchanger.

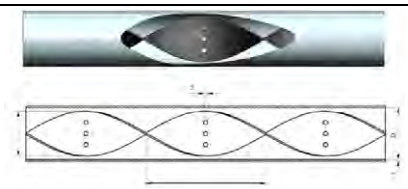
According to Kern's methodology, we assume a starting value for the overall heat transfer coefficient of the system, then, this value is compared with the calculated overall heat transfer coefficient, until the difference between them is within the accepted error range (<35%). Once the condition is reached, the pressure drop is calculated in both sections of the system (tube and shell) [8, 9].

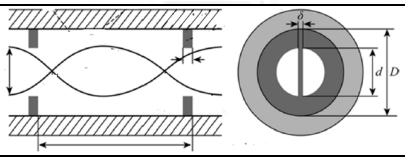
In the diagram of Figure 2, the expressions to estimate the total heat transfer area are calculated from the thermal load (Q), overall heat transfer coefficient (U), correction factor (F), and logarithmic mean temperature difference ($\Delta T_{ml}$).

$$A = \frac{Q}{U * F * \Delta Tml} \quad (1)$$

$$Q = m * C_p * \Delta T \quad (2)$$

Where, $m$ is mass flow, $C_p$, is the heat capacity and $\Delta T$ is the temperature difference. $\Delta T_{ml}$ and the correction factor F are given as:





$$\Delta T_{ml} = \frac{\Delta T_1 - \Delta T_2}{Ln\left(\frac{\Delta T_1}{\Delta T_2}\right)} \quad (3)$$

$$\mathrm{F} = \frac{Q}{NTU * \Delta T_{ml} * C_{min}} \quad (4)$$

| **Smooth twisted tape V-cut** [14] |  | $Nu = 0.0296 * Re^{0.853} * Pr^{0.33} * TR^{-0.222} * \left(1 + \frac{d_e}{W}\right)^{1.148} * \left(1 + \frac{w}{W}\right)^{-0.751}$<br>$fi = 8.632 * Re^{-0.615} * TR^{-0.269} * \left(1 + \frac{d_e}{W}\right)^{2.477} * \left(1 + \frac{w}{W}\right)^{-1.914}$ |
| **Smooth twisted tape with three center perforation** [5] |  | $Nu = 0.3528 * Re^{0.62} * Pr^{0.4} * TR^{-0.638} * \left(\frac{l}{di}\right)^{-0.00973}$<br>$fi = 6.2565 * Re^{-0.404} * TR^{-0.5828} * \left(\frac{d}{di}\right)^{-0.0113}$ |
| **Smooth twisted tape with circular ring** [4] |  | $Nu = 0.326 * Re^{0.724} * Pr^{0.4} * TR^{-0.406} * \left(\frac{l}{di}\right)^{-0.475}$<br>$fi = 13.99 * Re^{0.202} * TR^{-0.619} * \left(\frac{l}{di}\right)^{-0.927}$ |

NTU is the number of heat transfer units and $C_{min}$ is lower mass flow-heat capacity between the two streams.

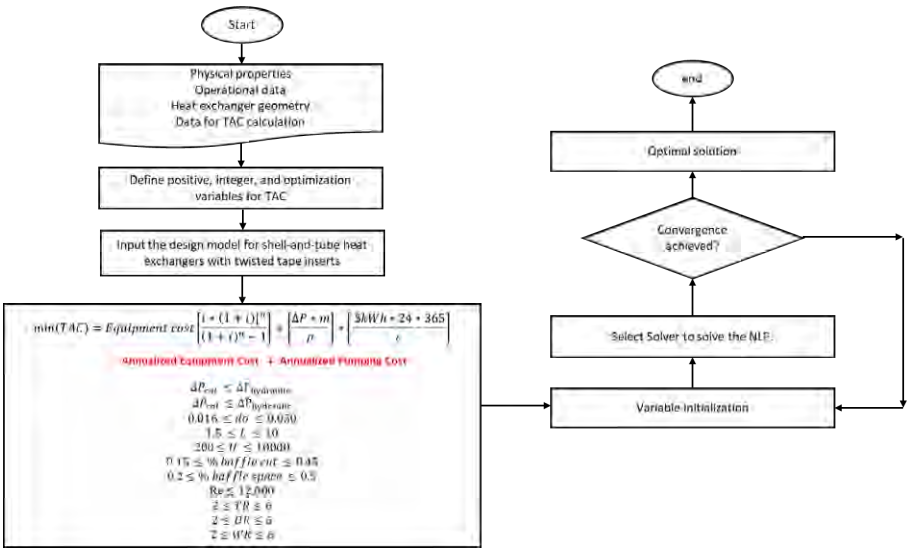
To calculate the overall heat transfer coefficient (U) the thermal-hydraulic correlations for Nusselt number and friction factor presented in Table 2 were employed.

$$U = \frac{1}{\frac{1}{h_i} + \frac{1}{h_s}} \quad (5)$$

The pressure drop in the tube is calculated by equation 6.

$$DPi = N * \left[8 * fi * \frac{L}{di} * \left(\frac{\mu}{\mu_w}\right)^{-0.14} + 2.5\right] * \frac{\rho * v_i^2}{2} \quad (6)$$

The expression for pressure drop in the shell side is:



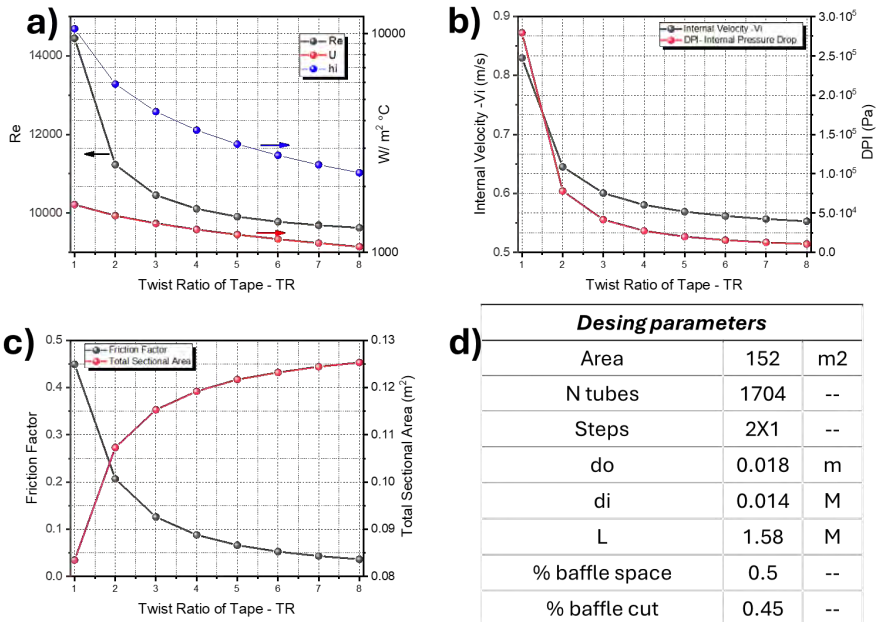


**Figure 3.** Methodology of optimization with twisted tape

d)

| di | 0.014 | M |
| L | 1.58 | M |
| % baffle space | 0.5 | -- |
| % baffle cut | 0.45 | -- |

**Figure 4.** Sensibility analysis of design of SH&T varying the twisted tape. a) Re, U and h vs TR; b) Internal velocity and pressure drop vs TR; c) Friction factor and total sectional area vs TR, and d) design parameters.

$$DPs = 8 * fs * \left(\frac{D_s}{d_e}\right) * \left(\frac{L}{l_B}\right) * \frac{\rho * v_s^2}{2} * \left(\frac{\mu}{\mu_w}\right)^{-0.14} \quad (7)$$

The mathematical model was implemented in GAMS software, as a Non-Linear Programming Model (NLP), and it was solved using the CONOPT solver. The optimization methodology to solve the SH&T heat exchanger with twisted tape inserts is based on reducing cost (TAC), which is in function on the equipment cost and the annualized energy consuming due to pumping. Figure 3 shows the design constraints.

## RESULTS AND DISCUSSION

From Figure 4, (a) and (b), it is evident that increasing the twist ratio (TR) of the twisted tape results in wider and less frequent twists, reducing the intensity of flow mixing and turbulence within the tube.

This leads to a decrease in fluid velocity (Vi), as it encounters less resistance, which in turn reduces the pressure drop (DPi) and the overall heat transfer coefficient (U). Higher TR values produce a smoother flow that

is less efficient in heat transfer, as the ability to effectively induce turbulence is diminished.

Figure 4(c) shows that the friction factor decreases as TR increases. The tape causes less obstruction, which reduces the fluid velocity and consequently lowers the pressure drop. Additionally, with higher TR, the tape occupies less space in the cross-section tube, increasing the available free cross-sectional area and allowing the fluid to flow more easily.

According to the results shown in Table 3, smooth

twisted tape turbulence promoters with circular rings and multiple perforations provide the highest percentage increase in the heat transfer coefficient (U), achieving improvements of 26.7% and 25.8% compared to a smooth tube. However, these results also exhibit the highest pressure drop increase ($DP_i$) of 97.9% and 93.5%, indicating a significant energy cost. In contrast, twisted tapes with V-cuts achieve a 21.1% increase in U while maintaining a lower pressure drop of 52.27%, positioning them as a more balanced option.

From case II (Table 4), TAC was estimated at 11,467 USD/year, where the largest contribution comes from the equipment cost (9,368 USD/year), while the pumping costs are 2,098 USD/year. This analysis shows that the convective heat transfer coefficient of the shell side ($h_s$) is significantly lower compared to that of the tubes ($h_i$), indicating that the heat transfer is controlled by the fluid flowing through the shell. This situation causes the improvement in heat transfer coefficient on the tube side, not being significant in the overall heat transfer coefficient. This prevents the inserts from achieving the intended operational performance. In this case, a better design configuration is to send the fluid with the lowest mass flow rate through the tubes. Yet, another operating feature that affects the magnitude in which a promoter enhances heat transfer is thermal effectiveness. Higher effectiveness heat exchangers tend to dampen the increment in heat load.

The results of the optimization methodology applied to Case III are presented in Table 5. It can be observed that the convective heat transfer coefficients, $h_i$ (4,434 W/m²°C) and $h_s$ (2,129 W/m²°C), are slightly more balanced compared to Case II. In this configuration, the mass flow rates are equal, which does not constrain the increase in the overall heat transfer coefficient. This is because heat transfer is more evenly distributed, attributed to the heat exchanger exhibiting a balanced thermal effectiveness and *C* relation average.

## CONCLUSIONS

Based on the sensitivity analysis results, it can be concluded that an increase in the twist ratio (TR) of the twisted tape promoter causes the twists to become wider. This reduces flow turbulence, which inversely affects fluid velocity, decreasing speed (Vi), pressure drop ($\Delta P_i$), and the overall heat transfer coefficient (U). The twisted tape with V-cuts shows a 21.1% increase in the overall heat transfer coefficient (U) and a 52.27% increase in the pressure drop (ΔPi) compared to the smooth tube without promoters, making it the best option to maximize heat transfer with minimal impact on energy consumption.

An optimization methodology was developed for the design of shell and tube heat exchangers with turbulence promoters. The results indicate two key issues that determine the magnitude of performance improvement achievable with turbulence promoters: (1) a larger overall performance increase is observed when the lower mass flow rate fluid passes through the tube, and (2) higher increases in heat load are achieved when turbulence promoters are used in units with low thermal effectiveness.

## ACKNOWLEDGEMENTS

Authors wish to express their gratitude to the Mexican Council of Science, Humanities and Technology (CONAHCyT) for the grant provided to Jamel Eduardo Rumbo-Arias during this research.

## ABSTRACT

Reaction processes require optimization to enhance key performance indicators (KPIs) such as yield, conversion, and selectivity. Techniques like Bayesian Optimization (BO), Model-Based Design of Experiments (MBDoE), and Goal-Oriented Optimal Experimental Design (GOOED) play pivotal roles in achieving these objectives. BO efficiently explores the design space to identify optimal conditions, while MBDoE maximizes the information gain by reducing kinetic model uncertainty. In contrast, GOOED focuses solely on maximizing the KPIs without considering the system uncertainty, identifying reactor conditions in the design space guaranteeing optimal performance. This study compares BO, MBDoE, and GOOED in optimizing methane oxidation in an automated flow reactor. Performance is assessed based on optimal methane conversion, reduced system uncertainty and minimal experimental efforts to achieve maximum conversion. BO quickly identifies high-conversion conditions, MBDoE minimizes experimental runs while providing insights into parameter sensitivities, and GOOED prioritizes conversion efficiency. The findings highlight trade-offs between convergence speed, robustness, and information gain, providing valuable insights for designing data-driven, physics-informed experiments..

**Keywords**: Bayesian Optimization, Model-Based Design of Experiments, Methane Conversion

## 1 INTRODUCTION

Reaction processes play a significant role in scientific and industrial applications in the production of chemicals, energy, and materials [1]. These processes are driven by interconnected factors such as reaction kinetics, thermodynamics, and transport phenomena [2], and their optimal performance in terms of key performance indicators (KPIs) such as yield, conversion, and selectivity depend on the precise control and fine-tuning of process parameters. Addressing these challenges requires advanced optimization techniques capable of navigating this intricate landscape.

Traditional methods like trial-and-error experimentation and design of experiments (DoE) [3] have proven effective in several applications. These techniques have been instrumental in refining reaction conditions, balancing exploration and exploitation of the design space, and offering insights into reactor behaviour. However, their limitations, particularly in high-dimensional, dynamic, or noisy systems, have spurred the development of novel approaches.

Emerging techniques such as Bayesian Optimization (BO) [4], Model-Based Design of Experiments (MBDOE) [5], and Goal-Oriented Optimal Experimental Design (GOOED) [6] provide more efficient strategies for optimizing reaction processes.

BO excels at identifying optimal conditions with a minimal number of experiments by balancing exploration and exploitation in black-box systems [7]. MBDOE emphasizes the maximization of information gain to improve parameter estimation and reduce uncertainty in physics-based model predictions. The MBDoE approach can also be applied to design experimental design campaigns online [8].

In contrast, GOOED focuses solely on achieving target KPIs, such as maximizing conversion, without prioritizing information gain or uncertainty reduction, making it

highly effective for applications where achieving maximum performance is the primary objective.

The goal of the study is to evaluate the relative merit of the different experimental design approaches and establish which among the three techniques (BO, MBDoE, and GOOED) represents the optimal experimental design scenario by examining the reaction for methane total oxidation in an automated flow reactor as a case study.

A comparative analysis of the three techniques as experimental design scenarios is carried out to quantify their relative performance in terms of (i) conversion of methane; (ii) uncertainty in the evaluation of the optimal conversion; (iii) confidence level of parameter estimates, and (iv) number of experiments required for the maximum KPI to be achieved. The analysis demonstrates how the three techniques can distinctly balance convergence speed and experimental robustness ultimately guiding the choice of more effective experimental design campaigns.

# 2 METHODOLOGY

## 2.1 Generic Model and System Description

The system under consideration is represented by a set of differential and algebraic equations (DAEs), where the measured variables $\mathbf{y}$ can be sampled at discrete time points:

$$\mathbf{f}(\dot{\mathbf{x}}, \mathbf{x}, \mathbf{u}, \boldsymbol{\theta}, t) = 0 \qquad \mathbf{y} = g(\mathbf{x}, \mathbf{u}, \mathbf{v}) \quad (1,2)$$

where **f** is a set of model equations, **x,** $\dot{\mathbf{x}}$ and are $N_x$ -dimensional vectors of state variables and their first derivatives respectively, **u** is a $N_u$ -dimensional vector of control variables, $t$ is time, **θ** is a $N_\theta$-dimensional vector of model parameters, **y** is a $N_y$-dimensional vector of response variables that are measurable.

Eq. (1), and (2) establish the fundamental structure upon which the specific methane oxidation reactor model is developed in Section 2.2

## 2.2 Methane Oxidation: System & Reactor Model

Building on the general modeling framework from Section 2.1, this section details a specific application to methane oxidation in flow reactor system as presented by Bawa et al. [12]. In their research, they presented a reactor model characterized by the following set of ordinary differential algebraic equations:

$$\begin{aligned}
\frac{dx_1}{dw} &= \frac{R.u_1}{u_2 P_{avg}} . (-r) \quad x_1(0) = u_4 \\
\frac{dx_2}{dw} &= \frac{R.u_1}{u_2 P_{avg}} . (-2r) \quad x_2(0) = u_3.u_4 \\
\frac{dx_3}{dw} &= \frac{R.u_1}{u_2 P_{avg}} . (r) \\
\frac{dx_4}{dw} &= \frac{R.u_1}{u_2 P_{avg}} . (2r) .
\end{aligned} \qquad (3)$$

For the methane oxidation system, the control variables (**u**) is defined in Eq. 4, while **y** represents the response variables for $CH_4$, $CO_2$, $O_2$ measured at the reactor outlet. The state variables **x,** control variables **u** and model parameters **θ** are defined for the reactor model as follows:

$$\begin{aligned}
\mathbf{x} &= [x_1, x_2, x_3, x_4] \\
\mathbf{u} &= [u_1, u_2, u_3, u_4] \\
\boldsymbol{\theta} &= [\theta_1, \theta_2, \theta_3, \theta_4, \theta_5, \theta_6]
\end{aligned} \qquad (4)$$

where $x_1$ $x_2$ $x_3$ $x_4$ are mole fraction of methane, oxygen, carbon dioxide and water, respectively, and $u_1, u_2, u_3, u_4$ represent temperature [℃], flow rate of the feed $[Nml\ min^{-1}]$, oxygen-to-methane mole fraction $R_{O_{2/CH_4}}$ $[mol\ mol^{-1}]$, and inlet methane mole fraction $[mol\ mol^{-1}]$ respectively. These controls form the design vector $\boldsymbol{\varphi}$ which is bounded within the experimental design domain as shown in Table 1. In the model $R$ $[J\ mol^{-1}\ K^{-1}]$ is the universal gas constant, $r$ $[mol\ g^{-1}\ min^{-1}]$ the reaction rate according to the kinetic model, and $w$ $[g]$ is the catalyst mass along the reactor. The experimental design examined the effects of key control variables on methane oxidation by varying them within defined ranges (Table 1).

**Table 1**. Experiment control variables

| Control Variables | Range | Units |
|---|---|---|
| Temperature | 250-350 | ℃ |
| Mass flow rate | 20-30 | $Nml\ min^{-1}$ |
| Oxygen to methane mole ratio | 2-4 | $mol\ mol^{-1}$ |
| Methane mole fraction | 0.005-0.025 | $mol\ mol^{-1}$ |

The Mars Van Krevelen (MVK) model reaction rate expression (Eq. 5) was adopted as the true model in this study as a representation of the system under consideration:

$$r_{ch4} = \frac{k_1 k_2 P_{CH_4} P_{O_2}}{k_1 P_{O_2} + 2\, k_2 P_{CH_4} + \frac{k_1 k_2}{k_3} (P_{O_2} P_{CH_4})} \qquad (5)$$

Eq. 5 was identified and validated in [11], where the authors calibrated the MVK model from flow reactor data. The authors also stressed that the oxidation of methane involved three steps: 1. Surface oxidation 2. Surface Reduction. 3. Desorption of product. Kinetic model parameters of the MVK model (i.e. rate constants $k$, and activation energies $E_a$) were identified and formulated with respect to these steps thus giving rise to six parameters, $k_1$ , $k_2$ , $k_3$, $E_{a_1}$, $E_{a_2}$, $E_{a_3}$. Furthermore, these parameters were reparameterised to the vector form **θ** and estimated as **θ** = [5.77, 6.72, 5.87, 9.51, 10.17, 7.98]. These parameter values are used as the true parameter vector in this work.

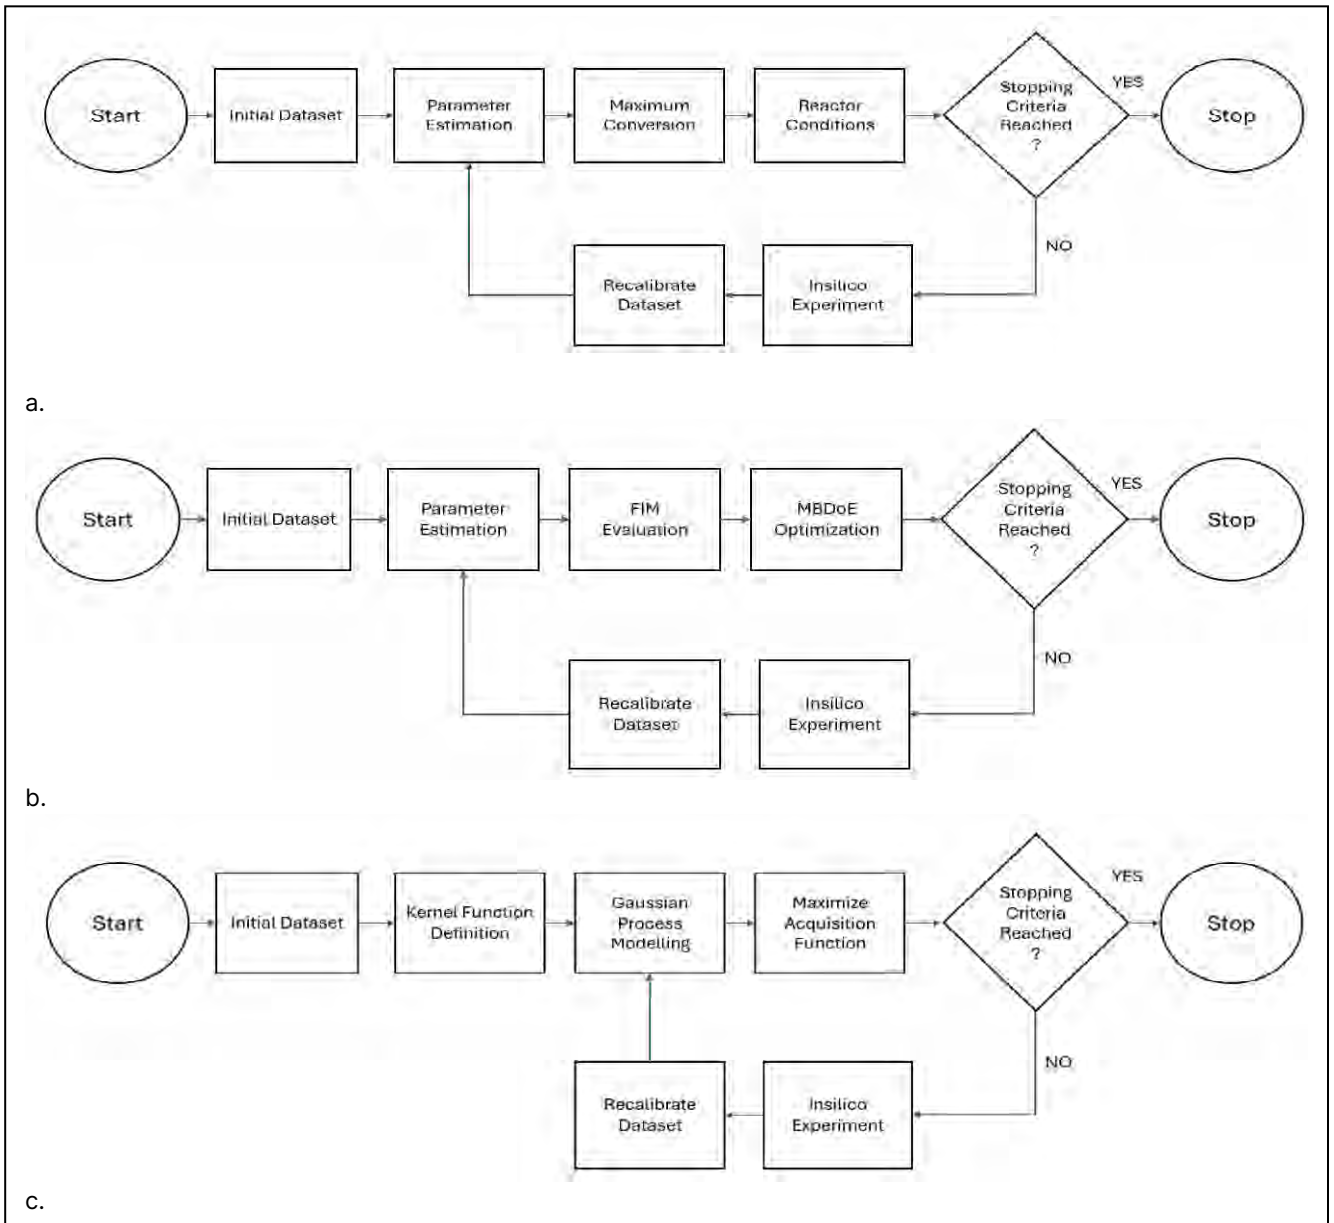

**Figure 1.** Procedural Framework showing workflow procedures for (a) GOOED (b) MBDoE and (c) BO scenarios.

## 2.3 Procedural Approach for GOOED, MBDOE, and BO

The procedural approach for the three experimental design scenarios is tailored to their distinct objectives as shown in Figure 1. GOOED (a) and MBDoE (b) are both exploitative approaches. While they have distinct objectives, they both focus on identifying the optimal point, albeit with different goals in mind. The objective of (a) is to maximise a specific KPI, whereas (b) focuses on the improvement of model predictions by minimising uncertainty in parameter estimation and (c) BO balances exploration and exploitation through adaptive learning to optimize system performance without using mechanistic modelling insights on the system. The stopping criteria used to terminate the procedures for any of the scenarios can be one of the following: a. experimental budget termination b. satisfied $t$ −test on model parameters.

The objective function that describes maximizing methane conversion and used by both GOOED and BO is shown in Eq. 6 below.

$$\mathbf{u}^* = argmin_{\mathbf{u}\in U} - h\,(\mathbf{u}) \tag{6}$$

where $h\,(\mathbf{u})$ is the predicted conversion at any experimental condition $\mathbf{u}$, The algorithms mostly perform minimization, so we minimize $-h\,(\mathbf{u})$, which is the same as maximizing $h\,(\mathbf{u})$, $\mathbf{u}^*$ is the optimal condition at maximum conversion. The design space, $U$, is the boundary

conditions of the control variables shown in Table 1.

### 2.3.1 GOOED

In the GOOED approach the objective is to maximize the conversion of methane. The objective function Eq. 7 which is a slight modification of Eq. 6 is shown below.

$$\mathbf{u}^{*}_{\boldsymbol{GOOED}} = argmin_{\mathbf{u}\in U} - h\,(\mathbf{u}) \tag{7}$$

The steps defining the GOOED procedure are illustrated in Figure 1a and summarised below.

1. *Initial Dataset*: An initial dataset from 12 preliminary experimental runs, created using statistical design of experiments (DoE) methodology as described in [11], serves as the starting point for the procedure.
2. *Parameter Estimation*: Using computational methods and Eq. 6, the observations are utilized to estimate model parameters and estimates are evaluated for statistical significance.
3. *Maximize Methane Conversion.* The optimization of methane conversion is guided by the experimental conditions defined in Table 1; the objective function is represented in Eq. 7. The system undergoes an optimization routine to identify the maximum achievable conversion of methane.
4. *Optimal Reactor Conditions.* During this process, the corresponding operating conditions that yield the maximum conversion are also determined.
5. *In Silico Experiment*: Simulations are run to forecast how the reaction will behave under the determined optimal conditions.
6. *Iterate Until Stopping Criterion*: The procedure continues, updating the dataset and improving predictions of the optimal conversion based on feedback from each experimental run.
7. *Procedure termination*: The process stops when the stopping criterion is met, i.e. the maximum experimental budget is exhausted, or the *t*-test results are statistically significant – both of which are the stopping criteria.

### 2.3.2 MBDoE

In the MBDoE approach, the objective function is designed to maximize the determinant of the Fisher Information Matrix (FIM), $H_{\hat{\theta}}$ this function is defined in Eq. 8 which represents dynamic systems.

$$\mathbf{H}_{\hat{\boldsymbol{\theta}}}(\hat{\boldsymbol{\theta}}, \boldsymbol{\varphi}) = [\mathbf{V}^{0}_{\hat{\theta}}]^{-1} + \sum_{i=1}^{n_{sp}} \left(\frac{d\hat{\mathbf{y}}}{d\hat{\boldsymbol{\theta}}}\right)_i^{T} \sum_{y}^{-1} \left(\frac{d\hat{\mathbf{y}}}{d\hat{\boldsymbol{\theta}}}\right)_i \tag{8}$$

where $\mathbf{V}^{0}_{\hat{\theta}}$is the $N_\theta\ x\ N_\theta$ prior variance-covariance matrix of model parameters, while $(\frac{d\hat{y}}{d\hat{\theta}})$is the $N_y\ x\ N_\theta$ matrix with first-order derivatives of model responses with respect to the parameters at time point *i*. The parameter estimates are obtained from Eq. 11, which provides the initial values for MBDoE based on the model and available data. To assess the quality of these estimates, Eq. 8 computes the Fisher Information Matrix (FIM) which allows to predict the expected precision of parameter estimates. The *t*-values are calculated as metric of parameter precision (see Section 2.4.1), and statistical conditions are checked to ensure the validity of the estimates.

The procedural approach for MBDoE (Fig 1b) is the following

1. *Initial Dataset*: Same as in GOOED
2. *Parameter Estimation:* Same as in GOOED
3. *FIM Evaluation:* The evaluation of the expected FIM was computed at the current value of the parameter estimates.
4. *Optimal Design of Experiment:* Based on the estimated parameters and uncertainties, new experimental conditions are determined by maximizing the determinant of the expected FIM [8].
5. *In Silico Experiment:* The new experimental conditions are applied, the experiment is simulated generating new data in silico, and the experimental dataset is updated.
6. *Iterative Process:* The process continues iteratively until the t-test results are statistically significant, or the experimental budget is terminated both of which are the stopping criteria.

### 2.3.3 Bayesian Optimization (BO)

In the third scenario, we adopted the BO technique due to its ability to effectively find the optimized value of the objective function. The objective function which is a modification of Eq. 6 is defined below in Eq. 9

$$\mathbf{u}^{*}_{\boldsymbol{BO}} = argmin_{\mathbf{u}\in U} - h\,(\mathbf{u}) \tag{9}$$

The choice of a composite kernel function Eq. 10 combining constant kernel *C*, and RBF kernel to effectively capture both global scaling and local variability in the relationship between experimental conditions $\mathbf{u}$ and the conversion of methane (Eq. 14). This combination helps the GP to represent system behaviour and optimize control variables for maximum conversion efficiency.

$$k(\mathbf{u}, \mathbf{u}') = C.RBF\ (\mathbf{u}, \mathbf{u}') \tag{10}$$

where $\mathbf{u}, \mathbf{u}'$ are two different sets of experimental conditions.

The procedural approach for the BO (Fig 1c) is outlined below:

1. *Initial Dataset*: Same as in GOOED
2. *Define the Kernel and Gaussian Process (GP) Model*: We defined the GP with a composite kernel function Eq. 10 where $C$ is a constant kernel with an initial value of 1.0 (bounded between $10^{-3}$ and $10^{3}$), and $RBF$ (Radial Basis Function) has a length scale initialized at 1.0 with bounds between $10^{-2}$ and $10^{2}$). The hyperparameters of the kernel are optimized during model training by maximizing the log marginal likelihood using gradient-based optimization technique [13].
3. *Train the GP Model*: The GP model is trained using an initial dataset to learn the relationship between the input conditions and the corresponding system response variables [14]. To account for noise in the data, the GP model incorporates the noise and variance from the preliminary dataset.
4. *Cross-Validation*: To ensure the GP model generalizes well, 5-fold cross-validation is performed on the initial datasets. The data is split into 5 subsets, where the model is trained on 4 subsets and tested on the remaining one [15], repeating the process 5 times. The average performance metric (e.g., RMSE) is used to assess model robustness and prevent overfitting.
5. *Define the Acquisition Function (AF)*: An AF is chosen to guide the search for optimal experimental conditions in our case we chose the Expected Improvement (EI).
6. *Optimize the AF*: The chosen acquisition function is then optimized this leads to selection of the next experimental condition $\mathbf{u}_{\text{new}}$ to test.
7. *In Silico Experiment*: At this new experimental condition $\mathbf{u}_{\text{new}}$, the experiment is simulated generating new data in silico, and the experimental dataset is updated.
8. *Procedure termination*: The process stops when the stopping criterion – the experimental budget is exhausted.
9. The next experiment is conducted at the selected reactor conditions, $\mathbf{u}_{\text{new}}$ The process continues iteratively until the experimental budget of 20 runs is reached, at which point the process stops.

## 2.4 Parameter Estimation

Parameter estimates (indicated as $\theta$) from the experimental data were computed by minimizing the difference between measured responses ($y$) and predicted responses ($\hat{y}$) through the negative log-likelihood function [6].

$$L(\hat{\boldsymbol{\theta}}) = \frac{N}{2}\log(2\pi) + \frac{n_{sp}}{2}\log\left(det|\boldsymbol{\Sigma}_{\boldsymbol{y}}\right) + \frac{1}{2}\sum_{i=1}^{n_{sp}}[\boldsymbol{y_i} - \hat{\boldsymbol{y}}_{\boldsymbol{i}}\,(\hat{\boldsymbol{\theta}})]^T\ \boldsymbol{\Sigma_y}^{-1}[\boldsymbol{y_i} - \hat{\boldsymbol{y}}_{\boldsymbol{i}}(\hat{\boldsymbol{\theta}})] \quad (11)$$

$n_{sp}$ is the number of sampling points considering all the Ne performed experiments, namely $n_{sp} = \sum_{i=1}^{N_e} N_{sp_i}$ is the number of sampling points in the $i_{th}$ experiment), $N$ is the total number of experimental measurements calculated as $N$. In GOOED and MBDoE the $\hat{y}_i$ is computed from the mechanistic model. In BO $\hat{y}_i$ is computed from GP predictions.

### 2.4.1 Uncertainty in Parameter Estimates

Parameter precision is quantified using the $N_\theta\ x\ N_\theta$-dimensional covariance matrix ($V_\theta$), approximated by the inverse of the observed Fisher Information Matrix ($H_\theta$) (Eq. 8). From the covariance matrix, the 95% confidence interval for the $ith$ parameter is calculated using Eq. 12 as the square root of the variance element $v_{\theta,ii}$, multiplied by the *t*-value at the 95% confidence level:

$$95\%\ \text{CI} = \sqrt{\boldsymbol{v_{\theta,ii}}} \times \text{t}\ (95\%, \text{DoF})\ \text{for i} = 1, \ldots, N_\theta \quad (12)$$

$$t_i = \frac{\hat{\boldsymbol{\theta}}_{\boldsymbol{i}}}{95\%\ Confidence\ Interval_i} \quad (13)$$

The *t*-value for each parameter was calculated by dividing the parameter estimate by the 95% confidence interval, as shown in Eq. 13. A high *t*-value indicates a reliable parameter estimate, while a low *t*-value suggests that the confidence interval may include zero, implying the parameter might not be statistically significant and could be excluded from the model, and the corresponding uncertainty is then computed for each parameter estimates.

## 2.5 Conversion of Methane

The conversion of methane is the KPI used in this study, and it is defined in Eq. 14 as the ratio

$$\alpha = \frac{Y_{CH_4} - y}{Y_{CH_4}}, \quad (14)$$

where $Y_{CH_4}$ and $y$ are the inlet and outlet concentration of methane respectively [12]. To account for uncertainties in methane conversion, error propagation of the uncertainties associated with the conversion was performed using statistical methods [16].

## 2.6 Preliminary Dataset

The preliminary dataset used in this study was derived from a series of experiments designed using DoE as reported in [11], aimed at investigating the kinetics of complete methane oxidation over the $Pd/Al_2O_3$ catalyst.

## 2.7 Performance Metrics for the Design Scenarios

Results are compared in terms of (a) conversion and

associated uncertainty; (b) operating conditions in the design space; (c) parameter estimation significance after the stopping criteria are reached; (d) number of experiments required to satisfy stopping criteria. Simulations for the three different scenarios were all implemented in Python including SciPy library functions, *scalar* and *minimize* functions while a custom class called Gaussian Regressor was specifically developed to solve the BO scenario.

## 3 RESULTS & DISCUSSION

This section compares the three (3) different scenarios using the performance metrics from 2.7.

### 3.1 Methane Conversion and Associated Uncertainty

Table 2 illustrates the conversion percentages and associated uncertainties for GOOED, MBDoE, and BO under the evaluated scenarios. Key observations are the following:

**GOOED:** Exhibited the highest conversion with values as high as 97 – 99%, but with high uncertainty, highlighting variability in the results.

**MBDoE**: Delivered a moderate conversion values hovering at 45% with low uncertainty values ensuring reliability and consistency.

**BO**: Achieved an optimal conversion (~87%) with moderate uncertainty, obtaining a balance between performance and reliability. Table 2 compares the scenarios, showing how GOOED maximizes conversion, MBDOE minimizes uncertainty, and BO essentially balances both objectives.

**Table 2:** Methane Conversion and Corresponding Uncertainty for GOOED, MBDOE, and BO Scenarios

| Exp | GOOED Scenario | MBDOE Scenario | BO Scenario |
|---|---|---|---|
| 13 | 99.00±94.00 | 42.90 ±0.57 | 43.9 ±9.81 |
| 14 | 99.04±64.00 | 88.90 ±0.37 | 87.45 ±5.78 |
| 15 | 97.70 ± 4.00 | 40.30 ±0.18 | 88.01 ±5.08 |
| 16 | 97.93 ± 4.26 | 37.00 ±0.16 | 87.71 ±4.98 |
| 17 | 97.95 ± 4.26 | 46.40 ±0.13 | 87.72 ±4.85 |
| 18 | 98.07 ± 4.28 | 79.20 ±0.08 | 87.72 ±4.78 |
| 19 | 98.07 ± 4.04 | 48.40 ±0.06 | 87.72 ±4.65 |
| 20 | 98.06 ± 4.13 | 44.80 ±0.05 | 88.01 ±4.08 |

### 3.2 Operating Conditions in the Design Space

Figures 2a, 2b, and 2c illustrates the distribution of the reactor conditions in the experimental design space for GOOED, MBDOE, and BO campaigns. Key observations include:

**GOOED:** The reactor conditions identified reflects a strong exploitation of known high-performing conditions, with no emphasis on uncertainty reduction**.**

**MBDoE:** The reactor conditions for this scenario show transition from exploration to exploitation ensures improved system understanding while maintaining reliability in predictions**.**

**BO:** The reactor conditions selected by BO demonstrate a balance between exploration and exploitation by achieving average conversion rates while exploring under-characterized areas for further improvement. The oxygen-to-methane ratio for the simulated reactor condition for the three scenarios is reported in Table 3.

**Table 3.** Simulated Oxygen to Methane Mole Ratio in (mol/mol)

| Exp | GOOED | MBDOE | BO |
|---|---|---|---|
| 13 | 3.8 | 3.9 | 3.5 |
| 14 | 4 | 4 | 3.9 |
| 15 | 4 | 4 | 3.9 |
| 16 | 4 | 4 | 4 |
| 17 | 3.7 | 4 | 3.9 |
| 18 | 4 | 2 | 3.9 |
| 19 | 3.9 | 2.1 | 4 |
| 20 | 3.8 | 2.1 | 3.9 |

### 3.3 Parameter Estimation Statistics

For the evaluation metrics based on significance of parameter estimates, we focused on only two of the scenarios: GOOED, and MBDOE. This is because BO is a data-driven process and has no kinetic model parameter representation.

**GOOED:** At the end of the twenty (20) experiments, the t-test value for the 4th parameter failed the test as its value were less than the reference *t*-value as shown in Table 4.

**MBDoE:** For this scenario, the parameter estimates all passed the t-test evaluation successfully as shown in Table 4, this occurred at the 17th experiment making it one of the most efficient scenarios based on minimum number of experiments, and uncertainty. Table 4 shows that *t*-values obtained from MBDoE were statistically significant, including the critical parameter $\boldsymbol{\theta_4}$, at the end of the 17$^{th}$ experiment as their values were all greater than the reference.

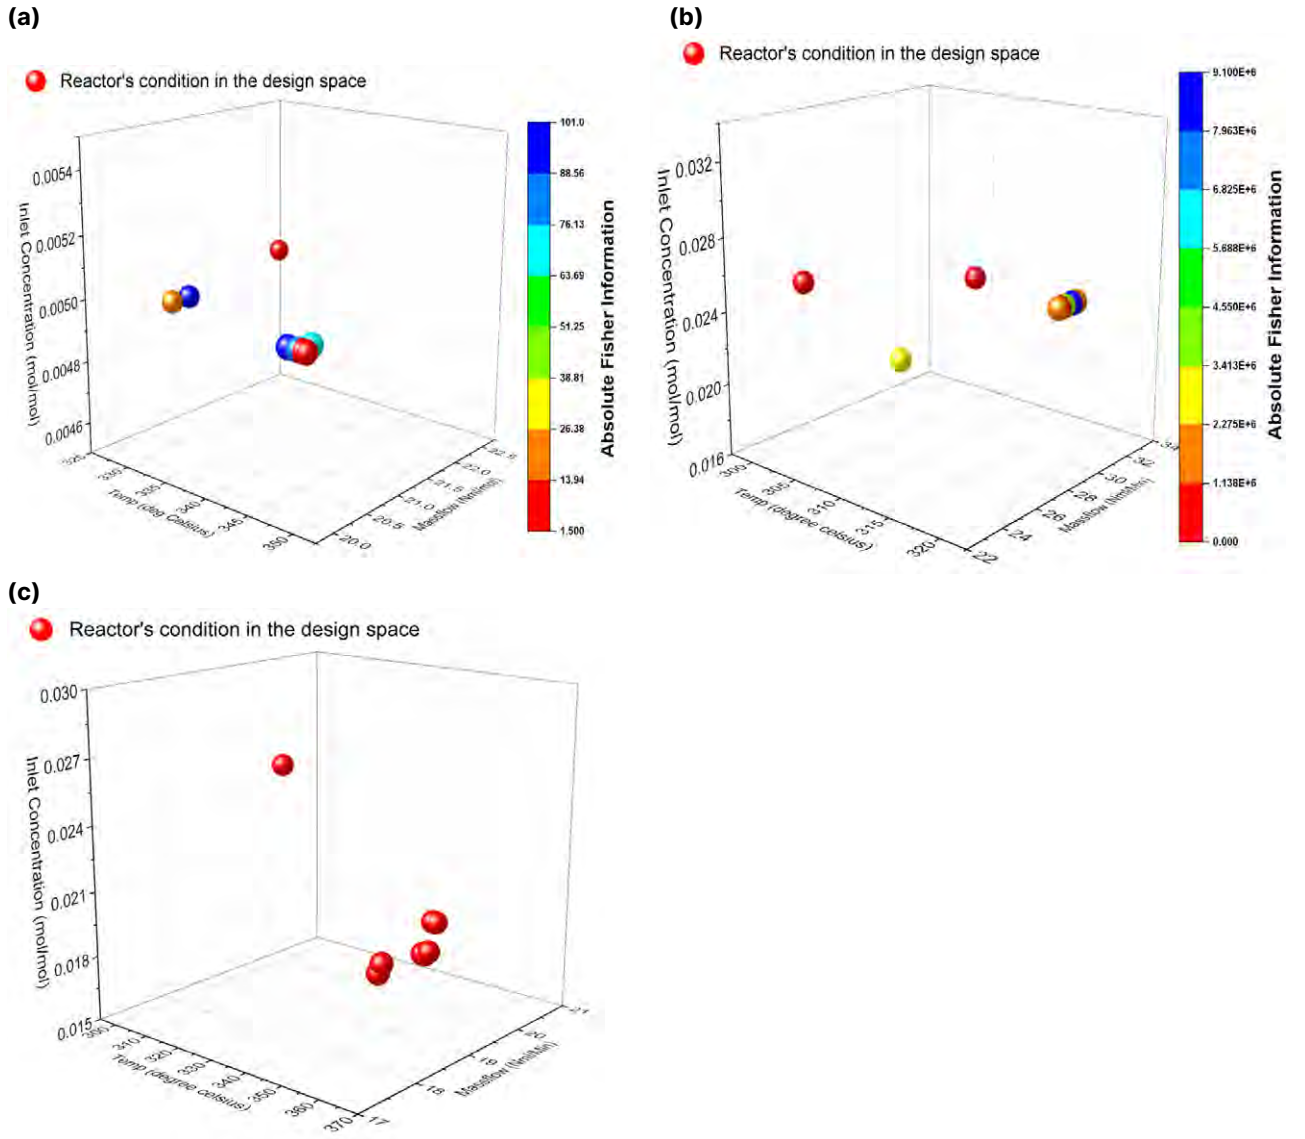

**Figure 2.** Plot of reactor conditions within the design space for the three scenarios: (a) GOOED, (b) MBDOE, (c) BO, respectively. The subplot (c) shows no Fisher information as they are not computed for the BO scenario

**Table 4.** Parameter estimation results for GOOED & MBDoE after stopping criteria successfully terminated (the reference *t*-value is $t^{ref}$ = 1.67, the parameter failing the t-test is indicated in boldface).

| S/N | Parameters | GOOED Estimates | *t*-value | MBDoE Estimates | *t*-value |
|---|---|---|---|---|---|
| 1 | $\boldsymbol{\theta_1}$ | 6.08 | 13.02 | 5.92 | 17.48 |
| 2 | $\boldsymbol{\theta_2}$ | 7.43 | 1.91 | 6.86 | 2.24 |
| 3 | $\boldsymbol{\theta_3}$ | 5.54 | 6.41 | 4.06 | 3.77 |
| 4 | $\boldsymbol{\theta_4}$ | 7.52 | 0.94 | 9.84 | 1.74 |
| 5 | $\boldsymbol{\theta_5}$ | 9.84 | 11.69 | 10.52 | 111.17 |
| 6 | $\boldsymbol{\theta_6}$ | 7.70 | 1.715 | 6.96 | 6.23 |

## 3.4 Number of Experiments

The minimum number of experiments (see Table 5) required to achieve optimal conditions were based on the pre-defined stopping criteria. The MBDOE achieved the lowest number of experimental runs as the parameters were successfully estimated at the 17th experiment.

**Table 5**. Minimum no. of experiments required

| **Scenarios** | GOOED | MBDOE | BO |
|---|---|---|---|
| **No of Experiment** | 20 | 17 | 20 |

## 3.5 Optimizing Conversion with Reduced uncertainty

In this study, the MBDOE demonstrated reduced

uncertainty, and required the fewest experiments. At the 17th experiment, it satisfied the stopping criteria. To validate the strength and performance of this scenario (MBDOE), we optimized the system to achieve maximum conversion at the 17th experiment for this scenario and the method achieved a predicted conversion of 95% which is a good conversion value for the system.

### 3.6 Best Scenario performance

The best scenario included the scenario providing the highest conversion value of methane, lowest value of conversion uncertainty and minimum number of experiments. Table 6 shows that MBDOE performed better than the other scenarios, as it had maximum predicted conversion with reduced uncertainty and satisfactory *t*-values with only 17 runs.

**Table 6**. Scenarios and Performance Metrics

| Scenarios | Conversion (%) | Uncertainty (%) | No. of Experiment | *t*-value Results |
|---|---|---|---|---|
| GOOED | 98 | ± 22.87 | 20 | Failed |
| MBDOE | 95 | ± 0.2 | 17 | Passed |
| BO | 87 | ± 5.5 | 20 | N/A |

## 4 CONCLUSION

In comparing GOOED, MBDoE, and BO, distinct differences emerge across conversion, parametric uncertainty, reactor conditions and experimental efficiency. GOOED achieves the highest conversions (98%) but the prediction of the KPI is affected by a significant uncertainty. MBDoE balances exploration and exploitation, delivering a high conversion (~95%) with the lowest uncertainty, requiring only 17 experiments to meet the parameter precision termination criterion. BO, while needing 20 experiments like GOOED, provides a moderate conversion (~87%) associated with a higher uncertainty, because of balancing exploration and exploitation in the design space. Overall, MBDoE proves to be the most efficient method as it shows minimum variance, reduced uncertainty across experiments, maximum conversion of methane and minimum number of experiments required to achieve maximum conversion.

## ACKNOWLEDGEMENTS

The authors are grateful to the Department of Chemical Engineering at University College London (UCL), the Petroleum Technology Development Fund (PTDF) and the Galvanin System Identification Group (GSIG) for their support in this research.

## ABSTRACT

The definition of strategies for operation of process networks is a key research focus in process systems engineering. This challenge is commonly formulated as a numerical constraint satisfaction problem, where most practical algorithms are limited to identifying inner approximations to the feasible operational envelope. Sampling-based approaches so far have only been developed for formulations that required coordinated operation of the units within the network. We propose a decomposition approach that enables decentralized operation for acyclic muti-unit processes by sampling. Our methodology leverages problem structure to decompose unit-wise and deploys surrogate models to couple the resultant subproblems. We demonstrate it on a serial, batch chemical reactor network. In future research, we will extend this framework to consider the presence of uncertain unit parameters robustly.

## INTRODUCTION

### Constraint Satisfaction and Process Operation

Significant interest within the process systems engineering community has been directed towards the numerical solution of constraint satisfaction problems (CSP) to define process operational strategies. This is underpinned by decision problems such as the feasibility and flexibility index, introduced in the early 1980s [1]. In pharmaceutical manufacturing, recent research has focused on design space characterization [2], as the multidimensional combination and interaction of input variables (e.g., material attributes) and process parameters that have been demonstrated to provide assurance of quality. The design space can be understood as the feasible space (FS) of operational parameters that ensure the process' defining constraints are satisfied.

Most research to date has focused on characterizing the FS within single-unit systems, with comparatively less attention to multi-unit systems [3]. However, manufacturing processes are inherently integrated, making it essential to investigate the interactions between unit operations. Typical approaches to identifying multi-unit FS are underpinned by mathematical programming and sampling [1,3]. The former approach is computationally efficient but has limitations in its application. For example, the problem formulation aims to identify a convex inner approximation to the FS – itself generally nonconvex - and defines a multilevel program. Therefore, identifying global optima is a challenge and significantly conservative solutions can be returned. Instead sampling approaches may aim to build a discrete set of operational parameter values that provide an inner approximation to the FS. Given they rely only on model evaluations they are an approach particularly suited to characterizing nonconvex FS [2].

In the context of multi-unit systems, there are two strategies: centralized (CO) and decentralized (DO) operation. These paradigms govern how decisions are made and how constraints are managed across interconnected units within a network. Effective management of such systems requires careful consideration of these strategies, as each offers distinct advantages and trade-offs. CO treats the system monolithically, with decisions made by a single entity that has complete visibility of the entire network. This approach enables the best coordination across units. For example, a CO can adjust upstream and downstream parameters jointly to meet constraints, ensuring that the system operates cohesively. However, it often requires complex communication

systems and can face bottlenecks when dealing with high-dimensional problems [5]. DO divides the system into smaller, autonomous units that make decisions locally. Each unit operates within its defined FS, independently of upstream or downstream units. This implies the decentralized FS is a subset of the centralized one. This approach reduces the need for communication and enables robust operations, particularly in distributed systems where central coordination is impractical. This autonomy enhances fault tolerance and scalability [5]. However, DO requires local FS to account for all possible interactions between adjacent units, which may lead to significantly reduced flexibility.

## Contributions

Two major challenges exist in the identification of decentralized multi-unit FS through sampling. The first is the system dimensionality. Applying the logic of the curse of dimensionality, as the size of the process network grows, the volume of the search space increases exponentially, which can imply a dramatic increase in computational expense. In this research, a decomposition strategy is proposed that formulates a series of unit-wise problems, solved incrementally via sampling. In doing so, the approach exploits network structure, retaining the advantages of sampling solutions and mitigating the curse of dimensionality. The second challenge is ensuring that the solution returned provides an FS of maximum volume. In the discussion below, we outline a methodology that leverages this network structure to enhance sampling efficiency for identification of a solution set of maximum volume. The key contributions include:

1. Developing a class of CSPs built upon a directed acyclic graph (DAG) structure representative of the process network to define a DO strategy.
2. Introducing constraint propagation methods that work relative to a precedence order defined by the DAG structure of the CSP.
3. Applying sampling-based solvers for constraint propagation to identify decentralized FS for multi-unit systems.
4. Formulation of a log marginal likelihood maximisation to optimize the volume of FS solution returned.

The paper is organised as follows. Section 2 introduces the methodology, then Section 3 provides details of case study and results, and conclusions are provided in Section 4. Note that details of sampling approaches to solve relevant CSP are omitted for conciseness. For discussion the reader is directed to [2].

# METHODOLOGY

## Problem Statement

The problem setup assumes a network of interconnected unit operations. This can be represented on a DAG, $\mathcal{G} \coloneqq (\mathcal{N}, \mathcal{E})$, where $\mathcal{N}$ is the set of units, denoted as $\mathcal{N} \coloneqq \{1, \dots, N\}$, and $\mathcal{E}$ represents the edges, which denote the order of connection between units, with $(i, j) \in \mathcal{E}$ indicating a connection from unit $i$ to unit $j$. The connectivity of the graph may also be expressed using an asymmetric adjacency matrix $A \in \{0,1\}^{N \times N}$, where $A_{i,j} = 1$ indicates a directed flow between unit $i$ and unit $j$. The following data and restrictions are assumed for simplicity of presentation:

- A set of upstream units, $\mathcal{N}_i^{in} \subset \mathcal{N}$, with $card(\mathcal{N}_i^{in}) \leq 1$, which provide feed streams to unit $i \in \mathcal{N}$ .
- A set of downstream units, $\mathcal{N}_i^{out} \subset \mathcal{N}$, with $card(\mathcal{N}_i^{out}) \leq 1$, which receive product streams from unit $i \in \mathcal{N}$.
- The attributes, $\boldsymbol{u}_i^j \in \mathbb{R}^{n_{u_{ij}}}$, of any feed stream connected to unit $i$ from upstream unit $j \in \mathcal{N}_i^{in}$.
- The attributes, $\boldsymbol{y}_i^k \in \mathbb{R}^{n_{y_{ik}}}$, of any product stream from unit $i$ connected to downstream unit $k \in \mathcal{N}_i^{out}$.
- The properties of the product streams of unit $i$ defined as,

$$\boldsymbol{y}_i^k = \boldsymbol{F}_i^k\,(\boldsymbol{v}_i, \boldsymbol{u}_i), \tag{1}$$

where $\boldsymbol{v}_i \in \mathbb{R}^{n_{v_i}}$ are process parameters local to unit $i$, and $\boldsymbol{u}_i \coloneqq \left(\boldsymbol{u}_i^j\right)_{j \in \mathcal{N}_i^{in}} \in \mathbb{R}^{n_{u_i}}$ denotes the concatenation of all inlet stream properties to unit $i$.

- The connection between the stream properties at the outlet of unit $i$ and those at the inlet of the downstream unit $k \in \mathcal{N}_i^{out}$, related by,

$$\boldsymbol{u}_k^i = \mathbf{C}_k^i(\boldsymbol{y}_k^i)\,. \tag{2}$$

- The inequality constraint functions imposed on each unit in the process train, expressed,

$$\mathbf{G}_i(\boldsymbol{v}_i, \boldsymbol{u}_i) \coloneqq \boldsymbol{g}_i(\boldsymbol{v}_i, \boldsymbol{u}_i, \boldsymbol{y}_i) \preccurlyeq \mathbf{0}. \tag{3}$$

Using the data associated with the setup, the centralized problem formulation is defined [3],

$$\mathbb{V}_{\mathrm{CO}} \coloneqq \left\{ \boldsymbol{v} \in \mathcal{K}_v \;\middle|\; \begin{array}{c} \forall i \in \mathcal{N}, \exists\, (\boldsymbol{u}_i, \boldsymbol{y}_i) \in \mathbb{R}^{n_{u_i}} \times \mathbb{R}^{n_{y_i}} : \\ \mathbf{0} \succcurlyeq \mathbf{G}_i(\boldsymbol{v}_i, \boldsymbol{u}_i) \\ \boldsymbol{y}_i^k = \mathbf{F}_i^k(\boldsymbol{v}_i, \boldsymbol{u}_i), \forall k \in \mathcal{N}_i^{out} \\ \boldsymbol{u}_k^i = \mathbf{C}_k^i(\boldsymbol{y}_k^i), \forall k \in \mathcal{N}_i^{out} \end{array} \right\}, \tag{4}$$

with $\mathcal{K}_v \coloneqq \prod_{\mathrm{i} \in \mathcal{N}} \mathcal{K}_{v_i} \subset \mathbb{R}^{n_v}$ denoting a compact set defined through prior knowledge. In [3], a solution approach is provided by approximately solving unit-wise subproblems,

$$\mathbb{VU}_{i,CO} := \left\{ (\boldsymbol{v}_i, \boldsymbol{u}_i) \in \mathcal{K}_{vu_i} \;\middle|\; \begin{array}{c} \mathbf{0} \succcurlyeq \mathbf{G}_i(\boldsymbol{v}_i, \boldsymbol{u}_i) \\ \forall k \in \mathcal{N}_i^{out}, \exists (\boldsymbol{v}_k, \boldsymbol{u}_k) \in \mathbb{VU}_{k,CO}: \\ \boldsymbol{u}_k^i = \mathbf{C}_k^i \left( \mathbf{F}_i^k (\boldsymbol{v}_i, \boldsymbol{u}_i) \right) \\ \forall j \in \mathcal{N}_i^{in}, \exists (\boldsymbol{v}_j, \boldsymbol{u}_j) \in \mathbb{VU}_{j,CO}: \\ \boldsymbol{u}_i^j = \mathbf{C}_i^j \left( \mathbf{F}_j^i (\boldsymbol{v}_j, \boldsymbol{u}_j) \right) \end{array} \right\}. \quad (5)$$

An exact solution to these subproblems ensures that the unit-wise parameters, $(\boldsymbol{v}_i, \boldsymbol{u}_i)$, i) satisfy constraints defined on the unit, ii) produce output stream properties that in turn provide feasible input stream properties to downstream units $k \in \mathcal{N}_i^{out}$, and iii) all input variables $\boldsymbol{u}_i$ are produced as a result of feasible operation of upstream units $j \in \mathcal{N}_i^{in}$.

The decentralized FS is a subset, $\mathbb{V}_{DO} \subseteq \mathbb{V}_{CO}$, of the centralized. A decentralized unit-wise subproblem may also be defined,

$$\mathbb{VU}_{i,DO} := \left\{ (\boldsymbol{v}_i, \boldsymbol{u}_i) \in \mathcal{K}_{vu_i} \;\middle|\; \begin{array}{c} \mathbf{0} \succcurlyeq \mathbf{G}_i(\boldsymbol{v}_i, \boldsymbol{u}_i) \\ \forall k \in \mathcal{N}_i^{out}, \exists (\boldsymbol{v}_k, \boldsymbol{u}_k) \in \mathbb{VU}_{k,DO}: \\ \boldsymbol{u}_k^i = \mathbf{C}_k^i \left( \mathbf{F}_i^k (\boldsymbol{v}_i, \boldsymbol{u}_i) \right) \\ \forall j \in \mathcal{N}_i^{in}, \forall (\boldsymbol{v}_j, \boldsymbol{u}_j) \in \mathbb{VU}_{j,DO}: \\ \boldsymbol{u}_i^j = \mathbf{C}_i^j \left( \mathbf{F}_j^i (\boldsymbol{v}_j, \boldsymbol{u}_j) \right) \end{array} \right\}. \quad (6)$$

This subproblem (6) differs subtly from (5) and ensures that the unit-wise parameter values $\boldsymbol{v}_i$, i) satisfy constraints defined on the unit, and ii) produce output stream properties that in turn provide feasible input stream properties to downstream units $k \in \mathcal{N}_i^{out}$ for all input variables values $\boldsymbol{u}_i$ produced as a result of feasible operation of upstream units $j \in \mathcal{N}_i^{in}$. Solving these unit-wise subproblems and taking the Cartesian product, $\mathbb{V}_{DO} := \prod_{i \in \mathcal{N}} \mathbb{V}_{i,DO}$ of the projection of the sets, $\mathbb{VU}_{i,DO}$ onto the subspace of unit-wise process parameters, $\mathbb{V}_{i,DO}$, yields the decentralized FS.

In practice, solving (6) is challenged as solution to any given unit requires knowledge of the solution to all other unit subproblems, i.e. one must already know a solution $\mathbb{V}_{DO}$. In the following, a sampling-based graph decomposition methodology is proposed that aims to identify a solution that maximizes a measure of the volume of $\mathbb{V}_{DO}$ with a minimum number of model evaluations.

## A Decomposition Approach

In this section, a sampling-based solution algorithm that acts with respect to a precedence ordering defined on the graph, $\mathcal{G}$, is presented. The algorithm provides incremental solution of unit-wise subproblems $i \in \mathcal{N}$, which provide approximations to,

$$\mathbb{V}_{i,DO} := \left\{ \boldsymbol{v}_i \in \boldsymbol{\mathcal{K}}_{v_i} \;\middle|\; \forall k \in \mathcal{N} \backslash \{i\}, \exists \boldsymbol{v}_k \in \mathcal{K}_{v_k}: (\boldsymbol{v}_j)_{j \in \mathcal{N}} \in \mathbb{V}_{DO} \right\},$$

where $\mathbb{V}_{DO} := \prod_{i \in \mathcal{N}} \mathbb{V}_{i,DO}$. Our main hypothesis is that a) solving this sequence of subproblems is more sample efficient than solving the problem directly, b) that doing so enables tuning of the solution set identified, and c) the solution yielded may be less conservative than other approaches by inheriting the advantages of sampling.

## Subproblem relaxations and propagations

In the following, two subproblem relaxations are presented that represent two separate steps of the methodology. The first is referred to as the backward propagation; and the second, the forward propagation. They are applied sequentially to approximate (6).

The backward propagation has previously been presented in [3], and so its presentation is brief. The subproblem relaxation deletes constraints enforcing feasible operation upstream,

$$\mathbb{VU}_{i,DO}^{(\mathrm{b})} := \left\{ (\boldsymbol{v}_i, \boldsymbol{u}_i) \in \mathcal{K}_{vu_i}^{(\mathrm{b})} \;\middle|\; \begin{array}{c} \mathbf{0} \succcurlyeq \mathbf{G}_i(\boldsymbol{v}_i, \boldsymbol{u}_i) \\ \forall k \in \mathcal{N}_i^{out}, \exists (\boldsymbol{v}_k, \boldsymbol{u}_k) \in \mathbb{VU}_{k,DO}^{(\mathrm{b})}: \\ \boldsymbol{u}_k^i = \mathbf{C}_k^i \left( \mathbf{F}_i^k (\boldsymbol{v}_i, \boldsymbol{u}_i) \right) \end{array} \right\} \quad (7)$$

with constraints only considering operational viability of the unit and those downstream. The search space $\mathcal{K}_{vu_i}^{(\mathrm{b})} := \mathcal{K}_{v_i} \times \mathcal{K}_{u_i}^{(b)}$ is estimated via an initialization procedure presented later in this paper. As discussed in [3], the relaxation admits an initial leaf unit problem that may be solved, given $\mathcal{N}_i^{out} = \emptyset$. As a result, the solution is according to the reverse of the precedence ordering. In principle the cartesian product set, $\mathbb{V}_{DO}^{(b)} = \prod_{i \in \mathcal{N}} \mathbb{V}_{i,DO}^{(b)}$ could be used as a search space reduction for identification of (4) as discussed in [3].

Utilizing the intermediate results in estimation of $\mathbb{VU}_{i,DO}^{(b)}$, the forward propagation is defined,

$$\mathbb{VU}_{i,DO}^{(\mathrm{f})} := \left\{ (\boldsymbol{v}_i, \boldsymbol{u}_i) \in \mathbb{VU}_{i,DO}^{(\mathrm{b})} \;\middle|\; \begin{array}{c} \mathbf{0} \succcurlyeq \mathbf{G}_i(\boldsymbol{v}_i, \boldsymbol{u}_i) \\ \forall k \in \mathcal{N}_i^{out}, \exists (\boldsymbol{v}_k, \boldsymbol{u}_k) \in \mathbb{VU}_{k,DO}^{(\mathrm{b})}: \\ \boldsymbol{u}_k^i = \mathbf{C}_k^i \left( \mathbf{F}_i^k (\boldsymbol{v}_i, \boldsymbol{u}_i) \right) \\ \forall j \in \mathcal{N}_i^{in}, \forall (\boldsymbol{v}_j, \boldsymbol{u}_j) \in \mathbb{VU}_{j,DO}^{(\mathrm{f})}: \\ \boldsymbol{u}_i^j = \mathbf{C}_i^j \left( \mathbf{F}_j^i (\boldsymbol{v}_j, \boldsymbol{u}_j) \right) \end{array} \right\}. \quad (8)$$

In addition to the properties of (7), (8) enforces that the selection of $\boldsymbol{v}_i$ be feasible given any unit input stream property from feasible upstream operation $j \in \mathcal{N}_i^{in}$. In contrast to (7), however, these subproblems are solved according to the precedence ordering of $\mathcal{G}$ proceeding from the root node forward. A solution may then be identified as $\mathbb{V}_{DO} = \prod_{i \in \mathcal{N}} \mathbb{V}_{i,DO}^{(\mathrm{f})}$.

## Approximate solutions for general problems

Due to the general assumptions made in problem definition, identifying closed forms for these approximations is highly challenging. Instead, as in [3], adaptive sampling schemes are deployed to gain a discrete inner-approximation $\overline{\mathbb{VU}}_{i,DO}^{(d)} \subset \mathbb{VU}_{i,DO}^{(d)} \quad \forall\, d \in \{b, f\}$.

Parameterizations may then be identified to tackle (7) and (8).

## Parameterizing the extended feasible space

As in [3] binary classifiers, $\overline{\mathbf{G}}_i: \mathbb{R}^{n_{v_i}} \times \mathbb{R}^{n_{u_i}} \to \mathbb{R}$ are learned to parameterize $\mathbb{VU}_{i,DO}^{(d)}$, as follows,

$$\mathbb{VU}_{i,DO}^{(\mathrm{d})} \approx \left\{(\boldsymbol{v}_i, \boldsymbol{u}_i) \in \mathcal{K}_{vu_i}^{(\mathrm{d})} \middle| 0 \geq \overline{\mathbf{G}}_i^{(\mathrm{d})}(\boldsymbol{v}_i, \boldsymbol{u}_i)\right\},$$

using training data generated in sampling the solution, $\overline{\mathbb{VU}}_{i,DO}^{(d)}$. Having detailed means to approximate the relaxations, discussion moves to outline a three-step solution methodology based on defining subproblems amenable to sampling solutions.

## Step 0: Initialization of the unit-wise search spaces

First, estimate of $\mathcal{K}_{u_i}^{(b)}\ \forall i \in \mathcal{N}$ is gained through a box-outer approximation to data generated from a sampling-based initialization procedure. The data is generated by forward simulation of the process network under parameter values, $\boldsymbol{v}$, sampled from $\mathcal{K}_v$ according to a Latin hypercube design.

## Step 1: Backward Propagation

Then, as in [3], approximation is made to (7). The existence conditions in (7) are recast as auxiliary optimization problems,

$$\mathbb{VU}_{i,DO}^{(\mathrm{b})} \approx \left\{(\boldsymbol{v}_i, \boldsymbol{u}_i) \in \mathcal{K}_{vu_i}^{(\mathrm{b})} \middle| \begin{array}{c} \mathbf{0} \succcurlyeq \mathbf{G}_i(\boldsymbol{v}_i, \boldsymbol{u}_i) \\ \forall k \in \mathcal{N}_i^{out}:\ 0 \geq \min\limits_{\boldsymbol{v}_k, \boldsymbol{u}_k} \overline{\mathbf{G}}_k^{(\mathrm{b})}(\boldsymbol{v}_k, \boldsymbol{u}_k) \\ s.t.\ \boldsymbol{u}_i^i = \mathbf{C}_k^i\left(\mathbf{F}_i^k(\boldsymbol{v}_i, \boldsymbol{u}_i)\right) \end{array}\right\}.$$

The solution set is sampled, $\overline{\mathbb{VU}}_{i,DO}^{(b)} \subset \mathbb{VU}_{i,DO}^{(b)}$, through evaluation of the process model and constraints $\mathbf{G}_i(\cdot)$ and solution of a box-constrained nonlinear program (NLP). It is worth noting that the equality constraint is reduced into the objective, as $\boldsymbol{u}_k^i$ is provided through evaluation of the process model; additionally, the surrogate constraints $\overline{\mathbf{G}}_k^{(\mathrm{b})}(\cdot)$ are available from the solution of units $k \in \mathcal{N}_i^{out}$.

## Step 2: Forward Propagation

With the approximation to (7) completed, approximation to (8) is then made. The robustness conditions in (8) are recast as auxiliary optimization problems. Conveniently evaluation of the existence conditions and constraints in (8) is avoided via the approximation. This removes the requirement for further process model evaluations, and instead only relies on the solution to general NLP defined on surrogates,

$$\mathbb{VU}_{i,DO}^{(\mathrm{f})} \approx \left\{(\boldsymbol{v}_i, \boldsymbol{u}_i) \in \mathbb{VU}_{i,DO}^{(\mathrm{b})} \middle| \begin{array}{c} \left.\begin{array}{c} 0 \geq \max\limits_{(\boldsymbol{v}_j, \boldsymbol{u}_j) \in \mathbb{VU}_{j,DO}^{(\mathrm{f})}} \overline{\mathbf{G}}_i^{(\mathrm{b})}(\boldsymbol{v}_i, \boldsymbol{u}_i) \\ s.t.\ \boldsymbol{u}_i^j = \overline{\boldsymbol{F}}_{j\to i}\left(\boldsymbol{v}_j, \boldsymbol{u}_j\right), \forall j \in \mathcal{N}_i^{in} \end{array}\right\}(i) \\ \left.\begin{array}{c} \forall j \in \mathcal{N}_i^{in}: \quad 0 \geq \min\limits_{(\boldsymbol{v}_j, \boldsymbol{u}_j) \in \mathbb{VU}_{j,DO}^{(\mathrm{b})}} \overline{\mathbf{G}}_j^{(\mathrm{b})}\left(\boldsymbol{v}_j, \boldsymbol{u}_j\right) \\ s.t.\ \boldsymbol{u}_i^j = \overline{\boldsymbol{F}}_{j\to i}\left(\boldsymbol{v}_j, \boldsymbol{u}_j\right) \end{array}\right\}(ii) \end{array}\right\}$$

where $\overline{\boldsymbol{F}}_{j\to i}(\cdot) \approx \boldsymbol{C}_i^j\left(\mathbf{F}_j^i(\cdot)\right)$ is an ML regressor identified in the backward propagation. Within the formulation above, (i) enforces conditions on $\boldsymbol{v}_i \in \mathbb{V}_{i,DO}^{(\mathrm{f})}$ with (ii) enforcing restrictions on $\boldsymbol{u}_i \in \mathbb{U}_{i,DO}^{(\mathrm{f})}$, such that $\mathbb{VU}_{i,DO}^{(\mathrm{f})} = \mathbb{V}_{i,DO}^{(\mathrm{f})} \times \mathbb{U}_{i,DO}^{(\mathrm{f})}$. Specifically, (i) ensures that the selection of $\boldsymbol{v}_i$ satsfies constraints defined on the unit, and that outlet stream properties ensure feasibility downstream, no matter the operation of units upstream; whereas (ii) enables identification of the set of unit input stream properties arising from feasible operation upstream, identification of which is required for the purpose of decomposition. It is worth noting that the root node problems have no upstream units and so are only constituted by a modified variant of (i),

$$\mathbb{VU}_{i,DO}^{(\mathrm{f})} \approx \left\{(\boldsymbol{v}_i, \boldsymbol{u}_i) \in \mathbb{VU}_{i,DO}^{(\mathrm{b})} \middle| 0 \geq \overline{\mathbf{G}}_i^{(\mathrm{b})}(\boldsymbol{v}_i, \boldsymbol{u}_i)\ \right\} \quad \forall i \in \mathcal{N}^r$$

with $\mathcal{N}^r = \left\{ i \in \mathcal{N} \mid \mathcal{N}_i^{in} = \emptyset \right\}$. As before solution sets are sampled $\overline{\mathbb{VU}}_{i,DO}^{(f)} \subset \mathbb{VU}_{i,DO}^{(f)}$, and a solution returned as $\mathbb{V}_{DO} \approx \prod_{i\in\mathcal{N}} \overline{\mathbb{V}}_{i,DO}^{(f)}$.

## Tuning step 2: A classifier backoff strategy

In most cases, multiple solution sets, $\mathbb{V}_{DO}$, exist, corresponding to different allocations of operational flexibility to each unit. Solving step 2 as defined provides greater operational flexibility to upstream units. To balance operational flexibility, we introduce tuning parameters, $\boldsymbol{\epsilon} \in \mathbb{R}_+^N$, in the forward propagation – one for each unit,

$$\mathbb{VU}_{i,DO}^{(\mathrm{f})}(\boldsymbol{\epsilon}) \approx \left\{(\boldsymbol{v}_i, \boldsymbol{u}_i) \in \mathbb{VU}_{i,DO}^{(\mathrm{b})} \middle| \begin{array}{c} 0 \geq \max\limits_{(\boldsymbol{v}_j, \boldsymbol{u}_j) \in \mathbb{VU}_{j,DO}^{(\mathrm{f})}(\boldsymbol{\epsilon})} \overline{\mathbf{G}}_i^{(\mathrm{b})}(\boldsymbol{v}_i, \boldsymbol{u}_i) + \epsilon_i \\ s.t.\ \boldsymbol{u}_i^j = \overline{\boldsymbol{F}}_{j\to i}\left(\boldsymbol{v}_j, \boldsymbol{u}_j\right), \forall j \in \mathcal{N}_i^{in} \\ \forall j \in \mathcal{N}_i^{in}: \quad 0 \geq \min\limits_{(\boldsymbol{v}_j, \boldsymbol{u}_j) \in \mathbb{VU}_{j,DO}^{(\mathrm{b})}} \overline{\mathbf{G}}_j^{(\mathrm{b})}\left(\boldsymbol{v}_j, \boldsymbol{u}_j\right) + \epsilon_j \\ s.t.\ \boldsymbol{u}_i^j = \overline{\boldsymbol{F}}_{j\to i}\left(\boldsymbol{v}_j, \boldsymbol{u}_j\right) \end{array}\right\},$$

with root node unit problems adjusted appropriately. This implies the solution set is dependent on the parameters, $\mathbb{V}_{DO}(\boldsymbol{\epsilon})$. In the following, we utilize an adaptive sampling scheme, namely nested sampling as in [2] to provide a discrete inner approximation $\overline{\mathbb{VU}}_{i,DO}^{(\mathrm{f})}(\boldsymbol{\epsilon}) \subset \mathbb{VU}_{i,DO}^{(\mathrm{f})}(\boldsymbol{\epsilon})$. Nested sampling was initially proposed to estimate the marginal likelihood in Bayesian estimation problems. In the context of feasibility, the marginal likelihood has an interpretation as a measure of the volume of a set. Here,

we exploit this as means of defining an objective for tuning the backoffs,

$$\min_{\boldsymbol{\epsilon}} -\sum_{i\in\mathcal{N}} \log Z_i(\boldsymbol{\epsilon}) \tag{9}$$

where $Z_i(\boldsymbol{\epsilon}) = \int_{(\boldsymbol{v},\boldsymbol{u})\in K_{vu_i}} l_i\,(\boldsymbol{v}_i,\boldsymbol{u}_i,\boldsymbol{\epsilon}) p(\boldsymbol{v}_i,\boldsymbol{u}_i) d(\boldsymbol{v}_i,\boldsymbol{u}_i)$ is the marginal likelihood associated with the solution to the unit $i$ subproblem, $\mathbb{VU}_{i,DO}^{(\mathrm{f})}(\boldsymbol{\epsilon})$. In implementation, $l_i\colon \mathcal{K}_{vu_i} \times \mathbb{R}_+^{\mathrm{N}} \to \mathbb{R}$ is a continuous, non-negative monotonic approximation to the indicator function which assesses set-membership. Here $l_i(\boldsymbol{v}_i,\boldsymbol{u}_i,\boldsymbol{\epsilon}) = \prod_{l\in\{i\}\cup\mathcal{N}_i^{in}} l_{i,l}\,(\boldsymbol{v}_i,\boldsymbol{u}_i,\epsilon_l)$,

$$l_{i,l}(\boldsymbol{v}_i,\boldsymbol{u}_i,\epsilon_l) = \begin{cases} sigmoid(0) & \boldsymbol{if}\ z_{i,l}^*(\boldsymbol{v}_i,\boldsymbol{u}_i,\epsilon_l) \le 0 \\ sigmoid\left(-z_{i,l}^*(\boldsymbol{v}_i,\boldsymbol{u}_i,\epsilon_l)\right) & \boldsymbol{otherwise} \end{cases}$$

with $sigmoid(\cdot)$ indicating the univariate, scalar sigmoid function, and $z_{i,l}^*(\boldsymbol{v}_i,\boldsymbol{u}_i,\epsilon_l)$ indicating the optimal objective value of the $l^{th}$ auxiliary optimization problem, or the tightened constraint value in the case of the root-node, in the approximate forward propagation, $\mathbb{VU}_{i,DO}^{(\mathrm{f})}(\boldsymbol{\epsilon})$. Given the use of $l_i(\cdot)$ and assessment of the unit-wise subproblems, $\mathbb{VU}_{i,DO}^{(f)}(\boldsymbol{\epsilon})$, rather than the indicator function itself and the unit-wise projections, $\mathbb{V}_{i,DO}^{(f)}(\boldsymbol{\epsilon})$, this yields an approximation to a measure of the FS.

# CASE STUDY

## Problem formulation

We demonstrate the decomposition approach on a batch chemical reactor network that consists of two batch reactors connected in series. The reaction mechanism characterizing the reactors is the same, and is that described in [3],

$$2A \to^{k_1} B \to^{k_2} C$$

where component B is the desired product. The reactor dynamics are ODEs that describe the evolution of component molar concentrations in continuous time. The system adheres to Arrhenius kinetics, with $k_r(T)$, indicating the temperature $(T)$ dependent rate constant of reaction step $r \in \{1,2\}$. For the definition of these Arrhenius kinetics please refer to the Digital Supplementary. The volume of both reactors is assumed $V = 1$ m$^3$. Each ODE system is given by,

$$\begin{aligned} \dot{c}_{A,j}(t) &= -2k_1(T_j)c_{A,j}(t)^2 \\ \dot{c}_{B,j}(t) &= \mathrm{k_1(T_j)c_{A,j}(t)^2} - \mathrm{k_2(T_j)c_{B,j}(t)} \\ \dot{c}_{C,j}(t) &= \mathrm{k_2(T_j)c_{B,j}(t)} \end{aligned}$$

where $c_{i,j}(t)$ $(kmol\,m^{-3})$ describes the molar concentration of component $i$ in reactor $j$; and $T_j$, the temperature in reactor $j$. Each reactor is operated over a time horizon, $t \in [0,\ \tau_j\ ]$, where $\tau_j$ is the batch time. The initial concentration of the first reactor is fixed, whereas the initial concentration of the second reactor is the first reactor's composition at the end of operation, subject to separation of C, as presented in [3]. This separation is considered perfect and, therefore, is excluded from the FS identification. The critical operational parameters in the characterization are the temperature and batch time of both reactors, such that $\boldsymbol{v_j} = [T_j, \tau_j]^T$. Inequality constraints are imposed to ensure the molar impurity of component C at the end of the first operation and on that of component B at the end of operating the second batch reactor:

$$\frac{c_{C,1}(\tau_2)}{c_{A,1}(\tau_2) + c_{B,1}(\tau_2) + c_{C,1}(\tau_2)} \le b_1$$

$$\frac{c_{B,2}(\tau_2)}{c_{A,2}(\tau_2) + c_{B,2}(\tau_2) + c_{C,2}(\tau_2)} \ge b_2$$

with $b_1 = 0.15$ and $b_2 = 0.74$. The search spaces $\mathcal{K}_{v_1}$ and $\mathcal{K}_{v_2}$ are defined such that $\tau_j \in [250,800]$ (min) and $T_j \in [250,1000]$ (K).

## Implementation Details

Full implementation details together with a description of the algorithm are available within Digital Supplementary. The Nested Sampling algorithm was utilised to solve each unit level problem using the DEUS package [2]. Each unit level problem was considered solved when $card\left(\overline{\mathbb{VU}}_i^{(d)}\right) = 2000$. Due to the nature of sampling algorithms a high degree of parallelisation was leveraged.

Initialization and then backward propagation steps were first applied, and neural network SoftMax binary classifiers and regressors with tanh activations were trained to high validation accuracy in solution to the unit level problems using the FLAX python package. Solution to the box-constrained NLP was provided by the L-BFGS-B implementation in OPTAX. The tuning problem (9) was then solved using a Bayesian optimization strategy. This consists of iteratively solving forward propagations using different values of $\boldsymbol{\epsilon}$. The decision bounds, $\boldsymbol{\epsilon} \in [0,0.5]^2$, were identified from knowledge of the range of the SoftMax binary classifier. An initial dataset was identified through a Latin hypercube space filling design on $\boldsymbol{\epsilon} \in [0,0.5]^2$ for 3 backoff values. In the forward propagations, the general NLP problems that couple the units were solved using IPOPT and formulated in CasADI. The ML surrogates were embedded using the CasADI callback feature, allowing JAX automatic differentiation routines to pass necessary Jacobian information. A Gaussian process model was built, exploited, and retrained to optimize (8) using the expected improvement acquisition function and a budget of 7 additional samples to the initial dataset.

## Results and Discussion

The results of the Bayesian optimization strategy to approximately solve (9) is shown in Fig. 1. Specifically, Fig. 1 shows the improvement in objective per evaluation

of the forward propagation. The figure shows that in general the objective is improved in each iteration highlighting the approach's utility in expanding the flexibility or volume of the decentralized FS.

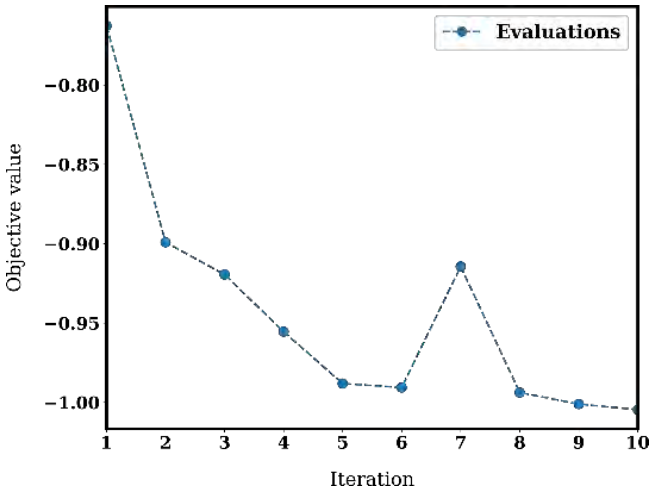

**Figure 1:** Tuning progress of the decentralized FS through Bayesian optimization.

The decentralized FS with largest volume from the optimization was identified during the 10th sample. The unit-wise projections of the discrete set to approximate (8) are plotted in Fig. 2 in red scatter. Also plotted in Fig. 2 are samples used to initialize the search spaces for the backward propagation (grey) and the centralized FS (blue). The latter was identified using the direct sampling method discussed in [3]. What is notable is that the decentralized FS is a proper subset of the centralized – yielding reduced flexibility. However, this is traded for a more robust operational strategy with lower capital overhead for implementation of control. The quality of the decentralized FS was verified by performing 10000 forward process network evaluations using operational parameters sampled from the approximation to $\mathbb{V}_{DO}$ – all of which yielded feasible operation. It should be emphasised that the approximation was identified using just 18092 evaluations of the unit models in total. Given the identified decentralized FS, $\overline{\mathbb{V}}_{DO} \subset \mathbb{V}_{DO}$, is constituted by $4 \times 10^6$ parameter settings this is a significant sample efficiency.

## CONCLUSION

In this research, a decomposition strategy has been presented to sample decentralized feasible spaces for multi-unit process networks. The methodology leverages DAG formulations of process networks, adaptive sampling and machine learning surrogates to define constraint propagation methods that return inner-approximations to the feasible space efficiently. The methodology was applied to a serial batch reactor network and demonstrated to be effective in identifying a subset of the centralized FS to enable decentralized operation. Future work will consider robust formulations to account for uncertain model parameters.

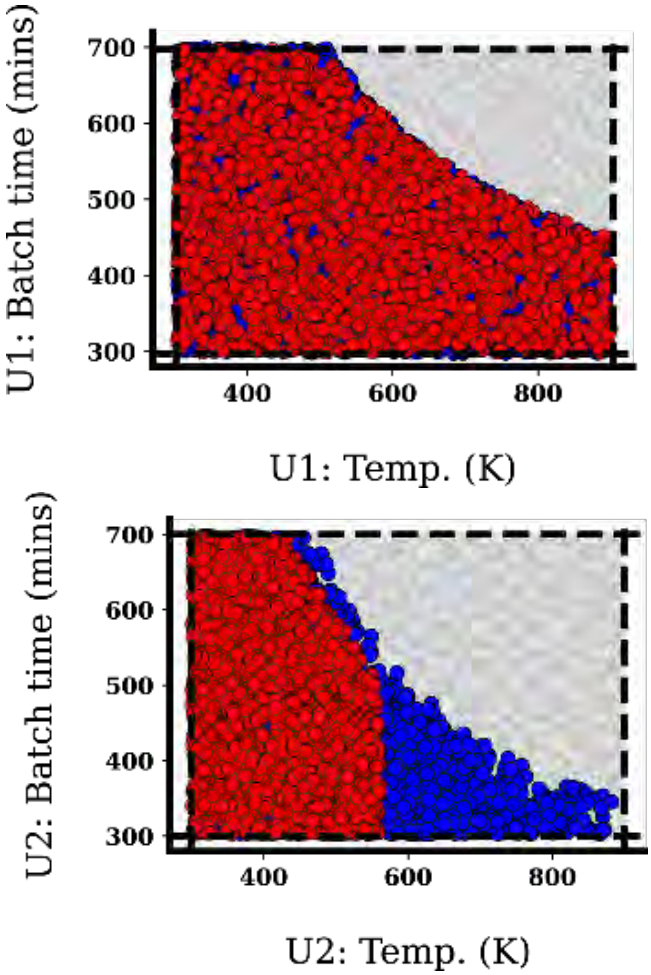

**Figure 2:** The optimized decentralized FS (red scatter), centralized FS projections (blue scatter), and samples used to initialise the search space (grey scatter).

## DIGITAL SUPPLEMENTARY MATERIAL

Digital supplementary is provided by a Python software package, **μF**, available at: https://github.com/maw-bray/mu.F. The DEUS package for solving numerical constraint satisfaction problems through Nested Sampling is available at https://github.com/omega-icl/deus.

## ACKNOWLEDGEMENTS

This work is co-funded by Eli Lilly & Company through the Pharmaceutical Systems Engineering Lab (PharmaSEL) and by the Engineering and Physical Sciences Research Council (EPSRC) as part of its Prosperity Partnership Programme under grant EP/T518207/1. EO would like to acknowledge the support of Petroleum Technology Development Fund (PTDF) under grant number PTDF/ED/OSS/MSC/EMO/5672.

## ABSTRACT

Hydrogen isotope separation is a critical component of the fusion fuel cycle, particularly for achieving the desired purity levels of deuterium and tritium while minimising tritium inventory. This study investigates the cryogenic distillation of hydrogen isotopes, with a focus on the effects of isotopic equilibrium reactions at reduced temperatures and different system configurations. A one-column architecture was analysed to evaluate the impact of feed and side stream equilibrator temperatures and flowrates on separation performance and tritium inventory. Additionally, a two-column architecture was studied, incorporating multiple isotopic equilibrators in interconnecting streams, to further reduce unwanted heteronuclear isotopologues and improve system efficiency. Comparative analysis of the proposed configurations highlights significant operational advantages of optimising equilibrator temperatures, including reduced tritium contamination and inventory. Results indicate that reducing equilibrator temperatures to 77.4 K not only improves separation efficiency but also enables reductions in the number of theoretical stages required, minimising tritium inventory. A case study of the ITER Isotope Separation System demonstrates that reducing equilibrator temperatures achieves comparable performance with fewer stages in key columns, validating the benefits of optimised equilibrator operation for practical application. These findings contribute to the development of more efficient, cost-effective designs for fusion fuel cycle isotope separation systems.

## INTRODUCTION

Global distribution of deuterium-tritium (DT) fusion power has the potential to provide a limitless supply of low-carbon energy and be revolutionary towards tackling today's climate crisis. One of the key challenges in realising DT fusion power plant development lies in designing a fuel cycle capable of achieving "tritium self-sufficiency" [1]. This condition is met when the fuel cycle can continuously supply tritium to sustain the fusion reaction while producing a surplus for the start-up of subsequent power plants. Achieving this is crucial, given the extremely limited global supply of tritium [2].

A pivotal factor in ensuring tritium "self-sufficiency" is minimising tritium losses throughout the fuel cycle. This involves two key strategies, i.e., enhancing separation performance to reduce losses to the environment and minimising the tritium inventory to limit decay-related losses [1]. Among the various systems within a given fuel cycle architecture, the cryogenic distillation processes for hydrogen isotope separation have been identified as a major contributor to high tritium inventories [3]. Therefore, optimising these processes to reduce tritium inventory without compromising on its separation performance is a priority for the fusion community.

### Hydrogen Isotope Separation System

The hydrogen isotope separation system (ISS) within a fusion fuel cycle is tasked with separating a mixture of hydrogen isotopes into at least two distinct product streams; a tritium-rich stream and a protium-rich stream (examples shown in figures 1 and 2). The tritium-rich product typically comprises a 50/50 mixture of tritium and deuterium, with minimal protium impurities, and is recycled to fuel the fusion reaction. Meanwhile, the protium-rich stream is discharged from the fuel cycle, either directly or through additional detritiation processes. The protium-rich product must adhere to stringent tritium emission limits to ensure the plant's compliance with environmental safety regulations [2, 4].

### Cryogenic Distillation Column Cascades

Cryogenic distillation is a well-established process for hydrogen isotope separation, leveraging the slight differences in boiling points of the hydrogen isotopologues ($H_2$ = 20.39 K, HD = 22.13 K, HT = 22.92 K, $D_2$ = 23.67 K, DT = 24.38 K, and $T_2$ = 25.04 K) [5]. Unfortunately, the presence of the heteronuclear isotopologues - arising from the isotope equilibrium reactions (given in equations (1) to (3)) catalysed by metals, light, or beta particle from tritium decay – adds significant complexity to the design of the cryogenic distillation systems [6]. For instance, the isotopologue HT is more volatile than $D_2$, making it challenging to remove excess $D_2$ in the distillate without contaminating the protium-rich product with HT.

$$H_2 + D_2 \rightleftarrows 2HD \quad (1)$$

$$H_2 + T_2 \rightleftarrows 2HT \quad (2)$$

$$D_2 + T_2 \rightleftarrows 2DT \quad (3)$$

### Isotopic Equilibrator Reactors

To address the issue of tritium contamination within HT in the protium-rich top product, isotopic equilibrator reactors are commonly integrated into the cryogenic distillation column cascades to remove the undesired heteronuclear isotopes from the system. The literature suggests various placements for isotopic equilibrators, including feed streams, column interconnections, and/or side streams [2, 4, 7]. However, there is very limited information on their optimal integration and operation.

An initial experimental study on a $H_2$-HD-$D_2$ cryogenic distillation separation system demonstrated that side stream location and flowrate are critical for effective removal of the undesired isotopologue (HD). The side stream must be positioned where HD concentration exceeds equilibrium composition, with a flow rate that matches the rate of HD entering the column [8]. Subsequent operational insights, such as those from the DTE1 campaign at JET, suggested that equilibrators should target locations with excess deuterium to facilitate the removal of unwanted HT [9].

In terms of modelling attempts of the isotopic equilibrium reactions, across the literature these reactions are assumed to take place instantaneously under room temperature conditions [10, 11]. There is limited experimental data and no rate-based models for isotope equilibrium reactions.

Uda et al. [12] measured first-order reaction rates for HD, HT, and DT formation of $7.0 \times 10^{-2}$ $h^{-1}$, $5.4 \times 10^{-2}$ $h^{-1}$, and $4.6 \times 10^{-2}$ $h^{-1}$, respectively (catalysed by the beta decay of 30.5 kPa tritium). McConville et al. [13] reported significantly higher rates of DT formation in a 304 stainless steel mixing chamber, with $k \approx 0.03$ $min^{-1}$ (1.8 $h^{-1}$) at 295 K (30% $T_2$ at 0.4 bara). Increased rates were likely observed due to differing tritium concentrations or metal impurities catalysing the reaction. They found that reaction rates peaked around 195 K ($k \approx 0.6$ $min^{-1}$) and suggested reaction kinetics for temperatures as low as 150 K are comparable, if not improved, to the kinetics observed at 298 K.

Sherman et al. [14] experimentally demonstrated that side stream equilibrators effectively remove the heteronuclear isotopologues (HD) for improved product purity. Iraola et al. [10] replicated the setup of Sherman et al. [14] in Aspen HYSYS, validating the thermodynamic package developed by Noh et al. [11] and demonstrating that the equilibrators achieving equilibrium at 298 K across a precious metal catalyst is an appropriate assumption.

Despite these insights, limited data exists on reaction rates under varied conditions or in the presence of different catalysts, highlighting a critical gap in understanding the kinetics of isotopic equilibrium reactions. Furthermore, while early studies emphasized the importance of isotopic equilibrator positioning and flowrates, recent research and optimisation efforts in hydrogen isotope separation have largely neglected the importance of these reactors within the system [2, 5, 15, 16]. Their placement within cryogenic distillation column cascades is often mentioned with minimal justification, leaving significant room for improvement in system optimization.

This work aims to address these gaps by exploring the impact of equilibrator operating temperature on separation performance, and comparing equilibrators integrated into side streams with those positioned at column interconnections to determine the optimal operational strategy. Additionally, this study underscores the need for experimental investigations into isotopic equilibrator reaction kinetics to validate and refine the proposed designs. Ultimately, the goal is to enhance hydrogen isotope separation performance while minimising tritium inventory.

## METHODOLOGY

### Simulation of the Isotope Separation System

Commercially available simulation software is a useful tool for the design and optimisation of industrial processes. In the literature, Aspen Plus has been used to study the cryogenic distillation processes used for hydrogen isotope separation. Several studies have provided guidance on the thermodynamic packages and hydrogen isotope property parameters required for accurate system simulation [5, 6, 10, 11].

## Thermodynamics and Physical Property Data

The isotope separation process was modelled in Aspen Plus using a thermodynamic package adapted from the work of Noh et al. [11]. This package modifies the Peng-Robinson equation of state with the Twu alpha function (Equation 4) to address inaccuracies in vapour pressure predictions at cryogenic temperatures. The Twu alpha function redefines the standard alpha function by incorporating regression analysis of pure component vapour pressure data from Souers [6] to obtain the coefficients, *L*, *M*, and *N* (values given in Table 1).

$$\alpha(T) = {T_r}^{N(M-1)} \exp\left[L\left(1 - {T_r}^{NM}\right)\right] \quad (4)$$

To accommodate gaps within the Aspen Plus physical property database for heteronuclear and tritium containing isotopologues (HD, HT, DT, and $T_2$), a complete set of physical property data and Antoine coefficients for all isotopologues were redefined from the physical property inputs reported by Wang et al. [5].

**Table 1:** Coefficients L, M, and N of the Twu alpha function of the modified Peng-Robinson equation of state regressed from the vapour pressure data of Souers [6].

| | $H_2$ | HD | HT | $D_2$ | DT | $T_2$ |
|---|---|---|---|---|---|---|
| **L** | 1.715 | 2.103 | 1.956 | 1.704 | 1.930 | 2.339 |
| **M** | -1.031 | -0.613 | -0.593 | -0.692 | -0.517 | -0.389 |
| **N** | 0.3266 | 0.3563 | 0.2914 | 0.3003 | 0.3581 | 0.4741 |

## Process Flow and Design Parameters

The ISS was modelled using the RadFrac distillation column in Aspen Plus. This study investigates the impact of isotopic equilibrator temperature on the separation performance of one- and two-column configurations. Three equilibrator configurations were evaluated:

1. **Feed Stream Integration**: Equilibrators placed in the feed streams of the distillation columns (equilibrator 1 in figures 1 and 2).
2. **Side Stream Integration**: Equilibrators integrated into column side streams (equilibrator 2 in figure 1).
3. **Interconnection Integration**: Equilibrators positioned between two distillation columns (equilibrators 2 and 3 in figure 2).

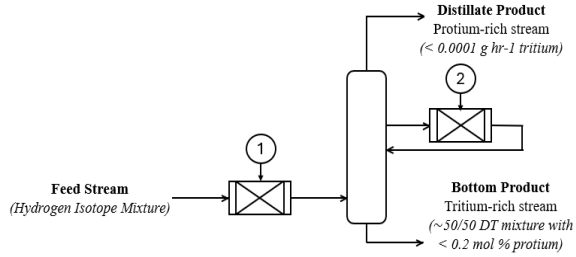

**Figure 1:** One-column configuration of a hydrogen ISS.

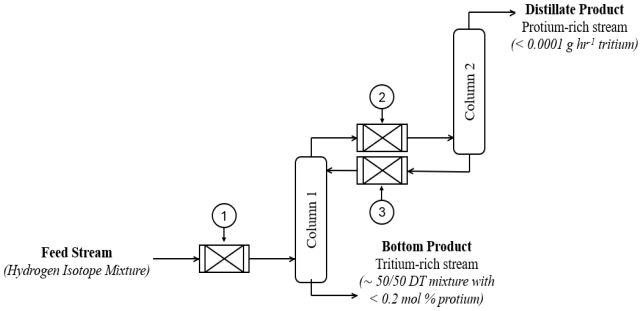

**Figure 2:** Two-column configuration of a hydrogen ISS.

The feed composition was maintained at 100 mol $h^{-1}$ with a molar ratio of H-D-T as 0.05:0.55:0.40. Design parameters for the one- and two-column configurations are summarised in tables 2 and 3, respectively. Feed location was adjusted proportional to changes in the number of stages within the column. Stage number is given by a top-to-bottom numbering scheme.

**Table 2:** Initial design parameters for the one-column configuration displayed in figure 1.

| Design Parameter | Value |
|---|---|
| Number of Stages | 50 |
| Feed Stage | 40 |
| HETP | 0.0667 m |
| Reflux Ratio | 35 |
| Boil-up Ratio | 11 |
| Column Diameter | 0.044 m |

**Table 3:** Initial design parameters for the two-column configuration displayed in figure 2.

| Design Parameter | Column 1 | Column 2 |
|---|---|---|
| Number of Stages | 45 | 45 |
| Feed Stage | 36 | 36 |
| HETP | 0.0667 m | 0.0667 m |
| Reflux Ratio | 1 | 20 |
| Boil-up Ratio | 15 | 1 |
| Column Diameter | 0.046 m | 0.042 m |

## Equilibrator Temperature Optimisation

Equilibrator temperatures ranging from 50 K to 298 K were investigated to assess their impact on separation performance and tritium inventory. The following cases were studied:

- **298 K (Base Case)**: Represents typical operational conditions.
- **150 K and 200 K**: Selected based on experimental data suggesting comparable or improved reaction kinetics relative to 298 K.
- **77.4 K**: Corresponds to liquid nitrogen temperature, offering a practical cooling source.
- **50 K**: Explores performance improvements at ultra-low temperatures.

For side-stream equilibrators, side stream flow rates up to 100 mol $h^{-1}$ were evaluated to determine optimal operating conditions.

### Modelling the Isotopic Equilibrator Reactions

The equilibrium constants for isotopic reactions, determined experimentally by Souers [6], are summarised in table 4. As observed, lower equilibrator temperatures favor the backward reaction, promoting homonuclear isotopologue formation while reducing unwanted heteronuclear species, such as HT. This behaviour is crucial for minimising contamination in the product stream. Regression analysis was performed to fit the constants A, B, C, and D in equation 5 (Table 5), enabling the calculation of the isotope equilibrium constants (Table 4) within ± 5 % accuracy across the 50-300 K temperature range.

$$\ln(K_{eq}) = A + \frac{B}{T} + C\ln(T) + DT \quad (5)$$

### Tritium Inventory Calculation

The tritium inventory calculation followed the methodology outlined by Wang et al. [5]. The temperature and hydrogen isotope composition data inputs were extracted from the Aspen Plus simulations and calculations performed using Excel.

Due to limited experimental data on the kinetics of the isotopic equilibrium reactions, the tritium inventory calculation cannot include the inventory contained within the reactors due to limited data availability for equipment sizing calculations. Hence, in this work the calculation method only accounts for tritium within the columns.

**Table 4:** Equilibrium constants ($K_{eq}$) for equations 1 to 3 [6].

| **Temperature *[K]*** | $H_2 + D_2 \rightleftarrows 2HD$ | $H_2 + T_2 \rightleftarrows 2HT$ | $D_2 + T_2 \rightleftarrows 2DT$ |
|---|---|---|---|
| 0 | 0 | 0 | 0 |
| 50 | 1.41 | 0.33 | 2.57 |
| 77.4 | 1.94 | 0.64 | 3.06 |
| 150* | 2.70 | 1.57 | 3.54 |
| 200 | 2.98 | 1.94 | 3.69 |
| 298* | 3.25 | 2.56 | 3.82 |

**Values obtained through interpolation.*

**Table 5:** Regressed constants for modelling the isotopic equilibrium reactions using equation (5).

| | $H_2 + D_2 \rightleftarrows 2HD$ | $H_2 + T_2 \rightleftarrows 2HT$ | $D_2 + T_2 \rightleftarrows 2DT$ |
|---|---|---|---|
| **A** | 4.761 | 7.049 | -0.3239 |
| **B** | -95.11 | -196.0 | -3.139 |
| **C** | -0.6997 | -1.186 | 0.3534 |

## RESULTS AND DISCUSSION

### One-Column Architecture

#### Effect of Feed Equilibrator Temperature on Inventory

Table 6 shows that when no heteronuclear isotopes are present (feed equilibrator temperature at 0 K), the system achieves the desired separation performance (displayed in Figure 1), producing a protium-rich distillate free of HT contamination. As feed equilibrator temperature rises, the formation of heteronuclear isotopologues (particularly HT) becomes significant, reducing separation efficiency and distillate purity. Achieving desired separation under these conditions without further design modifications becomes challenging. Additionally, increased feed equilibration temperature increases tritium inventory within the column due to enhanced HT formation. Formation of HT in the feed stream is directed up through the enriching section of the column, increasing the overall tritium inventory.

#### Effect of Side Stream Isotopic Equilibrator Temperature and Flow Rate

A potential solution to reduce HT contamination involves incorporating an isotopic equilibrator in a side stream of the cryogenic distillation column. The side stream is taken from the top tray, where HT concentration is highest, and returned to the second tray after passing through the equilibrator. Table 7 shows the system performance for a one-column configuration with a side stream flow rate of 100 mol $h^{-1}$. Compared to results without a side stream (Table 6), the separation performance (lower tritium content in the distillate) has improved for all equilibrator temperatures. However, this improvement comes at the cost of increased tritium inventory within the column.

