## PREFACE

**Introduction** ..... **xxviii**
Jan Van Impe, Grégoire Léonard, Satyajeet Sheetal Bhonsale, Monika Polanska, and Filip Logist

**Peer Review Policy** ..... **xxix**

**International Scientific Committee** ..... **xxxi**

## PEER REVIEWED CONFERENCE PROCEEDINGS

### Section 1: Modelling and Simulation

**Computational Intelligence Applied to the Mathematical Modeling of the Esterification of Fatty Acids with Sugars** ..... **2**
Lorenzo G. Tonetti, Ruy de Sousa Jr.

**Numerical Analysis of the Hydrodynamics of Proximity Impellers using the SPH Method** ..... **8**
Maria Soledad Hernández-Rivera, Karen Guadalupe Medina-Elizarraraz, Jazmín Cortez-González, Rodolfo Murrieta-Dueñas, Carlos E. Alvarado-Rodríguez, José de Jesús Ramírez-Minguela, Juan Gabriel Segovia Hernández

**Surrogate Modeling of Twin-Screw Extruders Using a Recurrent Deep Embedding Network** ..... **14**
Po-Hsun Huang, David Shan-Hill Wong, Yen-Ming Chen, Chih-Yu Chen, Meng-Hsin Chen, Yuan Yao

**Dimple Shape Design to Enhance Heat Transfer in Plate Heat Exchangers** ..... **20**
Mitchell J. Stolycia, Lande Liu

**Data-Driven Modelling of Biogas Production Using Multi-Task Gaussian Processes** ..... **26**
Benaissa Dekhici, Michael Short

**Synthesis of Liquid Mixture Separation Networks Using Multi-Material Membranes** ..... **33**
Harshit Verma, Christos T. Maravelias

**Transferring Graph Neural Networks for Soft Sensor Modeling using Process Topologies** ..... **40**
M.F. Theisen, G.M.H. Meesters, A.M. Schweidtmann

**Techno – Economic Evaluation of Incineration, Gasification, and Pyrolysis of Refuse Derived Fuel** ..... **46**
Matej Koritár, Maroš Križan, Juma Haydary

**Dynamic Operability Analysis of modular heterogeneous electrolyzer plants using system co-simulation** ..... **53**
Michael Große, Isabell Viedt, Hannes Lange, Leon Urbas

**High-pressure Membrane Reactor for Ammonia Decomposition: Modeling, Simulation and Scale-up using a Python-Aspen Custom Modeler Interface.** ..... **60**
Leonardo A. C. Avilez, Antonio E. Bresciani, Claudio A. O. Nascimento, Rita M. B. Alves

**A 2D Axisymmetric Transient State CFD Modelling of a Fixed-bed Reactor for Ammonia Synthesis** ..... **67**
Leonardo Bravo, Camilo Rengifo, Martha Cobo, Manuel Figueredo

**Kernel-based estimation of wind farm power probability density considering wind speed and wake effects due to wind direction** ..... **73**
Samuel Martínez-Gutiérrez, Daniel Sarabia, Alejandro Merino

**Thermo-Hydraulic Performance of Pillow-Plate Heat Exchangers with Streamlined Secondary Structures: A Numerical Analysis** ..... **79**
Reza Afsahnoudeh, Julia Riese, Eugeny Y. Kenig

**Optimisation of Biomass-Energy-Water-Food Nexus under Uncertainty** ..... **86**
Md Shamsul Alam, I. David L. Bogle, Vivek Dua

**A Century of Data: Thermodynamics and Kinetics for Ammonia Synthesis on Various Commercial Iron-based Catalysts** ..... **92**
Hilbert Keestra, Yordi Slotboom, Kevin H.R. Rouwenhorst, Derk W.F. Brilman

**Reaction Pathway Optimization Using Reinforcement Learning in Steam Methane Reforming and Associated Parallel Reactions** ..... **98**
Martín Rodríguez-Fragoso, Octavio Elizalde-Solis, Edgar Ramírez-Jiménez

**Integration of Yield Gradient Information in Numerical Modeling of the Fluid Catalytic Cracking Process** ..... **104**
Wenle Xu, Baohua Chen, Tong Qiu

**Hybrid Modelling for Reaction Network Simulation in Syngas Methanol Production** ..... **111**
Harry Kay, Fernando Vega-Ramon, Dongda Zhang

**Data-Driven Chance-Constrained Mixed Integer Nonlinear Bi-level Optimisation Via Copulas: Application To Integrated Planning And Scheduling Problems** ..... **117**
Syu-Ning Johnn, Hasan Nikkhah, Meng-Lin Tsai, Styliani Avraamidou, Burcu Beykal, Vassilis M. Charitopoulos

**Diagnosing Faults in Wastewater Systems: A Data-Driven Approach to Handle Imbalanced Big Data** ..... **123**
M. Zadkarami, K.V. Gernaey, A.A. Safavi, P. Ramin

**Modelling of a Heat Recovery System (HRS) Integrated with Steam Turbine Combined Heat and Power (CHP) Unit in a Petrochemical Plant** ..... **129**
Daniel Sousa, Miguel Castro Oliveira, Maria Cristina Fernandes

**Integrating Thermodynamic Simulation and Surrogate Modeling to Find Optimal Drive Cycle Strategies for Hydrogen-Powered Trucks** ..... **135**
Laura Stops, Alexander Stary, Johannes Hamacher, Daniel Siebe, Thomas Funke, Sebastian Rehfeldt, Harald Klein

**Wind Turbines Power Coefficient Estimation Using Manufacturer's Information and Real Data** ..... **141**
Carlos Gutiérrez Ortega, Daniel Sarabia Ortiz, Alejandro Merino Gómez

**Leveraging Pilot-Scale Data for Real-Time Analysis of Ion Exchange Chromatography** ..... **147**
Søren Villumsen, Jesper Frandsen, Jakob Kjøbsted Huusom, Xiaodong Liang, Jens Abildskov

**Model Based Flowsheet Studies on Cement Clinker Production Processes** ..... **153**
George Melitos, Bart de Groot, Fabrizio Bezzo

**Techno-economic analysis of a novel small-scale blue H2 and N2 production system** ..... **159**
Adrian R. Irhamna, George M. Bollas

**A Comparative Evaluation of Complexity in Mechanistic and Surrogate Modeling Approaches for Digital Twins** ..... **166**
Shreyas Parbat, Isabell Viedt, Leon Urbas

**Co-gasification of Crude Glycerol and Plastic Waste using Air/Steam Mixtures: A Modelling Approach ..... 173**
Bahizire Martin Mukeru, Bilal Patel

**Automated Identification of Kinetic Models for Nucleophilic Aromatic Substitution Reaction via DoE-SINDy .... 179**
Wenyao Lyu, Federico Galvanin

**System analysis and optimization of replacing surplus refinery fuel gas by coprocessing with HTL bio-crude off-gas in oil refineries. ..... 186**
Erik Lopez-Basto, Eliana Lozano Sanchez, Samantha Eleanor Tanzer, Andrea Ramirez Ramirez

**Surrogate Model-Based Optimization of Pressure-Swing Distillation Sequences with Variable Feed Composition ..... 192**
Laszlo Hegely, Peter Lang

**Economic Evaluation of Solvay Processes for Sodium Bicarbonate Production with Brine and Carbon Tax considerations ..... 198**
Dina Ewis, Zeyad M. Ghazi, Sabla Y. Alnouri, Muftah H. El-Naas

**Application of K-means for Identification of Multiphase Flows Based on Computational Fluid Dynamics ..... 203**
Patrick S. Lima, Leonardo S. Souza, Leizer Schnitman, Idelfonso B. R. Nogueira

**A New Method to Assess Performance Loss due to Catalyst Deactivation in Fixed- and Fluidized-bed Reactors ..... 209**
M. Andrea Pappagallo, Tilman J. Schildhauer, Oliver Kröcher, Emanuele Moioli

**Enhancing hydrodynamics simulations in Distillation Columns Using Smoothed Particle Hydrodynamics (SPH) ..... 216**
Rodolfo Murrieta-Dueñas, Jazmín Cortez-González, Roberto Gutiérrez-Guerra, Juan Gabriel Segovia Hernández, Carlos E. Alvarado-Rodríguez

**Kinetic Modelling and Optimisation of Co2 Capture and Utilisation to Methane on Dual Function Material..... 222**
Meshkat Dolat, Andrew D. Wright, Mohammadamin Zarei, Melis S. Duyar, Michael Short

**Data-Driven Dynamic Process Modeling Using Temporal RNN Incorporating Output Variable Autocorrelation and Stacked Autoencoder..... 229**
Yujie Hu, Lingyu Zhu, Han Gong, Xi Chen

**Real-time carbon accounting and forecasting for reduced emissions in grid-connected processes..... 235**
Rafael Castro-Amoedo, Alessio Santecchia, Henrique A. Matos, François Maréchal

**Twin Roll Press Washer Blockage Prediction: A Pulp and Paper Plant Case Study ..... 241**
Bryan Li, Isaac Severinsen, Wei Yu, Timothy Walmsley, Brent Young

**A Novel Bayesian Framework for Inverse Problems in Precision Agriculture ..... 246**
Zeyuan Song, Zheyu Jiang

**Role of process integration and green technologies utilization for the decarbonization of the watchmaking sector. ..... 252**
Pullah Bhatnagar, Daniel Florez-Orrego, Vibhu Baibhav, Manuele Margni, Francois Marechal

**Liquid Organic Hydrogen Carriers: comparing alternatives through H2 equivalent analysis ..... 258**
Elvira Spatolisano, Federica Restelli, Laura A. Pellegrini

**Towards the Decarbonization of a Conventional Ammonia Plant by the Gradual Incorporation of Green Hydrogen..... 264**
João Fortunato, Pedro M. Castro, Diogo A. C. Narciso, Henrique A. Matos

**Simulation and Experimental Validation of Biomass Gasification in a Spouted Bed Reactor: Troubleshooting Using DWSIM ..... 271**
C. Moliner, V. Carozzo, M. Curti, E. Arato

**Identification of Suitable Operational Conditions and Dimensions for Supersonic Water Separation in Exhaust Gases from Offshore Turbines: A Case Study ..... 276**
Jonatas de O. S. Cavalcante, Marcelo da C. Amaral, Ewerton E. da S. Calixto, Fernando L. P. Pessoa

**On Optimal Hydrogen Pathway Selection Using the SECA Multi-Criteria Decision-Making Method ..... 282**
Caroline Kaitano, Thokozani Majozi

**Energy Integration of an Intensified Biorefinery Scheme from Waste Cooking Oil to Produce Sustainable Aviation Fuel ..... 288**
Ma. Teresa Carrasco-Suárez, Araceli Guadalupe Romero-Izquierdo

**A Computational Framework for Cyclic Steady-State Simulation of Dynamic Catalysis Systems: Application to Ammonia Synthesis..... 294**
Carolina Colombo Tedesco, John R. Kitchin, Carl D. Laird

**Comparative Analysis of Conventional and Novel Low-Temperature and Hybrid Technologies for Carbon Dioxide Removal from Natural Gas ..... 301**
Federica Restelli, Giorgia De Guido

**Development of a virtual CFD model for regulating temperature in a liquid tank ..... 307**
Jinxin Wang, Feng Xu, Yuka Sakai, Hisashi Takahashi, Ruizi Zhang, Hiroaki Kanayama, Daisuke Satou, Yasuki Kansha

**Accelerated Process Modelling for Light-Mediated Controlled Radical Polymerization ..... 313**
Rui Liu, Xi Chen, Antonios Armaou

**Plantwide Control of a Green Formic Acid Production Process..... 320**
Mohammad Mahdi Ghasemi Aliabadi, Alexandros Anagnostou, Francia Gallardo Gonzalez, Shivam Pandey, Farzad Mousazadeh, Anton Kiss

**Energy Water Nexus Resilience Analysis Using Integrated Resource Allocation Approach ..... 327**
Hesan Elfaki, Mohammad Lameh, Dhabia M. Al-Mohannadi

**Technoeconomic Analysis of a Novel Amine-Free Direct Air Capture System Integrated with HVAC ..... 333**
Yasser M. Abdullatif, Ikhlas Ghiat, Riham Surkatti, Yusuf Bicer, Tareq Al-Ansarl, Abdulkarem I. Amhamed

**Exploiting Operator Training Systems in chemical plants: learnings from industrial practice at BASF ..... 339**
Frederic Cuypers, Tom Boelen, Filip Logist

**Comparative Assessment of Aspen Plus Modeling Strategies for Biomass Steam Co-gasification..... 346**
Usman Khan Jadoon, Ismael Díaz, Manuel Rodríguez

**Enhancing the Technical and Economic Performance of Proton Exchange Membrane Fuel Cells Through Three Critical Advancements ..... 352**
Željko Penga, Jure Penga, Yuanjing Zhao, Lei Xing

**Cell culture process dynamics and metabolic flux distributions using hybrid models ..... 358**
Rajiv Kailasanathan, Abhishek Sivaram, Seyed Soheil Mansouri

**Development and Integration of a Co-Current Hollow Fiber Membrane Unit for Gas Separation in Process Simulators Using CAPE-OPEN Standards ..... 364**
Loretta Salano, Ilaria Dagna, Mattia Vallerio, Flavio Manenti

**A Comparative Study of Aspen Plus and Machine Learning Models for Syngas Prediction in Biomass-Plastic Waste Co-gasification** ..... **370**
Usman Khan Jadoon, Ismael Díaz, Manuel Rodríguez

**Multiscale Modeling of Internal Reforming in Solid Oxide Fuel Cells: A Study of Electrode Morphology and Gradient Microstructures** ..... **376**
Hamid Reza Abbasi, Masoud Babaei, Constantinos Theodoropoulos

**Process simulation and thermodynamic analysis of newly synthesized pre-combustion $CO_2$ capture system using novel Ionic liquids for $H_2$ production** ..... **382**
Sadah Mohammed, Fadwa Eljack

**Mechanistic and Data-Driven Models for Predicting Biogas Production in Anaerobic Digestion Processes** ..... **388**
Rohit Murali, Benaissa Dekhici, Tao Chen, Dongda Zhang, Michael Short

**Dynamic analysis for prediction of flow patterns in an oscillatory baffled reactor using machine learning** ..... **394**
Hideyuki Matsumoto, Yuma Kambayashi, Shiro Yoshikawa, Shinichi Ookawara

**Comparative Analysis of PharmHGT, GCN, and GAT Models for Predicting LogCMC in Surfactants.** ..... **399**
Gabriela C. Theis Marchan, Teslim Olayiwola, Jose Romagnoli

**Short-Cut Correlations for CO2 Capture Technologies in Small-Scale Applications** ..... **406**
So-mang Kim, Joanne Kalbusch, Grégoire Léonard

**Numerical Modelling of Carbon Dioxide Adsorption in Dual Function Materials: An CFD approach** ..... **412**
Andrés F. Soto-Cañón, Rodinson R. Arrieta-Peréz, Camilo Rengifo, Martha Cobo, Manuel Figueredo

**Design Considerations for Hardware Based Acceleration of Molecular Dynamics** ..... **418**
Joseph Middleton, Joan Cordiner

**An Automated $CO_2$ Capture Pilot Plant at ULiège: A Platform for the Validation of Process Models and Advanced Control** ..... **423**
Cristhian Molina-Fernández, Patrick Kreit, Brieuc Beguin, Sofiane Bekhti, Cédric Calberg, Joanne Kalbusch, Grégoire Léonard

**New Directions and Software Tools Within the Process Systems Engineering Ecosystem** ..... **430**
S. Burroughs, B. Lincoln, A. Adeel, I. Severinsen, A. Lee, O. Amusat, D. Gunter, B. Nicholson, M. Apperley, B. Young, J. Siirola, T. G. Walmsle

## Section 2: Sustainable Product Development and Process Design

**Steady-State Digital Twin Development for Heat and Shaft-Work Integration in a Dual-Stage Pressure Nitric Acid Plant Retrofit** ..... **438**
Stanislav Boldyryev, Goran Krajacic

**Simulation of Decarbonization of Natural Gas to Methanol Conversion Process Using Microwave-Assisted Dry Reforming with Integrated Chemical Looping for Hydrogen Production** ..... **444**
Omar Almaraz, Srinivas Palanki, Jianli Hu

**Modeling and Simulation of a Novel Process that Converts Low Density Polyethylene to Ethylene** ..... **450**
Xiaoyan Wang, Omar Almaraz, Jianli Hu, Srinivas Palanki

**A global sensitivity analysis for a bipolar membrane electrodialysis capturing carbon dioxide from the air** ..... **456**
Grazia Leonzio, Alexia Thill, Nilay Shah

**Intensified Alternative for Sustainable Gamma-Valerolactone Production from Levulinic Acid ..... 462**
Brenda Huerta-Rosas, Melanie Coronel-Muñoz, Juan José Quiroz-Ramírez, Carlos Rodrigo Caceres-Barrera, Gabriel Contreras-Zarazua, Juan Gabriel Segovia-Hernández, Eduardo Sánchez-Ramírez

**Environmental assessment of the catalytic arabinose oxidation ..... 468**
Mouad Hachhach, Dmitry Yu. Murzin, Tapio Salmi

**Green Industrial-Scale Plant Design for Syngas Fermentation to Isopropyl Alcohol and Acetone: Economic and Environmental Sustainability Assessment..... 473**
Gijs J.A. Brouwer, Tamara Jankovic, Adrie J.J. Straathof, Anton A. Kiss, John A. Posada

**Energy Efficient Process Designs for Acrylonitrile Production by Propylene Ammoxidation..... 479**
Qing Li, Alexandre C. Dimian, Anton A. Kiss

**Optimizing the Selection of Solvents for the Dissolution and Precipitation of Polyethylene..... 485**
Riccardo Standish, Jian Yin, Mirjana Minceva, Jakob Burger, Amparo Galindo, George Jackson, Claire S. Adjiman

**Sustainable Downstream Process Design for HMF Conversion to Value-Added Chemicals.....491**
Norbert B. Mihály, Miruna Prodan, Vasile M. Cristea, Anton A. Kiss

**Solar Desalination and Porphyrin Mediated Visible-Light Photocatalysis in Decolouration of Dyes as Biological Analogues Applied in Advanced Water Treatment ..... 497**
Evans M. N. Chirwa, Bezza F. Andualem, Osemeikhain Ogbeifun, Shepherd M. Tichapondwa, Wesley Lawrence, Bonhle Manoto

**Technical Assessment of direct air capture using piperazine in an advanced solvent-based absorption process..... 503**
Shengyuan Huang, Olajide Otitoju, Yao Zhang, Meihong Wang

**Valorization of refinery fuel gas and biogenic gases from thermochemical conversion into low-carbon methanol ..... 509**
Eliana Lozano Sanchez, Erik Lopez-Basto, Andrea Ramirez Ramirez

**System scale design and mesoscale modeling for natural gas dehydration process .....515**
Zhehao Jin, Zhongde Dai, Yiyang Dai

**Digital Twin supported Model-based Design of Experiments and Quality by Design.....521**
Amy Koch, Jessica Ebert, Isabell Viedt, Andreas Bamberg, Leon Urbas

**Sustainable Development Goals Assessment of Alternative Acetic Acid Synthesis Routes..... 528**
Juan D. Medrano-García, Sachin Jog, Abhinandan Nabera, Gonzalo Guillén-Gosálbez

**Synergies Between the Distillation of First- and Second-Generation Sugarcane Ethanol for Sustainable Biofuel Production ..... 534**
Luiz M. Costa, Abhay Athaley, Zach Losordo, Adriano P. Mariano, John Posada, Lee R. Lynd

**Superstructure as a Communication Tool in Pre-Emptive Life Cycle Design Engaging Society: Findings from Case Studies on Battery Chemicals, Plastics, and Regional Resources..... 540**
Yasunori Kikuchi, Ayumi Yamaki, Aya Heiho, Jun Nakatani, Shoma Fujii, Ichiro Daigo, Chiharu Tokoro, Shinsuke Murakami, Satoshi Ohara

**Integration of renewable energy and reversible solid oxide cells to decarbonize secondary aluminium production and urban systems ..... 546**
Daniel Flórez-Orrego, Dareen Dardor, Meire Ellen Ribeiro Domingos, Reginald Germanier, Francois Marechal

**Assessing the economic viability of green methanol production: The critical role of CO2 purity in green methanol production ..... 553**
Franc González-Cazorla, Jordi Pujol, Oriol Martínez, Lluis Soler, Moisès Graells

**Gate-to-Gate Life Cycle Assessment of CO2 Utilisation in Enhanced Oil Recovery: Sustainability and Environmental Impacts in Dukhan Field, Qatar ..... 559**
Razan Sawaly, Ahmad S. Abushaikha, Tareq Al-Ansari

**Sustainable Two-Column Design for the Separation of Ethyl Acetate, Methanol, and Water ..... 565**
Prakhar Srivastava, Nitin Kaistha

**Robust Flowsheet Synthesis for Ethyl Acetate, Methanol and Water Separation ..... 571**
Aayush Gupta, Kartavya Maurya, Nitin Kaistha

**Environmental Impacts of Trichlorosilane: Process Optimization, Life Cycle Assessment, and the Importance of Processing History ..... 577**
Ethan Errington, Deniz Etit, Tom Vinestock, Jaewook Lee, Jerry Heng, Miao Guo

**Sodium bicarbonate production from CO2 captured in Waste-to-Energy plants: an Italian case-study..... 583**
Elvira Spatolisano, Giorgia De Guido, Laura A. Pellegrini, Elena Riva Redolfi, Mauro Corradi, Davide Alberti, Adriano Carrara

**Modelling of the Co-precipitation of Ni-Mn-Co Hydroxides. ..... 589**
Erik G. Resendiz-Mora, Solomon F. Brown

**A System-Dynamics Based Approach for Modeling Circular Economy Networks: Application to the Polyethylene Terephthalate (PET) Supply Chain..... 595**
Daniel Pert, Ana Inés Torres

**Sustainable production of L-lactic acid from lignocellulosic biomass using an alternative buffer system: Process development and techno-economic and environmental analysis.....601**
Donggeun Kang, Donghyeon Kim, Dongin Jung, Siuk Roh, Jiyong Kim

**Potential of chemical looping for green hydrogen production from biogas: process design and techno-economic-environmental analysis ..... 607**
Donghyeon Kim, Minseong Park, Donggeun Kang, Dongin Jung, Siuk Roh, Jiyong Kim

**Decarbonized Hydrogen Production: Integrating Renewable Energy into Electrified SMR Process with $CO_2$ Capture .....613**
Joohwa Lee, Haryn Park, Bogdan Dorneanu, Jin-Kuk Kim, Arellano-Garcia Harvey

**Assessing the Synergies of Thermochemical Energy Storage with Concentrated Solar Power and Carbon Capture .....619**
Nitin Dhanenjey R, Ishan Bajaj

**Modelling of Wood Biomass Gasification for Process Optimization..... 625**
Yu Hui Kok, Yasuki Kansha

**Optimal Design and Analysis of Thermochemical Storage and Release of Hydrogen via the Reversible Redox of Iron Oxide/Iron.....631**
Richard Yentumi, Constantin Jurischka, Bogdan Dorneanu, Harvey Arellano-Garcia

**Robust pharmaceutical tableting process through combined probabilistic design space and flexibility analysis ..... 637**
Ashish Yewale, Xuming Yuan, Brahim Benyahia

**Separation Sequencing in Batch Distillation: An Extension of Marginal Vapor Rate Method..... 644**
Prachi Sharma, Sujit S. Jogwar

**Steel Plant Electrification: A Pathway to Sustainable Production and Carbon Reduction .....651**
Rachid Klaimi, Sabla Y. Alnouri, Vladimir Stijepovic, Aleksa Miladinovic, Mirko Stijepovic

**Conceptual design of energy storage systems for continuous operations in renewable-powered chemical processes** ..... **656**
Andrea Isella, Alfonso Pascarella, Angelo Matichecchia, Raffaele Ostuni, Davide Manca

**Olefins production through sustainable pathways: techno-economic and environmental assessment** ..... **662**
Oktay Boztas, Meire E. G. R. Domingos, Daniel A. Flórez-Orrego, François Maréchal

**Integrating Chemical Recycling into Brownfield Processes: Waste Polyethylene Pyrolysis and Naphtha Steam Cracking** ..... **668**
Marc Caballero, Thanyanart Sroisamut, Anton A. Kiss, Ana Somoza-Tornos

**Integrated LCA and Eco-design Process for Hydrogen Technologies: Case Study of the Solid Oxide Electrolyser** ..... **674**
Gabriel Magnaval, Tristan Debonnet, Manuele Margni

**Assessing Distillation Processes through Sustainability Indicators Aligned with the Sustainable Development Goals** ..... **681**
Ömer Faruk Karaman, Peter Lang, Laszlo Hegely

**Integrating Direct Air Capture and HVAC Systems: An Economic Perspective on Cost Savings** ..... **687**
Ikhlas Ghiat, Yasser M. Abdullatif, Yusuf Bicer, Abdulkarem I. Amhamed, Tareq Al-Ansari

**Insights on $CO_2$ Utilization through Reverse Water Gas Shift Reaction in Membrane Reactors: A Multi-scale Mathematical Modeling Approach** ..... **692**
Zhaofeng Li, Anan Uziri, Zahir Aghayev, Burcu Beykal, Michael Patrascu

**Optimized integration strategies for the PMR-based $H_2$ production with $CO_2$ capture process** ..... **698**
Donghoi Kim, Zhongxuan Liu, Rahul Anantharaman, Thijs A. Peters, Truls Gundersen

**Design and Cost Analysis of a Reactive Distillation Column to Produce Ethyl Levulinate Using Excess Levulinic Acid** ..... **704**
Igor F. Fioravante, Riann de Q. Nóbrega, Rubens Maciel Filho, Jean F. Leal Silva

## Section 3: Large Scale Design and Planning/Scheduling

**Analysis for CFD of the Claus Reaction Furnace with Operating Conditions: Temperature and Excess Air for Sulfur Recovery** ..... **711**
Pablo Vizguerra Morales, Miguel Ángel Morales Cabrera, Fabian S. Mederos Nieto

**A Transparent Techno-Enviro-Economic Assessment of a Coal-Fired Power Plant: Integrating Biomass Co-Firing and $CO_2$ Sequestration Technology in a Carbon-Priced Environment** ..... **717**
N. F. E. Nor Fadzil, N. Abdul Manaf, N. Shah

**Genetic Algorithm-Driven Design of CCUS and Hydrogen Pipeline Networks: Decentralised Expansion with Complex Geographical Constraints** ..... **723**
Joseph Hammond, Solomon Brown

**A Forest Biomass-to-Hydrogen Supply Chain Mathematical Model for Optimizing Carbon Emissions and Economic Metrics** ..... **729**
Frank Piedra-Jimenez, Rishabh Mehta, Valeria Larnaudie, Maria Analia Rodriguez, Ana Inés Torres

**A Novel Detailed Representation of Batch Processes for Production Scheduling** ..... **735**
Alexandros Koulouris, Georgios P. Georgiadis

**Enhancing Large-Scale Production Scheduling Using Machine-Learning Techniques** ..... **741**
Maria E. Samouilidou, Nikolaos Passalis, Georgios P. Georgiadis, Michael C. Georgiadis

**Multiscale analysis through the use of biomass residues and $CO_2$ towards energetic security at country scale via methane production** ..... **747**
Guillermo Galán, Manuel Taifouris, Mariano Martín, Ignacio E. Grossmann

**Integrating Time-Varying Environmental Indicators into an Energy Systems Modeling and Optimization Framework for Enhanced Sustainability** ..... **753**
Marco P. De Sousa, Rahul Kakodkar, Betsie M. Flores, Saatvi Suresh, Harsh B. Shah, Dustin Kenefake, Iosif Pappas, Xiao Fu, Doga C. Demirhan, Brianna Ruggiero, Mete Mutlu, Efstratios N. Pistikopoulos

**Modular and Heterogeneous Electrolysis Systems: a System Flexibility Comparison** ..... **759**
Hannes Lange, Michael Große, Isabell Viedt, Leon Urbas

**Methods for Efficient Solutions of Spatially Explicit Biofuels Supply Chain Models** ..... **765**
Phuc M. Tran, Eric G. O'Neill, Christos T. Maravelias

**Integrating Carbon Value Vectors in the Energy and Materials Transition Nexus: A Case Study on Mobility Optimization** ..... **771**
Betsie S. M. Montano Flores, Rahul Kakodkar, Marco P. De Sousa, Shayan S. Niknezhad, Efstratios N. Pistikopoulos

**Assessing Operational Resilience Within the Natural Gas Monetisation Network for Enhanced Production Risk Management: Qatar as a Case Study** ..... **778**
Noor Yusuf, Ahmed AlNouss, Roberto Baldacci, Tareq Al-Ansari

**Minimization of Hydrogen Consumption via Optimization of Power Allocation Between the Stacks of a Dual-Stack Fuel Cell System** ..... **785**
Beril Tümer, Deniz Sanli Yildiz, Yaman Arkun

**A Novel Global Sequence-based Mathematical Formulation for Energy-efficient Flexible Job Shop Scheduling Problem** ..... **791**
D. Li, T.C. Zheng, J. Li

**Materials-Related Challenges of Energy Transition** ..... **798**
Fatemeh Rostami, Piera Patrizio, Laureano Jimenez, Carlos Pozo, Niall Mac Dowell

**A Modern Portfolio Theory Approach for Chemical Production with Supply Chain Considerations for Efficient Investment Planning** ..... **805**
Mohamad Almoussaoui, Dhabia M. Al-Mohannadi

**Optimization models and algorithms for the Unit Commitment problem** ..... **812**
Javal Vyas, Carl Laird, Ignacio E. Grossmann, Ricardo M. Lima, Iiro Harjunkoski, Jan Poland

**Development of a hybrid, semi-parametric Simulation Model of an AEM Electrolysis Stack Unit for large-scale System Simulations** ..... **818**
Isabell Viedt, Michel Große (né Mock), Leon Urbas

**Energy system modelling for studying flexibility on industrial sites** ..... **824**
Jon Vegard Venås, Lucas Ferreira Bernardino, Kasper Emil Thorvaldsen, Sigrid Aunsmo, Sigmund Eggen Holm, Halvor Aarnes Krog, Ove Wolfgang, Ingeborg Treu Røe

**An MIQCP Reformulation for the Optimal Synthesis of Thermally Coupled Distillation Networks** ..... **831**
Kevin Pfau, Arsh Bhatia, Carl D. Laird, George Ostace, Goutham Kotamreddy

**Multi-objective Optimization of Steam Cracking Microgrid for Clean Olefins Production** ..... **837**
Saba Ghasemi Naraghi, Tylee Kareck, Zheyu Jiang

**Pareto optimal solutions for decarbonization of oil refineries under different electricity grid decarbonization scenarios** ..... **844**

# Introduction

**Jan Van Impe, Grégoire Léonard, Satyajeet Sheetal Bhonsale, Monika Polanska, and Filip Logist (eds)**

The 35th European Symposium on Computer Aided Process Engineering (ESCAPE|35) was held at KU Leu-ven/Campus Gent, Belgium, July 6–9, 2025. Continuing a tradition that began in 1991 under the auspices of the EFCE Working Party on Computer Aided Process Engineering CAPE), the ESCAPE series stands as a premier annual event for the global Process Systems Engineering (PSE) community. ESCAPE returned to Belgium for the second time - following the 1998 edition in Bruges - and took place as part of KU Leuven's 600th anniversary celebrations. The 35th edition was organised jointly by KU Leuven/BioTeC+ and University of Liège/PEP.

The 2025 conference embraced the theme "Closing the Loop 2.0", underscoring the evolving role of PSE in ena-bling a circular economy. The program highlighted both core process engineering disciplines – such as modeling, con-trol, design, and optimization - and cutting-edge approaches involving artificial intelligence, machine learning, and quantum computing, applied across diverse sectors including energy, chemicals, biotechnology, and advanced mate-rials.

ESCAPE|35 received 673 abstract submissions, of which 563 were invited for a 5-to-8-page full paper or a 2- page short paper after a first review round. Upon rigorous re-review of all papers submitted, 423 full paper contribu-tions have been published in full open access (and LAPSE and DOI indexed) by PSE Press as a separate volume of the *Systems & Control Transactions* series. Another 140 contributions have been made available as two pages short pa-pers published by EUROSIS-ETI.

The scientific contributions were organized into thematic sessions, poster presentations, workshops, and demon-strations, within ten thematic tracks:

- T01: Modelling and Simulation
- T02: Sustainable Product Development and Process Design
- T03: Large Scale Design and Planning/Scheduling
- T04: Model-Based Optimisation and Advanced Control
- T05: Concepts, Methods and Tools
- T06: Digitalization and AI
- T07: CAPEing with Societal Challenges (Green Deal, Energy Transition, …)
- T08: CAPE Education and Knowledge Transfer
- T09: PSE4Food and Biochemical (*new in 2025*)
- T10: PSE4BioMedical and (Bio)Pharma (*new in 2025*)

Tracks T09 and T10 were introduced in this year's edition to broaden the application scope of PSE methods in food, biochemical, (bio)pharma and biomedical systems - fields of increasing relevance to the community.

We extend our sincere thanks to all authors, reviewers, topic coordinators, plenary and keynote speakers, and members of the Scientific and Organizing Committees. We gratefully acknowledge KU Leuven and University of Liège for their support and express our heartfelt appreciation to our numerous sponsors. This edition also marks the inaugural collaboration with PSE Press as the official publisher of the ESCAPE proceedings (full papers volume) - a milestone in promoting high-quality, open access dissemination of PSE research. Many thanks to EUROSIS-ETI as well for publish-ing the short papers volume, ISBN indexed.

We hope these volumes capture the scientific excellence, collaborative spirit, and forward-looking vision that defined ESCAPE|35 and continue to serve as a valuable reference for researchers and practitioners in the years ahead.

**ESCAPE|35 - European Symposium on Computer Aided Process Engineering**
Ghent, Belgium. 6-9 July 2025

# Peer Review Policy

## TERMINOLOGY

- **Conference Paper:** This is a peer-reviewed research paper describing an **original** research contribution and published in the conference proceedings.

## APPLICATION

- All conference papers are subject to peer review.

## PUBLICATIONS

- All conference papers which have passed peer review and have been accepted by the conference chairs will be published in the conference proceedings.

## PEER REVIEW PROCESS

### Initial Screening

The conference chairs will screen the initial submissions (one-page abstracts) of contributed papers. At their option, chairs may choose to reject these submissions for any reason, but the primary reasons for rejection at this stage are (a) subject does not match conference themes and topics; (b) in appropriate, unprofessional, unethical, or dishonest material; (c) duplicate submissions; (d) abandoned submissions; (e) multiple submissions from same presenter; (f) obvious poor quality; (g) reasonable suspicion of machine-generated text; (h) need to limit acceptances because of conference space constraints. Chairs may also transfer papers between sessions at this stage.

Conference chairs will then invite authors of the one-page abstracts that have passed the initial screening to submit a conference paper for peer review.

### Conference Paper Peer Review

Conference chairs act as editors. They will assign peer reviewers to assess the quality of the conference papers and manage the peer review process for each paper. Peer reviewers are generally selected from the International Scientific Committee who are scientists, engineers, or researchers with technical expertise in the conference topic. Peer reviewers must be considered technical experts in their field, hold a PhD, and have published peer reviewed scientific works previously. Each work must be reviewed by a minimum of two peer-reviewers.

A “single-blind” peer review system is used, in which the peer reviewers have access to the identities of the authors, but the authors are never given the identities of the peer reviewers. This is consistent with most journal peer-review procedures in our field.

Peer reviewers will be given a set of quality criteria that may include scientific and technical quality, quality of writing, originality and novelty, appropriateness for the conference topic and theme, interest to the community, and other factors of merit. Peer reviewers are expected to be rigorous and critical in their technical assessments and adhere to the highest standards in the field in order to ensure high quality. Peer reviewers are asked to comment on their assigned conference papers and issue a recommendation to the conference chairs based on this quality criteria. Reviewers may recommend one of the following:

- **Accept Paper.** No technical changes are necessary before publication. Only typographical, spelling, grammar, or other minor changes are necessary which do not require technical review.
- **Accept Paper with Minor Revisions.** Some minor technical issues need to be addressed either through technical changes to the manuscript or through rebuttal to reviewer comments. The reviewer does not believe the issues are significant enough to require additional technical review by the reviewers. The reviewer has provided enough commentary such that the editor can decide if the minor issues have been addressed in a future revision.
- **Revise Paper with Re-Review.** Major technical issues need to be addressed either through technical changes

to the manuscript or through rebuttal to reviewer comments. The reviewer believes the issues are significant enough to require that the revised manuscript receive additional review by the reviewers.

- **Reject Without Reconsideration.** The technical issues are so significant that it is unlikely that an acceptable manuscript could be produced by the deadline; or, the manuscript is out of scope, inappropriate, or computer-generated.

Peer reviewers may be asked to provide numerical scores or rankings, as well as provide written comments intended for the chairs and/or the authors. Peer reviewers are encouraged to provide specific and constructive feedback that will aid the authors in improving the work and provide advice to the chairs.

The conference chairs are responsible for making the final decision on each paper and may require several rounds of author changes if necessary to meet quality standards. Conference chairs are not required to follow the recommendations of the peer reviewers in making these decisions. It is possible that conference chairs will choose to not accept some papers that still pass through rigorous technical peer review, especially when limited by available space or when papers do not sufficiently promote conference objectives. Conference chairs may also transfer papers between sessions as desired.

## CONFLICTS OF INTEREST AND ETHICAL GUIDELINES

The chairs and peer reviewers must ensure they do not have a conflict of interest that may bias their decisions, such as ensuring that authors are at “arm’s length” and have no financial conflicts of interest. Peer reviewers and chairs must disclose if they have such a conflict of interest with a specific submission, and if so, a different chair and/or peer reviewer should be assigned to handle that submission.

To help determine conflicts of interest, and for all other ethical guidelines, we use the Systems and Control Transactions ethical guidelines described at: https://psecommunity.org/contributor-guidelines

## ABSTRACT

The mathematical modeling of enzymatic reactors for esterification of fatty acids with sugars in the production of biosurfactants has been a useful tool for studying and optimizing the process. In particular, artificial neural networks and fuzzy systems emerge as promising methods for developing models for those processes. In this work, regarding artificial neural networks application, coupling of networks to reactor mass balances was considered in hybrid models to infer reactant concentrations over time. Computationally, an algorithm was constructed incorporating material balances, neural reaction rates, and step-by-step numerical integration (employing the classical Runge-Kutta method). Besides, based on an available set of experimental data, fuzzy logic was applied for modeling and optimization of the conversion of esterification as a function of operational process parameters (such as time, temperature and molar ratio of substrates). All computational development was carried out using the Matlab software. The neural networks were able to predict the kinetic behavior of xylose esterification process by applying them to reactor mass balances, obtaining $R^2$ values above 0.94, indicating a good predictive capacity. The trained fuzzy models were able to simulate the relationships between input variables and the output variable, enabling the construction of surfaces and estimating the optimal operational condition at 60 h of reaction, 55°C, molar ratio of substrates of 5:1 and enzyme loading of 37.5 U/g. The same condition was obtained when applying the particle swarm optimization algorithm. Thus, this work presented a complete tool based on computational intelligence for modeling, simulation, and optimization of biosurfactant synthesis.

**Keywords**: Biosurfactants, Artificial neural networks, Fuzzy modeling.

## INTRODUCTION

Given the need for more sustainable alternatives to products available in the market, biosurfactants emerge as a promising option to synthetic surfactants [1]. Like as to synthetic surfactants, biosurfactants can form micelles and reduce surface and interfacial tensions, making them suitable for commercial applications [2]. Biosurfactants stand out to synthetic surfactants due to their biodegradability, low toxicity, use of substrates from renewable sources and waste from various production processes, which can reduce manufacturing costs, making them more attractive to industries [3,4]. Furthermore, biosurfactants are more efficient as they further reduce surface tension compared to chemical surfactants, requiring a lower concentration for maximum surface tension reduction, in a way that can be used in commercial products of the food, beverage, and cosmetics industries [5,6].

The esterification of fatty acids with carbohydrates has a significant commercial interest [7], because it yields sugar fatty acid esters, which find extensive applications in the food, pharmaceutical, cosmetic, and petrochemical industries [8]. This reaction can be carried out through either chemical or enzymatic routes, with the chemical route requiring high temperatures and an alkaline catalyst, potentially leading to the formation of toxic by-products [9]. In contrast, the enzymatic route offers mild reaction conditions, along with high selectivity, low toxicity, and high product quality and purity [10]. The mathematical modeling of enzymatic reactors for the esterification of fatty acids with sugars in the production of

biosurfactants can be a useful tool for studying and optimizing the process. Particularly, artificial neural networks and fuzzy systems emerge as promising methods for developing models for the mentioned process.

Artificial Neural Networks (ANNs) are a powerful technique for problem-solving in chemical engineering, capable of modeling nonlinear systems with a relatively simple neural network structure [11,12]. The use of ANNs in the mathematical modeling of enzymatic esterification reactors has been extensively studied by various authors, aiming to optimize the production of biodiesel, esters of aromatic carboxylic acids, and biosurfactants [13-15]. ANNs also may be used to enhance productivity, quality, and consistency, having applications in medical chemistry, hydrology, engineering, and pharmaceutical research [16,17].

The Adaptive Neuro-Fuzzy Inference System (ANFIS) is a technique that combines the power of neural networks and fuzzy inference systems, providing a method for the fuzzy modeling procedure to learn information on a data set [18,19]. ANFIS has been presented as a powerful tool for optimizing the reaction parameters of enzymatic reactors to produce biosurfactants and biodiesel, and other applications [20-22].

The production of biosurfactants through the esterification of fatty acids (oleic and lauric) and carbohydrates (fructose, lactose and xylose) in the presence of solvents such as tert-butanol and 2-methyl-2-butanol, using the commercial immobilized lipase B from *Candida antarctica* and with silica magnetic microparticles (SMMPs) as biocatalysts, has been experimentally evaluated by Lima et al. [23,24]. Torres [14], in turn, performed the kinetic modeling of this process through three distinct approaches: semi-mechanistic phenomenological modeling, the use of a model based on the Ping Pong Bi Bi mechanism; by using artificial neural networks in an empirical kinetic modeling; and the initial development of a fuzzy model.

In this context, the present work aims to contribute to the mathematical modeling of biosurfactant production by developing a hybrid-neural model capable of calculating xylose concentration values over time. This involves using neural networks to directly infer reaction rates. More specifically, hybrid-neural models for inferring the concentrations of reactants over time were developed, employing neural networks to directly provide reaction rates, being the kinetics coupled with reactor mass balances. Additionally, to complement the fuzzy model developed by Torres et al. [25] (also described in Torres [14]), data was incorporated from the factorial design by Lima et al. [23], allowing a more comprehensive understanding of the effect of input variables on the system output. This way, fuzzy logic was employed to create a model aimed at predicting optimal operational process conditions (such as time, temperature, molar ratio of substrates, etc.), to maximize product conversion.

# MATERIAL AND METHODS

## Application of Neural Networks to Infer Reaction Rates

For the development of artificial neural networks, data provided by Lima et al. [23] were employed, pertaining to the kinetics of xylose ester synthesis obtained through the esterification of oleic or lauric acid in tert-butyl alcohol medium. The experimental conditions included 300 rpm agitation, 1g of molecular sieve, a fatty acid/xylose molar ratio (SMR) of 5:1 (or 1:0.2), an enzyme activity load of 37.5 U/g of acid, and an initial xylose concentration of 20mM. Kinetic data were collected from the beginning of the reaction up till 72 hours, conducting experiments with both fatty acids at temperatures of 46ºC and 55ºC. The biocatalysts employed were commercial lipase B from *Candida antarctica* immobilized (CALB-IM-T2-350) and derivatives of CALB immobilized on silica magnetic microparticles (SMMPs) with octyl groups (CALB-SMMP-octyl) or with octyl and glutaraldehyde groups (CALB-SMMP-octyl-GLU).

To construct the neural network for the hybrid-neural model application, concentrations of xylose (mM) and reaction temperature were used. The neural networks were grouped based on the type of fatty acid and biocatalyst. The target response variable used in training the networks was the sugar consumption rate ($mmol.L^{-1}.h^{-1}$), calculated using the numerical derivative method from experimental data on concentration and time. Table 1 presents the sets of neural networks trained with experimental data for both temperatures, 46ºC and 55ºC.

**Table 1:** Specification of each trained ANN set.

| Network | Biocatalyst | Fatty Acid |
|---|---|---|
| ANN1-3 | CALB-IM-T2-350 | Oleic |
| ANN2-1 | CALB-IM-T2-350 | Lauric |
| ANN3-1 | CALB-SMMP-octyl | Lauric |
| ANN4-2 | CALB-SMMP-octyl-GLU | Oleic |
| ANN5-2 | CALB-SMMP-octyl-GLU | Lauric |

To develop the hybrid-neural model, the coupling of neural networks to reactor mass balances was performed, aiming to infer concentrations of reactants over time. As the experiments were conducted in a batch reactor, Equation 1 represents the mass balance for this reactor type.

$$\frac{dX}{dt} = -\Gamma_X \quad (1)$$

Where $\Gamma_X$ is the xylose consumption rate, $X$ is the xylose concentration, and $t$ is the reaction time. In the implementation of the hybrid-neural model, $\Gamma_X$ is the output

of the neural network; therefore, is possible to obtain xylose concentration values over time by solving the differential equation. For this purpose, the classical Runge-Kutta method can be used for integration. The integration method was applied using the "ode15s" subroutine in the software Matlab.

The construction and training of neural networks were performed using the "feedforwardnet" function in the software Matlab. This function also allows data splitting for training, validation, and testing, with a distribution of 50%, 25%, and 25%, respectively, ensuring at least three data points for each training stage.

In this work, feed-forward neural networks with an input layer, a hidden layer, and one neuron in the output layer were employed. The training was conducted using the "trainlm" function, which implements the Levenberg-Marquardt method. The model's performance criteria included evaluating the determination coefficients for both the network training stage and the final response of the hybrid-neural model.

## Development of Fuzzy Systems Modeling

For the development of the ANFIS modeling, kinetic data provided by Lima et al. [23] were employed for the xylose esterification with fatty acids (oleic or lauric) in tert-butyl alcohol medium. The experimental conditions included 300 rpm agitation, 1g of molecular sieve, a fatty acid/sugar molar ratio of 1:0.2, 20mM of xylose, and an enzyme load of 37.5 U/g of acid. Data collection spanned from the beginning of the reaction until 72 hours, conducting the experiment at temperatures of 46ºC and 55ºC for each type of biocatalyst used, namely CALB-IM-T2-350, CALB-SMMP-octyl, and CALB-SMMP-octyl-GLU.

In addition to the kinetic data provided by Lima et al. [23], data from an experimental design procedure were also utilized in this stage. The operational conditions are outlined in Table 2, with a reaction time of 48 hours. These data were used in conjunction with the kinetic data for constructing the fuzzy models.

**Table 2:** Operational Conditions of the factorial design [23].

| Fatty acid | Oleic | Lauric | |
|---|---|---|---|
| Temperature(ºC) | 40.6 | 46.0 | 51.30 |
| Acid/sugar ratio (SMR) | 0.60 | 1.00 | 1.39 |
| Enzymatic Load (U/g) | 30.10 | 37.50 | 44.90 |

The Neuro Fuzzy Designer tool in the software Matlab was employed for model construction, enabling the creation of the ANFIS model through graphical user interfaces. The datasets were separated based on the catalyst type used, resulting in three distinct models: ANFIS1 for CALB-IM-T2-350, ANFIS2 for CALB-SMMP-octyl, and ANFIS3 for CALB-SMMP-octyl-GLU. To enhance the fitting quality, additional data points were incorporated through interpolation in the kinetic data at the 36-hour mark.

The input data for ANFIS were organized in a file, with columns representing the values for fatty acid, temperature, SMR (substrate molar ratio), enzyme load, time, and xylose conversion, respectively. Each row represented one of the experimental data points. These data were loaded into the software, and in conjunction with the Neuro Fuzzy Designer tool, linguistic values of the model and the membership function were defined.

## Optimization of reaction parameters through PSO

From the trained ANFIS networks, the particle swarm optimization (PSO) algorithm was employed to assess the optimized operational condition for the xylose esterification reaction in each network and for each fatty acid. The software Matlab, utilizing the PSO routine, can be utilized for this purpose, enabling the application of the PSO algorithm in the fuzzy network. Due to the routine's nature of seeking the global minimum, the ANFIS network output was defined as negative to pursue the global maximum of the network [26]. Import to say that other optimization methods could also be considered, such as genetic algorithms or simulated annealing. All are classical robust algorithms often used to solve global optimization problems.

# RESULTS

## Development of Modeling by Artificial Neural Networks

The neural networks were trained with the aim to inferring xylose consumption rate in the esterification reaction during biosurfactant synthesis, using concentration and temperature information as input for the network. During training, the network utilized experimental data to learn data behaviors, while validation was conducted to assess the network's generalization ability using some data, and testing was performed to evaluate the neural model's performance. The adopted criterion was the coefficient of determination ($R^2$), obtained by comparing the network output value with the experimental value of the output variable. For the network to be considered promising, the final $R^2$ values need to exceed 0.95.

The number of neurons in the hidden layer was determined following the same training criterion, evaluating the final behavior of the network in the hybrid model. There is a possibility that the network is promising with two different quantities of neurons, or they differ only due to the randomness of the training initialization. For these reasons, it is possible to obtain more than one network for each dataset. The neural networks ANN1-3, ANN3-1, ANN4-2 and ANN5-2 have three neurons in the

hidden layer, while the neural network ANN2-1 has two neurons. Overall, all networks have $R^2$ values above 0.98, due to the criterion adopted during training, with some exceeding 0.99.

The developed neural networks were coupled to reactor mass balances in a hybrid model to infer the concentrations of reactants over time, using the Runge-Kutta method for numerical integration. To achieve this, Equation 1 is applied in conjunction with these networks, and the differential equations are solved using the "ode15s" subroutine. Figure 1 illustrates the resulting curves of the hybrid modeling for the ANN2-1 neural network, where the determination coefficients of the model with the experimental data at temperatures of 46°C and 55°C are, respectively, 0.9741 and 0.9935. Overall, the results obtained from the hybrid modeling with direct neural kinetics fully satisfy the conditions imposed as performance criterion, where the value of $R^2$ should be greater than 0.95 (except for the RNA4-2, which presented a slightly lower but also good value of 0.9249 at 46°C). Thus, the application of mass balance together with neural networks has successfully constructed kinetic curves capable of inferring the concentration of xylose throughout the esterification reaction.

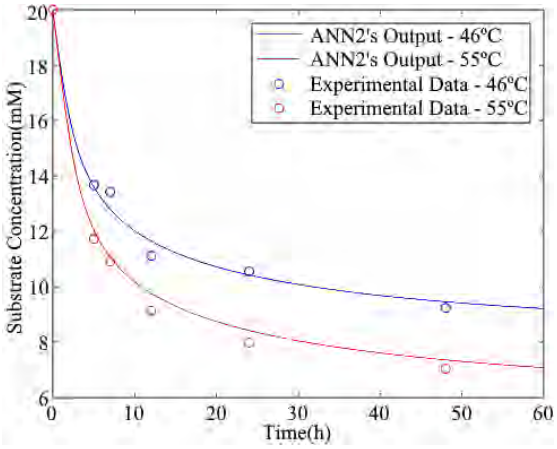

**Figure 1:** Response curves for the hybrid-neural model at temperatures of 46°C and 55°C, using the neural network ANN2-1.

## Development of Fuzzy System Modeling

The application of fuzzy logic in the mathematical modeling of biosurfactant production through esterification was carried out using a dataset derived from a factorial design and another set of kinetic data. These datasets were classified based on the catalyst used, generating fuzzy networks for each distinct catalyst. With the trained ANFIS models, the ability to simulate experimental data was tested. For this purpose, a regression of the model-derived data with experimental data was performed. Coefficient of determination values close to or greater than 0.98 were obtained, indicating that the training was effective in preparing the network to accurately infer the experimental data. Figure 2 illustrates the kinetics resulting from the fuzzy model prediction at temperatures of 46°C and 55°C, with the lauric acid experimental data.

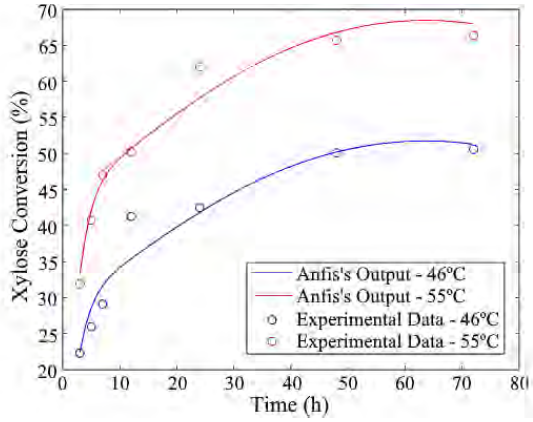

**Figure 2:** ANFIS modeling at temperatures of 46°C and 55°C from ANFIS3-1 network, for lauric acid.

Fuzzy modeling has a high ability to infer the output variable based on an input value within its domain. In this context, surface plots were developed from combinations of input variables, evaluating batch temperature (constant during each batch) combined with time (to terminate the batch), fatty acid/sugar ratio combined with enzyme load, and temperature combined with fatty acid/sugar ratio. Figure 3 illustrates these surfaces, allowing a comprehensive visualization of the fuzzy modeling. The problem had a pattern input of a fatty acid/sugar ratio of 5.0, temperature of 55°C, enzyme load of 37.50 UE/g, and a reaction time of 48 hours, when kept invariable (i.e., when some not being one of the variables whose effects are being analysed). The obtained results show the region with global maximum conversion under the following conditions: above 48 hours, temperature of 55°C, acid/sugar ratio of 1:0.2, and enzymatic load of 37.5 U/g, even with variations in linguistic values and the biocatalyst used. This is consistent with the results obtained by Torres [14]. Additionally, the local maximum appearing in regions of SMR values below 1:0.2 represent the optimal condition for the data obtained in the factorial design by Lima et al. [23]. One impact of including data from the experimental design is the possibility of also identifying this local maximum.

### Application of particle swarm optimization in the ANFIS model

The particle swarm optimization algorithm was applied to the constructed fuzzy models with the aim of optimizing operational conditions for biosurfactant synthe-

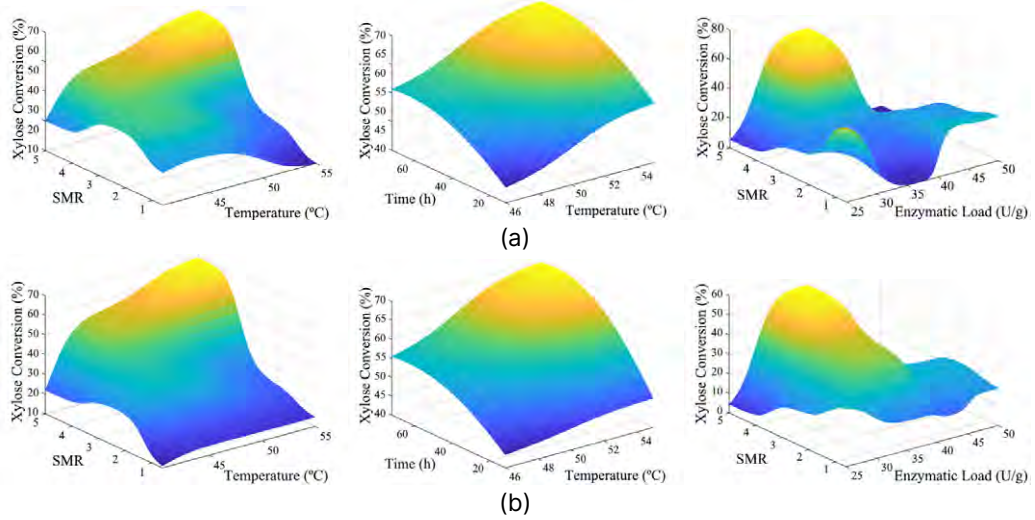

**Figure 3:** Surfaces developed by the ANFIS model for lauric acid (a) and oleic acid (b) from the ANFIS3-1.

sis. The optimization was carried out using the "particleswarm" command in software Matlab. Table 3 presents the optimized conditions obtained by the optimization algorithm for each of the developed models (the respective optimal temperature and SMR values for all networks are 55ºC and 5).

**Table 3:** Optimized conditions obtained by PSO.

| Network | FA | Load (U/g) | t (h) | (%) |
|---|---|---|---|---|
| ANFIS1-2 | Lauric | 37.48785 | 64.931 | 69.19 |
| ANFIS1-2 | Oleic | 37.48769 | 63.714 | 70.16 |
| ANFIS2-1 | Lauric | 40.41127 | 65.509 | 74.12 |
| ANFIS2-1 | Oleic | 40.41144 | 65.508 | 68.65 |
| ANFIS3-1 | Lauric | 36.90347 | 63.572 | 68.58 |
| ANFIS3-1 | Oleic | 36.90348 | 63.573 | 70.33 |

The global optimal conditions found by the particle swarm optimization algorithm show values close to the point with the highest conversion (temperature of 55ºC, SMR of 5, enzyme load of 37.5 U/g, and 72 hours of reaction).

## CONCLUSION

The training of neural networks was effective in producing neural networks capable of inferring experimental data. When applying the hybrid-neural model, the neural networks were able to predict the kinetic behavior of the xylose esterification process in biosurfactant synthesis, applied to reactor mass balances.

The fuzzy models were able to simulate the relationships between input variables (temperature, time, SMR, and enzyme load) and the output variable (xylose conversion), allowing the construction of various response combinations. The application of the particle swarm optimization to fuzzy models demonstrated the ability of this optimization technique to estimate the optimized operational condition.

## ABSTRACT

Mixing is a critical operation in numerous industrial processes, traditionally performed in agitated tanks to ensure homogenization. Despite its importance, the design of tanks and impellers is often neglected during agitation system selection, resulting in excessive energy consumption and inefficient mixing. To mitigate these challenges, Computational Fluid Dynamics (CFD) serves as a powerful tool for analyzing tank hydrodynamics and quantifying mixing times. CFD employs mathematical models to simulate mass, heat, and momentum transport phenomena within fluid systems. Among the latest advancements in modeling stirred tank hydrodynamics is Smoothed Particle Hydrodynamics (SPH), a mesh-free Lagrangian approach that tracks individual particles characterized by properties such as mass, position, velocity, and pressure. SPH provides significant advantages over traditional mesh-based methods by accurately capturing fluid behavior through particle interactions. In this study, the performance of three impellers—double ribbon, paravisc, and hybrid—was evaluated based on hydrodynamics and mixing times during the homogenization of water and ethanol in a 0.5 L stirred tank. The tank and impellers were meticulously designed, operating at 70% capacity, with the fluids exhibiting the following rheological properties: $\rho_1$ = 1000 kg/m$^3$, $\rho_2$ = 789 kg/m$^3$, $\mu_1$ = 1E-6 m$^2$/s, and $\mu_2$ = 1.52E-6 m$^2$/s. The simulations were conducted under turbulent flow conditions (Reynolds number of 10,000) for a duration of 2 minutes using the DualSPHysics software. The stirring speed was set at 34 rpm, and the initial particle spacing was configured to 1 mm, generating 270,232 fluid particles and 187,512 boundary particles representing the tank and agitator. The analysis included velocity profiles, flow patterns, vorticity, divergence, and density fields to assess mixing performance. The Q-criterion was employed to discern the dominance of rotational or deformational motion and to identify stagnation zones. The results revealed that the double ribbon impeller exhibited superior performance, achieving 88.28% mixing within approximately 100 seconds, while the paravisc and hybrid impellers reached mixing efficiencies of 12.36% and 11.8%, respectively. These findings underscore the potential of SPH as a robust computational approach for linking hydrodynamic behavior with mixing efficiency and identifying key parameters to optimize mixing processes.

**Keywords**: CFD, hydrodynamics, Proximity impellers, SPH, homogenization

## 1. INTRODUCTION

The numerical analysis of fluid distribution in stirred tanks is an essential tool for evaluating impeller performance. It enables the characterization of axial and radial flow patterns, velocity profiles, mixing times, stagnation zones, and vortex formation. These analyses are typically conducted using Computational Fluid Dynamics (CFD), which provides detailed insights that are often unattainable through experimental methods. However, CFD

simulations demand significant computational resources (Gelves et al., 2013). Analyzing mixing times numerically is particularly valuable for understanding the distribution of species within chemical or biological reactors. This parameter is critical for assessing the overall effectiveness of stirred tanks. Previous studies have extensively investigated the influence of stirrer geometry on hydrodynamics and mixing times in such reactors. Many of these efforts have focused on optimizing conventional impellers, such as the Rushton turbine, to enhance their performance. Despite these advances, there has been limited investigation into proximity impellers—specialized designs that operate at a short distance from the tank walls. These impellers are commonly employed for mixing non-Newtonian fluids and are characterized by lower operational speeds compared to conventional designs. In this work, the mixing process for achieving a homogeneous 50% water-ethanol solution is simulated using the Smoothed Particle Hydrodynamics (SPH) method. The primary objective is to develop a robust methodology for analyzing the hydrodynamics of mixing processes in stirred tanks equipped with different impeller designs. The performance of the impellers is subsequently compared to identify the most effective option for the fluids under investigation.

## 2. METHODOLOGY

### 2.1 CAD design of the impellers

In this work, three proximity impellers: double ribbon, paravisc and hybrid, were used to simulate the mixing process of the ethanol-water solution. Figure 1 shows the proximity impellers analyzed. The double Ribbon agitator consists of two opposite helical ribbons fitted on an axis, one of these ribbons has the job of moving the materials to be mixed in a single direction and the other does the same as the previous one, however, it does it in an opposite direction, as a consequence of these movements the materials to be mixed acquire a single direction, making this system ideal to be used as a continuous mixer (Londoño, 2019). This impeller is generally used in industries to be able to combine powdered, granulated and viscous materials. The effectiveness of the mixing process will depend on factors, such as the rotation speed, the design of the belts, the mixing time and the physical properties of the materials (Flores & Cuevas, 2008).

Paravisc is a proximity impeller that works efficiently with high viscosity mixtures, however, it can be coupled to different stages of the process with the possibility of accomplishing an efficient homogenization. This type of impeller, like the previous one, works inside a mixing tank with circular geometry, in which there is a minimum separation with the internal wall of the tank and also the space between the blades and the bottom surface, which means that the mechanical operation of this impeller is made circular through the action of the axial pumping. This type of impeller can work without problem with internal baffles to improve power, heat transfer and to obtain an adequate mixing incorporating all the solids of the more viscous medium. The hybrid agitator is a novel design reported by Alvarado-Rodriguez et al. (2023). It is a proximity stirrer that combines the characteristics of the anchor stirrer with the double ribbon stirrer. Its efficiency lies in favoring mixing in both axial and radial directions.

### 2.2 SPH method

Computational Fluid Dynamics (CFD) simulation has proven to be a powerful tool to study and optimize mixing processes, contributing to the development of more efficient processes (Yin, et al., 2022). CFD numerical analysis allows a better comprehension of the momentum, mass and energy transport phenomena of different systems. In stirring systems, emulsification, homogenization and mixing mechanisms are analyzed numerically to describe the behavior of fluids inside the tank (Zawawi, et al., 2018).

Recently, within computational fluid dynamics, the method of smoothed particle hydrodynamics has been implemented to analyze the behavior of fluids. SPH is a method for meshless Lagrangian and dissipative particle dynamics transporting physical properties such as mass, position, velocity and pressure. It is able to follow the trajectory of these particles, can analyze highly complex flows and where there are deformations or phenomena at macro or meso scale. It is able to handle complex geometries and boundary conditions. SPH tracks individual fluid particles by calculating their interactions to simulate the fluid behavior. Equations 1 to 3 present the equations describing the hydrodynamics of stirred tanks.

$$\frac{d\rho}{dt} = -\rho\nabla \cdot \mathbf{v}, \tag{1}$$

$$\frac{d\mathbf{v}}{dt} = -\frac{\nabla P}{\rho} + \frac{\mu}{\rho}\nabla^2\mathbf{v} + \boldsymbol{g}, \tag{2}$$

$$\frac{dC}{dt} = D\nabla^2 C - \nabla \cdot (C\mathbf{v}) + \mathbf{v} \cdot \nabla C, \quad (3)$$

where: $\rho$ is the density, $t$ is time, $\mathbf{v}$ is velocity, $P$ is pressure, $\mu$ is viscosity, $\boldsymbol{g}$ is gravity, $C$ is concentration and $D$ is the mass diffusion coefficient.

Equations 1 to 3 are shown in the SPH formalism in equations 4 to 6 which are closed by the Tait´s equation of state shown in the equation 7

$$\frac{d\rho_a}{dt} = -\rho_a \sum_b^n m_b \frac{\mathbf{v}_b}{\rho_b} \cdot \nabla W_{ab} \quad (4)$$

$$\frac{d\mathbf{v_a}}{dt} = -\sum_b^n m_b \left(\frac{p_a + p_b}{\rho_a \rho_b}\right) \nabla_a W_{ab} + 2\nu \sum_b^n m_b \frac{\mathbf{v}_{ab}\, r_{ab} \cdot \nabla W_{ab}}{\bar{\rho}_{ab} {r_{ab}}^2 + \varepsilon^2} + \boldsymbol{g} \quad (5)$$

$$\frac{dC_a}{dt} = \sum_b^n \frac{m_b}{\rho_b} \frac{C_{ab} D \cdot \nabla W_{ab}}{{r_{ab}}^2 + \varepsilon^2} - \sum_b^n m_b \frac{C_b}{\rho_b} (\mathbf{v}_a \cdot \nabla_a W_{ab}) \quad (6)$$

$$p = B\left[\left(\frac{\rho}{\tilde{\rho}}\right)^{\gamma} - 1\right] \quad (7)$$

where the subscripts *a*, *b* are referent to the mean particle *a* or neighbor particles *b*, *W* is the kernel function, *m* is the mass of the particle, $r_{ab} = r_a - r_a$, where *r* is the position vector, *v* is the kinematic viscosity, $\bar{\rho}_{ab} = \frac{\rho_a + \rho_b}{2}$, *D* is the diffusion coefficient, $C_{ab} = C_a - C_b$, $\varepsilon$ is a small regularization term to prevent singularities, $B = c^2\rho/\gamma$, $\gamma = 7$ for liquids, $\tilde{\rho}$ is a reference density and *c* is a numerical speed of sound which must be at least 10 times higher than the maximum velocity of the fluid in the system to ensure a maximum density fluctuation of 1% satisfying the compressibility condition.

Finally, the properties of the particles as de density, position, velocity and concentration are advanced from time $t^{n+1} = t^n + \Delta t$ using the Verlet algorithm according to equations 8 to 11.

$${\rho_a}^{n+1} = {\rho_a}^{n-1} + 2\Delta t \left(\frac{d\rho_a}{dt}\right)^n, \quad (8)$$

$${\boldsymbol{r}_a}^{n+1} = {r_a}^n + \Delta t \mathbf{v}_a^n + 0.5\Delta t^2 \left(\frac{d\boldsymbol{x}_a}{dt}\right)^n, \quad (9)$$

$${\mathbf{v}_a}^{n+1} = {\mathbf{v}_a}^{n-1} + 2\Delta t \left(\frac{d\mathbf{v}_a}{dt}\right)^n, \quad (10)$$

$${C_a}^{n+1} = {C_a}^{n-1} + 2\Delta t \left(\frac{dC_a}{dt}\right)^n, \quad (11)$$

Where n is the value of step and $\Delta t$ is the time step calculated with the equation 12.

$$\Delta t = min\left[\left(\frac{h}{{d\mathbf{v}_a}/{dt}}\right)^{1/2}, \frac{h}{(c + \Delta t_{v,a})}, \frac{h^2}{2D}\right] \quad (12)$$

Where h is the smoothing length of the kernel function and $\Delta t_{v,a} = max_b |h r_{ab} \cdot \mathbf{v}_{ab} / (r_{ab} \cdot r_{ba} + \varepsilon^2)|$.

Using the Verlet algorithm, numerical coupling of the discrete SPH equations is ensured during the evolution by alternating the step $t^{n-1}$ in in the first term of the right side in equations 8, 10 and 11 every N≈40 steps by the step $t^n$.

### 2.3 Numerical simulation

Numerical simulations were performed using the DualSPHysics software (Domínguez et al., 2022) which is based on the SPH method. The tank and impellers geometries generated in CAD were imported into the DualSPHysics software to generate the fixed and moving boundary conditions in the simulation. The tank was filled to 70% volume, being 35% water at the bottom and 35% ethanol at the top of the liquid. An isothermal mixing process at 25°C was considered. The initial distance between particles is 1 mm generating a total of 270232 fluid particles and 187512 contour particles (tank plus stirrer). The initial velocity of the liquids is zero and a no-slip boundary condition is established on the tank surface. The stirring speed for the three stirrers is 33.9 rpm setting a Reynolds number of 10000. The initial stirrer speed is zero and is accelerated at 16.95 rpm for 1 second until the constant stirring speed is reached. Two minutes of mixing time was simulated and the percentage of mixing over time was evaluated, as well as the average velocity after 1.5 minutes of stirring. The fluid parameters used in the simulation are shown in Table 1.

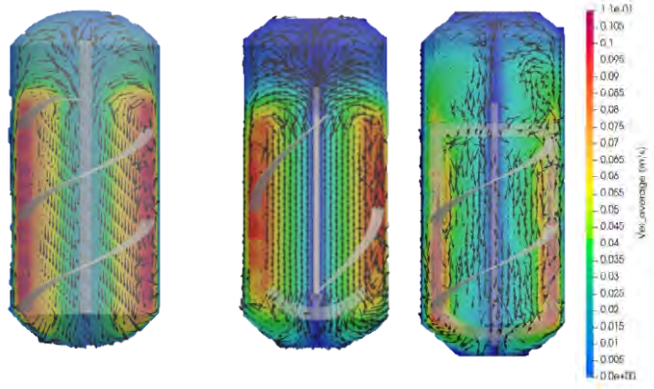

**Table 1.** Properties of water, ethanol and the mixture.

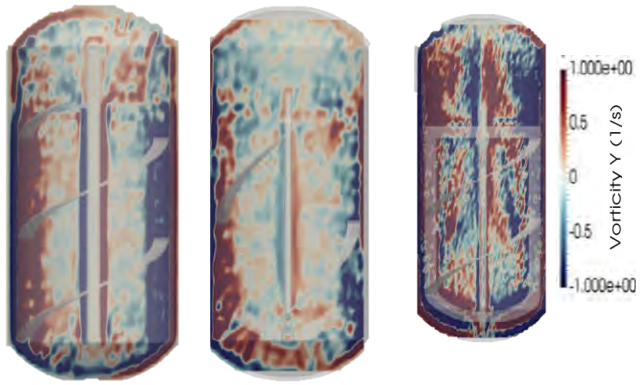
| | Water | Ethanol | Mixture |
|---|---|---|---|
| Density (kg/m³) | 1000 | 789 | 894.5 |
| Kinematic Viscosity (m²/s) | 1 E-06 | 1.52 E -06 | 1.17 E-06 |

## 4. RESULTS



The numerical simulations provided detailed insights into the mixing performance and hydrodynamic behavior within the stirred tank. Key parameters such as the mixing percentage over the simulated time, average velocity, velocity gradient, divergence, and vorticity of the flow were quantified. Additionally, the Q-criterion was employed to further analyze the hydrodynamic characteristics of the fluid within the tank. Density and density gradient fields within the tank were also visualized to identify regions of high mixing efficiency and to evaluate the relationship between the mixing performance and the flow patterns generated by each impeller. The primary

goal was to determine which impeller achieved the highest mixing percentage within 2 minutes and to correlate this performance with the hydrodynamic features induced by the impeller design. Figure 2 illustrates the average velocity profiles for the different impellers. For all configurations, the highest velocity was observed near the tank walls. Furthermore, vortices were consistently present in the regions of highest velocity for each impeller. These vortices facilitated fluid circulation, directing the flow upward along the tank walls and creating a downward flow in the central region of the tank. This circulation pattern played a crucial role in promoting effective mixing within the tank.

a) Double Ribbon b) Paravisc c) Hybrid

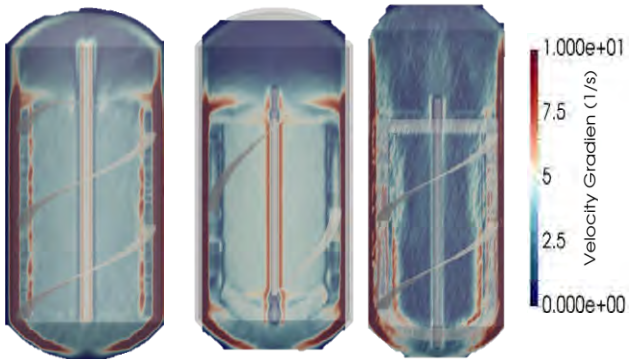


**Figure 2**. Average velocity generated by the impellers inside the tank.

a) Double Ribbon b) Paravisc c) Hybrid

**Figure 3**. Vorticity calculated from the average velocity.

Figure 3 shows the behavior of the vorticity generated by the fluid inside the tank in each impeller. The red color represents regions of high vorticity, indicating strong twists and rotations of the fluid in those areas. These regions usually form near the proximity stirrer blades due to the force imposed on the fluid. Conversely, low vorticity zones (blue color), indicate areas of more stable and less disturbed flow, suggesting a limited mixing pattern in this region. The intermediate colors show a more efficient and homogeneous mixing.Figure 4 shows the velocity gradient of the fluid inside the tank. This value indicates the change of direction of the fluid with respect to the movement of the impeller. According to Figure 4, the gradient is higher near the wall. However, the zone with the lowest gradient, which is the center, represents only half of this gradient.

a) Double Ribbon b) Paravisc c) Hybrid

**Figure 4**. Velocity gradient inside the tank.

a) Double Ribbon b) Paravisc c) Hybrid

**Figure 5**. Criterion Q obtained inside the tank.

Figure 5 is presenting the Q Criterion in our system which gives us a trend for zones where rotation is dominant over deformation. For positive values of Q the rotation is dominant and for negative values of Q the deformation is dominant. According to the results obtained, in the paravisc and hybrid proximity impellers shakers the fluid deformation predominates over vorticity, that is, the divergence value is much higher than the vorticity value mainly in the proximity of the impeller, this suggests that this type of impellers is recommended for viscous fluids or non-Newtonian fluids. Figure 6 shows the density field with the different impellers over time from 0 to 60

seconds, which is related to the mixing inside the tank. Initially, water is at the bottom and ethanol at the top. The volume fraction of both components corresponds to 50%. With the double ribbon impeller, a density field with values close to the density of the mixture is generated after 36 seconds and increases considerably after 60 seconds. For the paravisc impeller, the evolution of the density change is obtained in a representative manner up to 60 seconds of mixing. Using the paravisc impeller, it is observed that the mixing is obtained mainly in the center of the tank. Finally, the Hybrid impeller presents an intermediate homogenization between the paravisc impeller and the double ribbon impeller.

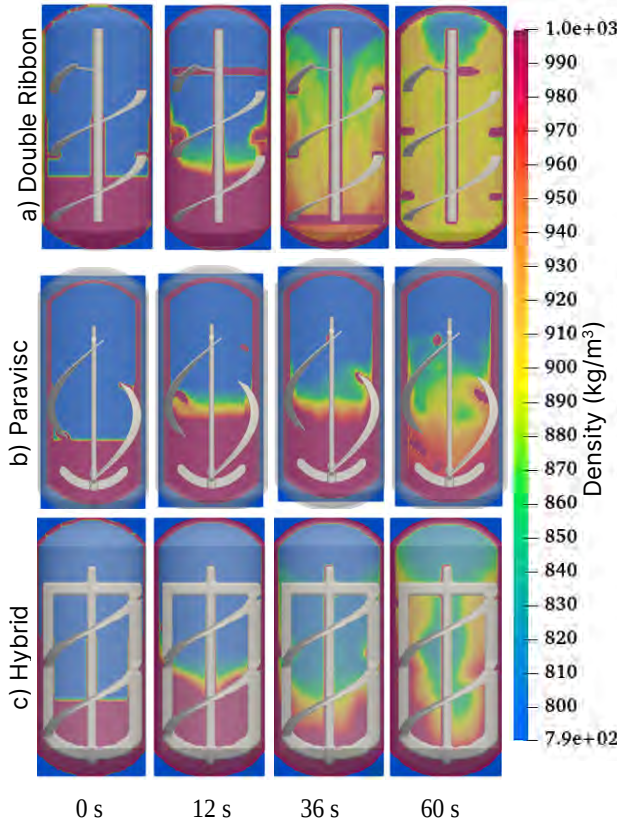

**Figure 6.** Density field at different times obtained in all cases.

## 5. CONCLUSIONS

This study presents a numerical analysis of the hydrodynamics of different impellers to evaluate their performance based on velocity profiles, vorticity, divergence, and the Q-criterion, which correlates fluid deformation with rotational motion within a stirred tank. The results demonstrate that the Double Ribbon impeller exhibited significantly superior performance compared to the Paravisc and hybrid impellers, achieving a mixing efficiency of 88.28% within approximately 100 seconds. The exceptional performance of the Double Ribbon impeller can be attributed to its unique design, featuring two intertwined ribbons that promote a more uniform and turbulent flow within the tank. This design enhances mixing efficiency and ensures effective homogenization of the fluid mixture. The findings underscore the critical role of impeller design in optimizing mixing performance and highlight the Double Ribbon impeller as a highly effective solution for applications requiring efficient and rapid homogenization.

## ABSTRACT

Optimizing twin-screw extruder (TSE) performance is critical in the plastics industry but is often resource-intensive. This study introduces a novel surrogate modeling approach using a Recurrent Deep Embedding Network (RDEN) that integrates deep autoencoders with recurrent neural networks to capture sequential dependencies and physical relationships in TSE processes. Leveraging Progressive Latin Hypercube Sampling (PLHS), the RDEN achieves robust predictions of key process variable, like mean residence time. Results demonstrate the model's accuracy, generalization capabilities, and potential for automated screw design optimization.

**Keywords**: twin-screw extruder, deep learning, surrogate modeling

## INTRODUCTION

Twin-screw extruders (TSEs) are extensively used in the plastics processing industry, with their performance highly dependent on operating conditions and screw configurations. However, optimizing these parameters through experimental trials is often time-consuming and resource-intensive. Although some neural network models have been proposed to tackle the screw arrangement problem [1], they didn't account for the physical and positional information of the screw elements. To overcome this challenge, we propose a recurrent deep embedding network (RDEN) that leverages a deep autoencoder with a recurrent neural network (RNN) structure to develop a surrogate model based on numerical simulation data [2, 3].

The details are as follows [4]. An autoencoder is a neural network architecture designed to learn latent representations of input data. In this study, we integrate the autoencoder with an RNN to capture the complex physical relationships between the operating conditions, screw configurations of TSEs, and their corresponding performance metrics. A schematic of TSEs simulation system is depicted in **Figure 1**. To further enhance the model's ability to represent screw positions, we incorporate an RNN layer and this addition allows the model to more effectively capture the spatial relationships between the screw elements.

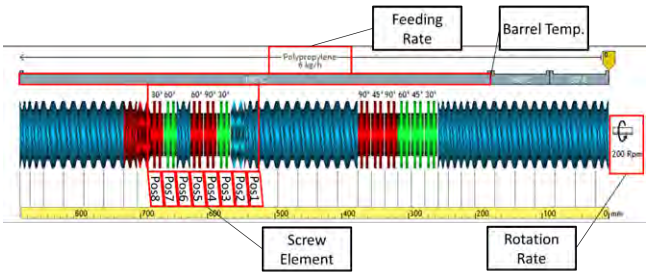

**Figure 1.** Schematic of TSEs simulation from Ludovic

## METHODOLOGY

In this section, we would introduce the methods used for data collection and RDEN model building.

### Progressive Latin Hypercube Sampling (PLHS)

Space filling is essential for sampling methods when working with small datasets, as it ensures optimal coverage of the parameter space while maintaining relatively few sample points. To address the problem, we apply Progressive Latin Hypercube Sampling (PLHS) [5].

PLHS is an extension of Latin Hypercube Sampling

(LHS), designed to enhance sampling efficiency in environmental modeling. Unlike LHS, which generates the entire sample set at once, PLHS progressively creates a series of smaller subsets while striving to maintain LHS characteristics in each subset. This approach is particularly advantageous for large and complex environmental models, offering improved stratification and more accurate representation of the input space.

To understand PLHS, we first describe the LHS method. For LHS, let $S(n,p)$ be a sample matrix containing $(n \times p)$ elements $x_{i,j} \in [0,1]$, where $i = 1,\dots,n$ and $j = 1,\dots,p$. The factor space $[0,1]^p$ is divided into $n$ non-overlapping intervals $([0,1/n),[1/n,2/n),\dots,[(n-1)/n,1])$, with each interval indexed by $q$ along each dimension, where $q = 1,\dots,n$. To represent the relationship between sampling points and intervals, we define an auxiliary binary variable $y_{q,j}$ as follows:

$$y_{q,j} = \begin{cases} 1 & \begin{matrix} if\ there\ exists\ any\ i \\ such\ that\ x_{i,j}\ lies\ within\ interval\ q \end{matrix} \\ 0 & otherwise \end{cases} \quad (1)$$

The sample matrix $S(n,p)$ is considered a Latin hypercube when the following condition is met:

$$\frac{1}{n \cdot p} \sum_{j=1}^{p} \sum_{q=1}^{n} y_{i,j} = 1 \quad (2)$$

This condition ensures that each interval is sampled exactly once in each dimension, maintaining the Latin hypercube property.

For PLHS, we extend this formulation by defining an auxiliary binary variable $y_{q,j}^t$ corresponding to the sample matrix $L^t = \cup_{k=1}^{t} S_k(n_k,p)$, where $t = 1,2,\dots,T$ represents the slice number. The number of sample points is $n_t = \sum_{k=1}^{t} n_k$, and the factor space $[0,1]^p$ is divided into $n_t$ non-overlapping intervals. The necessary and sufficient condition for the sample to be a progressive Latin hypercube is:

$$\frac{1}{n_t \cdot p} \sum_{t=1}^{T} \sum_{j=1}^{p} \sum_{q=1}^{n_t} y_{q,j^t} = T \quad (3)$$

The left side of the equation represents the sum of Latin hypercube properties across all $T$ slices. Thus, generating a PLHS can be expressed as an optimization problem:

$$\max\left( \sum_{t=1}^{T} \frac{1}{n_t \cdot p} \sum_{j=1}^{p} \sum_{q=1}^{n_t} y_{q,j}^t \right) \quad (4)$$

subject to the Latin hypercube constraints:

$$\begin{aligned} &\sum_{i=1}^{n_t} x_{i,j} = 1 \qquad \forall t, \forall j \\ &y_{q,j}^t \in 0,1 \quad \forall t, \forall q, \forall j \end{aligned} \quad (5)$$

where $x_{i,j}$ are decision variables representing sample point regions, and $y_{q,j}^t$ are auxiliary variables ensuring the Latin hypercube property.

The PLHS method offers several advantages for data collection. It allows for incremental addition of sample points, adapting to different computational budgets and analysis needs. By generating samples progressively, PLHS can better cover the input space with fewer points, avoiding repeated sampling in the same regions and reducing computational costs, and the workflow is shown in **Figure 2**.

In the workflow, PLHS enables progressive construction of RDEN dataset while allowing for additional constraints, ensuring desired stratification properties in each subset and combined set in further practical process applications.

## DEN with RNN Structure

The DEN has emerged as a powerful technique in TSE modeling, demonstrating the ability to extract latent physical information. However, the original model faces challenges of capturing sequential dependencies which are inherent in extruder element arrangements.

To address this limitation, we propose integrating the DEN with an RNN structure. Specifically, the input to the autoencoder structure consists of a series of screw elements, denoted as $z$, with each element represented in one-hot encoded format. The autoencoder reduces the dimensionality of the coding of each screw element while reconstructing it as $\hat{z}$. To ensure the latent variables extracted from different screw positions remain physically consistent, the autoencoder is designed to share the same parameters across all screw inputs.

For the prediction task, we employ Gated Recurrent Unit (GRU) cells to process the sequential arrangement of extruder elements and their associated process con-

ditions. The GRU utilizes the latent variables from the autoencoder, denoted as $h$, alongside the process conditions, represented by $c$. This integrated input allows the model to effectively capture sequential trends, enabling the transfer of information from earlier extruder elements to subsequent GRU cells.

The combined RDEN structure offers enhanced flexibility and scalability, making it well-suited for various extrusion process configurations. The model structure and pseudo code are depicted in **Figure 3** and the following section separately.

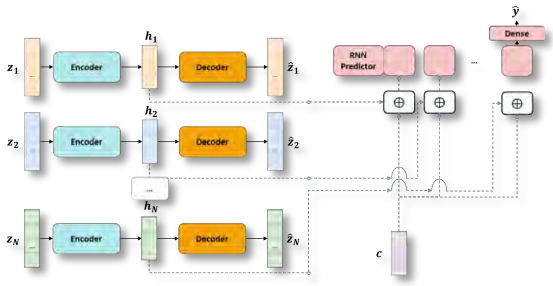

**Figure 3.** RDEN model structure

```
START ALGORITHM

END FOR
END ALGORITHM
```

The model outputs include predictions of materials' final physical properties, capturing the dynamic nature of the extrusion process, as well as the autoencoder reconstruction. For data normalization, the dataset is reshaped into three dimensions: samples, position series, and process variables; then, we apply the min-max scaling to inputs and the z-score to output, along the variables' direction. Such normalization ensures that the model preserves output trends without necessitating extensive hyperparameter tuning. The model's loss functions, incorporating both reconstruction and prediction errors, are mathematically represented in (6) and calculated using the mean squared error.

$$L_1 = E\left(\sum_{i=1}^{n}(z_i - \hat{z_i})^T(z_i - \hat{z_i})\right)$$
$$L_2 = E((y_i - \hat{y_i})^T(y_i - \hat{y_i})) \quad (6)$$

## RESULTS AND DISCUSSIONS

We successfully established the settings for the Ludovic simulation system and generated data based on the experimental design (DoE) table, presented in **Table 1**. The Ludovic system simulates a twin-screw extruder that models material flow, temperature, pressure, and residence time across the screw configuration. By incorporating detailed screw configurations and process conditions, the Ludovic simulation provides a detailed representation of the twin-screw extruder (TSE) process, modeling material flow, temperature distribution, pressure variations, and residence time across different screw configurations.

**Table 1:** DoE Table

| Factor | | Unit | Design Range |
|---|---|---|---|
| Screw Element | Position: [525, 545] | - | "20-20-L2", "20-20-R2", "KB-20-5-30a-L2", "KB-20-5-30a-R2", "KB-20-5-45a-L2", "KB-20-5-45a-R2", "KB-20-5-60a-L2", "KB-20-5-60a-R2", "KB-20-5-90a-L2", "KB-20-5-90a-R2", "SME-20-20-R2", "ZME-20-20-L2" |
| | Position: [545, 565] | - | |
| | Position: [565, 585] | - | |
| | Position: [585, 605] | - | |
| | Position: [605, 625] | - | |
| | Position: [625, 645] | - | |
| | Position: [645, 665] | - | |
| | Position: [665, 685] | - | |
| Temp | Position: [525, 685] | ˚C | [180, 220] |
| Rotation rate | Position: [525, 685] | rpm | [200, 300] |
| Feeding rate | Position: [525, 685] | kg/hr | [15, 25] |

This study focuses on a system with eight adjustable screw element positions, as illustrated in Figure 1,

where key design factors—the 8-position screw arrangement, feeding rate, barrel temperature, and rotation rate—are highlighted with red boxes. The arrangement is varied using a set of candidate screw elements, shown in **Figure 4**, including conveying elements (20-20-L2, 20-20-R2), kneading blocks with various staggering angles (KB-20-5-30a, KB-20-5-45a, KB-20-5-60a, KB-20-5-90a), and specialized mixing elements (SME-20-20-R2, ZME-20-20-L2). Building on this foundation, we systematically explored various element arrangements and analyzed their impacts on the process variables.

Detailed investigations into mean residence time were conducted, offering insights into their interdependencies and contributions to overall process efficiency. Furthermore, the incorporation of progressive Latin hypercube sampling provided a robust framework to optimize the sampling process, enabling comprehensive exploration of the factor space with proper sampling size.

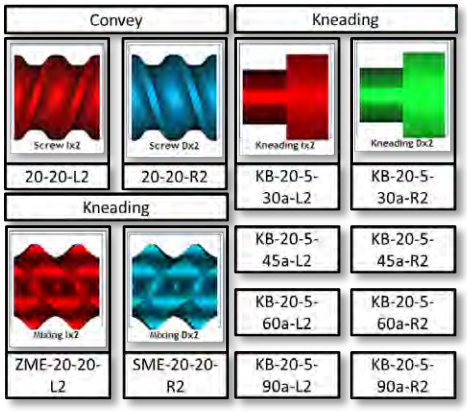

**Figure 4.** Schematic of Ludovic Screw Element

The objective of this study is to predict a critical process variable, the mean residence time, across the entire screw configuration system. Specifically, the model is designed to analyze an eight-position screw assembly, with each position containing a number of candidate screw elements.

To ensure the robustness and generalization of our model, the dataset was meticulously divided into training, validation, and testing sets, adhering to proportions as detailed in **Table 2**.

**Table 2.** Dataset Deviation

| | Sample Size | Percentage |
|---|---|---|
| Training set | 14386 | 0.85 |
| Validation set | 1690 | 0.10 |
| Test set | 844 | 0.05 |

For model training, we employ the RDEN framework described in the previous section to process the training set, guided with a carefully designed loss function. The parameters of both the autoencoder and the predictor are trained simultaneously on the training data. Additionally, the validation set is employed to fine-tune the model and mitigate the risk of overfitting.

The training process is managed using several callback functions to enhance model performance and ensure proper training. Specifically, we use early stopping to halt training when the model's performance on the validation set stops improving. Model checkpoints are used to save the model weights at each epoch, ensuring that the best performing model is retained. Furthermore, the best performing epoch is identified and recorded, helping to capture the model's peak performance.

The results demonstrate that the model performs exceptionally well across all three datasets, with $R^2$ scores over 0.99 and RMSE values below 1, which is within the commonly accepted tolerance for mean residence time. These findings highlight the model's accuracy. The final prediction results are presented below.

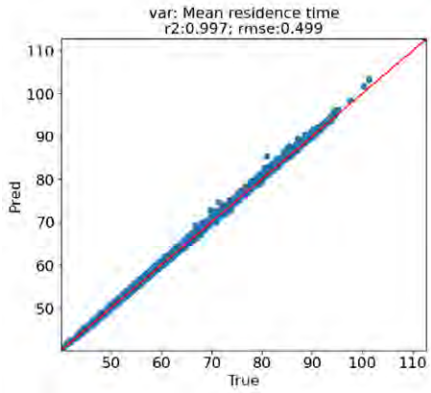

**Figure 5.** Parity plot of the training dataset for mean residence time

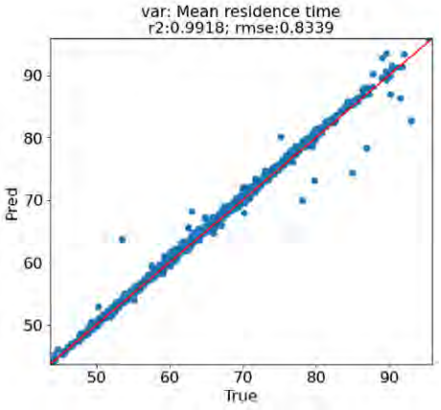

**Figure 6.** Parity plot of the validation dataset for mean residence time

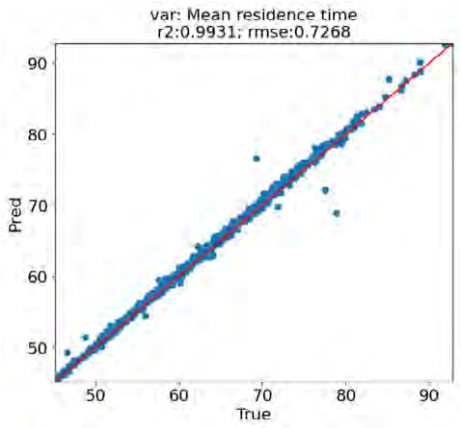

**Figure 7.** Parity plot of the test dataset for mean residence time

In TSE systems, screw elements are typically categorized according to their functionality. Conveying elements, such as 20-20-L2 and 20-20-R2, are primarily responsible for material transportation. Kneading elements, including KB-20-5-30a-L2, KB-20-5-45a-L2, KB-20-5-60a-L2, KB-20-5-90a-L2, KB-20-5-30a-R2, KB-20-5-45a-R2, KB-20-5-60a-R2, and KB-20-5-90a-R2, are designed to apply shearing forces to the material for better dispersion and distribution. Mixing elements, represented by SME-20-20-R2 and ZME-20-20-L2, enhance material blending through intensive mechanical mixing.

The latent space visualization in **Figure 8**. demonstrates distinct clustering patterns, revealing the model's ability to capture inherent physical characteristics of screw elements. For instance, a clear spatial separation was observed between left- and right-rotating elements. Additionally, the demarcation between kneading and conveying elements indicates that the learned representations align with the mechanical principles governing the extrusion process. These systematic clustering patterns across different screw configurations validate the model's capability to encode physical phenomena and provide insights into the functional relationships between various screw elements in the system. By analyzing these patterns, we gain a deeper understanding of the interrelations between the variables, emphasizing the model's capability to elucidate the intricate mechanisms governing the process.

## CONCLUSIONS

In this paper, we introduced a novel model, RDEN, which synergizes the strengths of Deep Embedding Networks and Recurrent Neural Networks. This hybrid architecture exhibits two key capabilities. First is physical information Extraction. The DEN component effectively captures latent physical information from the extrusion process data. Second is sequential prediction. The RNN structure accurately predicts sequential variables inherent in the arrangement of extruder elements. This is achieved through a three-dimensional data structure that significantly reduces redundancy in the dataset and training process, thereby enhancing computational efficiency without compromising performance.

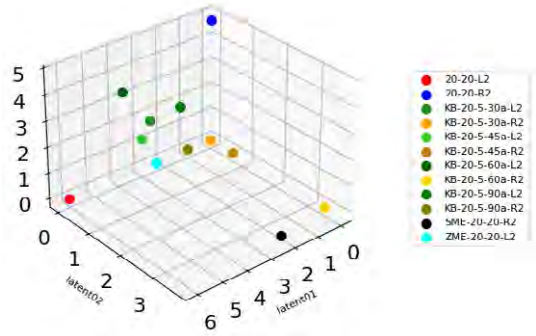

**Figure 8.** Scatter plot of latent variables

The predictive results for process variables demonstrate the model's reliability as a surrogate for extruder systems. Additionally, the latent screw representations learned by the model reveal meaningful patterns in the extrusion process, highlighting its potential for generating valuable process insights.

While our current work establishes RDEN as an effective modeling approach, the development of an optimization framework that leverages this model to recommend optimal screw arrangements remains a promising direction for future research, rather than a validated finding of this study. Our ongoing efforts will focus on exploring this potential application to further establish RDEN as a versatile and powerful tool for advanced process modeling and optimization in polymer extrusion and related fields.

# Dimple Shape Design to Enhance Heat Transfer in Plate Heat Exchangers

**Mitchell J. Stolycia[a], and Lande Liu***

## ABSTRACT

This article studies four dimple shapes: spherical, smoothed-spherical, normal distribution, and error distribution and how they enhance heat transfer on a plate within a plate heat exchanger using computational fluid dynamics. The dimple that showed the greatest efficiency of heat transfer was the normal distribution dimple, giving a temperature increase of 7.5 times of the smoothed-spherical and 15% more than the error distribution dimple shape. This was primarily due to the large increase in the turbulent kinetic energy caused by the eddies created upon the flow over the normal distribution shape. With the normal distribution shape being found to be the most effective in enhancing heat transfer, a layout of multiple normal distribution dimples based on the stage of flow development was also studied. It was found that a fully developed flow resulted in 9.5% more efficiency than half developed flow and 31% more efficient than placing dimples directly next to each other.

**Keywords**: Ansys Fluent, CFD, Dimple, Heat transfer enhancement, Plate Heat Exchangers

## INTRODUCTION

Heat exchangers play an important role in both everyday life and large-scale production. Heat exchangers can be found in many places, from some of the world's largest companies to the radiators in your very home. There are many kinds of heat exchangers, such as the ones in a refrigerator which use a coolant fluid to absorb heat [1], or a plate heat exchanger (PHE) of which was studied in this paper. The main function of a heat exchanger is to transfer heat from one source to another and they are generally used to heat or cool a required element via conduction [1, 2]. In an industrial setting, heat exchangers are often found between multiple reactors in order to increase or decrease the temperature of a fluid after one reaction, before entering the following reactor [3]. This is often done to reduce costs as less fluid material will be required and/or to reduce waste by recycling the stream. For these reasons, the efficiency of a heat exchanger is very important.

Plates within PHEs, are produced as a large sheet of metal with many indentations. These indentations are known as "dimples" and serve to increase the surface area of the plate and encourage turbulent flow [4]. When the surface area available for heat transfer as well as the Reynolds number increases, the temperature change should also increase. This makes the PHE more efficient than it would be otherwise.

In this paper, the plates within a plate heat exchanger were assessed and computationally experimented upon in order to provide an extensive coverage of how to improve the efficiency of a PHE by solely changing the shape of the dimples upon the plates within it. This was done via a computational fluid dynamics (CFD) program known as Ansys Fluent.

Computational fluid dynamics (CFD) is defined as "the method of mathematically modelling a physical phenomenon involving fluid flow and solving it numerically using analytical prowess" [5]. The primary benefit to using CFD in an industrial setting is that it is faster than and comparable to a physical experiment. This allows companies to run simulations in order to gain a realistic idea of what the final process of their production will be.

This paper aimed to simulate realistic fluid flow and dynamics over four different dimple shapes: spherical, smoothed-spherical, normal distribution and error distribution. This was done to obtain values for the Reynolds number, pressure and temperature change across a set

time and distance. A fair comparison of dimple shapes was to be achieved to effectively display which shapes and configurations were more efficient for the transfer of heat in a PHE.

## METHODOLOGY

This study was performed with 2D models and simulations due to the symmetrical structure of the dimple shape and flow channels in radial direction. Nonetheless, 2D models were deemed appropriate to realistically simulate what would occur in an industrial setting, as the results can still be used to compare the heat exchange between different dimple shapes. 2D models also accurately replicate a side-on view of a 3D model without the necessity of a third dimension, i.e. the temperature and velocity profiles would be similar between a 2D and a 3D simulation if viewed from the perspective where the z axis is equal to zero.

For the simulations whereby dimple shape was compared, a pipe was set up with a length of 1 m and a diameter of 0.1 m with the pipe walls being aluminium. The inlet pressure was set to 101325 Pa (1 atm) for all simulations.

For the method, two key areas were explored: simulations over different dimple shapes; and simulating over multiple dimples. The first of which was to find the most efficient dimple shape, and the latter to find the best layout for these dimples over a single plate in a PHE.

## SIMULATING OVER DIFFERENT DIMPLE SHAPES

### Set-up

A 0.5 m/s flowrate was selected, giving a Reynolds number of 48,500, and thus a very turbulent flow. The inlet streams were all set to 300 K, with the walls at a constant 350 K. Dimples were added separately to their respective simulations. Figure 1 demonstrates a sketch of a single spherical dimple.

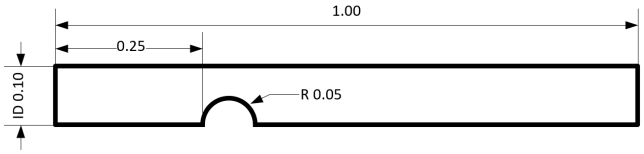

**Figure 1.** A sketch of a 2D pipe with a single spherical dimple, with dimensions in metres.

The cross-sectional area (CSA) of this dimple was then calculated to be $3.927 \times 10^{-3}$ m$^2$. This CSA was to be used across all dimple sizes in order to maintain a fair test, as well as all dimples having a peak height of 0.05 m, while being 0.3 m from the pipe inlet. Figure 2 shows the sketch for the smoothed-spherical dimple, while Figure 3 shows a diagram of the finalised normal and error distribution shapes respectively.

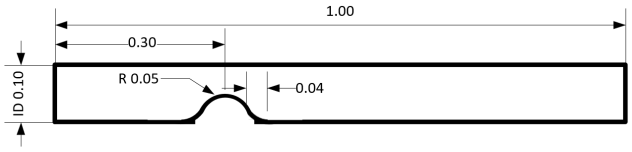

**Figure 2.** A sketch of a 2D pipe with a single spherical dimple, with dimensions in metres.

**Figure 3.** A diagram of the final pipe containing the normal and error distribution curves, respectively.

### Results

Of the different dimple shapes tested: spherical, smoothed-spherical (SS), normal distribution (ND), and error distribution (ED), the ND dimple demonstrated the greatest heat exchange rate, with the average water temperature increasing by 0.53 K in 1.5 s. This is displayed clearly in Figure 4.

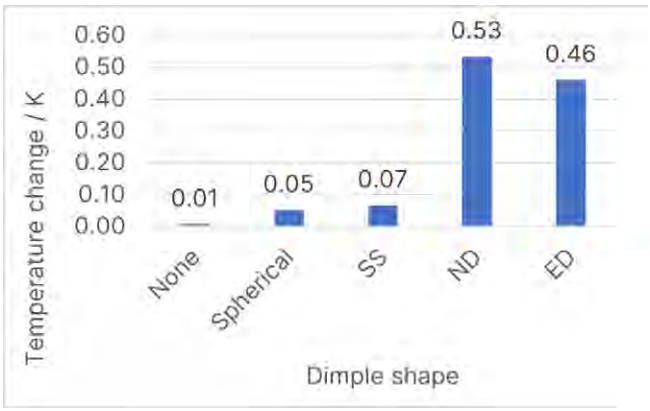

**Figure 4.** Average temperature change of water across different dimple shapes.

It was found that the primary driver for the temperature increase over the ND and ED dimples compared to the rest was the intensity of the eddies created. This was measured by comparing the average values for post-dimple turbulence kinetic energy (TKE), which represent "the mean kinetic energy per unit mass associated with eddies in turbulent flow" [6]. The values for post-dimple TKE are shown in Figure 5.

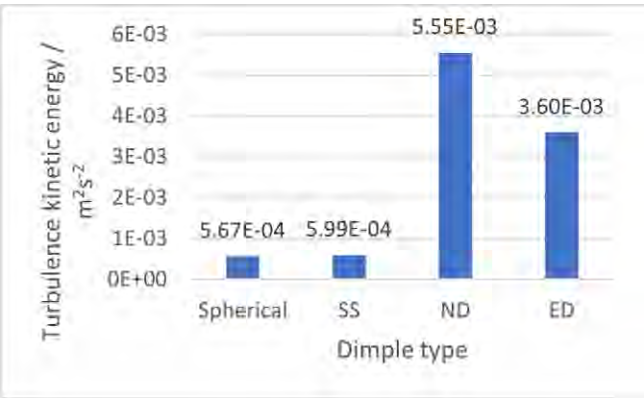

**Figure 5.** Post-dimple TKE for different dimple shapes.

Figure 5 demonstrates the effect eddies have on heat transfer as the values are proportional to the temperature values in Figure 4. Therefore, as the TKE and thus eddy intensity increases across the fluid flow, the heat transfer also increases.

Regarding the other variables that were measured – Reynolds number, pressure, and velocity – the normal distribution (ND) dimple showed surprisingly little change in most of these areas in comparison to the other dimple shapes. This is shown in Table 1.

**Table 1.** A comparison after 1.5 s between the simulation of a pipe with different dimple shapes while the fluid is heated by the pipe walls.

| **Dimple type** | ***Re* change** | ***P* change / Pa** | ***T* change / K** | ***u* change / m s$^{-1}$** |
|---|---|---|---|---|
| None | 0 | -0.3 | 0.01 | 0.00 |
| Spherical | 13536 | -82.7 | 0.05 | 0.14 |
| SS | 12597 | -78.9 | 0.07 | 0.13 |
| ND | 8480 | -142.6 | 0.53 | 0.09 |
| ED | 13354 | -141.8 | 0.46 | 0.14 |

Compared to the spherical and smoothed-spherical dimples, the ND dimple provides, at the least, 7.5 times more efficiency in terms of heat exchange with a pressure change that is less than doubled. Notably, the ND had the smallest velocity change, of the dimpled pipes, meaning the fluid had more time to heat up. The Reynolds number also had the lowest change of the dimpled pipes. However, since the fluid flow was very turbulent to begin with, and remained very turbulent throughout the pipe in all cases, a difference less than 4000 in the *Re* between the ND dimple and the spherical is negligible. Finally, while the ND dimple does prove to have the greatest pressure drop, the great increase in efficiency outweighs this minor drawback. Taking these factors into account, the ND dimple was clearly the most efficient overall and is the recommended shape, of these four, for a dimpled plate in a PHE despite the pressure drop.

## SIMULATING OVER MULTIPLE DIMPLES

### Set-up

Once the most efficient dimple shape for heat transfer was found to be the ND dimple, it was implemented multiple times into a 5 m long pipe. The distances between the dimples were varied in relation to the hydrodynamic entrance length for turbulent flow [7]:

$$\frac{L_e}{D} = 1.36Re^{\frac{1}{4}} \quad (1)$$

where $L_e$ is the entrance distance, $D$ is the inner diameter of the pipe and $Re$ is the Reynolds number. The $Re$ at the peak of the normal distribution dimple was found to be approximately 96000, giving a $L_e$ of 2.39 m. However, Çengel and Cimbala [8] write "in many pipe flows of practical engineering interest, the entrance effects become insignificant beyond a pipe length of 10 diameters" before showing that

$$L_e \approx 10D \quad (2)$$

In this case, the result obtained for the hydrodynamic entrance length was 1.0 m, thus the pipe was to be extended to 5 m for the resultant simulations. When comparing different dimple shapes, this did mean that fully developed flow had not recovered by the end of the 1 m pipe in Figure 1 and Figure 3. This made little difference to the previous single dimple shape comparison results however, as the difference in heat transfer values from one dimple shape to another will have been equally impacted.

Both $L_e$ distances were compared and gave average velocities approximately 4% from the average outlet velocity 5 m along the pipe, by which time the fluid had certainly fully developed. As both regions gave the same accuracy, the shorter 1.0 m distance was used. In industry, the shorter hydrodynamic entrance length will be favoured as more dimples can be used over a set area. This is because the fluid flow will be able to fully develop more often, and thus be disrupted more often, resulting in an increased rate of heat transfer.

Once the hydrodynamic entrance length of 1.0 m was established, simulations were run over a 5 m long pipe consisting of three ND dimples. For this setup, the following three simulations were run:

- Three ND dimples directly next to each other to simulate flow which was not at all developed. This meant that their peaks were 0.2 m from one another as the radius of the dimples was 0.1 m.
- Three ND dimples with their peaks 0.5 m apart from one another to simulate half developed (or developing) flow.

- Three ND dimples with their peaks 1.0 m apart from one another to simulate fully developed flow.

For all three of these simulations, the initial dimple was setup as before, with its peak 0.3 m into the pipe. An example of the half developed flow setup is shown below.

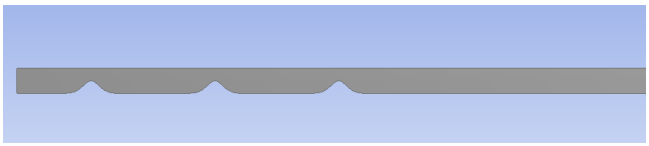

**Figure 6.** The first half of the final model for half developed flow over three ND dimples. The remainder of the pipe contains no dimples.

### Results

For multiple ND dimples, the temperature change across the entire pipe was 3.79 K, 4.54 K, and 4.97 K for a none developed flow, a half-developed flow, and a fully developed flow respectively. From this it is clear that the more developed the fluid flow is before being disrupted, the more heat is exchanged from the pipe walls to the fluid.

This is useful because it can be applied to design plates for PHEs in industry. Knowing that fully developed flow provides the best heat transfer between the plates and fluids within a PHE, companies that require specialist PHEs designed for their process should purchase plates that are distanced such to ensure fully developed flow between dimples. In this case for example, each dimple should be imprinted upon a plate 1 m apart in order to maximise heat transfer. Additionally, as the dimples are more spread out when compared to a less developed flow, firms could reduce their cost per plate as they will require a lower surface area, meaning less material is being used. Depending on the specific material required, the number of plates, and the size of the plates, the cost savings could differ significantly.

## REPEATING DIMPLES

In order to more accurately translate these results into industrial heat exchangers, ND dimples were also repeated as much as possible over a 5 m pipe, as opposed to using only three dimples. For these simulations, the dimples were repeated at distances of 0.2 m (directly next to one another), 0.4 m, 0.6 m, and 1.0 m (fully developed velocity profile).

In order from the least to most temperature change, these repeated dimples for the layouts of no dimples, 1 m between dimple peaks, 0.6 m between dimple peaks, 0.4 m between dimple peaks, and 0.2 m between dimple peaks (without the final dimple), showed average outlet temperatures of 306.4 K, 308.3 K, 309.5 K, 310.8 K, and 311.5 K respectively.

Contrary to the previous results, which showed fully developed flow to have the greatest temperature increase, these results argue in favour of the dimples being directly next to one-another, as is currently common practice in industry. However, each of these pipes, unlike in the previous simulations, have drastically different lengths – which is comparable to the surface area of a 3D model. The length of the pipe containing the dimples with their peaks 0.2 m apart had now increased by 13.9% from the original 5 m length of pipe, and a 6.2% increase in length from the pipe with dimples with 0.4 m between their peaks. As these simulations contain 0.3 m of pipe before a dimple peak is present, in an industrial setting these percentages would be even greater.

What this means is that while maintaining none-developed flow between dimples still shows promise in an industrial setting, this temperature change is offset somewhat by the increase in material required. Instead, a good alternative would be to remove every other dimple – which in this case is represented by the dimple peaks being 0.4 m apart – as it is still one of the most temperature-efficient models. This layout only has a decrease of 0.2% temperature change compared to completely none-developed flow, while saving half of the material used in the imprinting of dimples upon a plate.

## A MAJOR DRAWBACK OF 2D MODELLING

3D models are clearly the next step to further develop and analyse the results of this work.

3D models have been attempted over the course of this project. The models were created such that the different dimples to compare were the same as in the 2D models. This was done by revolving the dimple shapes around the y-axis. For these experiments, only the ND and spherical dimples were compared.

Simulations were performed over a square based pipe, and a circular based pipe. The circular based pipe however suffered from having the dimples clip through the wall, thus causing inequal losses in both volume and surface area between the different dimple shapes. This is demonstrated in Figure 7.

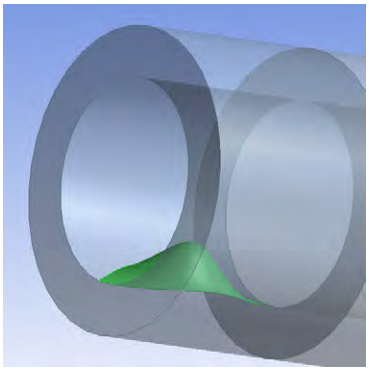

**Figure 7.** The ND dimple being cut due from the wall of a spherical pipe.

Due to this, for the following results, only the square based pipe results are presented.

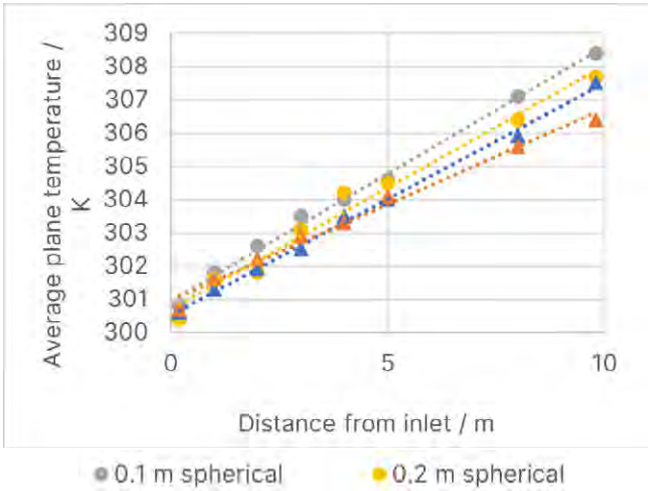

**Figure 8.** Average temperature of the fluid at different distances, both for the two dimple shapes and differing distances between dimples.

The heat transfer results shown in Figure 8 do not line up with the results achieved from the 2D simulations. This is clear as the spherical dimples outperform the ND dimples regardless of distance between dimple peaks – whether it be 0.1 m or 0.2 m for the spherical dimples, or 0.2 m and 0.4 m in the case of the ND dimples. The reason for this was that the control variable carried forward from the 2D simulations to 3D regarding dimple shape was the cross-sectional area (CSA) of the dimple. This worked well for a 2D simulation, but not when a third dimension was added.

When scaling the CSA of a 2D model up into a 3D model, the resultant measurements correlate to the volume of the dimple. These 3D simulations therefore unfairly compared the two dimple types, as they had different surface areas. This is important because the surface area should be a control variable, in order to maintain the same amount of surface in which the water could be heated over.

For future work, 3D simulations should be run with the surface areas of the dimples equal, as opposed to the cross-sectional area, which was carried over directly from its 2D counterpart.

## CONCLUSIONS & RECOMMENDATIONS FOR FUTURE WORK

The normal distribution (ND) dimple shape provided the greatest heat transfer showing an increase in temper-ature 7.5× the smoothed-spherical, with a 15% uplift from the error distribution (ED) shape. Despite having the greatest pressure drop of 142.6 Pa, the large increase in temperature far outweighed this downside.

Eddy intensity was the primary cause for this efficiency of heat exchange. The ND dimple demonstrated a 54% increase in turbulent kinetic energy over the next greatest – the ED dimple. This meant that the intensity and number of eddies produced proved more meaningful for heat transfer than the surface area of the plates.

Fully developed flow was more susceptible to being disrupted than other flow states, being 9.5% more heat transfer efficient than disrupting half developed flow, and 31% more efficient than none developed flow. However, when repeated over a larger scale, it is not wholly viable to have repeated dimples up to 1 m apart. Instead, a compromise should be made where dimples are separated by one-dimple length. In practice, this would mean removing every other dimple from the current plate-printing process. This would still ensure a high temperature change (a 0.2% decrease from none developed flow), while saving half the material used to imprint dimples.

The primary recommendation for future work is to develop and simulate 3D models for a more realistic approach and more easily applicable results to industry. This would be more demonstrative of how dimple shapes and flow development can affect heat exchange, due to its real-world nature. In contrast with the initial 3D models presented, future simulations would have dimple surface area as a control variable, in order to achieve fair an reliable results.

## ABSTRACT

This study introduces the novel application of a Multi-Task Gaussian Process (MTGP) model to predict biogas production and critical anaerobic digestion (AD) performance indicators (soluble COD, volatile fatty acids (VFAs)), addressing feedstock variability and dynamic process behavior. We compare the MTGP against the widely used mechanistic AM2 model to evaluate its accuracy and applicability for probabilistic modeling in AD systems. The MTGP framework leverages multi-output correlations and uncertainty quantification, trained on experimental data, achieving superior predictive performance over AM2in this study, with lower RMSE (SCOD: 0.32 g/L; VFAs: 0.87 mmol/L; biogas: 0.15 L/day) and higher $R^2$ values (SCOD:0.91, VFAs:0.94, biogas :0.88) under the conditions tested. While AM2 provides biochemical insights, its reliance on unvalidated assumptions may limits robustness. The flexibility of MTGP and precision suggest its potential for real-world applications such as Bayesian Optimization and Design of Experiments, enabling data-driven process enhancement without mechanistic constraints. This work establishes MTGP as a pioneering tool for AD optimization, bridging data-driven efficiency with practical bioenergy challenges.

## INTRODUCTION

Modelling and optimising anaerobic digestion (AD) processes is critical for designing wastewater treatment and biogas plants, evaluating system performance, and assessing the feasibility of diverse substrates under varying conditions [8]. AD models are broadly categorized as mechanistic models, which rely on biological, physical, and chemical principles, or empirical machine learning models, which leverage observed process data to establish relationships between inputs and outputs [8]. Mechanistic models describe AD processes through differential equations that capture bacterial growth, inhibition, and physico-chemical interactions. These models range in complexity: simpler ones address single-step processes, intermediate models like AM2 [6] incorporate multiple microbial populations and interactions, and advanced models such as ADM1 [5] offer comprehensive system descriptions but demand extensive parameter estimation. The AM2 model, in particular, balances simplicity and accuracy, making it suitable for monitoring and controlling AD processes rather than detailed simulations [9]. Machine learning techniques such as k-nearest neighbors (KNN), support vector machines (SVM), random forests (RF), artificial neural networks (ANN), Dynamic Mode Decomposition (DMD), and the Koopman operator theory [8,3,12] have all been applied to model the complex, nonlinear interactions in AD processes. In this work, we use Gaussian Process (GP) a non-parametric, Bayesian approach to regression that models the underlying distribution of data as a continuous stochastic process [4]. A GP based approach is utilised because of its capacity to manage intricate and uncertain systems. While GPs have been applied in various fields, their use in predicting biogas production from AD has not yet been tested. This problem is critical given the need for reliable models to optimise biogas production from highly variable waste materials. The GP model is used to predict biogas production and other key performance indicators in a continuous anaerobic digester fed with hydrothermal carbonization (HTC) products [1]. The feedstock consists of hydrochar and HTC liquor derived from sewage sludge

and agro-industrial waste, which exhibit significant variability in composition and degradation profiles, complicating predictive modelling. The remainder of this paper is structured as follows. Section 2 outlines the experimental procedures and data collection process, followed by the development of a mechanistic model for anaerobic digestion and a data-driven modeling approach based on Multi-Task Gaussian Processes (MTGP). Section 3 explores the structure of the dataset, presents the outcomes of parameter estimation for the mechanistic model, and evaluates the performance of the MTGP framework. A comparative analysis is provided to assess the relative strengths and limitations of the mechanistic and MTGP approaches. The paper concludes with a summary of key findings and recommendations for future work.

# METHODS

## Experimental Setup and Data Generation

The dataset used in this study stems from a 164-day AD experiment with HTC biomass as the substrate, previously detailed by the authors in [9]. The experiments investigated the effects of HTC process conditions and operational parameters, such as dilution rate (D), influent soluble chemical oxygen demand ($SCOD_{in}$), organic loading rate (OLR), and pH, on AD performance metrics, including biogas yield, effluent SCOD, and volatile fatty acids (VFA) concentrations. Conducted in laboratory-scale reactors under controlled conditions (**Figure 1**), these experiments aimed to enhance the biodegradability of organic feedstocks for improved biogas production [1]. The mechanistic AM2 model [6] was applied to describe the AD system dynamics. The same parameter estimation and simulation procedures were applied from the original study [9], ensuring consistency and facilitating direct comparisons with the MTGP approach.

## Mechanistic Model Development

In this study, the AM2 model developed within the framework of the Europe Research Project called AMOCO [6] is used due to its simplicity and accuracy in similar studies. The AM2 model represents AD in just two stages (Acidogenesis-Methanogenesis) and it is deduced from the mass balance law as in [9]:

$$\begin{aligned} \dot{S_1} &= D(S_{1in} - S_1) - k_1\mu_1(S_1)X_1 \\ \dot{X_1} &= (\mu_1(S_1) - k_{d1} - \alpha D)X_1 \\ \dot{S_2} &= D(S_{2in} - S_2) + k_2\mu_1(S_1)X_1 - k_3\mu_2(S_2)X_2 \\ \dot{X_2} &= (\mu_2(S_2) - k_{d2} - \alpha D)X_2 \end{aligned} \quad (1)$$

With

$$\mu_1(S_1) = \mu_{1max}\frac{S_1}{S_1+K_1}, \quad (2)$$

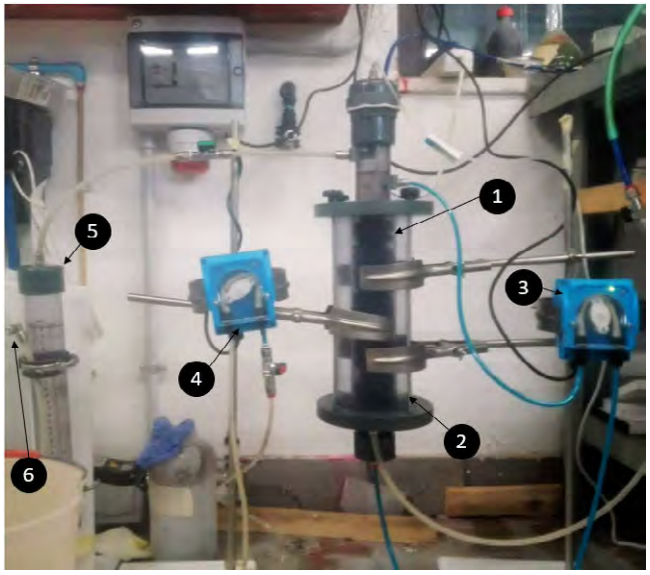

**Figure 1.** Laboratory picture of the anaerobic filter, in which: 1- Anaerobic filter, 2- Heating Jacket, 3- Recycle Pump, 4- Inlet Pump, 5- Biogas Measurement Device, 6- Outlet [1,9].

$$\mu_2(S_2) = \mu_{2max}\frac{S_2}{\frac{S_2^2}{K_i}+S_2+K_2}\left\{1 - \exp\left[-3\left(\frac{pH-pH_H}{pH_H-pH_L}\right)^2\right]\right\} \quad (3)$$

Where $X_1$ and $X_2$ represent the concentrations of acidogenic and methanogenic bacteria (g/L) respectively, while $S_1$ and $S_2$ denote the SCOD (g/L) and VFA (mmol/L) concentrations. $k_i$ are the stoichiometric coefficients associated with the two reactions. $D = \frac{F}{V}$ and $D$ is the dilution rate (F is the flow rate and V is the volume of the vessel), $S_{1in}$ and $S_{2in}$ are respectively the input concentrations of the substrates $S_1$ and $S_2$, and α is the fraction of the bacteria in the liquid phase. Death rates for $X_1$ and $X_2$ are $k_{d1}$, $k_{d2}$, respectively. The specific growth rate $\mu_1(S_1)$ and $\mu_2(S_2)$ are governed by Monod kinetics in (2) and Haldane kinetics in (3), with $\mu_{1max}$ and $\mu_{2max}$ as the maximum growth rates, $K_1$ and $K_2$ are the half-saturation constants, and $K_i$ are the inhibition constant for $S_2$. Additionally, $pH_L$ and $pH_H$ define the lower and upper pH bounds, with inhibition effects on $\mu_2(S_2)$ . The biogas flow rate ($CH_4$ plus $CO_2$) can be expressed as a function of the state variables given by:

$$Q_{biogas} = k_{gas}\mu_2(S_2)X_2 \quad (4)$$

Where $k_{gas}$ is the yield for biogas production. To identify the model that best fits the experimental data, an appropriate criterion must be selected for optimising the model's parameter vector. Various cost functions are commonly used for parameter estimation in AD models, typically based on output-error criteria that quantify the discrepancy between model outputs and actual system outputs. [9]. The sum of least squares is a widely used and effective cost function in optimisation procedures,

especially when measurement error variances fluctuate over time.

$$J(\theta) = \min \sum_{t=1}^{N} \left( \frac{Y_{Measured}(t) - Y_{Model}(t,\theta)}{Y_{Measured}(t)} \right)^2 \quad (5)$$

Where $J$ is the objective function to be minimised, $Y_{Measured}$ is the collected measurements vector, $Y_{Model}$ is the model-predicted outputs vector with respect to model parameters $\theta$ to be determined and *N* is the number of measurements point. The measurements vector $Y$ is defined by:

$$Y = \begin{bmatrix} S_1 & S_2 & Q_{biogas} \end{bmatrix}^T \quad (6)$$

The vector parameters $\theta$ is defined by:

$$\theta = \left[ \mu_{1Max}, K_1, \mu_{2Max}, K_i, K_2, k_1, k_2, k_3, k_{gas} \right]^T \quad (7)$$

The other parameters α, $k_{d1}$ and $k_{d2}$ have been fixed with analogy to [9].

## Multi-Task Gaussian Processes (MTGP)

### Gaussian Process overview

A Gaussian Process (GP) is a non-parametric, Bayesian approach to regression that models the underlying distribution of data as a continuous stochastic process [4]. GPs are well-suited for complex, nonlinear systems, as they do not require explicit formulation of system dynamics. Instead, they operate by defining a prior distribution over functions that is updated as data is observed, making them a powerful tool in predicting outputs with uncertainty quantification. A GP is commonly viewed as a prior over functions $f: \mathbb{R}^P \to \mathbb{R}$ where P denotes the dimensionality of the input space. Consider a set of P-dimensional input points $\boldsymbol{X} \in \mathbb{R}^{P \times N}$ and corresponding scalar outputs $\boldsymbol{y} \in \mathbb{R}^N$. A GP is defined by a mean function, often assumed to be zero without loss of generality, and a kernel function $k: \mathbb{R}^P \times \mathbb{R}^P \to \mathbb{R}$, which measures the similarity between input points. The GP regression model with noisy observations is expressed as:

$$\boldsymbol{y_i} = f(\boldsymbol{x}_i) + \epsilon, \quad f \sim \mathcal{GP}\left(0, k(x_i, x_i')\right), \quad (8)$$

Where $\epsilon \sim \mathcal{N}(0, \sigma^2)$ represents Gaussian noise. Alternatively, this can be written as a multivariate normal distribution:

$$\boldsymbol{y} \sim \mathcal{N}(0, \boldsymbol{K}_{XX} + \sigma^2 \boldsymbol{I}_N), \quad (9)$$

where $\boldsymbol{K}_{XX} \in \mathbb{R}^{N \times N}$ is the kernel matrix formed by evaluating $k(x_i, x_j)$ for all pairs of input points, and $\boldsymbol{I}_N$ is the identity matrix. Given a new set of inputs $\boldsymbol{X}_* \in \mathbb{R}^{P \times M}$, the conditional distribution of the corresponding outputs $\mathbf{f}_* \in \mathbb{R}^M$ is:

$$\mathbf{f}_* | \, \boldsymbol{y}, \boldsymbol{X}, \boldsymbol{X}_* \sim \mathcal{N}(\mu, \Sigma), \quad (10)$$

Where:

$$\mu = \boldsymbol{K}_{\boldsymbol{X}_* \boldsymbol{X}} \boldsymbol{K}_{\boldsymbol{XX}}^{-1} \boldsymbol{y}, \quad (11)$$

$$\Sigma = \boldsymbol{K}_{\boldsymbol{X}_* \boldsymbol{X}_*} - \boldsymbol{K}_{\boldsymbol{X}_* \boldsymbol{X}} \boldsymbol{K}_{\boldsymbol{XX}}^{-1} \boldsymbol{K}_{\boldsymbol{X} \boldsymbol{X}_*}. \quad (12)$$

The presented traditional GPs are limited to producing a single scalar output, but in many cases, it is essential to explore the relationship between inputs and multiple outputs.

### Multi-Output gaussian processes:

Standard GPs accommodate only a single scalar output. In practical applications, however, multiple outputs are often desired, such that $f: \mathbb{R}^P \to \mathbb{R}^Q$, where $Q$ denotes the number of outputs. A naïve solution involves employing $Q$ independent GPs, each modeling one output dimension [7]. However, this neglects correlations between outputs. To address this, advanced approaches like the Linear Model of Coregionalization (LMC) [10] have been developed. The LMC assumes L shared latent Gaussian processes $\{f_\ell\}_{\ell=1}^L$. The observed outputs for sample *i* are modeled as:

$$\boldsymbol{y_i} = \boldsymbol{W} \mathbf{f_i} + \boldsymbol{\epsilon}, \quad (13)$$

where $\mathbf{f_i} = [\mathrm{f_1(x_i)}, \ldots, \mathrm{f_L(x_i)}]^\top$, $\boldsymbol{W} \in \mathbb{R}^{\mathrm{Q} \times \mathrm{L}}$ is a matrix of loadings that maps latent functions to outputs, and $\boldsymbol{\epsilon} \sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{\sigma^2 I}_Q)$, Each latent function $f_\ell$ is drawn from a GP:

$$f_\ell \sim \mathcal{GP}(\boldsymbol{0}, \boldsymbol{K_\ell}) \quad (14)$$

where $\boldsymbol{K_\ell}$ is the kernel function for the $\boldsymbol{\ell}$-th latent GP. The covariance between outputs $y_{iq}$ and $y_{jq'}$ is given by:

$$Cov(y_{iq}, y_{jq'}) = \sum_{\ell=1}^{L} k_\ell(\boldsymbol{x}_i, \boldsymbol{x}_j) w_{q\ell} w_{q'\ell}, \quad (15)$$

where $w_{q\ell}$ is the element of $\boldsymbol{W}$ at row q and column $\boldsymbol{\ell}$. The joint distribution of all outputs $\boldsymbol{Y}$ is multivariate normal:

$$vec(\boldsymbol{Y}) \sim \mathcal{N}(\boldsymbol{0}, \Sigma + \boldsymbol{\sigma^2 I}_{NQ}), \quad (16)$$

Where:

$$\Sigma = \sum_{\ell=1}^{L} \boldsymbol{K}_\ell \otimes \boldsymbol{w}_\ell \boldsymbol{w}_\ell^\top, \quad (17)$$

with $\otimes$ denoting the Kronecker product and $vec\,(\cdot)$ the vectorization operator. If all latent GPs share the same kernel function, the covariance simplifies to:

$$\Sigma = \boldsymbol{K} \otimes \boldsymbol{W} \boldsymbol{W}^\top, \quad (18)$$

This model captures output correlations through $\boldsymbol{W}$, allowing flexible multi-output modelling while preserving non-linearities from the latent GPs. For this study, the MTGP framework jointly models three key AD outputs: biogas production $Q_{biogas}$, SCOD, and VFA concentrations.

Each task is modelled by a shared latent function structure, leveraging the correlations between outputs to improve overall prediction accuracy. We adopt the LMC with a Radial Basis Function kernel for latent functions:

$$k(x, x') = \sum_{\ell=1}^{L} B_\ell \exp\left(-\frac{||x-x'||^2}{2l_\ell^2}\right), \quad (19)$$

where $B_\ell$ is a coregionalisation matrix for latent function $\ell$, $l_\ell$ is the length scale, and L is the number of latent functions. The MTGP prior for task outputs $\mathbf{f} = [\mathbf{f}_1, \ldots, \mathbf{f}_D]$ follows:

$$\mathbf{f} \sim \mathcal{N}(0, \boldsymbol{K_f}), \quad (20)$$

where $\boldsymbol{K_f} = \sum_{\ell=1}^{L} \boldsymbol{B}_\ell \otimes \boldsymbol{K}_\ell(\boldsymbol{X}, \boldsymbol{X})$ capturing within-task and cross-task covariances. The MTGP model, trained over AD data across various conditions, maximises marginal likelihood using an Adam optimiser [11]. The likelihood is:

$$\log p(\boldsymbol{Y}|\boldsymbol{\theta}) = -\frac{1}{2}\boldsymbol{Y}^\top \boldsymbol{K_f^{-1}} \boldsymbol{Y} - \frac{1}{2}\log|\boldsymbol{K_f}| - \frac{nD}{2}\log(2\pi), \quad (21)$$

where $\boldsymbol{\theta}$ comprises hyperparameters. For new input $\boldsymbol{X}_*$ the predictive mean and variance are:

$$\boldsymbol{\mu}_* = \mathbf{K}(\mathbf{X}_*, \mathbf{X})\mathbf{K_f^{-1}}\mathbf{Y}, \quad (22)$$

$$\boldsymbol{\Sigma}_* = \boldsymbol{K}(\boldsymbol{X}_*, \boldsymbol{X}_*) - \boldsymbol{K}(\boldsymbol{X}_*, \boldsymbol{X})\boldsymbol{K_f^{-1}}\boldsymbol{K}(\boldsymbol{X}, \boldsymbol{X}_*). \quad (23)$$

These equations provide predictions along with uncertainty estimates, which are essential for assessing the reliability of all output's forecasts.

# RESULTS AND DISSCUSION

## Data Structure and Preprocessing

The dataset includes time-series input parameters (time, D, $SCOD_{in}$, OLR, and pH) and outputs (SCOD, VFA, and biogas production). Pre-processing steps included: i) Interpolation of missing or irregular data using cubic splines for consistent time scales; ii) Log transformation of outputs (with a small constant added) to stabilize variance and enhance model performance; and iii) Data splitting into training (one-third of the data) and testing subsets (half of the data) to ensure balanced coverage of operational variability for model development and validation. To assess the accuracy of the models, statistical metrics were calculated for each output, such as Root Mean Squared Error (RMSE) given by:

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}\left(Y_{Model,i} - Y_{Measuredi}\right)^2} \quad (24)$$

and the coefficient of determination ($R^2$) given by:

$$R^2 = 1 - \frac{\sum_{i=1}^{n}\left(Y_{Measured,i} - Y_{Model,i}\right)^2}{\sum_{i=1}^{n}\left(Y_{Measured,i} - \overline{Y}_{Measured}\right)^2} \quad (25)$$

Where $\overline{Y}_{Measured}$: Mean of the observed values

## Parameter Estimation for the AM2 Model

The AM2 model was employed to describe the dynamics of the AD process under investigation. Parameter estimation was conducted using the Pyomo optimisation framework with the IPOPT solver, offering an efficient and robust alternative to the MATLAB approach used in [9]. This procedure calibrated key kinetic and stoichiometric parameters based on a 164-day experimental dataset. Initial conditions and parameter guesses were derived from [9], and the optimisation problem was formulated as a nonlinear program. **Figure 2** compares model predictions for SCOD ($S_1$), VFA ($S_2$), and biogas production ($Q_{biogas}$) with experimental data, showing agreement. **Table 1** presents the estimated parameters, reflecting the kinetic and stoichiometric characteristics of the AD process. These parameters reflect the influence of HTC-treated substrates on microbial kinetics and reactor performance. The results confirm the utility of the AM2 model as a mechanistic tool for understanding and predicting the behavior of AD systems. The calibrated parameters provide valuable insights into substrate degradation and methane production dynamic, however there are clear areas of poor predictive performance.