Figure 3 illustrates the trade-off between separation performance and inventory. Higher side stream flow rates reduce tritium content in the distillate but increase overall tritium inventory. Notably, reducing the equilibration temperature simultaneously lowers both tritium content in the distillate and tritium inventory, making it a key factor in optimizing system performance.

**Table 6:** Separation performance and tritium inventory of the one-column configuration (as shown in figure 1 with design parameters given in table 2) with no side stream flow.

| Equilibrator 1 Temperature *[K]* | Tritium in Distillate *[g hr$^{-1}$]* | Tritium Inventory *[g]* |
|---|---|---|
| 0 K | 5.423 x 10$^{-5}$ | 3.076 |
| 50 K | 6.427 | 4.550 |
| 77.4 K | 8.302 | 4.642 |
| 150 K | 9.879 | 4.748 |
| 200 K | 10.33 | 4.779 |
| 298 K | 10.94 | 4.803 |

**Table 7:** Separation performance and tritium inventory of the one-column configuration (as shown in figure 1) with a side stream flow rate of 100 mol hr$^{-1}$.

| Equilibrator 1 and 2 Temperature *[K]* | Tritium in Distillate *[g h$^{-1}$]* | Tritium Inventory *[g]* |
|---|---|---|
| 0 K | 5.423 x 10$^{-5}$ | 3.076 |
| 50 K | 1.908 | 4.706 |
| 77.4 K | 2.497 | 4.860 |
| 150 K | 3.015 | 5.029 |
| 200 K | 3.166 | 5.079 |
| 298 K | 3.377 | 5.125 |

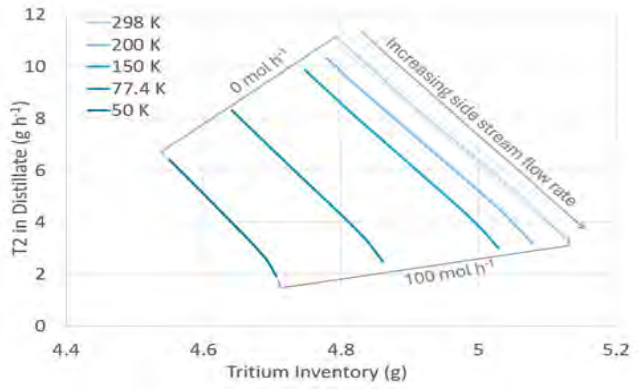

**Figure 3:** Separation performance vs tritium inventory at varying equilibrator temperatures for the one-column configuration with side stream flowrates from 0 to 100 mol hr$^{-1}$.

## Two-Column Architecture

### Effect of Column Interconnection Isotopic Equilibrators

Introducing a second column with isotopic equilibrators provides another method for reducing HT contamination in the distillate. Twelve case studies are presented in tables 8 and 9 evaluating the impact of operating isotopic equilibrators 1, 2, and 3 (see figure 2) at reduced temperatures (from 298 K to 77.4 K).

**Table 8:** Two-column configuration (as displayed in figure 2 with the initial design parameters displayed in table 3) with modified equilibrator temperatures.

| Case Study | Equilibrator Temperature *[K]* | | | T in distillate *[g hr$^{-1}$]* | Tritium Inventory *[g]* |
|---|---|---|---|---|---|
| | **1** | **2** | **3** | | |
| 1 | 298 | 298 | 298 | 0.1504 | 29.32 |
| 2 | 77.4 | 298 | 298 | 0.1148 | 27.67 |
| 3 | 298 | 77.4 | 298 | 0.1148 | 29.32 |
| 4 | 298 | 298 | 77.4 | 0.1495 | 29.30 |
| 5 | 77.4 | 77.4 | 298 | 0.08771 | 27.66 |
| 6 | 77.4 | 77.4 | 77.4 | 0.08726 | 27.65 |

**Table 9:** Two-column configuration (as shown in figure 2) with number of stages in column 1 is manipulated to keep tritium flow rate in the distillate constant (approximately 0.150 g h$^{-1}$).

| Case Study | Equilibrator Temperature *[K]* | | | Number of column 1 stages | Tritium Inventory *[g]* |
|---|---|---|---|---|---|
| | **1** | **2** | **3** | | |
| 7 | 77.4 | 298 | 298 | 38 | 26.78 |
| 8 | 298 | 77.4 | 298 | 38 | 28.33 |
| 9 | 77.4 | 77.4 | 298 | 34 | 26.21 |
| 10 | 77.4 | 77.4 | 77.4 | 34 | 26.19 |
| 11 | 298 | 298 | n/a | 45 | 29.32 |
| 12 | 77.4 | 77.4 | n/a | 34 | 26.19 |

Case studies 1–6 demonstrate improved separation performance and reduced inventory with lower equilibrator temperatures. Case studies 7–10 explore manipulating the number of stages in column 1 to maintain a top product tritium content of ~0.150 g h$^{-1}$ under reduced equilibrator temperatures. Results show that reduced equilibrator temperatures achieve comparable separation with fewer stages, lowering the tritium inventory. These findings align with prior studies (e.g., Urm et al. [16]), which report a trade-off between improved separation performance and increased tritium inventory for an increased number of stages. Key findings for individual equilibrators include:

- **Equilibrator 1** temperature reductions effectively reduce HT contamination within the system, reducing both tritium contamination in the distillate and inventory within the columns.
- **Equilibrator 2** temperature reductions effectively reduce HT flow to the distillate, though its impact on system inventory is minimal due to the small tritium inventory within column 2 relative to column 1.

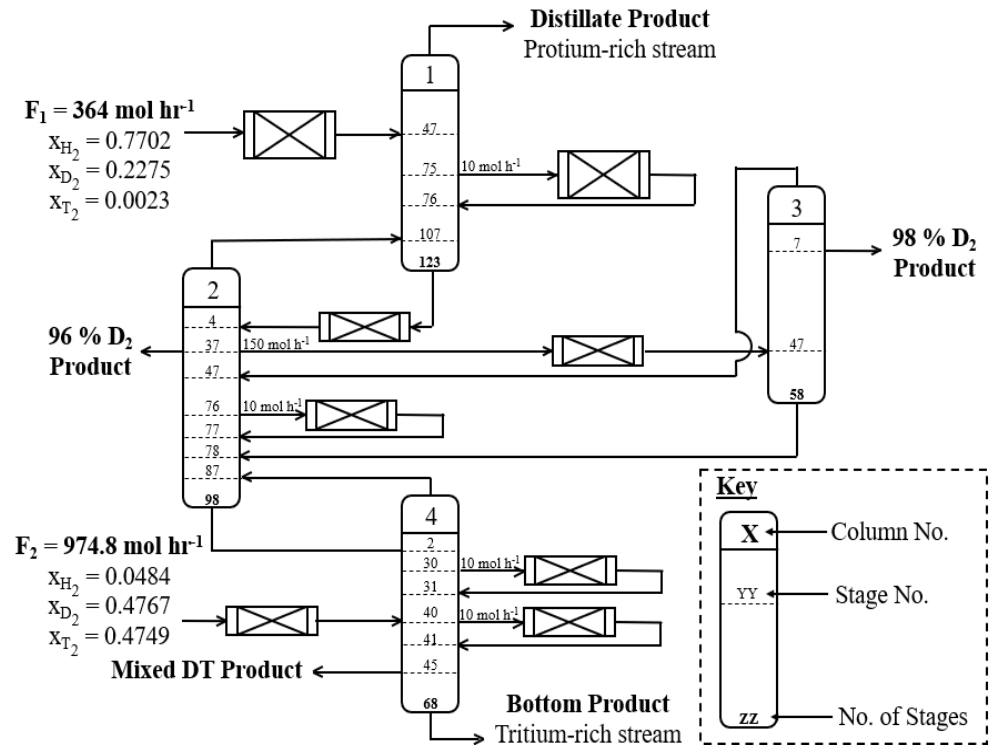

**Figure 8:** ISS configuration proposed for ITER.

- Case studies 11 and 12 (relative to case studies 1 and 10, respectively) indicate redundancy of **equilibrator 3** due to its proximity with equilibrator 2. This suggests that the internal inventory of this equilibrator will likely outweigh any marginal benefits to separation performance it provides.

The best configuration for minimizing tritium inventory within the two-column architecture is shown in case study 12, where equilibrators 1 and 2 operate at 77.4 K and equilibrator 3 is omitted. This configuration achieves a 10% reduction in tritium inventory compared to the baseline design (case study 1), demonstrating the importance of optimising equilibrator temperature.

## ITER Isotope Separation System

To assess the potential improvement for reduced equilibrator temperatures, the ISS configuration for ITER, as described in the work of Noh et al. [11], was analysed for comparison. The overall system configuration and design parameters, including feed flows and H/D/T ratios, were the same as in Noh et al. [11], however, the current work extends the analysis by investigating the effects of reducing temperature of the isotopic equilibrators from 298 to 77.4 K. Additionally, specific side stream flow rates (illustrated in Figure 8) were introduced in this study, as these were not reported in the original work.

Table 10 presents the results of this comparison. The DT flow rate in the tritium-rich bottom product was used as the key metric for separation performance. At 298 K, significant DT contamination was observed in the bottom product, but reducing the equilibrator temperatures to 77.4 K evidently decreased the DT contamination. Noh et al. [11] proposed that achieving the desired tritium purity in the bottom product requires 68 stages in column 4. The results of this work show that by reducing the equilibrator temperatures, a comparable separation performance can be achieved with only 60 stages in column 4. This reduction in stages—specifically, by removing 8 stages between the mixed DT product and the bottom theoretical tray—demonstrates a 10% reduction in tritium inventory, underscoring the dual benefit of improved separation and inventory reduction. These findings validate the hypothesis that reduced equilibrator temperatures enhance the system's overall performance and provide a compelling case for incorporating such modifications in future ISS designs.

**Table 10:** ITER ISS DT contamination in the tritium-rich bottom product and system tritium inventory for varying isotopic equilibrator temperatures.

| Equilibrator Temperature *[K]* | Number of column 4 stages | DT in bottom product *[mol hr$^{-1}$]* | Tritium Inventory *[g]* |
|---|---|---|---|
| 298 | 68 | 22.19 | 140.7 |
| 77.4 | 68 | 19.03 | 141.6 |
| 77.4 | 60 | 21.56 | 126.1 |

## CONCLUSION

This study presents a detailed investigation of hydrogen isotope separation via cryogenic distillation, with a focus on optimising isotopic equilibrator temperatures to enhance separation performance and minimize tritium inventory. Investigating a one-column configuration with an isotopic equilibrator within a side stream effectively reduced HT contamination in the distillate product. The two-column system demonstrated that reducing temperature of equilibrators significantly improved separation performance and allowed a reduction in the number of theoretical stages, thereby lowering inventory. Eliminating equilibrator 3 was shown to have negligible impact, suggesting opportunities for design simplifications.

A comparison with the ITER ISS validated these findings. Reduced equilibrator temperatures to 77.4 K achieved comparable performance with fewer stages in column 4, resulting in a 10% reduction in tritium inventory. Extrapolating these results to the DEMO, where 600 g of tritium is expected in the ISS, this reduction would equate to a 3.4% decrease in overall plant inventory, offering a meaningful improvement in operational safety and efficiency.

These findings underscore the importance of temperature optimisation in isotopic equilibrators and provide actionable insights for designing cost-effective, energy-efficient isotope separation systems critical to future fusion power applications.

## ABSTRACT

Implementing Model Predictive Control (MPC) for large-scale nonlinear systems is often computationally challenging due to the intensive online optimization required. To address this, various reduced-order linearization techniques have been developed. The Koopman operator linearizes a nonlinear system by mapping it into an infinite-dimensional space of observables, enabling the application of linear control strategies. While Artificial Neural Networks (ANNs) can approximate the Koopman operator in a data-driven manner, training these networks becomes computationally intensive for high-dimensional systems as the lifting into a higher-dimensional observable space significantly increases data size and complexity. In this work, we propose a technique, combining Proper Orthogonal Decomposition (POD) with an efficient ANN structure to reduce the training time of ANN for large order systems. By first applying POD, we obtain a low order projection of the system. Subsequently, we train the ANN with an efficient structure to approximate the Koopman operator, significantly decreasing training time without sacrificing accuracy.

**Keywords**: Koopman operator, efficient training of NN, large-scale systems, nonlinear systems, model predictive control, MPC, nonlinear control

## 1 INTRODUCTION

Model predictive control (MPC) is a well-known strategy for control of dynamical systems, offering key advantages such as handling constraints and optimizing the control input trajectory [1,2]. MPC of large order systems is challenging as the computational efforts required for online optimization is significant. Model order reduction (MOR) methodologies such as Proper Orthogonal Decomposition (POD), are generally exploited in such cases to project the original system onto a lower dimensional subspace, thereby reducing the computational burden of MPC [3–7].

For large order non-linear systems, only MOR, may still be insufficient, as the resulting nonlinear models remain challenging for optimization and stability analysis. An alternative is to linearize the system in a suitably reduced space [8] . In recent years, the Koopman operator framework has gained significant attention as a potential route to enable linear MPC for otherwise nonlinear systems [9–13]. According to Koopman theory, a nonlinear dynamical system can be represented as a linear system in an infinite-dimensional space of observables (i.e., functions of the state) [14]. In practice, a finite approximation of Koopman operator is necessary for its application in MPC [9,15,16].

A commonly used data-driven method to approximate the Koopman operator is Extended Dynamic Mode Decomposition (EDMD) [9]. In EDMD, the nonlinear state is augmented with a set of manually chosen state functions (observables). However, choosing the observables manually may limit the accuracy of approximation [15]. To address this, Artificial Neural Networks (ANNs) have been explored as a means of automatically learning suitable observables from data, thus improving approximation [15–17]. To train the ANN, usually large data set is required. Nevertheless, for large order systems the training of ANNs takes significant time.

While [15,17] use ANNs for Koopman approximation to automate the selection of lifting functions, these approaches do not address the challenges associated with training ANNs for high-dimensional systems. Recently, [18] proposed a POD-based Koopman approximation technique; however, their method does not incorporate

ANNs for Koopman approximation. In this work, we propose combining POD with ANN (PANN) for Koopman operator approximation. First, we apply POD to snapshot data to derive a low-dimensional state space in a purely data-driven manner. Subsequently, we employ ANNs to "lift" this low-dimensional state into a higher-dimensional space of observables, where the dynamics can be represented in a linear form. This approach significantly reduces the training time compared to directly learning the full-state observables, without sacrificing the accuracy of the Koopman operator approximation.

## 2 PRELIMINARIES

### 2.1 Koopman operator

Koopman operator theory was proposed by Bernard O. Koopman in 1931 [14]. The core idea is to embed the non-linear dynamics into an infinite-dimensional space of observables where the observables evolve linearly along the trajectories of the original nonlinear dynamics.

Consider a discrete nonlinear system represented by:

$$\boldsymbol{x}_{k+1} = f(\boldsymbol{x}_k) \tag{1}$$

where $\boldsymbol{x}_k \in \mathbb{R}^n$ is the state vector at the k$^{th}$ time step. Let the system be lifted to the space of observables using a transformation $\phi: \mathbb{R}^n \rightarrow \mathbb{R}^N$ where N>>n. The Koopman operator $\mathcal{K}$ acts on the on the lifted state $\boldsymbol{\psi}$ ($\boldsymbol{\psi}_k = \boldsymbol{\varphi}(\boldsymbol{x}_k)$) such that:

$$\phi(\boldsymbol{x}_{k+1}) = \mathcal{K}\ \phi(\boldsymbol{x}_k) \tag{2}$$

$$\boldsymbol{\psi}_{k+1} = \mathcal{K}\ \boldsymbol{\psi}_k \tag{3}$$

This framework can be applied to design a linear MPC for a nonlinear dynamical system. Consider a controlled dynamical system represented by:

$$\boldsymbol{x}_{k+1} = f(\boldsymbol{x}_k, \boldsymbol{u}_k) \tag{4}$$

where $\boldsymbol{u}_k \in \mathbb{R}^m$. Exploiting the Koopman theory a linear representation of the above system can be obtained as:

$$\boldsymbol{\psi}_{k+1} = \mathrm{A}\boldsymbol{\psi}_k + B\boldsymbol{u}_k \tag{5}$$

where $A \in \mathbb{R}^{N\ x\ \mathrm{N}}$ and $B \in \mathbb{R}^{N\ x\ \mathrm{m}}$. The original state can be reconstructed as:

$$\hat{\boldsymbol{x}}_k = C\boldsymbol{\psi}_k \tag{6}$$

where $C \in \mathbb{R}^{n\ \mathrm{x}\ \mathrm{N}}$. Notably since $\boldsymbol{u}_k$ has not been lifted and $\hat{\boldsymbol{x}}_k$ is assumed to be linear combination of $\boldsymbol{\psi}_k$, linear constraints can be applied on both, facilitating linear MPC of underlying nonlinear system.

Koopman matrices *A* and *B* can be obtained in a data-driven manner using EDMD. Despite being a data driven method, EDMD requires manual selection of observables which require prior understanding of the system for good approximation accuracy [8]. Randomly chosen observables may limit the accuracy of approximation. Alternatively, ANNs can be used to approximate the matrices *A* and *B*, eliminating the need for manual selection of observables. Nevertheless, for large-scale nonlinear systems, training ANNs is computationally intensive. Additionally, lifting such systems to a higher-dimensional space of observables further increases the computational burden associated with ANN training. To reduce the computational burden of ANN training we first reduce the dimensionality of the large-scale nonlinear system using POD. Subsequently, the reduced-order variables are lifted into a higher-dimensional observable space.

### 2.2 Proper Orthogonal Decomposition (POD)

Proper Orthogonal Decomposition (POD) is an effective technique for systematically reducing the dimensionality of large-scale systems, leveraging principles from spectral theory. The key idea behind POD is the decomposition of the solution space into a maximal invariant subspace corresponding to dominant modes (i.e., large eigenvalues), and its orthogonal complement containing less significant mode [4,19–21]. These dominant modes capture most of the system's energy or variance and thus characterize the essential dynamics.

Formally, POD decomposes the state variables into spatial and temporal components, where the spatial variation is captured by eigenfunctions, and the temporal variation is encapsulated by time-dependent coefficients [4]. Notably, POD does not require an explicit analytical form of the governing equations; it can be performed solely on snapshot data arising from simulations or experiments, making it a completely data driven method for MOR.

## 3. METHODOLOGY

Figure 1 shows an overview of the proposed POD and ANNs (PANN) framework for reduced order Koopman operator approximation. The detailed steps are as follows:

### 3.1 Snapshots collection

A high-fidelity simulation or experimental state data for the nonlinear system across discrete time steps is collected for appropriate range of parameters to form the snapshot matrix *S*, where each column represents a state vector $\boldsymbol{x}_k$.

$$S = \{\boldsymbol{x}_1, \dots\dots\dots\dots, \boldsymbol{x}_M\} \tag{7}$$

$S \in \mathbb{R}^{n\ x\ \mathrm{M}}$, where M is the total number of snapshots.

### 3.2 POD based dimensionality reduction

POD provides basis function for dimensionality reduction. After obtaining POD modes, only dominant modes are retained, yielding reduced order state $\boldsymbol{z}_k \in \mathbb{R}^{\mathrm{r}}$

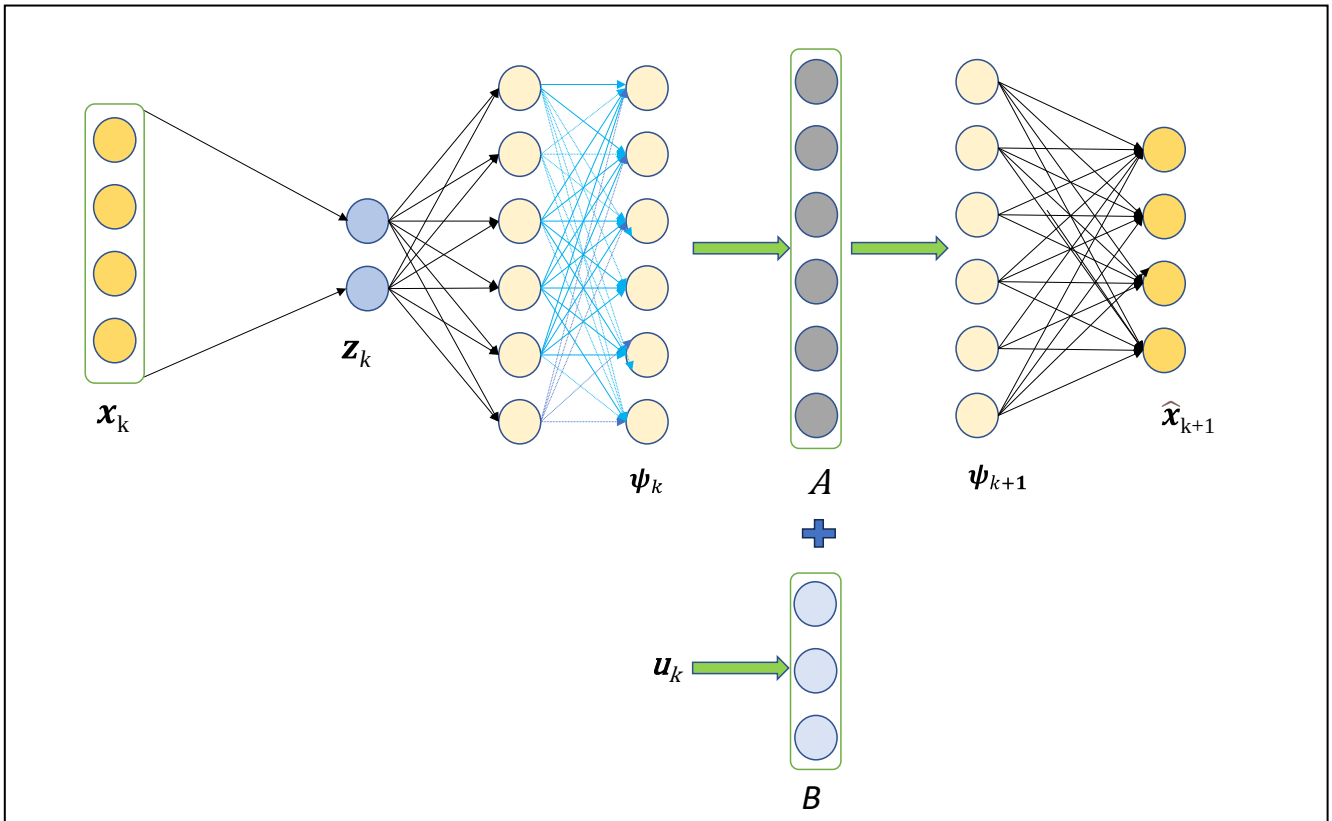

**Figure 1:** PANN framework for efficient approximation of Koopman operator for large-scale nonlinear systems.

(r<<n). Following are the steps:

1. After creating the snapshot matrix *S*, center the data by subtracting the mean state $\bar{x}$, creating matrix *S′*.

$$\bar{x} = \frac{1}{M}\sum_{k=1}^{M} x_k \tag{8}$$

2. Construct a correlation matrix $D \in \mathbb{R}^{M\,x\,M}$

$$D = \frac{1}{M} S'^{T} S' \tag{9}$$

3. Eigenvalue decomposition is performed on correlation matrix D

$$D v_i = \lambda_i v_i \tag{10}$$

where $\lambda_i$ are the eigenvalues, ordered in descending magnitude and $v_i$ are the corresponding eigenvectors.

4. POD modes ($\varphi \in \mathbb{R}^n$) are derived by projecting the centered snapshot data onto the eigenvectors $v_i$.

$$\varphi_i = \frac{1}{\sqrt{\lambda_i}} S' v_i \tag{11}$$

5. The number of retained modes r is determined based on the cumulative energy criterion:

$$\sum_{i=1}^{r} \lambda_i \geq \alpha \sum_{i=1}^{M} \lambda_i \tag{12}$$

$\alpha$ is chosen such that the retained modes capture most of the system's dynamics.

### 3.3 ANN based Koopman operator approximation

The ANN architecture (Figure 1) is designed to efficiently map the reduced-order state $z_k \in \mathbb{R}^r$ into a higher-dimensional observable space $\psi_k \in \mathbb{R}^N$, where N≫r. The architecture divided into 4 main sections:

1. **Section 1**: The role of this section is to lift the reduced-order state $z_k$ to $\psi_k$. It consists of an input layer (with r neurons), multiple hidden layers with ReLU activations, and an output layer (with N neurons).
2. **Section 2**: This section captures Koopman matrix A as described in equation 5. This NN layer is a shallow linear layer with bias=0.
3. **Section 3:** This section captures Koopman matrix B. This layer too is a linear layer with bias =0.
4. **Section 4:** This section reconstructs the original high dimensional nonlinear state $x_k$ from the lifted state $\psi_k$.

The ANN is trained to minimize the error between

the predicted and actual next-step observables, ensuring that the lifted dynamics approximate the Koopman operator.

## 4. IMPLEMENTATION

We applied the PANN method to a nonlinear tubular reactor system. The schematic of the tubular reactor [22] is given in figure 2. There is an exothermic reaction(A→B) going inside the reactor. To control the exit temperature of the product (B), the wall of the reactor is divided into three sections. The temperature of each section can be controlled independently. The temperature and concentration profile of the reactor exhibits a Hopf bifurcation (sustained oscillations) at a recycle ratio $r_c$ = 0.5.

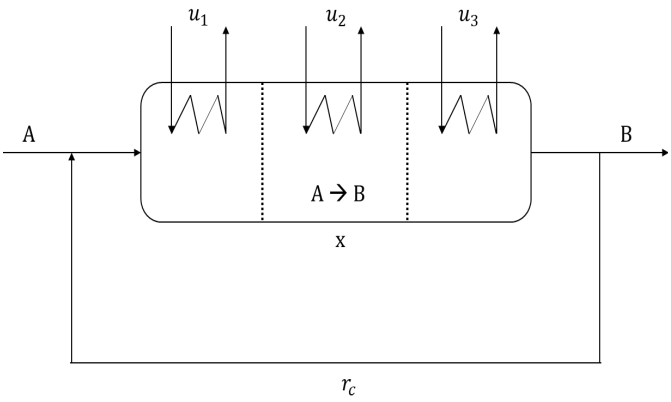

**Figure 2.** Schematic of the tubular reactor.

The system is governed by the set of following PDEs in terms of dimensionless variables:

$$\frac{\partial \mathbf{c}}{\partial t} = \frac{1}{P_m}\frac{\partial^2 \mathbf{c}}{\partial x^2} - \frac{\partial \mathbf{c}}{\partial x} - Da(1+\mathbf{c})\exp\left(\frac{\alpha_a \mathbf{T}}{1+\mathbf{T}}\right) \quad (13)$$

$$\frac{\partial \mathbf{T}}{\partial t} = \frac{1}{P_h}\frac{\partial^2 T}{\partial x^2} - \frac{\partial \mathbf{T}}{\partial x} + c_1 Da(1+\mathbf{c})\exp\left(\frac{\alpha \mathbf{T}}{1+\mathbf{T}}\right) + \beta(\mathbf{u_W} - \mathbf{T}) \quad (14)$$

The boundary conditions are given as:

$$\frac{\partial \mathbf{c}}{\partial x} = -P_m[(1-r_c)\mathbf{c}_0 + r_c\,\mathbf{c}|_{x=1} - \mathbf{c}\,|_{x=0}] \quad (15)$$

$$\frac{\partial \mathbf{T}}{\partial x} = -P_h[(1-r_c)\mathbf{T}_0 + r_c\,\mathbf{T}|_{x=1} - \mathbf{T}\,|_{x=0}] \quad (16)$$

$$\frac{\partial \mathbf{T}}{\partial x} = \frac{\partial \mathbf{c}}{\partial x} = 0 \qquad \text{at } x = 1 \quad (17)$$

Here c is the dimensionless concentration, T the dimensionless temperature, and $\mathbf{u_w}$ the dimensionless wall temperature. The model parameters were as follows:

**Table 1:** Parameter values for the tubular reactor system.

| Parameter | Value |
|---|---|
| Peclet number for mass transfer ($P_m$) | 7 |
| Peclet number for heat transfer ($P_h$) | 7 |
| Damköhler number (Da) | 0.1 |
| Activation energy ($\alpha_a$) | 10 |
| Adiabatic temperature rise ($c_1$) | 2.5 |
| Heat transfer coefficient (β) | 2 |
| Recycle ratio ($r_c$) | 0.5 |

The system was discretized into 15 nodes along the length of the reactor resulting into total 30 state variables with 3 manipulated variables. We generated 1000 trajectories each with 300 time steps. The snapshots were generated using randomized control inputs between 0.1 and 2. In the time interval between timesteps 10 and 150 we forced the control inputs to increase and between timesteps 150 to 300 to decrease, using randomised values, to ensure a wide representation of system states. For all the trajectories we used $r_c$ = 0.5.

A snapshot matrix *S*, of the system was obtained and POD was performed to extract the reduced order basis as described in section 2. The reduced order state $\boldsymbol{z_k}$ was obtained.

$\boldsymbol{z_k}$ was lifted to $\boldsymbol{\psi_k}$ using ANNs as depicted in figure 1. n=30 while N was chosen twice of input to the ANNs. The dataset was split into training and validation (80%, 20%) to prevent overfitting. The number of hidden layers in section 1 was 1. We employed the Adam optimizer for ANN training, a widely used adaptive optimization algorithm for faster and efficient ANN training. Unlike traditional stochastic gradient descent (SGD), which uses a fixed learning rate throughout training, Adam dynamically adjusts the learning rate.

## 5. RESULTS AND DISCUSSION

The spectrum of matrix D is depicted in Figure 3. Only two eigenvalues corresponding to two eigenmodes are significant. The rapid decay of singular values in the POD process indicates a clear separation of scales within the system, enabling the most significant modes to capture the primary dynamics.

**Table 2:** ANN vs PANN based Koopman operator approximation

| Method | MSE | Training time |
|---|---|---|
| ANN | $1.5 \times 10^{-8}$ | 4 hrs |
| PANN | $1.2 \times 10^{-8}$ | 12 min |

Figure 4 depicts the energy ($\alpha$) captured by the retained modes (r). More than ninety-nine percent of the energy is captured by retaining only two modes corresponding to the two highest eigenvalues as depicted in

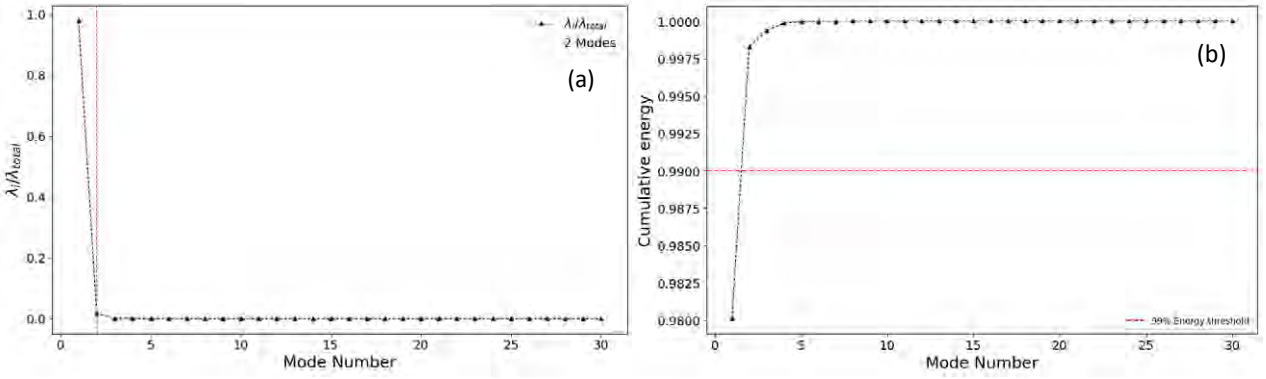

**Figure 3: (a)** POD modes **(b)** Cumulative energy captured by r number of modes

Figure 4.

Koopman operator was first approximated using standard ANNs with full nonlinear state ( $\boldsymbol{x}_k \in \mathbb{R}^n, n = 30$ ) as input and lifted dimension as 2n. The PANN framework was then applied with number of retained POD modes r =2 and the lifted dimension as 2r.

Table 2 provides the comparison of performance of both the methods. A significant speedup of the training time was noted in PANN framework.

## 6. CONCLUSIONS AND FUTURE DIRECTION

In this study, we proposed a hybrid framework, termed PANN, that integrates POD with ANNs to efficiently approximate the Koopman operator for large scale nonlinear systems. The incorporation of model reduction capabilities of POD significantly decreased the ANN training time while improving the accuracy of the approximation. We successfully demonstrated this framework on a non-linear tubular reactor system. The standard ANN for Koopman approximation took four hours to converge with the full-dimensional system, whereas PANN required only twelve minutes to train, owing to the pre-model order reduction. In future work, we aim to further reduce the training time by exploring different ANN architectures and training methods.

## ABSTRACT

The application of Real-time Optimization (RTO) to dynamic operations is challenging due to the complexity of the nonlinear problems involved, making it difficult to achieve robust solutions. The literature on RTO in Pressure Swing Adsorption (PSA) units relies on Model Predictive Control (MPC) and Economic Model Predictive Control (EMPC), which rely heavily on an accurate model representation of the industrial plant. Given the importance of PSA systems on multiple separation operations, establishing alternatives for control and optimization in real-time is in order. With that in mind, this work aimed to explore alternative model-free RTO techniques that depend on simple control elements, as is the case of Extremum Seeking Control (ESC).The chosen case study was Syngas Upgrading. Extremum Seeking Control successfully optimized the $CO_2$ productivity in PSA units for syngas upgrading/$H_2$ purification. The results demonstrate that ESC can be a valuable tool in optimizing and controlling PSA processes and does not require the unit to reach a Cyclic Steady State to adjust the operation.

**Keywords**: Extremum Seeking Control, Pressure Swing Adsorption, Real-time Optimization, Simple Control Strategies

## INTRODUCTION

The optimization of industrial plant operations is known for its complex nature. More often than not, the models employed in simple optimization are not representative of the plant to be optimized, leading to inaccurate optimization procedures. In the last 30 years, Real-time Optimization (RTO) has emerged to overcome some of optimization's weak points when applied to the industry by ensuring a better representation of the plant and continuous optimization to improve process performance autonomously [1, 2].

The fact that some operations have an inherent Dynamic nature still poses a challenge in a robust RTO application for most cases, although some alternatives have emerged [3]. Nevertheless, cyclic adsorption processes such as Pressure Swing Adsorption (PSA) and Temperature Swing Adsorption (TSA) never reach a traditional steady state; only a cyclic steady state (CSS) where identical dynamic behavior is obtained for consecutive cycles [4]. Control of the process in real time is essential to maintain or increase productivity. Disturbances can be critical if they prompt a CSS alteration, leading to extended periods of suboptimal operation. Furthermore, since the productivity of these processes is deeply intertwined with external conditions subject to frequent fluctuations, updating the process to fit those changes is crucial to ensure maximum profit [5].

There are very few works in the literature that contemplate the exploration of this field. In the case of PSA, the most common technique is Model Predictive Control (MPC). In the literature, it is possible to find MPC applications for PSA units for hydrogen recovery [6, 7] or syngas production [8-10], amongst others. These applications usually manipulate the durations of cycle steps to optimize the purity, recovery and/or the productivity obtained for the desired products within the different cases.

Nevertheless, the real-time optimization of PSA

units remains an underdeveloped subject in the literature with a notorious absence of alternative strategies to MPC and EMPC.

In other processes, several other RTO techniques have been employed [11]. A method that stands out when one wants to have some independence from the need to model the process is Extremum Seeking Control (ESC).

ESC is a method based on the constant perturbation of the system's input that analyses the response of the plant to determine the input that leads to the optimum of a given objective function and ensures the control of the plant. First proposed by Leblanc in 1922, ESC's essence has also been applied under different names such as extremum seeking regulator, optimizing control system, and hill-climbing systems [12, 13]. However, the ESC lacked a design analysis and stability proofs that were more recently developed by Luxat and Lees [14] and Krstić and Wang [15].

ESC has been applied to different contexts. Probably the most popular example of an ESC application is the Anti-lock Braking System (ABS). It was first approached by Drakunov et al. [16], in which the maximal value of the tire friction force is to be reached during emergency braking without prior knowledge of the optimal slip.

Looking more specifically at the chemical engineering field, the range of applications is broad, such as jet mixing technologies to maximize the decay rate and the mixing performance [17] or redox wastewater treatments to guarantee that the discharged water meets the specifications of Chemical Oxygen Demand [18].

Nevertheless, to the best of the authors' knowledge, using ESC in Cyclic Adsorption Processes remains an unexplored field in literature. Therefore, this work's primary goal is to explore the applicability of Extremum Seeking Control as a possible methodology for the real-time optimization and control of PSA units.

# METHODS

This work implemented ESC in a virtual syngas purification PSA unit. Syngas purification was chosen by its relevance in providing syngas to Fischer-Tropsch processes, known for representing an alternative path to fuel production [19]. Besides that, the same infrastructure can be adapted to provide $H_2$ for ammonia production and diminish the resulting $CO_2$ emission [20].

## PSA Model

The phenomenological model used in the simulations, together with descriptions of the experimental installation and mode of operation of the PSA unit can be found in the work of Regufe et al. [21].

In this case study, the goal was to maximize the $CO_2$ productivity (Equation 1). The integral limits are here defined by the beginning ($t_i$) and ending ($t_f$) of the cycle steps where $CO_2$ is be obtained (blowdown and purge) and consumed (rinse). This objective function also takes into consideration the cross-section area of the bed ($A_{bed}$), the mass of dry adsorbent ($m_{dry\ ads}$), the total duration of the PSA cycle ($t_{cycle}$), the superficial gas velocity ($u_0$) and the $CO_2$ concentration ($C_{CO_2}$). The manipulated variable was the duration of the feed step ($t_{feed}$) that impacts $t_{cycle}$ and the amount of $CO_2$ fed in the stream to be purified.

$$CO_2\ Productivity\ (mol_{CO_2} kg^{-1} h^{-1}) = \frac{A_{bed}}{t_{cycle} m_{dry\ ads}} \left( \int_{t_{i_{blow}}}^{t_{f_{blow}}} C_{CO_2} u_0|_{z=0}\ dt + \int_{t_{i_{purge}}}^{t_{f_{purge}}} C_{CO_2} u_0|_{z=0}\ dt - \int_{t_{i_{rinse}}}^{t_{f_{rinse}}} C_{CO_2} u_0|_{z=0}\ dt \right) \quad (1)$$

The motive for choosing this objective function was its capability of reaching a well-defined optimal value without the need to impose constraints to the process, as would be necessary for other objective functions.

## Extremum seeking control

The basic diagram for ESC is presented in Figure 1.

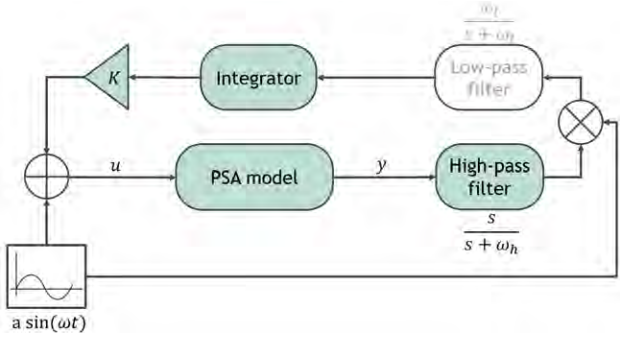

**Figure 1:** Extremum Seeking Control block diagram for Single-Input Single-Output problems.

In the diagram, the previously presented model will represent the plant and will be used to calculate the objective function value $y$ that one aims to optimize and control. A High-pass Filter (HF) and a Low-pass Filter (LF) clear the signal from the DC component and high-frequency noise, respectively, to get a clearer response to the changes affecting the system.

The signal of the input variable $u$ is constantly perturbed by a sinusoidal wave that assists in evaluating the evolution of the objective function by putting the system in constant disruption. By multiplying the filtered value of $y$ by the sinusoidal wave in a demodulation process, the true effect of the sinusoidal change in the manipulated variable $u$ on the response signal can be retrieved. Later, the demodulated and filtered signal will be integrated, providing the signal shift necessary to impose on the manipulated variable so that the objective function gets closer to the optimum, often affected by a gain $K$ to accelerate the convergency.

The low-pass filter was not included in the work here presented since the model output was considered noise-free, hence its washed-out color in Figure 1.

Three different case studies were used to test the ESC applicability in PSA operations, as displayed in Table 1. In case 1, the $t_{feed}$ only changes after 10 cycles of operation, the estimated amount for the process to reach the CSS. In cases 2 and 3, that update is made after each PSA cycle when the plant is in a transient state.

To ensure a similar starting point, a head start of 9 cycles was given before the first iteration in case 2, so that the optimization of both case 1 and case 2 was started after 10 PSA cycles. This ensures that the initialization of the unit does not lead to misguided results since the productivity is naturally lower in the first few cycles of operation. To verify the importance of these initiation cycles, case 3 was performed using the same ESC parameters as case 2 but with the optimization starting in cycle number 1.

**Table 1:** Tuning parameters and initialization procedure for three simulations of ESC of the $CO_2$ productivity with the manipulation of $t_{feed}$.

| Parameter | Case 1 | Case 2 | Case 3 |
|---|---|---|---|
| $a$ | 1 | 1 | 1 |
| $\omega$ | 20 | 20 | 20 |
| $K$ | 25 000 | 25 000 | 25 000 |
| $\omega_h$ | 15 | 15 | 15 |
| Number of PSA cycles per sample | **10** | 1 | 1 |
| Initial $t_{feed}$ (s) | 300 | 300 | 300 |
| Initialization | - | **Yes** | **No** |

## Computational resources

The phenomenological model was implemented in gPROMS Model Builder 7.0.7. Due to the communication protocols established between gPROMS and MATLAB, Simulink was the software chosen to run the optimization and control simulations. The MATLAB version used in the simulation results presented in this article was R2023b (23.2.02365128) 64-bit for Windows.

The solver used was a fixed-step method automatically chosen by Simulink, with a step size of 0.04 s (considered the sampling time) for an overall simulation time of 10 s. This means that Simulink operates for 250 samples. In each sample, an ESC cycle like the one in Figure 1 is executed. In the PSA model block, the simulation continues until the number of cycles assigned for each case in Table 1 is performed in that sample. It is also important to notice that the simulation time is inherent to the Simulink simulation and does not correlate to any real time measure in this case.

The option of a variable-step method was set aside because the perturbation imposed on the system was regular and cyclic. Furthermore, each sampling corresponds with one gPROMS communication after a given number of cycles. If one chose a variable-step method, the system would be out-of-phase since the number of cycles sampled would remain the same, independently of the time-step being 0.01 s or 1 s.

For the simulations presented in this work, the ode3 solver was chosen by the software.

As for hardware resources, the simulations were run on a computer with 128 GB of RAM and an AMD Ryzen 9 5950X 16-Core @ 3.40 GHz processor.

# RESULTS

Figures 2, 3, and 4 display the change in feed time obtained and its effect on $CO_2$ productivity as a function of the simulation time for cases 1, 2 and 3, respectively.

The objective function was considered stabilized in the optimum after 6 s of simulation time for cases 1 and 2 (corresponding to 150 samples). From 6 s to the end of simulation, $t_{feed}$ only increases 2 seconds with no visible alteration in the productivity of $CO_2$ for both cases.

Three different metrics were used to evaluate the different strategies studied. Their values are presented in Table 2.

**Table 2.** Evaluation metrics for the three case studies. (*= before the crash)

| | Case 1 | Case 2 | Case 3 |
|---|---|---|---|
| CPU time /s | 7 857 | 816 | 113 |
| Number of PSA cycles until optimal operation | 1510 | 160 | 18* |
| Time until the optimal operation /h | 4473.4 | 33.2 | 4.6* |

The CPU time relates to the computational effort required for the entire run in Simulink in each case. This metric accounts for the time spent in the PSA unit simulation in gPROMS and the effort to determine the new $t_{feed}$ in each ESC iteration. T

The number of PSA cycles until optimal operation aims to compare the number of PSA cycles required to reach stability in each case. In case 2, this value also considers the cycles used during the initialization procedure.

The time until optimal operation is the cumulative sum of the cycle's duration until stability is reached. It is calculated by Equation 2.

$$\text{Time until the optimal operation } (h) = \sum_{i=1}^{150}\left[\text{Number of PSA cycles per sample } \left(t_{feed,i} + t_{rinse} + t_{blow} + t_{purge}\right)\right] \quad (2)$$

where $t_{rinse}$, $t_{blow}$, and $t_{purge}$ are the duration of the rinse, blowdown and purge steps, respectively, and $t_{feed,i}$ is the input value for $t_{feed}$ for sample $i$.

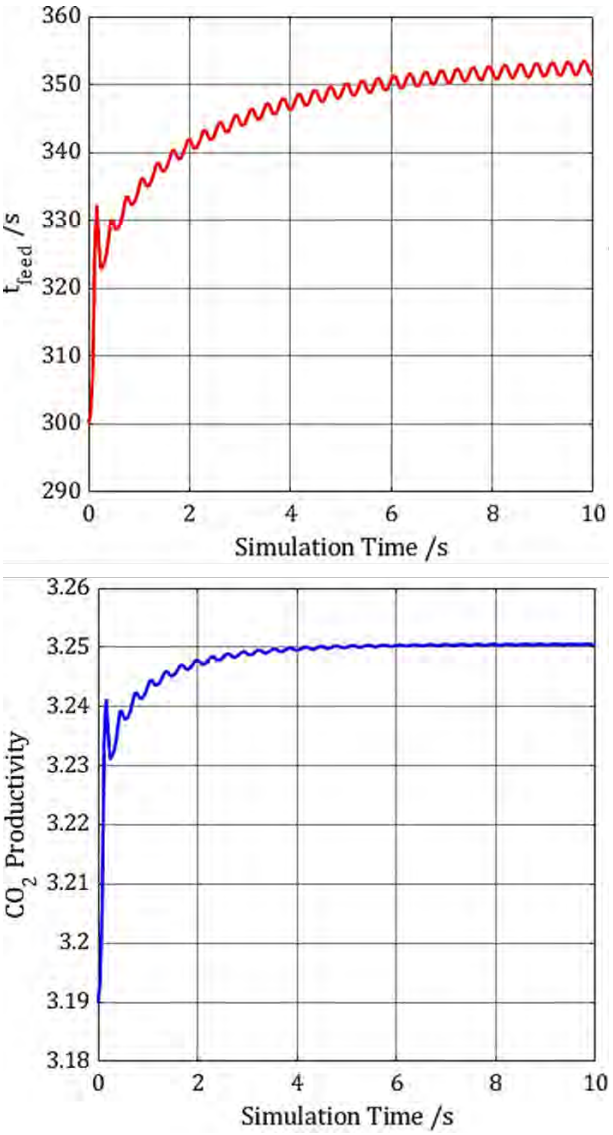

**Figure 2.** ESC action on time of feed value and effect on the productivity of $CO_2$ for case 1.

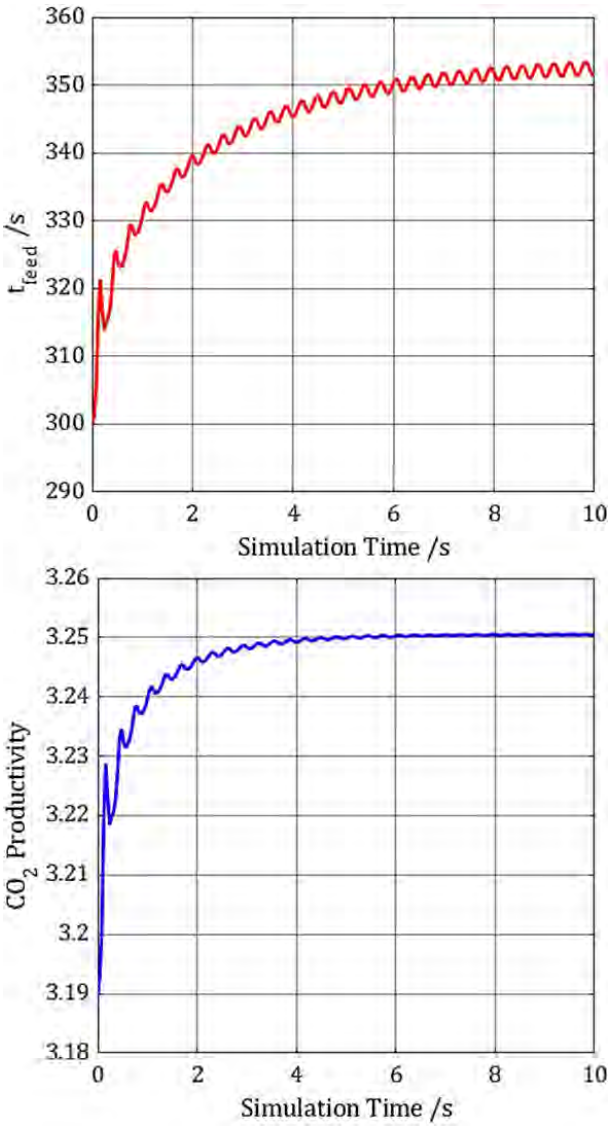

**Figure 3.** ESC action on time of feed value and effect on the productivity of CO2 for case 2.

As can be seen by the comparison between case 1 and case 2, there was no downside in operating the optimization in a transient state and not waiting for the plant to stabilize in a CSS operation before collecting data on the current value of the productivity. However, case 3 clearly demonstrates the relevance of letting the unit run a few cycles before initiating the ESC optimization.

Furthermore, it can also be observed that waiting for the CSS occurrence only delays convergence to the optimum because, although the first iterations achieve higher productivity faster in case 1, the stabilization occurs nearly at the same simulation time for cases 1 and 2, with equal productivity and $t_{feed}$ values achieved.

Therefore, considering the number of PSA cycles and the time until optimal operation, the transient application with initialization is far more advantageous than a cyclic steady-state one. One can even say that the time frame for case 1 is unrealistic since it approaches the 6 months operation for a single objective optimization. The dynamic evaluation reduces that time to a little over a day.

Regarding computational time, it is important to mention that a considerable amount of time is dedicated to the model simulation mechanisms between gPROMS and MATLAB. Despite that, case 2 presented a running time of 13.6 minutes that is not prohibitive.

As can also be perceived from Figures 2 and 3, ESC allows for smooth alteration of the manipulated variables, which can be considered an advantage of this technique, and can be employed in PSA units with encouraging

results. However, this is only the case if the unit has been properly initialized before the ESC application or if one waits for the CSS to update the parameters, otherwise the system tends to the instability, as shown in Figure 4.

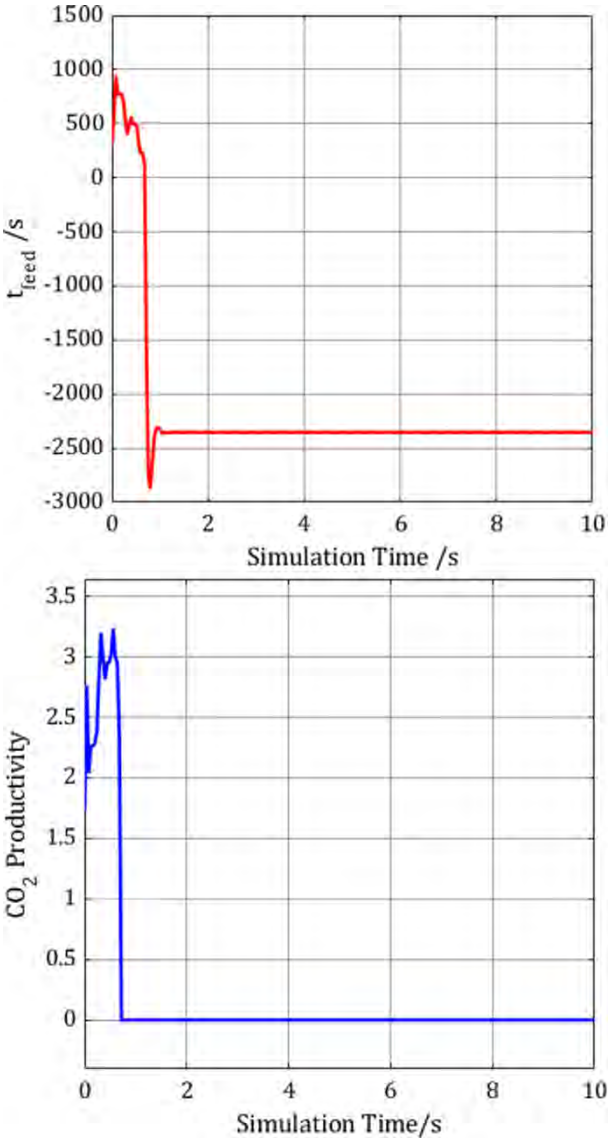

**Figure 4.** ESC action on time of feed value and effect on the productivity of CO2 for case 3.

## CONCLUSIONS

The main objective of analyzing ESC as an alternative to the mainstream methodologies in this understudied topic of RTO applied in PSA systems was fulfilled.

ESC has proven itself as a model-free viable technique for simultaneous control and optimization of PSA units. It has also been demonstrated that there is no need to wait for the unit to reach the CSS after each alteration of the $t_{feed}$ value if an initialization methodology is adopted (in this case, the occurrence of a certain number of PSA cycles before the ESC was activated).

Following this first approach on the ESC implementation in PSA units, some key aspects must be considered in the future work to be developed.

First, this work did not take into consideration the noise present in measurements that a real PSA unit would be subjected to. Despite ESC usually having a proper filter with the goal of filtering such noise (the low pass filter that was not implemented in this work), its capacity to actuate in the system in such circumstances must be evaluated.

In addition, the response to the external disturbances that can affect the process has not been studied in the scope of this work and remains a key aspect to be analyzed to further cement the ESC as an alternative to MPC.

Lastly, for this methodology to reach its full potential, the coordinated optimization of multiple objectives and multiple inputs is crucial. Some works in the literature already cover this topic [22]. However, no references for its application in cyclic adsorption processes could be found at this point, reinforcing the importance of the exploration of such topic.

## ABSTRACT

Monitoring chemical composition is key in several industrial-scale chemical processes. However, traditional composition sensors usually convey drawbacks, including high costs, short lifetimes, and frequent calibration requirements. As an alternative, software (soft) sensors have gained attention in recent years due to their accuracy, ease of training, and potential of integrating widely known machine learning techniques. This study presents the methodology followed to train a soft sensor for hydrogen sulfide monitoring in the gas treatment section of an industrial facility in Italy. In particular, this methodology includes a novel approach for steady-state determination from historical plant data in the presence of several steady states and noise. Unfortunately, only four steady states were found in the plant data, which was insufficient for accurate soft sensor training. As an alternative, these steady states were used to develop and validate a rigorous Aspen HYSYS process simulation. The relative error of the simulation compared to the steady states found was around 1%. This simulation was used to extract additional steady state data, which was sufficient for soft sensor training. The soft sensor, trained following a Kriging Gaussian Process regression, showed a relative error with respect to the rigorous simulation of around 0.7%. The high accuracy of the sensor suggests it is a quick, low-cost, and accurate alternative to estimate the hydrogen sulfide composition and identify potential operating conditions that may lead to off-specification conditions. Future work will focus on field implementation and evaluation of the trained sensor.

**Keywords**: Process Control, Soft sensor, Simulation, Steady-State

## INTRODUCTION

Control systems are key in the operation of chemical processes to maintain their stability, meet production targets, and fulfill safety, quality, and environmental constraints. Nowadays, most industrial-scale processes depend on conventional or classical control systems, based on closed loops of sensors, controllers, and final control elements [1]. Despite all these components playing an important role, sensors are particularly critical since the performance of the control loop depends on the quality of the data they provide [2].

Conventional sensors measure physical quantities to monitor key process variables like temperatures, pressures, levels, and flow rates. However, tracking variables such as compositions is complex, and the sensors required for this task are equally sophisticated. Moreover, these sensors usually convey several drawbacks, including high capital and operating costs, long measurement delays, short lifetimes, sensitivity to harsh environments, or frequent calibration requirements [2].

A widely spread alternative for composition evaluation is its indirect measurement. A classic example is evaluating the composition inside a distillation column using equilibrium calculations and the temperature measured at a determined stage. This method is particularly

efficient for binary or pseudo-binary mixtures [3]. However, composition inference increases in complexity in multi-component systems or when the mathematical correlation between variables is uncertain [4].

Novel methodologies for indirect composition measurement have benefitted from the growing interest in Machine Learning. In particular, inferential models built from process data called software sensors (or soft sensors) have gained attention in recent years [4]. They have been successfully implemented to assess the composition of complex mixtures present in processes such as polymeric isomerization [5] and fermentation [6].

Data quality significantly impacts the final model accuracy, as in any data-based approach. Therefore, it is essential not only to gather enough process data but also to preprocess it effectively to maximize the available information. In the literature, soft sensors are typically trained using datasets that require preprocessing steps, such as noise removal [7] or steady-state identification [8]. However, these studies often address only one of these tasks.

In the absence of a generalized methodology for steady-state detection in the literature, this work presents an innovative approach used in the steady-state detection of the gas treatment section of an oil regeneration plant in Italy. This methodology will support the development of a rigorous simulation of the process and posterior training of a hydrogen sulfide soft sensor.

## PROBLEM STATEMENT

The case study considered in this work is the gas treatment section of an industrial-scale plant located in Pieve Fissiraga, Italy. This plant, property of Itelyum S.p.A., produces high-quality lubricants from wasted oils, following the Revivoil™ process [9]. Combined with a second plant in Ceccano, Italy, Itelyum currently achieves a wasted oil treatment capacity of around 200 kt/y. Figure 1 presents the Block Flow Diagram (BFD) including the main unit operations of the Revivoil™ process.

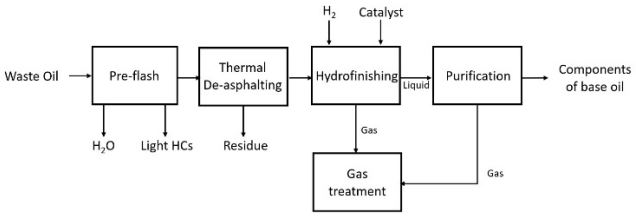

**Figure 1.** BFD of the Revivoil™ waste oil regeneration process.

The gas treatment section aims to remove acid gases such as hydrogen sulfide and carbon dioxide from gaseous products obtained in the hydro-finishing section of the plant. This is done via absorption in Diethanolamine (DEA) and its subsequent regeneration. Figure 2 presents a simplified scheme of the gas treatment section, highlighting the key process streams.

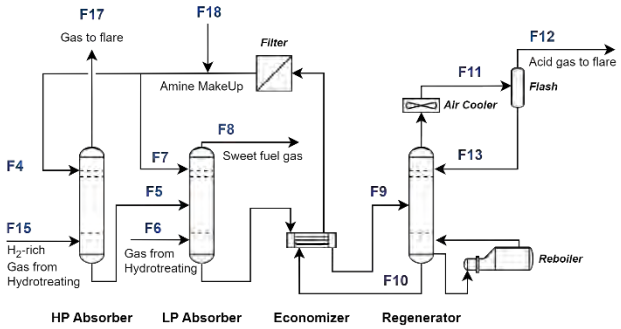

**Figure 2.** Simplified Process Flow Diagram of the gas treatment section showing key streams for the soft-sensor training.

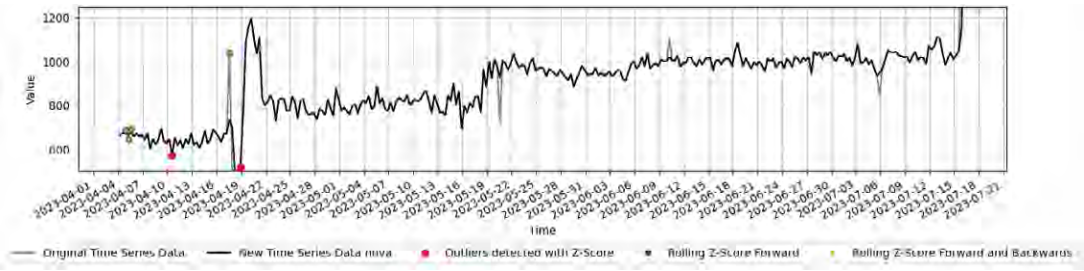

Hydrogen sulfide is a toxic gas that contributes to acid rain formation. Consequently, its emissions are strictly controlled, especially in the European Union [10]. Hydrogen sulfide composition in the facility considered in this work is measured in a laboratory via gas sample analysis by a gas chromatographer. This procedure has demonstrated delays of up to eight hours in the determination of hydrogen sulfide composition, which could potentially lead to long off-specification operation periods. Considering these complexities, a soft sensor of the gas treatment section would be a low-cost immediate solution to provide a quick and accurate estimate of hydrogen sulfide composition in order to identify operating conditions with the potential to lead the process off-specifications.

## PROCESS DATA AND PRE-PROCESSING

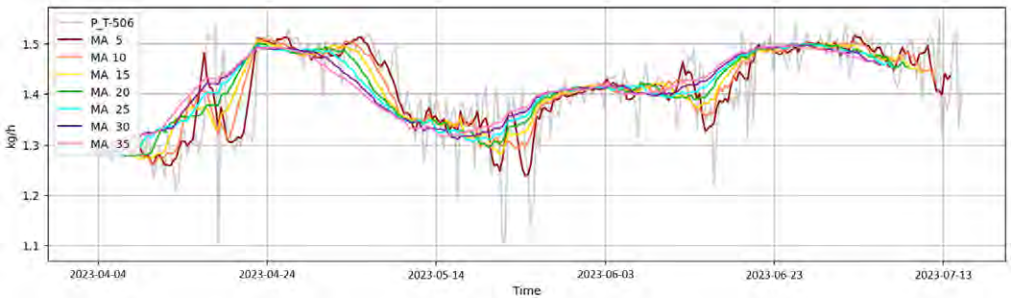

**Table 1:** Variables with a potential influence on the $H_2S$ concentration of the sweet fuel gas stream.

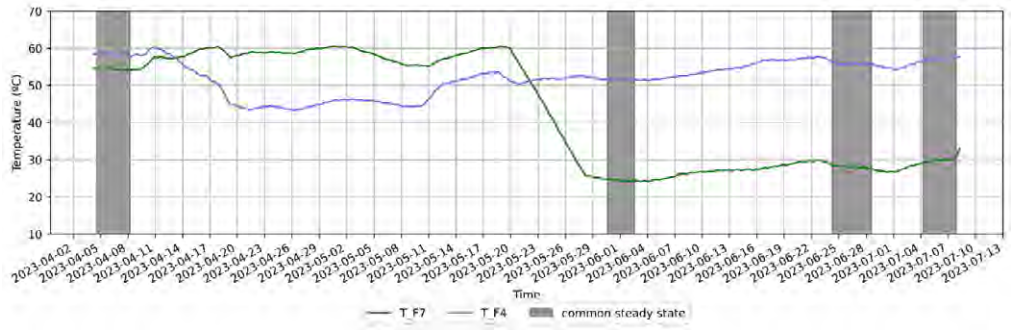
| Stream / Unit | Variables | Description |
|---|---|---|
| F15 | F, T | Gas stream entering HP absorber from hydrotreatment. |
| F6 | F, T | Gas stream entering LP absorber from hydrotreatment. |
| F18 | F, T | DEA makeup stream. |
| LP Abs. | P | Pressure in LP absorber. |
| HP Abs. | P | Pressure in HP absorber. |
| Regen. | P | Pressure in the regenerator. |



Historical data from variables expected to influence $H_2S$ composition in streams F8, F12, and F17 was obtained from the plant records (see Table 1). However, data pre-processing was required to extract the most

**a)** Outlier detection for the flow rate of stream F9. Outliers found with the forward z-scores method are highlighted in green, with the backward in red, and with both in gray.

**b)** Sensitivity analysis of the number of points in the rolling window for the noise reduction using the moving average approach using the pressure in the LP absorber.

**c)** Steady-state detection results showing the temperature profiles of F4 (purple), F7 (green), and the common steady states for all the analyzed variables as the zones shaded in grey.

**Figure 3:** Data preprocessing results for the historical data of the gas treatment section.

information from these records. Typical pre-processing activities include data normalization, outlier detection, missing data insertion, noise reduction, and data reconciliation. These methodologies were applied using the NumPy, SciPy, and Scikit Learn Python packages.

## Outlier detection

Outliers are data points that deviate from the dataset trend and could bias an eventual model, reducing its accuracy [11]. z-score methodology (Equation 1) is commonly used for outlier detection and removal.

$$Z_{score} = \frac{x-\bar{x}}{\sigma} \quad (1)$$

Where $x$ is the data point, $\bar{x}$ is the mean, and $\sigma$ the variance of the considered dataset. Nonetheless, this methodology may be unsuccessful if multiple steady states are present in the dataset. As an alternative, a rolling z-scores methodology was used. The methodology was applied to the dataset rolling it forward and backward. The number of points considered in each window was 10, which was visually verified to remove actual outliers while avoiding deleting points that may provide useful information. Figure 3.a presents the outlier detection for the flow rate of stream F9.

## Data reconciliation

Every sensor measurement involves errors, which may be systematic or random. The reliability of these measurements may increase by evaluating whether mass and energy balances using the measurements are respected or not by following a data reconciliation.

From a mathematical point of view, data reconciliation is an optimization problem, where mass balance errors are minimized. The mass balances for the gas treatment section are shown in Equations 2 to 6. The optimization constraints, which aim to keep the stability and physical meaning of the simulation are shown in Equations 7 and 8.

### Mass balances

$$\textbf{LP Absorber}: \ 0 = F4 + F15 - F17 - F5 \quad (2)$$

$$\textbf{HP Absorber}: 0 = F5 + F7 + F6 - F8 - F9 \quad (3)$$

$$\textbf{Regenerator}: \ 0 = F9 + F13 - F11 - F10 \quad (4)$$

$$\textbf{Condenser}: \quad 0 = F11 - F12 - F13 \quad (5)$$

$$\textbf{DEA balance}: \ 0 = F4 + F7 - F10 - F18 \quad (6)$$

### Optimization constraints

$$\textbf{HP Absorber}: \ F15 > F17 \quad (7)$$

$$\textbf{LP Absorber}: \ F6 > F8 \quad (8)$$

## Noise reduction

A standard methodology for noise reduction is the moving average. In this study, the moving average window size was studied for the specific problem. As an example, Figure 3.b presents the sensitivity analysis of the window parameter observed in the pressure of the LP absorber. A window size of 15 points was used so as not to lose relevant information from the dataset while reducing its noise.

## Steady-state identification

The estimation of the gas treatment section dead times was not possible due to limitations in the experimentation in the industrial-scale process. This impeded the direct training of a dynamic soft sensor of the system, such as in the approach of Herceg et al. for a 2,3-dimethylbutane dynamic soft sensor in an isomerization process [5]. As an alternative, a steady-state soft sensor was proposed. This is expected to provide information to identify operating conditions that could potentially lead the process out of specifications.

In the absence of a generalized methodology for steady-state estimation in noisy datasets with multiple possible steady state values, a novel approach was proposed. This methodology was based on the rolling window for outlier detection. In this case, the number of points contained in the sliding window was kept at 10. Inside each window, a linear regression model was fit. Then, the slope of the regression was compared to a threshold value, set at 0.6, to classify it as a steady state. This procedure was followed with all the involved variables to determine the presence of common steady states for all of them.

The results of the steady state determination are shown in Figure 3.c. Four steady states-common for all the analyzed variables of Table 1- were found. These states had between 3 and 5 days of stable operating conditions. The number of points in the rolling window and the slope threshold were graphically validated to confirm the presence of reasonable steady states.

# PROCESS SIMULATION

The small number of steady-states found in the historical data impeded the direct training of the data-based soft sensor. As an alternative, these steady states supported the development and validation of a rigorous process simulation in Aspen HYSYS, which was later used to simulate additional steady states.

The rigorous simulation considered DEA, water, hydrogen, hydrogen sulfide, carbon monoxide, carbon dioxide, nitrogen, methane, ethane, propane, butane, pentane, and a heavy mix of hydrocarbons as components. The thermodynamic package used was *Acid Gas and Chemical Solvents*, ideal for gas sweetening operations. The simulation was validated with process and laboratory data, and the results are shown in Table 2.

**Table 2:** Process simulation accuracy for flow rate [kg/h] compared to the steady-states found in historical data.

| Stream | Preprocessed | Simulation | Rel. Error |
|---|---|---|---|
| F4 | 829.0 | 828.0 | 0.1% |
| F15 | 170.4 | 163.4 | 4.1% |
| F17 | 147.9 | 146.3 | 1.1% |
| F5 | 851.5 | 845.1 | 0.8% |
| F7 | 156.1 | 154.5 | 1.0% |
| F6 | 150.2 | 153.0 | 1.9% |
| F8 | 116.5 | 115.7 | 0.7% |
| F9 | 1041.0 | 1037.0 | 0.4% |
| F13 | 279.4 | 279.2 | 0.1% |
| F11 | 334.6 | 334.5 | 0.0% |
| F10 | 986.2 | 981.6 | 0.5% |
| F12 | 55.2 | 55.7 | 0.9% |
| **Average** | | | **0.9%** |

The rigorous simulation demonstrated a high fidelity with the plant's historical data. However, its complexity and long computational times motivated its splitting into two sections: The first section included the high and low-pressure absorbers (Figure 4), and the second considered the DEA regeneration (Figure 5). The splitting increased the number of required variables, due to the presence of streams interacting in both simulations.

These streams are shown in Table 3. The pre-processing activities were repeated to consider the effect of the new variables.

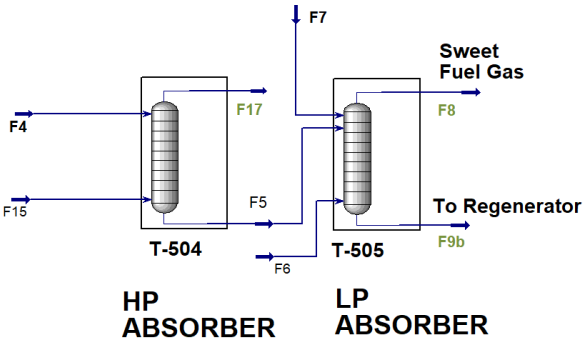


**Figure 4.** Simulation of the absorbers of the gas treatment section using Aspen HYSYS.

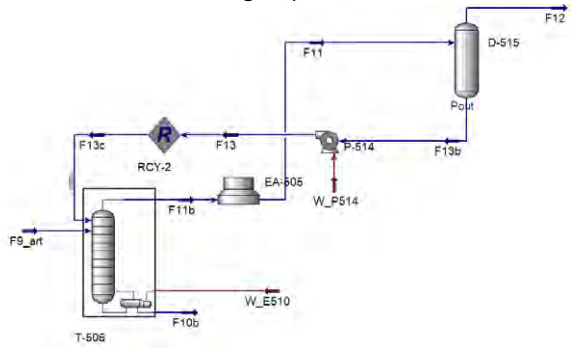

**Figure 5.** Simulation of the DEA regenerator of the gas treatment section in Aspen HYSYS.

**Table 3:** Additional variables with a potential influence on the $H_2S$ concentration of the sweet fuel gas stream due to simulation split.

| Streams | Variable | Description |
|---|---|---|
| F4 | F, T | DEA stream entering HP Absorber. |
| F7 | F, T | DEA stream entering LP Absorber. |
| F9 | F, T | DEA stream entering regenerator from absorbers. |

## SOFT-SENSOR TRAINING

The data-driven soft-sensor model was trained extracting steady-state data from the rigorous simulation. For this purpose, several different combinations of the simulation input values were evaluated via Design of Experiments (DoE). In total, the absorption section had 10 input variables from streams F4, F15, F7, and F6, and units LP Abs. and HP Abs., while the regeneration section had 5 input variables from streams F9 and F13, and the Regenerator unit (See Tables 2 and 3).

The algorithm chosen for DoE was the maximin-optimized Latin Hypercube method, one of the most widely implemented methodologies to guarantee the even spatial distribution of points [12]. A total of 150 combinations of input values for the absorbers section and 75 for the regeneration were tested in the rigorous simulation. These numbers correspond to 15 times the number of input variables, slightly higher than the 10 usually recommended as a minimum for effective computer experiments [13]. This number was selected to consider possible non-convergent simulations. In the end, 118 and 64 simulations for the absorption and regeneration sections reached convergence, respectively.

The generated data was divided into 80/20 partitions, where 80% of the data was used for model training and validation, and 20% for model testing. The training set was subsequently divided into 80/20 partitions used for model training and validation, respectively. The model chosen was the Kriging Gaussian Process with different common kernels such as Radial Basis Function (RBF), Linear, Polynomial, and Rational Quadratic (RQ). The most accurate kernel to model the hydrogen sulfide composition in streams F8, F17, and F12 was chosen via 5-fold cross-validation using the training and validation sets. The results for the accuracy of the soft sensor model evaluated in the test set are presented in Table 4.

**Table 4:** Soft sensor test set error for the output variables ($H_2S$ composition) of the gas treatment section.

| Stream | Variable | Best kernel | Rel. Error |
|---|---|---|---|
| F17 | $x_{H2S}$ | RBF | 0.05% |
| F8 | $x_{H2S}$ | RQ | 1.00% |
| F12 | $x_{H2S}$ | Linear | 0.93% |
| **Average** | | | **0.66%** |

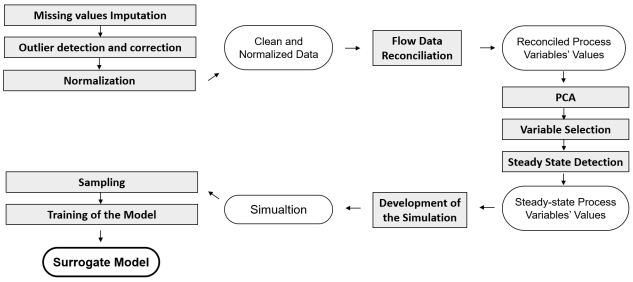

**Figure 6.** Final soft-sensor training methodology implemented for the soft-sensor training.

Table 4 shows the high accuracy of the trained soft sensor compared to simulation data, showing errors below 1%. In addition, the high accuracy of the rigorous process simulation suggests that the soft-sensor may be a practical alternative for hydrogen sulfide concentration estimation, in particular for the identification and prevention of potential off-specification operating conditions in

the gas treatment section of the plant. The methodology followed in this work, including the novel methodology for steady state identification for the soft-sensor training, is summarized in Figure 6.

## CONCLUSIONS

In this work, process data from the gas treatment section of an industrial-scale facility was pre-processed with literature standard methodologies, plus a novel steady-state detection methodology. This methodology considered the combination of a sliding window and a linear regression to assess the dataset which presented noise and multiple steady states. In the end, the steady state data was graphically validated, and used to train a rigorous process simulation of the process. This simulation supported the training of an accurate Kriging-based soft sensor with different kernel functions.

The relative error of the simulation compared to the real process was around 1%, while the relative error of the soft sensor model compared to the rigorous simulation was around 0.7%. The high accuracy of the soft sensor suggests that it is a quick, low-cost, and accurate alternative to estimate the exit composition of hydrogen sulfide and to identify potential operating conditions that may lead to off-specification conditions in the plant. Future work will focus on the implementation of the soft sensor in field operations.

# Principles and Applications of Model-free Extremum Seeking – A Tutorial Review

**Laurent Dewasme and Alain Vande Wouwer**

Systems, Estimation, Control and Optimization (SECO), University of Mons, 7000 Mons, Belgium [laurent.dewasme; alain.vande-wouwer@umons.ac.be]

## ABSTRACT

This article aims to tutorial a few important extremum seeking control approaches that can be used for the model-free optimization of industrial processes in various fields. The application of several methods is illustrated with a simple case study related to the production of algal biomass in photobioreactors. Other methods and applications are briefly reviewed.

**Keywords**: Process Control, Optimization, Biosystems

## INTRODUCTION

Extremum seeking (ES) has become a large family of perturbation-based methods whose origins can be traced back to the work of the French Engineer Leblanc in 1922, who sought to transmit electrical power to a train car contactlessly [1]. Since then, extremum seeking has gained significant attention, especially in the past three decades, notably thanks to the seminal work of Krstic and his co-workers, who provided conditions for convergence and stability analysis [2]. ES is a practical approach aimed at achieving optimal performance of a system by continuously seeking the extremum of an online-measured cost function. The method finds various applications in different fields, provided that the required measurement information is available, and an optimality principle can be formulated. While many simulation studies have confirmed the effectiveness of extremum seeking, relatively few experimental studies have been conducted to validate its real-world applications. This gap between theory and practice is a common challenge in real-time optimization and control.

This article will provide a tutorial introduction to the foundational principles and applications of extremum seeking control (ESC), using a simple case study of micro-algal growth in a photo-bioreactor (PBR) whose productivity can be adjusted by manipulating the dilution rate. More practical applications are briefly cited and available in previous review papers [3-5].

## TUTORIAL EXAMPLE

A dynamic Droop model describes the growth of micro-algae by the following differential equations:

$$\dot{X} = \mu(Q,I)X - D\,X \tag{1a}$$

$$\dot{S} = -\rho(S,Q)X - D\,(S - S_{in}) \tag{1b}$$

$$\dot{Q} = \rho(S,Q) - \mu(Q,I)\,Q \tag{1c}$$

where *X*, *S* and *Q* respectively stand for the biomass, nitrogen substrate source, and internal nitrogen quota, *I* is the light irradiance, $S_{in}$ the substrate concentration in the feed, $D = F_{in}/V$ the dilution rate (assumed to be the sole input). In this latter expression, $F_{in}$ is the feed flow rate, and *V* is the photobioreactor volume. $\mu$ and $\rho$ are the growth and substrate uptake rates, respectively, which are nonlinear functions of the states and light. $\mu$ is modeled by Droop kinetics:

$$\mu(Q,I) = \mu_{max}\frac{I}{K_{I,s}+I+\frac{I^2}{K_{I,i}}}\left(1-\frac{Q_{min}}{Q}\right) \tag{2}$$

and $\rho(S)$ by Monod kinetics:

$$\rho(S,Q) = \rho_{max}\frac{S}{S+K_S}\left(1-\frac{Q}{Q_{max}}\right) \tag{3}$$

where $\mu_{max}$ and $\rho_{max}$ are the maximum rate constants, $Q_{min}$ and $Q_{max}$ the minimum and maximum internal quota capacities, $K_{I,s}$ and $K_S$ the half-saturation constants, and $K_{I,i}$ is the rate inhibition constant. Parameter values relative to the strain Isochrysis galbana are reported in [6]. A bifurcation analysis is also achieved in this study, providing stability conditions on the input steady-state value $D_e$ as follows:

$$D_e < \mu_{max} \quad (4a)$$

$$D_e < \frac{\mu_{max}\,\rho_{max}}{\rho_{max} + \mu_{max}\,Q_{min}} \quad (4b)$$

Defining biomass productivity $y = D\,X$ as the cost function to optimize, a steady-state convex objective function can be obtained:

$$y(D_e) = \frac{D_e S_{in}(\mu_{max} - D_e)}{\mu_{max}\,Q_{min}} \quad (5)$$

and the corresponding optimal operating conditions:

$$D_e^* = \frac{1}{2}\mu_{max} \quad (6a)$$

$$y_e^* = \frac{S_{in}\,\mu_{max}}{4\,Q_{min}} \quad (6b)$$

The process model and optimal operating conditions are unknown in the following, but productivity can be measured online at a fast rate (every minute), and the objective of extremum seeking is to determine the optimal operating conditions quickly and reliably.

## PRINCIPLES OF ESC

### Modulation-Demodulation

The nowadays standard ES approach [2] consists of injecting a periodic perturbation signal (also called dither signal) in the system to extract information using a modulation-demodulation procedure, as represented in Figure 1. The perturbation can be a simple periodic signal, such as a sinusoid with adjustable amplitude and pulsation if only one parameter $\theta$ has to be estimated, or a combination of several periodic signals with different frequencies if several parameters have to be extracted. These parameters refer to a measurable static map

$$y = g(\theta) \quad (7)$$

of a dynamic system

$$\begin{aligned} \dot{x} &= f(x, y) \\ y &= h(x) \\ u &= q(x, \theta) \end{aligned} \quad (8)$$

If the perturbation signal changes slowly with respect to the system dynamics, the latter can be assumed in pseudo-steady state (the process output is then noted $y_{ss}$) and the following relations can be established for the modulated signal $y_{mod}(t)$, the high-pass filtered signal $y_{HP}(t)$, the demodulated signal $y_{demod}(t)$, and the low-pass filtered signal $y_{LP}(t)$

$$\begin{aligned} y_{mod}(t) &\approx y_{ss} + g' a \sin(\omega t) \\ y_{HP}(t) &\approx |G_{HP}(\omega)| g' a \sin(\omega t + \varphi_{HP}) \\ y_{demod}(t) &\approx |G_{HP}(\omega)| g' \frac{a^2}{2}(\cos(\varphi_{HP}) - \cos(2\omega t + \varphi_{HP})) \\ y_{LP}(t) &\approx |G_{LP}(\omega)||G_{HP}(\omega)| g' \frac{a^2}{2}\cos(\varphi_{HP}) \end{aligned} \quad (9)$$

If the cutoff pulsations of the filters $\omega_{HP}$ and $\omega_{LP}$ are well-chosen (they must be smaller than the pulsation of the perturbation signal), then

$$y_{LP}(t) \approx g' \frac{a^2}{2} \qquad if \quad \omega > \omega_{HP}, \omega_{LP} \quad (10)$$

and the low-pass filtered signal contains information about the gradient of the static map g(θ). Modulation-demodulation thus provides a way to estimate the gradient of the cost function to optimize, and the integrator, which follows the low-pass filter in the block diagram of Figure 1, will act as a simple controller pushing to zero this gradient, i.e., seeking for an extremum of the static map.

The application of BOF-ESC (for bank of filters as the modulation-demodulation approach uses several filters) to the microalgal PBR is shown in Figures 2-3.

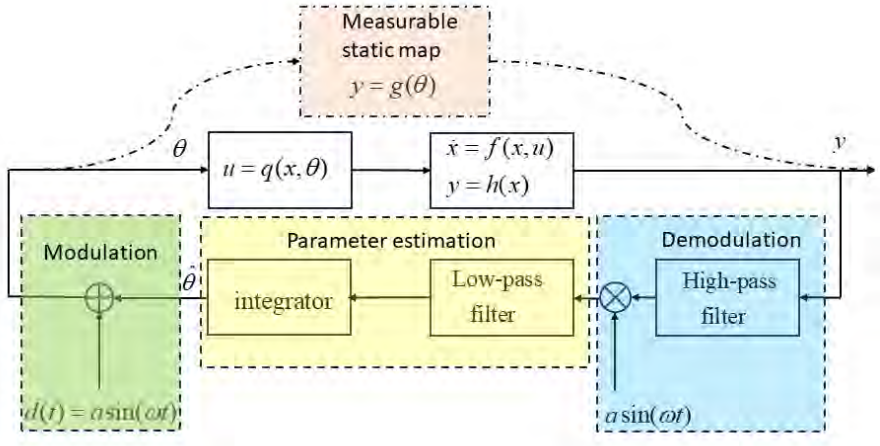

**Figure 1:** Extremum seeking control based on modulation with a dither signal, and demodulation and parameter estimation using demodulation and a bank of filters – BOF (high pass, low pass filters) + integrator.

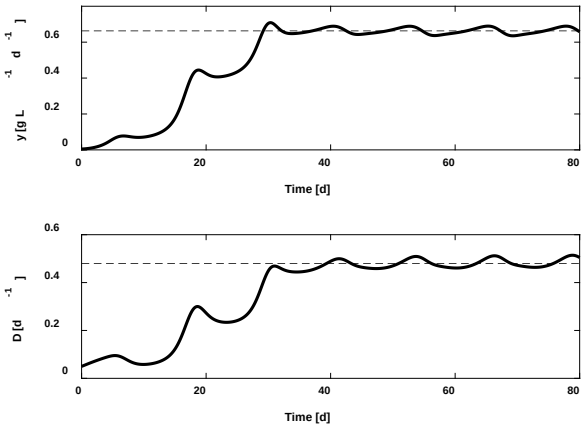

**Figure 2.** Productivity *y* and dilution *D* trajectories over time.

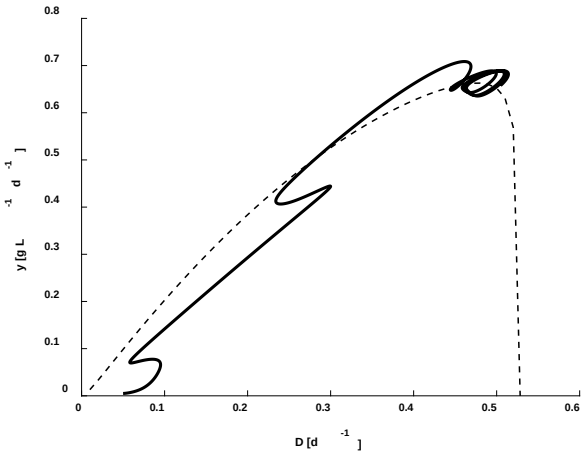

**Figure 3.** Productivity *y* vs dilution *D* diagram.

The perturbation signal is $d(t) = 0.02\,sin(\,0.5t)$, the high-pass filter pulsation $\omega_{HP} = 0.45$ rad/day, and the integrator gains 70. There is no low-pass filter in this design, as the integrator already plays an attenuation role. Figure 3 shows in the dashed line the static map and in the solid line the trajectory of the ESC, with sustained oscillation around the optimum due to the perturbation signal. Convergence is achieved in about 40 days, a pretty long time interval! This highlights the challenges of applying ESC to slow processes (such as those encountered in biotechnology) facing the limitation of the three-time scale separation:

- The process is considered as the fast dynamics;
- The perturbation signal is slow compared to the process dynamics but fast compared to the filter bandwidths;
- Parameter estimation is, therefore, the slowest.

BOF-ESC is a popular approach that has been applied in various fields (see the review paper [3] for a panel of applications) and has been successfully implemented for fast processes such as wind turbines or solar panels (see, for instance, [7] for an application to solar panels). For slower processes, it is critical to accelerate convergence, and various ways are explored in the following.

## PI Extremum seeking

One intuitive way to speed up convergence is to use a PI controller instead of a plain integrator, as initially proposed and analyzed in [8]. The results of applying this strategy to our PBR example by including a proportional action with a gain of 0.5 (see Table 1 for a summary of the parameter values) are shown in Figures 4-6. Convergence is twice as fast (i.e., about 20 hours).

## Block-Oriented Models and ESC

An alternative is to eliminate the filters and replace the modulation-demodulation approach with an estimator, e.g., recursive least-squares, as originally introduced in [9], or Kalman filters, as proposed in [10] where it is applied to the control of thermoacoustic instabilities (another fast system).

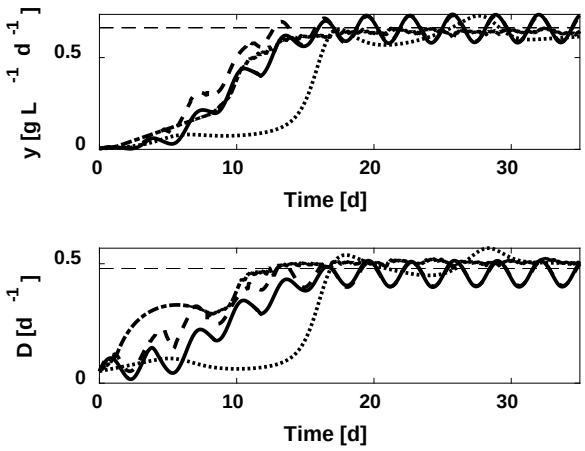

**Figure 4.** Productivity *y* and dilution *D* trajectories over time. Dotted line: PI-ESC; Continuous line: BOM-ESC; Dashed line: NB-ESC; Dashed-dotted line: STAB-ESC.

The structure of this ESC approach is displayed in Figure 7, where the controller can be a simple I control, a PI controller as in the previous subsection, or even a pole placement controller as in [11]. If we consider a recursive least square estimator it is also possible to describe the process in a slightly more detailed way to distinguish the static map from the dominant dynamics, as in Figure 8. The model of choice is a Hammerstein model, which combines a static block with a linear dynamic block (this type of model belongs to the family of block-oriented models – BOM in the following). The consideration of the process dynamics can improve parameter estimation and alleviate biased estimation. In our example, a quadratic map

**Table 1.** Parameter tuning of the reviewed extremum-seeking methods

| Parameter | PI-ESC | BOM-ESC | NB-ESC | STAB-ESC |
|---|---|---|---|---|
| $\omega_1$ (rad/d) | 0.5 | 2 | 2 | 100 |
| $\omega_2$ (rad/d) | / | 1 | 1 | / |
| $a_1$ ($d^{-1}$) | 0.02 | 0.05 | 0.05 | / |
| $a_2$ ($d^{-1}$) | / | 0.025 | 0.025 | / |
| $k_i$ | 70 | 6 | 6 | / |
| $k_p$ | 0.5 | 0 | 0 | / |
| g | / | 3 | 3 | / |
| $\lambda$ | / | 0.99 | 0.99 | / |
| $\omega_{HP}$ (rad/d) | 0.45 | / | / | / |
| $\alpha$ | / | / | / | 0.0002 |
| k | / | / | / | 4000 |

with two parameters, $M_1$ and $M_2$, is considered in combination with a first-order transfer function. The estimation of 4 parameters requires a sufficiently rich excitation signal and here $d(t) = a_1 \sin\omega_1 t + a_2 \sin\omega_2 t$. The quadratic map is a local approximation of the local convex optimum. The selected parameters are given in Table 1 and the results displayed in Figures 4-6.

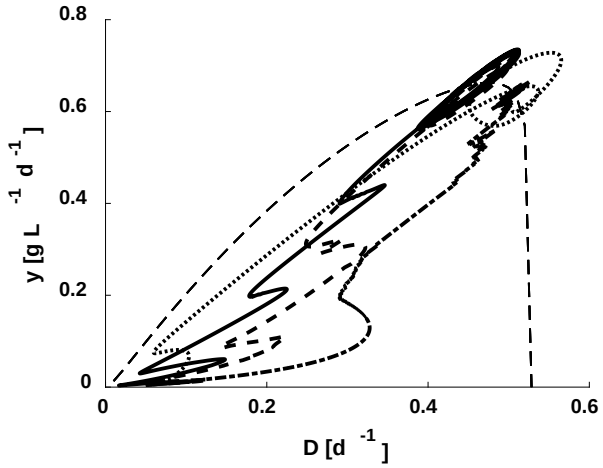

**Figure 5.** Productivity *y* vs dilution *D* diagram trajectories. Dotted line: PI-ESC; Continuous line: BOM-ESC; Dashed line: NB-ESC; Dashed-dotted line: STAB-ESC.

$$
\begin{aligned}
e &= y - \Phi^T \hat{\xi} \\
\dot{\hat{\xi}} &= K R^{-1} \Phi^T e \\
\dot{R} &= K(\Phi^T \Phi - \lambda R) \\
\dot{\hat{\theta}} &= k_i \, \hat{\xi} \\
\theta &= \hat{\theta} + d,
\end{aligned} \tag{11}
$$

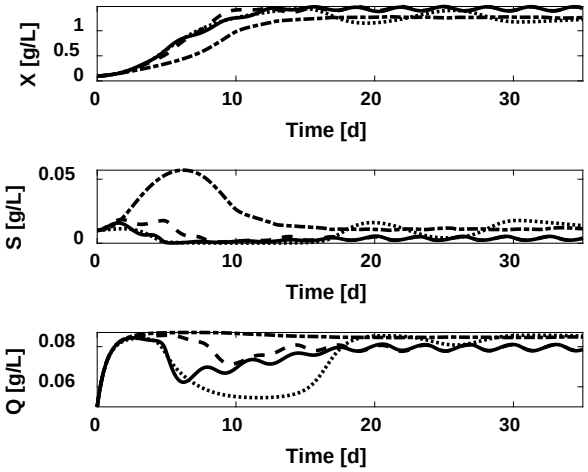

**Figure 6.** State trajectories over time. Dotted line: PI-ESC; Continuous line: BOM-ESC; Dashed line: NB-ESC; Dashed-dotted line: STAB-ESC.

## Newton seeking

It is also possible to improve ESC's line search by considering second-order information in addition to the gradient information. This allows scaling the gradient by the Hessian, as in the classical Gauss-Newton optimization algorithm. This approach was originally introduced in [12]. The application of this technique to our tutorial example is illustrated in Table 1 and Figures 4-6 (NB-ESC). When used in combination with a Hammerstein model, the Hessian is readily available in parameter $M_1$, which makes the application of the method particularly straightforward. Newton seeking is, however, mostly useful in multiple input problems with different relative gains, where the Hessian scaling will be particularly beneficial.

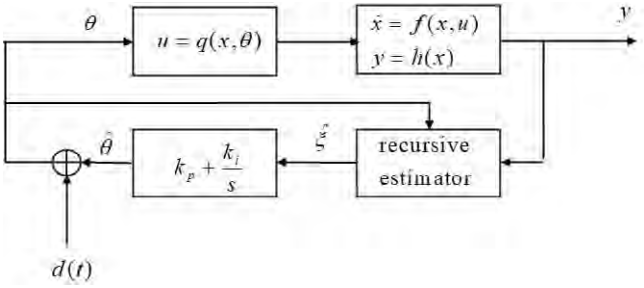

**Figure 7.** ESC using a parameter estimator (recursive least-squares or Kalman filtering) and a PI controller.

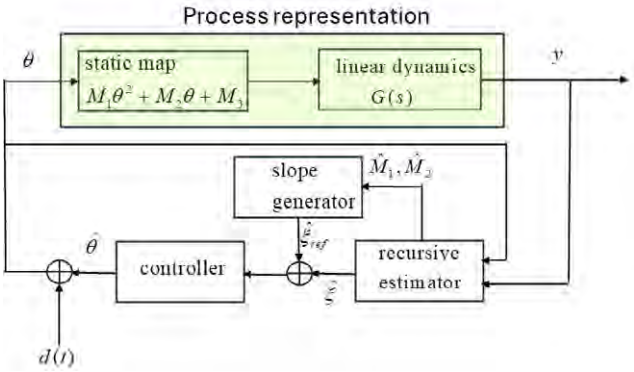

**Figure 8.** ESC using a parameter estimator (recursive least-squares or Kalman filtering), a block-oriented model (BOM) of the process, a slope generator and a generic controller.

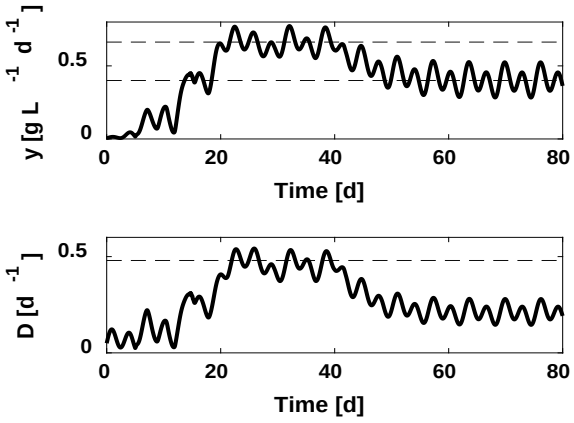

**Figure 9.** Productivity *y* and dilution *D* trajectories over time with BOM-ESC until 40 days ($y_{ref} = y^*$), followed by slope seeking ($y_{ref} = 0.4\ g\ L^{-1}\ d^{-1}$) until 80 days.

## Slope seeking

As illustrated in Figure 8, using ESC to achieve suboptimal operating points corresponding to non-zero gradients is also possible. Indeed, the controller can achieve any gradient setpoint. This can be used to alleviate the problem posed by a flat optimum, as might be the case in active flow control [13]. This can also be used in conjunction with a slope generator to achieve the desired level of productivity as suggested by [14].

Figure 9 shows a scenario where the extremum seeking is switched after 40 days to a specific slope set-point, corresponding to a productivity reference $y_{ref} = 0.4\ g\ L^{-1}\ d^{-1}$.

## Stabilizing Extremum seeking

In the search for more robustness, particularly to measurement noise, a new ESC framework was proposed in [15].

The cost function J, assumed to be a cost Lyapunov function (CLF), is included in the argument of a bounded periodic signal

$$\dot{\theta} = \sqrt{\alpha\omega}\cos(\omega t - kJ) \tag{12}$$

as shown in Figure 9.

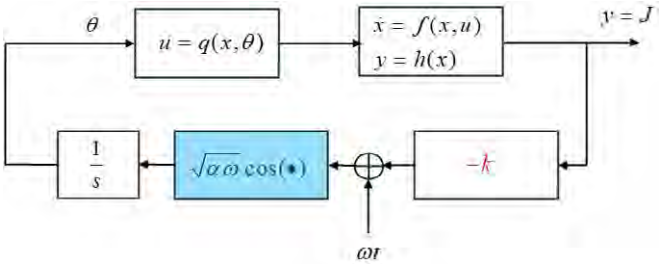

**Figure 10.** ESC using a parameter estimator (recursive least-squares or Kalman filtering) and a PI controller

As for the original proofs of convergence provided in [2], averaging techniques are required, with in addition, the concept of weak limits. This elaborate mathematical framework is detailed in [15] with the end result that

$$\dot{\hat{\theta}} = \frac{k\alpha}{2}\nabla J \tag{13}$$

The application of this technique is also shown in Table 1 and Figures 4-6.

# CONCLUSIONS

Extremum-seeking control is a multifaceted, versatile approach that allows optimizing process operation without the need for the tedious development of a dynamic model. It usually yields very satisfactory results in fast applications (MPPT in solar or wind systems, flow control, etc), but is more delicate to design and tune in slower processes, as illustrated in our tutorial application. Fundamental multi-input aspects can be found in [18]. The interested reader can also find experimental applications of ESC to micro-algae systems in [14, 16] and an application of the recent stabilizing ESC approach [15] to bioprocesses in [17].

## ABSTRACT

This paper introduces the Updated Absolute Expected Value Solution, U-AEEV, a heuristic for solving multi-stage stochastic programming (MSSP) problems with type 2 endogenous uncertainty. U-AEEV is an evolution of the Absolute Expected Value Solution, AEEV [1]. This paper aims to show how U-AEEV overcomes the drawbacks of AEEV and performs better than AEEV. To demonstrate the performance of U-AEEV, we solve 6 MSSP problems with type 2 endogenous uncertainty and compare the solutions and computational resource requirements.

**Keywords**: Stochastic Optimization, endogenous uncertainty, heuristics

## 1. INTRODUCTION

Multi-stage stochastic programming (MSSP) is a common mathematical framework used to solve decision-making problems, such as planning and process design problems, under uncertainty often encountered in the process industry [2-3]. In MSSP problems, the outcomes of uncertain events materialize over a given time horizon, and the realized outcomes distinguish given scenarios, allowing the decision-maker to take corrective action in distinguished scenarios. Taxonomically [4], there are two categories of uncertainty in stochastic programming: decision-independent, also known as exogenous uncertainty, and decision-dependent, also known as endogenous uncertainty. The endogenous uncertainty can be further categorized into three sub-classes: type 1, where the probability distribution is decision-dependent; type 2, where the information structure is decision-dependent; and type 3, where both probability distribution and the information structure are decision-dependent. As for type 2 endogenous uncertainty, which U-AEEV mainly deals with, decisions affect the resolution of uncertainty, i.e., information structure (the shape of a scenario tree) is decision-dependent. The non-anticipativity constraints (NACs) used to ensure the indistinguishability among scenarios before knowing the outcomes of future events cause significant complexities and computational intractability in solving real-life-sized problems. This challenge has motivated researchers to develop various heuristic and decomposition-based solution approaches, such as the sample average approximation algorithm [5], and Benders decomposition [6], to obtain solutions.

A heuristic, Absolute Expected Value Solution (AEEV), which our group developed [1], yields feasible solutions to MSSP problems with type 2 endogenous uncertainty. AEEV circumvents the computational intractability by decomposing scenarios of an original MSSP problem into multiple deterministic sub-problems with expected uncertain parameter values. In each period from the initial to the end of the time horizon, AEEV iterates to solve a sub-problem, fixes the here-and-now decision variable values, judges uncertainty realization, updates the expected uncertain parameter values based on the realized uncertainty, solves deterministic recourse sub-problems to determine corrective action, and fixes wait-and-see decision variable values. A drawback of AEEV is that it may fail to generate a feasible solution if the original MSSP problem does not have complete recourse. More precisely, the expected uncertain parameter for a recourse sub-problem does not always ensure feasible corrective action following uncertainty realization; accordingly, the sub-problem may be infeasible if the original MSSP problem lacks complete recourse.

In this paper, we introduce the Updated Absolute Expected Value Solution (U-AEEV), which expands the applicability of the AEEV to MSSP problems without complete recourse by eliminating the potential infeasibility is-

sues. The U-AEEV iteratively solves scenario-decomposed deterministic sub-problems using the outcomes of each scenario instead of the expected values of the uncertain parameters, evaluates the solutions to the sub-problems in terms of infeasibility and quality, and selects one. The U-AEEV yields tight feasible solutions without significant growth in computational time.

## 2. THE FRAMEWORK OF MSSP WITH TYPE 2 ENDOGENOUS UNCERTAINTY

MSSP problems with type 2 endogenous uncertainty consider multiple scenarios and a discretized time horizon, where scenarios gradually become distinguishable over the time horizon. Equations (1)-(15) represent a common formulation of MSSP with type 2 endogenous uncertainty (this is an extended formulation from [1]).

$$\min z = \sum_{s\in\mathcal{S}} p_s \sum_{i\in\mathcal{I},t\in\mathcal{T}} G_{i,t,s}\left(V_{i,t},\theta_{i,s},b_{i,t,s},x_{i,t,s},y_{i,t,s},w_{i,t,s}\right) \quad (1)$$

subject to

$$g\left(V_{i,t},\theta_{i,s},b_{i,t,s},x_{i,t,s},y_{i,t,s},w_{i,t,s}\right)\le 0 \quad \forall i\in\mathcal{I},\quad \forall t\in\mathcal{T},\quad \forall s\in\mathcal{S} \quad (2)$$

$$h\left(V_{i,t},\theta_{i,s},b_{i,t,s},x_{i,t,s},y_{i,t,s},w_{i,t,s}\right)= 0 \quad \forall i\in\mathcal{I},\quad \forall t\in\mathcal{T},\quad \forall s\in\mathcal{S} \quad (3)$$

$$b_{i,1,s}=b_{i,1,s'} \quad \forall i\in\mathcal{I},\quad \forall s,s'\in\mathcal{S} \quad (4)$$

$$x_{i,1,s}=x_{i,1,s'} \quad \forall i\in\mathcal{I},\quad \forall s,s'\in\mathcal{S} \quad (5)$$

$$b^{\mathrm{dif}}_{i,t,s}=b_{i,t,s}\Leftrightarrow Z_{t,s,s'}=H\left(b_{i,t,s}\right) \quad \forall i\in\mathcal{D}(s,s'),\quad \forall t\in\mathcal{T},\quad \forall s,s'\in\mathcal{S} \quad (6)$$

$$w^{\mathrm{dif}}_{i,t,s}=w_{i,t,s}\Leftrightarrow Z_{t,s,s'}=H\left(w_{i,t,s}\right) \quad \forall i\in\mathcal{D}(s,s'),\quad \forall t\in\mathcal{T},\quad \forall s,s'\in\mathcal{S} \quad (7)$$

$$Z_{t,s,s'}=H\left(b^{\mathrm{dif}}_{i,t,s},w^{\mathrm{dif}}_{i,t,s}\right) \quad \forall i\in\mathcal{D}(s,s'),\quad \forall t\in\mathcal{T},\quad \forall s,s'\in\mathcal{S} \quad (8)$$

$$\begin{bmatrix} Z_{t,s,s'} \\ b_{i,t+1,s}=b_{i,t+1,s'} \\ x_{i,t+1,s}=x_{i,t+1,s'}\end{bmatrix}\vee\left[\neg Z_{t,s,s'}\right] \quad \forall i\in\mathcal{I},\quad \forall t\in\mathcal{T}|t\le T-1,\quad \forall s,s'\in\mathcal{S} \quad (9)$$

$$\begin{bmatrix} Z_{t,s,s'} \\ y_{i,t,s}=y_{i,t,s'}\end{bmatrix}\vee\left[\neg Z_{t,s,s'}\right] \quad \forall i\in\mathcal{I},\quad \forall t\in\mathcal{T},\quad \forall s,s'\in\mathcal{S} \quad (10)$$

$$b_{i,t,s}\in\{0,1\} \quad \forall i\in\mathcal{I},\quad \forall t\in\mathcal{T},\quad \forall s\in\mathcal{S} \quad (11)$$

$$x_{i,t,s}\ge 0 \quad \forall i\in\mathcal{I},\quad \forall t\in\mathcal{T},\quad \forall s\in\mathcal{S} \quad (12)$$

$$y_{i,t,s}\ge 0 \quad \forall i\in\mathcal{I},\quad \forall t\in\mathcal{T},\quad \forall s\in\mathcal{S} \quad (13)$$

$$w_{i,t,s}\ge 0 \quad \forall i\in\mathcal{I},\quad \forall t\in\mathcal{T},\quad \forall s\in\mathcal{S} \quad (14)$$

$$Z_{t,s,s'}\in\{0,1\} \quad \forall t\in\mathcal{T},\quad \forall s,s'\in\mathcal{S} \quad (15)$$

The formulation includes two types of decision variables: here-and-now decision variables corresponding to $b_{i,t,s}$ (binary) and/or $x_{i,t,s}$ (continuous or integer), and wait-and-see decision variables corresponding to $y_{i,t,s}$ (continuous or integer), with the problem-specific index $i\in\mathcal{I}=\{1,2,\dots,I\}$, time index $t\in\mathcal{T}=\{1,2,\dots,T\}$, and scenario index $s\in\mathcal{S}=\{1,2,\dots,S\}$. Variable $w_{i,t,s}$ notates non-decision variables that are entirely dependent on here-and-now and wait-and-see decision variables. If a scenario pair $s$ and $s'$ becomes distinguishable due to uncertainty realization at time $t$, here-and-now decision variables can take different values at $t+1$ and after, as conditional NACs (9) imply. In other words, here-and-now decision variables must take the same values at $t$ because the decisions are made before realization at $t$. Since conditional NACs (9) do not ensure the scenario indistinguishability at $t=1$, here-and-now decision variables need initial NACs by separate equations (4)-(5). In contrast to here-and-now decision variables, wait-and-see decision variables can take different values at $t$ when scenario realization occurs to determine the corrective action after realization, as conditional NACs (10) imply. Equation (10) includes initial NACs for wait-and-see decision variables, i.e., wait-and-see decision variables can omit separate equations for the initial NACs. The binary variable $Z_{t,s,s'}$ in conditional NACs (9)-(10) is called the indicator variable, which is 1 if a scenario pair $s$ and $s'$ is indistinguishable at the end of time $t$ and 0 otherwise. The value of the indicator variable switches based on the values of particular binary decision variables or non-decision variables. We define the particular variables as differentiator variables, $b^{\mathrm{dif}}_{i,t,s}$ and $w^{\mathrm{dif}}_{i,t,s}$, in (6) and (7), i.e., a binary decision variable or a non-decision variable is a differentiator variable if the indicator variable is bounded using these variables. The differentiator variables switch the value of the indicator variable through the expression $H\left(b^{\mathrm{dif}}_{i,t,s},w^{\mathrm{dif}}_{i,t,s}\right)$ in (8). $\mathcal{D}(s,s')$ in (6)-(8) is a differentiator set, a set of $i$ that has different outcomes in an uncertain parameter pair $\theta_{i,s}$ and $\theta_{i,s'}$. The objective function (1) provides the optimum of expression $z$ based on the probability, $p_s$, of scenario $s$ and the contribution of the scenario, $G_{i,t,s}\left(V_{i,t},\theta_{i,s},b_{i,t,s},x_{i,t,s},y_{i,t,s},w_{i,t,s}\right)$. The two given parameters, $V_{i,t}$ and $\theta_{i,s}$, are deterministic and uncertain parameters, respectively. Equations (2)-(3) express scenario-specific inequality and equality constraints, such as demand constraints, capacity constraints, and material balances.

## 3. UPDATED ABSOLUTE EXPECTED VALUE SOLUTION APPROACH (U-AEEV)

The U-AEEV, similar to AEEV, is a scenario-decomposition approach to mitigating the computational intractability of an MSSP problem with type 2 endogenous uncertainty. The U-AEEV solves deterministic sub-problems using each scenario outcome for the uncertain parameters and enumerates multiple 'decision candidates' in a stage-wise (in the sense of MSSP) manner. It evaluates the 'decision candidates' and adopts a feasible and promising candidate for the current stage. After finding the end of the stage by detecting uncertainty realization,

U-AEEV stores the stage's decision variable values to ensure the indistinguishability of scenarios by fixing them when it solves sub-problems in subsequent stages.

**Figure 1** is an example (a process network synthesis problem [2]) to illustrate how U-AEEV works. Raw materials C and D are used to produce intermediate B through new Process 1 and Process 2, and intermediate B is used to produce product A through existing Process 3. The decision maker can purchase B and must satisfy the demand for product A by production or purchase while maximizing the expected net present value.

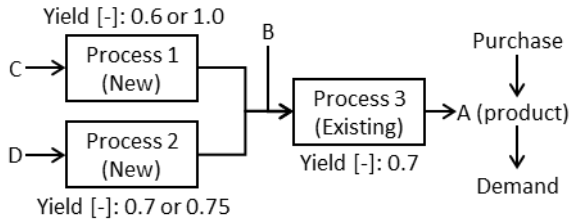

**Figure 1.** An example problem [2] to illustrate U-AEEV.

The here-and-now decisions of the example are the installation and capacity of each process, as well as the flow rates of raw materials and purchased intermediate B. The wait-and-see decision is the purchase rate of Product A. The source of endogenous uncertainty is the yield of Process 1 and Process 2, which materializes by installing and operating the process. The decision maker determines here-and-now decisions, such as installation, capacity, and flow rates, at the start of a time, waits until the yield of processes becomes clear, and then determines the rate of A purchased. **Table 1** lists scenarios and the yield and probability of each scenario.

**Table 1:** Scenarios, yields, and probabilities of the example problem in Figure 1.

| Scenario | Yield [-] | | Probability |
|---|---|---|---|
| | Process 1 | Process 2 | |
| $s1$ | 0.6 | 0.7 | 0.4 |
| $s2$ | 0.6 | 0.75 | 0.3 |
| $s3$ | 1.0 | 0.7 | 0.2 |
| $s4$ | 1.0 | 0.75 | 0.1 |
| Expected | 0.72 | 0.72 | - |

The U-AEEV starts by solving four deterministic sub-problems with each scenario outcome and enumerates the decision candidates suggested by each scenario, as shown in **Figure 2**. In the case of this example, Scenario 1 ($s_1$) suggests Candidate 1, in which neither Process 1 nor 2 is installed, Scenario 2 ($s_2$) suggests installing Process 2 at Time 1 ($t_1$) in Candidate 2, and Scenario 3 ($s_3$) and 4 ($s_4$) suggest installing Process 1 at Time 1 ($t_1$) in Candidate 3. Note that the time horizon of the example has three time periods.

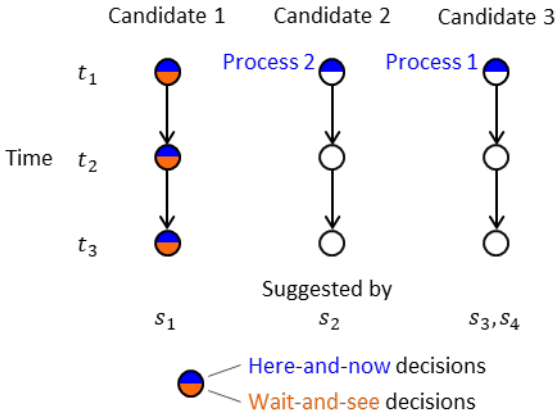

**Figure 2.** Decision candidates of the first stage (up to the first realization)

Since U-AEEV solves deterministic sub-problems stage-wise, decision candidates at this step refer to the decisions of the first stage (up to the first realization). In other words, the decision candidates of Candidate 1 are the here-and-now and wait-and-see decisions from Time 1 ($t_1$) to Time 3 ($t_3$) because Candidate 1 sees no uncertainty realization throughout the time horizon. Similarly, the decision candidates of Candidate 2 and 3 are the here-and-now decisions at Time 1 ($t_1$) because uncertainty partially materializes by installing and operating Process 2 or 1. For example, Scenarios 1 and 3 or Scenarios 2 and 4 become distinguishable through operating Process 2 in Candidate 2.

The U-AEEV picks up candidates to be evaluated based on the total probability of a candidate, $p^{\mathrm{c}}$, in (16) and weighted objective value, $\mathrm{obj}^{\mathrm{c}}$, in (17), where $p_s$ is the probability of the scenario $s$, $\mathrm{obj}_s$ is the objective value of the sub-problem solved with the outcome of scenario $s$, and $S^{\mathrm{c}}$ is a set of scenarios that suggest candidate $\mathrm{c}$.

$$p^{\mathrm{c}} = \sum_{s \in S^{\mathrm{c}}} p_s \tag{16}$$

$$\mathrm{obj}^{\mathrm{c}} = \frac{\sum_{s \in S^{\mathrm{c}}} p_s \, \mathrm{obj}_s}{\sum_{s \in S^{\mathrm{c}}} p_s} \tag{17}$$

The U-AEEV only evaluates the candidates on the Pareto front of the $p^{\mathrm{c}}$-$\mathrm{obj}^{\mathrm{c}}$ plane (**Figure 3**), i.e., the candidates with high probabilities and high objective values (in a maximization problem) are evaluated. In a minimization problem, the Pareto front is formed based on high probabilities and low objective values. The selection using a Pareto front helps to reduce computational time by focusing only on promising candidates. Since the example is a maximization problem, Candidates 1 and 3 on the Pareto front in Figure 3 are evaluated.

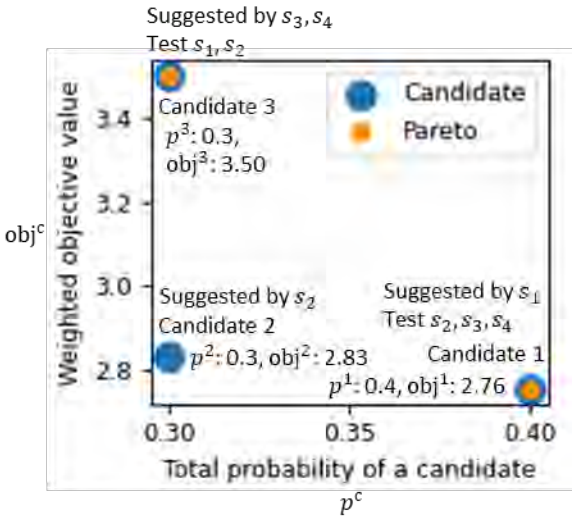

**Figure 3.** The total probability of a candidate ($p^c$) and weighted objective value ($\text{obj}^c$) plane for the evaluation of decision candidates

The U-AEEV checks feasibility and compares the expected objective values of candidates, $\underset{s\in S^{\text{InD}}}{\text{E}}[\text{obj}_s]$, in (18) on the Pareto front by testing each candidate with all other scenario outcomes that did not suggest the candidate. In the example, the U-AEEV solves sub-problems with Scenario 2 ($s_2$), 3 ($s_3$), and 4 ($s_4$) outcomes for Candidate 1, and Scenario 1 ($s_1$) and 2 ($s_2$) outcomes for Candidate 3, and adopts the best candidate regarding the expected objective value calculated with (18). $S^{\text{InD}}$ is a set of indistinguishable scenarios associated with the sub-problems, i.e., Scenarios 1, 2, 3, and 4 in the example, since none of the scenarios are distinguishable at the first stage.

$$\underset{s\in S^{\text{InD}}}{\text{E}}[\text{obj}_s] = \sum_{s\in S^{\text{InD}}} p_s \,\text{obj}_s \tag{18}$$

The candidate with the largest expected objective value is adopted in a maximization problem, and the candidate with the smallest expected objective value is adopted in a minimization problem. If a candidate turns out to be infeasible when solving sub-problems due to a lack of complete recourse, the U-AEEV excludes the candidate from the evaluation process. Then, it forms a new Pareto front and evaluates candidates located on the updated Pareto front. For example, the U-AEEV removes Candidate 3 from the evaluation process and evaluates Candidate 2, located on the updated Pareto front, if Candidate 3 is infeasible.

Finally, the U-AEEV finds the end of the stage, i.e., the time uncertainty realization occurs and distinguishable scenarios at the time, and stores the decision variable values of the stage. The stored decision variable values are used to fix the decision variables of the stage to ensure scenario indistinguishability when the U-AEEV repeats the same procedure in the following stage. The U-AEEV continues the procedure until the final stage, i.e., until no uncertainty realization is found.

Equations (19)-(27) are the formulation of sub-problems solved in U-AEEV.

$$\min z^{\text{UAEEV}} = \sum_{i\in\mathcal{I},t\in\mathcal{T}} G_{i,t}\left(V_{i,t},\theta_i^n,b_{i,t},x_{i,t},y_{i,t},w_{i,t}\right) \tag{19}$$

subject to

$$g\left(V_{i,t},\theta_i^n,b_{i,t},x_{i,t},y_{i,t},w_{i,t}\right) \le 0 \quad \forall i\in\mathcal{I}, \quad \forall t\in\mathcal{T} \tag{20}$$

$$h\left(V_{i,t},\theta_i^n,b_{i,t},x_{i,t},y_{i,t},w_{i,t}\right) = 0 \quad \forall i\in\mathcal{I}, \quad \forall t\in\mathcal{T} \tag{21}$$

$$\begin{bmatrix} b_{i,t} = b_{i,t}^{\text{str},n} \\ x_{i,t} = x_{i,t}^{\text{str},n} \\ w_{i,t}^{\text{dif}} = w_{i,t}^{\text{difstr},n} \end{bmatrix} \quad \forall i\in\mathcal{I}, \quad \forall t\in\mathcal{T}|t\le t^{\text{PRend},n} \tag{22}$$

$$y_{i,t} = y_{i,t}^{\text{str},n} \quad \forall i\in\mathcal{I}, \quad \forall t\in\mathcal{T}|t< t^{\text{PRend},n} \tag{23}$$

$$b_{i,t}\in\{0,1\} \quad \forall i\in\mathcal{I}, \quad \forall t\in\mathcal{T} \tag{24}$$

$$x_{i,t}\ge 0 \quad \forall i\in\mathcal{I}, \quad \forall t\in\mathcal{T} \tag{25}$$

$$y_{i,t}\ge 0 \quad \forall i\in\mathcal{I}, \quad \forall t\in\mathcal{T} \tag{26}$$

$$w_{i,t}\ge 0 \quad \forall i\in\mathcal{I}, \quad \forall t\in\mathcal{T} \tag{27}$$

Equations (19), (20), and (21) are the scenario-decomposed objective function and scenario-specific constraints corresponding to (1), (2), and (3). The uncertain parameter $\theta_{i,s}$ in (1), (2), and (3) is replaced with a scenario outcome $\theta_i^n$ in (19), (20), and (21), where $n$ denotes a sub-problem. Since the U-AEEV decomposes scenarios, it does not include NACs and indicator variable $Z_{t,s,s'}$ in its formulation. Instead, Equation (22) fixes all here-and-now decision variables and differentiator variables at and until the end time of the previous stage, $t^{\text{PRend},n}$, to ensure scenario indistinguishability using stored variables $b_{i,t}^{\text{str},n}$, $x_{i,t}^{\text{str},n}$, and $w_{i,t}^{\text{difstr},n}$. Similarly, Equation (23) fixes all wait-and-see decision variables using stored variable $y_{i,t}^{\text{str},n}$ until the previous time of the previous stage's end time.

The U-AEEV never fails to generate a solution even if a problem lacks complete recourse, as long as one of the decision candidates assumes the extremist (most pessimistic, optimistic, best, or worst) scenario. Also, it may locate tighter feasible solutions and yield smaller optimality gaps compared to the AEEV because the U-AEEV evaluates decision candidates suggested by all scenario outcomes and selects a good one, whereas decisions are offered only by the expected scenario outcomes (for example, the expected yields of Process 1 and 2 shown in Table 1 is 0.72) in AEEV. On the other hand, the U-AEEV may increase the computational time compared to the AEEV because it solves sub-problems with all scenario outcomes instead of solving sub-problems using only expected scenario outcomes. The U-AEEV offsets the increase in computational time by solving sub-problems stage-wise instead of AEEV's time-wise approach.

## 4. COMPUTATIONAL PERFORMANCE

We examine the U-AEEV performance using 6 published MSSP problems with type 2 endogenous uncertainty. **Table 2** lists the problem name, programming type (MILP or MINLP), the presence of complete recourse, the MSSP instance size, and the relative termination tolerance in solving the instances. The instance sizes are large, and the MSSP models cannot be solved to optimality within 48 hours. We implemented U-AEEV with Python 3.9.13, built optimization models using Pyomo 6.4.0, and solved all instances with CPLEX 20.10 for MILP or BARON 17.4.1 for MINLP problems, employing 48 processors (Intel(R) Xeon(R) Gold 6248R) and 380 GB of RAM on a node from Auburn University Easley Cluster. **Table 3** compares the computational performance of MSSP, U-AEEV, and AEEV. The second column from the left represents the optimality gaps reached at 48 hours for the MSSP models. The definition of the optimality gap, $\text{gap}^{\text{MSSP}}$, is the relative error between the feasible (upper/lower) and infeasible (lower/upper) bounds, $FB^{\text{MSSP}}$ and $IB^{\text{MSSP}}$, as defined in (28). The third and fourth columns from the left are the relative error, $\text{gap}^{\text{heu}}$, between the feasible bounds obtained as the MSSP solution and our heuristics ($FB^{\text{heu}}$), as defined in (29) and (30) for minimization and maximization problems, respectively. Negative gaps indicate that the feasible bounds yielded by our heuristics are better than those by the MSSP models. 'No sol.' in the AEEV column indicates that AEEV fails to generate a feasible solution because of a lack of complete recourse. The fifth and sixth columns from the left are the orders of magnitude, MAG, in computational speed defined in (31), where $t^{\text{MSSP}}$ and $t^{\text{heu}}$ are the computational time of MSSP and heuristic models, respectively. Equation (31) implies the computational speed is 10, 100, 1,000, and 10,000 times faster if the orders of magnitude are 1, 2, 3, and 4, respectively. Note that $t^{\text{MSSP}}$ is 48 hours in all instances.

$$\text{gap}^{\text{MSSP}} = \frac{\left|FB^{\text{MSSP}} - IB^{\text{MSSP}}\right|}{FB^{\text{MSSP}}} 100 \tag{28}$$

$$\text{gap}^{\text{heu}} = \frac{FB^{\text{heu}} - FB^{\text{MSSP}}}{FB^{\text{MSSP}}} 100 \tag{29}$$

$$\text{gap}^{\text{heu}} = \frac{FB^{\text{MSSP}} - FB^{\text{heu}}}{FB^{\text{MSSP}}} 100 \tag{30}$$

$$\text{MAG} = \log_{10}\left(\frac{t^{\text{MSSP}}}{t^{\text{heu}}}\right) \tag{31}$$

The U-AEEV yielded feasible solutions for all problem instances. However, the gaps in U-AEEV are large depending on the instance, as the gap of the demand-side response scheme planning problem shows 12.3 %. For this instance, we observed that only the candidate suggested by the worst scenario successfully generated a solution, while all other candidates failed due to the lack of complete recourse. This result implies the decision candidates suggested by scenario outcomes may not always include a good one. All failed candidates are infeasible in their corrective actions, which is caused by solving scenario-decomposed sub-problems without considering the information of other scenarios, unlike MSSP. Utilizing outcomes of other scenarios when solving sub-problems remains a topic for future work.

The gaps among comparable instances between U-AEEV and AEEV are smaller by 5.7 % in U-AEEV on average. However, U-AEEV yielded larger gaps than AEEV for some problems, as the gap of the offshore oilfield infrastructure planning problem is 2.43 % for U-AEEV, while 1.78 % for AEEV. We observed that only one extreme decision candidate was evaluated and selected in the evaluation process, which caused a larger gap in U-AEEV. The problem has many combinations of decisions based on three binary, one integer, and six continuous decision variables. Accordingly, each scenario outcome generates a different candidate. Since the probability of candidates is equal and the problem is a maximization problem, only one extreme candidate with the largest objective value forms the Pareto front in the evaluation process and is selected. This result implies the decision candidate suggested by the extremist (most pessimistic, optimistic, best, or worst) scenario is not always a better decision than a moderate decision suggested by an expected scenario outcome in AEEV. When an extreme candidate is selected, i.e., when the number of candidates and the number of scenarios suggesting candidates are the same and only one candidate is evaluated on the Pareto front, a moderate candidate suggested by the expected uncertain parameter may result in a tighter optimality gap. In other words, incorporating the idea of AEEV into U-AEEV

**Table 2:** MSSP problems with type 2 endogenous uncertainty to examine U-AEEV performance.

| Problem name | Programming type | Complete recourse | MSSP size | | Relative termination tolerance |
|---|---|---|---|---|---|
| | | | Variables | Constraints | |
| Clinical trial planning [7] | MILP | Yes | 556,033 | 1,806,849 | 0.01 % |
| Process network synthesis [2] | MILP | No | 8,577 | 57,489 | 0.01 % |
| R&D project portfolio management [5] | MILP | Yes | 20,097 | 298,881 | 0.01 % |
| Offshore oilfield infrastructure planning [3] | MINLP | Yes | 31,154 | 66,178 | 0.1 % |
| Vehicle routing [8] | MILP | No | 20,711 | 59,778 | 0.01 % |
| Demand-side response scheme planning [6] | MILP | No | 2,939,317 | 15,682,701 | 0.01 % |

**Table 3:** Computational performance of MSSP, U-AEEV, and AEEV.

| Problem name | Optimality gap [%] | Gap from MSSP feasible bound [%] | | Orders of magnitude in computational speed [-] | |
|---|---|---|---|---|---|
| | MSSP | U-AEEV | AEEV | U-AEEV | AEEV |
| Clinical trial planning | 4.86 | -1.33 | 8.96 | 1.4 | 4.5 |
| Process network synthesis | 16.0 | 3.69 | No sol. | 2.9 | - |
| R&D project portfolio management | 6.29 | -1.53 | 5.93 | 2.7 | 4.0 |
| Offshore oilfield infrastructure planning | 10.6 | 2.43 | 1.78 | 0.8 | 1.3 |
| Vehicle routing | 6.99 | 0.50 | No sol. | 3.7 | - |
| Demand-side response scheme planning | 27.3 | 12.3 | No sol. | 1.7 | - |

may be a promising idea for future work.

The computational speed of U-AEEV is 0.8 to 3.7 orders faster than MSSP, while it is 1.6 orders slower than AEEV. The difference in computational speed between U-AEEV and AEEV mainly depends on the number of scenarios, stages, and time periods. The U-AEEV needs to solve more sub-problems as the number of scenarios and stages is larger because it tests each scenario outcome stage-wise. On the other hand, the AEEV needs to solve more sub-problems as the number of time periods is larger because it solves sub-problems time-wise. For example, the number of maximum stages of the clinical trial planning problem (1024 scenarios and 12 time periods) is 10 in U-AEEV and 1 in AEEV, and U-AEEV solved 16789 sub-problems, while AEEV solved only 12 sub-problems. Note that the number of stages is not constant in MSSP problems with type 2 endogenous uncertainty because the shape of a scenario tree is decision-dependent.

## 5. CONCLUSIONS AND FUTURE DIRECTIONS

We introduced the Updated Absolute Expected Value Solution, U-AEEV, a heuristic for solving MSSP problems with type 2 endogenous uncertainty. We examined 6 MSSP problems involving Type 2 endogenous uncertainty with U-AEEV. The results showed that the U-AEEV generates a tight feasible solution even if the problem lacks complete recourse. The gap from the MSSP feasible bound was smaller by 5.7 % for U-AEEV than AEEV on average. The computational speed of U-AEEV is 0.8 to 3.7 orders faster than MSSP, while 1.6 orders slower than AEEV. Future studies will focus on publishing a Python package of U-AEEV. The package will automate the procedure of U-AEEV following converting the MSSP model into the U-AEEV sub-problem model utilizing input information, such as the model, here-and-now and wait-and-see decision variables, differentiator variables, uncertain parameters, and NACs of the original MSSP problem.

## ABSTRACT

Addressing challenges in process design and optimisation, especially with complex models and data uncertainties, requires effective tools for model development, selection, and identification. Techniques such as Model-based Design of Experiments (MBDoE) help support this task by screening and discriminating between models and, eventually, calibrating them. Open-source and user-friendly Python packages have implemented some model identification techniques. However, the need for a tool that can couple with various model simulators and account for the steps of model identification as well as physical constraints of systems in design of experiments remains unmet. In that light, we present the python package MIDDOE (Model-(based) Identification, Discrimination, and Design of Experiments) to address this gap. It integrates rival models screening, parameter estimation, uncertainty analysis, and MBDoE techniques, while adapting to various process constraints. These functionalities are demonstrated via an in-silico study for a semi-batch fermentation reactor model identification.

**Keywords**: model identification, model-based design of experiments, model discrimination, model calibration, open-source software

## INTRODUCTION

Process design and optimisation often requires the precise determination of underlying phenomena and identification of accurate models to describe them. This process becomes complex when multiple rival models and high uncertainty exist, and is further complicated by the costly data required for model discrimination and calibration. To address these challenges, numerical techniques have been introduced to streamline the pre-discrimination stage by screening models and narrowing the pool of candidates without additional experimental effort. Building on these techniques, MBDoE methods have been developed to design new experiments that maximize information, enabling easier discrimination between rival models (MBDoE-MD) [1]. Additionally, they reduce the confidence ellipsoid volume of estimated parameters by enriching the information matrix (MBDoE-PP) via optimal experiment design [1].

Open-source Python packages, most notably PYOMO [2], are essential tools for digital modeling frameworks. PYOMO facilitates parameter estimation using Parmest [3] and supports MBDoE-PP through DOE [4]. Despite many advantages in integrating with the PYOMO ecosystem, these tools have some limitations. They are effective when screening, reparametrizing, and discriminating between models are not required. Additionally, they rely on PYOMO's array and model structure, which makes them incompatible with other types of simulators. This dependency limits their flexibility in handling diverse model structures, solvers, and constraints related to design decisions. Another significant limitation is the lack of coherence in problem definitions across the entire workflow. This arises from the need to use different packages for tasks such as screening, identifying, designing experiments, validating, and illustrating results. Additionally, some of these tools are not readily available, further complicating the workflow.

These gaps are here addressed by proposing the Python package MIDDOE

(https://pypi.org/project/middoe), which wraps dynamic lumped models using standard Python/NumPy arrays and integrates seamlessly with simulators. MIDDOE provides tools not only for calibrating models, but also for screening, discriminating, and validating models. It provides flexibility to perform these tasks using local methods (single start or multi-core, multi-start) as well as global or joint methods (multi-core) ensuring high computational efficiency.

The package offers MBDoE techniques tailored for both discrimination and calibration, specifically adapted to the physical constraints of experimental campaigns and apparatus. Key features include options for enforcing constraints on design decisions and cost functions, with the flexibility to structure MBDoE optimization problems to accommodate these limitations. This functionality significantly aids experimenters in designing feasible and optimal experiments.

Finally, MIDDOE emphasizes user-friendliness by clearly distinguishing model components and enabling one-time definitions for all techniques, eliminating additional programming. Designed as a numerical wrapper, it can integrate with external simulators or internal Python/NumPy functions, enabling non-expert users to avoid specific programming syntaxes. Data import is simplified by allowing experimental data to be added as Excel files, organized into batches using separate sheets. It supports various data input types and automates the generation and restoration of results, data, and figures. By representing its structure, we demonstrate a part of its novel capabilities through an in-silico experimental campaign for identifying a generic model.

## PACKAGE ARCHITECTURE

MIDDOE is a Python library designed to provide a modular structure (see Figure 1) for performing essential model identification steps. These steps include: 1) setting up models and configuring control variables and constraints; 2), 3) screening models with sensitivity and estimability analyses; 4), 5) parameter estimation and uncertainty analysis; 6), 7) designing experiments for model discrimination and parameter precision; and 8) model validation. The package organizes these steps into a user-friendly syntax, beginning with the first step, which involves importing the model(s) for the identification problem and defining structured dictionaries to symbolically decode and classify model components. Models are imported as Differential-Algebraic Equations (DAEs) and solved using a method that efficiently handles both stiff and non-stiff problems simultaneously. Variables are categorized as time-variant or time-invariant inputs and outputs, while parameters are addressed separately. The design space, along with its associated physical constraints, is also defined, followed by specifying the solver properties. Furthermore, each module requires and received its own specific properties to ensure flexibility and adaptability.

For screening methods, the software includes two advanced techniques: Global Sensitivity Analysis (GSA) using the Sobol method [5] and Estimability Analysis (EA) using the orthogonalization method [6] corresponding to steps 2 and 3, respectively. EA, a key feature of the package, helps restructure parametrically complex models by ranking parameters from higher to lower significance. This analysis introduces a methodology for calculating corrected critical ratios and selecting an optimal subset of parameters for estimating, prioritizing those with the lowest corrected critical ratios. This selection ensures that the model structure avoids over-parameterization and biases.

Once the set of rival models is defined, parameter estimation and uncertainty analysis are employed to assess the precision of estimations and the predictability of the identified model, corresponding to steps 4 and 5. These steps are carried out with the flexibility to choose

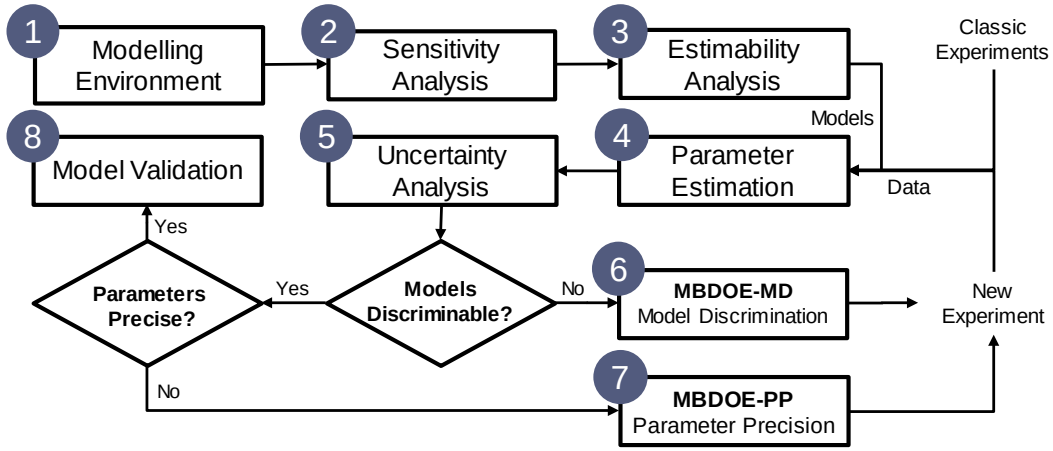

**Figure 1:** Model identification logic and modules provided in the package.

**Table 1:** True parametric values for in-silico experiments and their definitions in Monod model.

| Parameter | Units | Value | Definition |
|---|---|---|---|
| $\theta_1$ | $[\mathrm{h}^{-1}]$ | 0.31 | Maximum specific growth rate |
| $\theta_2$ | $[\mathrm{g.L}^{-1}]$ | 0.11 | Michaelis constant |
| $\theta_3$ | $[-]$ | 0.65 | Yield coefficient |
| $\theta_4$ | $[\mathrm{h}^{-1}]$ | 0.25 | Biomass loss rate due to non-modeled factors |
| $\theta_5$ | $[\mathrm{g.L}^{-1}]$ | 5.00 | Substrate inhibition constant |

**Table 2:** Design space for time-invariant and -variant process controls in Monod model.

| Variable | Units | Range | Approximation Profile | Definition |
|---|---|---|---|---|
| $y_{1,0}$ | $[\mathrm{g.L}^{-1}]$ | $1-10$ | – | Biomass initial concentrations |
| $y_{2,0}$ | $[\mathrm{g\cdot L}^{-1}]$ | $1-10$ | – | Substrate initial concentrations |
| $\mathbf{u_1}$ | $[\mathrm{h}^{-1}]$ | $0.05-0.2$ | Constant Piecewise-relaxed | Time-variant dilution rate |
| $\mathbf{u_2}$ | $[\mathrm{g\cdot L}^{-1}]$ | $5-35$ | Constant Piecewise-decreasing | Time-variant feed substrate concentration |

between global, gradient-free methods or local, gradient-based methods, supported by an internal Finite Difference Method (FDM) auto-differentiator. A key practical feature of the package addresses scenarios where the experimental campaign fails to effectively discriminate between rival models. In such cases, MBDoE-MD [7] is proposed as step 6. Similarly, MBDoE-PP is utilized in step 7 to design experiments that improve parameter precision in the selected model. Both modules offer flexibility in cost function selection, addressing discrimination and precision goals while incorporating physical constraints into the MBDoE framework.

Finally, an identified model can undergo iterative validation tests against experimental batches in step 8 to assess its robustness. Our proposed package also includes additional visualization tools to support the conclusions of the modeling campaign, such as:

- model fitting with calibration and validation data,
- visualization of inter-parametric confidence ellipsoid areas and hyper-ellipsoid volume shrinkage,
- parameter precision evaluation via t-values and confidence interval changes across batches, and
- p-value comparisons across models.

# CASE STUDY AND RESULTS

## Model structure and design space

As a matter of example, the software applies estimability analysis (step 3) and MBDoE-PP (step 7). However, executing steps 1, 4, and 5 is necessary to support these tasks. Simplified in silico simulated experiments with a normally distributed noise of 5% on both of the responses are considered using a generic Monod model [8]. This model predicts the concentrations of biomass ($\mathbf{y_1}$ $[\mathrm{g.L}^{-1}]$) and substrate ($\mathbf{y_2}$ $[\mathrm{g.L}^{-1}]$) in a semi-batch fermentation reactor with continuous feed. Table 1 presents the process model parameters for Eqs. (1) to (3), while Table 2 presents the design space for input variables. The experimental campaign begins with 2 experiments at the center, and maximum of design space boundaries, followed by up to five MBDoE-designed experiments. Each experiment has a budget of 6 sampling points and spans a duration of 10 hours. The use of E-optimality criterion ensures parameter precision exceeds the t-value threshold for all parameter estimations.

$$\frac{\partial y_1(t)}{\partial t} = (r - u_1(t) - \theta_4) \cdot y_1(t) \tag{1}$$

$$\frac{\partial y_2(t)}{\partial t} = -\frac{r \cdot y_1(t)}{\theta_3} \cdot u_1(t)(u_2 - y_2) \tag{2}$$

$$r = \left(\frac{\theta_1 \cdot x_2}{\theta_2 + x_2}\right) \cdot exp\left(-\frac{x_2}{\theta_5}\right) \tag{3}$$

## Estimability analysis

After providing the necessary information and specifications as domain knowledge (step 1) to the software and simulating the initial experiments, the initial observation matrix is formed. Then, this matrix is used for estimation of parameters (steps 4, and 5), providing enough information to return to Step 3: Estimability Analysis. This step evaluates the significance ranking of parameters and derives the optimal subset for estimation. The ranking of parameters based on their significance, from highest to lowest, is $\theta_4$, $\theta_3$, $\theta_1$, $\theta_5$, and $\theta_2$ for the first experiment observations, and $\theta_1$, $\theta_4$, $\theta_3$, $\theta_5$, and $\theta_2$ for the combined observations from the first and second experiments.

Based on this ranking, the estimability analysis calculates the corrected critical ratios for the estimated

subset of parameters as illustrated in Figure 2. With a limited observation matrix, it suggests retaining $\theta_4$ and $\theta_3$ and with an extended one it suggests retaining $\theta_1$, $\theta_4$, and $\theta_3$, as these correspond to the subset with the lowest critical ratio. For both cases, $\theta_2$ and $\theta_5$ are evaluated as insignificant and suggested to be dropped out in the identification procedure by fixing them to their rough estimation. This approach aligns with the t-values (a precision metric based on the 95% confidence intervals of parameters after estimation) obtained at the end of the identification campaign, viz. Figure 3 that indicates greater uncertainty in the estimation of $\theta_2$ with a t-value of 0.006.

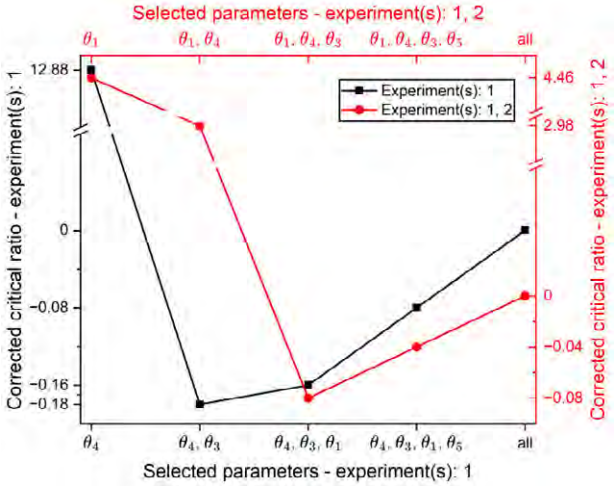

**Figure 2:** Corrected critical ratios across parameter subsets.

Assuming no additional experimental budget is available and avoiding further experimentation, $\theta_2$ and $\theta_5$ are fixed, resulting in a reduced model with only three parameters to estimate. This reduced model is subsequently employed for parameter estimation (Steps 4 and 5). It achieves a slight improvement in accuracy for all parameters by shifting the Probability Density Function (PDF) of estimates closer to the true values. Additionally, it significantly enhances precision, as indicated by the narrower distribution and more reliable estimates, although the t-values of $\theta_1$, and $\theta_3$ remain below the reference threshold of 2.08.

This module is particularly effective in scenarios with limited experimental budgets, where accurate predictions and precise estimation of key parameters are critical. However, to avoid structural simplifications and achieve higher precision in estimating the original model, we revert to its full form and design new experiments. In Step 7 (Figure 1), MBDoE-PP is employed to design new experiments, enhance the information content of the observation matrix, and estimate all parameters with acceptable precision.

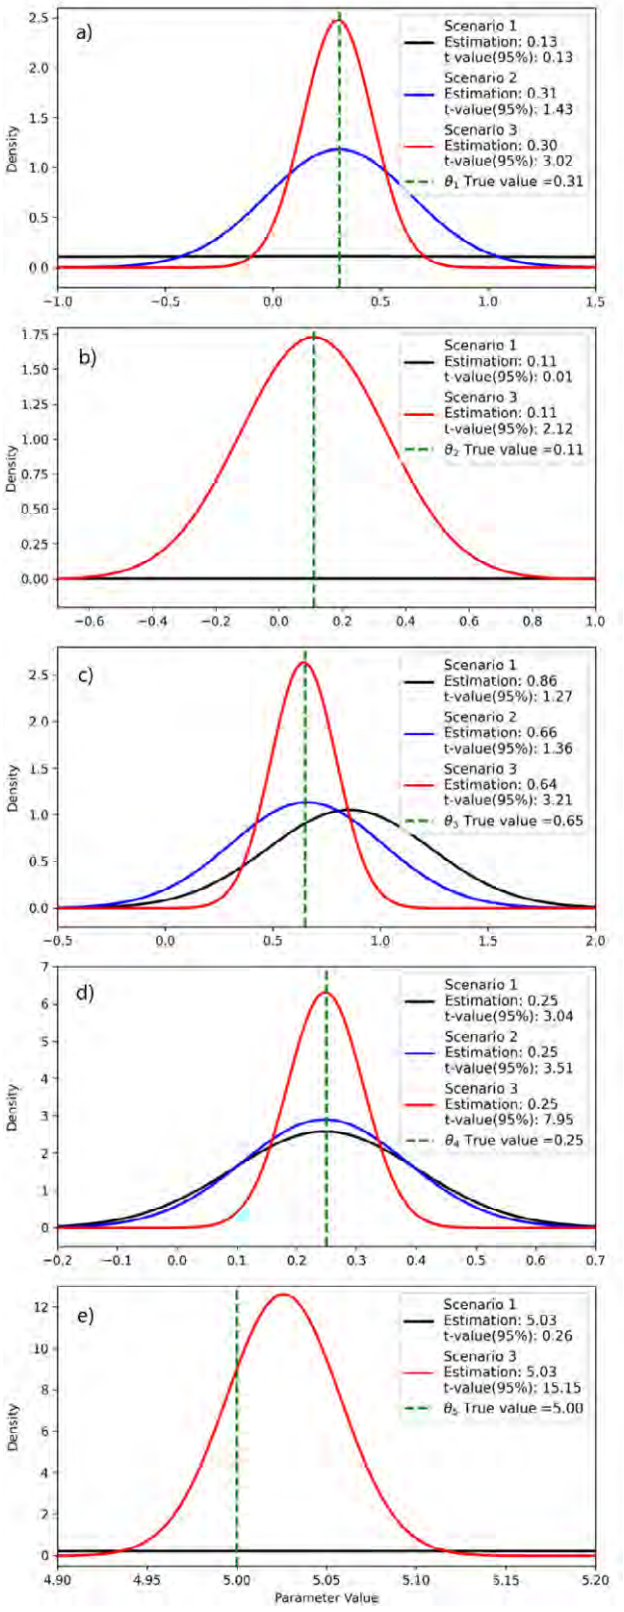

**Figure 3:** Estimation PDFs, mean and 95% t-values for a) $\theta_1$, b) $\theta_2$, c) $\theta_3$, d) $\theta_4$, and e) $\theta_5$, for the initial experiments (Scenario 1), reduced model (Scenario 2), and MBDoE-assisted campaign (Scenario 3).

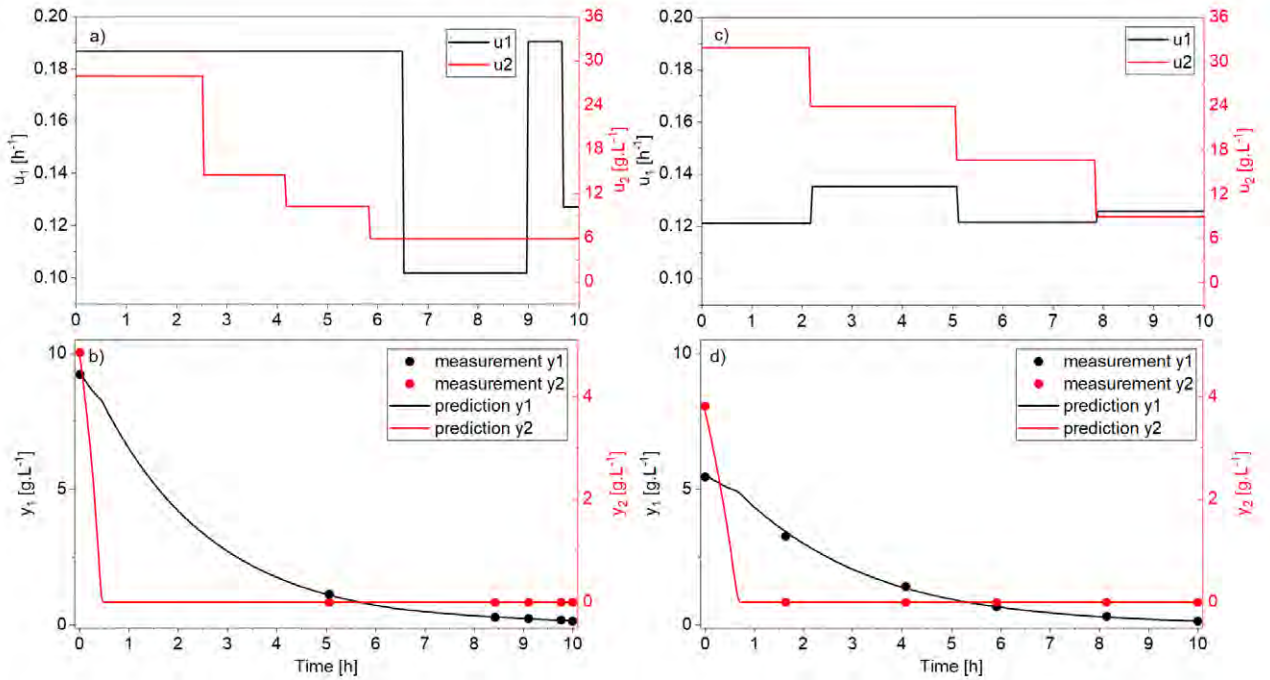

**Figure 4:** Control vectors $\mathbf{u_1}$ and $\mathbf{u_2}$ for a) 1st, and c) 2nd MBDoE designed experiments and experimental data and corresponding model responses $\mathbf{y_1}$ and $\mathbf{y_2}$ for b) 1st, and d) 2nd MBDoE designed experiments

## Model-based design of experiments

The MBDoE-related designs incorporate constraints detailed in Table 2 and additional physical constraints to demonstrate the capabilities of the code. These constraints include three switching times for time-variant controls, with a minimum signal variation of $\mathbf{u_1}$ and $\mathbf{u_2}$ set at 0.015 $[\mathrm{h}^{-1}]$ and 3.0 $[\mathrm{g \cdot L}^{-1}]$, respectively. Switching and sampling times are required to have a minimum interval of 15 minutes, and additional sampling is prohibited during the first and last 15 minutes of the experimental campaign. Not only the signal levels of controls but also the switching times and sampling times are part of the design decisions in the MBDoE-PP optimization problem.

The design decisions for the MBDoE problem are obtained using a global-local joint optimisation algorithm that employs Differential Evolution for the initial exploration of the design space, followed by Sequential Quadratic Programming (SQP) with a trust-region method for refinement. These results are illustrated in Figures 4a and 4c, showing that all obtained results comply with the previously enforced physical constraints of the system.

By simulating the experiments and complementing the observations matrix, steps 4 and 5 are repeated. The model is successfully identified using only two MBDoE-designed experiments when the t-value for all parameters exceeds the reference threshold of 2.02, while predictivity remains high with $R^2$=0.98. Figures 4b and 4d illustrate the model's behaviour in comparison with the experimental data, and Figure 3 summarizes the accuracy and precision achieved with this approach after the identification procedure.

The MBDoE-assisted experimental campaign improves the likelihood of identifying parameters previously considered insignificant or difficult to estimate with acceptable precision. These estimations are not only precise but also accurate, closely aligning with the true parameter values. However, in cases of limited experimental budgets or when restructuring the system or reproducing samples is infeasible, estimability analysis can help identify a predictive model that remains acceptably precise.

## CONCLUSION

We present a new Python library (MIDDoE) designed to perform essential model identification steps, including rival model screening, parameter estimation, uncertainty analysis, and model-based design of experiments (MBDoE). MIDDoE offers a modular and flexible workflow that accounts for process constraints and solver flexibilities, making it suitable for various physical systems and computational platforms. Part of these capabilities, aimed at improving the precision and accuracy of estimations, along with the application of estimability analysis and model-based design of new experiments, are demonstrated using an in-silico case study.

## ABSTRACT

This work approaches a detailed characterization of the aspects inherent to the innovative paradigm of Water and Energy Integration Systems (WEIS). These consists in conceptual physical systems which consider all potential energy-using and water-using processes in a site, all potential recirculation of material and energy streams between these and the integration of several categories of state-of-the-art technologies. The WEIS have the ultimate aim to promote the sustainability character associated to existing installations (through the reduction of energy and water input and contaminants output). The specific characteristics of WEIS are compared to existing similar process integration methodologies and a set of performance indicators are determined, having as a basis two previous case-studies approached for the Engineering project of WEIS. The performed analysis in this work revealed that the innovative paradigm is able to constitute Engineering projects with associated sustainability promotion potential, with the possibility to be modelled with existing computational tools and not being associated to impediments in terms of the maturity and availability of constituting technologies.

**Keywords**: Water and energy integration systems, water-energy nexus, energy recovery, sustainability, performance indicators

## 1. INTRODUCTION

The water-energy nexus has been introduced on the scope of the most relevant sustainability policies of each region of the world. This concept deals with all potential interdependencies between water and energy, and the full understanding of the inherent aspects is fundamental for the promotion of simultaneous water and energy use-related benefits [1–3].

The paradigm of Water and Energy Integration Systems (WEIS) was recently developed by a working group of researchers from both ISQ – Instituto de Soldadura e Qualidade and CERENA – Centro de Recursos Naturais e Ambiente [4]. It consists of physical systems encompassing a set of water and energy-using units in a site, and the water and energy recirculation between these units, with the goal of achieving economic and environmental benefits. In parallel to the development of this innovative paradigm, a digital twin-based computational tool has been developed by the authors for the virtual implementation of WEIS in the context of end-use sector case-studies, designated as ThermWatt [4–6].

The innovative WEIS paradigm was developed to expand the Total Site Integration (TSI) and Combined Water-Energy Integration (CWEI) concepts, and to attend to their limitations. The WEIS paradigm focus on energy-using and water-using processes as a whole (in opposition to a standalone focus on each process category), adapting conceptual elements from both TSI and CWEI and introducing new ones. These include technologies for energy recovery from water/ wastewater units (such as electrolysis) and the supply of thermal energy (direct waste heat) or electric energy (indirectly produced in thermodynamic cycles) to fulfill already existing energy requirements (hot utilities, in this case) and additional ones (wastewater treatment units).

In this work, it is performed a detailed description of the methodology inherent to the innovative paradigm of Water and Energy Integration Systems, subsisting on the

definition of most generic superstructures which may be furtherly adapted to each end-use sector case-study in specific. The specific characteristics associated to the WEIS methodology is compared to the existing methodology and a set of performance indicators are determined to assess the viability of these systems in terms of the integration of these on real-life Engineering projects.

## 2. METHODOLOGY

In general, the conceptualization of Water and Energy Integration Systems (WEIS) passes by the simultaneous application of the principles of water recirculation and heat recovery. In this prospect, two different configurations have been primarily conceptualized:

- **Configuration 1**: Standard Configuration (combustion-based process in continuous operation);
- **Configuration 2**: Dynamic Configuration (combustion-based process in continuous and batch operation and implementing thermal energy storage).

The general description points associated to all superstructures may be extensively defined as follows:

- The WEIS encompasses M combustion-based processes and N water-using processes;
- Each combustion-based process encompasses the feeding of a fuel stream (primary energy source) and combustion air stream;
- Each combustion-based process encompasses a set of waste heat streams, which jointly constitute a potentially recirculated heat stream (to the same process or other processes);
- The set of all combustion-based processes and its inlet and outlet streams constitutes the designated thermal process system;
- The set of a combustion-based process and recirculated heat streams that are transported from the outlet to the inlet of processes constitute a thermal process sub-system;
- In the context of the superstructures furtherly represented, the recirculated heat stream directed to a combustion-based process's inlet may (direct heat recovery) or may not (indirect heat recovery) be mixed with the inlet ambient air stream (it depends whether the recirculated heat stream is air or an exhaust gas, as commonly verified and implemented);
- The recirculated heat stream at the outlet of a combustion-based process may be recirculated to the same combustion-based process or the other M – 1 combustion-based processes;
- In Configuration 2, another recirculated heat stream is transported to an energy storage system (TES) to heat up a heat sink stream, which is then split to be fed to each combustion-based processes;
- For each water-using process is installed a WWT unit for the treatment of the wastewater stream at the outlet of the water-using process, in addition to a heater and a cooler;
- The set of all water-using processes, WWT units, heater, cooler and inlet, outlet and recirculated streams constitutes the water system;
- The set of a water-using process, associated WWT unit, heater, cooler and respective inlet, outlet and recirculated streams (which do not recirculate to other N – 1 water-using processes) constitute a water subsystem;
- Each water sub-system is fed by a freshwater stream and a discharged water stream results as an outlet stream;
- At the outlet of the water-using process, WWT unit, heater and cooler results several recirculated streams (recycled, reused and by-passed):
    - From the water-using process to the WWT unit inlet, heater inlet, cooler inlet, the WS outlet, other N – 1 heaters and other N – 1 coolers;
    - From the WWT unit to WP inlet, heater inlet, cooler inlet, the WS outlet, other N – 1 heaters and other N – 1 coolers;
    - From the heater to WP inlet, WWT unit inlet and WS outlet;
    - From the cooler to WP inlet, WWT unit inlet and WS outlet;
    - For each WWT unit, a sludge stream is generated and then directed to the inlet of a wastewater-to-energy module (mixed with the discharged water stream);
    - The generated energy (in the form of fuel) in the wastewater-to-energy is directed to the inlet of each combustion-based process sub-system and a combustion chamber which is (by hypothesis) installed within the thermodynamic cycle;
    - In the context of the configuration furtherly represented, the additional fuel stream may be (directly) mixed with the primary fuel stream or be (indirectly) transported to each combustion chamber.
- In addition to the recirculation within the thermal process system, the recirculated heat may be directed to the water system (the stream is divided for each water sub-system, and in its turn for each heater and WWT unit), a thermodynamic cycle (for the production of additional electric energy) and the WtE unit (according to the specific energy input in this process). The generated electricity is directed to each WWT unit and the WtE unit.

The most generic superstructure-based formulation of both WEIS configurations is presented in the sequence of Figure 1 (presented for Configuration 2, Configuration 1 is only different in the aspect that does not consider the Thermal Energy Storage unit).

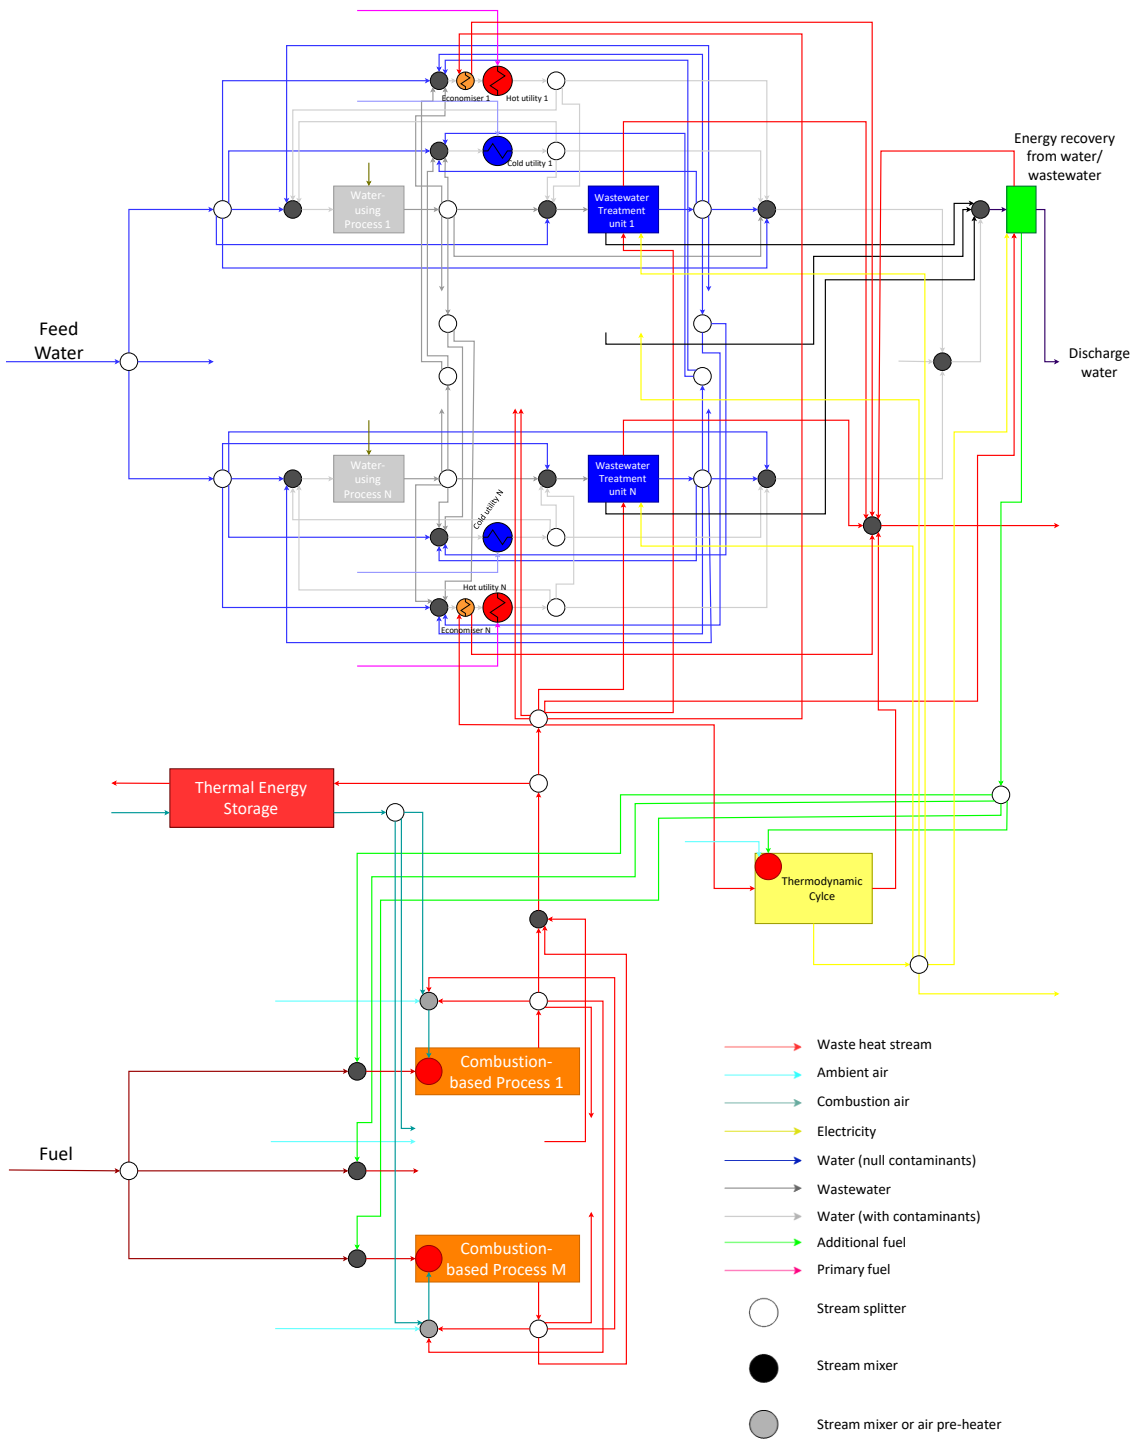

**Figure 1:** Generalized superstructure for WEIS Configuration 2 (Dynamic, transient state-based)

**Table 1:** Comparison between Methodologies

| Existing Methodologies | Water and Energy Integration Systems (WEIS) |
|---|---|
| **Combined Water and Energy Integration (CWEI)** [7] | • The object of study is a set of water-using and combustion-based thermal pro-cesses within a plant;<br>• It is based on the assessment of all potential recirculation points, in which waste heat streams may be recirculated to all pro-cesses with thermal energy requirements (combustion-based processes and water system hot utilities), as well as for the purpose of electricity generation, and discharge water streams may be recirculated from one unit operation of one water-using line to the inlet of the others within the same line and to the inlet of all the processes within the other water-using lines;<br>• The practical method is based on the valorisation of output streams, rather than on the rationalization of input streams;<br>• In terms of technological integration, it over-all encompasses the same technologies as CWEI and TSI and in addition units for the energy recovery from water/ wastewater. |
| • The object of study is a water network constituted by a set of water-using processes and wastewater treatment units;<br>• It is based on the application of steady state-based optimisation methodologies for the assessment of the most favourable levels of water stream recirculation in several points of the water network;<br>• Being based on the use of a resource as both an additional water and heat source, it only considers water streams for re-circulation. | |
| **Total Site Integration (TSI)** [8] | |
| • The object of study is a set of energy-using processes connected by a common utility system;<br>• It is based on the analysis of heat recovery between several processes through consumption and generation of utilities, in each the heating and cooling needs of each process are identified for the purpose of utility targeting;<br>• The supply of utilities with the aim to improve energy use may be performed through several measures (utility replacement, recirculated heat streams and renewable energy resources);<br>• For variable energy demand and supplies, it may involve the use of thermal energy storage units;<br>• It is itself an extension of the simpler heat integration methodologies (such as pinch analysis). | |

As may be evidenced by the analysis of Table 1:

- The innovative methodology may be considered a simultaneous expansion and combination of the CWEI and TSHI methodologies in conceptual terms. Such is attributed to it overall considering categories of processes that are not considered in CWEI (only approaching water-using processes and associated consumption of material and energy-related utilities) and TSI (only approaching energy-using processes and related utility system);
- While TSI does not only consider energy efficiency improvement but also on the adaptation/ substitution of energy inputs, the general concept of WEIS considers system-level improvements only through discharge stream recirculation (which would otherwise be classified as several types of wastes). The WEIS paradigm does not completely disregard the consideration of other energy inputs (such as renewable resources and alternative hot and cold utilities), it only focuses on waste stream valorisation.

## 3. PERFORMANCE INDICATORS

The overall assessment of the viability of the WEIS paradigm for practical implementation depends on the several aspects which may be analysed according to the determination of several performance indicators. In Table 2, it is presented the determination of several indicators according to each category of interest. The presented aspectual and numeric values have been gathered from the results associated to previous works by the authors, namely two cases (Cases 1 and 2) within a Portuguese ceramic industry plant [4–6]. The operation of the mentioned plant is associated to a 375.26 TJ/year energy consumption and a 10.77 $dam^3$/year water consumption. The WEIS Engineering projects include Organic Rankine cycle (ORC) units, multi-effect distillations (MED) units and a phase change material (PCM)-based heat exchanger unit (Case 2 only). The sustainability assessment has been performed considering the benchmark values of 2 – 3 year payback period and 0.722 kton $CO_{2,eq}$/year emissions reduction. An extensive description in respect to the characterization of the case-studies, developed simulation models (and final configurations), optimisation models and post-processing assessments is presented in the digital supplementary material (with information adapted from [4]).

In relation to the determined performance indicators presented in Table 2:

- The set of implemented simulation and optimisation modelling methodologies revealed to be suitable for the development of digital twins of set-to-be-implemented WEIS;
- The balanced combination of all capabilities associated to the Modelica and Python languages revealed to be effective for the development of a customised digital tool for WEIS;
- It is furtherly necessary to exploit the potential for the interface between Modelica-based simulation models and dynamic programming models, for a reason of achieving the highest possible integration associated to the digital tool;
- The determined sustainability assessment-based indicators revealed the sustainability promotion potential associated to WEIS-based case-studies;

Furthermore, in respect to the considered technology assessment-related indicators, it is possible to observe that the technologies considered for implementation in the context of the two approached WEIS with lowest technological maturity are in general associated to

the lowest technology readiness (TRL) level of TRL5. Such is significant that the considered technologies have been at least validated in a relevant operational environment. In this prospect, it may be affirmed that overall technological maturity is not a particularly relevant factor which affects the potential implementation of WEIS in real-life taking as a basis the conditions associated to the two approached case-studies, since the considered technologies have been at least validated for similar operational conditions. Moreover, it further proves the technological development potential associated to the WEIS paradigm, in which the requirement for the Engineering projects of these types of systems and their further real-life implementation (itself caused by significant needs for water and energy efficiency improvement in end-use sectors) necessarily creates the necessity for the implementation of the referred technologies in a real-life perspective (and thus the increase of the maturity of these from a development phase to a deployment phase).

**Table 2:** Determination of performance indicators

| Indicator | Case 1 | Case 2 |
|---|---|---|
| **Computational Model-based** | | |
| Simulation Model (OpenModelica) | Completed | Completed |
| Steady state-based Optimisation Model (Python GEKKO package) | Completed | Completed (Water System) |
| Dynamic Optimisation Model (OpenModelica) | Not applicable | Completed (Combustion-based Processes System) |
| Application of OpenModelica Python (OMPython) API | Completed | Semi-completed (Not between simulation model and DP optimisation model) |
| **Sustainability Assessment-based** | | |
| Energy Savings | 8.57% | 6.88% |
| Water Savings | 23.71% | 38.57% |
| Eco-efficiency promotion | 6.46% | 4.00% |
| Payback period | 1 year and 10 months | 2 years and 10 months |
| Emission reductions | 2.42 kton $CO_{2,eq}$/year | 1.76 kton $CO_{2,eq}$/year |
| **Technology assessment-based** | | |
| Technology readiness level (associated to the considered technology with the less maturity) | TRL5 (Heat-driven water/ waster treatment technologies with less maturity [9]) | TRL5 (Heat-driven water/ waster treatment technologies with less maturity [9]) TRL5-7 (Phase change material-based thermal energy storage [10]) |

## 4. CONCLUSIONS

This work approaches the fundamental aspects of the paradigm of Water and Energy Integration (WEIS) which has been created and approached in previous works by the authors, and which consists of an innovative methodology that compensates for conceptual gaps associated to similar methodologies. In this prospect, the innovative methodology (subsisting in two most generic superstructures for these types of physical systems), the comparison of this one with existing methodologies and a set of performance indicators have been presented and analysed.

In terms of the developed methodological framework and the determined performance indicators, the following affirmations may be performed:

- The WEIS methodology had already successfully expanded and complemented existing process integration methodologies;
- The WEIS methodology has still to be furtherly updated to include all potential categories of energy-using processes, in addition to combustion-based ones.
- The set of implemented modelling methodologies revealed to be suitable for the development of WEIS digital twins and the sustainability assessment procedure for two approached case-studies revealed the economic and environmental viability associated to the implementation of WEIS in real-life end-use sector sites (industrial plants);
- The implementation of WEIS in real-life is not substantially compromised by technological maturity of involved technologies, and it even has a potential to boost the TRL of less mature technologies;
- It is furtherly necessary to exploit the potential for a more automatic integration (co-simulation) of

simulation models and dynamic programming models.

Taking into account the aforementioned aspects, it is possible to affirm that the developed paradigm of Water and Energy Integration Systems is a relevant opportunity for end-use sectors, being able to constitute Engineering projects with associated sustainability promotion potential, possibility to be modelled with existing computational tools and not being associated to impediments in terms of the maturity and availability of constituting technologies.

## ABSTRACT

In process systems engineering (PSE), obtaining accurate process models for optimization can be expensive and time-consuming. Black-box Bayesian Optimization (BO) with Gaussian process (GP) surrogates offers a promising approach. However, full black-box optimization neglects valuable prior knowledge, which could otherwise improve the optimization process. This work explores methods of integrating prior knowledge in the form of low-fidelity data into BO by evaluating these methods on synthetic multi-fidelity test functions. Our results highlight possibilities for improved convergence of the BO optimization. However, our work further highlights potential pitfalls of these multi-fidelity models, such as bias, convergence to local optima, and overfitting on low-fidelity data. Hence, leveraging low-fidelity data in multi-fidelity models can improve BO convergence, but there are instances where the algorithms are more susceptible to failure.

**Keywords**: Process Design, Optimization, Machine Learning, Numerical Methods

## INTRODUCTION

Process models are not always available and can be prohibitively expensive to obtain for model-based optimization. Hence, the process systems engineering (PSE) community has gained an interest in Bayesian Optimization (BO). BO uses Gaussian process (GP) surrogate models as a probabilistic approximation of objective functions. The BO algorithm iteratively queries the black-box objective with experimental conditions obtained from optimizing over the so-called acquisition function [1]. Although BO is generally known as sample-efficient, treating chemical engineering design problems as fully black-box problems can still be prohibitively expensive, particularly for high-cost technical-scale experiments with many degrees of freedom (DoF). At the same time, the past 150 years of chemical engineering research provide extensive knowledge, modeling, and databases that are neglected by black-box algorithms such as BO. Hence, we investigate different possibilities of including such prior knowledge in the BO algorithm.

Other works from the PSE community investigate options to combine BO with known model equations, e.g., in compositions of GPs with mechanistic equations [2, 3]. In this work, however, we consider the case of available data, e.g., from low-cost simulations, approximate models, or similar processes.

One widely known option to include such prior knowledge in BO is prior mean modeling [4], where the user complements the BO algorithm with an initial guess, i.e., a prior mean. Such prior means may be derived from a scientist's intuition or fitted to available lower-fidelity data. A similar yet structurally different alternative are multi-fidelity GPs designed to handle lower-fidelity data [5]. These multi-fidelity models enhance the model's predictive capabilities by transferring knowledge from low-fidelity observations to the high-fidelity regime. Prominent methods are multi-task and multi-fidelity GPs utilizing special kernels to model the relations between different fidelities or the recursive GP model introduced by Kennedy and O'Hagen [6, 7].

In this work, we compare the usage of different multi-fidelity and prior mean modeling techniques for BO design problems. We focus on improving BO convergence in the high-fidelity regime, utilizing low-fidelity data as a supplementary source of information. Our analysis shows that utilizing lower-fidelity data in BO can generally improve the convergence of the BO optimization. However, our analysis also highlights some potential pitfalls and causes for failure, such as convergence to

local optima, overfitting, and model training errors. For this conference proceeding, we restrict our analysis to established multi-fidelity test functions, e.g., Forrester, Rosenbrock, and Rastrigin test functions.

## BAYESIAN OPTIMIZATION

Black-box optimization refers to optimization problems where the objective function $f(\mathbf{x})$ lacks an analytical expression or is expensive to evaluate. The general form of a black-box optimization problem is:

$$\min_{\mathbf{x}\in\mathcal{X}} f(\mathbf{x}) \tag{1}$$

Here, $\mathbf{x}$ is the vector of DoF from a feasible domain $\mathcal{X} \subseteq \mathbb{R}^{\mathrm{d}}$, and $f(\mathbf{x})$ is the objective function to be minimized. BO is a widely adopted approach for solving such problems, leveraging probabilistic surrogate models to approximate the objective function, enabling efficient exploration and exploitation of the search space while keeping the number of evaluations low.

GPs are a popular choice for the probabilistic surrogate model for BO due to their data efficiency and inherent uncertainty quantification. GPs are an extension of a multivariate normal distribution to infinite dimensions, i.e., continuous functions, with the prior distribution $p(f)$ of the objective function $f$ defined as:

$$p(f) = \mathcal{N}\left(f; \mu(\mathbf{x}), k(\mathbf{x},\mathbf{x}') = \mathcal{GP}\big(\mu(\mathbf{x})\big), k(\mathbf{x},\mathbf{x}')\right) \tag{2}$$

Here, $\mu(\mathbf{x})$ is the mean function representing the expected value of the objective function $f$, and $k(\mathbf{x},\mathbf{x}')$ is the covariance function describing the relation between two arbitrary vectors $\mathbf{x}$ and $\mathbf{x}'$. The joint distribution of the prior belief $f$ and exact observations $\mathbf{y}$ is Gaussian:

$$p(f,\mathbf{y}) = \mathcal{GP}\left(\begin{bmatrix}\mu(\mathbf{x})\\ \mathbf{m}\end{bmatrix}, \begin{bmatrix}k(\mathbf{x},\mathbf{x}') & k(\mathbf{x},\mathbf{X})^{\mathrm{T}}\\ k(\mathbf{X},\mathbf{x}) & \mathbf{K}(\mathbf{X},\mathbf{X})\end{bmatrix}\right), \tag{3}$$

The vector of means of the observations, $\mathbf{m}$, is typically set directly to the observations. For the case of exact observations, this simplifies to $\mathbf{y} = \{f(\mathbf{x}_i)\}_{i=1}^{N}$, where $N$ denotes the number of observations. The matrix $\mathbf{X} = \{\mathbf{x}_i\}_{i=1}^{N}$ represents the corresponding set of data points in the input dimension and $\mathbf{K}(\mathbf{X},\mathbf{X})$ corresponds to the covariance matrix evaluated at these data points, using a kernel function $k(\cdot,\cdot)$. Conditioning the GP prior $p(f)$ on the noise-free observation data $\mathcal{D} = \{\mathbf{x}_i, f(\mathbf{x}_i)\}_{i=1}^{N}$ yields the posterior $p(f|\mathcal{D})$, which is also Gaussian:

$$p(f|\mathcal{D}) = \mathcal{GP}(f; \mu_{\mathcal{D}}(\mathbf{x}), k_{\mathcal{D}}(\mathbf{x},\mathbf{x}')) \tag{4}$$

The posterior mean and covariance functions read:

$$\mu_{\mathcal{D}}(\mathbf{x}) = \mu(\mathbf{x}) + K(\mathbf{x},\mathbf{X})K(\mathbf{X},\mathbf{X})^{-1}\big(\mathbf{m} - \mu(\mathbf{X})\big) \tag{5}$$

$$k_{\mathcal{D}}(\mathbf{x},\mathbf{x}') = k(\mathbf{x},\mathbf{x}') - k(\mathbf{x},\mathbf{X})K(\mathbf{X},\mathbf{X})^{-1}k(\mathbf{X},\mathbf{x}) \tag{6}$$

Since the surrogate model is probabilistic, it allows the user to formulate an expression of a preference over the uncertain outcomes, also known as an acquisition function $\alpha : \mathcal{X} \to \mathbb{R}$. Thus, the inference of the next observation location $\hat{\mathbf{x}}$ boils down to maximizing the acquisition function:

$$\hat{\mathbf{x}} \in \underset{\mathbf{x}\in\mathcal{X}}{\operatorname{argmax}}\, \alpha(\mathbf{x},\mathcal{D}) \tag{7}$$

One of the most common acquisition functions is the expected improvement acquisition function, which is defined as:

$$\mathrm{EI}_{y^*}(\mathbf{x}) = \mathbb{E}_{f(\mathbf{x})}[\max(0, f(\mathbf{x}) - y^*)]\,, \tag{8}$$

where the incumbent $y^* = \max \mathbf{y}$ is the best function value observed so far [8].

### Bayesian optimization with available lower-fidelity data

In many chemical engineering problems, data often comes from simulations or experiments that can be performed at varying levels of detail, precision, or cost. These levels of detail are commonly referred to as fidelities. Each level of fidelity can be represented by a different function $f_t(\mathbf{x})$, where $t = 1, \ldots, T$ indicates the fidelity level, with $t = T$ representing the highest fidelity. Each fidelity level provides a set of data points, $\mathcal{D}_t = \{(\mathbf{x}_i, f_t(\mathbf{x}_i))\}_{i=1}^{N_t}$ where $\mathbf{x}_i$ represents DoF and $f_t(\mathbf{x}_i)$ the corresponding function evaluations, with $N_t$ denoting the number of observations in the $t$-th fidelity.

The goal of multi-fidelity optimization is to efficiently determine the optimal choice of the DoF $\mathbf{x}^*$ that minimizes the highest-fidelity function $f_T(x)$. This is achieved by leveraging data from the lower-fidelity levels $\{\mathcal{D}_t\}_{t=1}^{T-1}$, which are typically less expensive to compute, to inform and reduce the need for evaluations of $f_T(\mathbf{x})$. The challenge lies in effectively combining information from these fidelities to balance accuracy and computational efficiency.

While multi-fidelity optimization often incorporates a cost-aware perspective, assigning evaluation costs to fidelities and using a joint acquisition function to minimize expected cost, this work focuses solely on the highest-fidelity function. Here, lower-fidelity data is used to enhance the predictive model of $f_T(\mathbf{x})$, improving accuracy and reducing the number of high-cost evaluations required.

### Prior mean modeling

The prior mean function $\mu(\mathbf{x})$ of a GP is typically assumed to be either zero or a constant value in order to avoid any unwanted bias on our decisions caused by spurious structure in the prior process [1, 9]. By specifying the prior mean function $\mu(\mathbf{x})$ of the prior belief of the objective function $p(f)$, high-level information about the objective function can incorporated into the BO process. The GP posterior of the objective function $p(f|\mathcal{D})$ is then updated by the available data but still inherits the

previously encoded knowledge.

A practical approach to integrating low-fidelity data into the prior mean of a Gaussian process involves training a regression model on the low-fidelity dataset. The resulting model is then utilized as the prior mean function for the Gaussian process. In this study, we consider a fifth-order polynomial regression with L2 regularization and a neural network. For the polynomial regression model, the prior mean of the GP is defined as:

$$\mu(\mathbf{x}) = \Phi(\mathbf{x})\mathbf{w} \tag{9}$$

Here $\Phi(\mathbf{x})$ represents the feature matrix, and $\mathbf{w}$ the respective weights of the polynomial regression model. The prior mean of the neural network is defined as:

$$\mu(\mathbf{x}) = \mathrm{NN}(\mathbf{x}) \tag{10}$$

Here, $\mathrm{NN}(\boldsymbol{x})$ represents the neural network.

## Recursive co-kriging model

The recursive co-kriging model, commonly referred to as the auto-regressive (AR1) model, was first introduced by Kennedy and O'Hagen [6] and further elaborated upon by Gartiet [7]. This model is widely used for multi-fidelity modeling and leverages an auto-regressive structure to represent dependencies across fidelity levels. It assumes a Markov property, wherein each fidelity level is dependent only on the immediately preceding level. The general formulation of the AR1 model for $T$ fidelity levels can be expressed as:

$$f_t(\mathbf{x}) = \rho_{t-1} f_{t-1}(\mathbf{x}) + \delta_t(\mathbf{x}), \qquad t = 2, \dots, T \tag{11}$$

Here, $f_t(\mathbf{x})$ represents the GP associated with the $t$-th fidelity level, while $f_{t-1}(\mathbf{x})$ is the GP conditioned on the data from the preceding fidelity level. The parameter $\rho_{t-1}$ serves as a scaling factor that quantifies the influence of the $(m-1)$-th fidelity level on the current fidelity level. The term $\delta_t(\mathbf{x})$ is a GP that models the residual errors between the high-fidelity data at the $t$-th level and the predictions provided by $f_{t-1}(\mathbf{x})$.

Due to the AR1 model's Markov property, the data points at a given fidelity level only influence the predictions of that level and all subsequent fidelity levels, but not the preceding fidelity levels. Consequently, the model is well-suited for datasets with such a hierarchical structure.

## Multi-Fidelity Modeling

Unlike the recursive co-kriging model, which leverages an auto-regressive structure to model the fidelity relation sequentially, other multi-fidelity approaches adopt a joint modeling framework. A key challenge in such models lies in accurately defining and learning the cross-covariance structure between tasks or fidelities, which is critical for effective knowledge transfer.

Two notable examples of such an approach are the multi-task GP model formulation proposed by [10] and the multi-fidelity GP model formulation proposed by [11]. The multi-task model captures these relationships using a learnable inter-task covariance matrix. In contrast, the multi-fidelity model by [11] represents fidelity as a continuous parameter and employs a covariance function to describe inter-task dependencies. Both approaches rely on decomposing the covariance between outputs into components that reflect task/fidelity dependencies and input space similarities. This can be formally expressed as:

$$k_{multi}\big((\mathbf{x}, t), (\mathbf{x}', t')\big) = k_t(t, t') \cdot k_{\mathbf{x}}(\mathbf{x}, \mathbf{x}') \tag{12}$$

or equivalently in tensor form:

$$k_{multi}\big((\mathbf{x}, t), (\mathbf{x}', t')\big) = \mathbf{K}_t \otimes k_{\mathbf{x}}(\mathbf{x}, \mathbf{x}') \tag{13}$$

Here, $t$ and $t'$ denote task or fidelity indices, $k_t$ represents the covariance of tasks or fidelities, and $k_x$ encodes input space similarity. The choice of representation depends on whether tasks are treated as discrete entities, e.g., in multi-task GPs, or part of a continuous fidelity spectrum, e.g., in multi-fidelity GPs.

# RESULTS AND DISCUSSION

The different multi-fidelity BO methods are evaluated on optimization test problems, specifically on multi-fidelity versions of the Forrester, the Rosenbrock, shifted and rotated Rastrigin, and the Heterogeneous test functions. Both the shifted and rotated Rastrigin and the Heterogeneous function are multi-modal functions, i.e., these functions exhibit multiple local optima. The key characteristics are summarized in Table 1. For a detailed explanation of the test function, the reader is referred to the original source [12]. The different methods are compared to a baseline, i.e., a standard GP conditioned only on high-fidelity data. All evaluated methods are summarized in Table 2.

**Table 1:** Evaluated multi-fidelity test functions [12].

| # | Function | # Dimensions | # Fidelities |
|---|---|---|---|
| 1 | Forrester | 1 | 4 |
| 2 | Rosenbrock | 2 | 3 |
| 3 | Rastrigin | 2 | 3 |
| 4 | Heterogeneous | 1 | 2 |

The performance of the different methods is evaluated on the success rate of optimization runs. We evaluate the success of an optimization run using a convergence score. The convergence score is defined as:

$$\phi_i = \frac{f_{max} - y_i^*}{f_{max} - f_{min}} \tag{14}$$

Here, $f_{min}$ and $f_{max}$ are the minimum (optimum) and maximum function values in the search domain, respectively.

Here, $y_i^*$ is the incumbent from the methods in the i-th optimization step. The convergence score is then compared to a required convergence score $\phi \leq \phi_{req}$. If the required convergence score is reached, the optimization run will be deemed successful. Note that we can define the convergence score as we consider test functions with known optima.

**Table 2:** Evaluated multi-fidelity modeling methods.

| # | Methods | Description |
|---|---|---|
| 1 | Baseline | GP conditioned on high-fidelity data |
| 2 | Prior Mean Polynomial | GP conditioned on high-fidelity data and using a polynomial regression model trained on low-fidelity data. |
| 3 | Prior Mean NN | GP conditioned on high-fidelity data and using a neural network regression model trained on low-fidelity data. |
| 4 | Multi-Fidelity GP | Multi-fidelity GP model as described in [11], conditioned on multi-fidelity data. |
| 5 | Multi-Task GP | Multi-task GP model as described in [10], conditioned on multi-fidelity data. |
| 6 | Recursive Co-Kriging | Recursive Co-Kringing model as described in [6], conditioned on multi-fidelity data. |

All methods are run for a total number of 100 optimization runs, with varying initial data and with a maximum budget of 100 optimization steps. We use 10 initial data points per dimension for each low-fidelity function. Additionally, one data point per dimension in the target fidelity was considered as initial data. A small observation noise covariance prevents numerical instability, assuming exact observations otherwise. The logarithmic expected improvement is used as an acquisition function. The logarithm of the expected improvement is maximized to account for vanishing gradients in low-value regimes [8].

Figure 1 shows the evaluation results for the convergence score. Each subplot (1-4) corresponds to one optimization problem from Table 1, with the x-axis in logarithmic scale representing the number of iterations and the y-axis depicting the success rate, ranging from 0 to 100%. The success rate measures the proportion of the total optimization runs that successfully reached the desired performance threshold in each iteration step. The markers indicate failed optimization runs.

The Baseline achieves 100% success after 15, 31, 33, and 79 iterations for problems 1–4, respectively. For the Heterogeneous problem, 90% of runs converge by iteration 32, with a few requiring up to 79 iterations.

The Prior Mean Polynomial method slightly outperforms the Baseline for the Forrester problem, converging 1.5 iterations faster on average. It performs significantly better in the Rosenbrock problem during the first 15 iterations, achieving a 3.2 iteration faster average convergence while matching the Baseline for full convergence. Performance on the Rastrigin problem mirrors the Baseline, but for the Heterogeneous optimization problem, it falls short, with 32 runs failing to converge, achieving only a final success rate of 68%.

The Prior Mean Neural Network underperforms across all problems, with slower average convergence of 0.3, 2.9, 11.2, and 5.1 iterations, respectively, only considering successful runs. It fails to converge on three out of four optimization problems, with two failed runs for the Forrester problem, nine for the Rastrigin problem, and 34 for the Heterogeneous problem.

The Multi-Fidelity GP method encounters issues in the Forrester problem, with 23 runs failing due to model fitting errors (77% success rate). For successful runs, convergence is slower by 2.4 iterations. Meanwhile, the Multi-fidelity GP generally achieves faster convergence for problems 2–4, with average improvements of 4.6, 2.8, and 7.8 iterations, respectively. Nevertheless, one optimization trial in the Heterogeneous problem does not converge within the given iteration limit.

The Multi-Task GP excels in the Forrester problem, achieving 99% convergence within six iterations and full convergence in 11, outperforming the Baseline by 6.5 iterations on average. In the Rosenbrock problem, despite five model fitting errors lowering the success rate to 95%, successful runs converge 13.8 iterations faster. For the Rastrigin problem, 60% of runs converge within 21 iterations, averaging 3.5 iterations faster, but failed runs result in an overall slowdown of 2.1 iterations. In the Heterogeneous problem, the method achieves 75% success with an average speedup of 3.0 iterations, though eight runs fail to converge.

The Recursive Co-Kriging model demonstrates significantly faster convergence compared to the Baseline for the Forrester, Rosenbrock, and Heterogeneous problems, with average improvements of 5.8, 10.1, and 8.6 iterations. In the Rastrigin problem, 70% of runs converge 4.7 iterations faster, but the remainder either match or lag behind the Baseline, resulting in a marginal 0.3 iteration faster average overall.

The Prior Mean Polynomial regression model demonstrates that prior mean information can enhance convergence to the optimal solution, particularly for the Forrester and Rosenbrock optimization problems, where it outperforms the baseline. However, as seen in the Heterogeneous problem, the prior mean can also mislead the optimization. When convergence failed, excessive sampling at domain boundaries occurred, likely due to

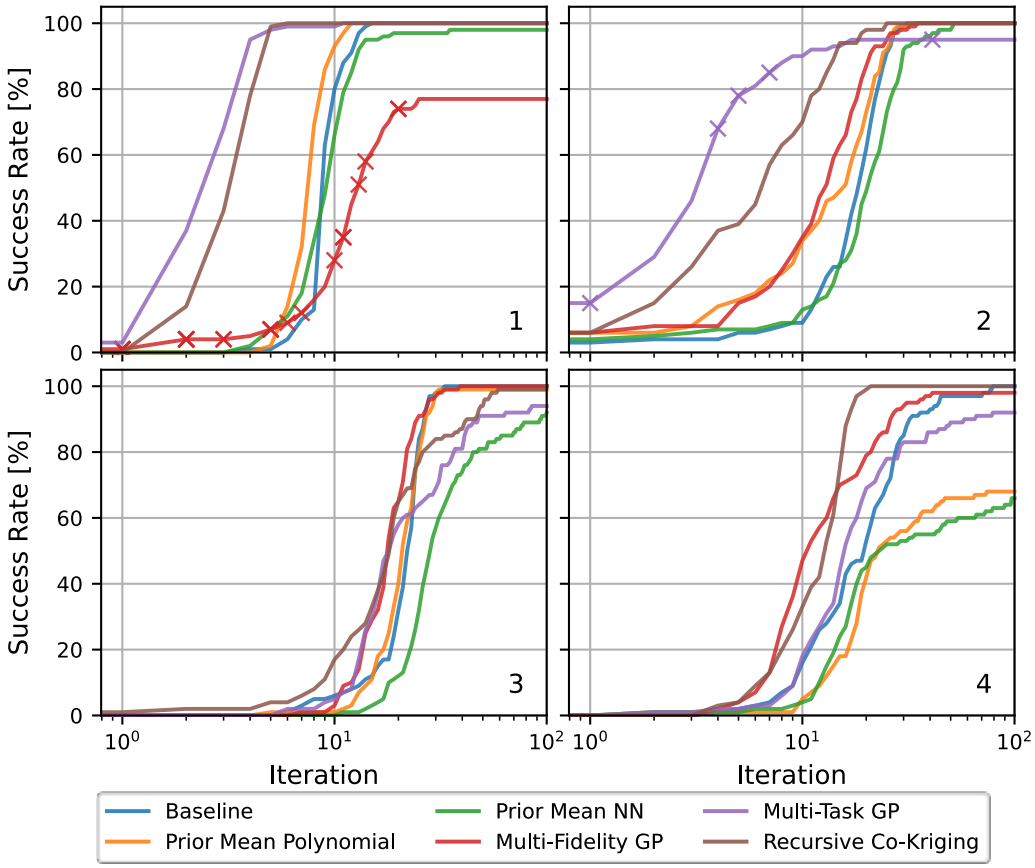

**Figure 1:** Success rate of the different multi-fidelity methods evaluated on the Forrester, Rosenbrock, Rastrigin and Heterogeneous multi-fidelity test problems (1-4). The success rate is plotted against the number of iterations for each method. The methods compared are: Baseline, Prior Mean Polynomial, Prior Mean NN, Multi-Task GP, Multi-Fidelity GP, and Recursive Co-Kriging. Markers indicate failed optimization runs.

unfavorable prior mean predictions leading to large lengthscale parameters, reduced predictive variance, and repeated boundary selections. In these instances, a near-linear structure of the polynomial regression prior biases the first BO step toward the domain boundary. A visualization of one of these instances can be seen in Figure 2. High regularization penalties further reinforce this tendency.

The cause of failure for the Neural Network regression model on the Heterogeneous test problem is similar to that of the Polynomial regression model. For the Rosenbrock test function, overfitting to the different fidelity observations contributes to the method's poor performance. For the Rastrigin test problem, the lower-fidelity functions penalize the region around the optimum, leading to repeated observations in areas of local optima.

Similar behavior is observed in the Multi-Task GP and Recursive Co-Kriging methods, for which the Multi-Task GP seems to generally struggle with the multi-modal test problems 3-4. The Multi-Fidelity GP method, on the other hand, outperforms the Baseline on test problems 2-4. Both the Multi-Task GP and the Multi-Fidelity GP tend to fail to converge during model training. This is likely due to their higher number of hyperparameters which complicates model training. Additionally, the Multi-Fidelity GP method assumes an ordering of the fidelity functions as the model assumes that the fidelity of the function is monotonic in the parameter [11]. If such a structure is not given, the model can fail during training due to an ill-conditioned covariance matrix. In summary, all multi-fidelity methods are prone to biases from poorly distributed initial low-fidelity samples, with the Multi-Fidelity GP being the most resilient. Among the considered methods, the Recursive Co-Kriging model is the most promising, consistently outperforming the Baseline on average across all optimization problems.

## CONCLUSION

This paper evaluates several common multi-fidelity modeling methods using multi-fidelity test functions and

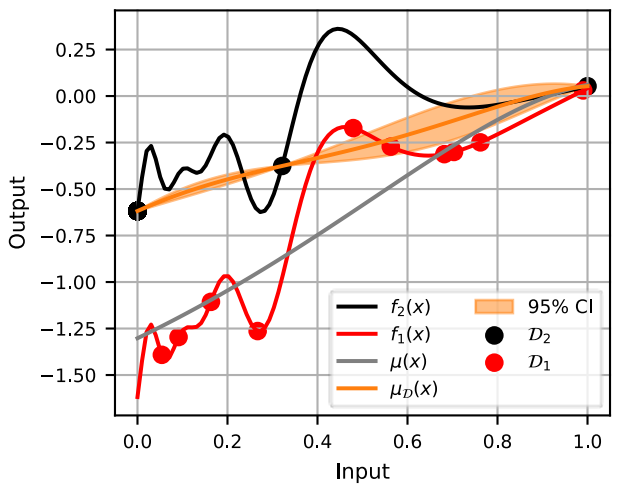

**Figure 2.** Failed optimization run of the Prior Mean method on the Heterogeneous test function showing the posterior GP prediction, conditioned on data points $\mathcal{D}_2$, using low-fidelity data $\mathcal{D}_1$ to train the polynomial regression mean $\mu(\mathrm{x})$, with the 95% confidence interval of the posterior GP indicated as CI.

identifies key pitfalls associated with these approaches. A fundamental limitation of all evaluated methods is their purely data-driven nature, making their performance highly dependent on data quality. If the available low-fidelity data is unfavorably distributed or biased, the optimization process may get misguided. This is especially evident for the prior mean modeling method, which, while being an easy-to-implement and potentially effective strategy, showed poor performance when using a Neural Network prior mean. The Neural Network severely overfitted the available data, encoding misleading information that negatively impacted optimization performance. Therefore, careful consideration is necessary when selecting and designing a prior mean model.

The more advanced multi-fidelity modeling methods may offer enhanced capability but are not exempt from the issue of misleading prior information, especially in the case of multi-modal objective functions. Among the evaluated methods, the Recursive Co-Kriging model demonstrated the most consistent performance, outperforming the baseline across all test problems, while the Multi-Fidelity GP proved the most resilient to the issue of misleading biases. To fully leverage the potential of multi-fidelity modeling, robust model fitting algorithms should be employed to improve reliability.

Finally, this study focuses on low-dimensional test functions. While the presented methods can be applied to high-dimensional problems, appropriate data scaling becomes crucial as dimensionality increases. Bayesian optimization often struggles in higher dimensions, but techniques like TURBO have been shown to improve performance [13].

## ABSTRACT

Job Safety Analysis (JSA) is critical for proactively identifying workplace hazards, assessing their potential consequences, and implementing effective control measures. However, traditional JSA methods can be inefficient and prone to errors, particularly in complex industrial environments. This paper introduces AutoJSA, a knowledge-enhanced framework that leverages large language models (LLMs) to automate and optimize the JSA process. We collected 73 high-quality JSA reports from a chemical engineering company and divided the JSA workflow into three key tasks: hazard identification, consequence identification, and control measure generation. Two approaches — fine-tuning and retrieval-augmented generation (RAG) — were employed on a base LLM (GLM-4-9B-Chat) to adapt it for these domain-specific tasks. Experimental results demonstrate that both fine-tuning and RAG significantly improve task performance relative to the unmodified model, with fine-tuning generally providing larger gains. While RAG offers the advantages of dynamic knowledge retrieval and simpler implementation, it yields more modest improvements compared to fine-tuning. Moreover, a direct combination of fine-tuning and RAG did not show additional benefits under the current approach. Overall, AutoJSA effectively addresses the limitations of traditional JSA by increasing the accuracy and efficiency of safety analysis, laying the groundwork for fully automated JSA report generation. The findings underscore the potential of advanced artificial intelligence and natural language processing techniques to enhance workplace safety management in complex and rapidly evolving industrial settings.

## 1. INTRODUCTION

In the chemical process industry, tasks such as calibrating temperature control systems, replacing seals on reactors, and conducting maintenance on pumps and compressors are essential for maintaining safe and efficient operations. However, these activities can expose workers to hazards like electrical shock, high-temperature burns, or poisoning. Job Safety Analysis (JSA) is crucial for mitigating these risks by systematically examining each task, identifying potential hazards, and implementing effective control measures [1].

Heinrich is considered the first scholar to introduce the term Job Safety Analysis [2]. Since then, JSA has been widely applied in industries such as process engineering, construction, and healthcare [3], with various guidelines available for conducting JSA [4,5]. A comprehensive JSA typically includes four key components: Job Description, Hazard Identification, Consequence Identification, and Control Measures Generation. JSA improves workplace safety by identifying and addressing potential risks before work begins, helping to reduce accidents and injuries [6,7], and identifying potential human errors to ensure quality performance [8].

However, traditional JSA faces several challenges: it may fail to identify all potential risks, especially those arising from unforeseen circumstances or complex scenarios [9]. Additionally, it is time-consuming, particularly in dynamic environments [10], and there can be significant variations in hazard identification quality, as different individuals may have different expertise levels [11].

To address these challenges, researchers have explored AI methods to automate JSA. For example, one study integrated JSA with a modified Petri net for non-

routine operations, which helped identify sequential anomalies. However, its static and semi-quantitative nature limits dynamic risk simulation and the ability to account for complex interactions [12]. Another study developed a knowledge graph for automatic JSA using GRAKN.AI, which provided solid risk assessments, but it relied on pre-existing JSA documents and lacked real-time data or natural language support [13]. Similarly, a third proposed an ontology-based framework combined with Building Information Modeling for automated JSA. However, it overlooks dynamic factors, such as site layout changes, and requires manual rule adjustments [14]. While these approaches are sophisticated, they often suffer from limited accuracy and adaptability due to their reliance on expert rules, structured data, and static models, which can miss subtle or emerging risks and restrict cross-domain applicability.

Large language models (LLMs), like ChatGPT and GPT-4 [15], present a solution by handling unstructured text, detecting new risks, and adapting across domains—making them ideal for automating hazard identification and safety reporting. Although some studies have explored the application of LLMs for similar tasks [16-18], systematic evaluation of LLMs for the entire JSA process remains limited.

This paper introduces AutoJSA, a knowledge-enhanced LLM framework using fine-tuning and retrieval-augmented generation (RAG) techniques to improve JSA accuracy, efficiency, and adaptability in complex industrial environments.

## 2. METHODOLOGY

### 2.1 Framework Overview of AutoJSA

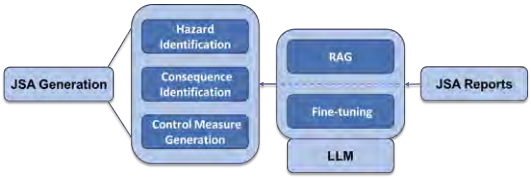

**Figure 1.** Framework overview of AutoJSA.

**Figure 1** illustrates the framework of this study, which aims to generate JSA reports using LLMs. The dataset consists of high-quality JSA reports for training, validation, and testing.

The JSA report generation is divided into three subtasks: hazard identification, consequence identification, and control measure generation. Each task has corresponding JSA reports split into training, validation, and test sets.

Fine-tuning and RAG are applied to each sub-task. Fine-tuning optimizes the base model for task-specific data, while RAG enhances information retrieval and output generation using a structured knowledge base. Both methods are evaluated through a predefined framework to assess performance under different parameters.

The best-performing parameters, selected from validation results, are tested on the test set to compare the fine-tuned model, RAG-enhanced model, and base model. The evaluation will determine the effectiveness of fine-tuning and RAG in improving JSA report generation.

### 2.2 Data Description

The data used in this study consists of 73 high-quality JSA reports obtained from a chemical engineering company. These reports cover various jobs and provide a detailed safety analysis for each step of the job. Each JSA report is composed of two main sections: JobInfo and JSA. A detailed description of the data structure can be found in **Figure 2**.

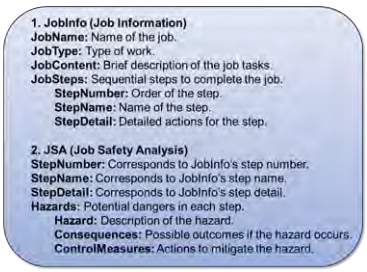

**Figure 2.** Detailed description of JSA report.

These reports are divided into three parts: 58 for training, 8 for validation, and 7 for testing.

### 2.3 Task Breakdown of JSA

AutoJSA subdivides the JSA process into three key tasks: Hazard Identification, Consequence identification, and Control Measure Generation. This division reflects the actual workflow followed during safety analysis, where each task builds upon the previous one to comprehensively assess and mitigate risks associated with a job.

Task 1 — Hazard Identification: This task identifies potential hazards for each job step. The inputs include the job name, job content, job step name, and step details. The output is a list of hazards associated with the specific step.

Task 2 — Consequence Identification: This task assesses the potential consequences of each identified hazard. The inputs include the same information as in Hazard Identification, plus the specific hazard. The output is a list of possible consequences.

Task 3 — Control Measure Generation: This task generates control measures to mitigate the identified hazards. The inputs include the job name, job content, job step details, hazard, and consequence. The output is a set of control measures.

**Table 1** shows the number of samples in the training

set, validation set, and test set for each task.

**Table 1:** Distribution of samples across training, validation, and test sets for each task.

| Task | Sample Size | | |
|---|---|---|---|
| | Train | Validation | Test |
| Task 1 | 241 | 38 | 30 |
| Task 2 | 759 | 117 | 92 |
| Task 3 | 759 | 117 | 92 |

## 2.4 Application of LLM

LLMs are advanced AI systems trained on extensive textual data to generate human-like text and perform tasks like text generation, translation, and question answering. In this study, LLMs automate and improve the JSA process, aiding in hazard identification, consequence identification, and control measure generation. Fine-tuning and RAG techniques are used to optimize the model for better accuracy and relevance in the JSA domain.

Considering the task's complexity and resource requirements, we use GLM-4-9B-Chat [19] as the base model. GLM-4-9B-Chat is a large language model with approximately 9 billion parameters, developed as part of the GLM-4 series by Zhipu AI. By fine-tuning and applying RAG, we adapt the model for JSA report generation, improving its ability to identify hazards, assess consequences, and suggest control measures.

### 2.4.1 Fine-tuning

**Figure 3:** A sample from the dataset used in Task 1. The data used in this study is in Chinese. For the convenience of reading, all related content here and in subsequent sections has been translated into English.

Fine-tuning involves adapting a pre-trained LLM to a specific task or domain by continuing its training on a smaller, domain-specific dataset [20]. While pre-trained models like LLMs are trained on large, diverse datasets to capture general linguistic patterns, fine-tuning helps the model specialize in a particular domain—in this case, JSA. This approach improves the model's ability to identify hazards, assess consequences, and generate control measures, ensuring that the outputs are relevant and accurate for the specific task.

Fine-tuning works by initializing the pre-trained model with knowledge from its original training, followed by further training on task-specific data. In addition to task-specific inputs (as described in Section 2.3), prompt engineering [21] is also employed to guide the model during training. **Figure 3** illustrates an example dataset used for Task 1, and similar datasets were created for Tasks 2 and 3. The corresponding datasets can be found in the supplementary materials. Fine-tuning is performed by adjusting parameters based on the loss values from the training and validation sets, and the model with the lowest validation loss is selected for testing.

### 2.4.2 RAG

RAG enhances LLMs by incorporating external retrieval mechanisms to provide domain-specific, up-to-date information [22]. Unlike traditional models that rely solely on pre-trained knowledge, RAG retrieves relevant external data to improve accuracy. In the RAG framework, the model retrieves documents based on the input query, enhancing generation for more contextually appropriate responses, which is crucial for tasks like JSA.

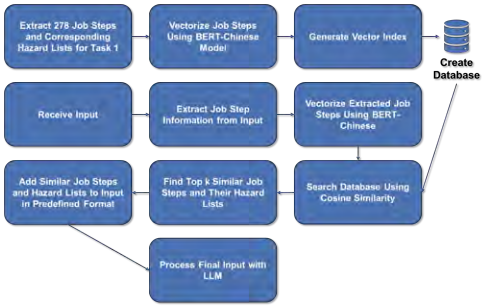

**Figure 4.** RAG framework uesd in this study.

For this study, we augmented the model's inputs with content retrieved via knowledge retrieval, as shown in **Figures 3** and **4**. For Task 1, a knowledge database was created by extracting 278 job steps and hazard lists. Using the BERT-base-Chinese model [23], we vectorized the job steps and indexed them. The model retrieves the **k** most similar job steps based on cosine similarity and incorporates the corresponding hazard lists into the input for the LLM. Similar processes were applied to Tasks 2 and 3, with variations in the search fields and content retrieved, and the RAG database used in this study is

available in the supplementary materials.