**Table 1:** Estimated model parameter values

| Parameter | Value | Unit |
|---|---|---|
| $\mu_{1_{max}}$ | 0.04 | 1/day |
| $K_1$ | 31.01 | g/L |
| $\mu_{2_{max}}$ | 0.08 | 1/day |
| $K_i$ | 19.93 | mmol/L |
| $K_2$ | 125.42 | mmol/L |
| $k_1$ | 2374.50 | -- |
| $k_2$ | 2975.26 | mmol/L |
| $k_3$ | 11558.51 | mmol/L |
| $k_{gas}$ | 593 | mmol/L |

## Multi-Task Gaussian Processes for Biogas Production Modeling

In this section, a data-driven approach was employed to predict AD outputs. The method leverages a MTGP framework, exploiting correlations among these multiple outputs to enhance predictive accuracy while providing uncertainty quantification. A dataset of $N$= 164 samples (where $N$ corresponds to the total number of time points in the experiment) was compiled to include five operational parameters: time, dilution rate D, influent SCOD, OLR, and pH as inputs to the GP. These were stacked into a matrix $\mathbf{X} \in \mathbb{R}^{164\times5}$. Three outputs: SCOD, VFA, and biogas production, were similarly arranged into a matrix $\mathbf{Y} \in \mathbb{R}^{164\times3}$. The MTGP model leverages a variational inference strategy, enabling simultaneous

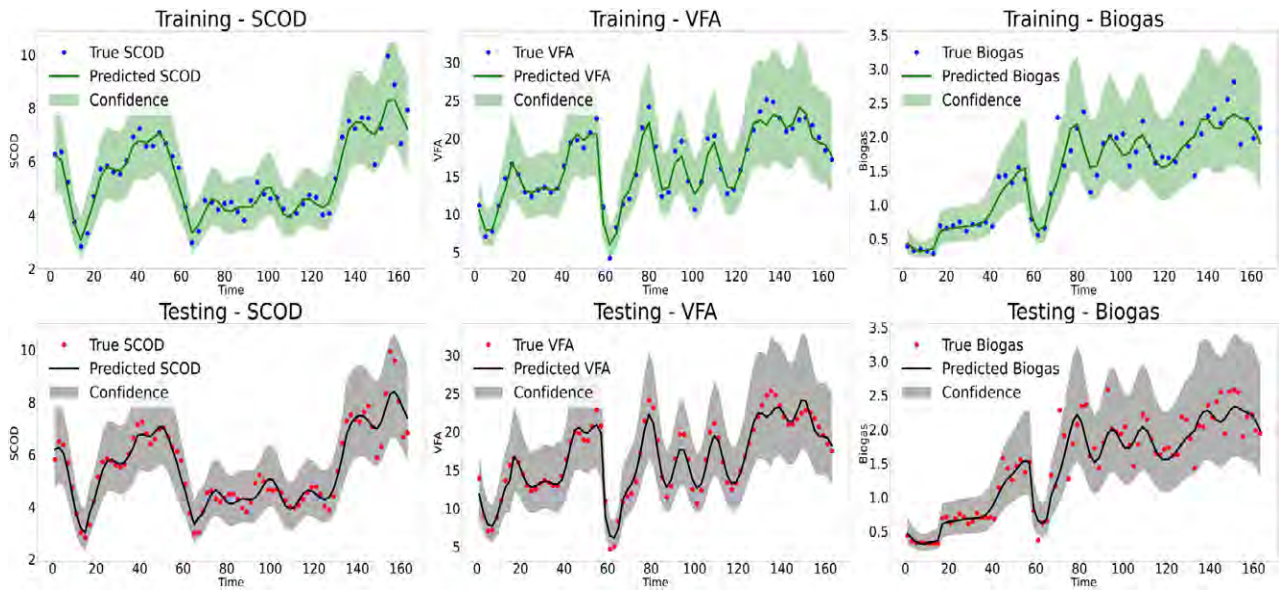

**Figure 3:** Comparison of MTGP model predictions with measured data for SCOD, VFA, and biogas production: training predictions and testing predictions, illustrating the model's performance in capturing AD outputs.

modelling of multiple outputs. Using the LMC with three latent functions, the model effectively shared information across tasks. With a training set of 55 data points, all served as inducing points, optimising computational efficiency for multi-output modelling. Confidence intervals provided insights into time points or operational regimes with greater uncertainty, crucial for real-world applications where factors like pH and substrate variability affect biogas yields. **Figure 3** illustrates the model's strong performance in tracking SCOD, VFA, and biogas production for both training and testing data, with confidence intervals conveying predictive accuracy and uncertainty. The MTGP framework demonstrated robust capabilities in capturing interdependencies among outputs, with inter-task learning enhancing predictive accuracy.

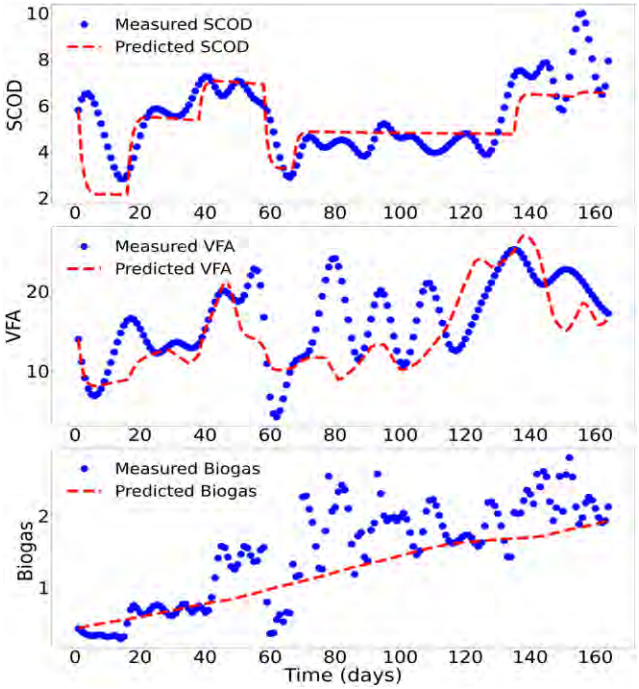

**Figure 2.** AM2 Model fit with experimental data using the set of optimal parameters obtained

## Model Performance Comparison

The evaluation metrics presented in **Table 2** and **Table 3** highlight a performance difference between the AM2 mechanistic model and the MTGP model. For SCOD predictions, the MTGP model achieved a lower RMSE (0.32 g/L) and a higher $R^2$ value (0.91) compared to the AM2 model (RMSE: 1.37 g/L, $R^2$: 0.15) in this dataset.

Similarly, for VFA predictions, the MTGP model showed improved accuracy for the conditions tested, with an RMSE of 0.87 mmol/L and $R^2$of 0.94, appearing to outperform the AM2 model, which had an RMSE of 4.62 mmol/L and $R^2$ of 0.11. For biogas production, the MTGP model also showed better predictive performance with an RMSE of 0.15 L/day and $R^2$ of 0.88, as compared to the AM2 model's RMSE of 0.47 L/day and $R^2$ of 0.52. These results suggest that the MTGP model can leverage multi-task learning and inter-output correlations to potentially yield more accurate and reliable predictions across all key outputs in this study. The comparison between the AM2 mechanistic model and the MTGP model highlights complementary strengths in their approaches to modeling AD processes. While the MTGP model exhibits superior predictive accuracy, with significantly lower RMSE and higher $R^2$ values across all outputs (**Table 3**), the AM2 model's interpretability and biochemical grounding remain critical assets. The AM2 model captures the intricate biochemical and microbial dynamics of AD, which are essential for understanding the underlying system behavior. The AM2 model incorporates acidogenic/methanogenic biomass states, enhancing biological interpretability, but its reliance on unmeasured microbial groups and assumed kinetics (e.g., growth rates) introduces predictive uncertainty without experimental validation. In contrast, the MTGP avoids microbial complexity, simplifying calibration at the cost of mechanistic detail.

**Table 2:** The RMSE and $R^2$ for the AM2 model

| Measurements | RMSE | $R^2$ | Unit |
|---|---|---|---|
| SCOD($S_1$) | 1.37 | 0.15 | g/L |
| VFA($S_2$) | 4.62 | 0.11 | Mmol/L |
| Biogas ($Q_{biogas}$) | 0.47 | 0.52 | L/day |

**Table 3:** The RMSE and $R^2$ for the MTGP model

| Measurements | RMSE | $R^2$ | Unit |
|---|---|---|---|
| SCOD | 0.32 | 0.91 | g/L |
| VFA | 0.87 | 0.94 | Mmol/L |
| Biogas | 0.15 | 0.88 | L/day |

## CONCLUSION

This work demonstrates the application of Multi-Task Gaussian Processes as a powerful data-driven framework for modelling and predicting the performance of AD systems. By leveraging input-output correlations and employing the linear model of coregionalisation, the MTGP model demonstrated improved predictive accuracy compared to the AM2 mechanistic model. While MTGP showed strong predictive accuracy and adaptability in this context, the AM2 model provided essential interpretability and biochemical insights, underscoring the complementary strengths of these two approaches.

Future research should explore the integration of these two approaches into hybrid models that combine the interpretability of mechanistic frameworks with the predictive power of data-driven techniques.

## ABSTRACT

The synthesis of membrane networks to recover components from liquid mixture is challenging due to an extensive array of feasible network configurations and the added complexity of modeling membrane permeators caused by nonidealities in liquid mixtures. We present a mixed-integer nonlinear programming (MINLP) framework for synthesizing membrane networks to recover multiple components from liquid mixtures. First, we develop a physics-based nonlinear surrogate model to accurately describe crossflow membrane permeation. Second, we propose a richly connected superstructure to represent numerous potential network configurations. Third, the two aforementioned elements are integrated into an MINLP model to determine the optimal network configuration. Finally, the effectiveness of the proposed approach is demonstrated through a range of applications.

**Keywords**: Liquid Mixture Separations, Membrane Network Synthesis, Superstructure-based Optimization, Mixed-Integer Nonlinear Programming.

## INTRODUCTION

Membranes for liquid separation are recognized as a promising technology, offering several advantages including low energy requirements and chemical-free operation [1]. Polymeric membranes, in particular, have emerged as a preferred choice due to their scalability. The two key properties of polymeric membranes are permeability and selectivity. High permeability facilitates enhanced recovery, while high selectivity ensures high purity. However, polymeric membranes inherently exhibit a trade-off between selectivity and permeability [2]. Therefore, utilizing a single-stage membrane unit to achieve both high recovery and purity simultaneously is often impractical or incurs high operating and capital costs. To address this limitation, a multi-stage membrane network must be synthesized.

Multiple configurations of membrane networks, differentiated by the number of membrane stages and stream connections, can be synthesized for a given separation task. However, the energy consumptions and capital costs of these configurations can vary significantly depending on the total utilized membrane area and the operating conditions. The two primary methods for synthesizing membrane networks are simulation-based and optimization-based methods. In the former, a network is chosen from various potential network configurations and the operating conditions are subsequently determined [3]. However, with an increase in the number of membrane stages, this method becomes increasingly cumbersome due to the significant increase in the number of potential network configurations, so only a limited number of network configurations can be evaluated, potentially leading to suboptimal designs. In optimization-based methods, the network configuration and operating conditions are determined simultaneously by solving an optimization model [4]. In general, a superstructure is constructed to include all potential network configurations. Then, a mixed-integer nonlinear programming (MINLP) model is formulated based on the superstructure, with binary and continuous variables used to represent the configurational and operational decisions, respectively. However, the accuracy of unit models is limited due to the approximations required to formulate a computationally tractable optimization model. This work

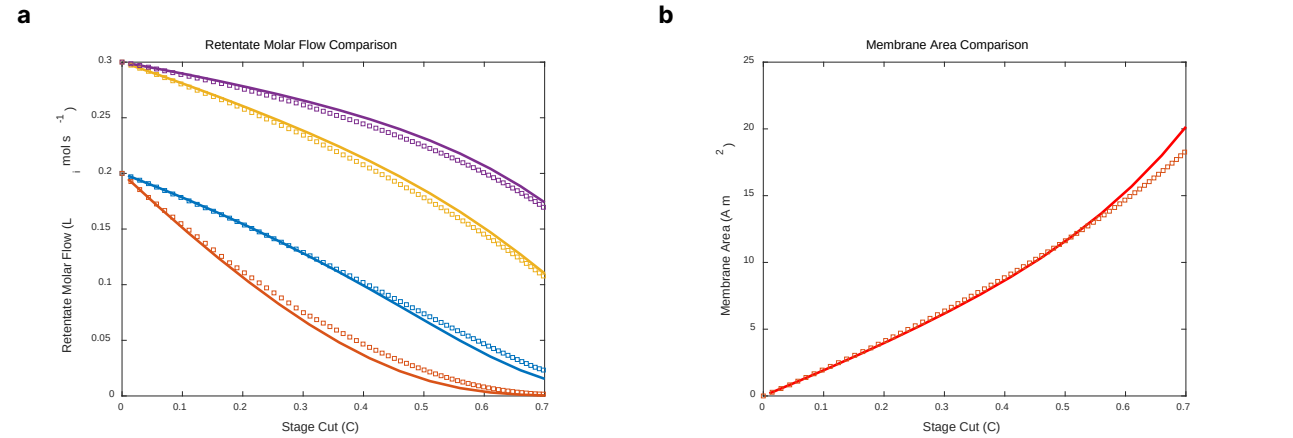

**Figure 1:** Comparison between the NLAE (solid lines) and the DAE (square markers) unit model. **a,** Retentate flow rate comparison: Blue, orange, yellow, and violet colors represent the flow rate of methyl acetate, ethyl acetate, isopropanol, and 1-butanol, respectively. **b**, membrane area comparison.

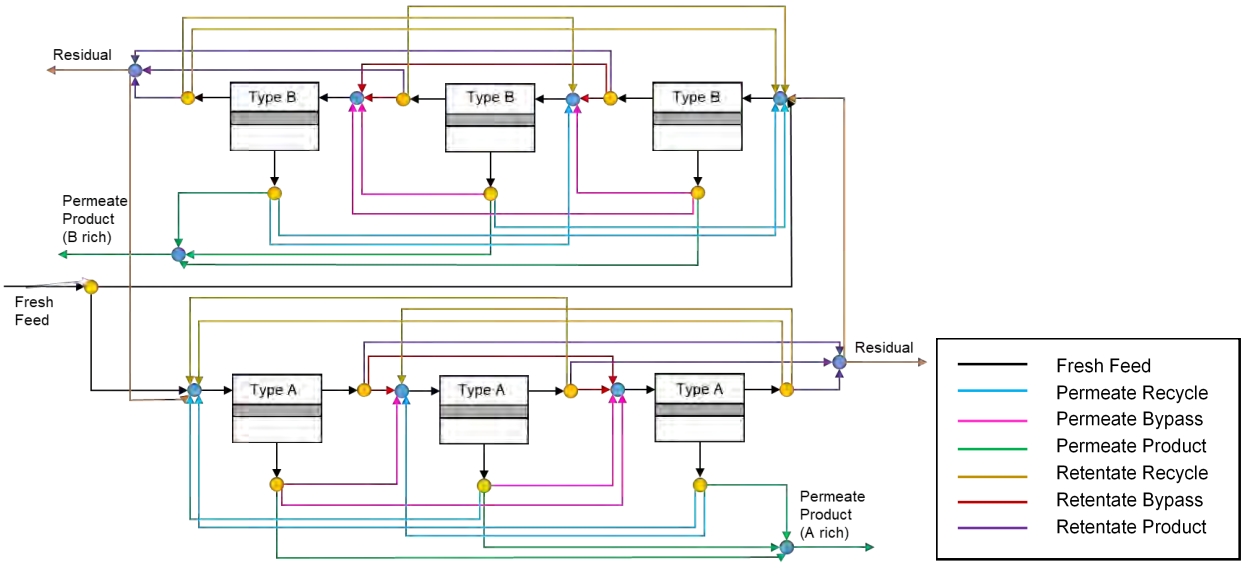

**Figure 2:** Schematic of a superstructure with two sub-network, each with three stages, with distinct membrane types. Yellow and blue disks represent splitters and mixers, respectively.

addresses this limitation by using an accurate membrane unit model.

Various membrane unit models for gas separation have been proposed. Marriott and Sørensen incorporated mass, momentum, and energy balances, employing partial differential-algebraic equations (PDAE), to model membrane separation [5]. The crossflow models proposed by Weller and Steiner [6] and Shindo et al. [7], formulated as differential-algebraic equations (DAE), have been commonly utilized to model the separation of gas and liquid mixture. However, integrating PDAE/DAE systems in an optimization model to achieve a globally optimal solution presents significant challenges [8]. Thus, various discretization techniques are employed to reformulate the PDAE/DAE systems into a system of algebraic equations. However, discretization schemes involve a trade-off between model complexity and solution accuracy. While finer discretization provides high accuracy, it also increases the number of nonlinear equations, making it computationally challenging to attain global optimality. Additionally, building on the work of Weller and Steiner [6] and Shindo et al. [8], Chen et al. [9] and Taifan and Maravelias [10] developed a unit model for the separation of multicomponent gas mixtures. Moreover, Chavez Velasco et al. [11] developed a unit model specifically for the separation of binary liquid mixtures. As a result, current unit models are limited to the separation of either binary liquid mixtures or multicomponent gas mixtures. Thus, there is a critical gap in the development of membrane unit models for the separation of multicomponent liquid mixtures.

Numerous computational methods have been proposed for the synthesis of membrane networks. Pathare and Agrawal [12] devised a method that

systematically enumerates all networks and solves a nonlinear program (NLP) for each. However, this approach becomes increasingly computationally intensive as the number of potential networks increases. Other existing optimization models for synthesizing membrane networks typically rely on local optimization or meta-heuristic methods [13–15]. The studies aiming to obtain global optimality generally focus on the separation of binary mixtures [11,14]. Moreover, the optimization models developed by Chen et al. [9] and Taifan and Maravelias [10] specifically target multicomponent gas mixtures and impose restrictions on the stream connections within the membrane network superstructure. This limitation excludes some feasible network configurations, potentially leading to suboptimal solutions.

In this work, we present a novel approach for synthesizing optimal membrane networks for multicomponent liquid mixture separation [16]. We propose a generalized optimization model that incorporates three elements. First, we develop a physics-based nonlinear surrogate unit model to describe crossflow membrane permeation for multicomponent liquid mixtures. Second, we propose a highly interconnected superstructure to represent an extensive array of potential network configurations. Third, we formulate an optimization model to determine the configuration and operating conditions that minimize the total required membrane area. Finally, we present multiple applications to showcase the effectiveness of our approach.

## MEMBRANE UNIT MODEL

First, we adapt the DAE-based crossflow membrane unit model from Shindo et al. [7] for multicomponent liquid mixtures. Next, the DAE unit model is reformulated to a nonlinear algebraic unit model (NLAE). Finally, we assess accuracy by comparing the NLAE unit model with the original DAE model.

### DAE Unit Model

In an idealized crossflow membrane unit, the liquid mixture on the feed-side exhibits plug flow with no longitudinal mixing. The permeating components selectively pass through the membrane and enter the permeate-side without mixing with the permeate bulk flow. The DAE unit model is based on the following assumptions: (1) component permeabilities are independent of pressure and composition, (2) material transport follows Fick's law of diffusion, (3) negligible concentration polarization, (4) only transmembrane pressure drop is observed, (5) isothermal operation, (6) negligible mass transfer resistance, and (7) uniform membrane thickness. In the DAE model, material transport across polymeric membranes is described by the solution-diffusion theory, which has been widely employed and extensively validated against experimental data from physical systems [17]. The DAE unit model for the pervaporation process is given by the following equations [7]:

$$\frac{dF_i^{\mathrm{F}}}{dA} = -\pi_i\left(G_i\hat{X}_i - \tau_i\hat{Y}_i\right) \qquad \forall\, i \in \mathbf{I} \qquad (1)$$

$$\hat{Y}_i = \frac{\pi_i(G_i\hat{X}_i - \tau_i\hat{Y}_i)}{\sum_{i'\in\mathbf{I}}\pi_{i'}(G_{i'}\hat{X}_{i'} - \tau_{i'}\hat{Y}_{i'})} \qquad \forall\, i \in \mathbf{I} \qquad (2)$$

$$\dot{F}^{\mathrm{F}}\hat{X}_i = F_i \qquad \forall\, i \in \mathbf{I} \qquad (3)$$

$$F_i^{\mathrm{F}}\big|_{\dot{F}^{\mathrm{F}}=\dot{F}} = F_i \qquad \forall\, i \in \mathbf{I} \qquad (4)$$

where $\hat{X}_i/\hat{Y}_i$ represent the molar fraction of component $i$ on the feed-side/permeate-side, while $F_i^{\mathrm{F}}/F_i$ and $\dot{F}^{\mathrm{F}}/\dot{F}$ denote the molar flow rate of component $i$ in the feed-side/fresh feed and the total molar flow rate in the feed-side/fresh feed, respectively; $G_i, \tau_i,$ and $\pi_i$ represent the activity coefficient, normalized permeate pressure, and permeance of component $i$, respectively. Finally, given the initial conditions and the desired separation specifications, composition profiles and the required membrane area can be determined.

### NLAE Unit Model

Discretization schemes are primarily employed to convert DAE systems into algebraic equations. However, this approach increases computational complexity, making it difficult for optimization solvers to achieve global optimality. We utilize a different approach, based on the assumption of a uniform collective driving force, $B$, and activity coefficients, $G_i$, across the membrane surface. The DAE model can be reformulated into differential equations, which can be integrated to obtain the following set of nonlinear algebraic equations:

$$\ln\left(\frac{L_i}{F_i}\right) = \left(\frac{\pi_i G_i}{B+\pi_i\tau_i}\right)\ln(1-C) \qquad \forall\, i \in \mathbf{I} \qquad (5)$$

$$\sum_{i\in\mathbf{I}} L_i = (1-C)\sum_{i\in\mathbf{I}} F_i \qquad (6)$$

$$A = \frac{1}{B}\left(\dot{F} - \dot{L}\right) \qquad (7)$$

where $F_i/L_i$ and $\dot{F}/\dot{L}$ are the molar flow rates of component $i$ and the total molar flow rate in the feed/retentate stream, while $C$ and $A$ represents the stage cut and the required area, respectively. Detailed reformulation steps are provided in the Supplementary Material. Further, the accuracy of the NLAE unit model is essential for its integration in the optimization model. Thus, we validate the developed NLAE unit model by comparing it with the DAE unit model using simulations in MATLAB, focusing on two key variables: the retentate flow rate and the membrane area, under varying final stage cut, $C$, for both models. Data for the simulation is provided in the Supplementary Material. For the DAE unit model, the retentate flow rate and the membrane area are determined by solving Eq. $(1), (2), (3),$ and $(4)$, while

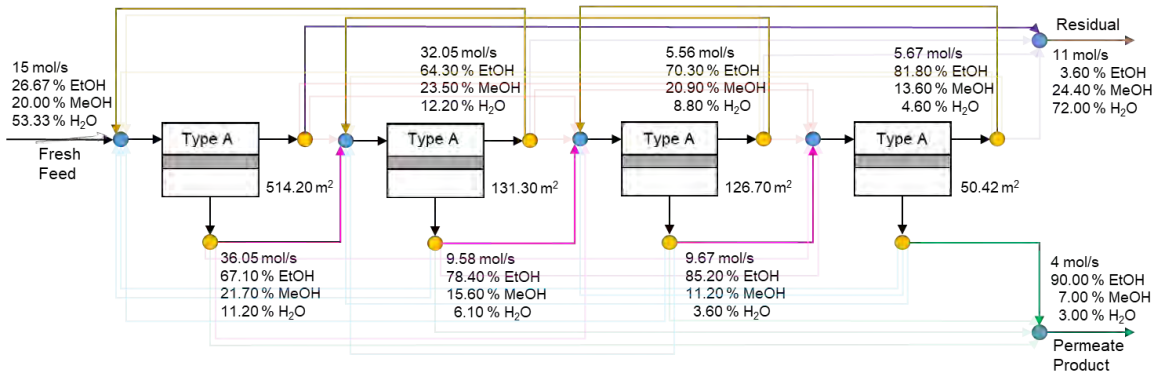

**Figure 3:** Single component separation: global optimal network to recover EtOH at the desired recovery and purity of 90%.

for the NLAE unit model, they are calculated using Eq. $(5), (6), \text{and } (7)$. Consequently, the comparison between the two unit models, shown in Figure 1, demonstrates good agreement.

## SUPERSTRUCTURE REPRESENTATION

We present a superstructure with rich interconnections designed to recover multiple target components from a liquid mixture. The superstructure can employ distinct membrane materials, each specifically selective for different target components. Moreover, it incorporates multiple sub-networks that are interconnected to achieve the required separation task. Within each sub-network, the superstructure employs a unique membrane material and allows for: (1) a retentate/permeate to be sent to any of the previous stages as a retentate/permeate recycle, (2) a retentate/permeate to be sent to any of the subsequent stages as a retentate/permeate bypass, and (3) a retentate/permeate to be collected from any stage as a retentate/permeate product. The permeate final product from a sub-network contains a recovered target component, while the retentate final product is fed into other sub-networks for further separation of remaining target components. Additionally, each sub-network utilizes one mixer for each feed entering a stage, two mixers for retentate and permeate products, two splitters for each retentate and permeate leaving a stage, and one splitter for the fresh feed stream. Finally, to minimize the number of symmetrical solutions, the fresh feed is allowed to enter only the first stage of each sub-network. For illustration, Figure 2 shows a schematic of a superstructure with two sub-networks, each with three stages employing Type A and Type B membranes, to recover target components A and B from a liquid mixture, respectively.

In the mathematical formulation, binary variables are utilized to denote the activation of membrane stages for specific membrane types. Thus, the binary variable $Z_{n,m}$ is introduced to denote whether stage $n$ of membrane type $m$ is active. Additionally, the location of the fresh feed inlet to one of the sub-networks plays a critical role. Therefore, the binary variable $Y_m$ is used to denote if the fresh feed enters the sub-network with membrane type $m$. Further, material balances are introduced around all the mixers, splitters, and around each stage of the sub-network. A detailed mathematical formulation is provided in the Supplementary Material. In practical applications, condensers and pumps are utilized to condense permeate vapors and adjust the pressure of the permeate stream for further recycling, bypassing, or collection of the permeate. However, the objective of the proposed model is to minimize the overall membrane area. Thus, calculations for condenser and vacuum pump units are excluded.

## APPLICATIONS

First, we study the behaviour of a membrane network that utilizes a single sub-network with a unique material for the separation of one target component from an alcohol/water mixture. Second, we show the effectiveness of the proposed method using an example with three components for the simultaneous separation of two target components. All optimization models are written in GAMS 46.4.1 and are solved using BARON 24.3.10 on a Windows machine with a 1.60 GHz CPU and 32 GB RAM.

### Single Component Separation

We analyze a membrane network system that processes a fresh feed, pressurized at 1 atm with a flow rate of 15 mol/s, of an alcohol/water mixture. The mixture consists of 26.67% ethanol (EtOH), 20% methanol (MeOH) and 53.33% water ($H_2O$) on a molar basis. The feed-side pressure in a membrane unit is set to match the pressure of the fresh feed, while the permeate-side

pressure is maintained at 0.01 atm to facilitate pervaporation. Isothermal operation is assumed at 323.15 K. The permeance values for EtOH, MeOH, and $H_2O$ for an ethanol-selective membrane are 0.088, 0.051, 0.018 (mol/m$^2$/s), and for a methanol-selective membrane type are 0.025, 0.18, 0.018 (mol/m$^2$/s) respectively, which fall in the range of Nafion membranes.

The proposed model is employed with a single membrane type, thus we construct a four-stage superstructure with an ethanol-selective membrane type (Type A), as shown in Figure S1. First, we determine the optimal network for the separation of ethanol from the liquid mixture at the desired purity and recovery of 90%. The model contains 309 equations and 247 variables (4 binaries) and is solved to global optimality within 60 s. The global optimal network configuration, shown in Figure 3, requires four membrane stages with a total area of 204.87 m$^2$. In the optimal network, EtOH permeates through the active stages of Type A membrane and is bypassed to the subsequent stages, facilitating effective separation by concentrating the EtOH rich permeate. Accordingly, the final permeate product is collected from the last stage meeting the higher recovery and purity specifications, while the residual mixture is collected as the retentate final product.

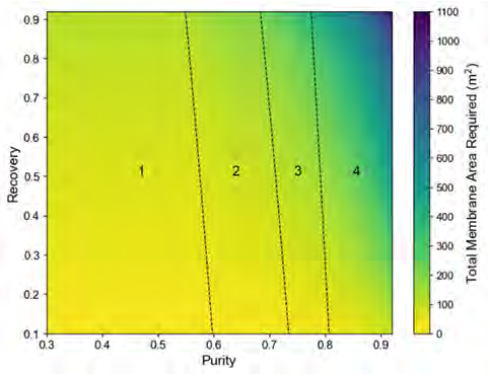

**Figure 4:** Total membrane area and number of required stages under varying recovery and purity specifications.

Next, we study the impact of purity and recovery specifications for EtOH on the network's configuration and operation by solving the model under varying purity and recovery specifications. Figure 4 illustrates the variation in the total required area and the number of stages needed as the desired recovery and purity increase. Accordingly, the purity specification significantly influences the network design, including the number of required stages and the total required area, compared to the specified recovery. However, the purity threshold for installing an additional stage is lower at higher recovery, suggesting a modest impact of specified recovery on network performance.

## Two Component Separation

The separation and recovery of iso-butanol (i-BuOH) and ethanol (EtOH) are of significant importance in biological systems, particularly in the context of biofuel production and sustainable energy solutions. However, their separation presents challenges due to their similar boiling points and azeotropic behaviours. Therefore, membrane-based separation technology can be employed to effectively recover both i-BuOH and EtOH. In this example, we study the simultaneous separation and recovery of i-BuOH and EtOH from an aqueous mixture using a multi-material membrane network system. We consider a fresh feed pressurized at 1 atm with a flow rate of 15 mol/s, consisting of an aqueous i-BuOH/EtOH mixture. This mixture comprises 26.67% i-BuOH, 20% EtOH and 53.33% water ($H_2O$) on a molar basis. The feed-side pressure in a membrane unit is set to match the pressure of the fresh feed, while the permeate-side pressure is maintained at 0.01 atm to facilitate pervaporation. Isothermal operation at 323.15 K is assumed. Permeance values for i-BuOH, EtOH, and $H_2O$ for an iso-butanol-selective membrane are 0.057, 0.023, 0.017 (mol/m$^2$/s), and for an ethanol-selective membrane type are 0.004, 0.138, 0.017 (mol/m$^2$/s), respectively.

We employ an iso-butanol-selective membrane type (Type A) and an ethanol-selective membrane type (Type B) across two interconnected sub-networks (see Figure 2). Additionally, we allow each sub-network to include four stages to facilitate separation at higher purity and recovery specifications. The proposed model is solved at the desired purity and recovery specification of 90% for both i-BuOH and EtOH, respectively. The model consists of 506 equations and 495 variables (10 binaries) and is solved to global optimality within 240 s. The globally optimal network configuration is shown in Figure 5.

The optimal network incorporates three stages of Type B membrane and utilizes all four available stages of Type A membrane, requiring a total area of 1158.3 m$^2$. The higher permeance of EtOH in Type B membrane, compared to the permeance of i-BuOH in Type A membrane, facilitates the separation of EtOH as the initial step. Therefore, the fresh feed is fed to the sub-network with Type B membranes. As a result, EtOH is first separated and gets collected in the final permeate product in the sub-network with Type B membranes. In contrast, the final retentate product from the sub-network with Type B membranes, mainly comprising i-BuOH and $H_2O$, is subsequently fed to the sub-network with Type A membranes for the further separation of i-BuOH from the remaining aqueous mixture. Finally, i-BuOH is separated and collected as the final permeate product from the sub-network with Type A membranes, while the remaining aqueous mixture, predominantly

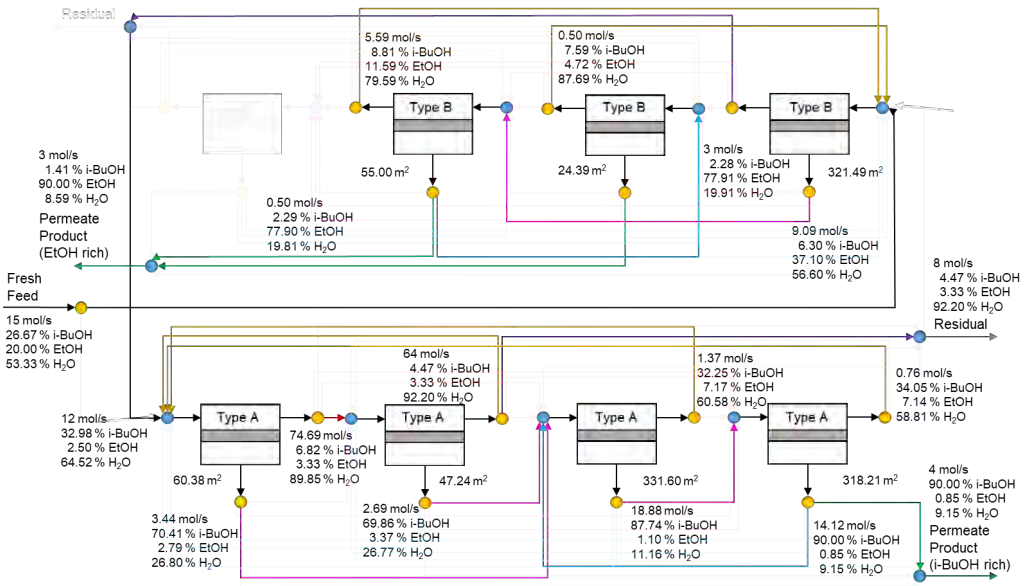

**Figure 5:** Two component separation: global optimal network to recover i-BuOH and EtOH at the desired recovery

containing $H_2O$, is collected as the residual.

## CONCLUSIONS

In this study, we proposed an optimization model for membrane network synthesis tailored for the separation of multiple components from liquid mixtures. First, we developed a physics-based nonlinear surrogate model to describe pervaporation-based crossflow membrane permeation for liquid mixtures. Second, we proposed a comprehensive superstructure, incorporating multiple sub-networks, each with distinct membrane types, featuring multiple stages with rich stream interconnections. Third, we formulated a mixed-integer nonlinear programming model, integrating the two aforementioned elements, to determine the network configuration and operating conditions that minimize the overall network area. The proposed optimization model effectively identifies the global optimal network, as illustrated by the applications presented.

## DIGITAL SUPPLEMENTARY MATERIAL

DAE unit model reformulation, simulation data, figures, and the mathematical formulation for the optimization model is presented in the Supplementary Material (LAPSE:2025.0008).

## ABSTRACT

Data-driven soft sensors help in process operations by providing real-time estimates of otherwise hard to measure process quantities, e.g., viscosities or product concentrations. Currently, soft sensors need to be developed individually per plant. Using transfer learning, machine learning based soft sensors could be re-used and fine-tuned across plants and applications. However, transferring data-driven soft sensor models is in practice often not possible, because the fixed input structure of standard soft sensor models prohibits transfer if, e.g., the sensor information is not identical in all plants. We propose a topology-aware graph neural network approach for transfer learning of soft sensor models across multiple plants. In our method, plants are modeled as graphs: Unit operations are nodes, streams are edges, and sensors are embedded as attributes. Our approach brings two advantages for transfer learning: First, we not only include sensor data but also crucial information on the plant topology. Second, the graph neural network algorithm is flexible with respect to its sensor inputs. This allows us to model data from different plants with different sensor networks. We test the transfer learning capabilities of our modeling approach on ammonia synthesis loops with different process topologies [1]. We build a soft sensor predicting the ammonia concentration in the product. After training on data from one process, we successfully transfer our soft sensor model to a previously unseen process with a different topology. Our approach promises to extend the data-driven soft sensors to cases to leverage data from multiple plants.

**Keywords**: Digital twins, Transfer learning, Data-driven modeling

## INTRODUCTION

Data-driven soft sensors promise to increase operating efficiency in chemical plants by providing real time estimates of hard to measure quantities. Previous works have shown the merit of soft sensors in many applications, e.g., estimating viscosity or product concentrations [2,3]. However, data scarcity remains a major hinderance in developing machine learning based solutions such as soft sensors in industry [4].

Transfer learning offers an opportunity to decrease data requirements for soft sensor modeling but is often not possible for processes with different topologies. In transfer learning, a machine learning model pretrained on one domain is transferred to another domain. Transfer learning for soft sensors has shown several advantages, such as reduced data requirements, zero-shot capabilities and improved performance [5]. In previous literature, transfer learning has been explored in multiple situations for reducing data requirements in soft sensor development. For domain adaptation, the model transfers knowledge between different operating points [2]. Similarly, transfer learning has been leveraged to transfer between batch runs [6]. It has even been applied to transfer between identical process lines [7,8]. While different types of models have been used in these works (multilayer perceptrons (MLPs), extreme learning machines,

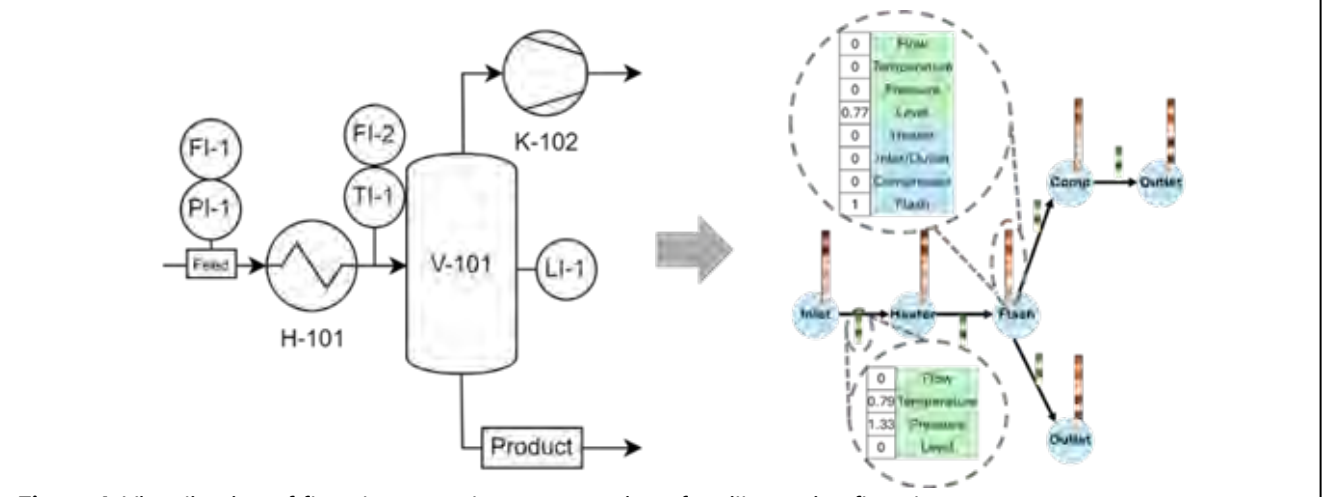

**Figure 1:** Visualization of flowsheet graph representation of an illustrative flowsheet.

recurrent neural networks), it is not possible to transfer these soft sensor models between plants with different topologies, e.g., with respect with to sensor locations or equipment types, due to the fixed input structure of the models.

We propose a new soft sensor architecture that uses spatio-temporal graph neural networks (GNNs) on the process topology and sensor data. This enables transfer learning between different processes due to its flexible input structure and topology-awareness. We model chemical processes as graphs, with unit operations as nodes, streams as edges and sensor data embedded as attributes. Our approach allows to incorporate information about the process topology along with the sensor measurements. We argue that this approach has two advantages for transfer learning: First, this data representation provides context of the process to the model. This enables the model to learn about the process and thus transfer information to related processes. Second, our graph-based model does not have a fixed input size, meaning that it can be transferred between processes with different sensor networks. We demonstrate our modeling approach on two ammonia synthesis loops. The processes are similar, but topologically different, making them challenging for standard transfer learning approaches.

# METHODS

## Spatio-temporal modeling of soft sensors with graphs

To enable transfer learning between processes, we utilize a graph-based representation of the process topology and the soft sensor data to enable topology-awareness together with a model that accounts for both spatial and temporal dependencies in the data.

We represent the underlying Process as a directed graph, representing the topology of the process, see Figure 1. We model unit operations as nodes. To model different types of units, we one-hot encode the unit type into the node attribute vector. We further represent streams as directed edges. The direction of the edge follows the direction of the material. Finally, we encode sensor measurements according to their location in the process into the attribute vectors of nodes and edges.

A complete overview of the modeling framework can be found in Figure 2. We model the spatial relationships between the graph-encoded data and the soft sensor target using GNNs for each timestep. We deploy a message passing GNN [9], allowing us to utilize both node and edge information. The output is an individual flowsheet embedding for each timestep, see Figure 2.

To model the temporal relationship and thus dynamics of the process, we use a transformer. The transformer encoder inputs the graph-encoded flowsheet embeddings. In its final layer, the encoder averages over the latent space along the number of timesteps, resulting in single output vector. A three layer MLP then predicts sensor target $\hat{y}_t$ for the current time step $y$.

## Transfer learning

The transfer learning process in this work is conducted in two stages. First, the model undergoes initial training on the source domain. Subsequently, a partial retraining is performed on the target domain. We also test the case of no retraining on the target domain, which is referred to as zero-shot transfer learning.

To further stabilize the training, we scale our input data by applying a log-scale. Since each process has a different topology and set of embedded sensor measurements due to different sensor information, different streams etc., we cannot uniformly apply per-feature normalization across them. We however found that with learning rates sufficiently small, the training is still stable.

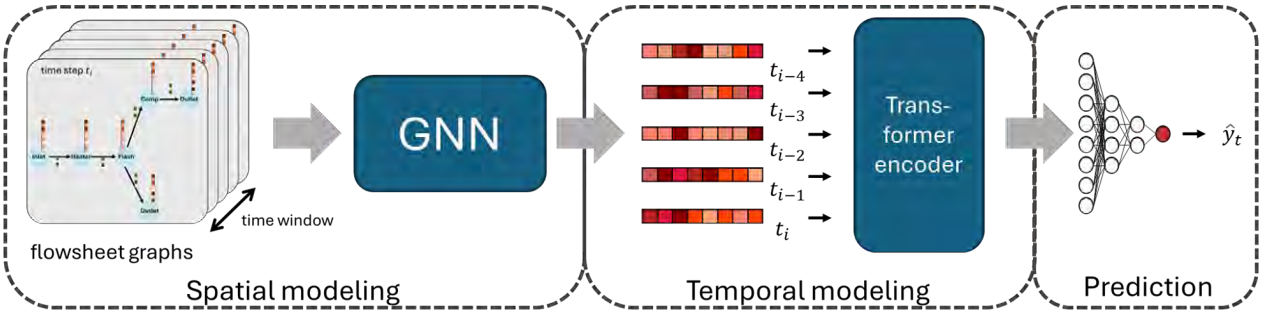

**Figure 2:** Illustration of the model used for spatio-temporal modeling, here with a look back window of 5 time steps.

We do normalize our soft sensor target to zero mean and unit standard deviation.

We evaluate the model prediction $\hat{y}$ against the ground truth $y$ on our test set $N_{\text{test}}$ for all time steps t using the root mean squared error (RMSE) on the normalized data:

$$RMSE = \sqrt{\frac{1}{N_{\text{test}}} \sum_{t=1}^{N_{\text{test}}} (y_t - \hat{y}_t)^2} \quad (1)$$

## CASE STUDY: AMMONIA SYNTHESIS LOOPS

We consider two ammonia synthesis loops as illustrative case studies with the same equipment sizing and feed flows but different topologies. In both processes, ammonia is produced from N2 and H2 under high pressure. The soft sensor target is the concentration of ammonia in the respective product streams. Both processes consist of four types of processing steps: (1) Compressions, (2) Separation via flashing, (3) Heating/Cooling, and (4) Reaction with three reactor beds. The combination of those major units however differs between the two processes, reflecting different topologies found in industry [1].

In Process A (see Figure 3, left), the feed is first compressed in compressor K-101 and mixed with the recycle. The mixture is then further compressed in compressor K-102 and heated before entering the reactor R-101. The effluent leaving the reactor is flashed in the flash V-101. The liquid phase leaving V-101 is the product stream while the vapor phase of flash V-101 is purged and mixed with the inlet gas.

In Process B (see Figure 3, right), the feed is first compressed in compressor K-101 and mixed with the reactor R-101 outlet. The mixture of the reactor effluent and the fresh feed is then cooled and flashed in V-101, removing the ammonia as a liquid. The liquid ammonia then leaves the process as its product. The vapor phase leaving the flash V-101 is further compressed in compressor K-102 and heated and after that sent into the reactor R-101. The reactor outlet is purged before being mixed with the inlet stream.

Both processes are controlled using PID control. The control scheme follows the “Mode I” as detailed by [10]. Both the feed and the purge stream are controlled with a flow controller (FC-1 and FC-2, respectively). The level in the flash vessels is controlled with a level controller (LC-1). The reactor inlet temperature is controlled with the temperature controller (TC-1).

We simulate dynamic operating datasets from the processes using the dynamic simulation software Aspen Plus Dynamics V12. As a design basis, we use the simulation files by Araújo and Skogestad [10]. To generate a dataset of dynamic operation, we randomly vary the set points of controllers in a range of 1-20% deviation from the original, running the simulation until steady state is reached on the new setpoint. Then, we revert the setpoint back to the original. This way, we simulate 80 hours of operation. We sample sensor data every 36 seconds. This results in approximately 8000 datapoints for both datasets. We split the dataset 80/20/20 between for training, validation and testing in a chronological split.

## RESULTS AND DISCUSSION

We carry out the transfer learning with our topology-aware GNN in a two-step process: (1) We first train our model on the dataset of Process A until we reach convergence on our validation set. (2) We then test the transfer capabilities of the GNN model on Process B.

To apply the transfer learning framework, we fine-tune the pretrained model on fractions of Process B, specifically on up to 51 points. This low number of training points reflects the often limited number of soft sensor target measurements available in industrial settings. For comparison, we also train a model on the data from Process B from scratch. We additionally test the zero-shot capability of the model pretrained on Process A. We train each model nine times using different seeds to mitigate the effects of training noise, and plot both the mean and standard deviation of the nine models combined. For

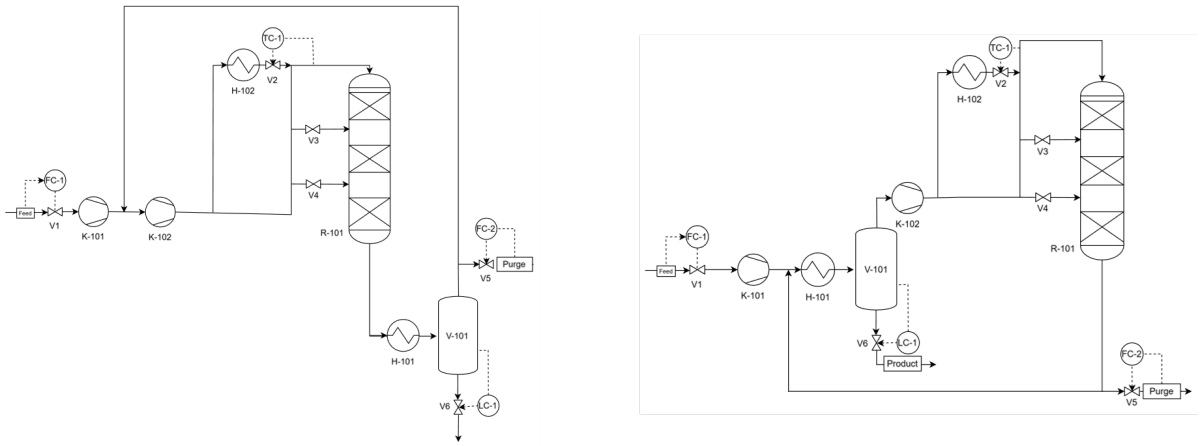

**Figure 3:** Two ammonia synthesis loops are used in this work. In Process A (left) the feed is first sent to the reactor and then flashed. In Process B (right), the feed is first mixed with the reactor outlet, then flashed and sent to the reactor.

training, we used a NVIDIA GeFORCE RTX 3090. The training times varied between 30 minutes for the full training dataset and less than 5 minutes for a fraction of the dataset.

The results are shown in Figure 4. We plot the fraction of the data from Process B used for training vs. RMSE on the test set of Process B. We also illustrate the zero-shot capabilities of the pretrained model by adding a data point for 0 datapoints used for training.

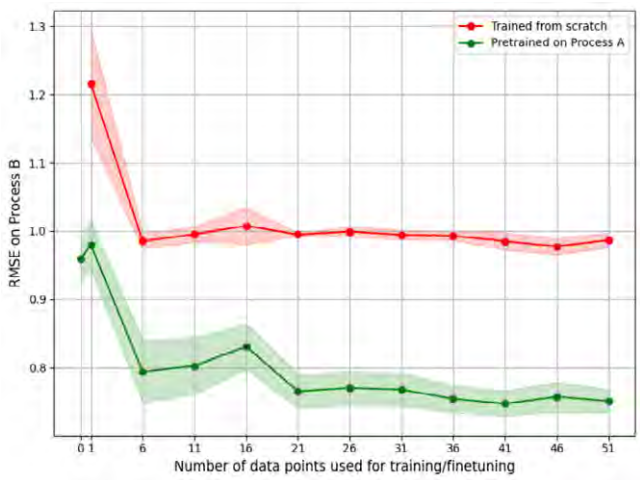

**Figure 4**: Pretrained vs training from scratch for varying number of datapoints. The shaded area shows the standard deviation due to different weight initializations.

By analyzing the results shown in Figure 4, we observe three notable trends: (1) The zero-shot performance of the pretrained model is significant, achieving an RMSE of 0.9753 on Process B without any training data from Process B. In contrast, the model trained from scratch requires 46 datapoints to reach a similar performance level. We attribute this to the pretrained model's ability to transfer learned dynamics from Process A to the previously unseen Process B. (2) Both models improve their RMSE scores on Process B when trained on more data. The pretrained model achieves an RMSE of 0.7633 when trained on 51 datapoints, while the model trained from scratch also shows improvement, reaching an RMSE of 0.9776. However, the pretrained model consistently outperforms the model trained from scratch across different training data sizes. (3) The performance of the pretrained model deteriorates when fine-tuned on a single datapoint from Process B, performing worse than its zero-shot performance. We hypothesize that this might be due to the lack of sufficient information in a single data point, which could lead to overfitting or misrepresentation of the underlying process dynamics of Process B.

**Table 1:** Average percentage RMSE reduction when using the pretrained soft sensor model compared to the model trained from scratch on Process B.

| Number of data points | RMSE reduction |
|---|---|
| 1 | 19.38% |
| 11 | 19.36% |
| 21 | 23.08% |
| 31 | 22.80% |
| 41 | 24.15% |
| 51 | 23.87% |

The relative reduction in RMSE when using the soft sensor model pretrained on Process A compared to the soft sensor model trained from scratch is further calculated in Table 1, showing up to 24.15% in reduction. It is notable that the relative reduction in RMSE increases with more training data from Process B. We thus hypothesize that the model pretrained on Process A may benefit more from additional training data of process B than the model trained from scratch in this limited data regime.

We further visualize the effect of finetuning in Figure 5. We visualize the ground truth alongside the zero-shot predictions from the pretrained model and the predictions from the finetuned model over time on the Process B test set. The zero-shot model under-predicts the ammonia concentration consistently. This is even the case during steady state, e.g., between minute 500 and 800. This can be explained by the fact that the ammonia concentration in Process A and Process B are not identical, and thus the model still predicts an ammonia concentration as it would occur in Process A. With fine tuning, this offset is reduced, as shown by the prediction of the finetuned model between minutes 500 and 800. Nevertheless, some of the dynamics, e.g., between minute 0 and 350, are still not well captured by the finetuned model.

## CONCLUSION

We propose a spatio-temporal soft sensor modeling framework using GNNs to enable transfer learning across topologically different processes. We utilize two similar but topologically different ammonia synthesis loops as our case study. We show that the topology-aware GNN is transferred from one process to the other. We further demonstrate how transfer learning reduces data requirement through good performance without any data on the target domain and even better performance on very little additional data. We show that using the pretrained model, we can reduce the RMSE by up to 24.15% when trained on 46 datapoints compared to the model trained from scratch.

This work presents a flexible framework that can be extended to various chemical process systems. Future work could focus on adapting this transfer learning framework to multi-process environments generalizing beyond one-process pretraining. Further, the approach is yet to be verified on industrial data, which often poses additional challenges.

## ABSTRACT

New ways of reducing environmental impact of solid waste are constantly developed. Thermochemical conversion with focus on material or energy recovery is one of the viable options. To make the feedstock properties more suitable for such a process, refuse derived fuel (RDF) is created. Although several studies have focused on thermochemical conversion in recent years, only few have comprehensively compared the main aspects of incineration, gasification, and pyrolysis processes from multiple aspects. This study focuses on mathematical modeling of these three processes in the Aspen Plus environment. Comparison from economic, safety, and environmental viewpoints was performed. As a base for the calculations, 10 t/h of RDF was selected. All three processes demonstrated the suitability to be used for energy recovery. Pyrolysis showed the greatest potential for material recovery. Payback period was used as a parameter of economic comparison with pyrolysis being the most profitable process. Based on the calculated Dow Fire and Explosion Index (F&EI) and Chemical Exposure Index (CEI) gasification was identified as the most hazardous process. In summary, based on this extensive techno-economic analysis, the ranking of processes from an economic standpoint is as follows: pyrolysis, incineration, gasification. From an environmental perspective, the ranking is: gasification, pyrolysis, incineration. In terms of safety, the order is: incineration, pyrolysis, gasification.

**Keywords**: refuse derived fuel, incineration, gasification, pyrolysis

## INTRODUCTION

Waste generation presents environmental challenges that require direct attention. Within the European Union, generation of waste remains a significant problem with the amount of municipal solid waste increasing each year. Landfilling emerges as the primary environmental consequence of MSW [1]. However, shifts in legislative require the decrease of landfill disposal. Sustainable solutions are being explored, emphasizing the optimization of recyclable material and energy recovery. Solid waste not suitable for material recycling still contains high calorific value and can serve as a partial replacement of fossil fuels. This waste can be transformed into refuse derived fuel (RDF), which has more suitable properties for thermochemical conversion. Heating value of MSW is around 8-12 MJ/kg [2], which is significantly lower than that of RDF reaching as high as 27 MJ/kg [3]. The most common method of energy recovery from MSW is incineration. Alternative processes of thermochemical conversion are gasification and pyrolysis, which provide higher efficiency of energy and material recovery compared to incineration. The main drawback of waste feedstock processing is that it contains contaminants. Common contaminants in MSW and RDF include sulfur and chlorine containing compounds and heavy metals, these are carried into the products of the treatment process, where they cause damage to the equipment. Moreover, they are environmental pollutants. Therefore, it is necessary to minimize their production and decrease their concentration in the products to acceptable levels by purification. This work aims to compare three processes of thermochemical conversion of RDF: incineration, gasification, and pyrolysis. Due to their complex nature, studies comprehensively comparing the techno-economic aspects of the processes using mathematical models are quite rare.

## SIMULATION

Aspen Plus simulation software was used to create mathematical models of all three processes. As a base for the calculations, 10 000 kg/h of non-pretreated RDF was chosen. Peng-Robinson equation of state was used as the main thermodynamic model in all calculations. Equilibrium thermodynamic model, minimizing free Gibbs energy of the entire system, was employed to simulate thermochemical conversion of feedstock with the following assumptions [4]:

- Steady state flow in the reactor.
- No temperature or concentration gradients.
- Infinite residence time, chemical equilibrium is reached.
- Only chosen compounds are evaluated.

Equilibrium model is not suitable for processes where the deviation from the chemical equilibrium is too large, e.g. pyrolysis. Therefore, a mathematical model applying experimentally determined yields of the main products and composition of gaseous and solid products was used. To calculate the exact composition of liquid pyrolysis product, elemental balance of representative compounds was applied.

### Feedstock properties

Proximate and ultimate composition of RDF pellets was determined in previous experimental work [5] and is shown in **Table 1**. Lower heating value (LHV) of the RDF sample was determined to be 23.89 MJ/kg [5].

**Table 1:** Proximate and ultimate composition of RDF [% mass]

| | | | |
|---|---|---|---|
| C | 55.6 | Moisture | 0.73 |
| H | 7.83 | Volatile matter | 77.10 |
| N | 0.63 | Fixed carbon | 7.78 |
| S | 0.35 | Ash | 15.12 |
| Cl | 0.88 | | |
| O | 19.58 | | |

### Incineration

Incineration was the least complicated of the three processes studied. Incineration generates heat, part of which is turned into electricity. Material outlet steams are

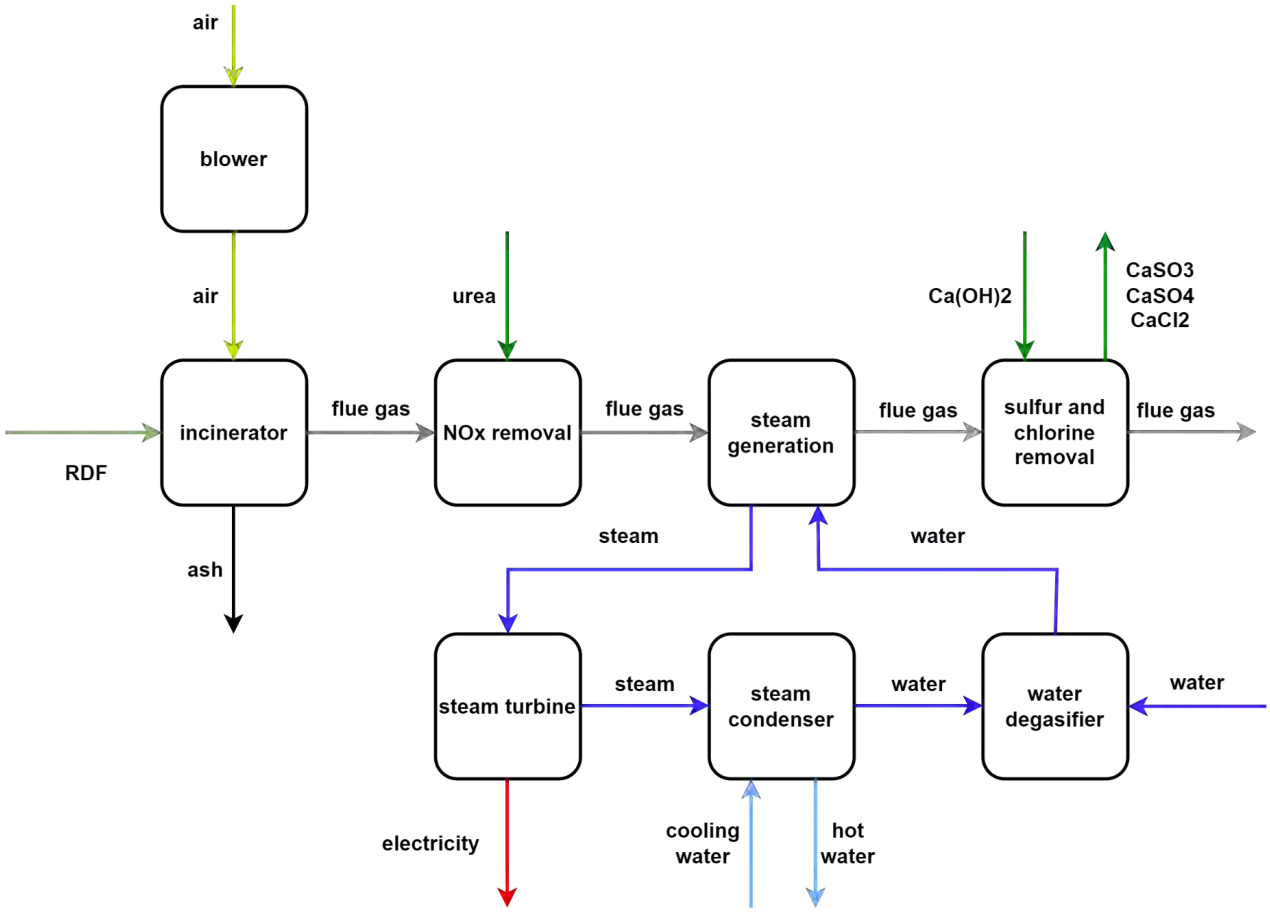

**Figure 1:** Simplified incineration flowsheet

flue gas and ash. Flue gas contained contaminants, such as $NO_x$, $SO_2$, $SO_3$, $Cl_2$ and HCl, and thus its purification was necessary. In **Figure 1**, a simplified flowsheet of this process is shown. Raw RDF enters the incinerator, where it burns in an excess of oxygen. Hot flue gas exiting the incinerator is purified to remove $NO_x$ contaminants by selective non-catalytic reduction (SNCR). $NO_x$ is reduced to $N_2$ via the reaction with urea in water solution. The still hot flue gas is then used for the generation of steam, which generates electricity in the steam turbine. From the cooled flue gas, sulfur, and chlorine contaminants are removed by adsorption using $Ca(OH)_2$.

The amount of incineration air was controlled to maintain 11% of oxygen in the flue gas [6]. Temperature of the exiting flue gas was 1 057°C and it was regulated by the temperature of the combustion air, which was preheated to 135°C. The amount of dry air required was 133 706 $Nm^3/h$. The process generated 1 361 kg/h of ash and 140 190 $Nm^3/h$ of flue gas.

Composition of flue gas exiting the incinerator is shown in **Table 2**. To purify it from $NO_x$ components, 758 kg/h of 9% urea aqueous solution was required. When the flue gas was cooled to 130°C, it was purified from $SO_2$ and HCl by the wet process using 140 kg/h of $Ca(OH)_2$. Flue gas purification processes were simulated using a stoichiometric reactor model with defined conversion [8]. Concentrations of contaminants in the purified syngas in **Table 2** were below the required values for the waste incineration, which are 200, 250, 250 and 10 $mg/Nm^3$ for $SO_2$, $NO_x$, CO, and HCl, respectively, for incinerators with nominal power below 100 MW [7].

**Table 2:** Composition of flue gas and contaminants concentrations in [$mg/Nm^3$] at 6% reference of $O_2$

| | Vol. fraction | Concentration in raw syngas | Concentration in purified syngas |
|---|---|---|---|
| $H_2O$ | 0.065 | - | - |
| $O_2$ | 0.114 | - | - |
| $N_2$ | 0.754 | - | - |
| $CO_2$ | 0.067 | - | - |
| CO | $5.35x10^{-4}$ | 0.51 | 0.51 |
| NO | $3.77x10^{-4}$ | 3 870.60 | 193.78 |
| $NO_2$ | $2.57x10^{-6}$ | 40.50 | 40.50 |
| $SO_2$ | $1.52x10^{-4}$ | 3 333.80 | 50.25 |
| $SO_3$ | $5.08x10^{-6}$ | 139.26 | 139.26 |
| HCl | $3.57x10^{-4}$ | 4 458.03 | 8.96 |
| $Cl_2$ | $3.84x10^{-8}$ | 0.93 | 0.93 |

Superheated steam (600°C, 9 MPa) was generated by flue gas cooling. This steam expanded to 0.25 MPa in the isentropic steam turbine with isentropic efficiency of 0.8, generating 9.5 MW of electric energy. Part of which was spent by the equipment in the process, mainly the air blower, which required 880 kW. To condense the steam exiting the turbine, water for district heating was generated with the heat content of 29.2 MW.

## Gasification

Simulation of RDF gasification was significantly more complicated than that of incineration due to the nature of the process. **Figure 2** shows a simplified

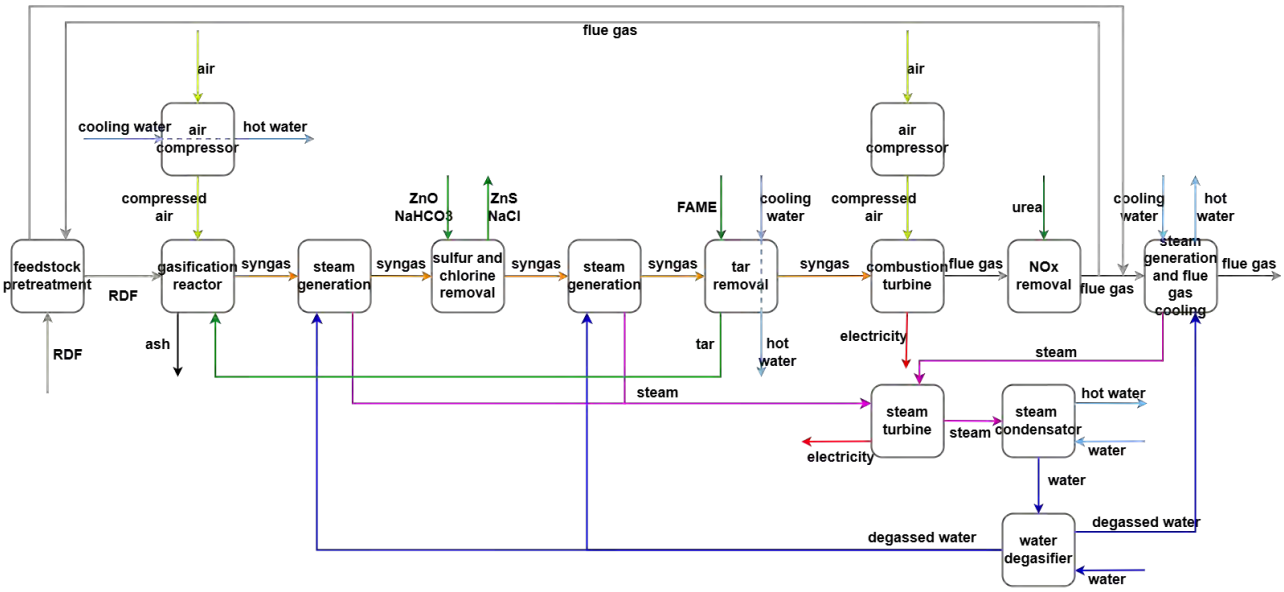

**Figure 2**: Simplified gasification flowsheet

gasification flowsheet. Before entering the gasification reactor, RDF was pretreated by drying using hot flue gas. Air, as the gasification medium, was compressed by a three-stage compressor with intercooling. Tar removed from syngas was recycled back into the reactor. Hot syngas exiting the reactor was purified from $H_2S$, HCl, and tar, while its energetic content was used for steam generation. Purified syngas was led into the combustion turbine to generate electricity. Hot flue gas from the turbine was purified only from $NO_x$ contaminants and used for steam generation.

To simulate the gasification reactor, an equilibrium model including tar generation was used. Concentration of tar in syngas was 3.15 g/Nm$^3$ [2], and tar was represented by naphthalene. Air entered the gasification reactor at 36 bars and 227°C. Such high pressure ensures that no additional syngas compression is required before the combustion turbine. Sub-stoichiometric amount of air was used in the process, which is 25 148 Nm$^3$/h. Gasification conditions were controlled by the amount of air led into the reactor so that 100% carbon conversion was achieved and LHV of syngas was maximized. The amount of syngas exiting the reactor was 37 690 Nm$^3$/h, with LHV of 4.38 MJ/Nm$^3$ and temperature of 902°C.

**Table 3:** Syngas composition and contaminants concentrations in [mg/Nm$^3$]

| | Vol. fraction | Concentration in raw syngas | Concentration in purified syngas |
|---|---|---|---|
| $H_2O$ | 0.049 | - | - |
| $H_2$ | 0.163 | - | - |
| $O_2$ | 0.000 | - | - |
| $N_2$ | 0.531 | - | - |
| NO | $1.35x10^{-13}$ | $1.81x10^{-7}$ | $1.81x10^{-7}$ |
| $SO_2$ | $3.60x10^{-11}$ | $1.03x10^{-4}$ | $1.03x10^{-4}$ |
| $Cl_2$ | $1.03x10^{-14}$ | $3.23x10^{-8}$ | $3.23x10^{-8}$ |
| HCl | $1.34x10^{-3}$ | 2 139.32 | 1.06 |
| CO | 0.206 | - | - |
| $CO_2$ | 0.048 | - | - |
| $H_2S$ | $5.88x10^{-4}$ | 879.34 | 4.34 |
| $NH_3$ | $3.70x10^{-4}$ | 275.06 | 275.06 |
| tar | $5.51x10^{-4}$ | 3 098.00 | 3.45 |

In **Table 3** syngas composition and contaminants' concentrations are shown. Dry method of purification was used to remove $H_2S$ and HCl from syngas by high temperature adsorption to 80 kg/h of ZnO and 191 kg/h of $NaHCO_3$ mixed with 2 707 kg/h of water. The process was simulated by the same method as in RDF incineration. Tar was removed by absorption into 124 kg/h of fatty acid methyl esters (FAME); methyl oleate was selected as a representative absorbent. Concentrations in the purified syngas met the requirements for combustion turbine fuel, which are 30, 20, and 1.5 mg/Nm$^3$ for tar, $H_2S$, and HCl, respectively [9].

**Table 4:** Concentrations of contaminants in purified flue gas

| | Concentration [mg/Nm$^3$] |
|---|---|
| NO | 213.58 |
| $NO_2$ | 17.95 |
| $SO_2$ | 3.43 |
| $SO_3$ | 0.03 |
| HCl | 0.45 |
| $Cl_2$ | $2.31x10^{-6}$ |
| CO | 73.30 |

Purified syngas, along with 44 938 Nm$^3$/h of air (36 bars, 697°C), entered the combustion turbine. Its amount was regulated so that 3% of $O_2$ was present in the flue gas exiting the turbine at 768°C. Turboexpander generated 30.5 MW of power, a portion of which was spent to power air compressors in the system. Hot flue gas was purified from $NO_x$ contaminants by the same process as in RDF incineration using 2580 kg/h of 9% aqueous urea solution. After purification (**Table 4**), flue gas met the purity requirements. In summary, 20.7 MW of electric energy was generated in the process and 24.3 MW of heat in form of hot water for district heating was generated using heat from steam condensation and cooling process streams.

## Pyrolysis

RDF pyrolysis was focused on recovery of material products, such as pyrolysis oil or activated carbon (AC) adsorbent, while the excess heat was used for district heating. **Figure 3** shows a process flowsheet of pyrolysis. Raw RDF was pretreated in the same way as in RDF gasification. Two streams exit the pyrolysis reactor: gas together with oil, and char. Char is upgraded to AC by steam gasification while pyrolysis oil is separated from the gas and upgraded by distillation into three fractions (**Table 6**). Gases from the pyrolysis and steam gasification reactors are mixed and combusted to generate heat required for the process. Flue gas is purified from the contaminants.

**Table 5:** Pyrolysis product yields [12]

| Product | Yield [%] | Mass flow [kg/h] |
|---|---|---|
| Char | 25 | 2 267.6 |
| Oil + water | 43 | 3 898.5 |
| Gas | 32 | 2 901.2 |

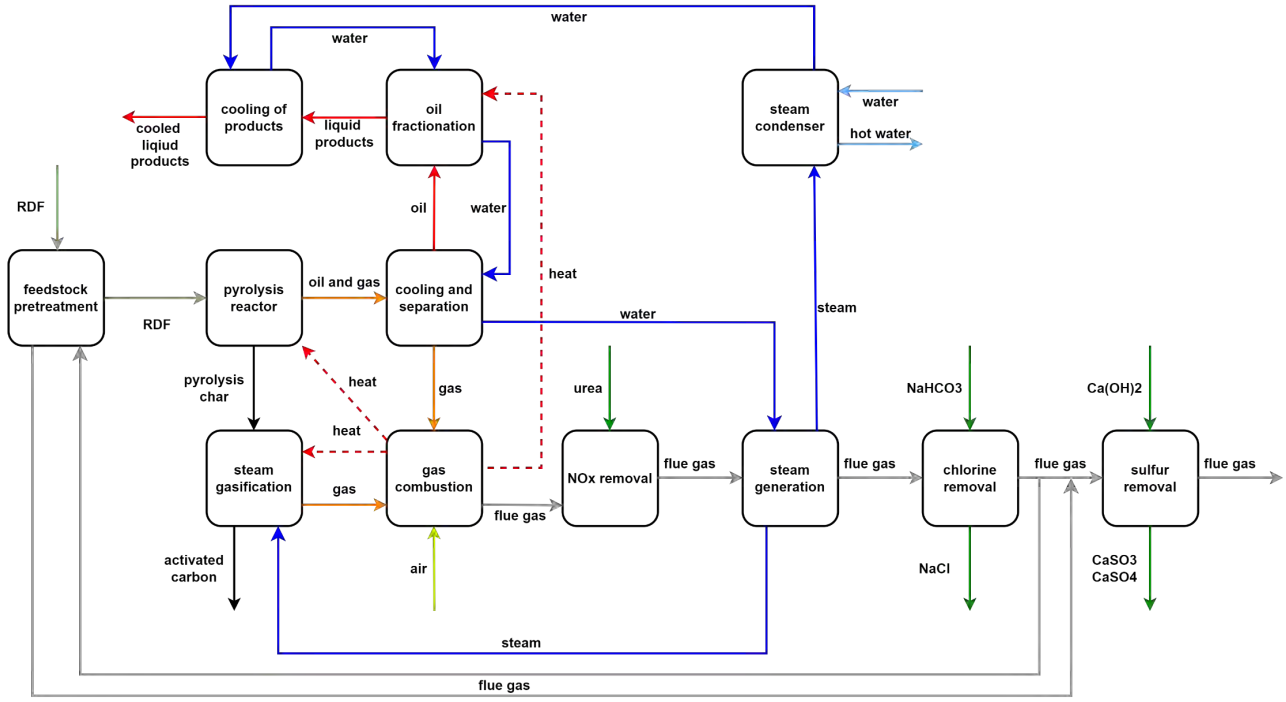

**Figure 3:** Simplified pyrolysis flowsheet

**Table 6:** Separated pyrolysis oil fractions

| Fraction | Mass flow [kg/h] | BP range [°C] |
|---|---|---|
| Light | 841 | 100 – 218 |
| Medium | 952 | 218 – 340 |
| Heavy | 1 781 | 340 – 438 |

Pyrolysis took place at 600°C. For these conditions, yields of the products (**Table 5**), composition of the gas phase and char [10], and representative molecules for the liquid phase [5], [11] were chosen. No oxidation medium was used in this process. The exact composition of pyrolysis oil was calculated from the elemental balance. For the pyrolysis process, 9.3 MW of heat was required. Steam gasification of char took place at 6 bars and 900°C, with the supply of 1140 kg/h of steam (1 MPa, 250°C) to the reactor at the rate of 0.0279 mol/g/h [13]. The reactor required an additional 3.2 MW of heat to produce 1 655 kg/h of AC. Following assumptions were made when calculating the yield and composition of AC:

- All volatile matter is converted into gas
- All ash stays in the AC
- Yield of AC is 73% [13]

Then, 4 980 kg/h of gas created in the process was combusted in the presence of 28 380 $Nm^3/h$ of air. This process was regulated to maintain 5% of $O_2$ in purified flue gas (**Table 7**). The same purification processes were employed as in RDF incineration and gasification. To achieve the desired purity, 134 kg/h of urea, 172 kg/h of $NaHCO_3$, 66 kg/h of $Ca(OH)_2$, and 8 330 kg/h of water were required and 10.5 MW of heat in form of hot water for district heating was exported from the process.

**Table 7:** Concentrations of contaminants in raw and purified flue gas in [$mg/Nm^3$]

| | Concentration in raw syngas | Concentration in purified syngas |
|---|---|---|
| CO | 47.96 | 47.96 |
| NO | 4 335.6 | 207.0 |
| $NO_2$ | 5.84 | 5.57 |
| $SO_2$ | 1 967.4 | 187.8 |
| $SO_3$ | 3.65 | 3.49 |
| HCl | 2553.6 | 9.75 |
| $Cl_2$ | 0.12 | 0.12 |

## Economic and safety analysis

Complex economic analysis was performed for all three processes of thermochemical conversion; results are provided in **Table 8**. Payback period (PBP) was used to compare economic feasibility of processes. The shortest PBP was in case of pyrolysis due to low EC and relatively high sales. However, this assumes that there is demand for the material products at the set price. Gasification was not economically feasible due to the high cost of equipment and operational costs. Incineration seemed less feasible than pyrolysis, however there will be always demand for electricity.

To compare the safety of the processes, Dow fire and explosion index (F&EI) as well as chemical exposure index (CEI) were used (**Table 9**). Equipment with the highest values was chosen as representative. Gasification had the highest risk of fire due to the high pressure in the process and handling of large amounts of flammable oils (FAME). The results for incineration and pyrolysis were similar.

**Table 8:** Economic parameters: equipment cost (EC) [$]; total capital investment (TCI) [$]; annual sales (AS) [$], and payback period (PBP) [years]

| | Incineration | Gasification | Pyrolysis |
|---|---|---|---|
| EC | $1.07x10^7$ | $4.93x10^7$ | $8.24x10^6$ |
| TCI | $5.66x10^7$ | $2.25x10^8$ | $4.86x10^7$ |
| AS | $1.32x10^7$ | $2.07x10^7$ | $1.79x10^7$ |
| PBP | 11.4 | 43.5 | 5.3 |

**Table 9:** Results of safety analysis

| | Incineration | Gasification | Pyrolysis |
|---|---|---|---|
| F&EI | 67.64 | 159.32 | 81.00 |
| Risk | Moderate | Severe | Moderate |
| CEI | 12.45 | 17.10 | 15.15 |
| Risk | Severe | Severe | Severe |

## CONCLUSION

In this work, RDF incineration, gasification and pyrolysis were compared considering technical, economic, safety, and environmental aspects. A mathematical model of each process was created in the Aspen Plus environment. Incineration is the simplest process focusing on energy recovery. In this process, 8.6 MW of electric energy and 29.2 MW of heat for district heating is generated. Gasification is more complicated from the technical point of view, providing 20.7 MW of electric energy and 24.3 MW of heat. Pyrolysis is focused mainly on material recovery, producing three fractions of pyrolysis oil with different boiling point ranges and 1 655 kg/h of activated carbon adsorbent, as well as 10.5 MW of excess heat exported as hot water for district heating. From the economic aspect, pyrolysis is the most feasible process, with a payback period of 5.3 years, assuming that there is a demand for its material products. From the safety aspect, incineration is the safest, followed by pyrolysis, and gasification. From the process and environmental point of view, requirements for the contaminants' concentration in syngas and flue gas were satisfied in all three processes. However, pyrolysis produces the most byproducts of gas purification and wastewater, followed by incineration, and gasification.

## ABSTRACT

In the upcoming decades, the scale-up of hydrogen production will play a crucial role for the integration of renewable energy into energy system. One scale-up strategy is the numbering-up of standardized electrolysis units in modular plant concepts. The use of modular plants can support the integration of different technologies into heterogeneous electrolyzer plants to leverage technology-specific advantages and counteract disadvantages. This work focuses on the analysis of technical operability of large-scale modular electrolyzer plants in heterogeneous plant layouts using co-simulation. Developed process models of low-temperature electrolysis components are combined in Simulink as shared environment. Strategies to control process parameters, like temperatures, pressures and flowrates in the subsystems and the overall plant, are developed and presented. An operability analysis is carried out to verify the functionality of the presented plant layout and control strategies. The dynamic progression of all parameters is presented for different operative states, like start-up, continuous operation, load change and hot-standby behavior. It is observed that the exemplary plant is operational, as all relevant process parameter can be held within the allowed operating range during all operative states. Some limitations, regarding the possible operating range of individual technologies, are introduced and solution approaches are conceptualized. Additionally, relevant metrics for efficiency, such as the specific energy consumption and flexibility are calculated to prove the feasibility and show the advantages of heterogeneous electrolyzer plant layouts, such as a heightened operational flexibility without mayor reductions in efficiency.

**Keywords**: Hydrogen, Modelling & Simulations, Process Control, Process Operations, MATLAB, Co-Simulation

## INTRODUCTION & BACKGROUND

The rising demand for hydrogen and the necessary integration of fluctuating energy sources into chemical value chains remains a mayor challenge for the transition to renewable energy and a more sustainable chemical industry [1]. The numbering-up of standardized electrolysis units in a modular plant has been conceptualized as a reliable way to scale-up hydrogen production quickly [2]. Furthermore, the use of the modular plant concept allows for a more individualized and flexible scale-up by enabling the combination of modules from different providers. That way electrolysis plants can be designed to include different electrolysis technologies more easily to leverage technology-specific advantages and counteract disadvantages [2], [3]. The necessary components within such modular electrolysis plants of different technologies have been outlined in [4] and can be used as a reference for scale-up scenarios. An exemplary modular, electrolysis system is depicted in Figure 1. Before such plant layouts of pre-engineered and generic Process Equipment Assemblies (PEAs), can be connected and operated, the functionality and operability of such a heterogeneous plant layout of different technologies and varying PEA providers must be verified to ensure safe and efficient operation.

This paper aims to support this verification of heterogeneous modular electrolysis plants investigating the different steps of a dynamic operability analysis with a simple but exemplary use case as depicted in Figure 1.

The study aims to identify prerequisites and efforts as well as potential and limitations to prove safe and efficient operation of a such systems by assessing their ability to hold parameters within a Desired Output Set (DOS) [5]. In the context of modular plants and the integration of renewable energy sources in Power-to-X value chains, the dynamics of the plant must be taken into account to assess the plant operation during load or state changes [6]. This necessitates the calculation of specific metrics for dynamic operability evaluation of processes, as described in [7], on top of the steady-state operability. The necessary metrics shall be specified for the utilized use-case in the following chapter.

The depicted plant, consisting of individual modules from potentially varying suppliers, must therefore be simulated in an overall dynamic system simulation. As the internal knowledge of the modules is protected, the dynamic models are provided as black box models with their respective input-output behavior [8]. The black box models, potentially developed in different tools and with their individual solvers, are combined as Functional Mock-Up Units (FMUs) in a system co-simulation, as the Functional Mock-Up Interface (FMI) "enables an unprecedented level of integration of models (as black boxes) provided by different and even competing suppliers." [9]

# METHODOLOGY

## Definitions & Assumptions

Goal of the dynamic operability analysis is to provide proof, that a developed modular electrolysis system is operable. An operable process is defined as:

> "A process is operable if the available set of inputs is capable of satisfying the desired steady-state and dynamic performance requirements defined at the design stage, in the presence of the set of anticipated disturbances, without violating any process constraints." [7]

This necessitates the definition of varying aspects, that must be included in the operability analysis of modular electrolysis plants, such as the DOS, the dynamic Available Input Space (dAIS), the dynamic Desired Operating Space (dDOpS) and the Expected Disturbance Space (EDS) [5, 8]. The assumption of a modular plant design makes the variation of design input variables of the PEAs unsuitable, which is why the focus is on the operational variables of the PEAs. The ability to operate the combined heterogeneous modular electrolysis system out of predefined PEAs is to be evaluated.

A list of the included variables, their description and allowed ranges can be found in Tables 1-3 for the aspects of the operability analysis and their respective PEA. As each PEA encapsulates their individual behaviour and requirements, the presented method is applicable independently of the chosen plant layout. Due to limitations in the model capabilities, identified optima, simplifications or limited available data, the setpoints for some potential operating variables, such as the lye mass fraction or load change rates, are kept constant.

The dAIS entails the remaining setpoints, including the temperature, pressure and flow rate setpoints of the circulation and the production rate setpoint of the Stack-Unit. Additionally, the chosen lye mass fraction setpoint and load change rates over time are included in Table 1.

**Table 1:** Operating input variables in the dAIS and ranges taken from [2] or mapped to showcase from [10]

| Operational input variable | Value/Range |
|---|---|
| Circulation: Outlet temperature setpoint [°C] | 50-80 |
| Circulation: Outlet flowrate setpoint [kg/s] | AEL: 30-90<br>PEMEL: 4.75-14 |
| Circulation: Gas outlet pressure setpoint [bar] | 3-16 |
| Circulation: Lye mass fraction setpoint [m%] | 30 |
| Stack-Unit: Load setpoint [%] | 20–100 |
| Stack-Unit: Upramp load change rate [%/s] | AEL: 30<br>PEMEL: 50 |
| Stack-Unit: Downramp load change rate [%/s] | AEL: 10<br>PEMEL: 40,6 |

The DOS includes the constraints, that apply for the PEAs, such as the allowed operating ranges for temperature, pressure, flowrate and component mass fractions in the entire system of PEAs. These constraints are extended by the dDOpS with the allowed change rates over time of the relevant parameters during nominal operation or in case of operational disturbances. The EDS includes the disturbances in the input variables that are assumed to enter the process, such as variations in the water inlet temperature or short outages of the cooling cycle.

**Table 2:** Output variables and dynamics in the DOS and dDOpS and allowed ranges assumed or adjusted from [2] and [10]

| Output variable | Value/Range |
|---|---|
| Maximum allowed temperature in the Stack-Unit [°C] | AEL: 100<br>PEM: 90 |
| Maximum temperature change rate in the Stack-Unit [K/min] | AEL: 1,5<br>PEMEL: 1 |
| Maximum fluid velocity [m/s] | 1 |
| Maximum "H2 in O2" or "O2 in H2" values [mol%] | 2 |
| AEL: Maximum pressure difference between stack-sides [bar] | 0.1 |

**Table 3:** Disturbances in the input variables and considered ranges

| Input variable disturbances | Value/Range |
|---|---|
| Fresh water inlet / cooling water inlet / ambient temperature [°C] | 15–30 |
| Cooling cycle restart time [min] | 5 |

These collected variables serve as the inputs and variations in the operability analysis of the heterogeneous modular electrolysis plant considered in this paper.

## Calculated metrics

The calculated metrics within the operability analysis in this paper include the Achievable Output Set (AOS), the dynamic Achievable Operating Space (dAOpS), the Desired Input Space (DIS) and the dynamic operability.

The AOS is the "set of controlled variables that the system can achieve for the considered AIS and EDS." [5] In this case study, it includes the behaviour of the controlled variables in the system, such as temperature, pressure, flowrate and mass fractions, at steady state.

The extension of the AOS is the dAOpS as the "operating space representing the dynamic performance that can be achieved by the system for a given choice of the dAIS, DOS, and EDS." [7] That way the dynamic behaviour of the plant can be considered and violations of the maximum change rates or short-term deviations from the permitted working range can be identified.

The DIS is the "set of input values required for the system to reach all outputs in the DOS" [5], [7] and shall be identified by comparing the dAOpS and the DOS. The resulting edge cases, at which the dAOpS deviates from the DOS restrict the allowed operating range in the AIS and EDS, that are suited for compliance with the DOS.

In addition to the operability evaluations, the specific energy consumption and the "Lange-Große-Coefficient for hydrogen demand" ($LGC_{H2}$) of the system can be calculated from the simulated data for each operating point to determine optimal operating points within the allowed operating range. The specific energy consumption of the overall plant serves as a metric to determine an optimal operation scheme at least qualitatively. It is calculated as:

$$e_{spec}\left[\frac{kWh}{kg_{H_2}}\right] = \frac{P_{sys,cons}}{\dot{m}_{H_2,sys}} \quad (1)$$

With $P_{sys,cons}$ as the power consumption of the entire modular plant in *kW* and $\dot{m}_{H_2,stacks}$ as the combined produced hydrogen in all Stack-Unit PEAs in *kg/h*. For the scope of this paper, the efficiency evaluation is limited to the overall system efficiency at 100 % load.

The $LGC_{H2}$ value shall serve as an initial measurement to assess the inertia and consequently the flexibility to output hydrogen for different system configurations or operating points. It can be calculated for each load step or for a production scenario according to:

$$LGC_{H2}\,[-] = \int_{t_{scenario,start}}^{t_{scenario,end}} \frac{abs(\dot{m}_{H_2,sys}(t) - \dot{m}_{H_2,sys,stat}(t))}{\dot{m}_{H_2,sys,stat}(t)}\,dt \quad (2)$$

With $\dot{m}_{H_2,sys}(t)$ as the current hydrogen production at time step $t$ and $\dot{m}_{H_2,sys,stat}(t)$ as the stationary hydrogen production of the load setpoint at time step $t$, both in kg/h. The result is the part of the hydrogen production in %, that could not be met by the system and operating point under consideration for a production scenario.

## Model capabilities & Implementation

The analysis is carried out as a co-simulation scenario of FMUs, that simulate the dynamic behavior of chosen PEAs identified in [4], namely the water supply, Stack-Unit and circulation PEAs, as depicted in Figure 2. Although the hydrogen purification PEA is neglected in the simulation the presented methodology is still applicable within the scope of this paper. The system simulation is set up in MATLAB Simulink as a co-simulation environment with the developed FMUs. In the context of protection of the PEAs internal knowledge a detailed description of the FMUs is not necessary for the presented method and beyond the scope of this paper. A basic description of the model, including capabilities, interfaces and setpoints shall suffice. A detailed model description and structure of the electrolyzer stack-units, the balance of plant components and control strategies shall be specified elsewhere [11].

The FMUs provide the dynamic input-output behaviour of the mass, components and energy in the individual PEAs to changes in their respective setpoints and inlets. The FMU interfaces follow the interface description in [12], providing ports for material streams, energy and information, such as setpoints for the controlled variables. Necessary system parameters of the individual technologies for the chosen scenario are taken from [13] for the AEL subsystem, are scaled from values in [14] for the PEMEL subsystem and are collected in Table 4.

Both subsystems are assumed to connect multiple Stack-Unit PEAs to one circulation PEA. Additionally, the circulation PEAs of each electrolyzer technology are both connected to the water supply PEA. For the scope of this paper, the only information exchange between the PEAs shall be the necessary supply of deionized water from the water supply PEA to the circulation PEA to hold the liquid level in the gas separation tanks constant. This necessary supply is used as the flowrate setpoint for the water supply PEAs internal flowrate control. The production load setpoint is used as input in the Stack-Unit PEA to control the hydrogen production rate. The operating variables temperature, pressure and flowrate in the Stack-Units and the rest of the system are controlled as setpoints in the circulation PEA. Restarting the cooling cycle is also controlled in the circulation PEA. Controlling these variables should suffice for the basic operation of the presented heterogeneous modular electrolyzer system.

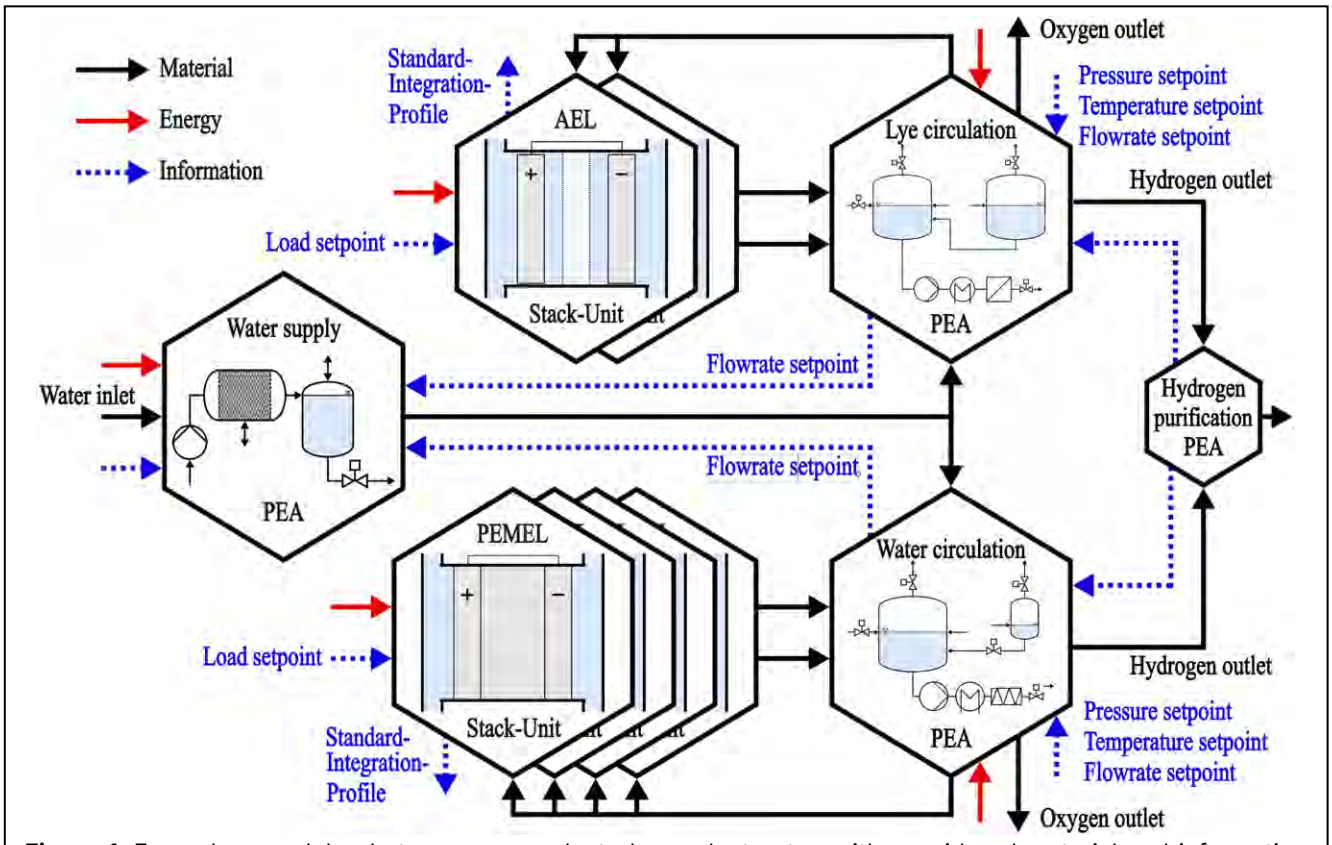

**Figure 1:** Exemplary modular, heterogeneous electrolyzer plant setup with considered material and information inlets and outlets in the dAIS and EDS

**Table 4:** Necessary system parameters of the individual subsystems taken or adjusted from [13] and [14]

| System parameter | Value PEMEL | Value AEL |
|---|---|---|
| Number of Stack-Units per system [-] | 4 | 2 |
| Number of cells per Stack-Unit [-] | 150 | 326 |
| Active area of an electrolysis cell [$m^2$] | 87.5e-3 | 2.66 |
| Nominal power of a Stack-Unit [MW] | 0.25 | 3 |
| Free volume of an electrolysis cell [$m^3$] | 8.75e-4 | 0.027 |
| Separation tank volume [$m^3$] | 1.06 | 14.14 |
| Maximum operating pressure [bar] | 55 | 16 |

## OPERABILITY ANALYSIS RESULTS

The operability analysis was successful as the modular, heterogeneous electrolysis system is operable in most of the operating states and ranges. However, at a few boundary conditions of the operating range and in the hot-standby state the DOS was exceeded, as shown for an exemplary inoperable operating point in Figure 2.

It can be seen, that at high temperatures, high pressures and low flowrates in the system, multiple criteria in the DOS are exceeded during nominal operation. The Stack-Unit outlet temperatures rise above the limit of 90 °C (upper left). Additionally, the $H_2$ in $O_2$ contamination in the AEL system exceeds the allowed threshold of 2 mol% at the 20 % Stack-Unit load setpoint (lower left). The temperature change rate during the cooling cycle shutdown rises above 1 K/min in the circulation however, in the Stack-Unit the temperature change rate stays below the threshold (upper right). The hot-standby state is not operable with the chosen PEAs and control strategies, as the difference pressure and the contaminations in the system rise above the set threshold in the dDOpS (lower left and right). Consequently, the current PEA selection and control strategies are not sufficient for the hot-standby state and complete operability is not given under the specified conditions. Further evaluations of specific energy consumption and $LGC_{H2}$ shall therefore be done for the nominal operation state without consideration of the hot-standby state. The DIS for the nominal operation state can be seen in Figure 3 as the filled circles in the evaluation of specific energy consumption and $LGC_{H2}$. The unfilled circles represent the operating points, that are not operable in the nominal operation state with the chosen PEAs and control strategies.

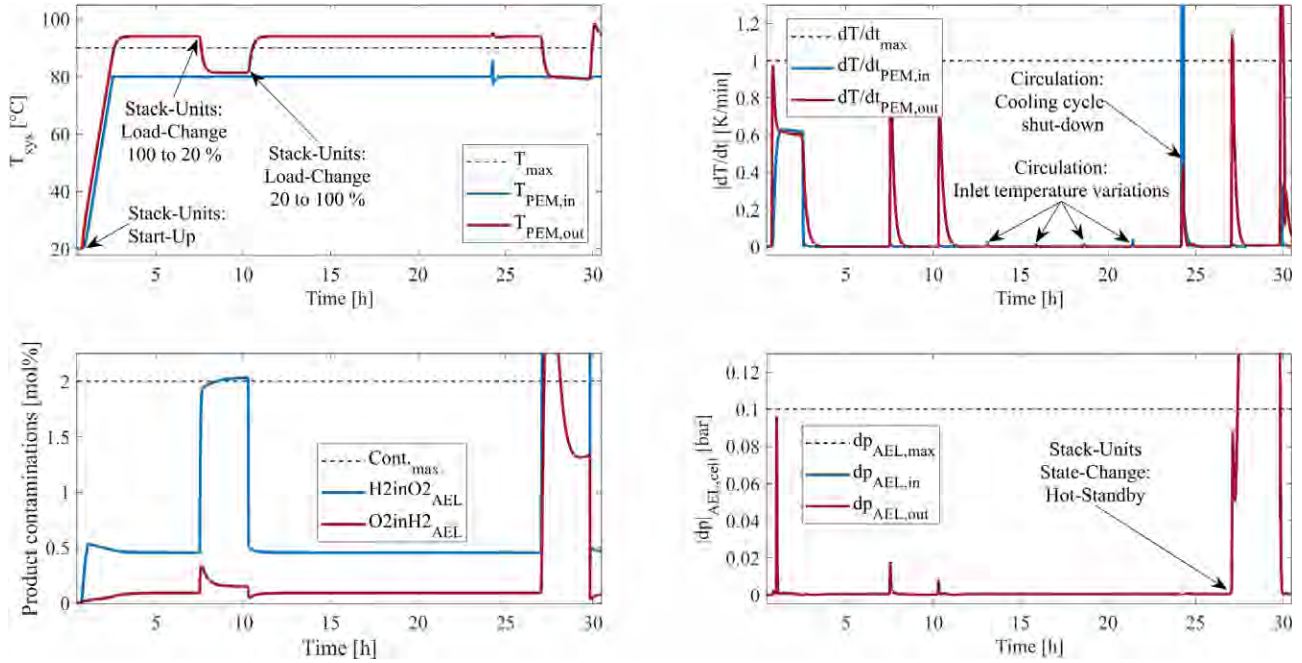

**Figure 2:** Examplary progression of relevant variables in the dAOpS with marked state changes for the dAIS setpoints: $T_{Set}$ = 80 °C, $p_{Set}$ = 16 bar, $f_{AEL,Set}$ = 30,6 kg/s & $f_{PEM,Set}$ = 4,76 kg/s

## System efficiency and LHCH2

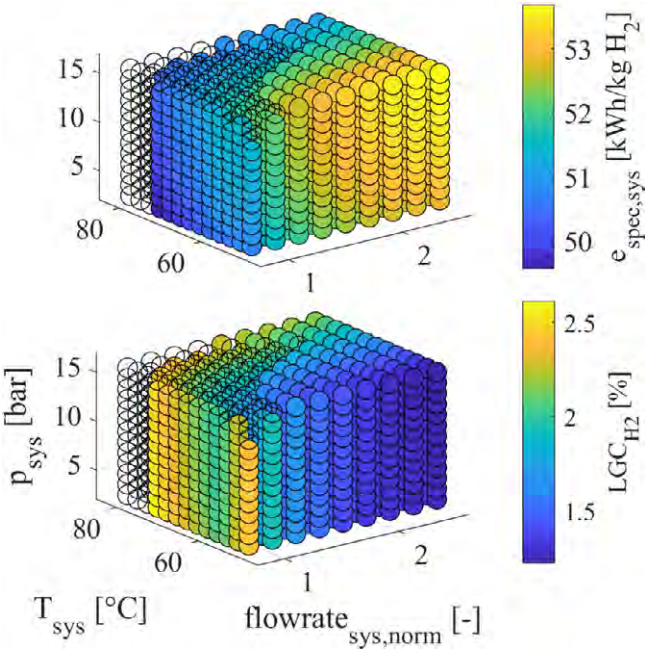

**Figure 3:** System efficiency and $LGC_{H2}$ evaluation

The relevant system efficiency and $LGC_{H2}$ are evaluated for all setpoints in the operable range of temperature, pressure and flowrate. Other system variables stay at their mean values in Tables 1-3. The results are depicted in Figure 3, with an optimal system efficiency of 49,57 kWh/kg H2, at the lowest pressure of 3 bar, the highest operable temperature of 72.5 °C and the lowest normalized flowrate of 0.85.

## Limitations & Solution approaches

As the plant layout and control strategies have been simplified for the scope of this paper, some limitations to the significance and validity of the presented results must be made. The first aspect that must be considered for a more reliable operability analysis is the extension of the plant structure to include the purification and post-processing of produced hydrogen. The current results for system efficiency and $LGC_{H2}$ are limited to the hydrogen generation and first separation stage leading to the assessment of high efficiency at lower pressures and high temperatures while neglecting potential losses due to necessary compression or drying of hydrogen in the post-processing. The inclusion of these steps in the operability analysis and system efficiency evaluation is necessary to provide a more meaningful understanding of electrolysis and their optimal operating conditions.

Secondly the hot-standby state can not be operated with the included control strategies due to a lack of inertization or strategies to deal with the gas crossover within the provided FMUs. Especially at high gas pressures, the difference in partial pressures between the hydrogen and oxygen side lead to a steady cross-over of gases in the hot-standby state. Without inerting or stopping the fluid circulation the contaminations and pressure differences between the gas sides rise.

## CONCLUSION & OUTLOOK

In conclusion the operability of a modular, heterogeneous electrolysis system was verified with restrictions.

The possible operating ranges and variations in the operating regiment have been collected and introduced to a dynamic operability analysis. Extensive simulation studies using co-simulation of FMUs show the operability of the presented plant in most of the outlined operating range. Possible disturbances to the system inputs can be dealt with in the required time. Operating points for optimal system efficiency and flexibility of the plant have been identified, although the applicability to a more complex electrolysis system with downstream equipment is limited. For future work the presented solution approaches and additions to the system layout and control strategies with additional information exchange between PEAs, such as states and safety relevant variables, can provide a more comprehensive understanding of the operability and optimal performance of modular, heterogeneous electrolysis plants.

## Digital supplementary material

The P2O Lab Learning Factory provides a Github-group repository which contains the individual model repositories of the developed simulation models. It is currently only available upon individual request at https://github.com/orgs/p2o-lab/teams/ap2_external/repositories. The repositories will be openly accessible starting from October 2025.

## ACKNOWLEDGEMENTS

## ABSTRACT

One of the current challenges for hydrogen-related technologies is its storage and transportation. The low volumetric density and low boiling point require high-pressure and low-temperature conditions for effective transport and storage. A potential solution to these challenges involves storing hydrogen in chemical compounds that can be easily transported and stored, with hydrogen being released through decomposition processes. Ammonia stands out as a promising hydrogen carrier due to its high hydrogen content (17.8% by weight), relatively mild liquefaction conditions (~10 bar at 25°C), and the availability of a well-established storage and transportation infrastructure. The objective of this study was to develop a mathematical model to analyze and design a membrane fixed-bed reactor (MFBR) for large-scale ammonia decomposition. The kinetic model for the Ru-K/CaO catalyst was obtained from the literature and validated using the experimental data reported in the original study. This catalyst was selected due to its effective performance under high-pressure conditions, which increases the drive force for hydrogen permeation in the membrane reactor. The model was developed in Aspen Custom Modeler (ACM) using a 1D pseudo-homogeneous approach. The governing equations for mass, energy, and momentum conservation were discretized via a first-order backward finite difference method. The effectiveness factor was incorporated to account for intraparticle mass transfer limitations, which are prevalent with the large particle sizes typically employed in industrial applications. The study further investigated the influence of sweep gas ratio, temperature, relative pressure, and space velocity on ammonia conversion and hydrogen recovery, employing response surface methodology generated through an ACM-Python interface. The proposed multi-tubular membrane reactor achieved approximately 94% ammonia conversion and 90% hydrogen recovery, operating at an inlet temperature of 380°C and a pressure of 40 bar. Under comparable conditions of temperature, pressure, and WHSV, the membrane reactor demonstrated an approximately 41.7% higher ammonia conversion compared to a conventional fixed-bed reactor. Furthermore, the developed model is easily transferable to Aspen Plus, facilitating subsequent process conceptual design and economic analyses.

**Keywords**: Hydrogen, Ammonia decomposition, Membrane reactor, Reactor design, Modeling and simulation

## INTRODUCTION

Hydrogen ($H_2$) is a key player in the transition to renewable energy sources due to its high energy density and $CO_2$-emission-free combustion [1]. However, hydrogen volumetric density is low compared to other conventional fuels such as gasoline, ethanol and natural gas [2]. Consequently, its storage and transportation present challenges, requiring energy-intensive methods like high-pressure compression and cryogenic liquefaction.

Currently, hydrogen is most stored as a compressed gas at 150-700 bar [3]. Another approach is liquid-phase storage, which offers a higher energy density but requires extremely low temperatures (-253°C at 1 bar)[4]. A novel potential solution involves storing hydrogen in chemical compounds that can be easily transported and

stored. Ammonia is a promising hydrogen carrier due to its high hydrogen content (17.8% by weight) and its moderate liquefaction conditions (~10 bar, 25°C), reducing transportation and storage [5].

For the strategy of using ammonia as a hydrogen carrier to be feasible, it is essential to study the decomposition process and develop more efficient reaction systems. Membrane fixed-bed reactors (MFBRs) offer advantages over conventional fixed-bed reactors, such as enabling operation at lower temperatures by selectively removing hydrogen, driving higher ammonia conversion, and reducing the costs associated with hydrogen purification. This study aimed to develop a mathematical model to analyze and design an MFBR for large-scale ammonia decomposition, using a Python-Aspen Custom Modeler (ACM) framework.

## METHODS AND MODELING

A simplified schematic of the reactor is presented in Figure 1. The multi-tubular membrane fixed-bed reactor proposed in this study is based on conventional steam methane reformer (SMR) furnaces.

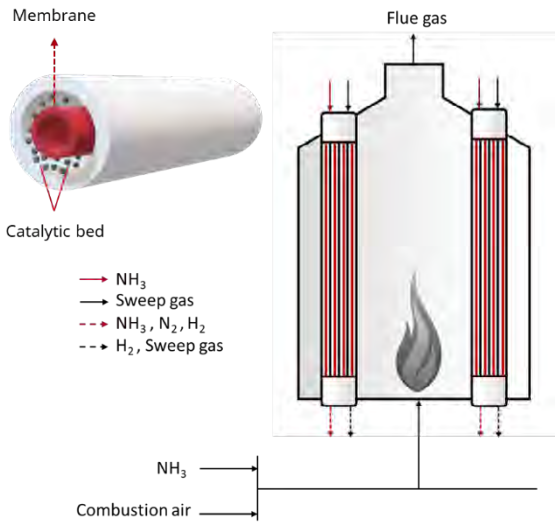

**Figure 1.** Simplified scheme of the multi-tubular membrane reactor.

The reaction system consists of two concentric tubes: an outer tube and an inner tube with a selective palladium membrane. The annular space between these tubes is filled with a Ru-based catalyst, where hydrogen is produced. This hydrogen permeates through the Pd membrane into the inner tube, allowing for selective separation from the reaction mixture. A sweep gas is fed into the inner tube to reduce the partial pressure of permeated hydrogen, enhancing the driving force for separation. The heat is provided to the reaction by flame using the combustion of ammonia itself, a COx-free process.

### Mathematical modeling

The membrane fixed-bed reactor model was developed using a pseudohomogeneous, one-dimensional approach in Aspen Custom Modeler v.12. The main hypotheses of the model are:

1. Steady-state condition;
2. Plug-flow both in reaction and permeation zone due to the high ratio of length to diameter;
3. Negligible axial dispersion due to high calculated Peclet number;
4. Negligible pressure drop in permeation tube;
5. Constant porosity;
6. Membrane 100% selective for hydrogen.

The mass balance for each component in the annular catalytic region is described by Equation 1, while Equation 2 presents the material balance for each component in the permeation tube [6].

$$\frac{dF_{i,a}}{dz} = \eta\, r_i\, \rho_b \pi (R_2{}^2 - R_1{}^2) - 2\pi\, R_1\, J_i \quad (1)$$

$$\frac{dF_{i,t}}{dz} = 2\pi\, R_1\, J_i \quad (2)$$

where $F_{i,a}$ is the component molar flow in the annular region, $\eta$ is the effectiveness factor, $r_i$ is the component reaction rate, $\rho_b$ is the bulk density, $R_2$ is outer tube radius, $R_1$ is the inner tube radius, $F_{i,t}$ is the component molar flow in the permeation region, and $J_i$ is the component permeation flux through the membrane.

The kinetic model for the Ru-K/CaO catalyst, along with its parameters, was obtained from Sayas et al. [7]. The $H_2$ permeation flux was calculated based on Sievert's law, utilizing parameters estimated for a Pd-Ag membrane [8]. The corresponding equations for the reaction rate and $H_2$ permeation flux are presented in the equations 3 and 4.

$$r_{NH_3} = k\, P_{NH_3}{}^a\, P_{H_{2,a}}{}^b \left(1 - \frac{1}{K_{eq}}\left(\frac{P_{N_2}\, P_{H_{2,a}}{}^3}{P_{NH_3}{}^2}\right)\right) \quad (3)$$

$$J_{H_2} = \frac{B_H}{\delta}\left(P_{H_{2,a}}{}^{1/2} - P_{H_{2,t}}{}^{1/2}\right) \quad (4)$$

where $r_{NH_3}$ is the ammonia consumption rate, $k$ is rate constant, $P_{NH_3}$ is the ammonia partial pressure, $P_{H_{2,a}}$ and $P_{H_{2,t}}$ represent the hydrogen partial pressures on the annular and permeate sides, respectively, $P_{N_2}$ is the nitrogen partial pressure, $K_{eq}$ is the thermodynamic equilibrium constant, $J_{H_2}$ is the hydrogen permeation flux, $B_H$ is the permeability, and $\delta$ is the membrane thickness.

For the effectiveness factor calculation, the kinetic

model was mathematically transformed into a pseudo-first-order kinetics, following the Pacheco et al. [9] framework. This transformation allows the Thiele modulus and the effectiveness factor to be calculated analytically.

Equations 5 and 6 present the energy balances for annular region and permeation tube [6]. It was considered that the membrane surface in contact with the reaction zone has the same temperature as the reaction itself. This assumption is reasonable because the metallic components of the membrane structure have high thermal conductivity, making their thermal resistance negligible [6].

$$\left(\sum_{i=1}^{3} F_{i,a}\, c_{p,i}\right)\frac{dT}{dz} = 2\pi\,[R_2(U_1(T_w - T)) - R_1(U_2(T - T_p))] + \pi\,(R_2{}^2 - R_1{}^2)\,\rho_b\,\eta\,r_{rxn}(-\Delta H_{rxn}) \quad (5)$$

$$\left(\sum_{i=1}^{2} F_{i,p}\, c_{p,i}\right)\frac{dT_p}{dz} = 2\pi\; R_1[U_2(T - T_p) - J_{H_2}[h_{H_2}(T_p) - h_{H_2}(T)]] \quad (6)$$

where $c_{p,i}$ is the component molar specific heat, $T$ is the temperature in the reaction region, $T_p$ is the temperature in the permeation region, $T_w$ is the wall temperature, $U_1$ is the overall heat transfer coefficient between the reactor's outer wall and the annular reaction zone, $U_2$ is the overall heat transfer coefficient between the reaction and permeation zones, $r_{rxn}$ is the ammonia decomposition rate, and $h_{H_2}$ is the specific enthalpy of hydrogen.

The overall heat transfer coefficient between reaction tube outer wall and reaction mixture ($U_1$) is calculated using Dixon correlation [10], whereas the overall heat transfer coefficient between the annular region and the permeation ($U_2$) is considered fixed with the value of 8.64 kJ/m²·h·K [11].

For the annular catalytic region, the pressure drop along the reactor's length is calculated using the Ergun equation, as shown in Equation 7.

$$-\frac{dp}{dz} = 150\,\frac{(1-\varepsilon)^2}{\varepsilon^3}\,\frac{\mu\,u}{{d_p}^2} + 1.75\,\frac{1-\varepsilon}{\varepsilon^3}\,\frac{u^2\rho_f}{d_p} \quad (7)$$

where $p$ is the pressure of the annular reaction zone, $\mu$ is the mixture viscosity, $u$ is the fluid superficial velocity, $d_p$ is the spherical equivalent particle diameter, $\varepsilon$ is the bed porosity, and $\rho_f$ is the fluid density.

Physical properties, including mixture density, dynamic viscosity, molar specific heat, and hydrogen specific enthalpy, were calculated using internal procedures within ACM, based on the PR-BM thermodynamic property package. This package employs the Peng-Robinson equation of state with Boston-Mathias modifications to determine the main thermodynamic properties.

The governing equations for mass, energy, and momentum conservation were discretized via first-order backward finite difference method and solved using a nonlinear equation solver. The reactor parameters are detailed in Table 1.

**Table 1:** Parameter setting of the ammonia cracking membrane reactor.

| Parameter | Value | Reference |
|---|---|---|
| Tube length (m) | 12 | [12] |
| Reactor internal diameter (m) | 0.1016 | [13] |
| Membrane diameter (m) | 0.0508 | Adopted |
| Membrane thickness (μm) | 7.5 | [8] |
| Catalyst particle diameter (mm) | 10 | [14] |
| Bed voidage (Estimated) | 0.404 | [15] |

## Sensitivity analysis: Python-ACM interface

ACM enables an automated interface with Python via the comtypes module, facilitating model analysis and response surface generation. Python controls model variables and parameters, sending commands to ACM to perform simulations and record responses. The output data are processed in Python, allowing for the generation of response surfaces and detailed sensitivity analysis.

First, an isothermal reactor was considered and the effect of temperature, space velocity, permeation tube pressure and sweep gas ratio in the ammonia conversion and hydrogen recovery. After establishing the operational conditions, the rigorous model of a non-isothermal reactor was then simulated.

# RESULTS

This section presents the isothermal reactor analysis to evaluate operational variables and define preliminary conditions, followed by the results for the non-isothermal model.

## Effect of pressure and temperature

Figure 2 shows the effect of the tube and reaction pressures on ammonia conversion at temperatures of 350°C, 400°C, and 450°C. The results demonstrate that increasing temperature enhances ammonia conversion, consistent with the endothermic nature of the reaction. At 450°C, near-complete conversion is achieved under favorable pressure conditions (low tube pressure and high reaction pressure).

Higher reaction pressures reduce ammonia conversion due to thermodynamic limitation; however, they also enhance the driving force for hydrogen permeation through the membrane, partially compensating for this limitation. Conversely, higher tube pressures reduce the driving force for hydrogen removal, which can lower conversion efficiency. Nonetheless, they provide the ad-

vantage of delivering pressurized hydrogen, thereby reducing recompression costs.

Another important metric to evaluate is hydrogen recovery (HR), defined as the ratio of the amount of hydrogen separated through the membrane to the total amount of hydrogen produced in the reaction. Figure 3 shows the effect of tube and reaction pressures on HR at temperatures of 350°C, 400°C, and 450°C.

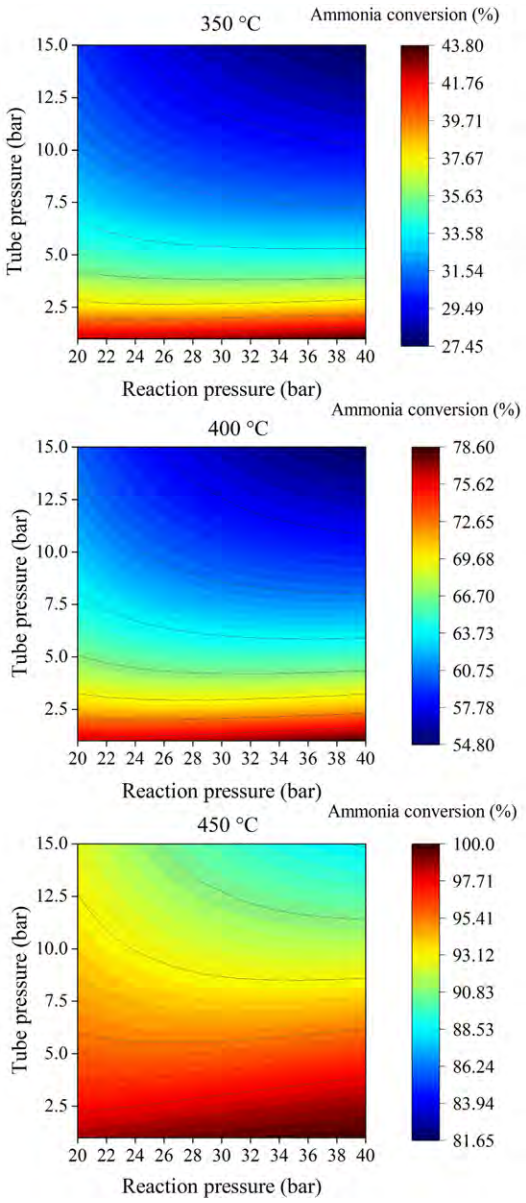

**Figure 2.** Effect of tube and reaction pressure at temperatures of 350°C, 400°C, and 450 °C on ammonia conversion (WHSV = 1000 g/L·h , sweep gas ratio = 0.25).

As expected, HR is enhanced by increasing the pressure difference between the reaction zone and the tube, which acts as the driving force for hydrogen permeation. Temperature also positively influences HR, as it increases the permeation rate of hydrogen. At a pressure difference of 30 bar and a temperature of 350 °C, HR is approximately 56.9%. In contrast, at 450 °C under the same pressure conditions, HR increases significantly, reaching 73.4%.

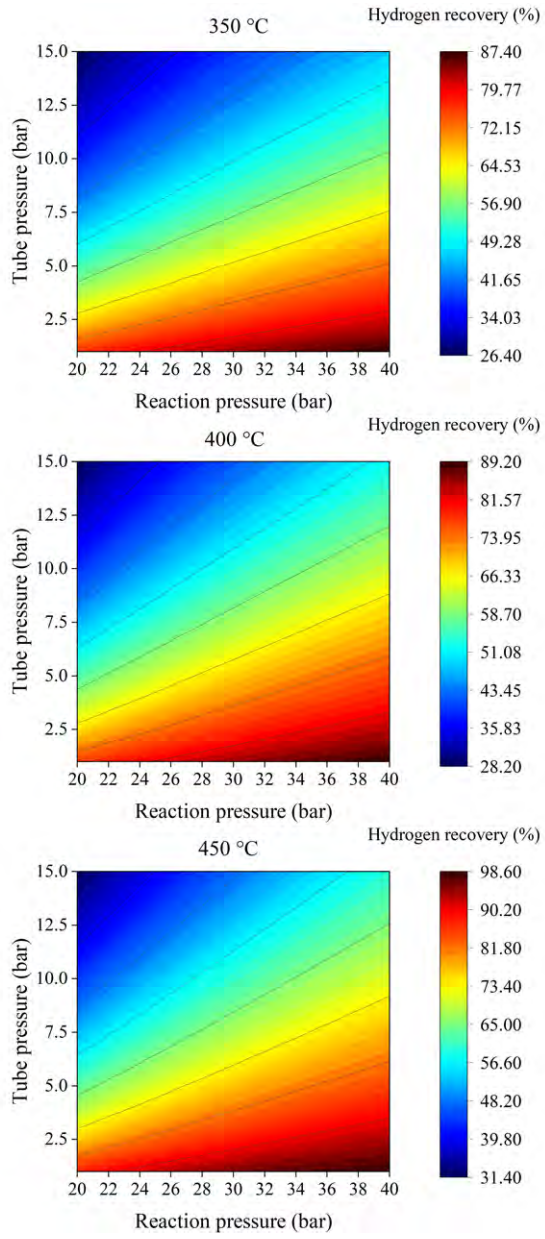

**Figure 3.** Effect of tube and reaction pressure at temperatures of 350°C, 400°C, and 450 °C on hydrogen recovery (WHSV = 1000 g/L·h , sweep gas ratio = 0.25).

## Effect of space velocity and sweep gas ratio

Figure 4 presents the effect of WHSV (weight hourly space velocity) and sweep gas ratio (SGR) on ammonia conversion for 400 and 450°C, while also comparing the performance of the membrane fixed-bed reactor design

(MFBR) with a conventional fixed-bed reactor. The SGR, defined as the molar ratio of sweep gas to feed ammonia, influences the driving force for hydrogen permeation by reducing the partial pressure of hydrogen on the permeation side of the membrane.

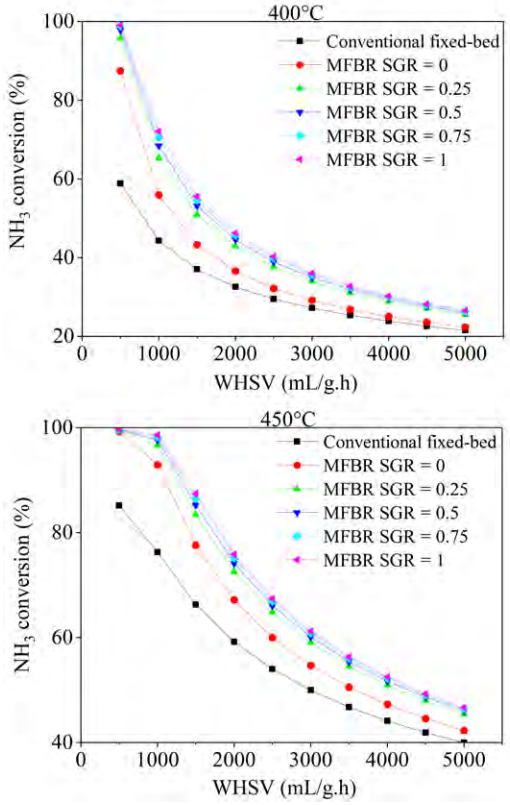

**Figure 4.** Effect of WHSV and sweep gas ratio (SGR) at temperatures of 400 and 450 °C on ammonia conversion (tube pressure = 5 bar, reaction zone pressure = 40 bar).

The results presented in Figure 4 indicated that the conversion gain of MFBR compared to the conventional fixed-bed reactor is more pronounced at lower WHSV values. For instance, at a WHSV of 500 mL/g·h, 400°C, and SGR of 0.25, the conversion increase is approximately 63%. In contrast, at a WHSV of 1500 mL/g·h under the same conditions, the conversion gain drops to 37%. When the temperature increases from 400 to 450 °C, overall ammonia conversion improves for both reactors due to enhanced reaction kinetics. However, at low WHSV values, the relative conversion gain of the MFBR compared to the conventional reactor reduces at 450 °C.

Additionally, increasing the SGR from 0 to 0.25 leads to considerable improvement in ammonia conversion. However, further increases in SGR beyond 0.25 yield only slight gains in conversion.

## Complete model and reactor design

A reactor configuration was proposed based on the analysis of key operating variables. To better represent industrial performance, the model was extended to include non-isothermal behavior and intraparticle mass resistance. Table 2 summarizes the selected operating conditions for the complete model and reactor design.

**Table 2:** Operating conditions for the MFBR Simulation.

| MFBR operating conditions | Value |
|---|---|
| Inlet reactor temperature (°C) | 380 |
| Sweep gas ratio | 0.25 |
| Reaction and tube pressures (bar) | 40/5 |
| WHSV (mL/g·h) | 500 |

Figure 5 compares ammonia conversion and reaction zone temperature profiles along the reactor length for MFBR and conventional fixed-bed reactors under the same operating conditions.

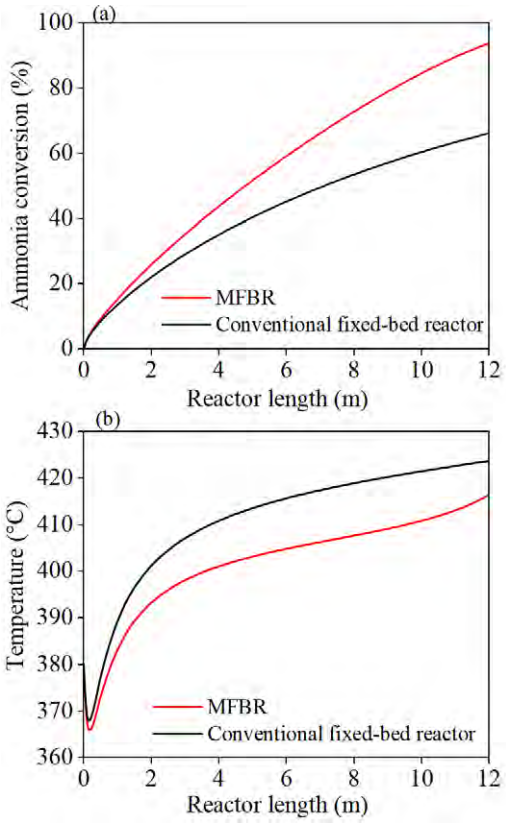

**Figure 5.** Profiles of ammonia conversion (a) and reaction zone temperature (b) along the reactor length for MFBR and conventional fixed-bed reactors ($T_w$ = 430 °C).

The proposed MFBR demonstrated an approximately 41.7% higher ammonia conversion compared to a conventional fixed-bed reactor. The conversion profile indicates that the reaction occurs along the entire reactor

length, ensuring effective utilization of the reactor volume without underutilized sections.

Regarding the temperature profile, an initial drop is observed in both reactors. This behavior can be explained by the reaction's endothermic nature, where a higher reaction rate near the reactor inlet, driven by the elevated partial pressure of ammonia, results in significant heat consumption. Despite the same fixed wall temperature for both reactors, the MFBR exhibits a lower temperature profile along the reactor length due to its higher ammonia conversion.

Considering a large-scale ammonia decomposition unit with the production of 200 tons per day of hydrogen, the proposed reactor would require 1017 tubes.

## CONCLUSION

A unidimensional pseudohomogeneous model describing a multi-tubular membrane reactor for ammonia decomposition was developed. The proposed reactor configuration achieves 94% ammonia conversion and 90% hydrogen recovery, representing a 41.7% higher conversion compared to the traditional reactor. These results are promising and provide a foundation for scaling up the ammonia decomposition process in membrane reactors.

Overall, the MFBR offers several advantages compared to the traditional fixed-bed reactor. It enables operation at lower temperatures due to its higher conversion rates and avoids the need for costly hydrogen separation steps, resulting in potential environmental and economic benefits. In future work, a more detailed 2D model incorporating radial dispersion effects will be developed and the results of both models will be compared.

## ACKNOWLEDGEMENTS

The authors gratefully acknowledge the support of the São Paulo Research Foundation (FAPESP) (#2022/15230-5, #2024/08858-9) and Petronas for the financial support and ANP (Brazilian National Oil, Natural Gas, and Biofuels Agency) for the strategic importance of its support through the R&D levy regulation.

## ABSTRACT

Power-to-Ammonia technology offers sustainable pathways for energy storage and chemical production, with fixed-bed reactors being critical components for efficient synthesis. Understanding reactor dynamics under varying conditions is essential for optimizing these systems, particularly when integrated with intermittent renewable energy sources. This study aims to develop and validate a 2D axisymmetric CFD model for analysing the dynamic response of a ruthenium-catalysed ammonia synthesis reactor to thermal perturbations. The model incorporates detailed reaction kinetics, multicomponent mass transport, and heat transfer mechanisms to predict system behaviour under transient conditions. Results reveal that a step increase in wall temperature from 400°C to 430°C enhances $NH_3$ concentration by 136% (from 2.2 to 5.1 vol.%), with rapid system stabilization achieved within 0.5 seconds. The thermals response maintains consistent heat transfer patterns, exhibiting ~400K differentials between inlet and maximum temperature zones

## INTRODUCTION

Power-to-Ammonia (PtA) technology offers a sustainable and efficient solution by integrating renewable energy sources with carbon-neutral fuel production. This approach allows energy to be stored in the form of ammonia, which can serve as a fuel, energy carrier, or key ingredient in fertilizers [1]. The core of the PtA process lies in its reaction system, featuring a packed-bed reactor (PBR) where ammonia is synthesized from hydrogen ($H_2$) produced via water electrolysis and nitrogen ($N_2$) captured from the atmosphere. Nevertheless, the synthesis process poses intricate multiscale challenges related to flow, heat, and mass transfer, largely driven by the highly exothermic nature of the reaction . Advanced modeling techniques, such as Computational Fluid Dynamics (CFD), are essential to address these challenges, enabling optimization of reactor performance, catalyst utilization, and overall energy efficiency [2].

Several studies have focused on CFD simulation of the PBR reactor in steady state. Gu et al. [4] explored decentralized ammonia synthesis for hydrogen storage and transport using a CFD model, focusing on a small-scale Haber-Bosch reactor with Ruthenium-based catalysts optimized for mild conditions. The model's accuracy was validated against experimental data and parametric studies were conducted to assess the impact of key operational parameters. The results showed that temperature is the most influential factor affecting ammonia production and pressure primarily affects the chemical equilibrium. Furthermore, the study identified an optimal gas hourly space velocity (GHSV) of 1.8·10^5 h^(-1) for efficient ammonia synthesis. Nikzad et al. [5] compared the performance of three different reactor configurations to find the optimal design to enhance nitrogen conversion and reduce pressure drops. The study used CFD simulations to analyze and compare the mass, energy and momentum conservation in a two-dimensional geometry of the three reactor types. The spherical reactors, particularly the spherical axial flow (SAF) configuration, were more efficient than conventional tubular reactors for

ammonia synthesis. Tyrański et al.[3] investigated the ammonia synthesis process in an axial-radial bed reactor using CFD focusing on understanding the influence of catalyst bed parameters, such as particle size and geometry modifications, on the efficiency of the reactor. The simulations demonstrated that smaller catalyst particles (1-2 mm) provided a higher ammonia formation rate, while larger particles show a slower reaction rate spread throughout the bed. Moreover, modifications in bed geometry could reduce the bed volume by half without losing efficiency.

However, in PtA systems, the intermittent nature of renewable energy sources, such as hydrogen production via electrolysis, introduces additional complexities in reactor performance. Boundary conditions and external disturbances, like variations in hydrogen flow or temperature fluctuations, can significantly impact key process variables, including reaction rates, heat transfer, and overall system stability. Therefore, understanding the reactor's transient response under such dynamic conditions is crucial.

This study focuses on developing a 2D axisymmetric transient CFD model for ammonia synthesis within a fixed-bed reactor, specifically analyzing the dynamic response to thermal perturbation at the reactor wall. By evaluating these transient states, the research aims to provide insights into reactor thermal behavior under temperature fluctuations that may occur in PtA systems.

| | $\mathbf{K}=\mu(\nabla\mathbf{u}+(\nabla\mathbf{u})^{\mathrm{T}})-\frac{2}{3}\mu(\nabla\cdot\mathbf{u})\mathbf{I}.$ | (15) |
| Continuity equation | $\frac{\partial\rho}{\partial t}+\nabla\cdot(\rho\mathbf{u})=0$ | (16) |

The governing equations describing the behaviour of the fixed-bed reactor for ammonia synthesis can be divided into two main regions: the catalytic region and the free fluid region.

## Kinetic Model for Ammonia Synthesis

The reaction follows a rate-limiting mechanism in which the dissociation of nitrogen is the lowest and most energy-intensive step. The overall reaction is represented as:

$$N_2(g)+3H_2(g)\rightarrow 2NH_3(g) \tag{17}$$

The reaction rate for ammonia synthesis on a ruthenium (Ru)-based catalyst is governed by a modified Temkin kinetic expression, which includes $H_2$ and $NH_3$ adsorption terms [4]. The rate expression is given by:

$$\frac{d\eta}{dt}=k\lambda(q)\left[\frac{(a_{N_2})^{0.5}\left[\frac{(a_{H_2})^{0.375}}{(a_{NH_3})^{0.25}}\right]-\frac{1}{Ka}\left[\frac{(a_{NH_3})^{0.75}}{(a_{H_2})^{1.125}}\right]}{1+K_{H_2}(a_{H_2})^{0.3}+K_{NH_3}(a_{NH_3})^{0.2}}\right] \tag{18}$$

The term $d\eta/dt$ represents the rate at which the limiting reactant is consumed, expressed in $mol\cdot h^{-1}\cdot dm_{cat}^3$. The kinetic constant for the reverse reaction (ammonia decomposition) is denoted as $k$, while $K_a$ refers to the equilibrium constant for the reaction [5].The activities of the reactants and product are indicated by $a_i$. The stoichiometric coefficient, $\lambda(q)$, is set to 1 or 3 depending on whether the $H_2/N_2$ feed ratio is 3 or 1.5, respectively [6]. The absorption equilibrium constants of reactants $K_{H_2}$ and $K_{NH_3}$ are expressed by [7]. The activity of the ith species ($NH_3, H_2$ *or* $N_2$) $a_i$ can be calculated as follows,

$$a_i=y_i\phi_i P \tag{19}$$

Where $P$ indicates the total pressure (atm), $y_i$ and $\phi_i$ denotate the mole fraction and fugacity coefficient of the ith species, respectively. The fugacity coefficients for the reactants and product are fitted by temperature (K) and

pressure (atm) using the equations in expressed by [5].

## RESULTS AND DISCUSSION

### Model Validation and Mesh Independence

A mesh independence study was conducted with four mesh configurations, as illustrated in Figure 1. The $NH_3$ production rate showed minimal variation between coarse (35.802 $kg \cdot m^{-3} \cdot s^{-1}$) and medium (35.825 $kg \cdot m^{-3} \cdot s^{-1}$) meshes (0.064% difference). The fine mesh (36.087 $kg \cdot m^{-3} \cdot s^{-1}$) was adopted, achieving an average element quality of 0.8155. Element quality, a dimensionless metric ranging from 0 to 1, evaluates the regularity of mesh element shapes, with values closer to 1 indicating optimal shape regularity and values near 0 signifying highly distorted or degenerated elements. This measure ensures numerical stability, geometric aligment, and computational accuracy. The selected mesh showed excellent agreement with experimental data from literature (35.5 – 36.5 $kg \cdot m^{-3} \cdot s^{-1}$) [7].