We evaluated different values of **k** to determine the optimal performance for each task, selecting the value that performed best on the validation set.

### 2.4.3 Evaluation Criteria

Model performance was assessed by measuring semantic similarity between model outputs and ground truth. Our similarity evaluation employs a BERT-based semantic encoding scheme: texts are first encoded using the BERT-base-Chinese model (768-dimensional hidden states), where the **[CLS]** token's hidden state serves as sentence embeddings. After L2-normalization, we compute cosine similarity through $\mathbf{sim}(a,b)=a^{\top}b$ to quantify semantic similarity.

## 3. RESULTS AND DISCUSSION

### 3.1 Fine-tuning

We adjusted the fine-tuning parameters based on the model's loss performance on the validation set. After multiple rounds of experimentation, we identified a set of reasonable parameters that resulted in a lower validation loss. The specific parameters used can be found in the supplementary materials. **Figure 5** illustrates the training and validation loss curves for the three tasks under these parameters during model training.

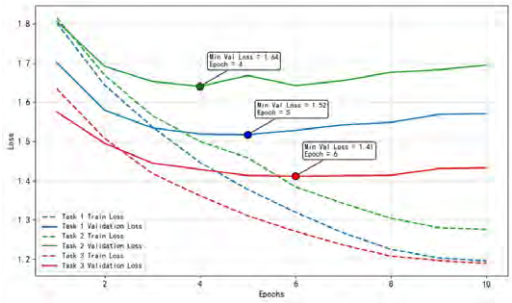

**Figure 5.** Training and validation loss for three tasks.

From the data trends, under the parameter settings used in this study, the training and validation losses for all three tasks showed a decreasing trend as the number of training epochs increased. This indicates that fine-tuning was effective for all three tasks. However, after a certain number of epochs, the validation loss for each task started to increase, suggesting overfitting. Based on these experimental results, we selected the models corresponding to the epochs with the lowest validation loss — 5, 4, and 6 epochs for Tasks 1, 2, and 3, respectively — to be tested on the test set.

### 3.2 RAG

In the construction of the RAG framework, we optimized the value of **k** for each task based on the validation set scores. **Figure 6** shows the model's scores on the validation set for the three tasks with different values of **k**, along with the time consumption per output generation.

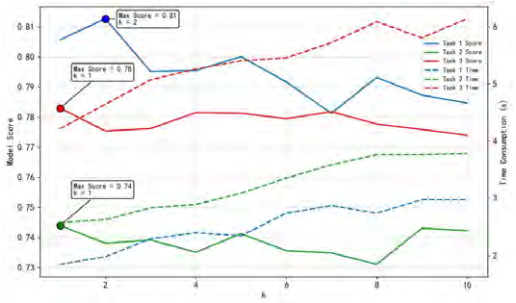

**Figure 6.** Model scores and time consumption vs. **k**.

During the RAG framework construction, the model's performance did not exhibit a significant trend with varying **k** values. However, when looking at all three tasks, smaller values of **k** already yielded good results. This suggests that the LLM places more importance on the most similar inputs, and it is more effective at leveraging the most relevant knowledge to solve the problem. As the value of **k** increases, more knowledge did not result in improved model performance. This could be due to the inclusion of more low-similarity knowledge, which may have interfered with the model's reasoning. Additionally, as **k** increases, the input text becomes longer, leading to longer inference times. Based on these observations, we selected **k**=2, **k**=1, and **k**=1 for Tasks 1, 2, and 3, respectively, for testing on the test set.

### 3.3 Test Results

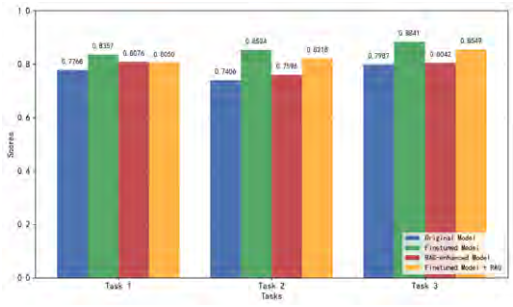

**Figure 7.** Different model scores on the test set.

**Figure 7** shows the performance scores of the original model, the fine-tuned model, and the RAG-enhanced model on the test set for the three tasks. It also includes the results of the fine-tuned model when further augmented with RAG.

The test results show that both the fine-tuned and RAG-enhanced models outperform the original model. However, RAG provides modest improvements, while fine-tuning offers more substantial gains. Fine-tuning requires more computational resources and a complex

| Model | Output | Score |
|---|---|---|
| **Original model** | Hot work causing fire or explosion, electrical equipment causing electric shock, lack of warning signs leading to unauthorized personnel entering hazardous areas, insufficient preparation of protective equipment leading to injuries. | **0.7135** |
| **Fine-tuned model** | Hot work risk, temporary electricity risk, inadequate equipment preparation, insufficient protective equipment. | **0.8477** |
| **RAG-enhanced model** | Improper handling of hot work and temporary electrical work permits, incorrect placement of warning signs, inadequate equipment preparation, insufficient preparation of gas detectors and protective equipment, insufficient personnel training. | **0.7725** |
| **Expected** | Fire or explosion caused by hot work, electric shock due to electrical equipment usage, failure to set up warning signs leading to unauthorized entry into hazardous areas, inadequate preparation of protective equipment resulting in injuries. | **-** |

**Table 2:** Comparison of output results.

implementation, while RAG is simpler and allows dynamic updates to the knowledge base, offering flexibility.

When we combined the fine-tuned model with RAG, no performance improvement was observed over fine-tuning alone. This suggests that a more advanced integration approach, such as using a separate model to combine the outputs of both, may be needed to fully leverage the strengths of both techniques for optimizing JSA report generation.

### 3.4 Case Study

**Table 2** shows the results of the original, fine-tuned, and RAG-enhanced models for hazard identification, as described in **Figure 3**. The original model provides a broad list of potential hazards in wastewater plant piping welding, covering a wide range of risks such as gas leaks, fire hazards, and equipment malfunctions. While comprehensive, this list can be overwhelming and less relevant to the task, requiring users to filter key risks.

The fine-tuned model provides a more focused output, listing four primary hazards: hot work operations, temporary electrical risks, inadequate equipment preparation, and insufficient protective equipment. This approach improves clarity and helps users quickly identify critical hazards, although it may overlook secondary risks. The RAG-enhanced model incorporates external databases, identifying five specific hazards, including non-compliance with safety permits and improper equipment placement. This model offers a detailed and practical identification of risks, but its effectiveness depends on the quality of the external data used.

In summary, the original model offers broad coverage but may lead to information overload. The fine-tuned model provides precise and efficient results, ideal for quick hazard identification. The RAG-enhanced model ensures comprehensive hazard identification with external knowledge. A better approach may involve strategically combining fine-tuning and RAG to enhance accuracy and detail.

## 4. CONCLUSION

The results demonstrate that the AutoJSA framework enhances the accuracy and efficiency of Job Safety Analysis by leveraging fine-tuning and RAG with LLMs. Both methods outperform the base model in hazard identification, consequence assessment, and control measure generation, with fine-tuning generally providing more significant improvements. The fine-tuned model produces more concise outputs, while the RAG-enhanced model generates more comprehensive results.

However, the study has limitations. The current framework does not explicitly incorporate traditional risk assessment factors such as hazard severity and probability of occurrence. The dataset of 73 Chinese JSA reports, while sufficient for proof of concept, may not fully represent the diversity of tasks in broader industrial settings or different linguistic contexts. Fine-tuning, though effective, involves high computational cost, and combining it with RAG did not yield additional benefits, suggesting potential inefficiencies in their integration. Additionally, the BERT-based similarity metric used may not capture all qualitative aspects of JSA effectiveness.

Future research directions could address current limitations by integrating risk assessment metrics into the framework, expanding the dataset to encompass diverse industrial scenarios across different linguistic and cultural contexts, exploring integration strategies for RAG and fine-tuning to enhance complementary benefits, and developing hybrid evaluation metrics that combine BERT-based similarity with qualitative safety performance indicators.

AutoJSA demonstrates AI's transformative potential in workplace safety management by enhancing hazard

identification, consequence Identification, and control measure generation. The framework paves the way toward fully automating JSA reports and ensuring safer operational practices in complex industries.

## ABSTRACT

Mechanical compression heat pumps are indispensable to facilitate the transition from thermally driven processes to renewable energy by electrification, upgrading low-temperature waste heat to recycle it at a higher temperature level. However, the implementation of such heat pumps up to date encounters limitations, due to equipment limitations and a lack of tools for the design of process concepts for the application of high-temperature heat pumps. The optimal design of heat pumps relies heavily on the selection of an appropriate refrigerant, as the thermodynamic properties significantly affect the heat pump cycle design and performance. While existing methods are capable of identifying thermodynamically beneficial refrigerants, they do not directly account for practical constraints such as limitations on the compressor discharge temperature, compression ratio, and vacuum operation. The current study proposes a fast-screening approach for arbitrary heat pump applications, considering a large set of established refrigerants. The method automatically assesses the performance of the refrigerants for a specified set of heat sink and source, adjusting the heat pump design with an optional internal heat exchanger in case of necessary superheating prior to compression. The approach is illustrated for the evaluation of heat pump-assisted distillation processes.

**Keywords**: Heat pump, Refrigerant, Screening tool, Energy integration, Distillation

## INTRODUCTION

In the context of global warming and increasing costs of $CO_2$ emissions, the transition to renewable energy sources and the improvement of energy efficiency are essential objectives for the chemical industry. One potential approach to achieve both of these goals in a single step is the implementation of heat pumps, which recover low-temperature waste heat that would otherwise be lost to the environment through cooling water and elevate the heat to a higher temperature level at which it can be reused or recycled within the process [1]. Heat pumps present a distinctive and transformative opportunity for the electrification of industrial processes, which can immediately improve the sustainability through an expanded share of renewable electricity generation. Furthermore, the integration of heat pumps may not even require significant modifications to the existing equipment, thereby rendering them a versatile solution for both new processes and retrofitting of existing processes. This allows for significant energy savings in existing plants without the need for extensive modifications [1]. While a variety of heat pump concepts can be used to upgrade the available heat, compression heat pumps are used in most applications [2].

The left-hand Clausius-Rankine cycle, which is employed to describe the thermodynamic process associated with a closed-cycle compression heat pump, is illustrated in **Figure 1 (a-c)**. The initial step of this cycle involves an irreversible pressure increase within the vapor phase, which is subsequently followed by an isobaric energy exchange in the form of heat as the refrigerant undergoes condensation. The condensed refrigerant is expanded during the isenthalpic pressure reduction, and subsequently, heat is exchanged during the evaporation of the refrigerant.

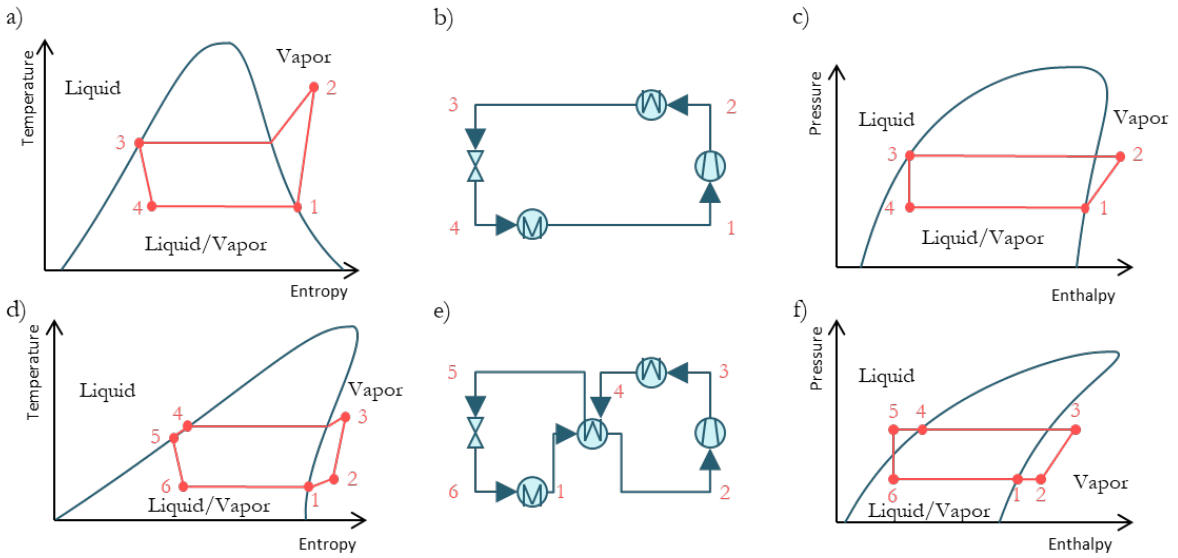

**Figure 1:** T-s diagram without a) and with d) superheating, heat pump cycle without b) and with e) superheating and p-h diagram without c) and with f) superheating

In the event that the refrigerant exhibits a hanging two-phase envelope the vapor needs to be superheated before entering the compressor to ensure that no liquid droplets form during compression which can cause damage to the compressor. For superheating the vapor, an additional heat exchanger and heat source are required. The additional heat exchanger can be implemented in the form of an internal heat exchanger (IHX), as shown in **Figure 1 (d-f)**. This configuration ensures the superheating through subcooling the refrigerant at higher pressure prior to expansion, thereby eliminating the need for external heating. However, this approach results in more complex behavior during start-up and limited operational flexibility for different temperature levels [3].

Today the implementation of heat pumps in industry is still limited due to a limited availability and experience on the use of high-temperature heat pumps, as well as the large investment costs, required for the expensive compressor [4]. In addition to these economic challenges, there are also persistent technical limitations to the application of compressors for industrial applications. Post-compression temperatures exceeding 160 °C and temperature lifts beyond 95 °C are still regarded as technically limitations [5], while exceeding these limits to yield sink temperatures up to 200 °C is expected to enable a huge range of applications [6]. Another important limitation dependent on the compressor type is the compression ratio, which is typically in the range of 2-4 with a practical limit of approximately 8 for the majority of compressor types [1]. However, some reciprocating compressors are reportedly capable of compression ratios as high as 12 at low flow rates [1]. High compression ratios can better be achieved by means of multistage compression cycles [7], or multiple cascade heat pumps with individual working fluid cycles, but these solutions are more complex and require significant investment costs, rendering them practically uneconomic [1].

The performance of external heat pumps depends largely on the specific refrigerant, which due to its thermal properties mandates the design of the compression cycle and the required work. The selection of an appropriate refrigerant for a given process depends on a number of criteria, including thermodynamic suitability, environmental compatibility, safety, efficiency and cost-effectiveness [4]. As no single refrigerant dominates all of these criteria, a trade-off must be made.

Various methods have been proposed to identify an appropriate refrigerant for a given process. Some methods focus on the thermodynamic properties and safety aspects of a range of different refrigerants, such as the work of Mateu-Royo et al. [8] and Koundinya and Seshadri [9], who evaluate refrigerants and cycle configurations quantitatively based on energy and exergy requirements, environmental impact, and economic considerations. Other authors, such as Kiss et al. [10] and Jiang et al. [11], propose general heuristics for the selection and assessment of heat pumps and refrigerants. The most general and recent methods investigate the sensitivity of refrigerants and heat pump configurations across a wide range of operating conditions [12] or solve the inverse problem, seeking an optimal refrigerant for a given application and cycle configuration based on continuous molecular targeting [13]. All these methods provide valuable tools for the identification of suitable refrigerants and

heat pump designs, given that the specific application has been fixed. However, none of these methods was integrated in conceptual process design studies.

The present study proposes a computationally efficient methodology for the rapid screening and identification of a suitable refrigerant and heat pump cycle design that can be integrated in process design studies. The method considers a wide range of established pure refrigerants to provide practical solutions, automatically evaluating heat pumps with adaptive use of IHX, required in case of superheating of the refrigerant prior to compression. The case study illustrates the application for a combined refrigerant selection and conceptual design of heat pump-assisted distillation processes, based on the shortcut screening approach proposed by Skiborowski [14].

## CALCULATION PROCEDURE OF A HEAT PUMP CYCLE

The calculations for the external heat pumps are based on the cycle designs and state diagrams illustrated in **Figure 1**. The computations only require the specification of the refrigerant's property parameters, as well as the temperature levels and heat duties of the source and sink. First, the lower pressure level of the heat pump is determined such that the saturated vapor temperature of the refrigerant has a pre-defined approach temperature to the minimum temperature of the heat source. Subsequently, the pressure after the compression is determined on the basis of flash calculations, ensuring that the refrigerant's saturated liquid temperature has the same approach temperature to the maximum temperature of the heat sink. In case the resulting pressure exceeds the critical pressure of the refrigerant, it is deemed thermodynamically unsuitable for this particular application, as it would create a trans- or supercritical heat pump process.

In case isentropic compression results in partial condensation, superheating prior to compression is facilitated by an IHX, which mitigates the need for an external heat source while simultaneously enhancing the specific enthalpy difference during the evaporation of the refrigerant. The degree of superheating is set such that the temperature of the refrigerant subsequent to isentropic compression must be at least equal to its saturated vapor temperature at the higher pressure level.

In this scenario, the specific enthalpy of the refrigerant on the higher pressure level after the IHX and prior to the throttle $h_5(T_5, p_{high})$ is determined based on the enthalpy balance of the IHX that is reduced to

$$h_5 = h_4 - (h_2 - h_1) \tag{1}$$

based on the specific enthalpy after the condensation in the heat exchanger with the external sink $h_4(T_{p_{high}}^{saturated\ liquid}, p_{high})$, and the difference between the specific enthalpy of the refrigerant at the low pressure level after the IHX and prior to the compressor $h_2(T_2, p_{low})$ and after the evaporation due to heat exchange with the source prior to the IHX $h_1(T_{p_{low}}^{saturated\ vapor}, p_{low})$. The specific enthalpy at the compressor inlet $h_2(T_2, p_{low})$ is calculated based on the temperature after superheating, which exceeds the saturated vapor temperature at the lower pressure by the degree of superheating. The specific enthalpy after compression

$$h_3(T_3, p_{high}) = \frac{h_{isentropic} - h_2}{\eta_{isentropic}} + h_2 \tag{2}$$

is calculated on the basis for the specific enthalpy for an isentropic compression $h_{isentropic}(T_{isentropic}, p_{high})$ and the isentropic efficiency $\eta_{isentropic}$, which results in an additional temperature increase due to the inefficiencies. Subsequently, the required refrigerant flow rate

$$\dot{n}_{Ref,sink} = \frac{\dot{Q}_{original,sink}}{|h_4 - h_3|} \tag{3}$$

for complete integration of the heat duty of the sink $\dot{Q}_{original,sink}$, and the refrigerant flow rate

$$\dot{n}_{Ref,source} = \frac{|\dot{Q}_{original,source}|}{h_1 - h_6} \tag{4}$$

for complete integration of the heat duty of the source $\dot{Q}_{original,source}$ are calculated. Note that the absolute value is considered, since heat duties for the sink are defined as negative values. The smaller of the two flow rates is then selected as the refrigerant flow rate $\dot{n}_{Ref}$, in order to guarantee complete integration of the smaller evaporation or condensation duty.

Adiabatic expansion results in the specific enthalpy of the refrigerant prior to evaporation at the lower pressure $h_6(T_6, p_{low})$ being equivalent to the specific enthalpy at the IHX outlet at the higher pressure $h_5(T_5, p_{high})$. In the absence of superheating, the specific enthalpy at the compressor inlet $h_2(T_2, p_{low})$ is equivalent to the saturated vapor enthalpy at lower pressure $h_1(T_{p_{low}}^{saturated\ vapor}, p_{low})$. Additionally, $h_5(T_5, p_{high})$ is equal to the saturated liquid enthalpy at the higher pressure $h_4(T_{p_{high}}^{saturated\ liquid}, p_{high})$.

In the following step, the remaining heat that is not covered by the heat pump is determined. In case the heat pump does not provide the full heat duty required by the heat sink

$$\dot{Q}_{sink} = \dot{Q}_{original,sink} - \dot{n}_{Ref} \cdot |(h_4 - h_3)| \tag{5}$$

must be provided by an external heat source, while an additional external cooling source with

$$\dot{Q}_{source} = \dot{Q}_{original,source} + \dot{n}_{Ref} \cdot |(h_1 - h_6)| \tag{6}$$

is required in case the heat pump cannot use all of the

heat from the heat source. Finally, the electrical compressor duty is determined as,

$$\dot{W}_{el} = \frac{h_3 - h_2}{\eta_{mechanical}} \quad (7)$$

taking into account a mechanical efficiency, $\eta_{mechanical}$.

## SHORTCUT-BASED SCREENING OF ALTERNATIVE PROCESS CONFIGURATIONS

The proposed method for the design of external heat pumps can directly be linked with a shortcut-based screening method for distillation-based processes, as presented by Skiborowski [14]. This shortcut method screens various distillation column configurations, including direct, indirect, and intermediate split configurations, as well as their thermally coupled versions on the basis of minimum energy demand calculations, building on the Rectification Body Method [15]. This provides the minimum energy demand and temperature levels of the condensers and reboilers of each configuration for a specified separation task. The proposed screening tool for external heat pumps can further evaluate the design of external heat pumps for any combination of heat source or sink from the respective process configurations, if not already utilized for another type of heat integration.

## CASE STUDY

The case study investigates the combination of the external heat pump evaluation and the shortcut-based screening for distillation-based process, for the separation of a zeotropic mixture of hexanol, octanol, and decanol. The mixture is fed with equimolar composition and a flow rate of 10 mol/s in the column, assuming saturation conditions at the operating pressure of the column, where it is separated into pure products under isobaric and adiabatic conditions at 80 mbar. The further discussion focuses exemplarily on the comparison of the two simple sequences, the direct split (DS) and indirect split (IS), and a thermally coupled dividing-wall column (DWC). For the purpose of this study, an isentropic efficiency of 85 % and a mechanical efficiency of 95 % are assumed for the compressor of the heat pumps. All computations are based on the extended Antoine equation in combination with the UNIQUAC model for the nonideality of the liquid and the Redlich-Kwong equation of state for the nonideality of the vapor phase. Additionally, DIPPR correlations are employed for the specific heat capacity and heat of vaporization. The respective property parameters are extracted from the AspenPlus PURE39 and NIST-TRC databases.

The temperatures in the heat exchangers and the energy demand of the different sequences without heat pumps are presented in **Table 1**. The dividing wall column has the lowest energy demand, 22 %/ 35 % lower than the DS/ IS sequence, since the thermal coupling reduces the internal mixing losses.

**Table 1:** Temperature in heat exchangers and energy demand of the different sequences without heat pumps.

| | DS | IS | DWC |
|---|---|---|---|
| $T_{Top}$ [°C] | | | |
| - Column 1 | 92.26 | 103.32 | 92.26 |
| - Column 2 | 122.78 | 92.26 | |
| $T_{Bottom}$ [°C] | | | |
| - Column 1 | 132.84 | 151.70 | 151.70 |
| - Column 2 | 151.70 | 122.78 | |
| Energy demand [kW] | | | |
| - Column 1 | 368.64 | 597.89 | 592.80 |
| - Column 2 | 386.62 | 322.03 | |
| - Net total | 755.26 | 919.91 | 592.80 |

For each of the possible heat sources and sinks possible implementations of external heat pumps are evaluated. The refrigerant screening is exemplary discussed for the DWC column. This configuration has the largest temperature difference between the reboiler and condenser of 59.44 K. Considering an approach temperature of 5 K requires the refrigerant condensation temperatures in the heat pump of 156.7 °C and the heat pump to perform a temperature lift of 69.44 K.

Half of the initial set of 38 refrigerants are discarded as the required high-level pressure exceeds their critical pressure. The individual heat pump design for the remaining 19 refrigerants and the respective minimum energy demands are listed together with the respective pressure levels and compressor discharge temperature in **Figure 2**. For all refrigerants, complete electrification of the DWC column is feasible, requiring only external cooling. The net energy demand can be reduced with a heat pump by 54 % with R1233zd and even 76 % with water (R718). Yet, water as refrigerant is practically infeasible in a single-stage heat pump due to the sub-atmospheric operation, and a compressor discharge temperature of 377 °C, which would mandate multi-stage compression with interstage cooling. Practical limitations of ambient pressure (dotted line) and 170 °C (dashed line) are indicated in **Figure 2**, in order to identify unpractical refrigerants.

The selection of the preferred refrigerant, among the practical suitable ones, focuses solely on the lowest net energy demand, which identifies acetone as the preferred choice, despite the additional heat exchanger required for superheating. While R1130 has a comparable energy demand without this additional heat exchanger, there are concerns about its toxicity and ozone depletion potential, underscoring important safety and environmental factors that were not considered in the current selection process and should be addressed in future

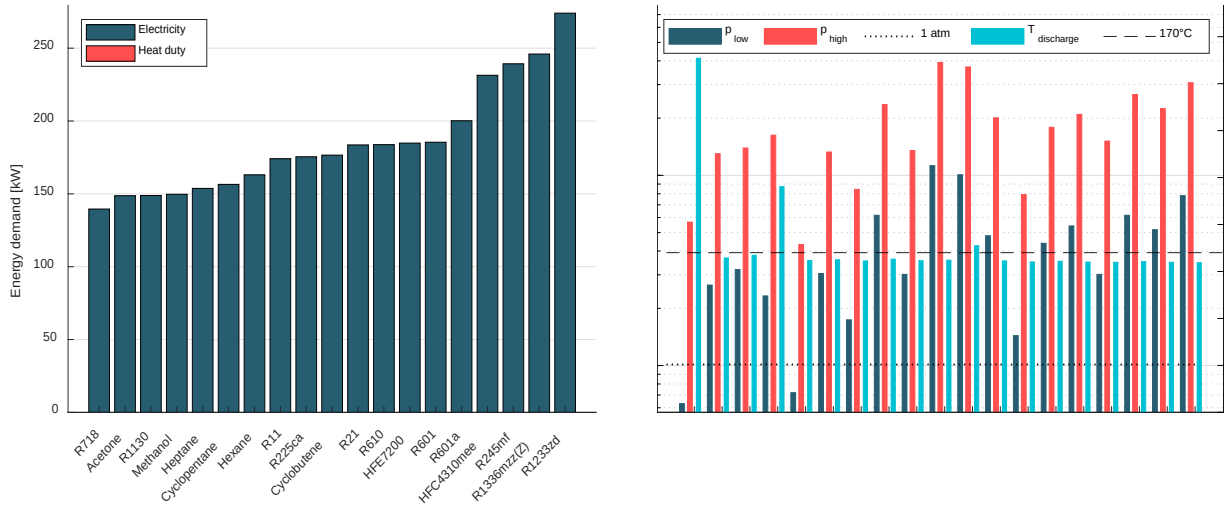

**Figure 2:** Energy demand (left) of DWC with heat pump and pressure levels (right) for thermodynamically feasible refrigerants.

evaluations.

As acetone is also among the preferred refrigerants in terms of total energy demand for DS and IS, it is utilized as a representative refrigerant for further performance comparison of the different sequences with heat pumps. Due to the fact that DS and IS possess two columns, four different configurations with a single heat pump, as well as two configurations with two heat pumps are possible, resulting in 16 different (heat pump-assisted) process variants for this separation task. The energy demand of the process variants and the potential energy saving of the best heat pump configuration compared to their process without heat pump are summarized in **Figure 3**.

With 83 % net energy savings the heat pump-assisted DS with two heat pumps does not only provide the largest saving potential but also shows the lowest net energy requirement overall. The study does not only highlight the potential of the integrated approach, but also illustrates that the heat pump-assisted simple sequence may require less energy that the heat pump-assisted DWC, which however requires only a single column shell and a single compressor and may be cost-beneficial.

The heat pump-assisted IS variants 11 and 14 in **Figure 3** employ a heat pump to utilize the heat from the condenser of column 2 to provide the necessary heat for the reboiler of column 1. These variants require additional

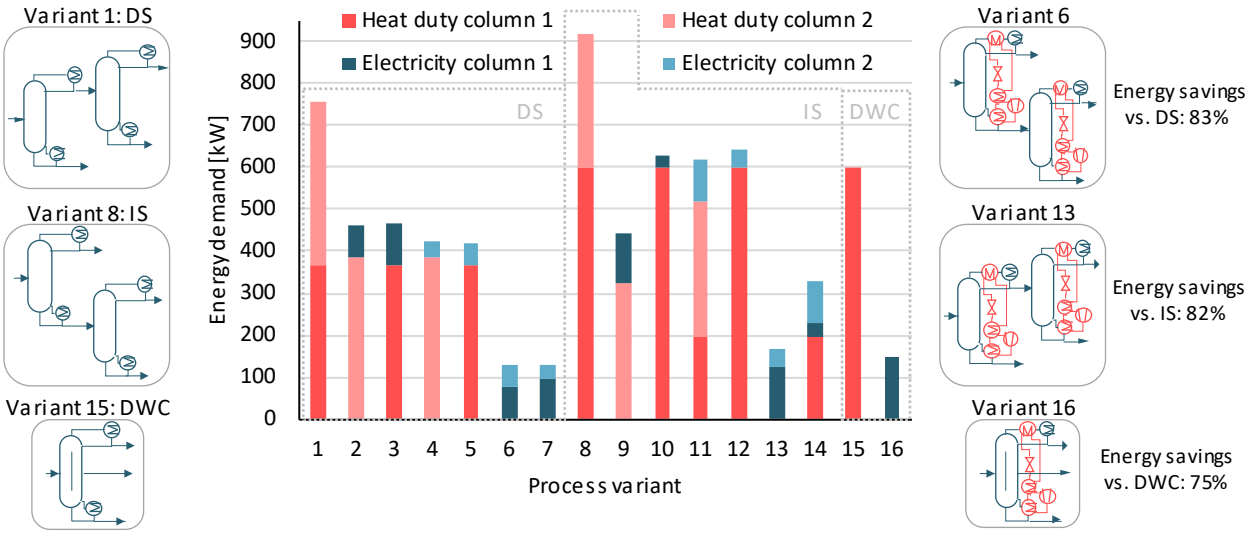

**Figure 3:** Energy demand for a selection of process alternatives and energy saving potential of intenfication with compression heat pumps with acetone as refrigerant.

heating for column 1, as the discrepancy in energy demand between the two columns (see **Table 1**) leads to the upgraded heat being insufficient to fully integrate the required energy demand of the reboiler. Consequently, the full electrification of process variant 14 is not feasible.

## CONCLUSION

The present study introduces a novel methodology for the efficient screening of heat pump cycles and refrigerants based on knowledge of the heat sink and source of the specific application, thereby facilitating its applicability to a wide range of industrial processes. The current implementation of the method assesses the heat pump design, energy demand, as well as thermodynamic and practical constraints of 38 pure refrigerants for a given application which is further showcased for the evaluation of heat pump-assisted distillation processes. As illustrated by the case study, the integration of heat pumps in distillation processes can be complemented by other energy integration methods, thus further reducing the energy demand, whereas possible combinations should be explored quantitatively on a case-specific basis. The scope of the study will be extended in further work to consider other energy-integrated distillation processes and additional heat sources and sinks.

## ABSTRACT

Electricity and carbon trading towards carbon reduction are highly coupled. The research on joint trading is essential for helping companies identify optimal strategies and enabling policymakers to detect potential policy loopholes. This study presents a novel game theory optimization model involving both power generation companies (GenCos) and factories to explore optimal operation strategies under electricity-carbon joint trading. By fully capturing the operational characteristics of power generation units and the technical energy consumption of electricity-consuming enterprises, it describes the relationship between renewable energy, fossil fuels, electricity, and carbon emissions detailedly. Considering the correlation between production volume and price of the same product, the case actually encompasses three trading systems: electricity, carbon, and commodities. Transforming this nonlinear model into a mixed-integer linear form through piecewise linearization and discretization, this study examines, through a virtual case with three GenCos and four factories, the impact of various emission reduction targets, comparisons of different carbon allocation mechanisms, and the influence of allowing zero-emission companies into carbon trading. Results reveal that since consumers may cut production rather than implement low-carbon technologies to lower emissions, driving up product prices to maintain profits, high electricity, and carbon prices become unsustainable for GenCos due to reduced electricity demand. Moreover, while intensity mechanisms can incentivize production, overall system profits decrease, which is undesirable for policymakers. Lastly, under strict carbon reduction targets, zero-emission companies may transform the carbon market into a seller's market by purchasing carbon to raise carbon prices, thereby reducing electricity prices and lowering their operating costs.

**Keywords**: electricity-carbon joint trading, game theory optimization, Nash equilibrium, decarbonization strategy, electricity-consuming factories

## INTRODUCTION

It is a consensus that trading is the most effective way to achieve carbon emission reductions [1]. Currently, in most parts of the world, both electricity and carbon trading exist, which are both capable of decreasing carbon emissions. The high overlap in the range of trading participants and the high correlation of traded items make electricity and carbon trading deeply coupled [2]. The transaction behavior and equilibrium of joint trading must be emphasized. Corporations can acknowledge their reasonable and optimal decisions for higher profits in advance and policymakers can both verify the validity and detect potential policy loopholes.

Previous studies about the electricity-carbon joint transaction mostly focus on power generation companies (GenCos) [3, 4], while a large number of electricity consumers directly emitting $CO_2$, such as steel producers, participate in carbon trading. Although a few studies included electricity consumers before, their descriptions were quite simplified. Studies provided relatively detailed descriptions of end-users only primarily relied on the

inverse function relationship between electricity price and demand [5], load curves and utility functions [6, 7]. The relationship between the consumption of electricity and fossil fuels in electricity consumption companies is seldom depicted. Thus, the transaction behavior of this class of firms participating in the electricity-carbon coupled market is always simplified. In addition, the competitive market for products between similar firms is naturally present and indispensable. Due to its prevalence and importance, the product market is one of the most vital factors for companies to make decisions [8], while it is hardly taken into consideration in previous electricity-carbon joint trading studies.

Therefore, this study proposes a novel game theory-based optimization model that includes both GenCos and electricity-consuming factories. Considering both the electricity-carbon joint trading and the competitive trading for substitution of similar products, this model detailedly depicts the correlations between the consumption of fossil energy, renewable energy, generation and consumption of electricity, as well as carbon emissions, through technologies and infrastructure, thereby obtain the Nash equilibrium for triple trading that is closer to the real trading situation. Moreover, this model is implemented on a virtual case with 3 GenCos and 4 electricity-consuming companies to discuss three problems: the enterprises' operational strategies under varying emission reduction requirements, the pros and cons of cap and intensity carbon quota allocation mechanisms, and the impact of integrating zero-emission enterprises into carbon trading.

# METHODOLOGY

## Modeling of power generation companies

The total power supply of each GenCo in each time slice $s$ in one day can be written as Eq.(1), where $\eta$ denotes the efficiency of batteries and the duration of each time slice is one hour, indicating that it is the sum of all kinds of generation $gi$ and the net discharge of battery. This day is assumed to be the only representative day in a year. The power generation of each technology, $pg_{GenCo,s,gi}$, is restricted by its installed capacity and maximum operation hours. Additionally, for simplicity, the fuel consumption and carbon emissions of GenCos are directly proportional to the corresponding fossil fuel power generation. The longest continuous charging and discharging time is limited to 2 hours.

$$pg.sum_{GenCo,s} = \sum_{gi} pg_{GenCo,s,gi} + pw.discharge_{GenCo,s} * \eta - pw.charge_{GenCo,s}/\eta \quad (1)$$

The operational goal of power generation companies is to maximize their positive profit, which can be expressed as Eq.(2), where the income equals the product of power supply and electricity price, $fix.cost_{GenCo}$ denotes the average annual investment and operating costs of generation units, $pg.grid.cost_{GenCo}$ is considered as the electricity grid connection cost that enterprises need to undertake, $ramp.cost_{GenCo}$ refers to the additional costs caused by changes in the output of fossil energy units.

$$pg.profit_{GenCo} = \sum_s pg.sum_{GenCo,s} * ep_s * 365 - fix.cost_{GenCo} - grid.cost_{GenCo} - fuel.cost_{GenCo} - ramp.cost_{GenCo} - \sum_s pg.tradecarbon_{GenCo,s} * cp_s * 365 \quad (2)$$

Obviously, due to the product of two variables, both from electricity and carbon trading, our model becomes nonlinear, as summarized in Eq.(3). To linearize it, we discretize the variable $y$ to $\{Y_i\}$ and introduce binary variables $b_i$, transforming the problem into Eq.(4), where $M$ is a positive big number. In our model, the price is discretized.

$$z = xy, x \text{ and } y \text{ are all constant variables} \quad (3)$$

$$\begin{cases} z = \sum_i \gamma_i Y_i \\ y = \sum_i b_i Y_i, \ \sum_i b_i = 1 \\ \gamma_i \le x, \ \gamma_i \ge x - M(1-b_i), \ \gamma_i \le M b_i, \ \gamma_i \ge -M b_i \end{cases} \quad (4)$$

## Modeling of electricity-consuming companies

In our case study, there are four factories A~D and only their direct carbon emissions are recognized to avoid duplicate accounting. Factory A and Factory B are both equipped with the same two technologies, but in different proportions, producing identical products P. Factory C does not emit $CO_2$, and only meets known electricity needs through purchased electricity and self-provided energy storage batteries. Factory D needs to complete the signed orders through two technologies. The operational goal of the four factories is the maximization of their positive profit. The revenue of Factory A and B is the product of their output and commodity prices, while the revenue and output of Factory C and Factory D have been determined through contracts. In order to describe the competition market for similar products P, we use the Cournor model to describe the negative correlation between production and price, as shown in Eq.(5), where $fac \in \{A, B\}$, $pi$ stands for two production technologies and a, b are given parameters. This relationship is linearized by Eq.(6), where $K$ is given.

$$P.price = a - b * \sum_{fac,pi,s} P.produce_{fac,pi,s} \quad (5)$$

$$P.price = a - \frac{Kb(i-1)}{n}, \frac{K(i-1)}{n} \le x < \frac{Ki}{n}, i = 1,2,\dots,n \quad (6)$$

The costs of all four factories consist of fixed costs, production costs, fuel costs, electricity purchase costs, and carbon trading costs. Production costs are positively proportional to production volume, which is strictly limited by installed infrastructure. In addition, for Factories

A, B and D, due to the different demands for fuels and electricity required by various technologies, and the consumption of fossil fuels often accompanied by carbon emissions, this model can reflect the negative correlation between the average electricity demand and direct carbon emissions per unit production of factories.

## Modeling of electricity-carbon joint trading and calculation of Nash equilibrium

Not considering the transaction center, our model assumes equal buying and selling prices for electricity and carbon, with prices stable throughout the day. Electricity trading should be in real-time and meet supply and demand balance. Carbon trading also needs to meet the supply and demand balance requirement. Unlike electricity trading, carbon trading only requires companies to fulfill their emission obligations at the final moment.

This model directly uses the results of Nash equilibrium to solve the equilibrium in the joint transactions, as shown in Eq.(7a), which equals Eq.(7b). Obviously, this introduces significant nonlinearity to the model. Therefore, special ordered sets of type 2 (SOS2) variables, $\lambda_i$, are introduced to make our model linear, as shown in Eq.(8).

$$\max obj = \prod_{GenCo} profit_{GenCo} \prod_{factory_i} profit_{factory_i} \quad (7a)$$

$$\max obj = \sum_{GenCo} LN(profit_{GenCo}) + \sum_{factory_i} LN\left(profit_{factory_i}\right) \quad (7b)$$

$$\begin{cases} profit = \sum_i \lambda_i * i \\ LN(profit) = \sum_i \lambda_i * LN(i) \\ \sum_i \lambda_i = 1 \end{cases} \quad (8)$$

In conclusion, this research set up a nonlinear problem(NLP) and transform it into a mixed-integer linear programming(MILP) problem through methods including discretization and piecewise linearization to describe the triple trading of electricity, carbon, and commodities involving both power generation and consumption companies.

## CASE STUDY

A diagram of our case study, including fundamental settings, is illustrated in Figure 1. Battery charging and discharging efficiencies are set at 90%, and the price for discharging photovoltaic and energy storage batteries into the grid is 0.1 yuan/kWh. The costs of coal-fired and gas-fired power due to changes in output are 0.05 yuan/kWh and 0.01 yuan/kWh, respectively. Electricity prices range from 0.5 to 1.5 yuan/kWh, while carbon prices range from 0.2 to 4.5 yuan/kg.

Factory A and Factory B both produce product P using two technologies, PT1 and PT2, with details provided in Table 1. The parameters in Eq.(5), a and b, are set as

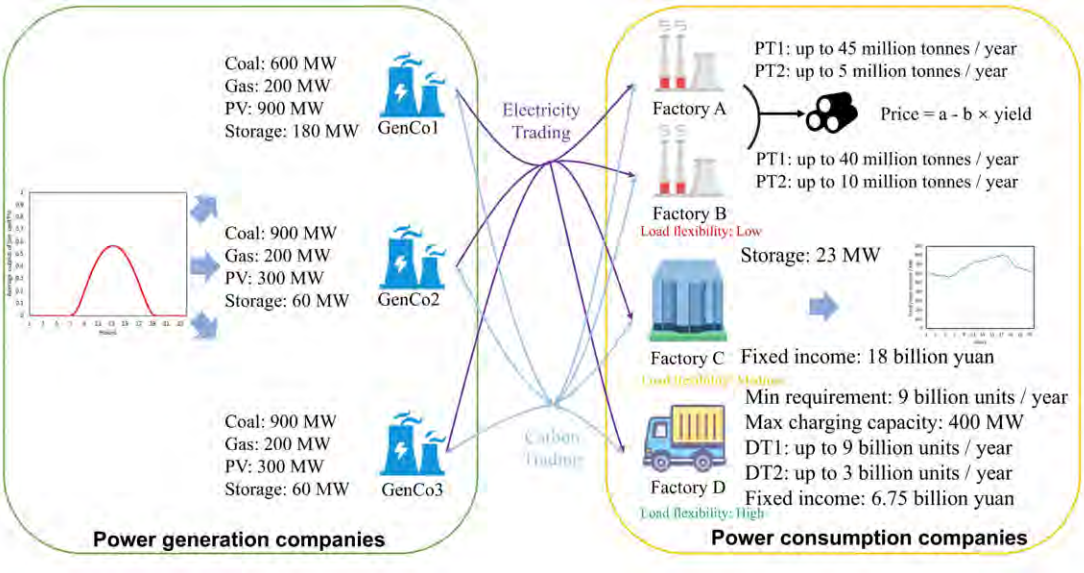

**Figure 1:** The diagram of the case study

**Table 1:** Detailed information of PT1 and PT2

| Name | Fixed price (¥ / tonne) | Produce price (¥ / tonne ) | Electricity demand (kWh / tonne) | $CO_2$ (kg / kg) | Ramp price (¥ / tonne) |
|---|---|---|---|---|---|
| PT1 | 160 | 3300 | 200 | 2.42 | 400 |
| PT2 | 160 | 3800 | 600 | 1.9 | 200 |

**Table 2:** Detailed information of DT1 and DT2

| Name | Fixed price (¥ / unit) | Fuel demand (kg or kWh / unit) | Fuel price (¥ / kg) | $CO_2$ (kg / unit) |
|---|---|---|---|---|
| DT1 | 0.012 | Fossil fuel: 0.0245 kg | 9.3 | 0.07791 |
| DT2 | 0.08 | Electricity: 0.66 kWh | Variable | 0 |

45 and 10. For Factory D, the specifics of its two technologies, DT1 and DT2, are given in Table 2.

## RESULTS AND DISCUSSION

### Enterprises' operational strategies under varying emission reduction requirements

Eight scenarios are established to analyze operational strategies and identify patterns. In the Base and the EM only scenario, carbon trading is not allowed, and the electricity price is designated as 0.75 yuan/kWh in the Base scenario. For the scenarios JM0.9 to JM0.4, both carbon trading and electricity trading are allowed, with prices negotiated among participants. Initial carbon quotas are set based on emissions from the EM only scenario; for instance, JM0.9 provides 90% of that carbon quota. Factory C is restricted from participating in carbon trading. Significant results are summarized in Table 3.

Different from previous studies which found that more stringent carbon reduction targets drive up both carbon and electricity prices simultaneously [9], our findings show that when emission reduction targets are exceptionally strict, carbon prices increase while electricity prices decrease. This phenomenon needs to be explained by combining the competition of similar products P and the carbon trading willingness of each enterprise shown in Figure 2(a-f).

**Table 3**: Trading prices, yield and generation structure under different reduction targets (MT is the abbreviation of million tonnes)

| Scenario | Electricity price (¥ / kWh) | Carbon price (¥ / kg) | Total yield of P (MT) | Price of P (¥ / tonne) |
|---|---|---|---|---|
| Base | 0.75 | / | 65 | 3900 |
| EM only | 1.1 | / | 60 | 3950 |
| JM0.9 | 1.2 | 0.2(min) | 50 | 4050 |
| JM0.8 | 1.25 | 0.2(min) | 45 | 4100 |
| JM0.7 | 1.25 | 0.2(min) | 40 | 4150 |
| JM0.6 | 1.25 | 0.8 | 35 | 4200 |
| JM0.5 | 1.2 | 2.0 | 30 | 4250 |
| JM0.4 | 1.0 | 3.75 | 24 | 4300 |

GenCos generally act as carbon sellers, profiting from both electricity and carbon sales, while factories tend to be buyers in both markets. GenCos can only sell electricity and carbon when consumers continue production, as reduced production means decreased demand for both electricity and carbon allowances. If both prices rise incredibly, consumers will choose to cut production to maintain their profit through raising unit prices, which can be seen from Table 3, then GenCos cannot sell so much. Therefore, electricity prices and carbon prices cannot both increase much. In addition, electricity price contributes more to electricity consumers' total costs

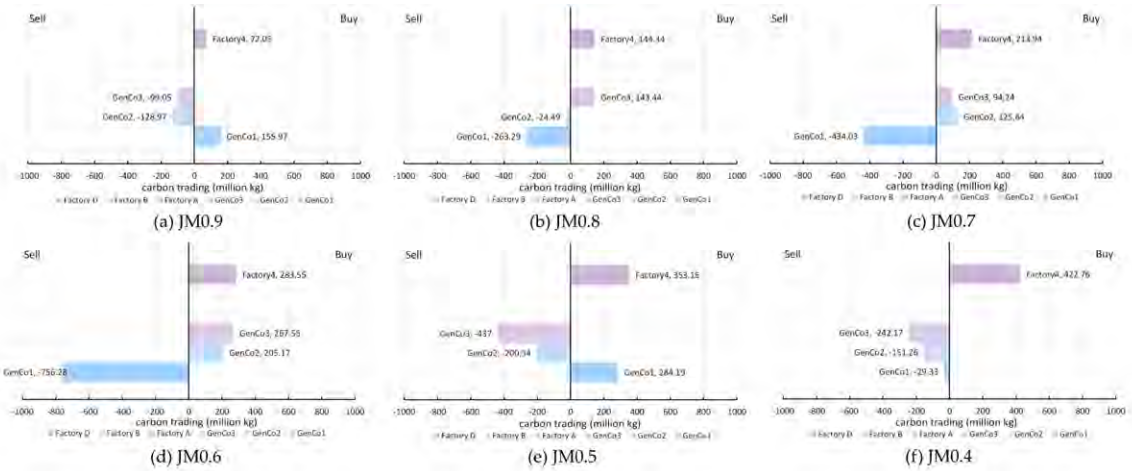

**Figure 2:** Carbon trading results under different reduction target

**Table 4:** Trading prices, yield and profit under different quota allocation mechanisms

| Scenario | Electricity price (¥ / kWh) | Carbon price (¥ / kg) | Total yield of P (MT) | Profit of each enterprise (Billion yuan) (GenCo1~3; factory A~D) |
|---|---|---|---|---|
| JM0.9 | 1.2 | 0.2(min) | 50 | 5.10, 5.16, 5.10; 4.80, 4.70, 5.87, 4.30 |
| JM0.8 | 1.25 | 0.2(min) | 45 | 5.00, 4.92, 5.00; 4.40, 4.35, 5.61, 4.31 |
| Int-JM0.9 | 0.9 | 0.8 | 55 | 3.87, 4.30, 4.60; 3.70, 3.77, 7.44, 3.90 |
| Int-JM0.8 | 0.8 | 0.8 | 45 | 1.97, 3.04, 4.34; 2.39, 2.40, 8.27, 4.21 |

compared with carbon cost; therefore, only when the electricity price is lower would they like to maintain a relatively high production volume. Previous studies were unable to reach these results because they often overlooked the probability of factories' reducing production and price yield relationship in commodity trading. The difference in conclusions also proves the necessity of considering the behavior of electricity-consuming factories more carefully in the electricity-carbon joint trading.

Although there is currently no empirical evidence to support the idea that electricity prices will drop as carbon prices rise due to end-use firms drastically reducing production to meet stricter emission targets, prior studies have observed similar patterns. When the cost of reducing carbon emissions becomes prohibitively high, end-use companies may opt to cut production and increase prices [10]. We speculate that this has not led to a reduction in electricity prices, possibly because these firms are not major electricity consumers within their regions, limiting their tariff negotiation power. However, this hypothesis requires further validation.

In addition, the results also state that factories are not willing to either use any expensive low-carbon technologies to reduce their emissions or purchase costly carbon quotas. This means that if there are no restrictions, the emission reduction of the system will mainly be achieved through the decarbonization of the power system and the reduction of factory production. However, the reduction of yield and the soaring of the price might not align with the goals of market regulators. Therefore, regulators must strictly limit the factories participating in the electricity-carbon joint market to prevent them from maliciously reducing production to maintain profits under the carbon target.

## Pros and cons of cap and intensity carbon quota management mechanisms

In order to quantitatively acknowledge the pros and cons of the cap and intensity quota management mechanisms, the two most widely implemented in carbon trading in reality, this study proposes two additional scenarios: Int–JM0.9 and Int-JM0.8. In the two intensity scenarios, the sum of each enterprise's carbon emissions and carbon trading volume does not exceed the fixed percentage of the product of its production and emission intensity under the EM only scenario. Key findings are shown in Table 4.

Results show that under the intensity mechanism, factories' production enthusiasm can be improved, which is consistent with official cognition, confirming the reliability of our study. The electricity price decreases and the carbon price rises, which seems to be beneficial to both the production and carbon reduction. However, the profits of enterprises involved in carbon trading are all vulnerable under the intensity mechanism, making the total market profit decline violently. Although all the firms in the system are 'selfish' and want to maximize their own profit, the governor of the system always wishes that the total profit would be as high as possible from an economic development perspective. From this point of view, the cap mechanism is much better.

## The impact of integrating zero-emission enterprises into carbon trading

Although some enterprises, such as Factory C in our case study, do not emit $CO_2$ directly, we still try to let them participate in carbon trading, exploring the impact of integrating zero-emission enterprises into carbon trading. Because that they do not own the initial carbon quota, leading to their non-negative net carbon purchases, thereby further promoting the system's carbon mitigation. The difference of involving Factory C into carbon trading is exhibited in Table 5.

**Table 5**: Trading prices, yield and profit under different quota allocation mechanisms

| Scenario | Electricity price (¥ / kWh) | Carbon price (¥ / kg) | Total yield of P (MT) |
|---|---|---|---|
| JM0.5-exclude | 1.2 | 2.0 | 30 |
| JM0.4-exclude | 1.0 | 3.75 | 24 |
| JM0.5-include | 1.0 | 4.5(max) | 30 |
| JM0.4-include | 0.95 | 4.5(max) | 24 |

First and foremost, the yield is not likely to be influenced. It can be also found that the inclusion of carbon-free enterprises in carbon trading will lead to a drop in electricity prices and an increase in carbon prices. These enterprises attempt to increase the scarcity of tradable quotas by increasing carbon trading volume, thereby raising carbon prices. Due to the fact that the electricity

and carbon price cannot increase violently simutanesouly, thus they can pay a smaller cost in exchange for a drop in electricity prices, thereby minimizing their total costs.

## CONCLUSION

This study proposes a non-linear program to describe the triple gaming and trading of electricity, carbon and commodity between both power generation and consumption companies. Transforming it into a MILP problem and using a case with 3 GenCos and 4 factories in 3 types, this study discusses the optimal operation mode of enterprises under coupled transactions. Results state that power consumers are more likely to achieve reduction targets through reducing yield instead of implementing low-carbon technologies or trading quotas, which also leads to the inability of electricity and carbon prices in the electricity-carbon joint trading to be high at the same time. Meanwhile, if zero-emitting enterprises participate in the carbon market, they can increase the scarcity of carbon in the market by purchasing carbon, thereby reducing electricity prices and ensuring their own profits. This study also provides ideas for market managers. It is necessary to strictly control the output of electricity consuming enterprises and prioritize the use of Cap carbon management mechanisms when considering the total profit of the system.

However, our study has certain limitations. Future research should incorporate more detailed considerations, such as real-time electricity prices, policy analyses based on our proposed model, and discussions on parameter sensitivity, to better support the ongoing development of the electricity-carbon joint market.

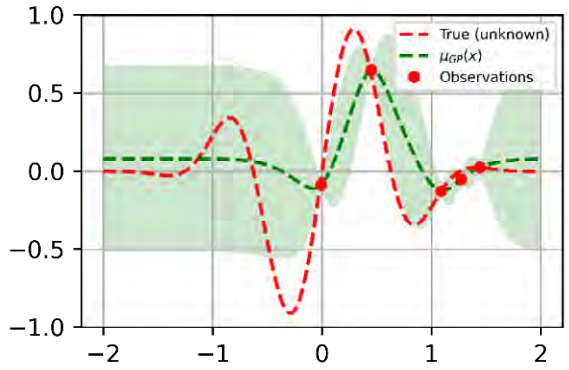
## ABSTRACT

Bayesian optimization is known to be able to search for the optimal conditions based on a small number of experiments. However, these experiments are insufficient to understand the experimental condition space. In contrast, we report the development of an algorithm that combines a low-confounding definitive screening design with Bayesian optimization, allowing for rapid optimization and ensuring sufficient experiments to understand the experimental condition space with a low confounding.

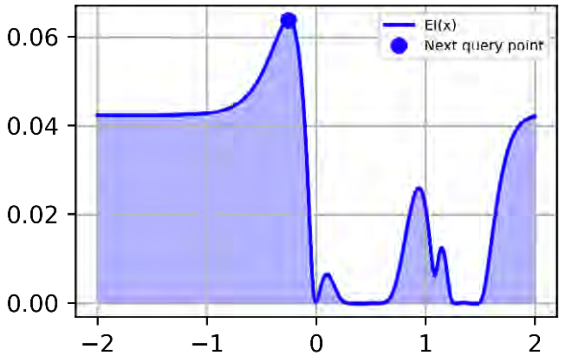
**Keywords**: Optimization, Algorithms, Bayesian optimization, Definitive screening design.

## INTRODUCTION



It has been established that Bayesian optimization (BO) [1,2] is capable of searching for the optimal conditions based on a limited number of experiments. Accordingly, prior to implementing the BO, preliminary experiments are conducted in accordance with the principles of the design of experiments. Many methods for the designs of experiment have been proposed, including the factorial design[3], the Plackett Burman design [4], the Box Behnken design [5], the central composite design[6], the Latin hypercube design [7], and the definitive screening design (DSD) [8]. The results of experiments designed by the DSD may contribute to an understanding of the chemical space with minimal confounding factors and a limited number of steps. Subsequently, preliminary experiments are conducted based on the design of experiment, utilizing the design of experiment methods, and a search for the optimal conditions is then undertaken by the BO. This enables the experimental space to be optimized following a comprehensive investigation and to gain insight into the surrounding conditions of the optimal parameters. However, as the design of experiment is conducted independent of the BO, it contributes no more than the preliminary experiments to the optimization process. As a result of comparing the Box Behnken design and response surface methodology with adaptive Bayesian optimization, the BO should be combined with the design of experiments, since the BO could not investigate the experimental space [9]. Therefore, in this study, the design of experiment was evaluated by the acquisition function from within the DSD, and the design of experiment is accordingly modified. The results of running the modified design of experiment are suitable for optimization by the BO, thus allowing the subsequent BO to rapidly search for the optimum conditions.

This paper presents the development of an algorithm that combines a small confounding of the DSD with the BO, thus allowing for rapid optimization and ensuring sufficient experiments to understand the experimental condition space with a small confounding.



## BAYESIAN OPTIMIZATION

The BO is a method that is known to converge towards the optimum value based on a limited number of experiments. A schematic representation of the process by which the subsequent trial point is formulated is provided in Figure 1. A regression is performed on the observed values with the base estimator frequently being a

Gaussian process regression. An acquisition function is calculated based on the regression model, and the point with the maximum acquisition function value is the next trial point. The acquisition functions most commonly employed are LCB (lower confidence bound), EI (negative expected improvement), PI (negative probability of improvement) and gp_hedge, which probabilistically combines them.

(a) Gaussian process regression from observations.

(b) Next query point by acquisition function.

**Figure 1.** Schematics of Bayesian optimization.

## DEFINITIVE SCREENING DESIGN

The DSD [1,2] is one of the famous design methods of experiments. The DSD is characterised by the following attributes:

- Low confounding between factors.
- A relatively limited number of experiments.

$$N = 2n + 1 + 4f \quad (1)$$

where $N$ is the number of experiments, $n$ is the number of factors, and $f$ is the number of fake factors.

- Three levels for each factor.

The fake factor allows the error to be estimated independently of model selection. The design of experiment with the DSD utilizing a 3 variables model without a fake factor is presented in Table 1. There are 7 $(= 2 \cdot 3 + 1 + 4 \cdot 0)$ entries for 3 variables and no fake factor.

**Table 1:** Designed experiments by the DSD with 3 variables and no fake factor.

| Entry | A | B | C |
|---|---|---|---|
| 1 | 0 | 1 | 1 |
| 2 | 0 | -1 | -1 |
| 3 | 1 | 0 | -1 |
| 4 | -1 | 0 | 1 |
| 5 | 1 | -1 | 0 |
| 6 | -1 | 1 | 0 |
| 7 | 0 | 0 | 0 |

## INTEGRATION OF DEFINITIVE SCREENING DESIGN AND BAYESIAN OPTIMIZATION

The algorithm proposed in this study is presented in the following section. The initial stage of the study comprises preliminary experiments, which are conducted in accordance with the design of experiment formulated by the DSD (Step 1). However, the design of experiment is modified with the objective of incorporating the experimental data into the subsequent BO process. Specifically, in order to calculate the acquisition function for each factor, a preliminary experiment is conducted in accordance with the planned methodology until each variable value is no longer unique (Step 2). Subsequently, the acquisition function is calculated for the remaining experiments, and the experiment with the highest acquisition function value is selected for experimentation (Steps 3, 4, and 5). This process is repeated for Steps 3, 4, and 5 until no further designed experiments remain (Step 6). Once all the designed experiments have been conducted, the optimal conditions can be identified through Bayesian optimization (Steps 7, 8, and 9). By prioritizing the condition with the largest acquisition function value in Steps 3, 4, and 5, the experimental values that are most suitable for the Bayesian optimization performed after Step 7 can be acquired. Furthermore, the planned experimental conditions based on the DSD satisfy the DSD characteristics of a small confounding and a small number of experiments to understand the experimental space.

Example) The proposed algorithm is applied to the designed experiment in Table 1. Step 1 is to formulate Table 1. Step 2 is to execute the experiment up to Entry 3 as designed. Step 3 is to calculate the acquisition function values from Entry 4 onwards. In step 3, the acquisition function values for entry 4 and subsequent entries are calculated. In order to preserve the sign, the

acquisition function values are calculated in the range 0 to 1 for the condition value 1, in the range 0 to -1 for the condition value -1, and in the range 0 for the condition value 0. In Step 6, Steps 3 to 5 are executed until no further entries remain. In Step 7, the condition with the maximum acquisition function over the entire range is identified based on the experimental results up to Step 6, and experiments are conducted using Step 8. In Step 9, Steps 7 and 8 are repeated until convergence is confirmed.

### Proposed Algorithm

Step 1: Design experiment by the DSD.

Step 2: Experiment until all elements are not unique under the DSD definition, in which + and – are the maximum and minimum between the chemical space, respectively.

Step 3: Determine all the remaining experimental conditions for the maximum acquisition function value within the same sign region.

Step 4: Select the experimental condition with the maximum acquisition function value between those of the remaining designed experiments.

Step 5: Perform an experiment with the determined conditions.

Step 6: Go to the next step if all the experiments are executed, else return to Step 3.

Step 7: Search the optimum condition for the maximum acquisition function value.

Step 8: Perform an experiment with the condition.

Step 9: Finish if the convergence conditions are satisfied, else go to Step 7.

## NUMERICAL SIMULATION

In order to ascertain the efficacy of the algorithm proposed in this study, a numerical comparison was conducted. In the present study, the design of experiment was formulated by the DSD and compared with nine different designs of experiment using PyDOE2 [10]. These included a factorial design, a Plackett Burman design, a Box Behnken design, and the DSD. The DSD had three types of designs of experiment (0, 2, and 4) depending on the number of fake factors. Furthermore, a comparison was conducted between the proposed algorithm and Bayesian optimization with randomly generated initial values and no design of experiment. In order to examine the differences between the design of experiment and Bayesian optimization in terms of how they are combined, the following cases were considered: In the case of 'Sequential BO', the BO was performed subsequent to the design of the experiment. In the case of 'In BO', the experimental conditions were set to the condition with the maximum acquisition function value based on the results of Step 3. In the case of 'In Remain BO', the experimental conditions were set to the condition with the maximum acquisition function value based on the acquisition function value and the order of the design with the latter being switched based on the acquisition function values, as determined by Step 4.

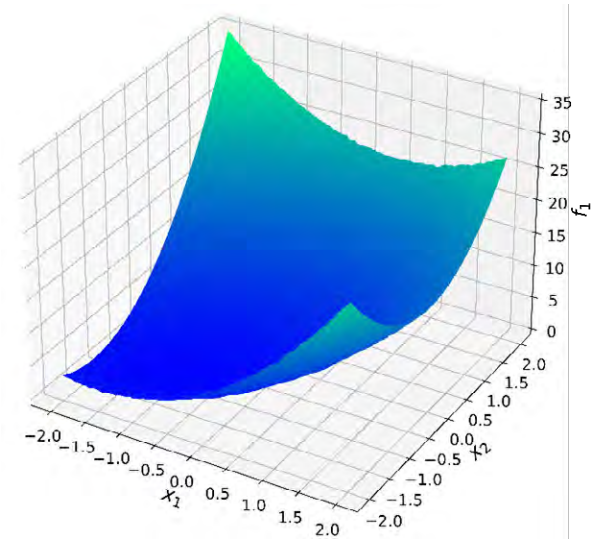


**Figure 2.** Quadratic objective function with one peak.

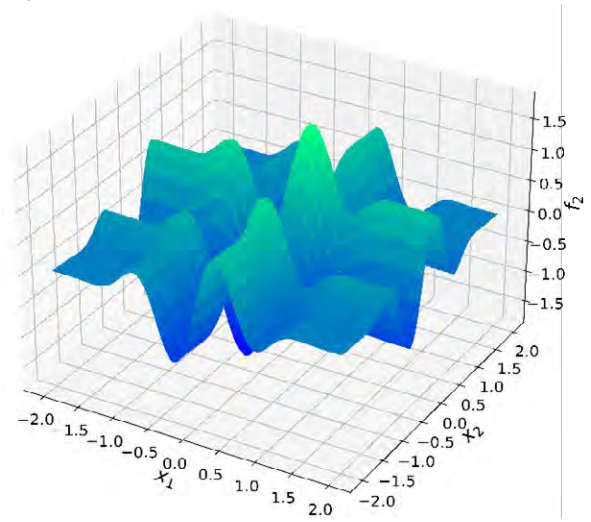

**Figure 3.** Tanh objective function with many peaks.

The objective functions were two distinct types: unimodal and multimodal. The former is illustrated in Eq. (2) (Figure 2), while the latter is shown in Eq. (3) (Figure 3). In Figure 3, $x_3 = 0$ for illustration.

$$f_1(x_1, x_2) = 3 + 2x_1 + 4x_2 - 2x_1^2 - 2x_1x_2 + 3x_2^2 \quad (2)$$

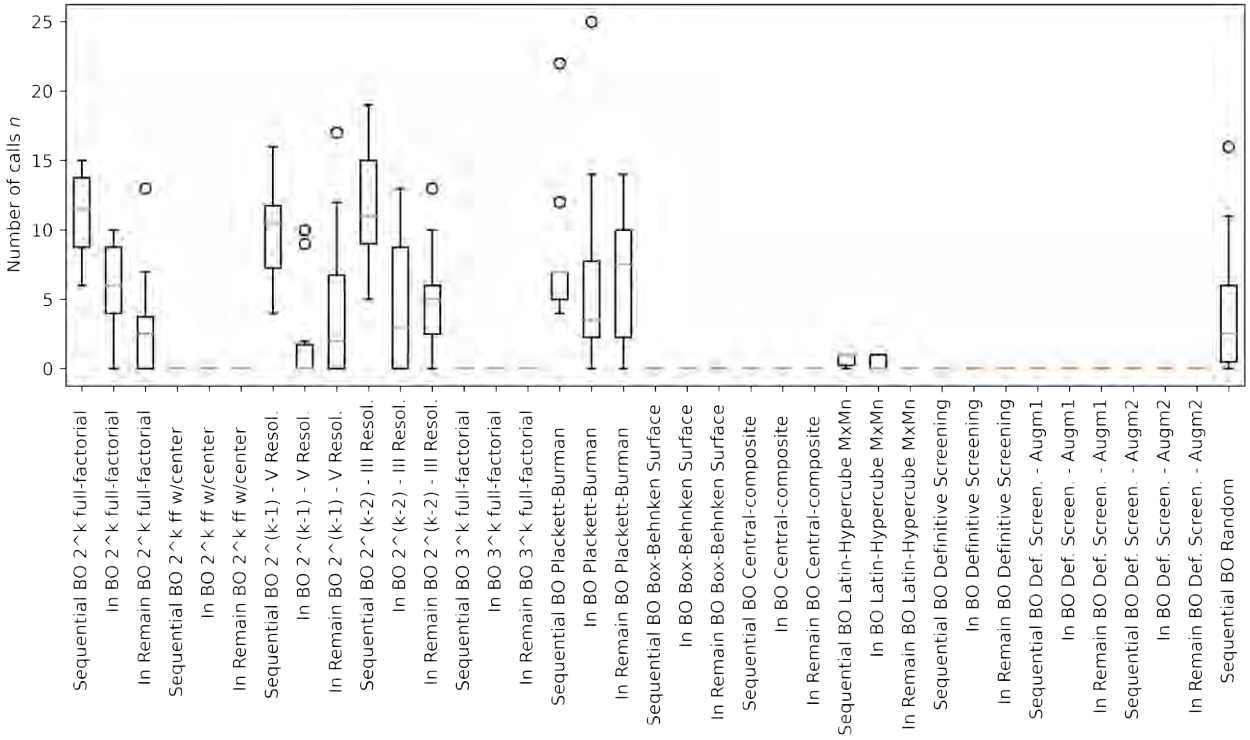

**Figure 4:** Box plots for number of iterations for quadratic function using each algorithm. Orange line represents 50%tile, box represents from 25%tile to 75%tile, whiskers represent minimum and maximum values, and circle represents outliers. For 'Sequential BO', the BO was executed after DoE. For 'In BO', DoE was affected by acquisition function. For 'In Remain BO', DoE was affected and rearranged by acquisition function. '2^k full-factorial' is 2 level general full factorial, '2^k ff w/center' is 2 level general full factorial with zero matrix, '2^(k-1) - V Resol.' Is V resolution 2 level fractional factorial, '2^(k-2) - III Resol.' Is III resolution 2 level fractional factorial, '3^k full-factorial' is 3 level general full factorial, 'Plackett-Burman' is Plackett Burman, 'Box-Behnken Surface' is Box Behnken, 'Central-composite' is central composite, 'Latin-Hypercube MxMn' is Latin hypercube, 'Definitive Screening' is the DSD, 'Def. Screen. - Augm1' is the DSD with 2 fake factors, and 'Def. Screen. - Augm2' is the DSD with 4 fake factors. 'Random' is random initial conditions.

$$f_2(x_1, x_2, x_3) = \sin(5x_1) \cdot (1 - \tanh(x_1^2)) + \sin(5x_2) \cdot (1 - \tanh(x_2^2)) + \sin(5x_3) \cdot (1 - \tanh(x_3^2)) \quad (3)$$

The functions were constrained as follows.

$$-2.0 \leq x_1 \leq 3.0, -3.0 \leq x_2 \leq 4.0, -2.0 \leq x_3 \leq 3.0 \quad (4)$$

A total of 10 trials were conducted for each case in the simulation.

## RESULTS AND DISCUSSION

### Case 1: unimodal objective function

Figure 4 illustrates the distribution of experiments conducted to optimize the unimodal objective function. The number of experiments designed by each method was quite different, the Plackett Burman required only 4 experiments but the 3 level general full factorial required 27 experiments. As the total number of experiments including the designed experiments was not suitable for evaluating the performance of Bayesian optimization after designed experiments, the number of calls after each designed experiment was counted. As the number of convergences of the BO varied between experiments, ten experiments were conducted until a neighbourhood of the optimum value of 3.0 was reached at 5.0. As the optimum value of the unimodal objective function is readily discernible, in numerous instances the experimental conditions proximate to the optimum value were attained during the preliminary experimental phase. The results demonstrated that convergence was achieved in a significantly reduced number of experiments compared to those conducted using the 'Sequential BO Random' method, in which the initial values were randomly generated.

In the case of the 2-level general full factorial, designated as a '2^k full-factorial', and the III resolution 2-

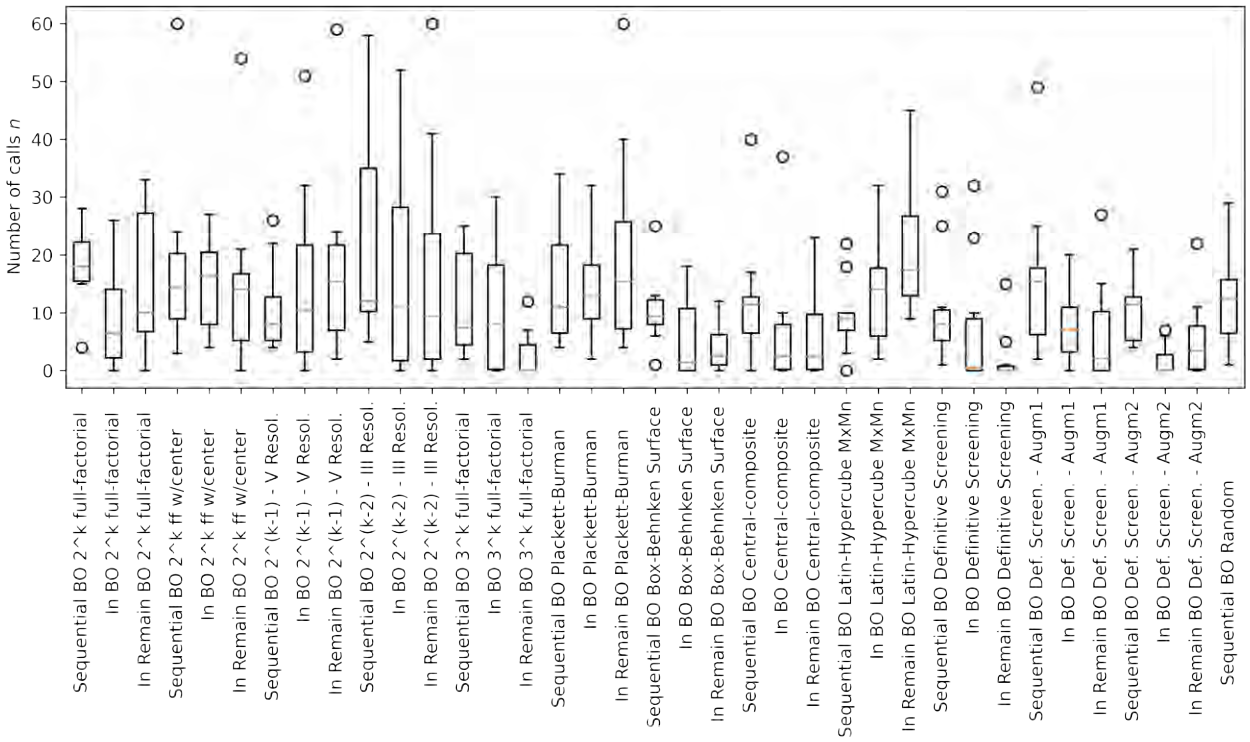

**Figure 5:** Box plots for number of iterations for quadratic function using each algorithm. Orange line represents 50%tile, box represents from 25%tile to 75%tile, whiskers represent minimum and maximum values, and circle represents outliers. For 'Sequential BO', the BO was executed after DoE. For 'In BO', DoE was affected by acquisition function. For 'In Remain BO', DoE was affected and rearranged by acquisition function. '2^k full-factorial' is 2 level general full factorial, '2^k ff w/center' is 2 level general full factorial with zero matrix, '2^(k-1) - V Resol.' Is V resolution 2 level fractional factorial, '2^(k-2) - III Resol.' Is III resolution 2 level fractional factorial, '3^k full-factorial' is 3 level general full factorial, 'Plackett-Burman' is Plackett Burman, 'Box-Behnken Surface' is Box Behnken, 'Central-composite' is central composite, 'Latin-Hypercube MxMn' is Latin hypercube, 'Definitive Screening' is the DSD, 'Def. Screen. - Augm1' is the DSD with 2 fake factors, and 'Def. Screen. - Augm2' is the DSD with 4 fake factors. 'Random' is random initial conditions.

level fractional factorial, designated as '2^(k-2) - III Resol.', it is evident that the case of 'In BO' converged. This occurred less frequently than in the cases of the 'Sequential BO' and 'In Remain BO'. The fact that the case of 'In BO' converged less often than the case of 'Sequential BO' demonstrates the value of optimizing the experimental conditions through the acquisition function during the preliminary experiment based on the design of experiment. This demonstrated the value of optimizing the experimental conditions with the acquisition function during the preliminary experiment based on the design of experiment. The case of the 'In Remain BO' converged fewer times than the case of 'In BO', indicating the benefit of utilizing the acquisition function to alter the design order during the preliminary experiment based on the design of experiment.

## Case 2: multimodal objective function

Figure 5 illustrates the distribution of experiments conducted for the purpose of optimizing the multimodal objective function. Similarly, for the unimodal function, to evaluate the performance of Bayesian optimization after designed experiments, the number of calls after each designed experiment was counted. Ten experiments were conducted for the multimodal objective function with the number of experiments continuing until a neighborhood of the optimum value of -2.8 was reached at -1.0. In comparison to the unimodal objective function, the search for the optimal value of the multimodal objective function was more challenging and necessitated the execution of several tens of experiments.

In a considerable number of designs of experiment, the case of 'In BO' converged less often than the case of 'Sequential BO', and the case of 'Sequential BO' converged less often than the case of 'In Remain BO'

In comparison to the 'Sequential BO Random' method, which employed randomly generated initial values, i.e., the Box-Behnken 'Box-Behnken Surface' and the

central Composite 'Central-composite' methods, the DSD 'Definitive Screening', and the 'Def. The following abbreviations were used: 'Screen', 'Augm1' and 'Def'. Furthermore, the 'Def. Augm1' and 'Def. Augm2' methods were also considered. The 'Screen. - Augm2' method demonstrated a high degree of convergence in a relatively small number of cycles. Notably, in the case of employing the proposed algorithm within the DSD framework, it exhibited a markedly superior convergence rate compared to the 'Sequential BO Random' method.

In both cases, the proposed algorithm, in which the DSD designed experiments were influenced and rearranged by the acquisition function, could converge faster than the 'Sequential BO Random' method. These findings highlight the value of optimizing the experimental conditions through the acquisition function, and of modifying the design of experiment order through the acquisition function during the preliminary experiment, independent of the objective function. Since faster convergence for BO means that the exploration of the experimental condition space was more useful. Therefore, in the proposed algorithm, the BO was able to perform on sufficient experiments designed by the DSD to understand the experimental condition space.

## CONCLUSIONS

We put forth a novel algorithm that integrates the DSD and the BO to address confounding factors and optimize the experimental conditions. Optimizing the magnitude and orders of the designed experiments of the DSD based on the BO contributed to effectively accelerate the convergence rate. Our proposed algorithm exhibits the potential for a faster convergence than existing algorithms in numerical experiments. Furthermore, we have demonstrated the value of rearranging the order of experiments in achieving more efficient outcomes. Furthermore, in the proposed algorithm, the BO was able to perform on sufficient experiments designed by the DSD to understand the experimental condition space.

In future work, we will investigate wet experiments to verify the efficacy of our proposed algorithm.

## ABSTRACT

This study presents an integrated approach combining the Analytic Hierarchy Process (AHP) with a Mixed-Integer Multi-Objective Linear Programming (MOMILP) model to evaluate sustainable power generation alternatives for Pamplona, Colombia. The MOMILP model includes solar, wind, biomass, and diesel technologies, aiming to minimize costs (net present value) and $CO_2$ emissions while considering design, operational, and budget constraints. The AHP method evaluates multiple criteria such as social acceptance, job creation, technological maturity, and environmental impact. The results show that solar panels are prioritized, with small diesel plants added due to resource limitations. The most sustainable option is a hybrid system with 49% solar, 29% wind, 14% biomass and 8% diesel, generating a net present value of 121,360 USD and 94,720 kg of $CO_2$ emissions. The proposed methodology can be applied to assess and select the most feasible alternative within a wide range of new projects for the integration of renewable energy systems for the extension of existing power grids.

**Keywords**: Analytical Hierarchical Process, Multi-objective optimization, Numerical Methods, Renewable and Sustainable Energy, Technoeconomic Analysis.

## INTRODUCTION

Energy systems are fundamental for economic and social development; however, around 66% of global energy supply still relies on fossil fuels, contributing to 75% of GHG emissions [1]. Given the continuous population growth and rising energy demand, these percentages are likely to increase in the future [2]. To address this issue, many countries have prioritized the integration of RES into their power distribution systems as a strategy to reduce GHG emissions and mitigate climate change [3]. Colombia, for instance, generates approximately 70% of its electricity from hydropower, significantly decreasing its reliance on fossil fuels [4].

Despite this progress, heavy dependence on hydropower poses a risk, as water resources are highly affected by climate variability [5]. Recognizing the need to diversify its energy mix, Colombia introduced Law 1715 in 2014 to regulate the integration of RES into the SIN. The law includes various incentives, such as income tax deductions, VAT exemptions, import duty exemptions, and accelerated asset depreciation, to promote the adoption of RES [6].

To effectively integrate RES into power grids, several studies have utilized MCDM methods. For example, Arikan et al. (2024) applied AHP and VIKOR to identify the most suitable non-conventional technology for a hotel's power supply, considering technical, economic, and environmental aspects [7]. Similarly, Xu et al. (2023) evaluated a hybrid RES using an optimization model combined with AHP, focusing on technical, economic, and environmental criteria [8]. However, these studies often overlook social factors, which are crucial for the successful design and implementation of hybrid energy systems. Ali et al. (2020) addressed this gap by incorporating social criteria, such as social acceptance and policy impacts, in their

assessment of RES options for a refugee camp in Bangladesh using the AHP method [9]. Despite the extensive body of research on RES integration, there is still a need for more comprehensive studies that consider social criteria and involve direct input from experts. Additionally, existing studies frequently fail to account for specific geographical characteristics of the case study area.

Addressing these gaps, this research employs a MOMILP model and the AHP to evaluate the integration of PV panels, biomass gasifiers, wind turbines, and diesel generators into the SIN to meet the energy demand of Pamplona, Colombia. The MOMILP model is designed with a 16-year planning horizon starting in 2024. It aims to minimize both costs and $CO_2$ emissions, considering design, operational, and budget constraints. The model also explores the potential for selling surplus electricity, which could contribute to local economic growth and enhance energy independence. To select the most sustainable alternative from the Pareto front, the AHP method is employed, using a comprehensive set of criteria: economic, technical, environmental, and social. It includes sub-criteria reflecting specific geographical aspects and social factors such as social acceptance and job creation. The weighting of these criteria and sub-criteria is determined through expert input, using the Delphi method and Saaty's scale. This integrated approach allows for a more holistic evaluation of RES integration strategies, ensuring that both technical and socio-economic factors are considered in the decision-making process.

## MATHEMATICAL FORMULATION

In this section, the objective functions and constraints of the MOMILP model are presented.

### Objective functions:

The objective functions aim to minimize the total generation system cost (NPV, which is the result of subtracting the energy costs — CAPEX, OPEX, and energy sales to the grid) (Eq. 1) and $CO_2$ emissions (Eq. 2):

$$NPV=\sum_t \frac{1}{(1+TD)^t}\cdot[\sum_p \widehat{InvCo}_{p,t}\cdot CaA_{p,t} + \sum_p \widehat{FixCo}_{p,t}\cdot CaT_{p,t} + \sum_p \widehat{VarCo}_{p,t}\cdot EnG_{p,t} + \sum_p \widehat{FuCo}_{p,t}\cdot FuR_{p,t} - \sum_p \widehat{SellCo}_{p,t}\cdot EnVe_{p,t}] \quad (1)$$

$$CO_2=\sum_t [\sum_p \widehat{Em}_p \cdot EnG_{p,t}] \quad (2)$$

### Operational constraints:

The operational constraints are included to meet the electricity and power demand of the community, as well as to account for energy and power surpluses for sale, ensuring system reliability.

**Energy balance:** The generated energy must meet the electrical demand, with 5% of the demand allocated for surplus energy sales

$$\sum_p EnG_{p,t} = \widehat{DE}_t + \sum_p EnVe_{p,t} \quad (3)$$

**Reserve margin:** To ensure system reliability, a reserve margin of 6% is set over the maximum power demand.

$$\sum_p PoG_{p,t} \geq (1+\rho)\cdot \widehat{DP}_t \quad (4)$$

**Availability factor:** The fraction of time during which generation plants operate without forced outages, maintenance, repairs, or climatic variations must be considered.

$$EnG_{p,t} = A_p \cdot DB_t \cdot PoG_{p,t} \quad (5)$$

**Capacity factor:** The ratio between the average power generated by the plant and the power that would be generated under ideal conditions.

$$PoG_{p,t} \leq F_p \cdot CaT_{p,t} \quad (6)$$

### Design constraints:

These constraints ensure that the system is not oversized by considering the capacity limits to be added, the construction time, and the specific consumption of available resources.

**Available installed capacity:** Existing capacity plus the newly added capacity of the generation plant.

$$CaT_{p,t} = ICa_{p,t}\cdot Op_{p,t} + \sum_{v \leq t-T_p} CaA_{p,t} \quad (7)$$

**Added capacity limits:** Limits are set on the added capacity to prevent oversizing and ensure that the capacities added during the planning horizon do not exceed the established maximum capacity.

$$\widehat{Camin}_p \cdot In_{p,t} \leq CaA_{p,t} \leq \widehat{Camax}_p \cdot In_{p,t} \quad (8)$$

$$\sum_t CaA_{p,t} \leq \widehat{Camax}_p \quad (9)$$

**Installed capacities per period:** The amount of plant constructions is limited during specific period

$$\sum_p In_{p,t} \leq 2 \quad (10)$$

**Limits on the specific consumption of available resources:** The primary resources used for energy generation must not exceed the available primary resources in the area.

$$\widehat{Rw}_{r,p} \cdot EnG_{p,t} \leq PriT_{r,t} \quad (9)$$

**Specific fossil fuel consumption (diesel plants):** The primary resource used in diesel plants is the amount of fossil fuel consumed.

$$\widehat{Rw}_{r,p} \cdot EnG_{p,t} = FuR_{r,t} \quad (10)$$

### Budgetary constraint:

The investment to add new capacities is limited by the budget allocated to the region of interest, as established by the Financial Support Fund for the

Electrification of Interconnected Rural Areas

$$\sum_t \frac{1}{(1+r)^t} \cdot [\sum_p \widehat{InvCo_{p,t}} \cdot CaA_{p,t}] \leq \widehat{BugCo} \quad (11)$$

The MOMILP model is built in Python using the Pyomo package and solved using the ε-constraint method with the 'GLPK' solver (SIMPLEX method), yielding 10 alternatives in the Pareto chart.

## Technical and financial parameters:

The parameters used to solve the MOMILP model are presented in Table 1. In addition, as the model considers later years, the financial parameters were projected with consumer price index (IPC) (Eq. 12):

$$C_n = C_0 * \left(\frac{IPC_n}{IPC_0}\right) \quad (12)$$

Where $C_n$ is the cost in the year to be projected, $C_0$ is the base year cost, $IPC_n$ is the IPC of the year to be projected and $IPC_0$ the IPC of the base year [10].

# MULTI-CRITERIA DECISION-MAKING METHOD (AHP)

## AHP approach:

**Hierarchy Structure:** The problem is decomposed into a hierarchical structure consisting of 4 criteria (C1. Economic, C2. Technical, C3. Environmental, C4. Social), 10 sub-criteria (C2.1 Efficiency, C2.2 Technological Maturity, C2.3 Reliability, C2.4 Access Routes, C3.1 Pollutant Waste, C3.2 Land Requirement, C3.3 Habitat Impact, C3.4 CO2 Emissions, C4.1 Job Creation, C4.2 Social Acceptance), and 10 alternatives (A1:A10) (Figure 1)

**Information Collection**: The individual weights of the criteria and sub-criteria are obtained through expert opinion collection using the Delphi method and a scale from 1-9 (Saaty scale).

**Pairwise Comparison between Criteria and Sub-Criteria:** This matrix comparison determines the relative importance of each criterion and sub-criterion compared to the others.

**Consistency Ratio (C.R.):** Consistency between the comparisons is verified through the consistency ratio (C.R.). If C.R. is less than 0.1, the comparisons are consistent.

**Evaluation of Alternatives:** The priority of each alternative is determined through pairwise comparisons, considering the relative importance (weights) of each criterion and sub-criterion.

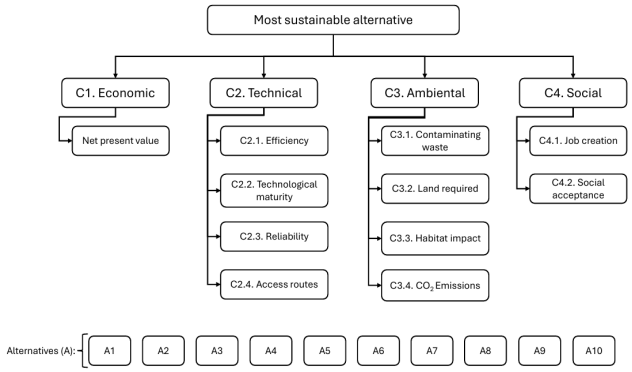

**Figure 1.** Hierarchical levels of the AHP method.

## Case study description

The MOMILP model was applied to the municipality of Pamplona, Colombia, due to its proximity to the high mountain region of the Santurbán páramo, which supplies water to around 2.5 million people and supports rich biodiversity. This municipality is connected to the National Interconnected System (SIN) and has an approximate population of 56,894 people [12] with an electricity demand of 699 MWh [13].

# RESULTS AND ANALYSIS

The 10 alternatives obtained on the Pareto front for the objective functions of net present value (NPV) and $CO_2$ emissions are shown in Table 2. The values of the NPV refer to the net gains up to the year 2040 resulting from the sale of excess electricity generated (5% of the electrical demand). The objective functions have a direct relationship, meaning that if the gains increase, $CO_2$ emissions also rise, and vice versa. Therefore, alternative A1 achieves the greatest profits, with a value of 159,470 USD, and the highest CO2 emissions, reaching 245.88 tons. Conversely, alternative A10 yields the smallest profits, amounting to 121,360 USD, and the lowest CO2

| Parameters | PV panel | Wind turbine | Biomass gasifier | Diesel plants |
|---|---|---|---|---|
| Availability factor | 0.21 | 0.74 | 0.58 | 0.98 |
| Capacity factor | 0.25 | 0.25 | 0.8 | 0.5 |
| Emissions factor ($kgCO_2/kWh$) | 0.0 | 0.0 | 0.68 | 0.79 |
| Construction time (years) | 1.0 | 2.0 | 3.0 | 2.0 |
| Investment cost (USD/kW) | 758.00 | 1,160.00 | 1,800.00 | 448.00 |
| Unit fixed O&M costs (USD/kW) | 0.02 | 0.01 | 0.09 | 4.74 |

**Table 1:** Technical and financial parameters of renewable energies [11].

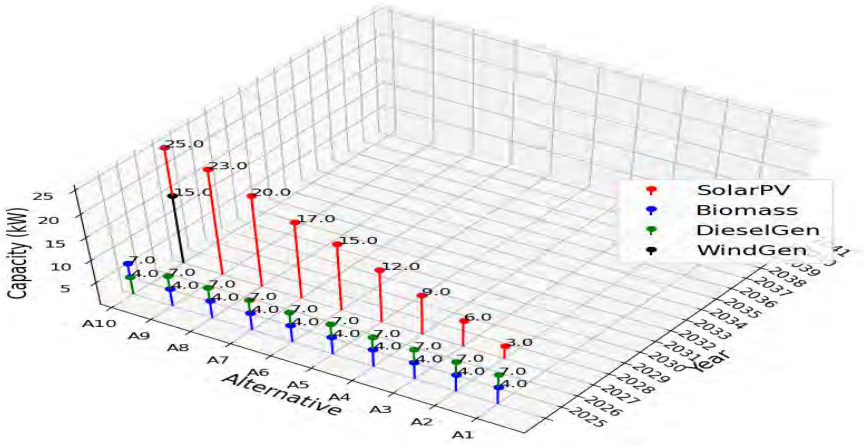

**Figure 2:** Added capacities in each alternative.

emissions, producing 94.72 tons.

**Table 2:** Pareto front alternatives.

| Alternative | NPV (USD) | $CO_2$ emissions (Ton) |
|---|---|---|
| A1 | 159,470 | 245.88 |
| A2 | 158,670 | 227.57 |
| A3 | 157,330 | 209.70 |
| A4 | 155,990 | 191.84 |
| A5 | 154,640 | 173.98 |
| A6 | 153,290 | 156.13 |
| A7 | 152,390 | 144.22 |
| A8 | 151,050 | 126.36 |
| A9 | 149,700 | 108.51 |
| A10 | 121,360 | 94.72 |

Each alternative considers adding different generation plant capacities (Figure 2). The obtained alternatives favour the addition of solar plants, biomass gasifiers, and diesel plants. Although diesel plants produce the highest $CO_2$ emissions, the available resources in the area lead to their inclusion to meet the electricity demand. Alternative A1 generates the highest profits but does not consider $CO_2$ emissions reduction. This alternative considers including only diesel plants and biomass gasifiers with proportions of 64% and 36%, respectively.

In contrast, alternative A10, while generating the lowest profits, seeks to minimize $CO_2$ emissions as much as possible, promoting the construction of solar plants, wind turbines, biomass gasifiers and diesel generators with proportions of 49%, 29%, 14% and 8%, respectively. This last alternative is the only one that includes wind generation, as the area's wind speeds are not strong enough to install plants with capacities greater than 1 kW.

The energies generated by the added capacities are shown in Table 3. Biomass gasifiers predominate as the main technology up to alternative A8, since they guarantee energy supply and produce less $CO_2$ emissions compared to diesel plants. From alternative A9 onwards, photovoltaic panels stand out as the main source of electricity generation. It should be noted that, in alternative A10, wind energy contributes a small proportion of the total electricity generation, which contributes to this alternative having the lowest emissions. Furthermore, due to the high $CO_2$ emissions produced by diesel plants, these are used only as backup sources to ensure a continuous and reliable electricity supply.

Applying the AHP method to the expert opinions

| Total energy generated by installed plants (kWh) (percentage) | | | | |
|---|---|---|---|---|
| **Alternative** | **Photovoltaic** | **Eolic** | **Biomass** | **Diesel** |
| A1 | 0 (0 %) | 0 (0 %) | 324,480.81 (91.16 %) | 31,482.24 (8.84 %) |

| A6 | 131,071.5 (36.82 %) | 0 (0 %) | 197,720.79 (55.55 %) | 27,170.77 (7.63 %) |
| A7 | 148,547.7 (41.73 %) | 0 (0 %) | 180,244.59 (50.64 %) | 27,170.77 (7.63 %) |
| A8 | 174,762.0 (49.10 %) | 0 (0 %) | 154,030.29 (43.27 %) | 27,170.77 (7.63 %) |
| A9 | 200,976.3 (56.46 %) | 0 (0 %) | 127,815.99 (35.91 %) | 27,170.77 (7.63 %) |
| A10 | 218,452.5 (61.37 %) | 839.45 (0.24 %) | 121,694.26 (34.19 %) | 14,976.85 (4.21 %) |

**Table 3:** Total energy generated by installed plants.

| Power plant | C1 | C2.1 | C2.2 | C2.3 | C2.4 | C3.1 | C3.2 | C3.3 | C3.4 | C4.1 | C4.2 | Total |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Solar | 0.086 | 0.02 | 0.005 | 0.004 | 0.002 | 0.056 | 0.015 | 0.008 | 0.042 | 0.006 | 0.074 | 0.302 |
| Biomass | 0.014 | 0.008 | 0.004 | 0.008 | 0.002 | 0.011 | 0.004 | 0.017 | 0.020 | 0.053 | 0.027 | 0.167 |
| Diesel | 0.183 | 0.010 | 0.018 | 0.017 | 0.002 | 0.005 | 0.002 | 0.053 | 0.004 | 0.025 | 0.012 | 0.331 |
| Wind | 0.026 | 0.008 | 0.012 | 0.002 | 0.002 | 0.056 | 0.015 | 0.005 | 0.009 | 0.019 | 0.045 | 0.200 |
| Total | 0.308 | 0.029 | 0.039 | 0.030 | 0.010 | 0.128 | 0.037 | 0.082 | 0.076 | 0.103 | 0.158 | 1.000 |

**Table 4:** Weights of the criteria, subcriteria, and power plants.

collected through the Delphi method, the prioritization scores for the criteria, subcriteria, and generation plants are shown in Table 4. The most important criterion is environmental, followed by economic, social, and technical. Social acceptance (C4.2) is considered by the experts as the second most important criterion for evaluating the alternatives, as it ensures that the beneficiary region or community makes the most of these sustainable technologies and contributes to their care. In addition, the job creation sub-criterion (C4.1) has a high weight due to its relevance for the socio-economic development of the region. As a result, in the AHP evaluation, conventional technologies can be given more weight in the prioritisation of alternatives. Although the diesel power plant produces the highest $CO_2$ emissions, it has the lowest habitat impact, the lowest investment cost, and the best technological aspects. These characteristics make the diesel plant the highest prioritized. Furthermore, since the alternatives obtained through MOMILP consider a mix of generation plants, the best alternative was selected based on the individual criterion and the percentage of energy generated by each plant throughout the planning horizon (Table 5).

**Table 5:** Percentage of alternatives prioritization.

| Alternative | Prioritization weight | Ranking |
|---|---|---|
| A1 | 0.1848 | 10 |
| A2 | 0.1930 | 9 |
| A3 | 0.2028 | 8 |
| A4 | 0.2126 | 7 |
| A5 | 0.2224 | 6 |
| A6 | 0.2322 | 5 |
| A7 | 0.2388 | 4 |
| A8 | 0.2486 | 3 |
| A9 | 0.2584 | 2 |
| A10 | 0.2601 | 1 |

Since electricity generation from diesel plants is similar across all alternatives, the prioritization is influenced by the installation of photovoltaic panels. Consequently, Alternative A10, with a score of 0.1848, turns out to be the least favourable option, as it does not include the implementation of any PV capacity. Similarly, the alternative A10, with a score of 0.268, is the preferred option to meet Pamplona's energy demand while simultaneously reducing $CO_2$ emissions.

## CONCLUSIONS

A Mixed-Integer Linear Multi-Objective Optimization model was implemented to evaluate the Pareto front alternatives that integrate solar, wind, biomass, and diesel power plants into the National Interconnected System, in order to meet the electricity demand of the municipality of Pamplona, Colombia. The alternatives promoted the construction of solar plants, aiming to minimize $CO_2$ emissions. Additionally, due to the limitation of available resources, diesel plants were required to generate energy to meet demand and sell to energy distributors. The most sustainable alternative was determined by collecting expert opinions using the Delphi method and the AHP method, which considered economic, technical, environmental, and social criteria, and included 10 subcriteria. The most important criterion was environmental, followed by economic, social, and technical. Among the power plants, the diesel plant is preferred due to its higher efficiency and lower impact on habitats. The evaluation of the alternatives determined that alternative A10 is the highest priority, which consists of implementing solar plants, wind turbines, biomass gasifiers and diesel generators with proportions of 49%, 29%, 14% and 8%, respectively. The proposed methodology can be applied to assess and select the most feasible alternative within a wide range of new projects for the integration of renewable energy systems for the extension of existing power grids.

## NOMENCLATURE

### Model parameters

*TD*: Discount rate
$\widehat{InvCo_{p,t}}$ : Unit investment costs (USD/kW)
$\widehat{FixCo_{p,t}}$: Unit fixed costs (USD/kW)
$\widehat{VarCo_{p,t}}$ : Unit variable costs (USD/kW)
$\widehat{FuCo_{p,t}}$ : Unit cost of fossil fuel (USD/fossil fuel unit)
$\widehat{SellCo_{p,t}}$: Unit Price of electricity (USD/kW)
$\widehat{Em_p}$ : CO2 emission factor (kgCO2/kWh)
$\widehat{DE_t}$ : Energy demand (kWh)
$\rho$ : Reserve margin (kW)
$\widehat{DP_t}$ : Peak demand (kW)
$A_p$ : Availability factor

$DB_t$ : Block duration
$F_p$ : Capacity factor
$\widehat{Camin}_p$ : Minimum capacity (kW)
$\widehat{Camax}_p$ : Maximum capacity (kW)
$\widehat{Rw}_{r,p}$ : Consumption factor of primary resources (primary resource units/kWh)
$\widehat{BugCo}$ : Total budget (USD)

## Sets

p: Power generation plants
r: Primary resources
t,v : Time period (2024-2040)
Tp: Construction time

## Decision variables

$CaA_{p,t}$ : Capacity to be added (kW)
$CaT_{p,t}$ : Total available capacity (kW)
$EnG_{p,t}$ : Energy generated (kWh)
$FuR_{r,t}$ : Fossil fuel unit
$EnVe_{p,t}$ : Surplus energy sold (kWh)
$PoG_{p,t}$ : Power generated (kW)

## Decision binary variables

$Op_{p,t}$ : If the installed capacity is operational
$In_{p,t}$ : If new capacity is to be installed

## Abbreviations

*RES* : Renewable Energy System
*SIN* : National Interconnected System
*IPC* : Consumer price index

## ABSTRACT

Uncertainty plays a crucial role in strategic supply chain design. In this study, we explore robust approaches to model uncertainty when the non-deterministic parameters are placed in the independent term, on the right-hand side (RHS) of the constraints. We consider the "disjunctive adjustable column-wise robust optimization" (DACWRO), a disjunctive formulation introduced previously in our group, and compare it with the adjustable column-wise robust optimization (ACWRO) formulation, a specific technique for solving robust optimization problems when the original robust optimization approach may assume too-conservative results. Given that the proposed method is based on the generalized disjunctive programming (GDP) technique, it is a higher lever modelling approach that represents the discrete nature of the decision process. In addition, it provides alternative MILP representations that can be further tested and compared. The analysis assesses the computational performance and reformulation tightness of both approaches in the context of the forest supply chain design problem.

**Keywords**: Design Under Uncertainty, Modelling, Optimization, Supply Chain, Biomass

## INTRODUCTION

The need to consider uncertainty in the decision-making process is widely acknowledged in the PSE community, which distinguishes three main modeling paradigms for optimization under uncertainty, namely robust optimization (RO), stochastic programming (SP), and chance-constrained programming (CCP). The last two paradigms are challenging due to the need for complete distributional knowledge or the involvement of non-linearities [1]. Instead, RO does not require the probabilistic behavior of uncertain parameters and strikes a good balance between solution quality and computational tractability [2].

One widely used method for RO is the static robust optimization one initially proposed by Bertsimas and Sim [3]. They proposed the budgeted uncertainty set, which allows flexible handling of the level of conservatism of robust solutions in terms of probabilistic limits of constraint violations. It defines for each uncertain parameter a deviation bound from its nominal value and a budget parameter to determine the number of uncertain parameters that are allowed to take their worst value in each equation. In the case that there is only one uncertain parameter in the independent term, on the RHS of the equations, this method may adopt a too-conservative perspective, considering the worst-case scenario for each constraint.

To address this concern, an extension of this method is proposed in [4] and applied to the water distribution system design problem. This method is recognized to better handle uncertainty in this context, such as in [5,6]. The method is called “adjustable column-wise robust optimization” (ACWRO) because it defines the number of uncertain realizations that the decision-maker is willing to satisfy. Initially presented as a nonlinear model, it is later reformulated to achieve a linear formulation.

Motivated by the disjunctive nature of the decision process of this case, the present paper proposes an alternative method applying a linear disjunctive

formulation, called "disjunctive adjustable column-wise robust optimization" (DACWRO). One of the contributions of this article is that it extends the use of Generalized Disjunctive Programming (GDP) to a new application domain. Additionally, taking advantage of the high-level representation capability of GDP, Big-M and Hull MILP reformulations are derived from the proposed formulation. Here, the proposed method is applied to the forest supply chain design problem and it is compared with the ACWRO approach for a large number of instances showing the tightness of each reformulation and computational performance.