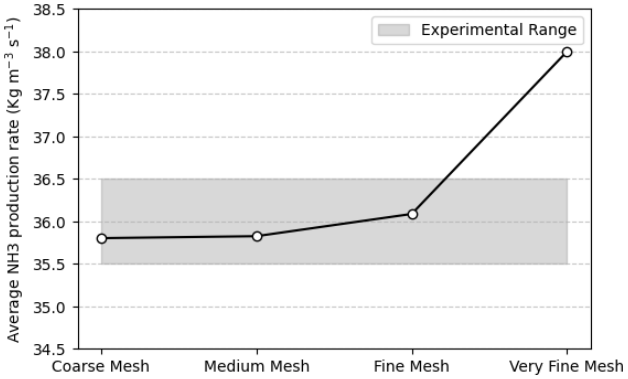

**Figure 1:** Effect of the mesh refinement on average $NH_3$ concentration under standard operating conditions (T=430 ℃, $P = 100$ bar, $GHSV = 180.000\ h^{-1}$).

### Reaction Kinetic and Thermodynamic Response

The kinetic response to the wall temperature step change from 400℃ to 430℃ resulted in a rate constant enhancement factor of 2.08, as shown in Figure 2(a). The relative low activation energy of the Ru/C catalyst (23 kcal/mol) compared to traditional Fe-based catalyst (32 – 35 kcal/mol) accounts for this significant kinetic enhancement, explaining why the $NH_3$ concentration rapidly increased from 2.2 vol.% to 5.1 vol.% after the temperature perturbation. As shown in Figure 2(b), the equilibrium constant (Ka) decreased by approximately 35% at higher temperature, which thermodynamically favours the reverse reaction. However, the observed increase in $NH_3$ production (136%) demonstrates that the kinetic enhancement dominated over the equilibrium constraints in this temperature range. The surface chemistry evolution, depicted in Figure 2(c), shows that the absorption constants for both $H_2$ and $NH_3$ decreased with increasing temperature.

### Thermal Dynamic Response Analysis

The dynamic behavior of the ammonia synthesis reactor under thermal disturbance was systematically investigated to evaluate its response to a step perturbation in the wall temperature. This analysis was conducted maintaining constant operating conditions of 70 bar pressure, GHSV of 180.000 $h^{-1}$, and $H_2/N_2$ feed ratio of 3.0, which represent steady-state operation parameters with the major production rates [7]. Figure 2(d) illustrates the magnitude of the wall temperature step, which was set to 30K based on the high sensitivity of Ru catalyst kinetics to temperature changes in this range, as demonstrated in previous studies [4], [6], [7]. This temperature step is also practically relevant, as it sits within the typical operating window (370-460℃) where Ru catalysts show high activity while avoiding excessive thermal stress on the reactor system.

### $NH_3$ Production

The system's response to the temperature perturbation reveals significant insights into the reactor's dynamic behavior, Figure 2(d). Initially, the $NH_3$ concentration rapidly increases from 0 to approximately 2 vol.% during the first 0.5 seconds showing the system's quick response to the initial operating temperature of 400℃. This is followed by a brief stabilization period where the concentration remains steady at around 2.2 vol.%. At t = 1.0 s, when the step increase in temperature from 400℃ to 430℃ is implemented, the $NH_3$ concentration exhibits a sharp response, rising from 2.2 vol.% to approximately 5.1 vol.%. This dramatic increase, representing a 136% improvement in $NH_3$ production, demonstrates the strong temperature dependence of the reaction kinetics. The smooth transition and stable final concentration suggest that the reactor maintains operational stability despite the sudden temperature change, which is crucial for practical applications in industrial settings.

### Thermal Distribution Evolution

The spatial temperature distributions before and after the step perturbation provide insights into the reactor's thermal behavior. Figure 3(a) shows the temperature field at t = 0.8 s, prior to the step change, where the wall temperature is maintained at 673.15 K (400℃). At this condition, the temperature ranges from 280 K at the inlet to 679 K near the reactor wall, displaying a significant thermal gradient characteristic of the exothermic ammonia synthesis process.

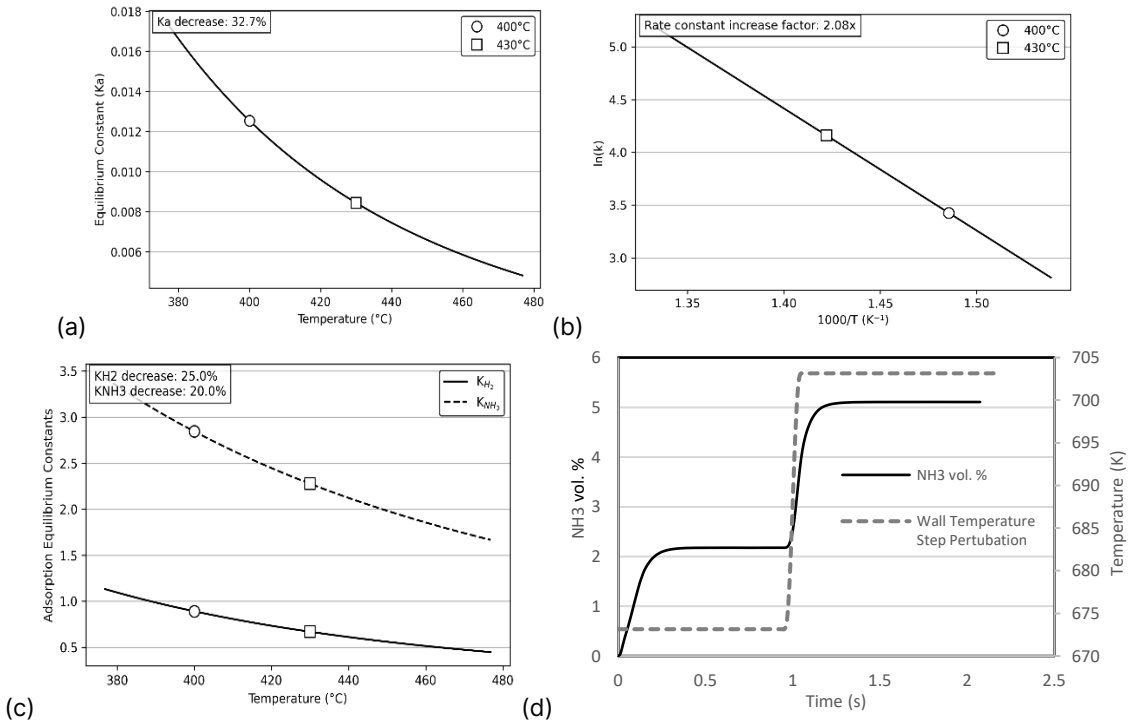

**Figure 2:** Thermal Dynamic Response of the Ammonia Synthesis Reactor. (a) Impact of temperature change on equilibrium constant. (b) Arrhenius behavior of $NH_3$ synthesis rate constant. (c) Temperature step change on adsorption constants. (d) Temperature step perturbation at the reactor walls and Dynamic respon of $NH_3$ volumetric concentration.

After the step perturbation (Figure 3(b), t = 2.0s), the system reaches a new thermal equilibrium with the elevated wall temperature of 703.15 K (430℃). The temperature distribution shows a similar pattern bit with higher overall values, ranging from 277 K at the inlet to 719 K in the reaction zone. The comparison between both states reveals that while the absolute temperatures have increased, the fundamental heat transfer characteristics remain consistent. The effective heat conduction through the catalyst bed is evidenced by the smooth temperature transitions, and the radial temperature distribution indicates significant wall-to-center heat transfer.

A notable observation is the persistence of steep temperature gradients near the inlet in both cases, with a temperature difference of approximately 400 K between the inlet and maximum temperature zones. This consistency in temperature differential, despite the step change in wall temperature, suggests robust heat transfer mechanisms within the reactor. The similarity in the thermal patterns before and after the perturbation indicates that the reactor design effectively manages heat distribution under changing thermal conditions, an essential characteristic for industrial applications where temperature fluctuations may occur.

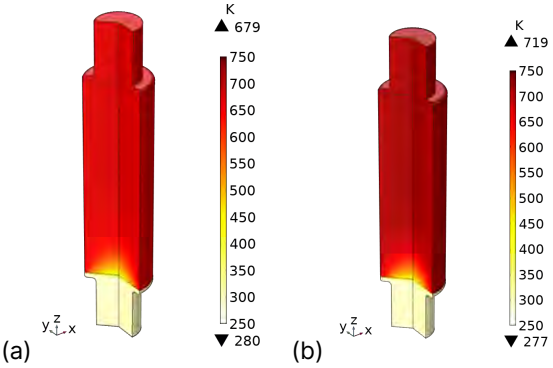

**Figure 3**. Temperature distribution in the reactor at (a) t = 0.8 s with wall temperature of 673.15 K (400℃) and (b) t = 2.0 s after step increase to 703.15 K (430℃).

## $NH_3$ Concentration Evolution

The evolution of $NH_3$ concentration over time, as depicted in Figure 3, clearly represents the fixed-bed reactor's response to a step change in wall temperature, with critical phases occurring at t=0.9 s, t=0.9s, t=1.07 s, and t=2.0 s.

At t=0.9 s, Figure 4(a), prior to the temperature step

change, the wall temperature is maintained at 400°C. During this phase, localized ammonia formation is observed near the reaction zone. This reflects the catalytic activity at the steady-state baseline operating conditions, where the reactor exhibits a controlled and predictable $NH_3$ synthesis rate driven by the Ru/C catalyst's kinetics at the lower temperature.

At t=1.07 s, Figure 4(b), the step temperature change is introduced, rapidly elevating the wall temperature from 400°C to 430°C. This thermal perturbation triggers an immediate enhancement in the reaction rate, as the Ru/C catalyst demonstrates strong sensitivity to temperature increases. The resulting $NH_3$ concentration begins to expand radially, highlighting the acceleration of catalytic activity throughout the reactor. This phase represents the transitional behavior of the system as it responds dynamically to the external thermal input, aligning with the thermal response observed in Figure 1(b).

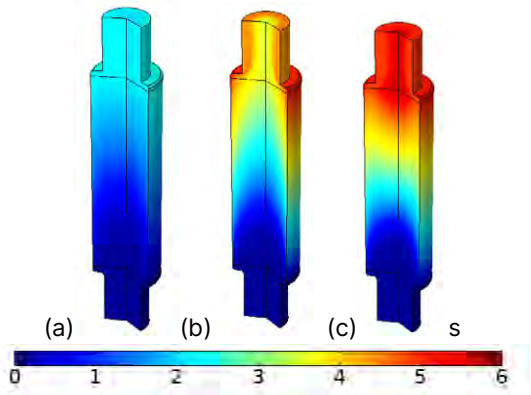

**Figure 4.** Temporal evolution of $NH_3$ concentration profiles at key time points. (a) Concentration profile at t = 0.9 s. (b) Concentration profile at t = 1.07 s. (c) Concentration profile at t = 2 s.

Finally, by t=2.0 s, the reactor achieves stabilization, characterized by a uniform $NH_3$ concentration distribution across the core of the reactor. This indicates that the system has reached a new dynamic equilibrium at the elevated temperature of 430°C. The smooth and rapid stabilization, coupled with a significant increase in $NH_3$ concentration compared to the initial conditions, demonstrates the reactor's efficiency in managing transient thermal changes. This behavior underscores the role of effective heat transfer and robust catalytic performance in maintaining stability despite fluctuating operating conditions.

These findings validate the transient modeling approach and highlight the reactor's capability to adapt quickly to external thermal disturbances. The results provide valuable insights for optimizing the design and operation of ammonia synthesis reactors in Power-to-Ammonia applications, particularly under the variable conditions imposed by intermittent renewable energy sources.

## CONCLUSION

This study developed and validated a 2D axisymmetric transient CFD model to analyze the dynamic response of a fixed-bed ammonia synthesis reactor under thermal perturbations. The results demonstrate a significant enhancement in $NH_3$ concentration (2.2 to 5.1 vol.%) following a temperature step increase from 400°C to 430°C, with rapid stabilization within 0.5 s. The kinetic advantage of Ru/C catalysts at moderate temperatures was found to outweigh thermodynamic limitations, contributing to increased ammonia production. Spatial temperature distributions exhibited consistent heat transfer patterns, maintaining ~400K differentials between inlet and maximum temperature zones.

Future work will address the broader impact of process conditions by extending the sensitivity analysis to include variations in pressure, gas composition, and flow rates. Additionally, a comparative evaluation of alternative reactor configurations and catalyst materials is under investigation to contextualize the advantages and trade-offs of the proposed system. Further assessment of industrial feasibility and scalability, including potential challenges in commercial implementation, will be explored to enhance the model applicability for Power-to-Ammonia applications. These ongoing efforts aim to refine the predictive capabilities of the model and provide deeper insights for optimizing ammonia synthesis under dynamic operating conditions

## ABSTRACT

This study compares the probability density function (PDF) of the power generated by a wind farm obtained analytically with the PDF considering the wake effect between wind turbines, a phenomenon that reduces the power generation capacity of wind farms. Instead of considering the wake effect in the analytical method, which is complex and difficult to solve, it has been proposed to use kernel estimators to obtain the PDF. To calculate it, a wind farm power output data set has been used. This data set was generated using historical wind speed and direction data and the Katic multiple wake model. Discrepancies between the analytical PDF and PDF fitted with the kernel estimators, can lead to an overstatement of the annual available energy by 4 an 9 %, depending on the complexity of the wind farm layout. These inconsistencies can have significant implications for production planning, wind farm design, and integration of wind power into the grid. Therefore, this analysis underscores the necessity of incorporating the wake effect in wind farm modelling, to guarantee more precise projections of generation and energy availability.

**Keywords**: Wake effect, wind farm power distribution, kernel estimators

## INTRODUCTION

When planning wind farm projects, it is crucial to quantify and assess the wind resource of the candidate site. This assessment is typically conducted using the wind energy density [1], also called wind power density [2], which requires the probability distribution of wind speed $f_V(v)$ and the power curve of a wind turbine $P_{WT}(v)$ to calculate it. Furthermore, based on $f_V(v)$, $P_{WT}(v)$ and using the change-of-variable technique, it is possible to obtain the probability density function of a wind turbine power output, $f_{PWT}(P_{WT})$, which provides additional insight into the energy that can be produced [3].

However, to optimize the management of a wind farm, it is necessary to know the probability density function of the power generated by the entire wind farm, $f_{PWF}(P_{WF})$. This function enables the estimation of the variability and availability of the power generated by the wind farm, facilitating production planning over a given period. It also ensures the integration of wind energy into the electricity grid by allowing the determination of the probability of achieving a specific power output. This probability-based approach supports optimal decision making [4]. One way to obtain $f_{PWF}(P_{WF})$ is through the probability distribution of wind speed $f_V(v)$, and the wind farm's power curve, $P_{WF}(v)$, as described before for the single turbines. This requires a simple analytical expression of the wind farm power curve $P_{WF}(v)$, which allows the change-of-variable technique to be used. For example, the power produced by a wind farm can be approximated as the power output of a single wind turbine multiplied by the number of turbines, $P_{WF}(v)=n_{turb}\cdot P_{WT}(v)$.

However, this approach has the disadvantage of not considering a significant source of power loss such as the wake effect (turbines shading each other) due to wind direction. A first alternative to consider the wake effect is to use a wind probability density function and a wind farm power curve that depend on wind speed ($v$) and direction ($\theta$): $f_{V,\Theta}(v,\theta)$, $P_{WF}(v,\theta)$. Nevertheless, deriving these expressions and applying the change-of-variable technique to bivariable distribution functions is highly complex.

For this reason, some authors have tried to keep the

$P_{WF}(v)=n_{turb}\cdot P_{WT}(v)$ approximation and add a wake coefficient term [5], simplifying a wake model such as Jensen's [6], but this approximation is only valid for wind farms with *nxm* rectangular geometry.

This paper proposes generating a sample of wind farm power output data based on historical wind speed and direction data from a given location. The Katic wake model [7] is used to calculate the effective incident velocity for each wind turbine. Subsequently, the power generated by each turbine, $P_{WT}(v)$, is determined, and the total wind farm power is obtained by summing the individual contributions. Finally, the wind farm power probability density function, $f_{PWF}(P_{WF})$, is estimated using kernel method. A similar application of kernel estimators to model the probability density function of a group of wind farms is described in [8]; however, their approach also neglects the wake effect.

The paper is structured as follows. Section 2 explains the two alternatives proposed to obtain $f_{PWF}(P_{WF})$ and the wake model used; section 3 gives a brief description of the data used; section 4 shows the results; and section 5 ends with some brief conclusions.

## MODELLING

This section begins with an explanation of the wake effect in wind farms and how it has been modelled in this work. Next, subsection *Theoretical wind farm power PDF* explains how the probability density function of the wind farm power is obtained theoretically. Finally, subsection *Wind farm power PDF considering wake effect* presents our proposal, based on kernel estimators, to obtain the probability density function of the wind farm power considering the wake effect.

### Wake effect

The wake effect is a phenomenon whereby wind turbines located geographically behind others in relation to the wind front will see their capacity to produce electrical energy diminished due to the loss of energy and increased turbulence that the wind undergoes after passing through a turbine.

Jensen's model is the simplest model to describe this phenomenon [6]. It is based on the assumption that there are no deterministic or periodic vortices immediately behind the turbine, but that the air behaves as a turbulent fluid (the particles move disorderly and the particle trajectories meet to form aperiodic vortices). This model also considers that within the wake, the velocity is constant rather than following a Gaussian or other distribution. As shown in Figure 1, the wake behind the turbine starts at the diameter of the turbine and opens linearly with distance, forming a cone.

In the case of wind farms where there may be more wakes that may also partially affect a turbine, the Jensen's multiple wake model or Katic's model [7] is applied.

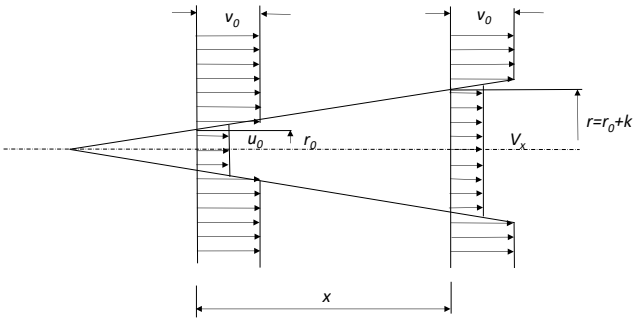

**Figure 1.** Wake generated by the turbine on the left at distance x downstream.

There are many ways to incorporate in a turbine *j* the wake effect of all other turbines *i* upstream. One possibility is to assume that the kinetic energy deficit in turbine *j*, attributable to a mixture of wakes with respect to the undisturbed wind $v_0$, is equal to the sum of the kinetic energy deficits in turbine *j* due to each individual wake of turbine *i* with respect to the undisturbed wind $v_0$, see equation (1).

$$\left(v_0 - v_j\right)^2 = \sum_{i=1}^{n}\left(v_0 - v_{ij}\right)^2 \tag{1}$$

Considering equation (1), together with the Katic's multiple wake model, equation (2) is derived.

$$v_j = v_0\left[1 - \sqrt{\sum_{i=1}^{n}\left(1-\sqrt{1-C_T}\right)^2\left(\frac{r_i}{r_i(x_{ij})}\right)^4\left(\frac{A_{sh,i}}{A_j}\right)^2}\right] =$$

$$v_0\left[1 - \sqrt{\sum_{i=1}^{n}\delta_{ij}^2\left(\frac{A_{sh,i}}{A_j}\right)^2}\right] \tag{2}$$

Where subscript *i* refers to the wind turbines generating a wake on a given wind turbine *j*, $v_0$ is the undisturbed velocity affecting the wind farm (at a position sufficiently far from all turbines), $C_T$ is the thrust coefficient of the wind turbine, $A_{sh,i}$ is the overlapping wake area of wind turbine *i* on wind turbine *j*, and $A_j$ is the swept area of the blades of wind turbine *j*. Finally, $r_i(x_{ij})$ is the radius of the wake of wind turbine *i* (wake generator) at the height of wind turbine *j* (affected by the wake), which can be calculated using equation (3) in terms of the radius of the wind turbine generating the wake, $r_i$, and the wake decay coefficient (4).

$$r_i\left(x_{ij}\right) = r_i + k\cdot x_{ij} \tag{3}$$

The wake decay coefficient is a function of the height of the wind turbine hub, *h*, and the roughness of the terrain, $z_0$.

$$k = \frac{0.5}{ln\left(\frac{h}{z_0}\right)} \tag{4}$$

Considering the different cones generated by the turbines, some of which do not necessarily fully affect the downstream wind turbines, the overlap area $A_{sh,I}$ can be calculated according to three situations:

- If the swept area $A_j$ is outside of the wake area, or wind turbine *i* is stopped, then $A_{sh,i} = 0$.
- If the swept area $A_j$ is completely inside the wake area, and wind turbine *i* is running, then $A_{sh,i} = A_j$.
- If the swept area $A_j$ is partially inside the wake area, and wind turbine *i* is running, then $A_{sh,i}$ is calculated using equation (5).

$$A_{sh,i} = \left[r_i(x_{ij})\right]^2 cos^{-1}\left(\frac{L_{ij}}{r_i(x_{ij})}\right) + r_j^2 \cos^{-1}\left(\frac{d_{ij}-L_{ij}}{r_j}\right) - L_{ij}\sqrt{r(x_{ij})^2 - L_{ij}^2} - (d_{ij}-L_{ij})\sqrt{r_j^2-(d_{ij}-L_{ij})^2} \quad (5)$$

Being $L_{ij}$ described in equation (6).

$$L_{ij} = \frac{r_i^2(x_{ij}) - r_j^2 + d_{ij}^2}{2\,d_{ij}} \quad (6)$$

## Analytical PDF of wind farm power

As mentioned in the introduction, the PDF of the wind farm power $f_{PWF}(P_{WF})$ can be obtained theoretically from the PDF of the wind speed $f_v(v)$ and from the power curve of a wind farm $P_{WF}(v)$, using the change-of-variable technique described in [3].

The power curve of a wind farm, if all wind turbines in the wind farm are equal, can be expressed in megawatts, according to equation (7) and the number of turbines *n_turb*.

$$P_{WF}(v) = \frac{n_turb}{10^6} \cdot P_{WT}(v) \quad (7)$$

The power curve of a wind turbine, $P_{WT}(v)$, establishes the relationship between the wind speed and the power generated by a wind turbine. It can be expressed theoretically as a piecewise function (8), whose parts are defined by $v_{in}$, which is the lower wind speed at which power can be extracted, $v_r$ is the wind speed at which the nominal power of the wind farm ($P_{RWT}$) can be obtained, and $v_{off}$ is the wind speed at which the wind turbine must be stopped in order to prevent damage. Between $v_{in}$ and $v_r$ the power extracted by the wind turbine is a function of the air density $\rho$, the radius $R$ of the area swept by the wind turbine blades, and the power coefficient $Cp$. This coefficient, in turn, is a function of the turbine rotation speed and the pitch angle. The value of this coefficient depends on the turbine model, and its maximum value is set by the Betz limit at 0.593 [9]. In this study, a fixed value has been calculated based on the rated speed of the wind turbine, the rated power of the turbine, and the mean air density at the location of the wind farms.

$$P_{WT}(v) = \begin{cases} 0 & 0 \le v < v_{in} \\ \frac{1}{2}\cdot\pi\cdot R^2\cdot\rho\cdot v^3\cdot Cp & v_{in} \le v < v_r \\ P_{RWT} & v_r \le v < v_{off} \\ 0 & v \ge v_{off} \end{cases} \quad (8)$$

The probability distribution function (PDF) of the wind speed is commonly modelled with a Weibull distribution [1], as it is shown in equation (9).

$$f_v(v) = \begin{cases} \frac{k}{C}\left(\frac{v}{C}\right)^{k-1}\cdot e^{-\left(\frac{v}{C}\right)^k} & v \ge 0 \\ 0 & v < 0 \end{cases} \quad (9)$$

Where *C* and *k* are the scale and the shape parameters, respectively.

Once $f_v(v)$ and $P_{WF}(v)$ are defined, it is possible to obtain the PDF of the wind farm power $f_{PWF}(P_{WF})$, which is described in the equation (10).

$$f_{PWF}(P_{WF}) = \begin{cases} \left(1 + e^{-\left(v_{off}/c\right)^k} - e^{-\left(v_{in}/c\right)^k}\right)\cdot\delta(P_{WF}) & P_{WF} = 0 \\ 0 & 0 < P_{WF} < P_{INWF} \\ \frac{k'}{C'}\cdot\left(\frac{P_{WF}}{C'}\right)^{k'-1}\cdot e^{-\left(P_{WF}/C'\right)^{k'-1}} & P_{INWF} \le P_{WF} < P_{RWF} \\ \left(e^{-\left(v_r/c\right)^k} - e^{-\left(v_{off}/c\right)^k}\right)\cdot\delta(P_{WF}-P_{RWF}) & P_{WF} = P_{RWF} \\ 0 & P_{WF} > P_{RWF} \end{cases} \quad (10)$$

Where $P_{WF}$ is the wind farm power, $P_{INWF}$ is the wind farm power to $v_{in}$, $P_{RWF}$ is the wind farm rated power, $\delta$ is Dirac's delta, and $K''$ and $C''$ are parameters that depend on the previous scale and shape parameters, $k'' = k/3$ and $C'' = (C^3\cdot\pi\cdot R^2\cdot Cp\cdot n_turb)/(2\cdot10^6)$.

Finally, the cumulative distribution function (CDF) of the wind farm power $F_{PWF}(P_{WF})$ is obtained by integrating the PDF of the wind farm (10) between zero and infinity, resulting in (11).

$$F_{PWF}(P_{WF}) = \begin{cases} \left(1 + e^{-\left(v_{off}/c\right)^k} - e^{-\left(v_{in}/c\right)^k}\right) & 0 < P_{WF} < P_{INWF} \\ 1 - e^{-\left(P_{WF}/C'\right)^{k'-1}} & P_{INWF} \le P_{WF} < P_{RWF} \\ 1 - e^{-\left(P_{WF}/C'\right)^{k'-1}} + e^{-\left(v_r/c\right)^k} - e^{-\left(v_{off}/c\right)^k} & P_{WF} = P_{RWF} \\ 1 & P_{WF} > P_{RWF} \end{cases} \quad (11)$$

## PDF of wind farm power considering wake effect

The PDF of the wind farm power obtained previously does not consider the wake effect in any way. In this paper it is proposed to use kernel estimators to estimate the PDF of the wind farm power including the wake effect $f_{PWF_WE}(P_{WF_WE})$. For this purpose, historical wind speed and wind direction data are used to calculate the incident wind speed at each wind turbine ($v_i$) of a wind farm using a valid wake model. In this study, Katic's model is used,

but another model could also be applied while the methodology and conclusions of this paper remain valid. Then, the power generated by each turbine is calculated using $P_{WT}(v)$. Finally, the power of the wind farm is obtained as the sum of the power generated by each turbine (12).

$$P_{WF_WE}(v) = \sum_{j=1}^{n_turb} P_{WT}(v_j) \quad (12)$$

Once the wind farm power data set has been generated, kernel estimators, whose basic equation is shown in equation (13), are used to fit the function $f_{PWF_WE}(P_{WF_WE})$. However, since the power of a wind farm is constrained between 0 and $P_{RWF}$, and the conventional kernel estimator does not consider this constraint, it is necessary to modify it. In this case, the reflection method [10] has been employed, as it is the approach implemented in the kdensity() function of the Statistics and Machine Learning Toolbox [11] from Matlab™ [12], and that will be used to perform the fitting.

$$\hat{f}(x) = \frac{1}{nh}\sum_{i=1}^{n} K\left(\frac{x-x_i}{h}\right) \quad (13)$$

Finally, $f_{PWF_WE}(P_{WF_WE})$ and $F_{PWF_WE}(P_{WF_WE})$ are described in equation (14) and (15) respectively.

$$f_{PWF_WE}(P_{WF_WE}) = \frac{1}{nh}\sum_{i=1}^{n}\left[K\left(\frac{x-2L+x_i}{h}\right) + K\left(\frac{x-x_i}{h}\right) + K\left(\frac{x-2U+x_i}{h}\right)\right] \quad (14)$$

$$F_{PWF_WE}(P_{WF_WE}) = \frac{1}{n}\sum_{i=1}^{n}\left[G\left(\frac{x-2L+x_i}{h}\right) + G\left(\frac{x-x_i}{h}\right) + G\left(\frac{x-2U+x_i}{h}\right)\right] - \frac{1}{n}\sum_{i=1}^{n}\left[G\left(\frac{-L+x_i}{h}\right) + G\left(\frac{L-x_i}{h}\right) + G\left(\frac{x-2U+x_i}{h}\right)\right] \quad (15)$$

Where $n$ is the number of power samples, $L = 0$, $U = P_{RWF}$, $K(\cdot)$ is the kernel estimator, $G(\cdot)$ is the cumulative of $K(\cdot)$, and $x = P_{WF_WE}$.

## Data

The comparison of the two methods will be carried out using simulated data from the New European Atlas [13], [14]. On the NEWA website [15] it is possible to access, free of charge, the time series of wind speed and direction at a given site at different heights (50, 75, 100, 150, 200, 250 and 500 metres), from 2005 to 2018 at half-hourly intervals, a total of 245424 data, of which 195 are missing.

The study is carried out with all data from 2005 to 2018 for two different sites, corresponding to the Rabinaldo wind farm (WF1), located in the province of Burgos (latitude 42° 35' 28.6", longitude -3° 42' 19.7"), and Las Panaderas (WF2) in the province of Valladolid (latitude 41° 47' 21.6", longitude -5° 1' 36.3"). Starting from the velocity time series at the heights available in NEWA, Hellman's law [16] is used to generate the velocity series at the heights of the wind turbine hubs (78 and 114 metres respectively).

However, for the wind direction data series, the NEWA height closest to the hub height (75 and 100 metres respectively) is chosen, since there is no simple analytical expression that relates the variability of the wind direction with height. Information on the wind farms comes also from various official sources. Figure 2 shows the resulting wind roses for each wind farm at wind turbine hub height.

In order to calculate the wake effect, it is also necessary to know the spatial distribution of the wind turbines in each wind farm, which are shown in Figure 3.

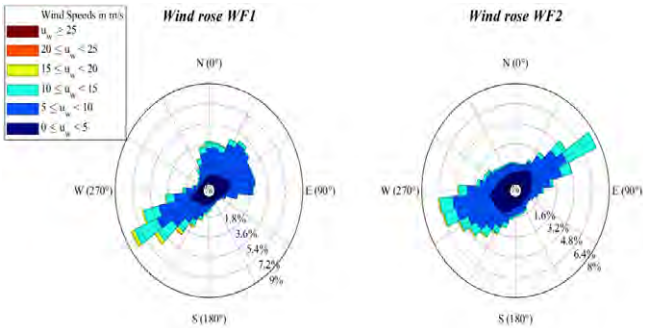

**Figure 2.** Wind roses of wind farms.

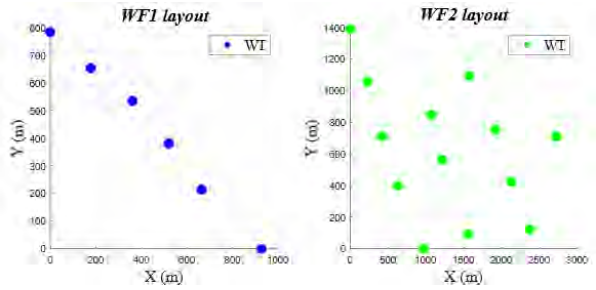

**Figure 3.** Wind farms layouts.

## RESULTS AND DISCUSSION

In this section, the probability density and cumulative distribution functions of the wind farms without taking into account the wake effect, $f_{PWF}(P_{WF})$ and $F_{PWF}(P_{WF})$, are compared with those that consider the wake effect, $f_{PWF_WE}(P_{WF_WE})$ and $F_{PWF_WE}(P_{WF_WE})$. For this comparison, a Gaussian kernel and the plug-in method were used as the optimal bandwidth selection method. The results can be seen in the Figure 4.

The first relevant result is that the bandwidth required to adequately represent $f_{PWF_WE}(P_{WF_WE})$ and $F_{PWF_WE}(P_{WF_WE})$ has very small values, being 2.8209E-4 for WF1 and 8.2103E-5 for WF2. This level of detail is crucial for capturing specific features, such as the zone of $f_{PWF}(P_{WF}) = 0$ between $P_{WF} > 0$ and $P_{WF} < P_{INWF}$, described in the theoretical approach. However, for the estimation with kernels, this $f_{PWF_WE}(P_{WF_WE}) = 0$ zone is smaller, because with the wake effect, $P_{INWF}$, is reduced. This can be clearly seen in Figure 5, an amplified view of the two PDFs

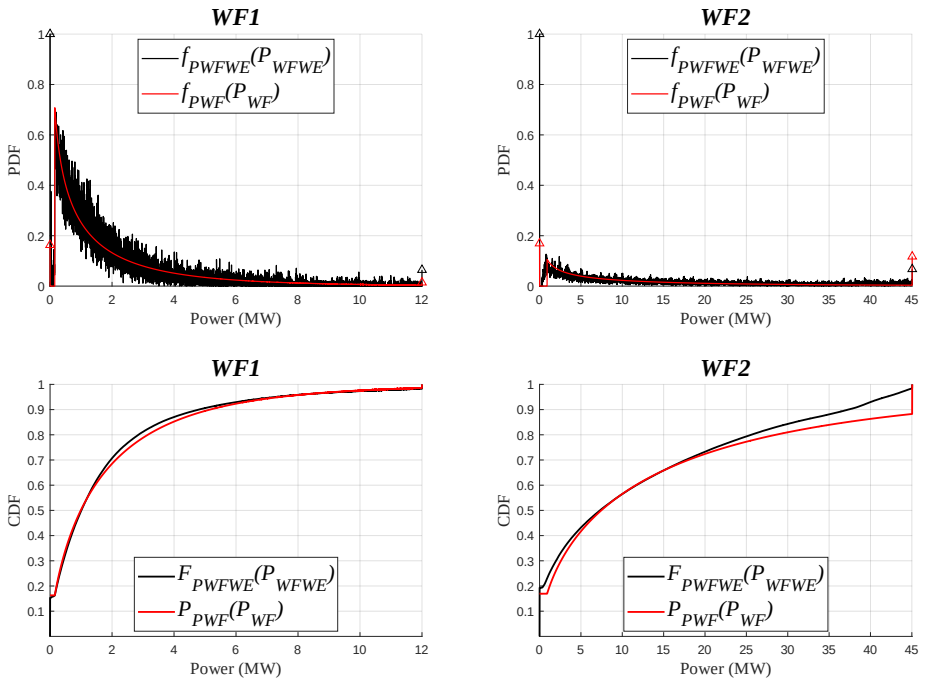

**Figure 4.** Probability density functions and cumulative distribution functions obtained analyticaly without wake effect $f_{PWF}(P_{WF})$ and $F_{PWF}(P_{WF})$ vs $f_{PWF_WE}(P_{WF_WE})$ and $F_{PWF_WE}(P_{WF_WE})$ with wake effect obtained using kernel estimators both for WF1 and WF2.

of WF1, which shows that for $f_{PWF}(P_{WF})$, $P_{INWF}$ is equal to 0.18 MW but for $f_{PWF_WE}(P_{WF_WE})$, $P_{INWF}$ is only 0.02 MW.

**Table 1.** Annual energy (AE) estimation using PDF without including wake effect and including it.

| | AE without wake effect | AE with wake effect | Overestimation |
|---|---|---|---|
| WF1 | 16,935 MWh | 16,250 MWh | 4 % |
| WF2 | 123,061 MWh | 111,813 MWh | 9.1 % |

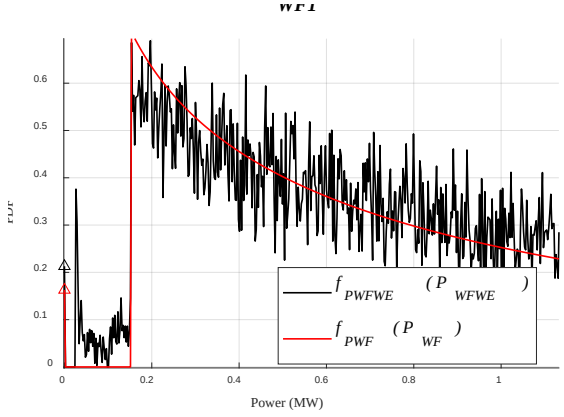

**Figure 5.** Zoom view of the PDFs of WF1.

Then, the annual energy generated by the wind farm (AE), which is simply the expected value of the probability distributions multiplied by the number of hours of the year, 8760, is calculated using $f_{PWF}(P_{WF})$ or $f_{PWF_WE}(P_{WF_WE})$ for WF1 and WF2. It can be seen in Table 1 that for WF1, which has a fairly simple layout and is properly oriented with respect to the prevailing wind directions (northeast-southwest) (Figure 2 and 3), the annual energy without considering the wake effect is 16,935 MWh, while taking the wake effect into account reduces it to 16,250 MWh, overestimating the producible energy by the wind farm by only 4%. The difference is small because along the predominant wind direction there is no wake effect, due to the specific layout of the wind farm. However, for WF2, which has a more complex layout with several wind turbines behind others even towards the prevailing wind direction (northeast-southwest) (Figure 2 and 3), the annual energy is 123,061 MWh without considering the wake effect, and 111,813 MWh with it, overestimating the wind farm's producible power by 9.1%.

There are also discrepancies for both wind farms between $F_{PWF}(P_{WF})$ and $F_{PWF_WE}(P_{WF_WE})$. This implies incorrectly estimating the probability of occurrence of the different power values or power intervals, which can have a negative effect on long-term production decisions. For example, for WF2, the wind farm most affected by the wake effect, the probability of $P_{WF}$ being less than 4 MW is 0.38 for $f_{PWF}(P_{WF})$ and 0.4 for $f_{PWF_WE}(P_{WF_WE})$. Although

this difference may seem small, it can have a large impact on energy production planification in the long run, as its effect is multiplied by the time interval of the decision period. These results highlight the importance of including the wake effect in the analysis because inadequate modelling can underestimate the available power density.

## CONCLUSIONS

In this study, it has been proposed to model the PDF of the power generated by a wind farm taking into account the wake effect, $f_{PWF_WE}(P_{WF_WE})$, and has been compared with the analytical modelling (without wake effect) of the PDF of the power of a wind farm $f_{PWF}(P_{WF})$. To model $f_{PWF_WE}(P_{WF_WE})$ it has been proposed to use a historical wind speed and direction data set and the Katic multiple wake model to generate a data set of wind farm power output, and then use kernel estimators to model the PDF.

A comparison of the two distributions shows that ignoring this effect can result in an overestimation of the available energy of up to 9.1% for wind farms with more complex layouts. The differences seen in PDF modelling also have an effect on the CDF, again proving how a competitive layout can have large differences in cumulative contributions in the low and high-power ranges. These discrepancies can have important implications for production planning and wind farm grid integration, highlighting the importance of incorporating the wake effect into wind farm modelling to ensure more accurate projections of generation and energy availability.

## ABSTRACT

Pillow-plate heat exchangers (PPHEs) represent a viable alternative to conventional shell-and-tube and plate heat exchangers. The waviness of their channels intensifies fluid mixing in the boundary layers and facilitates heat transfer. Applying secondary surface structuring can further enhance the overall thermo-hydraulic performance of PPHEs, thus increasing their competitiveness against conventional heat exchangers. In this work, streamlined secondary structures applied on the PPHE surface were studied numerically to explore their potential in enhancing near-wall fluid mixing. Computational fluid dynamics (CFD) simulations of single-phase turbulent flow in the inner PPHE channel were performed and pressure drop, heat transfer coefficients, and overall thermo-hydraulic efficiency were determined. The simulation results clearly demonstrate a favourable influence of secondary structuring on the heat transfer performance of PPHEs.

**Keywords**: Computational Fluid Dynamics, Surface structuring, Heat transfer intensification

## INTRODUCTION

Pillow-plate heat exchangers (PPHEs) are a promising alternative to conventional shell-and-tube and plate heat exchangers. PPHEs are formed by assembling multiple pillow plates (PPs) into a single unit. These PPs are manufactured by spot-welding two steel sheets and seam-welding along the edges, followed by hydroforming, resulting in characteristic pillow-like surfaces (see Fig. 1).

Piper et al. [2] conducted a CFD-based study of turbulent fluid flow in the inner channels (IC) of PPs. Their simulation results revealed that a fully developed turbulent flow in PPs is characterized by two zones: a recirculation zone arising in the wake of a welding spot and a core flow confined by the wall and the recirculation zones. The recirculation zones increase pressure drop and are characterized by slow heat transfer. By reducing the size of these zones, the performance of the PPHEs can be improved; thus, optimization of the PPHE geometry is possible. Therefore, Piper et al. [2] investigated the effect of the form and size of welding spots on the thermo-hydraulic performance of PPHE inner channels. They reported a 37% efficiency increase for a PPHE with streamlined oval-shaped welding spots in a longitudinal-type PP. Shirzad et al. [3] found that with increasing inflation height of the channel, Nusselt number increased while pressure drop decreased.

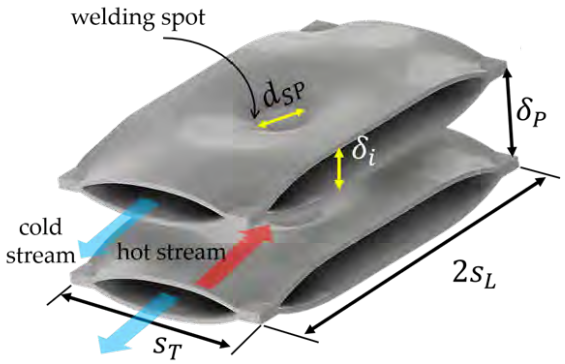

**Figure 1:** A digital image with the characteristic geometry parameters of PPs. Cold fluid flows through inner channels, hot fluid flows through outer channels [1].

Secondary structuring of surfaces has emerged as a method to further enhance PPHE performance. Djakow

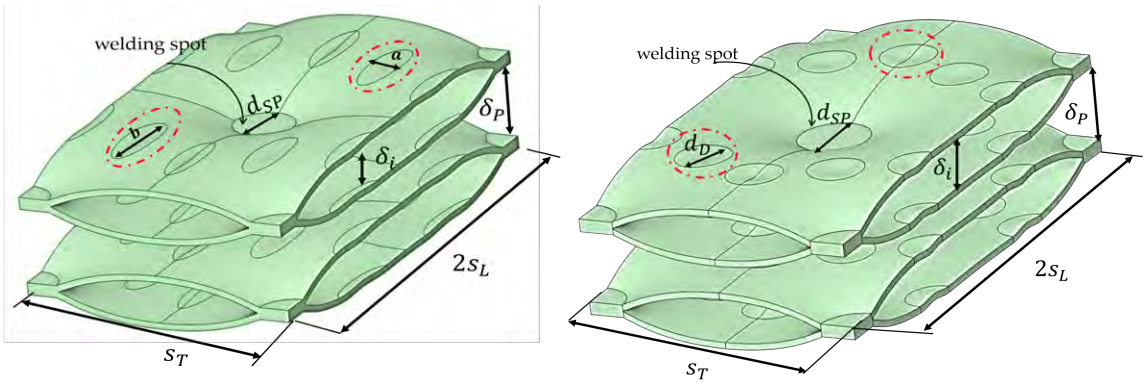

**Figure 2:** Digital images of the studied PPHEs with secondary structures: streamlined-ellipsoidal (left) and streamlined-spherical (right). Red dashed lines denote the secondary structures.

et al. [4] used electro-incremental hydroforming (EIHF) to apply dimples on PP surfaces; based on numerical simulations, they showed a 24% increase in heat transfer coefficient in an IC of the studied PPHE. Piper et al. [5] demonstrated that dimpled surfaces in the outer channels reduced the negative impact of the recirculation zones and improved efficiency. Afsahnoudeh et al. [1] extended this analysis to a wider range of secondary structures and found that streamlined secondary structures in the outer channels increased thermo-hydraulic efficiency by up to 6%.

Despite these promising results, applying secondary structures on PP surfaces presents challenges, as this method is mainly suitable for simple geometries while surface altering requires a substantial amount of energy (see [6]). Considering these limitations and considering that the main heat transfer resistance can be located in the inner channels [2,3], this work focuses on simple streamlined secondary structures that achieve a balance between performance, manufacturability, and cost. Detailed numerical simulations are conducted to evaluate the effect of secondary structures on flow characteristics and heat transfer efficiency.

## GEOMETRY GENERATION AND SURFACE STRUCTURING

To accurately simulate fluid dynamics and heat transfer in the ICs of PPHEs, a realistic digital representation of the PP geometry, which defines the computational domain, is necessary. We employed a forming simulation method detailed in [7] to generate the basic PP geometry. This geometry does not contain secondary structures and serves as a benchmark for the comparison with secondary structured PP. The benchmark has already been optimized with respect to the thermo-hydraulic performance (see [2, 3]).

In our previous work [1], we explored the thermo-hydraulic behavior of the outer channel with different secondary structures. It was found that the PPs with ellipsoidal secondary structures that resulted in a larger volume of the outer channel were most effective in reducing pressure drop and form drag. This geometry, in which both the arrangement and shape of the individual secondary structures are streamlined (Fig. 2, left) is denoted as *streamlined-ellipsoidal*. In [1], we also found that spherical (dimple) secondary structures were most effective in increasing heat transfer, yet with higher pressure drop. Therefore, in this work, we studied two competing PP geometries, the streamlined-ellipsoidal one and the *streamlined-spherical* geometry in which ellipsoidal forms are replaced by spherical forms. The digital images of the two studied secondary structured PPs are shown in Figure 2. In Table 1, the dimensions of the studied PPs are summarized.

## CFD MODELING

### Model and solution method

The numerical simulations were carried out with the commercial software Fluent 24.1 by ANSYS. The fluid flow was modeled as incompressible, single phase and turbulent, with constant fluid phase properties.

Due to the formation of recirculation zones downstream of the welding spots in an IC and the potential additional recirculation caused by secondary structures, it is crucial to select a turbulence model capable of accurately resolving flow separation. Additionally, the boundary layer separation is expected to induce laminar-turbulent transition. Therefore, to simulate the flow in the IC of the studied PPHEs, we employed the SST model combined with $\gamma$ (intermittency) transition model [8]. Here, $\gamma$

defines the extent of turbulence production in the flow. It has a value of zero for laminar flow, one for fully turbulent flow, and is between zero and one for the transitional flow. The turbulence production term in the SST model equations is multiplied by $\gamma$, which allows a smooth transition between laminar and turbulent regimes based on local flow conditions. This model is well suited for resolving separation-induced and crossflow-induced laminar-turbulent transition in complex geometries [8].

The simulation domain and boundary conditions are illustrated in Fig. 3. To reduce the computational effort, we made use of the flow and geometry symmetry by applying symmetric boundary conditions at $y = 0$ and $y = 0.5\, s_T$ (see Fig. 3). No-slip and constant temperature boundary conditions were set at the wall. Additionally, periodic boundary condition was applied at the inlet ($x = 0$) and outlet ($x = 2\, s_L$) boundaries of the channel, while prescribed values of mass flow and constant bulk temperature were given at $x = 0$. Using periodic boundary condition inherently restricts the investigation to the (periodically) fully developed region. Fluent 24.1 utilizes the method introduced by Patankar et al. [9] for simulating problems with periodic boundary conditions.

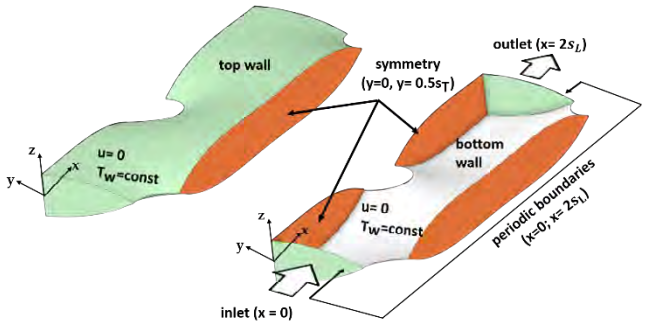

**Figure 3**: Computational domain and boundary conditions of the PP inner channel.

## Grid generation

The grid used was an unstructured poly-hexacore mesh generated with the Fluent-Meshing tool. A grid independence study was performed for all the investigated geometries. Depending on the specific geometry, different grids were generated. The grid was considered finalized when doubling the number of cells resulted in only negligible differences in pressure drop and heat transfer coefficient (less than 0.1%). The number of grid cells ranged between 36 and 42 million. For the finalized grid, the maximum value of the dimensionless wall distance ($y^+$) was about 0.05.

# THERMO-HYDRAULIC EVALUATION CRITERIA

To assess the thermo-hydraulic characteristics of the flow in PPs, the following criteria were used.

The Darcy friction factor ($\xi_{\Delta p}$) can be estimated by the Darcy-Weisbach equation:

$$\xi_{\Delta p} = \frac{2 d_h |\Delta p|}{\rho u_m^2 2 s_L} \quad (1)$$

where $u_m$ is the mean velocity in the IC, $d_h$ is its hydraulic diameter, which can be calculated by the method proposed in [7], and $\Delta p$ is the overall pressure drop, calculated as the difference between the surface-averaged pressure values at the inlet and outlet boundaries.

Using the Fanning friction factor ($\xi_R$), determined as

$$\xi_R = \frac{8 \tau_w}{\rho u_m^2} \quad (2)$$

the drag coefficient ($\xi_D$) is obtained by subtracting Eq. (2) from Eq. (1):

$$\xi_D = \xi_{\Delta p} - \xi_R \quad (3)$$

The Nusselt number is defined by:

$$Nu = \frac{h_m d_h}{\lambda} \quad (4)$$

where $\lambda$ is thermal conductivity, and $h_m$ represents the surface-averaged heat transfer coefficient which can be calculated as:

$$h_m = \frac{\dot{q}_w}{T_w - T_{bulk}} \quad (5)$$

In Eq. (5), $\dot{q}_w$ is the heat flux in the direction normal to the wall and $T_{bulk}$ is the bulk temperature:

$$T_{bulk} = \frac{\int_{A_{CS}} u T dA}{\int_{A_{CS}} u dA} \quad (6)$$

The thermo-hydraulic efficiency $\varepsilon$ is defined as a ratio of the transferred heat per unit time to the pumping power:

$$\varepsilon = \frac{\dot{Q}_w}{\dot{V} \Delta p} \quad (7)$$

where $\dot{V}$ is the volumetric flow rate, and $\dot{Q}_w$ is area-averaged wall heat flux.

The evaluation of the heat transfer coefficient and thermo-hydraulic efficiency of the studied secondary structured PPs is based on the relative deviation of these quantities from the relevant benchmark quantities:

$$Z^* = \frac{Z\,(secondary\ structures) - Z\,(benchmark)}{Z\,(benchmark)} \times 100\% \quad (8)$$

# MODEL VALIDATION

The validation of the CFD model was carried out for the benchmark geometry (PPHE without secondary structures). The comparison of the numerical results was performed with the correlations for the Darcy friction factor ($\xi_{\Delta p}$) and the Nusselt number ($Nu$) from [10].

As can be seen in Fig. 4, $\xi_{\Delta p}$ values obtained from

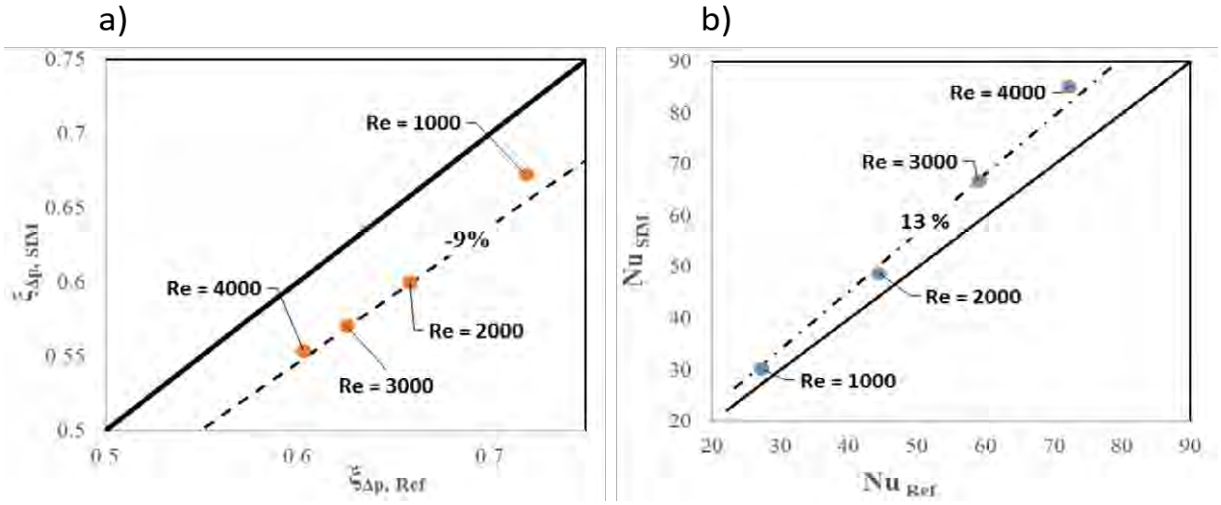

**Figure 4:** Comparison of simulated Darcy friction factor (a) and Nusselt number (b) with data obtained by correlations from [10].

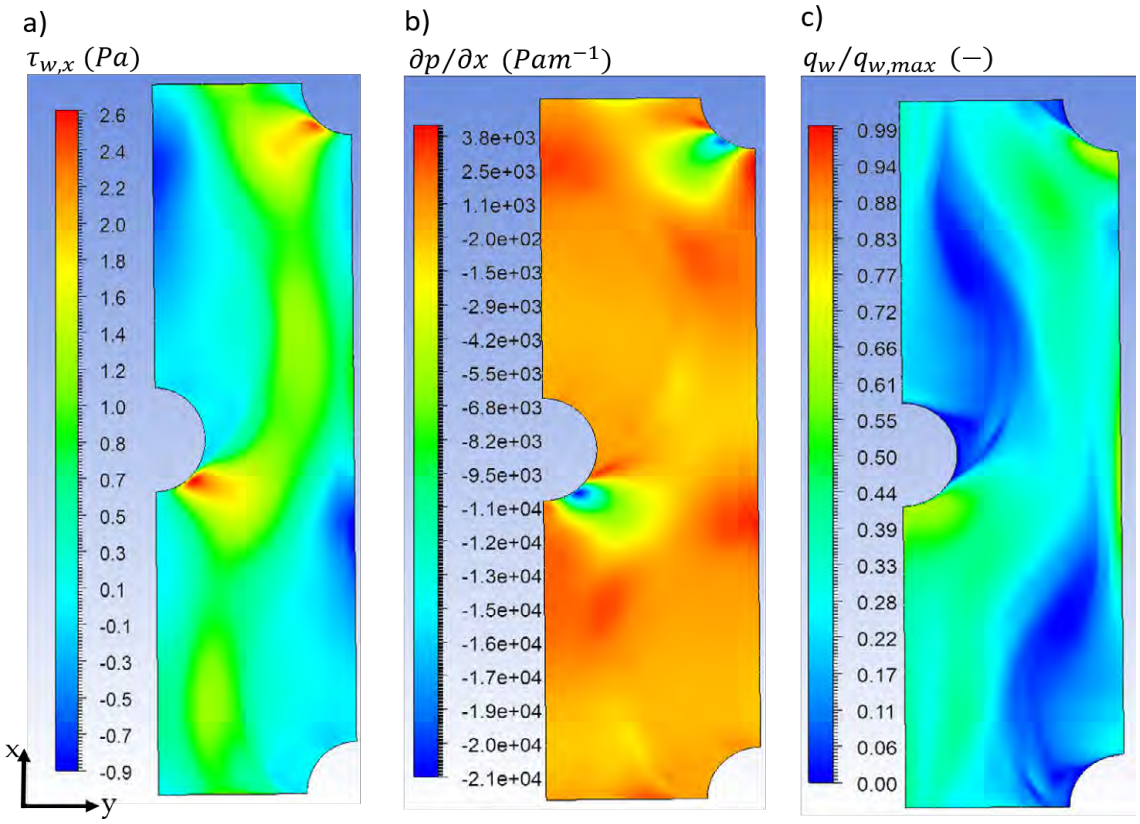

**Figure 5:** Local wall quantities: shear stress (a), pressure gradient in flow direction (b) and normalized heat flux (c).

the simulation are about 9% lower than the correlation data (Fig. 4a), while $Nu$ values are overestimated by about 13% (Fig. 4b) except for Re = 4000 which shows a higher deviation. Considering that the correlations taken from [10] have an accuracy of ±6% for the Darcy friction factor and ±15% for the Nusselt number, it can be concluded that the simulation results are within the accuracy of the correlations and, hence, the CFD model is validated.

## RESULTS AND DISCUSSION

With the validated CFD model, simulations were conducted to investigate the effect of secondary

structures on the flow characteristics and heat transfer. Results were obtained for Reynolds numbers ranging from 1000 to 3000.

In Figure 5, the simulation results of the benchmark IC are shown. The continuous variation in the cross-sectional area of the IC leads to frequent accelerations and decelerations of the flow, resulting in significant changes in wall shear stress (Fig. 5a) along the main flow direction (x-direction). At the maximum inflation height (largest cross-sectional area), the static pressure increases, leading to a positive pressure gradient in the flow direction (Fig. 5b). This causes boundary layer separation and increased form drag. As the flow approaches the welding spot, the cross-sectional area narrows, causing acceleration, a decrease in static pressure, and the development of a negative pressure gradient. The latter reaches its minimum at the stagnation point on the welding spot. Downstream of this point, another boundary layer separation occurs on the welding spot, forming recirculation zones. These zones are the primary contributors to form drag in the IC of the PP. As can be seen in Figure 5c, heat transfer in these recirculation zones is very slow, further emphasizing their detrimental impact on the overall performance.

Figure 6 shows the pressure gradient for the secondary structured PPs. These structures are located in such a way that they are aligned on the maximum inflation height. This alignment mitigates the pressure gradient variations along the main flow, resulting in milder accelerations and decelerations. Consequently, wall friction (Fanning friction factor) and form drag caused by boundary layer separation on the PP surface are reduced. As a result, the overall pressure drop for both secondary-structured PPs is lower than that of the benchmark. This reduction is demonstrated in Figure 7, which shows the Darcy friction factor defined by Eq. (1).

The secondary structures of the streamlined-ellipsoidal PP were most effective in reducing the pressure drop. For a better analysis of the impact of the secondary structures, Figure 8 depicts the Fanning friction factor and drag coefficient. It is evident that the streamlined-ellipsoidal structures primarily influence form drag. The ellipsoidal secondary structures are stretched along the flow direction, which smoothens variations in pressure gradient. This leads to lower wall shear stress (reducing Fanning friction) and minimizes regions with a positive pressure gradient, thereby mitigating boundary layer separation. The latter effect is particularly significant, as the drag coefficient for the streamlined-ellipsoidal PP is approximately 10% lower than that of the benchmark. The results for the streamlined-spherical PP reveal a different behavior compared to the streamlined-ellipsoidal design. While the Fanning friction factor remains nearly the same as for the benchmark, the drag coefficient is reduced by approximately 4%. For both secondary structured PPs, the drag coefficient was lowest at $Re = 2000$.

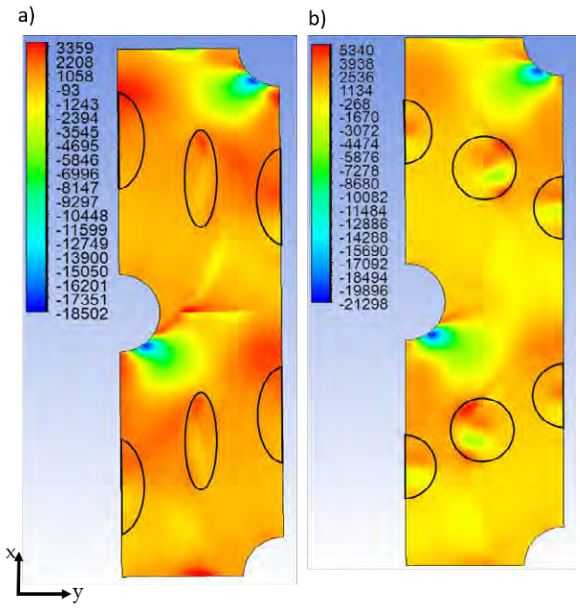

**Figure 6:** Pressure gradient in flow direction for different PPs: streamlined-ellipsoidal (a); streamlined-spherical (b). The secondary structures are denoted with black contours.

In Figure 9, the heat transfer coefficients of the secondary-structured PPs relative to the benchmark ($h^*$) are shown. While the streamlined-ellipsoidal PP effectively reduced the pressure drop, its heat transfer coefficient was lower due to lower wall friction and fluid mixing in the boundary layer. In contrast, the streamlined-spherical PP achieved higher heat transfer rate by enhancing fluid mixing in the boundary layer.

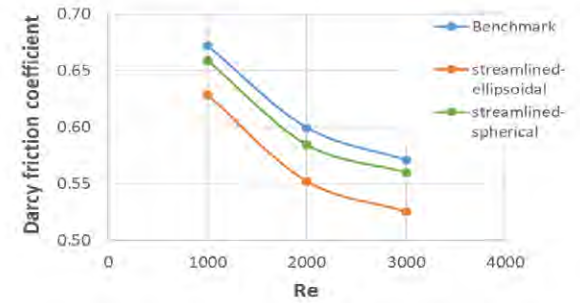

**Figure 7:** Darcy friction factor for studied PPHEs

From an industrial perspective, the thermo-hydraulic efficiency $\varepsilon$ defined by Eq. (7) provides a more meaningful performance evaluation. As shown in Figure 10, the streamlined-ellipsoidal PP consistently achieves a significant enhancement of thermo-hydraulic efficiency relative to benchmark ($\varepsilon^*$) across the entire range of studied Reynolds numbers. This indicates that the "more streamlined" secondary structures are more effective and show a high potential for optimizing the thermo-hydraulic

efficiency of PPHEs.

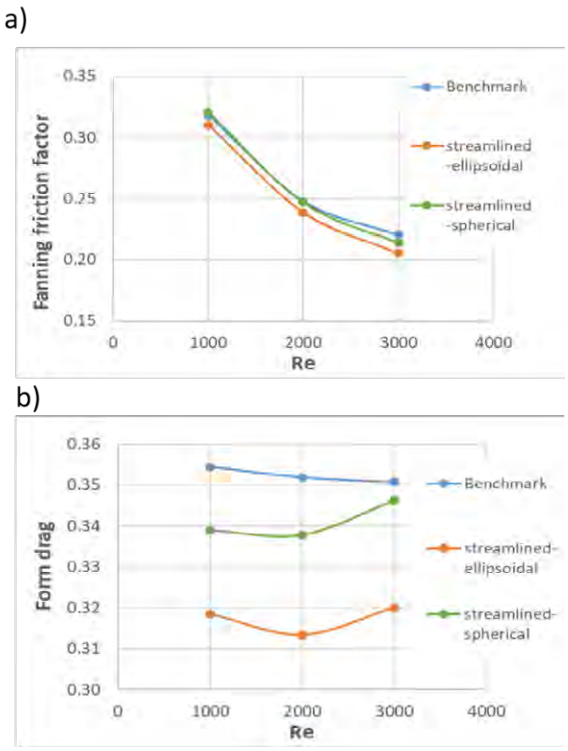

**Figure 8**: Friction coefficients: Fanning friction factor (a) and drag coefficient (b) for studied PPHEs.

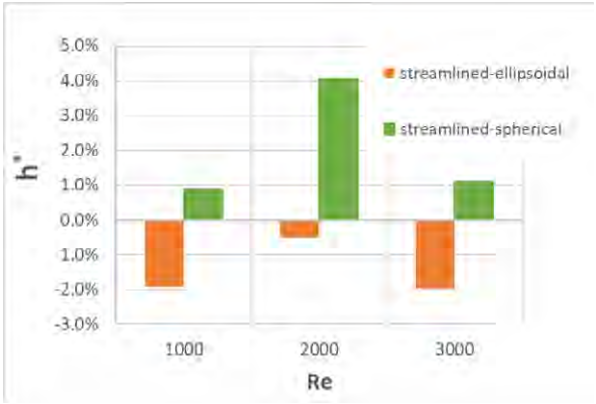

**Figure 9**: Heat transfer coefficient of the studied structured PPs relative to benchmark.

## CONCLUSION

In this work, a CFD-based study was conducted to analyse fluid flow and heat transfer in the inner channel (IC) of pillow-plate heat exchangers (PPHEs) with streamlined secondary structuring. Two designs, streamlined-ellipsoidal and streamlined-spherical, were compared with a benchmark representing an optimized PPHE geometry without secondary structures.

The streamlined-ellipsoidal design resulted in a significantly reduced pressure drop by minimizing boundary layer separation and levelling out pressure variations along the main flow direction. However, its streamlined shape resulted in lower near-wall mixing, and hence, lower heat transfer coefficient compared to the benchmark. In contrast, the streamlined-spherical design enhanced heat transfer by improving near-wall mixing but offered a lower reduction in pressure drop.

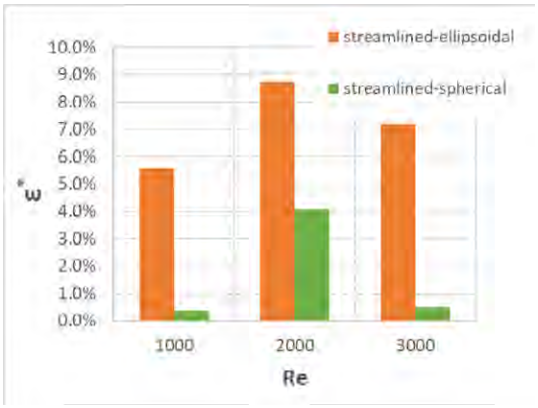

**Figure 10:** Thermo-hydraulic efficiency of the studied structured PPs relative to benchmark.

The overall performance was evaluated using thermo-hydraulic efficiency. The streamlined-ellipsoidal design outperformed both the benchmark and the streamlined-spherical design for all studied Reynolds numbers. This clearly highlights the potential of the streamlined secondary structures in optimizing the performance of the PPHEs.

Future work will focus on investigating the combined impact of secondary structuring on both inner and outer PPHE channels to allow a comprehensive optimization.

## ABSTRACT

The three systems, water, energy and food, are intertwined since the effect of any of these systems can affect others. This study proposes a mathematical model incorporating uncertain parameters in the biomass energy-water-food nexus system. The novel aspects of this work include formulating and solving the problem as a mixed-integer linear program and addressing the presence of uncertain parameters through a two-stage stochastic mathematical programming approach. Taking maximising economic benefit as an objective function, this work compares the results of the deterministic model with the results computed by incorporating uncertainty in the model parameters. The results indicate that incorporation of uncertainty gives rise to reduced profitability, but increased greenhouse gas emission (GHG) as compared to the deterministic model. On the other hand, when minimisation of GHG emission is considered as an objective function, a significantly greater reduction in the profitability is observed for both, stochastic and deterministic, models. The model results are used for allocating optimal resources, reducing carbon footprint, increasing economic potential and managing resources sustainably in the whole system.

**Keywords:** biomass energy, optimisation, uncertain parameters

## INTRODUCTION

The biomass energy-water-food nexus concept represents a complex interaction in managing limited resources in an innovative way [ 3, 4,11]. However, production of energy through fossil fuels is linked to global warming [1]. Achieving CO2 emission reduction target-2050 requires that the renewable energy share in electricity generation globally be increased from 29% in 2020 to over 60% in 2030 and to nearly 90% in 2050 [5]. Several studies postulate bioenergy as a cost effective and sustainable way to mitigate climate change [10,12]. Therefore, this study aims to create a mathematical model of biomass energy-water-food-nexus in the presence of uncertain parameter for optimal resource allocation. There are few studies reported on biomass-energy-water-food nexus incorporating uncertain parameters. Li *et al.* proposed a multi-objective optimisation model with a view to determining optimal policy options for the trade-off between financial benefit and environmental impact in the water-land-energy-livestock context with uncertain parameters in the nexus system [6]. Similarly, Lopez-Diaz *et al.* proposed an optimisation model to create efficient supply chain using material flow analysis among watershed, wastewater flown towards watershed, production and distribution of feedstocks, grains and biofuel [7]. Peña-Torres *et al.* proposed a multi-objective optimisation model with five different demands of resources with respect to water-food-energy nexus with a view to maximising economic benefits (EB) and reducing greenhouse gas emission (GHG) [9]. After analysing the literature, this study introduces novelties in the nexus which are described in the methods section.

## METHODS

This study incorporates two mono-objective functions: maximising economic benefit (EB) and minimising greenhouse gas (GHG) emissions. Novel aspects of this research include the addition of effluent treatment plants (ETP), the integration of rainwater harvesting systems and the implementation of solar power generation

systems across all sectors in the superstructure (figure 1). Moreover, this study has incorporated two-stage stochastic mathematical programming for managing uncertainty in the parameter. The superstructure of the system includes water subsystem comprised of water sources from power plants, aquifers, dams, rainwater and ETP. Moreover, fertiliser industry is included in the nexus for supplying fertiliser to agriculture sectors and external market.

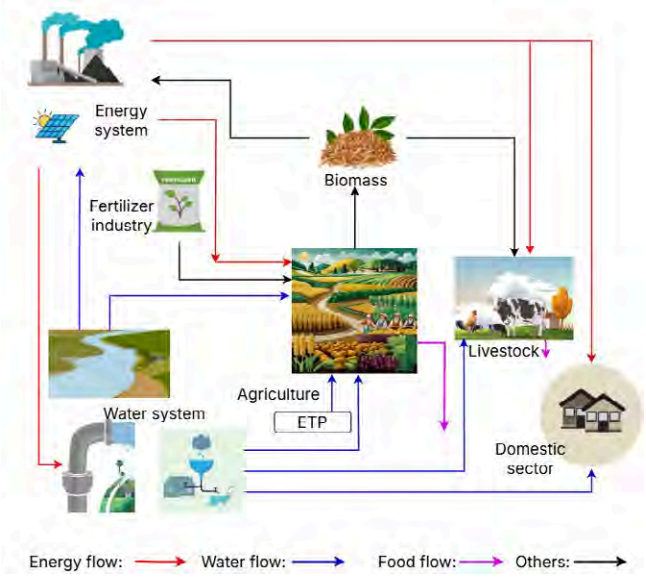

**Figure 1**: Superstructure of Biomass energy water food nexus

The energy subsystem mainly includes existing and new power plants, which utilise biomass, gasification gas and natural gas for producing electricity. On the other hand, electricity from the solar systems in each sector is used in the respective sector.

In this paper, we have generated results for each objective function separately instead of generating results for multi-objective function. The key features of the mathematical model are presented as follows:

**Objective function 1**: Maximising EB

$$Max\ EB = Revenue - TAC \quad (1)$$

**Objective function 2:** Minimising GHG

$$Min\ GHG = sum\ of\ GHG\ in\ all\ sectors \quad (2)$$

**Water mass balance:**

Amount of water remained in the sources within two time periods is equal to the sum of amount distributed and amount that already existed.

$$F_{o,t}^{Wsource} - F_{o,t-1}^{Wsource} = F_{o,t}^{existing} + \sum_A F_{o,A,t}^{Wsource-Actor} \quad (3)$$

Amount of water in actors is equal to the amount of water sent from water sources and the amount of water generated in rainwater harvesting systems.

$$F_{A,t}^{to-Actor} = \sum_o F_{o,A,t}^{WSource-Actor} + F_{A,t}^{Rain-Actor} \quad (4)$$

$$F_{A,t}^{Rain-Actor} = ARW_A . F_{A,t}^{precip} \quad (5)$$

**Energy balance:**

Amount of energy generation in unit is expressed in terms of amount of water utilised for this purpose in power plants.

$$GE_{g,t}^{Esource} = \epsilon^{fuel} . F_{g,t}^{Sea-Esource} \quad (6)$$

$$F_{g,t}^{Sea-Esource} = \omega^{water} . \left[NG_{g,t}^{Esource} + \sum_a AgWaste_{a,g,t}^{Esource} + \sum_h Gas_{h,g,t}^{Esource}\right] \quad (7)$$

Total energy in consuming bodies (actors) is equal to amount of energy flow from generation units to actor and the amount of solar energy generated in that sector.

$$E_{A,t}^{to-Actor} = \sum_g E_{g,A,t}^{Esource-Actor} + GE_{A,t}^{Solar-Actor} \quad (8)$$

$$GE_{A,t}^{Solar-Actor} = AsolarSector_A . SR_t \quad (9)$$

Domestic waste is used to produce gasification gas, which is sent to power plants for energy production and external market.

$$GGasDomWaste_{h,t} = \sum_g Gas_{h,g,t} + Gas_{h,t}^{ext} \quad (10)$$

**Food mass balance in agriculture and livestock sectors:**

Crops from agriculture sectors and meat from livestock sectors are sources of food which are distributed to domestic sectors and external markets.

$$AgL_{al,h,t}^{dom} = FoodDemand_{h,t}^{dom} \quad (11)$$

$$GRfood_{al,t}^{AgL} = AgL_{al,h,t}^{dom} + AgL_{al,t}^{ext} \quad (12)$$

**Mathematical equations related to two-stage stochastic program:**

Food demand in domestic sectors is considered as an uncertain parameter. The general formulation of two-stage stochastic program [2] is:

$$Max\ C^T x + \sum_k p_k q_k^T y_k \quad (13)$$

s.t. Ax=b

$$T_k x + W_k y_k = h_k \quad \forall k$$

$$x \geq 0, y_k \geq 0 \quad \forall k$$

Where $p_k$ is probability of occurrence of uncertain parameters, $x$ and $y_k$ are first and second stage decision variables respectively.

The following equation (14) represents that raw food flow from agriculture and livestock sectors to domestic

sector in time t is equal to uncertain food demand in domestic sector for scenario s.

$$AgL_{al,h,t}^{dom} = FoodDemand_{h,t,s}^{dom} \quad (14)$$

Similarly, total amount of food production in agriculture and livestock sectors is equal to amount sent to domestic sectors and external market for scenario s.

$$GRfood_{al,t}^{AgL} = FoodDemand_{h,t,s}^{dom} + AgL_{al,t,s}^{ext} \quad (15)$$

In this study, all decision variables, except variables related to uncertain parameter, are placed in the first stage. Ten scenarios of uncertain food demand in the domestic sectors are considered. The uncertainty is modelled through normal distribution with 20% standard deviation from the mean value. Distribution is done on twelve individual months of a year with 10 scenarios over three domestic sectors. The second stage decision variables are amount of food sent to domestic sectors and amount of food sent to the external market. The data for the base-case, deterministic model, is taken from Pena Torres *et al.* (2024) and Núñez-López, Rubio-Castro and Ponce-Ortega (2021). Both mathematical models are coded in GAMS software with CPLEX v. 22.1.0.0 solver for the MILP.

## RESULTS

This section presents results of both deterministic and two-stage stochastic solutions. Optimal solutions are presented for four cases such as deterministic solution for maximising EB, stochastic solution for maximising EB, deterministic solution for minimising GHG emission and stochastic solution for minimising GHG emission. Running the model with taking objective function as maximising EB, the stochastic solution provides 11.14% less profit (figure 2) and 3.85% higher GHG emission (figure 3) than deterministic solution. The risk associated with uncertainty is the main cause of such differences. Similarly, for minimising GHG emission cases, the stochastic solution provides 33.46% less profit (figure 2) than deterministic solution but nearly same amount of GHG emission in both models (figures 3). In four types of models, the main profit contributing agent in the system is fertiliser industry. For model with objective function 1, the revenue from fertiliser industry for stochastic solution is 4.93% higher than deterministic solution while running the model with objective function 2, it generates same amount of revenue in the fertilizer industry for both deterministic and stochastic programs (figure 4, tables 1 and 2). In the following tables and figures, monetary values are expressed in million USD and mass quantities in million tons, except for crop distribution in stochastic solution, which is expressed in tons.

**Table 1:** Optimal solution for first objective function

| Variables | Deterministic solution | Stochastic solution |
|---|---|---|
| EB | 8.54E+3 | 7.59E+3 |
| GHG | 2.27E+6 | 2.36E+6 |
| Crop supplied to domestic sectors | 2.13E-1 | second stage decision |
| Crop supplied to market | 4.23 | second stage decision |
| Revenue from fertilizer industry | 5.33E+4 | 5.59E+4 |

**Table 2:** Optimal solution for second objective function

| Variables | Deterministic solution | Stochastic solution |
|---|---|---|
| EB | 1.49E+3 | 9.91E+2 |
| GHG | 1.65E+6 | 1.65E+6 |
| Crop supplied to domestic sectors | 1.11 | second stage decision |
| Crop supplied to market | 0.00 | second stage decision |
| Revenue from fertilizer industry | 4.93E+4 | 4.93E+4 |

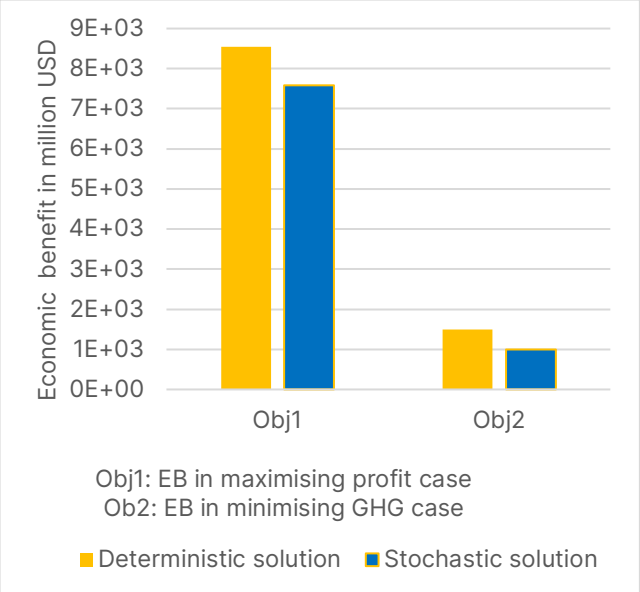

**Figure 2.** Economic benefit (EB) in two different mono-objective cases

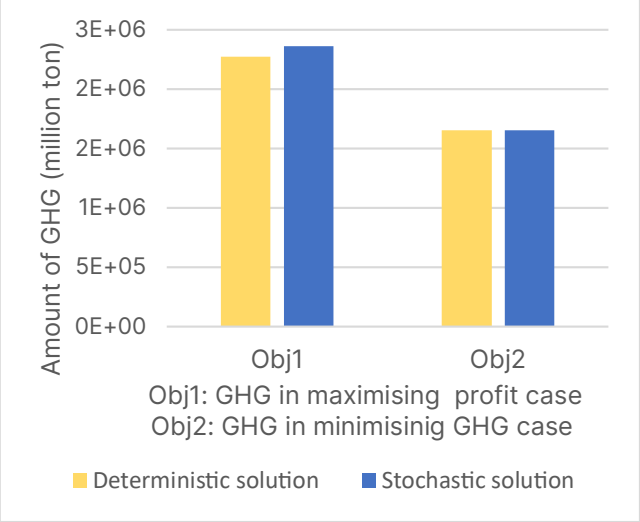

**Figure 3.** GHG emission in two different mono-objective cases

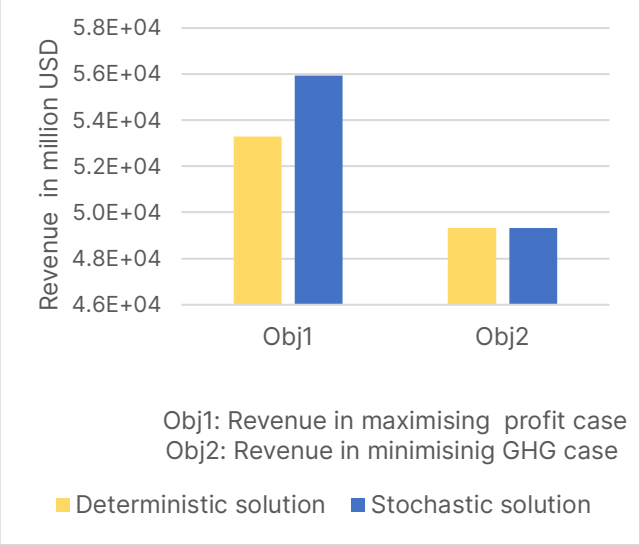

**Figure 4.** Revenue from fertilizer industry in two different mono-objective cases

Optimal number of installation decision has also been generated in this model for the four cases. The optimal number of installation decision of new power plant, gasification plant, rainwater harvesting system and solar panel for deterministic solution for maximising EB and minimising GHG emission cases are 0,0,1, 1 and 0,3,2,3 respectively; the increased number is due to focus on minimisation of GHG in the system. On the other hand, in the first stage of stochastic solution with maximising EB objective function case, the optimal number of installation decision of new power plant, gasification plant, rainwater harvesting system and solar panels are 0,0,1 and 3 respectively. However, the installation decision values become 0,3,2 and 3 respectively for minimising GHG objective function for stochastic solution. The second stage decision variables for stochastic solution are: amount of food, produced in agriculture and livestock sectors, sent to domestic sectors and amount of food sent to external market.

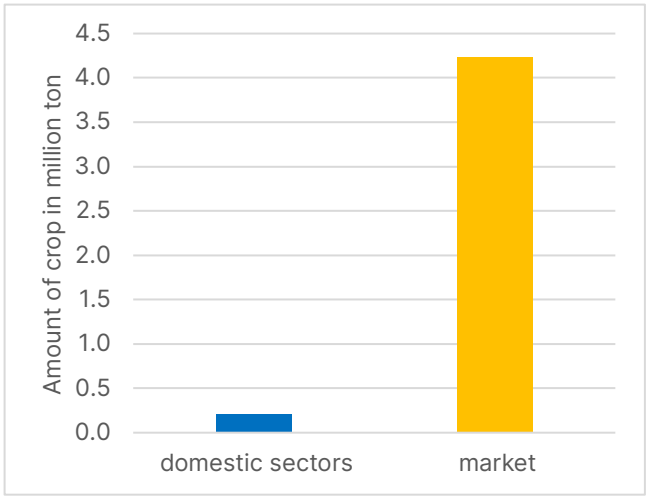

**Figure 5.** Deterministic solution: Crop supply from agriculture sectors to domestic sector and market (maximising EB case)

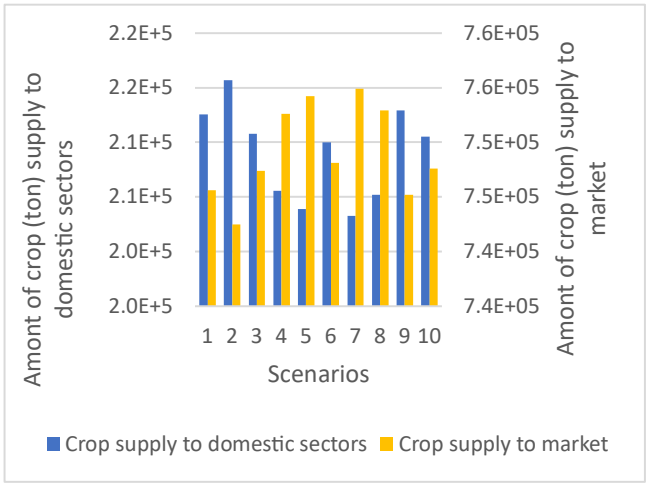

**Figure 6.** Stochastic solution: Crop supply from agriculture sectors (maximising EB case)

For all models, optimal solutions of meat production in livestock sectors are zero. For deterministic solution (scenario independent), it is found that the amount of food sent to external market is much higher than that sent to domestic sectors (figure 5). In the second stage, as soon as the demand scenario is realized, the distribution of food to domestic sectors and external market can be decided (figure 6 and 7). From the figures, it can be observed that the amount of food sent to market for the first mono objective function case is significantly higher than that amount of food sent to domestic sectors compared to second mono objective function case. Conversely, in first mono objective case, the amount of food

sent to domestic sectors is significantly lower compared to second mono objective function case (figure 6, figure 7).

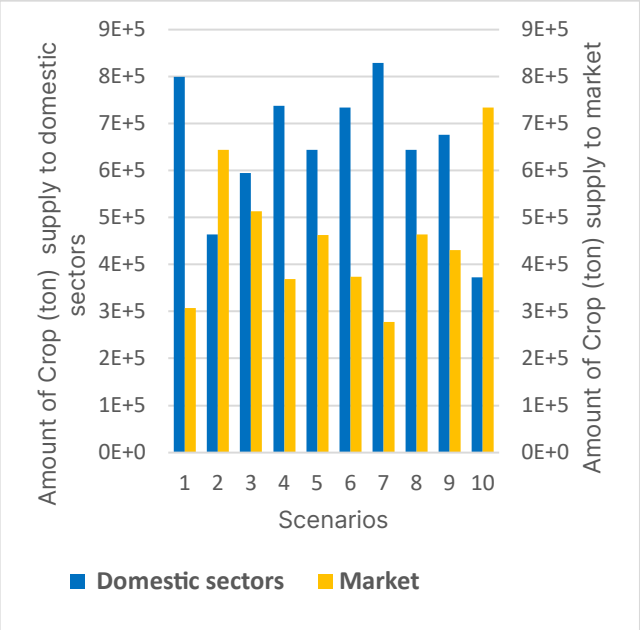

**Figure 7.** Stochastic solution: Crop supply from agriculture sectors (minimising GHG case)

## CONCLUSIONS

First and second mono objective function of this study are maximisation of economic benefit and minimisation of greenhouse gas emission respectively. Both deterministic and stochastic model have been constructed based on the first and second objective functions in the context of optimisation of biomass energy water food nexus. Running the models with objective function 1 and 2 separately, optimal solutions have been generated for four types of cases which are 1) deterministic solution for maximising EB 2) deterministic solution for minimising GHG emission 3) stochastic solution for maximising EB and 4) stochastic solution for minimising GHG emission. The obtained results are then compared. For objective function 1, two-stage stochastic program generates 11.14% less profit than deterministic solution but greenhouse gas emission is increased by 3.85% as there are risks involved in the stochastic solution due to uncertain food demand parameter. Conversely, the model incorporating objective function 2 resulted in significantly lower profit accompanied by a substantial reduction in GHG emission across both deterministic and stochastic solutions. Moreover, optimal installation decisions are different in different cases. In stage two, amount of food distribution decision is determined as soon as the demand parameter is realized. In this study, the optimal solutions of the decision variables in second stage are generated and analysed for objective functions 1 and 2.

## NOMENCLATURE

| Index | Description |
|---|---|
| o | Sources of water |
| a | Agriculture sectors |
| c | Livestock sectors |
| m | Livestock types |
| v | Crop types |
| h | Domestic sectors |
| t | Time period in months |
| A | Actor (water and energy consuming bodies) |
| g | Energy generation units other than solar panels |
| sc | Sectors such as livestock, domestic, industry, agriculture |
| al | Agriculture and livestock sector |

| Acronym | Description |
|---|---|
| AgLI | Agriculture, livestock, fertiliser industry |
| $ARW_A$ | Effective area for rainwater harvesting in the sectors |
| $AsolarSector_A$ | Effective area for solar radiation in the sectors |
| $AgL_{al,h,t}^{dom}$ | Raw food sent to domestic from agriculture and livestock sector |
| $AgL_{al,t}^{ext}$ | Raw food sent to market from agriculture and livestock sector |
| $AgL_{al,t,s}^{ext}$ | Raw food sent to market from agriculture and livestock sector in scenario s |
| EB | Economic benefit in USD |
| Esource | Electricity producing system such as power plants |
| $\epsilon^{fuel}$ | Fuel efficiency coefficient for energy production |
| $F_{A,t}^{Rain-Actor}$ | Water harvested in all sectors such as domestic, livestock |
| $F_{A,t}^{precip}$ | Rainwater precipitation flux in the sectors |
| $FoodDemand_{h,t}^{dom}$ | Amount of food required in domestic sector |
| $FoodDemand_{h,t,s}^{dom}$ | Amount of food required in domestic sector under scenario s |
| $F/E_{index}^{acronym}$ | Input variable such as water/energy flow to a system |
| GHG | Greenhouse gas emission (carbon equivalent in ton) |
| $GRfood_{al,t}^{AgL}$ | Production of raw food such as crop from agriculture and meat from livestock |

| | |
|---|---|
| $GGasDomWaste_{h,t}$ | Amount of gasification gas generated in domestic sector h |
| $Gas_{h,g,t}$ | Amount of gasification gas sent to power generation unit |
| $Gas_{h,t}^{ext}$ | Amount of gasification gas sent to external market |
| $GE_{g,t}^{Esource}$ | Energy generation in any unit |
| $GE_{A,t}^{Solar-Actor}$ | Solar energy generation in the sectors |
| $SR_t$ | Solar radiation flux in month t |
| TAC | Total annualised cost in USD |
| Wsource | Water source such as dam, deep well, aquifer, effluent treatment plant (ETP) |
| $\omega^{water}$ | Water efficiency coefficient for energy generation |

## ABSTRACT

This work presents an improved thermodynamic model, an equilibrium model, and a unified kinetic model for ammonia synthesis. The thermodynamic model accurately describes the non-ideality of the reaction system up to 1000 bar using a modified Soave-Redlich-Kwong Equation-of-State. The developed Langmuir-Hinshelwood kinetic model accurately describes ammonia synthesis on iron-based catalysts by incorporating N* and H* surface species, whereas H* species are mainly relevant below 400°C. The model fits an extensive dataset across diverse conditions (251-550°C, 1-324 bar, $H_2/N_2$ ratios 0.33-8.5, and space velocities of 1-1800 $Nm^3$ kg-$cat^{-1}$ $h^{-1}$) and accounts for catalyst activity variations through a Relative Catalytic Activity factor.

**Keywords**: Ammonia, Steady-state kinetics, iron catalyst

## INTRODUCTION

Ammonia, with a global demand of 185 Mt in 2020 [1], serves as both a crucial fertilizer component and a promising zero-carbon fuel and hydrogen carrier [2, 3]. Its production via the Haber-Bosch process (Equation 1) relies on iron-based catalysts operating at 350-500°C and 100-300 bar [4]. These catalysts, derived from magnetite ($Fe_3O_4$) or wüstite ($Fe_{1-x}O$) precursors, incorporate electronic promoters ($K_2O$) and structural promoters ($Al_2O_3$, MgO, $SiO_2$, CaO) to enhance activity and stability [5, 6].

$$3H_2 + 1N_2 \leftrightarrow 2NH_3 \;\; with \;\; \Delta H_r^\circ = -92\ \mathrm{kJ/mol} \qquad (1)$$

While various kinetic models exist for ammonia synthesis [7–10], they are typically based on single-catalyst datasets. This work introduces a comprehensive kinetic model applicable across commercial catalysts at diverse conditions (251-550°C, 1-324 bar), utilizing 11 datasets [7, 8, 10–14] spanning both magnetite and wüstite precursors. The model assumes that despite varying active site densities, the underlying reaction mechanism remains the same across catalysts, with differences in activity addressed through a Relative Catalytic Activity (RCA) correction factor.

Several optimization algorithms were evaluated to fit the kinetic parameters, including Particle Swarm Optimization (PSO), Differential Evolution (DE), Nelder-Mead, compact Genetic Algorithm (cGA), Cobyla, and Powell. The Covariance Matrix Adaptation Evolution Strategy (CMA-ES) proved superior, being the only algorithm to consistently converge to the global minimum across multiple initialization points, likely due to its mechanism to escape local minima in the complex parameter landscape of the kinetic model.

The datasets include various $H_2/N_2$ ratios and space velocities, making it particularly relevant for renewable ammonia plants with fluctuating hydrogen feedstock. In addition to the kinetic model, a simplified Arrhenius-type equilibrium description is presented for industrial temperature ranges (300-550°C), employing a modified Soave-Redlich-Kwong Equation-of-State with the Mathias alpha function using a polarity correction factor of 0.2368 for ammonia.

## THERMODYNAMICS

At high pressures, accurate ammonia synthesis thermodynamics requires an Equation of State (EoS) to account for gas non-ideality [15]. While the Soave-Redlich-Kwong (SRK) EoS is widely used, it poorly describes the polarity of molecules like ammonia at high pressures [16]. This work employs a modified SRK with a polarity correction factor, based on the Mathias alpha function [17], to overcome this limitation.

Existing alternatives to describe the non-ideality, such as Dyson and Simon's polynomials [18] or other EoS [19, 20], lack universal applicability because they are either difficult to implement in commercial flowsheeting software or are inaccurate at high pressures. To address this, a nested fitting method was developed to determine the polarity correction factor in the Mathias alpha function for the SRK EoS. The method was applied to equilibrium data in the range of 300-1100 °C and up to 1000 bar from multiple literature sources.

The resulting equilibrium expression uses a second-order polynomial for reaction enthalpy, simpler than previous higher-order approaches. For practical implementation in software like Aspen HYSYS, we also derived a simplified Arrhenius-type equation valid for 300-550 °C:

$$ln(K_f) = \frac{1}{R}\left(-33.415 - \frac{-4.4401 \cdot 10^4}{T} - 10.578\, ln(T)\right) \quad (2)$$

$$K_f = 1.3632 \cdot 10^{-6} e^{\left(-\frac{-5.1110 \cdot 10^4}{RT}\right)} \quad (3)$$

$$\frac{1}{K_f^2} = 5.3809 \cdot 10^{11} e^{\left(-\frac{1.0222 \cdot 10^5}{RT}\right)} \quad (4)$$

The fitting procedure employs the COBYLA algorithm [21] to optimize the polarity correction factor by minimizing Mean Squared Error, with convergence defined as no improvement beyond the 10th decimal place after 10 iterations.

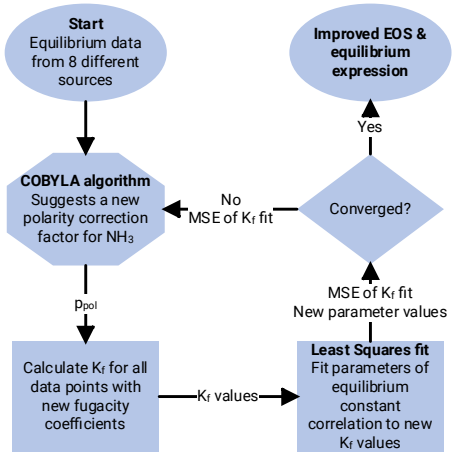

**Figure 1.** Schematic for the nested fitting method to obtain the polarity correction factor for NH3 and to fit the parameter values of the temperature-dependent equilibrium constant correlations.

The polarity correction factor for $NH_3$ was fitted to -0.2368 while the polarity factor of the other molecules were kept at zero.

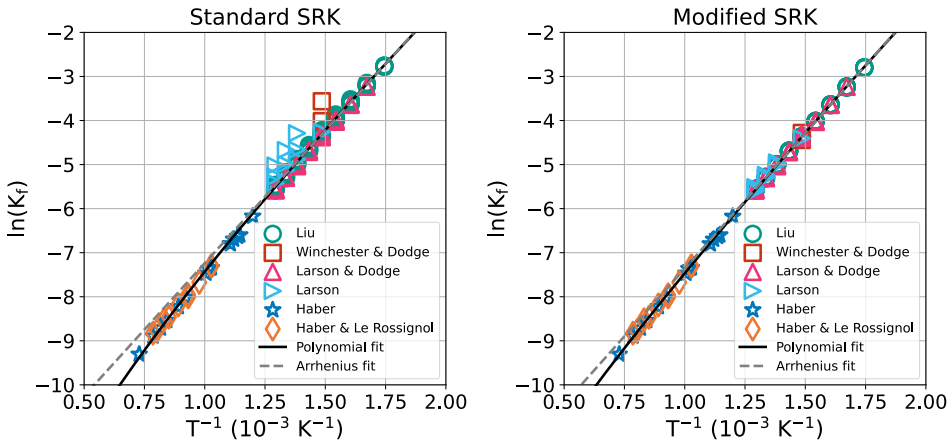

**Figure 2:** Equilibrium constant prediction by the polynomial (fitted to 300-1100 °C data) and Arrhenius type equation (fitted to 300-550 °C data) without (left) and with (right) polarity correction.

## KINETIC MODELLING

### Model derivation

The dissociation of surface-adsorbed dinitrogen to atomic nitrogen (Reaction 2 in Table 1) is the rate-determining step for ammonia synthesis on iron-based catalysts [22–24].

**Table 1:** The microkinetic reactions for ammonia synthesis.

| Number | Microkinetic reactions |
|---|---|
| 1 | $N_2(g) + * \leftrightarrow N_2*$ |
| 2 | $N_2* + * \leftrightarrow 2N*$ |
| 3 | $N* + H* \leftrightarrow NH* + *$ |
| 4 | $NH* + H* \leftrightarrow NH_2* + *$ |
| 5 | $NH_2* + H* \leftrightarrow NH_3* + *$ |
| 6 | $NH_3* \leftrightarrow NH_3(g) + *$ |
| 7 | $H_2(g) + 2* \leftrightarrow 2H*$ |

Molecular nitrogen dissociation (reaction 2 in Table 1) was taken as the rate-determining step, and N* and H* were taken as the most abundant surface species on the active sites of the catalyst [25]. A correction factor ($b_{cat}$) for activity differences between different catalysts was implemented. The derived kinetic model is given in Equation 5,

$$r_{NH_3} = b_{cat} k_{NH_3} f_{N_2} \left(1 - \frac{1}{K_f^2} \frac{f_{NH_3}^2}{f_{N_2} f_{H_2}^3}\right) \left(1 + \frac{f_{NH_3}}{K_N f_{H_2}^{1.5}} + \sqrt{K_H f_{H_2}}\right)^{-2} \quad (5)$$

where $f_i$ stands for the fugacity of a component which is calculated using the modified SRK with the unit bar. $K_f$ is the equilibrium constant calculated using Equation 3. And $r_{NH_3}$ is expressed in mol kg$^{-1}$ s$^{-1}$. $K_N$ and $K_H$ are adsorption constants for the N* and H* surface species. The adsorption constants and $k_{NH_3}$ follow an Arrhenius relationship and contain, thus, two parameters each.

### Modelling procedure

11 datasets found in Refs. [7, 8, 10, 11, 13, 14, 26] with a total of 1019 data points were fitted to the model in Equation 5, over a wide range of temperatures (251-550°C), pressures (1-324 bar), space velocities (1-1800 Nm$^3$ kg-cat$^{-1}$ h$^{-1}$ at NTP (25 °C and 1 atm)), and $H_2/N_2$ ratios (0.33-8.5). Only the gas-hour space velocity data were reported for the Fixed Nitrogen No. 660, Temkin & Phyzev, and Fixed Nitrogen Cat. A catalysts. Therefore, the density of those catalysts was assumed to be 3 g cm$^{-3}$.

The reactor was modelled as an isothermal plug-flow reactor. Due to the wide range of conditions and different orders in magnitude in measured $NH_3$ molar fractions, a type of normalisation was applied to the objective function. The objective function for the fitting is defined in Equation 6 and 7.

$$\chi^2 = \sum_{j=1} \sigma_j \left(\frac{y_{NH_3,j} - \hat{y}_{NH_3,j}}{y^d_{NH_3,\max}}\right)^2 \quad (6)$$

$$\sigma_j = \frac{1}{N_n} \; with \; j \in N_n \quad (7)$$

Where $y^d_{NH_3,\max}$ is the maximum value of the molar fraction in the dataset. Datasets were equally taken into account by calculating a weight ($\sigma_j$) so that the sum of all the weights in a sub-dataset ($N_n$) was equal to 1. Therefore, there is no bias towards larger datasets.

To improve the predictive capabilities of the model, 5-fold cross-validation was applied. Furthermore, the cross-correlation between parameters was reduced by applying the reference temperature approach by Schwaab et al. [27, 28].

### Optimization algorithm selection

Various optimization algorithms were tested to fit the kinetic parameters, including Particle Swarm Optimization (PSO), Differential Evolution (DE), Nelder-Mead, the compact Genetic Algorithm (cGA), COBYLA, and Powell. Among them, the Covariance Matrix Adaptation Evolution Strategy (CMA-ES) with a scale factor of 2.5 demonstrated superior performance, consistently converging to the global minimum across multiple initialization points. This performance is due to its ability to escape local minima in the complex parameter landscape of the kinetic model. The settings for the other algorithms followed the default configurations provided by the Nevergrad [29] optimization package from Meta Inc.

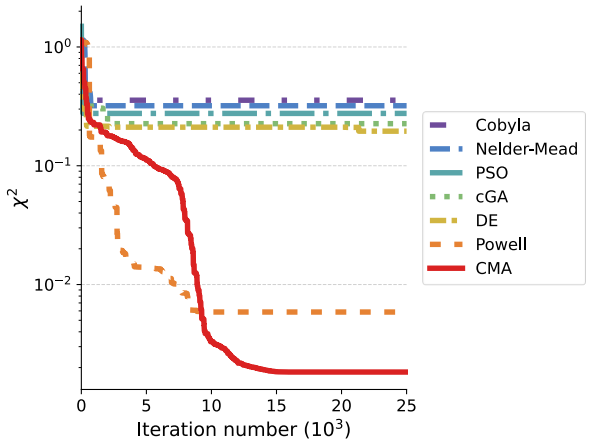

**Figure 3.** Progression of the optimization algorithms. The displayed error represents the lowest error found up to and including the corresponding iteration number.

### Overall fitting results

The calculated parameters for $k_{NH_3}$, $K_N$ and $K_H$ for the kinetic model are listed in Table 2. And the parameters for the Relative Catalytic Activity factors are found in

Figure 4.

**Table 2:** Calculated parameters with 95% confidence interval for the kinetic model.

| Parameter | Value | ± 95% CI | Unit |
|---|---|---|---|
| $k_{NH_3,A}$ | 2.215E+13 | 7.624E+13 | mol kg-cat$^{-1}$ bar$^{-1}$ s$^{-1}$ |
| $k_{NH_3,B}$ | 1.007E+05 | 7.876E+03 | J mol$^{-1}$ |
| $K_{N,A}$ | 2.455E-08 | 6.474E-08 | bar$^{-0.5}$ |
| $K_{N,B}$ | -1.795E+04 | 3.365E+03 | J mol$^{-1}$ |
| $\sqrt{K_{H,A}}$ | 3.276E+02 | 4.271E+02 | bar$^{-0.5}$ |
| $\sqrt{K_{H,B}}$ | -4.948E+03 | 4.887E+03 | J mol$^{-1}$ |

A parity plot comparing the experimental and predicted $NH_3$ mole fractions, based on the kinetic model in Equation 5 and the parameters from Table 2, is presented in Figure 4 (Left). This plot incorporates data from 11 datasets featuring different metal oxide precursors, including magnetite and wüstite. The strong agreement between experimental and predicted $NH_3$ mole fractions supports the hypothesis that all iron-based catalysts reported in literature exhibit similar behavior under operational conditions with respect to temperature and pressure. The primary variations arise from differences in the density of active sites and the effectiveness of promoters, which can be accounted for using a correction factor $b_{cat}$ for catalytic activity.

Multiple models were fitted using the same procedure, and their fitting quality metrics are presented in Table 3. The modified Temkin model, as described by Dyson and Simon [18], features the fewest parameters but exhibits the lowest fit quality, making it more suitable for a narrow operating range. When the model in Equation 5 assumes only N* species, it closely aligns with the model proposed by Nielsen et al. [7]. Substituting partial pressures for fugacities, as implemented by Sehested et al. [8], reduces the fit quality by approximately 20%.

**Table 3:** Statistical results for the fitted models.

| Model | Surface species | MSE | $\chi^2$ |
|---|---|---|---|
| Temkin (modified) | - | 2.55E-04 | 3.75E-03 |
| This work | N | 1.27E-04 | 1.67E-03 |
| This work (partial pressure) | N, H | 4.83E-05 | 7.77E-04 |
| This work | N, H | 4.05E-05 | 6.11E-04 |

## CONCLUSION

The modified Soave-Redlich-Kwong Equation-of-State, incorporating a polarity correction factor of -0.2368 for $NH_3$, effectively accounts for polarity effects at high pressure and accurately describes equilibrium up to 1000 bar. The developed Arrhenius-type equilibrium model and the unified Langmuir-Hinshelwood kinetic model are easily implemented in all commercial flowsheeting software.

The kinetic model successfully describes all available data using a single rate expression and a Relative Catalytic Activity factor per catalyst, capturing variations in active site density and promoter effects. This suggests that ammonia synthesis follows a highly similar mechanism for all iron-based catalysts, regardless of precursor, promoter, or preparation method. The model accurately predicts ammonia synthesis across a broad range of

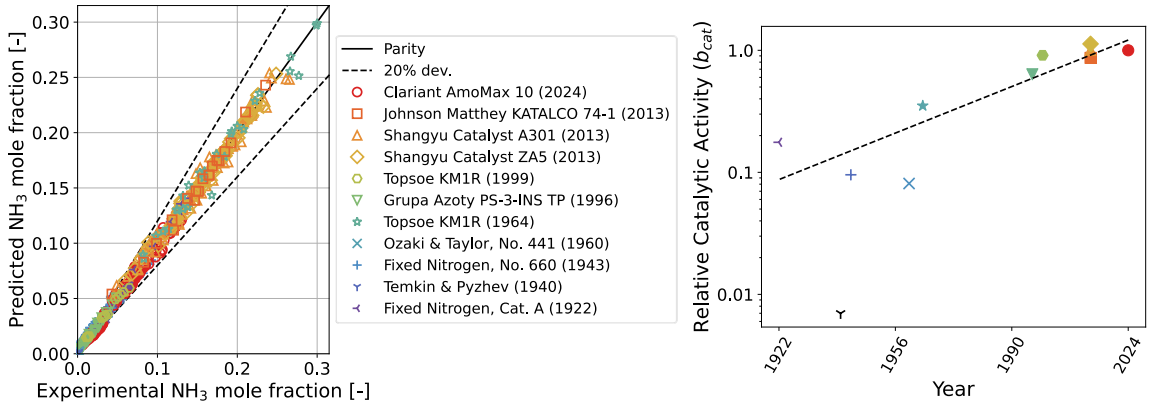

**Figure 4:** Left: Parity plot of the experimental $NH_3$ mole fraction in the outlet from Refs. [7, 8, 10, 11, 13, 14, 26] versus predicted $NH_3$ mole fraction for the same conditions using the model in Equation 5. Right: The calculated Relative Catalytic Activity ($b_{cat}$) for various datasets. The regression line excludes the Temkin & Pyzhev catalyst because this was the only non-promoted iron catalyst.

conditions (251–550 °C, 1–324 bar, $H_2/N_2$ ratios of 0.33–8.5, and space velocities of 1–1800 $Nm^3\ kg\text{-}cat^{-1}\ h^{-1}$). The inclusion of H* surface species are necessary to extrapolate to lower temperatures (<400 °C).

To optimize kinetic parameters, various algorithms were tested, with CMA-ES outperforming others by consistently converging to the global minimum due to its ability to escape local minima in the complex parameter landscape.

This work consolidates over a century of equilibrium and kinetic data for ammonia synthesis using iron-based catalysts with improved and more robust thermodynamic and kinetic models.

## ACKNOWLEDGEMENTS

The authors thank the PROVE-IT consortium (RVO MOOI42014) for providing the financial grants for this research. The authors thank Aayan Banerjee, Jimmy Faria, Leon Lefferts, and Sascha Kersten from the University of Twente for the valuable discussions. Furthermore, Tim van Schagen is thanked for their input on the modeling framework.

## ABSTRACT

This study presents the application of a Q-learning algorithm to optimize the selection of chemical reactions for methane reforming processes. Starting with a set of 11 candidate reactions, the algorithm identified three key reactions. These reactions effectively represent the experimental data while aligning with the underlying physics of the process and previously reported findings. The algorithm employed an epsilon-greedy policy to balance exploration and exploitation during the training process. Furthermore, simulations based on the identified reactions revealed trends consistent with experimental data. This work highlights the efficiency and adaptability of Q-learning in modeling complex catalytic systems and provides a framework for further exploration and optimization of methane reforming processes.

**Keywords**: Methane Reforming, Machine Learning, Optimization, Reaction Engineering, Reinforce Learning

## INTRODUCTION

Methane reforming is one of the key technologies for hydrogen production, an essential energy carrier in the transition toward cleaner energy systems. This process involves a series of simultaneous and coupled chemical reactions, among which Methane Steam Reforming (MSR) and the Water Gas Shift (WGS) reaction are particularly noteworthy. However, the complex and highly nonlinear nature of these reactions poses a significant challenge for process modeling and optimization.

Traditionally, kinetic models used to describe such processes are based on a fixed set of reaction rate equations derived from the Arrhenius equation. While this approach has proven effective in many cases, it can be limited when dealing with systems where operating conditions or predominant reaction pathways change significantly, such as in catalytic reforming in refineries, hydrodesulfurization, and fluid catalytic cracking (FCC). In this context, there is a need for tools capable of dynamically identifying the most relevant combinations of reactions to represent experimental data [1].

Reinforcement learning algorithms, such as Q-learning, offer a novel and powerful approach to tackle this problem [2]. These techniques enable the exploration and exploitation of potential solution spaces, iteratively learning optimal decisions based on a defined reward function. For methane reforming, the use of Q-learning facilitates the selection of reactions that best describe experimental data under varying temperature conditions, while simultaneously optimizing the associated kinetic constants.

This work describes the implementation of a Q-learning algorithm to identify the key reactions within an initial set of 11 reactions considered relevant for methane reforming. Based on this selection, the algorithm fits the experimental data using a model grounded in the Arrhenius equation.

This methodology not only contributes to a better understanding of the most significant reaction pathways but also opens new possibilities for optimizing the design and operation of complex catalytic processes.

## METHODOLOGY

### Q-Learning Framework

To optimize reaction pathways, a framework based on

reinforcement learning is adopted, utilizing a Q-learning process, as illustrated in Fig. 1. A $\epsilon$-greedy policy is defined due to its ability to balance exploration and exploitation. This approach allows the agent to explore new actions with a probability controlled by the epsilon ($\epsilon$) parameter while prioritizing actions with known rewards as learning progresses. This helps avoid suboptimal solutions that could arise from premature exploitation of the environment.

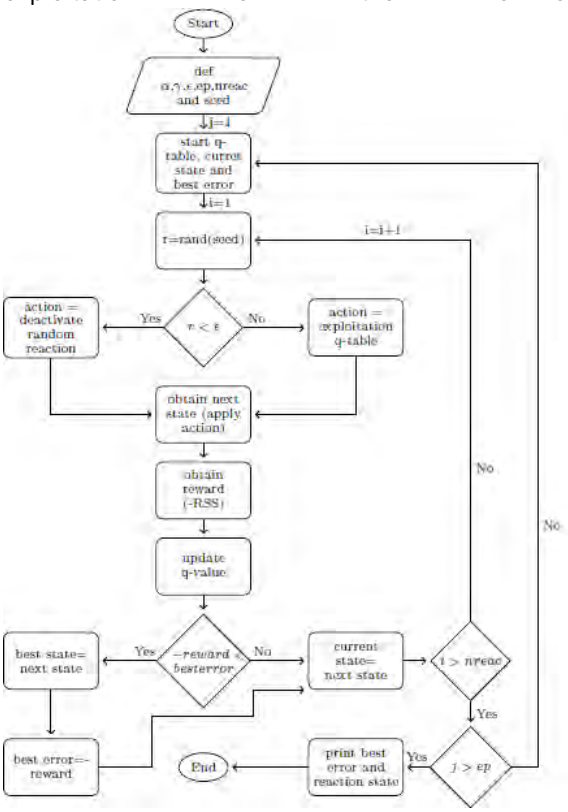

**Figure 1.** Proposed Methodology to select reactions.

This method relies on the iterative updating of Q values using the equation:

$$\mathrm{Q(s,a)} \leftarrow \mathrm{Q(s,a)} + \alpha\left[\mathrm{r} + \gamma \max_{\mathrm{a'}} \mathrm{Q}\,(\mathrm{s'},\mathrm{a'}) - \mathrm{Q(s,a)}\right] \quad (1)$$

Based on this equation, the parameters $\alpha$, $\gamma$, and $\epsilon$ must be defined considering the following criteria:

The learning rate ($\alpha$) controls how much the $Q(s,a)$ values are updated in each iteration. A low $\alpha$ ensures that updates are gradual, reducing the risk of abrupt oscillations in $Q(s,a)$. However, this may slow down convergence. This parameter directly affects the adjustment term:

$$\alpha\left[r + \gamma \max_{a'} Q\,(s',a') - Q(s,a)\right] \quad (2)$$

The parameter $\epsilon$ defines the exploration probability. At the beginning of the learning process, a high $\epsilon$ encourages exploration of the state space to avoid suboptimal local solutions. During training, the value of $\epsilon$ is dynamically adjusted according to:

$$\epsilon_{i+1} = \begin{cases} \epsilon_i * 0.99, & i < 10 \\ 0.1, & i \geq 10 \end{cases} \quad (3)$$

This adjustment allows for a controlled transition from an intensive exploration phase to more consistent exploitation in the final stages of training.

The discount factor ($\gamma$) determines the weight of future rewards. A high $\gamma$ prioritizes long-term rewards, favoring globally optimal strategies. This parameter affects the term:

$$\alpha\gamma \max_{a'} Q\,(s',a') \quad (4)$$

The values of the parameters used in this work for the Q-learning algorithm are summarized in Table 1.

**Table 1:** Q-learning Selected Parameters.

| Parameter | Value |
|---|---|
| Episodes | 30.00 |
| α | 0.10 |
| $\varepsilon_{in}$ | 0.95 |
| $\gamma$ | 0.90 |

This parameter configuration is designed to achieve a balance between learning stability, initial exploration, and efficient exploitation in advanced stages.

## Experimental Data

The experimental data used in this work were reported by Akers et al. [3] This dataset consists of five runs. The first four runs were conducted at the same temperature, varying the methane-to-water feed ratio. The experiments were performed at different reaction times. The reaction time for methane is directly proportional to the amount of catalyst and inversely proportional to the methane feed rate. This reaction time is expressed as a time factor, defined as the weight of the catalyst divided by the natural gas feed rate, expressed in moles per second.

**Table 2:** Experimental Sets Conditions

| *Set* | T [K] | Input molar ratio $\left(\frac{H_2O}{CH_4}\right)$ | W/F$_{max}$ $\left[\frac{kg \cdot s}{mol}\right]$ |
|---|---|---|---|
| 1 | 910 | 10:1 | 1.10× $10^{-3}$ |
| 2 | 910 | 5:1 | 7.00× $10^{-4}$ |
| 3 | 910 | 3.5:1 | 7.00× $10^{-4}$ |
| 4 | 910 | 2.5:1 | 7.00× $10^{-4}$ |
| 5 | 609 | 3:1 | 3.00× $10^{-4}$ |
| 6 | 671 | 3:1 | 3.00× $10^{-4}$ |
| 7 | 723 | 3:1 | 3.00× $10^{-4}$ |
| 8 | 779 | 3:1 | 3.00× $10^{-4}$ |

The fifth run aims to highlight the effect of temperature. For this purpose, the feed ratio and reaction time

were kept constant, while the temperature varied. A summary of the experimental data is presented in Table 2.

Since the catalyst was not used for more than 5 hours, its activity is assumed to remain constant for all runs conducted at the same temperature.

A total of 188 experimental data points is available, corresponding to the partial pressures of the components ($CH_4$, $H_2O$, $CO_2$, $H_2$, and CO). While this may appear to be a relatively small dataset, the use of first-principles models in combination with Q-learning algorithms is expected to yield optimal results. Moreover, the use of experimental data reduces potential errors associated with simulated data points and ensures that the selection of reaction pathways is not biased by the predefined conditions of simulated datasets.

## Kinetics Model

In the methane reforming process, a detailed kinetic model is essential to understand the reaction dynamics. This model considers a network of 11 reactions

The equilibrium constant for each reaction is determined as a function of temperature. Specifically, for each reaction $j$, the equilibrium constant is expressed as:

$$K_{\mathrm{eq},j} = A_j \cdot \exp\left(-\frac{\Delta H_j^{\circ}}{RT}\right) \tag{5}$$

where $A_j$ is a pre-exponential factor related to the standard entropy change ($\Delta S_j^{\circ}$), $\Delta H_j^{\circ}$ is the standard enthalpy change, $R$ is the universal gas constant, and $T$ is the temperature in Kelvin. The data for the equilibrium constants used in this model are compiled in Table 3, which includes values reported by various authors [3-8].

The reaction rate for each reversible reaction $j$ is given by:

$$r_j = k_{f,j} \prod_i P_i^{\nu_{i,j}} - k_{r,j} \prod_i P_i^{\nu'_{i,j}} \tag{6}$$

where $k_{f,j}$ and $k_{r,j}$ are the forward and reverse rate coefficients, respectively, and $P_i$ is the partial pressure of component $i$. The term $\nu_{i,j}$ represents the stoichiometric coefficients of the reactants, while $\nu'_{i,j}$ represents those of the products in reaction $j$. The forward rate constant $k_{f,j}$ is calculated using the Arrhenius equation:

$$k_{f,j} = A_{f,j} \cdot \exp\left(-\frac{E_{f,j}}{RT}\right) \tag{7}$$

where $A_{f,j}$ is the pre-exponential factor and $E_{f,j}$ is the activation energy for the forward reaction. These parameters $A_{f,j}$ and $E_{f,j}$, which are crucial for determining the forward reaction rates, are calculated through an optimization process, as described in the "Parameter Estimation" section of this work.

The reverse rate constant $k_{r,j}$ is related to the forward rate constant and the equilibrium constant $K_{\mathrm{eq},j}$ by:

$$k_{r,j} = \frac{k_{f,j}}{K_{\mathrm{eq},j}} \tag{8}$$

The rate law thus accounts for both the forward and reverse reactions, and the overall reaction rate depends on the partial pressures of the species involved in each reaction.

To maintain mass balance across the system, the rate of change of the partial pressure of any component $i$ is described by a mass balance equation:

$$\frac{dP_i}{d\left(\frac{W}{F_{\mathrm{CH_4}}}\right)} = \sum_{j=1}^{11} \nu_{i,j} r_j \tag{9}$$

where $W$ is the catalyst mass, $F_{\mathrm{CH_4}}$ is the molar flow rate of methane, and $\nu_{i,j}$ is the stoichiometric coefficient of component $i$ in reaction $j$. The set of equations for all components is solved simultaneously to predict the evolution of the partial pressures over time and catalyst mass.

Additionally, a Q-learning algorithm is used to optimize the reaction set. This optimization process dynamically selects which reactions from the set of 11 should be included or excluded from the kinetic model. The goal is to identify the reactions that best represent the methane reforming phenomena, based on experimental or simulated data.

## Parameter Estimation

**Table 3:** Reaction set and its Equilibrium Function [8].

| *I* | Reaction | $K_{pi}$ | Dimensions |
|---|---|---|---|
| 1 | $CH_4 + H_2O \leftrightarrow CO + 3H_2$ | $1.1669 \times 10^{13} \exp(-26380/T)$ | $(atm)^2$ |
| 2 | $CO + H_2O \leftrightarrow CO_2 + H_2$ | $1.767 \times 10^{-2} \exp(4400/T)$ | $(atm)^0$ |
| 3 | $CH_4 + 2H_2O \leftrightarrow CO_2 + 4H_2$ | $2.0620 \times 10^{11} \exp(-22430/T)$ | $(atm)^2$ |
| 4 | $CH_4 + CO_2 \leftrightarrow 2CO + 2H_2$ | $6.6038 \times 10^{14} \exp(-31230/T)$ | $(atm)^2$ |
| 5 | $CH_4 + 3CO_2 \leftrightarrow 4CO + 2H_2O$ | $2.1136 \times 10^{18} \exp(-40030/T)$ | $(atm)^2$ |
| 6 | $CH_4 \leftrightarrow C + 2H_2$ | $4.1066 \times 10^{5} \exp(-10614/T)$ | atm |
| 7 | $2CO \leftrightarrow C + CO_2$ | $5.8201 \times 10^{-10} \exp(20634/T)$ | $(atm)^{-1}$ |
| 8 | $CO + H_2 \leftrightarrow C + H_2O$ | $3.215 \times 10^{-8} \exp(16318/T)$ | $(atm)^{-1}$ |
| 9 | $CO_2 + 2H_2 \leftrightarrow C + 2H_2O$ | $1.7762 \times 10^{-6} \exp(12002/T)$ | $(atm)^{-1}$ |
| 10 | $CH_4 + 2CO \leftrightarrow 3C + 2H_2O$ | $4.2455 \times 10^{-10} \exp(22022/T)$ | $(atm)^{-1}$ |
| 11 | $CH_4 + CO_2 \leftrightarrow 2C + 2H_2O$ | $0.730 \exp(1388/T)$ | $(atm)^0$ |

The parameter estimation process involves solving the system of differential equations that describe the methane reforming reactions and adjusting the model parameters to best fit the experimental data. In particular, the activation energy ($E_a$) and the pre-exponential factor ($A$) of the forward reaction rate constants were estimated through optimization. To solve this system, it was used the `odeint` function from the `scipy.integrate` package in `Python`, with the `LSODA` integrator.

The objective function used to guide the optimization process is the residual sum of squares (RSS) of the partial pressures. The RSS is calculated as:

$$\mathrm{RSS} = \sum_{j=1}^{M} \sum_{i=1}^{N} \left( P_{i,j}^{\mathrm{exp}} - P_{i,j}^{\mathrm{calc}} \right)^2 \tag{10}$$

where $P_{i,j}^{\mathrm{exp}}$ and $P_{i,j}^{\mathrm{calc}}$ are the experimental and calculated partial pressures of component $i$ in condition $j$, respectively, and $N$ is the number of components, while $M$ is the number of conditions. This function serves as the reward function for the Q-learning process, where the goal is to minimize the discrepancy between experimental and model-predicted partial pressures.

The optimization process is carried out using the `minimize` function from the `scipy.optimize` library, with the `L-BFGS-B` algorithm [9-10].

The initial values for the parameters $\boldsymbol{A}$ and $\boldsymbol{E_a}$ are defined based on the literature. Moreover, the values of $\boldsymbol{A}$ and $\boldsymbol{E_a}$ are constrained to be positive, as negative values are physically meaningless in the context of reaction kinetics.

In addition to the parameter optimization, a mechanism is incorporated to optimize a set of parameters defined by a vector that activates or deactivates the reactions to be considered in the kinetic model, it ensures that the optimizer adjusts only the parameters corresponding to the active reactions. This is advantageous because it reduces the dimensionality of the parameter space, allowing the optimizer to focus on the relevant reactions.

This approach is particularly useful as the Q-learning algorithm subsequently refines the reaction set, selecting the most appropriate reactions based on experimental data.

# RESULTS & DISCUSSION

## Evaluation of Reaction Set Combinations

All possible reaction subsets were evaluated, covering every combination from single reactions to the full set of 11 reactions, leading to a total of 2048 cases.

The evaluation of all these combinations provides a comprehensive analysis of the different reaction sets, enabling the identification of the most suitable configuration to describe the methane reforming process. By evaluating every possible combination, it is possible to directly assess the performance of each reaction set based on how well it matches the experimental data. However, this exhaustive approach comes with significant computational costs, especially as the number of reactions increases.

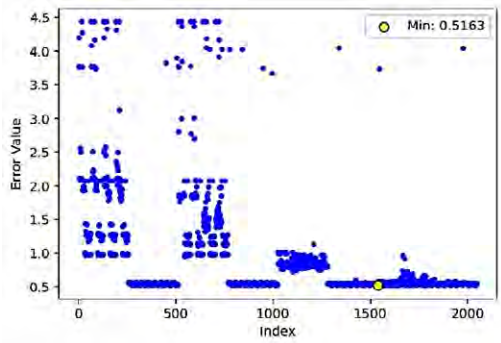

**Figure 2.** Combinatorial Errors from Reaction Set.

The Fig. 2 shows the evaluation of 2048 reaction set combinations, with each combination indexed on the x-axis and the corresponding residual sum of squares (RSS) on the y-axis. The RSS value indicates the accuracy of the model, with lower values representing a better fit to the experimental data.

The yellow-highlighted combination, with an RSS of 0.5163, is the optimal set, providing the best fit to the data. This combination represents the most accurate model of the methane reforming process among all evaluated sets.

The variation in RSS values illustrates the differing performance of the reaction sets, with most combinations yielding higher RSS values, indicating poorer fits. This emphasizes the importance of selecting the correct reaction set to accurately model the system.

## Q-Learning Optimization Results

Fig.3 illustrates the evolution of the best error achieved during the Q-learning training as a function of the number of iterations (11 iterations per episode). It is observed that the best error is reached after approximately 40 iterations, after which no further improvements are identified.

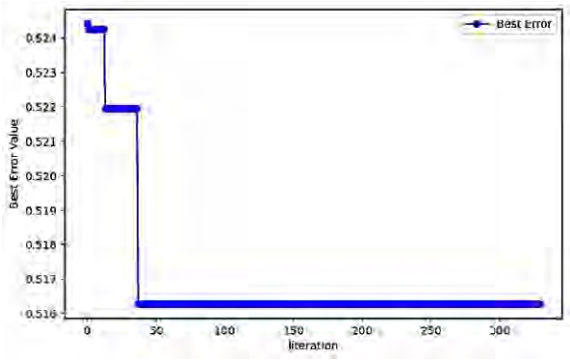

**Figure 3.** Best Error in training Q-learning.

This behavior suggests that the algorithm converges to the optimal set of reactions during the early stages of training, coinciding with episodes where the epsilon parameter (exploration) is high. As training progresses and epsilon decreases, the algorithm prioritizes exploiting the learned solutions, explaining the absence of better error values beyond this point.

The early convergence indicates that the method is efficient in rapidly identifying the most representative reaction combinations, offering significant advantages in terms of computational time and resource requirements

The Q-learning algorithm identified three key reactions from the initial set of 11 that best describe the methane reforming process reported in table 5.

**Table 4:** Active Reaction Selected by Q-learning.

| Reaction | Active Value |
|---|---|
| $CH_4 + H_2O \leftrightarrow CO + 3H_2$ | 1 |
| $CO + H_2O \leftrightarrow CO_2 + H_2$ | 1 |
| $CH_4 + CO_2 \leftrightarrow 2C + 2H_2O$ | 1 |

The first selected reaction is the Methane Steam Reforming (MSR) reaction, which serves as the primary pathway for hydrogen production by breaking down methane in the presence of steam. It is an endothermic reaction that sets the foundation for subsequent reaction pathways, the second is known as the Water Gas Shift (WGS) reaction, this exothermic reaction increases hydrogen yield while reducing carbon monoxide levels. It plays a crucial role in balancing the overall hydrogen and carbon species in the system, the third selected reaction leads to the formation of carbon deposits while consuming hydrogen and carbon dioxide. Its activation highlights the algorithm's ability to capture critical secondary effects that may influence the overall process, especially in systems prone to carbon formation.

The selection of these reactions demonstrates the algorithm's effectiveness in capturing the fundamental and secondary processes necessary for accurately modeling the methane reforming system. These reactions collectively represent the dominant pathways for hydrogen generation and associated carbon transformations under the studied conditions.

The Table 5 presents kinetic constants for the forward and reverse reactions of steam methane reforming (SMR), the water-gas shift reaction (WGS), and the reaction of carbonization. The analysis reveals trends consistent with thermodynamic expectations.

For SMR, the equilibrium shifts towards hydrogen production as temperature increases, aligning with the reaction's endothermic nature. For WGS, the equilibrium shifts towards reactants with increasing temperature. This behavior is expected for an exothermic reaction, were higher temperatures disfavor product formation, as predicted by Le Chatelier's principle.

For the carbonization reaction, the equilibrium similarly shifts to the left at higher temperatures. The reaction's exothermic nature favors the formation of carbon and water at lower temperatures.

## Simulation

The Fig. 4 is a parity plot comparing the calculated partial pressures to experimental values for all species. The results reveal a consistent underestimation of water conversion at higher temperatures and elevated methane feed ratios. This behavior is likely due to limitations in the kinetic model, which does not account for adsorption effects on the catalytic surface. Despite this underestimation, the general production trends for all species remain consistent with experimental data, suggesting the model captures the qualitative behavior.

The Fig. 5 presents a simulation of partial pressures as a function of W/F, which is analogous to reaction time. The model demonstrates a tendency to underestimate water conversion throughout the reaction path, consistent with the observations in the parity plot. In contrast, hydrogen production is overestimated, particularly at intermediate and high W/F values. This discrepancy

**Table 5:** Kinetic Coefficients from Selected Reactions.

| T(K) | $\left[\frac{\text{mol}}{\text{atm}\cdot\text{kg}\cdot\text{s}}\right]$ | SMR | WGS | Carbonization |
|---|---|---|---|---|
| 609.26 | $\mathbf{k_f}$ | $1.209 \times 10^{3}$ | $4.007 \times 10^{4}$ | $5.767 \times 10^{1}$ |
| | $\mathbf{k_r}$ | $6.601 \times 10^{8}$ * | $1.656 \times 10^{3}$ | $8.095 \times 10^{0}$ |
| 671.48 | $\mathbf{k_f}$ | $1.429 \times 10^{3}$ | $4.007 \times 10^{4}$ | $5.767 \times 10^{1}$ |
| | $\mathbf{k_r}$ | $1.412 \times 10^{7}$ * | $3.234 \times 10^{3}$ | $9.997 \times 10^{0}$ |
| 723.15 | $\mathbf{k_f}$ | $1.607 \times 10^{3}$ | $4.007 \times 10^{4}$ | $5.767 \times 10^{1}$ |
| | $\mathbf{k_r}$ | $9.586 \times 10^{5}$ * | $5.166 \times 10^{3}$ | $1.159 \times 10^{1}$ |
| 779.26 | $\mathbf{k_f}$ | $1.792 \times 10^{3}$ | $4.007 \times 10^{4}$ | $5.767 \times 10^{1}$ |
| | $\mathbf{k_r}$ | $7.734 \times 10^{4}$ * | $8.006 \times 10^{3}$ | $1.331 \times 10^{1}$ |

| | $\mathbf{k_r}$ | $7.112 \times 10^{2}$ * | $1.811 \times 10^{4}$ | $1.721 \times 10^{1}$ |

$*\rightarrow \left[\frac{\text{mol}}{\text{atm}^3\cdot\text{kg}\cdot\text{s}}\right]$

may arise from the same model limitations, including the omission of adsorption dynamics and potential inaccuracies in reaction rate parameters.

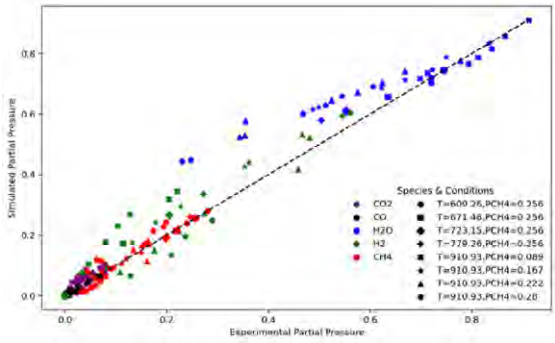

**Figure 4.** Parity Plot of Simulated Partial Pressures.

Nevertheless, the shapes of the curves and their evolution with W/F align with experimental trends, indicating the model adequately predicts the system's dynamic behavior. These results suggest that while the model requires refinement to improve quantitative accuracy, it reliably captures the qualitative aspects of methane reforming and hydrogen production under varying conditions.

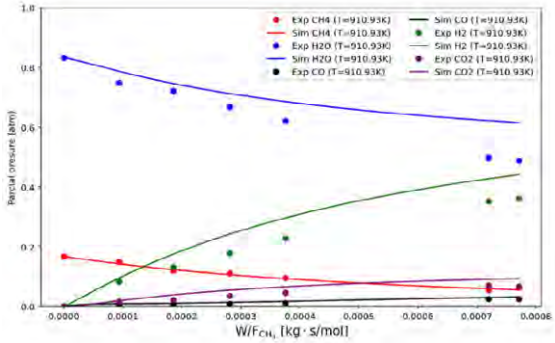

**Figure 5.** Simulation process with Active Reactions.

## CONCLUSIONS

The implementation of the Q-learning algorithm successfully identified the most relevant reactions to describe the methane reforming process. The selected reactions not only align with the physical principles of the process but also agree with previously reported studies, demonstrating the consistency and reliability of the approach. While the model accurately follows experimental trends, it exhibits a tendency to underestimate water conversion and overestimate hydrogen production at high temperatures and higher methane feed ratios. This limitation suggests that exploring alternative models could further enhance representativeness and predictive accuracy.

## ABSTRACT

Fluid catalytic cracking is a crucial process in the refining industry, capable of converting lower-quality feedstocks into higher-value products. Due to the variability in feedstock properties and fluctuations in product market prices, timely adjustment and optimization of the FCC unit are essential. In this context, data-driven models have garnered increasing attention for their capacity to handle the complex, nonlinear reactions involved in the FCC process. However, on account of the limited operating range of the plants and the black-box nature of data-driven models, relying solely on these models for optimization may lead to contradictory decisions in optimization processes. To address these challenges, we integrate gradient information of product yields with respect to key variables derived from the mechanistic model Petro-SIM, into the training process of data-driven models. To mitigate the high computational demands of the Petro-SIM model, we propose the use of active learning methods for efficient sampling and thereby constructing a surrogate model. The results demonstrate that the active learning approach reduces the required sampling size by 25%. More importantly, the data-driven model trained with gradient information improves the accuracy of trend direction prediction by 34.6%, significantly enhancing its effectiveness in supporting the optimization process. The code will be available at https://github.com/xwl514/fcc-hybrid-loss.

## 1. INTRODUCTION

Fluid catalytic cracking (FCC) is a crucial process in petroleum refining, converting heavy oils into lighter fuels, such as gasoline and diesel. This process enhances the utilization efficiency of crude oil, reduces resource waste, and meets market demand for light fuels, making it indispensable in both petroleum refining and the chemical industry. Fluctuations in upstream processes and market prices of FCC products necessitate timely adjustments and optimization of the catalytic cracking process conditions to maximize efficiency and profitability. Achieving such optimization depends on accurate modeling of the process, which enables the prediction of key variables directly linked to profitability in response to changes in operating conditions [1].

Modeling of the FCC process can be categorized into mechanism-based and data-driven approaches. Mechanistic models are founded on fundamental physical laws, such as mass conservation, energy conservation, and chemical reaction kinetics. However, due to the complexity of feedstock composition and reaction pathways in FCC, establishing a strict model is challenging. One common simplification is the lumped kinetic model, which consolidates numerous individual compounds into several virtual components based on their similar properties. Reaction pathways are then established for these virtual lumps, and the rate constants are calibrated using plant data. The earliest application in the FCC domain is a three-lump model, which predicts the conversion rate and product distribution under varying reaction conditions, thereby enabling the selection of an optimal operating mode based on production demands [2]. Subsequently, more detailed lumped models have been

developed, offering a more refined description of feedstock and product compositions [3, 4]. However, these traditional lumped models do not account for the molecular structure of the components and are not based on actual reaction mechanisms. In contrast to traditional lumping methods, the structure-oriented lumping (SOL) approach decomposes complex hydrocarbon molecules into molecular fragments or structural groups [5]. This method facilitates the modeling of reactant and product compositions at the molecular level and more closely aligns with the true reaction mechanisms of catalytic cracking, offering improved extrapolation capabilities. However, mechanistic models often require simplifications, which can lead to a loss of accuracy. Furthermore, the development and calibration of these models involve large-scale parameter estimation, a process that is time-consuming and demands high-quality data.

With the advancement of machine learning technologies, data-driven modeling methods have increasingly been applied to the modeling of the FCC process. Machine learning methods, especially deep learning techniques, possess strong nonlinear modeling capabilities and can demonstrate higher accuracy in FCC modeling. However, due to the typically limited operating range, the extrapolation capability of these models is constrained. Although several hybrid modeling approaches have been proposed, these methods often focus primarily on the interpretability and extrapolation of the predicted yield values [6, 7]. However, they do not directly account for the gradient information of product yield with respect to operational variables. Factors such as noise in the factory data can cause the model to unintentionally learn distorted gradient information, potentially leading to incorrect optimization directions.

To address these issues, this study aims to directly integrate the gradient information into the data-driven modeling process, thereby enhancing the model's effectiveness in optimizing the FCC process. The primary innovations of this study are as follows:

1. Active learning for mechanistic sampling: employ active learning methods to sample data from the mechanistic model, Petro-SIM. This approach significantly reduces the time and computational costs associated with data sampling.
2. Gradient calculation via surrogate model: utilize samples from the mechanistic model to construct a surrogate model. The gradient information of yield variables with respect to

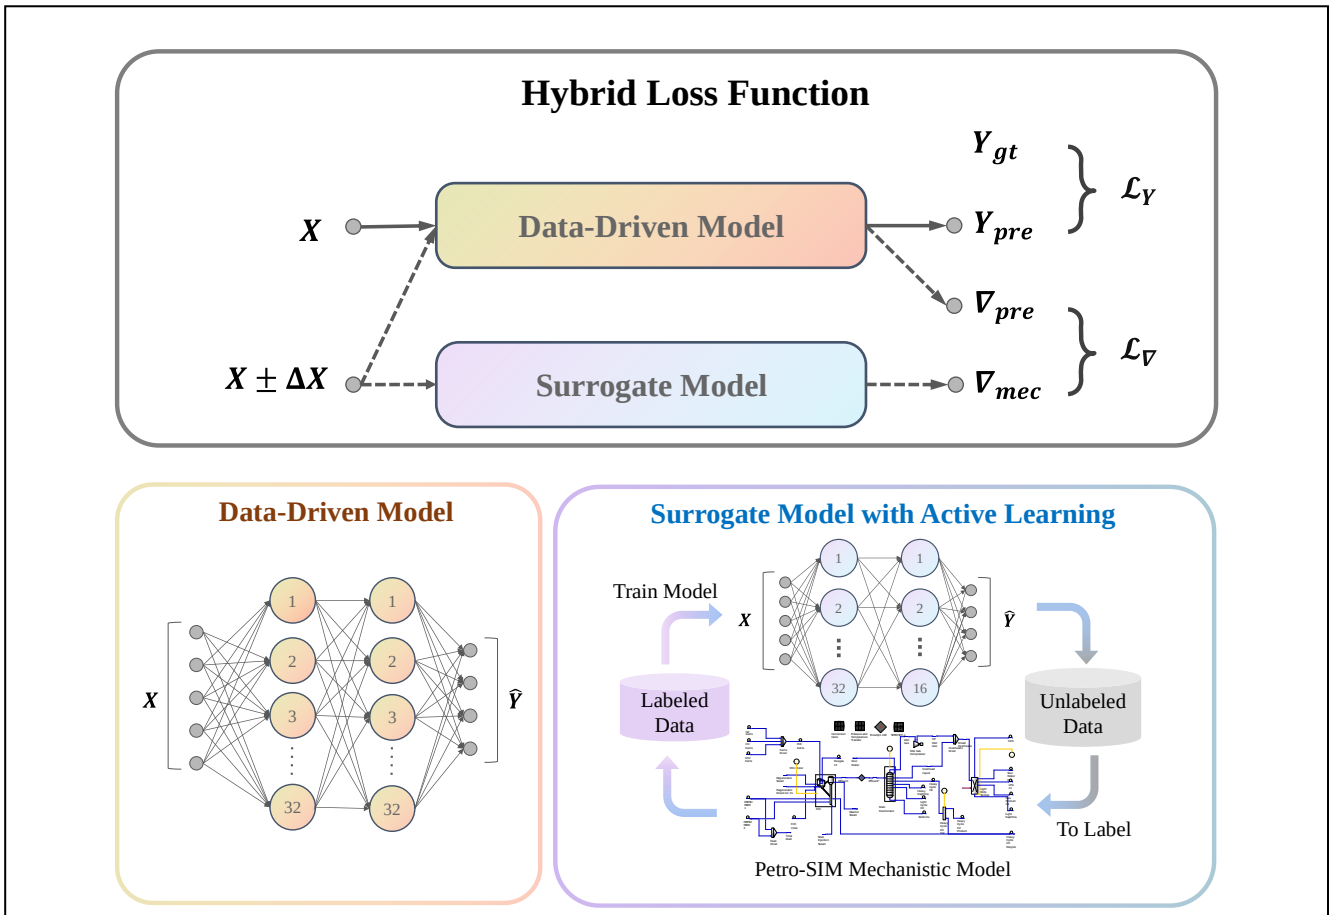

**Figure 1:** Overview of our hybrid loss function framework.

operational variables at plant sample points is computed using the central difference method.

3. Gradient loss function: introduce a novel product yield gradient loss function tailored for the FCC process. This function enables the training of data-driven models and enhances their reliability in optimization tasks.

## 2. METHODS

An overview of our method is shown in Figure 1. First, we apply active learning techniques to sample data from the mechanistic model and use the labeled samples to construct a surrogate model. Next, we develop a data-driven model, and during its training, we not only minimize the deviation between the model's output and the true values, but also minimize the gradient differences between the data-driven model and the surrogate model. A detailed explanation of these components is provided in the following sections.

### 2.1 Surrogate Model with Active Learning

In our hybrid loss function framework, we incorporate the gradient information of target variables with respect to operating variables. However, conducting response tests on operating variables over a wide range during plant operation is impractical, making it challenging to obtain accurate gradient information directly from factory data. To address this limitation, we leverage the mechanistic model, which is based on real reaction kinetics and provides reliable gradient information that reflects actual reaction kinetics.

However, computing the gradient information for each data point using the mechanistic model during every training epoch is computationally prohibitive, especially for the large plant data. When the training set consists of 100,000 points, training a single epoch could take hundreds of hours, making such a workload impractical. To overcome this challenge, we adopt a two-step strategy. First, we utilize active learning methods to sample data from the mechanistic model. By selectively sampling the most informative data points, we significantly reduce the number of required samples. Then, we construct a surrogate model to calculate the gradient information. This integrated approach ensures computational feasibility while maintaining high accuracy in gradient estimation.

We select the key operational variables as input variables and those that significantly influence economic performance as output variables, as shown in Table 1. These variables serve as inputs and outputs for the mechanistic model, surrogate model, and data-driven model.

**Table 1:** Key process input and output variables.

| Variable | Description | Unit |
|---|---|---|
| $x_1$ | Feed flowrate | ℃ |
| $x_2$ | Feed preheat temperature | ℃ |
| $x_3$ | Reflux flowrate | ℃ |
| $x_4$ | Reactor temperature | t/h |
| $x_5$ | Regenerator temperature | t/h |
| $y_1$ | Dry gas yield | wt% |
| $y_2$ | Liquefied gas yield | wt% |
| $y_3$ | Diesel yield | wt% |
| $y_4$ | Gasoline yield | wt% |

#### 2.1.1 Mechanistic Model

The mechanistic model we use is the FCC-SIM model from Petro-SIM (KBC Advanced Technologies Ltd., Walton-on-Thames, UK), which is widely used for the design and optimization of FCC units [7]. We develop an FCC model and calibrate it using factory data to ensure better alignment with the plant's operational conditions. The mechanistic model simulates the FCC process based on input variables and outputs the yields of key products, such as gasoline and diesel, which are the primary variables of interest.

#### 2.1.2 Active Learning

Building a surrogate model requires sampling from the mechanistic model. To reduce the time consumption associated with this sampling, we propose using active learning methods. By selecting the most valuable data for labeling based on criteria such as uncertainty or diversity, this approach minimizes the labeling effort, thereby improving both learning efficiency and model performance. The active learning sampling framework is illustrated in Figure 2.

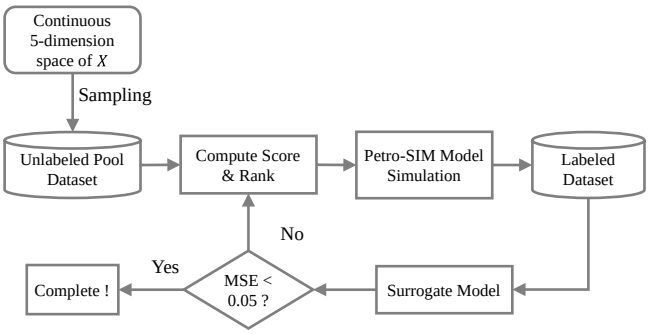

**Figure 2:** Framework of our active learning method.

Since the space of the operating variables is a continuous 5-dimensional space, we begin by performing sampling to obtain a discrete set of sample points. We randomly select 10,000 data points for simulation calculations, which serve as the validation set to verify the accuracy of the surrogate model. Initially, 3,000 samples

are randomly chosen to train the initial surrogate model. In each active learning iteration, we randomly select 10,000 samples from the unlabeled pool, evaluate them using our predefined active learning metric, and rank them according to their scores. The two active learning metrics are described below. The top 300 samples with the highest scores are then selected as inputs for the mechanistic model simulation. Once the outputs from the mechanistic model are obtained, we update the surrogate model with these new samples and decide whether to terminate the process based on the error on the validation set.

We design two active learning metrics, one based on the diversity of $X$ and the other based on the prediction' s uncertainty. For the active learning method based on the diversity of $X$, we query the nearest $k$ labeled samples to a selected unlabeled sample and take the average of their distances as the score for the unlabeled sample. This method identifies unexplored regions by evaluating the distance between unlabeled data points and labeled samples, thereby promoting more effective exploration of the variable space. It helps minimize redundant local exploration and ensures that the model samples more diverse areas of the operational variable space. The pseudocode for the process is as follows:

```
Strategy - X diversity:
Randomly select 10000 samples from the Unla-
beled_Pool
for each sample in selected_samples do
   Compute distances between the sample and
all samples in Labeled_Pool
   Sort the distances and select the small-
est k distances
   Diversity_score ← average of the k small-
est distances
End for
```

For the uncertainty metric, the variance of the model's predictions for an unlabeled point is used to quantify its uncertainty. We perform $T$ inference runs on a selected unlabeled sample using the surrogate model, incorporating Monte Carlo (MC) dropout during the inference process [8]. While dropout is typically disabled during standard inference, the key idea behind MC dropout is to enable dropout during the inference phase as well. This approach allows for the estimation of prediction variance through multiple forward passes, facilitating the assessment of uncertainty. High uncertainty for an unlabeled point suggests that the model has not adequately explored the surrounding space. Such data points are precisely the ones that need to be labeled. The pseudocode for the calculation process is as follows:

```
Strategy - Uncertainty:
Randomly select 10000 samples from Unla-
beled_Pool
for each sample in selected_samples do
   Perform T times inference with dropout
enabled
   Uncertainty_score ← variance of the T
predictions
End for
```

### 2.1.3 Surrogate Model

The surrogate model is based on a multi-layer perceptron (MLP) with two hidden layers. The model is trained using mean squared error (MSE) as the loss function, with a learning rate of 0.001. Each active learning iteration involves training the model for 100 epochs.

## 2.2 Hybrid Loss Function

For data-driven models used in FCC, the loss function typically includes mean squared error, mean absolute error, or other similar loss functions that quantify the deviation between predicted outputs and true values. However, for optimization tasks, solely considering the deviation between predicted values and true values is insufficient. Due to factors such as noise in factory data and overfitting, focusing only on errors in the yield variable during training can result in inaccurate gradients during the FCC optimization process. Therefore, it is crucial to integrate gradient information into the training process.

Consequently, we design a hybrid loss function to train the data-driven model, which not only considers the deviation between predicted values and true values of target variables but also accounts for the discrepancy in gradient directions between the data-driven model and the mechanistic model. The hybrid loss function is as follows:

$$\mathcal{L}_{Hybrid} = w_1\mathcal{L}_Y + w_2\mathcal{L}_\nabla \tag{1}$$

Where $\mathcal{L}_Y$ represents the deviation between the predicted values and the true values of the target variables, and $\mathcal{L}_\nabla$ is the loss function for the gradient component. $w_1$ and $w_2$ are the weights assigned to the two components.

### 2.2.1 Gradient Loss Function

We propose a gradient loss function to quantify the discrepancy between the data-driven model and the mechanistic model. In each epoch, for each training sample, we use the central difference method to compute the gradient of the yield with respect to the operational variables under the given conditions. The calculation formula is as follows:

$$\boldsymbol{\nabla} = \frac{\text{Model}(\boldsymbol{X}+\varepsilon\boldsymbol{I}) - \text{Model}(\boldsymbol{X}-\varepsilon\boldsymbol{I})}{2\varepsilon} \tag{2}$$

Where $\boldsymbol{I}$ is an $m \times m$ identity matrix, with $m$ referring to the number of operational variables. The above formula is used to compute the gradient of a given training

point for both the data-driven model and the surrogate model of the mechanistic model, denoted as $\boldsymbol{\nabla_{pre}}$ and $\boldsymbol{\nabla_{mec}}$. The loss function for the gradient component is computed as follows:

$$\mathcal{L}_{\nabla} = softsign\left(\boldsymbol{\nabla_{pre}} \cdot \boldsymbol{\nabla_{mec}}\right) \cdot \boldsymbol{\nabla_{mec}} \tag{3}$$

We use a sign function as a criterion to determine the directionality of the two gradients. When the directions of the gradients from the data-driven model align with those of the mechanistic model, the sign function yields zero, resulting in a loss function value of zero. This indicates that no correction is needed for the data-driven model. Conversely, when the gradients of the data-driven model and the mechanistic model point in different directions, the sign function returns 1. The subsequent product term $\boldsymbol{\nabla_{mec}}$ serves as a weight term, which increases the importance of points with large gradients and incorrect gradient directions. We use the hyperbolic tangent function because its gradient during the backpropagation process is smoother. The scaling factor $a$ affects the steepness of the hyperbolic tangent function. The $softsign$ formula is as follows:

$$softsign(x) = 0.5 \times \left(1 - \tanh(\alpha \cdot x)\right) \tag{4}$$

The accuracy of gradient direction determination for yield variables with respect to operational variables (denoted as $Acc_{\nabla}$) is also considered in the evaluation of our model, and is defined as follows:

$$Acc_{\nabla} = \frac{\sum_{i=1}^{m}\sum_{j=1}^{n} \mathbb{1}_{(\nabla_{pre}\cdot\nabla_{mec})_{ij}>0}}{m \times n} \times 100\% \tag{5}$$

Where $m$ refers to the number of operational variables and $n$ refers to the number of target variables. It calculates the proportion of gradient directions for all $y$ with respect to all $x$ that are consistent between the data-driven model and the mechanistic model, using the indicator function.

### 2.2.2 Data-Driven Model

Our hybrid loss function does not impose restrictions on the model type. In our experiments, we select an MLP model. The factory data is divided into training, validation, and test sets in a 0.6:0.2:0.2 ratio. The total size of the training set is 79,496 samples, while the validation and test sets each contain 26,499 samples. During the training process, we use our hybrid loss function.

## 3. RESULTS AND DISCUSSIONS

### 3.1 Active Learning Results

The MSE loss on the validation set for each iteration of the two active learning strategies is shown in Figure 3. A random labeling strategy is also included as a baseline. With the same number of labeled samples, the models trained using the active learning approaches show superior performance on the validation set compared to the random labeling strategy. Upon reaching the stopping criterion, the diversity-based and uncertainty-based strategies require only 5,400 and 5,700 labeled samples, respectively, while the random selection method demands 7,200 samples. These findings demonstrate that by leveraging our active learning strategies, it is possible to identify the most informative samples for simulation more efficiently, reducing labeling time by up to 25%.

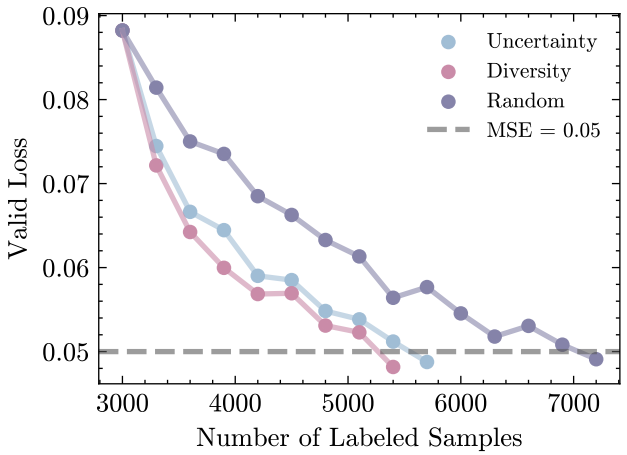

**Figure 3:** The MSE loss on the validation set for each iteration of active learning.

### 3.2 Surrogate Model Results

We select the model built using the diversity-based active learning strategy as our surrogate model. Its prediction performance on the validation set is shown in Figure 4. The accuracy of the surrogate model for the mechanistic model is high enough to ensure its reliability for subsequent precise gradient calculations.

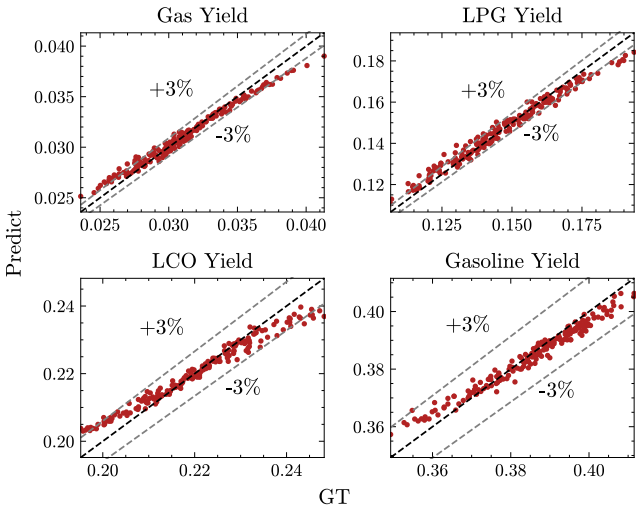

**Figure 4:** The prediction and Ground Truth (GT) on validation set of the surrogate model.

## 3.3 Data-Driven Model Results

The $\mathcal{L}_{MSE}$, $\mathcal{L}_{\nabla}$, and $Acc_{\nabla}$ of the data-driven model trained with the hybrid loss function on the training and validation sets are shown in the Figure 5. During the training process, we first train the model using only the MSE loss. After 50 epochs, we gradually increased the weight of the gradient loss component to $w_2$.This training strategy ensures a more stable training process. It is observed that when the model is trained solely using the MSE loss function, the loss on both the training and validation sets consistently decreases as training progresses. However, the $Acc_{\nabla}$ metric shows no improvement during the training processes. When the hybrid loss function is applied, $\mathcal{L}_{\nabla}$ decreases continuously as training progresses, and the gradient direction accuracy on both the training and validation sets shows consistent improvement. Furthermore, as the weight $w_2$ increases, the $Acc_{\nabla}$ on the validation set improves correspondingly.

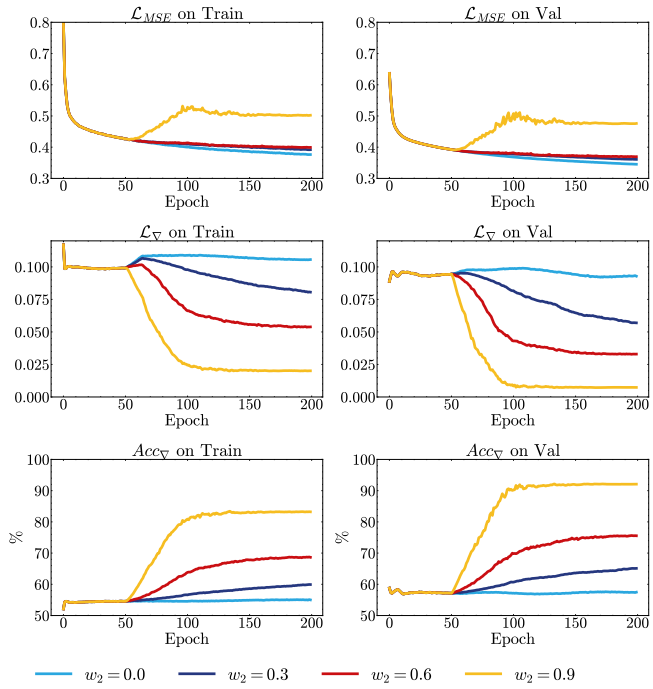

**Figure 5:** The $\mathcal{L}_{MSE}$, $\mathcal{L}_{\nabla}$, and $Acc_{\nabla}$ of the training process.

**Table 2:** The $\mathcal{L}_{MSE}$, $\mathcal{L}_{\nabla}$, and $ACC_{\nabla}$ on the test set.

| $w_2$ | $\mathcal{L}_{MSE}$ | $\mathcal{L}_{\nabla}$ | $Acc_{\nabla}$ % |
|---|---|---|---|
| 0.0 | **0.332** | 0.082 | 57.4 |
| 0.3 | 0.360 | 0.055 | 65.6 |
| 0.6 | 0.371 | 0.037 | 75.4 |
| 0.9 | 0.480 | **0.008** | **92.0** |

The $\mathcal{L}_{MSE}$, $\mathcal{L}_{\nabla}$, and $ACC_{\nabla}$ on test set are shown in the Table 2. The use of the hybrid loss function results in a significant increase on the $ACC_{\nabla}$ metric. When $w_2$ is set to 0.9, the gradient direction accuracy reached 92.0%, representing a 34.6% improvement compared to the model trained solely with the MSE loss function.

In addition, we randomly select 5 data points and visualize $\boldsymbol{\nabla_{pre}}$, as shown in Figure 6. Compared to the $\nabla_{pre}$ of the model trained using only MSE, the $\boldsymbol{\nabla_{pre}}$ of the model trained with the hybrid loss function aligns better to $\boldsymbol{\nabla_{mec}}$. The alignment with the mechanism model's gradient information enhances the reliability of the model, making it more suitable for optimization tasks.

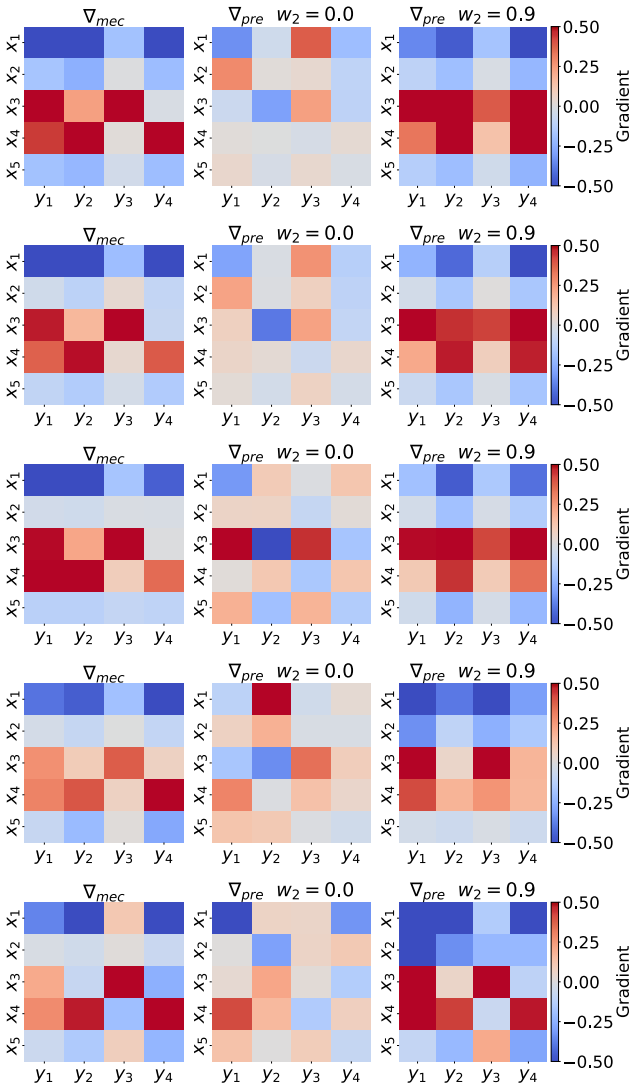

**Figure 6:** The $\boldsymbol{\nabla_{mec}}$ and $\boldsymbol{\nabla_{pre}}$ of the models with different loss function weights of different samples (each row).

## 4. Conclusions

We propose an active learning method based on diversity and uncertainty, significantly reducing the time and computational resources required for sampling from mechanistic models. By constructing a surrogate model from the sampled data, we can efficiently compute the gradient information for plant sample points. By incorporating the consistency of gradient information between

the data-driven model and the mechanistic model into the loss function, the accuracy of the gradient directions is improved by 34.6%. This loss function directly incorporates gradient information offers a novel approach to integrating mechanistic and data-driven models. It facilitates a more effective application of machine learning techniques to optimize operations in industrial plants.

## ABSTRACT

Sustainability is a thriving global topic of concern and following the advancement of technological progress and increased standards of living, the demands for energy, fuels, chemicals and other requirements have increased significantly. Methanol is one such chemical which has seen increases in demand due to its importance as a precursor in the development of widely used chemicals such as formaldehyde. In order to gain insight into the reaction mechanisms driving the process, it is beneficial to develop kinetic models that accurately describe the system for several reasons: (i) to develop process understanding; (ii) to facilitate control and optimisation; (iii) to reduce experimental burdens; and (iv) to expedite scale up and scale down of processes. Two commonly used kinetic reaction rate models are the power law and Langmuir-Hinshelwood expressions, however the strong assumptions made when developing such models may limit their predictive performance through the introduction of inductive bias (i.e. model structural uncertainty). A solution to counter these drawbacks is known as hybrid modelling where, the inauguration of a data-driven component within the kinetic modelling framework allows for any complex, less understood kinetics to be instead learnt from historical data by a machine learning model. In order to identify the pros and cons associated with each kinetic and hybrid modelling strategy for chemical reaction network modelling, a thorough comparison was made using syngas methanol production as a case study. It was shown that hybrid models offered increased predictive accuracy, robust uncertainty quantifications, and improved generalisability under limited data availability.

**Keywords**: Kinetic modelling, Hybrid modelling, Uncertainty estimation

## INTRODUCTION

Increases in global population and standards of living have intensified the demand for bulk and specialty chemicals, however growing sustainability concerns and economic pressures necessitate further process design innovations, and for optimisation of current production facilities. In order to combat such issues, advanced modelling techniques are required that describe bulk and specialty chemical reaction systems under industrial operation, allowing for the precise estimation of key process variables and reaction performance indicators. Typically, first principle based kinetic models are constructed in order to represent the reaction network of interest due to their inherent interpretability and capacity for proving deep kinetic insight when used to discriminate between reaction mechanisms with two of the most popular applied strategies being the Langmuir-Hinshelwood and power law models.

The Langmuir-Hinshelwood expression finds prominent application within heterogeneous catalysis, specifically for gas phase reactants on solid catalyst surfaces [1], however the model is also used for other catalytic reactions. In comparison, the power law model finds much broader application being employed within catalytic reactions [2], non-catalytic reactions [3], and within fields beyond kinetic modelling. Although kinetic models are interpretable and may be used to offer kinetic insight, it is often the case that many chemical reactions are governed by complex underlying physics, so the identification of a correct structure is challenging, typically required simplifications to be made which may be limiting and reduce generalisability. Because of this, model parameters will exhibit large uncertainties, preventing any

use for control and optimisation.

To address the challenges inherent to kinetic modeling, data driven models have gained significant attention within the literature in recent years. Machine learning based black-box models leverage the availability of extensive experimental datasets and do not require a detailed understanding of the underlying reaction mechanism, thus showing advantages in areas where complex phenomena are present. Machine learning has shown great potential in many fields such as (bio)chemical reaction kinetics predictions [4] and soft-sensing, however they are known to be inhibited by various disadvantages including the requirement for large volumes of data and a lack of interpretability, which hinders their ability to provide mechanistic insights.

In recent years, hybrid modelling has emerged as a potential solution to overcome the challenged associated with kinetic and data driven modelling through the combination of a mechanistic backbone with data-driven knowledge. The mechanistic backbone leverages available prior knowledge whilst the data-driven component accommodates for information not captured through the mechanistic structure. In this manner, the interpretability of the kinetic model is retained without the introduction of large inductive bias, and any available data can be exploited to quantify unknown kinetics that are not described by the kinetic structure. The advantages of hybrid modelling are shown clearly with its successful application in predicting complex reaction kinetics [5], boasting accurate predictions and robust uncertainty estimations.

Another crucial benefit of hybrid modelling stems from their reliable uncertainty quantification, which is especially important when encountering complex bio(chemical) reactions where large process variability or historical dependencies may be present. Typically, kinetic models may suffer with large parameter uncertainties and fail to account for historical dependencies, whereas data driven models may overfit when large batch to batch variability occurs, both of which prevent their application under such conditions. However, this is not true of hybrid modelling which has exhibited the capability to accurately describe process dynamics whilst maintaining narrow uncertainty ranges [6]. Even though the value of using hybrid modelling has been demonstrated, little research has focused on investigating its use within the field of chemical reaction kinetics nor on the effects of the kinetic component on model performance.

Therefore, in this work we present a study to explore the application of hybrid models for predictive modeling of chemical reaction kinetics. A key focus of this study is the role of the mechanistic backbone in hybrid model performance. Specifically, we investigate how the selection of different kinetic model structures influences the predictive accuracy and uncertainty quantification of hybrid models. To this end, two hybrid models were developed using the Langmuir-Hinshelwood and power-law rate expressions as their physical components, respectively. To demonstrate the potential of hybrid models for industrial applications, the methanol synthesis reaction from syngas, coupled with the water-gas shift reaction was chosen as a case study. The reliability of the hybrid models was evaluated from their uncertainty estimations and predictions across a broad range of operating conditions. Lastly, the study evaluated the potential of hybrid models to uncover new physical insights.

### Case study

In this work, the case study is an industrial reaction system consisting of the water-gas shift reaction and syngas methanol synthesis reaction [7]. The reaction system was catalysed by a $Cu/ZnO/Al_2O_3$ catalyst, and the reactions were conducted within fixed-bed, integral-operation microreactors. In total, 38 experiments were carried out, each containing the measurements of 5 states (i.e. reactants and products) at 4 equidistant points along the reactor length. The experiments were conducted under varying feedstock conditions with $CO$ to $CO_2$ ratios of 3:3, 3:1, and 3:0.3; reaction temperatures of 453 K, 463 K, 473 K, 483 K, and 493 K, and reaction pressures of 15 bar, 25 bar, 35 bar. Further details regarding the experimental setup and procedures are provided in [7]. The three possible reactions occurring under such conditions are shown in reactions 1, 2 and 3 below

$$CO_2 + \mathrm{H}_2 \rightleftharpoons CO + H_2O \quad (1)$$

$$CO_2 + 3\mathrm{H}_2 \rightleftharpoons CH_3OH + H_2O \quad (2)$$

$$CO + 2\mathrm{H}_2 \rightleftharpoons CH_3OH \quad (3)$$

where reaction 1 is the reverse water gas shift (RWGS) reaction, and reactions 2 and 3 are methanol synthesis from $CO$ and $CO_2$ respectively.

In this study, it is assumed that CO serves as the primary source of carbon for methanol synthesis. Whilst it is also possible to assume $CO_2$ as the primary carbon source for producing methanol, this choice is not expected to impact model performance because the hybrid models, developed in this work, are designed to incorporate unknown process knowledge through their data-driven components, enabling them to adapt and accurately represent the underlying system dynamics.

## METHODOLOGY

In this section, we will outline the development of two hybrid models based on different mechanistic backbones as shown in Figure 3. In previous literature, Langmuir-Hinshelwood kinetic structures have been proposed to describe reactions 1-3, however due to their

complexity, these often lead to high errors under broad operating conditions, and high parameter uncertainties [7]. Thus, to remove inductive bias, we simplify the equations by lumping complex kinetics into few parameters to be learnt and estimated by a data-driven component.

The second kinetic backbone adopts a power law structure as shown in Figure 3, however since the classical power law expression does not satisfy the thermodynamic constraint at equilibrium conditions [2], a modification has been made. This will ensure that, under equilibrium, the ratio of forward to reverse reaction rate constants are directly equal to the ratio of products to reactants raised to their stoichiometric coefficients.

Due to the complexity of the reaction network under a broad operating range, it is to be expected that some kinetic parameters may contain lumped information and therefore effectively be functions of the operating conditions and input states. Therefore, to construct an accurate and generalisable hybrid model, it is necessary to determine the minimum number of parameters that are dependent on reaction conditions which will be subsequently estimated by the data-driven component. To accomplish this, all parameters were initially assumed condition dependent and parameter estimation, using a modified least squares expression, was conducted to classify parameters as condition-dependent or condition-invariant.

A hybrid model was then constructed, using an artificial neural network (ANN), to estimate the identified condition dependent parameters given their respective operating conditions as shown in Figure 1. The input features to the ANN include $P_T, P_{CO}, P_{CO_2}, P_{H_2}, \frac{P_{CO}}{P_{CO_2}}, \frac{P_{CO}+P_{CO_2}}{P_{H_2}}$ and $T$ where $P_x$ refers to the partial pressure of species $x$, $P_T$ is the total operating pressure, and $T$ is the temperature of the experiment. To ensure high-quality solutions, Bayesian optimisation was employed for hyperparameter optimisation for the ANN.

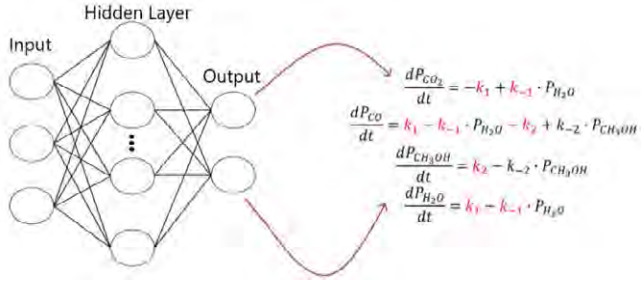

**Figure 1.** Schematic of the hybrid modelling framework using the Langmuir-Hinshelwood mechanistic backbone. The red highlights indicate condition dependent parameters estimated by the ANN.

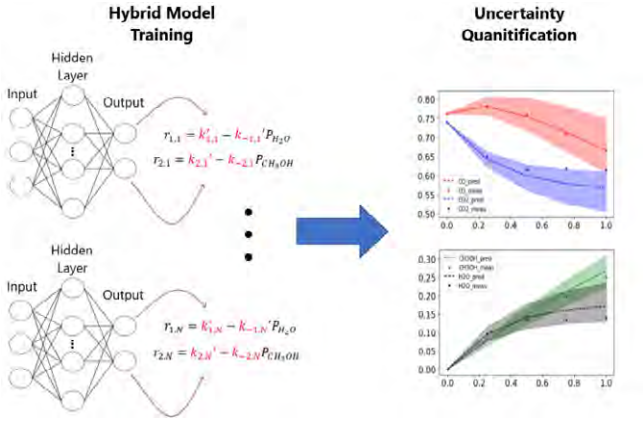
In this study, the uncertainty of the hybrid model stems predominantly from the condition varying parameters, and hence the ANN's predictions. This is because, during parameter estimation, it was found that the condition invariant parameters show little change across all experiments. Thus, it is paramount that the uncertainty of the ANN is estimated. To accomplish this, a bootstrapping framework was employed to generate a number of ANN's which, when integrated with the mechanistic backbone to attain the corresponding hybrid models, can be used to generate a mean prediction and its respective standard deviation as shown in Figure 2.



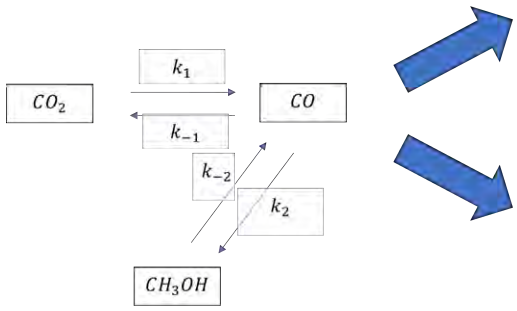


**Figure 2.** Schematic of the bootstrapping framework to estimate the hybrid models uncertainty where $N$ refers to the number of hybrid models constructed. The red highlights indicate condition dependent parameters estimated by the ANN.

## RESULTS AND DISCUSSION

### Results of the Langmuir-Hinshelwood based hybrid model

In the methanol synthesis reaction case study, hydrogen was always provided in excess thus exhibiting hydrogen partial pressure 100-10000 times greater than those of other species. As a result of the excess hydrogen, its consumption and production throughout the process is negligible (i.e., there are little changes in $P_{H_2}$). Consequently, after parameter estimation was conducted, it was found that further model reduction is required from the Equations shown in Figure 3. More specifically, $K_{H_{2,1}}$ and $K_{H_{2,1}}$ were estimated to be zero, and the products $k_1 P_{H_2}$ and $k_2 P_{H_2}$ needed to be lumped as one apparent kinetic constant to overcome identifiability issues. Additionally, $K_{CH_3OH} \cdot P_{CH_3OH}$ and $K_{H_2O} \cdot P_{H_2O} \ll 1$, and $K_{CO_2} \cdot P_{CO_2}$, $K_{CO,1} \cdot P_{CO}$, $K_{CO,2} \cdot P_{CO} \gg 1$, thus either dominating or having a negligible effect on the denominator of the kinetic model.

After model reduction, the Langmuir-Hinshelwood

**Langmuir-Hinshelwood model structure**

$$r_1 = k_1 \frac{P_{CO_2} P_{H_2}}{1 + K_{CO_2} P_{CO_2} + K_{H_{2,1}} P_{H_2}}$$

$$r_{-1} = k_{-1} \frac{P_{CO} P_{H_2O}}{1 + K_{CO,1} P_{CO} + K_{H_2O} P_{H_2O}}$$

$$r_2 = k_2 \frac{P_{CO} P_{H_2}}{1 + K_{CO,2} P_{CO} + K_{H_{2,2}} P_{H_2}}$$

$$r_{-2} = k_{-2} \frac{P_{CH_3OH}}{1 + K_{CH_3OH} P_{CH_3OH}}$$

**Power law model structure**

$$r_1 = k_1 P_{CO_2}^{\alpha_{CO_2,1}} P_{H_2}^{\alpha_{H_2,1}} P_{CO}^{\alpha_{CO,1}} P_{H_2O}^{\alpha_{H_2O}}$$

$$r_{-1} = k_{-1} P_{CO_2}^{-1+\alpha_{CO_2,1}} P_{H_2}^{-1+\alpha_{H_2,1}} P_{CO}^{1+\alpha_{CO,1}} P_{H_2O}^{1+\alpha_{H_2O}}$$

$$r_2 = k_2 P_{CO}^{\alpha_{CO,2}} P_{H_2}^{\alpha_{H_2,2}} P_{CH_3OH}^{\alpha_{CH_3OH}}$$

$$r_{-2} = k_{-2} P_{CO}^{-1+\alpha_{CO,2}} P_{H_2}^{-2+\alpha_{H_2,2}} P_{CH_3OH}^{1+\alpha_{CH_3OH}}$$

**Figure 3:** Thermodynamics inspired power law and simplified Langmuir-Hinshelwood models for the given reaction network where $P_j$, $K_j$, and $\alpha$ are the partial pressure, adsorption equilibrium constants, and reaction orders of species $j$, and $k_i$ and $k_{-i}$ are the forward and reverse reaction rate constants for reaction $i$. The red highlights indicate key process parameters that are modelled using a data-driven component.

expression devolved into a basic power law structure as seen in Figure 1, where the apparent rate constants contain lumped kinetics, and will therefore be estimated by an ANN. As described in the methodology, the condition dependent parameters were identified as $k_1$, $k_{-1}$, and $k_2$ where $k_1$ and $k_2$ are functions of $P_{H_2}$ because of any $H_2$ effects being combined into them, and $k_{-1}$ is a function of $P_{CO}$:$P_{CO_2}$ which is intuitive as it describes the forward water gas shift reaction where $CO$ and $CO_2$ are influential.

The results of the parameter estimation were then used to train the ANN such that the hybrid model can make its predictions on unseen data. In order to quantify the uncertainty predictions of all models, we use the relative percentage uncertainty (RPU) calculated as shown in Equation 4:

$$RPU\% = \frac{100}{N} \cdot \sum_{n=1}^{N} \frac{X_{UB,n} - X_{LB,n}}{X_n} \quad (4)$$

where $X_n$, $X_{UB,n}$ and $X_{LB,n}$ are the nominal, upper bounds and lower bound predictions of species $X$ at experiment $n$.

In total 16 training experiments were used and 22 testing experiments yielding percentage errors of 3.6% and 9.5%, respectively and an average testing RPU of 17%. The hybrid model prediction and uncertainty bounds are shown in Figure 4.

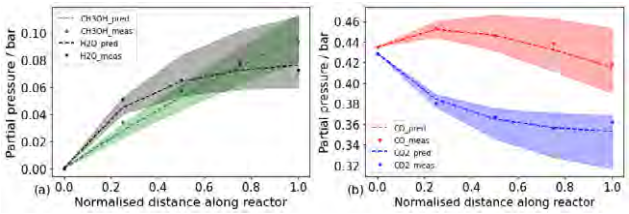

**Figure 4.** Plots showing the uncertainty and testing predictions of the Langmuir-Hinshelwood based hybrid model. (a) shows the predictions for $CH_3OH$ and $H_2O$ and (b) shows the predictions for $CO$ and $CO_2$. The scatter points and dotted lines refer to measured data and predictions, respectively.

It can be seen that the data-driven component has correctly learnt missing information from the simplified mechanistic backbone leading to the hybrid model possessing high accuracies. Furthermore, the similar testing and training performance indicates a high level of generalisability displaying the potential of hybrid modelling for use in chemical reaction kinetics prediction.

Although the Langmuir-Hinshelwood based hybrid model exhibits good predictive accuracy and uncertainty quantifications, it is limited due to it not conforming to well known physics and equilibrium constraints. It is known that kinetic constants are solely functions of temperature typically expressed using an exponential relationship, however it was discovered that, because of the lumped kinetics in the apparent rate constants of the

simplified kinetic model, the exponential temperature dependency was not observed. An example can be seen in the values of $k_1$ where, at temperatures of 453K, 463K, 473K, 483K and 493K, the lumped kinetic constants values are 0.004, 0.0047, 0.0027, 0.012, and 0.005 bar kg$^{-1}$, respectively.

A second limitation derives from the definition of the reaction equilibrium constant where, under equilibrium conditions, the ratio of forward to reverse rate constants should be equal to the ratio of products to reactants raised to their stoichiometric coefficients. As can be seen in Equations 5 and 6, this constraint does not hold true. This inconsistency limits the interpretability and insight that the Langmuir-Hinshelwood based hybrid model may offer, especially under equilibrium conditions.

$$\frac{k_1}{k_{-1}} = \frac{P_{H_2O}}{1} \tag{5}$$

$$\frac{k_2}{k_{-2}} = \frac{P_{CH_3OH}}{1} \tag{6}$$

## Results of the power law based hybrid model

Using the same methodology as for the Langmuir-Hinshelwood based hybrid model construction, parameter estimation was first used to classify condition dependent and condition invariant parameters using the thermodynamics inspired power law defined in Figure 3. Due to the excessive quantities of $H_2$ present in the system, $\alpha_{H_{2,1}}$and $\alpha_{H_{2,2}} = 0$ showing that $H_2$ has no effect on the forward reactions but instead inhibits the reverse reactions.

The exponents, $\alpha_{CO,1}$, $\alpha_{CO,2}$ and $\alpha_{CO_2}$ were found to be equal to 1, which can be reasoned by the large magnitudes of $P_{CO}$ and $P_{CO_2}$ in comparison to $P_{CH_3OH}$ and $P_{H_2O}$, thus any changes are less influential. Therefore, the only condition dependent exponents were $\alpha_{CH_3OH}$ and $\alpha_{H_2O}$. $\alpha_{H_2O}$ took negative values becoming less negative as temperature increased indicating that the role of water changes from inhibiting reaction $r_1$ (RWGS) to promoting the reverse reaction.

Further insight can be gained from the values of the reaction order of $CO$. Since the exponents, $\alpha_{CO,1}$, $\alpha_{CO,2} = 1$, from Figure 3 we can see that, as a product of the reverse water gas shift reaction, $CO$ facilitates the forward reaction. This can be explained by the fact that the use of $CO$ may remove adsorbed oxygen on the Cu catalyst which would ordinarily passivate it. Therefore, any metallic sites that would typically be unavailable for $CO_2$ activation, are now available. An alternative explanation is that the $CO$ may act to remove water from the reaction network which is beneficial because, on a Cu based catalyst, water can inhibit the methanol synthesis reaction from $CO_2$ to $CH_3OH$.

All reaction rate constants within the power law model were found to be condition dependent being solely functions of temperature. Additionally, the trends of the rate constants with respect to temperature all followed the Arrhenius expression as shown in Figure 5. This provides additional confidence into the power law based hybrid model as the results appear to conform to the underlying physics present without any constraints to enforce this and thus, the results are more likely to hold physical significance.

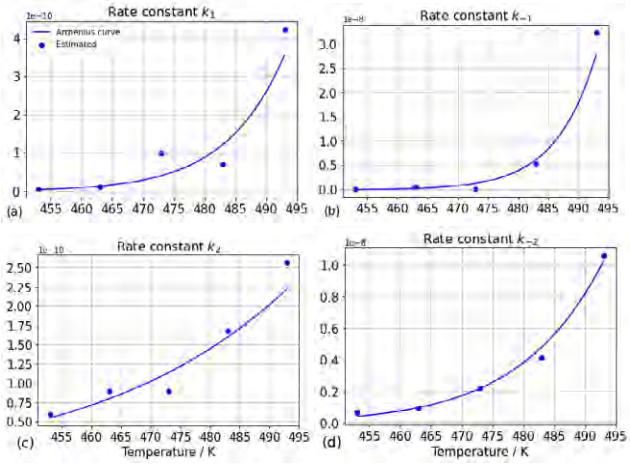

**Figure 5.** Plots showing the rate constants at different temperatures. The scatter points and lines represent the estimated parameter values and the values through fitting an arrhenius curve, respectively.

The results of parameter estimation were then used to train the ANN component in order to correlate the operating conditions and input states to the condition dependent parameters. The completed power law based hybrid model yielded average fitting and testing errors of 3.7% and 6.7%, respectively and an average relative percentage uncertainty of 13.0%. The similar training and testing performance proves the developed model is generalisable, whilst also boasting low prediction errors across a broad range of operating conditions. The hybrid model prediction and uncertainty bounds are shown in Figure 6.

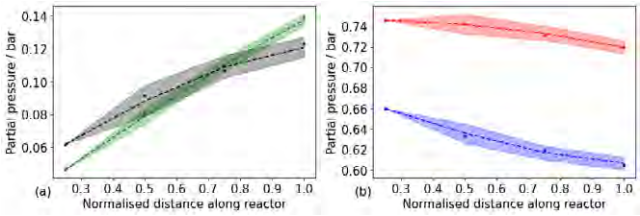

**Figure 6.** Plots showing the uncertainty and testing predictions of the power law based hybrid model. (a) shows the predictions for $CH_3OH$ and $H_2O$ and (b) shows the predictions for $CO$ and $CO_2$.

The fitting and testing results for both the power law based and Langmuir-Hinshelwood based hybrid model are similar with a slight increase in performance for the

former as well as a slight decrease in overfitting. The same conclusion can be drawn about uncertainty where both hybrid structures provide robust estimations that cover the majority of measured datapoints. However, the Langmuir-Hinshelwood based hybrid model holds less interpretability as the apparent kinetic constants are functions of the operating conditions and states whereas, it is widely known that the rate constants should be functions solely of temperature. This phenomenon has been successfully described by the power law based hybrid model, meaning that the results are more likely to hold physical significance. Additionally, we can gain kinetic understanding from the reaction orders of the power law structure.

## CONCLUSION

This study highlights the potential of hybrid modeling to address the limitations of traditional kinetic and data-driven approaches for complex chemical reaction systems. By combining mechanistic insights with the adaptability of data-driven models, the hybrid models developed provided interpretable structures with high predictive accuracy, and reliable uncertainty estimates without the requirement for large quantities of experimental data.

Two hybrid models based on Langmuir-Hinshelwood and power law rate expressions were constructed, demonstrating the flexibility of this approach, with the power law based model offering additional kinetic insights. These findings underscore the promise of hybrid modeling for industrial applications, particularly in process control and optimisation, where accuracy and uncertainty quantification are critical. Overall, this work emphasises the value of hybrid modeling in advancing our modelling capabilities and understanding in reaction engineering, especially for systems with incomplete mechanistic knowledge.

## ABSTRACT

Planning and scheduling are integral components of process supply chains. The presence of data correlation, particularly multivariate demand data dependency, can pose significant challenges to the decision-making process. This necessitates the consideration of dependency structures inherent in the underlying data to generate good-quality, feasible solutions to optimisation problems such as planning and scheduling. This work proposes a chance-constrained optimisation framework integrated with copulas, a non-parametric data estimation technique to forecast uncertain demand levels in accordance with specified risk thresholds in the context of a planning and scheduling problem. We focus on the integrated planning and scheduling problem following a bi-level optimisation formulation. The estimated demand forecasts are subsequently utilised within the Data-driven Optimisation of bi-level Mixed-Integer NOnlinear problems (DOMINO) framework to solve the integrated optimisation problem, and derive decisions with guaranteed demand satisfaction rates. Computational experiments demonstrate that our proposed copula-based chance-constrained optimisation framework can incorporate demand correlation and achieve higher joint demand satisfaction rate, lower total costs with higher efficiency.

## INTRODUCTION

In real-world applications, many optimisation problems are inherently difficult to find feasible solutions due to the lack of exact information, the presence of noisy data distributions, data correlations, and parameter uncertainties. As a result, data-driven optimisation approaches are increasingly adopted to efficiently explore solution spaces and identify improved outcomes [2]. Chance-constrained programming (CCP) is an optimisation-based approach that ensures stochastic constraints are met with a predetermined probability of satisfaction amongst all possible scenarios [5, 17]. Numerous studies have successfully integrated CCP within various optimisation problems [3]. However, the applicability of CCP to general optimisation problems is limited by the need of strict assumptions regarding the stochastic nature of the parameters studied. To this end, data-driven variants of CCP have gained increasing attention [15]. Copulas are data-driven coupling functions that capture the dependence structure between multiple uncertain parameters with inherent correlations. Incorporating copula formulations into CCP has the advantage of better modelling dependencies between variables under different scenarios when the underlying data exhibits complex distributions or non-trivial dependencies, such as correlated risks, thereby improving the accuracy of decision-making in optimisation problems with the presence of

uncertain parameters. In recent years, the integration of copula and CCP has shown significant promise. [16] formulated/employed joint chance constraints to address the capacity requirement in a multi-commodity network flow problem, using an Archimedean copula to estimate the dependencies between different capacity coefficient variables. [14] used a copula to model the dependency between resource consumptions of a stochastic resource-constrained shortest path problem. [11] proposed a joint chance-constrained method that integrates the best-performing copula from a set of widely applied bivariate copulas to characterise the uncertain probability distributions and the correlated nature of multi-period, multi-zone residential waste data.

In this work, we propose a data-driven chance-constrained optimisation framework to estimate the demand level within the context of planning and scheduling by leveraging the capabilities of copulas, which helps to achieve good efficiency and accuracy in estimating the multivariate demand data dependency structure. Moreover, we integrate our proposed framework with the DOMINO (Data-driven Optimisation of bi-level Mixed-Integer NOlinear problems) framework [2], which is a data-driven grey-box algorithm for addressing bi-level optimisation problems with various formulations at the lower levels [1].

# METHODOLOGY

## Copula Theory

A copula is a function that joins or "couples" multiple univariate marginal distributions to form a multivariate distribution. This enables the construction of any multivariate distribution using specified marginal distributions and the chosen copula, regardless of whether the underlying real distribution is fully understood. At a higher level, copulas are essential statistical tools for comprehensively analysing the dependency structures that exhibit in multiple random variables, effectively bypassing the marginal behaviour from joint dependence. By focusing on the joint cumulative distribution of marginal quantiles, copulas can capture complex, non-linear, and tail dependencies (extreme events) that traditional correlation metrics may often overlook [4].

The mathematical foundation of a copula is derived from Sklar's Theorem, which states that for any $n$-dimensional cumulative distribution function $F$ with marginal distributions $F_1, F_2, \dots F_n$, there exists a copula $C$ that models and encapsulates the dependency structure:

$$F(x_1, x_2, \dots x_n) = C(F_1(x_1), F_2(x_2), \dots F_n(x_n)) \quad (1)$$

where $x_1, x_2, \dots x_n$ are realisations of the random variables from each distribution, and the marginal distributions $F_i(x_i), i \in \{1, \dots n\}$ represent the individual variable behaviour. A few commonly applied copula models include Gaussian copula [18], t-copula [7], and Archimedean copula [13], each tailored to specific types of dependency structures.

## Chance constrained programming

Chance-constrained programming (CCP) is an optimisation technique that formulates probabilistic constraints to model uncertainty in decision-making problems [17]. This approach addresses uncertainty by allowing specific constraint(s) to be satisfied with a predetermined probability level, thus offering controlled flexibility to manage risk and account for the inherent variabilities in decisions related to demand, resource, or time availability. As a result, CCP provides a structured way to accommodate unpredictable conditions for many real-world problems in fields like energy production [23], finance [6], and supply chain management [19].

An individual probabilistic constraint, known as an individual chance constraint (ICC), requires that the constraint be met with a certain confidence level, denoted as a probability term $(1-\alpha)\%$, where $\alpha$ represents the risk level [5]. For example, setting $\alpha = 0.05$ means that the constraint must hold with at least $95\%$ probability while allowing for a $5\%$ risk tolerance for potential constraint violation. The formulation of a basic ICC can be represented as follows in the context of a production problem.

$$P[x_i \geq D_i] \geq 1 - \alpha_i, \;\; i \in \{1, \dots, n\} \quad (2)$$

where for each production constraint $i$, the production level decision variable $x_i$ must fulfil the uncertain demand parameter $D_i$ for at least $(1-\alpha_i)\%$ of the time. Joint chance constraint (JCC) is a variation of ICC, stressing that multiple constraints must be satisfied simultaneously with a given confidence level. Similarly, the JCC formulation can be expressed mathematically as:

$$P[x_i \geq D_i, i \in \{1, \dots, n\}] \geq 1 - \alpha \quad (3)$$

where the production level $x_i$ in all production scenarios $n$ must be sufficient to meet uncertain demand collectively with a joint confidence level of $(1-\alpha)\%$. As a result, JCCs impose stricter limitations on the feasible region of the solution space, making the problem generally more complex to solve.

The cumulative distribution function (CDF) provides a foundational basis for CCP in accumulating probabilities and facilitates the probabilistic guarantee of constraint satisfaction up to a given threshold. On the contrary, the quantile function, calculated as the inversed CDF, pinpoints a target probability level to the corresponding minimum production value required to meet the specified probability threshold.

## Data-driven chance constrained programming via copulas

In real-life applications, formulating chance constraints is generally challenging because the probability

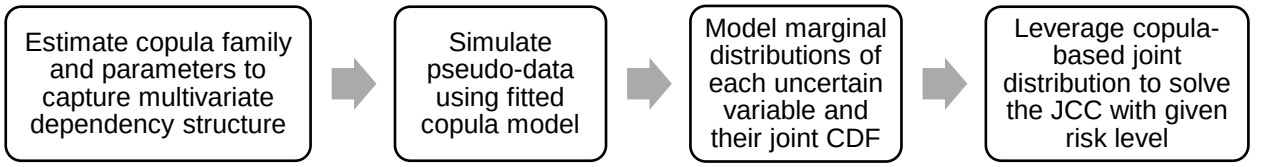

**Figure 1.** Logic flow for the proposed data-driven JCC framework with copula.

distribution of the uncertain parameters is often unknown or difficult to model with limited observed data. The difficulty of estimating an unknown distribution by existing parametric distributions (e.g., Gaussian distribution) is pronounced in high-dimensional or nonlinear contexts with no closed-form formulations, which often necessitates approximation or data-driven methods to adequately capture the distribution. This challenge becomes even more complex with JCCs, in which the dependency structure among the marginal demand distributions introduces correlation in the data. To tackle this issue, integrating the copulas technique into the modelling of JCCs offers a data-driven approach based on empirical data that models the marginal distributions of uncertain variables and their dependency structure to construct joint distributions.

We propose a data-driven framework that integrates copulas into data-driven JCC optimisation, as illustrated in Figure 1. We first employ pyvinecopulib [20] to fit the copulas to existing demand data using maximum likelihood estimation to estimate the best-fitting dependency structure and determine the copula family as well as its parameters. The selection of specific copulas family and dependency structure are based on optimising the AIC, BIC and log likelihood statistics using the pyvinecopulib package. Then, we use the fitted copula to construct a surrogate model that simulates correlated pseudo data while preserving the same dependency structure. The simulated pseudo data offers the advantage of scalability and enhancement by generating complete datasets with dependency structure when the original data may contain real-world data biases or missing values. Then, we can estimate the marginal distributions via non-parametric methods such as kernel density estimation [5] and in this approach, we adapt the built-in function in pyvinecopulib to estimate the marginal distributions and the joint CDF. Lastly, once the copula and marginal distributions are defined, the joint distribution can be estimated via (1) and utilised for approximating the quantile function and the risk level.

Following the data-driven copula framework above, we evaluate the JCC using Monte Carlo simulation. Each scenario generated from the copula-based quantile function is employed to compute the probability of constraint satisfaction across all realisations. By adjusting the number of empirical simulations, the confidence level for the JCCs can be calibrated to meet the desired level of risk tolerance $\alpha$.

### Data-driven mixed integer nonlinear bi-level optimisation

Historical production demand data of an integrated planning and scheduling problem is utilised to compute the copula-estimated demand set corresponding to a particular risk level following the procedure shown in Figure 1. The generated demand set can then be utilised as a demand scenario of integrated planning and scheduling optimisation problems [8, 10, 12] to be solved using the DOMINO framework. DOMINO is a data-driven strategy for solving general constrained bi-level optimisation problems which transform bi-level problems into single-level grey-box optimisations, utilising advanced data-driven techniques and deterministic solvers [22]. We refer the interested reader to [2] for a detailed description of the DOMINO framework and its application to solve integrated planning and scheduling problems under demand uncertainty in [1]. Figure 2 illustrates the workflow between the copulas and DOMINO framework. CCP offers a simplified uncertainty estimation approach based on risk level, which is more efficient compared to alternative methods such as stochastic programming, as originally proposed in [1], which requires explicit representation of all scenarios and since an increasing number of scenarios gives us a better understanding, incurs computational burden for high-dimensional problems.

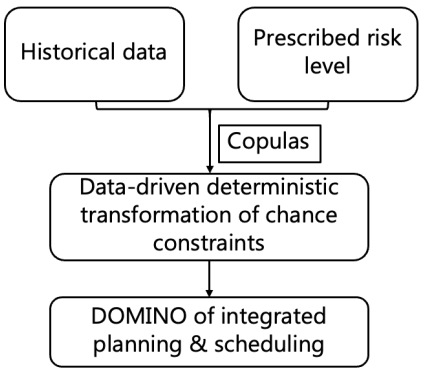

**Figure 2.** Integrated copulas-DOMINO solution workflow

## CASE STUDY

### Experimental setup

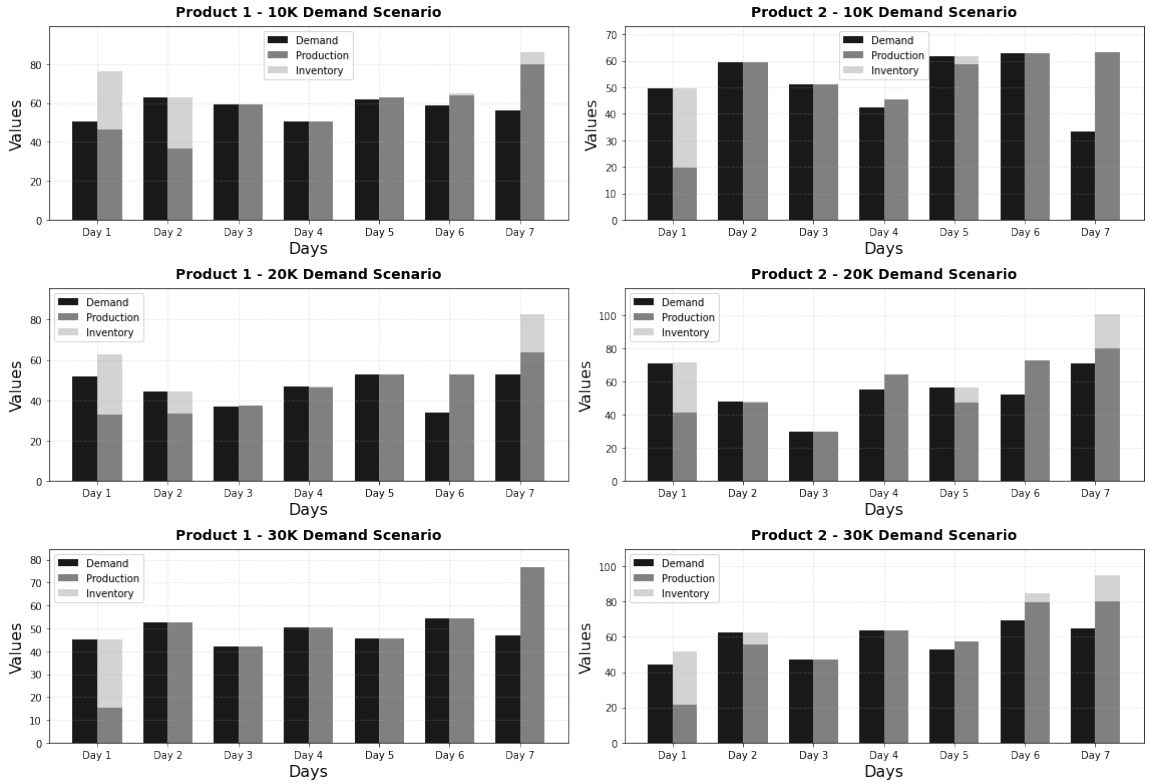

**Figure 3.** Production and inventory levels for the 2-product 7-day instance with copula-generated demand level under a specific number of scenarios (10, 20 or 30K). Planning cost values (scenario sizes): $7,085 (10K), $7,009.5 (20K). $6,850 (30K).

We employ our proposed approach to tackle the integrated planning and scheduling problem under product demand uncertainty. We consider a continuous single stage process with 2 products and 7 days, each with a 24hr duration. Firstly, we define the desired risk level and generate the corresponding demands, which are input as production targets into the DOMINO framework to tackle data-driven optimisation of the production level and evaluate the demand satisfaction rate via a simulation-based evaluation process. Throughout the experiment, two independent sets of scenario-based demands are generated: the first set is utilised to train the copula model designed to predict the empirical CDF and determine the quantile function for the joint chance constraint on demands. The second set serves as an evaluation benchmark during the simulation process to compute the demand satisfaction rate.

We employ the DOMINO framework for the solution of a bi-level optimisation problem case study with linear production planning and mixed-integer nonlinear scheduling from [21], and linear programming planning and scheduling case study from [1], respectively. Specifically, the nonlinear aspects of the integrated problem stem from the variable transition times in the scheduling of continuous manufacturing processes [9]. The case study is executed 10 times on a High-Performance Computing (HPC) machine using Red Hat Enterprise Linux 8.9 (Ootpa). The NOMAD algorithm within the DOMINO framework is executed serially using 1 core per node with 48GB RAM, starting from a random initial point.

## Results

We compute the copula-estimated demand set and input it into the DOMINO framework, wherein the integrated planning and scheduling problem is addressed. The production and inventory level outcomes are presented in Figure 3.

In our experimental design, we aim for 99% demand satisfaction during the generated production schedules. To evaluate, we will assess how the actual performance (a posteriori) in a real-world environment compares to our initially established reliability level (a priori) based on the copula-generated production target. That is, we calculate a fixed schedule derived from the copula-estimated demand level and aim to fix this target as a baseline. Subsequently, we employ copula to simulate the demand and evaluate the frequency with which the simulated demand satisfies all predefined scenarios.

The discrepancy between the a priori and a posteriori performance can arise because the copula method is data-driven and non-parametric. Since we do not require any prior assumption about the underlying distribution for

**Table 1:** Computational time and satisfaction rates for scenario sizes (averaged of 5 computational rounds).

| Products | Weeks | Scenarios | Compute Time (sec) | Multiplication of Individual Satisfaction Rates | Copula-estimated Joint Satisfaction Rates |
|---|---|---|---|---|---|
| 1 | 1 | 10k | 78 | 99.4% | 100% |
| 1 | 1 | 20k | 255 | 98.8% | 100% |
| 1 | 1 | 30k | 486 | 99.1% | 100% |
| 2 | 1 | 10k | 81 | 98.5% | 99.9% |
| 2 | 1 | 20k | 234 | 98.3% | 100% |
| 2 | 1 | 30k | 585 | 98.1% | 100% |
| 4 | 1 | 10k | 109 | 96.4% | 98.6% |
| 4 | 1 | 20k | 281 | 96.2% | 99.1% |
| 4 | 1 | 30k | 527 | 96.3% | 99.3% |
| 6 | 1 | 10k | 372 | 93.1% | 96.4% |
| 6 | 1 | 20k | 516 | 94.0% | 96.8% |
| 6 | 1 | 30k | 842 | 93.8% | 97.0% |

the demand data, we rely on the copula model to estimate the CDF of joint and individual demands. To analyse the impact of this discrepancy, we conduct the following experiment to evaluate the extent to which the scenario size employed during the copula model training influences the accuracy of prediction regarding demand satisfaction. Specifically, we utilise the joint and individual demand satisfaction rates as metrics to assess the quality of copula-generated demand under a certain risk level. The joint satisfaction rate represents the proportion of simulated scenarios for which all product demand targets are met. In contrast, the marginal satisfaction rate for each demand is individually independent, and the multiplication of these rates gives the independently joint satisfaction level, assuming all demands are individually met without considering any intercorrelation.

Table 1 showcases the satisfaction rate and computational time required to solve the offline copula model for different instance and scenario sizes with 7 days. Results demonstrate that the copula model, which assumes correlation among demands, yields higher joint satisfaction rates than the multiplication of individual rates, highlighting the copula model's capacity to capture the collective behaviour of demand data. Moreover, a higher joint satisfaction rate produced by copula suggests that interactions between demand levels may confer additional value. Incorporating these interactions could be crucial in increasing the overall demand satisfaction rate among all products. Furthermore, Table 1 shows a monotonic increase in the joint satisfaction rate when the total number of training scenarios increases from 10k to 30k for all instance sizes. This suggests that increasing the number of scenarios used to train the copulas model can enhance the accuracy of the estimated CDF, resulting in generating a fixed production level that ultimately raises the likelihood of demand satisfaction. The average computational time required for DOMINO to solve the integrated planning and scheduling problem is approximately 6 hours for the case study of 2 products and 7 days. This underscores the significance of managing uncertainty in an offline manner, as advocated by our proposed data-driven copulas framework. Additionally, our proposed copula approach requires estimating the CDF and solving the model only once, hence further enhancing its efficiency.

To summarise, we notice the advantages of our copula method are that the copula-generated plan (as an input to DOMINO) will be feasible for every possible scenario realisation for 99% of the times. Moreover, instead of solving the scenarios iteratively (as in [1]) and being very time-consuming, we can compute the copula-estimated CDF offline to massively save time at the cost of being slightly conservative (risk averse) with the actual demand satisfaction.

## Concluding remarks

We present a joint chance-constrained optimisation framework with data-driven copulas functions to effectively capture and model the multivariate demand data dependency structure for an integrated planning and scheduling problem. Our approach ensures feasible decision-making within a defined risk threshold. We validated the data-driven copulas-generated production targets using the DOMINO framework and tackled the data-driven optimisation. Our experiments demonstrate that the proposed approach is capable of identifying robust solutions that result in higher joint satisfaction rates for products and near-optimal performance, all while significantly reducing computational time compared to exact or stochastic optimisation methods. Plans for future research involve validating the efficiency and effectiveness of our approach through a number of case studies across an extended range of optimisation problems.

## ABSTRACT

Process monitoring is essential in industrial settings to ensure system functionality, necessitating the identification and understanding of fault causes. While a substantial body of research focuses on fault detection, fault diagnosis has received significantly less attention. Typically, faults originate either from abnormal instrument behavior, indicating the need for calibration or replacement, or from process faults, signaling a malfunction within the system. A primary objective of this study is to apply the proposed fault diagnosis methodology to a benchmark that closely mirrors real-world conditions. Specifically, we introduce a fault diagnosis framework for a wastewater treatment plant (WWTP) that effectively addresses the challenges posed by imbalanced big data commonly encountered in large-scale systems. In our study, four distinct fault scenarios were investigated: fault-free conditions, process faults only, sensor faults only, and simultaneous sensor and process faults. To enhance our research, we explored various techniques and approaches to optimally address the fault diagnosis problem. Implementing an undersampling technique based on clustering and determining appropriate hyperparameters proved challenging, alongside deciding the most effective approach for undersampling. Additionally, advanced time-series models, including Long Short-Term Memory (LSTM) and Bidirectional LSTM (BiLSTM), were employed, with particular emphasis on identifying the correct regularization factor and number of epochs being critical. When optimal model parameters are selected, each fault scenario achieves an accuracy of at least 90%, and the maximum simulation time does not exceed 15 minutes. Furthermore, we developed a Python-based GUI for this study to enable users to fully explore the capabilities of the proposed fault diagnosis algorithm.

**Keywords**: Artificial Intelligence, Big Data, Wastewater, Industry 4.0, Process Monitoring

## INTRODUCTION

Today, process monitoring has become an increasingly critical task in industries, driven by cutting-edge technologies capable of handling large volumes of data. This advancement has introduced new challenges, particularly related to big data aspects. In scientific literature, "big data" typically refers to datasets that exhibit at least two of the following characteristics, collectively known as the 5V: Volume, indicating a substantial quantity of data samples; Velocity, reflecting a high sampling rate of incoming data; Veracity, which denotes significant uncertainty and noise within the data; Variety, meaning the dataset is composed of smaller datasets of different types and formats; and Variability, referring to the degree of complexity in the data, such as noticeable fluctuations and peaks in data patterns. It is important to note that whether a dataset is classified as big data also depends on the specific application [1].

Deep learning architectures have emerged as an effective approach for handling big data in process monitoring. Their primary advantage lies in their ability to perform feature analysis systematically, enabling the efficient extraction of key information from large datasets without the need for designing and implementing separate feature extraction mechanisms. However, utilizing deep learning architectures presents certain challenges. Tuning the hyperparameters of these deep structures is

often time-consuming and complex. Additionally, due to their extensive layers and intricate structures, these models are highly susceptible to the vanishing gradient problem, which can lead to inaccurate and erroneous results [2].

In real-world applications, normal operating conditions occur more frequently than faulty ones. From an engineering perspective, process monitoring in such settings constitutes an imbalanced classification problem, where the majority class represents normal conditions. Most statistical and neural network models are typically designed for balanced or nearly balanced classification scenarios, making them ineffective for highly imbalanced tasks. This is because, in imbalanced datasets, the majority class tends to dominate the decision-making process of these models.

One common approach to addressing the imbalanced classification problem is undersampling the majority class, which involves removing samples from the majority class [3]. A straightforward method is to randomly eliminate samples from the majority class. However, this simplistic approach is often naive, as it can result in the loss of important information pertaining to the majority class.

A recent study on fault detection in wastewater treatment plants (WWTPs) utilized an undersampling technique based on Gaussian Mixture Models (GMMs) [3]. The core idea of their research was to cluster the majority class and remove samples associated with the smallest clusters. This method achieved promising fault detection results by effectively balancing the removal of samples while preserving key information and the inherent behavior of the majority class.

In this study, four distinct scenarios for fault diagnosis were generated for a typical WWTP using Benchmark Simulation Model No.2 (BSM2). The research addresses a complex multi-class imbalanced big data problem, which poses significant challenges in accurately identifying and diagnosing faults within the system. To tackle this issue, we expanded our investigation to explore various undersampling techniques, advanced time-series models, and hyperparameter tuning strategies. These approaches aim to enhance the performance of fault diagnosis by effectively managing the imbalance in the dataset and improving the robustness of the models. Furthermore, we developed a Python-based Graphical User

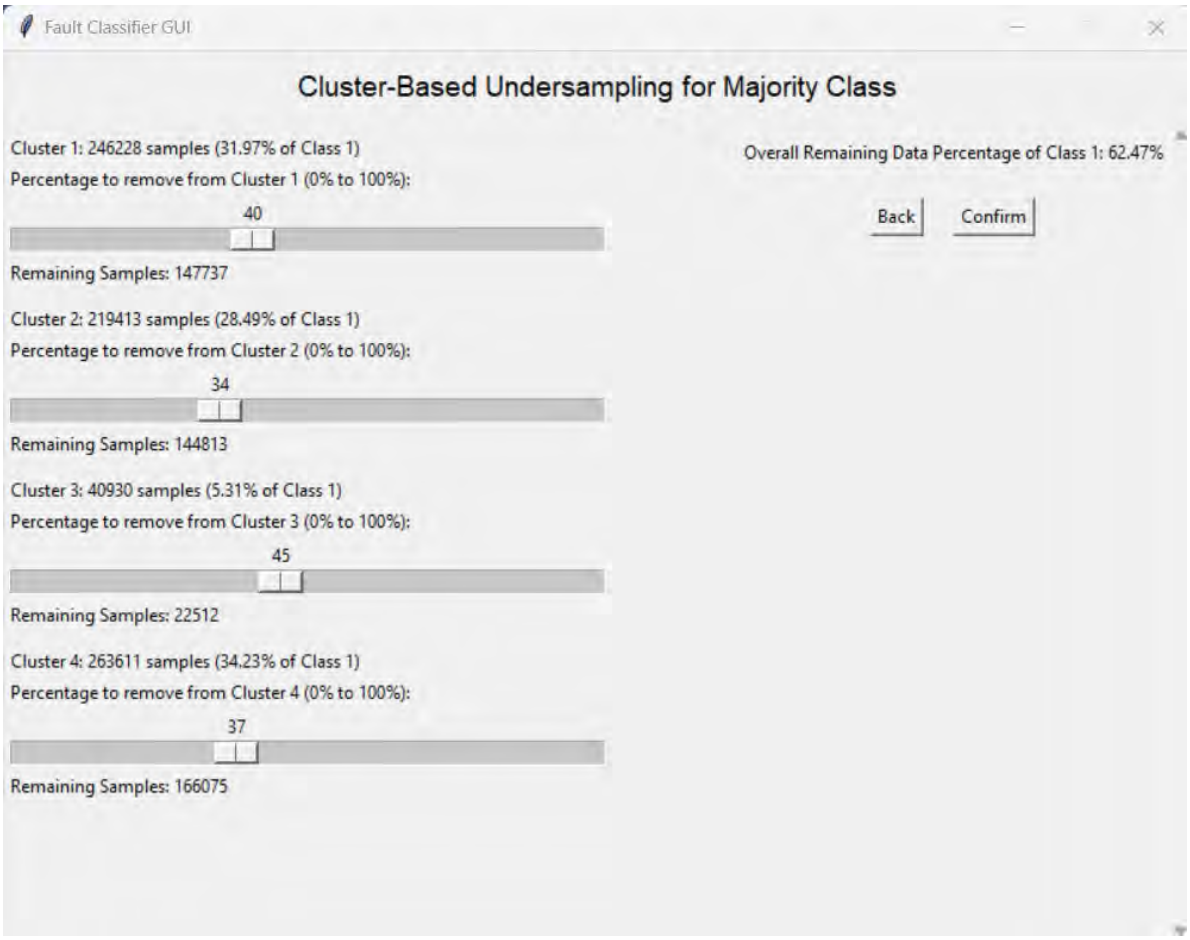

**Figure 1:** The second GUI window

Interface (GUI) to facilitate user interaction with the proposed models. The GUI allows users to deliberately select different models and their corresponding parameters, providing flexibility and ease of use. Additionally, it offers the option to save each modification made during the analysis process, ensuring that users can efficiently track and manage their experiments. The complete code for this study is publicly available on GitHub.

The structure of this paper is organized as follows. Section 2 presents the case study along with the generated data. Section 3 details the proposed fault diagnosis approach and its GUI. In Section 4, the process monitoring results are analyzed. Finally, Section 5 provides the conclusions of the study.

## CASE STUDY

The design of fault scenarios in this study is the same as the methodology outlined in [3, 4]. The faults are carried out on BSM2, closely simulating a real-world WWTP, containing process units listed as: a primary clarifier, activated sludge reactors, a secondary clarifier, a thickener, and a dewatering unit [3, 4]. Data acquisition is performed using 31 easily measurable variables, such as flow rate, Total Suspended Solids (TSS), Volatile Fatty Acids (VFA), among others, collected from various process units. The simulation duration of this plant-wide is 609 days with a sampling time of 1 minute, resulting in 876960 sample points. Therefore, for each fault scenario, a big dataset including 876960 sample points over 31 different measurements is investigated. To ensure the case study aligns more closely with real-world scenarios, the simulation period for normal operating conditions is set to be significantly longer than that for faulty conditions, resulting in an imbalanced big data distribution. The four fault scenarios and their contribution percentage is listed in Table 1.

As illustrated in Table 1, the majority class in this study, which is the normal operation condition, consists of 770182 samples and is designated as Class 1. Independent sensor faults and process faults are labeled as Class 2 and Class 3, respectively, each accounting for approximately 6% of the entire dataset. In this study, the process faults refer to the sludge bulking phenomenon and sensor faults represent an abnormality in the aerated reactors related the airflow. Lastly, only 330 samples (i.e. less than 0.1% of the dataset) indicate the simultaneous occurrence of both sensor and process faults, which are categorized as Class 4.

The aim of this study is to develop a fault diagnosis approach that by analyzing the 31-measurements anticipates which fault scenario is occurring. The primary challenge of this research work is to handle imbalance big datasets while striking a meaningful balance between the accuracy and the computational burden. Although the case study utilized in this research is identical to those presented in [3] and [4], the focus is on fault diagnosis, a multi-class classification problem, rather than fault detection, which is addressed as a binary classification problem. Moreover, aspects of big data must be considered when selecting appropriate parameters to ensure the effectiveness of the proposed approach. Finally, a GUI was developed for the proposed fault diagnosis algorithm, enabling users to easily select the desired model and adjust its parameters. Additionally, the GUI provides the capability to save the results of each stage of the algorithm independently.

**Table 1:** Fault Scenarios

| Stream | Description | Percentage |
|---|---|---|
| Class 1 | Normal | 87.82 |
| Class 2 | Only Sensor Fault | 6 |
| Class 3 | Only Process Fault | 6.14 |
| Class 4 | Both Sensor and Process Fault | 0.04 |

## FAULT DIAGNOSIS APPROACH

The proposed fault diagnosis workflow initiates by loading and preprocessing the dataset, generated by the update version of BSM2 [5], followed by identifying the majority and minority classes. The user is then prompted to input the desired number of clusters, after which the majority class data is segmented into the specified clusters. For each cluster, relevant information is displayed to the user, who determines the percentage of samples to remove. Based on this input, the appropriate number of samples is calculated and removed from each cluster. Subsequently, the undersampled majority class is combined with the minority classes, and the updated class distribution is presented. The user has the option to save the newly balanced dataset before proceeding to the modeling phase, thereby completing the preprocessing sequence.

The subsequent subsections present each window of the proposed fault diagnosis GUI designed to manage multi-class imbalanced big data distributions.

### The First Window: Data information

In the initial window, detailed information is presented, including the sample size of each class and the various imbalance ratios relative to the majority class (Class 1) for the generated fault scenarios of BSM2. In other words, the first window of the GUI displays the number of samples corresponding to each fault scenario: Class 1 contains 770,182 samples, Class 2 contains 52,583 samples, Class 3 includes 53,865 samples, and Class 4 has only 330 samples. Furthermore, the imbalance ratios (IR) are calculated to quantify the degree of class imbalance, yielding $IR_1$ = Class 1 / Class 2 = 14.65,

$IR_2$ = Class 1 / Class 3 = 14.30, and $IR_3$ = Class 1 / Class 4 = 2,333.88. More importantly, users have the option to select the number of clusters into which the majority class should be segmented. In this study, the diagnosis performance were studies for 2 to 6 clusters.

## The Second Window: Undersampling

In the second GUI window, the majority class is segmented based on the number of clusters selected in the preceding window. This window presents detailed information for each cluster, including the cluster size and its contribution percentage. The undersampling technique employed in this study involves initially clustering the majority class and subsequently removing samples randomly from each cluster. The removal percentage for each cluster can be determined through various methods: applying a uniform elimination percentage across all clusters, removing all samples from the smallest clusters sequentially until a predetermined overall removal percentage is achieved, or allowing the user to specify the removal percentage for each cluster individually. Figure 1 illustrates the second window of the developed fault diagnosis GUI.

## The Third Window: Confirmation

In this window, users can view the updated sample size of the majority class along with the revised imbalance ratios. To illustrate, the undersampling percentage applied to each cluster within the majority class (i.e., Class 1) is based on the values presented in Figure 1. As a result, the modified Class 1 is reduced to 481,137 sample points, leading to updated imbalance ratios of $IR_1$ = 9.15, $IR_2$ = 8.93, and $IR_3$ = 1,457.99. Although the dataset does not achieve a fully balanced distribution among the classes, removing the less informative samples from the majority class effectively reduces the degree of imbalance. Additionally, users have the option to save comprehensive information, including input measurements and output labels, for both the modified dataset and the removed samples. If the user is unsatisfied with the current elimination strategy, they can navigate back to the previous window to make adjustments. Otherwise, they can confirm and proceed to the next window.

## The Fourth Window: Time-Series Modelling

In this window, users can select their deep learning time-series model from Long Short-Term Memory (LSTM) and Bidirectional LSTM (BiLSTM). Upon selecting a model, users can adjust various model parameters, including learning rate, batch size, number of epochs, regularization factor, number of LSTM units, and dropout rate. Selecting appropriate values for epochs and the regularization factor is particularly challenging, as it requires balancing accuracy with computational efficiency. It is important to note that selecting lower values for the L2 regularization parameter can significantly increase the computational effort, improving the accuracy. On the other hand, increasing the number of epochs will extend the simulation time without necessarily guaranteeing an improvement in the classification accuracy for each class. Figure 2 illustrates the fourth window of the developed fault diagnosis GUI.

## The Fifth Window: Training Phase

In the fifth GUI window, the model begins training based on the previously provided information, while simultaneously displaying the ongoing simulation time. Monitoring the training time allows the user to terminate the process if the simulation duration exceeds expected limits.

## The Sixth Window: Results

In the final window, once the training phase is completed, the results are displayed, including simulation time, overall accuracy, confusion matrices, and class-specific accuracies for both training and testing datasets. Additionally, users have the option to save these results. It is important to note that overall accuracy may not be a reliable indicator for imbalanced data distributions; instead, ensuring high accuracy for each individual class is crucial. Figure 3 illustrates the last window of the developed fault diagnosis GUI.

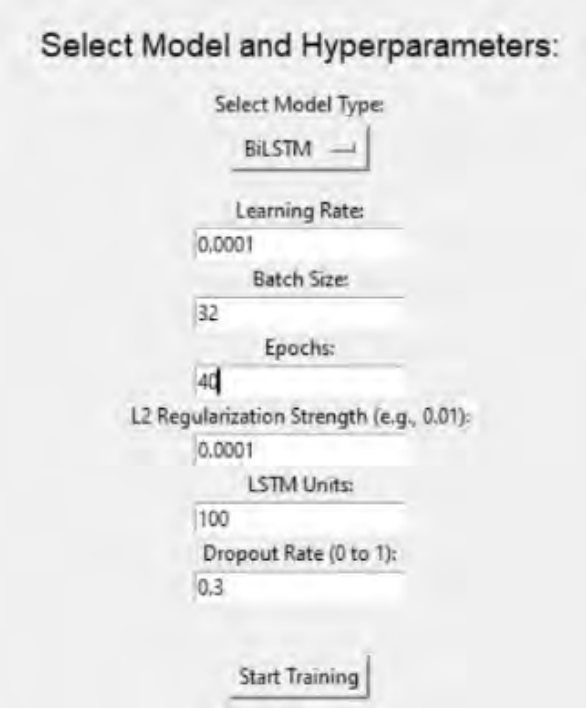

**Figure 2.** The fourth GUI window

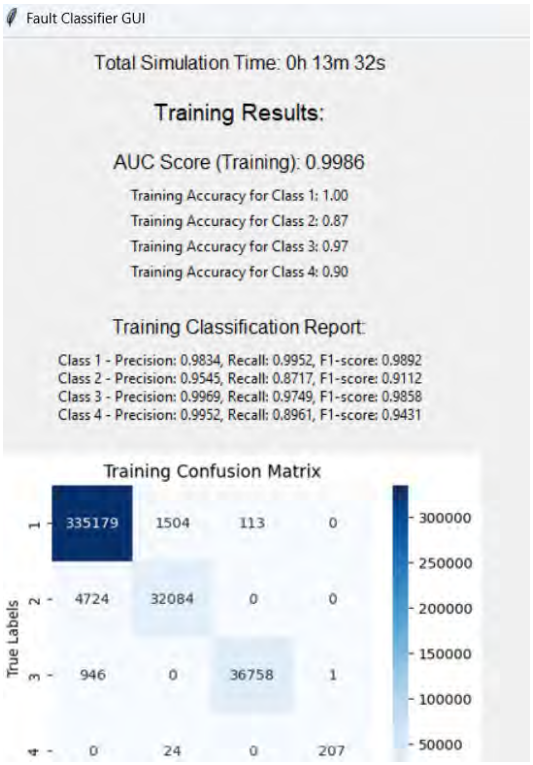

**Figure 3.** The sixth GUI window

## RESULTS AND DISCUSSION

As previously discussed, the regularization factor is crucial for obtaining optimal results. A regularization factor closer (L2) to zero typically enhances accuracy but also increases simulation time. Initially, we examine a fault detection algorithm that does not incorporate any undersampling techniques (Table 2), thereby directly inputting the imbalanced data into either an LSTM or BiLSTM model. In this setup, the parameters are configured with 40 epochs and a dropout rate of 30%.

**Table 2:** No undersampling approach (C denotes here as Class Accuracy)

| L2 | Model | C1 | C2 | C3 | C4 | Time(min) |
|---|---|---|---|---|---|---|
| 0.001 | BiLSTM | 99 | 43 | 76 | 0 | 17 |
| 0.001 | LSTM | 99 | 44 | 77 | 0 | 14 |
| 0.0005 | BILSTM | 99 | 60 | 84 | 0 | 20 |
| 0.0005 | LSTM | 99 | 58 | 84 | 0 | 16 |
| 0.0001 | BiLSTM | 99 | 80 | 95 | 94 | 20 |
| 0.0001 | LSTM | 99 | 80 | 94 | 91 | 18 |

**Table 3:** Comparing different epoch values (C denotes here as Class Accuracy)

| Epoch | C1 | C2 | C3 | C4 | Time (min.) |
|---|---|---|---|---|---|
| 100 | 100 | 91 | 98 | 96 | 34 |
| 40 | 99 | 89 | 97 | 91 | 14 |

According to Table 2, a regularization factor of 0.0001 is considered the highest acceptable value (L2 ≤ 0.0001), as exceeding this threshold leads to the accuracy of Class 4 dropping to zero or near zero.

With an established regularization factor of 0.0001, we proceed to identify the optimal number of epochs that achieves promising performance while minimizing computational time. The parameters fixed for this analysis are as follows: an undersampling rate of 40% (preserving 60% of the majority class) with 3 clusters for the majority class, a BiLSTM model configured with 100 units and a 30% dropout rate. Table 3 presents the classification accuracy for each class at epoch counts of 40 and 100, along with the corresponding simulation times.

Upon analyzing Table 3, it is evident that while the class accuracy of the model trained for 100 epochs is slightly higher than that of the model trained for 40 epochs, the computational cost is significantly greater for the 100-epoch model. Specifically, the fault diagnosis model with 100 epochs requires an additional 20 minutes of simulation time compared to the 40-epoch model. Therefore, it is reasonable to conclude that the 40-epoch configuration is more suitable in terms of both accuracy and computational efficiency.

With the L2 regularization value and the number of epochs established, we can now focus on investigating the number of clusters, determining the undersampling technique, and selecting a time-series model (LSTM or BiLSTM). Table 4 illustrates an undersampling rate of 40% applied uniformly across all clusters, whereas Table 5 demonstrates an undersampling rate of 40% achieved by eliminating the smallest clusters. Please note that in the simulation of Table 4 and 5, the L2 regularization value is 0.0001, drop out is 30%, batch size is 32, number of epoch is 40, the learning rate is 0.0001, and the employed LSTM units is 100.

**Table 4:** Uniformly removing samples from the clusters of the majority class (C denotes here as Class Accuracy)

| Cluster | Model | C1 | C2 | C3 | C4 | Time(min) |
|---|---|---|---|---|---|---|
| 2 | BiLSTM | 99 | 88 | 97 | 91 | 14 |
| 2 | LSTM | 99 | 87 | 96 | 86 | 11 |
| 3 | BILSTM | 99 | 89 | 97 | 91 | 14 |
| 3 | LSTM | 99 | 87 | 97 | 90 | 11 |
| 4 | BiLSTM | 99 | 87 | 97 | 89 | 13 |
| 4 | LSTM | 99 | 87 | 97 | 86 | 11 |
| 5 | BiLSTM | 99 | 87 | 97 | 89 | 13 |
| 5 | LSTM | 99 | 87 | 97 | 87 | 10.5 |
| 6 | BiLSTM | 99 | 88 | 97 | 94 | 11 |
| 6 | LSTM | 99 | 87 | 97 | 83 | 10.5 |

According to Tables 4 and 5, time-series models based on LSTM generally exhibit shorter computational times, averaging approximately three minutes. In contrast, fault diagnosis models utilizing BiLSTM achieve

higher accuracy values. Regarding the undersampling technique, uniformly removing samples from each cluster results in better accuracy compared to the approach of eliminating the smallest clusters. Additionally, the number of clusters has minimal impact on the performance of the proposed fault diagnosis algorithm.

**Table 5:** Removing samples from small clusters of the majority class (C denotes here as Class Accuracy)

| Cluster | Model | C1 | C2 | C3 | C4 | Time(min) |
|---|---|---|---|---|---|---|
| 2 | BiLSTM | 99 | 88 | 97 | 96 | 14.5 |
| 2 | LSTM | 99 | 88 | 98 | 83 | 11.5 |
| 3 | BILSTM | 99 | 87 | 96 | 91 | 13 |
| 3 | LSTM | 99 | 87 | 97 | 88 | 11 |
| 4 | BiLSTM | 99 | 87 | 96 | 96 | 14 |
| 4 | LSTM | 99 | 87 | 97 | 92 | 10.5 |
| 5 | BiLSTM | 99 | 89 | 97 | 85 | 13 |
| 5 | LSTM | 99 | 87 | 97 | 84 | 10.5 |
| 6 | BiLSTM | 99 | 87 | 98 | 99 | 13 |
| 6 | LSTM | 99 | 87 | 97 | 96 | 11 |

Finally, some implementation challenges related to parameter selection for the proposed fault diagnosis approach is highlighted. The total undersampling ratio is critical, as excessive removal of majority class samples may cause information loss. A 40% undersampling rate is recommended, retaining 60% of the majority class (i.e. class 1) samples [3]. For clustering, although the number of clusters has minimal effect, setting three or four clusters and uniformly removing 40% of samples from each cluster prevents losing essential data. Furthermore, both LSTM and BiLSTM models perform similarly, with suggested hyperparameters: learning rate of 0.0001, dropout rate of 0.3, batch size of 32, and 100 LSTM units. These parameters have limited effect on accuracy and simulation time. However, the L2 regularization parameter has a highly significant impact on model performance. Specifically, values greater than 0.0001 prevent the model from correctly identifying fault scenarios associated with Class 4, while values smaller than 0.0001 introduce a substantial computational burden. Additionally, the recommended number of training epochs ranges between 40 and 60. Increasing the number of epochs beyond this range does not necessarily improve classification accuracy but will considerably increase computational cost.

## CONCLUSION

This study presents a fault diagnosis framework specifically for a wastewater treatment plant, addressing the challenges of imbalanced big data typical in large-scale systems. It investigates four fault scenarios: fault-free conditions, process faults, sensor faults, and simultaneous sensor and process faults. The research utilizes clustering-based undersampling and optimizes hyperparameters, employs advanced time-series models such as LSTM and BiLSTM with careful regularization and epoch selection, and develops a Python-based GUI to allow users to effectively explore the fault diagnosis algorithm. The objective is to apply this methodology to benchmarks that closely reflect real-world conditions, enhancing the reliability and efficiency of industrial process monitoring. For future research, the development of an advanced optimization algorithm could be pursued to systematically and more effectively tune hyperparameters.

## DIGITAL SUPPLEMENTARY MATERIAL

The Python code for the proposed fault diagnosis GUI developed in this study is publicly available at https://github.com/Zadkarami/ESCAPE-2025.

## ABSTRACT

This study models a Heat Recovery System (HRS) within a petrochemical plant, assessing its economic and environmental viability. The system integrates four combustion processes and a condensing steam turbine combined heat and power (ST-CHP) generation unit, along with waste heat recovery technologies to reduce the plant's energy use. The developed system-based approach extends a previous methodology, initially focused on reducing energy consumption in production processes, to encompass energy supply systems (in which CHP is included) as well. Simulation models were developed for two improvement scenarios regarding the integration of the ST-CHP into the HRS: preheating either the combustion air stream or the inlet water of the ST-CHP's boiler. The latter demonstrated greater potential for reducing energy-related operational costs, thus an NLP optimisation model was developed based on that scenario. Both simulation and optimisation models were created resorting to the capabilities of the ThermWatt computational tool (comprising Modelica and Python languages). A payback period of about 2 years and 3 months and a reduction in equivalent carbon dioxide emissions of 5.14 kt $CO_{2,eq}$/year were estimated for the final system, which are significantly reasonable in comparison to benchmark values.

**Keywords**: Heat Recovery System, Combined heat and power, ThermWatt computational tool

## INTRODUCTION

In light of the ever-increasing emphasis on environmental protection, the European Union (EU) has introduced various policies and strategic frameworks aimed at fostering sustainable development across all member states. Central to this effort are the multiannual Environmental Action Programmes (EAPs), which have guided the EU's environmental policy since 1973 [1]. The most recent, the 8th EAP, came into effect in May 2022 and sets the legally binding framework for the EU's environmental goals until 2030. Building on the European Green Deal, it reiterates the EU's long-term vision to 2050 of living well and within planetary boundaries and outlines six priority objectives for 2030, along with measures to reach them. Among these objectives is meeting the 2030 greenhouse gas emissions reduction target, which seeks to cut the EU's emissions by 55% compared to 1990 levels [2]. Motivated by the substantial effort still required to meet the proposed targets and guided by the principles of the EU Energy System Integration Strategy (namely its first pillar, dealing with the promotion of the nexus between energy efficiency and circular economy) this work addresses the application of waste heat recovery practices aimed at reducing energy consumption of industrial plants, while delivering both economic and environmental benefits, primarily by reducing operational costs and lowering pollutant emissions.

The Heat Recovery Systems (HRSs) conceptualised in this work explore principles of waste heat recovery and expand a previous methodology (Water and Energy Integration Systems) [3,4], initially focused on reducing energy consumption in production processes, to encompass combined heat and power (CHP) generation systems, which fall under energy supply systems. The application of a unified heat recovery approach is based on

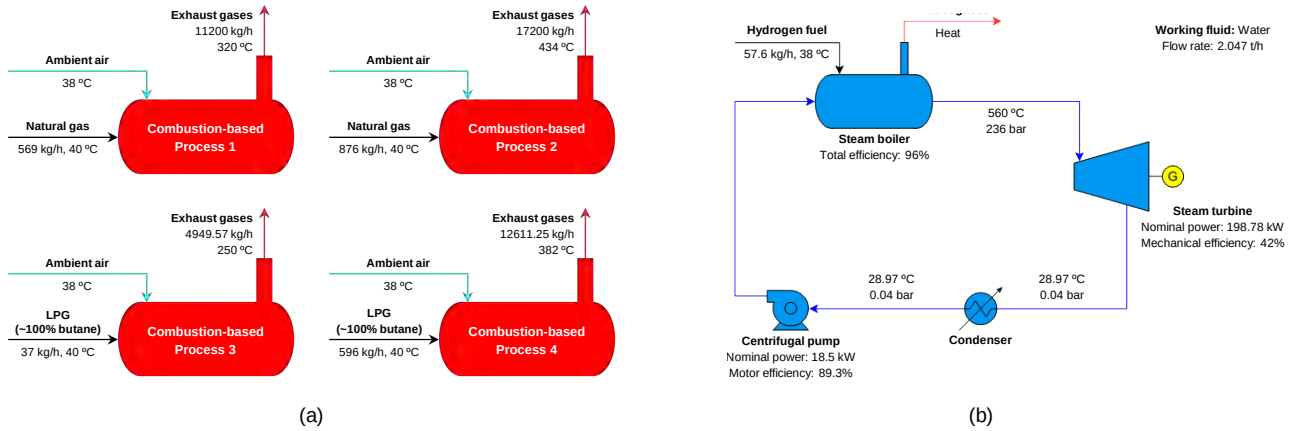

**Figure 1:** Information provided by the plant's stakeholders on the four CBPs (a) and the ST-CHP system (b).

the structural similarities and shared technologies between the two types of systems. This work uses the ThermWatt computational tool (owned by ISQ – Instituto de Soldadura e Qualidade [4]) to simulate and optimise an HRS integrated within a petrochemical plant.

## METHODOLOGY AND TOOLS

The methodological framework associated to this work begins with a clear problem definition, setting specific objectives and understanding the plant's processes. Based on this foundation:

1. The HRS for the targeted plant is designed, making an appropriate choice of heat recovery technologies to be installed in the plant and designing the superstructure of recirculated streams;
2. The ThermWatt computational tool is used to simulate and optimise the proposed HRS through a structured process:
   - 2.1 First, initial simulation models are developed to enable a preliminary analysis of improvement scenarios;
   - 2.2 Next, the most promising scenario is optimised to maximise total energy-related operational cost savings;
   - 2.3 Finally, the optimisation results are integrated back into the simulation model to achieve the system's final model.
3. The project's viability is assessed by calculating specific economic and environmental indicators, which are then compared against industry benchmarks for the chemical sector.

The Heat Recovery Systems are based on the steady-state thermal process subsystem of the Water and Energy Integration Systems (WEISs) [3,4] and seek to contribute with new processes and recirculation points to the existing conceptualised superstructure of WEISs. The HRS comprises N combustion-based processes (CBPs), each receiving fuel and air inputs and producing waste heat streams with recirculation potential (such as exhaust gas and hot air). A superstructure is designed accounting for all recirculation points, directing the mentioned heat streams back to the same CBP, to the other N – 1 CBPs, or to a thermodynamic cycle (TC) for electricity generation. Recirculated heat streams routed to a CBP merge into a single stream and transfer heat to incoming ambient air, either directly by mixing or indirectly via a heat exchanger, depending on the stream composition. For indirect heat recovery, the stream exits to the environment after the heat exchange. All the components and recirculation points mentioned thus far were already part of the WEISs. CHP systems are incorporated into the HRSs aiming to extend the scope of the WEISs to include the reduction of energy input in energy supply systems.

## CASE STUDY CHARACTERISATION

The case study approached in this work examines the implementation of a Heat Recovery System in a petrochemical plant. The plant is not yet operational, although the constituent unit operations have already been planned in terms of operational conditions and overall energy consumption levels. It is set to be located in Sines, Portugal and to operate for 7824 hours annually. The processes of the plant included in the case study are four CBPs and one condensing steam turbine CHP system (ST-CHP). Figure 1 displays information provided by the plant's stakeholders on the five processes. Currently, there is an interest of the plant's stakeholders on reducing consumption levels of natural gas and LPG, as well as on decreasing the use of hydrogen fuel in the ST-CHP

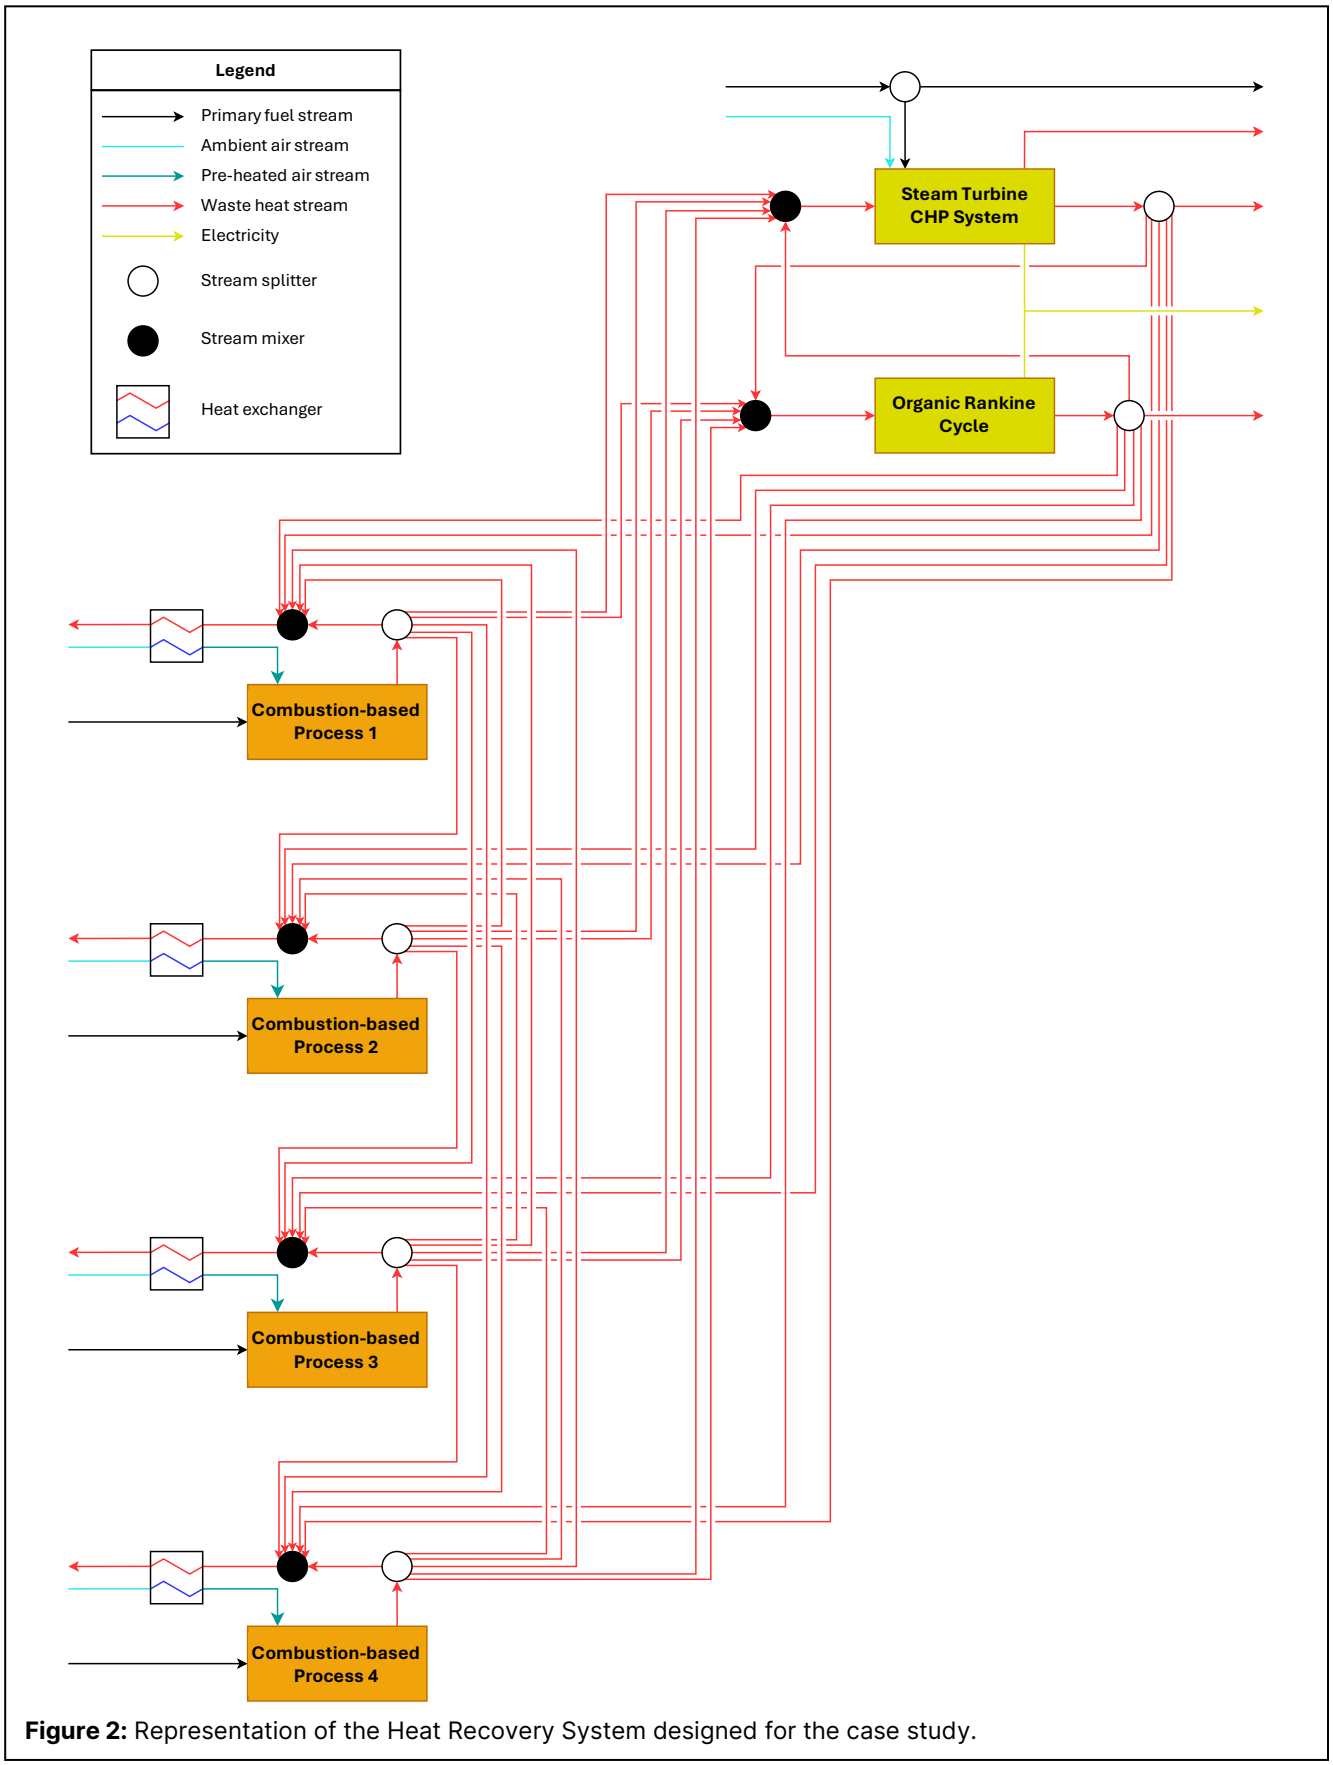

**Figure 2:** Representation of the Heat Recovery System designed for the case study.

system with the goal of reallocating the non-used hydrogen for other applications. The conceptualised HRS superstructure considering the planned energy-using units of the plant is illustrated in Figure 2.

Additional remarks for the implementation of the HRS include the assumption of 95 ºC as the minimum allowed temperature for the exhaust gas streams, ensuring these remain above the dew point. Furthermore, the air-fuel mass ratio was assumed constant. A reasonable maximum combustion air temperature of 300 ºC has been defined.

## SIMULATION

Two approaches have been exploited regarding the integration of the ST-CHP unit into the HRS, leading to two improvement scenarios:

- Scenario 1 involves installing an air preheater to preheat the steam boiler's combustion air to a maximum of 300 ºC, following the same approach applied to the CBPs;
- Scenario 2 proposes installing an economiser to preheat the steam boiler's pressurised feedwater to a maximum of 373.94 ºC, which corresponds to the critical temperature of water (the water in the steam boiler transitions directly to a supercritical state).

In this prospect, two simulation models were developed, one for each scenario, in order to assess which presents the greatest potential for reducing energy-related operational costs. The ORC model incorporated into the simulation models was adapted from one developed in prior work for implementing a WEIS in an industrial plant [4]. Table 1 presents key simulation results, showing that a basis for comparing both scenarios was successfully established, as the results between them differ only in terms of hydrogen consumption.

**Table 1:** Comparison of fuel costs and ORC-generated electricity savings (thus negative values) between the base case and both improvement scenarios, in M€/year.

| Energy vector | Base | Scenario 1 | Scenario 2 |
|---|---|---|---|
| Natural gas | 6.577 | 6.215 | 6.215 |
| LPG | 6.249 | 5.657 | 5.657 |
| Hydrogen | 1.911 | 1.747 | 1.209 |
| Electricity | – | -0.089 | -0.089 |
| Total | 14.737 | 13.530 | 12.992 |

Although the combustion air and inlet water of the steam boiler experienced similar temperature increases (an outlet temperature of 300 ºC was specified for both), the economiser in scenario 2 achieved a heat recovery rate of 2.418 GJ/h, which is 4.22 times higher than that of the boiler's air preheater in scenario 1. Consequently, scenario 2 resulted in significantly greater hydrogen savings. This difference is due to water's higher heat capacity compared to air. Furthermore, the heat recovery rate achieved by the boiler's air preheater of scenario 1 corresponds to its maximum value, as the combustion air temperature cannot exceed 300 ºC, while the economiser's recovery rate can be even higher, with the boiler feedwater capable of being preheated an additional 73.94 ºC. Given these aspects, scenario 2 indubitably offers greater potential for energy-related operational cost savings due to its superior capacity for overall energy consumption reduction. As a result, scenario 2 is the only one submitted to the optimisation procedure.

## OPTIMISATION

The system-level optimisation model of the second improvement scenario was formulated, for the most part, using the same set of parameters, variables and governing equations of the corresponding simulation model (refer to [5]). A few simplifications were applied, namely not calculating the composition of the streams, reducing the ST-CHP to the economiser and steam boiler, as well as simplifying the ORC system to a net efficiency parameter. The two streams recirculating heat between the ST-CHP and ORC had to be removed as they created an interdependency that made it impossible formulating the optimisation problem. The objective function was defined as the maximisation of energy-related operational cost savings. The resulting optimisation model is nonlinear, hence the use of open-source IPOPT solver.

A value of 6.07% was attributed to the ORC net efficiency parameter, aligning with the efficiency of the system adapted from the literature [4] initially implemented into the simulation model. The optimisation results showed that maximum heat recovery was achieved, as all the exhaust gas streams leaving the HRS had reached the minimum allowable temperature of 95 ºC, and that reducing fuel consumption was favoured over additional electricity generation. A sensitivity analysis, present in Figure 3, demonstrated that this preference occurred independently of the value attributed to the ORC net efficiency, within its feasible range (5-20%).

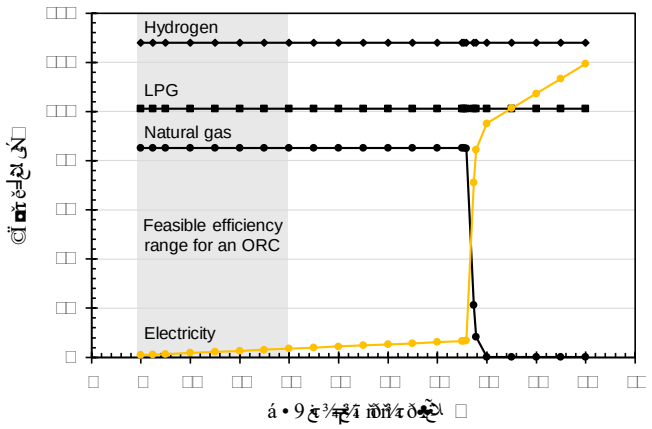

**Figure 3:** Results of the sensitivity analysis on the ORC net efficiency's impact on fuel and electricity savings.

Consequently, the optimised heat recovery rate of the ORC was significantly lower than the original design specifications of the simulated ORC system, failing to completely vaporise the working fluid, so it had to be resized prior to using the OpenModelica Python Package for incorporating the optimisation results into the simulation model. This was accomplished by adjusting the working fluid mass flow rate and pump outlet pressure via a parametric study, while also aiming for a new net efficiency of 12.5%.

Table 2 indicates that the final HRS reduced total energy-related operational costs by 16.9% compared to the base case and by an additional 42.3% compared to that obtained from the simulation of scenario 2.

**Table 2:** Energy consumption (TJ/year), costs (M€/year) and emissions (kt $CO_{2,eq}$/year) resulting from fuel consumption in the final HRS. The ORC-generated electricity savings (negative values) are also represented.

| Energy vector | Energy | Costs | Emissions |
|---|---|---|---|
| Natural gas | 458.29 | 5.912 | 29.38 |
| LPG | 198.13 | 5.458 | 12.49 |
| Hydrogen | 25.52 | 0.900 | – |
| Electricity | -0.53 | -0.017 | -0.03 |
| Total | – | 12.253 | 41.84 |

The final HRS flowsheet and detailed simulation results are provided as supplementary material. The optimisation resulted in no flow rate assigned to the ORC outlet purge stream, rerouting the high-temperature exhaust gas stream to the four CBPs. A similar outcome was observed for the exhaust gases at the outlet of the ST-CHP economiser, though a residual flow rate was still purged. The minimisation of purged high-temperature exhaust gas illustrates how these two recirculation points (exhaust gas stream splitters leaving the ORC and ST-CHP), which were absent in the WEISs, enhance the system's flexibility.

## VIABILITY ASSESSMENT

The economic and environmental indicators used to assess the final HRS project viability are the payback period ($PBP$) and the absolute reduction in equivalent carbon dioxide emissions ($Red.\ CO_{2,eq}$), which are calculated using Eq. (1) and (2).

$$PBP = \frac{Sav}{CAPEX} \quad (1)$$

$$Red.\ CO_{2,eq} = CO_{2,eq}^{BaseCase} - CO_{2,eq}^{HRS} \quad (2)$$

The total energy-related operational costs savings ($Sav$) is calculated using Eq. (3), while the equivalent carbon dioxide ($CO_{2,eq}$) emissions is determined via Eq. (4).

$$Sav = \sum_i \left(EC_i^{BaseCase} - EC_i^{HRS}\right) \cdot Price_i \quad (3)$$

$$CO_{2,eq} = \sum_i EC_i \cdot EF_i \quad (4)$$

In Eq. (3) and (4), $EC_i$, $Price_i$ and $EF_i$ represent the annual energy consumption, price and emission factor of the energy vector $i$ (electricity and fuels).

The capital expenditure ($CAPEX$) is determined as the sum of direct and indirect costs associated with the heat recovery technologies added to the base case. First, the equipment cost is estimated using correlations found in the literature [6,7] and adjusted to the current year using the CEPCI indexes. Then, the remaining direct and indirect expenditures are approximated as percentages of the installed equipment cost [8].

A payback period of less than 3 years is considered reasonable for an investment in waste heat recovery technologies within the industrial sector of the European Union [9]. Furthermore, a project conducted in a fertiliser industry in Norway achieved a reduction of $CO_{2,eq}$ emissions of 12-19 kt/year by increasing energy efficiency through the replacement of old electric motors with newer and more efficient ones [10]. If the estimated values are reasonable in comparison with these benchmarks, then the final HRS project is deemed viable.

Using the previously outlined procedure, the total CAPEX for the four air preheaters, economiser, and ORC system was estimated at 5.464 M€. Based on Tables 1 and 2, the total savings achieved by the final HRS amount to 2.484 M€, leading to a payback period of 2.20 years, or roughly 2 years and 3 months.

The final HRS achieved a reduction in $CO_{2,eq}$ emissions of 5.14 kt/year. While it falls short of the benchmark interval mentioned earlier, it is important to note that this comparison is based on absolute values, which does not consider several factors such as the size of the facility where the project used as a reference was implemented, the extent of the modifications and Norway's electrical energy mix (which influences the emission factor associated with electricity generation). Nevertheless, the final HRS results in a substantial 8.9% reduction in emissions

compared to the base case.

Taking into account the comparison between the estimated results for both indicators and the reference benchmarks, it may be considered that the engineering project associated to the conceptualised HRS presents a significant economic and environmental viability.

## CONCLUSIONS

This work represents an initial step in the design phase of an industrial project, in which a preliminary technical, economic and environmental assessment has been carried out. By exploring the capabilities of the ThermWatt computational tool it was possible to virtually integrate the conceptualised Heat Recovery Systems within a real plant and conclude that the final project not only enhances energy efficiency but also shows promising potential to improve the sustainability and competitiveness of the industrial plant in question. The addition of two new equipment-level models to the ThermWatt Modelica Library signified the further expansion of its capabilities, highlighting its versatility. Overall, this study shows the importance of waste heat recovery in promoting the principles of the circular economy within industrial operations by reducing waste and decreasing reliance on external energy sources through the reuse of thermal energy that would otherwise be lost.

## DIGITAL SUPPLEMENTARY MATERIAL

Digital supplementary material is available at https://psecommunity.org/LAPSE:2025.0007, including basic information regarding the involved energy vectors (lower heating value, prices and emission factors), the validation results of the new steam boiler model and the flowsheets and detailed simulation results of both improvement scenarios and final HRS.

# Integrating Thermodynamic Simulation and Surrogate Modeling to Find Optimal Drive Cycle Strategies for Hydrogen-Powered Trucks

**Laura Stops[a]*, Alexander Stary[a], Johannes Hamacher[a], Daniel Siebe[a], Thomas Funke[b], Sebastian Rehfeldt[a], and Harald Klein[a]**

## ABSTRACT

Hydrogen-powered heavy-duty trucks have a high potential to significantly reduce $CO_2$ emissions in the transportation sector. Therefore, efficient hydrogen storage onboard vehicles is a key enabler for sustainable transportation, as achieving high storage densities and extended driving ranges is essential for the competitiveness of hydrogen-powered trucks. Cryo-compressed hydrogen ($CcH_2$), stored at cryogenic temperatures and high pressures, emerges as a promising solution. This study presents a comprehensive dynamic thermodynamic model that is capable of simulating the tank system across all operating conditions and, therefore, enables thermodynamic analysis of drive cycles. The core of the model is a differential-algebraic equation system that describes the thermodynamic state of the hydrogen in the tank. Additionally, surrogate models based on artificial neural networks are applied to efficiently describe quasi-steady-state heat exchangers integrated into the tank system. Several use cases are explored to demonstrate the model's ability to simulate the thermodynamic behavior and to find optimal operating strategies. The optimal hydrogen density, when to stop driving and refuel the tank to maximize overall driving ranges, is investigated both in ideal and real operation, taking into account the limited availability of refueling stations in early market applications. Further, driving range and venting losses are considered for longer periods of dormancy. These results provide insights into how operational strategies can be tailored to maximize driving range, minimize hydrogen losses, and improve overall system efficiency, ultimately supporting the adoption of hydrogen in long-haul transportation.

**Keywords**: Hydrogen, Dynamic Modeling, Surrogate Model, Process Operations, Matlab

## INTRODUCTION

To reduce $CO_2$ emissions in transportation, hydrogen-powered heavy-duty trucks are a promising solution. Thereby, cryo-compressed hydrogen ($CcH_2$), stored at cryogenic temperatures and high pressures, is an efficient way for onboard hydrogen storage, as it achieves the highest storage densities [1]. In the CryoTRUCK project, funded by the German Federal Ministry of Digital and Transport (BMDV), such a $CcH_2$ storage is being developed. For optimal utilization of the stored hydrogen, good knowledge of the thermodynamic processes within the tank is essential. Thus, in previous works, thermodynamic models and computational fluid dynamics (CFD) analyses studying the heat exchangers of the tank system have been introduced [1-5]. This study applies and combines the thermodynamic models of the tank system to analyze and investigate optimal vehicle operation.

Therefore, surrogate models based on artificial neural networks (ANNs) are used to efficiently simulate the heat exchangers integrated into the system, enhancing simulation speed and reducing model complexity. This model reduction allows the export of the tank model in a compact way for integration into large vehicle models or

even for onboard simulations. Several use cases are explored in this study, focusing on optimal operation to maximize driving range or avoid hydrogen losses.

## METHODOLOGY

The applied model consists of a dynamic thermodynamic tank model and surrogate component models of two heat exchangers that will be discussed hereafter.

### Thermodynamic Tank Model

The considered $CcH_2$ tank is depicted in Figure 1. It consists of an aluminum liner wrapped in carbon fiber and insulated by vacuum and multi-layer insulation. Two heat exchangers are included in the system: an inner (iHEX) and an outer (oHEX) heat exchanger. The latter one heats up the cryogenic hydrogen that is discharged from the tank (mass flow rate $\dot{M}_{\mathrm{disch}}$) before the warm hydrogen is fed to the truck's fuel cell (FC). The iHEX is used to control the pressure in the tank by heating the tank (heat flow $\dot{Q}_{\mathrm{disch}}$). Therefore, hydrogen that has already been heated up in the oHEX is redirected via a three-way valve to the iHEX. After passing the iHEX, the hydrogen flows through the oHEX once more towards the FC.

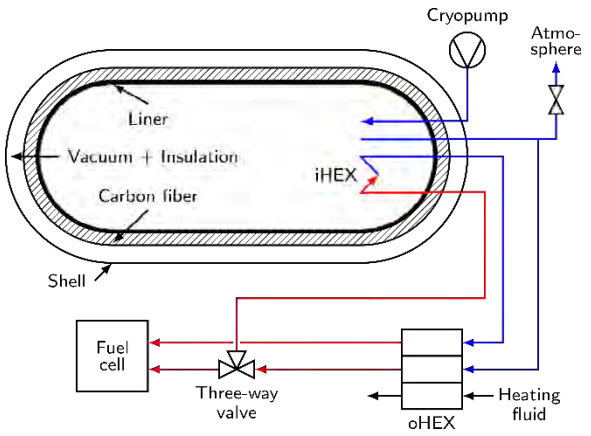

**Figure 1**. CcH2-Tank [2]

Three operating scenarios are considered in this study: discharge (or driving), refueling, and dormancy. In this study, it is assumed that in the refueling scenario, $CcH_2$ is always refueled with a constant mass flow rate $\dot{M}_{\mathrm{fuel}} = 60\ \mathrm{g/s}$ as described in [2]. Further, when the truck is parked for a long time, the pressure may rise above the venting pressure $p_{\mathrm{vent}} = 450\ \mathrm{bar}$ due to heat inleak from the ambiance (heat flow $\dot{Q}_{\mathrm{amb}}$), which requires venting hydrogen with the mass flow rate $\dot{M}_{\mathrm{vent}}$ to maintain the pressure $p_{\mathrm{vent}}$. It is assumed that exactly the amount required to maintain the pressure is vented.

When simulating a discharge process, a constant mass flow rate of $\dot{M}_{\mathrm{disch}} = 1\ \mathrm{g/s}$ is considered. As shown in previous work [1,2], the temperature and pressure in the tank decrease during driving. When the minimum pressure $p_{\mathrm{min}} = 15\ \mathrm{bar}$ required by the FC system is reached, the iHEX is turned on. [1] and [2] assume that the iHEX delivers exactly the heat required for maintaining the pressure $p_{\mathrm{min}}$, which will be referred to as *ideal iHEX*. In this study, it is assumed that the three-way valve in Figure 1 acts as on-off control, meaning that either all discharged hydrogen is passed through the iHEX or none. When the iHEX is on, the temperature and pressure in the tank rise. As soon as an upper threshold is reached, the iHEX is shut off again. Here, the upper threshold is set to 35 bar. The heat flow generated by the iHEX is calculated from surrogate models that will be discussed in the next section. This setup is hereafter referred to as *real iHEX*.

Thus, the $CcH_2$ tank is characterized by the mass and energy balance in Equation (1) and (2). For the sake of simplicity, no index is used for all variables describing the hydrogen within the tank.

$$\frac{\mathrm{d}M}{\mathrm{d}t} = \dot{M}_{\mathrm{fuel}} - \dot{M}_{\mathrm{disch}} - \dot{M}_{\mathrm{vent}} \tag{1}$$

$$\frac{\mathrm{d}U}{\mathrm{d}t} = \dot{M}_{\mathrm{fuel}} \cdot h_{\mathrm{fuel}} - \dot{M}_{\mathrm{disch}} \cdot h - \dot{M}_{\mathrm{vent}} \cdot h + \dot{Q}_{\mathrm{amb}} + \dot{Q}_{\mathrm{disch}} \tag{2}$$

As it is assumed that the hydrogen is ideally mixed, the hydrogen taken from the tank has the same temperature and pressure and, therefore, specific enthalpy $h$ as the hydrogen in the tank. The specific enthalpy $h_{\mathrm{fuel}}$ of the refueled hydrogen results from an isentropic compression from the refueling station pressure to the tank pressure $p$ with the efficiency $\eta_{\mathrm{pump}} = 0.78$ until the fill pressure $p_{\mathrm{fill}} = 400\ \mathrm{bar}$ is reached [2]. Further, only the hydrogen as well as the solid aluminum and carbon fiber parts are considered, while other solid components of the tank are neglected. As the solids are in good thermal contact with the hydrogen, a uniform temperature is assumed [1,2]. Based on the balances and several algebraic equations, a differential-algebraic equation system is defined in [1] and [2], describing the thermodynamic state of the hydrogen in the tank for all operation modes. All parameters used for this study are taken from [2].

### Surrogate Component Models

Within the CryoTRUCK project, rigorous component models of the two heat exchangers in the tank are being developed, based on thermodynamic correlations and CFD simulations [4,5]. Combining these models with the dynamic thermodynamic tank model would highly increase calculation time and model complexity. However, using the model for real drive cycle optimizations, integration into large vehicle models, or usage onboard the truck for driver assistance systems and tank state monitoring requires real-time calculations and low complexity. Thus, surrogate models of the heat exchangers are generated and integrated into the tank model. It is assumed that both heat exchangers are in a quasi-steady state in relation to the dynamics of the $CcH_2$ tank.

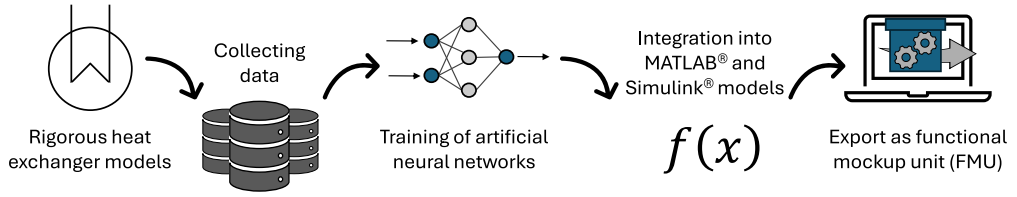

**Figure 2**. Workflow of building the surrogate models.

The workflow of generating these surrogate models is shown in Figure 2. The rigorous heat exchanger models are used to collect datasets of input-output relations for the steady-state heat exchanger characteristics. The inputs are chosen across the operation range using Latin hypercube sampling [6]. The data is used to train, validate, and test ANNs, which take all inputs of the respective rigorous models and return the hydrogen state at the outlet of the heat exchanger and the transferred heat flows. When the ANNs are inserted into the MATLAB® system model, the resulting reduced model includes only two differential equations and accurately represents the overall system while having low model complexity. Additionally, by integrating the ANNs into a Simulink® tank model and exporting it as a functional mockup unit (FMU), the model can be included in other simulation platforms and possibly run onboard a truck.

## RESULTS

This section investigates drive cycles with the ideal and real heat exchanger models. Further, two case studies of typical operating strategy problems are conducted.

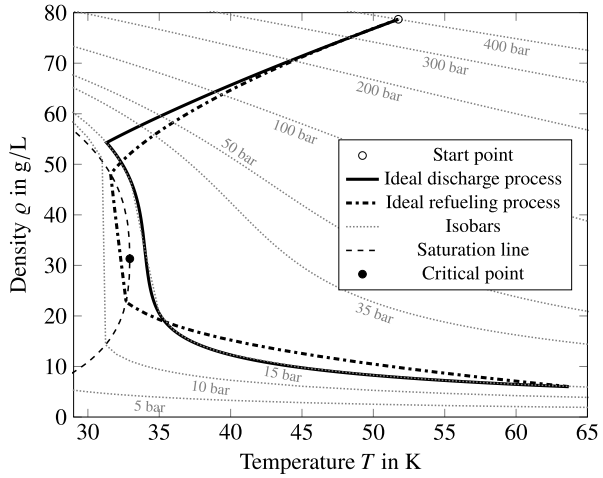

**Figure 3.** Drive cycle with ideal iHEX

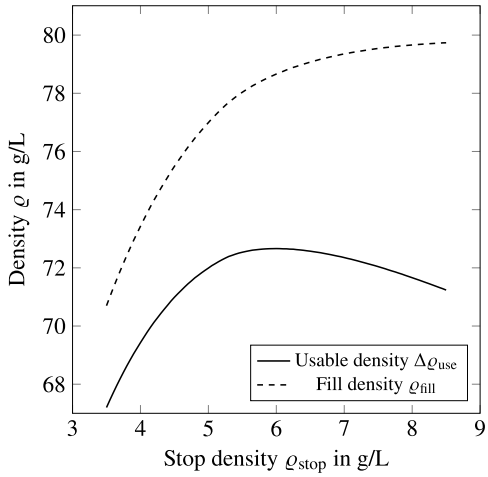
Figure 3 shows an ideal cycle of discharge and refueling with the ideal iHEX within a $(T, \varrho)$-diagram. At the beginning of the discharge, temperature and pressure decrease. When reaching $p_{\min}$, the iHEX is switched on and delivers exactly the heat flow required to follow the $p_{\min}$-isobar. As soon as a minimum density, also called stop density $\varrho_{\text{stop}}$, is reached, the truck is stopped and refueled up to $p_{\text{fill}}$, ending up at the same thermodynamic state as at the beginning of the idealized cycle.

The real discharge process, deploying the real iHEX simulated with the surrogate models and the on-off control, is depicted in Figure 5(a) alongside the ideal process. Generally, the real process follows the ideal one, however, due to the on-off control, a zigzag pattern is visible. When $p_{\min}$ is reached and the iHEX is turned on, more heat than required is transferred. Thus, temperature and pressure rise. When the iHEX is shut off at 35 bar, temperature and pressure fall back to the path of the ideal process. At the end of the discharge, much more heat is required to keep the pressure, and the intervals of heating become larger. However, the heating intervals highly depend on the mass flow rate and the starting conditions.

These findings are relevant when considering the influence of $\varrho_{\text{stop}}$ on the usable density $\Delta\varrho_{\text{use}}$ and the fill density $\varrho_{\text{fill}}$, which are plotted over the stop density in Figure 4 for the ideal process, assuming that refueling is possible at any time [2]. The fill density is defined as the density that results from refueling up to $p_{\text{fill}}$, starting from the thermodynamic state at the end of the discharge defined by $\varrho_{\text{stop}}$. The usable density $\Delta\varrho_{\text{use}} = \varrho_{\text{fill}} - \varrho_{\text{stop}}$ relates the current stop density to the subsequent fill density and, thus, to the potential driving range of the next drive cycle.