## DISJUNCTIVE ADJUSTABLE COLUMN-WISE ROBUST OPTIMIZATION APPROACH

In this section, we develop the DACWRO approach to deal with uncertainty when there is only one uncertain parameter in the constraint and it is on the right-hand side (RHS) of the equation. The novel approach is an alternative robust reformulation of the ACWRO. For details of this approach, the reader is referred to this reference [4]. Let us examine the following linear optimization model:

$$Min\ Z = \sum_j c_j \cdot x_j \tag{1}$$

$$\sum_j A_{i,j} \cdot x_j \geq \tilde{b}_i \quad \forall i \tag{2}$$

$$L \leq x_j \leq U \quad \forall i \tag{3}$$

where $\tilde{b}_i$ are the uncertain parameters. Here, the uncertain realization of each $\tilde{b}_i$ is handled by a box uncertainty set $U_{box} = \{(\boldsymbol{b}|b_i^L \leq \tilde{b}_i \leq b_i^U, \forall i)\}$. This defines the range of each uncertain parameter in the vector of uncertain parameters $\boldsymbol{b}$. That is, $b_i^L$ and $b_i^U$ represent the lower and the upper bounds of each uncertain parameter, respectively. Assuming a symmetric variation of the uncertain parameter, Eqs. (4) and (5) are presented:

$$b_i - \hat{b}_i = b_i^L \quad \forall i \tag{4}$$

$$b_i + \hat{b}_i = b_i^U \quad \forall i \tag{5}$$

where $b_i$ is the nominal value and $\hat{b}_i$ represents the maximal absolute variation that the uncertain parameter is subject to change. In the robust approach, each uncertain parameter $\tilde{b}_i$ is transformed into a decision variable that represents the value of the uncertain parameter the decision maker is willing to satisfy. Given Eqs. (4) and (5), this variable can be expressed by a new variable $\eta_i = (\tilde{b}_i - b_i)/\hat{b}_i$ that takes values in the interval $[-1,1]$. Additionally, a new redundant constraint is introduced, i.e., Eq. (2) is summed for all *i* and the RHS is rewritten in terms of parameters $b_i$, $\hat{b}_i$ and variable $\eta_i$, in Eq. (6).

$$\sum_i \sum_j A_{i,j} \cdot x_j \geq \sum_i b_i + \sum_i \eta_i \cdot \hat{b}_i \tag{6}$$

Eq. (6) is now rewritten as (7) introducing a protection function, where larger values of $\sum_i \eta_i \cdot \hat{b}_i$ result in higher protection against uncertainty. Thus, Eq. (6) is replaced by Eq. (7) and the variable $\eta_i$ takes values in the interval $[0,1]$. Note that $I$ is a set of uncertain parameters, $S_i$ is the subset of $I$ that takes their worst-case values. The number of elements of $S_i$ is given by the budget parameter $\Gamma$, that indicates the level of conservatism of the system. Conceptually, the protection function is a fundamental goal of robust optimization: finding a solution that not only maximizes the objective function *Z* but also assures that *Z* remains optimal with high probability given some error in predicting $\tilde{b}_i$ values [3]. This inner problem is reformulated by Eqs. (8) - (10).

$$\sum_i \sum_j A_{i,j} \cdot x_j \geq \sum_i b_i + \max_{\{S_i | S_i \subseteq I, |S_i| = \Gamma\}} \{\sum_i \eta_i \cdot \hat{b}_i\} \tag{7}$$

$$Max \sum_i \eta_i \cdot \hat{b}_i \tag{8}$$

$$0 \leq \eta_i \leq 1 \quad \forall i \tag{9}$$

$$\sum_i \eta_i \leq \Gamma \tag{10}$$

Given that problem in Eqs. (8)–(10) is feasible and bounded by $\Gamma$, its dual pair is also feasible and bounded with the identical objective value according to the strong duality property. The problem in Eqs. (1)–(3), (7)–(10) is reformulated as Eqs. (1), (3), (11)–(13).

$$\sum_i \sum_j A_{i,j} \cdot x_j \geq \sum_i b_i + \Phi \cdot \Gamma + \sum_i \Omega_i \tag{11}$$

$$\Phi + \Omega_i \geq \hat{b}_i \quad \forall i \tag{12}$$

$$\sum_j A_{i,j} \cdot x_j \geq b_i + \hat{b}_i \quad \forall i \tag{13}$$

Note that Eq. (11) is equivalent to Eq. (7) where $\Phi$ and $\Omega_i$ are dual variables. Variable $\Phi$ represents the common variation for all $b_i$ elements, i.e., $\Phi$ remains constant for each uncertain constraint $i \in I$, but the value of $\Omega_i$ differs according to the corresponding value of $\hat{b}_i$. Equation (12) determines to the sum of the dual variables corresponding to each equation from the primal model (Eq. (8) – (10)), while Eq. (13) replaces Eq. (2) assuming the Bertsimas and Sim approach [3]. That is, the worst-case scenario is assumed for each constraint subject to this type of uncertainty.

As mentioned, the aim of the proposed approach, as in [4], is to define the degree of uncertainty the decision maker is willing to cover. For this purpose, a disjunctive formulation is introduced to control the degree of conservatism $\Gamma$. Equation (13) is replaced by Eqs. (14) – (17). Note that Eqs. (14) and (15) ensure that for all $i \in I$, the uncertain parameter will remain between its nominal value and its worst-case value. The disjunction is introduced in Eq. (16) where $\Psi_i$ is a Boolean variable. In the positive case, the uncertain parameter of constraint $i \in S_i$ must take its worst value, which is determined by the auxiliary variable $\Lambda_i$ that is equal to the sum of the dual variables ($\Phi$ and $\Omega_i$) generated from the robust

reformulation. In the negative case ($\neg\Psi_i$), the uncertain parameter remains at its nominal value. Therefore, auxiliary variable $\Lambda_i$ and the specific variation of element $b_i$ determined by dual variable $\Omega_i$ are zero. Finally, the number of uncertain parameters that take their worst-case value is controlled by the $\Gamma$ parameter, as shown in Eq. (17). Note that the degree of conservatism ($\Gamma$) must necessarily be an integer parameter that takes values in the range $[0, |S_i|]$. Finally, DAWRO formulation is given by Eqs. (1), (3), (11)–(12), (14)–(17).

$$\sum_j A_{i,j} \cdot x_j \leq b_i + \hat{b}_i \qquad \forall i \qquad (14)$$

$$\sum_j A_{i,j} \cdot x_j \geq b_i + \Lambda_i \qquad \forall i \qquad (15)$$

$$\begin{bmatrix} \Psi_i \\ \Lambda_i = \Phi + \Omega_i \\ \psi_i = 1 \end{bmatrix} \vee \begin{bmatrix} \neg\Psi_i \\ \Lambda_i = 0 \\ \Omega_i = 0 \\ \psi_i = 0 \end{bmatrix} \qquad \forall i \qquad (16)$$

$$\sum_i \psi_i \geq \Gamma \qquad (17)$$

## FOREST SUPPLY CHAIN RE-DESIGN AND PLANNING PROBLEM

In this section the case study is briefly described. The problem consists of the optimal design and planning of the forest supply chain in the Argentinean context. There are feedstock nodes that produce pine and eucalyptus logs, forest residues, and sawmill residues; the processing facilities convert biomass into paper pulp, fuels, and intermediates; and the consumer nodes are biodiesel plants or petroleum refineries. There are some fixed facilities and some potential locations for new stand-alone and integrated facilities. The model decides in each time period the location of forest nodes, harvesting decisions, technologies and capacity levels in the industrial locations, product mix, production levels and compounds' flows along all transportations links to meet specific demand levels and minimize present costs. The complete model formulation and case study data is presented in [7]. Let introduce the uncertain constraint from this formulation given by Eq. (18), which means that the amount of product *o* delivered to each demand node *l* in each period *t* must satisfy the demand level given by uncertain parameter $\widetilde{\chi_{o,l,t}}$.

$$\sum_{\substack{m,k \\ m \in M_O}} F3_{o,k,m,l,t} \geq \widetilde{\chi_{o,l,t}} \qquad \forall\, (o,l) \in O_L, t \qquad (18)$$

Applying the proposed robust reformulation, the following set of constraints is introduced, as shown in Eqs. (19) – (24).

$$\sum_{\substack{o,k,m,l,t \\ m \in M_O \\ (l,o) \in O_L}} F3_{o,k,m,l,t} \geq \sum_{\substack{o,l,t \\ (l,o) \in O_L}} \left(\chi_{o,l,t} + \Omega_{o,l,t}\right) + \Phi^{de} \cdot \Gamma^{de} \qquad (19)$$

$$\Phi^{de} + \Omega_{o,l,t} \geq \hat{\chi}_{o,l,t} \qquad \forall\, (o,l) \in O_L, t \qquad (20)$$

$$\sum_{\substack{m,k \\ m \in M_O}} F3_{o,k,m,l,t} \leq \chi_{o,l,t} + \hat{\chi}_{o,l,t} \quad \forall\, (o,l) \in O_L, t \qquad (21)$$

$$\sum_{\substack{m,k \\ m \in M_O}} F3_{o,k,m,l,t} \geq \chi_{o,l,t} + \Lambda_{o,l,t} \quad \forall\, (o,l) \in O_L, t \qquad (22)$$

$$\begin{bmatrix} \Psi^{de}_{o,l,t} \\ \Lambda_{o,l,t} = \Phi^{de} + \Omega_{o,l,t} \\ \psi^{de}_{o,l,t} = 1 \end{bmatrix} \veebar \begin{bmatrix} \neg\Psi^{de}_{o,l,t} \\ \Lambda_{o,l,t} = 0 \\ \Omega_{o,l,t} = 0 \\ \psi^{de}_{o,l,t} = 0 \end{bmatrix} \quad \forall\, (o,l) \in O_L, t \qquad (23)$$

$$\sum_{\substack{o,l,t \\ (l,o,t) \in O_L}} \psi^{de}_{o,l,t} \geq \Gamma^{de} \qquad (24)$$

This formulation can be reformulated by applying Big-M and Hull reformulations, which are called DACWRO-BM and DACWRO-H, respectively.

## RESULTS AND DISCUSSION

The key features and dimensions of the sample runs are outlined in Table 1. Four supply chain structures are set corresponding to each example. For each example, a set of instances is determined by varying the budget parameter (third column). The number of instances for each example is presented in the fourth column. Model sizes are displayed in the last three columns. The supply chain structure in Example 1 has 10 supply sources, 3 kraft pulp mills, 13 potential biorefinery locations, and 10 demand nodes. In subsequent examples, the number of nodes gradually increased to 25 supply nodes and 23 demand nodes. Different levels of deviation in uncertain demand parameters are also considered.

Figure 1 shows that all approaches present very similar performance in terms of the mean value of the CPU time. As expected, as the size of the examples are increased, the execution time is also greater. In examples 1 to 3, all instances tested present an execution time near the mean value. However, heterogenous results are obtained among instances of example 4, that is, large dispersion is observed in the execution time, showing data dependency when the size of the model is increased. Figure 2 presents the ratio of the relaxed solution in the root node with respect to the final optimal solution for each method. It is noteworthy that the three methods present very tight results and they are homogeneous among the examples and approaches. Note that all mean values of this ratio are the same for each method what may explain the similar performance in terms of CPU time (Fig. 1). DACWRO is as good as the ACWRO in terms of computational performance, but it represents the disjunctive nature of level of uncertainty selection process in a more

straightforward way.

**Table 1**. Features of executed examples and their size

| Example | Reformulation | Budget parameter | Number of instances executed | Number of equations | Number of continuous variables | Number of binary variables |
|---|---|---|---|---|---|---|
| 1 | ACWRO | 20 to 70 | 6 | 27721 | 30531 | 2700 |
| 1 | DACWRO-BM | 20 to 70 | 6 | 27721 | 30531 | 2700 |
| 1 | DACWRO-H | 20 to 70 | 6 | 27791 | 30671 | 2700 |
| 2 | ACWRO | 30 to 100 | 24 | 29911 | 48261 | 2730 |
| 2 | DACWRO-BM | 30 to 100 | 24 | 29911 | 48261 | 2730 |
| 2 | DACWRO-H | 30 to 100 | 24 | 30011 | 48461 | 2730 |
| 3 | ACWRO | 10 to 150 | 30 | 30261 | 49311 | 2780 |
| 3 | DACWRO-BM | 10 to 150 | 30 | 30261 | 49311 | 2780 |
| 3 | DAWRO-H | 10 to 150 | 30 | 30811 | 50761 | 2780 |
| 4 | ACWRO | 10 to 200 | 30 | 45291 | 75461 | 3890 |
| 4 | DACWRO-BM | 10 to 200 | 30 | 45291 | 75461 | 3890 |
| 4 | DACWRO-H | 10 to 200 | 30 | 45591 | 76061 | 3890 |

## CONCLUSIONS

In this article a new method, named DACWRO, is proposed to model uncertainty that is compared to ACWRO [4]. These methods present the advantage that the decision maker can select the level of conservatism is willing to assume. These approaches are particularly interesting in the case the uncertain parameters are part of the independent term of the equations. The proposed method is based on a disjunctive formulation that is reformulated applying Big-M and Hull relaxations to obtain the equivalent mixed integer linear models.

To compare the approaches, the formulations were applied to the forest supply chain design problem assuming uncertainty in the demand constraints. A set of 270 instances were executed. From the instances tested, due to a tight reformulation, efficient and homogeneous results are obtained in all cases. The proposed method extends the use of GDP to a novel application domain. Additionally, it capitalizes on the high-level representational power of GDP to develop Big-M and Hull MILP reformulations based on the proposed formulation. Future work includes analyzing larger instances to evaluate the behaviour of the approaches for more challenging cases as well as expanding the scope of the present approach to other types of uncertainties. Also, new problem domains and case studies will be considered to check differences between methods in other contexts.

## ABSTRACT

Process systems engineering optimization problems may be challenging. These problems often exhibit nonlinearity, non-convexity, discontinuity, and uncertainty, and often only the values of objective and constraint functions are accessible. Additionally, some problems may be computationally expensive. In such scenarios, black-box optimization methods may be appropriate to tackle such problems. A general-purpose multi-agent framework for optimization has been developed to automate the configuration and use of hybrid optimization, allowing for multiple optimization solvers, including different instances of the same solver. Solvers can share solutions, leading to better outcomes with the same computational effort. Alongside cooperation, competition is introduced by dynamically allocating more computational resource to solvers best suited to the problem. Each solver is assigned a priority that adapts to the evolution of the search. The scheduler is priority-based and uses similar algorithms to those in multi-tasking operating systems. The impact on the number of priority levels is investigated. The framework allows for the use of both metaheuristic and direct search methods. Metaheuristics explore the full search space while direct search methods are good at exploiting solutions. The framework has been implemented in Julia, making full use of multiprocessing. A multiobjective case study on the design of a micro-analytic system is presented. The case study demonstrates the benefits of a multi-solver hybrid optimization approach with both cooperation and competition. The framework adapts to the evolving requirements of the search. Often, a metaheuristic method is allocated more computational resource at the beginning of the search while direct search methods are prioritized later.

## INTRODUCTION

Solving optimization problems in process systems engineering is often a challenging endeavor. These problems may exhibit nonlinearity, non-convexity, discontinuity, and uncertainty, which render derivative information unavailable or difficult to obtain. As a result, gradient-based optimization methods may not be appropriate. Instead, black-box optimization methods may be more convenient for tackling such problems as they require only the values of objective functions.

For some optimization problems in process systems engineering there may be another challenge: the computational expense required to evaluate the models may be large, such as when the models are based on differential equations. For problems that have high computational requirements, the number of times the objective function and the constraints may be evaluated will be limited. In these cases, the efficient use of multiple cooperating optimization methods may be necessary. Prior experience suggests that hybrid approaches can lead to better outcomes compared with using a single optimization method, with the same computational effort [1,2]. However, the effectiveness of each method depends on the problem and may actually vary throughout the search, posing difficulties for decision-makers in selecting the appropriate optimization methods. To address this, this paper introduces competition among optimization methods in the multi-agent system to dynamically allocate a finite computational resource. The aim is to have the

most effective methods given access to the resource at the right time during the evolution of the search.

## MULTI-AGENT FRAMEWORK

A multi-agent system consists of multiple autonomous computing elements, referred to as *agents*, that interact with one another by sending and receiving *messages* [3]. Such an environment can be used to facilitate the hybridization of optimization methods by assigning optimization methods to agents, with the agents working together to solve the same problem [4]. This concept has been exemplified in works such as [5] and [6].

A general-purpose multi-agent framework for solving optimization problems has recently been developed [1] to automate the configuration and use of hybrid optimization. This framework enables the use of multiple solvers to solve a given optimization problem, whether it is an NLP or MINLP. The solvers may be different optimization methods or variations of the same method with different parameter settings, a concept also used in [7]. Since the parameters associated with an optimization method affect its behavior, and identifying appropriate values often requires significant experimentation, incorporating variations of the same method may be beneficial.

A key distinction of this implementation is the decoupling of solvers from the model evaluation process. In this setup, the solvers do not have direct access to the model, which enables the implementation of a *scheduler* agent that allocates the computational resource to different solvers more efficiently.

The framework is implemented in the Julia programming language, which provides easy access to CPU threads and enables the full use of multiprocessing.

The multi-agent system includes the following agents:

- Multiple instances of a **solver agent** where each instance is a particular optimization method with specific parameter values;
- One or more instances of a **model agent**; this agent evaluates the model when given a point in the search space;
- A **scheduler agent** whose duty is to allocate points requested by the solvers to available model agents, based on the information provided by the analysis agent;
- The **analysis agent** which analyzes all evaluated points and provides the scheduler with information about the search domain, aiding in managing competition among solvers.

One feature of this framework is *cooperation*, where solvers share information at the scheduler agent level with support from the analysis agent. The purpose is to guide the search toward the most promising regions in the search space by distributing useful information about the search domain.

## INTRODUCING COMPETITION

The concept of competition is to reward the more effective solvers and penalize those that are not as effective. The reward consists of allowing more evaluations of points in the search requested by the solver agents. It is hoped that this will ensure the best use of the typically limited computational resource available. It is expected that the effectiveness of different solvers will vary during the evolution of the search. Therefore, the reward mechanism needs to be adaptive and based on the actual performance as the search progresses.

Competition among solvers is implemented by the scheduler agent. This agent manages two queues (shown in Figure 1):

- **Availability queue**, a single queue for messages from the model agents indicating their availability to accept a point for model evaluation;
- **Request queue**, consisting of $n_l$ levels of first-in-first-out (FIFO) queues for requests from solver agents for evaluation of a point in the search domain, where $n_l$ represents the highest priority level set by the user.

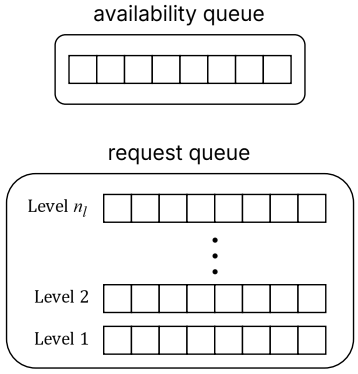

**Figure 1.** Data structures of the queues managed by the scheduler.

Each solver is assigned a priority [8], ranging from 1 to $n_l$. The value of $n_l$ is a configuration parameter for the agent system. The impact of the value of this parameter on the performance of the system is discussed below. The priority determines the placement of each request in the request queue and implicitly determines the solver's access to a model agent, with requests at the highest priority level gaining access first. These priorities are dynamic and subject to being adjusted throughout the search based on each solver's performance, also

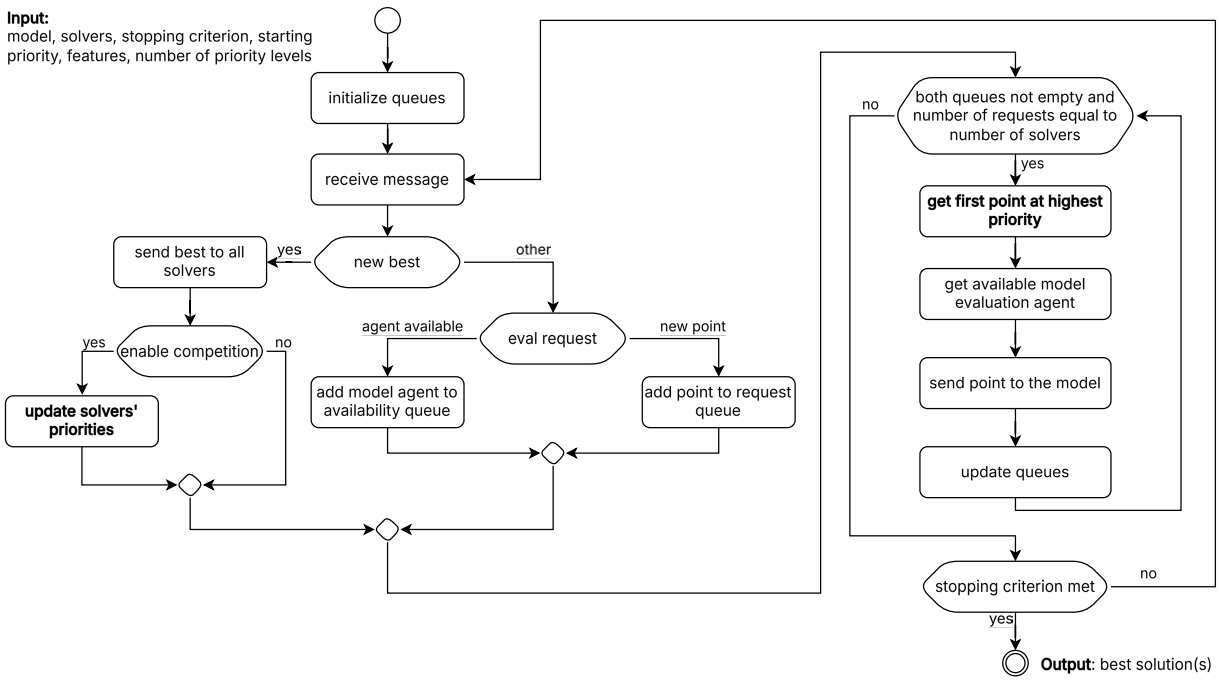

**Figure 2:** Flowchart illustrating the scheduler agent's process for allocating requests to model agents and managing competition when a new best message is received.

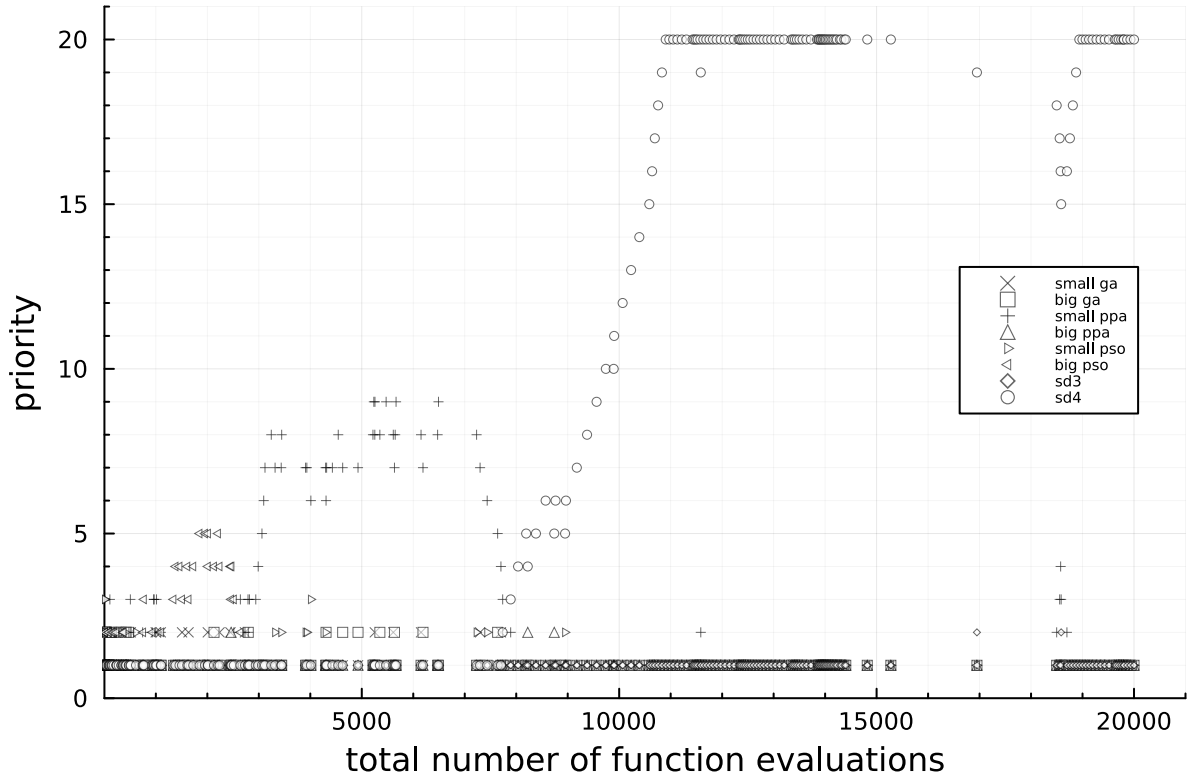

**Figure 3:** Priority profile of solvers when incorporating both cooperation and competition with 20 priority levels.

described below.

The flowchart in Figure 2 illustrates the main loop of the scheduler in the multi-agent system. Within this loop, the scheduler waits for incoming messages. The element

of competition comes into play when the scheduler receives a new *best* message from the analysis agent, indicating an improvement in the currently best known solution (or the introduction of a new point into the set of non-dominated points). This message contains information about the solution and the solver responsible for it. A solver that is responsible for the improvement is *rewarded* with an increase in its priority, while the priorities of other solvers may be *decreased*, provided they are not already at the lowest level.

Other messages the scheduler may receive can come from a solver agent or a model agent. Based on the type of message, each message is then processed and added to its corresponding queue, either the request queue or the availability queue. For requests from solver agents, this particular message (point) is placed at a specific level of the request queue according to the priority of the solver at the time the request is sent.

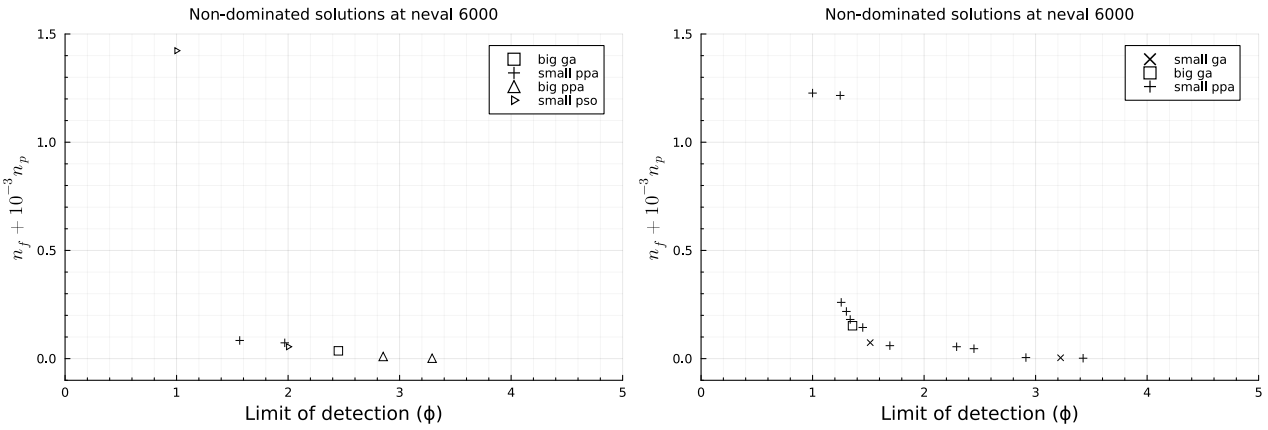
The scheduling of the queues occurs when both queues are not empty, and the number of requests is equal to the number of solvers. This assumes that all solvers will continue to submit points for evaluation, which may not be the case for direct search methods in general, as there may be cases where the direct search methods run out of points. For the problems we have considered, the issue has not arisen, but we will, in the future, generalize this condition to ensure that deadlock does not occur. The first point at the highest priority level in the request queue is dispatched to an available model agent. The request queue is then updated: the first entry in each FIFO queue is moved to the end of the next higher priority level if not already at the highest level. This scheduling approach resembles that used in the implementation of multitasking in operating systems [9], ensuring that all solvers are eventually allocated some computational resource.

There are different approaches to adjusting the priority levels and several such approaches have been investigated. One approach involves introducing a decay function for priorities as a function of the number of function evaluations. This decay function, however, introduces an additional configuration parameter. It may be difficult to identify *a priori* an appropriate value of this parameter for any given problem. Another approach considers adjusting the priority increment proportionally to the improvement in the objective function value when a solver finds a new best solution. However, this method is difficult to implement for multi-objective problems as it is difficult to define a metric which quantifies the quality of non-dominated solutions. The approach used in the results presented below is the simplest: reward the solver responsible for the improvement in the best known solution by increasing its priority by one and reducing the priorities of all the other solvers by the same magnitude.

## CASE STUDY: A DESIGN OF A MICROFLUIDIC ANALYSIS SYSTEM

An optimization-based design of a micro total analytic system ($\mu$TAS) for on-line detection of radionuclides [10] is presented to examine the impact of incorporating the element of competition into the framework. The goal of the design is to detect and identify the presence of two different radionuclides. The identification of designs is a problem of design under *uncertainty*, formulated as a set of differential equations with continuous design variables. This problem involves two objective functions: the first minimizes the system's limit of detection ($\phi$), and the second combines the number of false negatives ($n_f$) and false positives ($n_p$), with greater emphasis placed on the number of false negatives due to safety reasons.

This problem serves as a good test case for the proposed framework, as the problem is computationally expensive, and the search space is likely multi-modal [10]. Prior experience has demonstrated the benefits of information sharing; however, introducing competition may offer the potential for further improvement in outcomes more quickly.



This study employs two types of solvers: nature-inspired metaheuristic methods [11] and direct search methods [12]. The solvers used are as follows:

- Genetic Algorithm (GA)
- Plant Propagation Algorithm (PPA)
- Particle Swarm Optimization (PSO)
- Steepest Descent (SD)
- Coordinate Search (CS)

The key parameter for the GA and the PSO methods is the population size; for the PPA, it is the number of solutions considered for propagation. Multiple instances of the solvers are explored using different parameter values, defined as a function of the base population size, $n_s$ (set to 20 in this case study). For the GA, the population sizes are $2 \times n_s$(small) and $5 \times n_s$ (big). For the PPA, the number of solutions to propagate is $n_s/2$ (small) and $2 \times n_s$ (big). For the PSO, the sizes are $n_s$ (small) and $5\times n_s$ (big).

The instances of direct search methods, on the other hand, are explored by assigning different weighting factors, $\omega$, used in the weighted sum method to aggregate multiple objectives into a single objective function value. Four weighting factors are applied: 0.2, 0.4, 0.6, and 0.8. Direct search solvers treat the base initial population of size $n_s$ as a multi-start, initiating a search from each member of the population sequentially.

None of the implementations here could be considered the *best in class*, but we intend to assess the performance of the collection of algorithms to investigate

(a) Cooperating (b) Cooperating and competing ($n_l$=20)

**Figure 4:** Non-dominated solution sets at 6,000 function evaluations with different configuration settings. *Neval* represents the total number of function evaluations, with each solution labeled by the responsible solver. $n_f$ and $n_p$ denote the number of false negatives and false positives, respectively.

the impact of cooperation and competition. The stopping criterion is set to 20,000 total function evaluations by all the solvers.

## Impact of competition

To investigate the impact of competition, a set of 10 runs has been conducted incorporating both cooperation and competition, with the number of priority levels, $n_l$=20. Figure 3 illustrates the priority profiles of each solver during the search, with output printed whenever a new non-dominated solution is identified. Solver instances for the direct search methods are distinguished by the suffixes 1, 2, 3, and 4 corresponding to the weighting factors of 0.2, 0.4, 0.6, and 0.8, respectively.

Two phases of the search can be observed from Figure 3. Initially, the search focuses on exploration, during which metaheuristic solvers, particularly the small PPA, frequently find new non-dominated solutions, as reflected in their increasing priority. This is followed by the exploitation phase, where the SD4 solver (a direct search method) identifies improved solutions, although typically minor improvements. Toward the end of the search, the small PPA identifies some new non-dominated solutions, which are promptly refined by one of the direct search solvers through information sharing, similar to the findings from the previous study [1]. The CS solvers are omitted from the figures as they do not ever find a non-dominated solution.

## Sensitivity to the number of priority levels

The number of priority levels, $n_l$, is a configuration parameter that may influence the performance of the system. Comparing sets of runs with different values of $n_l$,: 5, 10, and 20, two observations are found. First, a higher number of priority levels results in greater difference between computational resource allocated to the most effective solver and to the others, with the largest difference observed when $n_l$=20. This occurs because solvers require more iterations to transition from the lowest to the highest priority level. Second, the distinction between the exploration and exploitation phases of the search becomes more apparent with higher $n_l$ values. For example, when $n_l$=20, the exploration phase lasts shorter compared with $n_l$=10, whereas for $n_l$=5, this distinction is blurred. Therefore, it can be concluded that the number of priority levels determines the degree of competition among solvers. A higher number of priority levels closely resembles the individual use of the most effective solver, while lower values result in minimal competition.

Given the motivation of this paper–to make efficient use of a limited resources–we compare sets of non-dominated solutions at 6,000 total function evaluation (Figure 4), where the advantages of incorporating competition are evident. Under computational time constraints, the combined use of both cooperation and competition with 20 priority levels leads to the best outcomes, being able to explore the search space most effectively, with many points covering the objective space.

Although the solution sets in Figure 4 differ, quantifying which is better can be challenging, particularly as the true Pareto front is unknown in this case study. Nevertheless, the results show that incorporating competition alongside cooperation is likely to enhance the exploration process, with almost the same computational effort, and the degree of improvement depends on the number of priority levels. This is particularly beneficial when acceptable solutions are required with limited computational resource. Although the methods are stochastic and repeated attempts will lead to different outcomes, the results presented here are representative.

## CONCLUSION

A generic multi-agent framework for hybrid optimization has been developed to automate the configuration and integration of metaheuristic and direct search optimization methods. While information sharing among solvers has been shown to improve outcomes [1], equal allocation of computational resource to all solvers may not be ideal as optimization problems often have evolving requirements at different stages of the search. This motivates the use of competition alongside cooperation in the framework, enabling solvers to be dynamically prioritized based on performance. The framework is able to dynamically allocate computational resource as the search progresses, for instance, prioritizing metaheuristic methods to explore the search space at the start of the search and later shifting emphasis to direct search methods to refine the solutions. The overall outcome is more effective use of limited computational resource. The degree of competition is defined by the total number of priority levels, a key configuration parameter of the system.

Future work will explore more sophisticated scheduling algorithms within the scheduler agent and examine the potential benefits when the scheduler has the knowledge about the properties of the methods and the objective space.

## ABSTRACT

A key step in developing high-performance industrial products lies in the design of their constituent molecules. Computer-aided molecular design (CAMD) has garnered significant attention for its potential to accelerate and improve the design process. The mainstream method involves using property prediction models to predict the properties of potential molecules and selecting the best candidates based on these predictions. However, prediction errors are inevitable, introducing unreliability into the design. To address this issue, this paper proposes a novel component property modeling framework based on a molecular similarity coefficient. By calculating the similarity between a target molecule and those in an existing database, the framework selects the most similar molecules to form a tailored training dataset. The similarity coefficient also quantifies the reliability of the property predictions. In tests across various properties, this framework not only provides a quantifiable evaluation of prediction reliability but also improves the prediction accuracy of molecules with high reliability, which has the potential to enhance the integrity of molecular design.

**Keywords**: Property prediction, Molecular design, Similarity coefficient

## 1. INTRODUCTION

Developing chemical products used as working media in industrial settings is a crucial aspect of the industrial process. One of the most important elements in this development is the design of molecular structures for these products. Traditional design methods, which rely on expert experience, are often time-consuming, labor-intensive, and prone to overlooking potentially excellent molecules. As a result, computer-aided molecular design (CAMD) is gaining increasing attention. This approach utilizes molecular property data in conjunction with efficient optimization algorithms to identify product molecules that exhibit optimal performance.

When designing a new product molecule, it is essential to predict the properties of unknown molecules based on existing molecular property data. This process is referred to as the property prediction model. The property prediction model primarily utilizes molecular structure information along with known data about molecular structures and their properties. It employs data fitting methods to establish the mapping relationship between molecular structures and their properties. Among the most classical molecular property prediction models are the Group Contribution (GC) method[1], Quantitative Structure-Property Relationship (QSPR) modeling[2], and ab initio quantum-mechanics-based methods[3]. With advancements in artificial intelligence, many new property prediction models and variations of classical models have been developed[4]. For instance, Zhang et al.[5] developed an accurate and interpretable QSPR molecular property prediction model based on deep neural networks. Alshehri et al.[6] introduced a new generation of molecular property prediction models based on Gaussian processes, which achieved higher accuracy compared to simpler GC-based models.

However, these models are not strictly mechanistic relationships between molecular structure and property,

so prediction errors are inevitable. In the process of molecular design using the property prediction model, the basis of molecular selection is the predicted value of molecular properties. Therefore, the prediction error of the property prediction model will directly affect the process of molecular screening, and easily lead to a serious mismatch between the properties of the designed molecules and the values of the experimentally verified properties. In other words, the reliability of the property prediction largely determines the reliability of the molecular design. At present, there is no quantitative method for the reliability of property prediction.

To solve this problem, this paper innovatively proposes a property prediction modeling framework based on molecular similarity. Firstly, this framework customizes a training set for the target molecules according to molecular similarity. The properties of target molecules are predicted using this training set, and the similarities between the molecules in the training set and the target molecules are used to provide a quantitative index of prediction reliability for target molecules.

## 2. MOLECULAR SIMILARITY COEFFICIENT

If the reliability of predicted property values can be assessed prior to experimental validation, the only information that can be utilized is that derived from the training molecules used in modeling these properties. Specifically, the adequacy of the information that training molecules provide for the target molecules is crucial. The greater the similarity between two molecules, the stronger the correlation in their properties. This similarity allows us to leverage the relationship between training and target molecules to gauge how adequately the training molecules can inform predictions about the target molecules. Consequently, it becomes possible to quantitatively measure the reliability of property predictions for the target molecules. Therefore, this paper introduces a novel method for calculating the molecular similarity coefficient.

Here, the group contribution method is used to describe the structure of a molecule. For molecules $M_1$ and $M_2$, their structures can be described as follows,

$$M_1: [n_{1\,1}, n_{1\,2}, n_{1\,3}, n_{1\,4}, \cdots, n_{1\,i}, \cdots, n_{1\,424}]$$

$$M_2: [n_{2\,1}, n_{2\,2}, n_{2\,3}, n_{2\,4}, \cdots, n_{2\,i}, \cdots, n_{2\,424}]$$

The 424 dimensions represent 424 groups which are used to form molecules [7,8]. $n_{1\,i}$ and $n_{2\,i}$ represent the number of the $i^{th}$ group inside the molecules. If a molecule doesn't have this group, then the value is just 0.

First, a classical mathematical method is introduced, that is, Jaccard similarity coefficient. It is an efficient tool to calculate the similarity between two sets. Its overall logic is to calculate the ratio of the number of elements in the intersection and union of two sets, and the general formula is as follows:

$$JSC(A,B) = \frac{|A \cap B|}{|A \cup B|} = \frac{|A \cap B|}{|A| + |B| - |A \cap B|}$$

Jaccard similarity coefficient ranges in [0,1]. Specially, when A is identical to B, then $JSC(A,B) = 1$. If two sets have no common elements, then $JSC(A,B) = 0$. If Jaccard similarity coefficient is directly applied to calculate the similarity between $M_1$ and $M_2$, the result is as follows.

$$\mathrm{JSC}(M_1, M_2) = \frac{\sum_1^{424} Minimum(n_{1\,i}, n_{2\,i})}{\sum_1^{424} Maximum(n_{1\,i}, n_{2\,i})}$$

However, this result only considers a molecule as a mathematical set containing the groups forming the molecule. In other words, it never considers the chemical features of a molecule, mainly the type of compound and the size of molecule here. As for the type of compound, the similarity of two molecules belonging to the same type of compound should be higher than that belonging to two different types of compounds. For example, based on the Jaccard similarity coefficient, the similarity of $CH_3(CH_2)_6SO_2CH_3$ and $CH_3(CH_2)_6CH_3$ is 0.89 while the similarity of $CH_3(CH_2)_6SO_2CH_3$ and $CH_3(CH_2)_4SO_2CH_3$ is 0.78. However, chemically speaking, the first set of molecules belong to two types of compounds and the second set of molecules belong to the same type of compound. Therefore, this leads to a phenomenon that the similarity of two molecules belonging to different types is higher than that belonging to the same type, which is unacceptable. As for the size of molecule, the difference of two molecules is determined by the absolute difference of the structure not the relative difference of the structure. For example, for molecules described by $[1,1,0,0,\cdots]$ and $[1,1,1,0,\cdots]$, their similarity is 0.67 while the similarity of molecules $[1,1,1,1,1,1,1,1,0,0,\cdots]$ and $[1,1,1,1,1,1,1,1,1,0,\cdots]$ is 0.89. The structure differences in these two sets of molecules are both one group, but their difference of similarity is so large. This is because of the difference of the molecular size. For small size of molecules, the effect of one different group is more significant than large size of molecules. However, the information one molecules can provide for another molecule in the first set is also relatively valuable like the second set of molecules. So, the difference on the similarity due to the molecular size is too large and needs to be reduced. Additionally, if it is not reduced, only large molecules can find similar molecules and small molecules are hard to find similar molecules which is unacceptable as well.

Based on the above analysis, this paper proposed a molecular similarity coefficient calculation method which considers the molecule as a chemical concept. First, consider the type of compound. The type of compound is determined by the type of group inside its molecule. If there

are some groups whose number is 0 in one molecule but not 0 in another molecule, then these molecules belong to two different types. If two molecules are composed of the same types of groups but only the number is different, then these molecules belong to the same type and their similarity increases as the number becomes closer. Therefore, a warping function here is used to transform the molecular group vector, as follows,

$$y = \log(x + 1)$$

The warping function needs to satisfy that the derivative is maximum when the input is near 0, and gradually becomes smaller as the input becomes larger, which conforms to the above analysis of molecular type discrimination. Then molecules $M_1$ and $M_2$ are transformed as follows,

$$M_1^{warping}: [\log(n_{1\,1}+1), \cdots, \log(n_{1\,i}+1), \cdots, \log(n_{1\,424}+1)]$$

$$M_2^{warping}: [\log(n_{2\,1}+1), \cdots, \log(n_{2\,i}+1), \cdots, \log(n_{2\,424}+1)]$$

Their intersection and union are:

$$Intersection^{warping}: [a_1, a_2, \cdots, a_i, \cdots, a_{424}], a_i = min(log(n_{1\,i}+1), log(n_{2\,i}+1))$$

$$Union^{warping}: [b_1, b_2, \cdots, b_i, \cdots, b_{424}], b_i = max(log(n_{1\,i}+1), log(n_{2\,i}+1))$$

Then, consider the molecular size. Since the ratio of the elements number of the intersection and the union is a relative comparison but the difference of the elements number is the absolute comparison, the division operation of the intersection and union elements needs to be converted into a subtraction operation. Therefore, for $M_1$ and $M_2$ after warping transformation, the following method is used to calculate their similarity,

$$\mathrm{MSC}_\alpha(M_1, M_2) = \frac{\alpha^{\sum_1^{424} a_i}}{\alpha^{\sum_1^{424} b_i}} = \alpha^{\sum_1^{424} a_i - \sum_1^{424} b_i}$$

where $\alpha$ is a parameter greater than 1. The number of intersection and union elements in the formula appear in the exponents in the numerator and denominator respectively, so the division is converted to subtraction. Finally, in order to convert the value range of the molecular similarity coefficient to [0,1], it is necessary to normalize it, as shown below.

$$\mathrm{MSC}_\alpha(M_1, M_2) = \frac{\alpha^{\sum_1^{424} a_i} - \alpha^{\min(\sum_1^{424} a_i)}}{\alpha^{\sum_1^{424} b_i} - \alpha^{\min(\sum_1^{424} a_i)}} = \frac{\alpha^{\sum_1^{424} a_i} - 1}{\alpha^{\sum_1^{424} b_i} - 1}$$

Here, $\alpha^{\min(\sum_1^{424} a_i)}$ is a normalized item, which is 1 obviously when the intersection elements are all 0.

## 3. MODELING FRAMEWORK BASED ON MOLECULAR SIMILARITY

When the formula of molecular similarity is proposed, a modeling framework based on it can be further proposed. The dataflow is shown in Figure 1. For a target molecule and a known database containing $m$ molecules, the similarity between the target molecule and all the molecules in the dataset should be calculated one by one to obtain $m$ similarities, namely, $\mathrm{MSC}_1$, $\mathrm{MSC}_2$, $\cdots$, $\mathrm{MSC}_\mathrm{m}$. Then, the $n$ molecules having the highest similarities will be selected to form a subset, which contains the molecules which can provide the most valuable information for the property prediction of the target molecule. Then this subset is used as the training dataset to train the model and use the target molecule as the input to get the predicted value of its property. Simultaneously, the similarities of the customized training molecules to the target molecule can be used to form a quantitative index that reflects the prediction reliability of the target molecule. In this paper, the maximum similarity of all the training molecules is employed as the reliability index defined by R. Consequently, the prediction result using this modeling framework is composed of two parts, that is, the predicted property and the reliability index R, which are used together to guide the molecular design. Additionally, the customized training set can provide much more pertinent and valuable information for the target molecule to improve the prediction accuracy of the target molecules with high reliability R.

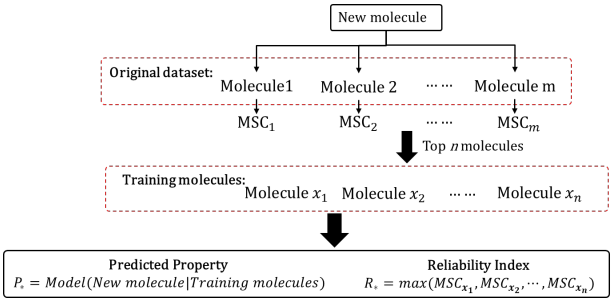

**Figure 1.** The dataflow of the modeling framework.

## 4. TEST AND DISCUSSION

### 4.1 Test method

To verify whether the property prediction framework proposed in this paper possesses the characteristics outlined, a series of tests were conducted. The modeling framework does not limit the types of models used, so three property prediction models were employed for the tests: a simple Group Contribution (GC) model[9], a Support Vector Regression (SVR) model[6], and an improved Gaussian Process Regression (GPR) model[10].

For each model, a test group utilized the proposed modeling framework, while a control group did not, allowing for a comparison to assess the framework's effectiveness. To ensure the test results are objective and reliable, nine different properties were selected for testing, as shown in Table 1. The data for each property was

divided into a candidate training set and a testing set, using an 80:20 ratio. Customized training molecules were chosen from the candidate training set.

**Table 1:** The information of 9 testing properties

| | Property | Symbol | Data volume |
|---|---|---|---|
| **1** | Critical volume (mL/mol) | Vc | 636 |
| **2** | Critical pressure (bar) | Pc | 651 |
| **3** | Auto ignition temperature (K) | Ait | 477 |
| **4** | Gibbs energy of formation at 298 K (kJ/mol) | Gf | 616 |
| **5** | Standard enthalpy of formulation (kJ/mol) | Hf | 787 |
| **6** | Hildebrandt solubility parameter at 298 K ($MPa^{1/2}$) | Hsolp | 1102 |
| **7** | Enthalpy of formation at 298 K (kJ/mol) | Hv | 326 |
| **8** | Liquid molar volume at 298 K (mL/mol) | Lmv | 855 |
| **9** | Critical temperature (K) | Tc | 706 |

To determine the optimal number of molecules to achieve the best prediction accuracy, the test group was further separated into two subgroups: using 10 molecules and 50 molecules for training. In contrast, the control group used all the molecules from the candidate training dataset for training. Finally, the predicted values and reliability indices for the molecules in the testing set were recorded.

## 4.2 Result analysis

### 4.2.1 Verify the quantification of the prediction reliability

In order to verify that the reliability index R can really be used as a quantitatively measure for the prediction reliability, two cases are displayed first in Figure 2.

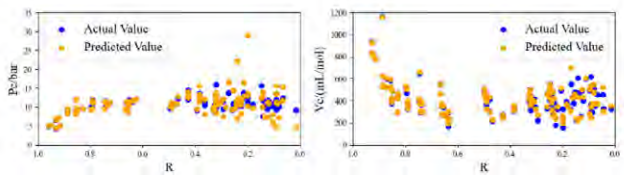

**Figure 2.** The results of Pc and Vc.

It can be seen that as R decreases from 1 to 0, the gap becomes much larger gradually. Further, the test results of all properties using the proposed modeling framework are displayed in Figure 3. Here, to eliminate the interference of some outlier data points, the following formula is used to calculate the Average Prediction Error (APE) of test molecules with reliability greater than u,

$$APE(R \geq u) = \frac{\sum_{R_i \geq u} error_i}{\sum_{R_i \geq u} 1}$$

All the test results are displayed with reliability R as the horizontal coordinate and APE as the vertical coordinate. From these results, as R decreases, APE always has an increasing tendency. Besides, when fewer molecules are used for training, APE increases more rapidly. From the result analysis above, the reliability index R based on the proposed molecular similarity coefficient can be used as a quantitative index for the reliability of property prediction without model limitation.

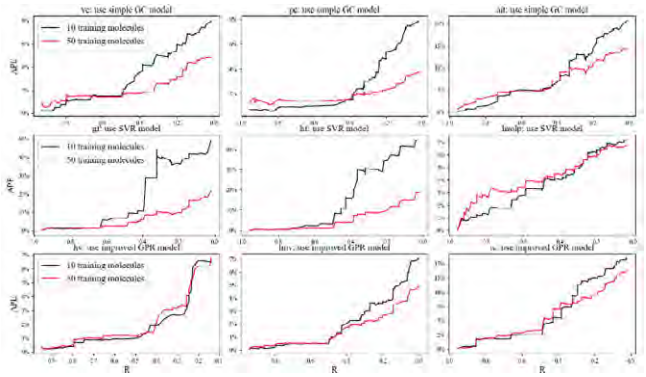

**Figure 3.** The results of 9 properties (list 3 properties for each model: Vc, Pc and Ait use simple GC model; Gf, Hf and Hsolp use SVR model; Hv, Lmv and Tc use improved GPR model).

### 4.2.2 Verify the improvement of the prediction accuracy

Then, in order to verify the prediction accuracy improvement of the proposed modeling framework, the results of all the properties are summarized according to different number of training molecules, namely, 10 training molecules, 50 training molecules and all the candidate training molecules. The average prediction error under different level of reliabilities is shown for different number of training molecules. The results using simple GC model, SVR model and improved GPR model are listed in Table 2, Table 3 and Table 4.

For each line representing the same level of reliability, we compare the prediction errors among three columns that utilize different numbers of training molecules. The green color scale indicates the case with the lowest prediction error, followed by a light green scale, and finally, the white scale, which represents the highest prediction error. From these tables, it is evident that regardless of the model used, when dealing with molecules that have high reliability (R), applying a subset of molecules from the candidate training dataset—specifically, the proposed modeling framework—results in significantly better prediction accuracy compared to the routine method that uses all candidate training molecules. Only when the reliability (R) is at a low level does the prediction accuracy of using all candidate training molecules surpass that of the proposed modeling framework.

The primary reason for this result is that when molecules with high similarity to the target molecules are identified, using a subset of these molecules can provide significantly more relevant information for predicting the properties of the target molecules. In contrast, molecules

**Table 2:** The result of simple GC model

| Reliability level | 10 training molecules | 50 training molecules | All candidate training molecules |
|---|---|---|---|
| R≥0.9 | 0.67% | 1.22% | 2.70% |
| R≥0.85 | 0.81% | 1.56% | 3.00% |
| R≥0.8 | 0.89% | 1.72% | 3.09% |
| R≥0.7 | 1.30% | 1.96% | 3.26% |
| R≥0.6 | 1.93% | 2.14% | 3.43% |
| R≥0.5 | 2.05% | 2.29% | 3.47% |
| R≥0.4 | 4.70% | 3.45% | 4.48% |
| R≥0.3 | 9.62% | 5.87% | 7.00% |
| R≥0.2 | 11.04% | 6.82% | 7.40% |
| R≥0.1 | 13.77% | 8.94% | 8.48% |
| R≥0 | 15.56% | 10.17% | 9.61% |

**Table 3:** The result of SVR model

| Reliability level | 10 training molecules | 50 training molecules | All candidate training molecules |
|---|---|---|---|
| R≥0.9 | 0.63% | 1.19% | 2.74% |
| R≥0.85 | 0.81% | 1.78% | 2.89% |
| R≥0.8 | 1.29% | 1.73% | 2.86% |
| R≥0.7 | 2.22% | 2.62% | 3.06% |
| R≥0.6 | 3.77% | 3.48% | 3.38% |
| R≥0.5 | 4.10% | 3.57% | 3.48% |
| R≥0.4 | 7.09% | 4.91% | 4.34% |
| R≥0.3 | 13.19% | 6.68% | 6.11% |
| R≥0.2 | 14.06% | 7.26% | 6.58% |
| R≥0.1 | 16.13% | 9.30% | 7.82% |
| R≥0 | 17.83% | 10.92% | 8.92% |

**Table 4:** The result of improved GPR model

| Reliability level | 10 training molecules | 50 training molecules | All candidate training molecules |
|---|---|---|---|
| R≥0.9 | 0.59% | 0.80% | 1.01% |
| R≥0.85 | 0.69% | 0.88% | 1.08% |
| R≥0.8 | 0.76% | 0.92% | 1.21% |
| R≥0.7 | 1.18% | 1.48% | 1.72% |
| R≥0.6 | 1.80% | 1.93% | 2.09% |
| R≥0.5 | 1.92% | 2.05% | 2.20% |
| R≥0.4 | 5.37% | 4.22% | 4.07% |
| R≥0.3 | 10.92% | 5.95% | 5.68% |
| R≥0.2 | 12.48% | 7.32% | 6.62% |
| R≥0.1 | 14.86% | 9.60% | 8.08% |
| R≥0 | 16.00% | 11.44% | 9.50% |

that are too dissimilar from the target molecules tend to offer little valuable information and may even lead to misleading conclusions; therefore, they have been excluded. This process enhances prediction accuracy. As the similarity among molecules in the training set decreases, the value and relevance of the information also diminish. If a small number of training molecules are still used, the prediction accuracy will decline due to insufficient data. Consequently, it is essential to increase the amount of data. When the reliability (R) approaches 0, it becomes challenging to find similar molecules for the target molecules within the candidate training dataset. At this point, maximizing the amount of data is crucial—using all available candidate training molecules is necessary to achieve the best prediction accuracy. However, even when all data is utilized, the informational value of these molecules regarding the target molecules remains minimal, resulting in significant prediction errors and low reliability, as demonstrated in the tables.

## 5. DATA CONSISTENCY TEST

Based on the molecular similarity coefficient, a methodology for data consistency testing can be established. If molecules with high MSC serve as the training dataset but the predicted property value of the target molecule deviates significantly from the actual value, it suggests that errors may exist in the property data of the training molecules or the target molecule itself.

For instance, in a property database of Tc, the prediction error for $CH_3(CH_2)_{16}COOH$ reached 10.55% while its prediction reliability was 0.9437. Table 5 details the 10 training molecules for further analysis.

**Table 5:** The training data before correction

| No | MSC | Tc (real)/K | $CH_3$ | $CH_2$ | COOH |
|---|---|---|---|---|---|
| Target molecule | 1 | 799 | 1 | 16 | 1 |
| Molecule 1 | 0.943662 | 474.2 | 1 | 17 | 1 |
| Molecule 2 | 0.940299 | 590 | 1 | 15 | 1 |
| Molecule 3 | 0.893333 | 809 | 1 | 18 | 1 |
| Molecule 4 | 0.880597 | 785 | 1 | 14 | 1 |
| Molecule 5 | 0.820896 | 693 | 1 | 13 | 1 |
| Molecule 6 | 0.761194 | 568 | 1 | 12 | 1 |
| Molecule 7 | 0.701493 | 591.15 | 1 | 11 | 1 |
| Molecule 8 | 0.641791 | 618 | 1 | 10 | 1 |
| Molecule 9 | 0.58209 | 654 | 1 | 9 | 1 |
| Molecule 10 | 0.522388 | 456.86 | 1 | 8 | 1 |

It can be noted that these molecules are of the same compound type, with the primary difference being the number of $CH_2$ groups. According to physicochemical principles, the property Tc of these molecules generally varies consistently with the number of carbon atoms (C). Consequently, the relationship between Tc and the number of carbon atoms before correction has been plotted in Figure 4. The Tc values of these molecules do not exhibit a consistent relationship with the number of carbon atoms (C). This observation suggests a significant possibility of errors in the Tc data for either the training molecules or the target molecule. To address this, we verified the actual Tc values of these molecules by ICAS[8] and discovered mistakes in the training data. The corrected data is shown in Table 6.

**Table 6:** The training data after correction

| No | MSC | Tc (real)/K | $CH_3$ | $CH_2$ | COOH |
|---|---|---|---|---|---|
| Target molecule | 1 | 799 | 1 | 16 | 1 |
| Molecule 1 | 0.943662 | 812[a] | 1 | 17 | 1 |
| Molecule 2 | 0.940299 | 793[a] | 1 | 15 | 1 |
| Molecule 3 | 0.893333 | 821[a] | 1 | 18 | 1 |
| Molecule 4 | 0.880597 | 785 | 1 | 14 | 1 |
| Molecule 5 | 0.820896 | 775[a] | 1 | 13 | 1 |
| Molecule 6 | 0.761194 | 765[a] | 1 | 12 | 1 |
| Molecule 7 | 0.701493 | 754[a] | 1 | 11 | 1 |
| Molecule 8 | 0.641791 | 734[a] | 1 | 10 | 1 |
| Molecule 9 | 0.58209 | 732[a] | 1 | 9 | 1 |
| Molecule 10 | 0.522388 | 722.1[a] | 1 | 8 | 1 |

a: checked in ICAS (Integrated Computer Aided System).

Similarly, the Tc values and the number of C after correction are plotted in Figure 4. It illustrates that after correction, the Tc values and the number of C atoms

exhibit a consistently increasing trend. This suggests that the dataset has likely been corrected at this stage. The corrected dataset is then utilized to predict Tc of the target molecule, revealing a prediction error of only 0.42%. This result further confirms that the errors in the original dataset have been addressed.

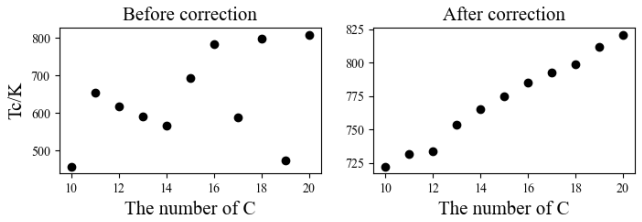

**Figure 4.** The data of Tc with the number of C.

## 6. CONCLUSION

This paper introduces a modeling framework based on the molecular similarity coefficient. This framework utilizes the similarity between molecules in a candidate training dataset and target molecules to create a customized training dataset specifically for the target molecules. Testing was conducted on nine properties. The results confirm that this modeling framework provides a quantitative measure of prediction reliability and significantly enhances the prediction accuracy for molecules with a high reliability index. For molecular design, the framework proposed in this paper offers a novel two-fold evaluation system. It emphasizes that the molecular design process should assess not only the predicted properties but also the reliability of those predictions. However, the analysis presented in this paper indicates that the prediction performance of the proposed framework is somewhat sensitive to data errors because using a smaller amount of data for model training amplifies the impact of mistakes in the training dataset. Therefore, the data consistency testing method proposed in this study should be further developed, and the modeling framework should be implemented alongside this testing method to achieve more reliable, accurate, and stable prediction performance.

## ABSTRACT

Rapid and robust simulation of chemical production processes is critical to address core scientific questions related to process design, optimization, and sustainability. Efficiently solving a chemical process, however, remains a challenge due to their highly coupled and nonlinear nature. Graph abstractions of the underlying physical phenomena within unit operations may help identify potential avenues to systematically reformulate the network of equations and enable more robust convergence of flowsheets. To this end, we further refined a flowsheet graph-theoretic abstraction that consists of a mesh of interconnected variable nodes and equation nodes. The new network of equations is formulated at the phenomenological level—agnostic to the thermodynamic property package—by extending equation formulations widely used to solve multistage equilibrium columns. Decomposition of the graph by phenomena linearizes material and energy balances across the flowsheet by decoupling phenomenological nonlinearities (e.g., phase equilibrium, chemical reactions). Additionally, we further improved a preliminary simulation algorithm which employs this phenomena-based decomposition and demonstrated that it can perform more rapid and robust simulation of large, highly-coupled systems than sequential modular simulation.

**Keywords**: Process Simulation, Graph-Theory, Flowsheet Convergence, Distillation, Liquid Extraction

## INTRODUCTION

Critical to the design and development of sustainable production processes, chemical process simulation seeks to model the flow rate of material and energy between unit operations and their internal components. Physical phenomena (e.g., phase equilibrium, chemical reactions, adsorption, and heat exchange) which drive a production process also introduce nonlinearities to the material and energy balances. This nonlinear coupling between unit operations is the core difficulty in solving for the steady-state solution of a production process in any algorithmic paradigm (e.g., sequential modular simulation, equation-oriented simulation, pseudo-transient modeling). Large, highly coupled systems lead to substantially longer computation time and lower rates of successful convergence than small, sparse systems [1]. This inability to scale the simulation of complex systems limits researchers' ability to optimize the sustainability of emerging production processes.

In sequential-modular simulation, each unit operation is treated as a black-box model with only material streams as inputs and outputs [2]. All mass, energy, and thermodynamic equations are formulated and solved independently within each unit operation. While specialized convergence strategies are employed to converge individual units, the convergence of recycle systems can be challenging due to nonlinear coupling between unit operations. Equation-based modeling leverages the full set of equations and employs algebraic differentiation to aid numerical methods in finding the steady state solution [3]. Equation-based modeling may be faster than the sequential modular approach particularly when the initial guess is close to the steady state solution. However, highly-coupled networks of equations introduce instabilities that lead to convergence failures.

If a process flowsheet could become aware of the connectivity of the governing phenomenological equations, robust solution strategies could be formulated that aggregate linear relationships and decouple nonlinearities. With the wealth of decomposition algorithms and computing architectures that enable the solution of

complex and large-scale problems, it may be feasible to screen for alternative problem formulations of a production process that result in more rapid and robust convergence. The problem formulation and the selection of a suitable solution method, however, is not a simple task. Graph-theoretic abstractions of the equations within unit operations may provide an avenue to systematically reformulate the network of equations and enable advanced, equation-based convergence of flowsheets.

In classical representations of a chemical process, units are represented as nodes and streams as edges. Fundamentally, each unit encapsulates a set of equations with internal variables and each stream carries a set of variables with a unique connection. At the phenomenological level, however, each variable may relate multiple equations and may not have a unique connection. For example, temperature may play multiple roles in thermodynamic phase equilibrium, energy balances, and reaction rates. Graphical abstractions of process phenomena may unfold the sets of equations and variables present in unit operations to capture how mass, energy, equilibrium, reaction, and transport equations are related through shared variables. Distillation column models are a classic example where equations are decoupled by phenomena. For example, the Wang-Henke bubble point method converges all stages by iteratively solving mass, equilibrium, summation, and enthalpy (MESH) equations [4].

In our previous work, we introduced a flowsheet graph abstraction which represents all the equations and variables as a bipartite graph of equation nodes and variable nodes [5]. Additionally, it was shown that decomposing the network of equations by phenomena improved the convergence speed of an extractive distillation process flowsheet. However, because of the redundancy between variables and how highly coupled the equations are, the abstraction was too complex to provide any key topological insights. The graph abstraction needs to be further refined by eliminating variable redundancy and strategically aggregating intermediary equations not relevant to the decomposition. Harmonizing the graph with respect to the decomposition is the next step towards gaining mathematical insight into how the decomposition improves convergence.

The goal of this study was to further refine and improve the graph abstraction and phenomena-based decomposition introduced in our last study for the broader goal of improving the convergence of large and highly coupled systems. To this end, we completed the following objectives: (i) refined the phenomena-based graph abstraction of chemical process flowsheets, (ii) generalized the graph-based decomposition scheme to any set of unit operations, and (iii) benchmarked a convergence algorithm leveraging this decomposition scheme. We implemented the phenomena-oriented simulation algorithm in BioSTEAM—an open-source process simulation platform implemented in Python [6]—and benchmarked its convergence against sequential modular simulation for an industrial process for the dewatering of acetic acid using ethyl acetate solvent.

## MATERIALS & METHODS

### Phenomenological Graph Framework

The graph abstractions in this study represent variables as grey ring nodes and equations as solid nodes. The color of equation nodes depends on what subset of equations they pertain to within the phenomena decomposition. Edges connect variables to equations and define shared variables among equations. It is also possible to obtain different graph representations by reformulating the equations. For example, variable nodes can be eliminated via substitution of equations and new edges may be formed to reflect changes in the equation formulation. Nodes that were not relevant to the phenomena decomposition scheme were eliminated to minimize the complexity. By aggregating equations in this manner, the various decomposition schemes are represented at a phenomenological level that is agnostic to the specific thermodynamic property package (e.g., the selection between ideal gas or mixture equations of state has no impact on the equations). Input variables that are held constant within a subgraph are not displayed to avoid creating edges between equation nodes that are decoupled. This reduces connectivity between equations and highlights how the decomposition scheme reduces complexity. PhenomeNode [5], an open-source Python library for phenomena-based graph representations, was used to automate the generation of graphical abstractions.

### Phenomenological decomposition

Key material and energy variables are represented by “$x$” while variables related to coefficients for the material and energy balances are denoted by “$y$”. Aggregated models (e.g., shortcut columns) are effectively stages with respect to the resolution of the flowsheet. To generalize the equations to an arbitrary reference stage, we introduce subscripts “$i$” and “$o$” that describe the unique connectivity of an inlet or outlet to its source or sink, respectively. If a variable does not have an “$i$” or “$o$” subscript, it means that the variable pertains to the reference stage. An “$s$” subscript is used to denote a variable specific to the source stage of a stream (e.g., temperature, phase ratio). In special cases, an additional subscript “$j$” may be used to reference outlet streams other than the arbitrary “$o$”. Function definitions are abstracted at the level that is relevant to the decomposition; detailed equations to compute phenomenological variables (e.g., enthalpy) are not described as they depend on the specific property package. Subscript, function, and constant definitions are detailed in Tables 1-3, respectively.

Central equations are presented in the same color as their respective nodes in the graph representations (e.g., material balances are purple). Equations to compute coefficients to the material and energy balances are not considered central equations. Within the graph abstraction, we strategically aggregate these equations to their respective central equations for simplicity. In this study, pressures are assumed to be constants (controlled by valves and pumps) and do not appear as a variable in the graphs nor equations.

**Table 1.** Subscript definitions.

| | Definition | | Definition |
|---|---|---|---|
| i | arbitrary inlet | j | arbitrary outlet |
| o | arbitrary outlet | F | flow rate |
| s | arbitrary stage | T | temperature |
| c | arbitrary component | Φ | phase ratio |
| γ | activity coefficient | S | separation factor |
| VLE | VLE-specific | R | reaction rate |
| LLE | LLE-specific | M | molar fraction |
| E | key energy variable | A | light phase |
| K | partition coefficient | B | heavy phase |

**Table 2.** Function outputs.

| Function | Definition |
|---|---|
| H | enthalpy flow rate |
| h | specific enthalpy |
| N | total flow rate |
| C | heat capacity flow rate |
| R | reaction rate |
| P | phase equilibrium variables |
| M | molar composition |
| S | separation factor |
| Φ | phase ratio (by Rashford-Rice equation) |
| γ | activity coefficient |

Table 3. Constants.

| Constant | Definition | Constant | Definition |
|---|---|---|---|
| Q | duty | t, b | split |

The material balance equations are used to solve for all flow rates, $x_{F,c}$, given the separation factors, $y_{S,c}$, and the generation (or consumption) of chemicals, $y_{R,c}$. The conservation of mass, material separation, and splitting equations are generalized for any stage as follows:

$$\Sigma_o x_{F,c,o} - \Sigma_i x_{F,c,i} = y_{R,c} \quad (1)$$

$$y_{S,c}\Sigma_{o \in B} x_{F,c,o} - \Sigma_{o \in A} x_{F,c,o} = 0 \quad (2)$$

$$x_{F,c,o \in A} - t_o \Sigma_{j \in A} x_{F,c,j} = 0 \quad (3)$$

$$x_{F,c,o \in B} - b_o \Sigma_{j \in B} x_{F,c,j} = 0 \quad (4)$$

$$y_{R,c} = R_c(x_{F,c,o}, x_T) \quad (5)$$

$$y_{S,c} = y_{K,c} x_\Phi \quad (6a)$$

$$y_{S,c} = S(x_{F,c,o}, x_T) \quad (6b)$$

Eq 6a is only relevant for an equilibrium stage while eq 6b is applicable to any module. The function $S$ will depend on the module. For shortcut columns, $S$ is an iteration of the Fenske Underwood Gilliland method, without bubble and dew point temperature calculations.

At steady state, the enthalpy balance equation at the reference stage and can be generalized as follows:

$$0 = \Sigma_o H_o(x_{F,c,o}, x_T) - \Sigma_i H_i(x_{F,c,i}, x_{T,i}) - Q \quad (7a)$$

Assuming $Q$ is constant, we can reformulate equation 7a in terms of a key energy variable (denoted by "E") by a 1st degree Taylor expansion:

$$\Sigma_{i,s} \Delta x_{E,s} \frac{\partial H_i(x_{F,c,i}, x_T)}{\partial x_{E,s}} - \Delta x_E \Sigma_o \frac{\partial H_o(x_{F,c,o}, x_T)}{\partial x_E} = \Sigma_o H_o(x_{F,c,o}, x_T) - \Sigma_i H_i(x_{F,c,i}, x_{T,i}) - Q \quad (7b)$$

We can reformulate eq 7b as a linear equation by isolating the nonlinear terms and separating variables:

$$\Sigma_{i,s} x_{E,s} y_{E,i} - x_E \Sigma_o y_{E,o} = y_{H,s} \quad (7c)$$

This equation may solve for a range of parameters that depend on the type of phenomena exhibited by the stage and its specifications. For example, VLE is most sensitive to the boil-up ratio, $x_\Phi$, (i.e., the ratio of vapor to liquid flow rate) while that LLE is more sensitive to the temperature, $x_T$, than the ratio of extract to raffinate. Assuming a constant liquid flow rate, the local sensitivity of $\Phi$ on the enthalpy of a stream leaving a stage in VLE is given by:

$$y_{E,o \in A} = \frac{\partial H_{o \in A}}{\partial x_{\Phi,s \in VLE}} = t_o h_{gas}(x_{F,c,o}, x_T) N(x_{F,c,j \in B}) \quad (8)$$

$$y_{E,o \in B} = \frac{\partial H_{o \in B}}{\partial x_{\Phi,s \in VLE}} = 0 \quad (9)$$

When a stream leaving a stage is not in VLE (i.e., superheated or subcooled), the key energy variable is assumed to be the temperature:

$$y_{E,o} = \frac{\partial H_o}{\partial x_T} = C(x_{F,c,o}, x_T) \quad (10)$$

Given these definitions, the term on the right-hand side of eq 7c becomes:

$$y_{H,s} = \Sigma_o H_o(x_{F,c,o}, x_T) - \Sigma_i H_i(x_{F,c,i}, x_{T,i}) - Q - \Sigma_{i,s} x_{E,s} y_{E,i} + x_E \Sigma_o y_{E,o} \quad (11)$$

The enthalpy balance is only relevant for stages where the duty, $Q$, is specified (e.g., adiabatic stages). Otherwise, when either temperature or vapor fraction is user-specified, the duty can be computed at the end of simulation, after all variables have converged.

Equations related to the VLE criteria depend on user specifications. The variables $y_K$ and $x_T$ for a VLE stage can be evaluated by a bubble point routine (within a

thermodynamic property package; eq 12a). If the temperature of a stage is specified, then $y_K$ and $x_\Phi$ are computed through a pressure and temperature flash routine (eq 12b). For other unit operations which include outlet streams in VLE (e.g., shortcut columns), the outlet temperature of each stream can be computed by bubble and dew point routines (eq 12c):

$$y_K, x_T = P_{VLE,c}(x_{F,c,o \in B}) \quad (12a)$$

$$y_K, x_\Phi = P_{VLE,c}(x_{F,c,o}) \quad (12b)$$

$$x_{T,o} = P_{VLE,c}(x_{F,c,o}) \quad (12c)$$

The partition coefficient, $y_K$, and the phase ratio, $x_\Phi$, for a LLE stage are evaluated using the pseudo-equilibrium approach and the Rashford-Rice equation, respectively:

$$y_{M,c} = M_c(x_{F,c,B}, T, y_{\gamma,c,A}) \quad (13)$$

$$y_{\gamma,c,A} = \gamma_c(y_{M,c}, T) \quad (14)$$

$$y_{K,c} = P_{LLE,c}(x_{F,c,B}, T, y_{\gamma,c,A}) \quad (15)$$

$$x_\Phi = \Phi(y_{K,c}, x_{F,c,o}) \quad (16)$$

## Phenomena-based simulation algorithm

The new simulation algorithm iteratively solves the complete flowsheet by sequential substitution. The phenomenological nonlinearities are solved first, then material and energy balances solved as systems of linear equations. To prevent the algorithm from failing due to poor conditioning of the initial guess (i.e., material and energy variables of all streams), we integrate sequential modular simulation for more robust convergence. All together, we propose the following algorithm as a preliminary architecture for phenomena-based simulation:

1. In the absence of an initial guess for $x_{F,c,o}$ and $x_E$, for each stage, run each unit operation sequentially and use the result as the initial guess.
2. For each unit operation:
   - 2.1 Simulate the unit operation and update all variables associated to the unit.
   - 2.2 Using the linear material balance equations (eqs 1–6), solve $x_{F,c,o}$ for all stages.
   - 2.3 Using the linear energy balance equations (eqs 7c–11), solve $x_{E,s}$ for all stages.
3. Using the VLE criteria (eq 12a-c), solve for $y_K$ and $x_T$ at each stage and/or stream.
4. Solve $y_{K,c}$ and $x_{F,c,o}$ for all LLE stages iteratively until they converge within a specified tolerance:
   - 4.1 Using the pseudo-equilibrium concept (eqs 13-15), solve $y_{K,c}$ for each stage.
   - 4.2 Using the material balance equations (eqs 1–6), solve $x_{F,c,o}$ for all LLE stages as a system of linear equations.
   - 4.3 If $y_{K,c}$ and $x_{F,c,o}$ have not converged, repeat steps 4.1 and 4.2
5. Using the Rashford-Rice equation (eq 16), solve $x_\Phi$ for all LLE stages.
6. Solve material and energy balances for the complete flowsheet (steps 2.2 and 2.3).
7. If any variables have not converged under a specified tolerance, repeat steps 2–5.

## Acetic Acid Purification Benchmark

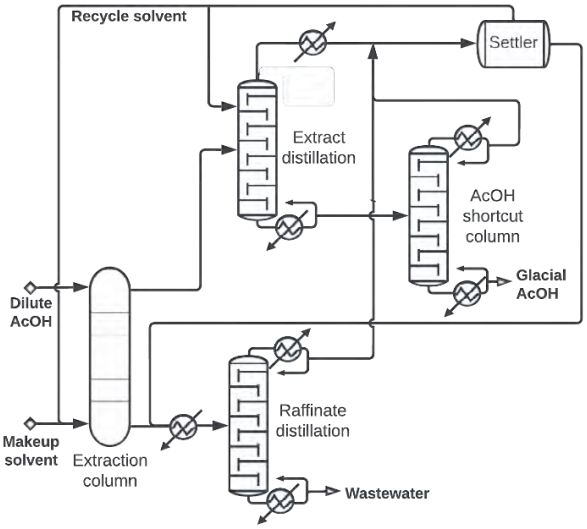

**Figure 1.** Process flowsheet for acetic acid dewatering.

The industrial separation of acetic acid from water (Figure 1) was chosen as a representative case to benchmark the new convergence algorithm against sequential modular simulation. The system includes highly coupled vapor-liquid equilibrium (VLE) and liquid-liquid equilibrium (LLE) stages and recycle loops that connect the end of the process with the start. In this process, ethyl acetate (EtOAc) is used to extract acetic acid from a dilute aqueous mixture [7]. The extract is distilled to recycle the solvent and recover glacial acetic acid. The raffinate is also distilled to recover EtOAc from the wastewater. Both distillates are sent to a decanter to separate the aqueous phase that forms after condensation. Only results pertinent to flowsheet convergence were considered, including duties and material flows across unit operations and stages. Sizing and costing of unit operations were not considered as they do not impact mass and energy balances and are therefore irrelevant to benchmarking.

The "true" solution of the process was considered to be the best solution (i.e. the solution with the minimum error) out of the two simulation strategies at the final iteration. The simulation error is defined as the sum of the

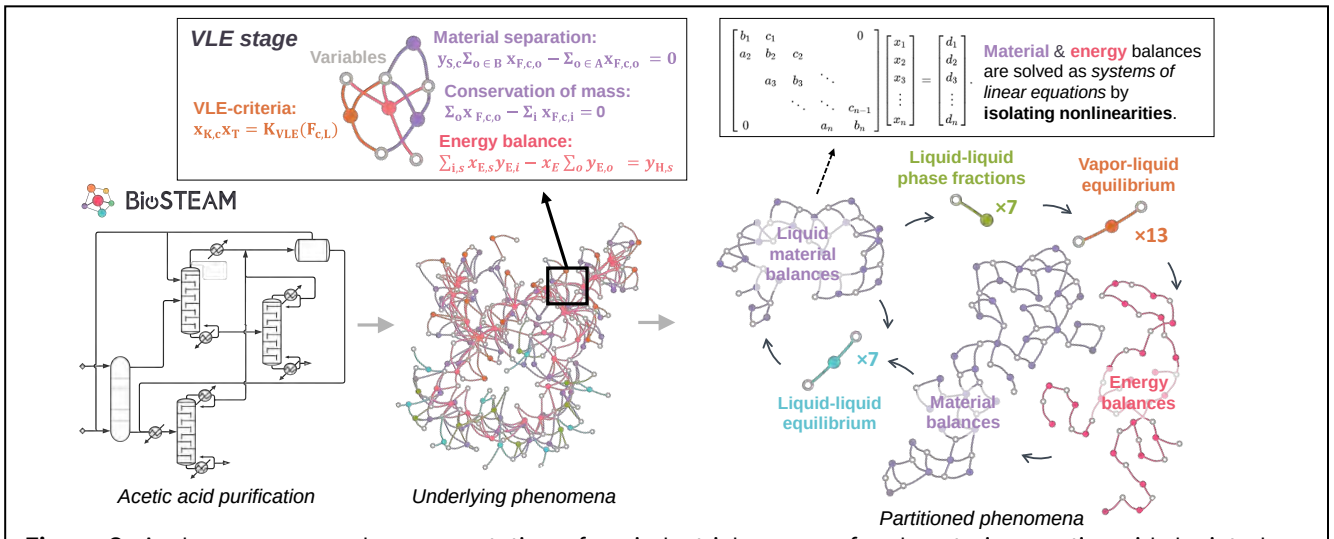

**Figure 2.** A phenomena graph representation of an industrial process for dewatering acetic acid depicts how decoupling phenomenological equations may result in a more maganeable formulation for complex systems.

change in component flow rates and temperatures of each stream after the simulation of each stage in parallel:

$$\text{Error} = \sum_{s}\sum_{o}\left(\left|x^{n}_{T,s,o} - x^{n-1}_{T,s,o}\right| + \sum_{c}\left|x^{n}_{F,c,s,o} - x^{n-1}_{F,c,s,o}\right|\right)$$

## RESULTS & DISCUSSION

The graph representation of the flowsheet for the purification of acetic acid, representing a complex system with 3 recycles and 48 stages, depicts how the phenomenological equations have an underlying structure (Figure 2). While there can be many effective ways to decompose the flowsheet (e.g, sequential or parallel modular), the phenomena-based decomposition has the advantage of linearizing the material and enthalpy balances across all unit operations and their stages by decoupling phenomenological nonlinearities. This decomposition can be considered a generalization of MESH formulations commonly used to solve multistage unit operations. For the special case of multistage vapor-liquid equilibrium columns, these equations reduce to the equations in Wang-Henke's bubble point method [4], which iteratively solves for the bubble point partition coefficients and temperature, then the boil-up ratios of all stages using the linear energy balance equations, and finally the material flow rates using the linear mass balance equations. Additionally, for the special case of multistage liquid-liquid equilibrium, these equations reduce to the decomposition in the Tsuboka method [8], which employs an inner loop using the pseudo equilibrium concept to iteratively solve partition coefficients and the material balance, phase fractions are solved by the Rashford-Rice equation, and, lastly, stage temperatures are solved using the linear energy balances. Although the decomposition of equations is specialized for the type of phenomena (e.g., vapor-liquid equilibrium vs. liquid-liquid equilibrium), these methods have an underlying structure that enables material flows and key energy variables to be solved as systems of linear equations. Through the phenomena-based graph abstraction and the generalization of the mass and energy balances, we can unfold the underlying equations in unit operations in manner that is consistent with classical decomposition approaches for multistage unit operations and leverage existing solution strategies at the unit level to develop a phenomena-oriented flowsheet simulation algorithm.

The new simulation algorithm is a fusion of the sequential modular approach with sequential substitution of the phenomena decomposition. In step 2, the material and energy balances are solved after each unit operation is simulated, enabling new information gathered from a single unit simulation to spread through the flowsheet while consolidating mass and energy balances. Phenomenological nonlinearities are then solved in steps 3-5 and the material and energy balances are solved in step 6, which follows common solution strategies for multistage equilibrium columns. Together, steps 3-6 may help accelerate convergence by treating the entire flowsheet as if it were a single unit operation.

In the benchmark flowsheet for the dewatering of acetic acid, the preliminary phenomena-based simulation algorithm converged in 75% less time than the sequential modular approach (Figure 3 A, B). The phenomena-based algorithm was also able to achieve greater numerical accuracy in simulations than the sequential modular approach. While the phenomena-based approach treats the flowsheet as a single unit, sequential modular accumulates numerical error as it simulates each unit

Ultimately, these results suggest that the phenomena-based approach may enable faster and more robust convergence for large, highly-coupled systems. It is important to note, however, that this approach was only

benchmarked against sequential modular simulation and equation-oriented simulation may converge faster. Additionally, this separation process is limited to only phase-based separations. Future work will focus on benchmarking systems with reactions and mass and energy transfer-based unit operations that are common in a production process against both the sequential modular and the equation-oriented approaches. It is possible that different decompositions may be more effective for different sets of physical phenomena and the decoupling strategies presented here may need to further refinement. We envision a family of phenomena-based simulation architectures that are optimized for different problems based on the relevant phenomena of the system, level of connectivity between unit operations, and chemical interactions that drive coupling between phenomenological equations. Ultimately, the phenomena graph representations introduced in this study may aid in the development of unified decoupling and linearization strategies that can allow for more rapid and robust flowsheet convergence.

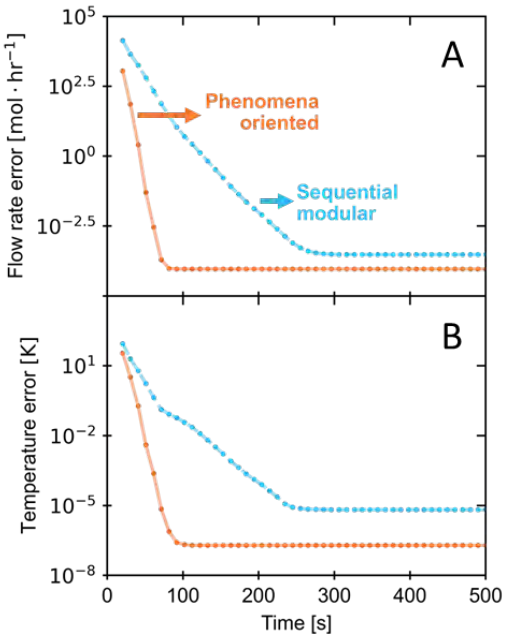

**Figure 3.** The total error of the flow rate (A) and temperature (B) across all streams is plotted over simulation time of the benchmark case for the phenomena-based (orange) and sequential modular (blue) approaches.

## CONCLUSION

Efficiently solving a flowsheet remains a challenge due to the tightly coupled, non-linear nature of chemical processes. The graph representations developed in this study helped identify how decoupling equations by phenomena can be used to formulate a strategy to converge the complete flowsheet. While the proposed algorithm showed promising advantages in convergence speed compared to sequential modular, further analysis is needed to fully characterize the speed, robustness, and applicability to a broader set of chemical processes.

## ABSTRACT

The green transition accelerates innovations and developments targeting the integration of green hydrogen in the chemical industry. However, all new hydrogen pathways and process designs must be tested on operability and safety. A big challenge is the typical fluctuating characteristic of green hydrogen supply that contrasts the steady-state operation of most conventional chemical processes. Therefore, to adequately assess control and monitoring techniques, a benchmark model tailored to the relevant aspects of the hydrogen economy is required. We introduce a benchmark model based on the production of green ammonia using the Haber-Bosch process that remains operable when coupled to a fluctuating hydrogen supply from water electrolysis. The main section of the process model is an adiabatic indirect cooled reactor system that provides realistic modeling of industrial applications. Like the ammonia reactor, all process units and the underlying control structure are precisely dimensioned to ensure feasible operation across various hydrogen supply rates. Eventually, the flexible operating ammonia benchmark model can serve as a new benchmark for analyzing process safety and control aspects.

**Keywords**: Simulation Benchmark Model, Renewable Ammonia Production, Process Safety

## INTRODUCTION

The relevance of green hydrogen is rapidly increasing because of its vital part in the transition to a more sustainable industry. Hydrogen can serve as both a sustainable feedstock and an energy carrier in heating and transport applications [1]. Accordingly, a great interest emerged in designing new process routes based on green hydrogen produced from water electrolysis. However, many challenges are still related to integrating green hydrogen into established chemical processes, like hydrogen storage, transportation, and safety [1,2]. In particular, coupling a fluctuating hydrogen supply, due to its production from renewable electricity, based on constantly changing weather conditions, with a conventional chemical process formally established for steady-state operation challenges all three areas.

One of the most prominent products of the chemical industry, stemming directly from hydrogen, is ammonia. Ammonia is the second most produced chemical globally, mainly because of its use in the fertilizer industry [2]. However, it also serves several more applications, *e.g.*, as a platform chemical [3] or as an energy carrier [4], and its global demand is predicted to increase further [4]. Traditionally, ammonia is produced using the Haber-Bosch (HB) process, which has seen only minor modifications since its inception in the early 20th century [5]. During the HB process, hydrogen reacts with nitrogen to form ammonia. The process requires a metal catalyst and high pressure and temperature conditions. Common HB plants use steam gas reforming for hydrogen production and, thus, generate high carbon emissions. Following the decarbonization trend, green hydrogen as feedstock drastically reduces ammonia's carbon footprint [6]. Eventually, the green hydrogen pathway to green ammonia will be applied on big industrial scales [3].

All green hydrogen pathways, including ammonia production, require thorough safety testing and

validation, and the variable nature of hydrogen production coupled with a chemical downstream process poses explicit challenges. Commonly, benchmark models are used to test and develop new process control and monitoring techniques. One of the most popular is the Tennessee-Eastman model, which mimics a standard fossil-based chemical process [7]. Many more benchmark models specialized for different niches developed over time, like the fed-batch fermentation model of penicillin production for biochemical applications [8] or the fluid catalytic cracking model for refinery processes [9]. Nevertheless, despite many recent developments, the hydrogen economy lacks an appropriately tailored benchmark model.

In the following, we aim to take the first step in providing a benchmark model that comprises the coupling of a fluctuating green hydrogen supply with a former steady-state chemical process, the HB process. This contribution focuses on designing and dimensioning of process units and control structures using steady-state simulations. We aim to design the HB process to be operable in a wide ammonia production rate range to promote its operation in combination with a variable supply of green hydrogen.

## PROCESS MODELING

We establish a process model for converting green hydrogen from water electrolysis and nitrogen from an air separation unit (ASU) to green ammonia. For realistic process modeling and dimensioning, we use AVEVA Process Simulation software and simulate all process streams based on pressure gradients between unit operations using steady-state simulations. The nominal production capacity of ammonia is defined as 500,000 t/y, but we consider variable product loads ranging from 30 to 130 % of its nominal value. The minimal purity of the produced ammonia is set to be 99.9 mol-%. We include a measurement and control structure in our process model comparable to real industrial systems to ensure feasible operation under different loads.

Figure 1 illustrates the process flowsheet and its separation into three sections: The feed stream compression, the ammonia reactor, and the ammonia purification. In the first section, multi-stage compression adjusts the feed streams to the favorable reactor operating conditions. In the ammonia reactor, the feed gases are converted to ammonia. Here, we model an industrial reactor system with advanced heat integration to recover the heat of the reaction. After the reactor, unreacted hydrogen and nitrogen are separated and recycled. Subsequently, the ammonia is purified to match the fixed purity constraint. In the following subsections, we explain the modeling of each part in detail and explicitly focus on the implemented control structure. Thereafter, we briefly describe the challenges posed by dimensioning the process units under variable loads.

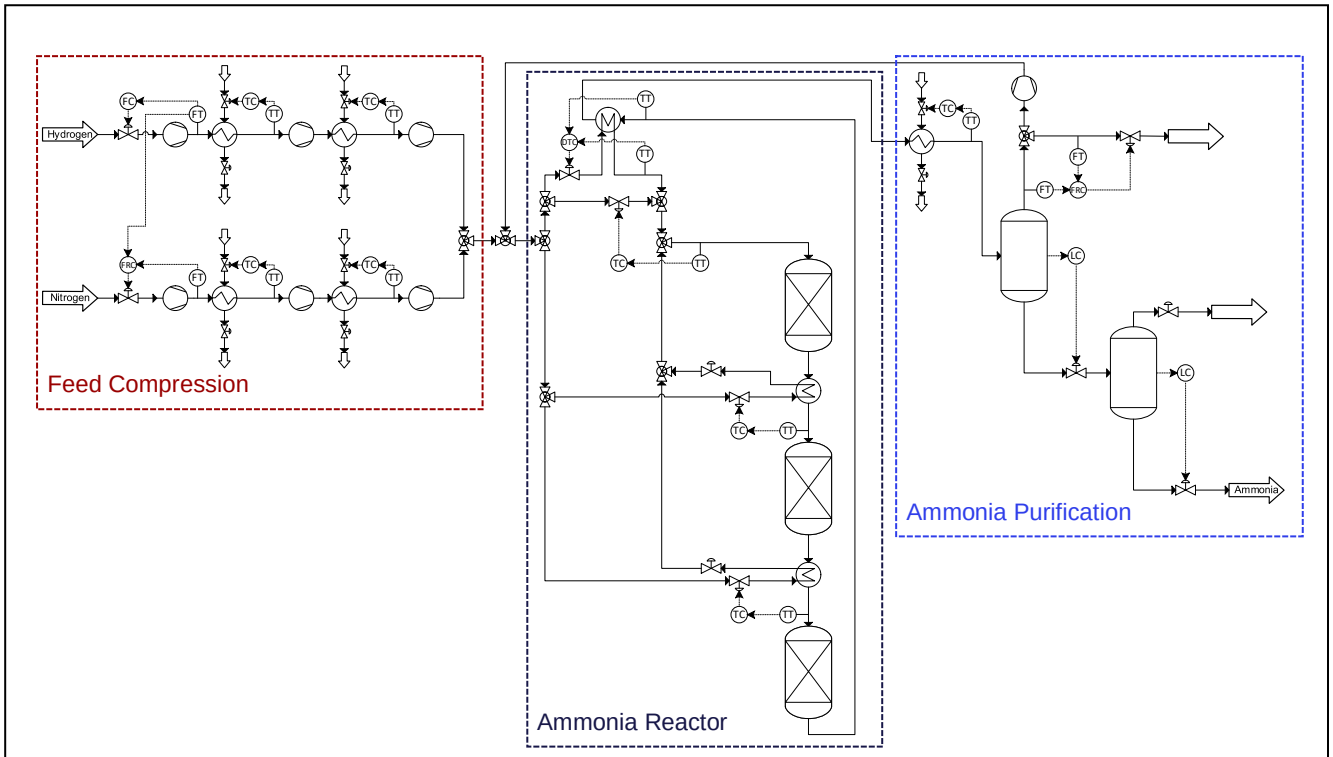

**Figure 1:** Process flowsheet of the Haber-Bosch process for green ammonia production separated into three sections: Feed compression, ammonia reactor, and ammonia purification

## Section 1: Feed Compression

For the feed streams, we consider pure hydrogen from a proton exchange membrane (PEM) electrolysis at 10 bar and 80 °C and nitrogen from an ASU at 10 bar and 25 °C with a small argon impurity (0.5 mol-%). We use the Soave-Redlich-Kwong equation of state model to capture nonidealities of the thermodynamic properties in the vapor phase. The feed streams are compressed by various compressors to reach the favored reactor pressure range from 100 to 250 bar. Each compressor is modeled with an adjusted adiabatic gas head curve, an isentropic efficiency of 75 %, and polytropic correction factors from Sandberg and Colby [10]. Between the three compressor stages, the gas streams are cooled to 50 °C to improve the compression efficiency. A flow controller adjusts the hydrogen inflow to simulate varying hydrogen supply. Last, to realize a nearly stoichiometric mixture of the reactants in front of the ammonia reactor, the nitrogen inflow is adjusted by a mass flow ratio controller.

## Section 2: Ammonia Reactor

Different types of ammonia reactors are operated in industry. All consist of multiple beds and different kinds of heat integration [11,12]. The adiabatic quench-cooled reactor (AQCR) is the most common in former fossil-based plants because of its comparatively easy control. However, because of higher conversion rates, the internal direct-cooled reactor (IDCR) and the adiabatic indirect-cooled reactor (AICR) are favored in new ammonia plants [11]. Our model focuses on the AICR type with three beds and interbed cooling using the feed stream. The bed inlet temperatures are controlled by adjusting the stream to the reactor feed effluent heat exchanger (FEHE) and the interbed heat exchangers. For a similar reactor setup, Rosbo *et al.* (2024) [11] showed that stable operation under varying loads can be obtained.

The control ability for the AICR is achieved by splitting the reactor feed inlet into four substreams. The first substream recovers heat from the reactor outlet in the FEHE. To operate the FEHE at a constant capacity, its tube mass flow is adjusted by a flow controller so that the minimal temperature difference between the shell inlet and tube outlet remains steady at 8 °C. Flow controllers also adjust the two substreams used for cooling in the interbed heat exchangers. Accordingly, the bed inlet temperatures of the second and third reactor beds can be constantly controlled to 650 K. The fourth substream is a bypass that is mixed with the three preheated substreams to adjust the temperature of the first reactor bed to 650 K. The split of the reactor feed stream enables controlling the bed inlet temperatures while efficiently integrating heat produced by the exothermic reaction

$$3\,\mathrm{H_2} + \mathrm{N_2} \rightarrow 2\,\mathrm{NH_3} \text{ with } \Delta \mathrm{H}_R = -92\ \mathrm{kJ/mol}. \qquad (1)$$

The reaction in the reactor beds is implemented with the Temkin-Pyzhev kinetic using kinetic and catalytic parameters from Mordu and Skogestad (1998) [13]. A separate plug flow reactor models each reactor bed, and the beds' dimensions increase to counteract the lower reaction rates at higher product fractions (see Table 1). The reactor operating pressure varies with the load; at nominal load, the pressure in front of the first reactor bed is about 210 bar. The occurring pressure drop over the reactor beds is calculated with the Ergun equation assuming a void fraction of 0.33 and an average particle diameter of 8 mm. Overall, the performance of the three-bed AICR can be calculated by the single-pass hydrogen conversion

$$X_{\mathrm{Single}Pass\ \mathrm{H_2}} = 1 - \dot{n}_{\mathrm{AICR\ Out\ H_2}} / \dot{n}_{\mathrm{AICR\ In\ H_2}}. \qquad (2)$$

**Table 1:** AICR beds' and flash drums' dimensions

| | Diameter D | Length L | Volume V |
|---|---|---|---|
| **AICR** | | | |
| Bed 1 | 2 m | 6 m | 18.84 $m^3$ |
| Bed 2 | 2.5 m | 7.5 m | 36.80 $m^3$ |

## Section 3: Ammonia Purification

The reactor effluent contains about 25 mol-% ammonia, unreacted hydrogen and nitrogen, as well as the inert gas argon. In the first step, the unreacted reactants are recovered using a flash separator at reactor pressure and 20 °C. Subsequently, we recycle the flash's top stream and merge it with the incoming feed streams before the reactor. However, 1 % of the recycle stream must be purged to prevent the accumulation of the inert gas argon. We stabilize the purge rate with a mass flow ratio controller that adjusts the opening of the purge valve. Eventually, the bottom stream of the first flash drum contains 98 mol-% ammonia and is purified further in a second unit at 16.8 bar. Table 1 shows the dimensions of both flash drums. The liquid levels in both separators are controlled by level controllers adjusting the respective liquid outflows. After the two-step flash separation, we obtain 99.9 mol-% pure ammonia.

## Dimensioning of Process Units

All process units are sized to be operatable for the above-mentioned ammonia load range. In particular, the valves and heat exchangers must be dimensioned precisely so that the control structure properly functions in the pressure-controlled fluid flow simulations. Accordingly, the valve flow coefficients $C_V$ are adjusted to be applicable for varying mass flows, and the areas of the heat exchangers are defined so that the minimal temperature differences can be calculated to about 10 °C. Hereby, we assume the overall heat transfer coefficients

U for internal heat integration to be 500 kW/kmol/K and for cooling 400 kW/kmol/K. The cooling medium is water at 15 °C and 1.5 bar, and flow controllers regulate the cooling flows to achieve the set process temperatures. With the precise sizing of each process unit, we ensure feasible process operation within a wide operating range from 30 to 130 % with respect to the nominal ammonia production rate.

## SIMULATION RESULTS

In our simulation study, we vary the ammonia production rate from 30 to 130 % of its nominal value. With the implemented control structure, the process model can adapt autonomously to the changing load conditions and adjust the feed flow rates, cooling water flow rates, and rector feed split rates. Further, the respective controllers keep the liquid levels in the flash drums and the purge ratio constant. Detailed results supporting the above-mentioned claims are shown and discussed below.

Figure 2 illustrates the linear increase of the feed mass flows of hydrogen and nitrogen for a rising ammonia rate. At the nominal ammonia load of 1370 t/d, the molar ratio of hydrogen and nitrogen in the reactor feed stream matches the stochiometric mixture of the reactants in Equation 2. At different ammonia loads, the recycle stream composition is altered because of varying reaction rates, which also affects the composition of the reactor inlet stream. However, by controlling the nitrogen feed rate according to Equation 1, we stabilize the reactor inlet stream composition for all ammonia demands, and the molar ratio of hydrogen and nitrogen only diverges slightly from its nominal value of three.

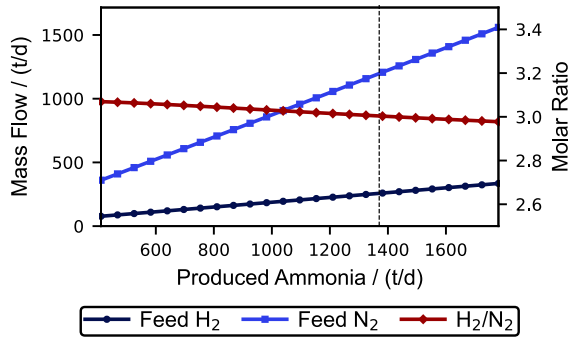

**Figure 2.** Feed streams mass flows and reactants ratio in front of the ammonia reactor for varying ammonia production rates

Since the reactor feed composition remains almost constant, changes in the reaction rate mainly depend on the AICR bed inlet temperatures and operating pressure. The reactor operating pressure is freely adjusted as described by Fahr *et al.* (2023) [14] in detail and enables effective usage of the hydrogen supply. This operation results in a constant high total hydrogen conversion of about 94.5 mol-% while meeting the ammonia purity constraint (refer to Figure 3). The changes in the reactor pressure result in bounding the single pass conversion to relatively little variations (23.7 to 36.1 mol-%) compared to its nominal value of 34 mol-% and, thus, stabilize the AICR's performance for varying ammonia loads. Our results align with those of Rosbo *et al.* (2024) [11], who found very similar conversion rates for their AICR model.

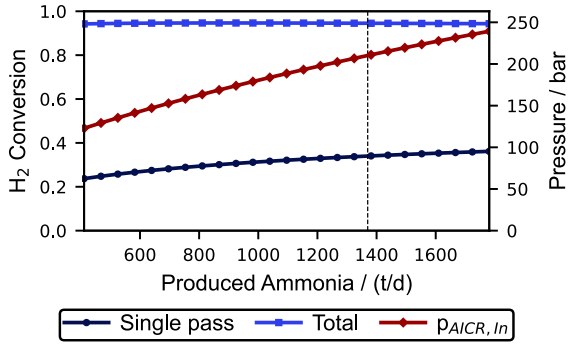

**Figure 3.** Molar hydrogen conversion and AICR inlet pressure for varying ammonia production rates

Contrasting the automatically adjusting reactor pressure, we set the AICR beds' inlet temperatures to 650 K. The temperatures are controlled with four mass flow controllers adapting the mass flows to the reactor FEHE, bypass, and interbed heat exchangers by opening and closing the respective valves. Figure 4 displays the interactions of the pre-reactor valves' opening positions and mass flows for different ammonia production rates. For low ammonia loads and thus a small total mass flow, the mass flow to the reactor FEHE is increased to ensure sufficient heat integration. Accordingly, the FEHE always works at the desired capacity independently of the stream conditions in the AICR outlet. For high ammonia production rates, more interbed cooling is necessary to stabilize the beds' inlet temperatures. Thus, the mass flow rates to the interbed heat exchanger are comparatively high for increased ammonia loads. Accordingly, at low ammonia loads, when relatively more heat is integrated, the split mass ratio of the bypass substream is reduced.

The adjusted opening positions of the corresponding valves mostly follow similar relations compared to their respective mass flows. However, the varying total mass flow and the reactor operating pressure also affect the valves' positions. This influence is exemplified by looking at the valve regulating the substream to the FEHE. Here, the split mass flow ratio decreases for higher ammonia rates, though the valve position is controlled to open more. That illustrates the complexity of controlling the mass flows before the AICR beds. Nevertheless, our

dimensioning of valves and heat exchangers resulted in a control structure that fulfills all defined process and product constraints and ensures feasible steady-state operations for the whole ammonia load range.

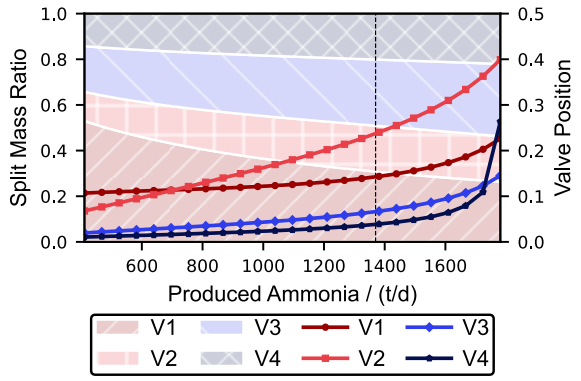

**Figure 4.** Split mass ratios (areas) of the AICR inlet substream to the FEHE (V1), the bypass (V2), the cooling heat exchanger before bed 2 (V3), and the cooling heat exchanger before bed 3 (V4), as well as the corresponding valve positions (lines) for varying ammonia production rates

One objective of flexibly operating green ammonia production is to reduce expensive hydrogen storage. The following exemplary power calculations assume a direct coupling of the PEM electrolyzer and the ASU with the HB plant. The total power demand for the production of ammonia comprises the power to produce hydrogen $P_{\mathrm{PEM}}$ and nitrogen $P_{\mathrm{ASU}}$ as well as the power demand of the HB process $P_{\mathrm{HB}}$, including the power for compressions and neglecting the power for cooling water pumping.

For the hydrogen production via PEM electrolysis, we assume a constant electrolyzer efficiency $\eta_{\mathrm{PEM}}$ of 85 % for all loads compared to the higher heating value [15]

$$P_{\mathrm{PEM}} = \frac{\dot{m}_{\mathrm{Feed\,H_2}} * \Delta \mathrm{H}^0}{\mathrm{M}_{\mathrm{H_2}} * \eta_{\mathrm{PEM}}} \text{ with } \Delta \mathrm{H}^0 = 285.9\ \mathrm{kJ/mol}. \quad (3)$$

In an ASU, gaseous nitrogen is produced as a by-product. Therefore, we do not include the total operational power of an ASU; instead, we only consider the fraction related to the production of pure nitrogen. We assume a linear relation between the ASU's power demand and production rate, according to Anele *et al.* (2015) [16]

$$P_{\mathrm{ASU}}/\dot{m}_{\mathrm{N_2}} = 0.421\ \mathrm{kWh/kg}\,. \quad (4)$$

Figure 5 illustrates that the total power demand is mainly influenced by the power required to produce hydrogen via PEM electrolysis. The power used to produce nitrogen and to operate the HB plant is comparatively low. Therefore, the total power range matches the investigated ammonia load range, stretching from 30 to 130 % with respect to the power demand at nominal conditions. Overall, the variable operation of the investigated system results in a high variability of the total power demand.

From the system's total power, the specific energy demand to produce green ammonia can be calculated by

$$e_{\mathrm{NH_3}} = P_{\mathrm{Total}}/\dot{m}_{\mathrm{NH_3}}\,. \quad (5)$$

Despite varying ammonia loads, the specific energy demand for our process setup varies little and amounts to about 9.6 MWh/t (refer to Figure 5), which is in the range of literature values for renewable ammonia production [4, 6].

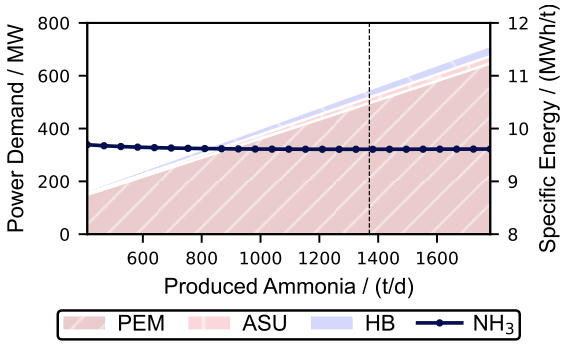

**Figure 5.** Power demand (areas) for hydrogen production via PEM electrolysis (PEM), nitrogen production via air separation (ASU), and the HB plant (HB), as well as the specific energy demand (line) of the ammonia production ($NH_3$) for varying ammonia production rates

Overall, the simulation results depict that the designed ammonia process can efficiently produce green ammonia for a wide range of varying rates. With the implemented control structure, the streams to the ammonia reactor are automatically adjusted, promoting efficient operation. This results in a constant specific energy demand at all production rates due to the primary influence of the PEM electrolyzer.

## CONCLUSION

We presented a new benchmark process model to produce renewable ammonia from green hydrogen through PEM electrolysis and nitrogen from an ASU with an advanced AICR system. The increased attention to flexible ammonia production from variable green hydrogen supply challenges the design of HB plants. In particular, the dimensioning of process units and control structures must be performed carefully. We showed that our precisely dimensioned process model can simulate production for a wide range of green ammonia rates at steady-state. Pivotal for this is the implemented control structure that autonomously controls the AICR operation for high process efficiency.

While the community traditionally relied on the Tennessee Eastman plant for benchmarking studies, this

reference becomes less relevant when studying the dynamics and operational challenges of the renewable hydrogen industry. Therefore, this new benchmarking approach is particularly valuable as it directly addresses the fluctuating nature of renewable hydrogen supply central to renewable ammonia production. In future works, the steady-state ammonia process model can be upgraded to feature transient simulations of dynamic interactions during the process operation, *e.g.*, failures and abnormalities. The obtained dynamic data could be valuable for developing new process safety and monitoring techniques and supporting ongoing innovations in the green hydrogen economy as a novel safety benchmark model.

## ABSTRACT

Graph neural networks (GNNs) have proven state-of-the-art performance in molecular property prediction tasks. However, a significant challenge with GNNs is the reliability of their predictions, particularly in critical domains where quantifying model confidence is essential. Therefore, assessing uncertainty in GNN predictions is crucial to improving their robustness. Existing uncertainty quantification methods, such as Deep ensembles and Monte Carlo Dropout, have been applied to GNNs with some success, but these methods are limited to approximate the full posterior distribution. In this work, we propose a novel approach for scalable uncertainty quantification in molecular property prediction using Stochastic Gradient Hamiltonian Monte Carlo (SGHMC). Additionally, we utilize a cyclical learning rate to facilitate sampling from multiple posterior modes which improves posterior exploration within a single training round. Moreover, we compare the proposed methods with Monte Carlo Dropout and Deep ensembles, focusing on error analysis, calibration, and sharpness, considering both epistemic and aleatoric uncertainties. Our experimental results demonstrate that the proposed parallel-SGHMC approach significantly outperforms Monte Carlo Dropout and Deep ensembles in terms of calibration and sharpness. Specifically, parallel-SGHMC reduces the sum of squared errors by 99.4% and 75%, respectively, when compared to Monte Carlo Dropout and Deep Ensembles. These findings suggest that parallel-SGHMC is a promising method for uncertainty quantification in GNN-based molecular property prediction.

**Keywords**: Uncertainty quantification, graph neural networks, property prediction

## INTRODUCTION

Graph neural networks (GNNs) have demonstrated promising potential in accelerating the computational estimation of molecular properties [1-3]. However, their reliability remains a significant challenge, e.g., in safety-critical applications where understanding model confidence is crucial. Accurately assessing the uncertainty of GNN predictions is essential for enhancing their robustness, particularly when predicting complex molecular behaviors.

Uncertainty in machine learning can generally be divided into two types: aleatoric and epistemic uncertainty [4]. Aleatoric uncertainty arises from inherent noise in the data generation process, such as experimental measurement errors or environmental variations, and is considered irreducible. In contrast, epistemic uncertainty stems from the lack of knowledge of a model, often due to limited data or an incomplete understanding of the process, and can be reduced through additional data collection or improved model design. For instance, in modeling complex chemical reactions, using a more advanced model architecture—such as incorporating reaction kinetics and thermodynamic principles—can reduce

epistemic uncertainty by capturing the process dynamics more accurately. Estimating both types of uncertainty is critical in domains like molecular property prediction, where errors can have substantial consequences.

Two popular methods for jointly uncertainty quantification of machine learning models are Deep ensembles and Monte Carlo Dropout (MC-dropout). MC-dropout [5] applies dropout during both training and inference, generating multiple stochastic forward passes to approximate the posterior distribution of the model. Deep ensembles [6] involves training multiple independent models and averaging their predictions, with the variance among them reflecting the model uncertainty. Although both methods have been widely adopted for scalable uncertainty estimation in molecular property prediction [7], they have some limitations. Deep ensembles primarily focus on the maximum a posteriori (MAP) estimate, neglecting broader regions of the posterior distribution. Conversely, MC-dropout samples from a single mode, overlooking the possibility of multiple modes in the posterior.

We propose a novel approach using Stochastic Gradient Hamiltonian Monte Carlo (SGHMC) [8] to quantify the uncertainty of GNNs for molecular property prediction task. Specifically, we incorporate a cyclical learning rate, which combines the strengths of both sampling strategies and has been successfully utilized in medical imaging domain [9]. We benchmark the proposed SGHMC method against Deep ensembles and MC-dropout on molecular property prediction tasks. Specifically, we evaluate the models with three different metrics: Error analysis, calibration, and sharpness.

# METHODS

## Preliminary

To quantify the uncertainty of GNNs in molecular property prediction tasks, the aim is to transform a single prediction (aleatoric uncertainty) and a deterministic weight (epistemic uncertainty) into a distribution, respectively [10]. For aleatoric uncertainty, the mean-variance estimation is often considered as the most practical approach. The mean-variance approach is simply splitting the last layers of neural networks to predict both mean $\mu(x)$ and variance $\sigma^2(x)$ of Gaussian distribution $N(y;\mu(x),\sigma^2(x))$. Therefore, during the inference time, the test case $y_i = \mu(x_i) + \epsilon(x_i)$ where $\epsilon \sim N\left(0,\sigma^2(x_i)\right)$. Additionally, the corresponding objective function (Eq. 1) becomes minimizing the Gaussian negative log-likelihood (NLL) loss function:

$$NLL(w) = \frac{1}{N}\sum_{i=1}^{N}\frac{1}{2}\left[\frac{1}{\sigma_w^2}(x_i)\left(y_i - \mu_w(x_i)\right)^2 + \log\left(2\pi\sigma_w^2(x_i)\right)\right] \quad (1)$$

Moreover, the Bayesian approach is used to get the epistemic uncertainty, which essentially approximates the prior distribution $p(w|D) \propto p(w)p(D|w)$. Therefore, during the inference time on a test case: $x_i$ :

$$p(y_i|x_i, D) = \int_w p(w|D)p(y_i|x_i, w)\, dw \quad (2)$$

However, in reality, the prior distribution and the integral are intractable. Therefore, they are commonly approximated with MC integration over samples $w_i$ drawn from an approximate posterior distribution $q(w)$:

$$p(y_i|x_i, D) = \frac{1}{M}\sum_{j=1}^{M} p(y_i|x_i, w_j),\ w_j \sim q(w) \quad (3)$$

## SGHMC

The proposed SGHMC [9] algorithm samples from the posterior distribution based on the Hamiltonian equation of motion. The Hamiltonian function is given by:

$$H(q,r) = U(q) + K(r) \quad (4)$$

where an object moves on a potential energy surface $U(q)$ with kinetic energy $K(r)$ where $q$ represents the positions and $r$ represents the momenta. Using the canonical distribution (probability of the states based on the energy), the joint probability distribution over positions and momenta can be defined as:

$$p(q,r) \propto e^{-H(q,r)} = e^{-U(q)}\, e^{-K(r)} \quad (5)$$

When the potential energy $U(q)$ is expressed as the NLL of the model combined with a prior, the canonical distribution with respect to $U(q)$ corresponds to posterior distribution of the model parameters $w$. Minimizing $U(w)$ is equivalent to finding the mode of the posterior distribution:

$$U(w) = -\log[p(w|D)] = NLL(w) + \lambda\left|\left|w\right|\right|^2 \quad (6)$$

The choice of distribution over momenta $r$ can be arbitrary. Here, we chose a quadratic form for the kinetic energy:

$$K(r) = \frac{1}{2}r^T M^{-1} r \quad (7)$$

resulting in Gaussian distribution over $r$. The mass matrix $M$, typically set to the identity matrix for simplification [11].

Therefore, the dynamics in the end are governed by equations:

$$dw = M^{-1} r\, dt \quad (8)$$

$$dr = -\nabla U(w)\, dt \quad (9)$$

Additionally, to address the computational challenge of evaluating the full gradient $\nabla U(w)$ in large datasets, SGHMC uses a noisy gradient estimate $\nabla\widetilde{U}(w)$ based on mini-batches. The introduced noise can be mitigated by a friction term A in the momentum update:

$$r_i = r_{i-1} - \nabla\widetilde{U}(w_{i+1})h - Ar_{i-1}h + \sqrt{2AhT}N(0, I) \quad (10)$$

This formulation is similar to SGD with momentum but includes an additional Gaussian noise term, controlled by temperature $T$. The temperature modulates the sensitivity of the posterior distribution to the potential energy: $T = 1$ yields the standard Bayesian posterior, $T < 1$ (cold posterior) increases sensitivity to low-loss regions, while $T > 1$ broadens exploration at potential cost of accuracy.

## Evaluation metric

The quality of uncertainty estimates in predictive models can be assessed using three key metrics: error analysis, calibration, and sharpness. For the metric error analysis, we utilize the root mean square error (RMSE) and the coefficient of determination (R2). Calibration methods assess how well predicted uncertainties align with observed errors. Here, we utilize two metrics: NLL and sum of squared errors (SSE). Rather than only using the NLL as a loss function during training, it is also used as a quantitative measure to assess the quality of the predictive distribution after training. SSE measures the total squared error between the predicted quantiles and the observed empirical quantiles. If the SSE is small, it means that the predictions of the models are well-calibrated with respect to the observed data. Sharpness measures the informativeness of uncertainty estimates with root mean predicted variance (RMV) and coefficient of variation $C_v$. Specifically, RMV is denoted as:

$$RMV = \sqrt{\frac{1}{n}\sum_{i=1}^{n} \widehat{\sigma_i^2}} \tag{11}$$

where $\widehat{\sigma_i^2}$ is predicted variance or uncertainty. A low RMV indicates the model on average predicts low uncertainty and thus low expected error. Additionally, $C_v$ is denoted as:

$$C_v = \frac{\sqrt{\frac{1}{N}\sum_{i=1}^{N}(\hat{\sigma}_i - \sigma_*)}}{\sigma_*} \tag{12}$$

where $\hat{\sigma}_i$ is the predicted standard deviation (uncertainty) of instance $i$ and $\sigma_*$ is the mean predicted standard deviation. A high $C_v$ suggests significant dispersion (heteroscedasticity), indicating that uncertainty estimates are highly dependent on the input. In contrast, a $C_v$ of zero indicates constant (homoscedastic) uncertainty, meaning the estimates are uninformative and do not vary with the input [10].

## Experiment design

The dataset used is the QM9 benchmark [12], consisting of 132,481 small organic molecules (CHONF) with 13 target properties, evaluated at the B3LYP/6-31G(2df,p) level. An 80:10:10 train/validation/test split was applied, using heat capacity at 298.15 K as the target property. The Directed Message Passing Neural Network (D-MPNN) is used as a base model implemented in Chemprop [13], with a mean-variance output and heteroscedastic noise model. The models contain three message passing layers and two feed-forward layers, each with a hidden size of 300.

All uncertainty methods were optimized using the Gaussian NLL loss function with a regularization parameter of $\lambda$ = 0.0001. The initial learning rate was set to 0.01, with an exponential decay (γ = 0.95) and a batch size of 50. MC-Dropout models are trained for 216 epochs with the SGD optimizer and a dropout rate of $p$ = 0.1, and 24 predictions are collected for the ensemble with different dropouts. Deep Ensemble models are trained for 650 epochs with the SGD optimizer (momentum $m$ = 0.9), with three ensemble predictions from different models. Parallel-SGHMC models are trained for 650 epochs with SGHMC (momentum $m$ = 0.9), with noise injected at $T$ = 0.01 after 60% of training. Posterior samples were collected every ten epochs after noise injection. 24 ensemble predictions are collected from posterior samples. To explore multiple local modes of the posterior, we additionally propose Cyclical-SGHMC model. It uses four cycles within a 650-epoch budget, with a reset learning rate of 0.00025 after the first cycle. Noise was injected with $T$ = 0.01 after 60% of each cycle. Similarly, 24 ensemble predictions are collected from posterior samples. All simulations ran on a Windows server with a 3.5 GHz 24-core Intel(R) Xeon(R) W-2265 CPU, an NVIDIA GeForce RTX 3090 GPU, and 64 GB of memory.

Figure 1 provides a conceptual representation of various posterior sampling strategies employed during a single training process. The x-axis represents the model parameter space www, while the y-axis shows the posterior probability distribution $P(w|D)$ given the data $D$. The black curve represents the posterior distribution with multiple modes. Deep Ensembles typically sample from a single local mode within a training cycle, limiting their ability to explore the broader posterior distribution. In contrast, both MC-Dropout and parallel-SGHMC exhibit similar sampling behaviours, generating multiple samples from the local regions surrounding the current mode. Notably, cyclical-SGHMC offers a more robust exploration of the posterior by sampling from multiple regions across different modes, facilitated by its cyclical learning rate, which enables escape from local minima and exploration of diverse posterior landscapes.

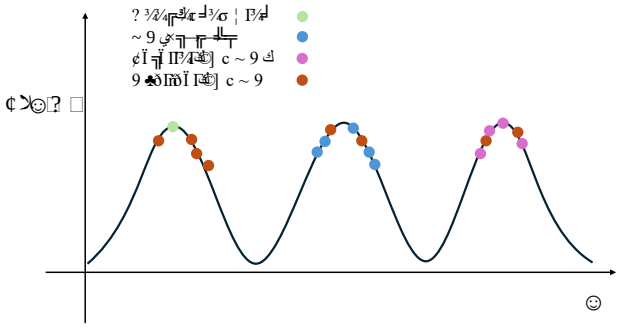

**Figure 1.** Conceptual representation of the different

**Table 1:** Uncertainty quantification results from four different models. RMSE stands for the root mean square error, R2 for coefficient of determination, SSE for the sum of squared errors, NLL for the negative log likelihood, RMV for the root mean predicted variance, and CV for coefficient of variation.

| Models | Error | | Calibration | | Sharpness | |
|---|---|---|---|---|---|---|
| | RMSE↓ | $R^2$↑ | SSE↓ | NLL↓ | RMV↓ | $C_V$↑ |
| Parallel-SGHMC | 0.6650 | 0.9735 | 0.0003 | -0.4921 | 0.5137 | 2.0178 |

posterior sampling strategies for one training process employed by Deep ensembles, MC-dropout, parallel-SGHMC, and cyclical-SGHMC.

## RESULTS AND DISCUSSION

Table 1 presents the performance of four uncertainty quantification models - parallel-SGHMC, cyclical-SGHMC, MC-Dropout, and Deep ensemble - on key evaluation metrics, including error, calibration, and sharpness.

In terms of error analysis, SGHMC-based models demonstrate superior performance with respect to predictive error. Specifically, cyclical-SGHMC achieves the lowest RMSE (0.6156) and the highest $R^2$ (0.9773), indicating that it provides the most accurate predictions. The potential reason is that cyclical-SGHMC samples a richer posterior, capturing parameter uncertainty more effectively than methods like MC-Dropout.

For the calibration category, parallel-SGHMC outperforms the other models with the lowest SSE of 0.0003 and the lowest NLL score of -0.4921. This indicates that its predicted uncertainties are highly aligned with the actual errors, suggesting that this model provides the most reliable uncertainty estimates. Cyclical-SGHMC, with an SSE of 0.0405 and an NLL of -0.3522, also performs well, although its uncertainty estimates are slightly less aligned with the observed errors compared to parallel-SGHMC. By contrast, MC-Dropout and Deep ensemble exhibit poorer calibration performance. Their SSE values of 0.0500 and 0.0012, respectively, and their higher NLL values (0.4678 and 0.4357) suggest that these models tend to overestimate uncertainty. This misalignment between predicted uncertainties and actual errors could lead to less reliable uncertainty estimates in practice, making these models less desirable for applications where accurate uncertainty quantification is important.

In terms of sharpness, parallel-SGHMC performs better than the other models, achieving the lowest RMV of 0.5137 and the highest $C_V$ of 2.0178. This suggests that its uncertainty intervals are narrow and focused, indicating high confidence in its predictions. Cyclical-SGHMC is the next best model with an RMV of 0.6393 and a $C_V$ of 1.6555, providing moderately sharp uncertainty intervals, which reflect a balance between confidence and calibration. On the other hand, MC-Dropout and Deep ensemble exhibit significantly less sharp uncertainty estimates, with RMV values of 0.9167 and 0.7905, respectively. Their lower $C_V$ values (0.9897 for MC-Dropout and 1.0112 for Deep Ensemble) further indicate that these models generate broader uncertainty intervals, reflecting lower confidence in their predictions. While broader intervals can be beneficial in risk-averse or highly uncertain environments, they are less desirable in scenarios where tight confidence bounds are required.

In summary, the parallel-SGHMC model is recommended for tasks requiring accurate predictions, well-calibrated uncertainties, and narrow confidence intervals. Cyclical-SGHMC provides a balanced alternative, while MC-Dropout and Deep ensemble may be more appropriate for scenarios where broader, conservative uncertainty estimates are desired.

## CONCLUSIONS

We proposed a novel approach to perform scalable uncertainty quantification for molecular property prediction with GNNs. Specifically, SGHMC with cyclical learning rate was researched for scalable uncertainty quantification in molecular property prediction with the D-MPNN architecture with mean variance. A comparative study was performed among SGHMC, Deep Ensemble and MC-dropout with the QM9 dataset with the heat capacity target property. Our results indicate that the proposed parallel-SGHMC approach outperforms MC-dropout and Deep ensembles in terms of calibration and sharpness. Specifically, parallel-SGHMC reduces the sum of squared errors (SSE) by 99.4% and 75%, respectively. These findings suggest that parallel-SGHMC is particularly suited for applications requiring narrow confidence intervals, where high precision in uncertainty quantification is essential, such as in safety-critical predictions or regulatory settings in pharmaceutical applications. While Deep ensemble and MC-dropout may offer advantages in scenarios where broader uncertainty bounds are required, such as in early-stage exploratory research.

# pyDEXPI: A Python framework for piping and instrumentation diagrams (P&IDs) using the DEXPI information model

**Dominik P. Goldstein[a], Lukas Schulze Balhorn[a], Achmad Anggawirya Alimin[a], and Artur M. Schweidtmann[a]***

[a] Process Intelligence Research Group, Department of Chemical Engineering, Delft University of Technology, Van der Maasweg 9, Delft 2629 HZ, The Netherlands

## ABSTRACT

Developing piping and instrumentation diagrams (P&IDs) is a fundamental task in process engineering. For designing complex installations, such as petroleum plants, multiple departments across several companies are involved in refining and updating these diagrams, creating significant challenges in data exchange between different software platforms from various vendors. The primary challenge in this context is interoperability, which refers to the seamless exchange and interpretation of information to collectively pursue shared objectives. To enhance the P&ID creation process, a unified, machine-readable data format for P&ID data is essential. A promising candidate is the Data Exchange in the Process Industry (DEXPI) standard. We present pyDEXPI, an open-source implementation of the DEXPI format for P&IDs in Python. pyDEXPI makes P&ID data more efficient to handle, more flexible, and more interoperable. We envision that, with further development, pyDEXPI will act as a central scientific computing library for the domain of digital process engineering, facilitating interoperability and the application of data analytics and generative artificial intelligence on P&IDs. We provide the pyDEXPI package with the documentation on GitHub at https://github.com/process-intelligence-research/pyDEXPI.

**Keywords**: Piping and instrumentation diagram, DEXPI, FAIR data, Data model, Software toolbox, Open-source

## 1. INTRODUCTION

Piping and instrumentation diagrams (P&IDs) are chemical engineering diagrams that depict the process equipment, piping, pumps, instruments, valves, and further fittings of a chemical plant [1]. They act as a central, interdisciplinary reference document throughout the plant's life cycle including construction, start-up, and operation [2]. For large-scale plants, such as petrochemical processes, P&IDs may span over 1000 pages, containing a vast amount of engineering data.

For such complex projects, many different departments from several companies and parties need to work together to plan, construct, and operate the process plant. The parties involved in this include engineering, procurement, and construction companies, owner-operators, vendors, site services, and authorities. A seamless exchange of P&ID data between contributors is crucial. In reality, however, this seamless exchange is obstructed by the lack of interoperability between different Computer-Aided Engineering (CAE) software systems and other systems used by the participating stakeholders. The software systems use different underlying data representations of the P&IDs, and it is difficult to extract information from these data representations to use in different software.

Missing interoperability of P&ID data representations not only hinders effective engineering workflows but also disrupts the adoption of novel digital process engineering tools, including data analytics or generative artificial intelligence (GenAI) [3]. Recent research works have demonstrated the potential rooted in GenAI to

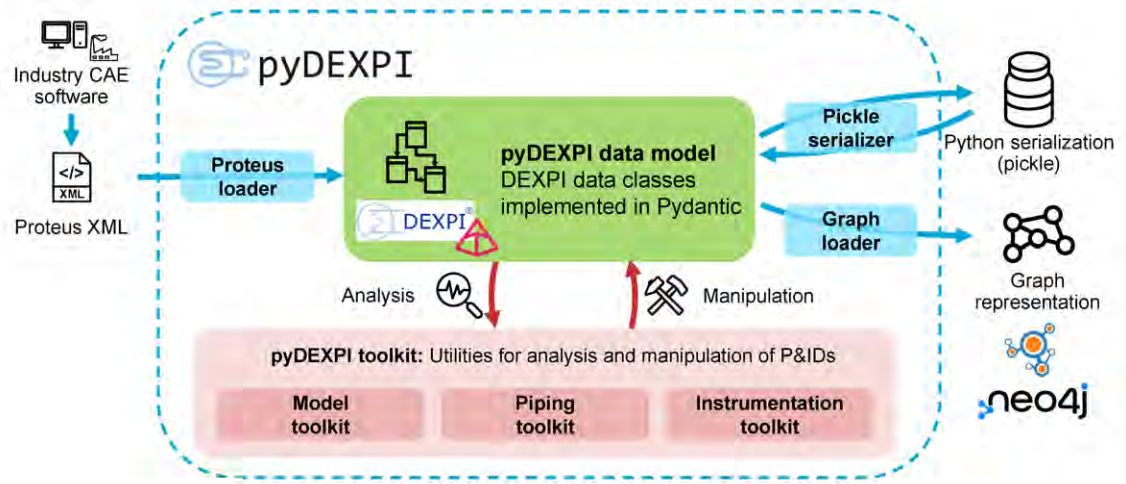

**Figure 1:** Overview of the pyDEXPI functionality. The Python implementation of the DEXPI data classes lies at the heart of the package (green). The package includes import and export of data (blue), and toolkit functionality for analysis and manipulation (red).

assist, automate, and improve the engineering process [4-9]. However, missing interoperability causes a lack of machine-readable data and hinders the integration of solutions into existing systems. To enable seamless exchange of P&ID data and facilitate integration of novel digital process engineering tools, a unified, machine-readable data format for P&ID data is necessary.

An emerging exchange format for P&ID data is the Data Exchange in the Process Industry (DEXPI) data format [10]. It defines a data model for P&IDs intended to facilitate the handover of data across CAE software. The DEXPI format was developed by the DEXPI initiative, which is supported by several industrial software vendors and chemical engineering companies. However, there is no open-source implementation of the DEXPI class framework. This makes it difficult to use this framework for interoperable data exchange in practice, and the application in digital process engineering.

To address the need for an open-source implementation of the industry-compatible DEXPI framework, we have created pyDEXPI, which implements the DEXPI information model for Python (Figure 1). P&ID data can be imported to pyDEXPI from DEXPI-conform Proteus XML files, saved in Python pickle files, and exported to NetworkX graphs. Within pyDEXPI, a model toolkit allows the analysis and manipulation of P&ID data, e.g., by retrieving certain objects with attributes of interest or reconnecting piping connections. With pyDEXPI, we aim to provide an interoperable and accessible informatics package for P&ID data.

## 2. DEXPI: DATA EXCHANGE FOR THE PROCESS INDUSTRY

The DEXPI initiative has defined the DEXPI information model with support from industrial software vendors, chemical companies, and academic partners. The objective of the information model is the definition of a system-independent, uniform data model for P&ID data that can be exported and imported by participating CAE software vendors [10]. The established version of DEXPI is Version 1.3, although the newest Version 1.4 was recently published in December 2024. The DEXPI data model defines a set of data classes and their relationships. DEXPI P&IDs are exchanged in the Proteus XML schema [11], therefore, the DEXPI specification also outlines how the data model is mapped into this XML schema.

The DEXPI 1.3 specification defines 473 data classes, data types, and enumerations organized into 11 packages. The packages are *DexpiModel*, *MetaData*, *PlantStructure*, *Equipment*, *Piping*, *Instrumentation*, *Customization*, *Enumerations*, *PhysicalQuantities*, *Graphics*, and *DataTypes*. The classes have five properties that define the class relationships and the stored information. First, a DEXPI class can have a set of supertypes, from which it inherits all properties. Second, a class can have subtypes, to which it passes on its properties. This is the inverse of the supertype relationship. Third, a class has a set of compositional attributes, which are lower-level DEXPI classes that the class conceptually consists of. Fourth, a class has reference attributes, which can be all other references to DEXPI classes that do not constitute a composition, such as the target of a pipe. Finally, a DEXPI class can have a set of data attributes, which store the class information in the form of basic data types or enumerations. The data types and enumerations are also defined within the DEXPI framework. For more details on

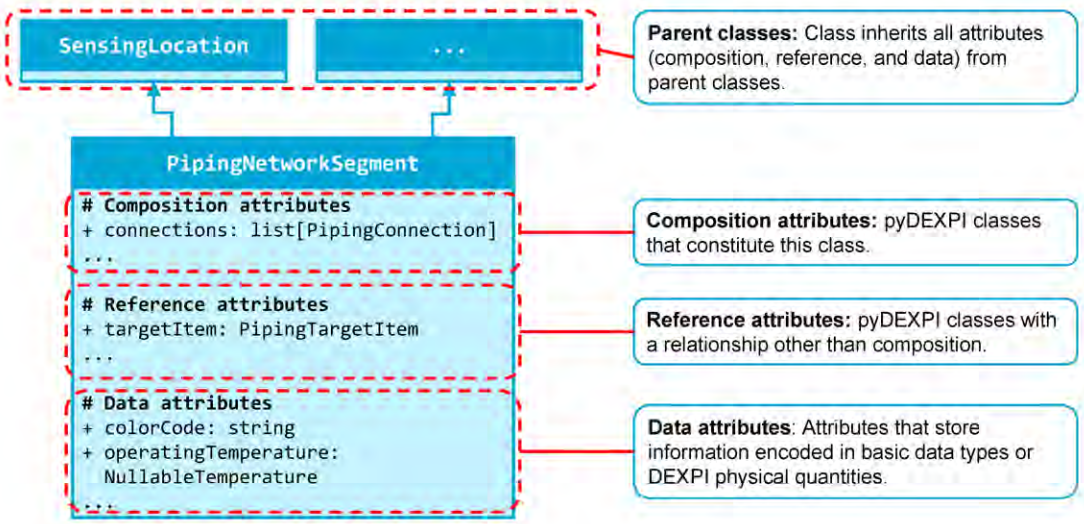

**Figure 2:** The partial UML diagram of the pyDEXPI class *PipingNetworkSegment* with an example parent class and example attributes.

the DEXPI information model, we refer the reader to the specification of the DEXPI information model [10].

While the DEXPI framework is a promising format for interoperable P&ID data, there was no open-source implementation available. The main, openly available tool for examining data in a DEXPI format is the P&ID Verificator [12]. This application has a comprehensive user interface to visualize a P&ID, investigate the underlying data model, and display verification messages. However, it is not open-source and has no interfaces for other software, which prevents it from being used for further applications beyond DEXPI data verification. Typically, DEXPI data is only exchanged via the Proteus XML schema. However, this is difficult to apply in practice due to the inconsistent design of Proteus XML and DEXPI [10]. Since no prior open-source implementation exists, the value of DEXPI for interoperability and its applicability for GenAI is limited.

## 3. THE PYDEXPI PYTHON PACKAGE

The pyDEXPI package provides an implementation of the DEXPI class framework in Python. Data can be imported and exported in several formats. To make the data more accessible to users, pyDEXPI also includes functionality to analyze and manipulate P&ID data. An overview of the functionality of pyDEXPI is depicted in Figure 1.

### 3.1. Implementation of the DEXPI information model as Python data classes

At the heart of pyDEXPI lie the data classes of the DEXPI information model. They are implemented as data classes of the Pydantic Python package [12], which specializes in data modeling and validation. The classes are organized into Python packages corresponding to the DEXPI framework's packages. All pyDEXPI classes inherit from a common base class called *DexpiBaseModel*, which defines some common behavior to use them effectively in Python programming. This includes defining a UUID for each class instance and assigning a new UUID if an object is copied. The data types of DEXPI are also implemented as Pydantic classes but inherit from a different common base class *DexpiDataTypeBaseModel*. This is because data types require different behavior than normal data classes. For example, a data class does not require an ID, but an evaluation of equality. The DEXPI classes representing basic data types, such as strings and integers, are omitted and replaced with the corresponding inbuilt data types of Python. The enumerations of DEXPI are implemented as Python enumerations.

The pyDEXPI classes implement the characteristics of the DEXPI classes with Python programming concepts. The class supertype relationship is implemented using regular class inheritance. Each class has the pyDEXPI classes corresponding to its supertypes as parent classes. This also covers the inverse, subtype relationship of DEXPI. Furthermore, each pyDEXPI class defines a set of attribute fields. The attribute fields have type annotations with the required data type defined in DEXPI, and the type annotations are enforced by Pydantic data validation. To distinguish between composition, reference, and data attributes, the pyDEXPI attribute fields are annotated with an additional indicator using the Pydantic field annotations functionality. The indicator *attribute_category* takes the values *composition*, *reference*, or *data*.

To illustrate the structure of a typical pyDEXPI class, Figure 2 depicts the partial UML diagram of the pyDEXPI

class *PipingNetworkSegment*. A *PipingNetworkSegment* is a child of *SensingLocation*, among others, and inherits all its attributes. A *PipingNetworkSegment* consists, among others, of *PipingConnections* which compose the segment as compositional attributes. In contrast, a *PipingNetworkSegment* references a *PipingTargetItem* as its target. The target item, which may be an equipment nozzle, for example, is in the compositional hierarchy of a different class. Finally, a *PipingNetworkSegment* contains a set of data attributes, which are stored in basic data types or pyDEXPI physical quantities.

### 3.2. Importing and exporting data with pyDEXPI

While the pyDEXPI class model established the structural foundation of the package, pyDEPXI also includes functional components to enable practical application for data import, export, and manipulation. These are essential for the effective utilization of pyDEXPI in data science applications. Most importantly, this includes importing and exporting of P&ID data in different formats.

pyDEXPI includes several possibilities for importing, exporting, loading, and saving data. The most notable import functionality is the import of P&ID data from DEXPI-conform Proteus XML files. This interface enables importing data extracts from DEXPI-compliant CAE tools, which unlocks access to a vast repository of P&ID data. Further, pyDEXPI supports saving and loading data quickly and easily in a Python pickle format.

Although pyDEXPI proposes a unified framework for the handling of P&ID data, downstream data analytics tasks require P&ID data in different formats and granularities to fit the needs of the method applied [3]. pyDEXPI supports exporting data as a graph, in the form of a NetworkX graph object. A P&ID is expressed as a graph intuitively since P&IDs depict the piping and signal connections between process equipment. Furthermore, a graph representation facilitates the application of novel graph machine-learning techniques for advanced P&ID tasks [3]. While the graph export is a very powerful export format, we envision a plethora of additional export formats, such as sequences like the SFILES 2.0 format [14], tables, etc. to accommodate more data representation requirements.

### 3.3. The pyDEXPI toolkit: Analyzing and manipulating P&ID data

Next to importing and exporting P&ID data, pyDEXPI offers some functionality to analyze and manipulate the data. The DEXPI framework of over 400 classes is extensive and includes complex class relationships and implicit rules. Therefore, it is difficult to find and retrieve data of interest from a model. The pyDEXPI toolkit offers methods to maneuver the class framework, e.g., by retrieving all objects in a model of a certain type or with certain attribute values. Further, the toolkits help assist in the modification of pyDEXPI P&IDs by automatically handling the design rules of the DEXPI framework.

The functions are organized in modules with respect to their scope. Model-level functions are grouped into the *model_toolkit*, functions about piping are in the *piping_toolkit*, and functions for instrumentation are found in the *instrumentation_toolkit*.

## 4. OUTLOOK: PYDEXPI IN PRACTICE

We envision pyDEXPI as a central computing library for P&IDs, accommodating expert usability, system interoperability, and data analytics and AI applications. Our vision is illustrated in Figure 3.

pyDEXPI already offers several utilities for P&ID data interoperability. On the one hand, integration with existing systems is available via the import of DEXPI-conform Proteus XML files. On the other, the pyDEXPI toolkit acts as a programming interface that makes P&ID data more accessible to users. We anticipate an expansion of the current functionality, e.g., by exporting data back into the interoperable Proteus XML format or by including a graphical interface for direct user interaction with P&ID data. Furthermore, we expect an expansion of pyDEXPI's capabilities for importing and exporting P&ID data in formats suitable for data analytics and AI tasks.

In some of our current work, we already demonstrate the value of pyDEXPI for data analytics and generative AI projects [3]. We envision that computer vision algorithms [15] with digitize image-/paper-based P&IDs and represent them as pyDEXPI P&IDs in the future. This makes them available to further, downstream GenAI applications. Schulze Balhorn et al. [16] propose autocorrection of P&ID based on a graph representation that is generated automatically from pyDEXPI. The algorithm detects errors in P&IDs through rule- and AI-based methods and replaces these with a corrected version. Alimin et al. [17] use P&ID graphs from pyDEXPI as inputs to large language models (LLM). This approach enables the LLM to retrieve information from the P&ID during text generation. Engineers interacting with such LLMs can easily access P&ID information through conversational queries, eliminating the need for manual lookup. This can assist with many time-intensive engineering tasks, such as hazard and operability studies (HAZOPs). In a notable contrast to previous work on AI on P&IDs, these case studies can leverage the interoperability of the pyDEXPI framework to interact with other tools and services, and potentially be integrated as plugins or services in different, existing CAE software with limited effort. They will also profit directly from future improvements to the framework.

We expect many more applications of pyDEXPI-based data representations in the future. For the existing

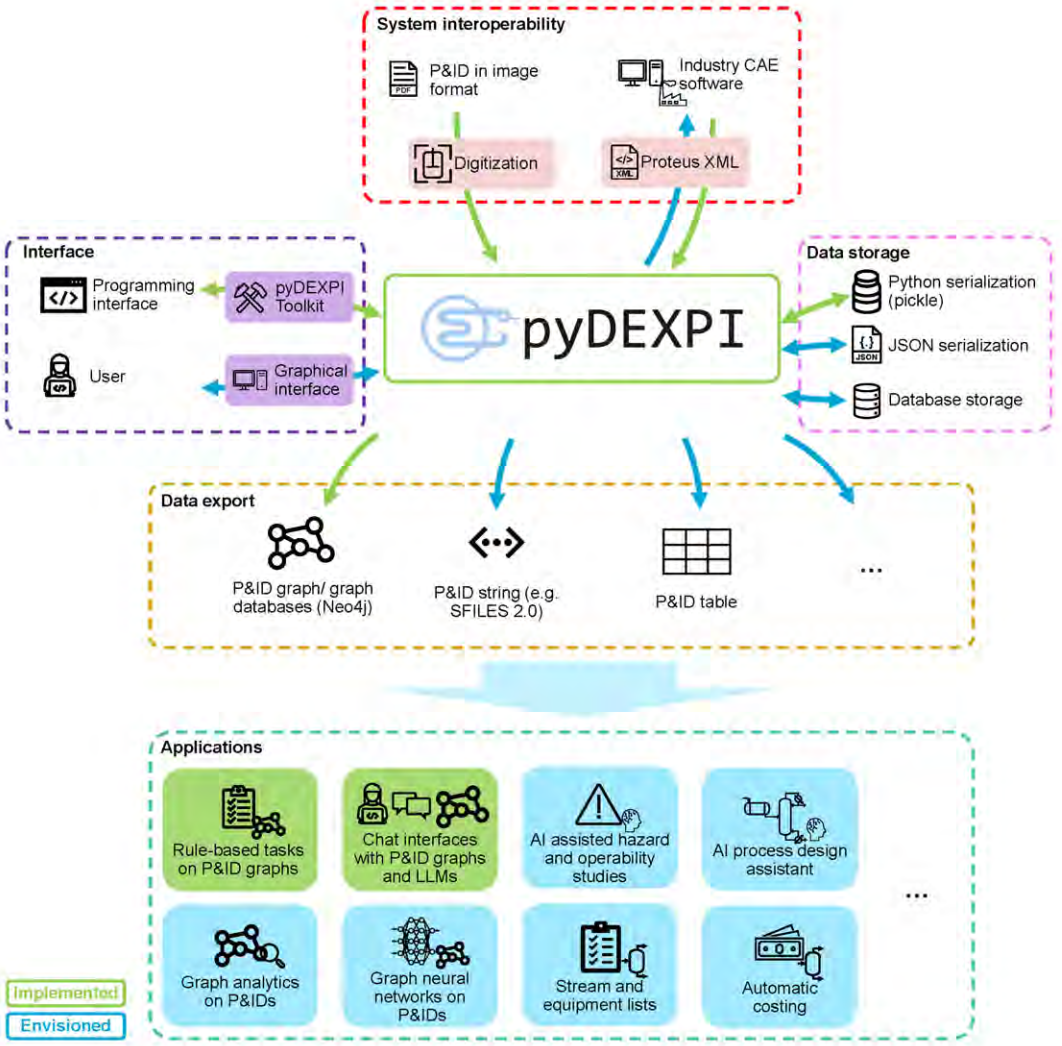

**Figure 3:** Our vision for pyDEXPI: A powerful P&ID informatics package that enables (1) interoperable data exchange between industry systems and import of digitized P&ID images (2) interfacing with users and other systems for P&ID analysis and manipulation (3) Saving and loading P&ID data in a variety of formats, depending on the requirements (4) Exporting P&ID data to a multitude of machine-readable data formats suitable for downstream data analytics, AI, and GenAI applications.

export of graph representations, future applications can include the use of graph analytics methods or graph neural networks on P&IDs. Additionally, we expect additional data export formats to become available in the future, such as sequences, strings, or tables. This will allow researchers and industry to select the most suitable data representation for their use cases and easily exchange their output with further tools or existing CAE software.

## 5. CONCLUSION

Addressing the need for interoperability for P&ID data, we present pyDEXPI, an open-source Python implementation of the DEXPI specification. pyDEXPI implements the data classes outlined by the DEXPI information model, which is widely supported by industry and research. pyDEXPI can import DEXPI data from the Proteus XML format, save and load it from a Python pickle file, and export it to a graph format suitable for graph data analytics and graph machine learning tasks. We anticipate a substantial expansion of pyDEXPIs data import, export, analysis, and manipulation capabilities, and envision pyDEXPI to become a central data analytics package for P&ID data. Finally, we foresee that pyDEXPI will be an enabling software for future development and adoption of GenAI technologies for the process industry [3].

# Kolmogorov Arnold Networks (KANs) as surrogate models for global process optimization

**Tanuj Karia[a], Giacomo Lastrucci[a], and Artur M. Schweidtmann[a]***

[a] Process Intelligence Research Group, Department of Chemical Engineering, Delft University of Technology, Van der Maasweg 9, 2629 HZ, Delft, The Netherlands

## ABSTRACT

Surrogate models are widely used to improve the tractability of process optimization. Some commonly used surrogate models are obtained via machine learning such as multi-layer perceptrons (MLPs), Gaussian processes, and decision trees. Recently, a new class of machine learning models named Kolmogorov Arnold Networks (KANs) have been proposed. Broadly, KANs are similar to MLPs, yet they are based on the Kolmogorov representation theorem instead of the universal approximation theorem for the MLPs. Compared to MLPs, it was reported that KANs require significantly fewer parameters to approximate a given input/output relationship. One of the bottlenecks preventing the embedding of MLPs into optimization formulations is that MLPs with a high number of parameters (larger width or depth) are more challenging to globally optimize. We investigate whether the parameter efficiency of KANs relative to MLPs can be translated to computational benefits when embedding them into optimization problems and solving them to global optimality. We propose a Mixed-Integer Nonlinear Programming (MINLP) formulation of a KAN and test its effectiveness using a case study on the optimization of an auto-thermal reforming process. We observe that KANs are a promising alternative as surrogate models particularly for cases with low number of inputs or outputs. For surrogate models with higher inputs or outputs, stronger formulations must be developed to improve global optimization of models with KANs embedded.

**Keywords**: Surrogate modeling, Kolmogorov Arnold Networks, Deterministic Global Optimization, Mixed-Integer Nonlinear Programming

## INTRODUCTION

Recent advances in machine learning have paved the way for increased use of surrogate models for mathematical optimization of chemical processes [1]. A large plethora of machine learning models are used for surrogate modeling and optimization, namely Gaussian processes [2], support vector machines [3], decision trees [4], and multi-layer perceptrons [5,6]. Among these models, the use of multi-layer perceptrons is widespread due to their ability to universally approximate any input/output relationship given a nonlinear activation function and a sufficiently high number of neurons in the hidden layer [7].

The most commonly used activation functions for multi-layer perceptrons are Rectified Linear Units (ReLU) and hyperbolic tangent (tanh) functions. Schweidtmann and Mitsos [8] conducted an extensive evaluation of the impact of varying architectures of multi-layer perceptrons embedded into optimization formulations on the computational effort required for deterministic global optimization. They reported that for multi-layer perceptrons with tanh activation function, increasing the size of the MLP makes them more challenging to solve to global optimality [8]. More recently, in a similar study conducted for MLPs with ReLU activation function solved using GUROBI [9], it was reported that GUROBI (v10) struggles to solve modestly deep MLPs containing six hidden layers with 500 neurons each [9].

Recently, a new class of machine learning models called Kolmogorov Arnold Networks (KANs) have been proposed [10]. KANs are based on the Kolmogorov representation theorem, which states that for a given vector $\boldsymbol{x_0}$ of $n_0$ variables, a continuous function $f(\boldsymbol{x_0})$ in a

bounded domain $\mathcal{X} \in \mathbb{R}^{n_0}$ such that $f: \mathcal{X} \to \mathbb{R}$ can be expressed with $2n_0 + 1$ additions of function $\Phi$, which is a finite composition of $n_0$ univariate functions $\phi$ [11]. Hence, a network based on the Kolmogorov representation theorem comprises an input layer, a single hidden layer with $2n_0 + 1$ neurons and an output layer. However, these networks are unlearnable in practice since the 1D functions $\phi$ may be non-smooth or fractal [10]. To overcome this issue, Kolmogorov Arnold networks were proposed, which is a generalization of the Kolmogorov representation theorem to consider networks of arbitrary depths and widths [10].

One of the advantages that KANs offer over MLPs is that they require fewer parameters to approximate a given input/output relationship relative to MLPs [10]. Hence, in this study, we aim to investigate whether this parametric efficiency offered by KANs can be translated into computational efficiency for deterministic global optimization of models with surrogate models embedded. We propose a Mixed-Integer Nonlinear Programming (MINLP) formulation of a KAN. We test the effectiveness of the formulation by considering the case study on optimization of the auto thermal reforming process [12]. Additionally, we also compare the performance of KANs with ReLU networks of varying architectures with deterministic global MINLP solver SCIP (v9.2) [13].

## BACKGROUND

For a Kolmogorov Arnold Network with $L + 1$ layers, including the input and output layers, the number of neurons in each layer is defined by the vector $\boldsymbol{N} := [n_0, n_1, \ldots, n_l, \ldots, n_L]$. Here, $n_0$ is the number of inputs, $n_l$ is the number of neurons in the $l^{th}$ layer of the KAN and $n_L$ is the number of neurons in the final layer $L$ equivalent to the number of outputs from the KAN, as shown in the directed acyclic graph in Figure 1.

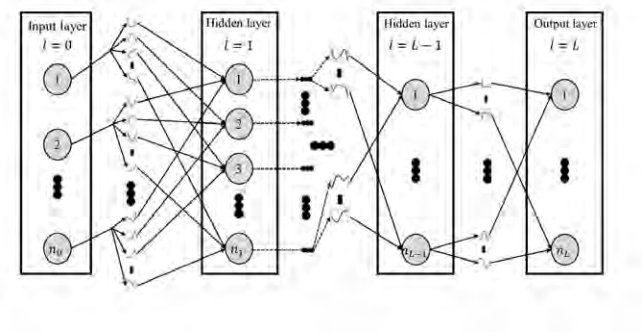

**Figure 1.** Directed acyclic graph of a Kolmogorov Arnold Network.

For a KAN, as opposed to an MLP, the activation lies on the edge connecting two neurons rather than on the neuron itself [10]. Denoting a neuron in the $l^{th}$ layer as $(l, i)$, where $i$ represents the index of the neuron in the layer $l$ and it can take values ranging from 1 to $n_l$. The activation ($\phi_{l,j,i}$) connecting the neuron $i$ in layer $l$ to neuron $j$ in layer $l + 1$ is a univariate function,

$$\phi_{l,j,i}(x_{l,i}),\ l = 0, \ldots, L-1, i = 1, \ldots, n_l, j = 1, \ldots,\ n_{l+1}. \tag{1}$$

Here, $x_{l,i}$ represents the pre-activation value of the neuron $i$ in layer $l$. For the input layer, this corresponds to the inputs to the network. Hence, the input to a neuron in the layer $l + 1$ is given by [10],

$$x_{l+1,j} = \sum_{i=1}^{n_l} \phi_{l,j,i}(x_{l,i}),\ j = 1, \ldots, n_{l+1} \tag{2}$$

Equation (2) can be equivalently represented as matrices,

$$\begin{pmatrix} x_{l+1,1} \\ \vdots \\ x_{l+1,n_{l+1}} \end{pmatrix} = \begin{pmatrix} \phi_{l,1,1}(\cdot) & \cdots & \phi_{l,1,n_l}(\cdot) \\ \vdots & \ddots & \vdots \\ \phi_{l,n_{l+1},1}(\cdot) & \cdots & \phi_{l,n_{l+1},n_l}(\cdot) \end{pmatrix} \begin{pmatrix} x_{l,1} \\ \vdots \\ x_{l,n_l} \end{pmatrix} \tag{3}$$

Compactly, Equation (3) can be expressed as,

$$\boldsymbol{x_{l+1}} = \boldsymbol{\Phi_l}(\boldsymbol{x_l}) \tag{4}$$

where, $\boldsymbol{\Phi}$ is the composition of univariate functions $\phi$. Hence, the overall network can be represented as:

$$\boldsymbol{x_L} = \mathbf{KAN}(\boldsymbol{x_0}) := \boldsymbol{\Phi_{L-1}}(\boldsymbol{x_{L-1}}(\ldots(\boldsymbol{\Phi_1}(\boldsymbol{x_1}(\boldsymbol{\Phi_0}(\boldsymbol{x_0})))))) \tag{5}$$

For a KAN, the activation functions ($\phi$) are weighted sums of a base activation function ($b$) and a spline function ($s$) expressed as [10],

$$\phi_{l,j,i}(x_{l,i}) = w^b_{l,j,i}\, b_{l,j,i}(x_{l,i}) + w^s_{l,j,i}\, s_{l,j,i}(x_{l,i}) \tag{6}$$

where $w^b_{l,j,i}$ and $w^s_{l,j,i}$ are the weights of each activation, and they are trainable parameters. This ensures that the overall KAN activation ($\phi$) is trainable, further distinguishing it from an MLP, where the activation is fixed. Typically, the Sigmoid Linear Unit (SiLU) function is used as the base activation function ($b$) in KANs [10],

$$b_{l,j,i}(x_{l,i}) := \mathrm{silu}(x_{l,i}) = \frac{x_{l,i}}{1 + e^{-x_{l,i}}} \tag{7}$$

Finally, the spline activation function can be defined as [10],

$$s_{l,j,i}(x_{l,i}) = \sum_{g=0}^{G+k-1} c_{l,j,i,g}\, B_{l,j,i,g,k}(x_{l,i}) \tag{8}$$

Here, $G$ represents the number of grid points used to characterise the spline basis functions $B$ of degree $k$. $c_{l,j,i,g}$ is the coefficient for each spline basis function $B_{l,j,i,g,k}$. $c_{l,j,i,g}$ is also a trainable parameter. For further information on KANs, the reader is referred to [10].

## METHODOLOGY

In this section, we propose a Mixed-Integer Nonlinear Programming (MINLP) formulation to optimize over a

trained KAN, provide details about the implementation of the formulation, and the case study used to test the MINLP formulation of a KAN.

## Formulation

The presence of a spline function in the activation makes each activation distinct. The spline basis functions are determined as

$$B_{l,j,i,g,0}(x_{l,i};\ \mathbf{t}) = \begin{cases} 1, & t_{l,j,i,g} \le x_{l,i} < t_{l,j,i,g+1} \\ 0, & \text{otherwise} \end{cases} \tag{9}$$

$$B_{l,j,i,g,d}(x_{l,i};\ \mathbf{t}) = \frac{x_{l,i} - t_{l,j,i,g}}{t_{l,j,i,g+d} - t_{l,j,i,g}} B_{l,j,i,g,d-1}(x_{l,i};\ \mathbf{t}) + \frac{t_{l,j,i,g+d+1} - x_{l,i}}{t_{l,j,i,g+d+1} - t_{l,j,i,g+1}} B_{l,j,i,g+1,d-1}(x_{l,i};\ \mathbf{t}), d = 1, \ldots, k \tag{10}$$

Here, $\mathbf{t}$ is a vector of $G + 1$ uniformly-spaced non-decreasing points in the range $[x_{l,i}^L, x_{l,i}^U]$, $B_{l,j,i,g,0}$ are zeroth-order spline basis functions and $B_{l,j,i,g,d}$ are higher-order spline basis functions defined up to the degree $k$ of the spline.

A Mixed-Integer Quadratically Constrained Programming (MIQCP) formulation has been proposed to model spline functions described in Equations (7) – (9) by Grimstad [14]. Herein, we adopt the proposed MIQCP formulation in [14] in our formulation for KAN. We represent the zeroth-order basis functions $B_{l,j,i,g,0}$ as binary variables. To ensure they are only activated for the case as described in Equation (8), we introduce the following linear constraints (Equations (10) and (11)) into the formulation:

$$(t_{l,j,i,g} - t_{l,j,i,0}) B_{l,j,i,g,0} + t_{l,j,i,0} \le x_{l,i}, g = 0, .., G + 2k - 1 \tag{11}$$

$$(t_{l,j,i,g+1} - t_{l,j,i,G+2k}) B_{l,j,i,g,0} + t_{l,j,i,0} \ge x_{l,i}, g = 0, .., G + 2k - 1 \tag{12}$$

To determine the higher-order spline basis functions ($B_{l,j,i,g,d}$) for $d = 1, \ldots, k$, we include the quadratic Equation (9) for all $g = 0, .., G + 2k - 1 - d$. Finally, we also include the partition of unity cuts [14] in our formulation as,

$$\sum_{g=0}^{G+2k-1-d} B_{l,j,i,g,d} = 1, d = 0, \ldots, k \tag{13}$$

Equations (10) – (13) allow for the calculation of $k^{\text{th}}$-order spline basis functions required to characterise the spline function ($s$) in Equation (8), which is also included in the formulation. The base activation function ($b$) is formulated as described in Equation (7). Finally, the overall activation is formulated as described in Equation (5). To model the connections in the network as shown in Figure 1, Equation (14) is added to the formulation.

$$x_{l+1,j} = \left(\sum_{i=1}^{n_l} \phi_{l,j,i}(x_{l,i})\right) + a_{l,j}, i = 1, \ldots, n_l, j = 1, \ldots, n_{l+1}, \text{and } l = 0, \ldots, L - 1 \tag{14}$$

The presence of the term $a_{l,j}$ distinguishes Equation (14) from Equation (1). While not necessary for a KAN, bias term $a_{l,j}$ is included in the implementation for sparsity regularization and improved training performance [10].

Therefore, the MINLP formulation of a KAN presented here consists of Equations (6) – (8), (10) – (14). For a trained KAN embedded into an optimization formulation $w_{l,j,i}^b$, $w_{l,j,i}^s$, $c_{l,j,i,g}$, and $a_{l,j}$ are fixed parameters. Hereafter, the overall formulation is denoted as **TKAN.** We would like to remind readers that all equations in the formulation are linear or quadratic except for Equation (7). Using the `SiLU` function as the base activation introduces the nonlinearity into the formulation.

## Case Study

We consider the case study of optimizing an autothermal reforming process used in the documentation of OMLT [15] and in a recent review article on optimization formulations for trained machine learning models [12]. The dataset comprises two inputs: Bypass fraction ($\alpha$) and natural gas steam ratio ($SR$). The bounds for $\alpha$ and $SR$ are [0.1, 0.8] and [0.8, 1.2] respectively. There are 12 outputs in the dataset: the steam flowrate, the reformer duty, and the composition of the outlet stream. Outlet stream comprises 10 components. The reader is referred to [15] for additional details about the case study. For the optimization problem formulation, only two outputs are of interest: the concentration of hydrogen in the outlet stream ($c_H$) and the concentration of nitrogen in the outlet stream ($c_N$). The objective of the problem is to maximize $c_H$ while constraining $c_N$ to be lower than 0.34. Hence, the optimization problem with KAN embedded is as follows:

$$\begin{aligned} \max_{\alpha, SR} \quad & c_H \\ s.t. \quad & \mathbf{TKAN}(\alpha, SR) = 0 \\ & c_N \le 0.34 \end{aligned} \tag{15}$$

Similarly, the optimization problem with MLP embedded is:

$$\begin{aligned} \max_{\alpha, SR} \quad & c_H \\ s.t. \quad & \mathbf{MLP}(\alpha, SR) = 0 \\ & c_N \le 0.34 \end{aligned} \tag{16}$$

Two different network architectures are considered: one considering the two outputs present in the optimization formulation as the two outputs from the network and another with all twelve outputs in the dataset as the outputs from the network.

## Implementation

The proposed MINLP formulation has been implemented using the Pyomo optimization framework [16]. Object-oriented programming framework is leveraged to create separate classes for an activation and a layer, enabling a simple definition of a KAN using a Pyomo block. For importing all the necessary parameters: $w_{l,j,i}^b$, $w_{l,j,i}^s$, $c_{l,j,i,g}$, $t_{l,j,i,g}$, and $a_{l,j}$, a method is written to export all these parameters to a JSON file on reading a trained KAN

model object. All KANs are trained using the pykan repository (v0.0.2) [10]. For comparing the effectiveness of a KAN with MLPs, MLPs with ReLU activation are trained using Tensorflow (v2.17.0) and imported into Pyomo using OMLT (v1.2.1) [15]. We consider MLPs with one, two and three layers, each with 20 neurons for comparison. We only consider the BigM formulation of ReLU MLPs for investigation. For all instances, a time limit of 300 seconds is imposed. Relative termination tolerance of $1.0E-4$ is used for all instances. All the instances are solved via Pyomo/GAMS (v48.6) using SCIP (v9.2) on a Dell Latitude 7440 laptop with 13th generation Intel Core i7-1365U processor @1.80 GHz with 16 GB of RAM running Windows 10.

## RESULTS AND DISCUSSION

This section presents the results related to training different networks and solving the optimization models with the trained network embedded.

### Training results

All networks are trained by splitting the dataset into training and testing subsets in the proportion of 0.75 : 0.25 (train : test). Detailed discussions in relation to training times of different networks are not provided because KANs require significantly more computational effort to train relative to MLPs [10]. A similar observation is also made in this study.

Both KANs are trained with one hidden layer comprising two neurons with six grid points ($G = 6$) using 125 training steps. For MLPs, the number of hidden layers ranging from one to three, each with 20 neurons, is considered. Hundred epochs with default learning rate and batch size are used to train all MLPs. Mean squared error (MSE) on the training and test sets and the number of parameters in the network are reported in Table 1.

In Table 1 for both cases of two and twelve outputs, we observe the parameter efficiency of KANs over MLPs. The KAN with 12 outputs (KAN12) has a training MSE of 5.11E-5, which is approximately half of the deepest ReLU MLP. Similarly, for the case with two outputs, KAN2 exhibits orders of magnitude lower train MSE than any of the ReLU MLPs trained. While we observe that the MSE on the test set is comparable for all the networks trained, the lower MSE on training sets indicates that KANs are more accurate than MLPs though inconclusive. Finally, it is important to point out that KANs have approximately the same number of parameters as MLPs with one hidden layer for both the cases of two and twelve outputs; they exhibit significantly lower MSE values on the training set than for any MLPs.

Table 1. Details of training for different networks. The network name is defined using the type of network (KAN or MLP) followed by the number of outputs (2 or 12) from the network. For MLPs, the number of hidden layers is shown in parentheses. For example, the network with the name 'ReLU12(2)' corresponds to a ReLU MLP with twelve outputs and two hidden layers.

| Network | Train MSE | Test MSE | # of param. |
|---|---|---|---|
| ReLU12(1) | 3.10E-4 | 4.30E-3 | 312 |
| ReLU12(2) | 1.08E-4 | 4.10E-3 | 732 |
| ReLU12(3) | 1.32E-4 | 3.80E-3 | 1152 |
| KAN12 | 5.11E-5 | 4.21E-3 | 311 |
| ReLU2(1) | 1.25E-4 | 4.90E-3 | 102 |
| ReLU2(2) | 1.41E-4 | 4.60E-3 | 522 |
| ReLU2(3) | 5.05E-4 | 4.30E-3 | 942 |
| KAN2 | 4.20E-8 | 4.73E-3 | 91 |

### Optimization results

All trained networks are solved to global optimality at the specified tolerance. For all the networks, the value of the objective, i.e., the concentration of hydrogen in the outlet stream ($c_H$) is found to be approximately $\approx 0.33$. The actual value of the global maximum is not known or reported. Hence, the ability of a network to accurately describe the global solution cannot be further evaluated. We repeat the global optimization of all networks using SCIP five times. The average wall time elapsed to achieve convergence to global optimality over the five runs is reported in **Figure 2**. Repeated runs are carried out to ensure higher confidence in the results since the wall time needed to achieve global optimality is low ( < 10 seconds for most cases).

On comparing the results between the two cases of twelve outputs and two outputs in **Figure 2**, we observe that reducing the number of outputs for MLPs has a minor effect on the computational effort to prove global optimality. For ReLU(2) and ReLU(3), there is a slight reduction in the average time taken to achieve convergence. Whereas, for ReLU(1), this increases slightly by reducing the number of outputs, albeit for both cases, the runtime is still less than 1 second. On the other hand, for the KAN, the runtime reduces by an order of magnitude. This observation can be explained by considering the nature of a KAN. For a KAN, the activation lies on the edge connecting two neurons in the network. On reducing the number of outputs from 12 to 2, the total number of activations in the network reduces from 28 to 8. Moreover, considering each activation comprises the spline function, which introduces $G + 2k$ binary variables (c.f. Equations (11) and (12)), reducing the number of activations in the networks significantly reduces the computational effort required to optimize the trained KAN to global optimality. We do not see the same for MLPs because, for an MLP, the activation lies in the neuron itself.

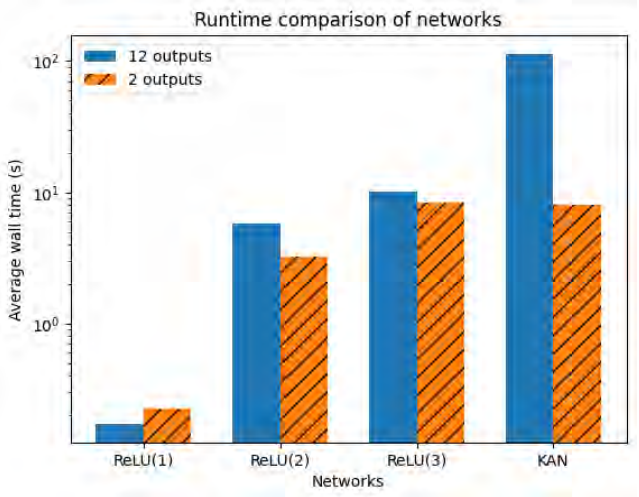

**Figure 2.** Comparison of runtimes among different networks. The networks compared are 'ReLU(1)', 'ReLU(2)', 'ReLU(3)', and 'KAN' corresponding to MLPs with one, two, and three hidden layers and a Kolmogorov Arnold Network, respectively. Two different cases of two and twelve outputs are considered shown by shaded orange bars and solid blue bars respectively.

Comparing KANs and MLPs, we observe that for the case of 12 outputs, KAN requires an order of magnitude higher computational effort to be solved to global optimality using SCIP relative to MLPs. Hence, it is not competitive with MLPs. However, when reducing the number of outputs, the computational effort required for KAN is comparable to that of MLPs with three hidden layers. However, it requires more computational effort than MLPs with one or two hidden layers. This behavior is explained by the fact that for a KAN, we solve an MINLP, but for a `ReLU` modeled using the BigM formulation, a Mixed-Integer Linear Programming (MILP) formulation is solved. MILPs are relatively easier to solve than MINLPs. Additionally, the algorithms to solve MILPs are more advanced than MINLPs.

For the case study considered, the MSE on the test set are comparable for both MLPs and KANs. However, KANs are expected to offer better generalization capabilities compared to MLPs [10]. Considering that the computational effort required to optimize KANs is comparable to MLPs with three layers, a comprehensive evaluation should be conducted with multiple other case studies to thoroughly evaluate the potential of KANs as surrogate models.

## CONCLUSIONS

In this study, we presented a Mixed-Integer Nonlinear Programming formulation for embedding Kolmogorov Arnold Networks into optimization formulations. Using an autothermal process optimization case study, we investigated the potential of using Kolmogorov Arnold Networks as surrogate models for process optimization. We observed that they are a promising alternative as surrogate models, particularly when a low number of inputs or outputs are involved.

For applications requiring a high number of inputs or outputs, stronger formulations for KAN need to be developed to improve their computational tractability for deterministic global optimization. Alternatively, activation functions such as `ReLU` should be investigated as base activation functions instead of `SiLU`. Doing so would potentially avoid the solution of an MINLP and a more tractable MIQCP would be solved instead. Finally, more extensive testing of the formulation with different case studies to comprehensively evaluate the effectiveness of KANs.

## ABSTRACT

Liquid-liquid extraction stages often deviate from equilibrium due to factors like insufficient mixing, making accurate efficiency modeling essential for process simulation. This study addresses the limitations of Aspen Plus (AP), which distorts equilibrium calculations by directly multiplying efficiency with the distribution coefficient. A modified Murphree efficiency definition, more suitable for liquid-liquid systems but absent in AP's Extraction Column module, was implemented using Aspen Custom Modeler (ACM). The custom multi-stage extraction column model replaces mole fractions with mole flows to better represent mass transfer and phase interactions, enhancing simulation accuracy when imported into AP. Two test cases validated the custom model's effectiveness. Test Case I, utilizing the UNIQ-RK thermodynamic model, compared the ACM model to AP's built-in module, revealing that the ACM model provides a more realistic representation of extraction processes under varying stage efficiencies. It captured gradual efficiency changes and aligned with expected mass transfer behavior, while the built-in module showed reduced sensitivity and accuracy. Test Case II, using the UNIF-LL thermodynamic model, demonstrated the model's robustness across different thermodynamic frameworks. It highlighted how varying Murphree efficiency from 0 to 1 directly affects separation performance, with higher efficiencies leading to better separation and increased extract phase composition. These findings confirm that the modified Murphree efficiency is a reliable and effective approach, enabling engineers to optimize liquid-liquid extraction processes with greater accuracy and efficiency.

## INTRODUCTION

Liquid-liquid extraction (LLX) is a widely used separation process in chemical engineering, particularly for systems where the components to be separated are not suitable for conventional distillation due to factors such as thermal sensitivity or low relative volatility [1]. In LLX, components are distributed between two immiscible liquid phases—typically an aqueous phase and an organic solvent phase—based on their relative solubility or affinity for each phase. This process is employed in diverse industries, including petrochemicals, pharmaceuticals, hydrometallurgy, and wastewater treatment [2].

Despite its broad applicability, LLX processes are often plagued by inefficiencies that result in deviations from ideal equilibrium. These inefficiencies arise from factors such as insufficient mixing, poor phase dispersion, non-ideal phase interactions, and mass transfer limitations [3, 4]. Insufficient mixing reduces the interfacial area available for mass transfer, leading to incomplete component transfer between phases. Similarly, operational factors such as stage design, solvent-to-feed ratios, and flow patterns can further exacerbate these inefficiencies, resulting in lower extraction performance. Experimental studies have shown that deviations from ideal mixing and equilibrium are significant, particularly in multi-stage extraction columns where the cumulative effect of inefficiencies can drastically reduce overall

separation performance [5].

Traditional approaches for modeling stage efficiency in liquid-liquid extraction (LLX) often oversimplify these complex behaviors. For example, simulation tools like Aspen Plus (AP) apply a concept sometimes referred to as "vaporization efficiency," which originates from its use in systems such as steam distillation. This method defines stage efficiency by scaling the component distribution coefficient ($Ki$) with an efficiency term ($Ei$), as represented in Equation 1:

$$E_i = \frac{x_i^{L2}}{K_i x_i^{L1}} \quad (1)$$

Here, $x_i$ represents the mole fractions of a component in stage $i$ in the liquid phases $L_1$ and $L_2$, respectively. While this formulation simplifies equilibrium calculations, it introduces significant limitations when applied to LLX systems. The concept of vaporization efficiency, as detailed in references such as Wankat's Equilibrium Staged Separations, is more relevant to steam distillation, where it is directly defined using vapor pressures [6]. This basis is not applicable to LL systems, where equilibrium is governed by distribution coefficients rather than vapor pressures. In LLX systems, directly scaling the equilibrium coefficient inherently distorts the mass transfer behavior, especially in non-ideal conditions where deviations from equilibrium are pronounced [7]. This limitation is particularly critical in systems with low efficiencies, where stage performance depends strongly on factors such as mixing quality, interfacial mass transfer rates, and phase equilibrium dynamics. Such discrepancies underscore the need for approaches better tailored to the specific complexities of LLX processes.

To address these challenges, this work introduces a modified Murphree efficiency definition tailored for LLX processes. The Murphree efficiency, traditionally applied in vapor-liquid systems, compares the actual performance of a stage to its ideal counterpart, effectively capturing deviations from equilibrium. For LLX systems, however, the use of mole fractions in the traditional Murphree definition fails to account for the continuous nature of mass transfer and phase interactions. Instead, this study proposes a modification wherein mole flows replace mole fractions, ensuring a more consistent and physically accurate representation of stage performance. The modified efficiency better reflects real-world process behavior by incorporating both the composition and the flow dynamics of the system.

The importance of accurately modeling stage efficiency cannot be overstated. Experimental studies have shown that small inefficiencies at individual stages can propagate through multi-stage columns, significantly reducing overall extraction efficiency and leading to suboptimal solvent utilization [8]. Furthermore, non-idealities such as solvent entrainment, phase back-mixing, and viscosity effects can further complicate the extraction process [9]. Addressing these inefficiencies requires models that not only account for equilibrium deviations but also reflect the dynamic interactions between feed and solvent phases. The modified Murphree efficiency presented here provides a step toward bridging the gap between idealized models and real-world LLX systems.

The proposed efficiency model was implemented in a multi-stage extraction column using Aspen Custom Modeler (ACM) and imported into AP for verification. It is important to emphasize that the tools used in this study, namely ACM and AP, serve merely as implementation platforms. The modified Murphree efficiency can be applied in any appropriate modeling environment capable of supporting custom efficiency definitions. This flexibility broadens the applicability of the approach, making it suitable for a wide range of LLX systems and scenarios.

In summary, this work presents a modified efficiency definition that addresses the limitations of existing models for LLX processes. By accounting for mass transfer dynamics and phase interactions more rigorously, the proposed approach provides a robust framework for simulating and optimizing LLX systems in a realistic way. The findings have implications for the design and operation of extraction columns, particularly in processes where deviations from equilibrium play an important role in determining overall performance.

## METHODOLOGY

The accurate modeling of stage efficiency in LLX processes requires an approach that accounts for both mass transfer and deviations from equilibrium. The proposed methodology addresses these challenges by redefining the Murphree efficiency for liquid-liquid systems, making it more applicable and realistic in representing stage performance.

The Murphree efficiency is traditionally defined for vapor-liquid equilibrium systems, evaluating the performance of a stage based on the deviation of the actual composition change from the ideal change. The original definition for vapor-liquid is expressed as:

$$E_i^M = \frac{x_i^V - x_{i-1}^V}{K_i x_i^L - x_{i-1}^V} \quad (2)$$

Here, $E^M$ represents the Murphree efficiency of stage $i$. $\mathrm{V}$ and $\mathrm{L}$ are stand for vapor and liquid phases, respectively. This definition is well-suited for vapor-liquid processes.

In liquid-liquid systems, the traditional Murphree efficiency is less effective because equilibrium is rarely achieved at each stage due to slower mass transfer rates and insufficient mixing. Additionally, it is worth noting that in liquid-liquid systems, the distinction between the two phases, analogous to vapor and liquid in vapor-liquid systems, is less clear. LL systems exhibit a more symmetric behavior in this regard, making it ambiguous which

phase should correspond to "V" or "L." Trials with both interpretations showed similar results, further supporting this symmetry. Furthermore, traditional mole fraction-based efficiencies for LL systems were also tested but presented challenges, particularly in cases where total molar flows varied. In such scenarios, linking mole fractions at the inlet and outlet becomes less logical, leading to somewhat inconsistent results. This issue is effectively addressed in the present formulation by using mole flows, which inherently account for variations in total molar flow and ensure consistency in the efficiency calculation. mixing. Moreover, mole fractions alone are insufficient to capture the phase interactions and mass transfer dynamics that are essential to understanding the performance of LLX stages. Instead, the mass transfer behavior in such systems is better represented by mole flows, which consider both the amount of material transferred and the phase equilibrium composition. To address these challenges, the Murphree efficiency was modified by substituting mole flows for mole fractions in the traditional definition. The modified efficiency for components is expressed as:

$$E^M = \frac{x_i^{L2}\,\dot{n}_i^{L2} - x_{i-1}^{L2}\,\dot{n}_{i-1}^{L2}}{K_i x_i^{L1} \varphi^{*,L1}\left(\dot{n}_i^{L1}+\dot{n}_i^{L2}\right) - x_{i-1}^{L2}\,\dot{n}_{i-1}^{L2}} \tag{3}$$

Here, $\dot{n}$ represent the molar flow rate, $\varphi*$ denotes the equilibrium phase fraction. This modification ensures that the efficiency definition aligns with the physical principles of mass transfer and captures the continuous nature of phase interactions in liquid-liquid systems. To incorporate this modified efficiency into the modeling framework, component and overall mole balances were established for the system. The component mole balance for the second liquid phase can be calculated from the overall mole balance of each component:

$$x_i^{L1}\,\dot{n}_i^{L1} + x_i^{L2}\,\dot{n}_i^{L2} = x_{i-1}^{L1}\,\dot{n}_{i-1}^{L1} + x_{i-1}^{L2}\,\dot{n}_{i-1}^{L2} \tag{4}$$

The overall mole balance for the system becomes:

$$\dot{n}_i^{L1} + \dot{n}_i^{L2} = \dot{n}_{i-1}^{L1} + \dot{n}_{i-1}^{L2} \tag{5}$$

These equations relate the modified Murphree efficiency to the principles of mass transfer and phase equilibrium, offering a framework for accurately representing stage performance. By incorporating the interplay between stage efficiency, composition and flow rates, the approach captures the dynamics of LLX systems.

To apply the modified efficiency, a multi-stage LLX column model was implemented. The model accounts for gradual changes in efficiency and composition across stages, reflecting the interactions between feed and solvent phases in a counter-current setup as represented in Figure 1.

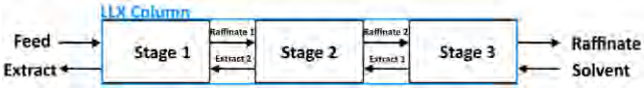

**Figure 1.** Counter-current LLX scheme with 3 stages.

The model was implemented using ACM, where the modified Murphree efficiency and mass balance equations were defined. It was then imported into AP for comparison with the built-in extraction modules. While ACM and AP were used for this study, the methodology itself is flexible and can be applied in other simulation environments capable of supporting custom efficiency definitions.

## RESULTS AND DISCUSSION

The performance of the modified Murphree efficiency in LLX was evaluated through two test cases that assessed its implementation in a custom ACM model imported into AP. These cases demonstrate the model's capacity to simulate stage efficiencies and its superiority over the built-in AP extraction module for realistic system behavior and accuracy. The system configuration for the LLX process is shown in Figure 2, where the feed and solvent streams enter the extraction column (LLX Column), and the resulting extract and raffinate streams exit the column. This setup highlights the counter-current interaction of the phases, which drives the separation process.

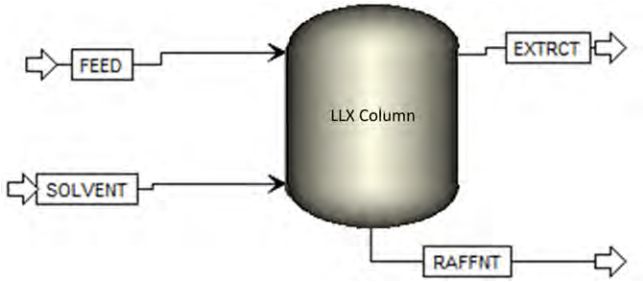

**Figure 2.** Schematic representation of a LLX column showing the flow of feed, solvent, extract, and raffinate streams.

### Test Case I: Comparison Between ACM and AP Built-In Models

The performance of the modified Murphree efficiency implemented in the ACM model was evaluated in comparison to AP's built-in extraction module. Test Case II focused on a LLX system involving three components: acetic acid (HAC), water, and n-hexane, operating over 3 to 7 stages with varying stage efficiencies. To model the phase behavior and distribution of components between the aqueous and organic phases, the UNIQ-RK thermodynamic model was employed.

Table 1 provides an overview of the feed and solvent

components along with their respective flow rates. The analysis emphasized column efficiency, component distributions, and overall extraction performance.

**Table 1:** Test case I feed and solvent components with flow rates.

| Stream | Description | Flow |
|---|---|---|
| Feed | Water | 8 kmol/hr |
| | HAC | 2 kmol/hr |
| Solvent | N-hexane | 30 kmol/hr |

The results from the ACM model, illustrated in Figure 3, showed a clear and consistent increase in column efficiency as the number of stages increased. The behavior aligns with expected mass transfer dynamics, where increasing the number of stages and improving efficiency enhances the separation performance. As illustrated in the Figure 3, constant Murphree efficiencies of 0.25, 0.5, and 1 demonstrated progressively higher column efficiencies. At an efficiency of 1, the column approaches equilibrium, achieving the maximum possible separation. Conversely, when the efficiency was set to 0, no separation occurred, and the extract and raffinate compositions mirrored the feed and solvent, confirming the physical expectation of no phase interaction.

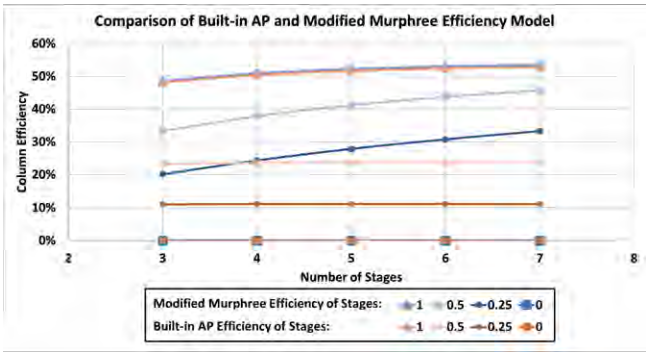

**Figure 3.** Comparison of column efficiency for built-in AP and modified Murphree models at varying efficiencies.

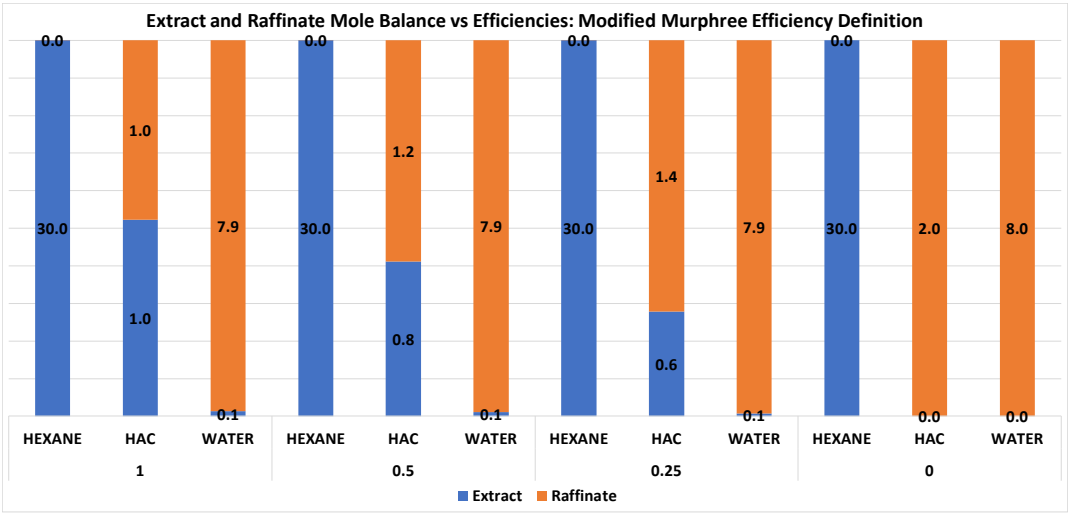
In contrast, the built-in AP model fails to capture the gradual and realistic changes in column performance, particularly at lower efficiencies. The results exhibit a discontinuous and overly simplistic response to variations in efficiency, where changes in stage performance are not reflected accurately. This lack of sensitivity is problematic for systems that require precise predictions of mass transfer behavior and separation performance across multiple stages. The inaccuracies become especially apparent when the efficiency is set to zero. Under this condition, the AP model produces physically unrealistic results, redistributing all of the solvent into the raffinate phase, as shown in Figure 4. This outcome violates fundamental mass balance principles and misrepresents the behavior of the system, where, in reality, no separation should occur, leaving the extract and raffinate phases identical to the feed and solvent compositions.

The results confirm that incorporating the modified Murphree efficiency into a custom ACM model provides a more realistic representation of liquid-liquid extraction. While the ACM model occasionally encountered convergence issues during integration with AP, its flexibility and ability to realistically simulate stage efficiencies offer significant benefits for process optimization. By addressing real-world inefficiencies, such as non-ideal mixing and deviations from equilibrium, the modified Murphree efficiency model provides a framework to evaluate extraction performance in multi-stage systems.

## Test Case II: Effect of Stage Efficiency on Column Performance

In the second test case, a system consisting of acetone and water as the feed and 3-methylhexane as the solvent was simulated in a multi-stage LLX column. The thermodynamic model used in this case was UNIF-LL, a liquid-liquid activity coefficient model tailored for systems with significant non-ideal behavior. This test case was specifically designed to demonstrate the robustness and versatility of the implemented modified Murphree efficiency model in handling different thermodynamic frameworks.

The feed and solvent components and their flow rates are summarized in Table 2. The model simulated constant Murphree efficiencies of 0, 0.25, 0.5, and 1 across 3 to 7 stages. Column efficiency, defined as:



$$Column\ Efficiency\ = \frac{n_E^{Feed} - n_E^{Raffinate}}{n_E^{Feed}} \qquad (6)$$

where $\dot{n}_E$ represents the molar flow rate of the extracted component $E$ (in this case, acetone) in the feed and raffinate phases.

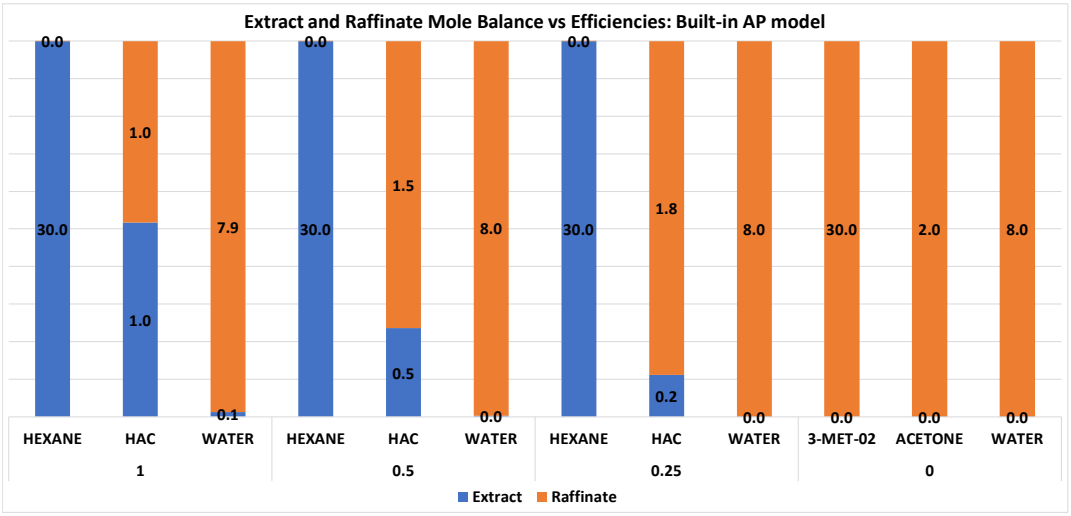


**Table 2:** Test case II feed and solvent components with flow rates.

| Stream | Description | Flow |
|---|---|---|
| Feed | Water | 8 kmol/hr |
| | Acetone | 2 kmol/hr |
| Solvent | 3-methylhexane | 10 kmol/hr |

The results, illustrated in Figure 5, show a clear relationship between Murphree efficiency and column performance. When Murphree efficiency was set to zero, no separation occurred, and column efficiency remained at 0%, as indicated by the flat blue line. This scenario reflects a system with no mass transfer, where the composition of the extract and raffinate phases is identical to the feed and solvent. As Murphree efficiency increased to 0.25 and 0.5, column efficiency improved steadily with the number of stages. This trend highlights the effect of additional stages in enhancing separation performance

(a)

(b)

**Figure 4.** Extract and raffinate mole balances at varying stage efficiencies for (a) the modified Murphree efficiency model developed using ACM and (b) the built-in AP model. The modified Murphree efficiency model shows a gradual and realistic distribution of components, while the built-in AP model demonstrates less sensitivity and unrealistic behavior at lower efficiencies.

under moderate efficiencies. At a Murphree efficiency of 1, the system achieved equilibrium conditions, resulting in the maximum column efficiency, as shown by the yellow line approaching 100%. Under these conditions, the separation was optimal, and the extract phase contained the highest amount of acetone.

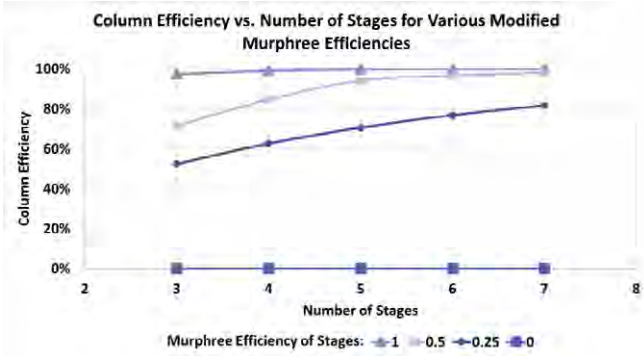

**Figure 5.** Effect of Murphree efficiency on column efficiency as a function of the number of stages. Lower efficiencies show limited separation performance.

The results highlight the significant influence of Murphree efficiency on extraction performance. Higher efficiencies lead to improved separation, whereas deviations from ideal conditions result in a notable decline in column performance. This emphasizes the importance of accurately modeling stage efficiency to better represent the behavior of LLX systems in practice.

## CONCLUSION

This work introduced a modified Murphree efficiency definition to address challenges in modeling stage efficiencies in LLX processes. By using mole flows instead of mole fractions, the approach provides a framework that better reflects the mass transfer and phase interactions in systems where deviations from equilibrium occur.

The implementation of this approach in a custom ACM model and its integration into AP were used to evaluate its applicability. Through test cases, the model demonstrated its capacity to capture the relationship between stage efficiency and separation performance under varying conditions. The observations showed how stage efficiencies influence the distribution of components between extract and raffinate phases and highlighted the limitations of existing built-in simulation modules.

The methodology is not restricted to the tools used in this study. It can be implemented in other simulation platforms capable of supporting custom efficiency definitions. This general applicability allows the approach to be used for further studies and practical applications in different extraction systems. By addressing the relationship between stage performance, efficiency, and mass transfer, the modified Murphree efficiency provides a foundation for understanding and improving LLX processes.

## ABSTRACT

Artificial Photosynthetic Bio-Electrochemical Systems (AP-BES) offer a promising approach for converting $CO_2$ to valuable bioproducts, addressing carbon mitigation and sustainable production. This study employs a stochastic techno-economic assessment (TEA) to estimate the viability of rhodopsin driven AP-BES, from carbon capture to product purification. Unlike traditional deterministic TEAs, this approach uses Monte Carlo simulations to model uncertainties in key technoeconomic parameters, including energy consumption, $CO_2$ conversion efficiency, and bioproduct market prices. The analysis generates probability distributions for economic metrics such as Operational Expenditure (OPEX), Capital Expenditure (CAPEX), and profit. Enhancements in light-harvesting efficiency and advancements in reactor materials were predicted to reduce the payback period to just one year, thereby making large-scale deployment a feasible option.

**Keywords**: Artificial Photosynthesis, Techno Economic Assessment, Carbon Conversion, Synthetic Biology.

## INTRODUCTION

Global warming has driven the need for sustainable energy generation and manufacturing, a 3°C rise in global temperatures could halve GDP growth by 2050 and dramatically increase species extinction rates and flood risks [1], [2]. Staying below this limit requires significant reductions in greenhouse gas emissions, particularly $CO_2$ [1], [2]. Carbon Capture and Utilization (CCU) presents itself as a solution, offering the benefit of mitigating climate change while enabling sustainable manufacturing.

Biologically mediated CCU shows promise due to its ability to operate under ambient conditions, potentially lowering operating costs. Artificial Photosynthetic Bio-electrochemical Systems (AP-BES) are a novel class of these technologies, integrating biological and electrochemical processes to mimic natural photosynthesis. Yet, despite their potential, the adoption of AP-BES is hindered by major challenges such as system inefficiencies, and economic uncertainties. Thus, we propose a comprehensive evaluation framework that addresses the inherent variability and uncertainties in both technical and economic factors through a Monte Carlo approach.

## SYSTEM PRINCIPLES

### The Rhodopsin Driven AP-BES Reactor

At the heart of the system lies a bio-electrochemical reactor utilizing rhodopsin, a light-sensitive protein, to drive $CO_2$ fixation [3], [4], as illustrated in Figure 1. When exposed to light, primarily at wavelengths around 530 nm, rhodopsin undergoes conformational changes that result in transmembrane proton pumping [5]. At the same time, an engineered electron transfer pathway, using the MtrCAB complex found in electroactive bacteria, facilitates extracellular electron uptake [3].This combination of light-driven proton pumping and engineered electron transfer enables the efficient regeneration of ATP and reducing equivalents within the system, accelerating $CO_2$ conversion as shown in Figure 1. The host bacteria used, *Ralstonia eutropha,* has been used to produce a range of bioproducts, from commodities such as biomass, to hydrocarbons and even to pharmaceuticals such as α-humulene (C15), a potential drug to treat cancer[6]. When utilized in an AP-BES, *R. eutropha* has been shown to produce, riboflavin and PHB [3], [4], [5]. Thus, we opted

to focus on these two, in addition to biomass (cells) as representative, high value, medium value and low value products respectively.

This integration of a rhodopsin-based light harvesting with the engineered electron transfer pathways has been demonstrated to result in a system with an estimated electron transfer efficiency of ~20%, significantly surpassing the typical efficiency of natural photosynthesis in most crops (~5%) [3], [4], [5], [7].

## System Integration and Efficiency

Evaluating the viability of our AP-BES reactor requires examining it in the context of a complete carbon capture and utilization (CCU) system. This consists of three subsystems: carbon capture, carbon conversion (the AP-BES reactor), and separation, as illustrated in Figure 1 (system boundaries fully defined in S2.1.). The carbon capture subsystem is designed to remove $CO_2$ from either flue gas (14% $CO_2$) [8] or directly from the atmosphere (480 ppm $CO_2$) [9]. After $CO_2$ conversion in the AP-BES reactor, the separation subsystem refines and purifies the resulting organic products, ensuring they meet the purity standards required for downstream applications. Both the carbon capture and separation systems are analyzed using a black-box approach, relying on first-order cost estimates (see S2.3.).

# METHODOLOGY

The stochastic approach in techno-economic analysis (TEA) estimates uncertainty in performance by combining a deterministic base model with probabilistic hyperparameter sampling. This uncovers behaviours often overlooked by deterministic models. Sensitivity analyses identify parameters that significantly affect system economics and performance, with the varied parameter treated as deterministic.

## Deterministic Basis

Our techno-economic assessment (TEA) of Artificial of the rhodopsin driven Photosynthetic Bio electrochemical System (AP-BES) focussed on the three subsystems: carbon capture, carbon conversion, and separation, with system boundaries (fully defined in S2.1.). We estimated operational expenditure (OPEX) primarily considering energy and maintenance costs (further discussed in S2.2.). Energy requirements for separation processes were calculated with thermodynamic efficiencies from literature (S2.2.). Yearly maintenance costs were estimated as 10% of capital expenditure (CAPEX) [10], while labour costs were estimated as 20% of base OPEX (excluding maintenance) [10]. For CAPEX estimates, we employed three model types: energy-based models using the Lange equation[11], literature-based results using the 6/10ths rule, and equipment-based models in order of increasing

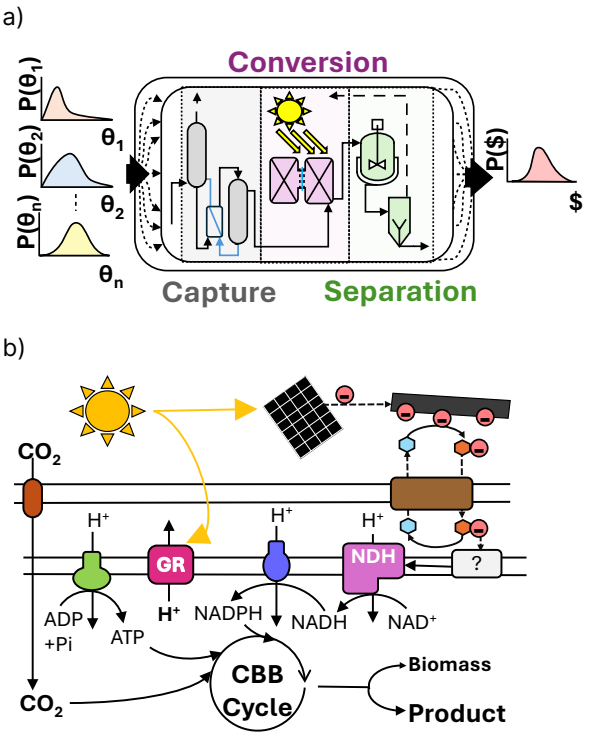

**Figure 1: (a)** Reference plant schematic (see S2.1) with stochastic TEA, model hyperparameters (e.g. separation efficiency) are modelled as random variables, from this an ensemble of predictions allows estimation of uncertainty. **(b)** Reference schematic at the cellular level for the reactor subsystem, through the inclusion of rhodopsin, ATP regeneration can be enhanced, thereby resulting in 'artificial' photosynthesis in this subsystem.

accuracy (further discussed in S2.3). In the reactor subsystem (the focus of this paper), equipment-based design and the 6/10ths rule were applied[10] for CAPEX estimates. To enhance accuracy, we applied correction factors such as Lang factors and the Chemical Engineering Plant Cost Index (CEPCI) to adjust for project complexities and inflation effects [10] (further discussed in S2.4) [16]. Total Annualised Cost (TAC) was calculated assuming a 10% interest rate and 10-year plant lifespan.

## Monte Carlo Sampling

To generate ensemble estimates of costs, we employed a Monte Carlo approach. Key parameters were modelled probabilistically using appropriate distributions based on their characteristics and available data (S2.6.). We performed 5,000 iterations for each operating condition assessed each time randomly sampling from the defined distributions. This approach aimed to capture inherent uncertainties and variabilities in the system, providing a more realistic representation of potential outcomes. Key parameters modelled stochastically included: Material Costs, efficiencies and Bioproduct market prices (see further in S2.6.). Statistical tests are outlined in S2.5.

## RESULTS & DISCUSSION

### Carbon Capture Subsystem

The techno-economic analysis of the carbon capture subsystem considered two scenarios: direct air capture (DAC) of $CO_2$ from ambient air at 440 ppm, and flue gas capture from an effluent stream containing 14 wt.% $CO_2$. For a complete system that converts 1 kilotonne of $CO_2$ a year (kt $yr^{-1}$), CAPEX for DAC ranged from £1.7M to £2.6M, compared to £0.9M to £1.2M for flue gas capture when considered at the reference condition (90% capture efficiency, 20% 2nd Law efficiency and a required purity of 95%, further defined in S.2.6.). Base OPEX (excluding maintenance), remained below £0.3M $yr^{-1}$ for both. Sensitivity analyses, shown in Figure 2, demonstrate how predicted OPEX shows strong dependency on both required effluent purity and second-law efficiency. Predicted OPEX was minimized when effluent purity was reduced to 10–20% and second-law efficiency approached 100% (further shown in Figure S1.1). Second-law efficiency, typically around 20% for systems of this type, emerged as the most significant driver of CAPEX variability. Constraining efficiency to 20% resulted in raw CAPEX (£) one order of magnitude greater than base OPEX (£/yr, excluding maintenance costs).

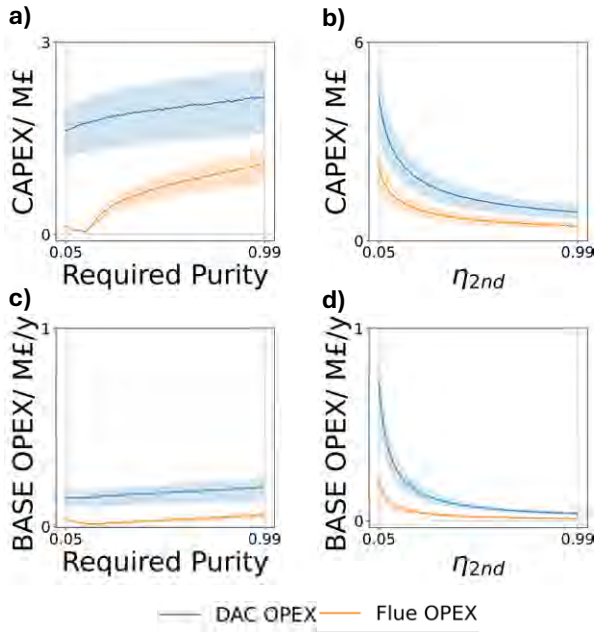

**Figure 2: ,** Plots of CAPEX (**a,b**) and Base OPEX **(c,d)** at a range of plant conditions for DAC (blue) and Flue (Orange). A reference condition of a 1 kilotonne scale, 90% capture efficiency, 20% 2nd Law efficiency and a required purity of 95% were used, all properties and parameters have an error of 50%. Plots **(a)** & **(c)**, examine the impact of required purity at the reference condition. Plots **(c)** & **(d)**, examine the impact of 2nd law efficiency at the operating point.

### Carbon Conversion Subsystem

The carbon conversion subsystem, the AP-BES reactor, enables the bio-electrochemical conversion of $CO_2$ into valuable bioproducts. To assess its economic performance, we analyzed the impact of light-harnessing efficiency, electrode materials, and membrane materials.

#### Impact of Electrode and Membrane Configurations

We assessed two electrode materials: carbon felt (CF), a low-cost, lower-performance option, and reticulated vitreous carbon (RVC), a higher-cost material with superior performance [12]. We also evaluated three membranes: Nafion (high-cost, high-performance)[13], BioChar (low-cost, low-performance), and earthenware (low-cost, low-performance)[14].

At the 1 kilotonne per year (kT $yr^{-1}$) scale, systems using RVC electrodes paired with low-cost membranes were predicted to be the optimal configuration, minimizing both expected OPEX and CAPEX as seen in Figure 3 (see table S1.1 for numerical results). Switching from CF to RVC significantly reduced expected OPEX (CF systems: 5.49-5.79 M£/yr; RVC systems: 4.26-4.60 M£/yr), with a p-value of less than 0.1% across all comparisons. For a given membrane, moving from CF to RVC reduced OPEX costs in 84.8% of cases, and when disregarding membrane choice (i.e. choosing a suboptimal membrane), this reduction occurred in at least 78.42% of cases. While Nafion was the best membrane for minimizing OPEX ($p<1\%$ within same electrode category), it only outperformed EarthWare in at most 61% of cases, confirming electrode material choice dominates OPEX considerations.

For CAPEX, electrode choice remained key, CF systems showed higher expected CAPEX (11.07-11.99 M£) than RVC systems (6.73-7.75 M£) with $p<0.001$. The probability of any RVC configuration providing lower CAPEX than any CF configuration was at least 69.04%, with RVC systems also exhibiting significantly lower uncertainty. Unlike OPEX, the optimal membrane choice for CAPEX favoured BioChar and EarthWare, which performed similarly (6.73-6.76 M£), while Nafion showed the highest costs (7.75 M£ for RVC+Nafion, $p<0.001$). BioChar outperformed Nafion with RVC electrodes in 82.64% of cases, with a significant expected difference of 1.02 M£ ($p<0.001$). The most economical configuration overall was RVC+BioChar or RVC+EarthWare, balancing expected OPEX (4.46-4.60 M£/yr) and expected CAPEX (6.73-6.76 M£).

#### Sensitivity to Light-Harnessing Efficiency

Sensitivity analysis of required light intensity (photosynthetic photon flux density: PPFD), shown in Figure 3, revealed predicted OPEX as highly dependent on PPFD

in all configurations. This is due to the direct coupling between required PPFD and energy. In contrast, reductions in required PPFD had minimal effects on CAPEX. Thus, research targeting enhanced light capture and utilization are critical for reducing OPEX of large-scale systems.

## Cost Distributions and Key Drivers

When evaluating impact of plant scale, CF-based systems had higher CAPEX with significant uncertainty due to increased specific volume requirements. In contrast, RVC-based systems exhibited tighter cost distributions, indicating greater predictability and lower financial risk. A similar trend was observed in OPEX, though cost distributions remained comparable across configurations. Despite the uncertainty in CF system cost estimates, RVC consistently lowered both CAPEX and OPEX across all tested configurations, reducing costs in at least 75% of cases when comparing systems at the same scale with the same membrane, highlighting RVC's cost advantage in developed models

Thus, we identified three primary cost drivers:

- **Electrode performance**: High-efficiency materials like RVC reduce OPEX & CAPEX by improving efficiency, particularly at larger scales.
- **Membrane selection**: Low-cost membranes provide substantial CAPEX reductions with minimal OPEX increases.
- **PPFD requirements:** Reducing light requirements directly impacts energy consumption, offering substantial OPEX reductions across all systems.).

These findings highlight the need for continued research into advanced reactor designs that balance performance and cost. By optimizing material choices and light utilization, the carbon conversion subsystem can achieve significantly reduced costs, supporting the commercialization of AP-BES technology.

## Separation Subsystem

The separation subsystem plays a crucial role in isolating the desired products from the reactor effluent, and its costs are primarily influenced by the product form and yield. We focused on three key products: riboflavin, polyhydroxybutyrate (PHB), and raw biomass, representing high (£60,000/T [15]), medium (£500/T [16], and low (£300/T [17]) added value products respectively. Figure 4 illustrates the impact of different process configurations on the capital expenditure (CAPEX) and operational expenditure (OPEX) at the 1 kilotonne scale. Costs are minimised when raw biomass is the sole product, but increase with additional products, peaking at zero biomass.