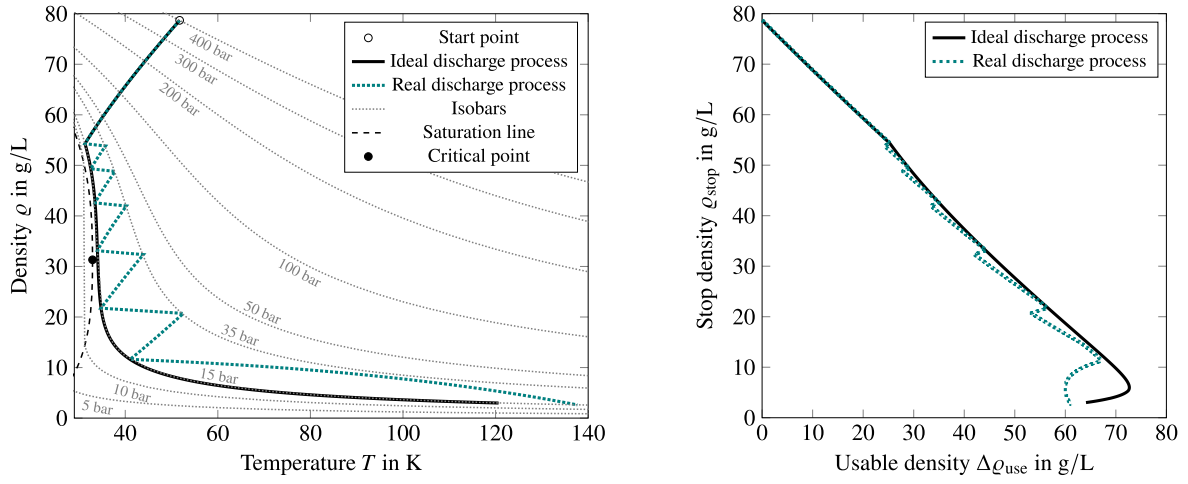


**Figure 4.** Usable and fill density as a function of the stop density

(a) Discharge process (b) Usable density

**Figure 5**. Discharge process and corresponding usable densities for refueling anytime during the discharge

The fill density highly depends on $\varrho_{\mathrm{stop}}$, as at the end of the discharge, the temperature rises fast when the $p_{\mathrm{min}}$-isobar slope becomes small (see Figure 3). For the following refueling process, however, low temperatures in the tank are preferable to achieve higher storage densities. Consequently, the fill density increases in Figure 4 for higher stop densities. Since stopping too early would not exploit the capacity of the tank, the usable density has a clear maximum. Thus, for the ideal process, an optimal stop density, at which it is best to stop and refuel for the maximum driving range, can be found by optimizing $\Delta\varrho_{\mathrm{use}}$. Therefore, the MATLAB® function `fminbnd` is applied to maximize $\Delta\varrho_{\mathrm{use}} = f(\varrho_{\mathrm{stop}})$. The underlying objective function calculates $\Delta\varrho_{\mathrm{use}}$ by simulating a refueling process, starting from the thermodynamic tank state defined by $\varrho_{\mathrm{stop}}$ and $p_{\mathrm{min}}$. The resulting optimal stop density is $\varrho_{\mathrm{stop}}^{\mathrm{ideal}} = 6.025\,\mathrm{g/L}$, which corresponds to a fill state of $\varrho_{\mathrm{fill}} = 78.69\,\mathrm{g/L}$, $T_{\mathrm{fill}} = 51.75\,\mathrm{K}$, and $p_{\mathrm{fill}} = 400\,\mathrm{bar}$. This is used as starting point for all remaining simulations.

When, instead, the real iHEX, including the on-off control, is considered, a different behavior is observed. Figure 5(b) shows the usable density that would be achieved when the truck is stopped and refueled at any time during the ideal and real discharge processes in Figure 5(a). Thereby, the thermodynamic state corresponding to each stop density in Figure 5(b) equals a state in Figure 5(a). The results of the ideal iHEX process are in accordance with the course in Figure 4 and show an optimum at $\varrho_{\mathrm{stop}} = 6.025\,\mathrm{g/L}$. The usable densities simulated with the real iHEX, however, are highly influenced by the peaks due to the on-off iHEX control. Whenever the iHEX is on and the temperature in the tank is high, refueling would be less efficient. Thus, the usable density is best when refueling just before the iHEX is turned on again. At the theoretical optimal stop density, the real process course for the considered starting conditions and mass flow rate is at the peak of a heating period, which is most unfavorable for refueling. Consequently, the real iHEX process would have roughly 5 g/L less maximal usable density compared to the ideal case. When still stopping at the theoretical optimal stop density, 12 g/L of maximal usable density is lost.

While this approach allows calculating optimal stop densities for the real system and could, thus, be used to recommend when to refuel, an even better approach to maximize the usable density would be to alter the iHEX control before refueling. When the truck operator provides the tank system with knowledge of the next refueling point, the iHEX could be turned off to ensure low temperature and pressure when refueling takes place.

## Case Study 1: Refueling Station Scarcity

In this section, the ideal and real discharge processes are investigated, considering that during early market entry, only limited hydrogen refueling stations exist. Two cases are defined: refueling stations are located (a) every 100 km, or (b) every 50 km. It is assumed that a truck has two tanks as defined in [2] and that a hydrogen truck consumes roughly 7 kg per 100 km [7]. Figure 6 highlights all options for refueling during the discharge process in a $(T, \varrho)$-diagram. The resulting usable densities at all refueling stations are depicted in Figure 7(a) and Figure 7(b) for the cases where refueling stations are located every 100 km or every 50 km. Most deviations between the ideal and real iHEX operation occur after long driving ranges because, for the considered mass flow rate and starting conditions, the drive cycle ends with a long period of heating of the real iHEX, which is non-ideal for the subsequent refueling.

In the 100 km case, the last two fuel stations lead to almost the same usable density in the real discharge

process, even though the last tank stop is located at the peak of the last heating period. The non-ideal refueling conditions at the last stop are balanced out by refueling too early at the second last option, not exploiting the usable density.

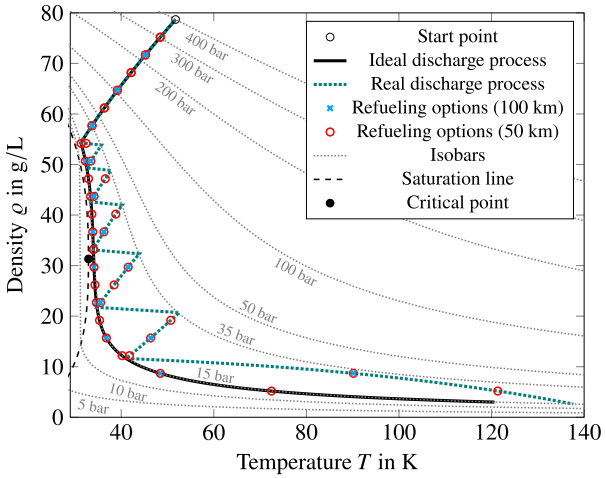

**Figure 6.** Discharge process with markers for refueling stations which are located every 100 or 50 km.

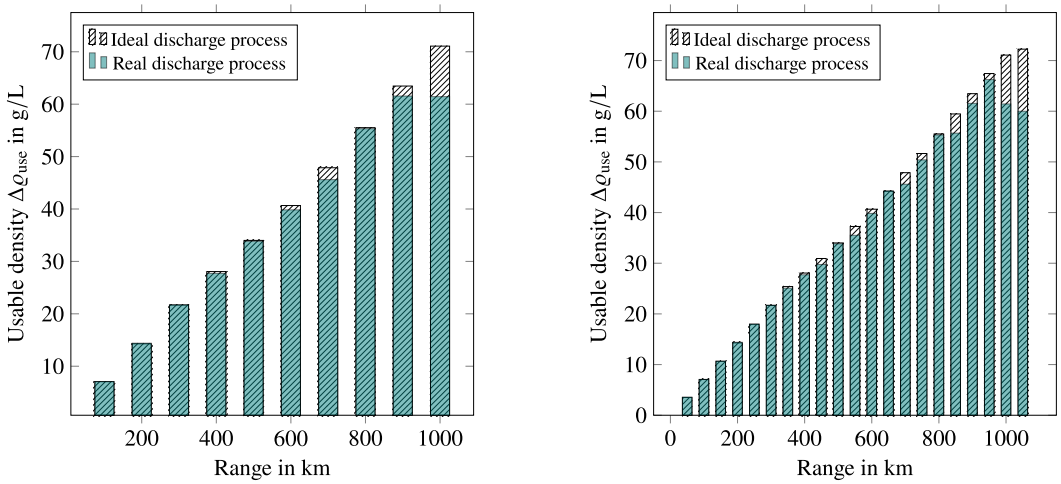
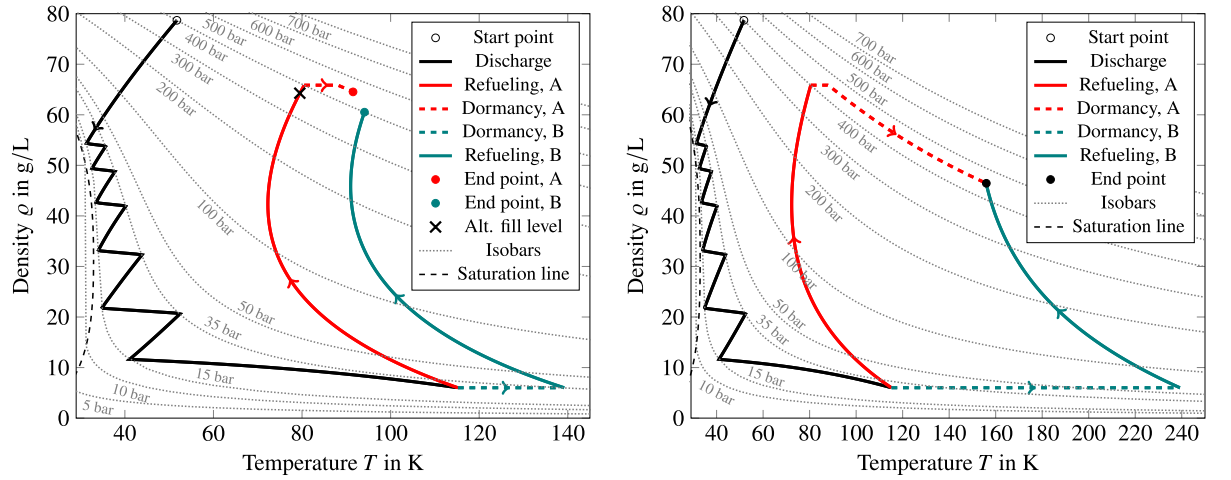


In the 50 km case, the third last stop option is the preferred one. Here, the refueling stop happens just before the next heating period starts. Thus, almost the usable density of the ideal iHEX process is reached. Stopping at the last option, however, would even be worse than the fourth last stop in terms of usable density.

## Case Study 2: Long Dormancies

In a second study, the effect of longer dormancies, e.g., when the truck is parked for the weekend, on the drive cycle operation is investigated. First, the truck is driving until the stop density $\varrho_{\mathrm{stop}} = 6.025\ \mathrm{g/L}$ is reached. Then, it can either be refueled before being parked for the weekend for 62 h (A), or afterward, before starting the next drive after the weekend (B). Figure 7(a) shows both options in a $(T, \varrho)$-diagram.



In both cases, temperature and pressure rise during dormancy due to heat leaking into the tank. When, in (A), the pressure reaches the venting pressure $p_{\mathrm{vent}}$ after more than 36 h, hydrogen is vented. Further, since the stop density is reached during a heating period, the refueling process is not ideal. Nevertheless, at the end of the cycle, the tank in (A) is fuller than in (B), where the empty truck is parked for the weekend and refueled after the dormancy, which prevents venting. In (B), the refueling conditions are worse than in (A) as the tank has warmed up during dormancy. Additionally, the temperature increases faster in an empty tank. Thus, even though in (A) 1.27 g/L of fill density is lost due to venting, a 4.06 g/L higher fill density is achieved. With a consumption of 7 kg per 100km, this translates to roughly 30 km extended range, enabling higher route flexibility and less refueling stops. However, as venting also means economic loss, an economically optimal operation can only be determined if all economic parameters are known.

For longer dormancy, the difference between the endpoints of (A) and (B) becomes smaller, and eventually, there is a turnover point. As it is assumed that in (B) the truck starts driving right after refueling, it could be filled, as compared to (A), to the venting pressure $p_{\mathrm{vent}}$. Considering this procedure, the turnover point is calculated by minimizing the difference in storage density at the end of (A) and (B) with `fminbnd`. Figure 7(b) shows the drive cycle with a dormancy of the calculated turnover point (27.5 days). At this point, 19.4 g/L are vented for case (A). Consequently, depending on whether venting should be prevented or the driving range maximized, an operation strategy can be chosen.

(a) Refueling stations located every 100 km (b) Refueling stations located every 50 km

**Figure 7**. Usable density for limited availability of refueling stations.

(a) Drive cycle with 62 h dormancy

(b) Drive cycle at turnover point (27.5 days)

**Figure 8**. Drive cycles of real iHEX consisting of (A) discharge, refueling, and dormancy, and (B) discharge, dormancy, and refueling.

Alternatively, by refueling slightly less than the fill pressure, venting can be fully avoided while still ensuring high fill density. For the 62 h dormancy, this could be achieved by filling to 369.2 bar instead of 400 bar, resulting in a fill density of 64.27 g/L slightly below the final density of case (A) (64.58 g/L). The alternative fill density is marked in Figure 7(a).

## CONCLUSION

The presented study combines a dynamic thermodynamic model of a $CcH_2$ tank for trucks with surrogate quasi-steady-state heat exchanger models based on ANNs. Therefore, this model allows for fast and low-complexity simulations. The resulting system model is used for several case studies, demonstrating the influence of driving strategies on driving ranges and boil-off losses.

## ABSTRACT

Dynamic modelling of wind turbines and their simulation is a very useful tool for studying their behaviour. One of the key elements concerning the physical models of wind turbines is the power coefficient *Cp*, which acts as an efficiency in the extraction of power from the wind. Unfortunately, this coefficient is often unknown a priori, as it does not usually appear in the information provided by manufacturers. This paper first describes a methodology for obtaining the power coefficient parameters of a commercial wind turbine model using the power curve provided by the manufacturer, which indicates the theoretical power that the wind turbine can produce at each wind speed. To achieve this, a parameter estimation problem is formulated and solved to determine the power coefficient parameters. Nevertheless, this information is often insufficient, requiring additional knowledge, such as operational data, to improve the fit. Finally, a new parameter estimation is performed using only real data measured from the process, validating the proposed methodology. The operational dataset was obtained from the SMARTEOLE project in France and corresponds to the pitch-controlled variable-speed Senvion MM82/2050 wind turbine.

## INTRODUCTION

As the world shifts towards renewable energy production, wind power has become a key player in reducing our dependence on fossil fuels. Wind turbines and their control systems are now more sophisticated than ever; however, they still face challenges such as wind fluctuations, maintenance costs, and the integration of wind power into the electricity market. To address these issues, digital twin technology is emerging as a promising solution, offering real-time virtual models that optimise wind turbine performance and reliability. This approach aligns with the WindEurope [1] roadmap for the digital wind sector in 2030, which defines the digital technologies to be implemented and aims to develop a comprehensive digital twin. A digital twin is essentially a virtual replica of a physical wind turbine (or a wind farm), continuously updated with real-world data [2]. This technology allows operators to monitor performance in real-time, predict failures before they occur, and adjust operations for maximum efficiency. This study explores a methodology on how to use the measured data to improve wind turbine models for dynamic simulation, which is the basis of a digital twin, specifically the power coefficient behaviour in different scenarios of wind speed, rotor speed, and blade pitch angles for a commercial wind turbine model. One of the most significant variables in the development of a macroscopic mathematical model of a wind turbine is its power coefficient. This coefficient, which will be described later, is crucial for calculating the electrical power supplied by the turbine; nonetheless, it is not typically provided by turbine manufacturers.

This study first describes the methodology for estimating the wind turbine power coefficient using data typically provided by turbine manufacturers, followed by the fitting procedure used when real data are available. The fitting results are then presented for three cases: (Fit 1) based only on real manufacturer data, (Fit 2) using manufacturer data corrected with certain knowledge from process measurements, and (Fit 3) relying solely on real process measurements, which improves the accuracy of the power estimations and validate the proposed methodology. Finally, the results are discussed, followed by

the conclusions and suggestions for future work.

## $C_P$ ESTIMATION WITH MANUFACTURER'S DATA

In the majority of cases, the information we can obtain from the wind turbine manufacturer's data is limited. Usually, we only have the power curve and some design characteristics of the turbine, such as the length of the blades, the wind speed range in which the wind turbine operates, the type of control system used to limit the generated power or regulate the rotor speed, the mechanical and electrical efficiency, or the air density. The power curve in Figure 1 relates the evolution of the electrical power generated by the turbine to the different wind speeds between the cut-in wind speed (the one from which the turbine starts to generate power) and the cut-out speed (the one from which the turbine is braked to preserve the integrity of its elements).

Even so, with this limited information, a family of power coefficient curves *Cp*() can be obtained for implementation in our models to perform dynamic simulations of wind turbines and wind farms. The power coefficient can be understood as the efficiency of the turbine in extracting the power contained in the wind and depends, among other variables, on the commercial model of the turbine or the characteristics of the wind in the area where the turbine is installed.

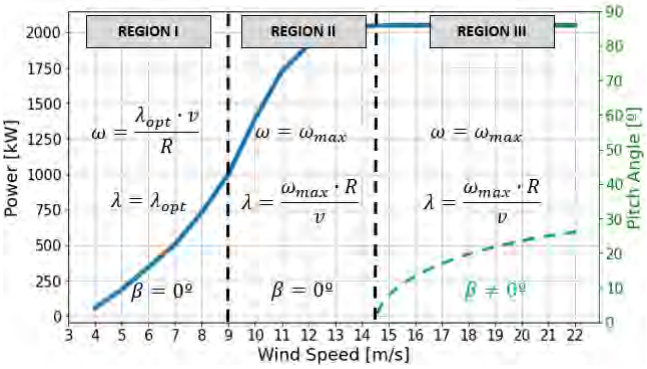

**Figure 1.** Power curve for the Senvion MM82/2050 turbine model [3].

However, the variables that affect the power coefficient can be reduced to two: the specific speed coefficient (or tip-speed ratio) $\lambda$, which is the quotient between the linear speed at the tip of the blades and the speed of the wind speed upstream of the turbine rotor, and the pitch angle $\beta$ (in the case that the turbine has a pitch control system), which is the angle formed by the blades with their rotation plane. This angle can be modified to reduce or increase the blades' resistance to the wind (and therefore, reduce or increase the power generated).

$$\lambda = \omega_r \cdot R / v \tag{1}$$

where $\omega_r$ is the rotor speed in rad/s, $R$ is the rotor radius in meters, and $v$ is the wind speed upstream of the rotor in m/s.

The theoretical limit for the power coefficient, known as the Betz limit, is 0.59 [4]. That is, for an ideal turbine, it is possible to harness only 59% of the power contained in the wind upstream of the rotor. In real turbines, this amount is always less, as will be shown later. The power coefficient can be modelled in three ways: following a polynomial equation, a sinusoidal equation, or an exponential one. The exponential equation has been found to work well for turbines with variable pitch and speed control [5], which is the type of turbine that is the focus of this study [6-7].

$$C_p(\lambda,\beta) = C_1\left(\frac{C_2}{\lambda_i} - C_3\beta - C_4\beta^{C_5} - C_6\right)e^{\frac{-C_7}{\lambda_i}} \tag{2}$$

$$\frac{1}{\lambda_i} = \left(\frac{1}{\lambda + C_8\beta}\right) - \left(\frac{C_9}{\beta^3+1}\right)$$

The generated power can be calculated by Equation (3) in terms of wind speed, power coefficient, and air density $\rho$ in kg/m$^3$.

$$\hat{P} = \frac{1}{2}\rho\pi R^2 v^3 C_P(\lambda,\beta) \tag{3}$$

The idea is to estimate the $C_k$ parameters of power coefficient (2) that make that curve replicate the behaviour of a given turbine for different $\lambda$ and $\beta$ values, which in turn will result in the power calculated with (3) replicating the actual power generated. The parameter estimation problem was formulated as a nonlinear optimisation problem, as described below, and solved using Pyomo 6.4.2 [8] in a Python environment using the IPOPT solver.

The aim of the optimisation problem (4) is to minimise, for each wind speed $v_i$, the error between the theoretical power of the manufacturer's curve $P_i$ and the power calculated using (3).

$$\min_{\{c_k,\beta_j\}} \sum_i \left(P_i - \hat{P}_i(\lambda_i,\beta_i)\right)^2 \tag{4}$$

To establish the constraints, it must be understood how the power curve behaves for each range of wind speeds. As shown in Figure 1, power curves can be divided into at least three regions owing to different operation conditions based on the wind speed value at each moment. Region I extends from the cut-in wind speed to the speed at which the rotor reaches the maximum speed. In region I, the pitch angle equals zero and the tip-speed ratio value is optimal as a consequence of *the maximum power point tracking* system (MPPT) [9]. Region II extends from the wind speed in which the maximum rotor speed is reached to the rated wind speed, when the generated power reaches its rated value. This region is characterised by a constant rotor speed (at its maximum value); therefore, the tip-speed ratio only varies with wind speed, and the pitch angle is still zero.

Region III extends from the rated wind speed to the cut-off wind speed, and between them there is an increase in the pitch angle, with the rotor speed value being constant at its maximum value.

The optimal tip-speed ratio for a pitch angle of $\beta$ = 0 (with wind speed values below the rated wind speed) is obtained by deriving expression (2) and equalling it to zero. The result is a relationship between the parameters $C_k$, as shown in (5). Moreover, this value must be equal to that obtained by calculating the tip-speed ratio with the rated rotor speed and the wind speed at which the maximum power coefficient is reached, which can be determined by clearing *Cp* from expression (3) and substituting *P* for the value obtained from the theoretical curve (assuming an ideal generator efficiency of 1 and standard air density of 1.225 kg/m$^3$).

$$\lambda_{opt} = \frac{C_2 * C_7}{C_2 + C_6 * C_7 + C_2 * C_7 * C_9} = \frac{\omega_{max} \cdot R}{v_{C_{p,i,max}}} \quad (5)$$

Pitch angle $\beta$ is zero for wind speed values less than the rated speed (6) but positive and increasing values with wind speed for wind speed above rated speed.

$$\beta_j = 0 \; \forall \; v_i \leq v_{rated}; \; 0 < \beta_j < \beta_{j+1} \; \forall \; v_i > v_{rated} \quad (6)$$

In addition, certain parameters $C_k$ must have positive values (7) to enable equality (5) to be true and to maintain the structure of term $\beta^{C_5}$ of equation (2).

$$[C_2, C_5, C_6, C_7, C_9] > 0 \quad (7)$$

There is no a priori information on how the pitch angle $\beta$ grows with wind speed. Only the moment when it starts increasing and the final pitch angle value at the cut-off wind speed are fixed, assuming typical wind turbine values.

## $C_P$ ESTIMATION WITH MEASURED DATA

The data used for this study belong to the SMARTEOLE project, which studied a wind farm in France with seven wind turbines [10], whose layout is shown in Figure 2. The manufacturer's data and the power curve of the Senvion MM82/2050 wind turbine model are presented in Table 1 and Figure 1, respectively. The objective of that project was to study the interactions between the different turbines that make up the wind farm in order to develop a wake-steering control system, which consists of misaligning the rotor of the turbines that are first affected by the wind in order to deflect the wakes that appear behind the rotor so that the downstream turbines are affected by them as little as possible, resulting in an overall increase in the available power in the wind farm. Data were recorded between 17 February and 25 May 2020 with a resolution of 1 min.

This study focuses on the SMV1 turbine because it is close enough to the *WindCube V1* measurement system, as will be explained later.

The necessary measured data to perform the calculations are *active power*, *blade pitch angle*, *wind speed*, *wind direction*, *nacelle position*, and *generator speed*. However, the rotor speed, which is the one we are interested in to obtain $\lambda(1)$, is not measured, but the generator rotational speed is measured, and the gear ratio is known. Therefore, under the assumption that the transmission is ideal (without losses), the rotor speed can be obtained as the quotient (8) between the generator speed $\omega_g$ and gear ratio *N*.

$$\omega_r = \omega_g / N \quad (8)$$

Next, the raw data are filtered to ensure that the dataset contains adequate and reliable information using the following criteria: i) The misalignment (*yaw error*) must be less than 0.1, to consider only situations where the turbine is fully aligned with the wind direction. ii) The generator speed must be positive. iii) The measured wind speed must fall within the turbine's operating range ($v_{cut\text{-}in} < v < v_{cut\text{-}off}$). iv) The generated power (active power) should be positive. As a result, the filtered dataset contains 1,131 points instead of the initial 134,661.

In addition to this filter, all negative but near-zero values of the pitch angle $\beta$ were replaced with zero, considering them as measurement errors, preventing errors in the calculation of the power coefficient.

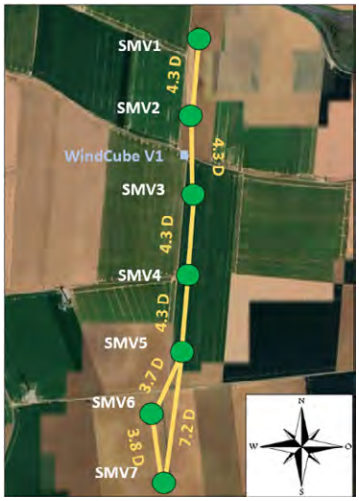

**Figure 2.** Wind farm layout [11].

An initial hypothesis is that the wind speed measured at the turbine is downstream of the rotor and, therefore, does not correspond to the upstream wind speed (with which the manufacturer's power curves are represented) but to a lower speed resulting from the decrease in wind power as it passes through the rotor.

To discard this initial hypothesis, a new filter is added to the data to have only west wind directions between 250º and 290º, so that the wind speeds measured by the *WindCube V1* system and at the turbine are not

affected by the wakes of other turbines. As shown in Figure 3, it is not clear whether one wind speed measurement is higher or lower than the other. Therefore, it is assumed that the wind speed measured at the turbine has been corrected to represent the upstream wind speed values. For calculation purposes, this corrected wind speed was used.

**Table 1:** Senvion MM82/2050 parameters.

| Parameter | Value | Units |
|---|---|---|
| Rated Power | 2050 | kW |
| Rotor Diameter | 82 | m |
| Power Control System | Pitch | |
| Min. rotor speed | 8.5 | rpm |
| Max. rotor speed | 17.1 | rpm |
| Cut-in wind speed | 4 | m/s |
| Rated wind speed | 14.5 | m/s |
| Cut-off wind speed | 22 | m/s |
| Gear ratio (*N*) | 106 | |
| Generator type | DFIG | |
| Max. Generator speed | 1800 | rpm |

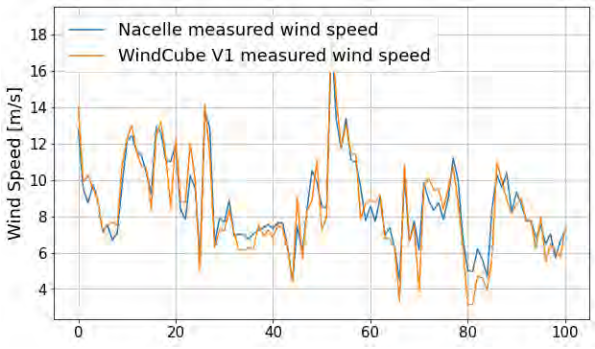

**Figure 3.** Measured wind speeds between 250° and 290° wind directions.

A crucial difference with respect to the previous estimation problem is the availability of pitch angle $\beta^m$ and wind generator speed $\omega_g^m$ measurements for each wind speed; therefore, it will not be necessary to approximate its behaviour using any of the constraints from Fit 1 and 2. Thus, the estimation problem was formulated as the optimisation problem (9) subject to (10), where the only decision variables are the $C_k$ parameters of the power coefficient curve (2). $P_i^m$ and $v_i^m$ represent the active power and wind speed measurements for each point *i* out of the 1131 points in the dataset, respectively.

$$\min_{\{C_k\}} \sum_i \left(P_i^m - \hat{P}_i(\lambda_i, \beta_i^m)\right)^2 \tag{9}$$

subject to:

*Power Coefficient Curve (2)*

$$\hat{P}_i = \frac{1}{2}\rho\pi R^2 (v_i^m)^3 C_P(\lambda_i, \beta_i^m)$$

$$\omega_{r,i} = \omega_{g,i}^m / N; \;\; \lambda_i = \omega_{r,i} \cdot R / v_i^m \tag{10}$$

$$[C_2, C_5, C_6, C_7, C_9] > 0$$

As mentioned before, the rotor speed is known at all times and is calculated using (8) so that the tip-speed ratio λ can be calculated directly using (1).

## RESULTS

The results of the three parameter estimation problems are shown below: using theoretical manufacturer's data (Fit 1), using theoretical manufacturer's but corrected data (Fit 2), and using measured real data (Fit 3).

### Parameter estimation with theoretical manufacturer's data (Fit 1)

Using the data from the theoretical power curve and those in Table 1, optimisation problem (4) was solved. The parameters of the power coefficient are shown in Table 2, and the family of power coefficient curves for different combinations of λ and *β* is shown in Figure 4. The maximum *Cp* value of 0.578 was reached at λ = 13 for *β* = 0. It can then be said that for *β* = 0, the optimal λ is 13. From this maximum, as both λ and *β* vary, *Cp* decreases. Moreover, if the *Cp* curve is divided into two regions for each pitch angle (to the left of optimal λ, and to the right of optimal λ), the turbine will generally work in the left region, since the opposite would imply that λ is higher than the optimal for wind speeds lower than rated, or that the rotor speed keeps increasing its speed from the rated one for wind speeds equal to or higher than rated (which does not happen, the rotor speed remains constant at its rated value from the moment it reaches it).

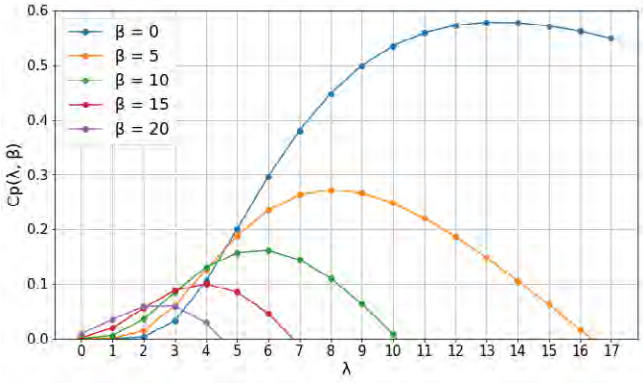

**Figure 4.** Power coefficient curves for Fit 1.

However, looking at the measured data in Figure 5, it is clear that some of the assumptions made do not correspond to the actual wind turbine behaviour. For example, the pitch angle starts to increase between 11 and 12 m/s, whereas initially this was assumed to occur from 14.5 m/s (rated wind speed $v_{rated}$). On the other hand, the rotor speed stabilises at its maximum value of 17 rpm for winds above 8 m/s, being the initial assumption that this occurred at 5.5 m/s.

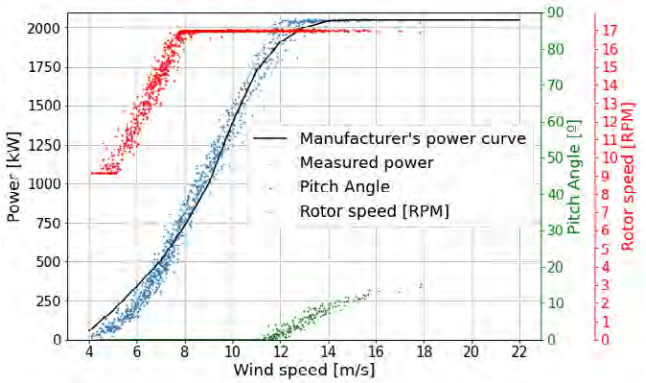

**Figure 5.** Actual power, pitch angle, and rotor speed data.

## Parameter estimation with theoretical manufacturer's corrected data (Fit 2)

Therefore, a second fitting is made by changing to 8 m/s the value of the wind speed at which the rated rotor speed is reached, and indicating that the pitch angle should start to grow from a wind speed of 12 m/s. The new family of power coefficient curves for different combinations of $\lambda$ and $\beta$ is shown in Figure 6, and the parameters of the power coefficient are also shown in Table 2.

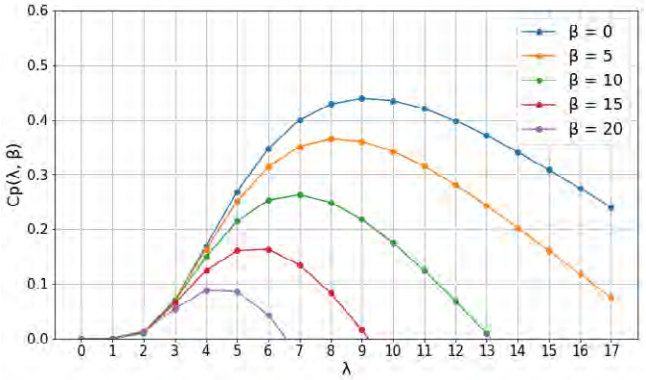

**Figure 6.** Power coefficient curves for Fit 2.

The solutions of the first problem and the new one are compared in Figure 7. In both cases, the pitch angle for the cut-off wind speed has been forced to be 20º (looking at the measured data, this seems reasonable). It can be observed that the new fitting is better than the first one owing to the incorporation of additional turbine performance information obtained from measured data.

## Parameter estimation with measured real data (Fit 3)

Using the measured real data and those in Table 1, the optimisation problem (9) is solved. Table 2 shows the solution for the $C_k$ parameters of the power coefficient curve. Next, Figure 8 shows how the family of power coefficient curves complies with all mentioned in the previous sections and also takes lower values than those of the case with theoretical data (Fit 1). By obtaining the curves from the measured data, all the inefficiencies that occur in the actual operation are included.

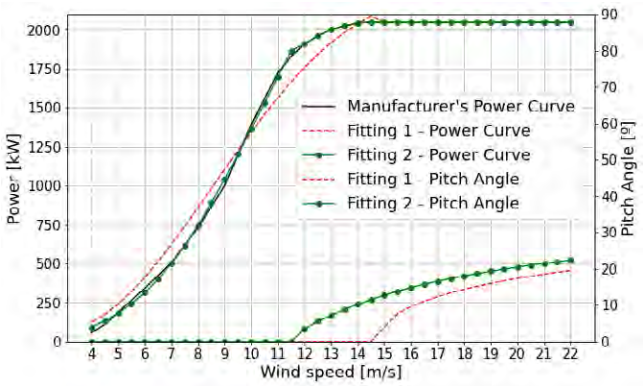

**Figure 7.** Fit 1 and 2 power curve comparison.

Figure 9 shows a comparison between the measured power, the power calculated with the coefficients of Figure 8, and the manufacturer's power curve, as well as the measured pitch angles. The fit is quite good in general, being worse at the starting zone (between 4 and 7 m/s), caused among other reasons by not having considered the changes in air density (all calculations have been made with a standard density of 1.225 kg/m$^3$) and by the influence of transient periods during braking of the turbines at low wind speeds or starting the turbines when the wind speed is again above the cut-in speed ($v_{in}$).

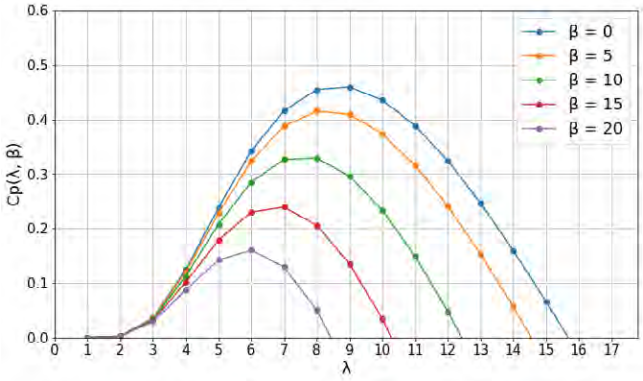

**Figure 8.** Power coefficient curves for Fit 3.

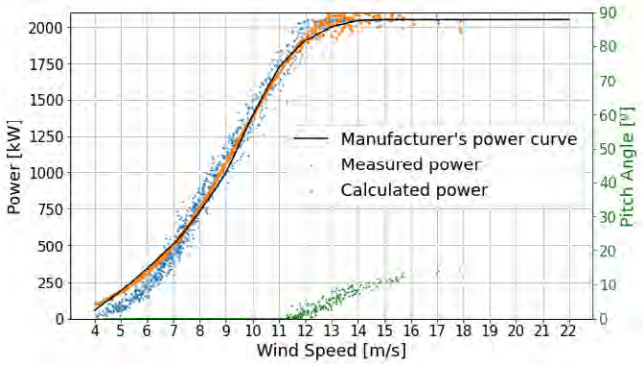

**Figure 9.** Calculated (fit 3), measured and theoretical power curves, and measured pitch angle.

**Table 2:** Power coefficient parameters for the three fits

| Decision variables | Initial values | Fit 1 values | Fit 2 values | Fit 3 values |
|---|---|---|---|---|
| $C_1$ | 1.0148 | 0.109 | 0.077 | 0.00029 |
| $C_2$ | 417.108 | 345.896 | 410.740 | 281927.469 |
| $C_3$ | 0.918 | 1.497 | 0.436 | 7.547e-08 |
| $C_4$ | 0.0021 | 3.540 | 0.071 | 97.864 |
| $C_5$ | 2.569 | 0.436 | 2.103 | 1.689 |
| $C_6$ | 37.058 | 5.702 | 16.491 | 17884.972 |
| $C_7$ | 28.642 | 17.868 | 14.739 | 19.278 |
| $C_8$ | 0.048 | 0.127 | 0.0032 | 0.0 |
| $C_9$ | 0.0 | 0.0024 | 0.00097 | 0.00033 |

## CONCLUSIONS AND FUTURE WORK

In this study, a methodology was developed to obtain power coefficients for use in digital twins. The methodology was tested with different levels of available information. After performing the three fits with different information, some conclusions can be drawn.

The first fitting, only with theoretical data from the manufacturer, can be useful to implement in a turbine model for dynamic simulations, since, roughly speaking, the power behaviour is being replicated with more or less accuracy. As for the pitch angle, those are obtained that make all the other constraints met, so they would also be useful, even though they may not be exactly the actual pitch angles. From the discrepancies observed between the initial assumptions and the measured real data of the turbine, the theoretical data are adjusted by correcting the wind speed value at which the rated rotor speed is reached and the wind speed at which the pitch angle starts to grow. It can be seen how the fitting improves, since the information it incorporates is more similar to that obtained from a real operating turbine. It can also be seen in the power coefficient curve families that the values reached for different pitch angles in fit 2 are closer than those in fit 1 curves to those obtained in fit 3, where wind turbine operating data are incorporated into the estimation problem. Finally, the solution to this new estimation problem enables an accurate estimation of the power coefficient *Cp* of a real wind turbine, which can then be included, for example, in a detailed dynamic simulation of a wind farm.

A future line of work is to implement these curves in wind turbine and wind farm models for dynamic simulation, which are intended to be fed with real operating data to update these models with new information. Just as the transition from Fit 1 to Fit 2 has been greatly improved by including more data, the idea is that by gradually incorporating more information into the model, it will become more precise in representing reality. It is also necessary to test this methodology in situations where the measured wind speed that appears in the data is the downstream wind speed without any correction, when the upstream wind speed is unknown, and also when the wind turbines are misaligned to the wind direction.

## ACKNOWLEDGEMENTS

This work is part of the project “Optimal real-time management under uncertainty for digital twins (Opti-Dit)”, PID2021-123654OB-C33, funded by the MCIN/AEI and by the European Union “FEDER”.

## ABSTRACT

This study evaluates the potential for computer-aided real-time monitoring and decision-making in pilot-scale ion-exchange chromatography operations using only historical data from the pilot-scale facility. Historical data of flow and conductivity were utilized from students running pilot-scale ion exchanges that resemble industrial ion exchange processes. A Lumped Rate Model (LRM) with a Steric Mass Action (SMA) isotherm was implemented and parameterized to characterize the fixed-bed column. The Discontinuous Galerkin Spectral Element Method (DGSEM), implemented in CADET-Julia, enabled efficient simulation and parameter estimation. Using DGSEM, the LRM with SMA was solved in less time than the sensor measurement frequency. This development allows for the prediction of batch evolution in real time for operators of the ion-exchange column. Despite challenges related to data preprocessing and manual operation inconsistencies, the results demonstrate the feasibility of integrating real-time analysis into pilot-scale operations.

**Keywords**: Ion-exchange chromatography, Real-time analysis, Pilot-scale, Computer-aided, Modelling, DGSEM

## 1. INTRODUCTION

Chromatography constitutes an important part of downstream bio-manufacturing, where it is used to separate valuable products of upstream production. Precise control over chromatographic processes aids in increasing product yield. Current conservative operational strategies sometimes lead to product loss, which may be remediable with real-time process insights [1].

Batch-to-batch variations in feed composition and operating conditions further complicate achieving optimal yields [2]. Improved understanding and monitoring of separation processes could enable operators to account for batch-to-batch variation, increasing yields without sacrificing product quality [2].

The complexity of chromatographic processes arises from their underlying mechanisms, which can be described using partial differential equations (PDEs) that model advection, diffusion, mass transfer, and adsorption. To enable real-time applications involving systems governed by PDEs, fast discretization methods are essential for solving these equations accurately and efficiently.

This study investigates the potential for real-time process analysis using a pilot-scale ion exchange column at the Technical University of Denmark (DTU) pilot facility. For more details on this facility, see [3]. Here, an ion exchange fixed-bed column equipped with sensors is used as a teaching instrument. The column and the exercises run on it resemble operations encountered in industrial ion exchange operations. The system is equipped with sensors that automatically log measurements every two seconds.

There exist historical data sets of these sensor measurements for experiments run by students from 2019 onwards. In this case, students use the data to perform calculations relating to upscaling the process. Beyond this, the data is not employed for other purposes. This has some resemblance to industrial process systems, where sensors are placed on systems for monitoring and quality control purposes, and process optimization using historical data is an afterthought. This study will evaluate whether the fixed-bed column can be characterized solely by historical data and whether such data provides a sufficient foundation for real-time process applications.

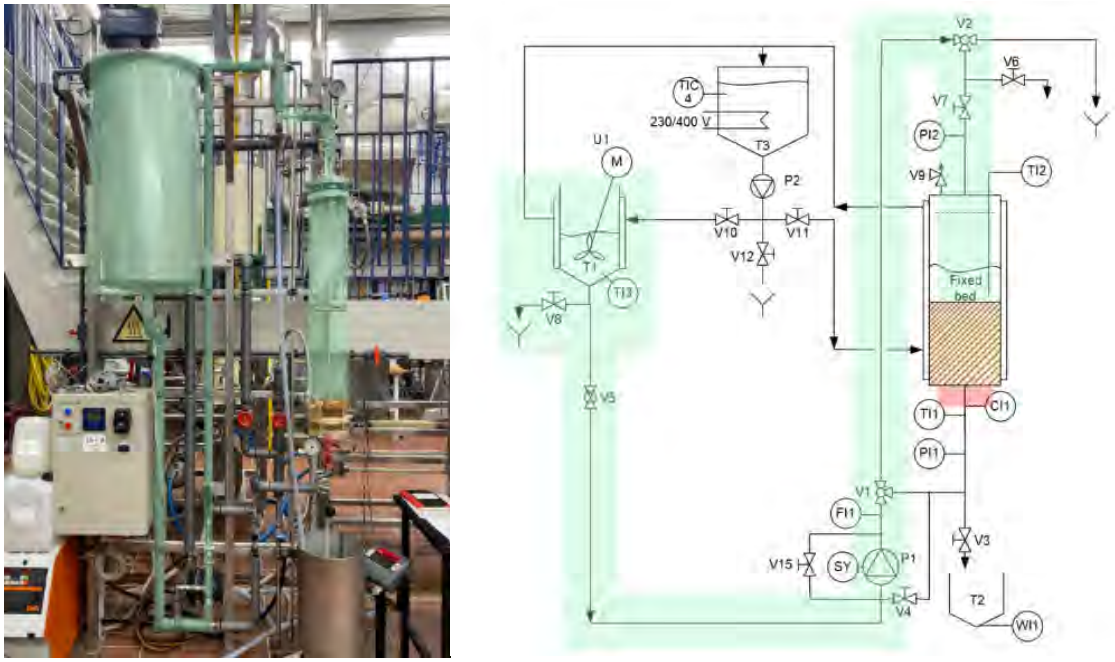

**Figure 1:** (Left) An image of the pilot-scale fixed-bed ion exchange column and (right) P&I diagram for the pilot-scale ion exchange fixed-bed column [8]. The green, orange, and red sections on both the image and the P&I diagram represent the in-flow pipes, the fixed-bed column, and the out-flow pipes, respectively.

## 2. METHODOLOGY

### 2.1 Scoping

There are two subjects of interest in this study. First is the ability to simulate operation of the ion-exchange system based entirely on historical data. The historical data gathered by students was not intended for applications such as those suggested in this study but rather as data to support other investigations. Here, this study investigates the degree to which this data can be repurposed for column characterization and process simulation.

Secondly, the study will investigate if, by using computationally fast numerical schemes, the ion-exchange breakthrough process can be simulated in less time than the measurement frequency of every two seconds. Achieving this would support the development of real-time applications, as the numerical scheme could be solved uniquely for each data point that is gathered. A real-time application of interest in this setting would be the prediction of the breakthrough profile, enabling feedback to the operators of the system as they operate the system.

### 2.2 Experimental Methods

The data used for this study stems from exercises performed by chemical engineering students at DTU [8]. The goal of the exercise is for students to evaluate breakthrough curves during the operation and regeneration of an ion-exchange system, and to determine isotherms and resin properties for scaling up a pilot plant unit.

#### Pilot Plant Setup

The experimental setup features a 10 cm diameter, 1 m tall column occupied by a fixed-bed ion exchange resin. In Figure 1, a piping and instrumentation (P&I) diagram for the system can be seen. The feed solution, stored in a 100 L tank (T1), is pumped through the column. The system includes the following instrumentation:

- Flow-through cell (CI1): Measures conductivity
- Magnetic flow indicator (FI1): Measures flow rate
- Pt100 sensors (TI1 & TI2): Monitor temperature
- Manometer (PI1): Records pressure

Data for time, flow, conductivity, temperature, and pressure are logged automatically every 2 seconds. The resin used is Amberjet 1200 in H-form. The operator must manually control the system by configuring the pump spend and configure valve settings.

#### Experimental Procedure

30 L of 0.1 N $NaNO_3$ feed solution is prepared by dissolving $NaNO_3$ in water, mixing thoroughly for homogenization, and transferring it to the feed tank.

Next, The feed solution of $NaNO_3$ is pumped through the column at a flow rate of 50-80 L/h. Exit flow and conductivity were recorded automatically. The process continued until an S-shaped curve was observed in the conductivity.

Finally, 10 L of water is pumped through the system and column to remove any $NaNO_3$ in the mobile phase.

During all operations, the operator must manually adjust flow rates and the water height inside the column by adjusting valve V3. This is to ensure the resin is always submerged, and to limit excess water in the column.

## 2.3 Modelling

To describe the ion-exchange chromatography process, the Lumped Rate Model (LRM) with the Steric Mass Action (SMA) was used. The LRM and the SMA isotherm are given for each component $i \in \{1, \dots, N_C\}$ in eq. (1)-(2).

$$\frac{\partial c_i}{\partial t} = D_{\text{ax}} \frac{\partial^2 c_i}{\partial z^2} - u \frac{\partial c_i}{\partial z} - \frac{1-\varepsilon}{\varepsilon} \frac{\partial q_i}{\partial t}, \tag{1}$$

$$\frac{\partial q_i}{\partial t} = k_{\text{kin},i}\left(k_{\text{eq},i} c_i \bar{q}_0^{\nu} - q_i c_0^{\nu}\right). \tag{2}$$

Here, $t$ is time, $c_i$ is the mobile phase concentration of component $i$, $q$ is the corresponding stationary phase concentration, $z$ is the spatial coordinate, $D_{\text{ax}}$ is the axial dispersion coefficient, $\varepsilon$ is the total porosity, $k_{\text{eq}}$ is the equilibrium adsorption constant, $k_{\text{kin}}$ is a kinetic constant, $\overline{q_0} = q_0 - \Sigma_j^{N_c} \sigma_j q_j$ is the number of free binding sites where $q_0$ is the bound salt concentration and $\sigma$ is the steric hindrance factor. The bound salt concentration is given by electroneutrality as $q_0 = \Lambda - \Sigma_j^{N_c} \nu_j q_j$ where $\Lambda$ is the ionic capacity and $\nu$ is the characteristic charge. The boundary conditions are given in eq. (3)-(4), respectively.

$$uc_{\text{in},i} = \text{uc}_i(t,0) - D_{\text{ax}} \frac{\partial c_i(t,0)}{\partial z}, \tag{3}$$

$$\frac{\partial c_i(t,L)}{\partial z} = 0, \tag{4}$$

where $L$ is the column length and $c_{\text{in}}$ is the inlet concentration. If assuming isotherm equilibrium, the equations eq. (1)-(2) must be discretized and solved as a differential algebraic equations system, setting eq. (2) equal to 0. Alternatively, one can set a large $k_{\text{kin}}$, value to approximate the equilibrium and still discretize and solve the system as an ordinary differential equation (ODE) system [4]. To solve the PDEs in eq. (1)-(4), the spatial domain of eq. (1) was discretized using the Discontinuous Galerkin Spectral Element Method (DGSEM) derived by Breuer et al [5]. The resulting system of ODEs was solved using the QNDF solver which is a stiff backwards differentiation formula solver using DifferentialEquations.jl [6,7].

### Column Characterization

To model the pilot-scale ion exchange fixed-bed column, CADET-Julia was used [4]. In Table 1, all values used for simulating the ion exchange system can be seen. The system was represented as three serially connected segments: the in-flow pipes, the ion exchange column itself, and the out-flow pipes. In Figure 1, this segmentation can be seen with respect to the physical system. Approximate measurements of pipe length and radii were used for the in-flow and out-flow sections. For the simulation, the value of the axial diffusion coefficient in the pipes, $D_{\text{ax, pipes}}$, was set to $10^{-3}$ $m^2/s$. This value was heuristically chosen to balance minimizing diffusion in the pipes while avoiding an excessively stiff system that would significantly increase the computational time.

For each batch, the median flow rate was calculated and applied as a constant flow in the simulated runs. The median flow was chosen to make the data cleaning more robust towards transmitted values that were deemed outliers. In some cases, pump start-ups were modelled by fitting flow profiles with second- or third-order polynomials, before transitioning to a constant flow profile.

The historical data of the washes were used to characterize the axial diffusion coefficient, $D_{\text{ax}}$, and resin porosity, $\varepsilon$. Parameter estimation was done by fitting a single value of $D_{\text{ax}}$ and a single value of $\varepsilon$ across all batches, ensuring they remain constant. Conductivity was converted to concentration by assuming the initial and final conductivity corresponded to concentrations of 0.1 and 0 N $NaNO_3$, respectively.

**Table 1:** Overview of variables used in simulation of the ion-exchange fixed-bed column using CADET-Julia.

| Symbol | Description | Value Used |
|---|---|---|
| $L_{\text{pipes, in}}$ | In-flow pipes length | 6.74 m |
| $L_{\text{pipes, out}}$ | Out-flow pipes length | 0.19 m |
| $L$ | Fixed-bed column length | 0.095 m |
| $r_{\text{pipes}}$ | Pipe radius | 0.005 m |
| $r_{\text{column}}$ | Column radius | 0.055 m |
| $D_{\text{ax, pipes}}$ | Axial diffusion coefficient in the pipes | $10^{-3}$ $m^2/s$ |
| $\sigma_{H^+}/\sigma_{Na^+}$ | Shielding factor | 0 / 0 |
| $\nu_{H^+}/\nu_{Na^+}$ | Characteristic charge | 1 / 1 |
| $k_{\text{kin}}$ | Kinetic coefficient | $10^8$ |

Subsequently, historical breakthrough curve data were used to fit the SMA model parameters: the ionic capacity, $\Lambda$, and the equilibrium coefficient, $k_{\text{eq}}$. Parameter estimation was done by fitting a single value of $\Lambda$ and a single value of $k_{\text{eq}}$ across all batches, ensuring they remain constant.

The ParticleSwarm algorithm from the Optim.jl package was utilized to perform global parameter searches, using the mean absolute error between simulated runs and historical data as the optimization metric [9].

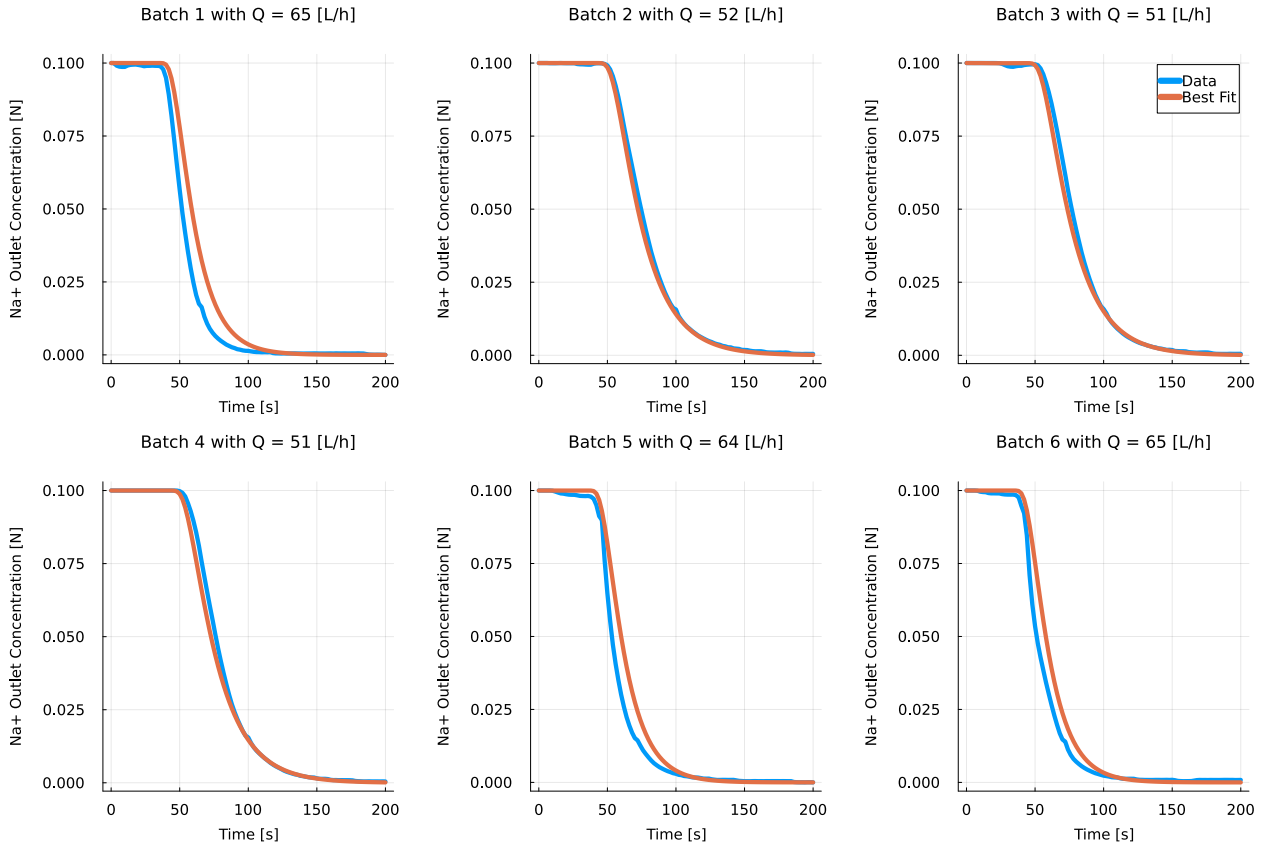

Figure 2: The six batch washes used for estimation of the axial diffusion coefficient, $D_{ax}$ and porosity, $\varepsilon$, alongside simulated runs using best-fit values. Q denotes the median flow rate of the batch.

# 3. RESULTS & DISCUSSION

## 3.1 Parameter Estimation

The batches of wash data were analyzed to estimate the best-fit values for the $D_{ax}$ and $\varepsilon$, which were determined to be $7 \times 10^{-5}$ m$^2$/s and 0.6, respectively. Using these parameter values, Figure 2 illustrates the experimental wash curves alongside their simulated counterparts.

Subsequently, the SMA isotherm parameters $\Lambda$ and $k_{eq}$ were estimated from breakthrough data, which yielded values of 4 eq/L and 3, respectively. Figure 3 presents the experimental breakthrough curves and corresponding simulations.

The LRM with SMA isotherm produces strong fits for both wash data and the breakthrough data. The simulations predict the timing of the initial break of the curve well and follow the same evolution as the observed data.

### Discussion

In Figure 2 and Figure 3, it can be observed that the simulations predict a delayed breakthrough when flow rates (Q) are higher, i.e. Q ≈ 65 L/h, compared to those with lower flow rates, i.e. Q ≈ 51 L/h. This indicates there may be some flow-dependent mechanisms present in the process not entirely explained by the LRM model.

Discrepancies between the simulated and experimental results may stem from uncertainties in the historical data and inconsistent execution across batches. Variations in how operators controlled the water height in the column could have affected the observed conductivity. Additionally, the exact concentration of the $NaNO_3$ solution is unknown; the concentration 0.1 N $NaNO_3$ is assumed based on the exercise instructions. Furthermore, measurement uncertainties in the flow meter and conductivity sensors further contribute to discrepancies between historical data and simulations.

When preprocessing the data, it was observed that parameter estimation was highly sensitive to the choice of $t = 0$, defined as when flow from the feed tank to the column begins. As $t = 0$ was not always clearly discernable, in some batches, it was approximated based on other batches where it was easier to identify. Horizontal translations of the wash curves significantly affected the converged values of the parameter estimation process.

The quality of the available datasets varied noticeably when evaluating historical data for parameter

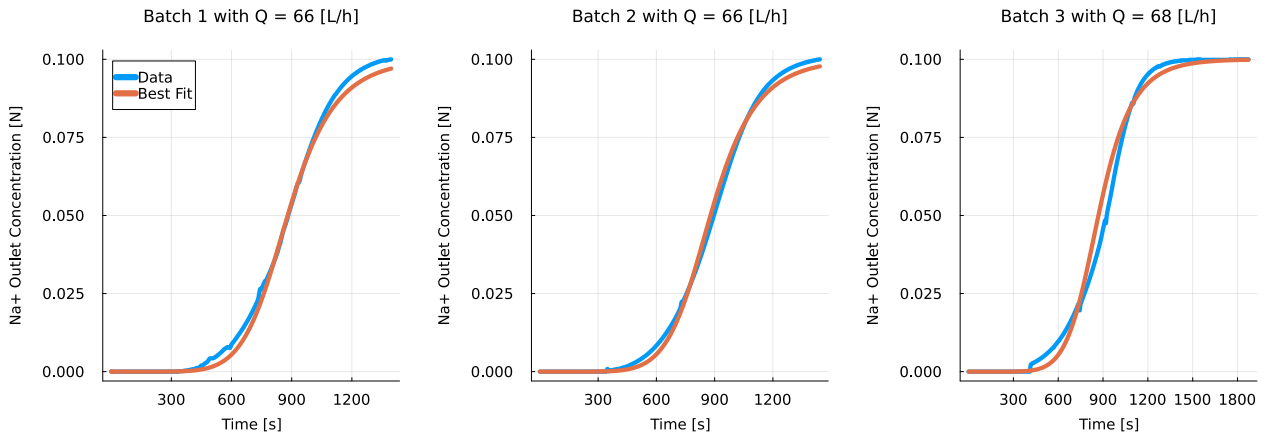

Figure 3: The three batch breakthroughs used for estimation of ionic capacity, $\Lambda$ and equilibrium constant, $k_{\mathrm{eq}}$, alongside simulated runs using best-fit values. Q denotes the median flow rate of the batch.

estimation. Smooth, undisrupted runs were critical to enabling parameter estimation. In this regard, some historical datasets were not considered for parameter estimation, and those used had to be preprocessed to make modeling feasible. The datasets most applicable to parameter estimation were those run by experienced operators conducting experiments for their research. "Data gathered by first-time operators often exhibited signs of process disruption and were rarely as directly usable for parameter estimation, compared to data produced with dedication to the purpose.

## 3.2 Computational Efficiency

In this study, the PDEs described in eqs. (1)–(4) were solved efficiently using DGSEM in CADET-Julia. On an i5-1345U processor (1.60 GHz), the equations were discretized and solved in under two seconds, below the measurement frequency. This was true for both the wash data, each consisting of approximately 100 data points, and the breakthrough data, containing up to 1000 points.

The global parameter searches for all washes and breakthroughs were completed in less than 10 minutes each. Notably, accounting for the inherent uncertainties in the system, adequate parameter values were identified already within the first 1–2 minutes. Additional search iterations refined these values, but the improvements exceed the level of accuracy achievable given the uncertainties present.

### Discussion

The ability to solve the LRM with the SMA isotherm within the 2-second measurement frequency showcases the model's potential for real-time computer-aided applications. In its current the state, the model can predict breakthrough profiles at a speed that enables it to be deployed in real-time. By connecting the model to live data feeds of the flow in the column, the model can alter its predicted breakthrough profile for every new data point.

Currently, the model predicts the entire breakthrough profile from $t = 0$ to the end of the data series, up to some 30 minutes in the future. The computation time can be further reduced by optimizing the routine to avoid redundant calculation on already-past data. The prediction horizon can also be limited, and more powerful hardware can be used to perform calculations.

This may bring the computation time below one second, and effort could then be spent in reducing the sensor measurement frequency to similarly match that. This naively ignores any time taken to retrieve data from the system.

The global parameter search can currently be completed in 1–10 minutes. To further accelerate this, an approach could be employing a local search algorithm with a well-informed initial guess. With tactics like this, the parameter estimation procedure could be reduced to sub-minute computation times.

This may enable real-time parameter adjustment, allowing the system to dynamically adapt to batch-to-batch variations. While it makes little sense for variables like, $D_{\mathrm{ax}}$, $\varepsilon$, $k_{\mathrm{eq}}$, or $\Lambda$ to change between batches, other parameters could be introduced to explain the effects of operating conditions and batch-to-batch variation.

## 3.3 Perspectives

The developed tool can be implemented directly to approximate breakthrough duration during operation. By evaluating the model in real-time, operators can see the impact of adjusting flow on the breakthrough profile.

To enhance the modeling capabilities demonstrated in this study, additional metadata on the process would be beneficial. Specifically, this includes:

- Timestamps for $t = 0$ as the precise point when all the flow from the T1 feed tank is directed into the column.

- Measured concentrations of the $NaNO_3$ solution used for breakthrough.
- Some indication of the operator's ability to maintain the water height within the column.

These lacking metadata mirror challenges frequently faced in industrial systems, where incomplete metadata, missing signals, and absent critical sensors hinder effective modeling.

The investigation has demonstrated the feasibility of characterizing pilot-scale equipment from historical data that mirrors industrial operational data. The methods employed here can be applied to historical data from industrial systems. Using fast numerical schemes or other methods, real-time computer-aided process insights and predictions could be granted to process operators. Parameter search optimizations can be employed for real-time determination of factors that vary from batch to batch.

The approach adopted in this study—leveraging historical data to identify areas of improvement—provides a framework for addressing these challenges. Drawing a clear connection between historical data and its value in developing real-time applications makes it possible to prioritize investments in metadata collection, new sensors, or dsata processing tools. These investments would provide a return in the improved ability to conduct real-time decision-making during operation to increase product yield.

Additional historical data and process understanding could be used to monitor the long-term health and efficiency of the system. In the case of ion-exchange, it could be used to quantify resin degradation and better schedule replacements.

## 4. CONCLUSION

This study demonstrates the potential for real-time analysis of ion-exchange chromatography using historical pilot-scale data of a fixed-bed ion exchange column. Despite challenges such as incomplete metadata and variability in manual operations, the findings confirm that the system can be accurately characterized using only operational historical data

By employing fast computational techniques, the study shows that the system can be modeled in real time, simulating entire breakthrough profiles within the two-second measurement frequency of the system. These findings underscore the potential of using historical data to develop valuable real-time computer-aided process applications in pilot and industrial-scale settings.

## ACKNOWLEDGEMENTS

The authors of this work acknowledge the efforts of students and staff at courses in experimental unit operations at the Department of Chemical and Biochemical Engineering for making data. Additionally, the authors would like to express gratitude to the Novo Nordisk Foundation for their support for the digital infrastructure of pilot facilities through grant NNF19SA0035474.

## ABSTRACT

Clinker is the main constituent of cement, produced in the pyroprocessing section of the cement plant. This comprises some high temperature and carbon intensive processes, which are responsible for the vast majority of the $CO_2$ emissions associated with cement production. This paper presents first-principles mathematical models for the simulation of the pyroprocess section; more specifically the preheating cyclones, the calciner and the rotary kiln. The models incorporate material and energy balances, the major heat and mass transport phenomena, reaction kinetics and thermodynamic property estimation models. These mathematical formulations are implemented in the gPROMS® Advanced Process Modelling Environment and the resulting index-1 DAE (Differential Algebraic Equation) system can be numerically solved for various reactor geometries and operating conditions. The process models developed for each unit are then used to build a cement pyroprocess flowsheet model. The flowsheet model is validated against published data, demonstrating the ability to predict accurately operating temperatures, degree of calcination, gas and solid compositions, fuel consumption and overall $CO_2$ emissions. The substitution of conventional coal with more sustainable fuels is also investigated, to evaluate the potential for avoiding $CO_2$ emissions by replacing part of the fossil-based coal fuel (used as a reference case). Trade-offs between different process KPIs (f.e. calcination efficiency, specific $CO_2$ emissions per tonne of clinker) are identified and evaluated for each fuel utilization scenario.

**Keywords**: Mathematical Modelling, Cement Production, Simulation, Alternative Fuels, Decarbonisation

## INTRODUCTION

The share of cement and concrete value chain to global $CO_2$ emissions is estimated at 6-7% [1]. These emissions originate from a series of several industrial activities. The first step is the extraction and mining of the raw materials, followed by the preparation and processing of them for the production of clinker, the main component of cement. Once clinker is formed, it is cooled and subsequently ground with gypsum and other additives to produce cement. Cement is then mixed with several aggregates, admixtures and water to form concrete. The stage responsible for the vast majority of the $CO_2$ emissions is the thermal processing (pyroprocessing) of the raw materials for the production of clinker.

The pyroprocessing section of a typical cement plant consists of four main processes: the preheating cyclones, the calciner, the rotary kiln and the grate cooler. From these processes, the calciner and the rotary kiln are responsible for almost 90% of the total emissions [2]. These two processes facilitate the chemical transformation of the raw materials into clinker. Specifically, in the calciner calcium carbonate (limestone) is decomposed into calcium oxide (lime) and carbon dioxide. This reaction is responsible for 60% of the total emissions, the so-called process emissions [1]. These emissions are unavoidable in principle since calcium oxide is the most important intermediate in the clinker formation process. After calcium oxide is formed it reacts with all the remaining raw materials (silicon dioxide, ferric oxide, alumina oxide) to form the final clinker product inside the rotary kiln. Most of the chemical reactions described above are endothermic and require a substantial amount of heat, which is provided to the process by internal combustion

of a solid fuel. The emissions due to fuel combustion are responsible for the remaining 40% of the carbon dioxide emissions [1].

The most common fuels used in the calciner, and the rotary kiln are the fossil-based pulverized coal or petcoke. However, the utilization of solid recovered fuels (SRF) is becoming a common practice in cement industry. These fuels originate from municipal solid waste processing and can play a crucial role in the mitigation of the direct $CO_2$ emissions of a cement plant. This is due to the high biogenic carbon content of such fuels, which emissions during combustion are considered neutral [3]. Based on their source and nature, alternative fuels have different chemical and mechanical properties which affect directly their performance upon combustion [4].

The chemical and physical phenomena occurring in the clinker production processes are rather complex and to this day, these processes have mostly been studied and modelled in literature as standalone unit operations. As a result, there is a lack of holistic model-based approaches on flowsheet simulations of cement plants in literature.

This work sets out to investigate the performance of the clinked production process in a holistic manner, utilizing mechanistic mathematical models. These are used to simulate a reference coal-fired cement plant, validated from literature data. Once the predictive ability of the models is verified, several case studies are presented in which different alternative fuels are used to replace coal, investigating the potential effect of fuel subtitution in the plant's emissions and performance.

# METODOLOGY

## Pyroprocess System Description

The pyroprocess system of a cement plant consists of the preheating cyclones, the calciner, the rotary kiln and the grate cooler. The solid raw meal feedstock is being heated inside the cyclones up to 800°C, then calcined in the calciner and finally converted into clinker reaching 1450°C inside the rotary kiln, while thermal energy from the hot clinker exiting the kiln is recovered in the cooler and recycled back to the former processes by the secondary air (to the kiln) and tertiary air (to the calciner) streams. A visual representation of the pyroprocessing system is presented in Figure 1. The mathematical modelling framework that has been developed and used to perform the simulations will be explained briefly. Given the greater potential for emission reduction, the study focuses on the carbon intensive processes (calciner, kiln) and the $CO_2$ reduction potential from alternative fuel combustion. These models are then used in a flowsheet simulation and the results are presented in the following Chapter.

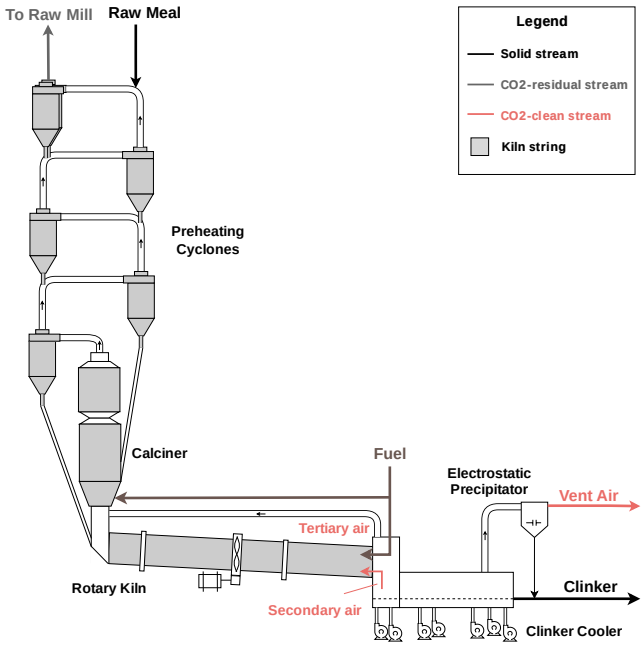

**Figure 1:** Cement Pyroprocess Plant (modified from [5]).

## Preheating Cyclones

The preheating cyclones are modelled as a direct heat exchange process, in which the hot exhaust gas is mixed with the cold solid. The two streams exchange heat inside the cyclones and then are separated in the underflow (solids) and the overflow of the cyclone (gas with dust). Assuming steady state operation the material balance for the solid (1) and gas phase (2) and the energy balance (3) for each cyclone are written as:

$$m_{s,j-1} + m_{es,j+1} = m_{s,j} + m_{es,j} - m_{m,j} \quad \forall\, j \in 1, N \quad (1)$$

$$m_{g,j} = m_{g,j-1} + m_{fa,j} + m_{m,j} \quad \forall\, j \in 1, N \quad (2)$$

$$m_s C_{p,s} T\big|_{j-1} + m_{es} C_{p,s} T\big|_{j+1} + m_g C_{p,g} T\big|_{j-1} + m_{fa,j} C_{p,a} T_a = m_s C_{p,s} T\big|_j + m_{es} C_{p,s} T\big|_j + m_g C_{p,g} T\big|_j \quad \forall\, j \in 1, N \quad (3)$$

Where $m_{i,j}$ (kg/s) is the mass flowrate of the phase *i* out of cyclone *j*, $Cp_{i,j}$ (J/kg*K) is the specific heat capacity of the phase *i* in cyclone *j* and $T_j$ (K) is the temperature inside cyclone *j*. Regarding the phases *i*, s refers to the solid phase, *g* refers to the gas phase, *es* refers to the solids entrained by the gas, *m* refers to the moisture of the raw meal and *fa* refers to the false air that is entering each cyclone.

Except for the mass and energy balances reported above, sub-models for the estimation of the heat losses and pressure drops around each cyclone are included as well, following approaches from relevant literature works [6-7].

## Calciner

The basis of the calciner model were general material and energy conservation balances:

$$\frac{dm_i(z)}{dz} = A_{calciner} * \sum_j R_{i,j}(z) \;\; \forall\, i \in solid, fuel, gas \;(4)$$

$$\frac{dH_t(z)}{dz} = A_{calciner} * (\Delta H_{cal} * R_{cal}(z) + \sum_c \Delta H_c * R_c(z)) \;(5)$$

where $m_i(z)$ (kg/s) is the specific mass flowrate of the component $i$ in the axial position $z$, $A_{calciner}$ (m$^2$) is the cross sectional area of the calciner, $H_t$ (kW) is the enthalpy of the mixture in the axial position $z$ and $R_{ij}(z)$ (kg/m$^3$*s) is the volumetric reaction rate of component $i$ in reaction $j$.

The rate expression for calcination reaction reads:

$$\mathrm{CaCO_3(s) \rightarrow CaO(s) + CO_2(g)}, \qquad \Delta \mathrm{H_{cal}} = 178 \frac{\mathrm{kJ}}{\mathrm{mole}}$$

$$R_{cal}(z) = k(z) * A_{CaCO_3}(z) * \rho_{CaCO_3} * \left(\frac{P_{eq}(z) - P_{CO_2}(z)}{P_{eq}(z)}\right) \;(6)$$

where $k(z)$ (kg/m$^2$) is the global calcination reaction constant, incorporating chemical and physical limitation terms [8], $A_{CaCO3}$ (m$^2$/kg) is the specific surface area of the solids as a function of conversion [9], $\rho_{CaCO3}$ (kg/m$^3$) is the solids density, $P_{eq}(z)$ (Pa) is the calcination equilibrium pressure [9] and $P_{CO2}$ (Pa) the $CO_2$ partial pressure.

Regarding fuel combustion, there are multiple heterogeneous and homogeneous reaction steps occurring. The first step is the evaporation of the fuel moisture, followed by the devolatization of the volatile part of the fuel, leaving the solid particle with just char and ash. The rate expression $R_{i,dev}(z)$ for the devolatization follows an Arrhenius type behaviour:

$$R_{dev}(z) = A_{dev} * e^{-\frac{E_{dev}}{R*T_p}} \quad (7)$$

where $T_p$ (K) is the particle temperature, $R$ (kJ/mole*K) is the ideal gas constant and $A_{dev}$ (1/s) and $E_{dev}$ (kJ/mole) are the kinetic parameters, which are different for different types of solids fuels, like coal and SRF [5]. After the release of the volatiles in the gaseous phase, the volatile mixture that consists of $CH_4$, $C_2H_4$, $H_2$, CO, $O_2$, $N_2$ and $S_2$ is oxidized though homogeneous gas phase reactions to produce the oxidized form of these gases ($CO_2$, $H_2O$, NO, $SO_2$) and provide heat to the system. The kinetic rate expressions for each reaction are extracted from relevant literature [9]. The remaining char is reacting with oxygen according to the following reaction with the respective reaction rate $R_{char}(z)$:

$$\mathrm{C(s) + xO_2(g) \rightarrow yCO(g) + zCO_2(g)}$$

$$R_{char}(z) = \frac{A_p}{V_p} \frac{k_{chem}(z) * k_{phys}(z)}{k_{chem}(z) + k_{phys}(z)} P_{O_2}(z) \quad (8)$$

where x, y, z are temperature dependent coefficients, $A_p$ (m$^2$) and $V_p$ (m$^3$) are the particle's surface and volume, $P_{O2}$ (Pa) is oxygen's partial pressure, and $k_{chem}(z)$ and $k_{phys}(z)$ (kg/m$^2$*Pa*s) are reaction constants, that are evaluated through expressions from literature [4,10].

## Rotary Kiln

For the rotary kiln system, the process model is divided into three sub-models that refer to: a) the motion of solid bed inside the rotating drum, b) the heat transfer phenomena between the solid bed, gas phase and rotating wall and shell, c) the chemical reactions occurring during clinkerization and fuel combustion. The first sub-model is used to calculate accurately the height of the bed, the residence time and velocity of the solids inside the kiln and the cross sectional and contact areas between the bed-gas-wall system, that are essential for the heat transfer model calculations. Due to page limitations the equations of these sub-models will not be displayed here, however the reader is referred to relevant literature works for both the bed motion [11] and heat transfer models [12-13]. For the chemical reaction sub-model, the four main clinker formation reactions were assumed, with the following kinetic rate expressions [13]:

$$2\mathrm{CaO(s) + SiO_2}(s) \rightarrow Ca_2SiO_4(s)\;(C_2S)$$

$$R_{C_2S}(z) = \rho_{bed} * k_{C_2S}(z) * y_{CaO}^2 * y_{SiO_2}$$

$$\mathrm{Ca_2SiO_4(s) + CaO}(s) \rightarrow Ca_3SiO_5(s)\;(C_3S)$$

$$R_{C_3S}(z) = \rho_{bed} * k_{C_3S}(z) * y_{C_2S} * y_{Cao}$$

$$3\mathrm{CaO(s) + Al_2O_3}(s) \rightarrow Ca_3Al_2O_7(s)(C_3A)$$

$$R_{C_3A}(z) = \rho_{bed} * k_{C_3A}(z) * y_{CaO}^3 * y_{Al_2O_3}$$

$$\mathrm{4CaO(s) + Al_2O_3(s) + Fe_2O_3(s) \rightarrow Ca_4Al_2Fe_2O_{10}(s)(C_4AF)}$$

$$R_{C_4AF}(z) = \rho_{bed} * k_{C_4AF}(z) * y_{CaO}^4 * y_{Al_2O_3} * y_{Fe_2O_3}$$

where $\rho_{bed}$ (kg/m$^3$) is the bed density, and $k_i$ (1/s) and $y_i$ (-) are the kinetic constants and mass fractions.

Following the common notation for the clinker phases in cement science, $C_2S$, $C_3S$, $C_3A$ and $C_4AF$ refer to $Ca_2SiO_4$, $Ca_3SiO_5$, $Ca_3Al_2O_7$ and $Ca_3Al_2Fe_2O_7$ respectively.

# RESULTS & DISCUSSION

## Base Case Coal Fired Simulation Results

In this part of the study, the models presented above will be solved simultaneously in a flowsheet simulation and the results will be validated against published data from a relevant work that is based on a cement process simulator developed by VDZ (Association of German Cement Works) [14]. The specification of all the inlet conditions were tuned in accordance with the literature source that was used to validate the results. The inlet conditions and properties of the raw meal and fuel inlet streams are presented in Table 1. The equipment design was taken identical as the one from the reference source [14]. The preheating tower string consists of 5 cyclones

and a calciner with a diameter of 3.88m and a length of 45m, while the kiln is 57m long with a diameter of 4.04m.

The results obtained from the simulation environment of gPROMS® were compared with the reference dataset, and the most important information is summarised in Table 2 and Figure 2. Starting from Table 2, the temperature predictions of the solid and gas streams around the cyclones-calciner string seem to align with the literature data, while the degree of calcination in the calciner is predicted accurately with a relative error of 0.5%.

**Table 1:** Raw Meal & Fuel Inlet Conditions.

| **Raw Meal Conditions** | | |
|---|---|---|
| Temperature (°C) | 60 | |
| Mass Flowrate (kg/s) | 55.2 | |
| $CaCO_3$ (wt.% dry basis) | 78.7 | |
| $SiO_2$ (wt.% dry basis) | 13.6 | |
| $Al_2O_3$ (wt.% dry basis) | 4.3 | |
| $Fe_2O_3$ (wt.% dry basis) | 2.4 | |
| CaO (wt.% dry basis) | 0.0 | |
| Moisture (wt.%) | 1.0 | |
| **Fuel Conditions** | **Coal** | **SRF** |
| Temperature (°C) | 60 | 60 |
| Mass Flowrate to Calciner (kg/s) | 2.42 | 2.85 |
| Mass Flowrate to Rotary Kiln (kg/s) | 1.40 | - |
| Fixed Carbon (wt.% wet basis) | 51.0 | 10.0 |
| Volatile Matter (wt.% wet basis) | 32.0 | 69.3 |
| Ash (wt.% wet basis) | 16.5 | 13.8 |
| Moisture (wt.% wet basis) | 0.5 | 6.9 |
| C (wt.% dry basis) | 69.5 | 45.2 |
| H (wt.% dry basis) | 4.0 | 7.0 |
| O (wt.% dry basis) | 9.0 | 33.0 |
| S (wt.% dry basis) | 0.5 | 0.1 |
| N (wt.% dry basis) | 0.5 | 0.0 |

**Table 2:** Comparison of Model Predictions from Literature Data [14].

| **Variables** | **gPROMS** | **VDZ** |
|---|---|---|
| Flue Gas Temperature (°C) | 315 | 314 |
| Preheated Solids Temperature (°C) | 762 | 760 |
| Calciner Gas Temperature (°C) | 865 | 864 |
| Kiln Feed Loss on Ignition (%) | 2.9 | 3.2 |
| Degree of Calcination (%) | 94.5 | 94.0 |

Moving onto the kiln system, it can be observed from Figure 2 that the prediction of the clinker phases composition is quite close to the reference data. Specifically, the mass fractions of $C_3S$ and free lime are predicted precisely, while the simulated mass fractions of $C_2S$, $C_3A$ and $C_4AF$ deviate from the reference data with relative errors of 3.5%, 3.9% and 4.5% respectively.

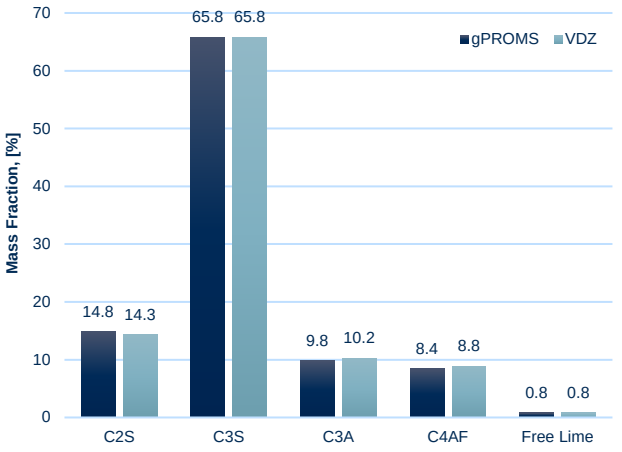

**Figure 2:** Model Predictions of Clinker Compositon.

## Coal Substitution with Solid Recovered Fuels

The chemical (ultimate analysis, composition) and physical (proximate analysis, particle size) characteristics of the simulated SRF were extracted from relevant literature works and are presented in Table 1 [5,14]. Two different case studies were investigated, in which different average particle sizes were assumed. In the first case (SRF-1) a very fine SRF was assumed with an average particle size of 250 μm [5]. In the second case (SRF-2) a SRF with average particle size of 750 μm was assumed [12]. The target is to re-design the calciner system, by modifying the residence time, in order to achieve complete fuel combustion and reach the same temperature and degree of calcination in the outlet of the reactor, since these two variables are the most important KPIs for the operation of the calciner. The biogenic content of the SRFs is assumed to be 80%.

As presented in Figure 3, the temperature and calcination profiles for the three cases are quite different, since the fuels used in each case have different properties that result to different combustion behaviour. That being said, it is important to highlight that no matter the variability of the temperature and calcination distributions for each case study, the values of the variables in the outlet of the calciner have been kept almost the same by modifying the residence time from 2.9 seconds for the base case to 3.3 seconds and 4.1 seconds for the SRF-1 and 2 cases respectively. This translates to a larger calciner with an increased cross-sectional area (diameter), since the length of the calciner is kept constant due to design restrictions.

Table 3 presents the conditions of the flue gas out of the calciner and the preheating tower for the coal and

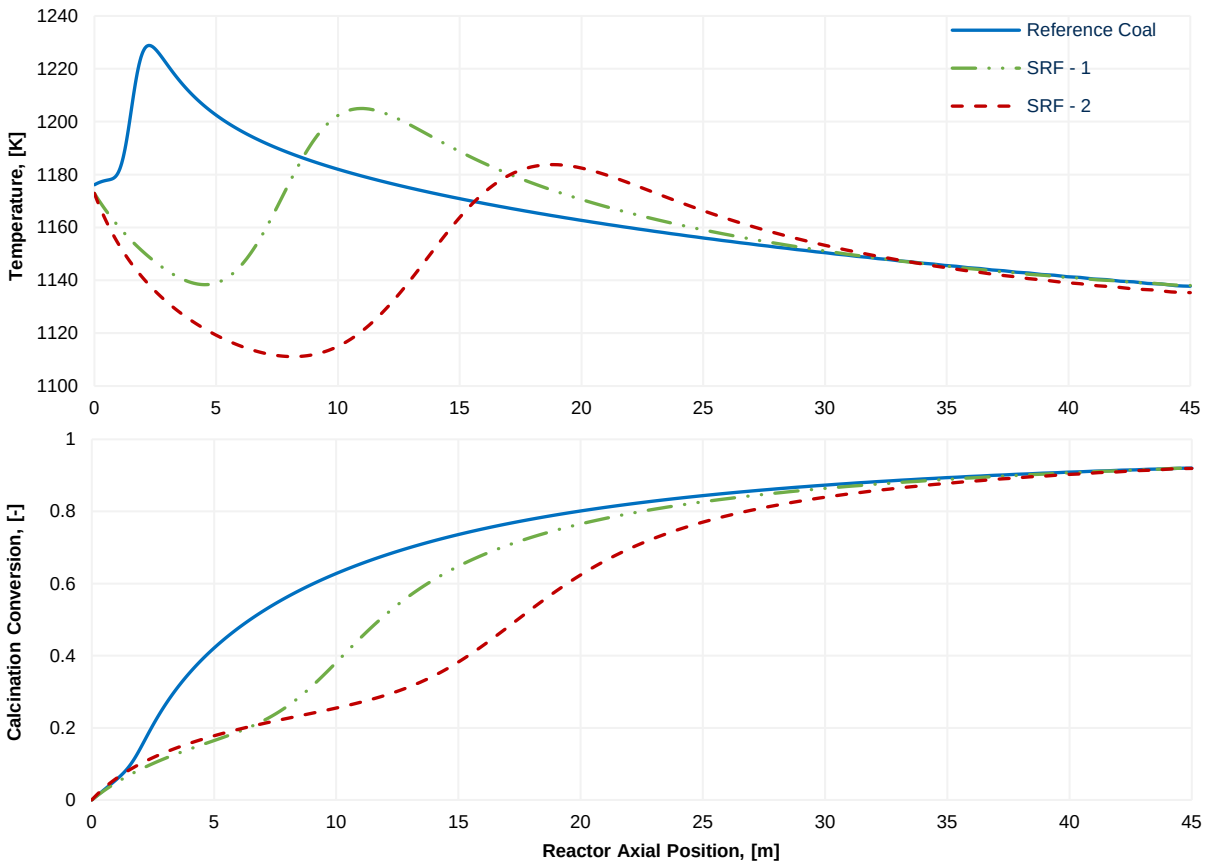

**Figure 3:** Comparison of temperature and conversion calciner profiles for the reference coal (50μm), SRF-1 (250μm) and SRF-2 (750 μm).

the SRF cases respectively. The concentration of $CO_2$ in the SRF-case flue gas is lower than the base case, while the oxygen and water concentrations are significantly higher. This is attributed to the very high moisture content of the SRF (7% in comparison with 0.5% for coal) which is transferred to the gas phase and the increased hydrogen to carbon ratio. In addition, the oxygen content of the SRF (33%) is significantly higher in comparison with coal (9%). It is also important to note that the total mass flowrate of flue gas is higher, since more moisture and oxygen are transferred from the solid fuel to the gas phase.

Table 4 summarises and compares the most important KPIs for both the calciner and the kiln systems in terms of specific $CO_2$ intensity. It is important to note that the fossil-fuel emissions in the calciner for the SRF cases are reduced by 78%. Moreover, it should be borne in mind that even though the substitution rate of coal in the calciner is 100%, there are still some fossil emissions related to the non-biogenic part of the Solid Recovered Fuel (around 20%). The overall plant's emissions are reduced by 18.5%.

**Table 3**: Exhaust Gas Conditions for Coal and SRF Cases.

| **Calciner Exhaust Gas** | **Coal** | **SRF** |
|---|---|---|
| Mass Flowrate (kg/s) | 63.3 | 64.0 |
| Temperature (°C) | 865 | 864 |
| $O_2$ (v/v wet basis) | 2.8 | 4.4 |
| $N_2$ (v/v wet basis) | 59.2 | 57.4 |
| $CO_2$ (v/v wet basis) | 33.1 | 30.6 |
| $H_2O$ (v/v wet basis) | 4.9 | 7.5 |
| **Preheating Tower Exhaust Gas** | **Coal** | **SRF** |
| Mass Flowrate (kg/s) | 66.2 | 66.8 |
| Temperature (°C) | 315 | 323 |
| $O_2$ (v/v wet basis) | 3.4 | 5.0 |
| $N_2$ (v/v wet basis) | 58.9 | 57.3 |
| $CO_2$ (v/v wet basis) | 31.4 | 29.0 |
| $H_2O$ (v/v wet basis) | 6.2 | 8.7 |

**Table 4**: Important KPIs.

| **Calciner** | **Coal** | **SRF** |
|---|---|---|
| Process Emissions ($kg_{CO2}$ / $ton_{clinker}$) | 510.3 | 510.3 |
| Fossil-Fuel Emissions ($kg_{CO2}$ / $ton_{clinker}$) | 181.3 | 26.2 |
| **Rotary Kiln** | **Coal** | **SRF** |
| Process Emissions ($kg_{CO2}$ / $ton_{clinker}$) | 35.0 | 35.0 |
| Fossil-Fuel Emissions ($kg_{CO2}$ / $ton_{clinker}$) | 112.3 | 112.3 |
| Total Emissions ($kg_{CO2}$ / $ton_{clinker}$) | 838.9 | 683.8 |

## CONCLUSIONS

This study highlights the importance of process modelling and simulation to accurately predict and evaluate the performance of a cement plant burning sustainable biogenic fuels instead of the conventional pulverized coal. Even though the quality (moisture, particle size, heating value) of such fuels is rather poor and the thermal performance of the plant decreases significantly, the overall $CO_2$ emissions showed a reduction of around 18.5%, just by replacing the fuel in the calciner. Apart from the energy penalty due to the significantly higher moisture content of the SRFs, the implementation of such a technology would also require increased capital investments, since SRF requires higher residence times (equipment) to combust completely. The flue gas out of an SRF-fired calciner has lower $CO_2$ and higher $H_2O$ and $O_2$ content, making it more difficult to capture in a post-combustion unit.

## ABSTRACT

This study presents an economic analysis of a blue $H_2$-$N_2$ production system, using a novel intensified reformer system with a hydrogen production efficiency of 80%. The system's ability to produce both high-purity $H_2$ and $N_2$ creates opportunities for small-scale blue $H_2$ and distributed ammonia production. The system consists of three identical, optimized fixed-bed reforming reactors, a heat recovery system, and shift reactors. A dynamic model was developed to simulate three small-scale $H_2$ production systems: 2.8 tpd, 7.1 tpd, and 17.1 tpd, enabling an evaluation of their economic viability. The results indicate that the cost of $H_2$ production ranges from 2.7 to 3.1 USD/kg$H_2$. Sensitivity analysis reveals that natural gas and $CO_2$ transportation costs have a significant impact on the variability of $H_2$ price. This research provides valuable insights into the economic feasibility of small-scale blue hydrogen production, offering a pathway to support the broader adoption of hydrogen technologies in advancing a cleaner energy future.

## INTRODUCTION

The use of hydrogen is critical for decarbonization efforts, serving as a replacement for fossil fuels. Approximately 80% of the projected future hydrogen demand stems from emerging applications, with around 27% attributed to the transportation sector [1]. Hydrogen use in medium- and heavy-duty vehicles, maritime shipping, aviation, and rail is among top priorities of the US Clean Hydrogen Strategy and Roadmap [2]. Manufacturers are already transitioning towards hydrogen-powered heavy-duty trucks, utilizing either fuel cells or internal combustion engines [3]. To support the widespread adoption of hydrogen, ensuring its availability and the development of infrastructure at points of use is essential.

However, centralized hydrogen production requires transporting and storing hydrogen, which has proven to be challenging and a significant bottleneck in hydrogen implementation. One proposed solution is blending hydrogen with the current natural gas infrastructure [4]. However, this practice has faced criticism due to safety concerns. Another approach under consideration involves storing hydrogen in the form of ammonia or methanol. This method is considered more economical for larger scale applications, such as continental export and import, given the long supply chain to the point of use [5].

An alternative strategy is smaller, distributed hydrogen tailored to the specific local needs. This approach aligns with hydrogen implementation in the transportation sector, which requires numerous hydrogen refuelling stations along vehicle routes. On-site hydrogen production can be achieved through either green hydrogen or blue hydrogen, depending on the location characteristics and the availability of energy sources and materials. Green hydrogen, while more environmentally friendly, is less cost-effective compared to blue hydrogen [5]. Locations with access to natural gas, biogas or limited renewable energy resources, should consider blue hydrogen technology as a more cost-effective solution for hydrogen production.

The discussion regarding blue hydrogen technology has predominantly focused on large-scale industrial

applications. Steam methane reforming with carbon capture storage (SMR-CCS), the most mature blue $H_2$ technology, continues to face challenges in achieving $CO_2$ capture rates above 80% [6], primarily due to $CO_2$ dilution in the flue gas stream. However, emerging technologies like chemical looping (CL) hydrogen production, show promising potential for blue hydrogen production, as they can achieve higher $CO_2$ concentrations in the downstream process, thereby facilitating more efficient carbon capture [7].

Our previous research demonstrated an optimized fixed-bed reactor for chemical looping hydrogen production that generates high concentrations of hydrogen while simultaneously producing concentrated streams of $CO_2$ and $N_2$ in three separate streams [7]. Our following work presented an optimized control strategy for an integrated multi-reactor system, incorporating heat recovery system and shift reactor components, specifically designed for small-scale hydrogen and nitrogen production [8].

This study presents a techno-economic analysis of a novel blue hydrogen and nitrogen production system designed to meet local demands. Prior studies primarily focused on large-scale hydrogen production, whereas this work provides cost estimates for small-scale distributed H2 production. Thus, it provides valuable insights for stakeholders assessing the feasibility and economic viability of small-scale hydrogen deployment, enabling more informed decision-making on investment and implementation.

# METHODOLOGY

## Small-scale Definition

First, the scale of $H_2$ production must be defined. Most studies on CL-based $H_2$ production plants focus on capacities above 60 tons/day [9-13]. Consequently, we define $H_2$ production of less than 20 tons/day as small-scale. This scale is intended for local applications, such as supporting hydrogen refuelling stations [14].

## The Blue $H_2$-$N_2$ Production System

Figure 1 illustrates the novel blue $H_2$-$N_2$ production system discussed in this work. The system consists of three major subsystems: (i) a train of reforming reactors, (ii) a heat recovery system, and (iii) a gas purification system. The reactor system uses the intensified reforming reactor discussed in [7], operating on the chemical-looping reforming (CLR) principle, with successive oxidation (OX), reduction (RED), and reforming (REF) stages. A minimum of three reactors operates simultaneously at different CLR stages to ensure a continuous product stream. In each stage the reactors produce three different streams: a N2-rich stream from OX, a CO2-rich stream from RED, and a H2-rich stream from REF.

The heat recovery system includes preheaters and steam generators installed along each downstream path to preheat the reformer feed. The hot streams used in the heat recovery system originate from the product streams of the multi-reformer system.

The gas purification system is designed to purify the primary product of each stream. In the $N_2$-rich stream, a methanator converts remaining CO and $CO_2$ into methane. In the $CO_2$-rich stream, a condenser removes steam to ensure a high $CO_2$ concentration output suitable for capture. For the $H_2$-rich stream, a water gas shift reactor converts remaining CO into $H_2$, and a pressure swing adsorption (PSA) separates $H_2$ from the other gases.

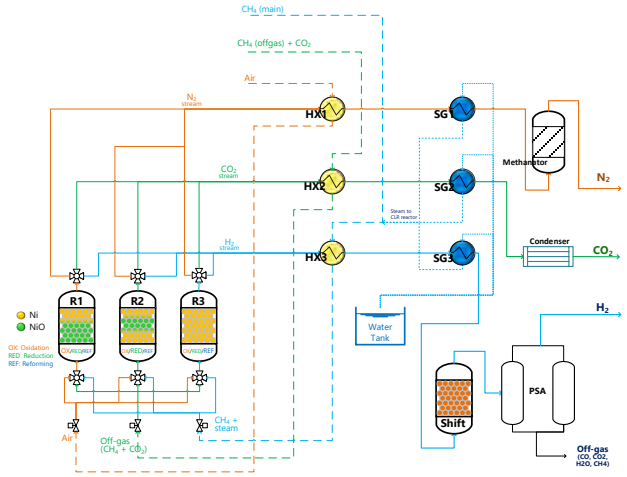

**Figure 1.** Simplified flowchart of the blue $H_2$-$N_2$ production system discussed in this work.

## Modeling and Simulation

The fixed bed reactors for the reforming and shift reactors were modeled using a 1D heterogeneous model, that incorporates mass, energy, and momentum balances, reaction kinetics, and mass-heat transfer correlations. The kinetics of the CL reformer is documented in [7], while that for the shift reactor is provided in [8]. The heat recovery system was modeled as a counter-current heat exchanger, incorporating mass and energy balance equations. The system's compressor was modeled as a two-stage compressor with intercoolers, operating with a mechanical and polytropic efficiency of 90%.

Details on the integrated blue $H_2$-$N_2$ production model, along with its validation and dynamic optimization can be found in [8]. The system is comprised of a set of Differential-Algebraic Equations (DAEs), which were solved using the equation-based process modeling platform gPROMS Process 2023.2.0 [15], with the DAEBDF solver.

To simulate systems of different scales, the reactor's length-to-diameter (L/D) ratio was maintained, while the inlet molar flow rate and reactor volume were

adjusted. Key system parameters, such as the steam-to-methane ratio, the $CO_2$-to-fuel ratio during the reduction stage, and the steam distribution across the steam generators, were kept constant.

## Economic Analysis

This techno-economic analysis covers from the purchase of natural gas to the downstream treatment of the $CO_2$ by product. The analysis was conducted following the framework outlined by DOE/NETL [16], as presented in Table 1.

**Table 1:** Methodology for techno-economic analysis used to estimate $H_2$ production cost based on the framework by DOE/NETL [16].

| Components | Formula |
|---|---|
| Capital Cost | |
| - Bare Erected Cost of j-components ($BECj$) | $\sum BEC_j$ |
| Total $BEC$ | |
| Engineering Procurement and Construction ($EPC$) | $10\%\ (BEC)$ |
| Contingency ($CON$) | $20\%(BEC\ +\ EPC)$ |
| Total Plant Cost ($TPC$) | $BEC + EPC + CON$ |
| Owner Cost & Other Financial Cost ($O\&OFC$) | $20\%\ (BEC)$ |
| Total Overnight Cost ($TOC$) | $TPC + O\&OFC$ |
| Total as spent Cost ($TASC$) | $TOC + 18\%TOC$ |
| Capital Cost per Year ($TASCpa$) | $TASC\ \times\ CCF$ |
| Annual Operation and Maintenance Cost ($O\&M$) | $O\&M$ |
| Total Annual Cost ($TAC$) | $TASCpa + O\&M$ |
| $H_2$ cost (USD/kg) | ${}^{TAC}/_{H2prod.}$ |

The capital cost was determined by summing the costs of the individual reactor components, incorporating additional costs such as Engineering, Procurement, and Construction (EPC), contingency, and overnight costs, resulting in the Total as Spent Cost (TASC). The annual capital cost was then calculated by multiplying the TASC by a capital charge factor (CCF) of 0.159, which assumes an interest rate of 10% and a plant lifetime of 20 years [17]. Component costs for the blue $H_2$ and $N_2$ production system were estimated using reference costs provided by DOE/NETL [16], as summarized in [11], and scaled using the exponential scaling formula shown in Eq. (1). The required capacity of each equipment for this cost estimation was obtained from simulation. Additionally, a balance of plant cost – piping, instruments, controls, and facilities – was included and assumed to be 0.8 of the total equipment cost [17], except for the CL reactor component.

$$\text{Cost}_j = \text{Cost}_{ref}\left(\frac{\text{Capacity}_j}{\text{Capacity}_{ref}}\right)^f \quad (1)$$

The annual operating and maintenance (O&M) costs were estimated by combining fixed and variable costs based on assumptions from [11]. Labor costs were assumed to be 90,000 USD/year/person. The O&M costs also accounted for the transportation of $CO_2$ to local storage sites or for utilization. The transportation cost was based on estimates from [18] for 1 million tons $CO_2$ per year transported within a 100-mile distance. Table 2 summarizes the key assumptions for estimating operating expenses.

**Table 2:** Assumptions for the calculation of the operation and maintenance (O&M) costs.

| Components | Formula |
|---|---|
| Fixed Costs | |
| Labor [USD/person/year] | 90,000 |
| Maintenance | $0.7\%\ TASC$ |
| Insurance | $1.5\%\ TASC$ |
| Variable Costs | |
| Oxygen carriers [USD/kg] | 20 |
| Shift catalyst [USD/kg] | 50 |
| Desulphurization/methanator catalyst [USD/kg] | 15 |
| Lifetime oxygen carriers [years] | 2 |
| Lifetime catalyst [years] | 5 |
| Natural gas cost [USD/$GJ_{LHV}$] | 6.5 |
| Steam cost [USD/$ton_{steam}$] | 0.13 |
| $CO_2$ transportation for 1 Mtpa, <100 miles distance, with low monitoring [USD/ton$CO_2$] | 16.5 |
| Electricity cost [USD/MWh] | 55 |

## RESULT AND DISCUSSIONS

We selected the proposed blue $H_2$-$N_2$ production system with three $H_2$ production scales: 2.8, 7.1, and 17.1 tons of $H_2$ per day. These production scales represent the potential demand for medium-sized hydrogen refuelling stations [14]. Simulation results for each scale were used to extract key parameters for the main equipment in the integrated system, as shown in Table 3. These parameters were subsequently used to estimate equipment costs using Eq. (1) and the points discussed in the previous section.

The techno-economic analysis was conducted using the methodology previously described, with the results summarized in Table 4. The analysis shows that the cost of blue $H_2$ for the proposed small-scale system ranges between 2.73 – 3.04 USD/kg$H_2$, with smaller scales incurring higher costs.

In terms of component costs, the CL reforming reactor accounts for the largest cost, comprising for 45-60% of the total equipment cost. Other significant components include the PSA unit, the heat recovery system, and $CO_2$ compressors.

Operational costs are dominated by the expense of natural gas followed by labor, electricity, and $CO_2$ transportation. However, natural gas costs are highly dependent on global market prices. Similarly, $CO_2$ transportation costs may vary based on the availability of local $CO_2$ utilization options, storage facilities, or reservoirs. Limited storage availability or longer transportation distances can increase costs. Although the cost of the oxygen carrier is relatively minor, it remains subject to variability depending on operational practices. The expense of oxygen carrier replacement may rise if the material demonstrates low durability, especially since CL technology still needs extensive field validation.

Figure 2 presents a sensitivity analysis of blue $H_2$ pricing with respect to potential changes in the natural gas prices, oxygen carrier price/lifetime, and $CO_2$ transportation costs. The analysis reveals that natural gas and $CO_2$ transport costs have the most significant impact on overall $H_2$ price. While natural gas prices are dictated by global market fluctuations, $CO_2$ transport costs depend on the availability and readiness of $CO_2$ storage and transportation infrastructure. Notably, the upper bound of \$88.9/ton$CO_2$ applies to scenarios involving small-scale $CO_2$ transport over long distances (500 miles) with extra monitoring for storage – conditions that are unlikely to be developed [18]. Previous studies suggest a practical cost range of \$4 to \$45/ton$CO_2$ for the transport and storage of $CO_2$ in Tier-1 countries such as the U.S [18]. In contrast, the cost of the oxygen carrier has a relatively minor impact on $H_2$ price unless its lifetime is short, necessitating more frequent replacement.

Figure 3 compares the price of the proposed blue $H_2$-$N_2$ production system with that of other CL-based $H_2$ production systems studied in the literature. Our proposed small-scale system is generally more expensive than the other technologies with larger $H_2$ production capacities. This discrepancy can be attributed to the much smaller production scale of our system, operating at two to three orders of magnitude below those reported in other studies. Additionally, this techno-economic analysis includes the cost of $CO_2$ transportation, which is often excluded in other studies. Despite these differences, Figure 3 reveals a general trend, offering valuable insights into alternatives for blue $H_2$ production at smaller scales.

## CONCLUSIONS

This paper presents a techno-economic analysis based on the dynamic model of a novel blue $H_2$-$N_2$ production system designed for small-scale applications. Utilizing the innovative CL principle, the estimated $H_2$ price is around 3.0 USD/kg$H_2$, which is more expensive than that of larger-scale plants. However, this small-scale approach reduces the need for long-distance hydrogen transportation, as required in centralized scenarios. It is important to emphasize that this scenario depends heavily on the natural gas infrastructure, which has been under scrutiny due to its fugitive methane emissions. Furthermore, ensuring access to local $CO_2$ utilization options and storage reservoirs is critical to minimize $CO_2$ treatment costs, enhancing the system's economic viability.

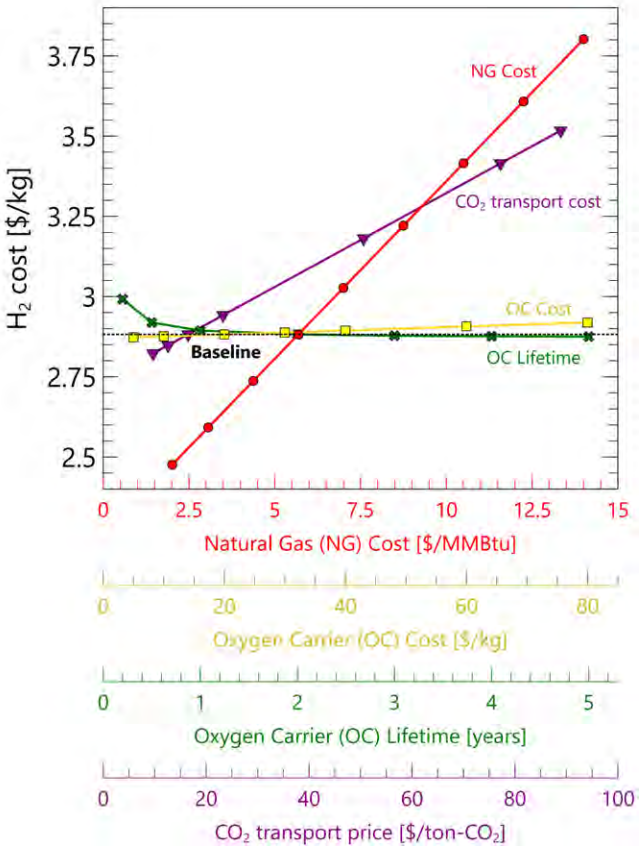

**Figure 2.** Sensitivity analysis of blue $H_2$ price relative to variations in natural gas prices, oxygen carrier (OC) price/lifetime, and $CO_2$ transport costs for the proposed system with 7.1 ton$H_2$ per day production rates.

**Table 3:** The key parameters for equipment price estimation. These values were obtained from the simulation of the proposed system at three different $H_2$ production rates: 2.8-, 7.1-, and 17.1-ton $H_2$ per day.

| Equipment | Scaling parameter | $H_2$ production rate | | |
|---|---|---|---|---|
| | | **2.8 tpd** | **7.1 tpd** | **17.1 tpd** |
| CL Reformer Reactor | Volume [$m^3$] | 5.39 | 15.71 | 47.99 |
| Shift Reactor | Shift gas flow [kg/s] | 0.22 | 0.59 | 1.42 |
| Heat recovery system | Heat duty per temp. [kW/K] | 1.346 | 3.428 | 7.675 |
| PSA | $H_2$ stream flow [m^3/s] | 0.08 | 0.27 | 0.64 |
| Desulphurizer | Methane feed [kg/s] | 5.88 | 14.71 | 35.31 |
| Methanator | $CO_2$ in $N_2$-rich stream [g/s] | 1.615 | 3.533 | 10.164 |
| Air Blowers | Total air flow [kg/s] | 0.47 | 1.18 | 2.83 |
| $CO_2$ compressors | Power [kW] | 130 | 290 | 720 |
| Heat rejection unit | Amount of heat [kW] | 165.4 | 412.9 | 907 |

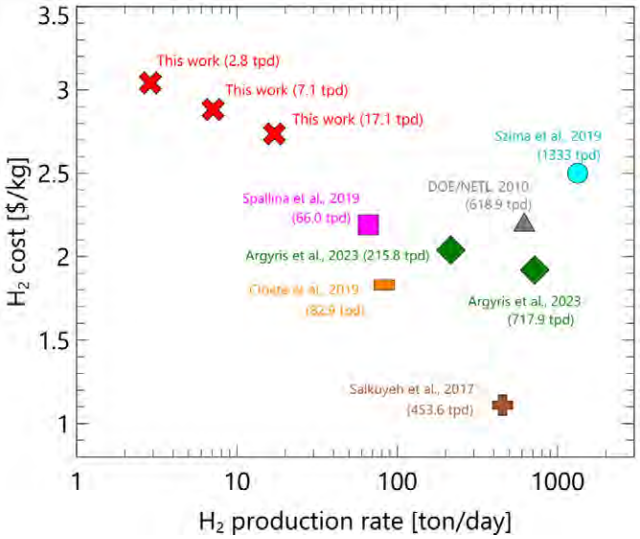

**Figure 3.** Comparison of $H_2$ prices for the proposed blue $H_2$-$N_2$ production system (red cross) with other blue $H_2$ technologies based on CL reforming principles from the literature [9-13], except DOE/NETL[16], which uses SMR-CCS.

## ABSTRACT

A Digital Twin (DT) is a purposeful digital representation of a physical entity that employs data, algorithms, and software to enhance operations, making it possible to e.g., forecast failures, or evaluate new designs through the simulation of real-world scenarios. DTs are enablers for real-time monitoring, simulation, and optimization. However, traditional simulation DTs often rely on complex, non-linear mechanistic models with high computational demands, complex structures, and a large number of specific parameters and thus pose quite a challenge to maintainability. Surrogate models, on the other hand, are simplified approximations of more complex, higher-order models. These approximations are typically built using data-driven approaches, such as Random Forest Regression, facilitating faster simulations, simpler adaptation, and quicker deployment. This study analyzes the complexity of mechanistic and surrogate modeling approaches in the context of DTs to aid model selection. A model with reduced complexity enhances computational efficiency, simplifies implementation, and supports real-time monitoring and predictive maintenance. Complexity analysis evaluates metrics such as analytical, structural, space, behavioral, training, and prediction complexity, resulting in an overall complexity score for model selection. However, the decision involves trade-offs, such as balancing high fidelity with low complexity or prioritizing high explainability over structural simplicity. Addressing these trade-offs is essential in selecting a model that balances the accuracy, usability, and efficiency of DTs. Using a stirred tank reactor as a use case, the mechanistic model is compared to a surrogate model to quantify complexity scores and select a less complex model for DT development.

## INTRODUCTION

Modeling and simulations provide the mathematical and conceptual foundation for Digital Twins (DTs) [1]. Multiple industries, including pharmaceuticals, manufacturing, chemicals, and food processing, heavily rely on modeling and simulations. One of the important aspects of the model-building process is model selection [2].

Mechanistic models are a critical foundation for DTs [3]. These mechanistic models are non-linear, time-consuming, expensive, and sometimes complex [4]. In such cases, surrogate models are used to approximate or regress the input-output relationships of a more complex, computationally demanding model [5] to reduce complexity by focusing on key elements and interactions, sacrificing some accuracy for efficiency and ease of use. Thermodynamic models for distillation and extraction processes, partial differential equations (PDEs), and computational fluid dynamics (CFD) simulations are examples of complex computational systems. Surrogate modeling techniques can effectively approximate these systems, reducing computational cost while preserving reasonable accuracy [6].

However, defining the complexity of such models is a crucial metric for supporting decision-making and selecting the most beneficial and optimal model for a particular process. The complexity level of a model is determined by its components, which depend on factors such as resolution, scope, size, and the interactions within the model. Assessing the complexity of a model is valuable

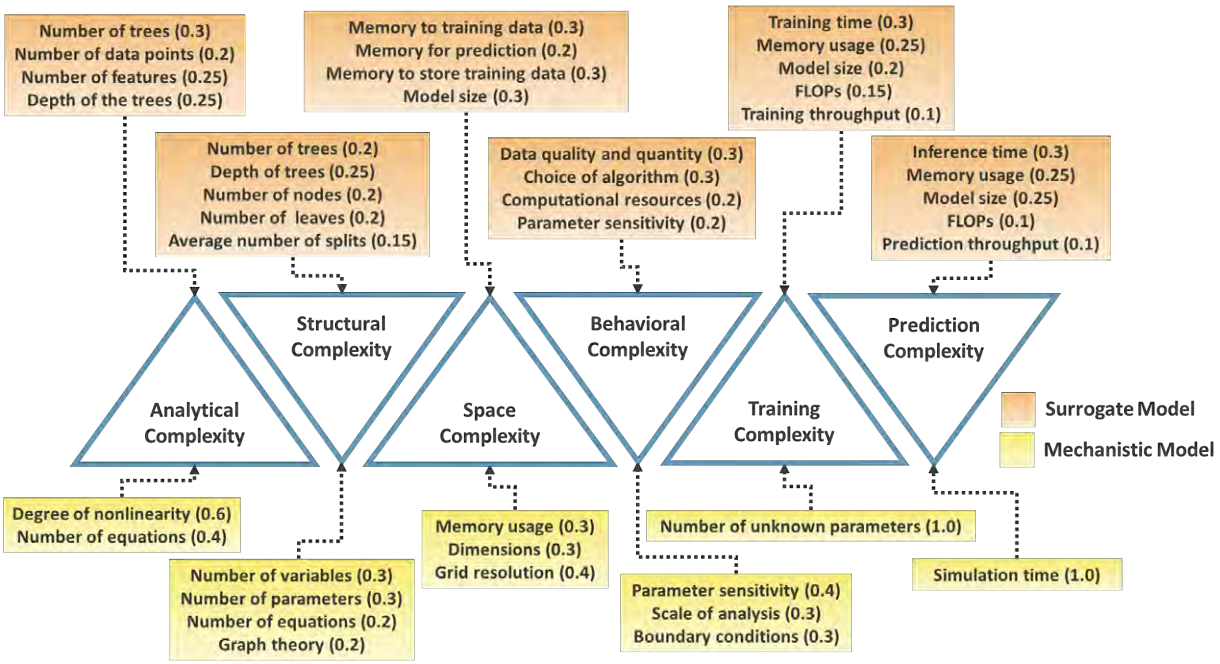

**Figure 1:** Complexity Metrics (analytical, structural, space, behavioral, training, and prediction complexity) and complexity contributors with individual weights

for several applications and is guided by several core principles that process engineers should consider [7]. For example, a Continuous Stirred Tank Reactor (CSTR) model may suffice for quick reactor analysis, but a CFD model might be needed for detailed heat or mass transfer studies. Process engineers must align model complexity with the application, data availability, and computational resources.

In this research, various complexity measures for mechanistic and surrogate models are investigated. The following section defines the different types of complexities associated with simulation models and analyzes their dependencies on several factors. The methodology for calculating complexity scores is presented, along with the rationale for assigning weights. A later section focuses on a simple use case of a stirred tank reactor, analyzing the complexities of both models in terms of reactor temperature. This case study illustrates the approach used to analyze model complexity, and the concept of the complexity score is then applied to these models. Finally, conclusions are drawn based on the proposed case study, and future work is discussed.

## MODEL COMPLEXITY

Complexity can be defined as the state or quality of being intricate [8], with several components and their interactions within a system helping to determine its complexity. Thompson defines model complexity as "The aggregation of a model's detail, external interactions and logical dependencies, and in many contexts its instantiation (input parameter settings) in a specific simulation scenario execution" [7]. In contrast, simple models are easier to understand, faster to implement, easier to verify and validate, more flexible, and simpler to modify [9]. However, some models are not easy to formulate, follow, validate, or verify, and such models can be classified as complex. In Modeling and Simulation, complexity can arise from the model itself or the software used to implement it [8].

### Complexity Metrics

In this work, complexity metrics are defined based on analytical, structural, space, behavioral, training, and prediction complexity. Table 1 outlines several complexities associated with models. Fig. 1 shows the components and contributors of these complexities, highlighting their dependencies on several factors for the models, along with the individual weights of contributors.

Complexities discussed in Table 1 are essential as they cover the entire model lifecycle, from the structure and theoretical foundation to practical implementation and application. Each complexity type addresses a specific challenge in developing, deploying, and maintaining a model, making them collectively crucial for ensuring the overall effectiveness and applicability of the model.

**Table 1:** Complexity Metrics and Definitions.

| Complexity metric | Definition |
|---|---|
| Analytical Complexity | Theoretical analysis of model complexity based on structure and operations |
| Structural Complexity | The complexity of the model architecture itself |
| Space Complexity | Memory required to store the model and data structures during the training and prediction phases |
| Behavioral Complexity | Complexity arising from how the model learns, adapts to data inputs, and responds to varying conditions |
| Training Complexity | Computational resources (time and space) required for model training |
| Prediction Complexity | Computational resources required for making predictions with a trained model |

As Hu et al. [10] discuss, model complexity encompasses various dimensions critical to ensuring models are effective and scalable. These dimensions include analytical complexity, ensuring the theoretical foundation of a model is sound and aligned with its purpose, as unreliable designs can hinder scalability. Structural complexity addresses the model's architecture, balancing interpretability and usability with the risks of impracticality in overly complex designs. Space complexity focuses on memory usage, critical for deploying models in resource-constrained environments like edge devices or real-time systems. Behavioral complexity assesses how the model adapts to varying inputs, ensuring robustness and reliability in dynamic real-world conditions. Training complexity evaluates the computational cost and time needed for model development, especially important in large-scale or iterative applications. Prediction complexity highlights the need for efficient real-time performance in applications such as performance monitoring, optimization, and control systems. These complexities collectively ensure a model is effective, scalable, and practical.

## Complexity Score

The simplest and most straightforward way to create an overall complexity score is the weighted aggregation of the individual complexity metrics. The overall complexity score and the individual complexity scores are calculated using Equations 1 and 2, respectively.

$$CS = \sum_{j=1}^{m} \left( (CS_{ind})_j \cdot W_j \right) \quad (1)$$

$$CS_{ind} = \sum_{i=1}^{n} C_i \cdot w_i \quad (2)$$

$$C_i = \frac{Observed\ Value - Min\ Value}{Max\ Value - Min\ Value} \quad \forall\ i = 1 \ldots n \quad (3)$$

where $CS$ is the overall complexity score, $CS_{ind}$ is the individual complexity score, $C$ is the normalized complexity contributor value (e.g. Number of equations for the mechanistic model and Number of trees for the surrogate model) obtained using the min-max scaling normalization formula (Equation 3), $w$ is the weight for the complexity contributors and $W$ is the weight for the complexity.

## Assignment of Weights to Complexity Metrics

The weights for the individual complexity metrics play an important role in determining the overall complexity score for a given model. These weights represent the relative contribution of each factor to the overall complexity of the model or system, determined primarily through logical reasoning and expert judgment. Table 2 provides the weights ($W$) assigned to the developed complexity metrics shown in Fig. 1.

**Table 2:** Weights ($W$) for Complexity Metrics.

| Complexity metric | Weight |
|---|---|
| Analytical Complexity | 0.15 |
| Structural Complexity | 0.2 |
| Space Complexity | 0.2 |
| Behavioral Complexity | 0.15 |
| Training Complexity | 0.15 |
| Prediction Complexity | 0.15 |

These weights ($W$) are selected based on the relative importance of each metric in the context of evaluating a model's overall complexity and considering the importance of each metric and contributor. Structural and space complexity metrics are weighted higher (0.2 each) because they have a more direct impact on the practical feasibility of the model, particularly in terms of usability, deployment, and hardware requirements [11]. Analytical, behavioral, training, and prediction metrics are equally weighted at 0.15, reflecting their secondary yet significant contributions [12]. They ensure the model is robust, adaptable, and efficient, but are less dominant than structural and space considerations in most applications.

Fig. 1 provides the weights ($w$) for individual contributors of model complexity, which are determined based on their relative contributions, primarily guided by logical reasoning and expert judgment. For mechanistic models, dominant contributors such as nonlinearity (analytical complexity) and grid resolution (space complexity) are assigned higher weights due to their significant anticipated computational impact [13]. In surrogate models, factors like tree depth and training time are prioritized, reflecting their expected influence on scalability and efficiency [11]. The weights are applied to ensure fair consideration of relevant factors, without allowing any single factor to disproportionately influence the outcome. Overlap, such as tree depth affecting both analytical and structural complexity, is mitigated through careful weight

calibration. This approach ensures the complexity metrics highlight the most impactful aspects of each model.

## COMPLEXITY EVALUATION – CASE OF A STIRRED TANK REACTOR

### Reactor Temperature Modeling

To monitor and optimize energy consumption and loss in an insulated Stirred Tank Reactor (STR), a DT for energy Key Performance Indicators (eKPIs) needs to be developed. Understanding energy dynamics is crucial and can be done by analyzing the temperatures of the reactor and jacket. By determining the temperature gradient, the heat loss and process energy consumption between the reactor and the jacket can be calculated. Modular plants are known for their flexibility [14], relying on historical or statistical data for model development is often not feasible. Generating synthetic data enables the creation of more accurate and adaptive models. This case study applies the proposed complexity evaluation concept to guide model selection by comparing a mechanistic and a surrogate model, illustrating how the methodology aligns the model with system requirements and operational constraints.

Modeling of the STR is conducted using the mechanistic and a surrogate model. As shown in Fig. 2, the feed enters the reactor at a specified temperature. The reactor, with a volume of 4L, is agitated at a certain speed and equipped with a water-heated jacket. The fluid properties and the heat transfer coefficient are assumed to be constant, and there is no fouling. Energy balances (Equations 4 and 5) are used to obtain the temperature trajectories for both the reactor and the jacket.

$$\frac{dT_r}{dt} = \frac{1}{V_r \rho_r C_{pr}} * (kA(T_j - T_r)) \quad (4)$$

$$\frac{dT_j}{dt} = \frac{1}{V_j \rho_j C_{pj}} * (m_j C_{pj}(T_{jin} - T_j)) - (kA(T_j - T_r)) \quad (5)$$

Where, $T_r$ is the reactor temperature, $T_j$ is the jacket temperature, $V_r$ is the reactor volume, $\rho_r$ is the reactant density, $C_{pr}$ is the reactant heat capacity, $k$ is the heat transfer coefficient, $A$ is the heat transfer area, $V_j$ is the jacket volume, $\rho_j$ is the jacket fluid density, $C_{pj}$ is the jacket fluid heat transfer capacity, $m_j$ is the jacket fluid mass and $T_{jin}$ is the jacket inlet temperature. The initial temperature of reactor ($T_r$) and jacket ($T_j$) of 293.15 K and jacket inlet temperature ($T_{jin}$) of 283.15 K. The gPROMS simulation results, obtained after nine minutes of reaction time, are shown in Fig. 3. The generated data is used to train a Random Forest Regressor as the surrogate model. The reactor temperature predictions from the surrogate model (Mean Squared Error = 0.015) are shown in Fig. 4.

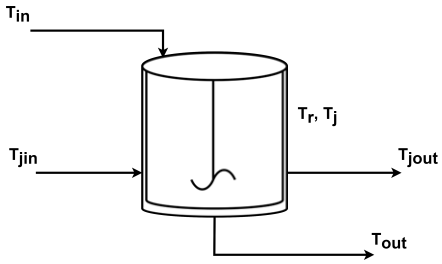

**Figure 2.** Stirred tank reactor: Energy flow.

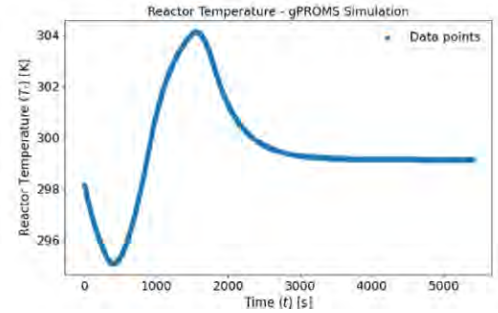

**Figure 3.** Reactor temperature: gPROMS simulation.

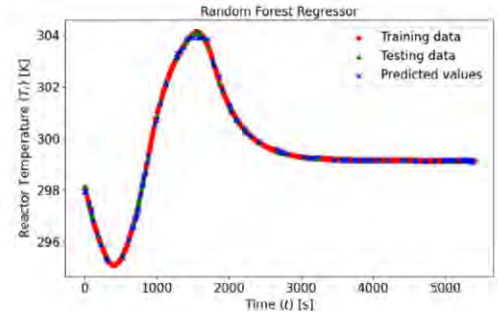

**Figure 4.** Reactor temperature: Random Forest model.

### Complexity Analysis for the STR Case

The models are analyzed for complexity using the developed complexity metrics. In this study, a surrogate model was developed to enable a direct comparison of its complexity with that of the mechanistic model. The surrogate model would not always be developed unless complexity analysis identifies it as the more appropriate choice. A detailed analysis has been conducted to evaluate analytical, structural, space, behavioral, training, and prediction complexities.

#### Analytical Complexity

The analytical complexity of the mechanistic model is minimal due to its linear nature, with two equations and a constant heat transfer coefficient assumed in this study. This simplicity ensures computational efficiency. In contrast, the analytical complexity of the surrogate model arises from parameters like the number of trees (T=300), data points (N=440), features per split (F=1), and tree depth (D=7). While the surrogate model captures nonlinear behaviors effectively, this comes at a higher computational cost. This trade-off highlights the suitability of mechanistic models for systems with well-

understood dynamics and the strength of surrogate models in handling complex, data-driven relationships.

### Structural Complexity

The structural complexity of the mechanistic model is determined by ten parameters, two variables, two equations, and three boundary conditions, with a graph representation of twelve nodes and two edges. This ensures low complexity, simplicity, and interpretability. In contrast, the surrogate model exhibits considerably higher structural complexity, consisting of 300 trees with an average depth of seven. It contains 46,016 nodes, 23,158 leaves, and an average of 153.39 splits per tree. While this allows for greater flexibility and detailed system representation, it also increases storage and computational demands. This comparison highlights the suitability of mechanistic models for lightweight and interpretable applications, whereas surrogate models are ideal for capturing complex systems with detailed requirements.

### Space Complexity

The space complexity of the mechanistic model is minimal, requiring storage for a 2×2 Jacobian matrix and a grid resolution of 1000 for discretization in two dimensions. For the surrogate model, space complexity includes memory for training data (0.006 MB), predictions (0 MB), and the model itself (3.25 MB), driven by the storage of tree structures. The low storage requirements of the mechanistic model make it ideal for resource-constrained, real-time applications. In contrast, the higher memory demands of the surrogate model may limit scalability but enable the handling of more complex systems with adequate computational infrastructure.

### Behavioral Complexity

The behavioral complexity of the mechanistic model depends on system dynamics, parameter variability, and boundary conditions, making it reliable but less flexible for unknown dynamics. The surrogate model relies on data quality, algorithm choice, and computational resources to capture complex patterns. Parameter sensitivity and hyperparameter tuning also impact their performance. Mechanistic models are ideal for data-scarce systems due to their physical foundation, while surrogate models excel in handling high-variability behaviors, offering adaptability in data-rich scenarios. Synthetic data from mechanistic models can mitigate data scarcity and reduce the behavioral complexity of surrogate models.

### Training Complexity

Training complexity for the mechanistic model is negligible since all parameters are known. For the surrogate model, training complexity is crucial, with metrics such as training time (117.32 s), peak memory usage (5.57 MB), model size (3.25 MB), and computational effort (924,000 FLOPs). With a throughput of 3.75 samples/second, the surrogate model demands considerable resources for data processing and hyperparameter tuning, making it the sole contributor to training complexity.

### Prediction Complexity

In mechanistic models, simulation time depends on system dynamics, with this study reporting 2.2 s. Complex systems, though efficient, may have higher computational costs due to detailed calculations. The surrogate model, with a 0.02 s inference time, excels in rapid predictions. It uses 0 MB of memory, has a model size of 3.25 MB, a computational complexity of 2100 FLOPs, with a prediction throughput of 6850.39 predictions/seconds. Here, the mechanistic model is slower and more computationally expensive, while the surrogate model provides faster predictions with lower computational demands, making it ideal for high-throughput applications.

## Complexity Score for the STR Case

Table 3 presents the individual complexity scores ($CS_{ind}$) for both modeling approaches, evaluated using Equation 2, along with dedicated weights for contributors and complexity metrics from Fig. 1.

**Table 3:** Individual complexity score of all complexities

| Complexity Metric | Mechanistic Model | Surrogate Model |
|---|---|---|
| Analytical Complexity | 0.4 | 0.533 |
| Structural Complexity | 0.9 | 1.0 |
| Space Complexity | 0.85 | 0.301 |
| Behavioral Complexity | 0.9 | 0.834 |
| Training Complexity | 0.0 | 0.95 |
| Prediction Complexity | 1.0 | 0.75 |

The complexity evaluation of both the mechanistic and surrogate models highlights the trade-offs between simplicity and flexibility. The mechanistic model scores higher in terms of space, behavioral, and prediction complexities, reflecting the efficiency and ease of implementation of the surrogate model. In contrast, the surrogate model exhibits higher analytical, structural, and training complexity, indicating that the mechanistic model is better suited to handle more complex behaviors.

Overall complexity scores (CS) for both models are determined using Equation 1, based on the individual complexity scores from Table 3 and their weights from Table 2. The overall complexity score shows that the surrogate model, with a CS of 0.72, exhibits higher complexity as compared to the mechanistic model, which has a

CS of 0.69 in this case study. This suggests that the surrogate model, while offering greater flexibility for complex scenarios, requires more resources, making the mechanistic model more suitable for simpler applications. These complexity scores enable developers to make informed choices based on the specific needs of the DT.

## CONCLUSION AND OUTLOOK

The complexity of modeling for the simulation DT is analyzed using the developed complexity metric and score, applied to both mechanistic and surrogate models. The evaluation framework helps identify model components, gather requirements, and inform decisions on model selection, which is crucial for DT development. In the STR case, the surrogate model exhibits a higher complexity score than the mechanistic model. The mechanistic model benefits from simplicity due to its analytical foundation and minimal training requirements, while the increased complexity of the surrogate model arises from structural and training demands. While surrogate models may not always be the final choice, their development offers strategic flexibility and valuable insights, particularly in complex or data-driven scenarios. Dual-model approaches, though rare in real-world plants, improve model selection by addressing diverse challenges, making them valuable in complex, specialized applications.

Future work will focus on enhancing the model selection framework with accuracy and stability analyses. Efforts will aim at reducing surrogate model complexity, improving computational efficiency, and enabling real-time monitoring and predictive maintenance. Temperature-dependent parameters will introduce nonlinearity to the mechanistic model, and surrogate modeling will serve as an alternative if complexity increases. These ongoing developments will provide refined tools for model selection and further optimize DT applications.

## ABSTRACT

This study evaluated the air/steam co-gasification of crude glycerol (CG) and linear low density polyethylene (LLDPE). It was demonstrated that operating the process using air or a mixture of air and steam has significant implications for carbon conversion efficiency (CCE), cold gas efficiency (CGE), lower heating value (LHV) gasifier output temperature and syngas concentration. The CCE reached a maximum value of 100% at equivalence ratio (ER) of 0.3 for 25% LLDPE and an ER of 0.35 for 75% LLDPE when air was used. When steam was introduced in the gasifier at a fixed rate (SFR =0.5), the CCE of 100% was maximised at ER of 0.25 for 25% LLDPE and 0.3 for 75% LLDPE content. An increase in the steam to feedstock ratio (SFR) did not alter the CCE for 25% LLDPE at a constant ER, but for that of 75% LLDPE, a CCE was maximized at an SFR of 0.25. In the case of CGE, a maximum value of 79.24% and 78.12% was reached at ER of 0.3 and 0.35 for 25% LLDPE and 75% LLDPE respectively when pure air was used. Keeping the SFR constant, the CGE slightly increased to 81.33 and 81.45% at ER of 0.25 and 0.3, respectively for 25% LLDPE and 75% LLDPE. The LLDPE content did not significantly alter the syngas LHV at a fixed ER or SFR. The gasifier temperature increased with an increase in ER but decreased when steam was fed into the gasifier. Furthermore, the syngas ratio ($H_2$:CO) achieved in this study can be useful for the synthesis of methanol and dimethyl ether.

**Keywords**: Syngas, Modelling and simulation, Co-gasification, Plastic waste

## INTRODUCTION

There has been unprecedented growth in the production of plastic waste, and current management techniques such as landfilling and incineration are unsustainable, particularly due to the environmental impact associated with these practices. Gasification is considered to be one of the most sustainable ways not only to address these issues, but also to produce energy from waste plastics. However, challenges such as tar and coke formation, and softening are associated with plastic waste gasification which reduces syngas quality[1].

Another typical waste in huge quantities is crude glycerol, with low value, which is a by-product of biodiesel production. The cost involved in its purification is exceedingly high; therefore, this limits its applications as a purified product. Co-feeding plastic waste with crude glycerol for syngas production cannot only address issues related to plastic gasification, but also allows the utilization of crude glycerol and improve syngas quality[2].

Co-gasification is an energy intensive process because it requires high temperatures to convert a blend of different feedstocks into syngas. To sustain the co-gasification process, heat is supplied to the gasifier autothermally [3]. In this case, endothermic reactions are driven by heat from the partial oxidation or substoichiometric combustion of a portion of the feedstock blend or syngas using air or pure oxygen. One of the key parameters pertaining to autothermal processes is the equivalence ratio (ER), which is defined as the ratio between the actual and stoichiometric air/oxygen mass flow rate. Increasing the ER increases the gasifier temperature. In an Aspen Plus simulation, the gasifier temperature is considered an output parameter. Depending on the ER value, the heat supplied to the gasifier can be equal to or greater than the required heat. Preferably, the heat supplied to the gasifier should be equal to the heat required

to avoid irreversibility. In other words, the gasifier should run adiabatically (Q = 0).