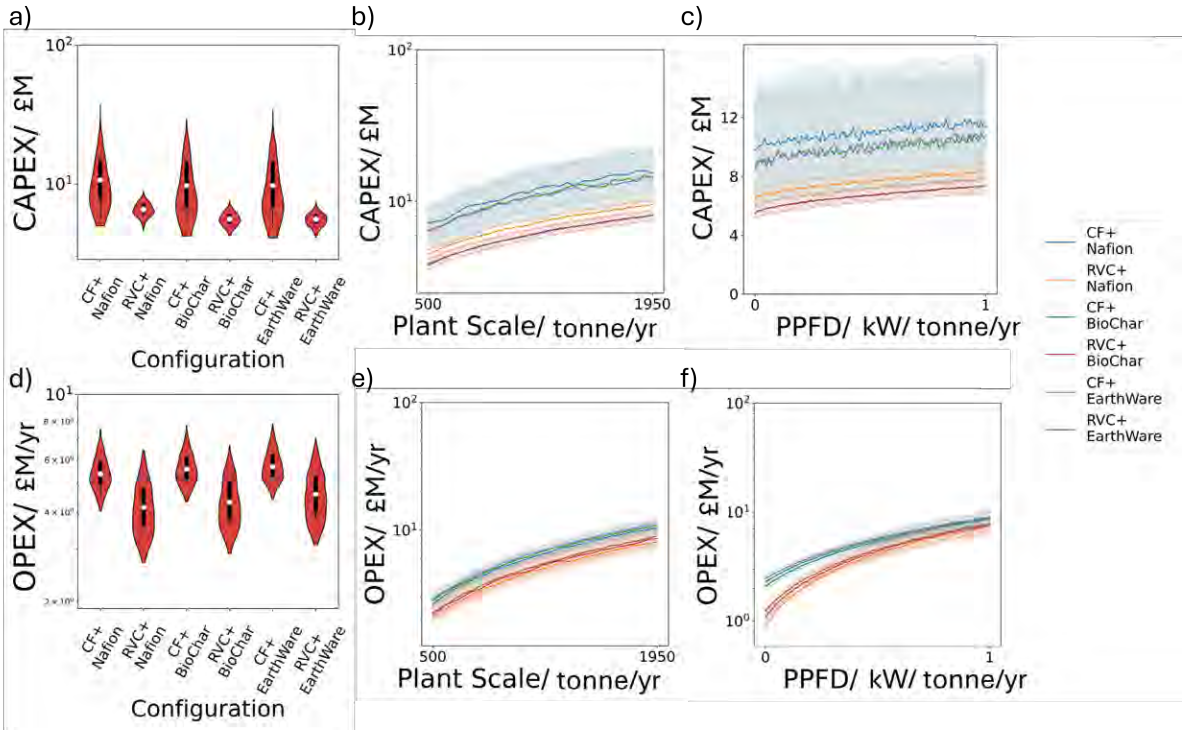

**Figure 3:** Plots of Estimated plant CAPEX **(a,b,c)** and OPEX **(d,e,f)** for each of the 6 key configurations. Electrodes of CF (Carbon Felt) and RVC (Reticulated Vitreous carbon), and membranes of Nafion, BioChar and Earthenware based materials are assessed. Plots **(a)** & **(c)**, examine the distribution of costs at the 1 kilotonne scale. Plots **(b)** & **(e)**, examine the impact of plant scale at the operating point. Plots **(c)** & **(f)**, examine the impact of required illumination on costs. All non-varied properties are fixed at the specified operating point defined in S2.6.

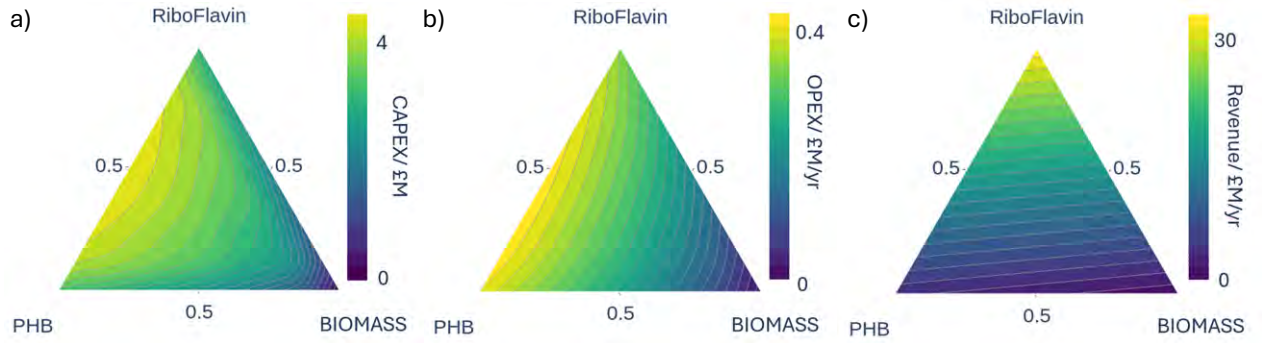

**Figure 4:** Plots of separation subsystem predicted CAPEX **(a),** OPEX **(b),** and Revenue **(c)** at the 1 kilotonne scale as a function of of product split between low (biomass), medium (PHB), and high (riboflavin) value added products.

Owing to its high value, separation subsystem revenue is predicted to be predominantly influenced by riboflavin yield, demonstrating the impact of high value end products. For a 1 kilotonne per year (kt $yr^{-1}$) plant, with riboflavin yields in the range of 10-20%, expected revenue is between £5 million and £15 million per year, with subsystem OPEX under £0.5 million per year and CAPEX ranging from £0.5 million to £5 million.

## Overall System Analysis

At the kilotonne scale both total CAPEX is estimated to be £12M and OPEX is estimated to be £8M/yr resulting in a TAC (total annualized cost) of approximately £10M, assuming Flue gas Carbon capture. Thus, at this scale riboflavin production is key to viability. To increase profit we identified 4 potential measures: (1) Reducing costs of the carbon capture subsystem, (2) Increasing bioreactor volumetric efficiency, (3) Reducing required illumination by engineering rhodopsin, (4) Using low-cost reactor materials.

Figure 5 shows the impact of each of these measures on estimated OPEX, CAPEX and profit at the 1 kilotonne scale with a 20% yield of Riboflavin when employing flue gas as a carbon source. With the current technology, the system can be considered unprofitable owing to the large volume of the reactor and the high energy and capital costs incurred. Cases 2 and 3 overcome this challenge in two different ways. Case 2 employs an RVC electrode, reducing required volume, simultaneously reducing required illumination and capital. Case 3 employs an engineered protein halving lighting requirement, significantly reducing OPEX. Thus, while OPEX reductions from using both novel reactor materials and engineered proteins is significant, a combination of these two approaches is required to have a reliably profitable system.

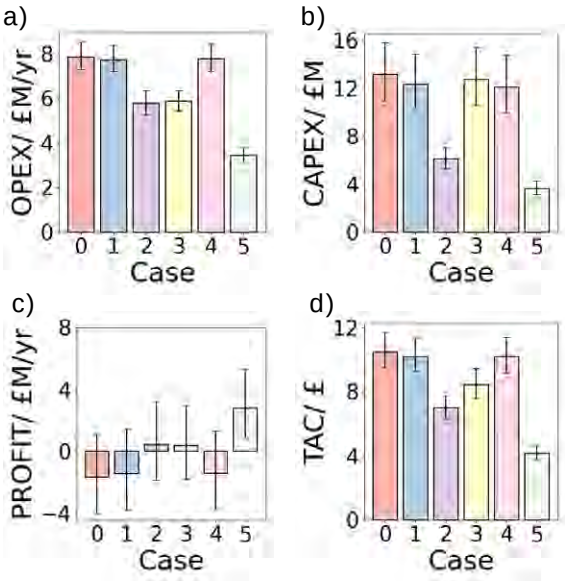

**Figure 5:** Plots of predicted CAPEX **(a)**, OPEX **(b)**, Profit **(c),** and TAC **(d)** at the 1 kilotonne scale assuming a 20% yield of Riboflavin. Case 0 represents the base case(a system with an unmodified carbon felt electrode with a Nafion membrane, the published state of technology[3], [4]) , Case 1 reduces required $CO_2$ purity to 20%, Case 2 implements an RVC electrode reducing required volume, Case 3 reduces required PPFD by 50%, Case 4 reduces Membrane cost to 0, Case 5 is the cumulative effect of all perturbations.

## SUMMARY

Our study reveals both challenges and opportunities for rhodopsin-driven BIO-ELECTROCHEMICAL synthesis in carbon capture and utilization (CCU). While the current configuration is not yet economically feasible at the 1 kilotonne scale, improvements in light-harvesting efficiency and reactor materials are predicted to achieve a one-year payback time, making large-scale deployment realistic. Our stochastic techno-economic analysis (sTEA) approach helps navigate technological uncertainties by considering parameter variability, providing crucial insights for optimization. This study thus serves as both an assessment of rhodopsin-driven Artificial Photosynthetic Bio-electrochemical Systems for CCU and a broader framework for evaluating emerging

technologies.

## ABSTRACT

Industrial process monitoring can benefit from utilizing historical data, providing insights for decision-making and operational efficiency. This study develops a soft-sensor-based approach leveraging multi-fidelity modeling to correct discrepancies between online sensors and laboratory analyses. A Gaussian process-based strategy is used to predict deviations between high-frequency low-fidelity sensor data and less frequent high-fidelity laboratory measurements. By exploring static and dynamic modeling frameworks, we assess their suitability for capturing process dynamics and addressing time-dependent variability. The multi-fidelity soft sensor noticeably improves predictive accuracy, outperforming high-fidelity and low-fidelity methods. This approach demonstrates applicability across various industrial settings where integrating diverse data sources enhances real-time process control and monitoring, reducing reliance on costly laboratory sampling.

**Keywords**: Machine Learning, Process Monitoring, Modelling, Information Management, Industry 4.0

## INTRODUCTION

Industrial processes rely on effective monitoring and control to ensure efficiency, safety, and optimal performance. Accurate process data, acquired through sensors and analyzers, form the foundation for decision-making and optimization [1]. Laboratory measurements provide precise, high-fidelity (HF) data but are often infrequent due to cost or logistical constraints. In contrast, online sensors generate low-fidelity (LF) data at high frequencies but can vary in reliability and accuracy [2]. Differences in the quality and frequency of these data sources have motivated the development of advanced modeling approaches to improve process monitoring [3].

Soft sensors (SS) [4] have emerged as a key tool for improving process monitoring by using predictive models to estimate process variables based on online measurements. These models typically rely on periodic calibration with HF data to address sensor drift and inaccuracies. However, traditional calibration processes often use HF data solely for single-point corrections, leaving the potential of historical HF data to improve predictive accuracy over time. Multi-fidelity (MF) modeling [5] addresses this limitation by combining LF and HF data, enhancing predictive accuracy and improving the reliability of process monitoring systems.

MF modeling utilizes historical datasets to develop predictive models that mitigate the discrepancies between LF and HF data. Both static and dynamic models offer viable approaches for capturing the underlying behavior of the system. Static models [6] are well-suited for representing systems in relatively stable states but lack the ability to incorporate time-dependent behaviors, making them less appropriate for processes with significant temporal variability. In contrast, dynamic models [7] explicitly account for temporal dependencies, offering a more comprehensive representation of process variability at the cost of increased structural complexity.

Techniques, such as the Kalman filter [8], can be applied to both static and dynamic models to improve predictive accuracy. By estimating and compensating for potential unmeasured errors or biases in real time, these tools enhance the reliability of predictions, particularly in noisy, high-frequency datasets. While dynamic models

commonly integrate these methods to manage process variability, traditional approaches like bias correction have long been employed in static models to address long-term drifts or measurement inaccuracies.

Gaussian Process Regression (GPR) has demonstrated effectiveness in both single-fidelity and multi-fidelity modeling contexts, providing accurate predictions and quantifying uncertainties in high-dimensional industrial datasets [9]. Within this study, GPR serves as a key tool for fusing LF and HF data, correcting LF signals by predicting deviations and applying these corrections to approximate HF data in real time.

In this context, we aim to develop a MF modeling framework that enhances industrial process monitoring by integrating LF online sensor data with HF laboratory measurements. This approach addresses challenges such as sensor faults and measurement anomalies by utilizing a soft sensor (SS) that estimates true values, reducing reliance on frequent and costly laboratory sampling. By combining static and dynamic methods within a MF modeling framework, this work demonstrates how soft-sensor-based correction can improve predictive performance and reliability in process monitoring applications.

## PROBLEM DEFINITION

This study considers two types of historical datasets: LF data obtained from online sensors, and HF data derived from laboratory measurements. LF data are collected continuously at a high sampling rate, offering detailed temporal information. In contrast, HF data are gathered less frequently and serve as reference points for calibrating and validating the LF sensors.

The time instances for LF measurements are represented as $\mathcal{T}_{LF} = \{t_1, t_2, \ldots, t_{n_{LF}}\}$, and for HF samples as $\mathcal{T}_{HF} = \{\tau_1, \tau_2, \ldots, \tau_{n_{HF}}\}$, with $\mathcal{T}_{HF} \subset \mathcal{T}_{LF}$. Typically, HF data are collected far less frequently than LF data, making $n_{HF} \ll n_{LF}$. The corresponding index sets for HF and LF data are denoted as $\mathrm{I}_{HF} \subset \mathrm{I}_{LF}$, respectively.

The objective is to create a predictive model that maps process variables $\boldsymbol{x} \in R^{n_x}$ to a target output $y \in R$. A linear model at the $i$-th time instant is expressed as:

$$\hat{y}_i = \boldsymbol{\theta}^T \boldsymbol{\varphi}_i + \epsilon_i, \tag{1}$$

where $\hat{y}_i$ is the predicted output, $\boldsymbol{\varphi}_i$ represents a vector of regressors, $\boldsymbol{\theta}$ is the parameter vector, and $\epsilon_i$ accounts for errors or unmodeled variability. Alternatively, a nonlinear model can be defined as:

$$\hat{y}_i = f(\boldsymbol{\theta}, \boldsymbol{\varphi}_i) + \epsilon_i, \tag{2}$$

where $f$ is a nonlinear function parameterized by $\boldsymbol{\theta}$. The structure of the regressor vector $\boldsymbol{\varphi}_i$ depends on the chosen modeling approach:

a) Static model: $\boldsymbol{\varphi}_i = \boldsymbol{x}_i$, this approach relies solely on current input values.

b) Dynamic model: $\boldsymbol{\varphi}_i = (\boldsymbol{x}_{i-1}, \ldots, \boldsymbol{x}_{i-j}, y_{i-1}, \ldots, y_{i-k})$, this approach incorporates lagged inputs and outputs to account for temporal dependencies.

Here, $j$ and $k$ denote the number of lagged values included for the input variables $\boldsymbol{x}$ and output $y$, respectively.

**Figure 1:** Soft sensor development flowchart.

## METHODOLOGY

This section outlines the methodology used to develop and compare static and dynamic modeling approaches (see Figure 1).

### Preprocessing

Raw data, denoted as $\boldsymbol{X}_{raw}$ for input features and $\boldsymbol{y}_{raw}$ for the dependent variable, often contain noise, outliers, and missing values due to plant disturbances. Preprocessing addresses these issues to ensure robust model development [10]. Outliers are detected and replaced while preserving temporal dependencies in the dynamic model, as discussed in [11].

### Feature Selection

Feature selection (FS) aims to identify a subset of relevant process variables, $\boldsymbol{\phi}$, enhancing model interpretability and reducing overfitting. Several methods guide feature selection, balancing statistical rigor with practical relevance informed by process knowledge. As detailed in [11], the following approaches were employed for both static and dynamic models:

a) Principal Component Analysis (PCA) reduces dimensionality by transforming the original variables into uncorrelated principal components (PCs) that maximize variance.

b) Partial Least Squares (PLS) Regression identifies latent variables that maximize covariance between the independent variables and the dependent variable.

c) LASSO Regression introduces an $\ell_1$-norm penalty to enforce sparsity and enhance interpretability.

d) Stepwise Regression (SR) iteratively selects variables based on statistical significance, guided by metrics such as Akaike Information Criterion (AIC), Corrected Akaike Information Criterion (AICc), and the Bayesian Information Criterion (BIC).

Beyond statistical selection, domain knowledge is incorporated to refine the feature set. Process experts review the ranked variables and identify unsuitable candidates that could introduce misleading correlations. The next-best ranked alternative from the best-performing FS method is substituted. This approach ensures the model captures the most relevant process features while maintaining transferability to similar environments with minor adjustments based on site-specific expertise. These methods enhance model interpretability, streamline computational efficiency, and minimize the risk of overfitting [12].

## Soft Sensor Training

The parameters of the model defined in Equation 1 are estimated by solving the following optimization problem:

$$\min_{\boldsymbol{\theta}} \frac{1}{2}||\boldsymbol{y}_l - \hat{\boldsymbol{y}}_l||_2^2 \equiv \min_{\boldsymbol{\theta}} \frac{1}{2}\Sigma_{i=1}^{n_l}(y_{l,i} - \hat{y}_{l,i})^2, \quad (7)$$

where $l \in \{LF, HF\}$ denotes whether the model corresponds to LF or HF data, and $n_l$ is the number of samples in the respective dataset.

## Multi Fidelity Soft Sensor Development

The MF SS integrates trained LF and HF models into a unified MF modeling approach. The predictor matrix $\boldsymbol{\phi}_{MF}$ is constructed as follows:

$$\boldsymbol{\varphi}_{MF,i} = (\boldsymbol{\varphi}_{LF,i}^T, \boldsymbol{\varphi}_{HF,i}^T, \boldsymbol{y}_{LF}^T, \hat{\boldsymbol{y}}_{LF}^T)^T. \quad (8)$$

This matrix combines features and predictions from both fidelity levels. An additional feature selection step can be conducted to further refine the input space.

Subsequently, the MF SS is trained by using a Gaussian Process (GP), which is defined as:

$$\hat{\boldsymbol{y}}_{MF} \sim \mathcal{GP}(m(\boldsymbol{\kappa}), k(\boldsymbol{\kappa}, \boldsymbol{\kappa}')), \quad (9)$$

where $\boldsymbol{\kappa}$ represents selected predictors derived from $\boldsymbol{\phi}_{MF}$. The mean function $m(\boldsymbol{\kappa})$ captures the expected output, while the covariance function, also referred to as the kernel $k(\boldsymbol{\kappa}, \boldsymbol{\kappa}')$, describes dependencies between data points.

In this model, the kernel is defined as:

$$k(\boldsymbol{\kappa}, \boldsymbol{\kappa}') = C.e^{-M} + e^{\frac{2sin^2 M}{\ell^2}} + \sigma^2.\delta_{\kappa,\kappa'}, \quad (10)$$

where $M = 1/2\,||\boldsymbol{\kappa} - \boldsymbol{\kappa}'||^2$ . The kernel comprises four components (from left to right): a constant term $C$, a radial basis function (RBF) kernel to capture smooth variations, a periodic kernel to model sinusoidal behaviors, and a white noise kernel accounting for measurement noise through $\delta_{\kappa,\kappa'}$. The parameters include $\ell$ (length scale), determining the range of influence, and $\sigma^2$, representing noise variance

# CASE STUDY

The alkylation process plays a pivotal role in refineries, producing high-octane branched isoparaffins, known as alkylate, which are crucial components of clean gasoline. This process involves the reaction of $C_3$–$C_4$ olefins with isobutane (i-$C_4$) under the influence of an acid catalyst. The reaction mechanism begins with the protonation of olefins, forming carbonium cations that subsequently react to generate $C_8$ isomers [13, 14].

Efficient alkylate production relies on maintaining an optimal reactant ratio. To ensure this, online analyzers are strategically deployed throughout the plant (Figure 2) to provide real-time measurements of key feed and recycle stream components. This enables precise process control. Over a six-month period, a comprehensive

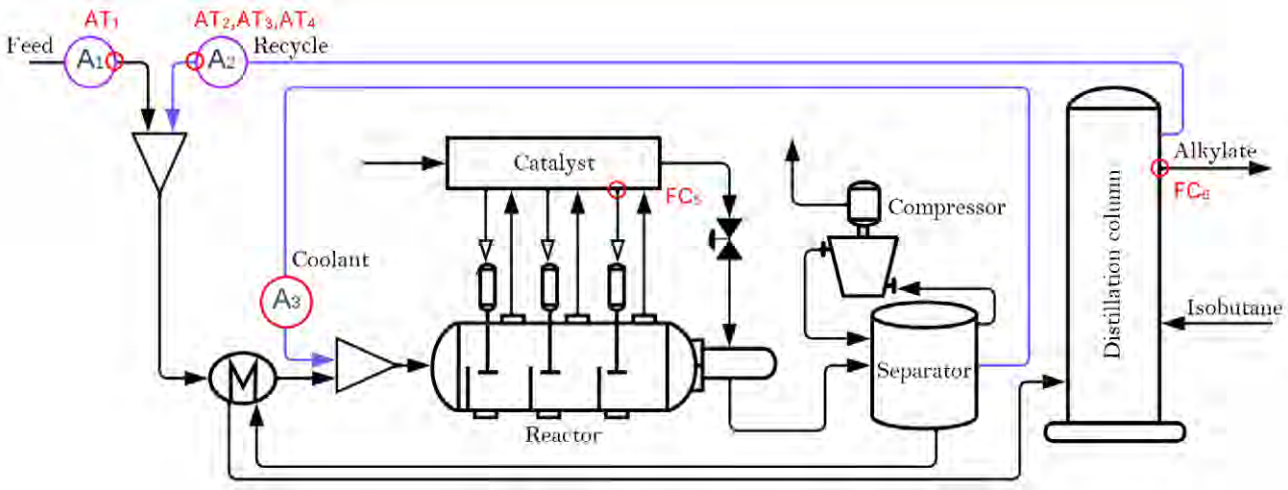

**Figure 2:** Simplified schematic of the alkylation unit, highlighting Analyzer $A_3$ (red) as well as the six selected variables used in soft sensor training.

dataset, $\boldsymbol{X}_{raw}$, was gathered, comprising more than 1085 process variables from online sensors, analyzers, resulting in $N \times 1085$ data points, while the laboratory samples correspond to a subset of these timestamps.

The study focuses on Analyzer $A_3$ and its corresponding laboratory reference data, $\boldsymbol{y}_{LF}$ and $\boldsymbol{y}_{HF}$. Analyzer $A_3$ monitors the i-$C_4$ concentration in the recycle stream but has demonstrated inconsistent performance. These inconsistencies often lead to an over-recycling of i-$C_4$, imposing additional downstream processing burdens, such as increased heating and treatment requirements. Therefore, improving the prediction of analyzer measurements is vital for optimizing production efficiency and minimizing by-products.

## IMPLEMENTATION

We preprocess the raw input data $\boldsymbol{X}_{raw}$ and corresponding raw output data $\boldsymbol{y}_{raw}$ (see Figure 1). The resulting preprocessed data, $\boldsymbol{X}_{proc}$ and $\boldsymbol{y}_{proc}$, are then split into training and testing sets in a 60% to 40% ratio. The training period spans four months, while the testing period covers two months. This selection is particularly relevant as seasonal variations during this timeframe can significantly influence process dynamics, including changes in the characteristics of the feedstream. Given the limited availability of HF data, chronological ordering was maintained to preserve time dependencies.

From the preprocessed dataset $\boldsymbol{X}_{proc}$, we identify the most relevant variables ($\boldsymbol{\phi}_i$) using the best-performing FS method outlined in the Feature Selection subsection. To address the limited HF data, we rely on the LF dataset during FS, as the sparsity of HF data may fail to capture key interactions and trends where the output variable is influenced by time-dependent changes across multiple inputs. By leveraging the more frequent LF measurements, we ensure that the selected features ($\boldsymbol{\phi}_{LF}$) reflect these dynamics more effectively, reducing the risk of missing correlations present in the data that would not be evident in $\boldsymbol{\phi}_{HF}$.

Both static HF and LF SSs ($\hat{\boldsymbol{y}}_{HF}$ and $\hat{\boldsymbol{y}}_{LF}$) are trained using the same set of features $\boldsymbol{\phi}_{LF}$, as described in Equation 1. These features are further refined with insider knowledge to enhance their operational relevance and consistency across both SSs. For the dynamic LF SS, we extend the feature set ($\boldsymbol{\phi}_{LF}$) by incorporating time-shifted versions determined by the model order to capture time-dependent system dynamics. We formulate the SS as a linear state-space model, and system identification is performed using the SIPPY (Systems Identification Package for Python) [15] library, employing the PARSIM-K robust identification method [16]. This approach, aimed for closed-loop data identification, ensures accurate representation of system dynamics with minimal number of parameters. The SS performance is further enhanced using information criteria such as AIC, AICc, and BIC for optimal model order selection. Additionally, a Kalman filter option of the PARSIM-K method is explored to refine the dynamic SS predictive accuracy.

We extend the LF models into MF framework by incorporating a GP model. This approach corrects deviations between LF and HF measurements, leveraging the strengths of both datasets for more accurate real-time monitoring of process variables (as illustrated in Figure 3). The MF SS effectively mitigates signal drift and compensates for the limited availability of HF samples.

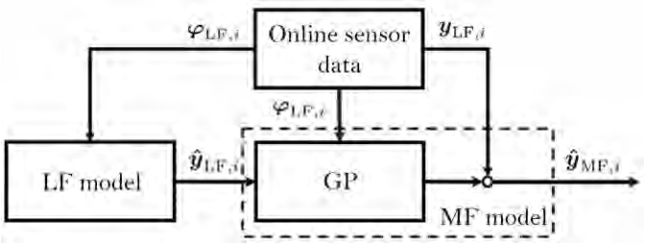

**Figure 3:** Workflow of the MF SS correction of the online analyzer $A_3$.

**Table 1:** RMSE comparison of the online analyzer against the static and dynamic LF prediction models.

| Method | Training RMSE | | Testing RMSE | |
|---|---|---|---|---|
| $\boldsymbol{y}_{LF}$ to $\hat{\boldsymbol{y}}_{LF,s}$ | 0.21 | | 0.37 | |
| $\boldsymbol{y}_{LF}$ to $\hat{\boldsymbol{y}}_{LF,d}$ | w KF | w/o KF | w KF | w/o KF |
| | 0.03 | 0.29 | 0.02 | 0.42 |

**Table 2:** RMSE comparison of the laboratory samples against the applied predictive approaches.

| Comparison | Training RMSE | Testing RMSE |
|---|---|---|
| $\boldsymbol{y}_{HF}$ to $\boldsymbol{y}_{LF}$ | 0.63 | 0.80 |
| $\boldsymbol{y}_{HF}$ to $\hat{\boldsymbol{y}}_{HF}$ | 0.18 | 0.91 |
| $\boldsymbol{y}_{HF}$ to $\hat{\boldsymbol{y}}_{MF,s}$ | 0.22 | 0.46 |
| $\boldsymbol{y}_{HF}$ to $\hat{\boldsymbol{y}}_{MF,d}$ | 0.31 | 0.38 |
| $\boldsymbol{y}_{HF}$ to $\hat{\boldsymbol{y}}_{MF,d_{KF}}$ | 0.21 | 0.46 |

## RESULTS

We standardize the dataset to ensure consistent variable scaling across all analyses. During FS, we prioritize the LF data, as it better captures the time-dependent relationships between input ($\boldsymbol{X}_{proc}$) and output ($\boldsymbol{y}_{proc}$). The sparse nature of $\boldsymbol{y}_{HF}$ can overlook these dynamic interactions, as it fails to capture the nuances of how $\boldsymbol{y}_{LF}$ responds to changes in $\boldsymbol{x}$ over time. We select SR as the most suitable feature selection method based on the results from [11]. Additionally, we refine these features with domain knowledge, improving their relevance and ensuring consistency across both static and dynamic models. The final feature set includes six critical variables, highlighted in Figure 2: four concentrations ($AT_1$ to $AT_4$) and

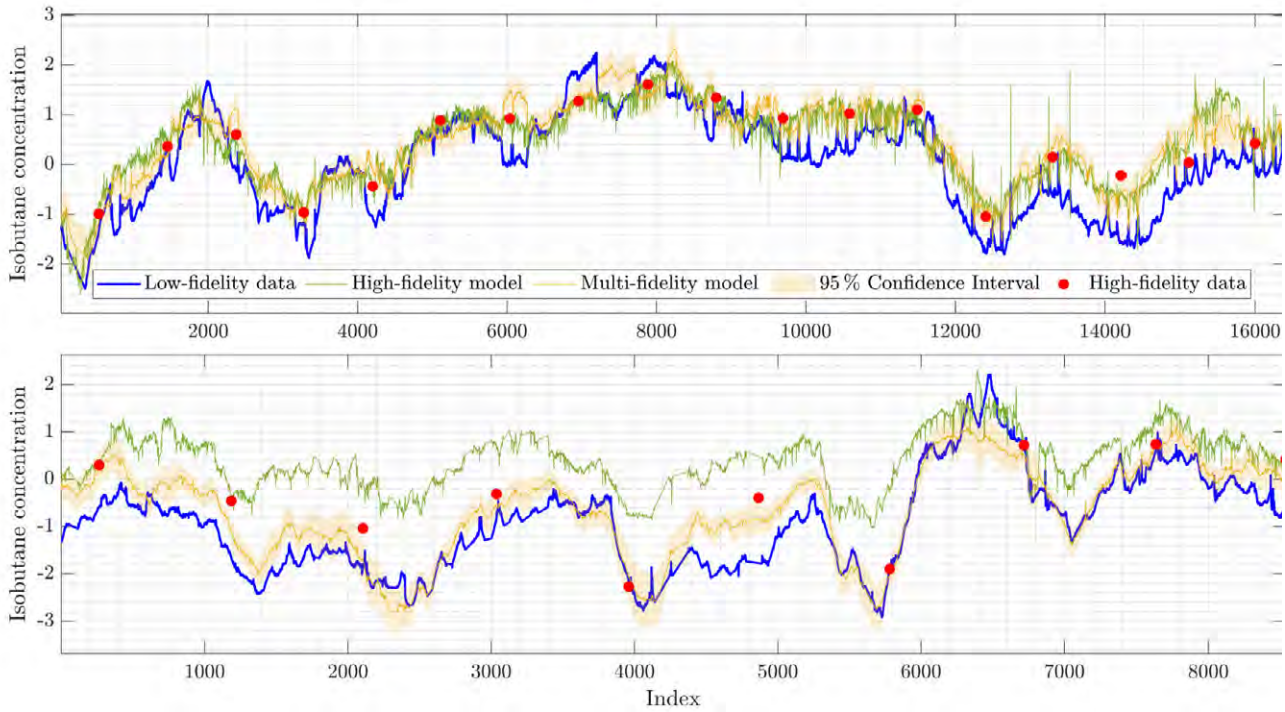

**Figure 4:** Predicted normalized i-$C_4$ concentration for the training set (top) and testing set (bottom) as time series.

two flow rates ($FC_5$ and $FC_6$).

We aim to predict the measurements from the online analyzer $A_3$. We train a static LF SS $\hat{\boldsymbol{y}}_{LF,s}$ with the six previously selected inputs. This approach achieves RMSE values of 0.21 during training and 0.37 during testing (Table 1). However, the alkylation unit operates with multiple recycles, where process streams re-enter the system at different stages, causing data variations. These recycles introduce complexities that static models cannot address. We develop a dynamic LF model $\hat{\boldsymbol{y}}_{LF,d}$ to address the temporal dependencies in the data. We optimize the SS complexity through system identification and select a 4th-order model to balance accuracy and computational efficiency based on AIC, AICc, and BIC criteria. We achieve a RMSE value of 0.29 for training and 0.42 for testing. To improve predictive accuracy, we integrate a Kalman filter into the $\hat{\boldsymbol{y}}_{LF,d}$, defined as $\hat{\boldsymbol{y}}_{LF,d_{KF}}$, significantly reducing RMSE values to 0.03 for training and 0.02 for testing. The Kalman filter proves instrumental in mitigating disturbances and improving reliability.

The performance metrics for all predictive approaches are summarized in Table 2, with laboratory data ($\boldsymbol{y}_{HF}$) compared against all SSs. The current online analyzer $A_3$ ($\boldsymbol{y}_{LF}$) exhibits RMSE values of 0.63 for training and 0.80 for testing, resulting in inaccurately capturing the real process trends.

The HF SS $\hat{\boldsymbol{y}}_{HF}$ (green line in Figure 4) achieves an RMSE of 0.18 on the training set, which increases to 0.91 on the testing set. This increased RMSE value highlights that both, the features selected, and the limited amount of HF data available likely hamper the SS ability to capture the full variability within the HF dataset; as further visual analysis suggests that the HF SS effectively captures the trends in the HF data.

To obtain the MF SS output, we train a GP to predict deviations of the LF analyzer data from the HF laboratory measurements, defined as $\boldsymbol{\Delta}_{HF,i} = \mathbf{y}_{HF,i} - \mathbf{y}_{LF,i}, \forall i \in \mathfrak{I}_{HF}$. This approach enables operators to monitor $\boldsymbol{\Delta}_{HF}$ and its dispersion, offering a practical means to assess the calibration of the online analyzer and identify potential deviations in its accuracy. The GP model can incorporate either the static LF model ($\hat{\boldsymbol{y}}_{LF,s}$) or the dynamic LF model ($\hat{\boldsymbol{y}}_{LF,d}$) as an additional input, with the latter having two variations: with ($\hat{\boldsymbol{y}}_{LF,d_{KF}}$) and without Kalman filtering. PCA is applied to reduce the dimensionality of the input variables, consisting of the original six process variables and the selected LF model, into four principal components (PCs). Depending on the chosen input, the MF SS predictions are denoted as $\hat{\boldsymbol{y}}_{MF,s}$, $\hat{\boldsymbol{y}}_{MF,d}$, or $\hat{\boldsymbol{y}}_{MF,d_{KF}}$.

The static MF SS ($\hat{\boldsymbol{y}}_{MF,s}$) achieved an RMSE of 0.22 during training and 0.46 during testing. Although this approach provides promising results during training, its higher testing RMSE indicates similar limitations in addressing the aforementioned system dynamics.

When selecting the most suitable additional input within the dynamic MF SS ($\hat{\boldsymbol{y}}_{MF,d}$), $\hat{\boldsymbol{y}}_{LF,s}$ achieves a lower RMSE when compared to $\boldsymbol{y}_{LF}$ (0.37 compared to 0.42 for testing, as shown in Table 1), it exhibits significant deviations from $\boldsymbol{y}_{HF}$. In contrast, $\hat{\boldsymbol{y}}_{LF,d}$ better aligns with the trends in $\boldsymbol{y}_{HF}$, as evidenced by smaller maximum and

minimum errors relative to $\boldsymbol{y}_{HF}$. This suggests that the dynamic SS, despite a higher RMSE against $\boldsymbol{y}_{LF}$, provides a more reliable representation of process dynamics.

The Kalman-filtered dynamic MF SS ($\hat{\boldsymbol{y}}_{MF,d_{KF}}$) amplifies certain LF anomalies, propagating biases that reduce the GPs ability to make unbiased predictions (RMSE = 0.46). Consequently, the non-Kalman dynamic MF SS ($\hat{\boldsymbol{y}}_{MF,d}$) enhances predictive accuracy while mitigating the influence of LF anomalies (RMSE = 0.38). As shown in Figure 4, the blue solid line represents the original LF data ($\boldsymbol{y}_{LF}$), the orange line denotes the MF SS predictions ($\hat{\boldsymbol{y}}_{MF,d}$), and the red markers indicate the HF laboratory data. The orange shaded region illustrates the 95% confidence interval of the GP model.

Ultimately, the most accurate MF SS ($\hat{\boldsymbol{y}}_{MF,d}$) accounts for LF discrepancies with GP-predicted corrections, achieving RMSE values of 0.31 for training and 0.38 for testing. These findings highlight the importance of time-dependent behavior, enabling us to capture system dynamics and adapt to temporal variations, which leads to improved performance over static soft sensors.

## CONCLUSION

In this work, we compare static and dynamic modeling approaches within a multi-fidelity framework to improve the accuracy of online measurements. The static models ($\hat{\boldsymbol{y}}_{LF,s}$) fail to capture temporal dependencies, which limits their applicability in complex systems with time-varying dynamics. Dynamic models ($\hat{\boldsymbol{y}}_{LF,d}$), especially those incorporating Kalman filtering, effectively address these challenges, achieving an improvement in capturing the underlying process behavior. However, incorporating the Kalman filter into the MF SS increases the RMSE, negatively impacting performance in the MF framework. The most viable SS ($\hat{\boldsymbol{y}}_{MF,d}$) demonstrates a 52.50% enhancement in accuracy over the currently implemented online analyzer, significantly improving the alignment between online LF measurements and laboratory HF values.

Future work will focus on refining dynamic modeling techniques by addressing process non-linearities and further optimizing GP implementations to enhance accuracy and robustness.

## ABSTRACT

The performance of chemical plants is inevitably related to knowledge about the current state of the system. However, both process and equipment drifts may distort state information. Deviations of process values caused by equipment malfunction may be misinterpreted as process drifts and vice versa. Determining the cause of the drift is further complicated by the fact that equipment drifts typically occur in combination with process drifts. This paper presents a method that uses available additional equipment data to reliably detect and decouple combined equipment and process drifts in chemical plants by combining statistical methods with model-based approaches. The utility of additional equipment information is assessed based on its effect on the decoupling of process and equipment drifts. First results demonstrate the feasibility of the approach in a real plant.

**Keywords**: Fault Detection, Modelling, Process Monitoring, Coupled Drifts, Namur Open Architecture

## 1 MOTIVATION

In the chemical industry a combination of high plant availability and desired product quality is required to operate economically. This is achieved if the desired operating point is maintained, which requires accurate information about the state of both the process and the equipment. If inaccurate process information is used, the plant cannot be operated with sufficient accuracy. The result is loss of quality and, in the worst case, plant shutdowns and a reduction in plant availability. Equipment drifts, such as fouling or wear in sensors or actuators, can lead to inaccurate process information. Measurement deviations that are caused by equipment malfunction or insufficient calibration can be misinterpreted as process drifts and vice versa. When this happens, the operating point is updated even though the process has not changed. As a result, the quality of the product is reduced.

Such equipment drifts typically occur in combination with process drifts. Very often, the data collected in the process control systems and historians is not sufficient to clearly determine the causes of the drifts. However, additional equipment information, such as device health information, is typically collected in modern devices. It has the potential to enable the differentiation and decoupling of coupled drifts. For this reason, a method is developed that uses this additional information to detect and decouple combined process and equipment drifts.

This paper is organized as follows: first, fundamentals of drift types and their detection methods are presented. Then, the developed methodology is explained by describing its assumptions, requirements and workflow for detecting and decoupling of coupled drifts. Furthermore, the evaluation of additional equipment information is explained. A case study in a real plant demonstrates the applicability and feasibility of the approach. Finally, the method is critically evaluated.

## 2 BACKGROUND

### 2.1 Definition of Drifts

In the literature various definitions of process drift and equipment drift can be found. According to Kadlec et al. [1], process drifts affect the measured data and the state of the process. Sensor drifts only affect the measured data. Actuator drifts are not mentioned. In contrast, the NAMUR Recommendation 107 on Self-Monitoring and

Diagnosis of Field Devices [2] describes status signals for the diagnosis of appliances and field devices. Diagnostic bits are used to differentiate between possible error sources. However, only equipment failures are considered. In addition, the International Electrotechnical Commission defines a drift as a "change in the indication of a measuring instrument, generally slow, continuous, not necessarily in the same direction and not related to a change in the measurand" [3]. This definition corresponds to equipment drift.

Each of these definitions is missing some type of drift, and if both process and equipment drift were defined, the definitions would no longer work. Therefore, the information on process drifts affecting the state of the process is taken from Kadlec et al. [1]. In addition, NAMUR Recommendation 107 [2] and the International Electrotechnical Commission [3] provide necessary information on equipment drifts.

Based on this information and in the context of this research, process drift and equipment drift are defined as occurrences with the following results:

**Process drift:**

> unacceptable, unforeseen variation of predefined critical process parameters from their desired operating point for an unacceptable period of time

**Equipment drift:**

> unacceptable, unforeseen variation in the operating principle of measuring or control devices for an unacceptable period of time

## 2.2 Drift Detection Approaches

In the literature, various approaches have been found to detect drifts, some of which also diagnose the cause of the drifts. According to Venkatasubramanian et al. [4], methods of detection are divided into model-based and data-based.

Common model-based approaches are observers and redundancy-based methods. Observers are models that continuously update and improve an estimate of the system state [5]. Redundancy-based methods generate optimal reference values for measured sensor data [6]. Residuals, the differences between the estimated and measured states or the redundant values, are calculated and compared to drift detection thresholds [5], [6]. As model-based approaches describe the system using equipment and process knowledge the modeling effort increases significantly with the complexity of the system. For applications in large chemical plants, it can be concluded that high system complexity can lead to a disproportionate modeling effort [4].

Common data-based approaches are statistical methods and machine learning. Statistical methods are utilized to reduce the dimensions of the data. For instance, cluster analysis is used to divide the data into clusters of normal and abnormal variation. A cluster is an area with specific characteristics, such as an area with a certain drift or an area without any drift. Drifts are detected by analyzing if data points belong to the cluster with normal or abnormal variation [7], [8], [9]. The difficulty with statistical methods is that enough data must be available from the time a drift occurs. Machine learning trains and tweaks models such as neural networks to classify the data. The outputs are different categories such as no drift or drift [10]. However, to build a data-based model, classified data is needed for training, which is very often not available for chemical plants. The reason for this is that it is not known when a drift occurs and what kind of drift it is.

None of these approaches addresses combined drifts and their decoupling. In recent years, the amount of available data has increased greatly due to digitalization. This is not considered in the proposed approaches of the relevant literature. Modern devices record a range of additional information complementing the primary measurement value. If these additional information streams can be accessed, e.g. via the process control system or a side-channel such as the NAMUR open architecture, and utilized, they can help to differentiate between process and equipment drifts and their coupling.

# 3 METHODOLOGY

Due to the large amount of data available in chemical plants nowadays, it is reasonable to use data-based methods such as statistical methods. These methods divide the data into clusters. But there is a problem - after such a cluster analysis it is not possible to assign which cluster belongs to which drift. The solution is to combine statistical methods with model-based approaches. Possible drifts are modeled and compared with the clusters to assign them to the drifts. The idea of decoupling is to reconstruct the individual drifts and span drift vectors to characterize them. Data points that are drift couplings are then also represented as vectors. Drift decomposition splits these data point vectors into individual drifts and decoupling is complete.

However, the combination of these approaches and the decoupling of combined drifts is only possible if process data and additional equipment information are available and can be used.

## 3.1 Assumptions and Requirements

First, assumptions are made about the method being developed. They also address the process and equipment for which the method can be used.

1. Data from the equipment under consideration is accessible. This includes primary measurement

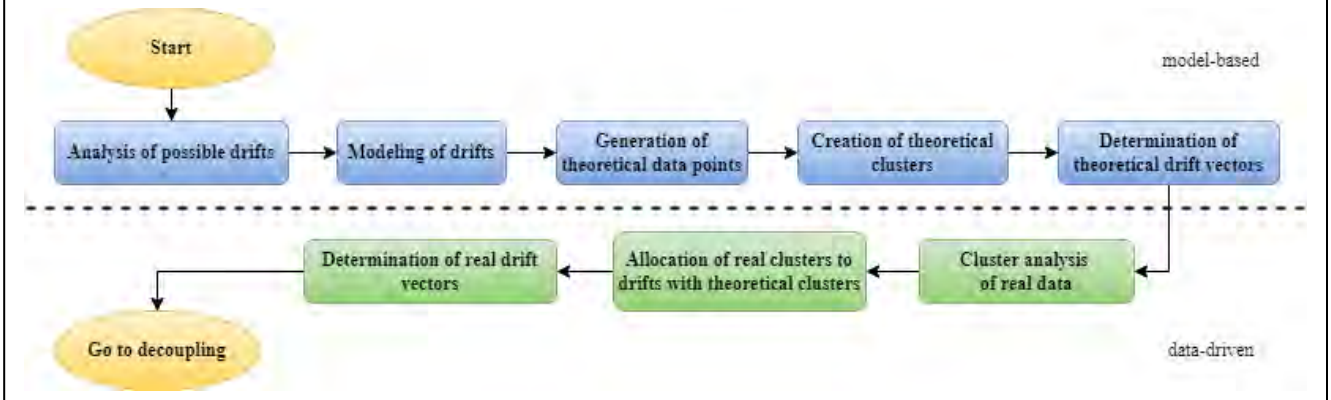

**Figure 1:** Workflow for the identification of drift areas. These steps are necessary to decouple coupled drifts. Yellow is the start and end of the workflow, blue is the model-based part, and green is the data-driven part.

values as well as additional equipment information.

2. Devices without additional equipment information can also be used with this method. Primary measurement values and the information streams of other devices in the chemical plant help to compensate for the lack of additional equipment information.
3. It is known what drifts can occur on the equipment under consideration and their approximate impact on the data streams.
4. The drifts are considered to be independent.
5. The available data can be separated by cluster analysis.
6. The process must be continuous with a steady state setpoint and low dynamics. The method cannot be used for processes with varying process conditions, changing target states or high dynamics.

Requirements related to the goal are:

1. Drift detection.
2. Distinguishing between process and equipment drifts.
3. Determining the cause of the drift.
4. Detecting and unambiguous decoupling of combinations of known drifts.
5. Evaluation of what additional equipment information is needed to decouple the drift combinations.

## 3.2 Drift Areas Identification/Characterization

At the beginning, it is necessary to identify and characterize the areas of the drifts to perform the developed method. The workflow for this is shown in Figure 1. The first step is to analyze possible drifts in the equipment and plant under consideration. These drifts are then modeled mechanistically, allowing the creation of theoretical data points. These theoretical data points are used to build theoretical clusters as a reference for specific clusters. When modeling, it is important to ensure that the theoretical clusters do not overlap. If they overlap during the modeling process, increase the modeling dimension with the help of additional equipment information until they no longer overlap. After that, the centers of the theoretical clusters are formed, e.g. if the theoretical data points are uniformly distributed, as the geometric center of their theoretical data points. To characterize the theoretical drift clusters, vectors are drawn from the center of the cluster without drift to the centers of the drift clusters. These theoretical drift vectors are determined by their direction and their length is positive.

Next, real data is used to perform a cluster analysis. The real clusters are assigned to the drifts by comparison with the theoretical clusters. Then, their centers are calculated, e.g. as the geometric center of their real data points. To characterize the real drift clusters, vectors are drawn from the center of the cluster without drift to the centers of the drift clusters. These real drift vectors are determined by their direction and their length is positive.

## 3.3 Decoupling of Coupled Drifts

When the drift areas are identified and characterized, new data points can be categorized. The first step is to check if the data point belongs to a real cluster. If so, the new data point is assigned to that cluster and the associated drift. Drift detection is complete.

However, if the data point does not belong to a real cluster, there is a high probability of a coupled drift, because only a combination of at least two drifts leads to this area. Vector decomposition and vector addition are

used to determine the individual drifts that are combined. First, a vector is drawn from the center of the cluster without drift to the data point to be categorized. This vector is called the data point vector $\boldsymbol{v}_{\mathrm{DP}}$. Then $\boldsymbol{v}_{\mathrm{DP}}$ is decomposed into individual drifts. This is shown schematically in Figure 2. To decompose $\boldsymbol{v}_{\mathrm{DP}}$, it is compared with the existing real drift vectors $\boldsymbol{v}_{\mathrm{r}}$. The real drift vector that is most parallel to $\boldsymbol{v}_{\mathrm{DP}}$ is selected. In Figure 2 $\boldsymbol{v}_{\mathrm{r1}}$ is more parallel to $\boldsymbol{v}_{\mathrm{DP}}$ than $\boldsymbol{v}_{\mathrm{r2}}$. Therefore, $\boldsymbol{v}_{\mathrm{r1}}$ is chosen. The selected vector is then weighted by projecting $\boldsymbol{v}_{\mathrm{DP}}$ onto it. The resulting vector $\boldsymbol{v}_{\mathrm{rG}}$ corresponds to the first decomposition vector or factor $\boldsymbol{v}_{\mathrm{F1}}$.

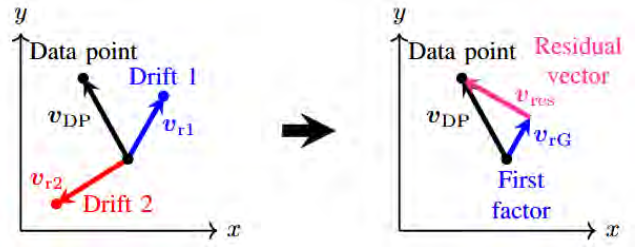

**Figure 2:** Schematic of the decomposition of a data point vector $\boldsymbol{v}_{\mathrm{DP}}$ into individual drift vectors $\boldsymbol{v}_{\mathrm{r}}$. The first factor of the decomposition $\boldsymbol{v}_{\mathrm{rG}}$ and the remaining residual vector $\boldsymbol{v}_{\mathrm{res}}$ are calculated.

Then, it is determined whether this resulting first factor $\boldsymbol{v}_{\mathrm{F1}}$ points to a point within a specified boundary around the data point. For this purpose, the residual vector $\boldsymbol{v}_{\mathrm{res}}$ is spanned from the superposition of the previously determined factors to the new data point. If the square sum of the length of $\boldsymbol{v}_{\mathrm{res}}$ is less than a specified threshold, it is inside the boundary and the decomposition is complete. However, if the computed square sum is greater than a specified threshold, it is outside the boundary. In this case, $\boldsymbol{v}_{\mathrm{res}}$ is used to perform the steps like $\boldsymbol{v}_{\mathrm{DP}}$, from comparing $\boldsymbol{v}_{\mathrm{res}}$ with the existing real drift vectors $\boldsymbol{v}_{\mathrm{r}}$ up to calculating more decomposition factors $\boldsymbol{v}_{F2}, \ldots, \boldsymbol{v}_{Fn}$. At the end of each determination of a new factor, it is checked whether the superposition of the decomposition factors points to a point within the specified boundary around the data point. If this is the case, the decomposition is complete. The calculated factors are the individual drifts that together form the drift coupling:

$$\boldsymbol{v}_{\mathrm{DP}} = \boldsymbol{v}_{\mathrm{F1}} + \cdots + \boldsymbol{v}_{\mathrm{Fn}}. \tag{1}$$

## 3.4 Derivation and Evaluation of Additional Equipment Information

The space with its dimension and axis in which the drifts are modeled and the cluster analysis and decoupling will be performed, is defined with the help of additional equipment information. This can include signal-to-noise ratio, a measurement gain, position feedback, a control value or energy data about the device.

In an ideal world, the combined drifts should be uniquely decoupled. This is the case when the coupled drifts can be unambiguously decomposed into any combination of individual drifts. To achieve this, the drift vectors of the possible individual drifts must be linearly independent. Thus, n drift vectors must span a n-dimensional space. If for example only two drifts occur, a 2-dimensional space is needed. In this space, combinations of the two occurring drifts can be unambiguously decomposed as shown in Figure 3. The vector $\boldsymbol{v}_{\mathrm{DP}}$ of the coupled drift is a combination of the drift vectors $\boldsymbol{v}_{\mathrm{D1}}$and $\boldsymbol{v}_{\mathrm{D2}}$:

$$\boldsymbol{v}_{\mathrm{DP}} = \mathrm{a}\boldsymbol{v}_{D1} + \mathrm{b}\boldsymbol{v}_{D2}. \tag{2}$$

The drift vectors are linearly independent when

$$\mathbf{0} = \lambda_1 \boldsymbol{v}_{D1} + \lambda_2 \boldsymbol{v}_{D2} \tag{3}$$

and the only solution of the system of equations is $\lambda_1 = \lambda_2 = 0$. So $\boldsymbol{v}_{\mathrm{D1}}$and $\boldsymbol{v}_{\mathrm{D2}}$ span the 2-dimensional space. They are defined by their direction and their length is positive. This means that every data point lies in the positive range of both drift vectors.

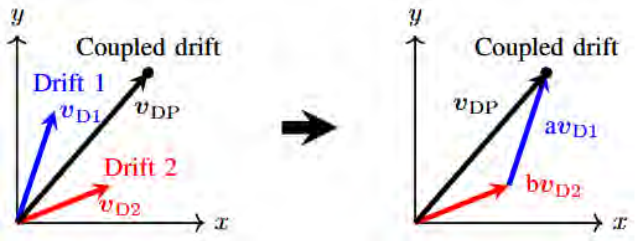

**Figure 3:** Schematic decomposition of a coupled drift vector $\boldsymbol{v}_{\mathrm{DP}}$ in two individual drifts $\boldsymbol{v}_{\mathrm{D1}}$ and $\boldsymbol{v}_{\mathrm{D2}}$.

When the number of occurring drifts become larger than the dimension of the space, the decomposition becomes ambiguous. The drift vectors get linearly dependent. To get from such an ambiguous to an unambiguous decomposition, more additional equipment information is needed. The dimension of the space must be increased to the number of occurring drifts. To derive the necessary information that increases this dimension, available additional information of the equipment under consideration is analyzed. Using assumed connections in the real data, an estimate of the most useful additional information is made. The data used for cluster analysis is extended with the selected information, cluster analysis is performed, and the drift vectors are calculated. The independence of the drift vectors is checked. If they are still linearly dependent, other additional information must be examined until they are linearly independent or no more information is available.

The value of the additional equipment information is judged by its contribution to spanning the n-dimensional space. If the information provides a dimension, it can be used immediately. If not, it is examined to see if it can contribute in combination with other information.

## 4 CASE STUDY

A case study on a real-world brownfield chemical plant is performed to demonstrate the applicability and feasibility of the method. Consider a control valve in a chemical plant through which a fluid flows. Due to the presence of solids, an abrasive mixture is formed. Gas bubbles may also be present. Under the assumption that the control valve is recently installed, four independent drifts may occur in the valve:

- Equipmentdrift 1: Increased amounts of gas bubbles that cause inaccuracy in measuring the flow through the valve.
- Equipmentdrift 2: Increased amounts of solids that cause inaccuracy in measuring the flow through the valve.
- Processdrift 1: Reduced density of the fluid.
- Processdrift 2: Increased density of the fluid.

These four drifts are modelled, and theoretical clusters and drift vectors are determined, as Figure 4 shows. The white areas outside the clusters are where unclassified and unknown drifts or couplings of drifts can occur.

The modeling space is defined with the help of additional equipment information. In particular, the measurement gain and the signal-to-noise ratio of the valve are used along with the main measurements of density and temperature of the mixture. The reason for this is that this additional information adds dimensions to the space so that the theoretical clusters and drift vectors can be well distinguished. The emerging four theoretical drift vectors are linearly independent and span a 4-dimensional space.

The cluster analysis of the real data from the control valve is performed in the 4-dimensional space of the theoretical drift vectors. In this context, the statistical part benefits from the modeling part of the method. The result of the cluster analysis shows only three clusters and outliers. Together with the modelled drifts, these real clusters can be assigned to the drifts. One of the real clusters is the cluster without drift, the other two are drift clusters. Only Equipmentdrift 1, the gas bubbles, and Processdrift 1, a reduced density, occur in the data. These results are shown in the 2-dimensional space of density and measurement gain in Figure 5.

The outliers from the cluster analysis are passed to the method as possible drift combinations. However, if some drifts are not represented in the data, a combination of real and theoretical drift vectors is required. Otherwise, some drift coupling may not be detected and decoupled. This is because drift coupling can only be diagnosed if the drift vectors of the individual drifts that are combined are present. Thus, a 4-dimensional space is created from the real drift vectors of Equipmentdrift 1 and Processdrift 1 and the theoretical drift vectors of Equipmentdrift 2 and Processdrift 2. When the outliers are categorized by the method in this 4-dimensional space, different combinations of drifts are detected and diagnosed. For example, there are couplings of individually occurring drifts, such as the drift coupling data point in Figure 5. This data point is a combination of Equipmentdrift 1 and Processdrift 1. Thus, the vector of the data point $\boldsymbol{v}_{\mathrm{DP}}$ is a linear combination of the vectors of Equipmentdrift 1 $\boldsymbol{v}_{\mathrm{Eq1}}$ and Processdrift 1 $\boldsymbol{v}_{\mathrm{Pd1}}$:

$$\boldsymbol{v}_{\mathrm{DP}} = a\boldsymbol{v}_{\mathrm{Eq1}} + b\boldsymbol{v}_{\mathrm{Pd1}}. \tag{4}$$

This linear equation system is solved, and the parameters a and b are uniquely determined. There are also other combinations of drifts, such as Equipmentdrift 1 and Processdrift 2.

Finally, this use case demonstrates that drift couplings can be detected with the help of additional equipment information. The cause of these drift couplings can also be diagnosed with a high degree of certainty.

## 5 DISCUSSION AND OUTLOOK

In this paper, a method is developed to detect and decouple combined process and equipment drifts. To achieve this goal, statistical methods are combined with model-based approaches. Cluster analysis is performed, and the real clusters are assigned to the drifts using previously modeled clusters. To characterize these theoretical and real clusters, drift vectors are spanned. Drift combinations are then diagnosed using vector decomposition. The key to getting the right data space for the unambiguously decoupling of drift couples is the use of additional equipment information. The n drift vectors of the n possible drifts must span an n-dimensional space. For this purpose, a combination of theoretical and real drift vectors is used. Additional equipment information helps to obtain the required n-dimensional space.

The application of the method on a control valve in a brownfield chemical plant demonstrated that the detection and diagnosis of simultaneously appearing process and equipment drifts is successful. Thus, the feasibility of the approach is shown.

The critical evaluation shows that the developed approach is successful in plants with a continuous process, a steady state setpoint and low dynamics. However, most chemical plants do not meet these requirements. Often there are varied process conditions and changes in the target state. In addition, existing drifts change, and new drifts occur. If the drifts are dependent on each other, this is not considered.

Future directions of research are the development of new strategies to deal with changing process conditions and high dynamics as well as the detection and handling of dependent drifts. Furthermore, the development

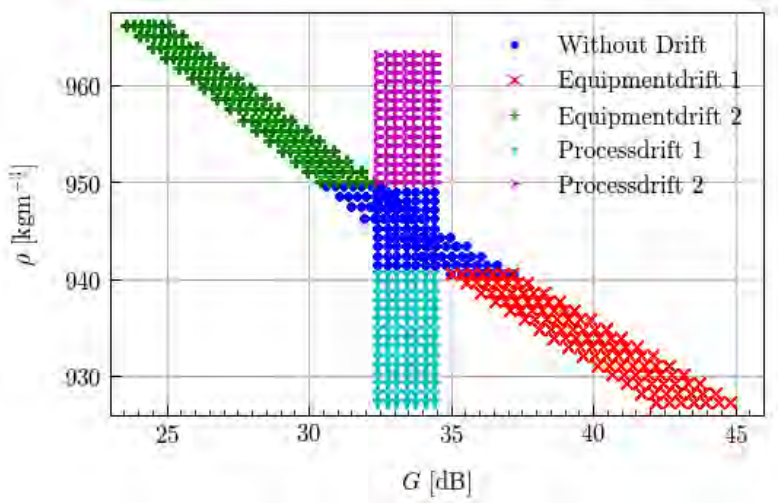

**Figure 4:** Modeled clusters – one cluster with no drift and four with different drifts. The process parameter $\rho$, the density, is the main measured value. The variable G, the measurement gain, is a typical additional information from the same equipment.

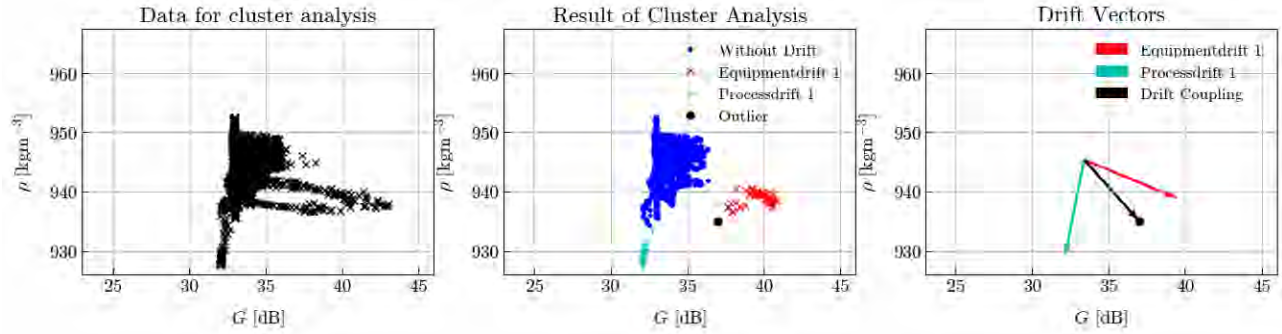

**Figure 5:** Data and results of the case study. Two drifts with their drift vectors and outliers as drift couplings were detected. The process parameter $\rho$ , the density, is the main measured value of the equipment. The variable G, the measurement gain, is a typical additional information from the same equipment.

of a unified equipment data standard deserves to be a topic of future research.

# Enhanced Reinforcement Learning-driven Process Design via Quantum Machine Learning

**Austin Braniff[a], Fengqi You[b], and Yuhe Tian[a]***

## ABSTRACT

In this work, we introduce a quantum-enhanced reinforcement learning (RL) framework for process design synthesis. RL-driven methods for generating process designs have gained momentum due to their ability to intelligently identify optimal configurations without requiring pre-defined superstructures or flowsheet configurations. This eliminates reliance on prior expert knowledge, offering a comprehensive and robust design strategy. However, navigating the vast combinatorial design space poses computational challenges. To address this, a novel approach integrating RL with quantum machine learning (QML) is proposed. QML leverages theoretical advantages over classical methods to accelerate searches in large spaces. Built upon our prior work, the approach begins with a maximum set of available unit operations, represented in a flowsheet structure using an input-output stream matrix as RL observations. A Deep Q-Network (DQN) algorithm trains a parameterized quantum circuit (PQC) in place of a classical neural network (NN). The design structures generated by the RL agent are optimized using the IDAES Process Systems Engineering Framework, with the optimization objectives used as rewards to RL (e.g., cost, productivity). This quantum-enhanced algorithm is performed on a hydrodealkylation process case study, showcasing its efficiency and improved performance in navigating complex design spaces.

**Keywords**: Process Design, Process Synthesis, Quantum Computing, Reinforcement Learning

## 1. INTRODUCTION

In the modern era of digitalization, industries are undergoing rapid transformation, driven by advancements in artificial intelligence (AI) and machine learning (ML). These technologies have fundamentally reshaped how chemical and energy processes are designed and optimized, enabling greater efficiency, adaptability, and innovation. Among the many applications of ML, reinforcement learning (RL) has emerged as a particularly promising approach in process systems engineering (PSE) [1-2].

RL-driven process synthesis offers a systematic methodology to identify optimal process configurations without relying on predefined superstructures or flowsheet configurations. By allowing an agent to automatically and intelligently explore and evaluate design decisions, RL minimizes the influence of prior assumptions and heuristics. Despite the potential, RL-driven process synthesis faces significant challenges including the vast combinatorial design space, which often renders the search computationally expensive or even intractable.

Quantum computing presents an exciting opportunity to overcome these limitations by harnessing quantum machine learning (QML) [3-4]. QML algorithms have demonstrated the potential for computational speedups in solving problems that are traditionally constrained by the limitations of classical computation [5]. Leveraging advances in quantum hardware and algorithms, QML can accelerate the search process and address bottlenecks in RL-driven process synthesis. Building on our prior research, this work proposes a novel integration of QML with RL to enhance the efficiency, robustness, and performance of process design frameworks.

This paper introduces the principles, methodologies, and innovations underpinning our quantum-enhanced RL framework for process flowsheet synthesis (Fig. 1). Section 2 reviews the methodology for classical RL-driven process design, touching on key features of

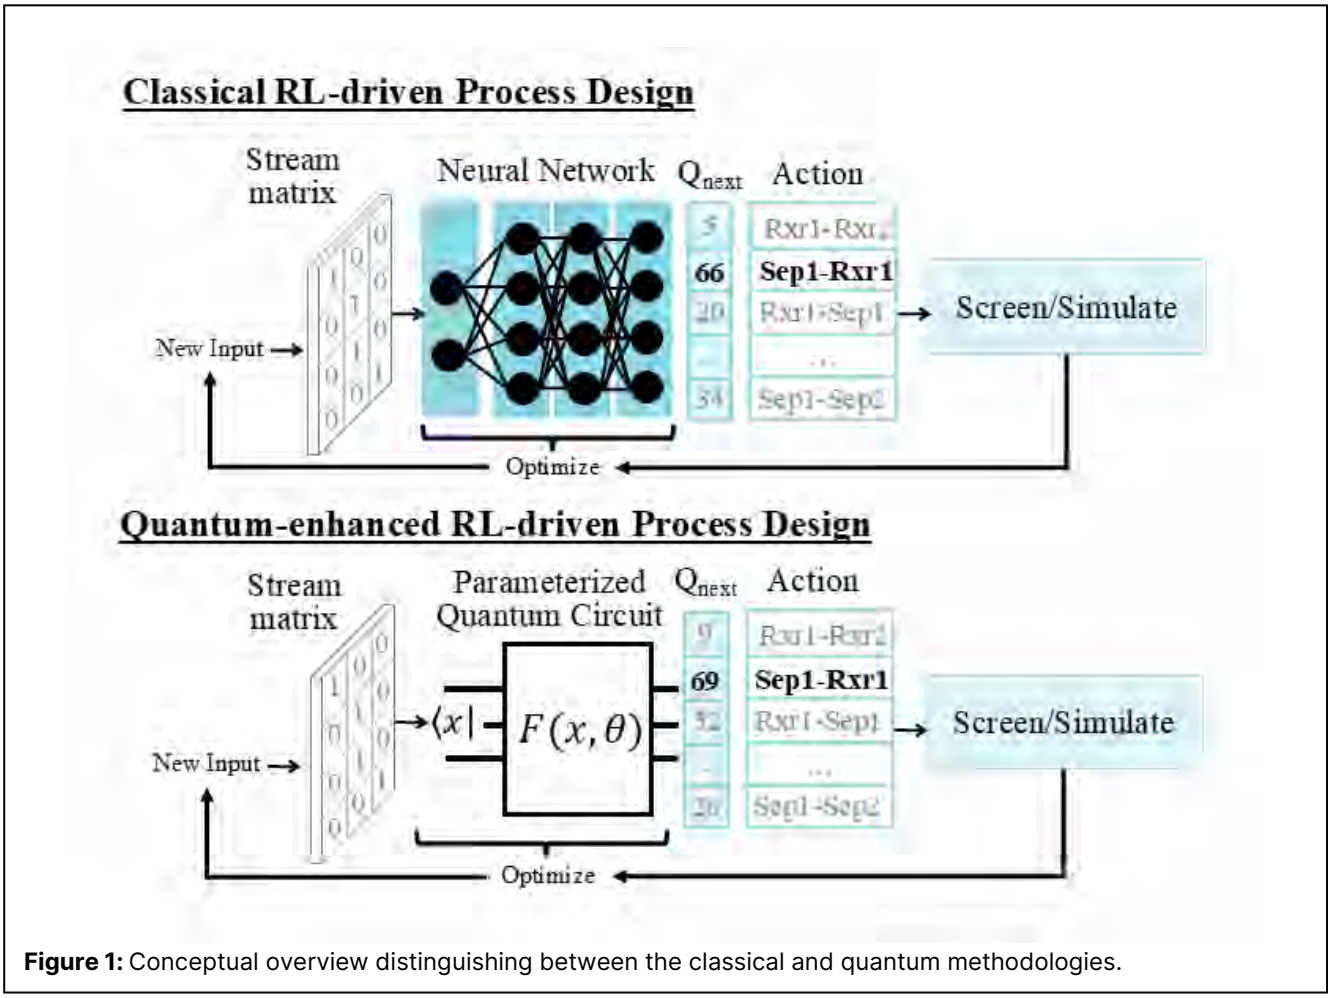

**Figure 1:** Conceptual overview distinguishing between the classical and quantum methodologies.

the algorithm. Section 3 introduces the topic of quantum machine learning and presents our integrated quantum-enhanced framework. Section 4 applies the framework to a representative case study on hydrodealkylation process design, highlighting the methodological advantages over conventional RL approaches. Section 5 concludes with a discussion of ongoing work.

## 2. RL-DRIVEN PROCESS SYNTHESIS

In this section, we briefly review the fundamentals of Deep Q-Network (DQN) algorithm and the prior work [2,7] on RL-driven process synthesis which set up the foundation for the current work.

### 2.1 Deep Q-Network

The DQN algorithm is a form of Q-Learning and is essential to model-free RL. It is designed to address the challenges of high-dimensional state-action spaces using neural networks (NNs). The traditional Q-Learning algorithm approximates the optimal action-value function $Q^*(s,a)$, which represents the maximum cumulative reward achievable from a given state $s$ when taking action $a$ and following the optimal policy thereafter. However, as the state space becomes more complex, approximating the Q-function $Q(s,a)$ becomes computationally intensive. DQN overcomes this limitation by employing an NN as a function approximator to estimate the Q-function instead as $Q(s,a,\theta)$ where $\theta$ denotes the network parameters. The NN serves as a computationally friendly alternative over other methods such as tabular Q-Learning.

Central to this algorithm is the Bellman equation, expressed in Eq. 1 where $s$ and $a$ are the current state action pair, $s'$ and $a'$ are future state-actions, $r$ is the instantaneous reward, and $\gamma$ is a discount factor for future rewards. This equation recursively relates present state-action values to the rewards of future values enabling optimal decision making that considers all future paths.

$$Q(s,a) = r + \gamma \max_{a'} Q\,(s',a') \tag{1}$$

In DQN, the Q-functions on the right and left of Eq. 1 are approximated by NNs. The right being the target network which is periodically updated and the left being the evaluation network which is updated at each transition step. This update is performed by minimizing the mean squared error (MSE) between the current Q-value estimate and the target value, as seen in Eq. 2 where $\mathcal{L}$ is the loss function (in this case MSE), $\theta$ is the vector of

tunable parameters in the evaluation network, and $\theta^-$ is the vector of tunable parameters in the target network.

$$\min_{\theta} \mathcal{L}(\theta) = E\left[\left(r + \gamma \max_{a'} Q(s', a'; \theta^-) - Q(s, a; \theta)\right)^2\right] \quad (2)$$

When the target network is updated, it becomes a copy of the evaluation network at that time (i.e., $\theta^- = \theta$). This approach helps to achieve stability and mitigate bias in the algorithm. In the landmark paper for DQN [6], the authors have established a few other key techniques that help make this algorithm efficient and successful such as experience replay and an epsilon-greedy approach to action selection. The experience replay allows the expectation to be taken over a randomly sampled batch of stared state-action-reward transitions which reduces both recency bias and correlations between consecutive transitions. The epsilon-greedy policy is utilized as a method to balance the tradeoffs between exploration and exploitation. In the early stages of learning random actions are taken more often to explore the state-space while later, once the Q-function is better approximated, the predicted optimal actions are taken more frequently.

## 2.2 Classical RL-Driven Process Synthesis Framework

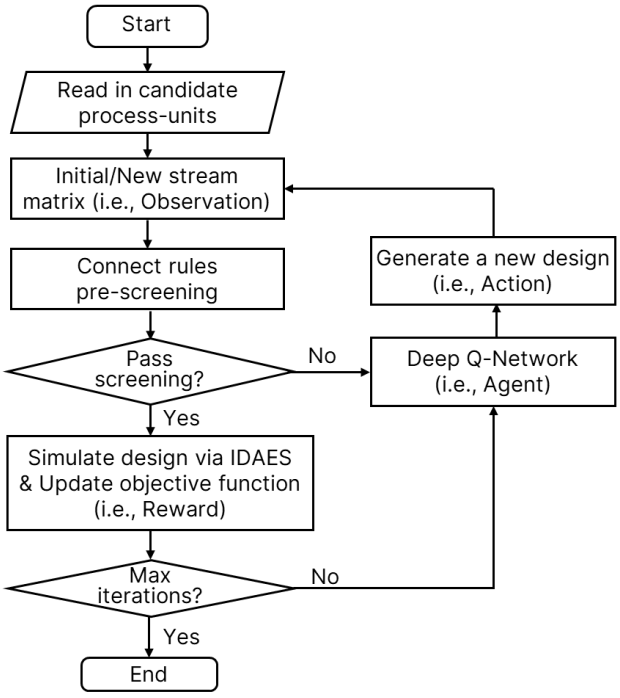

**Figure 2.** RL-driven process synthesis.

Wang et al. [2] developed a RL-driven process synthesis method as summarized in Fig. 2, based on which our previous work [7] enhanced the method with subspace search to more effectively address the combinatorial design space. For a brief review of this classical approach, RL is integrated with the IDAES platform [8] leveraging its extensive process modeling and simulation capabilities to enhance the design and optimization process. This approach begins with the definition of a pool of candidate process units, including reactors, heaters, and flash drums, with user-specified limits on the maximum number of units available. Unlike classic superstructure-based process synthesis approaches, RL-driven process synthesis eliminates the need for prior pre-postulations regarding flowsheet connectivity, allowing for a more thorough exploration of design spaces.

A critical step in this approach is the representation of process flowsheets as stream matrices, where binary variables encode the inlet and outlet relationships between unit operations. These matrices provide compact and efficient representations for the RL agent, enabling it to analyze and manipulate flowsheet structures. The update of these input-output stream matrices, as determined by the RL agent, synthesizes the new flowsheet structure. To ensure feasibility, generated flowsheets are pre-screened against connectivity rules, such as avoiding self-loops and ensuring proper sequencing of unit operations (e.g. a cooler does not directly connect to a heater).

The framework utilizes a DQN algorithm (as summarized in Section 2.1) to train an RL agent in generating optimal process designs. The agent takes stream matrices as inputs to NNs that are used to predict Q-values that correspond to actions such as adding, removing, or reconfiguring unit operations. The new flowsheet is then simulated and optimized using the IDAES platform, which determines the optimal operating variables using nonlinear optimization. The resulting rewards are used to update the parameters of the evaluation network, enabling continuous improvement over successive iterations.

# 3. QUANTUM RL-DRIVEN PROCESS SYNTHESIS

In this section, we introduce quantum machine learning, summarize the key techniques that are pertinent to this work, and present our novel methodology that leverages these for RL-driven process synthesis.

## 3.1 Quantum Machine Learning

QML is an exciting research field that explores the intersection of quantum computing and classical machine learning by implementing classical, quantum, or hybrid algorithms on quantum hardware which performs operations on qubits. The core of QML revolves around parameterized quantum circuits (PQCs), which are regarded as the quantum counterpart of NNs [9]. PQCs (Fig 3.) are quantum circuits that encode data as quantum states, have tunable parameters (e.g., rotation angles within quantum gates), and provide outputs through their observables. These are analogous to input features,

weights and biases, and outputs in NNs where the tunable parameters are optimized with respect to a loss function (e.g., backpropagation). The observables of a circuit are representations of measurements taken from each qubit at the end of the circuit. Common expressions for these relate the Pauli sums or Pauli products of qubits in their final measured states.

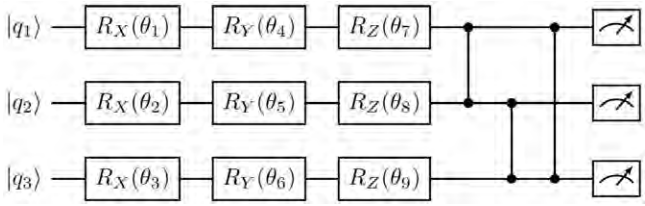

**Figure 3.** Parameterized quantum circuit.

Fig. 3 depicts a three qubit PQC with each being operated on by $R_X$, $R_Y$, and $R_Z$ rotation gates followed by a daisy chaining of CZ gates. The rotation gates perform a manipulation in their respective x, y, or z axis by an angle of rotation specified by $\theta_i$. CZ gates flip the phase of a qubit depending on the state of another qubit thereby imparting entanglement. PQCs similarly serve as universal function approximators and can approximate more efficiently and accurately than their classical counterparts [5]. A common way to increase the expressiveness or efficiency of these circuits is to re-encode data throughout the circuit. This idea is quite similar to the use of skip connections in residual NNs (ResNets) except instead of directly injecting the data into a layer along with that layer's inputs, the data is used in a single qubit gate and can feature its own tunable multiplier (Fig. 4) behavior more like a weight. These circuits are referred to as re-uploading PQCs.

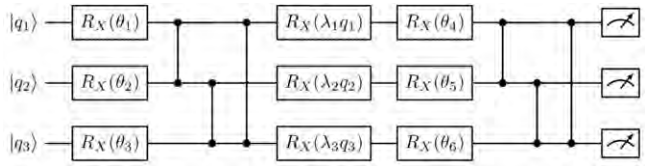

**Figure 4.** Re-uploading parameterized quantum circuit.

Fig. 4 illustrates a re-uploading PQC with three qubits. Each with an $R_X$ gate and then a series of CZ gate operations before reaching another set of $R_X$ gates where the angles are instead a function of the input data rather than a tunable parameter. Here, the angle of rotation is specified by $\lambda_i q_j$ where $\lambda_i$ is a tunable multiplier and $q_j$ is the input data encoded into the $j^{th}$ qubit. In addition to data re-uploading, tunable output weights can be used to increase performance and may be required if the PQC output range cannot sufficiently represent the desired output range (e.g. unconstrained continuous spaces).

## 3.3 Quantum-Enhanced Process Synthesis

Consistent with existing research efforts in quantum reinforcement learning [10], we remove the NNs in our method and incorporate PQCs in their place. This is highlighted in Fig. 1 where the transition is conceptualized. The same underpinning concepts of DQN algorithm are employed with the only distinction being that PQCs are used for the Q-function approximators instead of NNs.

The optimization problem (Eq. 2) is still performed but the vector $\theta$ corresponds to all tunable parameters for the evaluation circuit. In general, this adjustment to the algorithm requires special attention to data encoding and Q-value mapping. For data encoding, it is critical that input data be transformed or scaled in a way that it can be represented by a quantum state. In the context of flowsheet matrices, the binary values can easily be mapped to a quantum state. The observables (circuit outputs) must correspond to an action in the action space which greatly relies on the current problem. In our algorithm, we formulate a unique mapping from one observable to a corresponding action.

Our quantum-enhanced framework broadly follows Fig. 2 by integrating QML into RL-driven process design, replacing classical NNs with PQCs within the DQN architecture. The RL agent similarly uses input-output stream matrices to observe flowsheet structures, and PQCs are trained to approximate Q-functions that implicitly relate to optimal flowsheet designs. The quantum-enhanced DQN retains algorithmic principles to prevent model divergence and biases. This approach is implemented using the IDAES-PSE software for flowsheet simulation and optimization, where operational cost and productivity serve as performance rewards for the RL agent. This approach takes advantage of the novel and promising abilities of quantum computing to outpace classical methods in machine learning and optimization while also utilizing the established principles of RL algorithms.

# 4. HYDRODEALKYLATION CASE STUDY

In this section, we demonstrate the effectiveness and potential advantages of our quantum-enhanced RL-driven process design framework through a hydrodealkylation process benchmarked by the classical RL-driven approach.

## 4.1 Process Description

In line with the prior work [2,7], this study aims to design a hydrodealkylation (HDA) process which uses hydrogen ($H_2$) and toluene ($C_6H_5CH_3$) to form benzene ($C_6H_6$) as shown in Eq. 3. This reaction occurs in the vapor phase and is assumed to occur without any side reactions for the simplification of this analysis.

$$H_2 + C_6H_5CH_3 \rightarrow H_2 + C_6H_6, \Delta H = -1.08 \times 10^5 \frac{\text{J}}{\text{mol}} \quad (3)$$

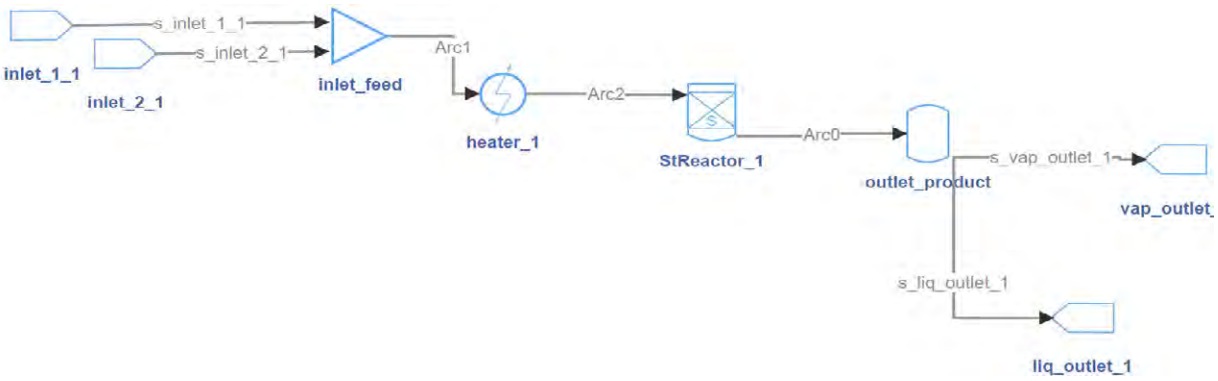

**Figure 5:** Optimal flow sheet design.

The feed streams, detailed in Table 1, include a vapor stream composed of hydrogen and methane, along with a liquid stream of toluene. The available process units are as follows: feed (combined with a mixer), product (integrated with flash operation), heater, cooler, stoichiometric reactor, mixer, flash, splitter, and compressor. The operating constraints of each unit are specified, such as maintaining an outlet temperature between 500–600 K. The product specification requires achieving a vapor product with a benzene purity exceeding 0.55. Mixture separations are assumed to follow ideal vapor-liquid equilibrium behavior. The design objective is to identify processes that optimize the vapor product's flowrate.

Table 1: Feed conditions for inlet process streams.

| | Liquid Feed | Vapor Feed |
|---|---|---|
| Temperature (K) | 303.2 | 303.2 |
| Pressure (kPa) | 350 | 350 |
| Flowrate (mol/s) | | |
| Hydrogen | 0.30 | 0.00 |
| Toluene | 0.00 | 0.30 |
| Methane | 0.02 | 0.00 |
| Benzene | 0.00 | 0.00 |

For this study, the available unit ops to be selected are a heater and a reactor. This provides the minimum necessary conditions to reach the optimal flowsheet design. The selection of more units leads the quantum algorithm to become computationally intractable when being simulated on a classical machine. It is of ongoing work to investigate more capable simulators or move to real-world quantum hardware to provide additional studies.

## 4.2 Performance Comparison

Both the classical and the quantum-enhanced method were able to converge to the optimal flow sheet design in very few iterations. As given in Fig. 5, this flowsheet consists of a heater with an outlet temperature of 536.9 K, followed by a reactor with an outlet temperature of 897.8 K and a flash unit that generates process effluent at 705.7 K and approximately 1 atm. The operational variables of interest are a benzene purity of 0.75, a benzene flowrate of 0.225 mol/s, and an annual revenue of $\$7.65\times10^5$ with the cost data provided by the IDAES simulation platform. This solution is generated on the 63$^{rd}$ epoch for both methods.

Plots of instantaneous reward for each epoch are shown in Figs. 6-7 for the classical and quantum approaches respectively. A large reward (~1500) implies that a suitable stream matrix has been found. This occurs 9 times for the classical approach whereas the quantum-enhanced algorithm discovers 13. The reward plots are nearly identical for around the first 800 epochs and then they start to diverge. This can be attributed to the epsilon-greedy policy from the DQN algorithm prioritizing random exploration in the initial stages. Both methods are performed using the same random generator seeds, so they explore the same scenarios at the same rate.

Not only is the PQC able to provide more solutions over the given amount of training steps, but it does so with less parameters. The PQC has a total of 88 trainable parameters whereas the NN has 1,092. The simulation time for the classical and quantum techniques were 0.58 and 9.06 minutes respectively. These results are summarized in Table 2. The calculation time for the quantum-enhanced approach has the potential to be greatly reduced when moving to real quantum machines and it is important to note that there is little correlation between simulated and true quantum hardware time. Regardless of current computational limitations, the quantum-enhanced framework shows promise in more efficiently searching the design space as compared the prior classical approach.

**Table 2:** Algorithm and model performance indicators.

| | Classical | Quantum |
|---|---|---|
| Max Reward Solutions | 9 | 13 |
| Tunable Parameters | 1,092 | 88 |
| Computational Time (min) | 0.58 | 9.06 |

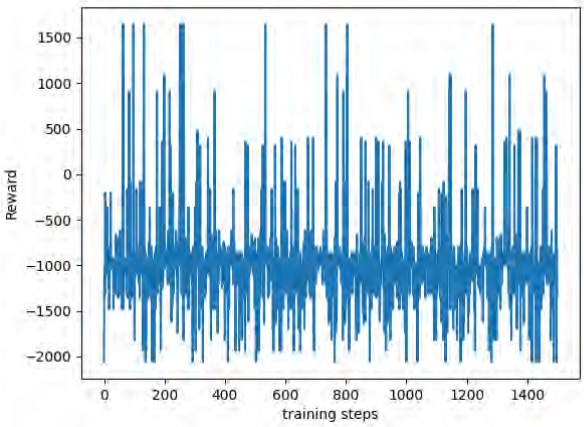

**Figure 6.** Classical RL agent reward for each episode.

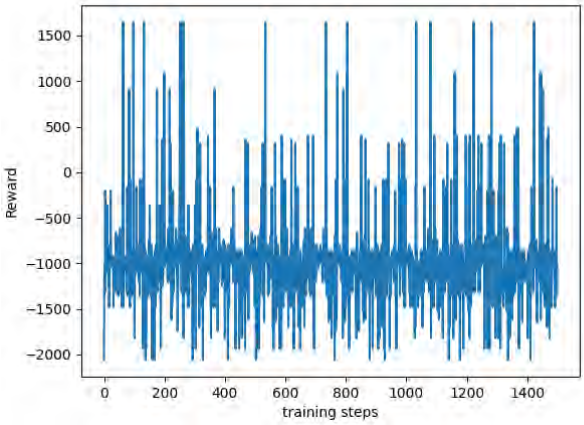

**Figure 7.** Quantum RL agent reward for each episode.

## 5. CONCLUDING REMARKS

This work presents a novel quantum-enhanced RL-driven process design framework, addressing challenges of large combinatorial design spaces. We demonstrate significant potential for improving efficiency and performance for RL algorithms in process synthesis by integrating QML techniques. Ongoing research focuses on expanding the range and scale of applications and scenarios by investigating better quantum simulators and exploring quantum hardware capabilities. Additionally, more efforts will be put into investigating how the hyperparameters of both PQCs and NNs affect the performance of these RL agents.

## ABSTRACT

New research on complex intensified distillation schemes has popularized the use of several commercial process simulation software. The interfaces between process simulation and optimization-oriented software have allowed the use of rigorous and robust models. This type of optimization is mentioned in the literature as "*Black Box Optimization*", since successive evaluations exploits the information from the simulator without altering the model that represents the given process. Among process simulation software, Aspen Plus® has become popular due to their rigorous calculations, model customization, and results reliability. This work proposes a comparative study for Aspen Plus software and Microsoft Excel VBA®, Python® and MATLAB® interfaces. Five distillation schemes were analyzed: conventional column, reactive column, extractive column, column with side rectifier and a Petlyuk column. The optimization of the $TAC$ (Total Annual Cost) was carried out by a modified Simulated Annealing Algorithm (m-SAA). The evaluation criteria are the time per iteration $(TI)$ and $TAC$ values. The results indicate that the best option to carry out the optimization was by using the VBA interface, however the one carried out with Python did not differ radically (12%).

## INTRODUCTION

The optimization of complex processes is challenging because optimization problems tend to be nonconvex, discontinuous and nonlinear, and consequently, there is not certainty to the global optimum solution [1]. The absence of precise derivatives in their models and the convergence failures that can generate discontinuities in the optimization "surfaces" of the functions make the task of finding the global optimum very difficult.

The optimization of processes using stochastic algorithms has become very relevant because they can be implemented in a relatively simple way by making an interface with commercial process simulators that are responsible for solving mathematical problems by modeling the involved units in the process [2]. Commercial process simulators act as a powerful calculator for highly nonlinear mathematical models without losing model rigorously. This type of software is also known as black box modeling software [3] because the user typically does not come into direct contact with the model equations that describe the process it simulates.

Optimization algorithms began to be developed to directly use the interface between Aspen Plus-VBA using Excel as an IDE [4-5]. MATLAB developed its direct interface with Aspen Plus becoming one of the most popular options to solve chemical process optimization problems [6]. Most recently, the Aspen Plus–Python connection has been studied showing good results in its implementation [7] making use of stochastic optimization libraries developed by the scientific community [8]. The literature is extensive for all the cases and has been applied for single and multi-objective optimization.

There are studies comparing interface methodologies for Aspen Hysys® software [9], but not for Aspen Plus. Ponce-Rocha et al. [10] compare the computing

time between iterations and the best solution between the Aspen Plus-MATLAB and Aspen Plus-Python interfaces for a case study of a bottom distillation train, finding that the interface with Python has the shortest time and the best solution compared to the one made with MATLAB.

## METHODOLOGY

### Optimization framework

In the black box optimization, the writing/reading results are from the contribution of 1) Process simulation software, 2) Middleware protocol, 3) Wrapper protocol and the 4) Platform with the optimization algorithm [11]. The middleware protocol allows the automation of the process simulator and the transfer of information in both directions, for Windows it is ActiveX automation. The Wrapper protocol works to interpret the information transferred by the previous protocol and make it useful for both parties. Accordingly, to Muñoz López et al. [11] interface can be divided into four other parts:

- **Simulation:** The simulation is carried out with the desired characteristics, for a set of variables where its convergence is ensured. The necessary techniques are applied to ensure that the simulation is not corrupted when beginning the optimization process. Aspen Plus V12 software was used.
- **Control interface:** ActiveX (COM) framework is used to build this interface. It allows you to have the API (Application Programming Interface) to manipulate applications that run on Windows.
- **Information interface:** Transfer the required data. The middleware is a set of ASCII type files that contain variable information (name, value, scale factor, specification, units, etc.) and is generated only when the simulation converges. This information makes the Aspen Plus–Optimizer routine possible. Middleware is considered the bottleneck of computational performance.
- **Optimization:** The optimization is carried out according to the optimization algorithm. For Python, Spyder IDE 5.4.1 was used. In the case of MATLAB, R2022a was used. For VBA, Excel Microsoft® 365 2022 version was used.

This overall process is shown in Figure 1. Table 1 presents some general commands to perform any activity that requires connection with any of the programming languages discussed. Step (1) refers to the line of code to open the Aspen Plus document.

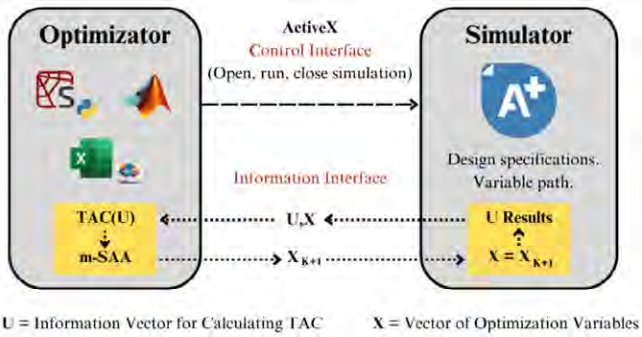

**Figure 1.** Overview of the interface implemented between Aspen Plus and MATLAB/Excel (VBA)/Spyder (Python).

It is possible to work with the *.bkp* or *.apw* extension file. In this work the *.apw* extension file was used. This form of programming is designed so that both, the code file and the simulation are at the same address, so that simply entering the name of the simulation is enough. In the case of MATLAB, it is necessary to define the version of Aspen Plus that will be used. In the case of VBA, the "On Error Resume Next" code is used, and this is to close the pop-up screens that are typical of the language each time a step is carried out. For Python, the "import os" library is used to identify the location address where the code file is saved, while the “import win32com.client” library is the one that allows the Aspen Plus software to operate.

Step (2) and (3) are commands for filling information in Aspen Plus and calling simulation results respectively (In the case of Python it is necessary to place double \ to avoid errors in communication). y is a number, and X is a variable that will be used for subsequent operations. Step (4) is the command to restart the simulation. This command is not recommended if working with complex simulations difficult to converge. In the cases of MATLAB and VBA the use of this command affects the time per iteration to almost double it. Step (5) is the command to run the simulation and step (6) is to close it.

It must be considered that in an optimization process steps (1) and (6) are only performed once per optimization, that is, the simulation is opened, the optimization process is executed for $n$ iterations and once this finished, the simulation is closed. This is because opening and closing the simulation as an environment takes a long time and this could affect the demand for RAM memory resources of the computer equipment. In the case of Python, the iterative process of this type of optimization causes RAM to accumulate, so it is necessary to reset the connection every certain number of iterations to avoid exponential growth in the time per iteration. This work recommends resetting the connection every 125 iterations.

**Table 1:** Starting and execution of the Aspen Plus application from each platform and its main commands for filling and reading information.

| Platform | Step | Code |
|---|---|---|
| MATLAB | (1) | `Aspen = actxserver('Apwn.Document.38.0');`<br>`[stat,mess]=fileattrib;`<br>`Aspen.invoke('InitFromArchive2',[mess.Name '\Simulation_Name.apw']);` |
| | (2) | `Aspen.Application.Tree.FindNode("Simulation\Variable\Path").Value = y;` |
| | (3) | `X = Aspen.Application.Tree.FindNode("Simulation\Variable\Path").Value;` |
| | (4) | `Aspen.Reinit;` |
| | (5) | `Aspen.Engine.Run2();` |
| | (6) | `Aspen.Close;` |
| Excel VBA | (1) | `Set Aspen = GetObject(ThisWorkbook.Path & "\Simulation_Name.apw")`<br>`On Error Resume Next` |
| | (2) | `Aspen.Tree.FindNode("Simulation\Variable\Path").Value = y` |
| | (3) | `X = Aspen.Tree.FindNode("Simulation\Variable\Path").Value` |
| | (4) | `Aspen.Reinit` |
| | (5) | `Aspen.Engine.Run` |
| | (6) | `Aspen.Close` |
| Python | (1) | `import os`<br>`import win32com.client as win32`<br>`Aspen = win32.Dispatch('Apwn.Document')`<br>`Aspen.InitFromArchive2(os.path.abspath('Simulation_Name.apw'))` |
| | (2) | `Aspen.Tree.FindNode("Simulation\\Variable\\Path").Value = y` |
| | (3) | `X = Aspen.Tree.FindNode("Simulation\\Variable\\Path").Value` |
| | (4) | `Aspen.Reinit()` |
| | (5) | `Aspen.Engine.Run2()` |
| | (6) | `Aspen.close()` |

An error called "ExceptionDump" may occur, which appears when the call is fast enough to prevent the completion of the protocols described above and corrupt the optimization process. This error displays the legend:

**"An unexpected error has occurred. An error log has been generated in: C:*file\location*\aspenplus_ExceptionDump_*date*.dmp"**.

The authors recommend using a delay time between 0.05 and 0.1 seconds that gives the platforms time to finish the calling protocols. These are shown in Table 2. `delay` is a number that refers to the delay time that will be carried out between each iteration. The line of code must be written before line (5) mentioned in Table 1.

In the case of the Python platform, it is necessary to call "from time import sleep" to be able to execute the action. In VBA it is not necessary to place a delay as it is rare to see this error in your process.

**Table 2:** Recommended lines of code to avoid the connection error between the platform and Aspen Plus.

| Platform | Code |
|---|---|
| MATLAB | `pause(delay);` |
| Python | `From time import sleep`<br>`sleep(delay)` |

The optimization was performed using the m-SAA algorithm proposed by Cabrera Ruiz et al. [2] which makes use of dynamic bounds and normalization of variables to improve the search for the optimum and find it faster. This algorithm was programmed in the same way for all platforms without the reinit function (line (4) in Table 1), the only difference between programming languages are their own random number functions. Additional parameters of the optimization algorithm are presented in Herrera Velázquez et al. [12]. The normalization of the variables is done as shown in Eq. 1.

$$VN_i = \left(B_{upper} - V_i\right)/\left(B_{upper} - B_{lower}\right) \quad (1)$$

where $VN_i$ is the value of the normalized variable $V_i$, $B_{upper}$ and $B_{lower}$ are the upper and the lower bound of variable $i$ respectively. The stopping criterion was defined the same way for all schemes and platforms: 6 reannealing's of 350 iterations each, giving a total of 2,100 iterations, ensuring a study of at least 200 iterations for each variable. The computer used for all optimizations has an Intel(R) Xeon(R) W-3235 CPU at 3.30 GHz with 48 GB of RAM with the Windows 10 operating system (which is the most stable version for all platforms).

## Case Studies

The five case studies are shown in Figure 2. $N_T$

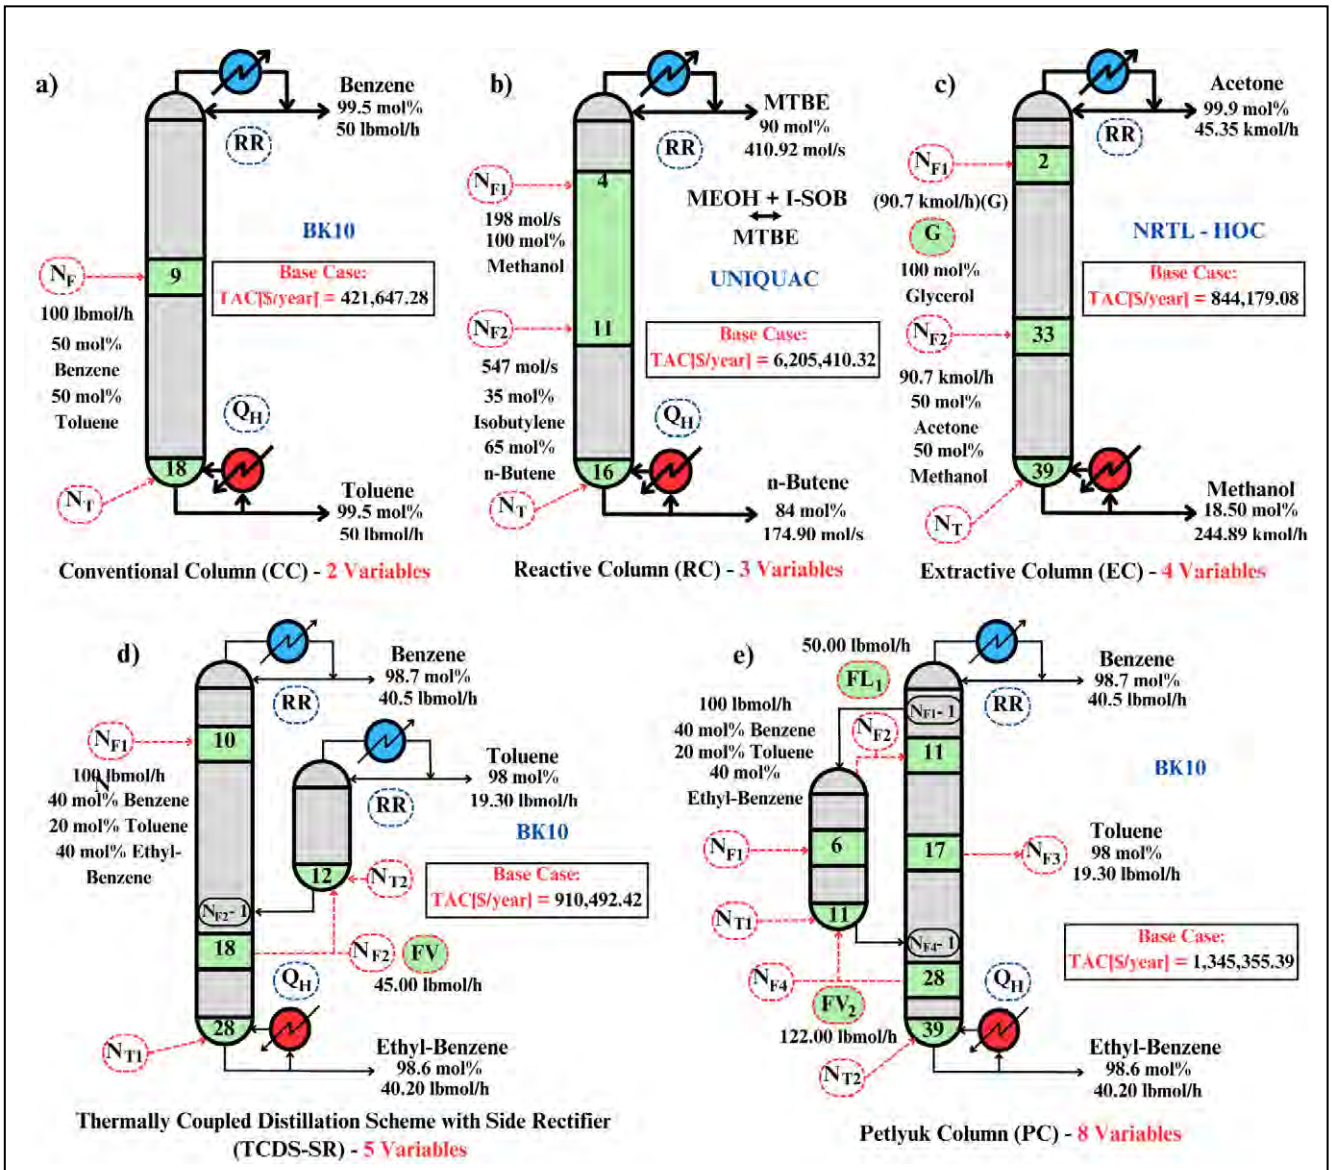

**Figure 2:** Representation of the proposed schemes to carry out the tests and their proposed optimization variables and their thermodynamic model used: a) Conventional Column, b) Reactive Column [13] and c) Extractive Column [14], d) Thermally Coupled Distillation Scheme with Side Rectifier and e) Petlyuk Column.

refers to the total number of stages, $N_F$ is the feed stage, $G$ is the ratio of entrainer to feed, $FV$ is the vapor flow and $FL$ is the liquid flow, both in kmol/h. For the $CC$, $RC$ and $PC$ schemes (Figure 2a, 2b and 2e) the purity and recovery constraints are satisfied by adjusting the reflux ratio ($RR$) and the reboiler load ($Q_H$) through internal design specifications in the simulator. For the $PC$ scheme it is done on the largest column. In the case of the $EC$ and $TCDS-SR$ schemes (Figure 2c and 2d), the constraints are adjusted with the $RR$ on the respective domes, and the $Q_H$ for the $TCDS-SR$ scheme. The optimization limits for each scheme are presented in Table 3.