The co-gasification of crude glycerol and plastic wastes has not received significant attention in the literature. Mukeru and Patel [4] have recently investigated the co-gasification of glycerol and polyethylene plastic wastes for syngas production using a stoichiometric targeting model. The model was compared with the Aspen Plus simulation. Although the study provided a starting point for crude glycerol and plastic co-gasification, there is still potential for improvements in terms of operational mode. The authors only investigated the co-gasification process in Aspen Plus at different steam to feedstock ratios and the temperature was set to 1000K which does not represent real processes and cannot be used as a guide for pilot and full-scale experimental investigations for the co-gasification of crude glycerol and low linear density polyethylene. Therefore, it is important to develop an air and air-steam co-gasification model whereby the gasifier temperature (GT) is considered as an output parameter along with the syngas concentration based on an autothermal process.

## METHODOLOGY

In this study, a model to evaluate the performance of air and air-steam co-gasification of crude glycerol and polyethylene plastic for hydrogen-rich syngas production, which is developed using Aspen Plus as shown in figure 1. Co-gasification performance indicators such as lower heating value (LHV), carbon conversion efficiency (CCE) and cold gas efficiency (CGE) are used for the evaluation. Equations (1), (2) and (3) were used to calculate these performance indicators [5,6].

$$LHV = 10.78x_{H_2} + 12.63x_{CO} + 35.8x_{CH_4} \quad (1)$$

$$CCE = 100 * \frac{C_{syngas}}{C_{feed}} \quad (2)$$

$$CGE = 100 * \frac{Q_{syngas} * LHV}{LHV_{feed}} \quad (3)$$

Where LHV, CCE, CGE, Q, C and $x_i$ ,the lower heating value (MJ/Nm$^3$), carbon conversion efficiency, cold gas efficiency, syngas flow rate (Nm$^3$/h) the carbon flow rate (mol/s) and mole fraction, respectively.

The first step was to specify all components involved in the simulation, such as crude glycerol, polyethylene plastic waste, $H_2$, $CO_2$, C (solid), CO, $CH_4$, $H_2O$, etc. Crude glycerol and polyethylene were added in Aspen Plus as non-conventional on the basis of their ultimate and proximate analyses [7], [8]. Once the components were specified, the next step was to select a suitable thermodynamic property. Given the fact that crude glycerol and polyethylene plastic waste co-gasification requires high temperatures, Peng-Robinson with Boston-Mathias modifications was selected as a thermodynamic property method [5]. The model developed is depicted in figure 1. The feed stream contains a mixture of crude glycerol and polyethylene plastic waste at standard conditions that is fed to the dryer (R-01) for moisture removal. The dryer is modelled as a stoichiometric reactor operating at 100 ℃. The dried mixture is separated from water vapour using a separator (SEP) and fed to a yield reactor (R-02) whereby it is decomposed into elements according to the ultimate analysis before being fed to the gasifier (R-03). The gasifying agent, air or air-steam mixture is fed to the gasifier whereby partial oxidation/sub-stoichiometric combustion takes place. The product from the gasifier (PROD) consists of gases ($H_2$, CO, $H_2O$, $CO_2$, $CH_4$, $N_2$) and solid (char + ash). A cyclone (CY-01) is used to separate the gases from the solid stream (char and ash). The heat streams Q-1 and Q-2 show the heat integration between the three unit operations (R-01, R-02 & R-03).

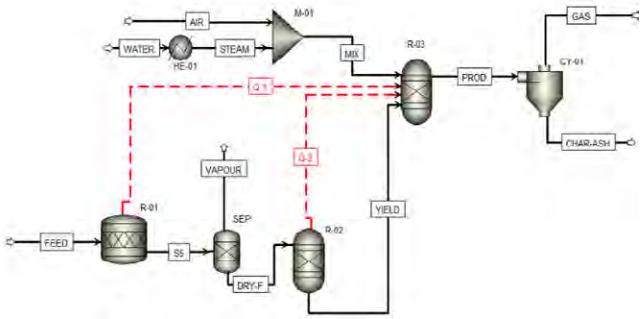

**Figure 1**: Actual Aspen Plus model development

## RESULTS AND DISCUSSIONS

### Effect of equivalent ratio on syngas concentration

Figure 2 shows the effect of ER on the syngas composition (dry basis) and GT for air co-gasification of crude glycerol and LLDPE. In figure 2, it is shown that an increase in ER initially increases CO concentration until it attains a maximum value at an ER of 0.3 and 0.35, respectively, for 25 and 75% LLDPE. The increase in CO concentration is due to partial oxidation of carbon content in the feedstock. However, as the ER was further increased beyond 0.3 and 0.35, the trend of CO concentration decreases. This implies that when more air is supplied in the gasifier, the combustion reaction is favoured over partial oxidation, thus decreasing CO concentration and increasing that of $CO_2$. $H_2$ concentration also decreased with an increase in ER for 25% LLDPE. This is because there is more oxygen available for the oxidation of $H_2$ to form $H_2O$. In the case of 75% LLDPE, increasing the ER to 0.1, $H_2$ concentration initially increased slightly due to low oxygen and high hydrogen content in the feedstock. At an ER of 0.1, the air supplied to the gasifier

promotes methane reforming reaction, thus increasing $H_2$ concentration. Beyond an ER of 0.1, $H_2$ concentration from the gasification of 75% LLDPE followed a trend similar to that of 25% LLDPE. Because an increase in ER increases the gasifier temperature, and favours combustion reactions, $CH_4$ concentration showed a significant decrease. Similar trends were observed for the air co-gasification of biomass (casuarina wood) and polyethylene plastic waste [5] and air gasification of municipal solid waste [9]. Syngas ratio ($H_2$/CO) is an important parameter for downstream processes. Methanol and dimethyl ether (indirect synthesis) require a minimum $H_2$/CO of 2. In this study, a syngas ratio of 2.02 is attained at an ER of 0.2 (GT= 697℃) for 75% LLDPE. DME synthesis (direct route) requires a $H_2$/CO of 1. 25% LLDPE achieves a $H_2$/CO of 1.06 at an ER of 0.35 (GT =932℃) while 75% LLDPE attains 1.01 at the same ER of 0.35 (GT=837℃).

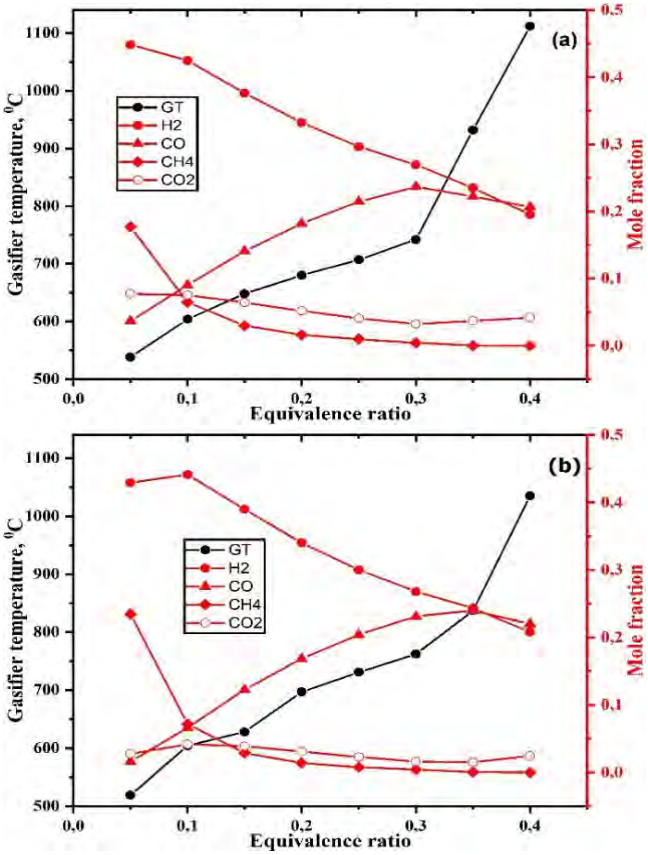

**Figure 2.** Effect of ER on syngas concentration for air co-gasification, (a): 25% LLDPE, (b): 75% LLDPE

## Effect of the equivalence ratio on syngas concentration at a SFR of 0.5

Figure 3 shows the effects of ER on crude glycerol and LLDPE co-gasification at a fixed steam to feedstock ratio (SFR) of 0.5. As ER increased from 0.05 to 0.4, the GT increases but at a lower rate than air co-gasification. This is because steam will absorb a portion of heat generated by exothermic reactions, thus reducing the GT. As summarized in figure 3 a &b, $H_2$ concentration slightly increases when the ER was increased from 0.05 to 0.1. Given the fact that the amount steam introduced in the gasifier is not sufficient to promote steam reforming reactions, $H_2$ concentration decreases with an increase in ER. In other words, $H_2$ starts to oxidize to form $H_2O$. However, the presence of steam in the system results in higher $H_2$ concentration than using air only. Due to lack of sufficient steam, the carbon content in the feedstock still undergoes partial oxidation to form CO when the ER is increased and thus decreases $CO_2$. On the other hand, $CH_4$ concentration is higher at low ER due to insufficient air and low GT but decreases with an increase in the ER. A syngas ratio of 2.03 was achieved at an ER of 0.25 for 25% LLDPE.

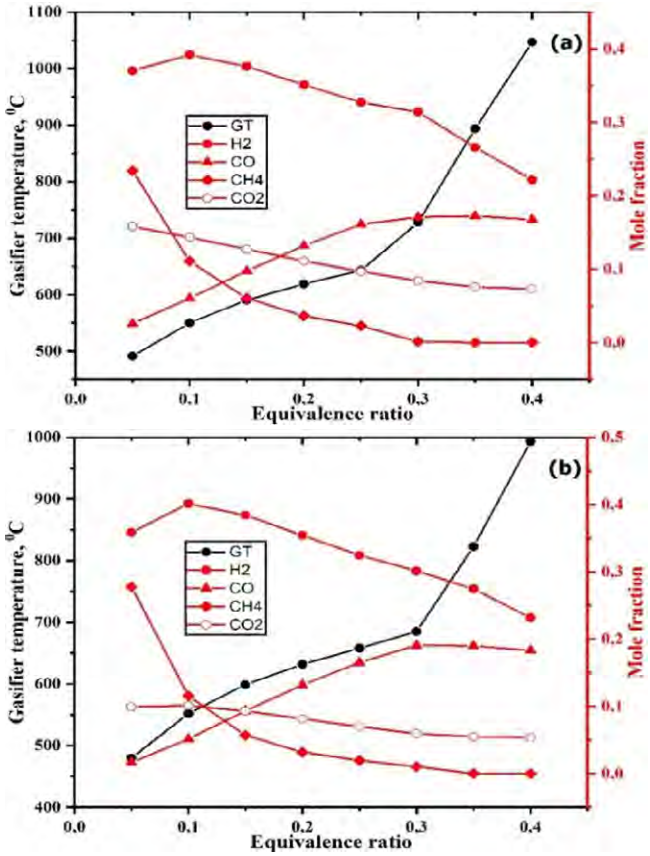

**Figure 3**: Effectof ER on syngas concentration at a fixed SFR of 0.5, (a): 25% LLDPE content, (b): 75 % LLDPE content

## Effect of steam to feedstock ratio (SFR) at a fixed ER

When steam is introduced in the gasifier at a fixed ER of 0.3, the behaviour of GT and syngas concentration differ as shown in figure 4 a & b. An increase in SFR reduces the GT. This implies that the heat generated by the

exothermic reactions during the co-gasification process is used to supply energy to the endothermic steam reforming reactions and since there is no enough energy available the GT drops. An increase in SFR promotes methane steam reforming and water gas shift reactions which results in high $H_2$ and $CO_2$ concentration as shown in figure 4. CO concentration was expected to increase as steam reforming reactions are favoured but it will be consumed by the water has shift reaction, which reduces its concentration with an increase in SFR. A syngas ratio of 2.19 and 2.28 was achieved at SFR of 0.75 and 1 for 25% LLDPE and 75% LLDPE content, respectively which is favourable for downstream applications. The concentration of $CH_4$ remained almost unchanged when the SFR was increased from 0 to 2 at a constant ER value of 0.3 for 25% LLDPE. However, increasing the LLDPE content to 75%, resulted in a slight increase in $CH_4$ concentration at an SFR of 0.5. This rise is due to the methanation reaction, whereby the high carbon content in the feedstock reacts with $H_2$ to form $CH_4$. However, increasing the SFR further, favours methane steam reforming and subsequently reduces $CH_4$ concentration.

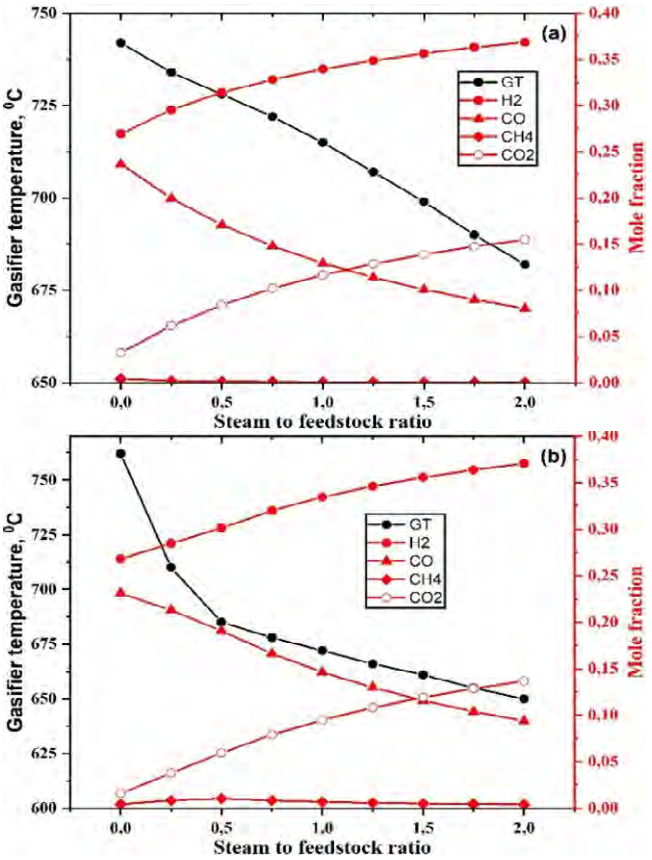

**Figure 4**: Effect of SFR on syngas concentration and GTat a fixed ER of 0.3 (a): 25% LLDPE, (b): 75% LLDPE

## Performance indicators

The lower heating value (LHV) of syngas on a dry basis, carbon conversion efficiency (CCE), and cold gas efficiency (CGE) were used as performance indicators for the co-gasification of CG and LLDPE as depicted in figure 5 (using air), figure 6 & figure 7 (mixture of air and $H_2O$). From 5, it is evident that the CCE increases with an increase in ER until it attains a maximum value at an ER of 0.3 and 0.35 for 25 and 75 % LLDPE respectively due to accelerated oxidation of carbon content in the feedstock. This is in line with figure 2 whereby the CO concentration attained a maximum value at an ER of 0.3 (for 25% LLDPE) and 0.35 (for 75% LLDPE). An opposite trend is observed for LHV whereby it decreases with an increase in the ER. The LHV is significantly reduced at lower ER due to a decrease in $H_2$ and $CH_4$ concentrations. In an ER range of 0.15-0.4, the syngas LHV decreases slightly. However, the decrease in LHV in this range is less for 75% LLDPE. The CGE attains its peak at the point where all the carbon in the feedstock has been converted into CO or $CO_2$, thus maximum CCE (ER =0.3 for 25% LLDPE and ER =0.35 for 75% LLDPE) as presented in figure 4. Beyond an ER value of 0.3 and 0.35, the CGE starts to decrease because the system starts to transit into a combustion regime. The performance indicators from this study are in line with those reported in the literature for the air gasification of municipal solid waste [10].

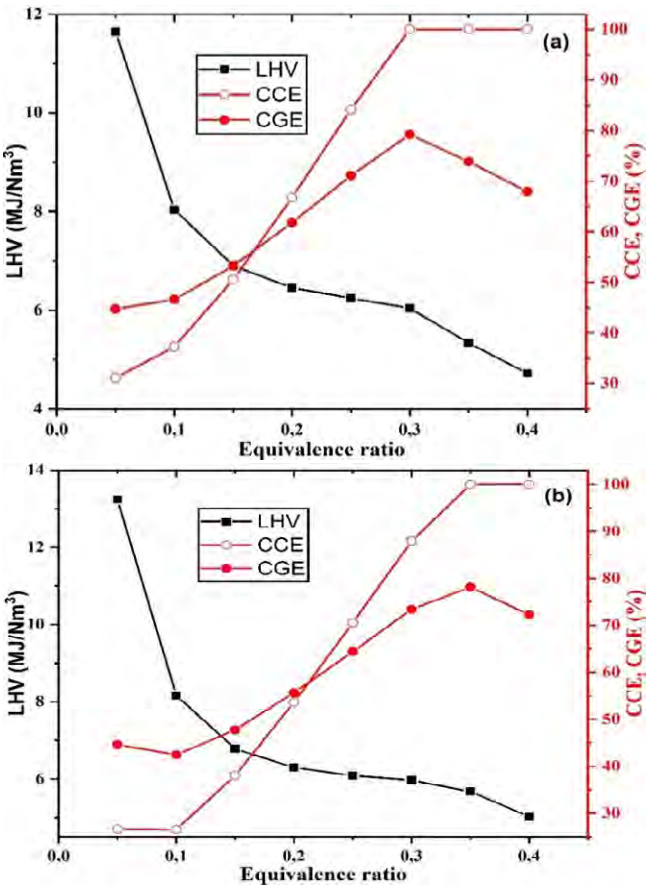

**Figure 5.** Effects of ER on CCE, CGE and LHV for air-cogasification, (a): 25% LLDPE, (b): 75% LLDPE

Figure 6 (a &b) summarizes the effect of ER on CCE, CGE and syngas LHV at a fixed SFR.These performance indicators follow a pattern similar to that of air co-gasifcation. The addition of steam to the gasifier at a constant rate decreases the syngas LHV but remains higher than that of air gasification.The main reason for the decrease in syngas LHV is the decrease of $H_2$ and $CH_4$ concentration,which largely contributes to LHV when the ER was increased. Figure 6 (a &b) shows further that, the presence of steam in the gasifier reduces the amount of air required to achieve a maximum CCE and CGE. Additionally, steam enhances the CGE by promoting steam reforming reactions.

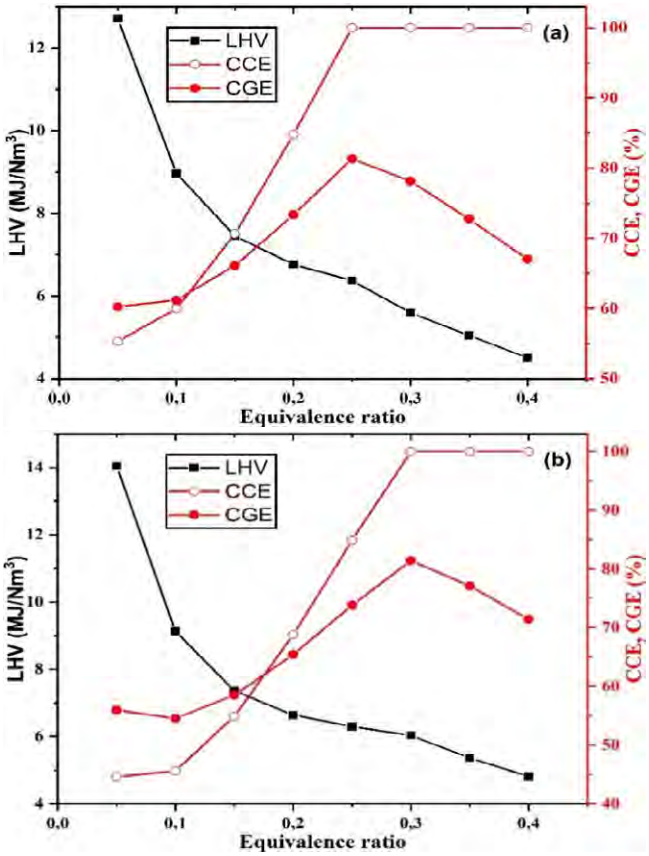

**Figure 6**: Effects of ER on CCE, CGE and LHV at fixed SFR of 0.5, (a): 25% LLDPE, (b): 75% LLDPE

The effect of SFR on syngas LHV, CCE and CGE at a fixed ER is also shown in figure 7 a& b. An increase in SFR increases $H_2$ and $CO_2$ concentration but decreases that of CO and $CH_4$. Since $CH_4$ and CO have lower heating values higher than $H_2$ per unit volume and $CO_2$ has no energy content, this will result in a slight reduction in syngas LHV as presented in figure 7a. As the LLDPE content is increased to 75% (figure 7b), the syngas LHV intially increases with an increase in the SFR.This is because $CH_4$ concentration slightly increased with an increase in SFR due to high carbon and hydrogen content of the feedstock which results in $CH_4$ formation via methanation reaction. As the SFR is further increased, the syngas LHV slightly decreases due to a decrease in $CH_4$ concentration caused by methane steam reforming reactions.The CCE for 25% LLDPE was not influenced by an increase in SFR as it has already attained a maximum value at an ER of 0.3. This resulted in a slight decrease in the CGE when the SFR was increased from 0 to 2. In the case of 75% LLDPE, the CCE increased and attained a maximum value at an SFR of 0.5. Thus, the CGE also attained its maximum value at the same SFR of 0.5.

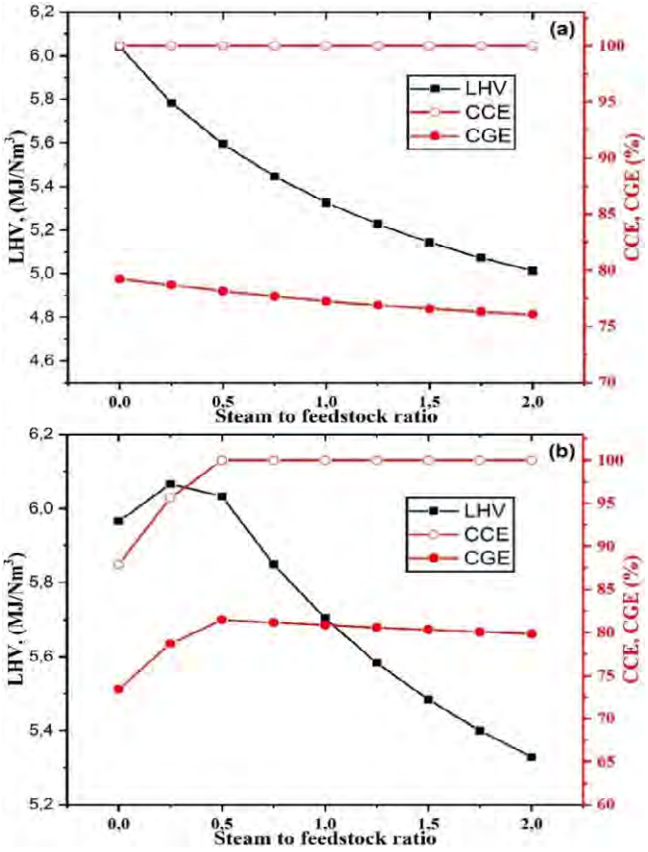

**Figure 7**: Effects of SFR on CCE, CGE and LHV at fixed ER value of 0.3, (a): 25% LLDPE, (b): 75% LLDPE

## CONCLUSION

This study evaluated the air and air/steam co-gasification of crude glycerol and LLDPE using Aspen Plus. Results indicated that an increase in ER or SFR significantly influenced the co-gasification product behaviour. For air co-gasification process, an increase in ER raised the GT and increased CO concentration until it reached a maximum value at an ER of 0.3 (25% LLDPE) and 0.35 (75% LLDPE). At the same time, $H_2$ and $CH_4$ concentration decreased which resulted in a decrease of syngas LHV. Furthermore, the CCE and CGE increased with an increase in ER and attained their maximum values at the CO concentration peak. The introduction of steam in the gasifier at a constant rate reduced the amount of air required

for the gasification process and subsequently enhanced not only the syngas composition, LHV but also the CGE. Additionally, when steam was introduced in the gasifier at a constant ER, the GT decreased significantly with an increase in SFR. Also, as the SFR increased, $H_2$ and $CO_2$ concentration increased but that of CO and $CH_4$ decreased due to steam reforming reactions which resulted in a moderate syngas LHV and CGE. Furthermore, the air gasification of 75% LLDPE achieved a flexible syngas ratio ($H_2$/CO) at an ER of 0.2 for the synthesis of methanol while syngas ratio from 25% LLDPE can be used useful for the synthesis of dimethyl ether. 25% LLDPE achieved a syngas ratio of approximately 2.03 when steam was introduced in the gasifier but 75% LLDPE did not achieve a desirable syngas ratio. When the SFR was increased at a constant ER, the syngas ratio increased and both 25% LLDPE and 75% LLDPE achieved a syngas ratio of 2.19 and 2.28, respectively at an SFR of 0.75 and 1. Therefore, this study offers a sustainable solution for waste management and promotes a circular economy by converting crude glycerol and LLDPE into valuable products. Future work should investigate the environmental and economic feasibility for crude glycerol and LLDPE co-gasification.

## ABSTRACT

Nucleophilic aromatic substitutions (SNAr) are key chemical transformations in pharmaceutical and agrochemical synthesis, yet their complex mechanisms (concerted or two-step) complicate kinetic model identification. Accurate kinetic models for SNAr are essential for scale-up, optimization, and control of the reaction process, but conventional methods struggle with mechanism uncertainty driven by substrates, nucleophiles, and reaction conditions, with data collection being difficult due to its source-intensive nature. We address this using DoE-SINDy, a data-driven framework for generative modelling without complete theoretical understanding. A benchmark study on the SNAr reaction of 2,4-difluoronitrobenzene with morpholine in ethanol was conducted, incorporating parallel and consecutive side-product formation. Ground-truth kinetic models validated in prior studies were used to generate in-silico data under varying noise levels and sampling intervals. DoE-SINDy successfully identified the true kinetic model with minimal runs, quantifying the impact of key design factors such as inlet concentrations, residence time, sample size and experimental budget on model identification.

## 1. INTRODUCTION

Nucleophilic aromatic substitution (SNAr) reactions play a crucial role in synthesizing natural products, pharmaceuticals, and agrochemicals. Accurate kinetic model identification is essential for optimizing SNAr reaction conditions, improving process efficiency, and enabling predictive control in manufacturing [1]. SNAr reactions can proceed via a classical two-step pathway or a concerted mechanism (cSNAr), with the preferred pathway influenced by substrate, nucleophile, leaving group, and environmental conditions such as solvation and fluid dynamics. These factors complicate kinetic identification, especially at process scales [2].

While quantum chemical methods like DFT offer detailed mechanistic insights, they are computationally intensive. Molecular descriptors provide a user-friendly alternative but require broader datasets for generalization [3]. Integrating solvent, fluid dynamics, and operational factors is essential for process-scale simulations, which requires computational-experimental approaches [2]. Obtaining reliable experimental data is resource-intensive, especially when integrating multiple effects [4]. Though recent innovations in continuous-flow platforms and experimental design have improved data collection efficiency [2,4–6], their reliance on predefined kinetic models limits the application to systems with incomplete mechanistic understanding. Recently, automated model-building approaches, such as such as AI-DARWIN [7], PySR [8] and SINDy [9], have been developed to rapidly identify interpretable models with minimal data requirements and without requiring fully predefined model expressions.

Motivated by these challenges, a systematic model identification framework named DoE-SINDy is employed in this paper to simultaneously generate mechanistic model structures and estimate model parameters from a small dataset [10], with the ultimate objective to provide

a robust and accurate representations of concentration profiles in SNAr reactions.

## 2. METHODOLOGY

### 2.1 DoE-SINDy framework

A dynamic model of a chemical reaction system can be formulated as a set of differential-algebraic equations (DAEs) as:

$$\begin{cases} \mathbf{f}(\dot{\mathbf{x}}, \mathbf{x}, \mathbf{u}, t, \boldsymbol{\theta}) = 0 \\ \hat{\mathbf{x}} = \mathbf{h}(\mathbf{u}, t, \boldsymbol{\theta}) \end{cases} \quad (1)$$

where $\mathbf{f}$ and $\mathbf{h}$ are sets of model equations, $\mathbf{x}$ is the observable state variable vector, $\mathbf{u} \in \mathrm{U}$ the control variable vector, $t$ time and $\boldsymbol{\theta}$ the parameter vector, and $\hat{\mathbf{x}}$ the predicted measurable state variables. This research focuses on simultaneously identifying the model structure $\mathbf{f}$, and parameters $\boldsymbol{\theta}$.

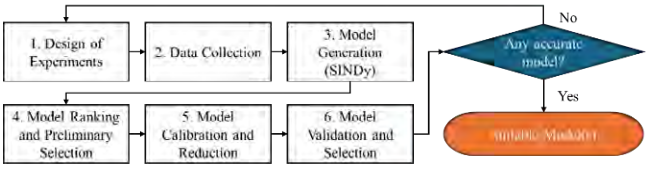

**Figure 1.** Framework of DoE-SINDy for identifying the most suitable models from experimental data [10].

Sparse identification of nonlinear dynamical systems (SINDy) [9] is a sparse regression-based approach that derives nonlinear models from a user-defined candidate term library and reaction profiles data. Assuming a process model is governed by a few key terms, SINDy ensures both accuracy and physical interpretability of the identified models. Building upon SINDy, Lyu & Galvanin proposed an iterative model identification framework named DoE-SINDy to address variability in model generation and enhance identifiability and reliability of identified models [10]. The procedure is articulated in steps illustrated in Figure 1.

In block (1), the DoE-SINDy framework begins with a preliminary design of experiments (DoE) using the minimum number of required runs to explore conditions underlying physical constraints. Step (2) requires the collection of time-varying state variable measurements, the numerical approximation of time derivatives and data splitting into training and testing subsets. In the model generation step (3), the SINDy algorithm, developed in [11,12], is called to build multiple candidate models from subsets of the training dataset. The resulting models are ranked by complexity, and the simplest candidates are selected (4). To improve parameter robustness, maximum likelihood estimation using the full training dataset is performed during the model calibration step (5), followed by model refinement to eliminate non-significant terms that minimally impact reaction profiles, further reducing unnecessary complexity. A sensitivity-based practical parameter identifiability analysis is integrated before and after calibration to ensure that only identifiable models are retained. Calibrated models then undergo model validation for statistical adequacy and check whether the models pass user-defined stopping criteria (6). If no model meets the stopping criteria, the framework iteratively returns to step (1), generating new candidate models using expanded datasets. This iteration continues until at least one model meets the stopping criteria or the experimental budget is exhausted. When the iteration stops, the output will be the statistically acceptable models or the models from the final iteration sorted in terms of Akaike Information Criterion (AIC).

The framework for DoE-SINDy is established in Python. ***PySINDy (v1.7.5)*** is the primary package used for model generation and numerical approximation of time derivatives [11,12]. Additionally, ***scipy*** is employed for ODE integration, parameter estimation, and statistical evaluations, including $\chi^2$ test, normality test and $t$ test.

### 2.2 Assessment criteria for DoE-SINDy identified models

The DoE-SINDy framework evaluates identified models using three main criteria. The first check is if the model is **statistically acceptable.** Goodness-of-fit test evaluates whether a model adequately represents experimental data considering measurement noise. A two-tailed $\chi^2$ test assesses if residuals between predictions and measurements align with assumed noise distribution, detecting underfitting or overfitting cases [13]. However, since DoE-SINDy focuses on identifying promising model structures with limited data, precise parameter estimates are not guaranteed at this stage. A normality test, as a less strict alternative, checks if residuals follow a zero-mean Gaussian distribution [14], allowing inclusion of models that may subsequently improve through refined parameter estimation and additional data. Four options for user-defined stopping criteria are possible:1) passing both tests ('and') 2) passing only $\chi^2$ test ('chi2'); 3) passing only normality test ('normality'), or 4) passing either ('or'). These are ranked from the most to the least strict, and determines when the iteration will stop, with models passing the chosen criterion labelled as "statistically acceptable".

To assess if the identified models successfully recover the ground-truth model structures, the second and the third criteria check if the model is **structurally promising,** as defined in Equation (2), or matches the **ground-truth**, as defined in Equation (3)**:**

$$\mathcal{I}(\boldsymbol{\theta}^{true}) \subset \mathcal{I}(\hat{\boldsymbol{\theta}}) \quad (2)$$

$$\mathcal{I}(\boldsymbol{\theta}^{true}) = \mathcal{I}(\hat{\boldsymbol{\theta}}) \quad (3)$$

where $\boldsymbol{\theta}^{true}$ and $\hat{\boldsymbol{\theta}}$ represent coefficient matrices of

**Table 1:** Potential scenarios for the models identified by DoE-SINDy.

| Performance | Statistically acceptable | Structurally promising | Structurally Ground-truth | Circumstance |
|---|---|---|---|---|
| Best | T | T | T | Statistically acceptable and structurally ground-truth model identified |
| Good | T | T | F | Statistically acceptable and structurally promising model identified |
| Poor | T | F | F | Statistically acceptable but missing term(s) in the ground-truth model |
| | F | T | T | Structurally ground-truth but poor fit |
| | F | T | F | Structurally promising but poor fit |
| Worst | F | F | F | Poor fit and missing terms(s) in the ground-truth model |

ground-truth and identified models, respectively. Each matrix has dimensions corresponding to the number of equations by the size of candidate term library. A non-zero entry in these matrices indicates the presence of a specific term in the model, with its value representing estimated parameters of that term. The notation $\mathcal{I}(\cdot)$ denotes the set of position indices of non-zero elements in the coefficient matrix of each identified model. For example, if the true and identified coefficients matrix of the differential equation for component A are $\theta_{c_A}^{true} = [2\ 0\ 0\ 3\ 0\ 0]$ and $\hat{\theta}_{c_A} = [2\ 0\ 0\ 3\ 1\ 0]$, the true and identified coefficient indices are $\mathcal{I}(\theta_{c_A}^{true}) = \{1,4\}$ and $\mathcal{I}(\hat{\theta}_{c_A}) = \{1,4,5\}$. The model is structurally promising since $\{1,4\} \subset \{1,4,5\}$, meaning that the identified structure contains all terms from the ground-truth model but with additional terms. It is structurally ground-truth if its structure exactly matches the true underlying model, even if parameter uncertainty is still present. For example, a model with the coefficient matrix $\hat{\theta}_{c_A} = [1.8\ 0\ 0\ 3.2\ 0\ 0]$ is considered structurally ground-truth because all the model terms are correctly identified.

## 2.3 Scenarios for DoE-SINDy identified models

Based on the assessment criteria defined in Section 2.2, labels are assigned to each identified model, as summarized in Table 1. The most desirable scenario is 'TTT,' where the identified model is both statistically acceptable and structurally ground-truth. Scenario 'TTF' is also acceptable, as the identified model contains all the ground-truth terms, with extra terms removable after additional data collection and parameter re-estimation. In practice, 'TFF' models are selected for their statistical adequacy when the ground-truth is unknown but may be eliminated through model discrimination techniques [15]. Scenarios 'FTT', 'FTF' and 'FFF' occur when no acceptable model is generated within the available experimental budget. In such cases, redefining the library of candidate terms or adjusting DoE-SINDy setting is recommended before conducting additional experiments.

# 3. CASE STUDY AND IMPLEMENTATION

## 3.1 In-silico data generation

A benchmark case study evaluated the performance of DoE-SINDy in identifying the rate models for the nucleophilic aromatic substitution (SNAr) of 2,4-difluoronitrobenzene 1 with morpholine in ethanol. The reaction produce a mixture of desired product *ortho*-substituted 3 and side products *para*-substituted 4 and *bis*-adduct 5 through parallel and consecutive elementary reaction steps as shown in Figure 2 [5,6].

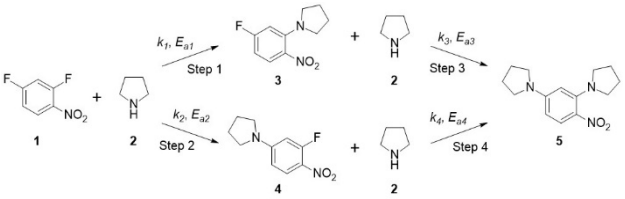

**Figure 2**. Assumed mechanism scheme for SNAr [5,6].

Data was generated through in-silico experiments simulating an automated continuous-flow reactor system with controlled linear flow ramps as in Hone *et al.* [5] and Agunloye *et al.* [6]. The residence time $\tau$ was manipulated through volumetric flow rate changes within a fixed-length reactor. The range of the time axis is equal to the residence time of the experiment with the longest operation time among the set of experiments in the ramp. The three experimental design variables in this system are: 1) initial concentrations; 2) sample size of the concentration-time profile; 3) experimental budget. The molar balance equations for the system, based on the reaction scheme are:

$$\frac{dc_1}{d\tau} = -(k_1 + k_2)c_1c_2 = \theta_1 c_1 c_2$$

$$\frac{dc_2}{d\tau} = -(k_1 + k_2)c_1c_2 - k_3c_2c_3 - k_4c_2c_4$$

$$= \theta_2 c_1 c_2 + \theta_3 c_2 c_3 + \theta_4 c_2 c_4 \quad (4)$$

$$\frac{dc_3}{d\tau} = k_1 c_1 c_2 - k_3 c_2 c_3 = \theta_5 c_1 c_2 + \theta_6 c_2 c_3$$

$$\frac{dc_4}{d\tau} = k_2 c_1 c_2 - k_4 c_2 c_4 = \theta_7 c_1 c_2 + \theta_8 c_2 c_4$$

Experiments were conducted for 2.4 minutes at 130°C, with ground-truth reaction rate constants were defined as $k_1, k_2, k_3, k_4 = [1.21, 0.21, 0.0, 0.057]$. Identifying dynamic models via DoE-SINDy requires multiple trajectories of time-varying states variables. Thus, design of experiment technique, Latin Hypercube Sampling, is applied to design multiple sets of initial concentrations within the experimental design space (Table 2). Notably, the initial concentration of $c_2(0)$ was defined as $c_2(0) = c_1(0) \cdot c_2^{equiv}(0)$.

**Table 2**: Experimental design space for control variables, initial concentrations, employed in the case study [6].

| Limits | $\boldsymbol{c_1(0)}$ (M) | $\boldsymbol{c_2^{equiv}(0)}$ | $\boldsymbol{c_3(0)}$ (M) | $\boldsymbol{c_4(0)}$ (M) |
|---|---|---|---|---|
| Lower | 0.0967 | 0.2054 | 0 | 0 |
| Upper | 1.6917 | 2.5400 | 0.5000 | 0.5000 |

In-silico data were generated by adding random normally distributed noise with zero mean and given standard deviation to the noise-free simulated values of state variables. Subsequently, the time derivatives of the noisy state variables (concentrations) were numerically approximated using Kalman derivative as the measurement errors are assumed to follow a standard normal distributions [12].

The performance of DoE-SINDy in identifying models achieving specific target scenarios was evaluated using a metric, *Target Scenario Achievement Rate (TSAR)*, which is defined as:

$$\text{TSAR} = \frac{\text{Number Of Datasets with Models Meeting the Target Scenario}}{\text{Total Number Of Datasets}} \quad (5)$$

The robustness of DoE-SINDy was tested across three different experimental budgets (10, 15, and 20 experiments), three noise levels ($\sigma = [0.1\%, 1\%, 10\%]$), ten sample sizes (8, 12, 16, 18, 20, 24, 30, 36, 48, 60), and 50 sets of initial concentrations.

## 3.2 Application of DoE-SINDy for model identification

The DoE-SINDy implementation utilized the collected measurements and their time derivatives for model identification. In the model generation step (3), the candidate term library is constructed with the following set of features: $\boldsymbol{g}(\boldsymbol{c}) = [c_1c_2, c_1c_3, c_1c_4, c_2c_3, c_2c_4, c_3c_4]$. The Stepwise Sparse Regressor (SSR) is employed to generate models from data. In step 4 of the proposed procedure, the top three simplest models are selected for further analysis. four different stopping criteria were evaluated to assess their impact on model identification performance.

# 4. RESULTS

This section compares DoE-SINDy example models for the SNAr reaction rate, evaluating the TSAR for achieving 'TTT' and 'TTF' scenarios using four stopping

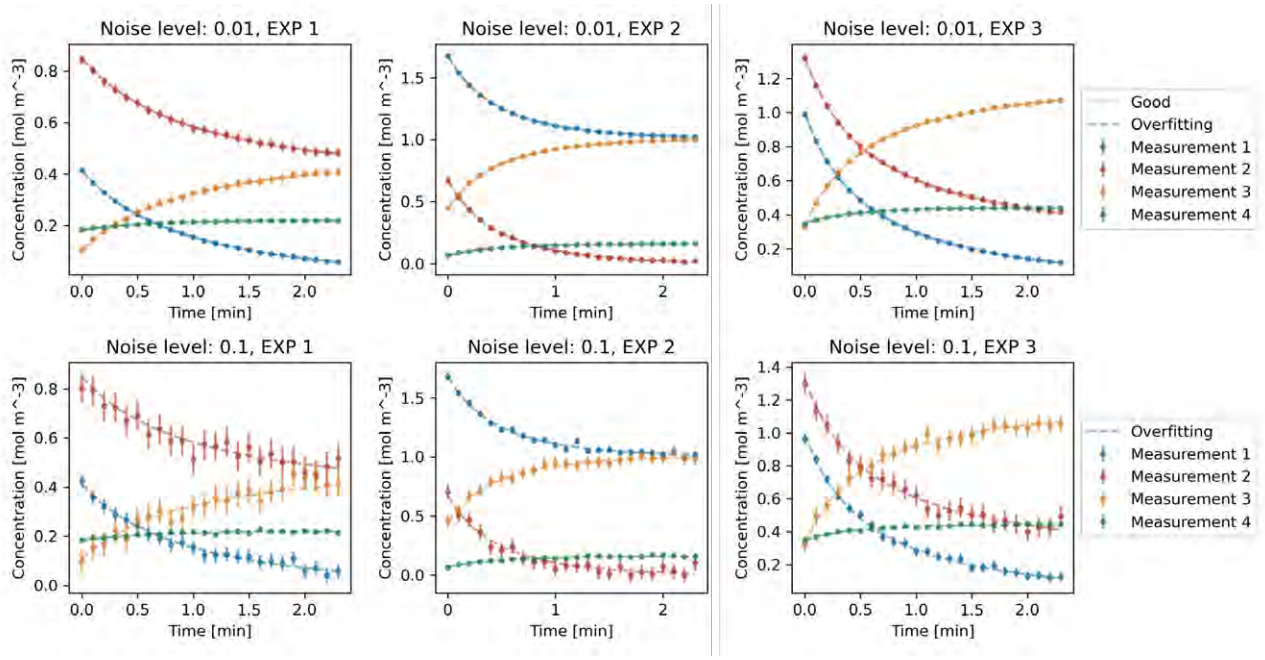

**Figure 3:** Simulations for example 'TTT' scenario models tested as good fit or overfitting based on the $\chi^2$ test, under varying initial conditions and noise levels ($\sigma$=0.01 and 0.1, sample size=24, budget=20 experiments).

**Table 3:** Estimated coefficients ($\hat{\theta}$) and corresponding $t$-values of models achieving 'TTT' scenario (sample size=24, budget=20). Results are presented for three noise levels ($\sigma = 0.1\%, 1\%\ and\ 10\%$).

| | $\theta_{i,ref}$ ($M^{-1}min^{-1}$) | $\hat{\theta}_{i,\sigma=0.1\%}$ | $t\ (t_{ref}(95\%) = 1.97)$ | $\hat{\theta}_{i,\sigma=1\%}$ | $t\ (t_{ref}(95\%) = 1.97)$ | $\hat{\theta}_{i,\sigma=10\%}$ | $t\ (t_{ref}(95\%) = 1.97)$ |
|---|---|---|---|---|---|---|---|
| $\theta_1$ | $-1.42$ | $-1.42$ | $2.06 \times 10^{-3}$ | $-1.41$ | $2.05 \times 10^{-3}$ | $-1.43$ | $2.08 \times 10^{-3}$ |
| $\theta_2$ | $-1.42$ | $-1.42$ | $2.06 \times 10^{-3}$ | $-1.42$ | $2.06 \times 10^{-3}$ | $-1.43$ | $2.07 \times 10^{-3}$ |
| $\theta_3$ | 0.00 | 0.00 | - | 0.00 | - | 0.00 | - |

| $\theta_7$ | 0.21 | 0.21 | $3.09 \times 10^{-4}$ | 0.21 | $3.10 \times 10^{-4}$ | 0.21 | $3.11 \times 10^{-4}$ |
| $\theta_8$ | $-0.057$ | $-0.057$ | $1.13 \times 10^{-4}$ | $-0.055$ | $1.26 \times 10^{-4}$ | $-0.057$ | $1.22 \times 10^{-4}$ |

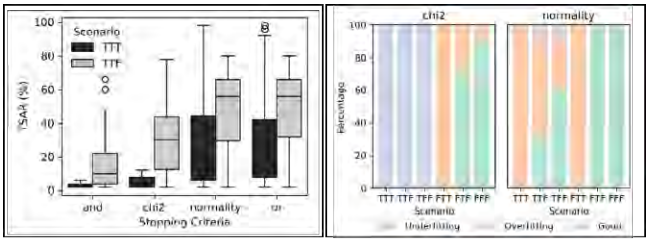
criteria ('and', 'chi2', 'normality', 'or') under varying experimental designs and data conditions.

## 4.1 Identified SNAr reaction rate models

Figure 3 shows simulated reaction profiles for models achieving the 'TTT' scenario under varying noise levels. When $\sigma = 0.01$, the profiles of the good-fit and overfitting models overlap, indicating similar prediction performance. At $\sigma = 0.1$, no good-fit models are identified but the overfitting model aligns perfectly with the observations. These graphical results suggest that both good-fit and overfitting models perform well in representing the dynamic system when the 'TTT' scenario is achieved.

Scenario 'TTT' is the most desirable outcome, where the identified models are statistically acceptable and aligned with the ground-truth. DoE-SINDy successfully identifies 'TTT' models with at least 7 experiments.

We examine three 'TTT' models identified using data with a sample size of 24 and an experimental budget of 20 noise levels of $\sigma$=0.1%, 1% and 10%. As shown in Table 3, the estimated parameter values ($\hat{\theta}_i$) are generally consistent with reference values ($\theta_{i,ref}$), and close to the reference at higher noise levels ($\sigma$=1% and 10%). Figure 3 shows that these models reflect the system dynamics well, even when some parameters deviate slightly from the reference. Parameter $\theta_3$ and $\theta_6$ consistently yield zero estimates, indicating that Step 3 is inactivated in the reaction network, consistent with the assumed reaction mechanism as shown in Figure 2 [5,6].



Although the models represent the system well, they might be statistically inadequate due to overfitting as indicated by the $\chi^2$ test. Furthermore, small $t$ values for all parameters suggest significant uncertainty in the estimates, pointing to the need for more informative data to improve parameter precision.

## 4.2 TSAR comparison across stopping criteria

The comparison of TSAR values across stopping criteria provides critical insights into DoE-SINDy's effectiveness in identifying suitable models for the SNAr reaction system. Higher TSAR indicates better performance in achieving specific scenarios.

Figure 4(a) shows that the strictness of stopping criteria significantly affects model identification. For the 'TTT' scenario, the 'normality' criterion achieves the highest average TSAR (over 20%), whereas 'chi2' achieves less than 5%, and 'and' nearly zero. This highlights 'normality' as the most effective criterion for identifying structurally and statistically adequate models. For the 'TTF' scenario, relaxing criteria from 'and' to 'or' improves TSAR from around 10% to 55%, with 'normality' and 'or' performing similarly. Less stringent criteria enable better identification of statistically adequate models, balancing efficiency and reliability.

The box plots reveal high dispersion in TSAR across datasets, reflecting the sensitivity of DoE-SINDy to data quality and experimental design. This underscores the importance of high-quality data and well-designed experiments for reliable model identification.

(a) (b)

**Figure 4:** (a) TSAR distribution for 'TTT' and 'TTF' scenarios under different stopping criteria across various data conditions; (b) Scenario distribution based on the $\chi^2$ test using 'chi2' or 'normality' stopping criteria.

The distribution patterns observed in Figure 4(b) demonstrate the goodness-of-fit of the models categorised in each scenario. Notably, for the 'FTT' scenario under both the 'chi2' and 'normality' criterion, most models correctly identify the ground-truth structure but are excluded as overfitting. These models, with parameter re-estimation, are highly likely to achieve 'TTT'. Using 'normality' as the stopping criterion is more likely to retain such models compared to using 'chi2', explaining higher TSAR values of 'normality' shown in Figure 4(a). Its reliability is supported by Figure 3, where overfitting models passing the normality test align with experimental data under varying noise levels and experimental conditions.

## 5. CONCLUSION

This study demonstrates the effectiveness of DoE-SINDy in identifying kinetic models for SNAr reaction, successfully reconstructing statistically acceptable and structurally ground-truth models with as few as 7 experiments. Adopting the 'normality' stopping criterion allows to achieve the highest TSAR for identifying promising 'TTT' models, while stricter criteria, such as 'chi2' and 'and', tend to reject structurally accurate models due to overfitting.

However, the performance of DoE-SINDy varies under different experimental designs and data conditions. Further investigations into the impact of experimental design variables are necessary to optimize model identification and reduce experimental demands. The significant uncertainty in estimated parameters highlights the need for integrating techniques as model-based design of experiments (MBDoE) in the framework to improve parameter precision [16].Finally, as the ground-truth model is typically unknown in practice, further model discrimination is required to identify the most accurate representation of the system.

## ABSTRACT

This study evaluates the introduction of Carbon Capture and Utilization (CCU) process in two Colombian refineries, focusing on their potential to reduce $CO_2$ emissions and their associated impacts under a scenario aligned with the Net Zero Emissions by 2050 Scenario defined in the 2023 IEA report. The work uses a MILP programming tool (Linny-R) to model the operational processes of refinery sites, incorporating a net total cost calculation to optimize process performance over five-year intervals. This optimization was constrained by the maximum allowable $CO_2$ emissions. The methodology includes the calculation of surplus refinery off-gas availability, the selection of products and CCU technologies, and the systematic collection of data from refinery operations, as well as scientific and industrial publications. The results indicate that integrating surplus refinery fuel gas (originally used for combustion processes) and HTL bio-crude off-gas (as a source of biogenic $CO_2$) can significantly lower scope 1 and 2 $CO_2$ emissions, aligning with long-term decarbonization goals. However, these advantages carry additional costs due to significant increases in utility demands. In the high-complexity refinery, electricity consumption increases by a factor of 10, and steam demand and water usage each increase by a factor of 2.5 and 3, respectively. Similarly, in the medium-complexity refinery, electricity consumption rises by a factor of 11, steam demand by a factor of 4, and water usage by a factor of 6. The renewable energy requirements for water electrolyzers and $CO_2$ capture units primarily drive these increases. Furthermore, despite achieving $CO_2$ neutrality in scope 1 and 2 emissions by 2050, scope 3 emissions increase due to additional $CO_2$-based methanol production. Economic analyses highlight profit opportunities in the long term. The production costs of $CO_2$-based methanol are lower than the forecasted cost of production of fossil-based methanol, enhancing their economic viability in the long term. The study emphasizes the critical influence of refinery complexity levels on the scale and timeline for implementing these technologies to achieve short- and long-term $CO_2$ reduction targets. However, further evaluation is necessary to align these results with national electrical grid capacity, water supply availability, and expansion plans.

## INTRODUCTION

Reducing $CO_2$ emissions and reaching $CO_2$ neutrality in the long term are the objectives of this study, which focuses on two oil refineries that together contribute with more than 50% of their Scope 1&2 $CO_2$ emissions from

Ecopetrol (the Colombian state oil and gas industry). The process heating requirements via refinery fuel gas are responsible for 50 to 60% of the total scope 1 emissions.

Previous studies on this topic have found that for reducing $CO_2$ emissions, refineries require a portfolio of technologies, including low-carbon hydrogen (Low-C H2), sustainable energy, carbon capture, utilization, and storage (CCUS), bio-feedstocks, and product changes. Colombia's biomass resources offer opportunities for deploying advanced biofuel technologies like Hydrothermal Liquefaction (HTL) in the refineries. HTL produces biocrude compatible with the existing refinery infrastructure; however, co-processing with fossil streams is challenging and is a topic of ongoing research [1]

Alongside biocrude production, the process delivers a rich-biogenic $CO_2$ gas stream with untapped potential to be used in CCU processes. This research is grounded on the opportunity to repurpose the surplus refinery fuel gas that is generated by switching into more sustainable fuels such as Low-C H2, and utilize this refinery fuel gas and (HTL) biocrude off-gas in a conversion processes to produce more valuable and sustainable products, such as Methanol (see Figure 1 for the simplified system block diagram).

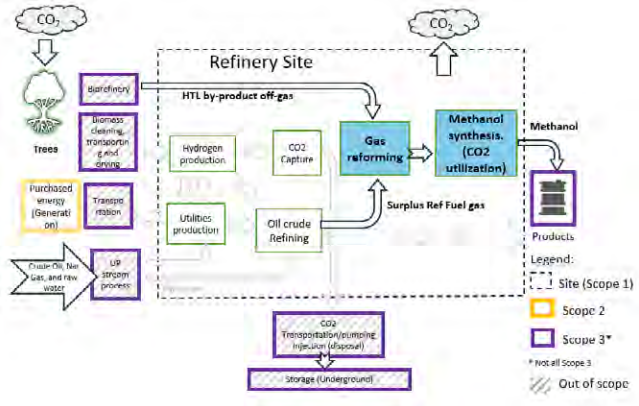

**Figure 1.** Simplified system block diagram.

This research aims to evaluate the impact of introducing CCU processes for methanol synthesis using alternative carbon sources and by-products as feedstock on the refinery performance, considering both short and long-term targets.

## METHODS

This research evaluates the future integration of alternative feedstock in methanol production /CCUS/biogenic C from biomass into two Colombian refineries and redirecting their $CO_2$ to storage. A simplified process flow diagram of the system evaluated is presented in Figure 1.

The methodology comprised five steps. In the first step, surplus refinery fuel gas was estimated. Note that HTL bio-crude off-gas was selected as the source of biogenic $CO_2$ from a biorefinery, which we assume to be installed next to the refinery and converted via thermocatalytic processes into methanol based on a previous study [2]. Second, potential CCU technologies were screened, which resulted in the selection of steam reforming and thermocatalytic hydrogenation to convert refinery fuel gas and biocrude off-gas into methanol.

Next, data was collected. The techno-economic data was sourced from literature and Aspen Plus simulations, therefore, a detailed techno-economic assessment [2] was used as input for this study. Lozano's work identified that up to 44 % of HTL Bio off-gas can be mixed with Refinery fuel gas without an external $H_2$ supply. Furthermore, this research uses data from two refineries owned by Ecopetrol. The two refineries, one with a medium level of process complexity and one with a high level of process complexity, process 7.7 Mtpd and 11.5 Mtpd of crude oil, respectively. The main characteristics of the two refineries are shown in Table 1.

**Table 1:** Main characteristics of the refinery case study

| | | Cartagena | Barrancabermeja |
|---|---|---|---|
| | **Unit** | **Value** | **Value** |
| Complexity level [1] | | High | Medium |
| Crude oil Capacity | Mt/y | 7.7 | 11.9 |
| Annual $CO_2$ emissions | Mt $CO_2$-eq /y | 2.5 | 3.4 |
| Gas fuel consumption | PJ/y | 19.8 | 30.4 |
| Electricity production | PJe/y | 3.2 | 4.9 |
| Steam production | PJth/y | 16.8 | 25.3 |
| Hydrogen production | kt/y | 84 | 28.7 |
| Total Conversion Yield | % | 96.7 % | 77 % |

**1:** The refinery complexity is defined by the Nelson Complexity Index, which quantifies the type of process units in a refinery and their capacity relative to the atmospheric distillation unit by assigning a factor [3].

In the fourth step, a mixed-integer linear programming (MILP) in Linny-R software was used to model and evaluate techno-economic and environmental parameters and energy and material balances at the system level (see Figure 2). Linny-R works with the Gurobi solver for minimizing the system costs under $CO_2$ emission constraints over time. The model was built based on previous work that optimized the basket of low-carbon H2 production technologies and CCS for the two Colombian refineries to achieve the $CO_2$ reduction emissions targets [4]. In the final step, the results were analyzed.

We evaluated this system under a favorable decarbonization scenario aligned with the Net Zero Emissions by the 2050 Scenario (NZE Scenario) defined in the 2023 IEA report [5]. In this scenario, the world moves towards decarbonization by significantly reducing fossil fuel use, having fewer incentives to explore and produce natural gas, and promoting the adoption of renewable energy sources. The parameters defined in the scenario are summarized in Table 2.

The mass and energy balances obtained from the model were compared to the refineries' 2020 material and energy balances. The model results varied less than 5% from real-world data. The model performs a single objective optimization aiming to achieve the largest total cash flow through total cost minimization in every period. In this work, every period involves 5 years. To minimize the total cost (eq 1).

$$\text{Objective function} = \min \; OC_t = \left(\sum_{p=1}^{n}[C_o - C_i]p\right)_t , \quad (1)$$

Where, OC is the overall costs [€], Co is cost output [€], Ci is cost input [€], p is a process in the refinery, and t is the time period.

Cost input is the sum of all cost, including the cost of raw materials, feedstocks, utilities, and Capex and Opex and maintenance of the new technologies, as well as an carbon taxes/penalties that increase as in the IEA scenario[5]; while the cost output category is the sum of the income associated with selling the products. Furthermore, Net margin is calculated as total cash flow divided by crude oil processing throughput. Techno-economic parameters and the calculation of annualized Capex and Opex are described in detail in the supplementary data document [6].

There are some assumptions in this work. First, the processing capacity of the Cartagena refinery will be expanded from 155 kbbl to 205 kbbl in the period between 2020-2025, according to existing plans. Additionally, to be able to use the maximum capacity for both oil refineries, there is a plan to expand the H2 production capacity in the medium term. In the short term, there is a project to interconnect the refineries to the Colombian electric grid through a 70 MW line to reduce their carbon footprint. The Colombian electrical grid has a lower carbon footprint compared with the auto-generated electricity generated at the refineries through natural gas power combined cycles because 70% of Colombian electricity is hydropower. Additionally, as a consequence of the increase in energy efficiency initiatives, there is a goal to achieve the best performance in the peer group (North and South America) in 2035. Thus, the Cartagena refinery will reduce 11% of energy consumption, and Barrancabermeja will reduce 9% of total energy consumption [7] in the short and medium term horizons.

The methanol production is expected to be expanded to fulfill the demand in modules of 500 t/d of methanol.

## RESULTS AND DISCUSSION

The results show that using HTL biocrude off gas (as a source of $CO_2$) with surplus refinery gas utilization (as a source of $H_2$) can significantly reduce scope 1 $CO_2$ emissions. Table 3 shows that the refinery's fuel gas consumption is projected to decrease significantly by 2050 by down to 0% and 39% of the 2020 levels for high-complexity and medium-complexity refineries, respectively. This substantial reduction is due to the substitution of conventional refinery fuel gas with low-carbon hydrogen produced within both refineries. The hydrogen demand for fuel uses would account for 41% and 85% of the total hydrogen requirement by 2050 in the high-complexity and medium-complexity refineries, respectively.

The results show significant reductions in Site direct and Indirect $CO_2$ emissions ( Scope 1&2) for both refinery types, as detailed in Figure 3. However, when use of products $CO_2$ emissions (scope 3) are taken into account, the results show an increase in net emissions due to the introduction of CCU processes, which produce methanol from a external source of mass (HTL biocrude off gas) and the use of refinery fuel gas changes from scope 1 (combustion) to products (scope 3)—as shown in Figure 3.

Furthermore, utilizing surplus refinery fuel gas and coprocessing with HTL bio-crude off-gas significantly increases resource demand in both refineries. Electricity demand rises by 10 and 11 times, respectively, primarily due to the reliance on renewable electricity to power water electrolyzers for the additional low-carbon hydrogen. Consequently, water demand increases by 3 and 6 times for the high-complexity and medium-complexity refinery, respectively. In addition, steam demand increases by 2.5 and 4 times for high-complexity and medium-complexity refineries, respectively, which is driven by the requirements of the $CO_2$ capture units integrated with the steam methane reforming (SMR) and biomass combustion and gasification for Low-C H2 production.

The optimized solution identified for both refinery sites can achieve the long-term $CO_2$ emissions reduction targets regarding scopes 1 and 2, as shown in Figure 3. However, this result is accompanied by a significant Underground storage capacity demand of 33 Mt for the HC refinery and 57 Mt CO2 for the MC refinery at 2050. Furthermore, the net margin is reduced in the order of 34% (high complexity) and 65% (medium complexity) over the long term.

Current Methanol cost of production. 307 €/t. Methanol, EUR (Europe): Methanol, export contract price, fob, Netherlands. [10]

Table 4 also highlights a potential profit opportunity, as the current cost of methanol production is competitive, falling within the same range of fossil-based methanol. In the middle and the long-term, our methanol is expected to be cheaper than the fossil-based methanol due to increasing carbon taxes [5] and the expected limited availability of fossil fuels, particularly in the region of this case study [8] and [9]; however, the current production cost is higher than the European cost ( +10% compared to Europe Methanol, export contract price, fob, Netherlands)[10].

## CONCLUSIONS

In this study, we conducted a comprehensive system analysis and optimization of introducing a CCU technology to produce methanol and olefins using surplus refinery fuel gas and HTL/FP off biogas in two Colombian oil refineries operating at different levels of complexity. The results revealed the significant impact of the refinery's complexity level on the scale and timeline required for implementing these technologies to achieve the committed $CO_2$ emissions reduction goals in the short and long term.

As shown in the results, the introduction of CCU technologies using surplus refinery fuel gas and biogenic CO2 source ( HTL/FP off biogas) enables long-term $CO_2$ emissions reduction for refineries. However, this transition generates a substantial financial cost, with a significant decrease in Net Margin (34% for high-complexity refineries and 65% for medium-complexity refineries). Furthermore, the adoption of CCU technologies significantly increases electricity demand, primarily due to renewable electricity requirements for water electrolyzers producing low-carbon hydrogen as a substitute for refinery fuel gas. Water and steam demand also rise considerably, driven by $CO_2$ capture units.

The results also indicate that both refineries can achieve scope 1 and scope 2 $CO_2$ neutrality by 2050 as modeled, assuming a favorable scenario. However, scope 3 $CO_2$ emissions increase due to the production of additional products like methanol through CCU processes. However, in contrast to the increased emissions associated with scope 3, the production of CO2-based methanol can result in a modest profit opportunity,

The production costs of the $CO_2$-based methanol presented in this study align with the projected cost range of electrochemical-methanol and are lower than current fossil-based methanol in the long term, thereby enhancing its economic competitiveness.

Finally, the results should be further verified against the existing capacities of the national electrical grid and

water supply in these specific areas, as well as the national expansion plans for both. Additionally, uncertainty analysis should be included in further works to evaluate the impact of it on the results.

## ABSTRACT

Pressure-swing distillation (PSD) is a frequently applied method to separate pressure-sensitive azeotropic mixtures; however, its energy demand is very high. In continuous mode, PSD is performed in a system consisting of a high- and a low-pressure column. If the composition of the feed is between the azeotropic compositions at the two pressures, it can be introduced into any of the columns, leading to two possible column sequences. Depending on the feed composition, one of the sequences is optimal whether in terms of energy demand or total annual cost (TAC). In the present work, surrogate model-based optimization is applied to determine the optimal TAC value as a function of the feed composition between the azeotropic ones. As a first step, the column sequence with feeding into the high-pressure column is studied here. The mixture to be separated consists of water and ethylenediamine, which form a maximum-boiling azeotrope. The columns are modeled separately and a large number of simulations are performed in points generated by Latin hypercube sampling, then, algebraic surrogate models are fitted to the simulation results. The resulting surrogate optimization problem is solved for different feed composition values and the accuracy of the models is verified by rigorous simulations, as well. The energy cost and TAC has a maximum as a function of the composition. The error of the estimation of TAC remains under 6 % except at the lowest water concentration studied.

## INTRODUCTION

For separating azeotropic mixtures, special distillation methods must be used, such as pressure-swing (PSD), extractive or heteroazeotropic distillation. The advantage of PSD is that it does not require the addition of a new component. However, it can only be applied if the azeotrope is pressure-sensitive, and its energy demand can also be high. The configuration of the system depends on not only the type of the homoazeotrope but also the feed composition (z). If z is between the azeotropic compositions at the pressures of the columns, the feed can be introduced into either the low- (LP-HP sequence) or the high-pressure column (HP-LP sequence). Depending on the value of z, one of the sequences will be optimal, whether with respect to energy demand or total annual cost (TAC).

Optimization of PSD systems is typically performed either by local methods (e.g. [1]) that might fail in finding the global optimum or by global, evolutionary algorithms (e.g. genetic algorithm, GA), which, however, require a large number of simulations. A potential approach to reduce the computational intensity is surrogate model-based optimization (SMBO), where the objective function is estimated with surrogate models fitted to the results of simulations. To the best of our knowledge, SMBO was only applied to optimize PSD systems by Bubel et al. [2] and Karaman et al. [3].

Bubel et al. [2] minimized the total energy demand of the separation of the maximum-boiling azeotropic mixture acetone-chloroform. They applied artificial neural networks as surrogate models, but did not consider the geometrical parameters (numbers of trays, feed locations) as optimization variables, only the operational ones. Two SMBO approaches were tested: fitting the models to individual columns or to the whole flow-sheets, with the first approach showing better results.

Karaman et al. [3] studied the separation of a maximum-boiling azeotropic mixture water-ethylenediamine by PSD, where z (35 mol% water) was between the azeotropes at 0.1 and 2.02 bar. The TAC of both sequences was minimized without and with heat integration. The LP-HP sequence was more favorable at this composition. The optimization was performed by two methods: a GA and SMBO. By SMBO, algebraic surrogate models were fitted to simulation results of the whole flow-sheet by the ALAMO software [4] and the resulting optimization problem was solved. Different decomposition techniques were tested with the models fitted (1) to elements of TAC (heat duty of LPC, column diameters), (2) to capital and energy costs or (3) to TAC itself. The best results were achieved with the highest level of decomposition. Although the TAC obtained by SMBO was lower than that of GA only once, the difference was always within 5 %.

In this work, our aim is to (1) improve the accuracy of surrogate models, thus, the performance of SMBO and (2) study the influence of z on the optimum of the HP-LP sequence, using the case study of Karaman et al. [3]. The first goal is achieved by fitting the models to the results of the single columns instead of the two-column system. Achieving the second goal requires repeated optimization at different feed compositions, which would be very time-consuming with conventional optimization methods. However, an advantage of SMBO is that z can be included as an input variable of the models. This enables quickly finding the optimum for any feed composition. By performing the optimization for the LP-HP in a future work, it will be possible to determine for both column sequences the range of z where the given sequence is optimal.

The novelty of our work consists of determining the optimal PSD system for the first time as a function of the feed composition by SMBO. Additionally, this is the first work that uses ALAMO to fit the models to be used in the optimization to the individual columns since Karaman et al. [3] fitted them to the two-column system. While Bubel et al. [2] did the model fitting to the individual columns, they only considered operational parameters as optimization variables.

## PROCESS DESCRIPTION

Water(A) and ethylenediamine(B) form a maximum-boiling azeotrope below 4-4.5 bar. The azeotrope is pressure-sensitive, with its A content decreasing from 44.1 mol% at 0.10 bar to 25.6 % at 2.02 bar. The phase equilibrium calculations were performed by UNIQUAC [3].

The flow rate of the feed is F=100 kmol/h; its pressure and temperature are 2.02 bar and 46.85 °C, respectively. Its composition is assumed to be able to vary roughly between the two azeotropic compositions: $0.27 \leq z \leq 0.44$. Both components must be recovered with a purity of 99.5 %.

The feed is introduced into either the high- (HPC, 2.02 bar) or the low-pressure column (LPC, 0.101 bar), leading to the two column sequences HP-LP and LP-HP (Figure 1). Both columns have a pressure drop of 2.74 mbar/tray. (Note that Karaman et al. [3] used constant pressure drop values of 0.2407 and 0.0492 bar for HPC and LPC, respectively.) A is obtained as the distillate of HPC ($D_{HP}$). The bottom product's composition is close to the azeotropic one at the column pressure, and it is fed into LPC, where B is produced as distillate ($D_{LP}$). The bottom product is then led to HPC. The distillate flow rates can be calculated from the material balances written for the feed and the distillates as linear functions of z:

$$D_{HP} = F - D_{LP} \tag{1}$$

$$D_{LP} = F \frac{x_{DHP} - z}{x_{DHP} - x_{DLP}} \tag{2}$$

According to the purity specifications, the concentration A in $D_{HP}$ and $D_{LP}$ is $x_{DHP}$=0.995 and $x_{DLP}$=0.005, respectively.

In the present work, since only the HP-LP sequence is studied, the bottom product of LPC can be considered as a recycle stream ($F_{rec}=W_{LP}$).

## CALCULATION METHOD

Simulation of the individual columns or the whole PSD process is performed with the professional flowsheet simulator CHEMCAD 7.

The total annual cost (TAC) is calculated from the total capital (TCC) and total energy cost (TEC) [1, 5]:

$$TAC = \frac{TCC}{PBP} + TEC \tag{3}$$

where PBP=3 y is the payback period. The capital cost includes the cost of the columns, condensers and reboilers. The energy cost is the cost of the low- and middle-pressure heating steam used to heat the reboiler of LPC and HPC, respectively. A detailed description of the cost calculation is given in Ferchichi et al. [5].

Apart from the numbers of theoretical trays ($N_{HP}$, $N_{LP}$), which are input parameters, the following results are needed for the calculation of TAC: the column diameters ($Di_{HP}$, $Di_{LP}$), the condenser ($Q_{cHP}$, $Q_{cLP}$) and reboiler heat duties ($Q_{rHP}$, $Q_{rLP}$) and temperature of the bottom products ($T_{WHP}$ and $T_{WLP}$). (The temperatures of the distillates are also required to calculate the condenser areas, but they are constant due to the specified purities.) Therefore, surrogate models are fitted to the above results to calculate an estimation of TAC.

Contrary to our previous work [3], the two columns are modelled separately for the fitting of the surrogate models. An overview of the surrogate model system is

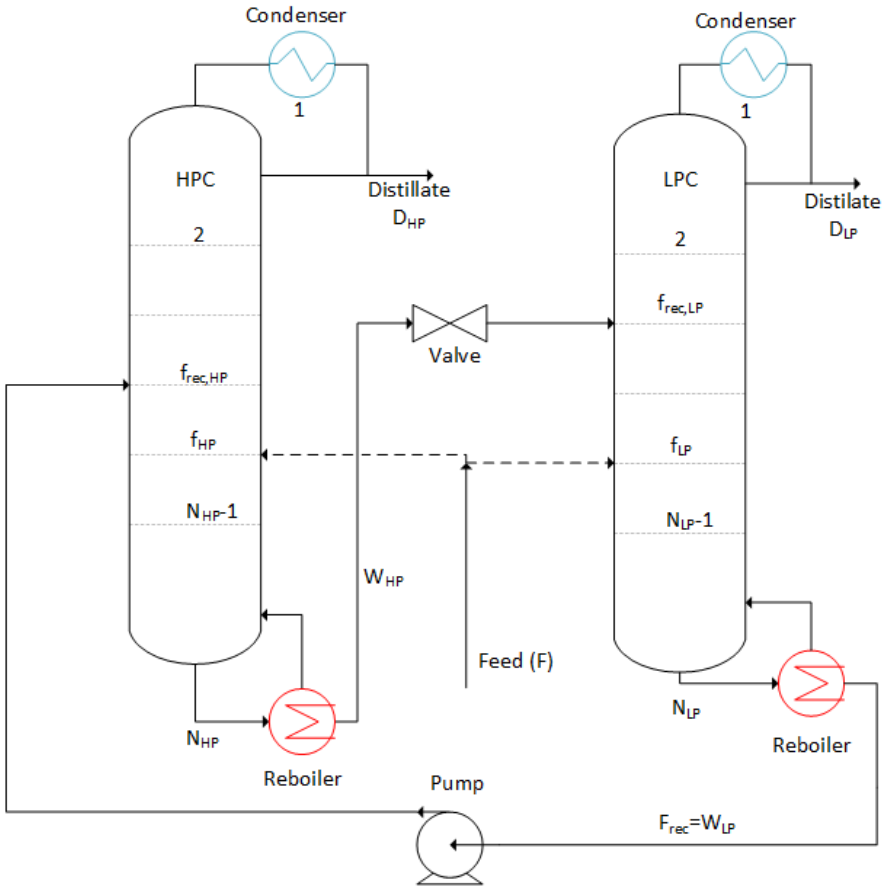

**Figure 1:** Common flow-sheet of the column sequences HP-LP and LP-HP. Depending on the sequence, the feed is either introduced into HPC or LPC (shown by dashed line)

shown in Figure 2. Symbols with * denote values calculated from surrogate models. The input variables for both columns are the number of trays, $F_{rec}$, the composition of the bottom product of LPC ($x_{WLP}$) and z. The flow rate ($W_{HP}$) and composition ($x_{WHP}$) of the feed of LPC are calculated by material balances from $F_{rec}$, $x_{WLP}$ and $D_{LP}$. For both columns, 500-500 points are generated in the four-dimensional space of the input variables by using Latin hypercube sampling (LHS). The ranges of the input variables are given in Table 1. In each point, the column is simulated with the distillate composition and bottom product flow rate as column specifications. For the given input variables, the optimal feed locations are determined by minimizing the reboiler heat duty. Initial locations are set as $f_{rec}=0.1324 \cdot N_{HP}$, $f_{HP}=0.8971 \cdot N_{HP}$, and $f_{rec,LP}=0.2778 \cdot N_{LP}$ based on the optimal values of Karaman et al. [3]. The feed locations are then varied (in the case of HPC, one by one) until reaching the minimum of the heat duty. This procedure guarantees optimal feed locations while eliminating them as input variables, thereby reducing the dimensionality of the surrogate models.

By using ALAMO, algebraic surrogate models are fitted to $Q_{rHP}$, $Di_{HP}$, $Q_{cLP}$, $Q_{rLP}$ and $Di_{LP}$ as functions of the four input variables by minimizing the Bayesian information criterion or, in the case of the mean square error. ALAMO is permitted to select, apart from a constant value, linear, exponential, logarithmic and polynomial functions of the variables, as well as different powers of the binary or tertiary products and ratios of the variables. Models of the diameters are forced to be integer or half-integer values in feet, as CHEMCAD calculates discrete values of diameters. $Q_{cHP}$ is expressed as a linear function of $Q_{rHP}$. In order to be able to estimate the bottom product temperatures of the columns, it is also necessary to describe them by surrogate models. 400 boiling point values are generated by combining 20 pressure and 20 water concentration values. The pressure range is determined by calculating the minimum and maximum possible pressure drops from the range of N used. The concentration ranges used are $0.26 \leq x_{WHP} \leq 0.34$ and $0.40 \leq x_{WLP} \leq 0.44$. ALAMO is then used to fit models to the boiling points.

With the surrogate models, it is possible to calculate TAC*, an estimation of TAC, and minimize it for different values of z. The optimization problem can be written as:

$$\min_{N_{HP},N_{LP},F_{rec},x_{WLP}} TAC^*(N_{HP},N_{LP},F_{rec},x_{WLP},z) \qquad (4)$$

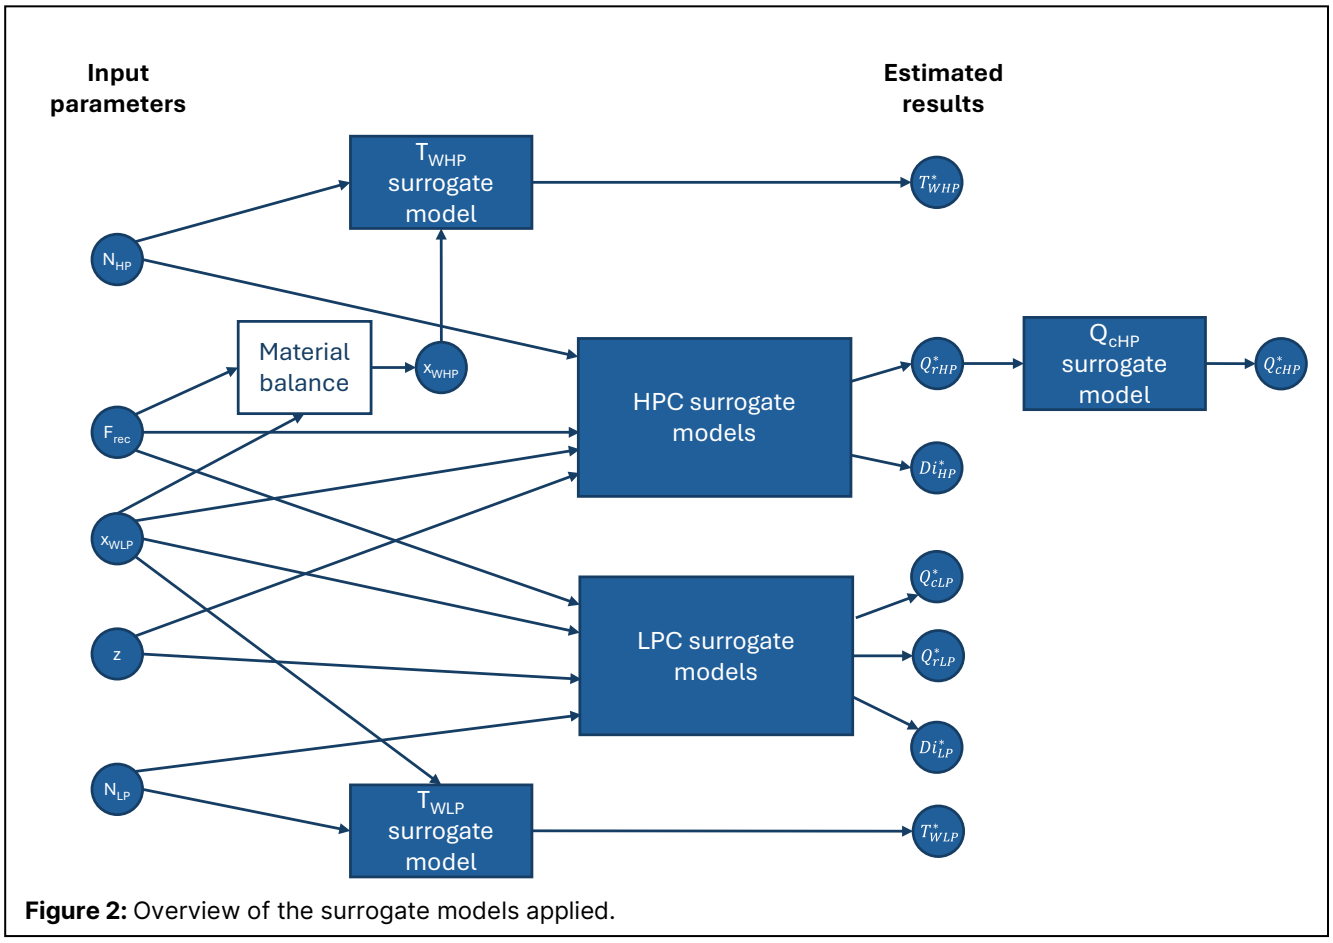

**Figure 2:** Overview of the surrogate models applied.

**Table 1:** Ranges of the input variables used for surrogate model fitting.

| Variable | Minimum | Maximum |
|---|---|---|
| $N_{HP}$ | 50 | 100 |
| $N_{LP}$ | 15 | 60 |
| $F_{rec}$, kmol/h | 80 | 220 |
| $x_{WLP}$ | 0.42 | 0.44 |
| z | 0.27 | 0.43 |

The only constraints of the problem are the lower and upper bounds of the variables (Table 1) to avoid extrapolation with the surrogate models. The optimization problem is solved by sequential quadratic programming in Maple.

After solving the surrogate optimization problem, it is necessary to check the results by creating a three-dimensional plot of TAC* as the function of two variables. This can also help with the identification of local optima, but its most important aim is the following. It often occurs that the value of one or more variables is on the lower or upper bound. This might mean that the (constrained) optimum is truly on said bound, indicating that it is necessary to extend the range of the variable as the true optimum lies outside the current range. However, this can also be an artefact of the surrogate models, which can have a large error close to the bounds, where the concentration of simulation points is lower. If the direction of the errors improves the objective function, an erroneous optimum can be found. This can be prevented by the above graphical analysis and, if necessary, the application of a constraint to exclude the problematic region.

## RESULTS

Karaman et al. [3] optimized the process at z=0.35 both by using a GA and SMBO (Table 2). The SMBO process was followed by determining the optimal feeding locations, as well. Note that the results are not completely comparable to the ones obtained here since they used constant pressure drop values.

In the present work, out of the 500 simulations, 408 converged in the case of HPC and 264 in the case of LPC. The size (number of elements), the adjusted coefficients of determination ($\bar{R}^2$) and root mean square error (RMSE) of the models are given in Table 3.

The linear model of $Q_{cHP}$ and those of the bottom temperatures have a very good fit. The $\bar{R}^2$ values of the other heat duties are relatively high, as well. The least good fit occurs by the column diameters. However, for the majority of the data points, the error of the diameter is only one or two sizes.

**Table 2:** Optimization results of Karaman et al. [3] for z=0.35.

| | GA | SMBO |
|---|---|---|
| $N_{LP}$ | 68 | 72 |
| $F_{rec}$, kmol/h | 161.1 | 184.8 |
| $N_{LP}$ | 36 | 35 |
| $x_{WLP}$ | 0.435 | 0.424 |
| TCC, $10^6$ $ | 1.901 | 1.992 |
| TEC, $10^6$ $/y | 1.989 | 2.045 |
| TAC, $10^6$ $/y | 2.622 | 2.709 |

**Table 3:** Ranges of the input variables used for surrogate model fitting.

| Variable | Model size | $\bar{R}^2$ | RMSE |
|---|---|---|---|
| $Q_{cHP}$ | 2 | 0.998 | 296 MJ/h |
| $Q_{rHP}$ | 37 | 0.962 | 1100 MJ/h |
| $Di_{HP}$ | 21 | 0.679 | 0.122 m |
| $Q_{cLP}$ | 24 | 0.909 | 980 MJ/h |
| $Q_{rLP}$ | 26 | 0.896 | 981 MJ/h |
| $Di_{LP}$ | 11 | 0.635 | 0.177 m |
| $T_{WHP}$ | 7 | 1.00 | $2.93 \cdot 10^{-4}$ °C |
| $T_{WLP}$ | 13 | 1.00 | $6.34 \cdot 10^{-5}$ °C |

The optimization problem is solved for 9 different z values. Table 4 shows the optimal values of the optimization variables. $N_{HP}$ and $F_{rec}$ do not show a monotonous variation; their values are notably higher at z≥0.35. $F_{rec}$ gradually decreases above this value, but both variables clearly show a decrease when approaching z=0.43. $N_{LP}$ always equals 25 except for z=0.35. It must be noted that it was necessary to use a constraint of $N_{LP}$≥20 to avoid false optima at 15, the lower bound $N_{LP}$. $x_{WLP}$ also reached its lower bound at z≤0.29 and z≥0.37. However, this seems not to be due to a particularly high error of TAC*, indicating that it would be necessary to decrease the lower bound of $x_{WLP}$ when performing LHS. As shown in Figure 3 for z=0.35, it seems that two local optima exist, one at $x_{WLP}$=0.42 and another around $x_{WLP}$≈0.43. One of these is found at every z value.

**Table 4:** Optimal values of the optimization variables as a function of z, determined by SMBO.

| z | $N_{HP}$ | $F_{rec}$, kmol/h | $N_{LP}$ | $x_{WLP}$ |
|---|---|---|---|---|
| 0.27 | 68 | 156.8 | 25 | 0.42 |
| 0.29 | 69 | 155.4 | 25 | 0.42 |
| 0.31 | 65 | 148.8 | 25 | 0.4296 |
| 0.33 | 65 | 152.8 | 25 | 0.4296 |
| 0.35 | 75 | 189.9 | 26 | 0.4295 |
| 0.37 | 75 | 187.4 | 25 | 0.42 |
| 0.39 | 76 | 179.9 | 25 | 0.42 |
| 0.41 | 71 | 169.4 | 25 | 0.42 |
| 0.43 | 67 | 150.1 | 25 | 0.42 |

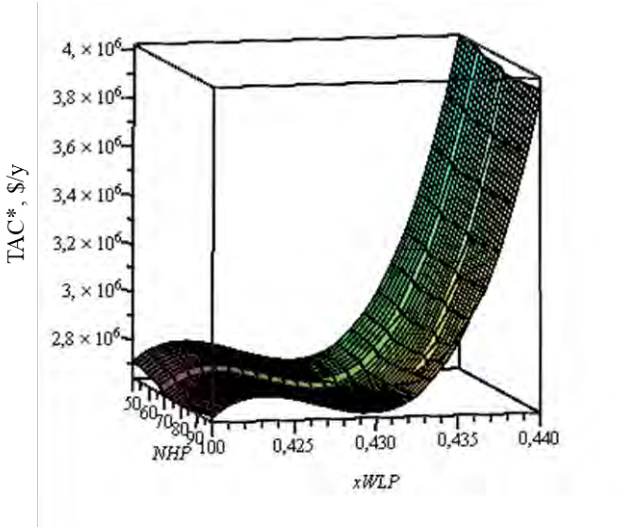

**Figure 3.** TAC* as a function of $N_{HP}$ and $x_{WLP}$ at z=0.35, $F_{rec}$=189.9 kmol/h and $N_{LP}$=26.

Figure 4 shows the costs calculated with the surrogate models in the optima given in Table 4 with dashed curves. At each z value, a simulation is also performed with the optimal values, and the costs are also calculated from the simulation results (shown with continuous curves). TCC* has a maximum as a function of z at z=0.35, but it hardly changes between 0.35 and 0.41. TEC* also has a maximum, but at a much higher value: z=0.41. Below z=0.33, a considerable increase can be observed on the increase of z. Due to the small changes in TCC*, the behavior of TAC* is similar to that of TEC* with a maximum at z=0.41.

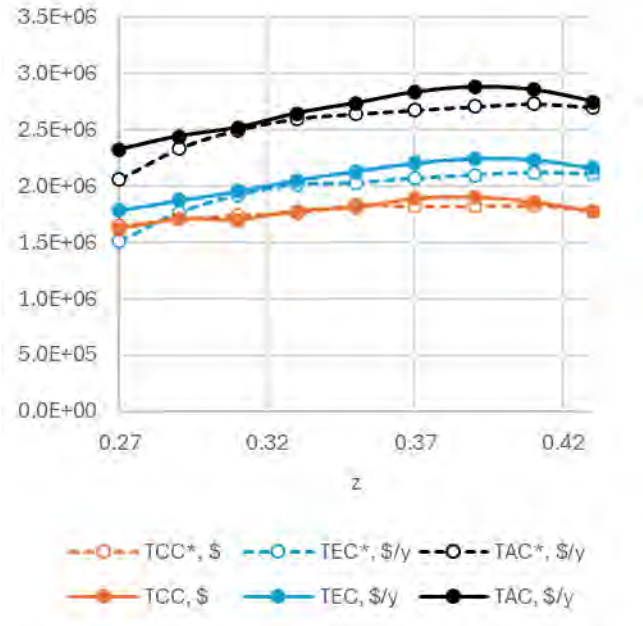

**Figure 4.** Estimated and rigorously calculated costs in the determined optima as functions of z.

The rigorously calculated TCC also shows a limited variation only, mostly explained by changes in $Di_{HP}$, and a maximum of z=0.39. Both TEC and TAC behave similarly to their estimated values, but their maxima are more pronounced and occur at a lower z value, also at z=0.39. The maximum in TEC, and thus in TAC, can be explained by the fact as z increases, more distillate has to be produced in HPC and its heat duty increases, while that of LPC decreases. It must be noted that these TAC values are probably not optimal, only approximations of the optima.

Comparing the estimated and rigorously calculated cost, it can be seen that the error of TCC is relatively low at all z values, with a maximum of 4 % at z=0.39. The error of TEC is low around z=0.32 and 0.43, and it is always below 7 % except at z=0.27 (15 %). The accuracy of TAC is similar to that of TEC. Its error is 11 % at z=0.27, but lower than 6 % otherwise. TEC and TCC are always underestimated by the surrogate models, but this is the case by TCC.

The values of $N_{HP}$ and $F_{rec}$ determined by Karaman et al. [3] by SMBO (Table 2) are close to the ones obtained here, while the values by GA are similar to those calculated for z ≤0.33. $N_{LP}$ is considerably higher by both methods. The $x_{WLP}$ value obtained here is between that of GA and SMBO. Karaman et al. [3] achieved a TAC lower by 1.0 % by SMBO and 4.2 % by GA. The error of TAC estimated by the surrogate models was 3.7 % compared to 3.5 % in this work.

## CONCLUSIONS

The separation of maximum-boiling azeotropic mixture, water-ethylenediamine by pressure-swing distillation (PSD) was studied. The feed composition (z) was between the azeotropic compositions at the pressures of the columns. From the two possible column sequences, the HP-LP one is studied, where the feed is introduced into the high-pressure column (HPC). The total annual cost (TAC) of the PSD system was previously minimized by Karaman et al. [3] for a given feed composition (z=35 mol% water) using a genetic algorithm and surrogate-model based optimization (SMBO). By the latter method, surrogate models were fitted to a large number of simulation results of the two-column system.

In the present work, SMBO was applied by fitting the models to the results of the individual columns. Another novelty was that z was now included as an input variable of the models. The other input variables were the numbers of trays of the columns and the molar flow rate and water content of the bottom product of the recycle stream, that is, the bottom product of the low-pressure column. Using the surrogate models, it was possible to estimate TAC. The resulting surrogate optimization was solved for different values of z. The accuracy of the estimated TAC was verified by rigorous simulations, as well. The energy cost (TEC) and TAC had a maximum as a function of the composition. The capital cost was estimated with a maximal error of 4 %. The errors were higher for TEC and TAC. In the case of TAC, the error of the estimation of TAC remained under 6 % except at the lowest water concentration studied. The minimal TAC at z=35 % found in this work is only by 1 % higher than the SMBO result of Karaman et al. [3] and 4 % than the optimal value found by the genetic algorithm. In conclusion, the accuracy of the SMBO method is acceptable.

In the future, the SMBO of the LP-HP sequence will be performed, as well. This will make it possible to determine for both column sequences the range of z where the given sequence is optimal.

## ABSTRACT

Reject brine discharge and high $CO_2$ emissions from desalination plants are major contributors to environmental pollution. Managing reject brine involves significant costs, mainly due to the energy-intensive processes required for brine dilution and disposal. In this context, Solvay process represents a mitigation scheme that can effectively reduce reject brine salinity and sequestering $CO_2$ while producing sodium bicarbonates simultaneously. The Solvay process represents a combined approach that can effectively manage reject brine and $CO_2$ in a single reaction while producing an economically feasible product. Therefore, this study reports a systematic techno-economics assessment of conventional and modified Solvay processes, while incorporating brine and carbon tax. The model evaluates the significance of implementing a brine and $CO_2$ tax on the economics of conventional and $Ca(OH)_2$ modified Solvay compared to industries expenditures on brine dilution and treatment before discharge to the sea. The results show that the conventional Solvay process becomes profitable after applying a brine tax of 1 dollar per meter cube of brine and a $CO_2$ tax of 42 dollars per tonne $CO_2$ —both figures lower than the current costs associated with brine treatment and existing carbon taxes. Moreover, the profitability of the $Ca(OH)_2$-modified Solvay process increases even further with minimal brine and $CO_2$ taxes. The findings highlight the significance of adopting modified Solvay process as an integrated solution for sustainable brine management and carbon capture.

**Keywords**: Solvay Process, Brine Management, Carbon Dioxide Capture, Carbone Tax.

## INTORODUCTION

Carbon dioxide ($CO_2$) is a major contributor to climate change that is responsible for the considerable temperature rise. Considering the current fossil fuels consumptions, it is expected that by 2050, the $CO_2$ emission would reach 50 gigiatons per years that would cause the global temperature to increase by 2.5 °C [1]. However, implementing carbon pricing policies and technologies would limit the temperature increase to 1.5 and the $CO_2$ emission to 20 gigatons per year [2]. In addition, desalination plants produce tremendous amounts of reject brine of a concentration of 70 g/L, which is 20 times higher than the natural seawater concentration. This would cause direct harm to the aquatic species leading to serious consequences for the marine environment. In this context, Solvay process is a combined approach that can effectively mitigate $CO_2$ and reject brine in a single reaction. The traditional method involves the reaction of $CO_2$ and reject brine in the presence of Ammonia ($NH_3$) as a reagent to produce sodium bicarbonates ($NaHCO_3$). Then, $NH_3$ is recovered from the reactor effluents through the effluent reaction with calcium hydroxide $Ca(OH)_2$. The traditional Solvay process can effectively reduce the water salinity and $CO_2$ content by more than 30% and 80%, respectively [3]. The traditional Solvay process reactions are shown by equations 1 and 2.

$$NaCl + NH_3 + CO_2 + H_2O \leftrightarrow NaHCO_3 + NH_4Cl \quad (1)$$

$$2NH_4Cl + Ca(OH)_2 \rightarrow CaCl_2 + 2NH_3 + 2H_2O \quad (2)$$

Despite that, the traditional Solvay process utilizes $NH_3$ as a reagent, which is an environmentally hazardous

chemical besides it is high recovery cost. To mitigate this problem, El-Naas et al [4] proposed the use of $Ca(OH)_2$ as a reagent instead of NH3 to minimize the environmental footprint and the process cost (equation 3). The proposed $Ca(OH)_2$ modified Solvay process showed a $CO_2$ and reject brine salinity reduction percentages of 99% and 35%, respectively.

$$2NaCl + 2CO_2 + Ca(OH)_2 \leftrightarrow 2NaHCO_3 + CaCl_2 \quad (3)$$

In this work, the economic feasibility of the conventional and $Ca(OH)_2$ modified Solvay are evaluated. The model evaluates the influence of different brine salinity on the process performance in terms of $CO_2$ and salinity reduction, product production, and process profitability. Furthermore, the process profitability with implementing carbon and brine taxes is investigated.

## METHODOLOGY

Reject brine is mixed with an alkaline reagent in a mixer. The mixer is introduced into a bubble column (BR) in the case of conventional Solvay; Whereas in case of $Ca(OH)_2$ modified Solvay, the mixture is fed into a novel inert particle spouted bed reactor (iPSBR) developed by Muftah et al.[5]. Inside the reactor, the $CO_2$ is reacted with the mixture to produce $NaHCO_3$ and byproducts. The effluent from the reactor is introduced into filter to separate $NaHCO_3$ from low salinity water. However, in case of conventional Solvay, the effluent is introduced into a recovery reactor to recover $NH_3$ through the reaction of the effluent with $Ca(OH)_2$, which is an energy intensive process. The block flow diagram of the two processes is shown in Figure 1. The mathematical model of the conventional and $Ca(OH)_2$ modified Solvay processes including mass balance, energy consumption, and costing are shown in our previous study[3].

## Constraints and assumptions

The process is considered to be steady stead without any side reactions taking [4]. Also, flue gas is assumed to be ideal gas, and the main constituent of the brine is sodium (Na). Moreover, the plant lifetime is set to 20 years. Table 1 shows the parameter used in the model obtained from experimental data [4, 6]. The current market chemical price for $NH_3$, $Ca(OH)_2$ and $NaHCO_3$ are around 9.81$/kg, 0.11 $/kg and 0.28 $/kg, respectively [7].

**Table 1.** List of experimental parameters used in the model.

| Parameters | Conventional Solvay | $Ca(OH)_2$ modified Solvay |
|---|---|---|
| Brine mass flow rate (kg/min) | 1000 | |
| Reagent wt% | 25 | 2 |
| Flue gas wt% | 17 | 17 |
| BR/iPSBR conversion | 0.86 | 0.6 |
| Reactor temperature (°C) | 20 | |
| $NH_3$ recovery unit conversion | 1 | - |
| Reactor resistance time (minutes) | 20 | |
| Reagent to sodium ratio | 0.03 $NH_3$: NaCl (Mass ratio) | 0.3 $Ca(OH)_2$: NaCl (Molar ratio) |
| Recovery molar ratio | 2 $Ca(OH)_2$: $NH_4Cl$ | - |

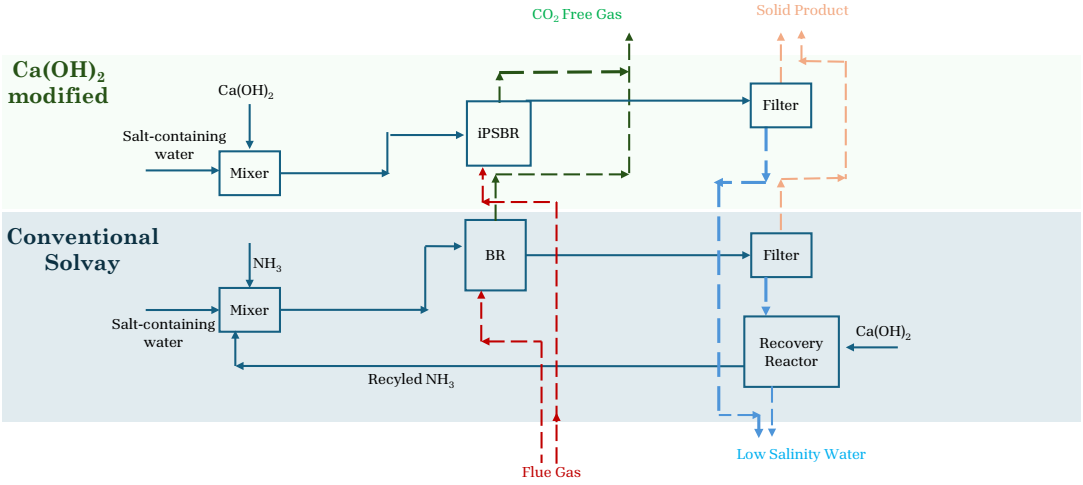

**Figure 1**. Block flow diagram of Conventional and $Ca(OH)_2$ modified Solvay processes.

## RESULTS AND DISCUSSION

The $CO_2$ and sodium reduction percentages as well as the associated profit at different brine water salinities for conventional and $Ca(OH)_2$ modified Solvay processes are shown in Figure 2. It can be observed from Figure 2a that the CO2 removal percentage at brine salinity of 30 g/L, which is sea water quality, attain a CO2 and sodium removal of around 33% and 30%, respectively. The associated expenses is around 10 $\$/m^3_{of\ brine}$ which is mainly due to the low amount of $NaHCO_3$ produced at the indicated water salinity. At water salinity 70 g/L and 90 g/L, the $CO_2$ removal percentage is constant at around 80%, while the sodium removal percentage decreases from around 33% to 22%. In addition, the associated profit is negative and constant at -6 $\$/m^3_{of\ brine}$, which indicates that the conventional Solvay requires expenses to be operated. The constant profit value is mainly due to the constant production rate of $NaHCO_3$ that is also confirmed by the constant consumption of $CO_2$.

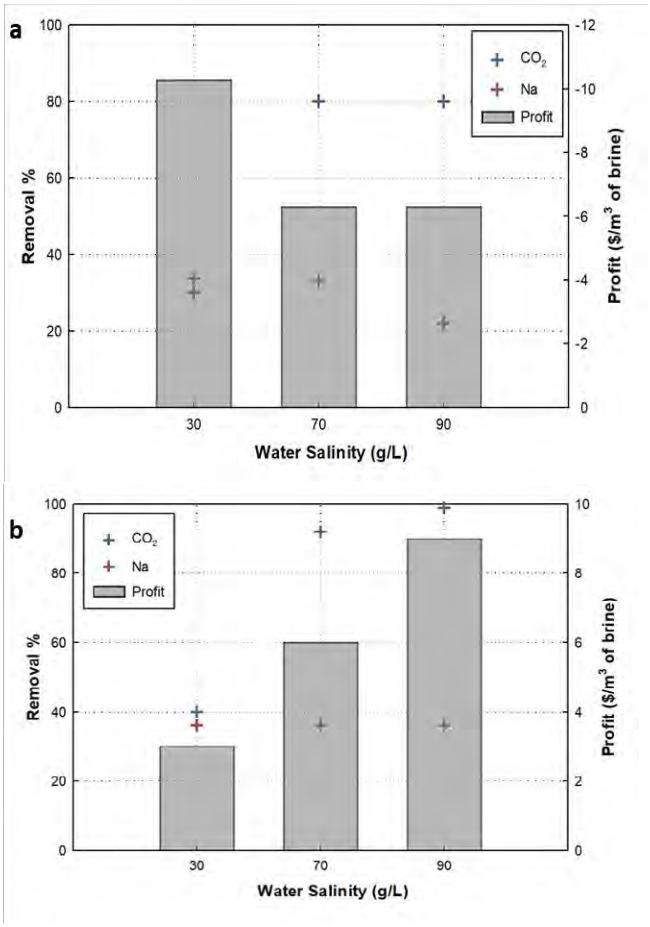

**Figure 2.** The Sodium, $CO_2$ reduction and process profitability of (a) conventional (b) $Ca(OH)_2$ modified Solvay.

On the other hand, it can be seen from Figure 2b that the $Ca(OH)_2$ modified Solvay that $CO_2$ removal increases from 40% to around 99% as the water salinity increases from 30 g/L to 90 g/L; yet the sodium removal is constant at 36%. This is due to the fact that the experimental data utilized the optimized $Ca(OH)_2$:NaCl molar ratio for the maximum sodium removal as indicated in Table 1. Yet, the associated profit is positive and increases from 3 $\$/m^3_{of\ brine}$ to around 9 $\$/m^3_{of\ brine}$. This is mainly due to the rise in $NaHCO_3$ production rate as the brine salinity increases and this is confirmed by the increase in $CO_2$ removal%. These results underscore the economic viability of the $Ca(OH)_2$ modified Solvay besides its high sodium and $CO_2$ reduction percentages for different water quality that varies from sea level salinity up to reject brine salinity level.

The results demonstrated above confirmed the economic feasibility of $Ca(OH)_2$ modified Solvay besides it superb $CO_2$ and sodium reduction percentage. Therefore, implementing $CO_2$ and/or brine tax will further increase the process profitability. Thus, herein, the influence of $CO_2$ and brine tax on the conventional Solvay profitability is investigated. The study considered brine tax values that ranges from 0 $\$/m^3_{of\ brine}$ to 6 $\$/m^3_{of\ brine}$ and $CO_2$ tax values that ranges from 0 \$/tonne $CO_2$ to 120 \$/tonne $CO_2$. Those values covers the range of the implemented tax in countries including Europe, Canada, and Mexico [8]. In fact, the economy of carbon tax is huge; It estimated that in 2023 that the world revenues from carbon tax and Emission Trading Systems (ETSs) are around 29.3 and 75 billion US dollars, respectively, as shown in Figure 3.

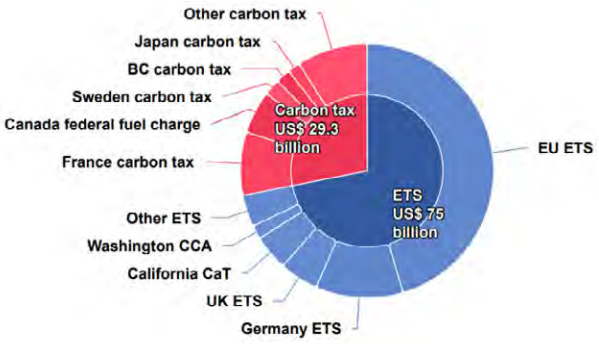

**Figure 3.** Countries contribution to carbon tax and ETSs [8].

Figure 4 shows the 3D plot of the combined effect of brine and $CO_2$ tax on the conventional Solvay process profitability. It is obvious that brine tax has a negligible influence on the Conventional Solvay profitability, whereas carbon tax influences the process profitability significantly. The figure clrearly shows that the conventional Solvay requires a considerable amount of expense. However, implementing carbon and brine tax reduces the expenses required and eventually the process reaches

the breakeven point. Table 2 demonstrates that considering a zero-brine tax, the conventional solvay reaches the breakeven point after implementing carbon tax of 42.5 $/tonne $CO_2$. While the optimum profit is obtained at the maximum implemnted carbon and brine tax.

**Table 2.** Conventional Solvay profitability.

| Parameter | Brine tax | Carbon tax | Profit |
|---|---|---|---|
| Optimum Profit | 7.03 | 116.56 | $6.21x10^6$ |
| Conventional Solvay breakeven | 0 | 42.5 | 0 |

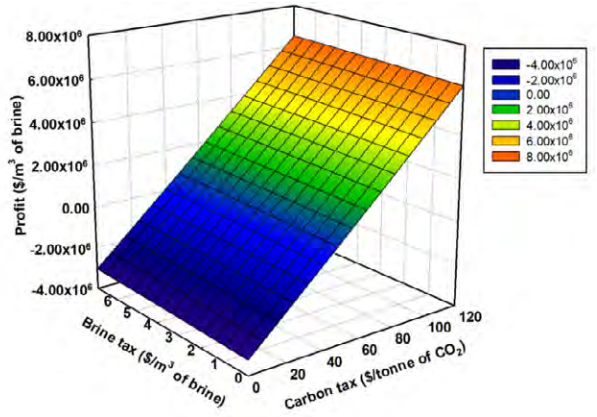

**Figure 4** 3D plots of the combined effect of carbon and brine tax on the Conventional Solvay profitability.

Table 3 shows a summary of the conventional and $Ca(OH)_2$ modified Solvay process performance from experimental and the model used in this study. It is evident that the $CO_2$ and sodium reduction percentages obtained from the model are close to the experimental data, which confirms the validity of the model. In addition, it can be seen that without the implementation of carbon tax, the $Ca(OH)_2$ modified Solvay generates profit of around 3.68 million dollars per year, while conventional Solvay requires expenses of 3.32 million dollars per year. Nevertheless, after implementing a carbon tax of 50 $/tonee $CO_2$, Conventional Solvay generates a profit of 0.6 million dollars per year, while $Ca(OH)_2$ modified Solvay becomes more profitable. This carbon tax value is much lower than the current value implemented in Europe countries and Canada, while is similar to the current value implemented in countries including Hungary, and Iceland. Figure 4 shows the carbon tax implemented in different countries in 2024. It is evident that, adopting conventional Solvay in those countries could contribute to carbon tax reduction if implemented the tax is implemented on industries as it in returns produces a considerable profit. More importantly, implementing the $Ca(OH)_2$ modified Solvay process could significantly reduce the carbon tax burden on both industries and individuals, as the process generating substantial profits from $NaHCO_3$ production, all without necessitating the imposition of a carbon tax. As a result, reducing carbon taxes for industries potentially leads to increased profit margins and enhanced competitiveness in both domestic and international markets. However, this could also result in poor investment in clean energy; therefore, it is substantial to implement a reasonable carbon tax value to ensure long term economic and environmental benefits.

**Table 3.** Summary of the experimental and model results.

| Parameter | Experimental | | Model | |
|---|---|---|---|---|
| | Conventional | $Ca(OH)_2$ modified | Conventional | $Ca(OH)_2$ modified |
| Brine concentration (mg/L) | 71,700 | | 70,000 | |
| Inlet $CO_2$ wt% | 17% | | | |
| Reagent wt% | 25% | 2% | 25% | 2% |
| $CO_2$ removal % | 83 | 99 | 82 | 92 |
| Na removal % | 29 | 35 | 33 | 36 |
| Profit ($/m$^3$ of brine) (without tax) | - | - | $-3.32x10^{-6}$ | $3.68x10^6$ |
| Profit with carbon tax ($/m$^3$ of brine)(50 $/tonne $CO_2$) | - | - | $6.20x10^5$ | $7.62x10^6$ |

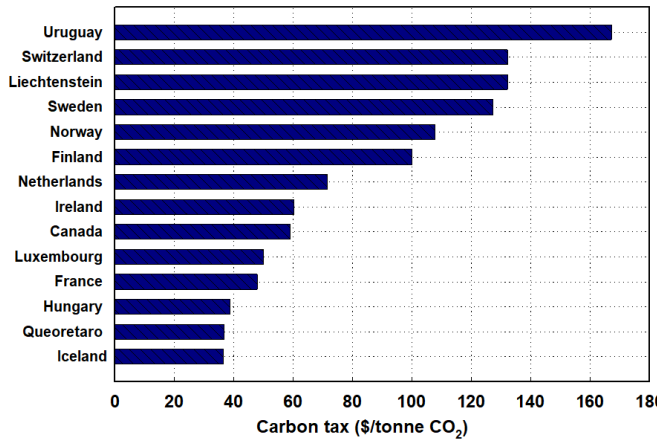

**Figure 4.** The implemented carbon tax in different countries in 2024 [8].

## CONCLUSION

This work demonstrated a systematic techno-economic assessment of Conventional and $Ca(OH)_2$ modified Solvay process considering different brine salinities and brine and carbon tax. The results indicated that $Ca(OH)_2$ modified Solvay sodium and $CO_2$ reduction capability outperform conventional Solvay for all studied brine salinity values that varies from seawater to reject brine salinity level. In addition, conventional Solvay requires considerable expenses, but it becomes profitable after implementing a carbon tax of 50 $/tonne $CO_2$, while $Ca(OH)_2$ modified Solvay is profitable without any carbon tax implementation. These results underscore the economic viability of $Ca(OH)_2$ modified Solvay process besides being an environmentally friendly process compared to conventional Solvay.

## ABSTRACT

This study explores multiphase flow dynamics with a focus on the annular flow regime using Computational Fluid Dynamics (CFD) simulations. The methodology included defining the physical model, generating the computational mesh, and analyzing flow patterns. The Volume of Fluid (VOF) model captured fluid interactions, while the k-ω SST turbulence model ensured accurate flow predictions. Simulations examined mixture density behavior and identified optimal configurations. A dataset was generated and analyzed using k-means clustering to classify flow patterns effectively. The results demonstrate the reliability of this approach for improving multiphase flow systems, with applications in oil-water processes.

**Keywords**: Multiphase Flow, Computational Fluid Dynamics, k-Means Clustering, Flow Pattern Classification

## INTRODUTION

Multiphase flows play an essential role in various industrial sectors, being characterized by the interaction of two or more phases, such as liquid, gas, or solid, moving together.

This phenomenon is present in applications ranging from oil and gas extraction and transportation processes to refrigeration systems and sediment transport in rivers. A detailed understanding of these flows is fundamental for optimizing processes, reducing operational costs, and ensuring safety in industrial operations.

In the oil and gas industry, for instance, multiphase flows are frequently associated with the transportation of mixtures of oil, gas, and water in pipelines. The efficiency of these operations directly depends on understanding the interactions between phases, as well as the ability to predict behaviors such as bubble formation, flow patterns, and pressure gradients [1,2].

Among the various regimes of multiphase flow, core annular flow (CAF) stands out as a highly relevant configuration. One example of this regime can be seen in Figure 1, a central phase, core in red, is surrounded by another phase, annulus in blue, offering significant advantages in applications such as the transportation of high-viscosity fluids. In the oil and gas industry, core-annular flow is widely employed for transporting ultra-viscous oil through pipelines. By surrounding the viscous oil with a layer of less viscous water, this regime reduces wall friction, allowing the fluid to be transported more efficiently and economically [3,4].

**Figure 1**. Example of CAF.

The identification of multiphase flow patterns in real systems has been a critical area of research, given its impact on industrial process optimization and safety.

Traditional experimental methods, such as high-speed imaging, electrical capacitance tomography (ECT), and pressure drop analysis, have been widely employed for flow visualization and pattern classification. For instance, Hewitt (1978) provided a foundational approach to visualizing flow regimes in horizontal and vertical pipes, emphasizing the role of flow characteristics such as velocity, phase distribution, and interfacial dynamics in defining patterns [5]. Another notable contribution was made by Soleimani et al. (2006), who demonstrated the effectiveness of ECT in reconstructing real-time images of multiphase flows, offering a non-intrusive method to map flow patterns accurately [6].

While these methods provide valuable insights, they often require sophisticated equipment and are limited by

operational constraints in high-pressure or high-temperature environments.

Another approach to address these challenges, advanced tools like Computational Fluid Dynamics (CFD) have emerged as powerful approaches. CFD enables the precise simulation of complex flows, providing detailed insights into critical variables such as flow patterns and pressure gradients. However, the detailed analysis of the data generated by these simulations requires methods for identifying and classifying flow regimes.

This article explores the application of the K-means algorithm to identify flow regimes applied data generated by CFD in the context of core-annular flow systems for transporting ultra-viscous oil.

## METHODOLOGY

The methodology was divided into three main stages. In the first stage, the physical model used for the simulation was defined. Subsequently, the process of mesh generation for the system was developed, where the control volumes were defined. These volumes are the elements where the mass and momentum balance equations of the system are solved. Furthermore, in this stage, the models of viscosity, turbulence, and interface governing the interactions between fluids with different properties were established.

In the second stage, individual simulations of different flow patterns were performed, based on the previously constructed geometry and mesh. During these simulations, the behavior of the mixture's density over time was observed, with the objective of understanding and identifying the most suitable approaches for identifying the system.

Finally, in the third stage, 24 simulations were conducted to generate a dataset, which was analyzed using the k-means clustering method. This procedure evaluated the efficiency of the technique in identifying flow patterns, enabling conclusions about its applicability. The resume methodology of this work can be seen in Figure 2.

**Figure 2.** Resume of methodology.

## PHYSICAL STRUCTURE MESH AND MODEL

To induce annular flow, it is common to use a nozzle that allows the simultaneous injection of oil and water through separate orifices. An example of such a setup can be seen in Figure 3.

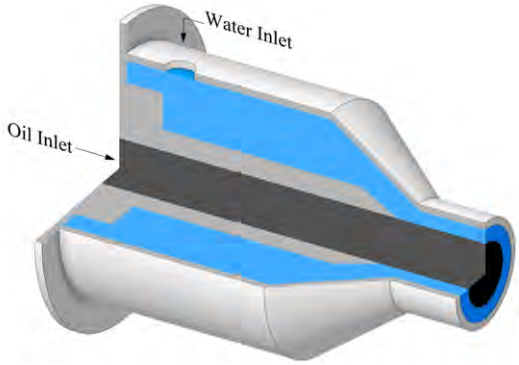

**Figure 3.** Example of nozzle.

To simplify the system's geometry and make the computational cost of the simulation more reasonable, the structure was adapted to a two-dimensional system, as shown in Figure 4.

**Figure 4.** Simplification of nozzle inlet.

This geometry features a centralized inlet of 40 mm for oil injection, along with two additional inlets of 5 mm for water injection. Connected to this inlet structure is a straight horizontal tube with a length of 1000 mm.

In general, any simplification that reduces the dimensionality of a problem results in lower computational effort at the cost of potentially minimizing certain three-dimensional effects. However, the two-dimensional simulations conducted in this study proved to be sufficiently representative in describing the classic multiphase flow patterns reported in the literature.

After preparing the geometry, a mesh was created to solve the partial differential equations for mass balance and the Navier-Stokes equations. The mesh consists of around 10000 elements and can be visualized in Figure 5.a and Figure 5.b with zoom.

**Figure 5.a.** Mesh of system.

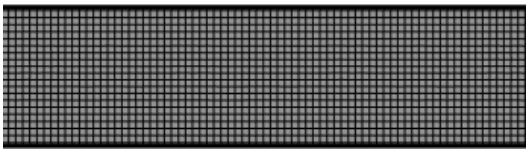

**Figure 5.b.** Mesh of system with zoom.

The mesh scale was determined based on a heuristic approach, and it was considered reasonable when it successfully represented flow patterns closely resembling those already established in the literature.

Since the primary objective of this work was to explore a strategy for identifying flow patterns rather than performing a numerical validation of simulations against real experiments, the choice of a cost-effective mesh was prioritized.

From a rigorous perspective, creating a dedicated numerical mesh for each type of flow pattern would be necessary, but this was not within the scope of the study. Instead, a balanced approach was adopted to ensure computational efficiency while still achieving meaningful results.

The model that was used to simulate the system was Volume of Fluid (VOF). The VOF model was employed to simulate the interfaces between immiscible fluids in the system. This model is well-suited for resolving complex interfacial dynamics, as it uses a single set of momentum equations for the domain and tracks the volume fraction of each fluid. This approach allows for an accurate representation of the interactions between fluids with different properties and is widely used in multiphase flow simulations [7].

During the simulation, an isothermal system was considered, where the physicochemical properties of the fluids water and oil remained constant.

The water density was assumed to be 998.2 kg/m³, while the oil density was set to 854 kg/m³. The dynamic viscosity was defined as 0.001 Pa·s for water and 0.62 Pa·s for oil, with an interfacial tension of 0.032 N/m between the fluids [8].

Another fundamental part of one CFD simulation is the turbulence model. For this application, we use k-ω SST turbulence model due capability to handle flows with adverse pressure gradients and boundary layer separation. It combines the advantages of the k-ω model near walls with the k-ε model in free-stream regions, providing reliable performance across a wide range of flow regimes [9].

## REPRODUCTION OF PATTERN FLOW

In this section, classic flow patterns reported in the literature were simulated [3]. To enhance visualization, oil was represented in red and water in blue, with the transition between colors indicating the interface between the two fluids.

Additionally, the average fluid density at the pipe outlet was monitored over time. It is important to note that the pipe was initially filled entirely with water. As a result, during the early stages of the simulation, the time signal often closely resembled the density of water, as some time was required for the oil to travel from the pipe inlet to its outlet.

The first flow pattern simulated was the oil in water dispersion. This pattern is characterized by small oil droplets dispersed within the water. As shown in Figure 6, the fluid density over time remains close to the density of water, with minor oscillations caused by droplets of varying sizes passing through the pipe outlet.

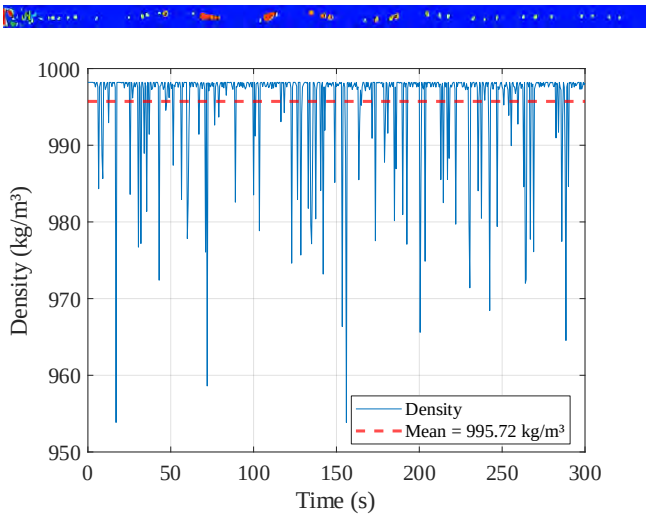

**Figure 6.** Oil in water dispersion signal in the time.

The second simulated flow pattern was the bubbly flow, where the droplets observed in the oil in water dispersion evolve into larger bubbles. This transition leads to a slightly lower average density compared to the previous pattern as shown in Figure 7.

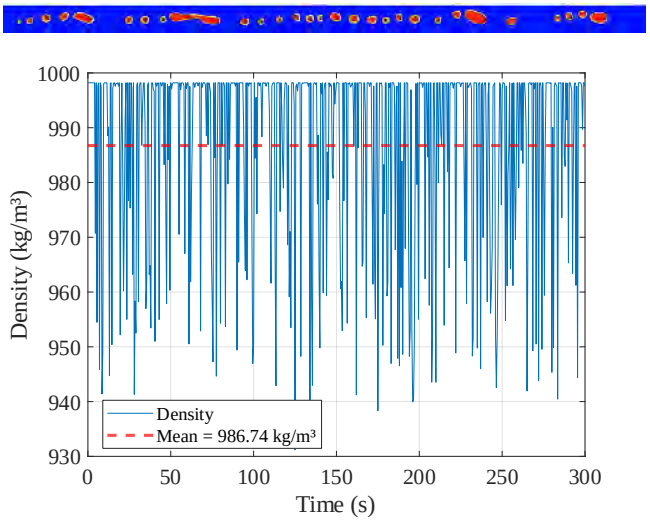

**Figure 7.** Bubble signal in the time.

The third simulated flow pattern was slug flow, which follows a similar progression to bubbly flow. In this regime, the increased volume of oil promotes the coalescence of bubbles, forming elongated oil slugs. These slugs occupy significant portions of the pipe cross-

section, resulting in a further reduction of the average fluid density over time. As depicted in Figure 8, the density signal exhibits larger and more pronounced oscillations, reflecting the alternating passage of oil slugs and water segments at the pipe outlet. This pattern highlights the impact of bubble coalescence on flow dynamics and density distribution.

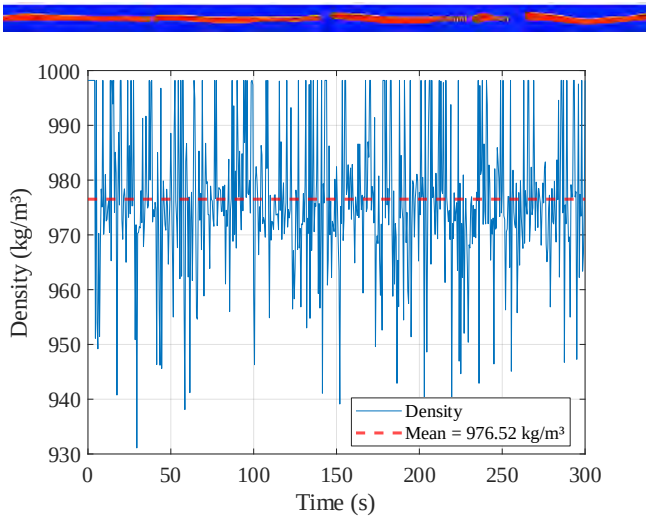

**Figure 8**. Slug signal in the time.

The fourth simulated flow pattern was stratified flow, characterized by oil and water flowing in distinct layers along the pipe. In this regime, the oil does not achieve sufficient velocity to traverse the pipe effectively. As a result, buoyancy forces become significantly relevant, allowing the oil mass to accumulate at the top of the pipe. This behavior increases the likelihood of oil deposition on the pipe walls, leading to fouling over time. As shown in Figure 9, the density signal stabilizes at a lower average value due to the layered separation of the fluids and the reduced mixing between phases. This pattern emphasizes the importance of managing flow conditions to minimize fouling risks in pipeline systems.

The fifth simulated flow pattern was annular flow, that can be seen in Figure 10, which exhibited the lowest average density among all patterns. This observation aligns with expectations, as annular flow contains the highest volume of oil within its cross-section. A notable characteristic of this pattern is the smooth and consistent behavior of the density signal, which contrasts with the noisier signals observed in other patterns. This is attributed to the well-defined interfaces between oil and water, resulting in reduced fluctuations at the pipe outlet. The stability and distinct separation of phases in annular flow highlight its unique dynamics and emphasize the importance of precise modeling for accurate system analysis.

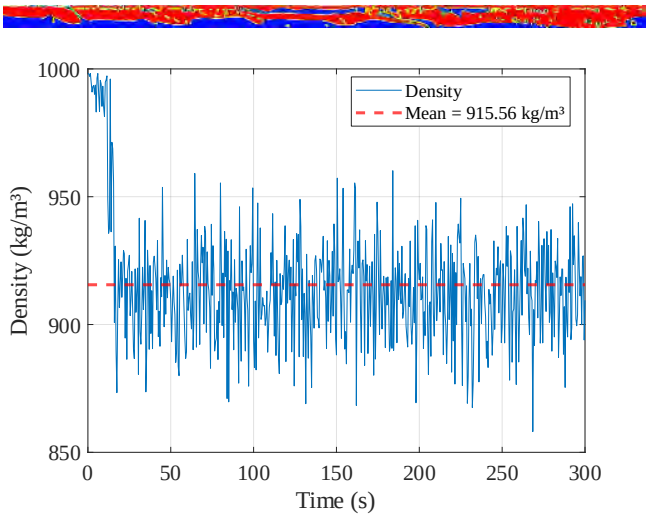

**Figure 9.** Stratified flow signal in the time.

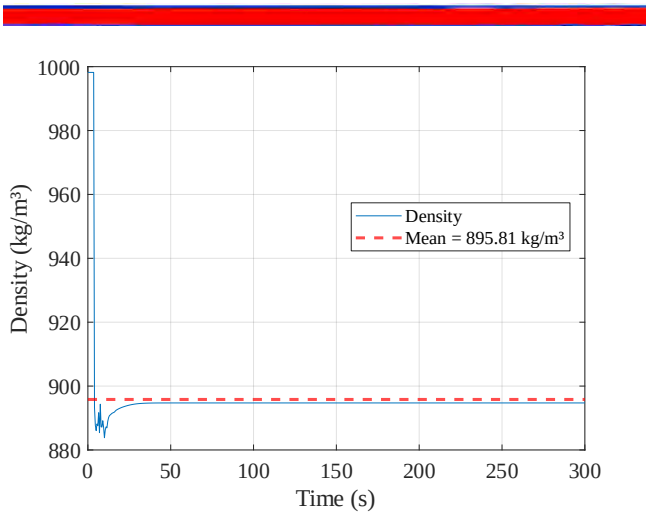

**Figure 9.** Annular Flow sign al in the time

## CLUSTERING AND IDENTIFICATION

To analyze the flow patterns, a one-dimensional k-means clustering was performed, considering the average density of the time signal as the primary variable. To minimize the impact of transient effects in the system, the first 50 seconds of each simulation were excluded from the analysis. This adjustment ensured that the calculated average density more accurately reflected the steady-state behavior of each flow pattern.

A total of 25 simulations were conducted, each running for 300 seconds under varying boundary conditions. This approach allowed for the evaluation of a wide range of scenarios, capturing the diversity in flow dynamics. The use of average density as a clustering metric provided a straightforward yet effective means of distinguishing between patterns, particularly in cases where differences were more pronounced, such as with

core-annular flow.

The Figure 10 shows the results of clustering performed using the k-means method with five clusters based on the average density of the time signal for 25 simulations conducted under different boundary conditions. Each point in the graph represents a specific simulation, while the dashed lines indicate the cluster centers identified by the algorithm.

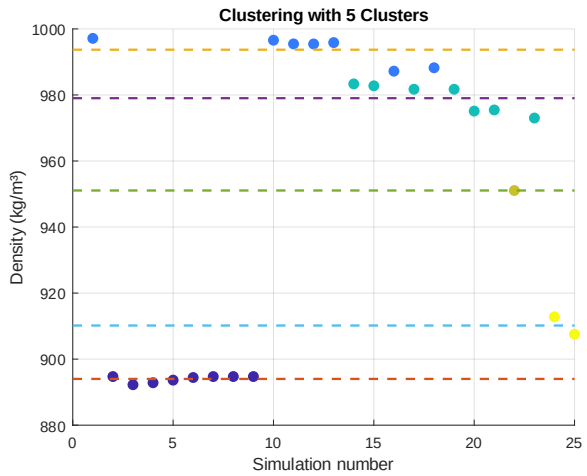

**Figure 10.** Results of K-means

The clusters are well defined and distributed along the density axis, reflecting the differences in the simulated flow patterns. Most points are closely grouped around their respective cluster centers, suggesting that average density was an effective parameter for distinguishing between the different patterns. Additionally, the low variation within each cluster indicates that this parameter reliably captures the general behavior of the flow patterns.

The cluster with the lowest density, located below 900 kg/m³, corresponds to the annular flow pattern, characterized by the highest volume of oil in the pipe's cross-section. This significantly reduces the average density of the signal and shows a clear separation from the other clusters.

On the other hand, the intermediate clusters, such as those around 920 kg/m³ and 940 kg/m³, represent patterns like slug flow and stratified flow, where there is greater interaction between phases. In these cases, some overlap in average density values can be observed, indicating that the boundaries between these patterns may not be perfectly distinct depending on the boundary conditions.

The cluster with the highest density, near 1000 kg/m³, is associated with patterns such as oil in water dispersion, where the amount of oil in the mixture is smaller, and the behavior is dominated by the characteristics of water. This cluster is well-separated from the others, emphasizing the uniqueness of this pattern in terms of average density.

Overall, the results presented in the image demonstrate that the k-means method was effective in identifying flow patterns based on average density. However, the overlap of values observed between some intermediate clusters highlights the need to explore more complex approaches in future studies. These approaches could include the use of multiple variables or the consideration of temporal relationships to improve the discrimination of patterns with very similar characteristics.

## CONCLUSIONS

The strategy of identifying multiphase flow patterns using the k-means clustering method has proven to be promising, as it allowed for a reasonable clustering of results. This approach was particularly effective for core annular flow, which exhibits a highly distinct behavior compared to other patterns due to its low density oscillations over time. However, for other flow patterns, some challenges may arise. Depending on the boundary conditions, there can be an overlap of values between patterns that are very similar, making differentiation more difficult.

Despite these limitations, this study successfully demonstrated a functional method, aligning with its premise of developing a simple approach for flow pattern identification. At the same time, it opens the door for further research into more advanced clustering techniques or methodologies. Future approaches could explore grouping data across multiple dimensions and incorporating temporal relationships, moving beyond reliance on a single variable to achieve more robust and comprehensive results.

# A New Method to Assess Performance Loss due to Catalyst Deactivation in Fixed- and Fluidized-bed Reactors

**M. Andrea Pappagallo[a,b], Tilman J. Schildhauer[a], Oliver Kröcher[a,b], and Emanuele Moioli[a,c]***

## ABSTRACT

A new methodology for the assessment of the performance loss in catalytic reactors due to deactivation was developed and applied to fixed- and fluidized-bed CO methanation, with catalyst subject to coking. The methodology is based on the solution of heat and mass balances, by decoupling the reactor and deactivation dynamics. This is possible by using consecutive 1D, steady-state calculations for the characterization of the reactor performance. In this way, the progressively lower values of catalyst activity along the time on stream are computed with the integration of a dedicated dynamic model. This method has shown promising results in the characterization of the loss of performance of the reactor over time. The model correctly describes a progressive deactivation of the catalyst in fixed-bed reactors, while it shows that the decrease in activity is sudden for the whole reactor volume in fluidized bed reactors and occurs after a critical time-on-stream. Besides, it was observed that the fluidized bed reactor is in general more resistant to deactivation by CO, with the time needed to reach 25% conversion being 1.5 to 2 orders of magnitude higher than for a fixed bed in similar conditions – for example around 250 hours against 50 for a fixed bed at 300°C. This will allow optimizing the reactor with respect to deactivation, hinting the modifications possible in the conditions or in the reactor geometry to maximise the time-on-stream prior to loss in the product quality.

## INTRODUCTION

The increasing amount of anthropogenic greenhouse gases in the atmosphere is a major driver for the development of new technologies that can abate such gas emissions. A widely investigated option to address this challenge is the production of fuels from unconventional and renewable feedstocks, like $CO_2$ from carbon capture processes, biomass, and green waste. This option shows the advantage of emitting the same amount of $CO_2$ that was naturally captured during the production of such feedstocks [1–3], making the overall cycle carbon-neutral. However, these carbon-containing streams are usually contaminated by various additional molecules. In particular, the presence of CO and other organic molecules, which are natural constituents of such feedstock, may lead to catalyst deactivation by decomposition of such molecules and consequent coking of the surface. This may strongly hinder the rate of the reactive steps of the process over time [4]. The development of methods that minimize the impact of coking in these reactions is therefore a key to ensure the efficiency of the whole process and its long-term performance and competitiveness. For this scope, it is crucial to model these deactivation phenomena, both in terms of their intrinsic kinetics and of their impact on the reactor performance. These models should target the optimization of the operating conditions in the reactor to reduce the impact of deactivation.

The main difficulty in modelling catalyst deactivation in catalytic reactors is caused by the different characteristic time scales of the phenomena involved: while the reaction has characteristic times below the order of magnitude of seconds, and the same is valid for the transport phenomena in the reactor, the deactivation by coking has

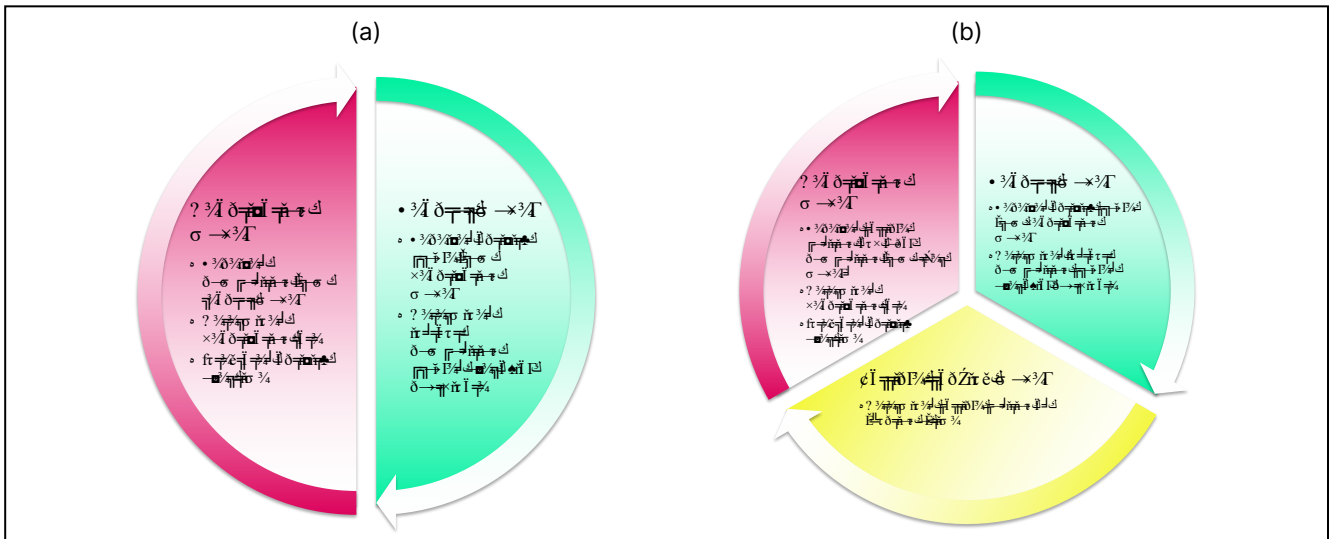

**Figure 1:** Model structure for the (a) pseudo-dynamic model in case of a fixed bed and (b) moving observer model in case of fluidized bed.

a visible impact on the reactor performance only after hours to days [5]. In the case of a fluidized-bed reactor, an additional modelling difficulty is originated by the chaotic movement of particles [6], which has a decisive impact on the deactivation, as the position of the particle at each given instant determines the amount of coke precursors in the gas around it. It is, however, too computationally cumbersome to model this motion for the entirety of the particles in a fluidized bed of a commercially usable scale [7]. This study develops a new methodology that unifies in a single model the information on the effects of catalyst deactivation at different scales, resulting in a computationally affordable model. This model can predict the decrease in the activity of the catalyst over time, the effect of particle motion in fluidized bed reactors on catalyst deactivation and the evolution of the concentration profiles over time. Thanks to the prediction of these various indicators, the model can be used to predict the time the reactor can operate before the outlet concentration is not in line anymore with the requirements of the system in which it is installed. To contextualize the methodology in a case of practical interest, the methanation of syngas is considered as case study for this work.

## METHODS

This work focuses on the development of a model for the evaluation of the impact of catalyst deactivation on chemical reactors. The time scales of the phenomena determining the operation of the reactor and the deactivation of the catalyst are significantly different and can thus be decoupled. The resulting model characterizes the conversion in the reactor in one spatial dimension, and the activity of the catalyst in time, plus one spatial dimension for the fixed-bed case.

The activity of the catalyst is defined in Equation (1), where $r$ represents the local rate of reaction and $r_0$ the rate of the same reaction at the same local conditions of pressure, temperature and composition of $r$, but calculated assuming the catalyst is unaffected by deactivation.

$$a = r/r_0 \tag{1}$$

**Figure 1** shows a schematic representation of the workflow leading to the complete deactivation models for the two reactor types (fixed- and fluidized-bed).

The deactivation model for the fixed-bed reactor has been labelled as pseudo-dynamic model due to its constitution as a series of consecutive steady-state calculations to model the performance loss in time. Starting from a time t=0 and an initial activity a=1, the pseudo-dynamic model follows this procedure for each time step:

1. It calls the steady-state model of the reactor, which solves the model equations for the current steady state,
2. it determines the composition profiles and the partial pressures of the two main components involved in deactivation (CO and $H_2O$),
3. it calculates the deactivation rate from the partial pressures, obtaining the rate of loss of activity as a function of the position in the reactor $da/dt = f(z)$,
4. it integrates the loss of activity and moves to the next step.

The deactivation model for the fluidized bed is referred here as moving observer model because it follows the average catalyst particle through its motions in the bed through a Eulerian-Lagrangian approach. It shows similitudes with the pseudo-dynamic model, with the addition of a model for the position of the particle as a function of time. The activity is therefore no longer calculated as a function of the position, but as a value relative to the single catalyst particle. It is then assumed to be the same throughout the whole reactor due to the very fast mixing inside the system.

## Case study

The methanation of CO is used as case study. The fixed-bed model is based on a plate-cooled fixed-bed reactor with 1 m of length, 50 cm of width and 5 cm of spacing between the plates [8]. The channels between the plates are alternatively filled with the catalyst bed and with the cooling medium (boiling water) at the same temperature of the reactor inlet. The reactor is operated with a stoichiometric inlet stream (3:1 $H_2$/CO) at a pressure of 8 bar and inlet temperatures between 300 and 360°C.

The fluidized-bed model is instead based on a reactor of 2.5 m of length, 22.4 cm diameter and cooled by an inner coil where a cooling oil is circulated. This reactor is also operated with a stoichiometric inlet stream (3:1 $H_2$/CO), at a pressure of 8 bar and uniform reactor temperatures between 300 and 360°C.

The kinetic model used is obtained from the work of Kopyscinski et al. [9] for the methanation of CO and Koschany et al. [10] for the methanation of $CO_2$ (Sabatier reaction), and it consists of three reactions, outlined in **Table 1**.

**Table 1:** Reactions in the kinetic model for CO methanation [9,10].

| Reaction | Equation |
|---|---|
| CO methanation | $CO + 3H_2 \rightleftharpoons CH_4 + 2H_2O$ |
| $CO_2$ methanation | $CO_2 + 4H_2 \rightleftharpoons CH_4 + 3H_2O$ |
| Water-gas shift | $CO + H_2O \rightleftharpoons CO_2 + H_2$ |

The effect of the Boudouard reaction, i.e., the decomposition of CO to coke (assumed as elemental carbon, C) and $CO_2$, leading to coking of the catalyst, has not been taken into account in the reaction kinetics due to its low extent in the residence time of the system (few seconds). Future works might explore this aspect further.

## Fixed-bed reactor digital twin

The fixed-bed digital twin was developed on a 1D pseudohomogeneous assumption, i.e., the catalyst and the gas were modelled as a single pseudophase and gradients were neglected in any direction other than that of the gas flow. Equations (2) and (3) are the component and energy balance for the reactor, respectively. The activity term $a(t)$ is calculated from the deactivation model, as explained in the dedicated subsection.

Component balance

$$\frac{dF_i}{dz} = \rho_c(1-\varepsilon)Aa(t)\sum_{j=1}^{NR}\nu_{ij}r_j \quad (2)$$

Heat balance

$$\frac{dT}{dz} = -\frac{\rho_c(1-\varepsilon)A}{\dot{m}\hat{c}_P}a(t)\sum_{j=1}^{NR}\Delta h_{Rj}r_j - \frac{2W}{\dot{m}\hat{c}_P}U(T-T_e) \quad (3)$$

This digital twin was developed according to state-of-the art models for the calculation of steady-state profiles in fixed beds [11]. The model consists of NC+1 ordinary differential equations, where NC is the number of species considered. The equations were solved in MATLAB via built-in solvers which integrate them in the axial reactor coordinate $z$.

## Fluidized-bed reactor digital twin

For the fluidized bed, a two-phase model was chosen, dividing the reactor in two pseudophases being the bubble and the emulsion or dense phase [4]. The bubble is assumed to contain no catalyst – therefore no reaction happens in it – and to be in a plug-flow regime. The emulsion is instead considered to carry out the reaction since it contains the catalyst, and to be perfectly stirred by the continuous recirculation operated by the bubbles. For the same reason, the reactor is considered isothermal. The component balances for each phase are shown in Equations (4) and (5).

Component balance – bubble phase

$$\frac{dF_i^B}{dz} = -K_i A_B\left(\frac{F_i^B}{Q_B} - \frac{F_i^D}{Q_D}\right) \quad (4)$$

Component balance – dense phase

$$0 = F_i^{D,IN} - F_i^D + \int_0^L K_i A_B\left(\frac{F_i^B}{Q_B} - \frac{F_i^D}{Q_D}\right)dz + V(1-\delta)(1-\varepsilon_{mf})\rho_c\sum_{j=1}^{NR}a(t)\nu_{ij}r_j \quad (5)$$

This digital twin was also developed from state-of-the-art models for fluidized-bed systems [12]. Due to the presence of an integral term, the model could not be solved by numerical integration and must instead be converted to a nonlinear algebraic system by discretization of the derivatives. Such system was then solved via built-in solvers in MATLAB for algebraic equations.

## Particle motion model

A model for particle motion has been derived from the experimental data obtained by Lefebvre et al. [13], normalized on the dimensions of the reactor studied in this work. The wave of the position of the particle in time has been decomposed according to a Fourier transform in the attempt to divide it into components accounting for gross and local circulation phenomena. The advantage of the Fourier transform over other tested approaches (i.e.,

artificial neural networks) is that it conserves the periodicity of the function. Wave components with a negligible impact on the particle position have been filtered out to make the function simple. The goal of the function is not to reproduce accurately the data, but more to learn the trend relative to the time an average particle spends at each height in the reactor.

## Deactivation model

The deactivation model was developed in this work and is based on a reparameterization of a model by Sun et al. [4]. The new parameters were obtained from the catalyst deactivation data during CO methanation reported by Zhang et al. [5], and the resulting model is based on the following equations:

| | | |
|---|---|---|
| Deactivation rate | $\frac{da}{dt} = -r_d a$ | (6) |
| Kinetic equation | $r_d = k_d P_{CO}^{\alpha} f_{H_2O}$ | (7) |
| Temperature dependence (Arrhenius) | $k_d = k_d^0 \exp\left(-\frac{E_d}{RT}\right)$ | (8) |
| Correction factor for water | $f_{H_2O} = \frac{x_{H_2O}-1}{(1-c)x_{H_2O}-1}$ | (9) |

The correction factor is used to account for the hindering effect that a high concentration of water has on the deactivation rate. Water is in fact known to be able to prevent the formation of coke on catalyst particles, slowing down their deactivation [4]. The correction factor in Equation (9) is empirical. The effect of water on deactivation will be studied in more detail in future works.

# RESULTS

The results show the prediction of deactivation profiles in the two reactor types by application of the models described in the methods section.

## Pseudo-dynamic model – fixed-bed

**Figure 2** and **Figure 3** illustrate the results of a simulation of the deactivation effects in the fixed-bed reactor conducted with the pseudo-dynamic model. The evolution of the activity and conversion profiles in time shows that, in the initial moments of the simulation, the activity decreases significantly only at the inlet of the reactor, to then generate a wave of decreasing activity that propagates through the catalyst bed in the axial direction. This is in line with what is expected in fixed bed reactors, where the first layers of catalyst operate as 'filter' for the impurities [4]. The deactivation wave reaches the end of the reactor after about 40 h of operation, when the CO conversion at the outlet starts decreasing from an initial value close to 100%. After 50 h, the catalyst has lost most of its activity throughout all the reactor, which leads to a final conversion of 25% and a hotspot temperature of around 420°C (130°C milder compared to the values during effective operation). This decrease in the hotspot temperature is due to the different distribution of the reaction rate on a partially deactivated catalyst. This reduces the reaction rate at the reactor inlet, hence distributing the conversion over a larger area of the reactor than at the operation start.

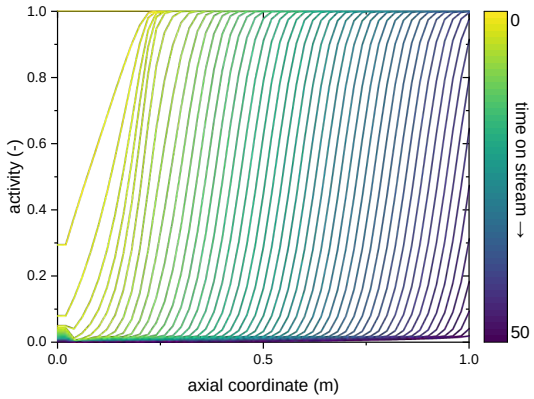

**Figure 2:** Results of the pseudodynamic model for stoichiometric inlet, $T_{in}$ = 300°C, p = 3 bar – deactivation wave.

The different deactivation velocity appears to be mostly due to the difference in temperature throughout the reactor shown in **Figure 4**: as the deactivation rate strongly depends on the temperature through the Arrhenius equation, the deactivation is much faster in the temperature hotspot. The hotspot itself is moving as a result of the wave of decreasing activity, since the less active catalyst in the initial portions of the bed leads to significantly slower reaction rates and therefore to a less prominent heat release. The reaction rate strongly increases once the reactants reach a portion of the bed where the catalyst is still active, and this leads to the generation of a new hotspot there. Both the decrease in activity and the moving hotspot are coherent with experimental observations for similar systems [4].

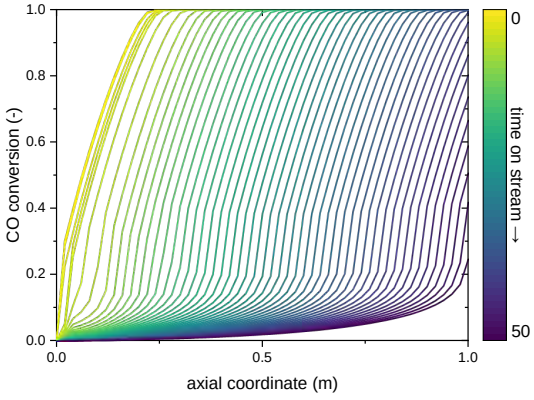

**Figure 3:** Results of the pseudodynamic model for stoichiometric inlet, $T_{in}$ = 300°C, p = 3 bar – conversion profile.

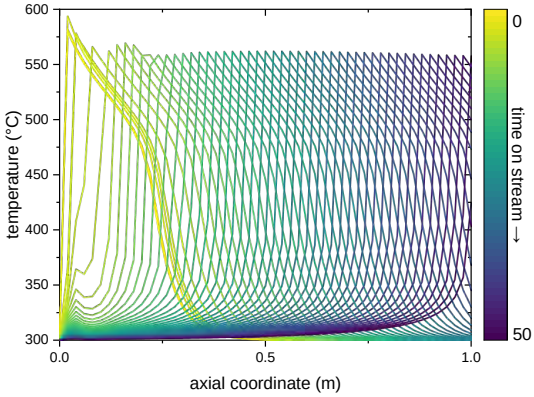

**Figure 4:** Results of the pseudodynamic model for stoichiometric inlet, $T_{in}$ = 300°C, p = 3 bar – moving hotspot.

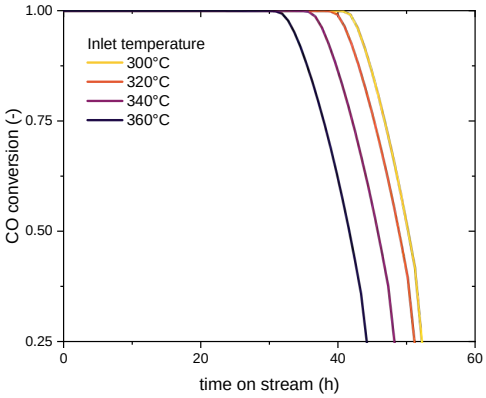

**Figure 5:** Results of the pseudodynamic model for stoichiometric inlet, p = 3 bar – effect of inlet temperature.

**Figure 5** shows the CO conversion at the reactor outlet over time. As expected in fixed-bed reactors operating the $CO_x$ hydrogenation, the conversion remains high until the deactivation wave reaches the terminal part of the reactor (see **Figure 2**). The figure also shows the effect of an increasing inlet temperature on the time required for significant loss of performance of the reactor. A higher inlet temperature leads to higher temperatures throughout the whole reactor, which increase the rate of deactivation as per Equation (8). This leads to a faster propagation of the deactivation wave and consequently to an earlier loss of performance.

## Moving observer model – fluidized-bed

The results of the integration of the moving observer model are shown here. **Figure 6** reports the decrease in conversion over time. In the fluidized-bed reactor, the conversion loss does not follow a wave form, but it is uniform over the axial coordinate. This is an effect of the assumption of perfect mixing for the dense phase. The deactivation is limited to a small portion of the reactor, in the initial section, prior to the full consumption of CO. However, the constant and quick motion of the particles throughout the bed ensures that the particles can be assumed to deactivate all at the same rate. The effect of the zones at low CO concentration is, in turn, prevalent due to their significant size compared to the CO-rich ones, which results in an overall slower deactivation. The time on stream required for a significant loss of performance is therefore longer and the CO conversion curve over time takes a different shape than in the fixed-bed reactor.

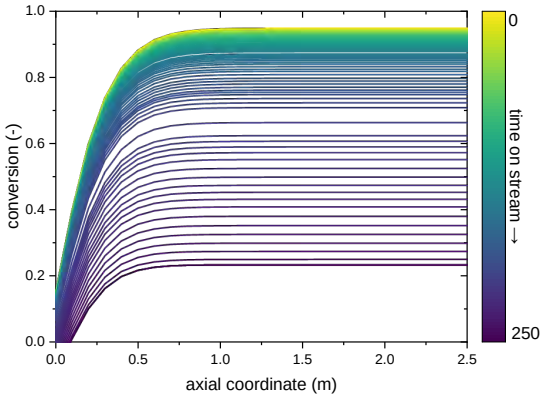

**Figure 6:** Results of the moving observer model for stoichiometric inlet, T = 300°C, p = 8 bar – conversion profile.

These conversion terms are shown in **Figure 7**. The general behaviour is the same as for the fixed-bed case, but the effect of the temperature is reversed: higher temperatures lead here to slower deactivation and loss of performance. Additionally, the drop in CO conversion occurs more suddenly in the fluidized bed reactor, because deactivation is distributed over the catalyst volume, so that when the critical activity of the catalyst dropping the CO conversion is reached, this is reflected by the entire dense phase. This is challenging for the operation of a fluidized-bed reactor, as the conversion drop is sudden and more difficult to predict than in the fixed-bed reactor.

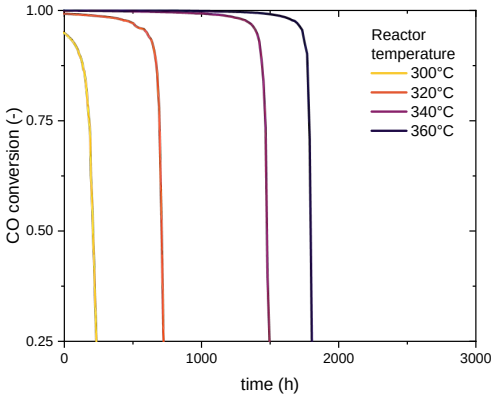

**Figure 7:** Results of the moving observer model for stoichiometric inlet, p = 8 bar – effect of reactor temperature on conversion.

**Figure 8** shows instead the evolution of the catalyst activity over time. The slower deactivation at higher temperatures is due to the faster consumption of CO, which reduces the length of bed in which a significant amount of CO is present and leaves the rest of the bed with low amounts of CO and high amounts of water. This results in a shorter contact time between the particle and a CO-rich gas, therefore a slower deactivation.

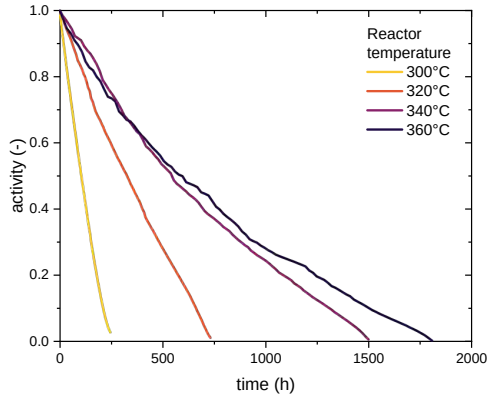

**Figure 8:** Results of the moving observer model for stoichiometric inlet, p = 8 bar – effect of reactor temperature on activity.

The higher temperature also leads to a stronger impact of the position of the particle on the deactivation rate, as shown by the profile at 360°C being less smooth than that at 300°C. This is due to the sharper variations in composition throughout the reactor at higher temperatures, which amplify the variation of the deactivation rate with the particle position.

## CONCLUSIONS

This paper developed a new methodology to describe the reactor deactivation due to coking in fixed- and fluidized-bed reactors. Deactivation can be modelled in fixed-bed reactors by coupling a reliable steady-state model for the calculation of the composition profiles in given conditions, with a model for the deactivation of the catalyst as a function of the local operating conditions (temperature, gas phase composition). The same is possible for fluidized-bed reactors with the addition of a particle tracking model that can express the position of the average catalyst particle as a function of time. Such models are effective in characterizing the loss of performance along the time on stream as a function of key operating conditions of the reactor like the inlet composition, the inlet/operating temperature, pressure etc., and therefore provide the possibility for optimization of such conditions with respect to productivity and minimizing the effect of deactivation. The impact of the operating conditions can in fact be studied in detail with the help of this model, which allows the selection of those sets of conditions that minimize the long-term impact of deactivation on reactor performance.

In the specific case analyzed we observed the behavior of both reactor types at the four temperature values of 300, 320, 340, and 360°C. We considered the catalyst deactivated when a conversion of CO of 25% was reached at the outlet, at which point the simulation was stopped. The most relevant result is the slower deactivation for the fluidized bed, by 1.5 to 2 orders of magnitude.

Future works will be focused on improving the model. Aging experiments will be run on the catalyst, with the goal to gather more deactivation data and improve the model parameters and structure to better characterize the catalyst deactivation and its dependence on temperature and composition. A deeper investigation will also be conducted on particle behavior in the fluidized bed, with the aim of refining the existing model, for example by adding a term accounting for stochasticity.

## ABSTRACT

This study presents a numerical simulation of the liquid-vapor (L-V) equilibrium stage in a sieve plate distillation column using the Smoothed Particle Hydrodynamics (SPH) method. To simulate the equilibrium stage, periodic temperature boundary conditions were applied. The column design was carried out in Aspen One, considering an equimolar benzene-toluene mixture and an operating pressure ensuring a condenser cooling water temperature of 120°F. The Chao-Seader thermodynamic model was employed for property calculations. Key outputs included liquid and vapor velocities per stage, mixture viscosity and density, operating pressure, and column diameter. The geometry of the distillation column stage and sieve plate was developed using SolidWorks, and Computational Fluid Dynamics (CFD) simulations were performed using the DualSPHysics code. The results demonstrate the influence of sieve plate design on velocity and temperature distributions within the stage, providing insights for enhancing stage design and operational efficiency.

**Keywords**: CFD, Simulation of distillation, hydrodynamics, SPH, Sieve tray

## 1. INTRODUCTION

Distillation remains the most widely utilized unit operation in Chemical Engineering due to its exceptional capability for product purification. However, conventional distillation processes are often associated with significant inefficiencies, driving the pursuit of alternative strategies to improve thermodynamic efficiency in equipment design and operation. While many of these alternatives have been evaluated using MESH equations and sequential simulators, less attention has been given to their modeling using Computational Fluid Dynamics (CFD), primarily due to its inherent complexity.

CFD employs either Eulerian or Lagrangian approaches. Eulerian methods rely on mesh-based discretization of the medium, producing spatially averaged results at the interfaces between fluids. Examples include the finite volume and finite element methods, with the former being widely adopted for simulating hydrodynamics, mass transfer, and momentum within distillation columns (Haghshenas et al., 2007; Lavasani et al., 2018; Zhao, 2019; Ke, 2022). However, Eulerian methods face limitations, including challenges in interface modeling, achieving convergence, and selecting appropriate turbulence models to accurately simulate turbulent flows.

In contrast, Lagrangian methods provide detailed insights into interfacial phenomena by discretizing the continuous medium into mesh-free points. This approach enables precise evaluation of flow, concentration, and temperature distributions within a system. Smoothed Particle Hydrodynamics (SPH) is a Lagrangian method particularly suited for modeling discontinuous media and complex geometries. It replaces the need for mesh generation by representing the medium with particles, making it applicable to a wide range of scenarios, including microbial growth (Martínez-Herrera et al., 2022), sea wave dynamics (Altomare et al., 2023), and stellar phenomena (Reinoso et al., 2022), demonstrating its flexibility and robustness.

Building on these advantages, this study presents a numerical simulation of a liquid-vapor (L-V) thermal equilibrium stage within a tray distillation column using the SPH method. The study focuses on Sieve trays, incorporating periodic temperature conditions to facilitate the simulation of the equilibrium stage.

## 2. METHODOLOGY

In this work a methodology for the simulation of the hydrodynamics and thermal equilibrium of tray distillation columns is proposed. This methodology consists of 3 stages: rigorous design of the distillation column in Aspen Plus, 3D design of the column - sieve trays and hydrodynamic analysis of the columns using the SPH method.

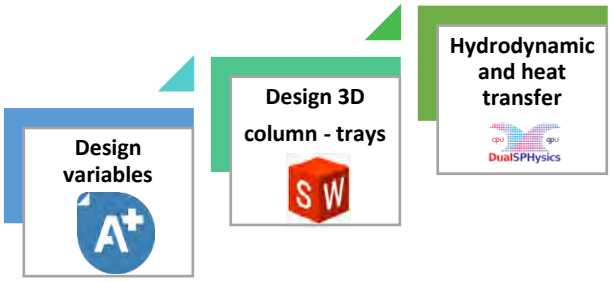

**Figure 1.** Methodology for the numerical simulation of the hydrodynamics and equilibrium of distillation columns.

### 2.1. Rigorous design of the distillation column

The column's sizing was conducted using Aspen One, considering an equimolar mixture of Benzene-Toluene and an operational pressure guaranteeing a condenser cooling water temperature of 120°F. The thermodynamic model applied was Chao-Seader, and sieve trays were employed. The column featured ten stages, with stage 5 designated for feeding, and both components assumed a 98% purification and recovery rate. This information yielded crucial data, including liquid and vapor velocities per stage, mixture viscosity and density, operating pressure, and column diameter. Three-dimensional CAD files of the distillation column and the sieve tray were developed using SolidWorks. Subsequently, these files were imported into DualSPHysics (Domínguez et. al., 2022) for CFD numerical simulation to ascertain flow and temperature profiles at an equilibrium stage. Stage 7 was selected for analysis, given their position below the feed stage.

The design of the distillation column was performed by rigorous methods, solving the MESH equations. **M** represents the total mass balance and the mass balance per component. **E** represents the equilibrium ratios present in the distillation process. **S** represents the sum of the mole fractions of the components of the mixture. **H** represents the total heat balance of the distillation column. This model is represented by equations 1 to 4.

Mass balance:

$$\frac{dM_j}{dt} = L_{j-1} + V_{j+1} + F_j^L + F_j^V - (L_j + U_j) - (V_j + W_j) \quad (1)$$

Equilibrium relationships:

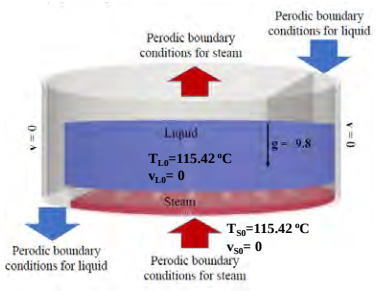
$$Y_{i,j} = K_{i,j} X_{i,j} \quad (2)$$

Summation constraints:

$$\sum_{i=1}^{NC} K_{i,j} X_{i,j} - 1.0 = 0 \quad (3)$$

Energy balance:

$$\frac{d(M_j \overline{U}_{i,j})}{dt} = L_{j-1}\overline{h}_{j-1} + V_{j+1}\overline{H}_{j+1} + F_j^L \overline{h}_j^L + F_j^V \overline{H}_j^V - (L_j + U_j)\overline{h}_j - (V_j + W_j)\overline{H}_j + Q_j \quad (4)$$



### 2.2. Column and sieve tray sizing

The 3D design of the column and trays was carried out in SolidWorks. The design parameters used were: column diameter, effective and downspout areas, obtained in Aspen Plus. The distance between trays was proposed to be 0.15m. Stainless steel 316L was chosen as construction material. Figure 2 shows, the 3D design of the tray, the stage and the initial conditions.

## 2.3. Hydrodynamics and heat transfer

Smoothed Particle Hydrodynamics (SPH) is a Lagrangian, meshless method with applications in the field of Computational Fluid Dynamics. Originally invented for astrophysics in the 1970s (Monagan J, 1992) it has been applied in many different fields, including fluid dynamics (Alvarado-Rodríguez C.E. et al., 2019). The method uses points named particles to represent the continuum and these particles move according to the governing equations in the fluid dynamic. When simulating free-surface flows, no special surface treatment is necessary due to the Lagrangian nature of SPH, making this technique ideal for studying violent free-surface motion.

For the numerical simulation the conservation equations of mass (Eq. 5), momentum (Eq. 6) and energy (Eq. 7) in Lagrangian formalism are considered.

$$\frac{d\rho}{dt} = -\rho\nabla\cdot\mathbf{v} \tag{5}$$

$$\frac{d\mathbf{v}}{dt} = \frac{-1}{\rho}\nabla \mathrm{P} + \frac{\mu}{\rho}\nabla^2\mathbf{v} + \mathbf{g} + \mathbf{F}^{\boldsymbol{B}} \tag{6}$$

$$\frac{dT}{dt} = \frac{1}{\rho C_p}\nabla\cdot(k\nabla T) \tag{7}$$

where $\rho$ is the density, $t$ is the time, $\mathbf{v}$ is the velocity vector, $P$ is the pressure, $\mu$ is the viscosity, g is the gravitational acceleration vector, $T$ is the temperature, $Cp$ is the heat capacity and $k$ is the thermal conductivity coefficient.

The motion of the fluid due to the change in temperature is provided by Boussinesq approximation (Eq. 8):

$$\mathbf{F}^{\boldsymbol{B}} = -\boldsymbol{g}\beta(T - T_r) \tag{8}$$

where $\beta$ is the thermal coefficient of volumetric expansion, and $T_r$ is the reference temperature of the fluid.

The momentum, continuity and energy equations can be discretized using the SPH formalism and gives:

$$\frac{d\rho_a}{dt} = -\rho_a\sum_b^n m_b\frac{\mathbf{v}_b}{\rho_b}\cdot\nabla W_{ab} \tag{9}$$

$$\frac{d\mathbf{v_a}}{dt} = -\sum_b^n m_b\left(\frac{P_b}{\rho_b^2}+\frac{P_a}{\rho_a^2}\right)\nabla_a W_{ab} + \sum_b^n m_b\frac{4\upsilon\, r_{ab}\cdot\nabla W_{ab}}{(\rho_a+\rho_b)({r_{ab}}^2+\varepsilon^2)}\mathbf{v}_{ab} + \boldsymbol{F}^{\boldsymbol{B}} \tag{10}$$

$$\frac{dT}{dt} = \frac{1}{C_p}\sum_b^n \frac{m_b}{\rho_a\rho_b}\frac{(k_a+k_b)r_{ab}\cdot\nabla_a W_{ab}}{{r_{ab}}^2+\varepsilon^2}(T_a - T_b) \tag{11}$$

Equations (Eq. 9)-(Eq. 11) are coupled by the Tait state equation (Eq. 12)

$$P = B\left[\left(\frac{\rho}{\tilde{\rho}}\right)^{\gamma} - 1\right] \tag{12}$$

where $P$ is the pressure, $\tilde{\rho}$ is the reference density, $B = c^2\rho/\gamma$, $\gamma = 7$ = 7 for liquids and $\gamma = 1.4$ for gases.

Different approaches and methods have been proposed to simulate multiphase flows (Tartakovsky & Meakin, 2006; Monaghan & Kocharyan, 1995; Sigalotti et al., 2014). In this work several new approaches are added to the standard formalism. These features permit to properly simulate multiphase flows, where the main contribution lies in the improved management to interphase with highly nonlinear deformations.

The instability and artificial surface tension produced in a multiphase flow using the standard SPH has been reported by (Colagrossi & Landrini, 2003, and Gómez Gesteira et al, 2010). For this work we have replaced the Eq. (10) used in the standard SPH formulation by the Eq. (13) which to permit that higher density ratios in simulations avoiding the artificial surface tension (Colagrossi & Landrini, 2003). The method is rather robust, even for large free-surface fragmentation and folding, efficient and relatively easy-to-code and results stable and capable to easily treat a variety of density ratios.

$$\frac{d\mathbf{v_a}}{dt} = -\sum_b^n m_b\left(\frac{P_b+P_a}{\rho_a\rho_b}\right)\nabla_a W_{ab} + \sum_b^n m_b\frac{4\upsilon\, r_{ab}\cdot\nabla W_{ab}}{(\rho_a+\rho_b)({r_{ab}}^2+\varepsilon^2)}\mathbf{v}_{ab} + \boldsymbol{F}^{\boldsymbol{B}} \tag{13}$$

Higher density ratios can be simulated with the use of this expression avoiding the artificial surface tension.

According to (Colagrossi & Landrini, 2003) the pressure of each phase is calculated using the equation of state (14), which is calculated using appropriate parameters according to each phase reference density. So, the equation of state (14) is calculated for each phase using:

$$P_\alpha = B_\alpha\left[\left(\frac{\rho}{\tilde{\rho}_\alpha}\right)^{\gamma_\alpha} - 1\right] \tag{14}$$

where the subscripts $\alpha$ denote the phase

The constant $B_\alpha$ is chosen form the liquid phase to permit a small compressibility of the higher density fluid, that is $v_{max\alpha} = c_\alpha \ll 1$ 1, where $v_{max\alpha}$ is the maximum velocity of the fluid with higher density expected in the considered problem. Then $B_\alpha$ must be matched to the liquid and gas phases in the equation of state for the fluid with lower density to create a stable pressure at the interphase. This formulation allows the simulation of high-density ratios (e.g. 1:1000, which is like the air-water ratio).

This method was implemented for the numerical analysis of the distillation columns under the following considerations: periodic conditions were used to perform the hydrodynamic and equilibrium analysis. The initial properties of the fluids are shown in Table 1. In all cases, no-slip boundary conditions were considered in the interaction between fluid and boundary particles using the dynamic particle method.

## 3. DISCUSSION OF RESULTS

From the results obtained using the SPH method in numerical simulations, it is possible to analyze the velocity profile and the temperature profile inside the stage. In addition, it is possible to approximate the time it requires for the stage to reach equilibrium under the initial conditions established.

The simulation was performed with a total of 7,261,750 particles of which 1,386,940 are bound, 4,230,940 are liquid and 1, 643,870 are vapor. 60 seconds of real time were simulated. The simulation was completed in a total of 17.5h on the GPU NVIDIA GeForce 3060 of ITESI.

In Figure 3 is shown the evolution of velocity field obtained in the simulation. A higher velocity is obtained in the area where the fluid enters from the downspout, the velocity distribution is not completely homogeneous, however, there are not dominant streamlines in the stage, meaning a good distribution of the flow in the stage.

In Figure 4 the evolution of the temperature in the stage is shown, which due to the good flow get the equilibrium temperature in the simulated time. It is observed that in the downcomer section the fluid velocity is the highest and that the velocity distribution is uniform throughout the tray.

In Figure 5 is shown the distribution of the temperature from a top perspective at 22.5 seconds. The dsitribution of the temperature is almost homogeneus at this time. The liquid temperature and vapor temperature are very nearly at equilibrium. In addition, vapor accumulation zones can be observed which show very high temperatures and therefore no interaction between liquid and vapor.

In Figure 6 is shown a Reynolds map from a top perspective calculated from the average velocity shown in the Figure 3. This figure shows that the highest Reynolds values occur in the holes of the deck area and are consistent with the thermal behavior of Figure 5. This shows that the greater the interaction of the liquid with the vapor, the greater the heat transfer.

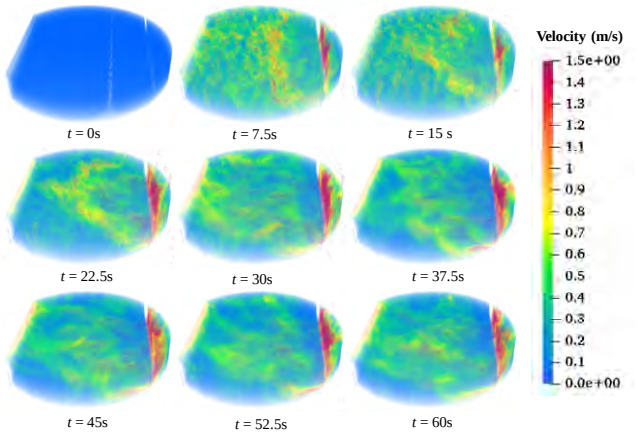

**Figure 3.** 3D perspective of the velocity field evolution in the stage.

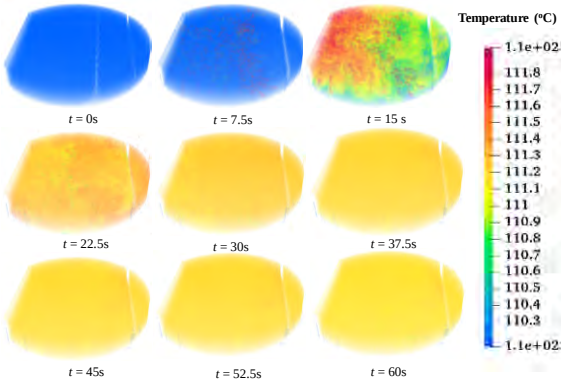

**Figure 4.** 3D perspective of the temperature field evolution in the stage.

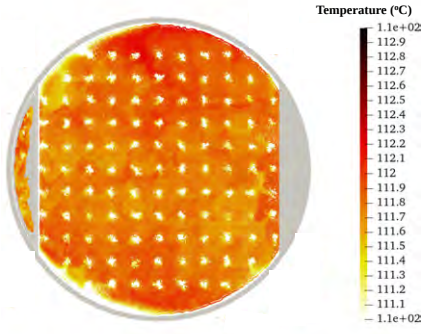

**Figure 5.** Top perspective of the temperature distribution .

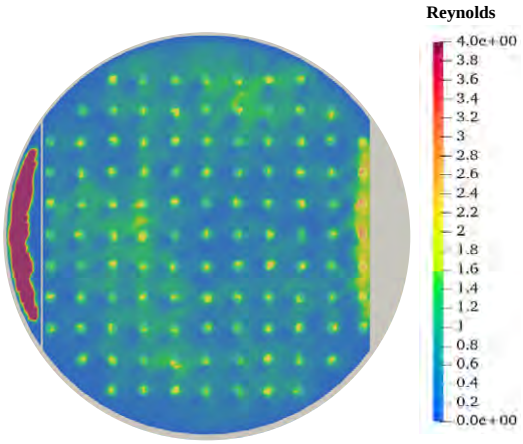

**Figure 6.** Top perspective of the Reynolds map calculated from the average velocity shown in Figure 3.

## 4. CONCLUSIONS

This study presents the CFD numerical simulation of a stage within a distillation column. The column and tray geometries were designed in SolidWorks and subsequently exported to DualSPHysics to carry out simulations based on parameters obtained from rigorous simulations in Aspen Plus. The numerical simulations provide detailed insights into the flow and heat transfer within the stage, accounting for the interaction between the vapor and liquid phases and their respective temperature variations. This data enables the development of a novel methodology for calculating the global heat transfer coefficient in the stage, which can be leveraged to enhance tray design and facilitate comparative analyses of different tray types. In conclusion, the results highlight the effectiveness of applying initial and boundary conditions to simulate thermal equilibrium in distillation columns. Additionally, the SPH method proves to be a powerful and flexible tool for numerical simulations of fluid dynamics and thermal equilibrium, offering valuable contributions to the design and optimization of distillation equipment.

## ACKNOWLEDGEMENTS

We are in agreement with the National Technological Institute of Mexico for the support provided for this research.

## ABSTRACT

Dual function materials (DFMs) integrate $CO_2$ capture and conversion, offering a streamlined approach to Power-to-Gas (PtG) processes. This study develops a cyclic steady-state model for the DFM-based methanation of $CO_2$ using the finite difference method. The model captures the adsorption, purge, and methanation stages and incorporates a semi-implicit numerical scheme for stability and accuracy. Bayesian optimisation is used to explore operational and design parameters to maximise methane productivity, $CO_2$ conversion, and product purity. Multi-objective optimisation reveals key trade-offs among these metrics, while the impact of pressure, hydrogen concentration, DFM weight, geometry and cycle times is systematically evaluated. Results reveal that lower flow rates enhance recovery and purity, while higher flow rates improve productivity. Extended adsorption times favour purity, whereas longer methanation times significantly benefit recovery and productivity. Multi-objective optimisation, presented through Pareto fronts, highlight trade-offs among performance metrics. Variations in hydrogen pressure, DFM mass, and $H_2$ concentration further emphasise their impact on the system's efficiency. This work provides a scalable, reproducible framework for optimising DFM-based PtG systems, advancing their potential for sustainable energy storage and decarbonisation.

## INTRODUCTION

Power-to-Gas (PtG) technology offers a transformative solution for mitigating the intermittency of renewable energy sources by converting surplus electricity into synthetic natural gas (SNG). This process uses renewable hydrogen to react with $CO_2$ via the Sabatier reaction, enabling decarbonisation of downstream sectors, reducing reliance on fossil fuels, and promoting renewable energy adoption in traditionally hard-to-electrify domains like heating and heavy transport. It can also integrate with anaerobic digestion (AD) plants to capture $CO_2$ from biogas, converting it into additional bio-methane and enhancing its emission reduction potential. In future, hydrogen injection into natural gas pipelines will further decarbonise sectors such as residential heating and industrial applications, with a portion also supporting PtG processes for efficient renewable energy storage [1]. While PtG offers dual benefits of $CO_2$ utilisation and energy storage, challenges like high $CO_2$ capture costs, thermodynamic and kinetic barriers in methanation, and reactor heat and mass transfer management must be addressed to enhance economic and technical viability.

A notable advancement in this field is the development of dual function materials (DFMs), which integrate $CO_2$ capture and hydrogenation into a single operational unit [2]. This novel approach simplifies the process flow by eliminating the need for energy-intensive intermediate purification steps. DFMs, typically composed of an alkaline component for $CO_2$ adsorption and a catalytic metal for methanation, enable direct conversion of $CO_2$ from dilute streams into methane under operating conditions conducive to both capture and conversion. Previous studies [3] have demonstrated the feasibility of these materials, highlighting their ability to facilitate cyclic $CO_2$ adsorption and hydrogenation operations without

significant performance degradation.

Very few studies have explored the modelling and optimisation of DFM processes. So far there is one dynamic kinetic model developed to describe the $CO_2$ adsorption and hydrogenation on Ru-$Na_2CO_3$/$Al_2O_3$ catalysts [4] which focuses on reaction kinetics and surface coverage through unsteady material balance equations. Mass transfer limitations were neglected in their setup, simplifying their model while limiting its application to scenarios where similar conditions hold. However, the study lacks detailed experimental parameters, making it difficult to extrapolate; it does not investigate cyclic performance systematically; and it does not incorporate systematic optimisation techniques to explore the optimal process conditions and the effect of many important features of the DFM cycle design. Furthermore, the model's software implementation is neither open-source nor clearly detailed.

One recent study [5] adopted a relevant approach, focusing on the methanation step. They employed Computational Fluid Dynamics (CFD) to simulate the performance of a packed-bed reactor, based on calculations of physical parameters such as active surface area and external mass transfer coefficients. However, their study primarily examines the methanation stage, leaving gaps in the cyclic analysis of adsorption and purge phases.

### Contribution

Building on these foundations, this study develops an advanced finite difference model (FDM) in Python, leveraging a semi-implicit numerical approach to address the shortcomings in prior studies. For the first time, cyclic performance of DFMs is systematically designed and analysed, providing a comprehensive understanding of adsorption, purge, and methanation stages in an integrated manner. Furthermore, Bayesian optimisation is applied to identify optimal process parameters, yielding deeper insights into trade-offs between methane productivity, $CO_2$ conversion efficiency, and the product purity. This work addresses existing gaps by offering a reproducible, open-source framework that enhances the design, scalability, and efficiency of PtG systems based on DFM technology.

## METHODOLOGY

The modeling of the DFM process involves the formulation of a system of partial differential equations (PDEs) to describe the dynamics of gas-phase and surface-phase interactions within the reactor. These equations capture the temporal evolution of species concentrations and the coverage of adsorption sites across the reactor length and during the four stages of adsorption, purge, hydrogenation and final purge. The model builds upon the frameworks established in recent studies [4], extending them to incorporate a more efficient open-source numerical approach. This enhanced methodology explicitly incorporates cyclic operations and is tailored for advanced optimisation methods, enabling systematic exploration of optimal operational and design parameters.

### Dynamic DFM simulation model

The model is based on an experimental setup featuring a packed bed reactor loaded with DFM on granular alumina precursors. During the adsorption phase, a mixture of $CO_2$ and inert gas ($N_2$) is introduced into the column, where $CO_2$ is adsorbed onto the active sites of the DFM. Pure $N_2$ is employed during the purging stages, while a mixture of $H_2$ and $N_2$ is used during the hydrogenation phase. In this stage, the introduced $H_2$ aids the removal of adsorbed $CO_2$, driving its hydrogenation into methane. A final purge with pure nitrogen sweeps off the remaining gas components and facilitates the system condition for the next cycle.

### Assumptions

The following assumptions are made in formulating the mathematical model and solving the pertinent equations:

- The process operates isothermally, with the reactor temperature held constant at feasible hydrogenation temperature during all four stages of the process.
- Radial gradients are neglected, assuming uniform distribution of species and properties across the reactor cross-section.
- External and internal mass transfer limitations are considered negligible with similar conditions outlined in the reference study.
- The ideal gas law applies to describe the gas-phase behaviour.
- The reactor column is in thermal equilibrium with its surroundings and the entering feed. Positioned within the flue gas environment, heat transfer between the column and its surroundings is negligible.
- Pressure drop along the length of the reactor is considered negligible.

### Governing equations

The gas-phase concentrations of $CO_2$, $H_2O$, $H_2$, $CH_4$ and $N_2$ are governed by a PDE model assuming plug flow with axial dispersion. The temporal changes to the concentration of component $i$ ($C_i$) in the gas phase is calculated according to the below equation:

$$\frac{\partial C_i}{\partial t} = -\frac{u}{\varepsilon}\frac{\partial C_i}{\partial x} + \frac{D}{\varepsilon}\frac{\partial^2 C_i}{\partial x^2} + \frac{\rho R_i}{\varepsilon} \quad (1)$$

Where, $u$ is the gas linear velocity and $D$ is the axial

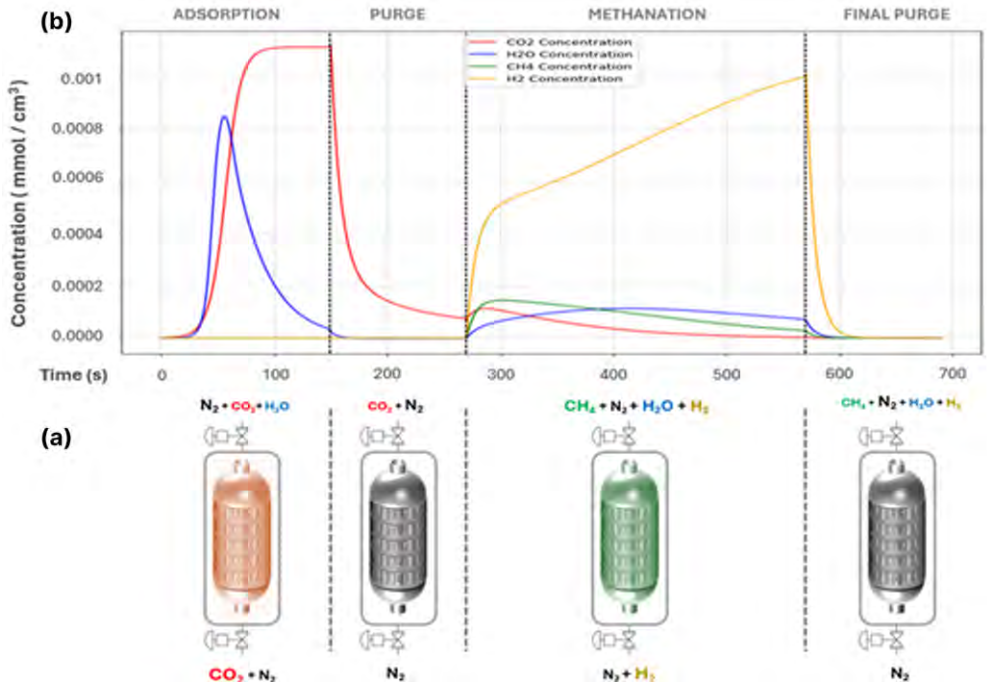

**Figure 1:** (a) The schematic diagram of the 4-stage carbon capturing and methanation in DFM process. (b) The base-case simulation column outlet concentration profile for $CO_2$ (red), $H_2O$ (blue), $CH_4$ (green) and $H_2$ (orange) curves for adsorption, purge 1, hydrogenation and purge 2.

dispersion coefficient. The parameters $\rho$ and $\varepsilon$ are the bed density and void fraction.

The unsteady state component mass balance in the sorbent phase can be expressed in terms of temporal changes to the fraction of the sorbent surface area covered with the component ($\theta_j$) according to Equation 2:

$$\frac{\partial \theta_j}{\partial t} = \frac{R_i}{\Omega_j} \tag{2}$$

Where, $\Omega_j$ is the adsorption capacity of carbon dioxide on the DFM and $R_i$ is the rate of formation for component $i$ which can be expressed in terms of the coverage area ($\theta_j$), stoichiometric coefficient of the component present in the reaction and the intrinsic rate of reaction which are outlined in the reference work [4]. Each rate expression corresponds to a specific chemical reaction within the $CO_2$ capture and conversion mechanism.

Equation (2) is only applied to $CO_2$ and $H_2O$ assuming the adsorption of other gaseous components negligible.

## Bespoke cyclic steady-state model

The PDE system is discretised along the axial direction using finite differences. Central differences are used for spatial derivatives, and backward differences are employed for temporal integration to ensure numerical stability. Also, Danckwert boundary conditions are used at the reactor outlet to ensure mass conservation under convective and diffusive fluxes. The resulting system of ordinary differential equations is solved using a semi-implicit scheme, with convergence criteria set for species concentrations and surface coverages.

The kinetic parameters, including rate constants and activation energies, were determined by fitting the developed PDE model to reference work experimental data using the least squares method. The concentration profiles at the reactor outlet were used for this estimation, with adjustments made to account for the delayed response of the analyser. Following the parameter identification, the bespoke model was applied iteratively to simulate the cyclic performance of the DFM process. The simulation was designed to achieve cyclic steady-state (CSS), defined as the point where consecutive cycles exhibit negligible variation in species concentrations and surface coverages. The CSS was modelled by systematically iterating the cyclic stages—adsorption, purge, hydrogenation, and final purge—until a stable operational pattern was observed. This validated model was then employed for process optimisation to improve system efficiency and performance.

Figure 1 depicts the four stages of DFM process and showcases the concentration profile for each of the components exiting the reactor at each stage after reaching CSS condition. The key design and operational parameters related to this base line model is specified in Table 1.

## Surrogate model optimisation

To optimise the performance of the DFM cyclic process, Bayesian optimisation was employed using Optuna, a robust open-source optimisation library in Python. The optimiser directly evaluates the developed PDE-based kinetic model, treating it as a black-box surrogate within the search space. Unlike traditional grid or random search methods, Optuna employs a tree-structured Parzen estimator (TPE) which models the distribution of hyperparameters that yield favourable outcomes and samples from this distribution in subsequent trials. This allows for a more efficient and adaptive exploration of the parameter space for computationally expensive surrogate models [6].

The developed kinetic model was integrated with Optuna to maximise methane productivity, $CO_2$ conversion efficiency, and purity. The optimisation encompassed a range of design and operational variables, including stage durations, flow rates, reactor geometry, and feed compositions. Multi-objective optimisation was performed to generate Pareto fronts, providing insights into trade-offs among key performance metrics.

**Table 1:** Base-case reactor model parameters for simulating the 4-staged DFM process.

| Parameter | Value |
|---|---|
| Bed density, $\rho$ (g/cm$^3$) | 1.4 |
| Column inner diameter, $d_i$ (mm) | 10.3 |
| DFM weight, $W_{DFM}$ (g) | 3.0 |
| Gas overall flowrate, $F_{gas}$ (mL/min) | 20 |
| Max. adsorption capacity, $\Omega$ (mmol/g) | 0.38 |
| Porosity, ε | 0.35 |
| Temperature, $T$ (K) | 623 |
| Hydrogenation Pressure, $P_{hyd}$ (atm) | 1.0 |
| $CO_2$ ads. feed gas (Vol.%) | 5.7 |
| $H_2$ hyd. feed gas (Vol.%) | 5.7 |

## Objectives, variables and statistics

In this work, the optimisation objectives are to maximise recovery, productivity, and purity at CSS as defined hereunder:

$$Recovery = \frac{mol_{CH_4}|_{out,hyd}}{mol_{CO_2}|_{in,ads}} \quad (3)$$

$$Productivity = \frac{mol_{CH_4}|_{out,hyd}}{(W_{DFM})(\boldsymbol{t_{cycle}})} \quad (4)$$

$$Purity = \frac{mol_{CH_4}|_{out,hyd}}{mol_{CO_2}|_{out,hyd}+mol_{H_2}|_{out,hyd}} \quad (5)$$

For calculating the total number of moles of component $i$ into or out of a stage $k$ we use:

$$mol_i|_k = \int_0^{t_k} F_{total}\, C_i(t)\, dt \quad (6)$$

The parameters influencing cycle performance include process times for each stage, gas linear velocity, column geometry, overall flue gas flow rate, concentrations of $CO_2$ ($C_{CO2}$) and $H_2$ ($C_{H2}$), DFM weight ($W_{DFM}$) and process conditions such as temperature and pressure. These parameters collectively form the degrees of freedom for the optimisation process (9 degrees of freedom in total).

While the impact of certain parameters, such as hydrogen pressure ($P_{hyd}$), $C_{H2}$ and $W_{DFM}$ (referred to as the first group of variables) is relatively straightforward (e.g., increasing hydrogen concentration or DFM weight directly enhances performance metrics), other parameters, such as stage durations, channel diameter, and gas flow rate (the second group), have less predictable or potentially conflicting effects on performance metrics.

This variability necessitates a series of multi-objective optimisation runs for each parameter in the first group. As a result, for each fixed value set of first-group variables, the optimisation explores a range of values for the second group, resulting in a unique Pareto curve for each case.

Each optimisation run includes 500 iterations per pair of two-objective Pareto points. With a minimum number of time steps of $N_t$ = 1000 for each stage, the optimisation takes 300-400 minutes. Previous trials indicate that changes in species concentrations and surface coverages are typically less than 1% after 5 cycles. To enhance computational efficiency, the maximum number of cycles required to achieve CSS has been limited to 5.

# RESULTS AND DISCUSSIONS

The Pareto fronts resulting from the multi-objective optimisation for maximising (a) Purity vs. Recovery, (b) Purity vs. Productivity, and (c) Productivity vs. Recovery are shown in Figures 2a, 2b, and 2c, respectively. In these figures, the iteration points (grey dots) represent the evaluated solutions generated by the CSS model during each iteration of the optimisation process. The Pareto front points (blue markers) highlight the optimal trade-offs between the respective objectives, such as purity and recovery.

For these results, only the second group of variables was manipulated, while the first group of variables was held constant at their base values. The variation bounds and the optimal values of the second group of variables corresponding to the extreme points on each Pareto curve (indicated by numbers) are detailed in Table 2. For simplicity, time steps were initially allowed to vary independently. However, to optimise the number of columns and ensure continuous operation, time steps will be balanced in future work.

**Table 2:** Optimisation results for pareto front extreme points in figures 2a, 2b, and 2c.

| No. | $t_{ads}$ | $t_{prg1}$ | $t_{hyd}$ | $t_{prg2}$ | $d_i$ | $F_{gas}$ |
|---|---|---|---|---|---|---|
| | s | s | s | s | mm | mL/s |
| **1** | 176 | 42 | 42 | 162 | 8.7 | 5.0 |
| **2** | 27 | 42 | 333 | 162 | 15.2 | 5.0 |
| **3** | 151 | 35 | 42 | 24 | 10.3 | 5.0 |
| **4** | 64 | 35 | 235 | 24 | 9.97 | 15.0 |
| **5** | 21 | 29 | 77 | 20 | 13.7 | 21.0 |
| **6** | 24 | 42 | 328 | 110 | 9.4 | 5.0 |

$20 \leq t_{ads} \leq 200$ ; $20 \leq t_{prg1,2} \leq 180$ ; $20 \leq t_{hyd} \leq 400$ ; $8.0 \leq d_i \leq 20$ ; $5 \leq F_{gas} \leq 30$

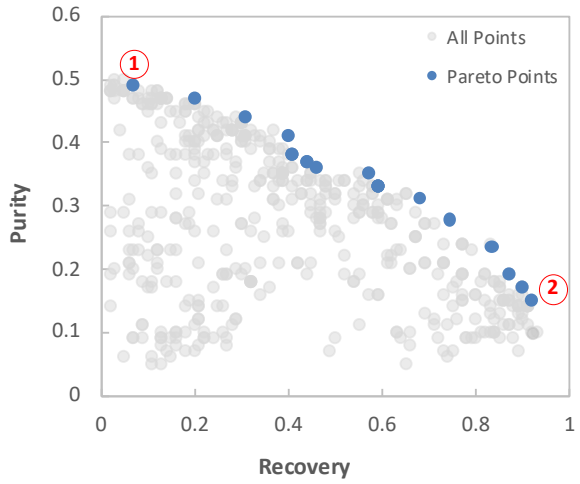

**Figure 2a.** Purity vs. Recovery Pareto Front and iteration points (No. 1 and 2 indicate the extreme points).

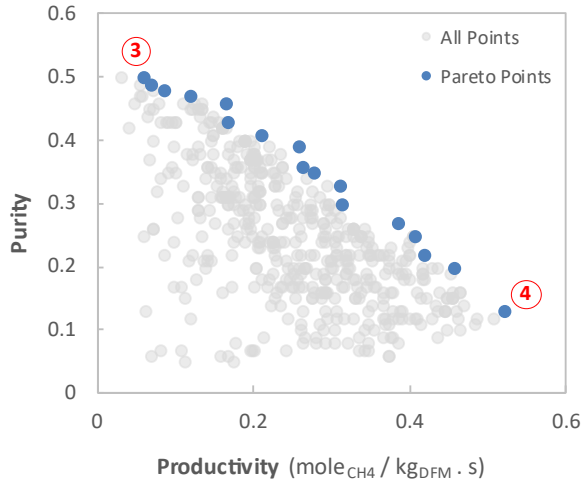

**Figure 2b.** Purity vs. Productivity Pareto Front and iteration points (No. 3 and 4 indicate the extreme points)

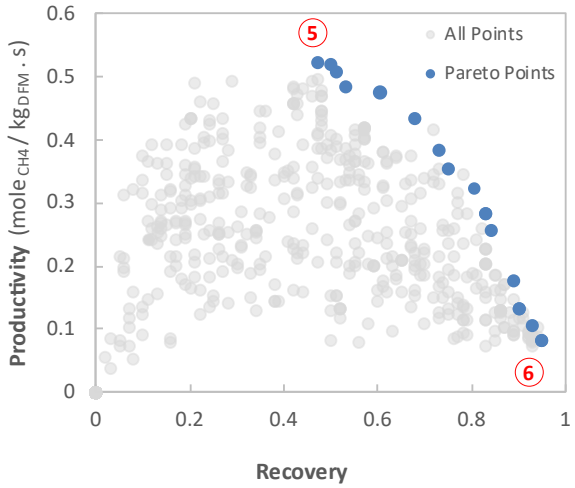

**Figure 2c.** Productivity vs. Recovery Pareto Front and iteration points (No. 5 and 6 indicate the extreme points).

The results reveal that a low gas flow rate is generally preferred when increasing purity and recovery, whereas higher flow rates are favoured for maximising productivity. Both recovery and productivity benefit from extended hydrogenation time ($t_{hyd}$), with recovery showing a stronger preference for longer durations than productivity. Similarly, adsorption time ($t_{ads}$) tends to increase to enhance purity, while the opposite trend is observed for recovery and productivity.

In all cases, the first purging period is reduced toward its lower bound. This is because extended purging times result in greater $CO_2$ loss from the adsorption sites, reducing the surface coverage and consequently diminishing methane production potential during the subsequent hydrogenation stage. Productivity, in particular, minimises this parameter more aggressively than other metrics. The final purge stage has negligible impact on any of the metrics, as the objective function is largely insensitive to its variation. Consequently, purge durations can be minimised to their operational limits, ensuring the removal of residual gases from the previous stage without compromising performance.

The changes to the Pareto curves resulting from variations in the first group of variables are qualitatively predictable. However, to quantitatively illustrate their impact on performance metrics and due to space constraints, only the effects of selected parameters are presented here. Figure 3 demonstrates the influence of two hydrogenation pressure levels, three $H_2$ concentration levels, and two DFM loading weights on the purity-recovery Pareto fronts. In this graph, H10, H30, and H50 represent hydrogen concentrations of 10%, 30%, and 50%, respectively. W6 and W10 indicate DFM weights of 6 g and 10 g, while P5 and P10 correspond to methanation pressures of 5 atm and 10 atm.

Changes to the first group of variables involve

energy and material costs, requiring a detailed analysis to evaluate trade-offs between metric improvements and expenses such as hydrogen compression or purification. Increased DFM weight also leads to higher material costs, pressure drops and longer columns, further impacting costs.

The figure highlights key parameter effects on purity and recovery. For example, increasing hydrogen pressure to 5 atm is more effective than quadrupling the DFM loading, but the scale of performance gains diminishes exponentially with further pressure increases. Similar diminishing returns are observed for other parameters. This further emphasises the necessity for a more detailed cost analysis to derive meaningful techno-economic conclusions.

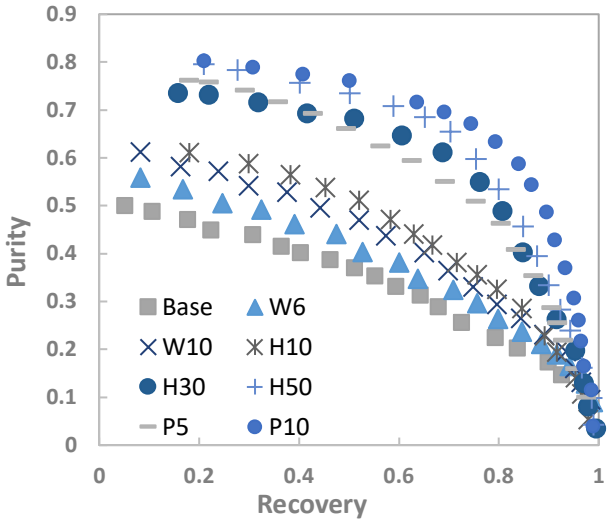

**Figure 3.** changes to Purity vs. Recovery pareto fronts due to step changes to the 1st group of variables.

## CONCLUSIONS AND FUTURE WORK

This study presents a comprehensive cyclic steady-state model for optimising DFMs in PtG applications. Using a semi-implicit numerical approach and Bayesian optimisation, the model systematically evaluates operational parameters, revealing key trade-offs among $CO_2$ conversion, methane productivity, and purity. Results show that lower flow rates enhance recovery and purity, while higher flow rates improve productivity. Extended adsorption times favour purity, while longer methanation times are critical for improving recovery and productivity. Multi-objective optimisation highlights Pareto fronts, illustrating the trade-offs between competing performance metrics. Variations in hydrogen pressure, DFM weight, and $H_2$ concentration demonstrate their substantial influence on system efficiency, with hydrogen pressure showing diminishing returns at higher levels. These insights highlights the importance of optimising both operational and design parameters to achieve industrial scalability. Future work will focus on detailed techno-economic analyses and cost-energy trade-offs to further enhance DFM-based PtG systems. Further fundamental studies on mass transfer, incorporating efficient finite volume approaches, are also recommended.

## DIGITAL SUPPLEMENTARY MATERIAL

## ABSTRACT

Dynamic process modeling in process industries has been extensively studied, especially with the development of deep learning techniques. Recurrent neural networks (RNN) and stacked autoencoders (SAE) are two powerful tools for dynamic modeling and data processing. However, most existing research primarily focuses on extracting features from process input data, often neglecting the temporal autocorrelation of output variables. In this work, a hierarchical model based on time-series RNN structure is proposed. The upper layer employs a long short-term memory (LSTM) network to extract temporal features from process input data. The lower layer uses a gated recurrent unit (GRU) to model the temporal dependencies of output variables across samples. These two parts are concatenated to form the model. Additionally, SAE is utilized to perform dimensionality reduction and reconstruction of process input, seamlessly integrating the reconstruction process with the RNN into a unified framework, termed the AR-SAE-RNN model. Distributed training is employed to effectively learn the model parameters. The proposed AR-SAE-RNN model has been applied to an industrial distillation column. The results demonstrate the model's effectiveness in capturing the dynamic behavior of the system.

**Keywords**: Dynamic process modeling, RNN, SAE

## 1. INTRODUCTION

In recent years, with the rapid advancement of production and information technologies, as well as the shift towards customized and refined product demands, process industries, represented by chemical processes, have become increasingly complex. The various coupled unit operations and energy consumption reduction strategies have made process industry modeling a challenge. On the timescale, process industry modeling can be classified into two categories: steady-state models and dynamic models, with dynamic models playing a dominant role as they better capture the temporal dependencies in real-world production processes. There are generally three approaches to dynamic process modeling: mechanistic-driven, data-driven, and hybrid mechanistic-data-driven models. Among these, mechanistic-driven and hybrid-driven models typically involve the modeling and solving of ordinary differential equations (ODE) or differential-algebraic equations (DAE), which require significant computational resources and time. In contrast, data-driven models, due to their simplicity and low dependence on process-specific backgrounds, have strong potential for application in dynamic modeling.

Data-driven models, in short, involve distinguishing between input and output variables of process data and constructing black-box models between these variables. The burgeoning amount of process data in the process industry has highlighted the advantages of deep learning techniques **[1]**. Among these, structures such as stacked autoencoders (SAE) **[2]**, recurrent neural networks (RNN) **[3]**, and their variants have been widely applied **[4,5]**.

Stacked Autoencoders and their variants are powerful tools for semi-supervised learning and handling missing data. When applied to dynamic modeling, they can perform feature extraction, dimensionality reduction, and denoising on the input data in a semi-supervised manner, making the data more suitable as model inputs **[6-8]**. RNN can extract temporal features from input variables, and variants such as gated recurrent units (GRU) and long short-term memory (LSTM) networks, by introducing gating mechanisms and memory units, further address the issues of vanishing and exploding gradients in traditional RNN, making RNN increasingly powerful in dynamic modeling **[9,10]**.

However, research on the application of RNN to dynamic modeling in process industries has primarily focused on the input process variables **[10,11]**, neglecting the autocorrelation of output variables over time. Specifically, the past states of output variables can also influence the current state. Although some studies **[12]** have included past output variables as inputs, this approach requires the actual values of the output variables from previous time steps, which imposes high demands in practical industrial settings and may introduce delays. Therefore, for dynamic systems with highly autocorrelated output variables, it is crucial to indirectly incorporate the influence of historical states into the RNN model.

Furthermore, most research on the application of SAE and its variants to dynamic modeling typically first uses SAE for input reconstruction, then constructs a dynamic model based on the reconstructed inputs, with the two processes being independent and lacking effective integration. Based on this, this paper proposes a temporal RNN model with an integrated SAE module that considers the autocorrelation of output variables. The model effectively learns the parameters through distributed training, and its effectiveness is validated in a real-world soft sensor case for a distillation column.

## 2. MODEL CONSTRUCTION AND TRAINING

In dynamic modeling, the conventional approach typically involves using RNN models to extract temporal features from input data for each sample, followed by fitting the corresponding output data. However, this approach often neglects the autocorrelation of the output variables or the inter-sample correlations. To address this limitation, we propose a hierarchical model. The upper layer extracts temporal features from input data within each sample, while the lower layer captures temporal dependencies of output data across samples. The features from both layers are concatenated to predict the output variables. Given the complexity of processing high-dimensional input data in the upper layer, we employ the LSTM model for its advanced feature extraction capabilities. In contrast, the lower layer focuses solely on the temporal modeling of output variables, allowing us to simplify the structure by utilizing a GRU model. Additionally, we incorporate a SAE module to reconstruct input data, effectively integrating input reconstruction and model regression into a unified framework. This integrated model is termed the Autoregressive-Stacked Autoencoder-Recurrent Neural Network (AR-SAE-RNN).

### 2.1 Sample Reorganization

Before introducing the AR-SAE-RNN model, we preprocess the standard sample data by reorganizing it. For an input-output dataset ($\boldsymbol{X'}$, $\boldsymbol{Y'}$):

$$X' = [x'_i]_{i=1}^{N} \tag{1}$$

$$Y' = [y'_i]_{i=1}^{N} \tag{2}$$

where $\boldsymbol{N}$ is the total number of samples, $\boldsymbol{x_i}$ represents the input data of the $\boldsymbol{i}$-th sample, and $\boldsymbol{y_i}$ is its corresponding output data. We then reorganize the samples, combining $\boldsymbol{K}$ consecutive original samples into a single new sample:

$$x_j = [x'_i, x'_{i+1}, \cdots, x'_{i+K-1}]_{i=j} \tag{3}$$

$$y_j = [y'_{i+K-1}]_{i=j} \tag{4}$$

To maximize data utilization, we set the sliding step size to 1 during the reorganization process, generating the following reorganized samples:

$$X = [x_j]_{j=1}^{N-K+1} \tag{5}$$

$$Y = [y_j]_{j=1}^{N-K+1} \tag{6}$$

After reorganization, the total number of samples becomes $\boldsymbol{N-K+1}$, effectively discarding the first $\boldsymbol{K-1}$ original samples. In the reorganized dataset, the $\boldsymbol{K}$ input samples are used to predict the output variables of the $\boldsymbol{K}$-th sample.

### 2.2 Model Architecture

The structure of the proposed AR-SAE-RNN model is shown in Fig. 1 and comprises three components:

(1) SAE Module: This module performs dimensionality reduction and reconstruction of the raw input $\boldsymbol{x}$, extracting deep features $\boldsymbol{z}$.

(2) LSTM Module: Using the deep features $\boldsymbol{z}$ extracted from the SAE module as input, this module captures temporal features of the input data within each sample, generating hidden states $\boldsymbol{h_t^k}$.

(3) GRU Module: Taking the hidden state $\boldsymbol{h_T^k}$ of the $\boldsymbol{T}$-th time step of the LSTM unit in each sample as input, this module extracts temporal features of the output variables across samples.

Finally, the hidden state $\boldsymbol{s_{k+K}}$ of the $\boldsymbol{K}$-th sample in the GRU module is concatenated with the hidden state $\boldsymbol{h_T^{k+K}}$ of the $\boldsymbol{T}$-th time step in the LSTM module to predict the output variables of the $\boldsymbol{K}$-th sample.

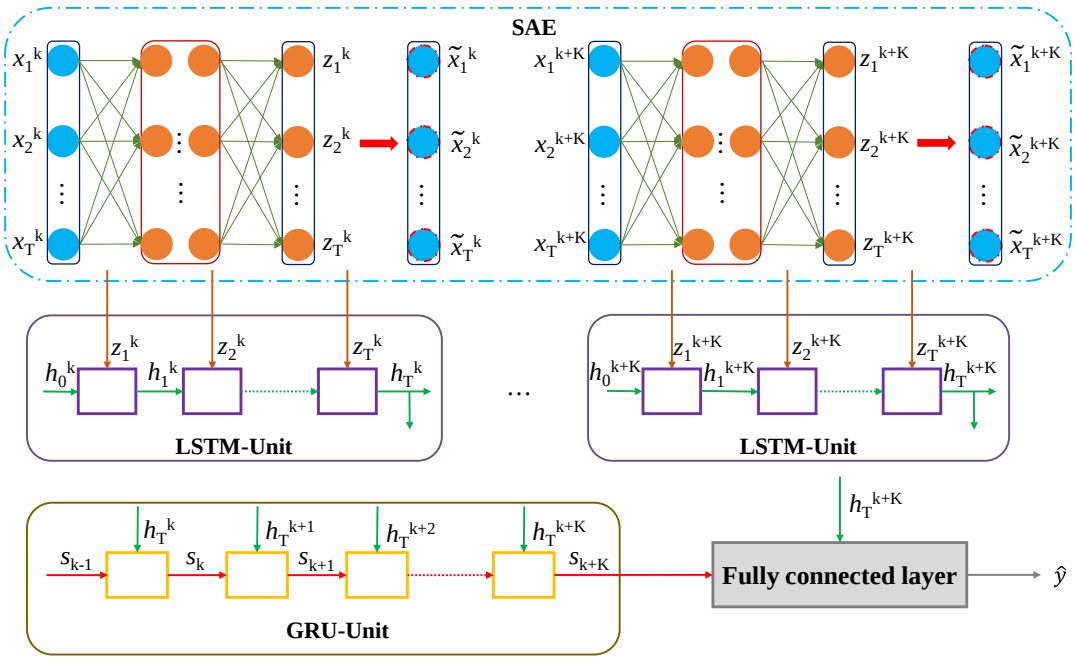

**Figure 1.** AR-SAE-RNN Model Architecture.

Assuming there are ***E*** stacked layers, the SAE module can be expressed as:

$$z^{(0)} = x \tag{7}$$

$$z^{(e)} = \sigma\left(W_{SAE}{}^{(e)} z^{(e-1)} + b_{SAE}{}^{(e)}\right) \tag{8}$$

$$e = 1,2,\cdots,E \tag{9}$$

where $\boldsymbol{W_{SAE}}$ and $\boldsymbol{b_{SAE}}$ are trainable parameters, $\boldsymbol{\sigma}$ is the activation function, and ***E*** is a hyperparameter.

The second component is a standard LSTM unit, except that its input is the deep feature ***z*** from the SAE module instead of the raw input ***x***. The LSTM unit model for the ***k***-th sample at the ***t***-th time step is defined as:

$$f_{(t)} = \sigma\left(W_{fz} z_t^k + W_{fh} h_{t-1}^k + b_f\right) \tag{10}$$

$$i_{(t)} = \sigma\left(W_{iz} z_t^k + W_{ih} h_{t-1}^k + b_i\right) \tag{11}$$

$$o_{(t)} = \sigma\left(W_{oz} z_t^k + W_{oh} h_{t-1}^k + b_o\right) \tag{12}$$

$$\tilde{C}_{(t)} = tanh\left(W_{cz} z_t^k + W_{ch} h_{t-1}^k + b_c\right) \tag{13}$$

$$C_{(t)} = f_{(t)} \odot C_{(t-1)} + i_{(t)} \odot \tilde{C}_{(t)} \tag{14}$$

$$h_t^k = o_{(t)} \odot tanh\left(C_{(t)}\right) \tag{15}$$

$$t = 1,2,\cdots,T \tag{16}$$

where $\boldsymbol{W_{fz}}$, $\boldsymbol{W_{fh}}$, $\boldsymbol{b_f}$, $\boldsymbol{W_{iz}}$, $\boldsymbol{W_{ih}}$, $\boldsymbol{b_i}$, $\boldsymbol{W_{oz}}$, $\boldsymbol{W_{oh}}$, $\boldsymbol{b_o}$, $\boldsymbol{W_{cz}}$, $\boldsymbol{W_{ch}}$, $\boldsymbol{b_c}$ are trainable parameters, $\boldsymbol{\sigma}$ and ***tanh*** are activation functions, and ***T*** is a hyperparameter.

The third component is a standard GRU unit, with its input being the hidden state output by the LSTM module. The GRU model for the ***k***-th sample (considered as the ***k***-th time step in the GRU module) is defined as:

$$r_{(k)} = \sigma\left(W_r h_T^k + U_r s_{k-1}\right) \tag{17}$$

$$gz_{(k)} = \sigma\left(W_{gz} h_T^k + U_{gz} s_{k-1}\right) \tag{18}$$

$$\tilde{s}_k = \varphi\left(W_g h_T^k + U_g\left(r_{(k)} \odot s_{k-1}\right)\right) \tag{19}$$

$$s_k = gz_{(k)} s_{k-1} + (1 - gz_{(k)})\tilde{s}_k \tag{20}$$

$$k = 1,2,\cdots,K \tag{21}$$

where $\boldsymbol{W_r}$, $\boldsymbol{U_r}$, $\boldsymbol{W_{gz}}$, $\boldsymbol{U_{gz}}$, $\boldsymbol{W_g}$, $\boldsymbol{U_g}$ are trainable parameters, $\boldsymbol{\sigma}$ and $\boldsymbol{\varphi}$ are activation functions, and ***K*** is a hyperparameter.

The final prediction of the output variables is given by:

$$\hat{y}_{k+K} = W_{LSTM} h_T^{k+K} + W_{GRU} s_{k+K} \tag{22}$$

where $\boldsymbol{W_{LSTM}}$ and $\boldsymbol{W_{GRU}}$ are trainable parameters. To prevent overfitting on the training set, regularization and dropout modules were incorporated into both the LSTM and GRU models.

## 2.3 Loss Function Design

For general dynamic modeling tasks, the loss function is typically defined as the difference between the predicted output variables and the actual value. In the proposed AR-SAE-RNN model, to effectively integrate input reconstruction and model regression, the loss function includes not only the prediction error of the output variables but also the reconstruction error of the input:

$$l = \alpha \frac{1}{N_{Train} T} \sum_{k=1}^{N_{Train}} \sum_{t=1}^{T} \left(\tilde{x}_t^k - x_t^k\right)^2 + \frac{1}{N_{Train}} \sum_{k=1}^{N_{Train}} (\hat{y}_k - y_k)^2 \quad (23)$$

where $\alpha$ is the hyperparameter representing the weight of the input reconstruction, and $N_{Train}$ denotes the number of training samples. The calculation model for the reconstructed input $\tilde{x}_t^k$ can be referenced from the literature **[6]**.

## 2.4 Model Training and Evaluation

The proposed AR-SAE-RNN model is relatively complex, and training all the parameters simultaneously may lead to divergence. Therefore, a distributed training strategy is adopted: the model parameters are trained sequentially in the order of SAE, LSTM, and GRU. At each step, only the parameters of one module are trained while freezing the others. After all modules are pre-trained, a fine-tuning process is applied to jointly optimize all parameters. Notably, distributed training is also required for the SAE module, and the specific method can be referred to in the literature **[6]**.

After training, the model performance is evaluated using two widely accepted metrics: root mean square error (RMSE) and the coefficient of determination ($R^2$):

$$RMSE = \sqrt{\frac{1}{N_{Train}} \sum_{k=1}^{N_{Train}} (\hat{y}_k - y_k)^2} \quad (24)$$

$$R^2 = 1 - \frac{\sum_{k=1}^{N_{Train}} (\hat{y}_k - y_k)^2}{\sum_{k=1}^{N_{Train}} (\overline{y_k} - y_k)^2} \quad (25)$$

where $\overline{y_k}$ represents the mean value of the output variables in the training set.

# 3. INDUSTRIAL APPLICATION

The industrial case study presented in this paper focuses on the distillation column in the product separation section of the production process, as shown in Fig. 2. In this distillation column, the bottom product stream is composed of heavy key components with a high purity. The top product stream consists of a mixture of various components, which undergo secondary separation downstream.

The purity of the heavy key components in the top liquid product directly influences the purity of the bottom product and the difficulty of the downstream secondary separation. This is a critical indicator in the system, referred to as HKC. Therefore, this study constructs a dynamic model with other process variables as inputs and the HKC purity as the output, aiming to achieve real-time soft sensing of HKC purity.

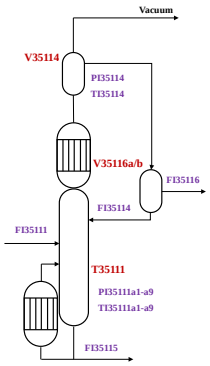

**Figure 2.** Separation Distillation Column.

As shown in Fig. 2, all process variables were sampled at a frequency of 1 minute. The HKC purity was measured online using Raman spectroscopy at a frequency of 10 minutes, which is costly. We collected 70 days of process data for model development. We first applied the 3σ rule to remove outlier samples. For the remaining valid samples, we used cubic spline interpolation to impute missing values in the process data. Finally, to ensure stable training of the neural network model, both the process data and output variables were normalized. Then, the dataset was divided into training, validation, and test sets in a ratio of 5:1:4.

To evaluate the performance of the AR-SAE-RNN model, the standard LSTM model was used as the baseline. Additionally, SAE-LSTM and LSTM-GRU models were included to assess the individual contributions of each module to prediction accuracy. All hyperparameters mentioned in this paper, including training-related parameters such as learning rate, were optimized through grid search.

The prediction performance on the test set is shown in Fig. 3, while the RMSE, $R^2$, and training time are summarized in Table 1. The results of hyperparameter tuning are summarized in Table 2. The standard LSTM model, benefiting from a large amount of training data, achieved accurate predictions for overall trends. However, its local prediction accuracy was suboptimal, with significant errors observed in many regions. By incorporating input dimensionality reduction through SAE, as well as temporal modeling of the HKC purity across samples using GRU, the AR-SAE-RNN model not only maintained accurate overall trend predictions but also significantly improved local prediction accuracy, achieving a 25% improvement in RMSE. Additionally, LSTM is designed to capture long-term dependencies but lacks inherent noise-filtering mechanisms, meaning it learns and propagates both useful patterns and noise through its hidden states. In contrast, the AR-SAE-RNN model integrates a SAE and a GRU, both of which contribute to noise reduction. The SAE compresses and extracts key features from the input data, filtering out irrelevant fluctuations before they

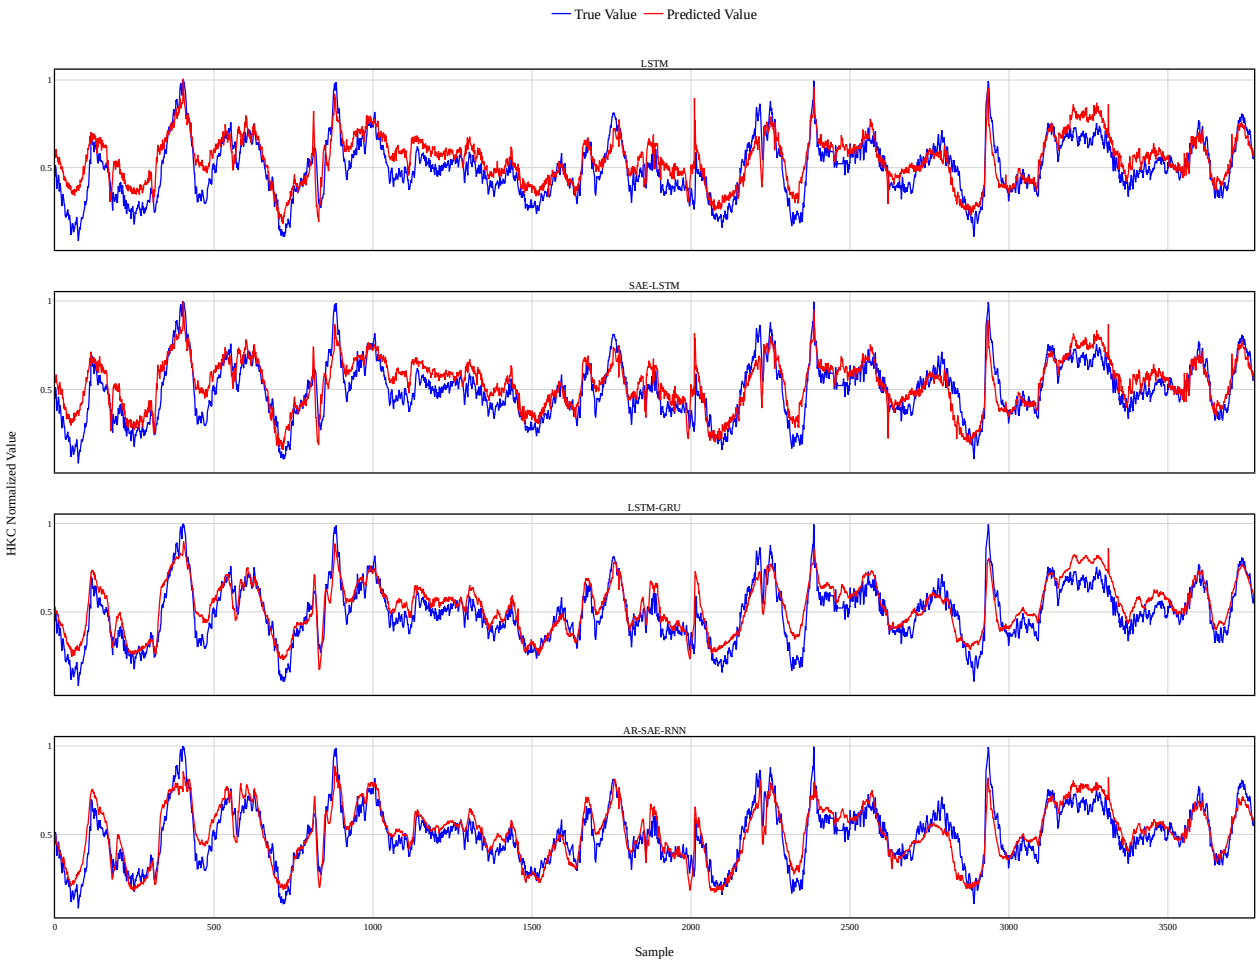

**Figure 3.** Comparison of predicted results and ground truth among four models.

reach the recurrent layers. Additionally, the GRU, with its simpler gating mechanism, is more resistant to noise accumulation, refining the hidden state representations and further attenuating residual noise. As a result, the AR-SAE-RNN model produces smoother and more robust predictions, making it more effective for handling noisy industrial data.

**Table 1:** Summary of Results for Four Models.

| Model | RMSE | $R^2$ | Training-Time(min) |
|---|---|---|---|
| LSTM | 0.09636 | 0.7142 | 0.25 |
| SAE-LSTM | 0.09006 | 0.7503 | 0.97 |
| LSTM-GRU | 0.07764 | 0.8144 | 0.45 |
| **AR-SAE-RNN** | **0.07262** | **0.8377** | **1.38** |

**Table 2:** Hyperparameter Results.

| Hyperparameter | Result |
|---|---|
| $E$ | 3 |
| $T$ | 4 |
| $K$ | 14 |
| $\Gamma$ | 0.3 |
| Lr(Pre-Trained) | 1e-3 |
| Lr(Fine-Tuning) | 1e-6 |
| Batch | 400 |
| LSTM Hidden Size | 64 |
| GRU Hidden Size | 32 |
| Epoch(SAE) | 200 |
| Epoch(LSTM) | 200 |
| Epoch(GRU) | 70 |
| Epoch(Fine-Tuning) | 50 |
| Dropout | 0.2 |

From Table 1 and Fig. 3, it is evident that the GRU module has the most significant impact on improving prediction accuracy. This underscores the importance of considering the autocorrelation of output variables in dynamic modeling. Furthermore, the proposed model does not rely on the actual values of past output variables as inputs, making it more practical for industrial applications.

## 4. CONCLUSION

To address the challenges of dynamic modeling, the proposed AR-SAE-RNN model introduces a novel approach compared to traditional RNN models by effectively accounting for the autocorrelation of output variables. The model integrates temporal modeling of output variables across samples while leveraging SAE to reconstruct input features. This unified framework has demonstrated excellent performance in the soft sensing case study of the distillation column.

Moreover, we aim to enhance our model in three key aspects as part of our future work. First, we will upgrade the SAE to a Variational Autoencoder (VAE), which encodes data as a probability distribution rather than a deterministic value, improving robustness by filtering noise in abnormal process data. Second, we will incorporate an attention mechanism into the GRU modeling of output variable autocorrelation, allowing the model to focus on the most relevant hidden states and improving predictive accuracy. Finally, we aim to integrate a mechanistic model for the distillation unit by constructing a simplified dynamic wave model that captures the temporal and spatial distribution of component compositions along the column height. This framework will decompose the temporal network into three components: sequential modeling of process data, autocorrelation modeling of output variables, and spatial correlation modeling of output variables, which will be combined to enhance predictive performance.

## ABSTRACT

Real-time carbon accounting is crucial for advancing policies that effectively meet sustainability objectives. This work introduces a carbon tracking tool specifically designed for the European electricity grid. The tool collects hourly data on electricity consumption and generation, cross-border power exchanges, and weather information to assess the real-time environmental effects of electricity use, employing locally-specific emission factors for the generation sources. It utilizes weather data from various stations across Europe to produce week-ahead forecasts of carbon intensity in the grid. Predictions are created using a random forest regressor, integrated within the optimal controller of an operational industrial batch process. This prediction-based optimizer seeks to reduce total emissions tied to the process schedule's electricity consumption by implementing a rolling horizon strategy. By leveraging enhanced energy flexibility, the controller provides significant opportunities for load shifting and emission reductions, though at a higher cost. An industrial batch process demonstration highlights the potential of this approach, showing environmental savings ranging from 4% in grids with low renewable energy to 32% in nations that incorporate a substantial proportion of renewable energy in their energy mix.

## INTRODUCTION

European countries aim for carbon neutrality by 2050, driving a shift from fossil fuels to renewable energy and widespread electrification. Real-time carbon accounting is critical for effective green policies, while forecasting aids planning and operations [1]. The GHG Protocol [2] introduced a "location-based" method for reporting scope 2 emissions, improving accuracy over the market-based approach. In the same vein, Brander et al. [3] recommended this method to avoid misrepresenting responsibility.

However, the “location-based” method does not reflect real-time consumption emissions. Spork et al. [4] used real-time data to improve carbon reporting in Spain but faced boundary limitations. Significant improvements came from the introduction of input-output lifecycle assessment (IO-LCA) methods, as applied by Claus et al. [5], which expanded system boundaries for better accuracy and highlighted the importance of cross-border carbon transfers. More recently, Tranberg et al. [6] refined this with flow tracing, supporting dynamic carbon taxes.

A major objective with such approach is to be able to schedule operations in periods of low-carbon electricity. However, operational scheduling based on carbon forecasts remains uncommon. Models by Ma et al. [7] and Chen et al. [8] either assumed fixed carbon factors or focused solely on costs. More advanced models, like those by Zhang et al. [9], still lacked real-time carbon integration. Oftentimes, time-dependent carbon data is used in technology design studies, such as in Castro-Amoedo et al. [10].

### Contributions

This study presents a dynamic life-cycle assessment framework for real-time carbon tracking in the

European electricity grid, expanding previous models by including ten more countries and using data from 200+ weather stations for week-ahead carbon forecasts. Key contributions include:

1. Optimized Industrial Operations: Using emission forecasts to control industrial batch processes, enabling load shifting and emission reductions.
2. Grid Digitalization: Emphasizing the need for granular electricity data to support broader carbon reduction strategies.

## METHODOLOGY

The tool uses data provided by the ENTSO-E database [11] to quantify the impact of electricity consumption in each European country. It considers real-time electricity production mixes, electrical power exchanges across borders, and locally differentiated carbon intensities [12] of the energy sources to calculate current or past environmental indicators for each European country with a data granularity of one hour.

The implementation allows interfacing with optimization algorithms in such a way that the data stream indicators can be automatically fed into operation scheduling problems. As a result, the tool provides the basis for carrying out optimization with environmental objectives (i.e. minimization of the carbon footprint associated with production), or, alternatively, it can be used as a post-computation phase to assess the real-time environmental performance of a process by calculating its sustainability indicators. Our methodology includes :

3. Data Acquisition: Fetching real-time data on electricity production, consumption, and cross-border exchanges.
4. Data Validation: Ensuring accuracy by checking production limits, technology mix consistency, and eliminating invalid data.
5. Environmental Indicator Calculation: Computing indicators like carbon footprint, renewable energy share, and ecological impact.

### Mathematical Approach

The carbon intensity arising from the consumption of electricity from the grid in each country is obtained by solving a linear system of equations representing the carbon flows in the European network [6]. The calculated values represent the greenhouse gas footprint of 1 kWh consumed inside a given country. The footprint is measured in $gCO_2$ equivalent, meaning that each greenhouse gas is converted into its carbon dioxide equivalent in terms of climate change potential. For each country $i$, the balance of eq. (1) can be written, where $D_i$ is the total electricity demand, $P_i$ is the total electricity production, and $I_i$ and $E_i$ are the total import and export of electricity, respectively.

$$\mathrm{D}_i = P_i + I_i - E_i \tag{1}$$

By extending eq. (1) to balance the carbon flows of country $i$, one obtains eq. (2), where $x_i$ is the carbon intensity of electricity consumption, $e_{i,r}$ is the carbon intensity of resource $r$ in country $i$, $P_{i,r}$ is the total electricity production using resource $r$, $x_j$ is the carbon intensity of electricity imported from country $j$, $I_{i,j}$ is the electricity import to country $i$ from j, and $E_{i,k}$ is the electricity export from country $i$ to $k$.

$$x_i \mathrm{D}_i = \sum_r e_{i,r}\ P_{i,r} + \sum_j x_j\ I_{i,j} - \sum_k x_i\, E_{i,k} \tag{2}$$

Considering from eq. (1) that $D_i + E_i$ equates to $P_i + I_i$, and writing for each country, the following linear system results (eq. 3).

$$\begin{bmatrix} P_1 + I_1 & \cdots & -I_{1,n} \\ \vdots & \ddots & \vdots \\ -I_{n,1} & \cdots & P_n + I_n \end{bmatrix} \times \begin{bmatrix} x_1 \\ \dots \\ x_n \end{bmatrix} = \begin{bmatrix} \sum_r e_{1,r}\ P_{1,r} \\ \dots \\ \sum_r e_{n,r}\ P_{n,r} \end{bmatrix} \tag{3}$$

Where:

$$\mathrm{P}_1 = \sum_r P_{1,r}\ \ and\ \mathrm{I}_1 = \sum_j I_{1,j} \tag{4}$$

Because the $CO_2$ equivalent emissions of each country depend not only on its own electricity mix but also on that of its neighbours, the $CO_2$ mass flow balance of all countries must be addressed simultaneously. The same procedure was adopted to calculate other environmental indicators, such as renewable energy (RE) share.

The carbon intensities $e_{i,m}$ are location-dependent and specific to each energy resource. Such emission intensities account for the whole life cycle of electricity production, from plant construction and fuel treating, i.e. including all upstream activities, disposal and decommissioning. The impact of each resource $r$ is calculated using all the technologies $m$ associated with such a resource that is available in the country generation mix ($\mathbf{M}^r$). The impact factors $e_{i,m}$ are calculated by weighting each technology by the corresponding market share $s_m$ [12](eq. 5).

$$e_{i,r} = \sum_m^{M^r} s_m \times e_{i,m} \tag{5}$$

### Application to Case Study

A prediction-based optimizer with a weekly (168-hour) horizon is applied to an industrial batch process, simulated over one month with hourly rolling updates. The scheduling model, based on Mixed-Integer Linear Programming (MILP), is solved iteratively. The model is described in Santecchia et al. [13]. Unlike prior studies, this model focuses on minimizing emissions from electricity consumption rather than costs. The objective function is adjusted, extending the scheduling window from 72 to 504 time slots, corresponding to 20-minute intervals.

The predictive controller updates the process

schedule hourly, retrieving electricity and weather data from ENTSO-E and the Visual Crossing API (Fig. 1). This data feeds a random forest regressor to update carbon intensity forecasts. The optimization is solved for each production line to meet minimum environmental impact goals, repeating hourly until the end of the month (N = 720).

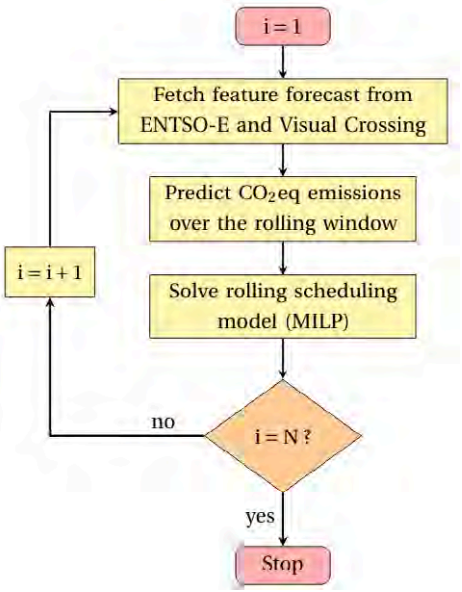

**Figure 1.** Flow diagram of the online scheduling algorithm with MPC approach.

### Feature selection

The framework generates day-ahead and week-ahead carbon emission forecasts using data on projected generation, consumption, solar and wind output, cross-border electricity flows, and day-ahead market prices from the ENTSO-E database. To extend forecasts beyond one day, it integrates weather data (wind speed, direction, temperature, precipitation, cloud cover) from over 200 European weather stations via the Visual Crossing API.

To reduce computational demands, a statistical feature selection method evaluates the relationship between input variables and carbon emissions. This involves constructing a normalized covariance matrix over 1–3 years using Pearson Correlation Coefficients (PCC). Features with strong correlations are flagged as redundant, while weakly correlated ones are removed, ensuring efficient modelling without significant data loss. A PCC of 0.6 was chosen as threshold to distinguish strong and weak correlations, and was not subject to optimization.

### Prediction algorithms

Due to feature selection reducing the dataset - sometimes to as few as two variables - various learning algorithms were tested, including simpler models. These included linear regression with batch and stochastic gradient descent for error minimization, along with LASSO (L1 regularization), Ridge regression (L2 regularization), and their combination through Elastic Net Regression to mitigate overfitting. Multivariate polynomial regression was explored for modeling non-linear relationships, and the RANSAC algorithm was applied to detect outliers.

While these simpler methods aimed to avoid unnecessary complexity, they often lacked sufficient prediction accuracy or failed with high-dimensional data. To address this, advanced models like artificial neural networks (Multi-layer Perceptron, Dense networks) and random forests were implemented. Despite higher computational demands, these models delivered greater accuracy with minimal data pre-processing and tuning. Random forests outperformed other algorithms in early evaluations and were chosen for prediction tasks due to their robustness with complex datasets and resistance to outliers. To further prevent overfitting, hyperparameter tuning was systematically applied using a combinatorial search approach. For random forests, key hyperparameters such as the number of trees, tree depth, and minimum samples per leaf were optimized to balance model complexity and generalization. A grid search and random search were employed to explore different hyperparameter combinations, followed by k-fold cross-validation to evaluate model stability and prevent data leakage. Additionally, cross-validation techniques were employed to assess model performance and ensure that the selected hyperparameters led to robust predictions on unseen data.

## RESULTS

### Accuracy improvements on carbon accounting standards

The real-time carbon tracking method offers greater accuracy than traditional approaches used by organizations for carbon accounting. Typically, impact factors in scope 2 reporting (GHG Protocol Corporate Standard) are based on annual electricity production data. Fig. 3 illustrates the potential improvement of real-time tracking, showing the mean relative error reduction across various time scales (hourly, daily, weekly, monthly). These values estimate the reporting errors in indirect emissions from purchased electricity.

Since the exact real-time environmental impact is unknown, the tool's indicators are treated as accurate. The improvement is assessed using bootstrapping, where random samples from the 2023 environmental impact database are repeatedly drawn to measure deviations from the annual average. This process uses a sample size of 1,000 and is repeated 10,000 times to approximate the accuracy distribution.

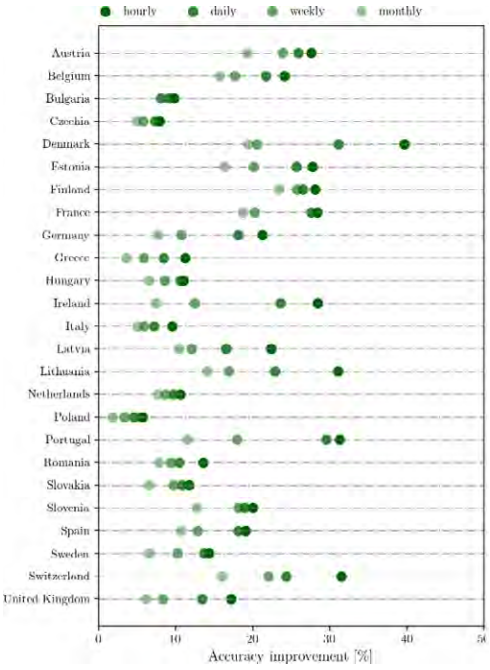

**Fig 3** - Accuracy improvement of real-time carbon tracking compared to current accounting standards, showing average relative improvements across hourly, daily, weekly, and monthly intervals.

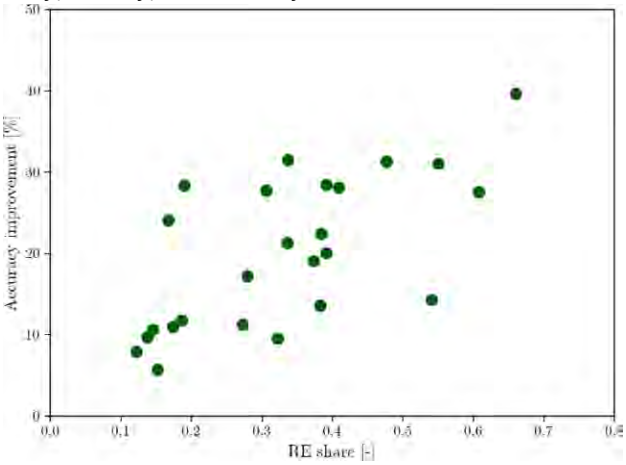

**Fig 4** - Accuracy improvement [%] of the real-time carbon tracking method as a function of the RE share [-] by country.

Hourly accuracy improvements vary by country and are more significant in grids with high renewable energy penetration (Fig. 4). The method shows the smallest benefit in Poland (6%) due to its reliance on coal (15% renewable share) and the largest in Denmark (40%), where renewables account for 66% of electricity. This correlation highlights that greater variability in renewable generation leads to more accurate carbon accounting. Implementing real-time carbon tracking is essential for accurately estimating indirect emissions in renewable-heavy grids, supporting Europe's transition to a decarbonized energy system.

## Emissions forecast with Random Forest

The random forest regressor is trained on the emissions database, split into 80% for training and 20% for testing. While it offers high predictive accuracy, it risks overfitting. A balanced dataset size is essential—too large, and the model overfits past grid data; too small, and it misses key grid patterns. Testing datasets of 1–2 years, closest to the prediction window, ensures optimal accuracy.

Fig. 5 illustrates a week-ahead $CO_2$ prediction (January 1–7, 2023) for Germany. The model accurately tracks carbon intensity trends, with a mean absolute error (MAE) and an R^2 value of 0.86.

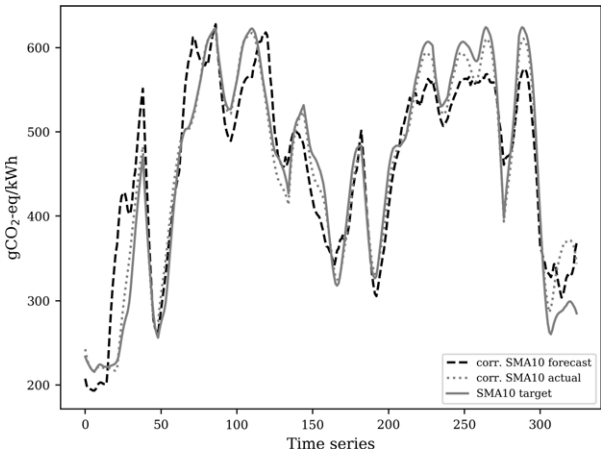

**Fig 5** - Week-ahead prediction trend in Germany (January 1–7, 2023) using a random forest regressor trained on 2020–2022 data. The SMA10 tracks prediction accuracy, with the 'actual' curve showing model output. Key metrics: MAE (19.4 actual, 54.9 forecast) and $R^2$ (0.952 actual, 0.728 forecast).

## Reducing emissions in a batch process

Fig. 6 presents the cumulative average emission profiles for two rolling schedules. In the first scenario (process 1d), emissions are minimized using day-ahead grid carbon intensity predictions with a 24-hour rolling window, limiting the ability to anticipate favorable conditions beyond that period. This approach results in an 11.6% reduction in emissions compared to the baseline scenario (BAU, shown in red).

Extending predictions to a week ahead leads to a greater reduction in emissions. With improved insight into future grid conditions, the optimizer schedules operations more effectively, especially during periods of high carbon intensity (e.g., between 10:00 and 15:00). Unlike the short-term model, the week-ahead schedule shifts energy-intensive tasks to low-emission periods, reducing $CO_2$ emissions by 17.5% compared to BAU and 6.6% compared to the day-ahead scenario.

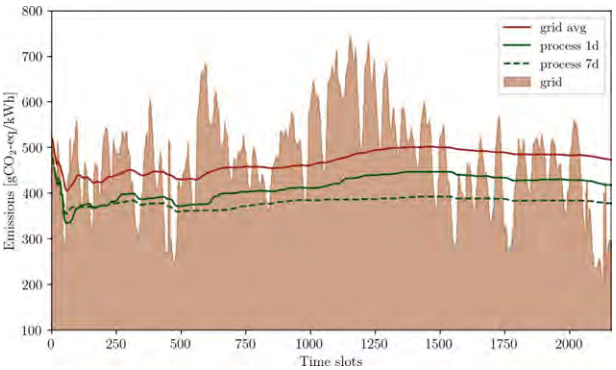

**Fig 6** - Cumulative average emissions of the MPC for an industrial batch process in Germany, comparing day-ahead (solid green) and week-ahead (dashed green) predictions. The shaded area shows hourly grid intensity, and the red line represents the BAU scenario.

## Benefits of optimal operations scheduling with emission targets in Europe

The process was simulated across various European countries using 1-day and 7-day prediction windows. Results in Table 1 show that emission reductions vary by country. Significant improvements occur in nations with high renewable energy use, like Denmark (-28.6%) and Lithuania (-32.4%), while countries reliant on fossil fuels, such as Czechia (-9.2%) and Poland (-4.4%), see smaller gains. This difference stems from the greater variability in carbon intensity within renewable-heavy grids, allowing long-term planning to be more effective. On average, carbon emissions dropped by 15%.

**Table 1:** Results of the MPC simulations by country, showing emission reduction for both the short- (daily) and long-term (weekly) optimizers.

| | Emissions ($gCO_2$/kWh) | | | % |
|---|---|---|---|---|
| Country | Grid | Process 1d | Process 7d | Max reduction |
| Austria | 271.1 | 253.8 | 235.6 | -13.1% |
| Czechia | 763.5 | 731.2 | 692.8 | -9.2% |
| Denmark | 207.0 | 180.4 | 147.8 | -28.6% |
| Estonia | 583.0 | 567.5 | 517.1 | -11.3% |
| Finland | 191.7 | 181.3 | 172.5 | -10.0% |
| Germany | 473.5 | 418.4 | 390.6 | -17.5% |
| Greece | 666.0 | 614.3 | 523.5 | -21.4% |
| Italy | 382.9 | 358.9 | 334.7 | -12.6% |
| Lithuania | 227.9 | 189.3 | 154.1 | -32.4% |
| Poland | 947.4 | 925.4 | 905.3 | -4.4% |
| Spain | 232.5 | 215.6 | 201.3 | -13.4% |
| Sweden | 37.4 | 34.1 | 30.8 | -17.7% |
| UK | 270.8 | 248.3 | 203.1 | -25.0% |

## CONCLUSIONS

This study introduces a real-time carbon tracing method for the electricity grid, using hourly data on electricity consumption, generation, cross-border power flows, and weather conditions to calculate environmental impacts with locally differentiated emission factors. This method improves accuracy over traditional carbon accounting, with emission reporting improvements ranging from 6% in Poland to 40% in Denmark, especially in grids with high renewable energy penetration.

The framework also generates day-ahead and week-ahead carbon emission forecasts based on projected generation, consumption, renewable output, electricity trade, prices, and weather data from ENTSO-E and Visual Crossing APIs. To enhance efficiency, a feature selection algorithm removes redundant data using Pearson Correlation Coefficients.

A random forest algorithm is used for forecasting, with hyperparameter tuning to prevent overfitting. Training the model on one to two years of data achieved reliable carbon intensity predictions ($R^2$ = 0.86).

This model is integrated into a mixed-integer linear programming (MILP) optimizer for an industrial batch process in Germany, reducing emissions by 17.5% and increasing renewable energy use by 9.7 percentage points compared to BAU. Simulations across Europe show greater benefits in countries with high renewable energy shares (-32.4%) and smaller gains in fossil-fuel-dependent countries (-4.4%).

## ABSTRACT

The pulp and paper industry has significant potential to reduce its carbon footprint by optimizing energy and water usage, contributing to global efforts toward net-zero emissions. A critical unit operation in this industry is pulp washing using twin roll press washers, which enhance pulp quality. The filtrate from this unit operation can be concentrated and combusted to generate a significant amount of energy for the plant and nearby industries. However, these washers are prone to blockages that disrupt production and decrease energy efficiency. Despite their importance, models for managing blockages in twin roll press washers are lacking. This study addresses this gap by developing empirical models to predict roll speed based on key process parameters. These models performed well on a case study of un-sanitized data from a real pulp and paper plant, achieving $R^2$ of the order of 0.7. The models can potentially be used by operators to ensure uninterrupted production, and optimize resource usage, supporting the industry's sustainability and decarbonization goals.

**Keywords**: Pulp Washing, Twin Roll Press Washer, Empirical Model

## INTRODUCTION

Achieving net-zero emissions is essential for energy-intensive chemical and process industries to help combat climate change and ensure environmental sustainability. These industries – including mining, iron and steel, aluminum, pulp and paper, chemicals, petrochemicals, cement, and glass – account for approximately 20% of the world's $CO_2$ emissions, totaling 6.2 Gt of $CO_2$ in 2018 [1]. Amongst them, the pulp and paper industry has the potential to reduce its carbon footprint by 30% via reducing its overall energy and water consumption [2].

Pulp washing using twin roll press washers is a crucial unit operation in pulp and paper plants [3]. Pulp washing using twin roll press washers can be compared to an industrial-scale filtration process, similar to squeezing a wet sponge to remove impurities. In this process, wet pulp is combined with hot wash water and passed through the narrow gap (nip) formed by two rotating rolls under high pressure. This action effectively extracts the liquid filtrate, known as weak black liquor, while producing a drier pulp with improved consistency and reduced levels of dissolved organic and inorganic solids. This efficient separation process enhances the overall quality and processability of the pulp in paper manufacturing. The weak black liquor, containing organic and inorganic dissolved solids and a small amount of fiber, is concentrated and combusted for on-site power generation. If the pulp washing process is optimized, the energy generated from the combustion can account for most of the plant's onsite energy consumption and even power neighboring industries. The weak black liquor recoverable from twin-roll press washer is the fifth most significant fuel globally [4], as 1.2 billion tonnes of concentrated black liquor are processed in recovery boilers across the world. This leads to the recovery of 14 million tonnes of cooking chemicals, a decrease in waste, and the generation of 635 million tonnes of steam [5].

Twin roll press washers are prone to blockage issues, which can decrease the plant's energy efficiency, and disrupt operations and productivity. Blockages can be acute and/or chronic. Acute blockage is caused by an inappropriately high dewatering rate, typically due to high roll pressure, high fiber content (pulp consistency),

low pulp flow rate, and low and solid buildup (chronic). Chronic blockage is typically due to the accumulation of pulp fibers, contaminants, or debris within the machinery. When blockages occur, the wash water flow rate is increased in an effort to either rehydrate the pulp or wash off the buildup solids. If this strategy is insufficient, production is ceased, and the solid buildup is manually removed. Disruptions of this process are disastrous, as increasing the wash water flow rate to remove blockages leads to a heavier energy load on the downstream weak black liquor concentrators. Furthermore, pausing the process to address the severe blockage issues leads to not meeting the production demand and reduced power cogeneration.

Fault management studies in the pulp and paper industry have focused on the heat recovery network in thermomechanical pulp process [6], particle formation in recovery boilers [4], and the drying process [7]. Searching "Twin Roll Press Washer" on Scopus yielded one relevant study on its fatigue and failure structure analysis [8], with no first-principles, data-driven machine learning, or hybrid models developed for blockage correlations at all despite its importance. Therefore, this study aims to develop the empirical, machine learning models of the twin roll press washer's roll speed as a function of key process parameters. Successful prediction of roll speed will potentially assist operators in pulp and paper plants to adjust key process setpoints with more certainty. Such an outcome will help prevent blockages by ensuring safe roll speeds, ensuring uninterrupted production, and optimal water and energy usage.

## DATA AND METHODS

Pulp washer plant data was obtained from an operating pulp and paper plant in New Zealand over a 12-month period from the plant's distributed control system. The data was collected at a sampling frequency of 1 minute. Data during plant shutdown periods was manually removed. No denoising algorithms were applied to the industrial data.

Simple linear regression was employed first to identify simple empirical models from the plant data. For these simple empirical models, the first half year of the data was used for model development, while the second half year was used for validation. The first simple empirical model was a model that is only a function of varying roll pressure ($P$) and pulp flow rate ($Q$), while all other process parameters were kept "constant" (within 1% deviation from their setpoints) by filtering the plant data. Since controlled process parameters may deviate from their setpoints, this first model is limited in its accuracy and application. Hence, a second simple empirical model was built which covered a wider range of operating conditions: all ranges of $Q$ and $P$ and larger ranges (within 10% deviation from setpoints) of inlet pulp consistency ($C$) and wash water flow rate (also quantified by dilution factor, $DF$).

A black-box machine learning model was then developed using a feedforward neural network with ReLU activation function to capture complex dependencies and non-linearities in the data better. The model was defined using PyTorch v2.2.2. The model was designed with three hidden layers and employed batch normalization and dropout for regularization. The first hidden layer consisted of 32 neurons, followed by 16 neurons in the second hidden layer, and 4 neurons in the third hidden layer, all equipped with batch normalization. The model was trained using the Adam optimizer with a learning rate of 0.001 and the mean squared error loss function. The above hyperparameters were chosen manually with trial-and-error. A maximum of 100 epochs was allowed. Early stopping was incorporated with a patience of 10 epochs, halting training if the validation loss did not improve. Due to the large numerical difference between variables of different attributes ($Q, P, C, DF$), the dataset was first normalized. Filtered data used to develop the second simple empirical model was used to train, validate, and test the neural network. 70% of the first half year of data was used for training, the remaining 30% of which was used for validation; all of the second half year of the data was used for testing.

## RESULTS AND DISCUSSION

### Simple regression models

Pulp can be likened to a soaked sponge. As the sponge becomes drier, the friction between it and any surface it contacts increases. The dewatering rate of a soaked sponge increases with higher applied pressure and a lower feed rate. Similarly, in the case of pulp, its dryness, and therefore friction, increases with higher roll pressure and lower pulp feed rates, which in turn results in a reduced roll speed. Assuming other process parameters remain constant, this relationship can be mathematically expressed in Equation (1):

$$N = f(Q, P) = k\frac{Q}{P} + b \quad (1)$$

Where $N$ is the twin roll press washer's roll speed, and $k$ and $b$ are the fitted parameters.

Hence, plotting $N$ against $\frac{Q}{P}$ should reveal a straight line, as is indeed is observed in **Figure 1**. The $R^2$ value of the fitted trendline using data from the first half of the year is 0.85, indicating a strong fit. Data from the second half of the year also aligns closely with the trendline, demonstrating that the model remains robust despite seasonal variations and other uncontrollable factors, such as feedstock quality, irregular machine maintenance, and unquantifiable chronic solid buildup. This

provides a solid foundation for developing more practical empirical models that accommodate a broader range of operating conditions.

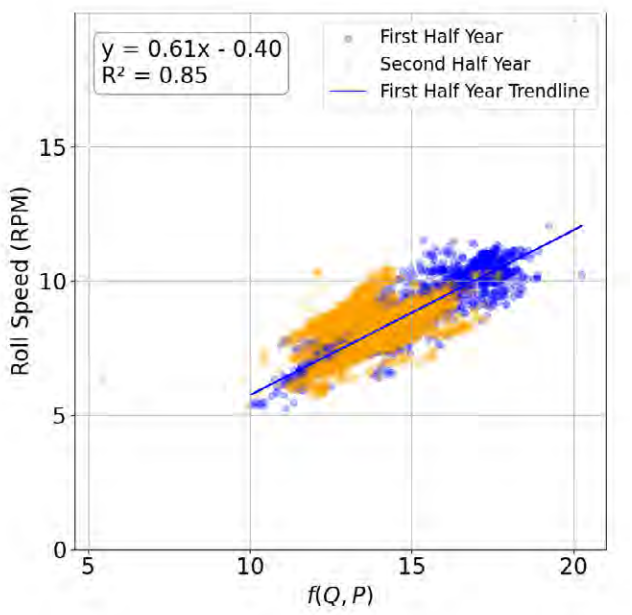

**Figure 1.** The simple first empirical model. Scatter plot of twin roll press washer's roll speed as a function of pulp flow rate and roll pressure, with constant inlet pulp consistency and dilution factor (1% deviation from setpoints).

After introducing data with a 10% variability in the inlet pulp consistency and dilution factor relative to their setpoints, the performance of the initial empirical model declined significantly, achieving an $R^2$ value of only 0.65 (**Figure 2**). This underscores the importance of developing a second empirical model that can maintain robust performance despite such variability.

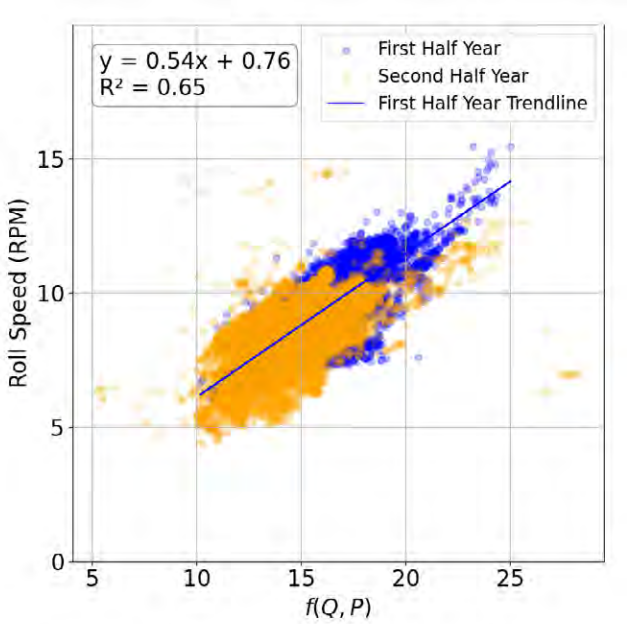

**Figure 2.** The simple first empirical model. Scatter plot of twin roll press washer's roll speed as a function of pulp flow rate and roll pressure, with varying inlet pulp consistency and dilution factor (10% deviation from setpoints).

The second empirical model builds on the first one, and aimed to achieve a better goodness of fit by including the inlet pulp consistency and dilution factor in the Equation (2).

$$N = f(Q, P, C, DF) = k\left(\frac{Q}{P} + m\right) + b \quad (2)$$

Where the correction factor, $m = \frac{Q}{\log P}\sqrt[3]{\frac{DF}{C}}$.

Fitting a trendline between roll speed and $\frac{Q}{P} + m$ yielded an $R^2$ value of 0.7 (**Figure 3**), which suggests that introducing the correction factor was able to improve the model's accuracy. This model can be used to inform the operator that when $\frac{Q}{P} + m$ is smaller than 15, roll speed may be lower than 5 rpm, and the roll pressure setpoint should be lowered to increase $\frac{Q}{P} + m$ and hence the roll speed to prevent blockages.

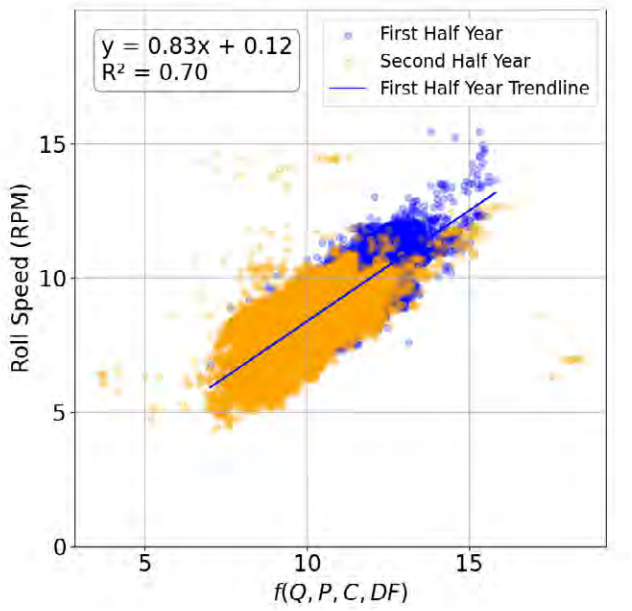

**Figure 3.** The improved second empirical model. Scatter plot of twin roll press washer's roll speed as a function of pulp flow rate and roll pressure, with varying inlet pulp consistency and dilution factor (10% deviation from setpoints).

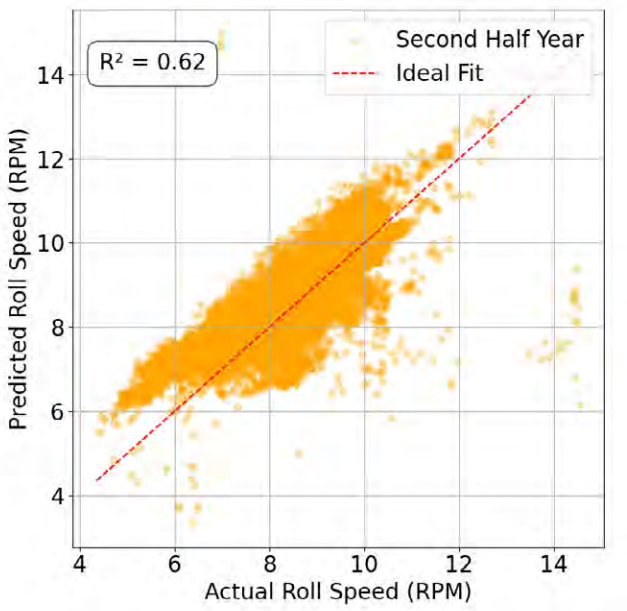

**Figure 4.** The feedforward neural network machine learning model. Scatter plot of predicted vs actual twin roll press washer's roll speed in the test dataset.

### Feedforward neural network model

Given that the simple regression model achieved an $R^2$ of only 0.7 when applied to a broader range of operating conditions, a feedforward neural network was investigated to potentially improve performance. The improvement observed after incorporating the nonlinear correction factor $m$ suggests that the effects of dilution factor and inlet pulp consistency on roll speed are likely nonlinear. Hence, a ReLU activation function was chosen to better capture these relationships. The feedforward neural network model yielded an $R^2$ of 0.62 (**Figure 4**). The low performance can be attributed to the simplicity of the feedforward neural network used in this study, as well as systematic variations over the extended time span between the training and test datasets. These variations include seasonal changes, which can significantly affect the characteristics of wood chips – such as moisture content, density, and composition – ultimately influencing pulp washing performance.

## CONCLUSIONS AND FUTURE WORK

In conclusion, this study successfully developed the first empirical models to predict roll speed in twin roll press washers based on key process parameters. The simple regression models demonstrated strong fits, with the second model being more applicable by incorporating additional variables such as inlet pulp consistency and dilution factor, achieving an $R^2$ value of 0.70. The machine learning model achieved an $R^2$ of 0.62, which may be able to be improved by modifying the feedforward neural network architecture and implementing physics-informed neural networks. However, already, models such as these have the potential to be used by operators to optimize roll speed, prevent blockages, and ensure uninterrupted production, ultimately supporting the pulp and paper industry's goals of sustainability and decarbonization.

Future work could focus on enhancing model adaptability and predictive accuracy by incorporating online learning approaches to continuously update both empirical and machine learning models in response to seasonal variations, machine maintenance, and feedstock quality fluctuations. Additionally, a comparative analysis with alternative modeling techniques such as physics-informed neural networks could provide insights into trade-offs between accuracy, interpretability, and generalization to unseen operating conditions, particularly in roll speed prediction for blockage prevention. Furthermore, a techno-economic analysis could help quantify the trade-offs between maximizing washing efficiency, preventing blockages, and optimizing energy recovery, providing a

holistic view of process improvements.

# A Novel Bayesian Framework for Inverse Problems in Precision Agriculture

**Zeyuan Song, and Zheyu Jiang***

## ABSTRACT

An essential problem in precision agriculture is to accurately model and predict root-zone (top 1 m of soil) soil moisture profile given soil properties and precipitation and evapotranspiration information. This is typically achieved by solving agro-hydrological models. Nowadays, most of these models are based on the standard Richards equation (RE), a highly nonlinear, degenerate elliptic-parabolic partial differential equation that describes irrigation, precipitation, evapotranspiration, runoff, and drainage through soils. Recently, the standard RE has been generalized to time-fractional RE with any fractional order between 0 and 2. Such generalization allows the characterization of anomalous soil exhibiting non-Boltzmann behavior due to the presence of preferential flow. In this work, we focus on inverse modeling of time-fractional RE; that is, how to accurately estimate the fractional order and soil property parameters of the fractional RE given soil moisture content measurements. Specifically, we introduce a novel Bayesian variational autoencoder (BVAE) framework that synergistically integrates our in-house developed fractional RE solver and adaptive Fourier decomposition (AFD) to accurately estimate the parameters of time-fractional RE. Our proposed AFD-enhanced BVAE framework consists of a probabilistic encoder, latent-to-kernel neural networks and convolutional neural networks. The BVAE framework is theoretically explainable and enhanced by the AFD theory, a novel signal processing technique that achieves superior computationally efficiency. Through illustrative examples, we demonstrate the efficiency and reliability of our AFD-enhanced BVAE framework.

Keywords: Artificial Intelligence, Machine Learning, Numerical Methods, Food & Agricultural Processes, Water

## INTRODUCTION

Precision modeling and forecasting of soil moisture are essential for implementing smart irrigation systems and mitigating agricultural drought. Most agro-hydrological models are based on the standard Richards equation [1], a highly nonlinear, degenerate elliptic-parabolic partial differential equation (PDE) with first order time derivative. However, standard RE is limited by its incapability of characterizing preferential flow in anomalous soil exhibiting non-Boltzmann behavior, a common and realistic scenario. To overcome this limitation, time-fractional RE of the following form [2] is developed and employed to model water flow dynamics in real soil systems:

$$\partial_t^{\alpha}\theta + \nabla \cdot \mathbf{q} = S, \tag{1}$$

$$\mathbf{q} = -(C(\theta)\nabla\theta + K(\theta)\nabla z). \tag{2}$$

where $\theta$ denotes the soil moisture content (in, e.g., $m^3/m^3$), $\mathbf{q}$ represents the water flux (in, e.g., $m^3/m^2 \cdot s$), $S$ denotes the sink term measuring water uptake rate by roots, $K(\theta)$ is unsaturated hydraulic water conductivity (in, e.g., $m/s$), $C(\theta)$ is soil moisture diffusivity (in, e.g., $m^2/s$), $t \in [0, T]$ denotes the time (in, e.g., $s$), $z$ corresponds to the vertical depth (in, e.g., $m$), and $\alpha$ is a soil-dependent parameter indicating subdiffusion ($0 < \alpha < 1$) and superdiffusion ($1 < \alpha < 2$) [2]. For unsaturated flow, both $C$ and $K$ are highly nonlinear functions of soil moisture content and soil parameters, thereby posing significant computational challenges for solving the standard Richards equation itself [3]. Thus, most existing research focuses on developing accurate and efficient numerical solvers for the time-fractional RE given soil parameters [2], which is also known as solving the forward problem.

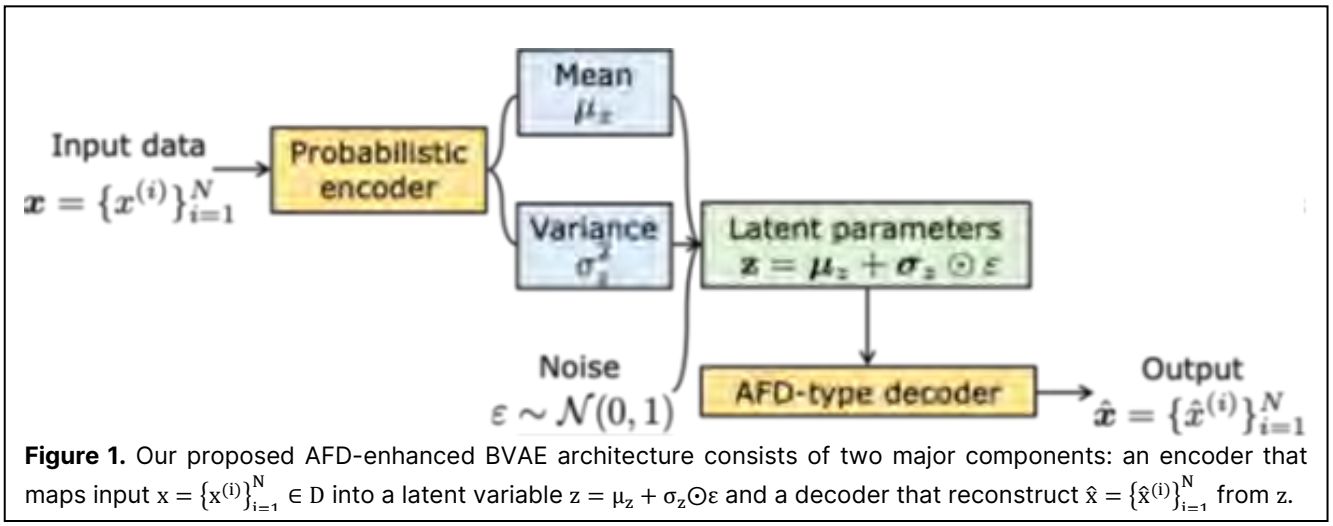

**Figure 1.** Our proposed AFD-enhanced BVAE architecture consists of two major components: an encoder that maps input $x = \{x^{(i)}\}_{i=1}^{N} \in D$ into a latent variable $z = \mu_z + \sigma_z \odot \varepsilon$ and a decoder that reconstruct $\hat{x} = \{\hat{x}^{(i)}\}_{i=1}^{N}$ from $z$.

Meanwhile, an equally important problem, which is to accurately estimate soil parameters given the soil moisture profile, is known as the inverse problem and is often less studied. This is primarily because inverse problems are generally ill-posed due to insufficient and/or inaccurate information (e.g., soil moisture solutions) and thus face significant computational challenges. Nevertheless, with recent advancements in soil sensing technologies and increasing adoption of in situ soil moisture sensors, farmers now have real-time access to massive arrays of root-zone soil moisture data. This poses great need and opportunity to develop more accurate and computationally efficient algorithms for solving inverse problems of time-fractional RE, so that one can extrapolate soil parameters estimated from local in situ soil sensing measurements to model field-wide soil moisture profiles.

Existing approaches to solve inverse problem for standard and/or time-fractional RE can be categorized into deterministic or probabilistic methods. Deterministic methods, which solve the inverse problem as a nonlinear optimization problem [4-6], tend to be trapped in local optima and are sensitive to data noise. Meanwhile, probabilistic methods, such as Markov chain Monte Carlo (MCMC) [7] or variational autoencoder (VAE) [8], can explore the entire solution space. However, state-of-the-art probabilistic methods scale poorly as problem size (e.g., the number of parameters to be estimated) increases, leading to scalability issues [9].

To address these challenges, in this work, we propose a novel Bayesian variational autoencoder (VAE) framework that is built upon our in-house developed time-fractional RE solver [11] and the adaptive Fourier decomposition (AFD) techniques [12,13]. This integration enables precise parameter estimation for time-fractional RE. The AFD-enhanced BVAE framework consists of a probabilistic encoder, latent-to-kernel neural networks, and convolutional neural networks. The probabilistic encoder will map the input data (i.e., soil moisture measurements) to a latent space. To preserve useful mathematical properties and physical insights, we further restrict the latent space to its reproducing kernel Hilbert space (RKHS) via the use of latent-to-kernel neural networks. The AFD-based convolutional neural networks are then applied to the resulting RKHS as decoder for parameter estimation. These neural networks are trained end to end, in which the training data are soil moisture profiles produced by our time-fractional RE solver. Through a simple 3-D time-fractional RE example, we demonstrate the accuracy of our AFD-enhanced BVAE framework in solving inverse problems by comparing it with conventional BVAE approach whose decoder structure is not specially designed.

## AN EXPLAINABLE BAYESIAN FRAMEWORK

### Bayesian VAE framework

Here, we first provide a brief overview of the BVAE framework. The standard variational autoencoder (VAE) is a generative model that learns a structured latent space while reconstructing input data. As shown in Figure 1, VAE consists of two primary components, an encoder that maps input $x \in D$ into a set of latent variables $z$, and a decoder that reconstruct $x$ from $z$.

VAE defines the marginal likelihood as the probability of the observation $x$ under the generative model. Given latent variables $z$, the marginal likelihood is expressed as:

$$p(x) = \int p(x|z)p(z)\,dz, \tag{3}$$

where $p(z)$ is the prior distribution over latent variables (often a standard Gaussian). Since direct computation of the RHS of Equation (3) is intractable, VAE approximates the true posterior $p(z|x)$ using a variational distribution $q(z|x,\phi)$, and maximizes the Evidence Lower Bound (ELBO):

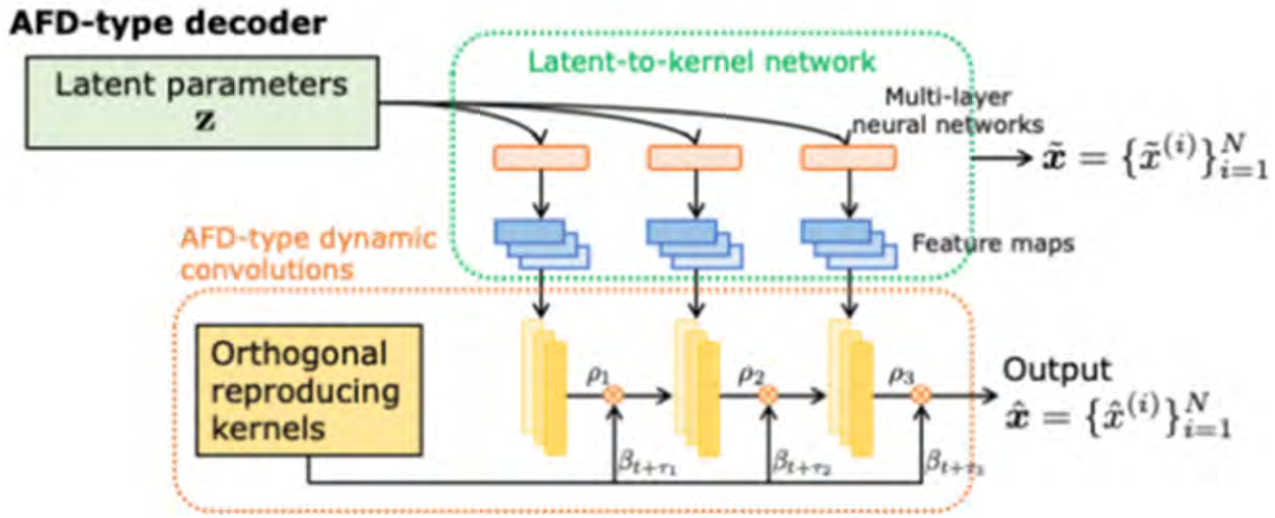

**Figure 2.** The decoder structure of our AFD-enhanced BVAE framework, which consists of two primary components: 1) latent-to-kernel neural networks which will map the latent variables $z$ to $\tilde{x} = \{\tilde{x}^{(i)}\}_{i=1}^{N}$ lying on an RKHS, and 2) dynamic convolutional kernel network that will reconstruct $\hat{x} = \{\hat{x}^{(i)}\}_{i=1}^{N}$.

$$\mathcal{L}_{ELBO} = \sum_{x \in D} \mathcal{L}_{\Theta,\phi}(x), \tag{4}$$

$$\mathcal{L}_{\Theta,\phi}(x) = \mathbb{E}_{q(z|x,\phi)} \log p(x|z,\Theta) - D_{KL}[q(z|x,\phi)\|p(z)] \tag{5}$$

where the first term of Equation (5) ensures accurate reconstruction and the second term regularizes the latent space by minimizing the Kullback-Leibler (KL) divergence between the approximate posterior and the prior distribution.