**Table 3:** Optimization bounds [lower, upper].

| | Variables |
|---|---|
| $CC$ | $N_T = [10, 30]; N_F = [2,\ N_{T1} - 1]$ |
| $RC$ | $N_{T1} = [10, 30]; N_{F1} = [2,\ N_{T1} - 2];$ $N_{F2} = [N_{F1} + 1,\ N_{T1} - 1]$ |
| $EC$ | $N_{T1} = [35, 45]; N_{F1} = [2,\ N_{T1} - 2];$ $N_{F2} = [3,\ N_{T1} - 1]; G = [1, 2.5]$ |
| $TCDS - SR$ | $N_{T1} = [20, 40]; N_{T2} = [5, 15];\ N_{F1} = [2,\ N_{T1} - 2];$ $N_{F2} = [3,\ N_{T1} - 1]; FV = [40, 100]$ |
| $PC$ | $N_{T1} = [5, 15]; N_{T2} = [25, 45];$ $N_{F1} = [2,\ N_{T1} - 2]; N_{F2} = [3,\ N_{T1} - 1];$ $N_{F3} = [N_{F2} + 1,\ N_{T2} - 3]; N_{F4} = [N_{F3} + 2,\ N_{T2} - 1];$ $FL_1 = [20, 110]; FV_2 = [20, 150]$ |

## Mathematical Treatment

The $TAC$ is calculated as show in Eq. 2.

$$TAC\left[\frac{\$}{Year}\right] = C_{Vapor} + C_{Cooling} + \frac{\left(\frac{CEPCI_{2022}}{CEPCI_{2001}}\right)(C_{Shell} + C_{Plates} + C_{Reboiler} + C_{Condenser})}{Recovery\ time\ (Years)} \quad (2)$$

$$s.t. \quad Conv = 0$$

The $TAC$ equation is calculated using the Guthrie method [15] where $C$ is the cost of each module. 5 years of recovery time was used. $Conv$ is a convergence constraint, $Conv = 1$ when the simulation does not converge in Aspen Plus, in this case, the objective functions have a penalty value that is 3 times the value of each function evaluated for the base design, these values are given in Figure 3. $Conv = 0$ if the simulation converges and the functions are calculated with the described model. $TI$ is taken from the time of the complete optimization process (without considering the (1) and (6) steps of Table 1, and in Python considering the time of the restarts every 125 iterations) divided by the total number of iterations.

The optimization was repeated 10 times for each case study. To find anomalous data, hypothesis testing (Grubbs Test) was used [16], which is denoted by Eq. 3 for this work. The test was applied to the $TAC$ and $TI$. The test was done to achieve 90% confidence (i.e., 2.29).

$$H_O: \left[\frac{|TAC_i - \overline{TAC}|}{S_{TAC}} \leq 2.29, \frac{|TI_i - \overline{TI}|}{S_{TI}} \leq 2.29\right]$$
$$H_A: \left[\frac{|TAC_i - \overline{TAC}|}{S_{TAC}} > 2.29, \frac{|TI_i - \overline{TI}|}{S_{TI}} > 2.29\right] \quad (3)$$

where $TAC_i$ is the $TAC$ of optimization $i$, $\overline{TAC}$ and $S_{TAC}$ are the average and standard deviation. The same procedure was followed for $TI$. If $H_O$ is true for both, the $TAC$ and $TI$ are accepted and if $H_A$ is true these results are rejected.

# RESULTS

A delay of 0.05 second is considered to avoid communication errors, this time is considered in the results shown. Table 4 summarizes the results of 10 independent optimizations for each of the platforms and for each of the proposed schemes, totaling 150 total optimizations (30 for each scheme). The results show the average value and standard deviation calculated after applying the Grubbs test. Figure 3 shows the frequency of appearance of each platform as the best solution in each of the evaluated aspects (shown in bold in Table 4).

Of 130 optimizations performed, 6 were eliminated via Grubbs test (4.61%), of which 4 are from the MATLAB platform (3 by $TI$ and 1 by $TAC$), 1 from the Python platform and 1 from VBA (both by $TAC$).

**Table 4:** Summary of results for each scheme and each platform. (M = MATLAB, V = VBA, P = Python).

| CASE | | $TAC$ [$/Year] | $TI$ [$s$] |
|---|---|---|---|
| CC | M | 284,384 ± 1,181 | 0.8783 ± 0.0066 |
| | V | 290,131 ± 1,181 | **0.7445 ± 0.0246** |
| | P | **283,154 ± 204** | 0.8678 ± 0.0085 |

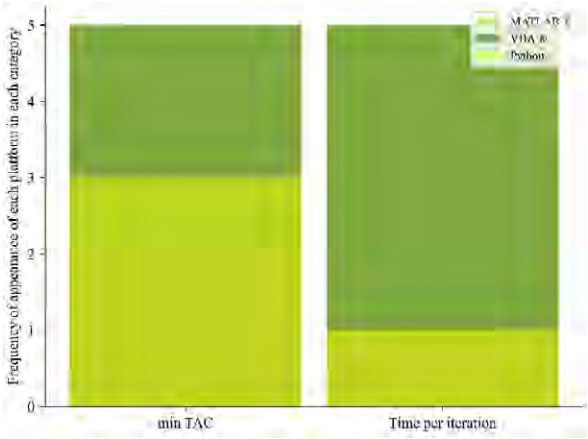

**Figure 3.** Frequency of appearance of platforms in each category.

# CONCLUSIONS

The results indicate that Python is the platform that shows the best numerical results from the $TAC$, especially in simple and complex schemes. The platform that shows the best $TI$ is VBA, although in complex schemes it shows a slight disadvantage compared to Python. Although the $TAC$ results show a certain deviation between platforms, the $TI$ vary a little (12%) between them. This study does not seek to define which platform is better or worse than another, it only seeks to find the areas of opportunity and improvement between them, as well as to define which is the best for the researcher who uses it. According to the results, VBA is the best option; however, MATLAB and

Python may be better options for numerical results (due to the way random numbers are generated on each platform). If a more customizable and open-source environment is needed, Python is the best option, and if more specialized mathematical tools are needed, MATLAB may be the best option.

## ABSTRACT

Bilevel optimization is an active area of research within the operations research community due to its ability to capture the interdependencies between two levels of decisions. This study introduces a metamodeling approach for addressing mixed-integer bilevel optimization problems, exploiting the approximation capabilities of neural networks. The proposed methodology employs neural network embeddings to approximate the optimal follower's response, bypassing the inner optimization problem by parametrizing it with continuous leader's decisions. The use of Rectified Linear Unit (ReLU) activations allows the forward pass of the neural network to be represented as a set of mixed-integer linear constraints. Thereby, the bilevel structure is simplified into a single-level optimization model. A case study based on a two-echelon supply chain demonstrates the effectiveness of the approach, with solutions comparable to traditional bilevel optimization methods. The results suggest that neural network embeddings offer a promising alternative for tackling complex bilevel problems even when discrete decisions are involved and unveil the trade-off between prediction accuracy and computational demands. This methodology provides a versatile and efficient framework for solving mixed-integer bilevel optimization problems across diverse domains.

**Keywords**: Bilevel Optimization, Neural Network Embeddings, Supply Chain Planning, Surrogate Modelling, MILP reformulation

## INTRODUCTION

Many problems relevant to process engineering involve multiple stakeholders with conflicting interests and whose individual decisions are affected by each other's actions. Such hierarchical decision-making processes can be effectively modelled as bilevel optimization problems, where upper-level problems are constrained by inner optimization problems.

The nested structure of these models makes bilevel optimization one of the most complex branches of mathematical programming. Specifically, the development of solution algorithms is particularly difficult as it depends on the nature of the inner optimization problem and the interaction between both levels. This complexity is further amplified when the problems involve mixed-integer variables, leading to mixed-integer bilevel problems (MIBPs).

From Moore and Bard's foundational studies on mixed-integer bilevel problems [1], significant progress has been made under the assumption of linearity. In general, the methods to solve mixed integer linear bilevel problems (MILBPs) typically begin with a high-point relaxation—optimizing the upper-level objective while considering both levels' constraints—and systematically explore the feasible region to identify optimal solutions. Strategies such as branch-and-bound, branch-and-cut, Benders decomposition, parametric integer programming, or their combinations have been effectively applied [2]. While these methods often converge to exact solutions for MILBP, solving mixed-integer nonlinear bilevel problems (MINLBPs) remains more challenging, with most algorithms achieving only ε-optimal solutions.

Given the inherent difficulties of MIBPs, data-driven alternatives have gained considerable attention over the recent years. Despite the evident advantages of sophisticated methods such as reinforcement learning (RL), which has demonstrated considerable potential and in

the field of game theory [3,4], neural network embeddings remain a powerful and flexible alternative to conventional methods [5,6,7].

Our proposed approach builds on the idea of using fully connected deep neural networks to approximate the follower's optimal response. When the network induces non-linearity via piecewise linear activation functions, it can be formulated as mixed-integer linear constraints and embedded into the leader's optimization problem. We illustrate the capabilities of the methodology in the optimization of a simplified supply chain, which highlights the potential advantages of this approach and reveals its remaining challenges.

## MATHEMATICAL FRAMEWORK

In this study, we focus on mixed-integer bilevel due to its countless applications in process engineering in areas such as supply chain management and energy systems. The leader's problem, defined in Eq. 1, aims to optimize the function $F(x^L, y^L, x^F, y^F)$ subject to constraints $G(x^L, y^L, x^F, y^F)$. Here, $x^L \in \mathbb{R}^{q^L}$ and $y^L \in \mathbb{Z}^{p^L}$ represent the leader's continuous and integer decision variables, while $x^F \in \mathbb{R}^{q^F}$ and $y^F \in \mathbb{Z}^{p^F}$ denote the follower's continuous and integer decision variables, respectively.

$$\begin{aligned} \min \quad & F(x^L, y^L, x^F, y^F) \\ s.t., \quad & G(x^L, y^L, x^F, y^F) \leq 0 \\ & (x^F, y^F) \in \psi(x^L, y^L) \\ & x^L \in \mathbb{R}^{q^L} \\ & y^L \in \mathbb{Z}^{p^L} \end{aligned} \tag{1}$$

The function $\psi(x^L, y^L)$ corresponds to the parametric solution of the follower's optimization problem, which is presented in Eq. 2. This hierarchical structure introduces significant computational challenges, as the leader must anticipate the follower's optimal response while solving their own problem. Analogously, the leader's decisions influence the follower's objective $f(x^L, y^L, x^F, y^F)$ and feasible set, defined by constraints $g(x^L, y^L, x^F, y^F)$.

$$\begin{aligned} \psi(x^L, y^L) = \quad & \operatorname{argmin} \quad f(x^F, y^F, x^L, y^L) \\ & s.t., \quad g(x^F, y^F, x^L, y^L) \leq 0 \\ & x^F \in \mathbb{R}^{q^F} \\ & y^F \in \mathbb{Z}^{p^F} \end{aligned} \tag{2}$$

## METHODOLOGY

Our approach is grounded in the work developed by Dumouchelle et al. (2022) [8], which utilized neural network embeddings to tackle two-stage stochastic programming problems. The proposed workflow, outlined in **Figure 1**, involves the following steps.

### 1. Identification of the linking variables

As starting point, the bilevel model must be formulated and its structure must be carefully analysed to understand the interaction between both levels. This inspection is essential to identify linking variables that connect the upper and lower levels and contain the information exchanged between the players.

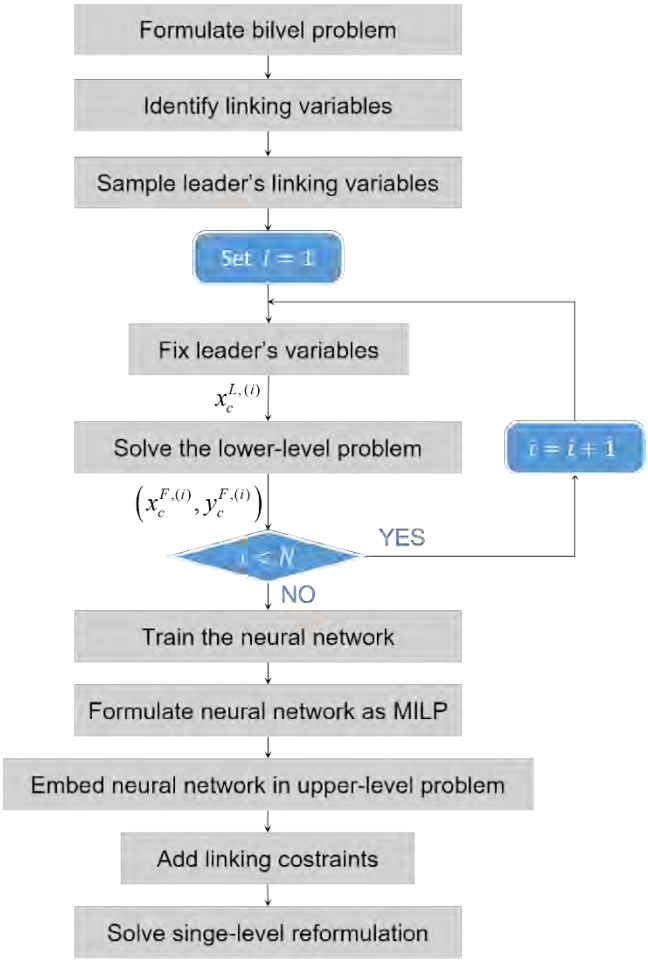

**Figure 1:** Overview of the proposed methodology

Linking variables play a key role in this work, since they constitute the inputs and outputs of the neural network used to approximate the optimal response of the follower. Notably, not all of the leader's variables necessarily influence the follower's decisions, and vice-versa. Identifying this subset helps reducing the dimensionality of the input and output spaces, simplifying the network architecture. Therefore, the linking variables will be a subset of the leader's decision variables $(x_c^L, y_c^L) \subseteq (x^L, y^L)$.

Although in general both leader's continuous and discrete decisions impact the follower's solution, we exclusively contemplate lower-level problems parametrized by continuous leader's decisions (i.e., $\psi(x_c^L)$), since training neural networks with endogenous integer variables is out of the scope of this study.

## 2. Generation of training data

The neural network is trained in a supervised manner. Thus, a set of input-output pairs is required so that it learns the mapping $\psi$ from $x_c^L \mapsto (x^F, y^F)$. Such dataset is generated through an iterative procedure.

First, a set of feasible solutions of the upper-level problem is randomly sampled using strategies such as Latin Hypercube Sampling. Both the sampling method and the number of data points must ensure a representative coverage of the feasible region in problem 1. Then, for each sampled leader's solution, the corresponding label is computed by solving the lower-level problem in Eq. 2, where the leader's variables function as parameters.

## 3. Training of the neural network

A fully connected neural network $(x_F, y_F) = \mathcal{N}(x_L; \theta)$ is trained to predict the optimal follower's decisions as a function of the leader's decisions. Here, coefficients $\theta$ represent the weights and biases of the network that must be optimized during training. Rectified Linear Unit (ReLU) activations introduce non-linearity to the outputs of each neuron in hidden layers, whereas linear transformations are applied in the output layer.

The prepared dataset is divided into training (70%), validation (20%) and test (10%) subsets. The training set is used to fit model weights, the validation set for architecture selection and hyperparameter tuning, and the test set to evaluate model performance.

## 4. Neural network as MILP

Mathematically, the output of a ReLU-activated neuron $j$ in layer $m$ can be written as

$$h_j^m = \max\left(0, \sum_{i=1}^{n_{m-1}} w_{ij}^{m-1} h_i^{m-1} + b_j^{m-1}\right) \tag{3}$$

where $w_{ij}^m$ is the element of matrix $W^m$ at the $i$-th row and $j$-th column and $b_j^m$ is the $j$-th element of vector $b^m$, being $W^m$ and $b^m$ the weights and biases associated with layer $m$, respectively.

Since the expression in Eq. 3 merely describes a piecewise linear function, the forward propagation step of a neural network with ReLU activations can be modelled as a set of linear constraints. Though different reformulation alternatives have been proposed in the literature, they all involve the introduction of binary variables to indicate which region of the ReLU function is active [9]. Following the extended Big-M reformulation proposed by Serra et al. (2017) [10], a representation of an $l$-layered feed-forward neural network is shown in Eq. 4, where $n_m$ identifies the number of neurons in a given layer $m$.

$$\begin{aligned}
&\textstyle\sum_{i=1}^{n_0} w_{ij}^0 x^L + b_j^0 = \hat{h}_j^1 - \check{h}_j^1 && \forall\, j \in \{1, \dots, n_0\} \\
&\textstyle\sum_{i=1}^{n_{m-1}} w_{ij}^{m-1} \hat{h}_j^{m-1} + b_j^{m-1} = \hat{h}_j^m - \check{h}_j^m && \forall\, j \in \{1, \dots, n_m\},\ m \in \{2, \dots, l-1\} \\
&\textstyle\sum_{i=1}^{n_l} w_{ij}^l \hat{h}_j^l + b_j^l = \beta_j && \forall\, j \in \{1, \dots, n_l\} \\
&\hat{h}_j^m \le M^{+m}_j z_j^m && \forall\, j \in \{1, \dots, n_m\},\ m \in \{1, \dots, l-1\} \\
&\check{h}_j^m \le M^{-m}_j \left(1 - z_j^m\right) && \forall\, j \in \{1, \dots, n_m\},\ m \in \{1, \dots, l-1\} \\
&\hat{h}_j^m, \check{h}_j^m \ge 0 && \forall\, j \in \{1, \dots, n_m\},\ m \in \{1, \dots, l-1\} \\
&z_j^m \in \{0,1\} && \forall\, j \in \{1, \dots, n_m\},\ m \in \{1, \dots, l-1\}
\end{aligned} \tag{4}$$

Note that the pair $(\hat{h}_j^m, \check{h}_j^m)$ is complementary, meaning that only one can be non-zero, and only the non-negative counterpart $\hat{h}_j^m$ of the weighted sum is propagated through the network. This exclusive disjunction is enforced by binary variables $z_j^m$. The outputs of the neural network are denoted as $\beta_j$.

In addition, Big-M coefficients $M^+$ and $M^-$ must be carefully chosen to ensure tight linear programming (LP) relaxations. For this purpose, we adopt the propagation rule introduced by Serra et al. [10].

## 5. Single-level reformulation

Replacing the inner optimization problem by the MILP representation of the surrogate model of $\psi(x^L)$ transforms the original bilevel problem in Eq. 1 into a single-level model, which can be directly handled by state-of-the art optimization solvers. The proposed single-level reformulation is presented in Eq. 5.

$$\begin{aligned}
\min \quad & F(x^L, y^L, x^F, y^F) \\
s.t., \quad & G(x^L, y^L, x^F, y^F) \le 0 \\
& \text{Equations in 4} \\
& \text{Linking block} \\
& x^L \in \mathbb{R}^{q^L} \\
& y^L \in \mathbb{Z}^{p^L}
\end{aligned} \tag{5}$$

The Linking block refers to the set of constraints that map $\beta \mapsto (x^F, y^F)$, being therefore case-dependent.

# RESULTS AND DISCUSSION

To illustrate the application of the proposed methodology, we consider the simplified two-echelon supply chain in **Figure 2**, adapted from Yue and You (2017) [11].

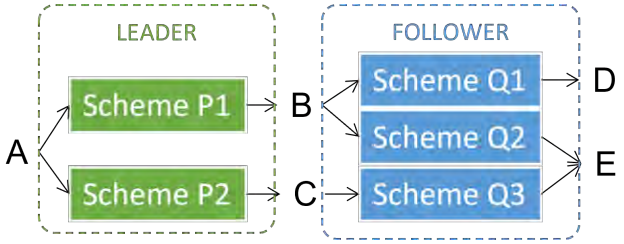

**Figure 2:** Supply chain superstructure

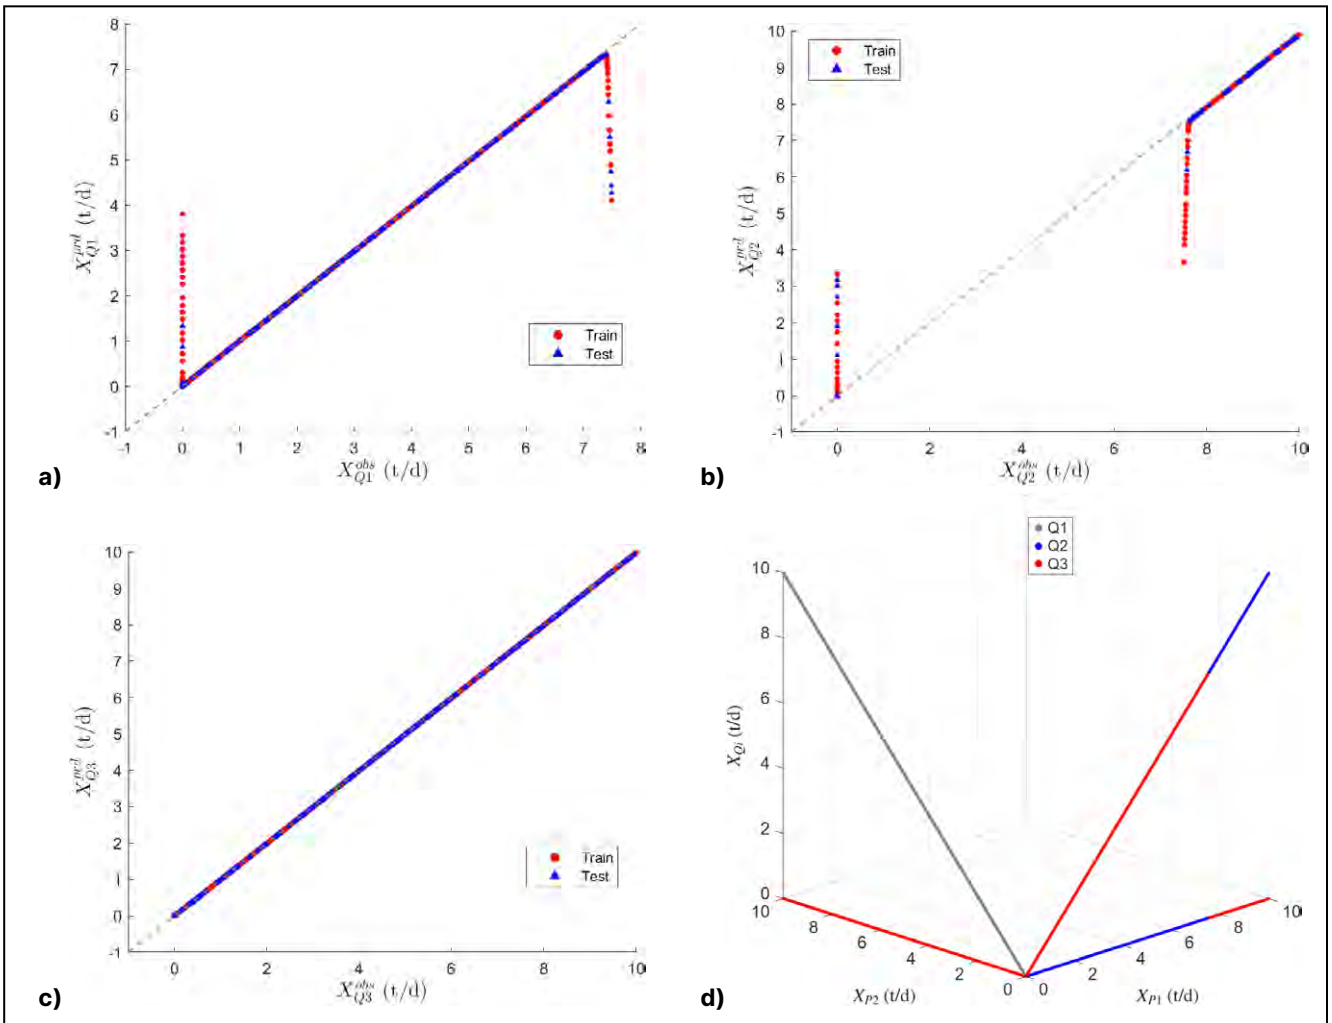

**Figure 3:** Observations versus predictions for the network outputs across training and testing datasets. Subplots (a), (b), and (c) show the predicted versus observed values for $X_{Q1}$, $X_{Q2}$ and $X_{Q3}$, respectively, with the dashed line representing the ideal $y = x$ relationship. Subplot (d) provides a 3D visualization of the network outputs ($X_{Q1}$, $X_{Q2}$ and $X_{Q3}$) as a function of the inputs ($X_{P1}$ and $X_{P2}$).

In this Stackelberg game with a single leader and a single follower, both participants aim at maximizing their own profits. The optimization problems for the upper and lower levels are formulated below.

- Upper-Level Problem (Leader):

$$
\begin{aligned}
\max\ & \text{sales}^L - \text{costs}^L && && (6)\\
s.t.\ & \text{sales}^L = p_B^L X_{P1} + p_C^L X_{P2} + p_E^L (X_{Q1} + X_{Q2}) && \\
& \text{costs}^L = \textstyle\sum_{i \in I^L} (p_A^L + v_i) X_i + f_i Y_i && \\
& \textstyle\sum_{i \in I^L} X_i \le C^L && \\
& \textstyle\sum_{i \in I^L} Y_i \le 1_i && \\
& X_i \ge C^L Y_i && \forall\, i \in I^L \\
& X_i \in \mathbb{R}^+, Y_i \in \{0,1\} && \forall\, i \in I^L \\
& I^L = \{P1, P2\} && \\
& (X_{Q1}, X_{Q2}, X_{Q3}, Y_{Q1}, Y_{Q2}, Y_{Q3}) = \psi(X_{P1}, X_{P2}) &&
\end{aligned}
$$

- Lower-Level Problem (Follower):

$$
\begin{aligned}
& \psi(X_{P1}, X_{P2}) = && && \\
& \max\ \ \text{sales}^F - \text{costs}^F && && \\
& s.t.\ \ \text{sales}^F = p_D^F X_{Q1} + p_E^R (X_{Q2} + X_{Q3}) && && \\
& \quad \text{costs}^F = p_B^F X_{P1} + p_C^F X_{P2} + \textstyle\sum_{i \in I^F} v_i X_i + f_i Y_i && && \\
& \quad \textstyle\sum_{i \in I^F} X_i \le C^F && && (7)\\
& \quad \textstyle\sum_{i \in I^F} Y_i \le 1_i && && \\
& \quad X_i \ge C^F Y_i && \forall\, i \in I^F && \\
& \quad X_i \in \mathbb{R}^+, Y_i \in \{0,1\} && \forall\, i \in I^F && \\
& \quad I^F = \{Q1, Q2, Q3\} && && 
\end{aligned}
$$

To approximate the solution of problem 7, a neural network was trained to predict the follower's optimal real-valued decisions $X_{i \in I^F}$, while binary variables $Y_{i \in I^F}$ are subsequently inferred from the network's predictions. In the above formulations, the parameters $C^L$ and $C^F$ represent the productive capacity of the leader and the follower, respectively. Similarly, $p_s^L$ and $p_s^F$ refer to the selling or purchase price of species $s$, depending on the player.

A dataset containing $5000$ points was generated by solving problem 7 for different combinations of $(X_{P1}, X_{P2})$. CPLEX was used as optimization algorithm and the data generation time rose to $964$ s.

Different network architectures (e.g., varying the number of layers and neurons per layer) were considered. First, we employed Hyperband search to explore the predefined hyperparameter space and select the best architecture. The learning rate was further optimized using the learning rate range test [12]. The network with the optimal hyperparameter configuration was finally trained for $200$ epochs on a combined training and validation set using Adam optimizer. Its performance was then assessed both on the train and test sets, reporting the corresponding mean absolute error (MAE) in **Table 1**. All models were implemented and trained using TensorFlow 2.16.1.

The results, as shown in **Table 1**, indicate low MAE scores, proving the suitability of the neural network as an accurate surrogate for the optimal lower-level solution. The accuracy of the network outputs, as indicated by the low MAE scores, is further validated by the observation-versus-prediction plots in **Figure 3**. Subplots **a**–**c** illustrate that the predictions closely align with the labels across both training and testing datasets, as the points cluster tightly around the diagonal line. Minor deviations are observed only in regions where the original function exhibits discontinuities, consistent with the patterns seen in the 3D representation in **Figure 3d**. Such sharp transitions are inherently challenging for neural networks—or most regression models—to predict, since they are well-suited for capturing differentiable patterns. In this case, these mispredictions are localized and do not compromise the method's overall effectiveness, as the model properly captures the underlying system's behaviour.

Nevertheless, its performance could be improved by either exposing the network to more data during training or adopting more complex network architectures, which, however, are more prone to overfitting. The former approach would increase the data generation time, which is already the bottleneck of the process. In contrast, the latter would negatively impact the convergence rate of the single-level model due to the expansion in size of the neural network embedding. Hence, there is a clear trade-off between prediction accuracy and computational demand.

**Table 1:** Neural network configuration and performance

| | |
|---|---|
| Neurons per layer | $[16,16,16]$ |
| Learning rate | $2 \cdot 10^{-3}$ |
| Batch size | $32$ |
| Optimizer | Adam |
| MAE | $0.052$ (train); $0.054$ (test) |
| Training time (s) | $43.4$ |

**Table 2:** Results comparison

| | NN solution | KKT solution |
|---|---|---|
| Profit Leader (MU/h) | 350 | 350 |
| Profit Follower (MU/h) | 150 | 150 |
| $X_{P1}$ (ton/d) | 0 | 0 |
| $X_{P2}$ (ton/d) | 10 | 10 |
| $X_{Q1}$ (ton/d) | 0 | 0 |
| $X_{Q2}$ (ton/d) | 10 | 10 |
| $X_{Q3}$ (ton/d) | 0 | 0 |
| Solving time (s) | 0.79 | 0.53 |

The single-level reformulation of the original problem, based on the neural surrogate, is given in Eq. 8.

$$
\begin{aligned}
\max\ & \text{sales}^L - \text{costs}^L && (8)\\
s.t.\ & \text{sales}^L = p_B^L X_{P1} + p_C^L X_{P2} + p_E^L\left(X_{Q1} + X_{Q2}\right)\\
& \text{costs}^L = \textstyle\sum_{i\in I^L}(p_A^L + v_i)X_i + f_i Y_i\\

The Big-M reformulation applied to the disjunction in Eq. 8 results in a set of linear constraints that constitute the so-called $\text{Linking block}$ in Eq. 5. These equations are designed to mitigate the neural network approximation error and ensures that non-selected production schemes of the follower have a production rate of exactly 0. In this context, the parameter $\varepsilon$ acts as a tolerance threshold that accounts for the prediction error of the neural network. Specifically, it limits an allowable margin around the predicted values that guarantees consistency between the network's outputs and the logical conditions of the optimization problem.

For comparison purposes, the original model is solved by applying a direct reformulation using Karush-Kuhn-Tucker (KKT) conditions for all feasible combinations of binary variables. Both models were implemented in Pyomo 6.8.2, using CPLEX 22.1.1.0 as MILP solver and reach identical results, as **Table 2** summarizes, due to the effect of linking constraints.

Since the objective of this work was to demonstrate

the effectiveness and reliability of the proposed methodology in solving mixed-integer bilevel instances, the selected case study was not complex enough to evaluate the potential advantages of the methodology in terms of solution speed compared to traditional approaches. Consequently, future research will focus on exploring the benefits of neural network embeddings in large-scale models.

## CONCLUSION

This contribution presents a metamodeling approach to mixed integer bilevel optimization, where the inner-level problem is parametrized by continuous decisions of the leader. In this study, the lower level is bypassed using a neural network that approximates the optimal follower's response to the leader's decisions. By employing Rectified Linear Unit activations, the neural network can be reformulated as a set of mixed integer linear constraints that are integrated into the leader's problem as a single-level reformulation. Additional constraints are introduced to map the network outputs to the corresponding follower decision variables and to infer their discrete behaviour where needed.

The approach was showcased on a two-echelon supply chain case study, achieving solutions whose quality is comparable to traditional bilevel optimization methods. These results suggest that further effort to improve the use neural network embeddings in mixed-integer bilevel optimization tasks could lead to significant advantages, especially when applied to larger-scale instances. Future research should primarily focus on ensuring prediction accuracy, which remains a critical challenge of the proposed methodology, while carefully balancing model complexity, computational resources and reliability to enhance its competitiveness in terms of computational efficiency.

## ABSTRACT

Waste lubricant oil (WLO) is a hazardous residual that requires proper management, being WLO regeneration the preferred approach. However, regeneration is only viable if the WLO does not coagulate in the equipment. Otherwise, the process needs to be shut down for cleaning and maintenance. To mitigate this risk, a laboratory test is currently used to assess the WLO coagulation potential before it enters the process. This laboratory test is, however, time-consuming, presents several safety risks, and is subjective. To expedite decision-making, process analytics technology (PAT) and machine learning were used to develop a model to classify WLOs according to their coagulation potential. Three approaches were followed, spanning linear and non-linear models. The first approach (benchmark) uses partial least squares for discriminant analysis (PLS-DA) and interval PLS combined with standard chemometric preprocessing techniques (27 model variants). The second approach uses wavelet transforms to decompose the spectra and PLS-DA for feature selection (10 model variants). Finally, the third approach uses convolutional neural networks (CNN) to estimate the optimal filter for feature extraction (1 model variant). These models were trained on real industrial data. The results show that the three modelling approaches can attain high accuracy, with an average of 91%. The spectral filtering using wavelet transforms proved to be a viable option to reduce the number of models to explore compared to the benchmark approach. The CNN was also able to streamline the preprocessing selection by implicitly estimating the optimal filter. The models also provided physical insight into the WLO coagulation phenomenon.

**Keywords**: Waste lubricating oil, Multiblock analysis, PLS, CNN, Classification.

## INTRODUCTION

Waste lubricant oil (WLO) is a hazardous material with the potential to cause severe environmental harm if not properly managed. Within the European Union's waste management hierarchy, regeneration is identified as the preferred method for addressing this type of residual. In Portugal, the entire WLO regeneration supply chain is managed by Sogilub, with the primary objective of recovering base oil – the main component of lubricant oil – from WLO. However, WLO regeneration is only viable if the WLO does not coagulate during processing. Otherwise, the process must be stopped for cleaning and maintenance, and subsequent disposal of the entire production batch. To mitigate this risk, the coagulation potential of WLO is currently assessed using a laboratory test involving an alkaline treatment with potassium hydroxide (KOH) [1]. While effective, this test is time-intensive, poses safety concerns, due to the formation of foams and use of high temperatures, and relies on a subjective visual interpretation by the analyst. As an alternative, the implementation of a process analytical technology (PAT)-based classification system offers a promising solution to accelerate WLO processing, improve safety, and enhance the analytical capacity of laboratories.

This study aims to evaluate and compare the performance of traditional linear models and modern non-linear models in leveraging mid-infrared (MIR) spectroscopy to classify WLO before regeneration. Three methodologies were considered: (i) partial least squares (PLS) [2] and interval partial least squares (iPLS) [3] combined with chemometric preprocessing techniques; (ii) iPLS

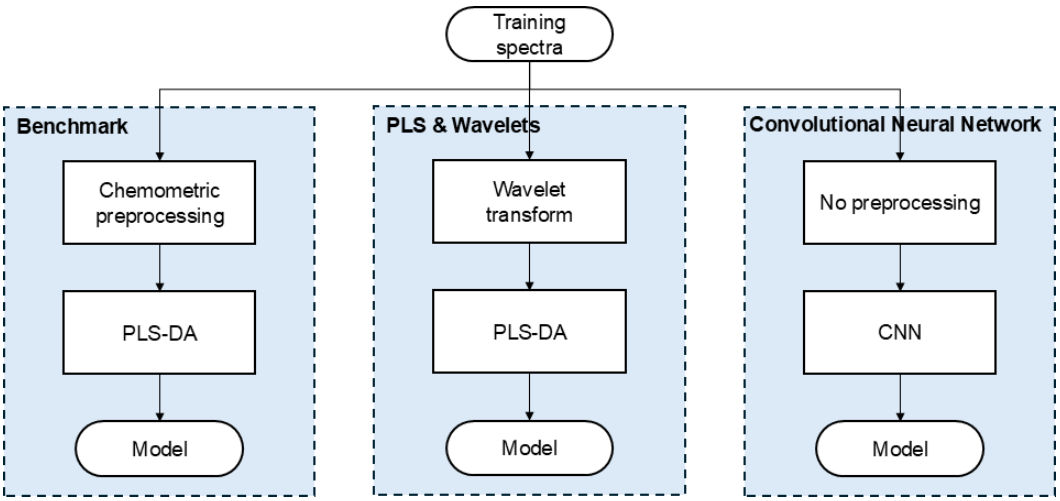

**Figure 1** Overview of the models under comparison using combinations of preprocessing and modeling approaches.

combined with wavelet transforms [4]; and (iii) convolutional neural networks (CNNs) [5].

The remainder of this article is structured as follows. The Methodology section encompasses the preprocessing techniques and modeling methodologies employed. In the Results section, an analysis of the results obtained in this study is made. Finally, the Conclusion section offers a concise summary of the conclusions drawn from the findings.

## METHODOLOGY

This study aims to develop a suitable data-driven model to predict the coagulation potential of WLO using PAT techniques. To achieve this end, three modeling approaches were considered and systematically compared using the SS-DAC framework [6].

In the following subsections, an overview of the preprocessing techniques and modelling methodologies used for model development are described. A simplified diagram of the models under comparison is presented in Figure 1.

### Spectral Preprocessing

Preprocessing of the spectral data is often used to mitigate potential artifacts that may arise due to unintended interactions between light and the sample under examination. Two main classes of preprocessing techniques were considered: (i) classical chemometric approaches; and (ii) wavelet transforms.

### Chemometric Preprocessing

From the class of classical preprocessing techniques typically found in the literature (e.g. [7]), the following were considered:

- Standard Normal Variate (SNV) [8];
- Multiplicative Scatter Correction (MSC) [9];
- Savitzky-Golay differentiation (SGD) [10].

Different combinations of these preprocessing techniques, as well as different parameterizations of SGD (identified as SGD-{derivative order}-{window size}) were examined, leading to nine distinct preprocessing variations (see Table 1).

### Wavelet Transforms

As an alternative to the classical chemometric preprocessing, wavelet transforms were used to decompose the spectra into multiple frequency components by convolution with (fixed) linear filters. The obtained wavelet coefficients were then fed to the modeling methodologies for variable selection.

The discrete wavelet transform (DWT) can be efficiently performed using the recursive algorithm proposed in [4]. Several wavelet filter can be found in the literature [11–13], being the Haar, Daubechies and Symlets wavelets the most common and those used in this study (see Table 1).

### Modeling Methodologies

Two main classes of modeling methodologies were considered in this study: (i) linear; and (ii) non-linear.

From the linear class, partial least squares (PLS) for discriminant analysis (PLS-DA) [14] using the full spectra and two interval-based extensions of PLS, namely forward interval PLS (FiPLS) and backward interval PLS (BiPLS) were used. These models were combined with classical chemometric preprocessing approaches and represent the benchmark. Additionally, wavelet

transforms were used to decompose the spectra by convolution with fixed filters and their wavelet coefficients were then used as features by FiPLS and BiPLS.

From the non-linear class, convolutional neural networks (CNNs) were used. CNNs have recently been considered as a potential alternative to classic chemometric methods for modeling of spectroscopic data [5,15]. The main benefit of CNN models lies in their ability to perform automatic feature extraction of the raw spectra, tailored for each specific dataset and target variables. For better interpretability, we consider only a single convolutional layer with a single filter. After the convolutional layer, the extracted features are passed through a non-linear activation function and multiple hidden layers. Since the problem is a binary classification problem, the output layer has a logistic activation function, and the Binary Cross Entropy loss function is used to estimate the CNN model parameters using the Adam optimizer. We further consider $L_2$ regularization of the loss function to prevent model overfitting.

## Feature Importance

For MIR data, different spectral bands can be associated with specific functional groups. Thus, the analysis of feature importance can provide insights on the critical chemical compounds related with the coagulation phenomenon. For the PLS-based approaches, feature importance was assessed using the Variable Importance in Projection (VIP) method [16,17]. In turn for the CNN model, the feature importance was determined using the Integrated Gradients (IG) method [18]. Whereas the VIP values are calculated based on the entire training dataset, IG values are calculated for each individual spectral sample. In addition, due to the stochastic weight initialization, the IG feature importance was repeated 30 times and the results averaged.

# RESULTS

WLO samples were provided by Sogilub, a non-profit organization responsible for the management of WLO in Portugal. A total of 109 WLO samples were collected for analysis. The coagulation potential of each sample was assessed using a coagulation test involving an alkaline treatment with potassium hydroxide (KOH). Based on the outcomes of this test, the laboratory analyst labeled the samples into two categories: "coagulates" (43 samples) or "does-not-coagulate" (66 samples). Additionally, MIR spectra comprising 1814 wavenumbers in the range of 4000 to 500 $cm^{-1}$ with a resolution of 2 $cm^{-1}$ were obtained for each sample in triplicate.

A total of 38 models, encompassing both linear and non-linear models, were compared using the SS-DAC framework. The first class of models, serving as the benchmark, employed PLS-DA, FiPLS and BiPLS, combined with standard chemometric preprocessing techniques, yielding 27 model variants. The second approach used wavelet transforms to decompose the spectral data into multiple frequency components through convolution with linear filters, followed by feature selection using FiPLS and BiPLS, resulting in 10 model variants. Finally, the third approach used CNN (without preprocessing) for non-linear feature extraction and modeling (1 model variant).

For the BiPLS and FiPLS methodologies using the chemometric preprocessing approaches, the MIR spectra were split into 30 equal intervals. For FiPLS and BiPLS using wavelet transforms the spectra were divided in intervals with a dyadic length of 64 $cm^{-1}$ (leading to into 29 intervals).

In the first stage of the SS-DAC framework, the raw dataset was randomly divided into two datasets: a

* The short name of the Savitzky-Golay differentiation preprocessing is coded as SGD-{D,W}, where D is the devative order and W is the window size.

training dataset comprising 80% of the samples and a test dataset containing the remaining 20% of the samples, ensuring balanced distributions across both datasets. Additionally, the replicates of the same sample were assigned to the same dataset to maintain consistency. The hyperparameters of the PLS-based models (number of latent variables and intervals kept in the model) were selected using the training dataset and Monte Carlo Cross-Validation (MCCV). In turn, the hyperparameters of the CNN (learning rate, regularization weights, kernel size, number and size of hidden layers, activation function and type of pooling), were selected by Bayesian Optimization (BO) [19] based on stratified 10-fold cross validation. All models were trained by maximization of the accuracy (ACC) given by:

$$ACC = \frac{TP+TN}{n} \quad (1)$$

where, $TP$ is the number of true positives, $TN$ is the number of true negatives, and $n$ is the total number of samples.

Subsequently, in the second stage of SS-DAC, the models' performance was evaluated on the test dataset using the accuracy as the key performance indicator (KPI).

In the third stage of the SS-DAC, the models were compared using bootstrap to obtain multiple realizations of the KPI in test conditions, and the Wilcoxon signed-rank test [20] to statistically assess the significance of the differences in accuracy of every pair of models. For each pairwise comparison, if a model had a statistically significant higher KPI, it was awarded a "victory", while the competing model received a "defeat". In cases where the accuracy of both models was deemed not statistically different, the comparison outcome was recorded as a "tie". A performance score was then calculated for each model by summing up the number of victories and ties. Models achieving higher scores, characterized by a larger number of victories and ties, were considered to exhibit consistently superior accuracy. The model's score, ranked from highest to lowest score are presented in Figure 2. Table 1 provides the mean accuracy obtained by each model.

The results obtained show that PLS with wavelet transforms, namely the FiPLS-Daubechies-6 model, achieved the best performance (highest score; first place), with a mean ACC of 0.93 and a standard deviation of 0.07. The CNN attained the second place, with a mean ACC of 0.92 with a standard deviation of 0.11. In the benchmark approach (PLS & Chemometric preprocessing), the best model was FiPLS-SNV-SGD-{2-9}, which ranked third place with a mean ACC of 0.90 and a standard deviation of 0.09. Thus, all model classes were able to attain high accuracy levels.

To achieve a high accuracy level using PLS and chemometric preprocessing it was however necessary to screen over several models, being that 26% of them have a mean accuracy lower then 0.80. The full-spectrum PLS models exhibited low performance since they rely on the entire spectral range, which makes them more susceptible to spectral noise. Similarly, the BiPLS-based models also showed low performance since they retained many intervals, leading to a less focused feature selection.

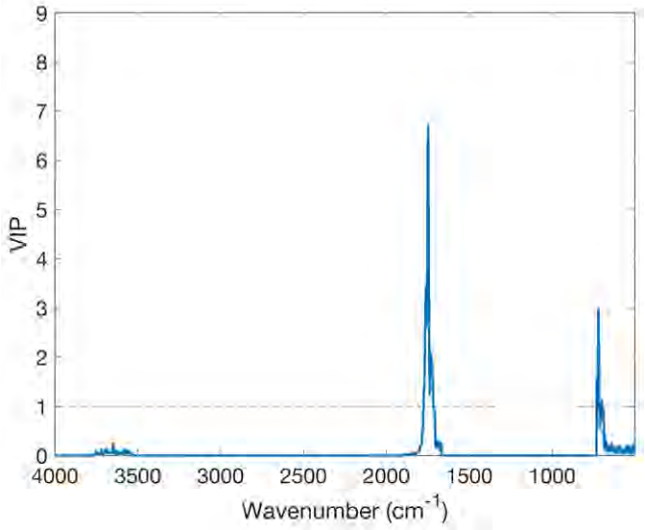

**Figure 3** Feature importance for FiPLS-SNV-SGD-{2-9}.

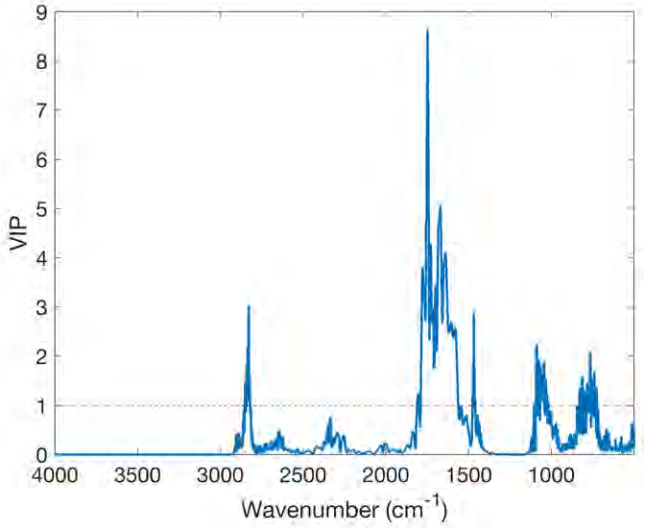

**Figure 4** Feature importance for FiPLS-Daubechies-6.

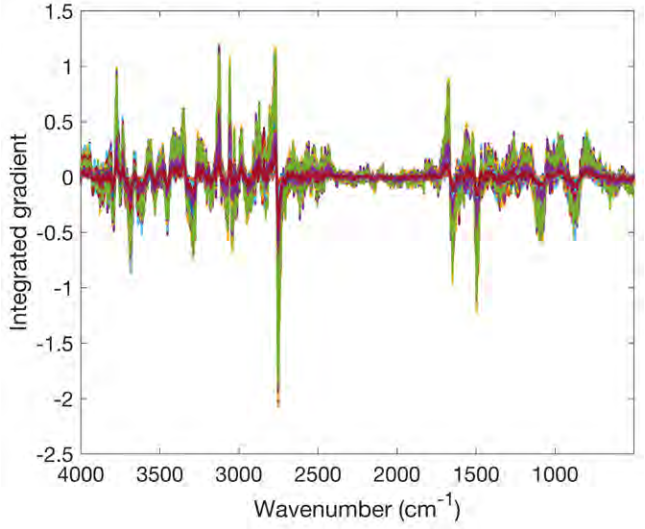

**Figure 5** Feature importance for CNN, calculated for each spectral sample. Refer to the online version for color.

In turn, all models based on PLS with wavelet transforms and CNN have a mean accuracy greater than 0.80. Thus, they are deemed as better modelling alternatives. The CNN model shows good performance even without any preliminary preprocessing of the spectra, which highlights their ability to perform automatic feature extraction. The BO of the CNN hyperparameters resulted in a large kernel, with a size of 184 and a larger structure, with 3 hidden layers with 82 units each. This high number of parameters can justify the slightly larger standard deviation of the CNN model compared to the more parsimonious PLS models.

In terms of feature importance, the FiPLS-SNV-SGD-{2-9} model distinctly identified the spectral band between 1775 and 1700 $cm^{-1}$ as the most critical for classification (Figure 3). Similarly, the FiPLS-Daubechies-6 model highlighted a broader region, identifying the 1790–1574 $cm^{-1}$ band as relevant (Figure 4). In contrast, other FiPLS models, whether using chemometric or wavelet preprocessing, included additional bands beyond this range, which negatively impacted their performance. Unlike the interval PLS models, the identification of the relevant features is less clear for the CNN model, due to the lack of explicit feature selection. Contrary to the other models, the band around 2700 $cm^{-1}$ is identified as the most important, which is related to the C-O stretch, possibly indicating a non-linear relationship with this band and the coagulation class.

Among the spectral bands consistently selected by most models, the 1750–1735 $cm^{-1}$ band stands out. This region is associated with the ester functional group [21]. Based on this, it is conjectured that esters may have a significant effect on the WLO coagulation phenomenon.

As the reference laboratory test is inherently subjective, there is some uncertainty in the WLO labels. Nevertheless, as the large majority of the samples are well discriminated, we believe this label uncertainty does not have a significant impact on the models' overall performance.

## CONCLUSION

The modeling methodologies employed in this study produced models with high predictive accuracy, with a mean ACC ranging from 0.90 to 0.93. The performance of PLS-based models was significantly affected by the choice of preprocessing techniques, emphasizing the importance of evaluating multiple preprocessing strategies during model development.

The use of wavelet transforms to preprocess the spectrum proved to be competitive against the traditional chemometric preprocessing approaches and can reduce the search space during preprocessing selection. The CNN exhibited good performance even without preprocessing. This advantage can reduce the effort typically required by exhaustive preprocessing selection by trial

and error. However, the CNNs requires the optimization of hyperparameters, for which BO is a compelling approach within the realm of automated machine learning.

The top-performing models allowed for the identification of esters as a potential factor in WLO coagulation, offering critical insights into the underlying mechanisms of the coagulation phenomenon.

## ABSTRACT

Random signals are crucial in chemical and process engineering, where industrial plants generate big data that can be used for process understanding and decision-making. This makes it necessary to unveil the underlying probability histograms from these signals with a finite number of bins. However, the search for the optimal number of bins is still based on empirical optimisation and general rules of thumb. In this work, we introduce an alternative and general method to unveil probability histograms. Our method employs a novel variable-order QMOM, which adapts automatically based on the relevance of the information contained in the random data. The number of bins used to recover the underlying histogram is found to be proportional to the information entropy, where a search algorithm is developed that generates bins and assigns probabilities to them. The algorithm terminates when no more significant information is available for assignment to the newly created nodes, up to a user-defined threshold. In conclusion, our method is a universal histogram reconstruction technique that only requires enough numbers of moments to work. The method has been validated intensively using synthetic random signals and real-life problems.

## INTRODUCTION

Random signals are vital in chemical and process engineering, data science, and machine learning. Industrial plants collect and analyze large volumes of data for process understanding, data compression, and decision-making, modelling industry 4.0 and 5.0 transformation and equipment or even process digital twins [1, 2, 3]. However, this data is not free of instrumental errors, where signal processing corrects it, enhances data accuracy and reliability. Despite advanced techniques that have been available, basic methods are commonly used due to resources' limitations which still depend on basic statistical representation methods [1]. In the sense of data compression, probability histograms are widely used as non-parametric density estimators, essential for visualizing data and deriving summary quantities like entropy from the underlying density, determining mechanical and physiochemical properties of particles from industrial systems and for real time online monitoring and control purposes [1]. However, the accuracy of these quantities is influenced by the number of bins selected for the histogram, which, in turn, determines the bin width based on the data range. Moreover, the empirical assumption of using uniform bin width has no solid theoretical support, where in most cases it is used for the simplicity of mathematical treatment [4, 5]. Unfortunately, finding the optimal number of bins is still based on empirical optimization and general rules of thumb. These methods are based on empirical formulas for the uniform optimal bin width by minimizing the integrated mean squared error of the histogram model H(x) as compared to the true and unknown underlying density f(x). Two popular formulas after Freedman and Diaconis [5] and that of Scott [6] were commonly used in which the bin width is inversely proportional to the cubic root of the number of data points in the set, while the proportionality constants are different but depend on the variance and the interquartile range of the data. On the other hand, one of the recent approaches is centered around a data-based method to estimate the optimal uniform bin-width of histograms using an optimization algorithm but not an

explicit empirical formula [4]. The disadvantages include the potentially large number of bins, the uniform bin distribution regardless of weights, and the inconsistency of the histogram with the low-order moments of the true distribution.

In this contribution we took a different approach that is free of the two main drawbacks in the previous work: The histogram's bin width and number of bins. We relaxed the assumption of uniform bin width and the number of the bins are evolved based on the available feasible information in the data set according to Shannon information entropy: $S = -\sum[p_i \ln(p_i)]$ with the constraints that $m_0 = \sum[p_i] = 1$ where $m_0$ is the normalized zeroth moment of the data set and $p_i$ is the $i^{th}$ probability associated with the $i^{th}$ bin of the histogram. Our simple search algorithm for N (Number of data points in the data set) is constrained by the feasible range of the data $R = [x_{min}, x_{max}]$ and the relevance of the probabilities $p_0$ and $p_{N-1}$ of the data in the first and last histogram bins.

## THE VARIABLE ORDER QMOM

As a data compression method, the Quadrature Method Of Moments (QMOM) works based on the calculated moments of the unknown probability density function. In its original formulation, the QMOM algorithm provides closed integrals (and hence moments as special case) of the unknown pdf based on the availability of its low-order moments. It is mainly used to close integrals when the weight function is not known explicitly. Since its introduction by McGraw [7], the QMOM has been the subject of considerable theoretical and applied research during the last two decades. These applications cover wide areas which include aerosols microphysics, nanoparticle formation, turbulent mixing, dispersed phase flows, crystal morphology, cell growth and differentiation and uncertainty propagation through dynamical systems, to name but a few [8]. As an ill-conditioned inverse moment problem, there is no simple and general inversion algorithm to reconstruct the unknown probability histogram from which the moments are calculated or measured. Because of this, the QMOM is rarely used or thought of as a method that can recover the underlying histogram from the available information in the nodes and weights provided by the method itself.

### The QMOM

The QMOM can be mathematically presented as an adaptive data compression method where information about the random signal is converted into a finite set of low-order moments irrespective of the size of the data set. Therefore, given a set of low-order moments $m_r, \mathrm{r} = 0, 1, \ldots 2N_q - 1$ as calculated from a pdf, the QMOM algorithm calculates a set of $N_q$ nodes and weights ($\zeta$, w) with the same principle as that of the Gauss-Legendre quadrature. The domain of the node set $\zeta \in (0,\infty)$ or $\zeta \in [x_{min}, x_{max}]$ depending on the bounds of the random data from which the set $m_r$ is calculated. The QMOM algorithm used in this work is chosen based on the efficient derivation of Upadhyay [9] using the Chebyshev orthogonal polynomials. This can handle large number of nodes that are not necessarily positive when compared to the classical product-difference algorithm (PDA) that was presented by [7]. Actually, Upadhyay [9] showed that the Chebyshev-QMOM (ChebQMOM) is superior to the PDA and is found to be more robust and can be used for a wider class of problems when high number of nodes is required as in our present work.

### The Variable-Order QMOM Algorithm

To proceed in the derivation of the Variable-Order QMOM (VOQMOM), we have to show that the weights ($w_i$, i = 0, 2, ..$N_q$-1) as calculated by the ChebQMOM are nothing more than probabilities of the function f(x;:) that are placed at the corresponding nodal points ($\zeta_i$, i = 1,2, ..$N_q$-1).

$$w_i = \int_{\zeta_{i-1/2}}^{\zeta_{i+1/2}} \mathrm{f(x;:)}dx \tag{1}$$

where ($\zeta_{i-1/2}$, $\zeta_{i+1/2}$) are unknown grid boundaries, which will be referred to as histogram bins. The bins boundaries should satisfy the inequality ($\zeta_{i-1/2} < \zeta_I < \zeta_{i+1/2}$) and the bins are not necessarily equal in width. The estimation of these grid boundaries is given by: $\zeta_{i+1/2} = \frac{1}{2}(\zeta_{i-1} + \zeta_i)$ which are functions only of the low-order moments of the given random signal. To reconstruct the probability histogram $H(\zeta_i)$ with probability ($w_i$) which is placed at ($\zeta_I$), we make use of the integral of the square of errors as defined by [4]:

$$E(H,f) = \int_0^\infty [H(x) - f(x)]^2 dx \tag{2}$$

Since the nodal points ($\zeta_I$) are roots of orthogonal polynomials by definition of ChebQMOM, we can close the integral of Eq.(2) as follows:

$$E(H,f) = \sum_{j=0}^{N_q} \left( w_j f(\zeta_j) - w_j H(\zeta_j) \right) \tag{3}$$

In Eq.(3), we have forced the histogram probability $H(x)$ to have low-order moments that are equal to those of $f(x)$, which is an enough assumption to deem the consistency of the reconstructed histogram w.r.t. the underlying density from which the moments are calculated. Now, for the error in Eq.(3) to vanish at the collocation points ($\zeta_I$), it is sufficient to have:

$$H(\zeta_i) = f(\zeta_i) = \frac{1}{\Delta\zeta_i} \frac{w_i}{\sum w_i} \tag{4}$$

where $\Delta\zeta_i = \zeta_{i+1/2} - \zeta_{i-1/2} = \frac{1}{2}(\zeta_{i+1} - \zeta_{i-1})$.

It is not difficult to show that the order of approximation of $H(\zeta_i)$ in Eq.(4) is $O(\Delta\zeta_i^2)$ because the approximation in Eq.(4) is equivalent to using the midpoint rule to

approximate the integral in Eq,(1). Note that Eq.(4) provides a complete theoretical inversion of the unknown probability density function f($\zeta_i$,:). The order of convergence is proportional to the square of the distance between the (i-
1) and (i+1) bin centers divided by 4.

The question now is how many bins (or quadrature nodes) that are sufficient to resolve the histogram probability $H(x)$ given a set of low-order moments that are computed from the random signal? The answer is nontrivial as it is related to the Shannon information entropy based on the available probabilities ($w_i$):

$$S = -\sum_i w_i \ln(w_i) \quad (5)$$

From Eq.(5), it is evident that as the number of bins used to recover the underlying histogram increases, so does the information entropy, until no more information is required. This implies that adding extra bins will not contribute any relevant information to the histogram, as indicated by very low probability values, signifying the irrelevance of newly added nodes. In the hypothetical limit where the data has zero information entropy (Dirac delta function), the number of bins is reduced to one. In the variable order QMOM realm, the number of bins is determined through a simple search algorithm that optimally assigns nodes through sampling the unknown function or process from which the random data is generated. The algorithm terminates when no more significant information is available for assignment to the newly created nodes, up to a user-defined threshold. If the data originates from a dynamic source with varying mean and variance, the number of bins and its boundaries will adjust itself to reflect the nature of the dynamic data. The complete detailed algorithm is shown in Figure 1. Note that the "while loop" implements the simple search and variable order of the ChebQMOM algorithm where the order is determined if the last computed weight (probability) "$W_{N-1}$" is less than very small, specified tolerance (Tol) and if the maximum and minimum computed nodes are outside their physical range. The algorithm is initiated by providing a vector of computed low-order moments "MOM", initial order "N = 2", Tol, $x_{min}$ and $x_{max}$. The output is a set of computed nodes and weights (ζb, wb). These conditions are found in all simulated cases to correspond to the maximum entropy, as given by Eq.(5). After reaching this point, the entropy "S" begins to decrease because the weights at least on one end of the distribution fall to zero. In Figure 4, the VOQMOM process is illustrated with a real-life sample showing the workflow and the significance of the random signal identification with 22 low-order moments associated with the reconstructed histogram. Also, the plateau of the information entropy is clear near the maximum number of bins. Note that the ChebQMOM is implemented in an efficient way to reduce the numerical round-off errors using MATLAB.

## RESULTS AND DISCUSSION

In this section we will present sample of results using synthetic random signals and real-life case studies. Also, in addition to the static sampling, we present a dynamic case study by solving the simultaneous particle aggregation and growth in a closed batch process.

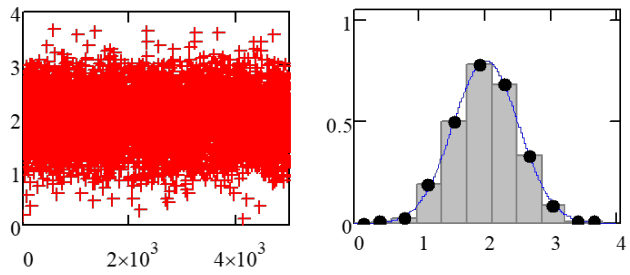

**Figure 2.** Unveiling random signal produced from normal distribution (mean = 2, std = 0.5) using 5000 samples. On the right-hand side is the recoverd probability histogram using 11 bins with 22 low-order moments.

This case study demonstrates how the VOQMOM identifies the data that is coming from a dynamic source with varying mean and variance where the boundaries of the bins move in a dynamic way. In addition to this, similar case studies were conducted on particle breakage in closed and open systems, particle breakage and coagulation, an industrial scale mixer where a light liquid phase is dispersed in water as the continuous phase.

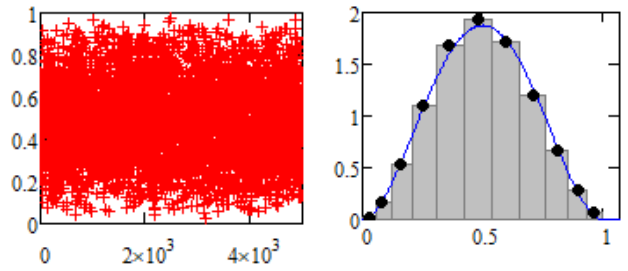

**Figure 3.** Unveiling random signal genrated from a beta distribution (parameters a = 3 and b = 3) using 5000 samples. On the right-hand side is the recovered probability histogram using 11 bins based on 22 low-order moments.

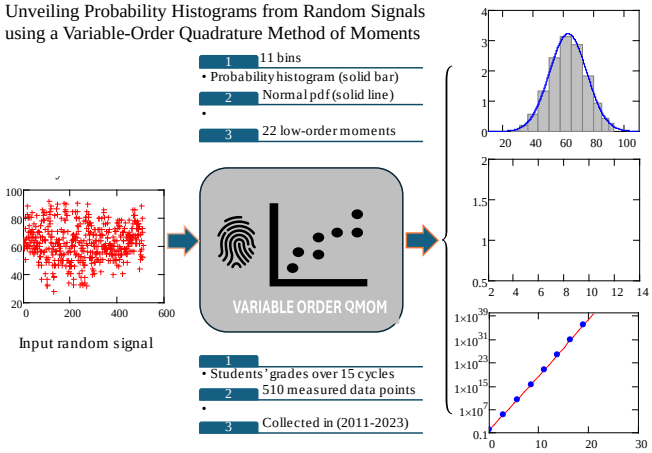

**Figure 4.** Moment-consistent histogram unveiled from students' grades using the Variable-Order QMOM (VOQMOM). To the left is the random signal of students' grades during 15 cycles. In the center is the VOQMOM process, and on the top right is the unveiled density histogram (with 11 bins) compared to the normal pdf with the same mean and variance as the data set. On the right (middle) is the information entropy of the data set as function of number of bins, while on the right bottom is the predicted (filled circles) and original set of moments (solid line).

## Unveiling probability histograms from Synthetic random signals

A sample of three case studies that were synthesized to prove the concept of the VOQMOM using random sampling from normal, beta and lognormal probability density functions (pdf). The random variable "x" is normalized using the relation: $u = \frac{x - x_{max}}{x_{max} - x_{min}}$ and the moments of the sampled data were calculated using the relation $m_r = \frac{1}{N}\sum_{j=0}^{NoSamles} u_j^r \ , r = 0, 1, \ldots \ NoSamples$. This moment transformation results in a moment space that is decreasing exponentially showcasing the irrelevant information contained in the high-order moments which are usually address the information content in the tail of the pdf. Figure 2 (Left) shows the 5000 random samples that are drawn from a normal probability density function with mean = 2, and std = 0.5. The VOQMOM algorithm identified this random signal using the algorithm of Figure 1 which discovered an 11-bin probability density histogram as compared to the original normal pdf showen in Figure 2 (Right). In addition to this, the histogram is consistent w.r.t. 22 low-order moments of the original data. Similarly, Figure 3 shows the results of identifying 5000 random samples drawn from the beta probability density function by the VOQMOM ending with an 11-bin histogram. In Figure 5, the VOQMOM is challenged by 5000 random samples that are drwan from the unsymmetrical log pdf (mean = 1.349 and std = 0.419). Again, with 11 discovered bins, the unveailed probability density histogram is very close to the orignal pdf.

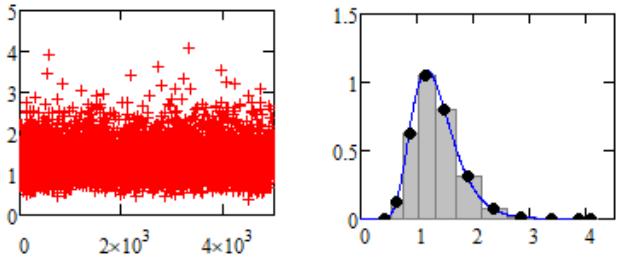

**Figure 5.** Unveiling random signal genrated from a lognormal probability density function (mean = 1.349 and std = 0.419) using 5000 samples. On the right-hand side is the recovered probability histogram using 11 bins based on 22 low-order moments.

**Table 1:** Unveiled probability histograms using the VOQMOM based on different real-life random data.

| Case | Description | No of bins |
|---|---|---|
| 1 | mean maximum air to surface temperature in Amman | 13 |
| 2 | adult diastolic blood pressure | 11 |
| 3 | abalone total weight data | 12 |
| 4 | students' grades for 15 cycles. | 11 |
| 5 | mean wind speed data | 12 |
| 6 | droplet size distribution data | 11 |

From these results, it is evident that the VOQMOM discovers incrementally new nodes and decides to stop when the individual probability carried by the terminal nodes (first & last nodes) becomes less than a user specified tolerance (Tol = 10-12). Also, the physical bounds placed on the terminal nodes is checked accordinglly where the probabilities of the terminal nodes approach zero when the physical bounds are exceeded.

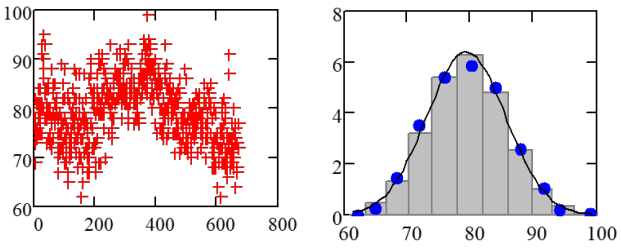

**Figure 6.** Unveiling random signal based on measured diastolic blood pressure of a male adult (age 50-56) using 671 samples. On the right-hand side is the recoverd probability histogram using 11 bins based on 22 low-order moments as compared to the normal pdf.

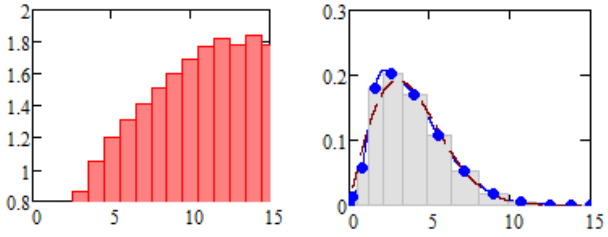

**Figure 7.** Unveiling random signal based on measured mean wind speed [10] using ~35000 samples. On the left-hand side is the information entropy as function of bins number and on the right-hand side is the recoverd probability histogram using 12 bins based on 24 low-order moments., The dashed line is the Weibull pdf with shape and scaling parameters calculated based on the correlations from [10].

## Unveiling probability histograms from real-life random signals

Having validated the concept of the simple search algorithm of the VOQMOM using random signals from a reference pdf, we demonstrate the validity of the method using real-life data sets. Figure 6 (Left) shows 671 random measurements of diastolic blood pressure for an adult male (50-56 years old) during a time span of 6 years. The search algorithm of the VOQMOM identified an 11-bin probability histogram behind these random data set as shown in Figure 6 (Right). The histogram is consistent w.r.t. 22 low order moments. Comparing this unveiled histogram to the normal pdf, it is clear that the data is well presented by this pdf with mean and standard deviation as those of the original data. In the second real case study, a random measured data set of size ~ 35000 which represents mean wind speed data [10] as shown in Figure 7. On the left-hand side of this figure is the information entropy as function of bins number. It is clear when new node or bin is added, the information entropy increases until a point where the probabiltiy of the added node approaches zero. At this point we observed that the entropy drops slightly in all the investigated case studies signifiying the termination of the algorithm at the maximum possible node number. On the right-hand side of Figure 7 is the recoverd probability histogram using 12 bins based on 24 low-order moments. Also, the results are compared to the Weibull pdf (dashed line) with shape and scaling parameters calculated based on the correlations derived by Shu and Jesson [10] using mean wind speed data. It is clear that this data set is well represented by the Weibull pdf. The last case study consists of a data set of abalone total weights in mg that is measured from 4177 individuals [12]. Figure 8 (Left) shows the increase in the information entropy until a flat plateau is reached near the best number of bins (12). The unveiled histogram from these random data is shown in Figure 8 (Right) and is compared to the Weibull distribution with shape and scaling factors that are calculated by correlations from [10]. It is noteworthy to mention here that the optimal number of uniform bins obtained from this data set was found to be 14 using an optimization algorithm of Knuth [4]. Furthermore, Table 1 shows many cases studies which are based on real-life experience with main observation that the number of bins predicted by the VOQMOM ranges from 11 to 14.

## Unveiling probability histograms by solving the population balance equation

In this case study we tested the VOQMOM for the dynamic evolution of simultaneous particle growth and coagulation under constant coagulation rate and growth velocity given by $G(x) = G_0 x/3$ . From the initial condition $f(x) = 3x^2 \exp(-x^3)$, the number of bins is found to be 11. After 10 seconds of simulation time using Heun's method with a time step of 0.025 seconds and $\Lambda$ = 0.75 (ratio of coagulation to growth rate), the number of bins discovered by the VOQMOM is 13. Figure 9 shows the normalized histogram (w.r.t. zeroth moment) at t = 0 (Left) and at t = 10 seconds (Right). All the 22 low-order moments were calculated with high accuracy when compared to the analytical solution of Gelbard and Seinfeld [11]. In spite of the growth of the particle size around 20 times of its initial value, the solution at t = 10 s is free of numerical diffusion due to the integral representation of the growth term thanks to the QMOM. Note that the integral source term in the population balance equation is integrated with a variable order QMOM at each instant of time. The CPU time using Heun's method for this case is in the order of 5 seconds using a state of the art msi-laptop (Intel(R) Core(TM) i7, CPU at 2.6 GHz & 8 GB RAM). The dominance of coagulation over particle growth is manifested by the increase of information entropy from 1.68 to 1.77 that is reflected by the increase of nodes from 11 to 13.

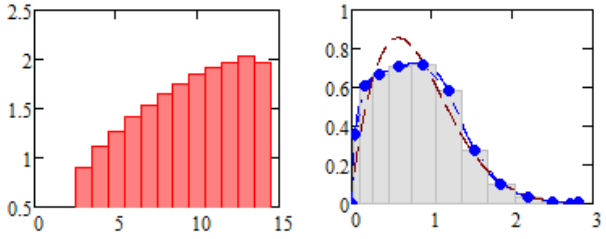

**Figure 8.** Unveiling random signal based on measured abolane total weight in mg using 4177 samples. On the left-hand side is the information entropy as function of bins' number and on the right-hand side is the recoverd probability histogram using 12 bins based on 24 low-order moments as compared to Weibull pdf (dashed line) with shape and scaling parameters calculated based on the correlations of Shu and Jesson [10].

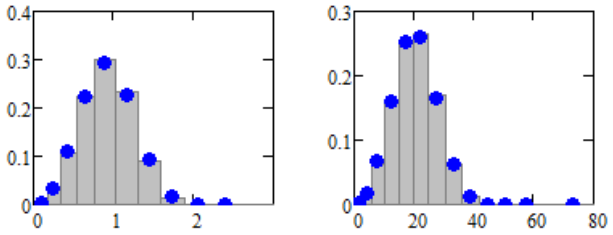

**Figure 9.** Particle growth & coagulation with $\Lambda$ = 0.75 in a simplified batch crystallizer. Left: Normalized histogram at t = 0 with 11 bins. Right: Normalized histogram as compared to the exact ones (filled circles) with number of moving bin centres = 13 at t = 10 s.

## SUMMARY AND CONCLUSIONS

The VOQMOM is a non-parametric method that can be used to identify general probability histograms by processing big random data which is drawn from real-life problems. It works through compressing a given set of random data into low-order moments, which are then processed to encode the underlying pdf from which the data is generated. It uses a simple linear search algorithm coupled with ChebQMOM and needs only a sufficient number of nodes and weights to work with negligible computational cost. Using different analytical and practical case studies, it is found that 10 to 14 bins were sufficient to reconstruct the pdf with a local accuracy of $O(\Delta\zeta_i 2)$. The algorithm terminates when no more informaiton is available to assign to the terminal nodes.

## ABSTRACT

In applications involving fine powders and small particles, the accuracy of numerical simulations, particularly those employing the Discrete Element Method (DEM) to predict granular material behavior, can be significantly affected by uncertainties in critical parameters. These uncertainties include the coefficients of restitution for particle-particle and particle-wall collisions, viscous damping coefficients, and other related factors. In this study, we use stochastic expansions based on point-collocation non-intrusive polynomial chaos to perform a sensitivity analysis of a fluidized bed system. We treat four key parameters as random variables; each assigned a specific probability distribution over a designated range. This uncertainty is propagated through high-fidelity Large Eddy Simulation (LES)-DEM simulations to statistically quantify its impact on the results. To effectively explore the four-dimensional parameter space, we analyze a comprehensive database comprising over 1,200 simulations. Notably, our findings reveal that variations in the particle and wall Coulomb friction coefficients have a more pronounced influence on streamwise particle velocity than variations in the particle and wall normal restitution coefficients.

**Keywords**: CFD-DEM, gas-solid fluidization, global sensitivity, gPC, linear spring-dashpot model, spring stiffness.

## INTRODUCTION

Gas-solid fluidized bed reactors are widely used in energy and chemical conversion processes due to their high heat and mass transfer rates, thermal homogeneity, and operational flexibility. Despite these advantages, designing and optimizing such reactors remains challenging due to complex multiphase interactions and limited diagnostic capabilities under extreme conditions.

Computational Fluid Dynamics coupled with the Discrete Element Method (CFD-DEM) has emerged as a powerful tool for studying these systems, offering detailed particle-scale resolution but at a high computational cost. CFD-DEM simulations rely on model parameters such as spring stiffness, restitution, and friction coefficients, which significantly impact flow behavior. However, these parameters are often uncertain due to experimental limitations and material variability. While previous studies have analyzed their influence, they typically consider only one or two parameters at a time, limiting the broader understanding of parametric interactions. Given the nonlinear and highly coupled nature of fluidized bed hydrodynamics, a systematic global sensitivity analysis is essential. This study aims to identify critical CFD-DEM model parameters affecting fluidized bed hydrodynamics. Using a statistically designed set of CFD-DEM simulations, we explore parameter sensitivities through uncertainty quantification techniques. The analysis is based on a lab-scale rectangular fluidized bed containing approximately 9,240 particles. A total of 1,200 simulations are conducted using high-performance computing resources, making this one of the most extensive sensitivity analyses of dense-phase particulate flows. The results provide insights into the dominant parameters governing bubble dynamics and particle interactions, contributing to improved predictive capabilities of CFD-DEM models.

Stochastic approaches have been increasingly used

in recent years for uncertainty quantification and sensitivity analysis in numerical flow simulations [3,4]. In this framework, three CFD-DEM input parameters-spring stiffness, normal damping, and friction coefficient-are treated as random variables with prescribed probability distributions. The uncertainty is then propagated through the computational model to statistically quantify their effect on the results. To reduce computational costs, a surrogate model is employed to construct a continuous response surface in the parameter space. A widely adopted non-intrusive approach is the generalized polynomial chaos (gPC) expansion, which represents the quantities of interest as spectral expansions in terms of orthonormal polynomial bases associated with the random parameters. While gPC has been extensively applied to turbulent flow simulations, it has been rarely used in gas-solid fluidized bed simulations. To the best of our knowledge, this study is among the first to employ this approach in such a context, providing new insights into uncertainty quantification in multiphase flow systems.

## STOCHASTIC MODELING AND METHODS

Instead of resorting to Monte Carlo simulations for uncertainty quantification, stochastic expansions based on point-collocation non-intrusive polynomial chaos are used to mitigate computational expenses. The point-collocation strategy involves constructing a surrogate model, employing a least squares approach (i.e., polynomial response surface), by using CFD-DEM output obtained at several Latin Hypercube sample points for uncertainty propagation. In most practical applications, the stochastic response function $M(\xi)$ of, for example, the time-averaged quantity like bed height, pressure loss, distribution of voidage at a specified height in the flow field, which are referred to as the Quantity of Interest (QoI), are function of $m$ independent stochastic variables $\xi_i$ that form the vector $\xi = [\xi_1, \cdots, \xi_m]$. Each random variable $\xi_i$ is characterized by a probability density function (PDF), $w_i(\xi_i)$ in the domain $E_i$. The main idea in this work is to estimate the effect of $\xi$ on the statistics of $M(\xi)$. To do this, a complete probability space $P = (\Omega, \Sigma, dP)$ is defined, where $\Omega$ refers to the set of random events and the probability measure $dP$ is characterized by the $\sigma$-algebra $\Sigma$. The vector $\xi$ follows the probability density function $W = \prod_{i=1}^{m} w_i(\xi_i)$, defined in the domain $E = \prod_{i=1}^{m} E_i$. This stochastic space is spanned by a polynomial basis $\Psi = \{\Psi_0, \Psi_1, \dots\}$ which is orthogonal to $W$ with respect to the inner product $\langle \Psi_j, \Psi_k \rangle = \int_E \Psi_j \Psi_k W d\xi = \delta_{jk} \langle \Psi_j, \Psi_j \rangle$.

The polynomial basis is normalized so that $\langle \Psi_j, \Psi_j \rangle = 1$. When $m > 1, \Psi$ is defined by the tensor product of the unitary polynomials $\psi^{(i)}$, as in $\Psi = \otimes_{i=1}^{m} \psi^{(i)} = \{\Psi_0, \Psi_1, \dots\}$. The base is truncated to a finite number of polynomials by limiting the order of $\Psi_j$ to $p$. In that case, the Quantity of Interest $M$ is written in spectral form as

$$\mathcal{M}(\xi) = \sum_{i=0}^{P} c_{(i)} \Psi_i(\xi)$$

In theory, this series is infinite, but for practical implementation of the polynomial chaos expansions, it is truncated and discretely summed over several output modes, $(P+1)$.

Two parameters determine the number of samples required to generate the response surface: the number of uncertain variables, $n$ and the order of the response surface polynomial, $p$. The total number of samples$N_s$ is then expressed as $N_s = (P+1) = (n+p)!/n!\,p!$.

The Point-Collocation method commences by replacing a stochastic response or random function with its polynomial chaos expansion. Subsequently $N_s$ vectors are selected in random space, and the deterministic code (the CFD flow solver in this case) is evaluated at these points. Finally, a linear system of $N_s$ equations is formulated and solved for the spectral modes of the random variables. Due to the bounded nature of epistemic input uncertainties, Legendre polynomials were used in this study as the basis functions. Additional insights into polynomial chaos theory are provided by Ghanem and Spanos (2003). Sobol indices (global nonlinear sensitivity indices) were utilized to rank the relative contributions of each closure coefficient to the total uncertainty in the output quantities of interest. Sobol indices can be derived via Sobol Decomposition, a variance-based global sensitivity analysis method. This derivation utilizes the polynomial chaos expansion coefficients. First, the total variance, D, can be expressed in terms of the PCE as $D = \sum_{j=1}^{P} c_{(j)}^2 \langle \Psi_j^2(\xi) \rangle$. Then, as demonstrated in [2], the total variance can be decomposed as

$$\mathrm{D} = \sum_{i=1}^{n} \mathrm{D}_i + \sum_{1 \le i < j \le n}^{n-1} \mathrm{D}_{i,j} + \sum_{1 \le i < j < k \le n}^{n-2} \mathrm{D}_{i,j,k} + \cdots + \mathrm{D}_{1,2,\dots,n}$$

where the partial variances $(D_{i_1,\dots,i_s})$ are given by:

$$\mathrm{D}_{i_1,\dots,i_s} = \sum_{\beta \in \{i_1,\dots,i_s\}} c_{(\beta)}^2 \left\langle \Psi_\beta^2(\xi) \right\rangle, \quad 1 \le i_1 < \dots < i_s \le n$$

Then the Sobol indices $(S_{i_1 \cdots i_s})$ are defined as

$,S_{i_1 \cdots i_s} = \frac{D_{i_1,\dots,i_s}}{D}$, which satisfy the following equation:

$$\sum_{i=1}^{n} \mathrm{S}_i + \sum_{1 \le i < j \le n}^{n-1} \mathrm{S}_{i,j} + \sum_{1 \le i < j < k \le n}^{n-2} \mathrm{S}_{i,j,k} + \cdots + \mathrm{S}_{1,2,\dots,n} = 1$$

The Sobol indices provide a sensitivity measure due to the individual contribution from each input uncertain variable $(S_i)$, as well as the mixed contributions $(\{S_{i,j}\}, \{S_{i,j,k}\}, \cdots)$. As demonstrated by [5], the total (combined) effect $(S_{T_i})$ of an input parameter $i$ is defined as the summation of the partial Sobol indices that include the particular parameter $S_{T_i} = \frac{L_i}{D_{i_1,\dots,i_s}} D$, where$L_i = \{(i_1, \cdots, i_s) : \exists k, 1 \le k \le s, i_k = i\}$. From these formulations, it is evident that the Sobol indices can be utilized to

provide a relative ranking of each input uncertainty to the overall variation in the output, considering nonlinear correlations between input variables and output quantities of interest.

## MODELING PARTICLE DYNAMICS IN THE CFD-DEM FRAMEWORK

In the Computational Fluid Dynamics-Discrete Element Method (CFD-DEM) framework, the motion of individual particles is described by Newton's second law, which is expressed as follows:

$$m\frac{du_p}{dt} = \mathbf{f}^{\text{col}} + \mathbf{f}^{f\to p} + mg,\; I\frac{d\psi}{dt} = \mathbf{T}^{\text{col}} + \mathbf{T}^{f\to p}$$

where $u_p$ denotes the particle velocity, $t$ represents time, $m$ is the particle mass, $f^{\text{col}}$ represents contact forces resulting from particle-particle or particle-wall collisions, $f^{f\to p}$ indicates fluid-particle interaction forces (e.g., drag and lift forces), and $g$ denotes the gravitational force. Similarly, $I$ and $\psi$ represent the moment of inertia and angular velocity of the particle, respectively, while $T^{\text{col}}$ and $T^{f\to p}$ denote the torques due to contact forces and fluid-particle interactions, respectively.

The particles are modeled as soft spheres with inter-particle contacts represented by an elastic spring and a viscous dashpot to compute collision forces and torques. In this framework, the collision force $f^{\text{col}}$ acting on particle $i$ is computed as the sum of all pairwise forces $f_{j\to i}^{\text{col}}$ exerted by the $N_p$ particles and $N_w$ walls in contact. As particles and walls are treated similarly during collisions, the index $j$ refers to both; thus, $f^{\text{col}} = \sum_{b=1}^{N_p+N_w} f_{j\to i}^{\text{col}}$, with $f_{j\to i}^{\text{col}} = f_{n,j\to i}^{\text{col}} + f_{t,j\to i}^{\text{col}}$. The normal and tangential contact forces $f_{n,j\to i}^{\text{col}}$ and $f_{t,j\to i}^{\text{col}}$ are determined as follows:

$$f_{n,j\to i}^{\text{col}} = \begin{cases} -\kappa_n \delta_{ij} n_{ij} - 2\gamma_n m_{ij} u_{n,ij}, & \text{if } \delta_{ij} > 0 \\ 0, & \text{otherwise} \end{cases}$$

where $n_{ij} = (x_j - x_i)/\|x_j - x_i\|$ is the unit normal vector from particle $i$ towards particle $j, \delta_{ij} = r_i + r_j - (x_i - x_j)\cdot n_{ij}$ represents the overlap between particles $i$ and $j, m_{ij}$ is the effective mass, $u_{n,ij} = \left((u_{p,i} - u_{p,j})\cdot n_{ij}\right) n_{ij}$ is the normal component of relative velocity, $u_{t,ij} = u_{ij} - u_{n,ij}$ is the tangential component of relative velocity, and $t_{ij} = u_{t,ij}/\|u_{t,ij}\|$ is the unit tangential vector. In the case of a particle-wall collision, the wall is considered as a particle with infinite mass and null radius. This model requires three user-defined parameters: $\kappa_n, \gamma_n$, and $\mu_{\text{friction}}$, representing the spring stiffness, normal vidamping, and friction coefficient of the $i-j$ binary system, respectively. The viscous damping coefficients are computed as

$$\gamma_n = \frac{2\sqrt{m_p k_n} ln\ e_n}{\sqrt{\pi^2 + ln^2\ e_n}}$$

where $e_n$ is the normal restitution coefficient. The other terms involved in the computation of DEM can be found in [1], as the focus of this work is to study the uncertainties of the soft sphere model.

## DATABASE

**Table 1**: Parameters of DEM-LES simulations

| | |
|---|---|
| Fluid phase | |
| Fluid density $\rho_f$ [kg/m$^3$] | 1.2 |
| Fluid viscosity $\mu$ [Pa·s] | $1.8 \times 10^{-5}$ |
| Superficial gas velocity $u_\infty$ [m/s] | 0.6 – 0.9 |
| Solid phase | |
| Number of particle | 9240 |
| Particle diameter $d_p$ [mm] | 1.20 |
| Particle density $\rho_p$ [kg/m$^3$] | 1000 |
| Inter-particle restitution coefficient $\epsilon_{\text{dry}}$ | [0.0,1.0) |
| Particle-wall restitution coefficient $\epsilon_{\text{dry}}$ | [0.0,1.0] |
| Inter-particle restitution coefficient $\mu_c$ | [0.0,1.0] |
| Particle-wall friction coefficient $\mu_c$ | [0.0,1.0] |
| Geometry and Mesh | |
| Bed $L_x \times L_y \times L_z$ [mm$^3$] | $44 \times 288 \times 10$ |
| Grid number $\mathcal{N}_x \times \mathcal{N}_y \times \mathcal{N}_z$ | $16 \times 120 \times 4$ |
| Non-dimensional parameters | |
| Particle Reynolds number $\mathcal{R}\epsilon_p$ | 48, 72 |
| Stokes number $\mathcal{S}t$ | 2.66 – 4 |
| Archimedes number $\mathcal{A}r$ | $6.27 \times 10^4$ |
| Galileo number $\mathcal{G}a$ | 250.41 |

Simulations of a fluidized bed have been performed, and the parameters considered in this study are reported in **Table 1**.

Since the inter-particle restitution coefficient, particle-wall restitution coefficient, and particle-wall friction coefficient are assumed to represent either uncontrolled variations in experiments or unknown perturbations in the DEM model, there is no a priori knowledge of their probability density function. For this reason, the simplest and most general PDF is chosen to describe the distribution of the investigated parameters. Specifically, the PDFs are assumed to be uniform. Given this choice, the Legendre polynomial family is employed for the spectral projection.

The solver used to perform these simulations has been extensively described and validated in previous studies. The reader is referred to [1] for further details.

## RESULTS AND DISCUSSION

In the present simulations of fluidized bed systems, achieving consistency with experimental measurements can be challenging, as illustrated in **Figure 1.** Arbitrary variations in input parameter values may result in significant discrepancies. To address this, we propose an

improved calibration approach by analyzing the sensitivity of the simulations to uncertainties associated with different input parameter values.

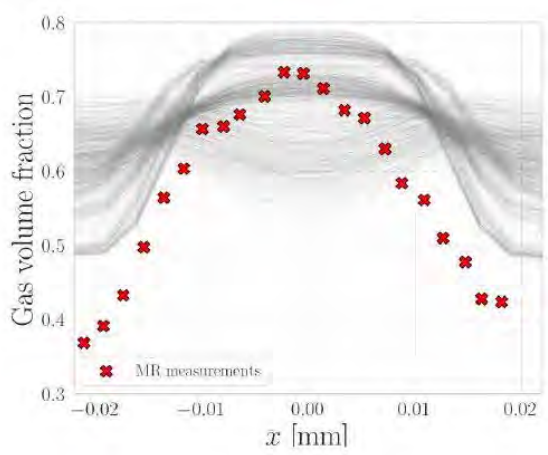

**Figure 1:** Comparison between different set of simulation of fluidized bed and measurements of [8]. Each simulations use different set of values for the input parameters.

We now present the results of the surrogate models alongside the sensitivity analysis in **Figure 2-5**.

As previously outlined, the model aims to simulate four key variables, which are considered our target variables and are believed to carry the uncertainty. Initially, the polynomial degree for the Polynomial Chaos Expansion (PCE) is set to 5. This choice is motivated by the relatively low computational requirements, in terms of the number of simulations to be performed, while still delivering good performance for the surrogate model. One of the main advantages of PCE is its ability to estimate the leave-one-out error analytically.

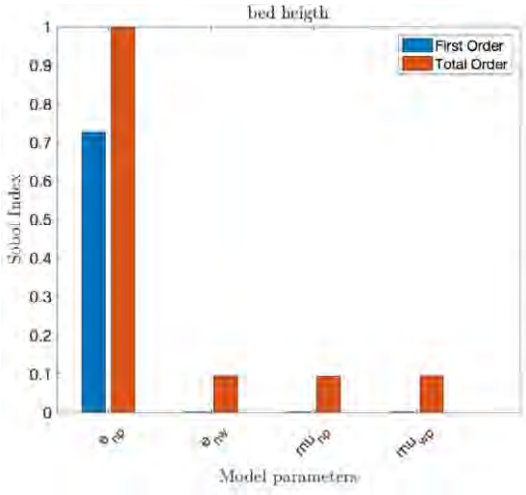

**Figure 2**: Sobol' indices (First order in blue and Total Order in orange) for the four quantities of interest in the model: mean bed height

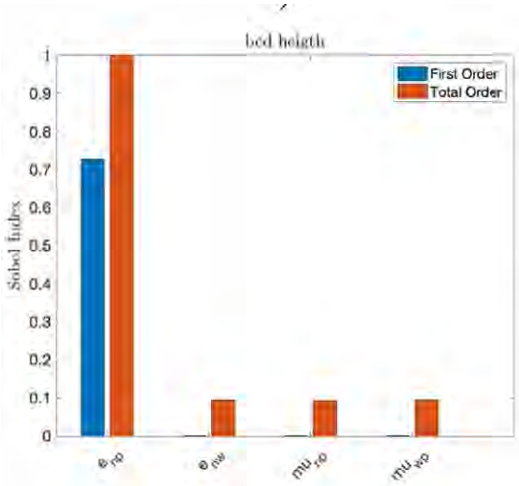

**Figure 3**: Sobol' indices (First order in blue and Total Order in orange) for the four quantities of interest in the model: standard deviation of bed height

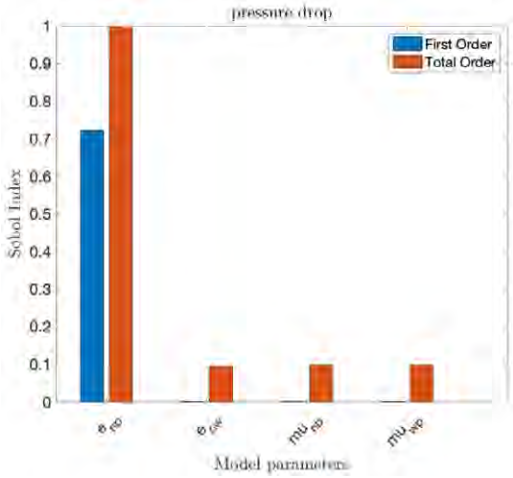

**Figure 4**: Sobol' indices (First order in blue and Total Order in orange) for the four quantities of interest in the model: mean pressure drop.

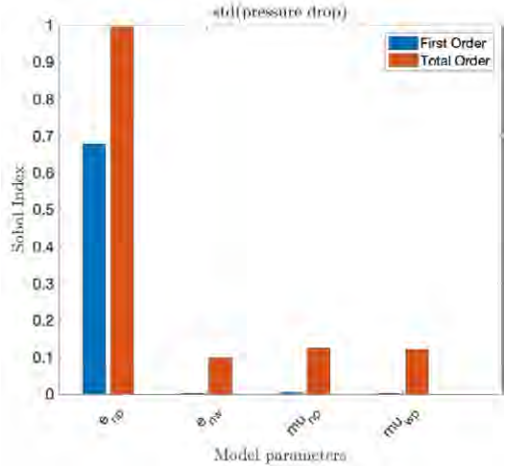

**Figure 5**: Sobol' indices (First order in blue and Total Order in orange) for the four quantities of interest in the model: standard deviation of pressure drop.

In our case, the error value is on the order of $10^{-5}$. This indicates that the error introduced by the polynomial truncation, as well as that arising from the coefficient estimation, is acceptable, thereby enabling a careful sensitivity analysis of the model parameters. Subsequently, using the developed PCE, a sensitivity analysis is carried out following the expansion methodology outlined in the previous section. The results are presented in Figure 2. For each of the quantities of interest, the Sobol' indices for each model parameter are estimated, with both first order and total order indices considered. Our results show that the sensitivity indices exhibit a similar shape across all quantities of interest. Notably, the variable $e_{np}$ is primarily responsible for driving the uncertainty. However, total-order Sobol' indices indicate that uncertainty can also be attributed to the interactions between the four variables. While most of the uncertainty is explained by $e_{np,}$ interactions with the other variables can account for up to 40% of the total uncertainty. These findings highlight the challenges encountered in previous studies when attempting to accurately calibrate such models to experimental data.

## ABSTRACT

Artificial neural networks are widely used as data-driven models for capturing complex, nonlinear systems. However, suboptimal training remains a significant challenge due to the nonlinearity of activation functions and the reliance on local solvers, which makes achieving global solutions difficult. One solution involves reformulating activation functions as piecewise linear approximations to convexify the problem, though this approach often requires substantial CPU time. This study demonstrates that a tailored branch-and-bound algorithm can effectively address these challenges by efficiently navigating the solution space using linear relaxations. The proposed method achieves minimal training error, offering a robust solution to the training bottleneck. Unlike traditional mixed-integer programming approaches, which often struggle to converge within reasonable CPU times, the SOSX algorithm shows superior scalability, with computational demand growing almost linearly rather than exponentially as problem size increases. Experiments on datasets with the same dimensionality confirm that the algorithm's efficiency is not specific to a particular dataset, as it demonstrates consistent CPU time trends across multiple datasets.

**Keywords**: artificial neural networks, piecewise linear functions, convex formulation, mixed-integer linear programming, computational complexity.

## INTRODUCTION

A mechanistic process model relies on physical laws governing the system, but developing such models is in general time-consuming and challenging. In contrast, data-driven models offer a straightforward alternative, especially for representing nonlinear and complex systems. Artificial neural networks (ANNs), inspired by human brain neurons, are a popular type of data-driven models. Among them, feedforward neural networks (FNNs) are simpler, with data flowing in one direction from the input to the output layer, comprising an input layer, output layer, and user-defined hidden layers connected via activation functions.

Common activation functions include Rectified Linear Unit (ReLU), hyperbolic tangent ($tanh$), and sigmoid. ReLU is piecewise linear, while tanh and sigmoid are nonlinear and symmetric. These functions introduce nonlinearities, making ANN training a non-convex optimization problem classified under nonlinear programming (NLP). This can result in issues like underfitting, overfitting, or suboptimal solutions [1]. A major challenge is the reliance on local solvers, as global solvers often struggle to converge or require excessive CPU time due to nonlinearities in the activation function [2].

One way to address the non-convexity of neural network training is by using the piecewise linear (PWL) representation of nonlinear activation functions. Various methods for PWL formulations have been explored such as defining binary variables [3] or special ordered set variables [4]. This transforms the problem from an NLP formulation to a mixed-integer linear programming (MILP) formulation. In addition to these methods, Keha et al. proposed “SOSX variables,” which eliminate the need for

binary variables and enable PWL functions to be modelled with linear programming (LP) subproblems by modifying branching algorithms, yielding equivalent solutions to special ordered set type II (SOS2)-based MILP formulations [5].

Many studies have focused on optimizing ReLU-based neural networks, utilizing their naturally piecewise linear structure. Research on PWL ReLU-trained neural networks has primarily aimed at reducing computational time [6-8]. Beyond ReLU-based formulations, several studies have explored MILP formulations incorporating hyperbolic tangent activation functions in ANNs [9-10]. Similarly, Sildir and Aydin utilized the PWL representation of the hyperbolic tangent function during training with feature selection, effectively reducing the risk of suboptimal training and enhancing test accuracy [11]. However, a key limitation of this approach lies in the MILP formulation. As the number of features, neurons, and hidden layers in the NN increases, the number of binary variables grows exponentially, significantly increasing CPU time. This challenge underscores the need for more efficient MILP formulations to reduce computational demands while maintaining performance. Notably, studies addressing MILP-based neural network training remain relatively limited in the literature.

This work employs PWL approximations for the hyperbolic tangent activation function in a single-layer FNN [10-11] at the training phase. To address computational complexity, the approach by Keha et al. [5] is used to transform the MILP training problem into sequential LP problems by modifying the branching scheme, offering significant computational benefits. The novelty of this research lies in formulating the FNN training problem entirely as specially tailored LP subproblems.

## METHODOLOGY

A feed-forward, fully connected artificial neural network with an identity function as the output layer can be expressed as:

$$\hat{y} = w_2 f(w_1 u + b_1) + b_2 \quad (1)$$

where $\hat{y}$ is the predicted output, $u$ is the input, $w_1$, $w_2$, $b_1$ and $b_2$ are the weights and biases for the hidden and output layers, respectively. Typically, during training, mean squared error (MSE) is minimized. The objective function is given by:

$$\min_{w_1,w_2,b_1,b_2} MSE = \frac{1}{N}\sum_{i=1}^{N}(w_2 f(w_1 u_i + b_1) + b_2 - y_i)^2 \quad (2)$$

where $N$ is the number of training data points and $y_i$ is the actual $i^{th}$ output value. To simplify the optimization and avoid the nonlinearity introduced by the square term, the mean absolute error (MAE) can be minimized instead. The objective function then becomes:

$$\min_{w_1,w_2,b_1,b_2} MAE = \frac{1}{N}\sum_{i=1}^{N}|w_2 f(w_1 u_i + b_1) + b_2 - y_i| \quad (3)$$

However, the absolute value introduces challenges for gradient-based optimization methods due to non-smoothness and non-differentiability at certain points. To address this, a linearized form of the absolute value can be used:

$$\min_{w_1,w_2,b_1,b_2} |\emptyset'| = \frac{1}{N}\sum_{i=1}^{N}|w_2 f(w_1 u_i + b_1) + b_2 - y_i| \quad (4a)$$

$$\emptyset' \le |\emptyset'| \quad (4b)$$

$$-|\emptyset'| \le \emptyset' \quad (4c)$$

Here, $|\emptyset'|$ is the modified objective function. For simplicity, the weight matrix of the output layer, $w_2$, can be extracted during regular training as $w_2^*$ which is an extreme machine learning procedure [11-12].

Hyperbolic tangent (tanh) is a commonly used activation function in neural network training. To mitigate issues caused by its nonlinearity, several studies employ PWL approximations [9-11]. For 3-piece approximation, breakpoints can be defined as [-4,-1,+1,+4]. The 3-piece approximation of $tanh$ function can be defined as [3,10,11]:

$$tanh\,(x)_{3-piece} \approx \begin{cases} 0.08x - 0.68, & -4 \le x \le -1 \\ 0.76x, & -1 \le x \le +1 \\ 0.08x + 0.68, & +1 \le x \le +4 \end{cases} \quad (5)$$

Using a piecewise linear approximation of tanh, the training problem can be reformulated as a MILP problem:

$$\min_{w_1,w_2,b_1,b_2} |\emptyset'| = \frac{1}{N}\sum_{i=1}^{N}|w_2^* f(w_1 u_i + b_1) + b_2 - y_i| \quad (6a)$$

s.t.

$$x = w_1 u_i + b_1 \quad (6b)$$

$$p_0 \le w_1, b_1, b_2 \le p_P \quad (6c)$$

$$\Delta_k = p_k - p_{k-1} \quad (6d)$$

$$g_k = f'(p_k) - f'(p_{k-1}) \quad (6e)$$

$$\forall\, k \in \{1, \dots, P\} \quad (6f)$$

$$p_0 \le x \le p_P \quad (6g)$$

$$x = p_0 + \sum_{k=1}^{P} y_k \quad (6h)$$

$$f'(x) = f(p_0) + \sum_{k=1}^{P} \frac{g_k}{\Delta_k} y_k \quad (6i)$$

$$\lambda_0 \le z_0 \quad (6j)$$

$$\lambda_m \le z_{m-1} + z_m\,, \forall m \in \{1, \dots, P-1\} \quad (6k)$$

$$\lambda_m \le z_{m-1} \quad (6l)$$

$$\sum_{m=0}^{P-1} z_m = 1 \quad (6m)$$

$$z_m \in \{0,1\} \quad (6n)$$

where $x$ is the input to the piecewise linear function, $p_k$ denotes the $k^{th}$ breakpoint, $\Delta_k$ represents the difference between consecutive breakpoints, and $g_k$ is the difference in the function's value between these breakpoints. The parameter $P$ specifies the number of pieces in the approximation. The variables $y_k$ capture the differences used to define the input to the piecewise linear function, $\lambda_m$ are nonnegative auxiliary variables, and $z_m$ are binary variables that aid in formulating the problem as a MILP.

To simplify the problem and allow for formulation as a linear program (LP) before modifying the branching scheme, the following constraints can be used instead of (6j–6n) [13]:

$$\Delta_m s_{m+1} \le \Delta_{m+1} s_m \; \forall m \in \{1, \dots, P-1\} \quad (7a)$$

$$y_1 \le \Delta_1 \quad (7b)$$

$$y_P \geq 0 \quad (7c)$$

Finally, after obtaining the current solution $\tilde{y}$ with with $\tilde{y}_k < u_k$ and $\tilde{y}_{l+k} > 0$ for some $k \in \{1, \ldots, P-l\}$, the following branching options exist [13]:

$$Branch\ 1: y_k = \Delta_k, Branch\ 2: y_{k+1} = \cdots = y_P \quad (8)$$

Since formulations without binary variables provide the same LP bound as those that include them, maintain local ideality, and are more compact, they serve as superior models for PLFs compared to MIP models [5]. The algorithm can be summarized as follows where M denotes the number of neurons:

```
for i=1 to N do:
   for j=1 to M do:
      for k=1 to P do:
         Solve the model:
            Minimize Eq. 6a
            Subject to Eq. 6b-6i,Eq. 7a-7j
            If ỹ_k<u_k and ỹ_{l+k}>0 then
               Branch 1: y_k=△_k
               Branch 2: y_{k+1}=…=y_P
```

Implementing the SOSX algorithm in feedforward neural network training ensures reproducibility of results due to the convexity of the problem formulation. This property guarantees that the same training performance is achieved in every run, whereas regular training may converge to different solutions, potentially leading to suboptimal outcomes.

## RESULTS AND DISCUSSION