On the other hand, the BVAE framework extends this by placing priors not only on the latent variables z but also on the model parameters θ, resulting in a Bayesian formulation:

$$p(\Theta|D) \propto p(D|\Theta)p(\Theta). \tag{6}$$

The likelihood function is then defined as:

$$p(x|z,D) = \int p(x|z,\Theta)p(\Theta|D)\, d\Theta \tag{7}$$

and the marginal likelihood as:

$$p(x|D) = \iint p(x|z,D)p(z)\, dz\, p(\Theta|D)\, d\Theta. \tag{8}$$

The BVAE enables more robust parameter estimation and improved uncertainty quantification. Instead of relying on a single point estimate for Θ, BVAE marginalizes over its posterior distribution, leading to better generalization and reliability in low-data regimes. By jointly inferring $p(z|x,D)$ and $p(\Theta|D)$, BVAE offers a fundamental way to incorporate uncertainty into both data representation and model parameters, making it particularly useful for applications requiring high-confidence decision-making.

## A novel, explainable encoder structure in our AFD-enhanced BVAE framework

One common way to enhance the explainability of a neural network is to modify its structure based on the approximation theory (e.g., the universal approximation theorem [14]). In this work, we propose to achieve this by adopting AFD, a novel signal decomposition method that adopts adaptive orthogonal bases and thus leads to higher accuracy and significant computational speedup compared to conventional Fourier decomposition [12,13]. Specifically, as shown in Figure 2, we innovate the decoder structure by combining latent-to-kernel neural network with mathematically interpretable dynamic convolutional kernel network (CKN). In terms of latent-to-kernel network, our proposed structure consists of a multi-layer neural network that will first take the latent parameters $z$ obtained from the encoder and generate $\tilde{x} = \{\tilde{x}^{(i)}\}_{i=1}^{N}$, which belongs to the Hilbert space $H$ of the same manifold $\mathcal{M}$ that $z$ belong to. Next, the latent-to-kernel network consists of feature maps $FM(\tilde{x})$ that project $\tilde{x}$ to its reproducing kernel Hilbert space (RKHS) [15]. This way, our latent-to-kernel network will try to learn the feature maps from $H(\mathcal{M})$ to its nearest RKHS, where the convolutional Kernel is unique and satisfies the reproducing property [16]. This naturally brings in dynamic CKN for local feature extraction, which is mathematically grounded in the RKHS framework. Furthermore, the dynamic CKN structure shown in Figure 2 mathematically resembles AFD in the sense that each dynamic convolutional layer performs cross-correlation between $FM(\tilde{x})$ and the orthogonal reproducing kernels β, i.e., $FM(\tilde{x}) \star \beta_i$. With this, the final output of the dynamic CKN, assuming

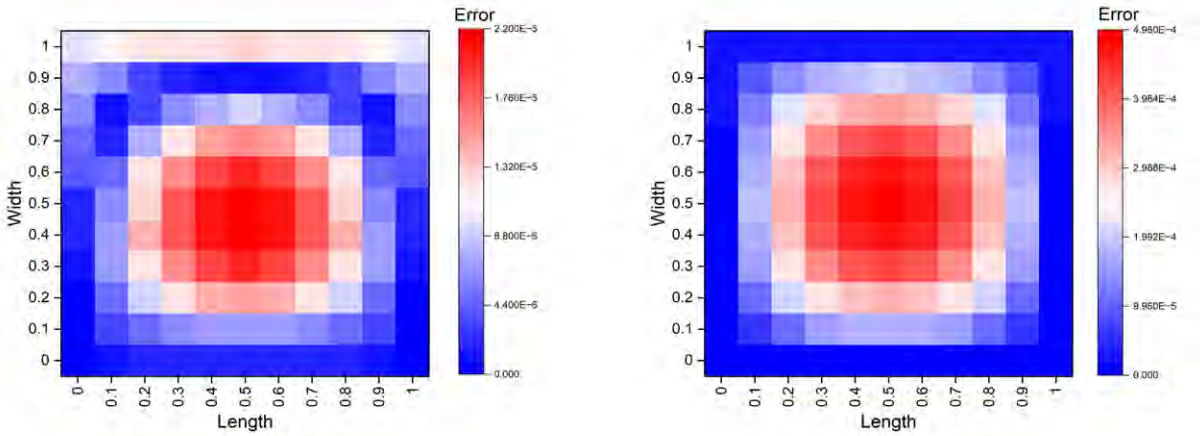

**Figure 3.** The error is obtained by substituting the parameters estimated by our proposed AFD-enhanced BVAE framework (Left) and conventional BVAE (Right) into the time-fractional RE solver [11] and taking the difference the numerical solution with the analytical solution of Equation (12). Ground truth value for the parameters are $\alpha = 0.5$ and $a = 0.001$. The parameters estimated by our proposed AFD-enhanced BVAE framework are $\alpha = 0.496 \pm 0.005$ and $a = 0.00102 \pm 7 \times 10^{-9}$, while those of conventional BVAE are $\alpha = 0.440 \pm 0.004$ and $a = 0.00094 \pm 2 \times 10^{-9}$

that there are a total of $N$ convolutional layers, is given by:

$$\hat{x} = \sum_{i=1}^{N} \rho_i (FM(\tilde{x}) \star \beta_i)\beta_{i+\tau_i}, \qquad (9)$$

where $\rho_i \in (0,1)$ are scaling factors and $\tau_i$ can choose between 0 to $N - i$ for layer $i$. The choices of $\rho_i$ and the orthogonal reproducing kernels must satisfy weak maximal selection principle and convergence theorem [10,12], respectively.

It can be shown that Equation (9) is equivalent to AFD operation [10,12,13]. Thus, with a specially designed structure, the AFD-type dynamic CKN will enjoy significant computational speedup and rigorous performance guarantees just like the AFD. The full AFD-enhanced BVAE model will be trained end to end by minimizing the following total loss function:

$$\mathcal{L} = \|x - \hat{x}\|^2_{H(\mathcal{M})} + \|\tilde{x} - FM(\tilde{x})\|^2_{H(\mathcal{M})} + w D_{KL}[q(z|x,\phi)\|p(z)], \qquad (10)$$

where $w$ is a regularization parameter.

## Using AFD-enhanced BVAE framework to solve inverse problems

Here, we describe the procedure for applying our AFD-enhanced BVAE framework to solve the inverse problem. That is, we would like to reconstruct or estimate the soil-dependent parameters, including $\alpha$ and parameters of hydraulic conductivity function and water retention curve, from soil moisture content profiles through direct sensor measurements. Without loss of generality, we denote those parameters and the corresponding soil moisture content as $\gamma$ and $\theta$, respectively. To train the model, various sets of soil parameters $\gamma$ will be sent to our in-house developed fractional RE solver to generate a set of soil moisture profile solutions. These solutions and their associated soil parameters $\gamma$ will then be sent to the encoder to extract latent parameters $z$, which are then used by the decoder to reconstruct soil parameters $\hat{\gamma}$. During the training process, the total loss function of Equation (10) will be minimized such that the output of the decoder, $\hat{\gamma}$, shall match with the given $\gamma$ as closely as possible.

Once training is complete, our AFD-enhanced BVAE model will only take the actual soil moisture measurements or solution profiles $\theta$ as input and produce the soil-specific parameter estimates $\hat{\gamma}$ as output, which can be used by the fractional RE solver for extrapolation and field-wide soil moisture modeling.

## AN ILLUSTRATIVE EXAMPLE

Here, we present a proof-of-concept example to demonstrate the accuracy enhancement of our proposed AFD-enhanced BVAE framework by considering a simple 3-D time-fractional RE where $K = \theta$ and $C = a(\theta + 1)$. The width, length as well as depth are 1. The boundary conditions are zero at all boundaries and the initial condition is given by:

$$\theta(x, y, z, 0) = (x - x^2)(y - y^2)(z - z^2). \qquad (11)$$

For $a = 0.1$ and $\alpha = 0.5$, the problem has an analytical solution and is given by:

$$\theta(x, y, z, t) = t(x - x^2)(y - y^2)(z - z^2). \qquad (12)$$

Assuming that we do not know the values of $\gamma$ (i.e.,

$\alpha$ and $a$), we generate a total of 10,000 sets of $(\theta, \gamma)$ solutions using our in-house developed fractional RE solver. Both AFD-enhanced BVAE and conventional BVAE models contains three hidden layers and 256 neurons per layer. The Adam optimizer and ReLU activation function are used for training. Figure 3 shows the error of soil moisture profiles between analytical solution and the numerical solution obtained from substituting the estimated soil parameters into our fractional RE solver, where the solution across two dimensions (width and length) are drawn better visualization. For the third dimension (depth), the error employs a similar behavior due to symmetry of this problem. Our AFD-enhanced BVAE model not only produces more accurate parameter estimates, but also enhances the accuracy of our fractional RE solver by at least an order of magnitude compared to conventional BVAE model. This illustrates the synergistic improvement in model accuracy when combining advanced numerical solver (for solving the forward problem) with our AFD-enhanced BVAE model (for solving the inverse problem). Furthermore, the data-driven nature of our proposed framework makes it particularly suitable for integrating in situ soil moisture sensing technologies to equip farmers with accurate tools that will bring "eyes inside the soil".

For comparison, we also implement a simple Kalman filter (KF) algorithm as a benchmark method to solve the same inverse problem. The results of KF are $\alpha = 0.517$ and $a = 0.00114$, which are further away from the ground truth solutions compared to our AFD-enhanced BVAE model.

Lastly, we point out that, unlike MCMC approach, our AFD-enhanced BVAE algorithm does not experience a significant increase in computational time as the number of unknown parameters to be estimated grows. This suggests that the BVAE-type approaches are quite scalable with respect to the dimensionality of the parameter space [17].

## CONCLUSIONS

In this work, we propose a novel AFD-enhanced BVAE framework to accurately solve the inverse problem of time-fractional Richards equation. Our proposed framework synergistically integrates BVAE, neural network, dynamic convolutions, and AFD theory to offer computational speedup and great mathematical explainability. Furthermore, by designing a tailored decoder structure that resembles AFD operation, our new framework significantly improves soil parameter estimation accuracy. In addition, by using this framework in conjunction with our accurate time-fractional RE solver [11], we can achieve synergistic advancement in root-zone soil moisture modeling. Moreover, we remark that our proposed AFD-enhanced BVAE model is a generalized framework that can be leveraged in solving various inverse problems in large-scale and/or complex partial differential equation systems (e.g., convection-diffusion equation, Schrödinger equation, etc.), as well as in other fields such as image processing, data analytics, and so on. We will explore these aspects in our future works.

## ABSTRACT

Decarbonizing the watch industry and improving its sustainability requires enhancing the energy efficiency, intensifying the waste heat recovery and integrating renewable energy resources to significantly reduce the energy consumption and reduce the overall process emissions. The watchmaking industry operates across different periods, each one characterized by own levels of average power demand, plant activity, and duration. While working days (Work D) experience the highest energy demand; other periods, such as weekend (Wend D1, Wend D2 and Wend N), exhibit a substantial drop in energy consumption. It requires a suitable selection of utility systems and an energy planning that can meet the energy requirements regardless of the different operation regimes, reducing the consumption of fossil resources. To this end, this work leverages a systematic framework to perform the techno-economic analysis and explore the feasibility of incorporating alternative energy conversion (e.g. electrification) and storage solutions (for heat) in the watchmaking industry, accounting for the monthly variations of energy demand and environmental conditions.

**Keywords**: Audit, Energy Recovery, Decarbonization Technologies, Optimizing, Operational strategy

## INTRODUCTION

While considerable work had focused on decarbonizing energy-intensive industries like iron and steel, refineries, and chemicals, there has been limited research on non-energy-intensive sectors such as the watchmaking industry.

As governments and international organizations push for net-zero emissions, industries face growing pressure to adopt sustainable practices. The challenges of decarbonizing the watchmaking industry include:

- Limited understanding of the industry
- Multiple decarbonization options to evaluate
- Seasonal effects on energy consumption

Some research has explored energy recovery in batch process industries, considering characteristic power variations (Lin, 2024). Similarly, studies in European textile plants (Zuberi, 2020) identified potential energy savings of 21–43%, depending on time of day and season. However, gaps remain in integrating decarbonization technologies and analyzing their combined effects with seasonal power variation and energy recovery strategies in the luxury and watchmaking industry.

This work aims to evaluate the current operations of the watchmaking industry, emphasizing the role of seasonal and characteristic power variations (also known as characteristic day). It will also explore how energy recovery, building shading, and decarbonization technologies affect the industry's performance under seasonal variations.

## METHODOLOGY

The section there will begin with a brief description of energy audit of the industry, then focusing on energy recovery from CNC(Computer numerical control) and compressor, then analysing the effect of integration of decarbonization technology in the industry and

discussing the methodology to optimize the choice of technology.

## Energy audit

The study begins with an energy audit in a watchmaking industry in the Swiss Jura region. The technologies used in the watchmaking plant are shown in Figure 1. The industrial operation is divided into five characteristic days for the plant operations. Each day is defined by typical average power demand, plant activity, and time. In addition, the changes in the demand in technologies, defines a characteristic day, explained in the Table 1.

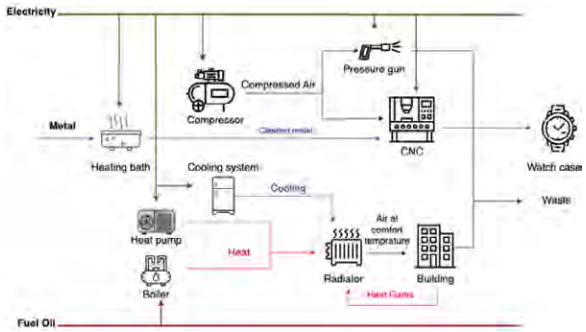

**Figure 1.** Process and utility flow diagram for watchmaking industry.

**Table 1:** Technology power variation depending upon characteristic day ($P_{CNC}$- Max CNC power, $P_{Com}$- Max compressor power and $P_{Bath}$ - Max power heat bath).

| Day | CNC Power (kW) | Compressor Power (kW) | Heat bath (kW) |
|---|---|---|---|
| Work D | $P_{CNC}$ | $P_{Com}$ | $P_{Bath}$ |
| Work N | 0.85* $P_{CNC}$ | 0.79* $P_{Com}$ | $P_{Bath}$ |
| Wend D1 | 0.6* $P_{CNC}$ | 0.56* $P_{Com}$ | $P_{Bath}$ |
| Wend D2 | 0.55* $P_{CNC}$ | 0.51* $P_{Com}$ | $P_{Bath}$ |
| Wend N | 0.55* $P_{CNC}$ | 0.51* $P_{Com}$ | $P_{Bath}$ |

As shown in figure 1, the industry requires two utilities which are electricity and fuel oil(mazout) which helps in meeting all the requirements for the processes. Raw material consumed in industry can be different kind of metals(high qulaity steel, platinum, gold and etc). The materal is heated up in a bath to remove all the impurities and then different machining operation are performed through CNC and Pressure gun. These technology require compressed air, supplied by a compressor. The energy requirement (heating or cooling) of a building depends on the season and the characteristic day. Figure 2 explains the changes in energy requirement for a characteristic day (Work D) depending upon month, and it helps in understanding the changes in building requirement depending upon the month. During winter months there is a heat requirement and during summer month there is a cooling requirement. Figure 3 explains the variation of building energy requirement for a day (beignning with 6h of Work N, 12h of Work D and then again 6 h of Work N) for a month of May.

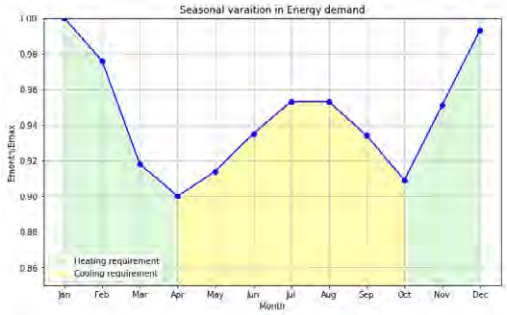

**Figure 2.** Variation in the energy demand for a typical working day in different months.

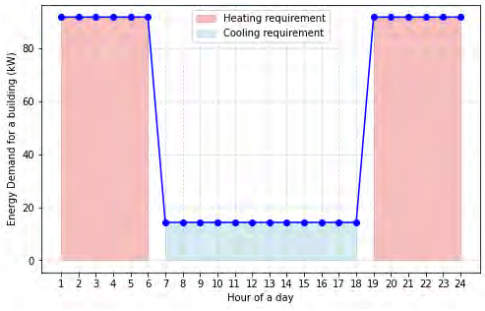

**Figure 3.** Variation in the energy requirement in a day ( beignning with 6h of Work N, 12h of Work D and then again 6 h of Work N) in a month of May.

The energy distribution among different technology is dependent on characteristic day and month. Figure 4 discusses the energy distribution among different technologies for month of December on a characteristic Work D. It is depicted that highest share of energy is going towards the working of CNC and Compressor.

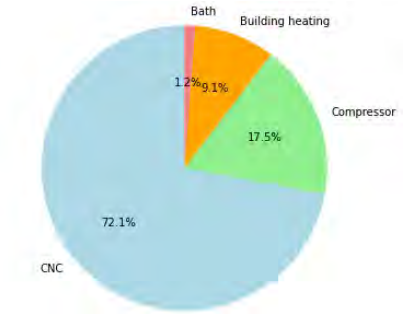

**Figure 4.** Distribution of energy among different technology and building requirement for the month of December.

In the analysis there are certain assumption which are adopted. It is assumed a year has 48 working weeks.

Distribution of characteristic day in a typical week is depicted in figure 5. A typical week consists of 5 Work D and 5 Work N, a characteristic Work D is followed by Work N. After 5 Work N there is Wend D1 for then followed by Wend D2 which is followed by Wend N.

**Figure 5.** Distribution of total number of hours of a week for different characteristic day.

## Energy recovery in CNC and Compressor

An untapped potential for waste heat recovery is observed from the existing energy technologies installed in the watchmaking industry. For instance, the waste heat that can be recovered from compression units depends on the different parameters shown in Eq(1), where , $m_{in}$(kg/s) is the mass flow rate of the compressed air, $Cp_{air}$ (J/kg.K) is the heat capacity of air and $T_{in}$ (K) is the inlet temperature :

$$Q_{rel} = m_{in} * Cp_{air} * (T_{out} - T_{in}) \quad (1)$$

Moreover, the outlet temperature $T_{out}$ is calculated using Eq.(2), where P (-) is the pressure ratio, $T_{in}$ (K) is the inlet temperature ,$\gamma$ is ratio of specific heat capacity, $\eta_{is}$ is the compressor isentropic efficiency. The quality of waste heat depends upon the temperature level which will be computed with the help of Eq (1, 2).

$$T_{out} = T_{in} + \left[\frac{T_{in}*\left(P^{\frac{\gamma-1}{\gamma}}-1\right)}{\eta_{is}}\right] \quad (2)$$

In the case of CNC the waste heat recovery is assumed as 80% of the total power consumption of the CNC machine (Fecko ,2021). The waste heat dissipated in the machining process is recovered with the cooling fluid the temperature of fluid increases from 12.5°C to 17.4°C (Teyu), as per the audit results. Recovering heat these technologies will improve the energy efficiency. As it is reducing the heating requirement for the building and also reducing the excess electricity required for cooling CNC and compressor.

## Shading

For months between April to October, there is a need for cooling to maintain comfort temperature. Cooling requirement can be reduced with installation of shades as it reduces the heat gain.

## Decarbonisation technologies

Some of the technologies which can be incorporated are Photovoltaic system (PV), Solar Thermal (ST) and Thermal Storage. Details of these technologies are discussed below-

## Modeling of the PV for solar electricity production

PV panels can help harvesting the solar energy for producing electricity, therefore reducing the electricity import. The solar irradiance, the temperature of the panel and the area of the panel are important design parameters that can influence the amount of power generated as shown in the Eqs. (3) :

$$T_{panel} = U_{glass} * (T_{ext} + 273.15)/(U_{glass} - \eta_{var} * Irr) + Irr * (f_{glass} - \eta_{ref} - \eta_{var} * T_{ref})/(U_{glass} - \eta_{var} * Irr) \quad (3)$$

where Irr is Irradiance in (W/m$^2$), $U_{glass}$ is the heat transfer coefficient by the glass (W/m$^2$.K) , $\eta_{var}$ (1/K) is efficiency dependent upon the temperature of the panel, and $T_{ref}$(K) and $T_{ext}$(K) are reference and external temperature respectively. The net electricity produced can be calculated with Eq.(4)

$$E_{default} = Irr * A_{real} * (\eta_{ref} - \eta_{var} * (T_{panel} - T_{ref}) \quad (4)$$

where $A_{real}$(m$^2$) is the effective area for the power generation.

### Modelling of the ST for heat production

ST allows producing high grade heat by concentrating solar radiation. The amount of heat can be calculated according to Eqs(5 and 6) The net heat released is sum of $Q_1$ and $Q_2$ which corresponds to heat at two different temperature. The heat is available in two different temperature ranges, $Q_1$ is available between 92°C – 85°C and $Q_2$ is available between 110°C – 92°C.

$$Q_1 = DNI * A_{real} * \eta_1 * 0.9/1000 + 0.0001 \quad (5)$$

$$Q_2 = DNI * A_{real} * \eta_2 * 0.9/1000 + 0.0001 \quad (6)$$

where DNI is Direct Normal Irradiance (W/m$^2$), $A_{real}$ (m$^2$) is the effective solar irradiated area and $\eta_1$ and $\eta_2$ are the efficiency. The value of $\eta_1$ and $\eta_2$ is 0.5 and 0.05 respectively.

## Modelling of the Thermal Storage for storage system

The thermal storage technology helps in storing the heat when there is excess heat generated and supplying when there is a demand for the heat., there are some assumptions the storing fluid is water and the losses are assumed to be nill. The system are modeled using Eqs(7

and 8) respectively:

Charging

$$Q_c = Cp_w * m_w * (T_c - T_h) \quad (7)$$

Discharging

$$Q_d = Cp_w * m_w * (T_h - T_c) - Q_l \quad (8)$$

where $T_c$ (70°C ) and $T_h$ (80°C) are cold or mean initial storing temperature and hot or mean final storing temperature respectively; $m_w$(kg/s) is the mass of the thermal storage fluid ,$Cp_w$(J/kg.K) is the heat capacity of the fluid) and $Q_l$(kW) is the amount of heat lost to the environment during the storage time.

## Optimization strategy for the selection of the energy technology and operation strategy

The optimization process is performed in the OSMOSE (a tool for the design and analysis of integrated energy system performs multi-objective optimization) platform considering all possible technological options (PV, Heat pump, Solar Thermal and Thermal Storage). To this end, OSMOSE solves the Mixed Integer Linear Programming (MILP) problem that selects the energy technologies and operating conditions based on some objective function relevant for the watchmaking industry.

## Objective function

Some of the relevent obejctive function taken in this analysis are discuused below:

CAPEX

It is an economical indicator which helps in evaluating all the investment related decision. It takes care of the money invested in buying the new technology. Investement cost of different technology is taken into consideration are shown in Table 2.

**Table 2:** Cost of decarbonisation technology (TSE 2019), (FSS). (In this $kWh_{st}$ stands for stored amount of energy)

| Technology | Investment Cost |
|---|---|
| PV panel | 400 (CHF/$m^2$) |
| Solar Thermal (ST) | 400 (CHF/$m^2$) |
| Photovoltaic Thermal (PVT) system | 750 (CHF/$m^2$) |
| Thermal storage (TS) system | 630 (CHF/$kWh_{st}$) |

OPEX

It is an economical indicator which helps in evaluating all the resources an industry needs to buy for operation of system The cost of resources for the watchmaking industry taken into consideration are shown in Table 3.

**Table 3:** Cost of resources (Stat, 2024), (Migrol, 2024).

| Resource | Operational Cost |
|---|---|
| Electricity | .304 (CHF/kWh) |
| Mazout | .1174(CHF/kWh) |

TOTEX

It is an economical indicator which helps in determining the total cost incurred by the system . It include both CAPEX and OPEX, it is better to convert CAPEX into annualized cost which can be calculated using, Eq(9):

$$CAPEX_{ANN} = \left[\frac{i*(i+i)^n}{(i+i)^n-1}\right] * CAPEX \quad (9)$$

Where CAPEX(CHF) is the total investement of the technology and $CAPEX_{ANN}$ (CHF/year) is the annualized investment cost, where I is the interest rate and n is total lifetime of technology. The total lifetime of each technology is assumed to be 20 years and interest rate of 8%.

## Operation strategy for thermal storage system

The storage and dispatch strategy depends on month. During extreme winter conditions, like in January and December, maximum heating is required in these months as environmental temperatures is low. Additionally, solar thermal energy generation is minimal in these months because of low irradiance. As a result, heat can only be stored on the characteristic day (Wend D) which has minimum requirement. The characteristic day (Work N and Wend N) where there is no sunlight they use heatpump to full-fill the demand.

In months like February, March, and November, there is potential for storing heat on Work D. As heating demand during these months is lower compared to extreme winter months, and irradiance is slightly higher. However, the stored heat is still insufficient to fully meet nighttime heating demands, so the system continues to rely on a heat pump at night but the cosnumption form the heat pump decreases.

For the rest of the month in the year, solar thermal system is capable of providing all the necessary heat. As a result, heating requirements for all characteristic days will be met using solar thermal energy and thermal storage alone.

# RESULT

The section begins with a discussion of result on improvement in energy efficiency by recovering energy from compressor and CNC, the section also discusses the result on reducing the energy demand by incorporating different decarbonization technology (like PV, Solar Thermal and Thermal Storage). The section is concluded with discussing result of optimization for the industry from the options (like PV, Solar Thermal and Thermal Storage) provided.

## Energy remarks and energy efficiency

In the watchmaking industry, potential sources for waste heat recovery includes compressor intercooling, chemical baths cooling and CNC machines lubricant refrigeration. Heat recovery can reduce fuel oil consumption amount to 1.27 (MWh/year) and decreasing energy consumption by 316 (MWh/year). It is because the heat integration reduces the electricity demand for heat pumps and also reduces fuel oil demand for heating. Shading reduces cooling requirements in summer, cutting annual energy consumption by 120 (MWh/year) by limiting solar heat gains, particularly from April to October. Combining waste heat recovery and building shading improves energy efficiency by 436 (MWh/year). Figure 6 illustrates the monthly impact of these measures on energy efficiency.

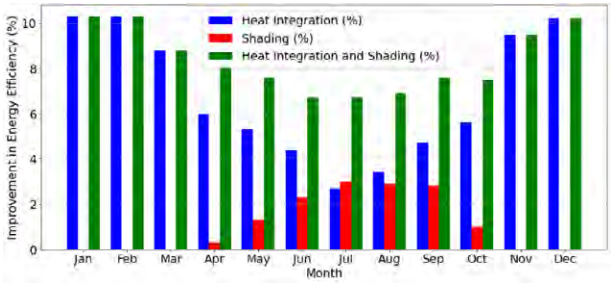

**Figure 6.** Improvement in energy efficiency depending upon the season, blue color corresponds to improvement in efficiency because of heat integration and red corresponds to improvement in efficiency because of shading and green is showing effect of integrating both these technologies.

## Incorporating decarbonisation technology

Implementing technologies like PV and ST can help reducing the grid electricity demand. The area available for these technologies are 3000 $m^2$. Integrating PV entails 700.3 (MWh/year) electricity savings, while ST reduces electricity consumption by 350 (MWh/year), as it offsets heating needs previously met by heat pumps. Integrating both the technologies (which is also called as Photovoltaic-Thermal system (PVT)) decreases the electricity demand by 1050.1 (MWh/year). Thermal storage further reduces energy demand in the watchmaking industry, offering an annual reduction of 580 MWh/year compared to using PVT alone. The cost of the storage technology is 1.2 MCHF. The reductions in the energy demand are most significant from April to October, as heat stored during these months can be used at night for heating purposes (explained in the section operation strategy for thermal storage system). The efficiency of the ST and Thermal Storage depends on the charging and discharging temperature because if the charging temperature is higher than the temperature range in which ST is working then heat from solar storage cannot be used. Therefore, it is important to tune the temperature range such that heat from ST can be used in Thermal Storage. Figures 7 and 8 illustrate the monthly impact of implementing these technologies and the reduction in monthly energy demand.

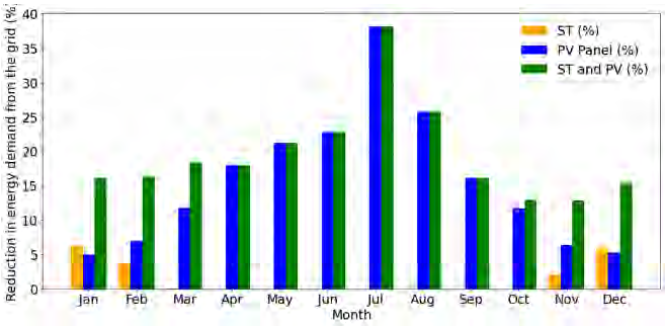

**Figure 7.**Reducing energy demand from the grid depending upon the season and technology installed, blue color corresponds to reducing deamnd from grid because of ST, orange corresponds to reducing deamnd from grid because of PV and green is for PVT technology.

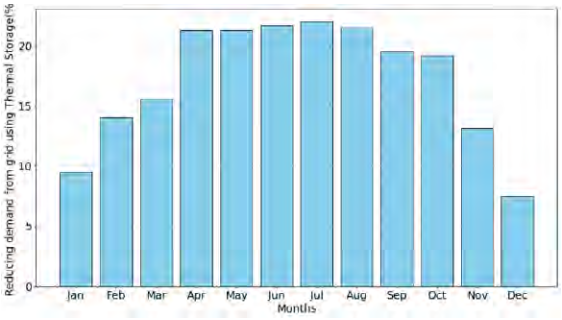

**Figure 8.** Reducing energy demand from the grid depending upon the season and technology installed, blue color corresponds to reducing deamnd from grid because of thermal storage integrated with PVT system.

## Choice of technology

The choice of technology depends upon the type of objective function taken into consideration. There can be multiple function like Total cost, Operational cost, Capital cost and Emissions.

Table 4 helps in estimating how different choices of technology will be affecting the economical indicator. In the

With Capital cost as the objective function the system most optimal solution will be Business As Usual (BAU) case. As the optimizer will try not to install any technology.

If there is a change in the optimizer to Total cost it will try to choose technology where maximum saving is observed it will be PV (without storage) and PVT and TS (with storage).

Now lastly if we keep Optimizer to Operational cost the system will choose PVT system and PVT system with

storage if storage is included.

**Table 4:** Capital cost and savings in operational cost observed for the different technology.

| Technology | CAPEX (kCHF/year) | OPEX savings (kCHF/year) |
|---|---|---|
| BAU | 0 | 0 |
| PV panel | 122 | 219 |
| ST | 122 | 109 |
| PVT system | 229 | 318 |
| TS system | 122 | 166 |

## CONCLUSION

Watchmaking industry are low energy intensive industry. There efficiency can be improved with recovering waste heat released from Compressor and CNC and by reducing the cooling requirement with shading. Incoporating technologies like PV, ST and PVT can help in reducing electricity and heating demand. Incorporating technology like Thermal Storage will help in reducing heating demand in night when there is excess heat in the day. In the consideration if taking total cost as the optimizer chooses to install PV as the savings in total cost will be (97k CHF/year) without considering storage. When considering storage the optimizer chooses to install PVT system with TS as the savings in total cost will be (137k CHF/year).

## ACKNOWLEDGEMENTS

I would like to thank CIRAIG which is helping me in performing such project and analysis.

# Liquid Organic Hydrogen Carriers: comparing alternatives through $H_2$ equivalent analysis

**Elvira Spatolisano[a]*, Federica Restelli[a], Laura A. Pellegrini[a]**

[a] Politecnico di Milano, Italy

## ABSTRACT

Liquid Organic Hydrogen Carriers (LOHCs) represent a promising solution for the efficient transport and storage of hydrogen, addressing critical challenges associated with its low volumetric density and safety concerns in gaseous and liquefied forms. LOHCs are oil-like substance, capable of reversibly binding and releasing hydrogen through catalytic hydrogenation and dehydrogenation. Hydrogenation is performed where renewable energy is extensively available: at the loading terminal, green $H_2$ is produced and is chemically bonded to the LOHC molecule. In this way, the hydrogenated molecule is transported safely under ambient conditions using existing liquid fuels infrastructures. At the delivery site, the dehydrogenation process releases high-purity hydrogen for industrial or mobility applications, with the regenerated LOHC carrier being recycled back to the $H_2$ production site for reuse. In view of highlighting critical issues associated to LOHCs implementation at large scale, this paper explores green $H_2$ transport through toluene and dibenzyltoluene. Considering the overall $H_2$ transport value chain, the performances of these two alternatives are assessed by means of equivalent $H_2$ methodology. As a result, insights are provided on their role in enabling a sustainable and efficient hydrogen economy.

**Keywords**: green H2 transport, LOHC, clean energy, toluene, dibenzyltoluene.

## INTRODUCTION

In the transition towards sustainable energy, green hydrogen has gained attention as a low-emission alternative. However, its transport is hindered by its low volumetric density. To address this challenge, various hydrogen carriers have been proposed as a more practical solution. These hydrogen-bearing compounds can be transported more easily at milder conditions and dehydrogenated upon arrival to release hydrogen. Among all the possible options, liquid organic hydrogen carriers (LOHCs) are considered promising due to their compatibility with existing infrastructures [1]. Various LOHCs have been explored in the literature. While some compounds are more suitable for hydrogenation and dehydrogenation, certain criteria help in identifying optimal candidates. The ideal LOHC should have a low melting point and high boiling point to avoid solidification and volatility issues, respectively, a high hydrogen storage capacity, low dehydrogenation enthalpy, low toxicity and be cost-effective at the same time [2].

Once the hydrogen carrier is selected, a detailed techno-economic assessment of the entire $H_2$ value chain is essential to compare alternatives and demonstrate their feasibility. The $H_2$ value chain typically includes: hydrogenation of the organic molecule exploiting green $H_2$, produced where renewable energy sources are extensively available, transport of the hydrogenated compound to its final destination and, upon arrival, dehydrogenation to release hydrogen.

In this framework, the aim of this work is to present a systematic methodology for comparing different $H_2$ value chains. Toluene (TOL) and dibenzyltoluene (DBT) are selected as representative carriers due to their promising characteristics. A harbor-to harbor scenario is discussed, to study long distance $H_2$ transport. The hydrogenation and dehydrogenation stages were designed in Aspen Plus V11®. Based on process simulations, a detailed technical assessment is provided. Each stage of the value chain (*i.e.*, hydrogenation, seaborne transport, dehydrogenation) is technically discussed. Energy consumptions are expressed in terms of equivalent $H_2$,

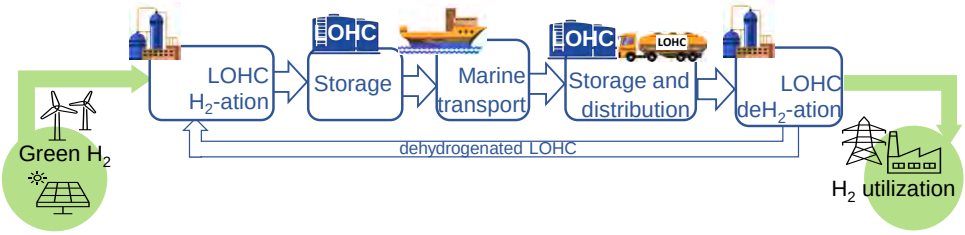

**Figure 1**: Hydrogen value chain exploiting LOHCs as $H_2$ carriers.

which, in the end, lowers the amount of hydrogen delivered at the utilization hub. In this way, the efficiency of each stage can be easily quantified. Weaknesses and drawbacks are pointed out, to pave the way for future process intensification.

## $H_2$ TRANSPORT SCENARIO: BASIS OF DESIGN

The $H_2$ value chain considering LOHCs as $H_2$ carriers is reported in Figure 1.

A harbor-to-harbor $H_2$ transport scenario is assumed. At the loading terminal, a flat $H_2$ production by 100 MW alkaline electrolysers is considered. These electrolysers, operating at 20 bar, are responsible for delivering 20000 $Nm^3/h$ of $H_2$. The assumed production scale of the alkaline electrolysers results in significantly lower $H_2$ production compared to conventional steam reforming plants. This limitation arises because renewable energy-driven industrial sites must align their scale with the land requirements of renewable energy installations.

At the loading terminal, $H_2$ is reacted with an organic carrier through an exothermic hydrogenation process and the resulting hydrogenated compound stored before seaborne transport.

The maritime distance between harbours is 2500 km, with the ship powered by traditional fossil-based fuels (IFO 380 1%S).

Upon arrival at the unloading terminal, the hydrogenated carrier is transported to a $H_2$ valley located 100 km inland via truck.

At the $H_2$ valley, the carrier undergoes a dehydrogenation reaction to release hydrogen. The released hydrogen meets industrial application standards, being produced at 30 bar with a purity exceeding 99.9 mol%.

The conversion and reconversion stages are the core of the whole hydrogen value chain: for this reason, a detailed technical assessment is performed by means of Aspen Plus V11® process simulations, discussed in the following section. Details about the thermodynamic property package are provided elsewhere [4]. On the other hand, for storage, maritime and road transport, reference is made to the available literature [3]. As the organic carriers are oil-like substances, they are compatible with existing oil-handling infrastructure, making their integration seamless.

## SIMULATION OF THE COST-DRIVING PROCESSES

Hydrogenation section for toluene and dibenzyltoluene are reported in Figure 2.

Referring to toluene hydrogenation section, reported in Figure 2a, toluene, both from the unloading terminal and from make-up stream, enters the process unit's battery limits. It is pressurized and heated to the reaction conditions of 20 bar and 210°C [4]. Reactants pre-heating is performed into a process-to-process heat exchanger (PREHEAT in Figure 2a) to recover the high enthalpy of the reaction products. The hydrogenation reaction (1) is highly exothermic: $N_2$ acts as a thermal diluent. Its flowrate is such that its concentration in the reactor inlet stream (REAC-IN in Figure 2a) is approximately 17 mol% [5]. Alongside nitrogen and toluene, green hydrogen produced via water electrolysis (stream $H_2$ in Figure 2a) is also supplied to the battery limits.

$$C_7H_8 + 3H_2 \rightarrow C_7H_{14} \quad (1)$$

The reactor outlet stream (REAC-OUT in Figure 2a), consisting of unreacted hydrogen, nitrogen, and methylcyclohexane, is cooled in the PREHEAT exchanger before proceeding to the separation stages. The separation section, comprising two flash drums in series (FLASH 1 and FLASH 2 in Figure 2a), purifies the reactor output from heavy ends, before and, then, from light ends. The resulting methylcyclohexane (MCH in Figure 2a) is stored and transported by ship to the unloading terminal. Unconverted hydrogen (stream LIGHTEST in Figure 2a) is compressed in COMP and recycled back to the reaction section.

On the other hand, Figure 2b shows the dibenzyltoluene (DBT) hydrogenation process. The organic carrier, H0-DBT in Figure 2b, is sourced from the unloading terminal. Along with a minimal make-up stream, it is routed to the reactor after being pressurized and heated. The reactor (B2 in Figure 2b) is fed with dibenzyltoluene, hydrogen, and nitrogen, with $N_2$ flow rate set identically to that used in the toluene hydrogenation process.

The reactor, operated at 35 bar and 210°C [6], performs DBT hydrogenation as in reaction (2).

$$C_{21}H_{20} + 9H_2 \rightarrow C_{21}H_{38} \quad (2)$$

The reaction products, primarily the hydrogenated species, are cooled and stored for transportation to the unloading terminal. In this case, the separation section downstream of the reactor is simplified, as hydrogen conversion is complete and by-product formation during the reaction is negligible. This characteristic is widely recognized in the literature as a key advantage of dibenzyltoluene as a hydrogen carrier [7]. Additionally, DBT's higher molecular weight compared to toluene enables more effective separation based on vapor-liquid equilibrium, as the larger difference in relative volatilities enhances separation efficiency for lighter compounds.

For the sake of comparison between toluene and dibenzyltoluene hydrogenation, Table 1 reports the thermal energy consumptions and Table 2 provides the electric energy consumptions, retrieved from process simulations.

The dehydrogenation process for both methylcyclohexane and perhydro-dibenzyltoluene (H18-DBT) is shown in Figure 3. As for methylcyclohexane (Figure 3a), it enters the process, it is pressurized and directed to the reaction section. The reactor (REACTOR in Figure 3a) operates at 350°C and is responsible for producing toluene and hydrogen according to reaction (3).

$$C_7H_{14} \rightarrow C_7H_8 + 3H_2 \quad (3)$$

**Table 1:** Thermal energy consumption for hydrogenation sections of Figure 2. Duty is assumed positive when entering the system.

| COMPR | 20 | 35 | 550.6 |

The reactor's outlet mixture, composed of minor undesired byproducts (primarily benzene), together with

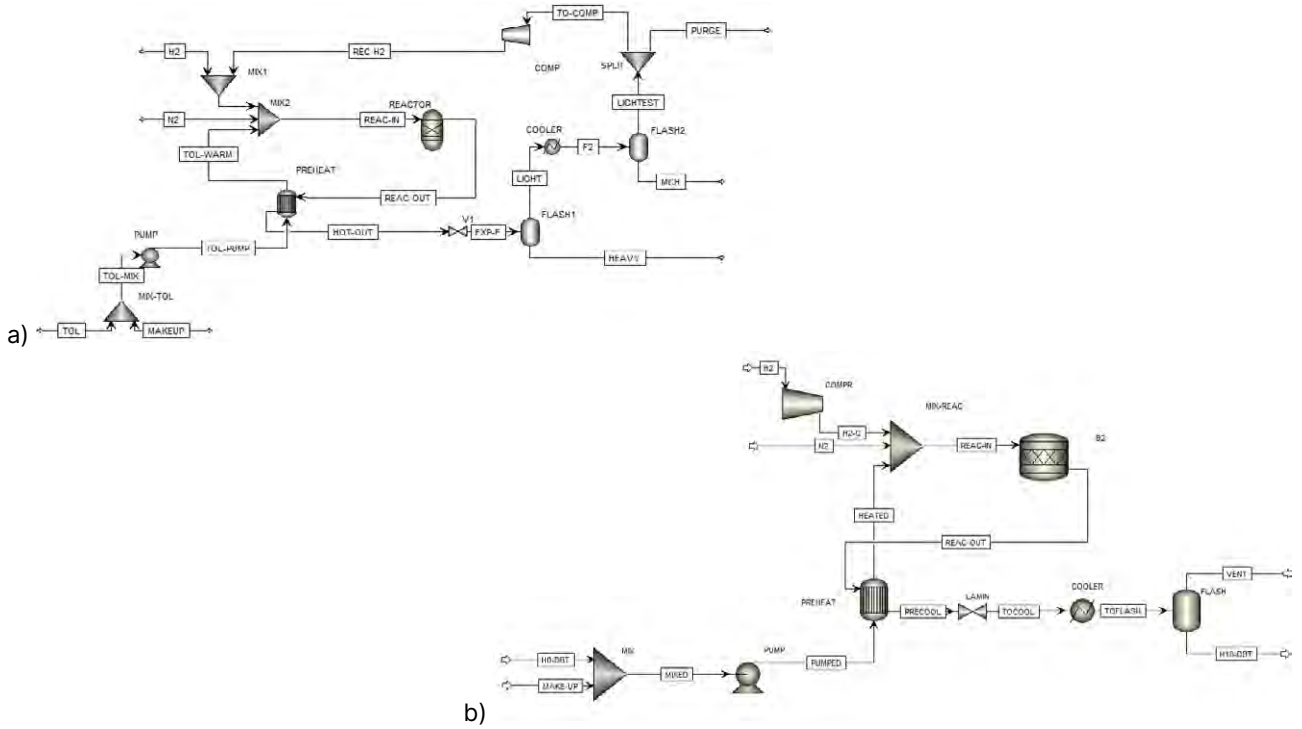

**Figure 2**: Hydrogenation section for: a) toluene and b) dibenzyltoluene. Simulation in Aspen Plus V11®.

toluene and hydrogen, is sent to the downstream separation train. The separated toluene stream (OUT-TOL in Figure 3a) is stored and subsequently routed back to the loading terminal. Hydrogen is purified via pressure swing adsorption (PSA) to achieve the necessary purity specifications for its intended applications.

The dehydrogenation reaction is highly endothermic, requiring a significant heat supply. This heat is provided by burning a portion of the hydrogen produced, along with waste streams (V and VENT in Figure 3a). As a result of this arrangement, the high endothermicity of the dehydrogenation reaction reduces the net amount of hydrogen available for utilization.

In a similar fashion, Figure 3b shows the process simulation performed for the H18-DBT dehydrogenation. The H18-DBT entering the system is pressurized and directed to the reaction section. The reactor (REACTOR in Figure 3b) operates at 320°C and 1.1 bar. In this unit, $H_2$ is obtained according to reaction (4).

$$C_{21}H_{38} \rightarrow C_{21}H_{20} + 9H_2 \quad (4)$$

The reactor's output mixture, consisting of DBT and hydrogen, is processed through a series of separation stages downstream of the reaction section. The recovered DBT (DBT-OUT in Figure 3b) is stored and transported back to the loading terminal, while the hydrogen, which is nearly pure, is compressed and sent to the hydrogen valley for utilization.

Table 3 and Table 4, provide, respectively, the thermal energy consumptions and the electric energy consumptions of the processes depicted in Figure 3.

To assess the viability of toluene and dibenzyltoluene as $H_2$ carriers and compare their performances, the equivalent $H_2$ methodology is applied, which is described in the following section.

## TECHNICAL ASSESSMENT: EQUIVALENT $H_2$ METHDOLOGY

The Equivalent Hydrogen Methodology (EHM) provides a common metric for evaluating the energy content and efficiency of $H_2$ production, storage and transportation. By calculating the net equivalent hydrogen consumption (*NEHC*) of each energy-consuming process, the Equivalent Hydrogen Methodology enables a more accurate assessment of the total energy required for the full hydrogen cycle, from production to utilization. Then, by subtracting the *NEHC* to the $H_2$ entering the process battery limits, the net equivalent $H_2$ delivered (*NEHD*) to the utilization hub is evaluated, as shown in equation (5).

$$NEHD = F_{H_2,in} - NEHC \quad (5)$$

In this way, this methodology allows to standardize and simplify the comparison of different $H_2$ carriers, in view of identifying the most cost-effective hydrogen solution.

For the evaluation of *NEHC*, heating above the ambient temperature ($NEHC_{h,i}$), cooling below ambient temperature ($NEHC_{c,i}$) and electric power supply ($NEHC_{e,i}$) are accounted for, thus neglecting heating below ambient temperature (< 25°C) and cooling above ambient temperature (> 25°C) [8] (equation (6)).

$$NEHC = \sum_i NEHC_{h,i} + NEHC_{c,i} + NEHC_{e,i} \quad (6)$$

$$NEHC_{e,i} = \frac{W_i}{\eta_{FC} \cdot LHV} \quad (7)$$

In the present case-study, heating above ambient temperature is achieved by process-process heat exchange, when feasible. Otherwise, heating is provided by either burning part of the hydrogen produced, as in the

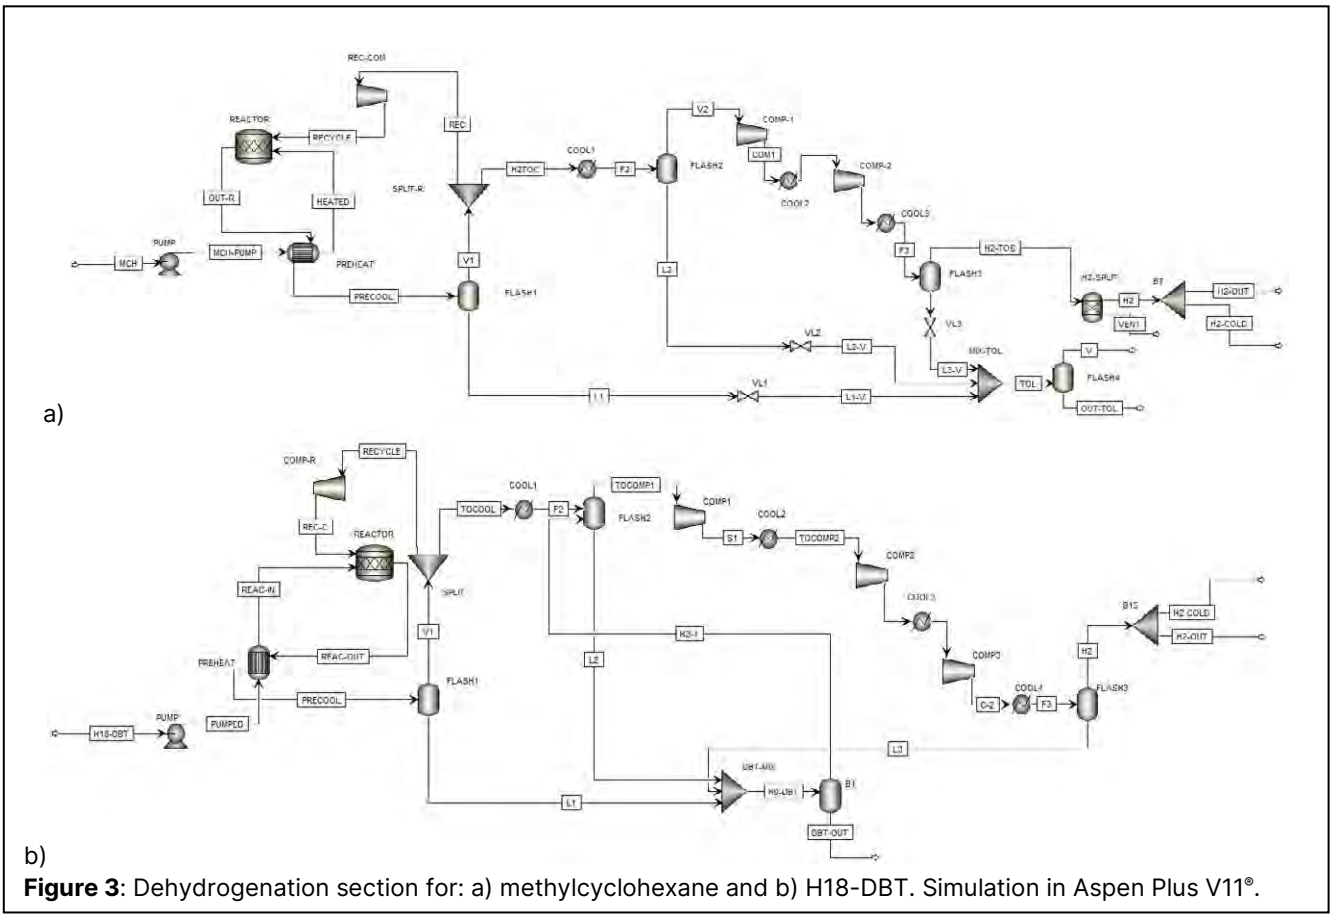

**Figure 3**: Dehydrogenation section for: a) methylcyclohexane and b) H18-DBT. Simulation in Aspen Plus V11®.

dehydrogenation section. In this case, the term $NEHC_{h,i}$ of equation (6) is retrieved from process simulation [3]. In addition, cooling below the ambient temperature is not required considering the value chain of Figure 1. Finally, the Net Equivalent Hydrogen Consumed for supplying electric power ($NEHC_{e,i}$), used for driving compressors and pumps, is calculated according to equation (7), assuming $H_2$ utilization in fuel cells with an efficiency ($\eta_{FC}$) of 60%. In equation (7), $W_i$ is the electric power consumption retrieved from Aspen Plus V11® simulations, while *LHV* is the $H_2$ lower heating value, assumed equal to 120 MJ/kg.

## CONCLUSION

Figure 4 summarizes the results of the equivalent $H_2$ methodology, considering both toluene and dibenzyltoluene as $H_2$ carriers.

As can be observed from Figure 4, dibenzyltoluene is more effective for $H_2$ transport than toluene, allowing for a higher $H_2$ flow rate delivered at the unloading terminal.

In both cases, part of the green hydrogen entering the battery limits is lost in the hydrogenation stage. The toluene hydrogenation stage is more energy-intensive than the dibenzyltoluene one: this is due to the higher electric consumption of the hydrogenation stage, because of the $H_2$ recycle compressor.

As opposite to other $H_2$ carriers (*i.e.*, liquefied hydrogen or ammonia), no $H_2$ losses because of the carrier boil off occur during storage and seaborne transport. One of the main advantages of LOHCs is their capability of storing hydrogen without significant degradation or loss over time, making them ideal for balancing seasonal variations in renewable energy supply. In addition, they are stable under ambient temperature and pressure, reducing the risks associated with hydrogen's volatile and explosive nature.

Regarding the dehydrogenation process, the perhydro-dibenzyltoluene dehydrogenation turns out to be less efficient than the methylcyclohexane one. However, for both of the instances analysed, dehydrogenation processes require significant energy input, which reduces the overall efficiency. A non-negligible amount of the $H_2$ delivered to the unloading terminal is burnt to cope for the endothermicity of the reaction. Moreover, the use of precious metal catalysts (e.g., Pt-based) in hydrogenation and dehydrogenation reactions increases operational costs and catalyst deactivation over time adds to maintenance expenses.

As a result, this assessment confirms that the LOHCs can store significant amounts of hydrogen by

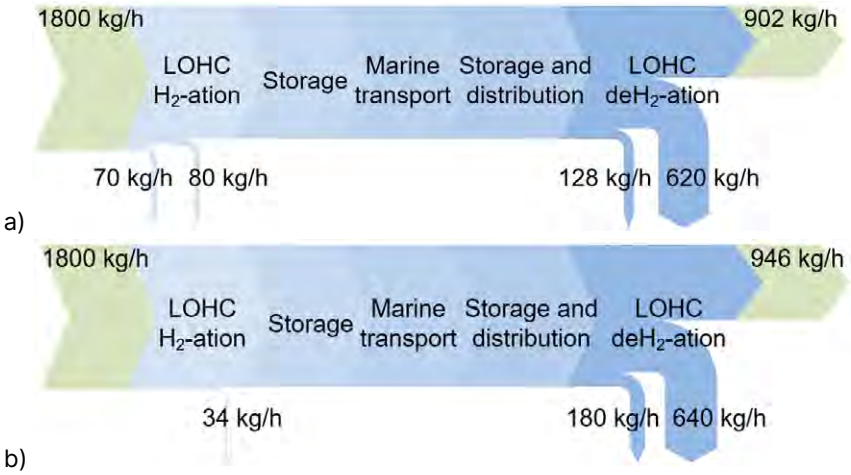

**Figure 4.** Results of the equivalent $H_2$ methodology for: a) toluene and b) dibenzyltoluene as $H_2$ carrier.

chemically binding it, offering high volumetric hydrogen storage density compared to gaseous or cryogenic hydrogen. The liquid-like nature of LOHCs allows them to be transported using existing fuel distribution and storage infrastructure, including pipelines, tanks, and ships.

The carrier molecules can be regenerated and reused for multiple cycles of hydrogenation and dehydrogenation, making LOHC systems sustainable over the long term.

On the other hand, their dehydrogenation is highly energy intensive. For this reason, it is essential to identify species with a lower dehydrogenation enthalpy to enhance the dehydrogenation section energy balance. Also, more active and selective catalysts are needed to enable the dehydrogenation at milder operating conditions.

Finally, it must be noted that both of the LOHC molecules involve fossil-derived feedstocks, raising concerns about the overall environmental footprint if not sustainably sourced, despite the closed cycle realised. Future research should be focus on finding suitable carriers derived from renewable feedstocks, improving the life cycle assessment of the whole value chain.

## ABSTRACT

As initiatives to decarbonize societies increase, industry is also being considered for policies to encourage its sustainability. Ammonia ($NH_3$) industry relies entirely on Haber-Bosch (HB) process, consuming fossil fuels for hydrogen production and energy purposes, accounting for more than 1 % of anthropogenic carbon dioxide ($CO_2$) emissions. Emerging technologies such as the electrochemical synthesis of $NH_3$ promise sustainable production from water, air, and renewable energies, but low TRLs are still reported. The electrification of the HB process opens a more viable path for sustainable $NH_3$ production in the near future, where hydrogen ($H_2$) is produced by electrolysis of water, powered from renewable energy sources. Many studies have focused on the production of 100 % green $NH_3$ using only electric HB. In this work, a different approach is presented, which consists of studying the gradual incorporation of green $H_2$ into a conventional $NH_3$ plant. An *Aspen Plus® V14* model of the methane-fed HB process was developed, and the limitations of the process were identified by sequentially incorporating 0 to 10 % green $H_2$. To avoid overheating the equipment in the natural gas reforming stage, a new configuration is suggested for this step. With this modification, the study is extended to incorporating higher percentages of green $H_2$, up to a limit of around 61 %. Finally, the impact of the reforming temperature tolerance on the green $H_2$ incorporation limits for the suggested configuration was studied.

**Keywords**: Ammonia, Haber-Bosch Process, Green Hydrogen

## INTRODUCTION

At the beginning of the 20th century, the agricultural sector was under pressure to find a source of nitrogen allowing the increase of food production in response to the growing population. Until then, nitrogen, one of the most critical needs for crop development, relied on limited natural sources (such as guano). In 1909, Fritz Haber succeeded in fixing atmospheric nitrogen ($N_2$) by synthesizing ammonia ($NH_3$) through its reaction with hydrogen ($H_2$), using an iron-based catalyst (Equation (1)). In 1913, Carl Bosch adapted the process for industrial scale, which is known to this day as the Haber-Bosch Process (HB), considered one of the most important technological developments of humankind [1].

$$N_2 + 3\,H_2 \leftrightarrow 2\,NH_3 \quad (1)$$

Ammonia is currently the second most produced chemical worldwide, with around 85 % of its production used in the nitrogen fertilizer industry (urea, ammonium nitrate, among others). It is estimated that half of the world's current population depends directly on the application of these fertilizers in the agricultural sector. In addition, ammonia also finds uses in the pharmaceutical industry, textiles, explosives production and de$NO_x$ technologies [2].

The global relevance and scale of the HB process makes it responsible for the consumption of 2 % of the final energy consumed and the emission of 1 to 2 % of the world's carbon dioxide ($CO_2$) emissions. This is justified by its high dependence on fossil fuels, not only for process heat, but also as a feedstock for hydrogen production. Around 75 % of $NH_3$ is produced from light hydrocarbons such as natural gas and naphtha. In Europe, almost all plants operate with natural gas consumption, producing $H_2$ by Steam Methane Reforming (SMR), which

is considered the Best Available Technology for its high energy efficiencies and lower emissions. The remaining 25 % is produced using coal and heavy fuel oil, which are consumed mainly by Asian ammonia industry [2,3].

Driven by carbon neutrality and energy independence policies, the ammonia industry is striving for decarbonization. In the European Union, the Renewable Energy Directive III requires that, by 2030, 42 % of the hydrogen consumed in industrial processes should come from renewable sources [4]. The decarbonization of the sector has driven the development of technologies that allow $NH_3$ production to move away from the HB process, which is more decentralized, less carbon and energy intensive, more flexible and with the possibility of fully incorporating renewable energies These include electrochemical, electrocatalytic and plasma synthesis, among others. However, these technologies are still at a low Technology Readiness Level (TRL). The most mature green $NH_3$ production technology relies on the electrification of the HB process, where the SMR process is replaced by water electrolysis – powered via renewables – as the source of hydrogen [1,2].

However, the flexibility of the HB synthesis has yet to be proven, specifically, under the fluctuating supply of $H_2$ when coupled with a renewable power source, which poses major challenges in managing its operation. Many papers have been published on the production of fully green $NH_3$, especially on energy management to ensure the continuous operation of the HB process. The effectiveness of this management is, in most of these works, only achieved by storing hydrogen in tanks or by storing energy in batteries [4]. As the paradigm of $NH_3$ manufacture is changing towards green production, this creates a challenge for the ammonia industry, largely relying on fossil fuels. Namely, this raises questions about how plants will adapt to remain competitive and make the most of the capital invested in the current infrastructure.

The European ammonia industry is starting to adapt and try to position itself in the new reality. Fertiberia, in Spain, and Yara, in Norway, are examples of companies with a long-established position in the ammonia market that have recently begun to introduce green hydrogen into their conventional plants, albeit in small quantities [4]. A single study related to this practice is found in the literature [5], with a maximum green $H_2$ incorporation of around 20 %, limited, among other factors, by overheating of equipment. Inspired by the operating procedures at one real-life plant, this work addresses the challenges of gradually incorporating green $H_2$ into a conventional ammonia production plant and presents a new configuration to achieve higher incorporations.

## GREY TO GREEN AMMONIA

To simulate a conventional methane-fed HB process, an Aspen Plus® V14 model was developed. This model can be divided into two different sections: the SMR section and the HB synthesis section, as shown in Figure 1.

### SMR Section

The SMR section produces hydrogen from natural gas (~$CH_4$), which is initially purified by hydrodesulphurization. The removal of sulphur compounds prevents catalysts' poisoning in multiple process units. This stream is heated, mixed with steam, and fed into a reforming section made up of two separate reactors. In the first reformer, Ref-I, H2 is produced by steam consumption, according to Equations (2) and (3). Steam is supplied in excess to minimize carbon formation reactions and shift the equilibrium towards the products.

$$CH_4 + H_2O \leftrightarrow CO + 3\,H_2 \quad (2)$$

$$CO + H_2O \leftrightarrow CO_2 + H_2 \quad (3)$$

The effluent gas mixture from Ref-I is mixed with compressed hot air and fed into the second reformer, Ref-II, where the conversion of unreacted $CH_4$ is completed ($CH_4$ molar fraction below 0.005). The air stream flowrate ($N_2$ ~0.78, $O_2$ ~0.21, Ar ~0.01 molar fractions) supplied to Ref-II is adjusted to achieve the desired $H_2/N_2$ ratio in the $NH_3$ synthesis section, although simultaneously the oxygen ($O_2$) feed must be fully consumed in this unit according to Equation (4). Argon (Ar) is introduced in this stage and remains as a chemical inert in all process units.

$$CH_4 + 0.5\,O_2 \leftrightarrow CO + 2\,H_2 \quad (4)$$

From Ref-II, the gas mixture is cooled and the carbon monoxide (CO) formed in the reforming stages is converted. This conversion is described by Equation (3) and takes place in two different stages: high-temperature shift (HT) followed by low-temperature shift (LT).

Carbon dioxide is then removed by scrubbing the mixture with an ammonia solution. The removal of $CO_2$ from the syngas stream, as well as all oxygen compounds, is critical to the HB synthesis operation, since these compounds act as poisons to the iron-based catalysts in this stage. The unconverted CO fraction and the uncaptured $CO_2$ undergo a methanation step, consuming a small amount of $H_2$ and generating $CH_4$ and water ($H_2O$), Equations (5) and (6).

$$CO + 3\,H_2 \leftrightarrow CH_4 + H_2O \quad (5)$$

$$CO_2 + 4\,H_2 \leftrightarrow CH_4 + H_2O \quad (6)$$

Like Ar, $CH_4$ is an inert chemical in the HB section and water is separated by molecular sieve adsorbers, ensuring that no oxides are admitted to the HB section. The gas mixture obtained is therefore mostly composed of $H_2$ and $N_2$ in a 3:1 molar ratio, with small amounts of $CH_4$ and

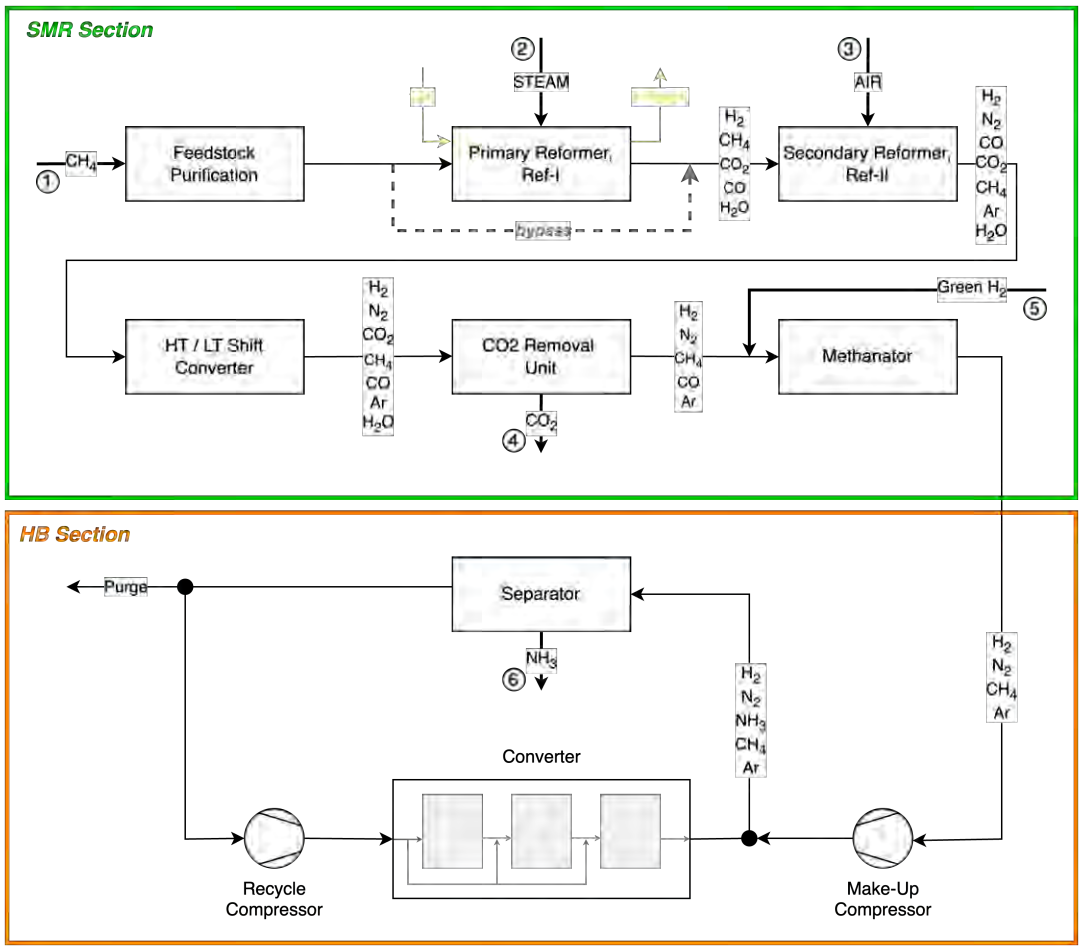

**Figure 1:** Simplified schematics of the model developed, divided into SMR and HB section (adapted from [4]). The first part of this work studies the incorporation of green H2 (stream ⑤) with manipulation of the flow rate of the natural gas stream (stream ①). The second part studies a new configuration of the reforming section, with bypass to primary reforming (as illustrated in dashed line).

Ar. Some metrics of the SMR section are listed in Table 1.

**Table 1:** Main consumptions in the SMR section for hydrogen production of 3 000 kmol/hr, based on the model developed.

| | |

| ① Natural Gas Consumption [ton/hr] | 15.7 |
| ② Steam Consumption [ton/hr] | 51.1 |
| ③ Air Consumption [ton/hr] | 41.2 |

## HB Section

The formation of $NH_3$, according to Equation (1), is highly exothermic and thermodynamically favored by high pressures and low temperatures. However, low temperatures favor low reaction rates. To achieve higher rates, the industry synthesizes $NH_3$ at pressures between 150 and 300 bar and temperatures ranging from 400 to 450 ˚C [4].

Due to the high exothermicity of the synthesis reaction, the reactor is usually divided into three catalytic beds, which promotes a more efficient strategy for effluents' temperature control. This is achieved by splitting the feed stream and introducing it in stages at the entrance to each of the catalytic beds as shown in the HB Section in Figure 1 (Converter).

The conversions achieved per pass are typically low (less than 25 %) and require the recycling of unconverted nitrogen and hydrogen, which must be separated from the $NH_3$ produced to achieve economic viability. Several configurations on the arrangement of reactor beds, stream splits and process units have been reported; the model developed in this work is fully consistent with the process diagram shown in Figure 1.

After leaving the third catalytic bed, the effluent is cooled in a heat exchanger network where the syngas feed is pre-heated and steam is generated (not visible in the diagram). This stream is then mixed with the compressed syngas makeup from the SMR section. Cooling

in the separator stage allows ammonia to be separated from this mixture in the liquid phase, and the gaseous phase is purged to avoid the accumulation of $CH_4$ and Ar. The remaining gas stream is slightly compressed to compensate for the pressure drop, heated, split and admitted to the reaction beds, closing the ammonia synthesis loop. Some indicators of the HB section can be found in Table 2.

**Table 2:** Production and yield achieved in HB section.

| | |
|---|---|
| Ammonia Production [kton/year] | ~200 |
| Ammonia Yield [%] | 93.4 |

## Green Hydrogen Incorporation

The introduction of green $H_2$ into the process was considered immediately upstream of the methanation step (in the SMR section, stream ⑤) and its intake leads to two different operating strategies: S-I and S-II. The S-I reduces the production of grey $H_2$ by reducing natural gas and process steam in the SMR section. The intake of green $H_2$ allows $NH_3$ production to remain fixed. In strategy S-II, grey $H_2$ production remains unchanged, resulting in higher $H_2$ feed to the HB section. By taking in larger quantities of process air, higher $NH_3$ production can be achieved in HB section. Table 3 summarizes the main changes to the process according to the operating strategy considered.

**Table 3:** Effect on the quantities of air, natural gas and steam consumed and on the quantity of $NH_3$ produced with the incorporation of green $H_2$, for S-I and S-II.

| | **Natural Gas** ① | **Steam** ② | **Air** ③ | **$NH_3$ Prod.** ⑥ |
|---|---|---|---|---|
| **S-I** | ↓ | ↓ | = | = |
| **S-II** | = | = | ↑ | ↑ |

Although both strategies lead to a certain degree of decarbonization of $NH_3$ production, it was the authors' decision to focus on the S-I study in this work as it better represents the industrial reality of reaching a certain product capacity to be sold on the market, as well as the effective replacement of grey $H_2$ with green $H_2$. For this study, the input of green $H_2$ by a pure stream ($xH_2 = 1$) was assumed, without modelling the upstream electrolysis process; and full availability of green $H_2$ was considered, with no limit on its supply to the process. The incorporation of green $H_2$ was defined as a function of the total amount of H2 (green + grey) that is supplied to the HB section. To maintain this total amount of $H_2$ unchanged, the natural gas flow (stream ①) is manipulated as the amount of green $H_2$ introduced increases (stream ⑤). To keep the carbon/steam ratio at Ref-I, the steam flow rate (stream ②) is also adjusted.

# RESULTS

## Standard SMR

The incorporation of $H_2$ was considered from 0 to 10 % and the results obtained (Figure 2) show a very similar relationship between the incorporation of green $H_2$ and the reduction in natural gas consumption, as well as with the decarbonization of the process (only the $CO_2$ emissions directly generated by the production of $H_2$ are taken into account, which are those obtained in the $CO_2$ removal unit – stream ④, without the emissions associated with burning natural gas for energy purposes).

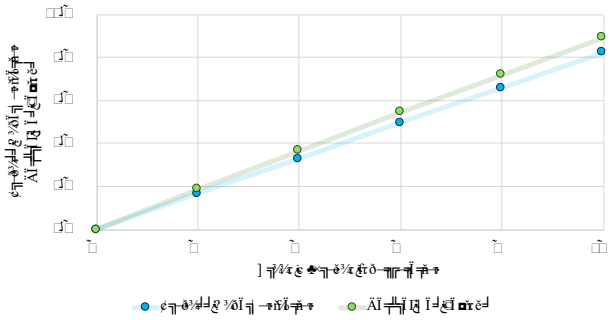

**Figure 2:** Process decarbonization and natural gas savings for an incorporation of green $H_2$ of 0 to 10 %.

Although the reduction in $CH_4$ consumption has an influence on all the stages of the SMR section, the main effects are found in the reforming step, more specifically in Ref-II. Figure 3 shows the results obtained for the $CH_4$ flowrate and the temperature of the Ref-II outlet. These variables are highlighted because they can constrain higher values of green $H_2$ incorporation, due to the possible incomplete consumption of $O_2$ and overheating of the equipment, as explained below.

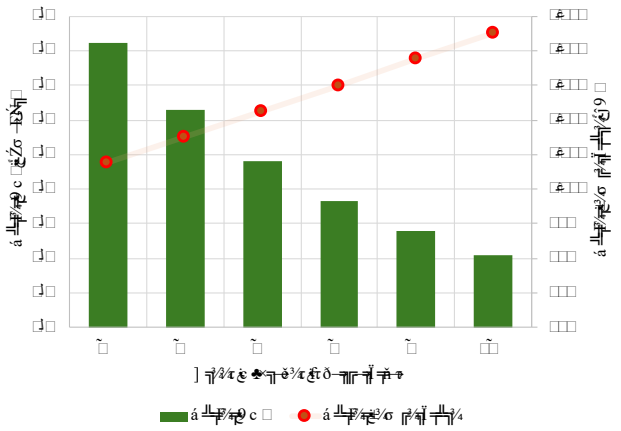

**Figure 3:** $CH_4$ flowrate and effluent temperature of the second reformer for an incorporation of green $H_2$ between 0 to 10 %.

The reduction in the flowrate of $CH_4$ exiting Ref-II is justified by the reduction in natural gas and the requirement to consume the same amount of atmospheric $O_2$. Recalling the importance of this $O_2$ consumption, the declining trend in the amount of CH4 in the effluent may result in incomplete $O_2$ consumption for greater incorporations of green $H_2$. This can lead to $O_2$ being carried over to the HB section and impact on the lifespan of the catalyst used in $NH_3$ synthesis.

The temperature of the effluent is influenced by the exothermicity of the reaction and the heat release is dissipated by a smaller volumetric flow of effluent, due to a lower supply of natural gas. The increase in temperature (around 75 °C for a green $H_2$ incorporation of 10 %) over the already high temperatures of the base case (~1000 °C, 0 % green $H_2$) can lead to equipment overheating, not only of the Ref-II but also downstream. The same results were obtained in a similar study [5], although the variation in temperature obtained by those authors was less sharp than that obtained by the current simulation. The authors also stress the importance of temperature in determining the incorporation of green $H_2$ and limited its variation to a maximum of 100 °C, which resulted in an incorporation of between 15 and 20 % of green $H_2$. Applying the same criteria to this work would result in a maximum limit close to 12 %.

## Adapted SMR

The challenge of introducing green $H_2$, while producing the remaining grey $H_2$, and ensuring the necessary $N_2$ input, total $O_2$ consumption and controlling the temperature of Ref-II is a challenge that could unlock greater incorporations of green $H_2$ and more extensive decarbonization of $NH_3$ production. This can be achieved by a different balance of the fraction of natural gas that is processed in Ref-I and Ref-II. The diverting of $CH_4$ from Ref-I to Ref-II can avoid the obligatory consumption of $CH_4$ per pass in Ref-I, guaranteeing the amount of $CH_4$ necessary for total $O_2$ consumption and grey $H_2$ production and, eventually, temperature control in Ref-II.

To study this possibility, a new configuration was considered for the reforming stage, highlighted by the dashed lines in Figure 4. This new configuration includes a bypass to Ref-I, which gives the model the flexibility it needs to manage $CH_4$ consumption between Ref-I and Ref-II. In this study, the outlet temperature of Ref-II effluent is kept constant and equal to the base case (~1015 °C, 0 % green $H_2$), by adjusting the bypass fraction accordingly.

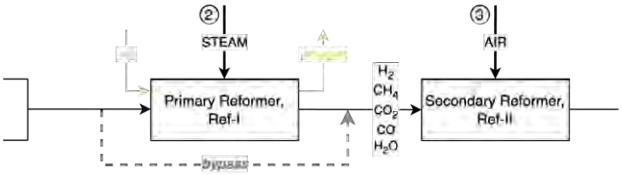

**Figure 4:** New proposed configuration, with Ref-I bypass (detail from **Figure 1**).

For an incorporation of green $H_2$ from 0 to 10 %, Figure 5 shows a similar relationship between the decarbonization of the process and the reduction of natural gas. The same figure shows the results obtained for the bypass fraction, which suggest a linear behavior with the increasing incorporation of $H_2$. For example, introducing 10 % of green $H_2$ means that only around 80 % of the flow is fed to Ref-I. The flow reduction in Ref-I is, however, even more pronounced compared to the base case, since the natural gas flow is already reduced to allow only 90 % of the total hydrogen to be produced.

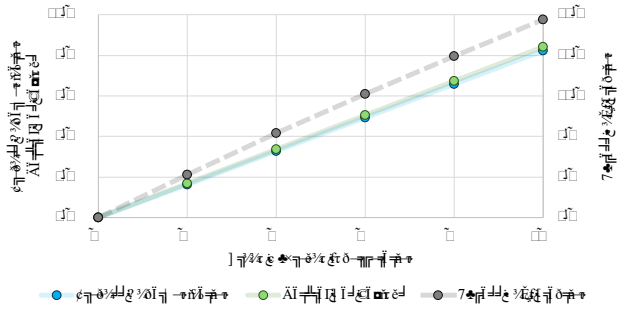

**Figure 5:** Process decarbonization, natural gas savings and bypass fraction for an incorporation of green $H_2$ of 0 to 10 % (adapted SMR with Ref-I bypass).

By analyzing the effluent from Ref-II, whose temperature and molar flow of $CH_4$ are shown in Figure 6, it is possible to identify that temperature control also allows the reduction of $CH_4$ in this stream to be less dependent on green $H_2$ incorporation, possibly leading to a less sudden and delayed depletion of this compound.

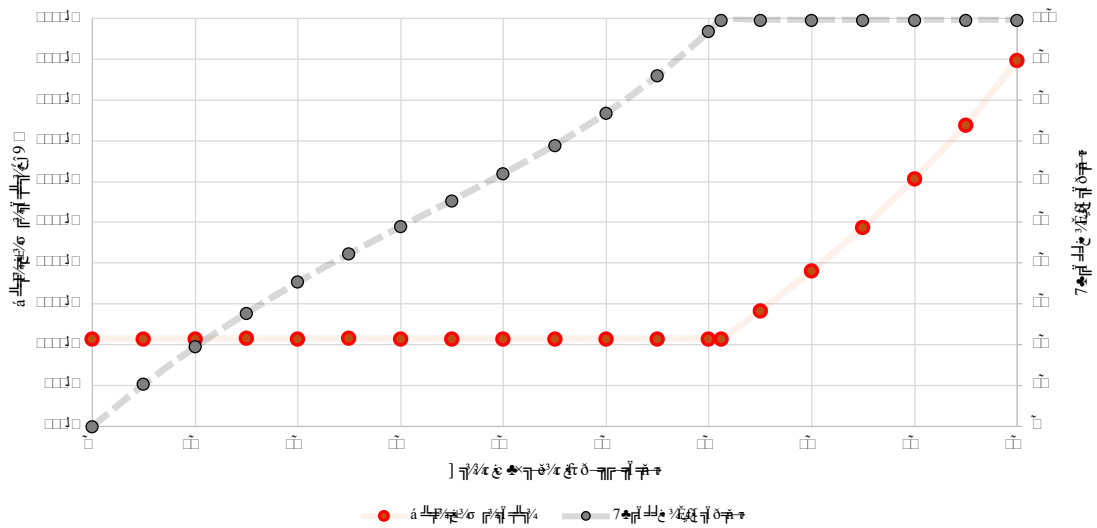

**Figure 7:** Effluent temperature of the second reformer, Ref-II, and bypass fraction for an incorporation of green $H_2$ of 0 to 90 % (adapted SMR with Ref-I bypass).

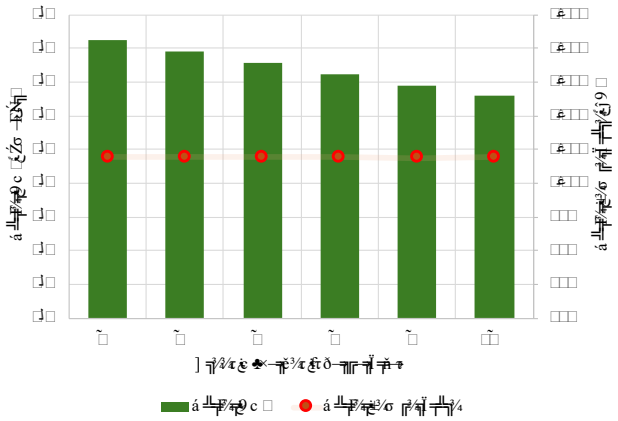

**Figure 6:** $CH_4$ flow rate and effluent temperature of the second reformer for an incorporation of green $H_2$ of 0 to 10 % (adapted SMR with Ref-I bypass).

Once control of the effluent temperature and the presence of enough $CH_4$ to consume $O_2$ were ensured by the new Ref-I bypass configuration, further incorporation of green $H_2$ was studied. Figure 7 shows the behavior of the effluent temperature and the evolution of the bypass fraction for incorporations of 0 to 90 % green $H_2$. Adjustment of the bypass fraction allows the temperature to be controlled up to around 61 % of green $H_2$ intake, at which point the bypass fraction is total, meaning the Ref-I is no longer in operation. This is one of the important points of this analysis, from which the introduction of green $H_2$ is limited by the inability to control the temperature of Ref-II. However, operating at values close to this point implies operating Ref-I with very small flow rates that are far from its nominal capacity.

At this stage, no minimum limit on the volume of gas fed to Ref-I and Ref-II (or any other equipment) has been considered, which could be useful in a future study where the effect of their minimum operating capacities should be addressed. Nevertheless, it is to be expected that the assumption of a minimum capacity value for Ref-I will inevitably result in a limitation of the maximum bypass fraction and, as a result, this limit point will be reached for a smaller incorporation of green $H_2$.

Another important point will be the start of the bypass operation. In this study, the start of operation of the bypass coincides exactly with the start of the green $H_2$ intake because no tolerance to the temperature of the base case (~1015 °C) was considered. Moreover, if it is possible to increase the Ref-II outlet temperature, its effect is found as the % of green $H_2$ incorporated. Assuming a tolerance in that temperature of + 50 and + 100 °C, the start of the bypass becomes increasingly distinct from the start of the incorporation of green $H_2$, and the temperature can be controlled for increasingly higher incorporations. Table 4 summarizes the results obtained.

**Table 4:** Influence of the Ref-II outlet temperature tolerance (ΔT) on the operation of the Ref-I bypass.

| ΔT [°C] | $T_{out}$ [°C] | % Bypass >0 [% Green $H_2$] | % Bypass ~100 [% Green $H_2$] |
|---|---|---|---|
| + 0 | 1015 | 0 | 61 |
| + 50 | 1065 | 7 | 64 |
| + 100 | 1115 | 13 | 67 |

## CONCLUSIONS

The incorporation of green $H_2$ into a conventional

NH3 plant was investigated using a model developed in Aspen Plus® V14. The incorporation of green $H_2$ reduces natural gas consumption and $CO_2$ emissions. It was found that the increase in the temperature of the second reformer could limit extensive incorporation of green $H_2$. A new configuration of the reforming section has been proposed, consisting of a bypass to Ref-I, which allows 61 % of green $H_2$ to be incorporated while maintaining the temperature recorded in conventional operation at 0 %. By studying the influence of the tolerance of this temperature, according to the proposed configuration, it was concluded that greater tolerances make it possible to extend the incorporation of green $H_2$ even further and thus decarbonise the plant to a greater extent.

## DEDICATION

The authors would like to dedicate this article to the memory of Professor Pedro Castro, who was involved in the discussion of this work. His guidance, knowledge and friendship will be greatly missed.

## ACKNOWLEDGEMENTS

## ABSTRACT

Simulation plays a crucial role in the design and optimization of gasifiers by providing a detailed understanding of the involved physical processes and complex chemical reactions without the need for extensive trial-and-error experiments. It can also serve as a valuable tool for identifying potential technical issues in experimental devices that operate below expected performance. This study presents a comprehensive simulation of biomass gasification using the open-source software DWSIM. The simulated results were compared with experimental data from a pilot-scale spouted bed reactor, featuring a square-based design with a 20 kWth capacity, using pruning of apple tress as feedstock. Experimental results revealed that the reactor operated effectively at temperatures exceeding 850°C, maintaining stable conditions across a wide range of equivalence ratios. However, the distribution of products—particularly hydrogen ($H_2$)—did not match expected results based on both literature and simulations. A joint analysis of experimental data and expected behavior from simulation helped identify the observed inefficiencies and optimize the reactor's performance.

**Keywords**: Biomass, Syngas, Energy Efficiency, Gasification, Spouted Bed

## INTRODUCTION

Simulation-based activities play a crucial role in assessing reactor performance by providing a deeper understanding of underlying processes without the need for costly and time-consuming experiments. Process simulation tools offer a structured approach to modeling chemical reactors, enabling engineers and researchers to analyze, optimize, and predict reactor behavior under various operating conditions, including gasifiers. Among the available simulation platforms, commercial software such as Aspen Plus has long been a standard in chemical engineering, particularly for thermochemical reactions [1], due to its extensive database and robust computational capabilities. However, its reliance on proprietary licenses and limited customization options presents challenges, especially for academic research and collaborative projects.

An alternative to commercial software is the use of open-source process simulators, such as COCO [2], which has been used to simulate the gasification of agricultural residues. Another example is DWSIM, developed by Daniel Medeiros [3], which provides a comprehensive suite of tools for modeling a wide range of chemical engineering processes, including reactors. DWSIM features a freely accessible database with over 1,500 compounds and more than 20 property methods [4].

In this study, a previously developed and validated DWSIM model [4] is used to simulate the gasification of pruning of apple tree in a spouted bed reactor. With an annual availability of 2.23 Mt in Italy [5], along with its renewable nature and favorable properties—such as low to moderate moisture content and high cellulose and lignin levels—apple tree prunings are an ideal feedstock for thermochemical conversion processes.

A 20 kWth spouted bed reactor (SBR) was used for the gasification reactions. An SBR differs from traditional fluidized bed reactors by replacing the perforated base

with a single central gas inlet. This design creates three distinct zones within the reactor: a central spout where the fluidizing agent flows, an annular region surrounding the spout, and a fountain-like region above the bed surface where solids circulate [6]. Due to this configuration, a systematic cyclic circulation of solids is established, enhancing mass and heat transfer rates [7]. SBRs have been successfully applied to the gasification of coal, biomass, and biomass-plastic mixtures [8].

In this study, a previously validated model was used to critically evaluate the experimental results from the spouted bed pilot plant. Specifically, discrepancies in the experimental $H_2$ content were observed, and comparison with the model outputs helped identify the source of the experimental error.

## MATERIALS AND METHODS

### Biomass properties

Pruning of apple trees (PAT) were gasified in a spouted bed reactor [9]. Table 1 summarises their proximate and ultimate analysis and its initial higher heating value (HHV). The moisture content was equal to 8.13 %wt.

**Table 1:** Proximate and ultimate analysis of biomass (% w/w on dry basis, besides for moisture) and HHV (MJ/kg)

| **Proximate Analysis** | | **Ultimate Analysis*** | |
|---|---|---|---|
| Ash | 2.87 | C | 48.88 |
| Fixed carbon | 19.95 | H | 5.71 |
| Volatile matter | 77.18 | O | 42.15 |
| HHV | 18.73 | Ash | 2.87 |

* 0.39%wt of N and S

### Spouted bed reactor and testing conditions

The experimental unit is a pilot plant located in Biella, Italy, designed to operate with a biomass feed rate of 200 g/min, providing a thermal output of 20 kWth. The main components of the plant include a blower, a spouted bed reactor, a biomass feeding system, a gas preheater, and equipment for cleaning the gaseous product stream (filter, scrubber, and cyclone). To enhance mass and energy transfer within the reactor, an inert solid bed is used. This bed consists of 2 kg of silica sand, corresponding to an initial height of 17 cm.

**Figure 1.** Spouted bed reactor

PAT were evaluated under different equivalence ratios (ER). The ER represents the ratio of the actual oxygen supplied to the system to the oxygen needed for full stoichiometric combustion. The air inflow was maintained constant (17 $Nm^3/h$) and the biomass feed was varied to match the ER (Table 2).

**Table 2**: Experimental conditions

| **ER** | **Biomass feed (g/min)** | **Temperature of the bed (°C)** |
|---|---|---|
| 0.42 | 150 | 880 |
| 0.65 | 99 | 911 |

Details on the reactor design, operating procedure, and reaction steps—including preheating, stabilization, and product analysis—are available elsewhere [9].

## Simulation set-up using DWSIM

DWSIM (V8.6.5) was used to simulate the gasification of PAT. A detailed description of the model and its validation using literature data can be found in [4]. In summary, steady-state simulations were performed under isothermal conditions using the Peng-Robinson property method at atmospheric pressure, with no pressure drops considered. The modeled gaseous components included $H_2$, $H_2O$, CO, $CO_2$, $CH_4$, and $N_2$, while char was represented by its main constituents (C(s), O, N, and H) based on experimental data [9].

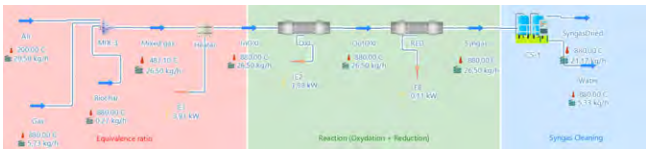

**Figure 2.** DWSIM flowsheet of the gasification plant.

**Table 3**: Kinetic reactions

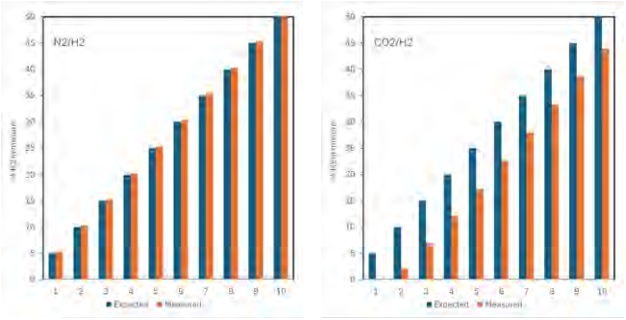
| | Rate (mol/m³·s) | k (sec⁻¹) | Ea (KJ/mol) |
|---|---|---|---|
| $1.25C(s) + O_2 \rightarrow 0.5CO + 0.75CO_2$ | $r = k \cdot T \cdot e^{(-Ea/RT)} \cdot [O_2]$ | $3.7 \cdot 10^{10}$ | 150 |
| $CH_4 + 0.5O_2 \rightarrow CO + 2H_2$ | $r = k \cdot e^{(-Ea/RT)} \cdot [O_2]^{0.8}[CH_4]^{0.7}$ | $1.58 \cdot 10^{12}$ | 202 |
| $CO + 0.5O_2 \rightarrow CO_2$ | $r = k \cdot e^{(-Ea/RT)} \cdot [O_2]^{0.25}[CO][H_2O]^{0.5}$ | $1.78 \cdot 10^{10}$ | 180 |
| $H_2 + 0.5O_2 \rightarrow H_2O$ | $r = k \cdot e^{(-Ea/RT)} \cdot [O_2]\ [H_2]$ | $1.08 \cdot 10^{7}$ | 108 |
| $C + H_2O \leftrightarrow CO + H_2$ | $r = k \cdot T \cdot e^{(-Ea/RT)} \cdot [H_2O]\ [C]$ | 0.008 | 499 |
| $CO + H_2O \leftrightarrow CO_2 + H_2$ | $r = k \cdot e^{(-Ea/RT)} \cdot [CO]\ [H_2O]$ | 278 | 126 |
| $CH_4 + H_2O \leftrightarrow CO + 3H_2$ | $r = k \cdot e^{(-Ea/RT)} \cdot [H_2O]\ [CH_4]$ | $4.92 \cdot 10^{-11}$ | 125 |
| $C + CO_2 \leftrightarrow 2CO$ | $r = k \cdot e^{(-Ea/RT)} \cdot [C]$ | $1.05 \cdot 10^{13}$ | 135 |
| $CO_2 + H_2 \leftrightarrow CO + H_2O$ | $r = k \cdot e^{(-Ea/RT)} \cdot [CO_2]\ [H_2]^{0.5}$ | 258 | 126 |

The flowsheet is shown in Figure 2. The volatilization stage was modeled using an Excel file (embedded in the program) to calculate the mass balances (Gas and Biochar inlet streams), as described by Pio et al. [10]. The mass balance calculations (yields of pyrolysis products and composition of biochar) were specified, the temperature of decomposition was imported from the input data and the resulting compositions were exported to the corresponding input streams. Successively, the two inlet streams were mixed with the quantity of air (Air) ensuring autothermal conditions, as experimentally specified. Two Plug Flow Reactors (PFRs), with the geometries of the experimental device [9], were used to carry out the oxidation and reduction reactions. Both reactors were considered as isothermal at 880°C and their dimensions were set as 0.3 m of height for the oxidation reactor (corresponding to the bed of particles), 2 m for the reduction reactor (corresponding to the freeboard section) and 0.25 m of internal diameter in both cases. Kinetic reactions (Table 3) and parameters (Table 4) were set according to [11-13] to provide a more accurate representation of the reactor performance for reliable process predictions [14]. Lastly, the cleaning section, corresponding to the removal of moisture and tar before entering the analysing system, was simulated through a compound separator to obtain the final dry syngas stream.

## RESULTS AND DISCUSSION

Table 4 presents the experimental and simulated results of the gasification of PAT under the described operational conditions. The balance term in the analyzer accounts for all products not measured, ensuring the total sums to 100%. In the simulations, this balance term corresponds to the $N_2$ concentration.

**Table 4**: Experimental and simulated results (%vol/vol) at ER=0.42 and ER=0.62



| **ER = 0.42** | **CO** | **$CO_2$** | **$H_2$** | **$CH_4$** |
|---|---|---|---|---|
| Experimental | 10.2 | 19.9 | 4.7 | 2.8 |
| DWSIM | 12.9 | 17.5 | 10 | 4.7 |
| **ER = 0.65** | **CO** | **$CO_2$** | **$H_2$** | **$CH_4$** |
| Experimental | 5.9 | 20.3 | 3.0 | 1.0 |
| DWSIM | 11.3 | 18.1 | 7.2 | 3.5 |

As expected, the CO and $CO_2$ concentrations were estimated with high accuracy, while $CH_4$, and especially $H_2$, were overestimated in the simulations. A consistent trend was observed when comparing the equivalence ratio (ER), with CO increasing and $CO_2$ decreasing as the ER decreased. Additionally, methane and hydrogen concentrations increased as ERs decreased, a trend that was effectively captured by the model. Energy balances were also examined in detail. The measured temperature at the bed of particles was used as the reaction temperature in isothermal conditions to ensure a fixed reaction temperature, as indicated by the experimental setup. According to the simulations, the exothermic contribution was insufficient to sustain the reduction reactions, and it was estimated that around 5 kW would need to be added to the system to achieve autothermal conditions. However, the experimental device performed well, and the gasification reactions occurred in a stable isothermal regime.

An evaluation was conducted to identify the potential experimental reasons for the large discrepancies observed in $H_2$ content and reaction temperature. Possible causes include:

- Unaccounted Heat Losses: Heat losses may reduce reaction efficiency, impacting syngas composition and temperature of reaction.
- Temperature Variations: If the actual operating temperature differs from the model's assumption, it can shift equilibrium reactions (such as the water-gas shift reaction, $CO + H_2O \rightleftharpoons CO_2 + H_2$), which can affect $H_2$ content.
- Unaccounted Side Reactions: Tar formation was not considered due to the lack of experimental data, though its contribution is likely to be significant under real operating conditions.
- Incomplete Mixing or Mass Transfer Limitations: mass transfer limitations, or localized temperature variations are not accounted for in the model.
- Calibration Issues: Gas chromatographs or other analytical instruments may not be properly calibrated, leading to inaccurate measurements.

To ensure consistency between input data, operating conditions, and gas composition measurements, the calibration of the gas analyzer (MCA100 Syn-P, ETG) was first checked. Two gas mixtures—$CO_2/H_2$ and $N_2/H_2$—with known compositions were used to test the instrument calibration. The calibration curve for $N_2$ (Figure 3a) showed perfect alignment between measured and applied compositions. However, the $CO_2/H_2$ calibration curve (Figure 3b) revealed underestimations of about 7%vol of $H_2$ (in average) between the measured and applied compositions, while the contribution from C-based compounds was accurately measured.

(a) (b)

**Figure 3.** Calibration of gas analyser

In summary, by simulating the experimental conditions and comparing the model's predictions with observed data, the study highlighted discrepancies that pointed to specific areas of concern, such as the H2 content in the product stream, led to the critical review of the experimental conditions, as measurement inaccuracies. Modeling is proven to be a powerful troubleshooting tool, enabling researchers to systematically isolate and address these issues, thereby improving the reliability and accuracy of the experimental results. This approach not only enhances the robustness of the current campaign but also provides a framework for optimizing future experimental designs.

## CONCLUSIONS

This study demonstrated the effectiveness of using the open-source software DWSIM to simulate biomass gasification in a spouted bed reactor, providing valuable insights into the process and identifying potential sources of error in the experimental campaign. The simulation results were compared with experimental data from a pilot-scale reactor using pruning of apple tree as feedstock, revealing discrepancies in the hydrogen ($H_2$) content and other gas compositions. The model accurately predicted trends in CO and $CO_2$ concentrations but overestimated $H_2$ and $CH_4$ compositions. Key potential sources of error identified include unaccounted heat losses, temperature variations, side reactions such as tar formation, mass transfer limitations, and calibration issues with analytical instruments. By leveraging the model as a troubleshooting tool, the study successfully pinpointed these inefficiencies, enabling a critical review of experimental conditions and improving the reliability of the results. In successive steps, the other identified sources of error will be studied and analysed for their experimental assessment. This approach not only optimized the current gasification process but also established a robust framework for future experimental designs, emphasizing the importance of integrating simulation with experimental validation to enhance the accuracy and efficiency of biomass gasification systems.

## ABSTRACT

In offshore environments, where space, weight, and energy efficiency are critical constraints, the effective removal of water from turbine exhaust gases is essential to enhance gas treatment processes. In this context, replacing conventional methods, such as molecular sieves, with supersonic separators (SSRs) emerges as a promising alternative. This study aims to determine the most suitable operating conditions and design parameters for water removal via supersonic separation (SS) in turbine exhaust gases (TxGs) on offshore platforms. Simulations were performed in Aspen HYSYS using a unit operation extension, based on typical TxGs compositions from offshore platforms. Key parameters, including operating conditions, separator dimensions, and shock Mach number, were evaluated to maximize efficiency while minimizing equipment footprint. The results indicated a water capture efficiency of 99.45%, demonstrating that SS technology is not only compact but also a viable and efficient alternative for water removal from exhaust gases, particularly in space-constrained environments.

**Keywords:** Water, Supersonic Separation, Turbine Exhaust Gases, Offshore, Aspen HYSYS

## INTRODUCTION

Climate change is primarily driven by the accumulation of greenhouse gases (GHGs) in the atmosphere, which has increased because of human activities such as deforestation, industrial processes, and fossil fuel consumption. These activities amplify the Earth's natural greenhouse effect, resulting in rising global temperatures, sea level increases, more frequent and severe extreme weather events, and widespread disruptions to biodiversity and ecosystems [1, 2].

In response to these challenges, the development of technologies aimed at mitigating GHG emissions and promoting sustainability has become increasingly urgent. Initiatives such as the Paris agreement and the United Nations' sustainable development goals (SDGs) have spurred significant advances in decarbonization efforts across multiple sectors [3, 4].

Within the oil and gas industry, particularly on offshore platforms, the efficient removal of water from turbine exhaust gases (TxGs) is crucial to enhancing $CO_2$ capture efficiency. Traditional methods, such as molecular sieves, have been widely employed for natural gas (NG) dehydration in production units operating in Pre-salt fields. However, these technologies often involve substantial energy consumption and require large, complex infrastructure, making them less suitable for the spatial and weight constraints typical of offshore operations [5, 6].

In this context, supersonic separators (SSRs) have emerged as a compelling alternative. Utilizing adiabatic expansion, SSRs efficiently cool and condense water and other condensable components without relying on moving parts, thereby reducing maintenance demands. Their compact design, combined with the ability to recover part of the pressure energy lost during the shock, makes

supersonic separation (SS) particularly well-suited to meet the operational and logistical demands of offshore platforms [6, 7].

For $CO_2$ SS in TxGs, the initial removal of water improves process efficiency. Pre-dehydration prevents operational issues such as hydrate formation and reduced $CO_2$ capture efficiency while minimizing moisture impact on downstream equipment [8, 9].

The literature has extensively explored $CO_2$ SS in NG and water SS in NG and TxGs, both through HYSYS simulations and CFD studies. As observed in studies such as those by Saidi and Farokhi, Chen, Arinelli, and Hammer, various approaches have been developed to model SS in different contexts. However, this study is the first to specifically apply supersonic water separation in TxGs using Aspen HYSYS. This novel application demonstrates the feasibility and advantages of SS technology in offshore turbine exhaust processing, addressing an existing gap in the literature [8, 10–13].

Aiming to fill this gap, this study explores the application of SSRs for water removal from TxGs on offshore platforms as an alternative dehydration method and a preparatory step for $CO_2$ capture via SS. The analysis is conducted through process simulation in HYSYS, focusing on the adjusted TxGs compositions from Hammer's study to determine the best operational conditions, as well as the SSR dimensions and shock Mach number. The objective is to increase process efficiency while minimizing equipment size, considering the constraints and specificities of the analyzed case [8].

## METHODOLOGY

The operational scenario was analyzed based on adjusted data from Hammer (Table 1) [8].

**Table 1:** Conditions for the evaluated scenario

| | Unit | Scenario |
|---|---|---|
| Temperature | °C | 87.00 |
| Pressure | bar a | 1.01 |
| Flow rate | t/h | 243.00 |
| $CO_2$ | %mol | 3.24 |
| $N_2$ | %mol | 76.21 |
| $O_2$ | %mol | 13.99 |
| Ar | %mol | 0.92 |
| $H_2O$ | %mol | 5.64 |

Additionally, the following constraints were defined for the process development:

- Compressors must not be used;
- The minimum temperature available for cold utility is 26°C;
- The residual gas stream must contain a maximum of 500 ppm of water;
- The capture stream must contain a maximum of 50 ppm of $CO_2$;
- The SS system must consist of a maximum of 10 and a minimum of 5 SSRs arranged in a battery.

The Peng-Robinson equation of state (PR-EOS) was adopted in this study to model the thermodynamic behavior of the system in Aspen HYSYS. This selection was made due to PR-EOS's well-documented accuracy in predicting phase equilibrium in hydrocarbon and light gas mixtures, including $CO_2$ and water condensation under offshore conditions. Previous studies have demonstrated its suitability for modeling multiphase flows in SSR, reinforcing its application in this study. Its ability to represent water condensation in natural gas has already been demonstrated in previous studies, highlighting its precision in predicting liquid phase composition under condensation conditions. Applications in HYSYS for SS have further reinforced its suitability for modeling $CO_2$ capture in TxGs, emphasizing its applicability to multiphase systems. This performance was expected, considering that the version of PR-EOS implemented in HYSYS has undergone enhancements to handle mixtures containing polar components, such as water, improving its accuracy in non-ideal conditions [8, 13–16].

Considering the previously defined conditions and constraints, the process was modeled in Aspen HYSYS, as shown in Figure 1, outlining the main stages of the SS process. Initially, the TxG stream is cooled in the Cooler "E-1", lowering its temperature to enable effective separation even at low pressures. Next, the flow is split in the Multiplier module "MULT-1", simulating the operation of a SSR battery. The divided stream (FEED) is then directed into the Unit Operation Extension (UOE), where separation occurs, resulting in two distinct streams: "CAPTURE", which contains the captured water, and "PRODUCT", comprising the residual gases.

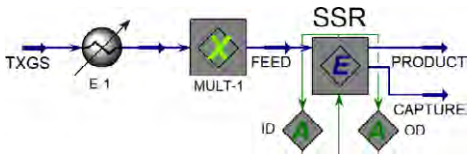

**Figure 1.** Flow diagram for SS modeling of water in TxGs

The UOE used in this study was developed for Aspen HYSYS to enable the modeling of the thermodynamic behavior of SS. This tool was used to assess water removal efficiency under various conditions and refine parameters for offshore applications.

To provide a clear overview of the UOE operation, Figure 2, which illustrates the user interface of the SS model in Aspen HYSYS.

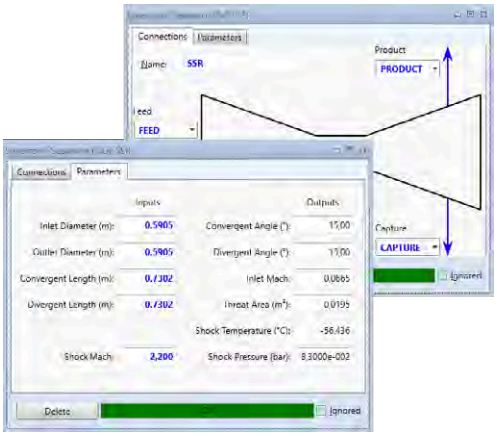

**Figure 2.** User Interface of the SSR UOE

The UOE was validated by reproducing the same input parameters and conditions as those used by Arinelli *et al.*, who applied a rigorous thermodynamic approach to model SS in Aspen HYSYS. The comparison of the obtained results allows for assessing the accuracy of the implemented modeling, ensuring consistency between the predictions of the model used in this study and those presented in the literature [13].

The SSR design adhered to engineering standards to meet the specific requirements of offshore platforms. Inlet and outlet internal diameters were determined using nominal pipe sizes (NPS) and standard thicknesses as defined by the ASME B31.3 and API RP 14E standards [17, 18]. Additionally, the Adjusts "ID" and "OD" (Figure 1) were employed to define the lengths of the convergent and divergent sections, adopting a nozzle angle of 15°, which has been identified in the literature as an efficient design choice for supersonic applications. This configuration balances operational efficiency and compactness, minimizing flow turbulence. The reduced pressure drop and stable supersonic flow contribute to energy efficiency and make the design suitable for space-constrained offshore environments [19].

The simulations evaluated the impact of varying operational and dimensional parameters on the efficiency of water removal in TxGs, while ensuring compliance with the constraints established by the plant. The objective was to systematically assess the trade-offs between maximizing water removal and minimizing $CO_2$ capture during the dehydration stage, considering the interplay between process conditions and equipment dimensions.

The "Case Studies" tool in Aspen HYSYS was utilized to systematically evaluate and determine the most suitable operational conditions and dimensions for the process. In this study, the molar fraction of water in the "PRODUCT" stream and the molar fraction of $CO_2$ in the "CAPTURE" stream were defined as dependent variables, while the temperature of the "FEED" stream and the shock Mach number were adjusted as independent variables. This analysis was conducted across a wide range of scenarios, considering multiple diameter configurations, defined according to the previously mentioned standards, and various multiplier factors whose equivalent divisors were integer values. The "Case Studies" tool was executed for every possible combination of diameter and multiplier factor, ensuring a comprehensive assessment of the process conditions. Table 2 presents the parameters and ranges used in the study.

**Table 2.** Range of variables studied.

| Variable | Unit | Start | End | Step Size |
|---|---|---|---|---|
| FEED Temperature | ºC | 26.0 | 87.0 | 0.1 |
| Shock Mach | - | 1.1 | 2.5 | 0.1 |
| Diameters (NPS) | in | 16.0 | 32.0 | - |
| Multiplier factor | - | 0.1 | 0.2 | - |

Each executed "Case Studies" run was evaluated, and the results were later compared to identify trends and determine the most suitable configuration. To ensure that all variables were comparable and to eliminate the differences in scale between the analyzed parameters, the dependent variables were normalized. This procedure allows variables with distinct units and magnitudes to be evaluated equitably within the performance metric. The normalization was performed using Equation (1):

$$x_{norm,i} = \frac{x_i - x_{min}}{x_{max} - x_{min}} \quad (1)$$

Where $x_i$ represents the original value of the variable, and $x_{min}$ and $x_{max}$ are the minimum and maximum values within the dataset.

After normalization, the Euclidean distance was employed as a proximity criterion between the simulated scenarios and the ideal configuration defined for the study. This method quantifies the similarity between each scenario and the desired condition, enabling the classification of configurations based on their alignment with the established objectives. The Euclidean distance was calculated using Equation (2):

$$d_E = \sqrt{\sum_{i=1}^{n} \left(x_{norm,i} - x_{ideal,i}\right)^2} \quad (2)$$

Where $x_{ideal,i}$ represents the normalized value of the ideal configuration for each variable.

This structured approach allowed for ranking all simulated scenarios from the lowest to the highest distance, facilitating not only the identification of the most suitable configuration for the evaluated conditions but also revealing performance trends, trade-offs between operational parameters, and alternative configurations that could be advantageous depending on specific process constraints.

## RESULTS

The model validation was performed by comparing the simulation results with the numerical data from Arinelli *et al.* The model yielded a shock pressure of 15.20 bar, with an absolute error of 0.99% compared to the reference value (15.05 bar). Similarly, the shock temperature was -38.59°C, resulting in an absolute error of 0.81% compared to the reported value (-38.28°C). These small deviations indicate a strong agreement between the model and the reference data, validating the approach used for the SSR simulation [13].

The total dataset generated by the "Case Studies" tool comprised 439,920 cases. After evaluating the Euclidean distances, the most suitable configuration was identified as the scenario with a diameter of 24 in NPS Std and a multiplier factor of 0.1, corresponding to a battery of 10 SSRs. Within this subset, 9,165 cases were initially considered, of which 7,314 had valid solutions, and 34 met the restrictions defined in the methodology.

The case evaluation revealed key performance trends and trade-offs between operational parameters. The analysis highlighted those configurations with smaller diameters resulted in lower "FEED" stream temperatures and, consequently, higher liquid phase fractions, which could compromise the stability of the supersonic flow. On the other hand, configurations with larger diameters exhibited lower pressure drops, but at the expense of requiring more space, impacting the overall equipment footprint.

The case evaluation indicated that a temperature of 35.20°C in the "FEED" stream and a shock Mach number of 2.2 resulted in the lowest Euclidean distance, therefore representing the most suitable operating conditions. The final simulation results are presented in Table 3.

It is important to highlight that these conditions ensured operation close to the saturation temperature of 35.26°C, resulting in a liquid phase fraction of only 0.02% in the "SSR" feed. This minimal amount does not compromise the stability of the supersonic flow and, consequently, preserves the efficiency of the separation process. Additionally, this operating condition provides a ΔT of approximately 10°C for the cold utility, favoring heat exchange and contributing to the system's energy efficiency [9, 20].

The evaluation of this scenario revealed that a battery of 10 SSRs offers significant advantages. This configuration achieves a well-balanced trade-off between the diameter of each separator, total space occupied by the battery, and modularization required to handle flow rate variations. This balance ensures technical feasibility while providing the operational flexibility needed to adapt to fluctuations in demand.

The TXGS stream contains 3.68 MW of available heat in the "E-1" Cooler, which can be recovered for energy integration. When utilized, this energy can reduce the need for hot utilities, a particularly valuable advantage for offshore platforms.

As expected from the data processed in the spreadsheet, the molar fractions of the "PRODUCT" and "CAPTURE" streams remained within the constraints defined in the methodology. Additionally, the process achieved a water capture efficiency of 99.45%, demonstrating that SS technology is not only a compact and efficient alternative but also a promising solution for TxG dehydration, capable of meeting industry requirements for water

**Table 3.** Operational results and parameters of the simulated scenario

| | Unit | FEED | PRODUCT | CAPTURE |

removal while providing additional energy integration benefits.

## CONCLUSIONS

This study demonstrated the feasibility and potential of SS as an efficient and compact alternative for water removal from TxGs on offshore platforms. By integrating the Aspen HYSYS simulator with the SSR UOE, a comprehensive analysis of operational and dimensional parameters was conducted, ensuring process efficiency while addressing the spatial and weight constraints typical of offshore environments. The results confirm that the proposed configuration successfully balances technical performance, energy efficiency, and modular adaptability, making SS a competitive alternative to conventional dehydration methods.

The implementation of an SSR battery proved to be viable not only from a technical perspective but also operationally, offering flexibility to accommodate flow variations. The determined "FEED" stream temperature (35.20°C) ensured stability in the supersonic flow, directly contributing to high water removal efficiency while minimizing $CO_2$ co-capture. Furthermore, the study highlighted the significant potential for energy integration, with opportunities to recover and reuse heat from the TxG stream, enhancing the overall sustainability of offshore processing systems.

Beyond its technical feasibility, SS technology aligns with industry demands for lower environmental impact and improved process integration. Its potential to minimize equipment footprint and energy consumption makes it particularly attractive for offshore applications, where operational efficiency is critical. These findings reinforce SS as a promising alternative for TxG dehydration, paving the way for its future application in supersonic $CO_2$ capture.

Further research should focus on detailed economic and environmental assessments to validate large-scale applicability, as well as experimental studies to complement numerical modeling. Additionally, investigating policy incentives and technological advancements, such as enhanced separator designs and hybrid separation strategies, will be essential to accelerate the adoption of SS technology in offshore operations.

## ABSTRACT

The increasing global population has resulted in the scramble for more energy. Hydrogen offers a new revolution to energy systems worldwide. Considering its numerous uses, research interest has grown to seek sustainable production methods. However, hydrogen production must satisfy three factors, i.e., energy security, energy equity, and environmental sustainability, referred to as the energy trilemma. Therefore, this study seeks to investigate the sustainability of hydrogen production pathways through the use of a Multi-Criteria Decision- Making model. In particular, a modified Simultaneous Evaluation of Criteria and Alternatives (SECA) model was employed for the prioritization of 19 options for hydrogen production. This model simultaneously determines the overall performance scores of the 19 options and the objective weights for the energy trilemma in a South African context. The results obtained from this study showed that environmental sustainability has a higher objective weight value of 0.37, followed by energy security with a value of 0.32 and energy equity with the least at 0.31. Of the 19 options selected, steam reforming of methane with carbon capture and storage was found to have the highest overall performance score, considering the trade-offs in the energy trilemma. This was followed by steam reforming of methane without carbon capture and storage and the autothermal reforming of methane with carbon capture and storage. The results obtained in this study will potentially pave the way for optimally producing hydrogen from different feedstocks while considering the energy trilemma and serve as a basis for further research in sustainable process engineering.

## INTRODUCTION

Energy is a fundamental component of life and is critical for sustaining modern living standards. Increasing global population and industrialization have driven energy demand to unprecedented levels, placing significant strain on the energy sector [1]. Currently, approximately 85% of energy demand is met by fossil fuels, resulting in substantial $CO_2$ emissions. This has contributed to a 1.1°C rise in global temperatures since the pre-industrial era, with projections of further increases [2].

The energy sector also faces challenges from economic fluctuations, such as those induced by the COVID-19 pandemic, which temporarily reduced global energy demand, emissions, and investment but left renewable energy less affected [3]. As demand pressures persist, governments and organizations are pursuing policies and innovations to transition toward sustainable energy systems emphasizing reliability, environmental sustainability, and affordability [4].

Hydrogen is emerging as a promising clean energy carrier capable of addressing the limitations of traditional renewable energy sources, such as intermittency and lack of inherent storage capacity. With a high energy density (120 $MJ \cdot kg^{-1}$), hydrogen offers versatility in production, storage, and applications, including transportation and grid stabilization [5]. However, the widespread adoption of hydrogen faces challenges related to cost-effective and environmentally sustainable production methods. Current hydrogen generation technologies, primarily reliant on fossil fuels, emit $CO_2$, necessitating a shift toward carbon-free alternatives.

Hydrogen production pathways vary widely in economic, environmental, and technological performance.

Reforming methods are cost-effective but environmentally damaging, while electrolysis, powered by renewable energy, is sustainable but capital-intensive. Multi-criteria decision-making (MCDM) approaches are essential to evaluate and select optimal hydrogen production pathways that balance energy security, equity, and sustainability [6].

This study aims to identify the optimal hydrogen production pathway for South Africa using an MCDM framework. A literature review informs the methodology, followed by an evaluation of the performance of selected processes.

## LITERATURE REVIEW

MCDM methods are effective tools for addressing decision-making problems involving multiple conflicting objectives and stakeholders. Various MCDM techniques have been applied to assess and prioritize hydrogen production technologies. For example, some authors employed the Analytic Hierarchy Process (AHP) [7–8], while others integrated the decision-making trial and evaluation laboratory (DEMATEL) with AHP to improve hydrogen production sustainability [9]. Other studies utilized methods like TOPSIS, VIKOR, and hesitant fuzzy AHP to evaluate hydrogen production pathways based on sustainability criteria[10–11].

Recent advancements in MCDM include integrating fuzzy logic to handle subjective and vague human judgments, such as using the Z-number Best Worst Method (ZBWM) and ELECTRE models [12] or employing fuzzy SWARA and IVIF-WASPAS [13]. Despite these innovations, most methods remain subjective, relying heavily on expert opinions, which introduce inconsistencies and uncertainties. Moreover, these methods typically separate criteria weighting from alternative ranking, thereby limiting integration and efficiency.

Few studies have addressed hydrogen production within the framework of the energy trilemma. Additionally, geographical context, such as the South African unique energy landscape, has received little attention. South African abundant resources and environmental challenges necessitate tailored hydrogen production strategies. However, research gaps persist in addressing the interplay of energy trilemma factors and region-specific conditions.

This study introduces the Simultaneous Evaluation of Criteria and Alternatives (SECA) method, a multi-objective nonlinear programming model that simultaneously calculates criteria weights and ranks alternatives. SECA overcomes the limitations of traditional MCDM methods by optimizing and ranking solutions in a unified framework. The study focuses on identifying the optimal hydrogen production pathway for South Africa, accounting for the complexities of the energy trilemma, thereby filling a critical gap in published literature and offering practical insights for stakeholders in energy policy and planning.

## METHODOLOGY

The study follows three key stages: (1) Defining selection criteria and identifying suitable hydrogen production options, (2) Constructing a decision-making matrix, and (3) Developing a multi-objective nonlinear programming model for optimization.

Environmental sustainability, economic viability, and reliability/availability were chosen as selection criteria, addressing the core challenges in hydrogen production pathway selection. The SECA model [14], a multi-objective nonlinear approach, is applied to determine the optimal method in the South African context. It optimizes three objectives: (1) maximizing overall performance, (2) minimizing deviation in criterion weights within-criterion variation, and (3) minimizing deviation in criterion weights based on between-criterion variation. Unlike traditional methods, SECA does not require expert input for scoring criteria and relies on standard deviation and correlation as reference points for weight minimization.

To enhance model applicability, the study replaces the original SECA normalization method with Min-Max Normalization, addressing the issue of zero-value elements in evaluation matrices. This modification expands the usability of the model across diverse datasets and ensures a more comprehensive assessment framework.

A multi-criteria decision-making (MCDM) problem with *n* alternatives and *m* criteria is represented by the decision matrix:

$$x = \begin{bmatrix} x_{11} & x_{12} & \cdots & x_{1m} \\ x_{21} & x_{22} & \dots & x_{2m} \\ \vdots & \vdots & \ddots & \vdots \\ x_{n1} & x_{n2} & \cdots & x_{nm} \end{bmatrix} \quad (1)$$

Where $x_{ij}$ represents the performance of alternative $i$ alternative on criteria $j$ with $x_{ij} \geq 0$. Normalization is applied based on benefit and cost criteria using Min-Max scaling:

$$x_{ij}^{N} = \begin{cases} \dfrac{x_{ij} - \max x_{ij}}{\max x_{ij} - \min x_{ij}}, j \in BC \\ \dfrac{\max x_{ij} - x_{ij}}{\max x_{ij} - \min x_{ij}}, j \in CC \end{cases} \quad (2)$$

where BC and CC are benefit and cost criteria, respectively.

The SECA model determines criteria weights directly from the decision matrix, using standard deviation $(\sigma_j)$ and correlation $(r_{jl})$. The standard deviation, which indicates the dispersion of data, captures the within-criterion variation. The correlation calculates the contrast intensity in the interaction of the alternatives in each criterion to assess the between-criterion conflict.

$$\sigma_j = \sqrt{\frac{1}{m}\sum_{i=1}^{m}\left(X_{ij} - \overline{X_{ij}}\right)^2}, \quad \pi_j = \sum_{l=1}^{m}\left(1 - r_{jl}\right) \tag{3}$$

The normalized reference points for weight calculation are given by:

$$\sigma_j^N = \frac{\sigma_j}{\sum_{l=1}^{m}\sigma_l} \quad , \quad \pi_j^N = \frac{\pi_j}{\sum_{l=1}^{m}\pi_l} \tag{4}$$

The multi-objective nonlinear programming model consists of three objectives:

1. Maximizing overall performance:

$$\max S_i = \sum_{j=1}^{m} w_j \, x_{ij}^N \qquad \forall_i \in \{1,2,\dots,n\} \tag{5}$$

2. Minimizing deviation from standard deviation-based reference weights:

$$\min \lambda_b = \sum_{j=1}^{m}\left(w_j - \sigma_j^N\right)^2 \tag{6}$$

3. Minimizing deviation from correlation-based reference weights:

$$min\, \lambda_c = \sum_{j=1}^{m}\left(w_j - \pi_j^N\right)^2 \tag{7}$$

Subject to:

$$\sum_{j=1}^{m} w_j = 1 \;\; , \varepsilon \le w_j \le 1 \;\; , \;\; \forall_j \in \{1,2,\dots,m\} \tag{8}$$

where ε is a small positive value (set to $10^{-3}$) ensuring a lower bound on weights.

To transform the multi-objective problem into a single-objective optimization, a weighted sum method is applied:

$$\max Z = \lambda_a - \beta(\lambda_b + \lambda_c) \tag{9}$$

with constraints:

$$\lambda_a \le S_i \;\; , \;\; S_i = \sum_{i=1}^{m} x_{ij}^N \, w_j \, , \quad \forall_i \in \{1,2,\dots,n\} \tag{10}$$

$$\lambda_b = \sum_{j=1}^{m}\left(w_j - \sigma_j^N\right)^2, \;\; \lambda_c = \sum_{j=1}^{m}\left(w_j - \pi_j^N\right)^2 \tag{11}$$

The parameter $\beta$ balances deviations from reference weights, and different $\beta$ values generate alternative rankings. The stability of rankings is evaluated using the Spearman correlation coefficient, ensuring consistency in final rankings.

## CASE STUDY

A pathway database was developed from the literature. The data was collected according to affordability, availability, and environmental sustainability criteria. The affordability was characterized by the cost of hydrogen ($/kg), and the data was adapted from [15].

Environmental sustainability data was collected from different sources in the literature [16–19]. This criterion was characterized by global warming potential (GWP), which is the amount of carbon dioxide produced by the process per amount of hydrogen produced (kg $CO_2$ / kg $H_2$).

Availability is the third criterion, and it measures the raw materials required in a particular process to obtain hydrogen. The measure was rated regarding how much raw material is available. Raw material availability was chosen because neglecting resource availability may cause a model to select a production process that is not well suited to a region of interest. In this research, a rigorous methodology was employed to calculate the availability rating of critical raw materials. The availability rating was determined using the following equation, which was modified from the general efficiency equation:

$$Availability\ rating = \frac{Total\ raw\ material\ available}{Total\ raw\ material\ required} \tag{12}$$

The study considered the total quantities of raw materials required for a 100-year projection assuming stoichiometry. The availability rating for each raw material was calculated individually, offering a detailed assessment of their respective contributions to the overall availability. Furthermore, an average availability rating was computed to provide a holistic perspective on the raw material supply chain. The results reveal a surplus beyond the required quantities, emphasizing the robustness of the production system and its capability to meet demands efficiently. This comprehensive approach to assessing availability contributes valuable insights to the optimization of hydrogen production processes.

A hydrogen demand value of 6 million tons per annum obtained from [20] was used to calculate the amount of raw materials required per pathway. This was done using stoichiometric ratios, assuming 100 % conversion of the limiting reactant. The average raw materials required for a particular pathway were used as the availability rating.

## RESULTS AND DISCUSSION

A decision-making matrix was developed based on a pathway database comprising 19 hydrogen production routes. The matrix was constructed using GAMS modeling software with the Antigone solver to handle the

complex interrelationships and variables within the decision framework.

**Table 1:** The evaluation matrix of the pathway database

| Process | Cost ($/kg) | GWP ($kgCO_2$/ kg $H_2$) | Availability rating |
|---|---|---|---|
| **SMR with CCS (S1)** | 4.84 | 3.40 | 11.65 |
| **SMR without CCS (S2)** | 4.43 | 12.00 | 11.65 |
| **CG with CCS (S3)** | 3.48 | 15.50 | 2.10 |
| **CG without CCS (S4)** | 2.86 | 24.20 | 2.10 |
| **ATR of methane with CCS (S5)** | 3.16 | 3.98 | 7.78 |
| **Methane Pyrolysis (S6)** | 3.18 | 5.00 | 3.02 |
| **Biomass Pyrolysis (S7)** | 3.75 | 2.40 | 6.26 |
| **Biomass Gasification (S8)** | 4.14 | 2.67 | 6.26 |
| **Direct bio Photolysis (S9)** | 3.77 | 0.70 | 6.26 |
| **Indirect bio photolysis (S10)** | 2.51 | 67.00 | 6.26 |
| **Dark Fermentation (S11)** | 4.65 | 16.29 | 6.26 |
| **Photo Fermentation (S12)** | 5.12 | 0.60 | 3.13 |
| **Solar PV Electrolysis (S13)** | 28.23 | 2.00 | 3.13 |
| **Solar thermal electrolysis (S14)** | 15.15 | 2.50 | 3.13 |
| **Wind Electrolysis (S15)** | 12.71 | 0.97 | 3.13 |
| **Nuclear Electrolysis (S16)** | 11.25 | 2.00 | 3.13 |
| **Nuclear Thermolysis (S17)** | 4.66 | 0.63 | 3.13 |
| **Solar Thermolysis (S18)** | 15.91 | 0.68 | 3.13 |
| **Photo-Electrolysis (S19)** | 18.73 | 2.00 | 3.13 |

To ensure consistency, all cost data were standardized to the reference year 2021 using the Chemical Engineering Plant Cost Index (CEPCI). The matrix provides a structured framework for evaluating and comparing pathways against the energy trilemma criteria. **Table 1** presents the evaluation matrix.

## Normalizing the decision-making matrix

The data in **Table 1** were normalized using Equation (2). Affordability and environmental sustainability were identified as cost criteria, given that they need to be minimized. Conversely, availability was identified as a benefit criterion, given that it needs to be maximized.

## Criteria weights analysis

Determining criteria weights is crucial for prioritizing processes. The SECA model was solved for $\beta$ values (0.1, 0.2, 0.3, 0.4, 0.5, 1, 2, 3, 4, 5, 6, 7), extending the initial study by [14] to observe trends beyond $\beta$ = 5. Twelve sets of criteria weights were generated, with variations shown in **Figure 1**. The optimal $\beta$ was selected where consecutive solutions differed by less than 0.01, ensuring near-constant weights.

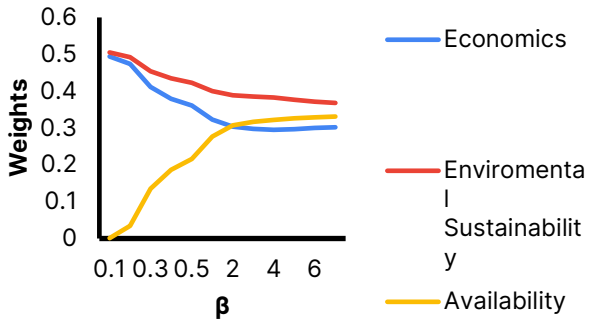

**Figure 1:** The variation of criteria weights related to $\beta$

A clear decrease in the objective function value was observed as $\beta$ increased, as shown in **Figure 2**. The parameter $\beta$ played a critical role in influencing criteria weights, with some criteria gaining importance while others diminished as $\beta$ increased. This dynamic interaction optimized the decision-making process by balancing trade-offs between criteria.

A transition point was identified where criteria weights stabilized, signaling the critical balance of the model. Notably, this stabilization coincided with the maximum value of the objective function, indicating the optimal state of the model. Thus, $\beta$ acted as a lever to achieve a stable and balanced weighting while optimizing the overall objective function.

For $\beta$ values exceeding 3, criteria weights exhibited increased stability, with differences between consecutive weights dropping below 0.01 as $\beta$ approached 5. This indicated a balanced state between decision criteria, leading to the selection of $\beta$ = 5 for determining final weights.

The resulting criteria weights highlighted environmental sustainability as the most significant factor (0.373), emphasizing eco-friendly practices. Availability, particularly of raw materials, ranked second (0.316), underscoring resource reliability. Affordability received the lowest weight (0.310), indicating lower priority in the decision-making process. This prioritization reflects a focus

on sustainability and resource availability.

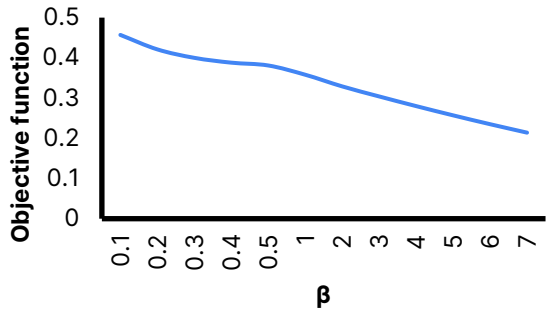

**Figure 2:** Objective function with varying $\beta$

## Analysis of the performance of alternatives

The overall performance of each alternative *Si* was assessed using the SECA model with normalized data and criteria-specific $\beta$ values. The rankings, aligned with the original pathway database (e.g., S1 correspond to "SMR with CCS"), enabled the identification of the most promising pathways based on the three selected criteria.

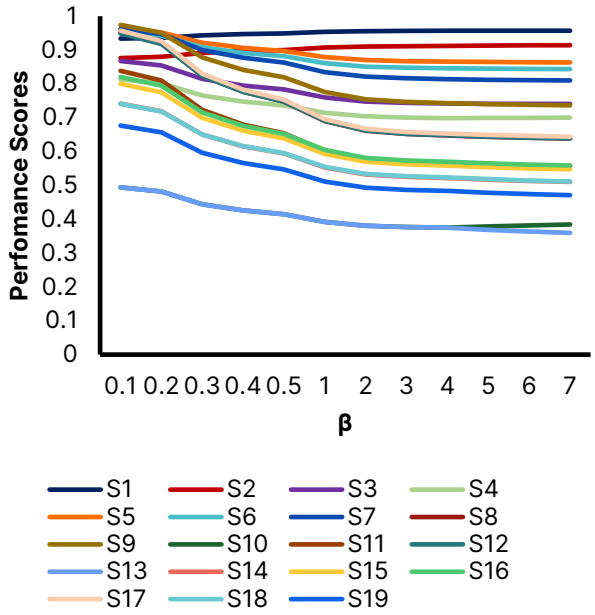

**Figure 3:** Variations in the performance scores related to $\beta$

**Figure 3** provides a graphical representation of performance scores, offering a clear visual understanding of pathway performance and trends for informed decision-making. Rankings were determined based on *Si*, with the highest score indicating superior performance. For $\beta \geq 3$, rankings remained stable (Spearman's correlation coefficient = 1), validating $\beta$ = 5 as the optimal value for final rankings.

Among 19 pathways, steam reforming with CCS emerged as the top option with *Si* = 0.956, balancing energy trilemma criteria due to reduced $CO_2$ emissions, technological maturity, and low raw material costs. This finding aligns with [21], who also identified its robustness using different criteria. Steam reforming without CCS ranked second (*Si*= 0.913), followed by autothermal reforming with CCS (*Si* = 0.845).

Indirect bio-photolysis and solar PV electrolysis were the least preferred pathways, with *Si* values of = 0.448 and 0.400, respectively, primarily due to high economic costs. These results provide a clear framework for selecting the most effective and economically viable hydrogen production pathways, supporting energy sustainability objectives.

## CONCLUSION

In conclusion, this study demonstrated the effectiveness of the SECA multi-criteria decision-making method in optimizing hydrogen production pathway selection within the South African energy landscape, addressing availability, affordability, and environmental sustainability. Using a multi-objective nonlinear programming model, SECA adjusted criteria weights and ranked alternatives, identifying environmental sustainability as the most critical factor, followed by availability and affordability. A $\beta$ value of 5 provided the most stable results, with steam reforming with CCS emerging as the optimal pathway, followed by steam reforming without CCS and autothermal reforming with CCS, while indirect bio-photolysis and solar PV electrolysis ranked lowest due to economic constraints. These insights offer strategic guidance for aligning hydrogen production with sustainability and resource reliability in South Africa.

## ABSTRACT

Sustainable aviation fuel (SAF) is a proven alternative to reduce $CO_2$ emissions in the aviation sector, supporting sustainable growth. However, SAF processes remain economically uncompetitive with fossil-derived jet fuel, prompting interest in strategies to address these challenges. In 2022, Carrasco-Suárez et al. explored process intensification in the SAF separation zone of a biorefinery using waste cooking oil (WCO), achieving a 3.07% reduction in $CO_2$ emissions and lower operational costs for steam and cooling water. Despite these gains, the WCO biorefinery remains economically unviable with high energy demands. This work presents the energy integration of the entire WCO biorefinery addressed from the pinch point methodology, combined with separation zones intensification (EI-PI-S), using the principles of sections movement for distillation columns; these energy efficiency strategies were applied on the biorefinery in Aspen Plus V.10.0 in order to improve the scheme. Key indicators—total annual cost (TAC), energy investment per product energy (EI-P), energy investment per main product mass (EI-MP), and $CO_2$ emissions per main product mass ($CO_2$-MP)—were used to compare the conventional scheme (CS) and the intensified scheme before energy integration (PI-S). The EI-PI-S scheme achieved the best performance, reducing steam and cooling water requirements by 14.34% and 31.06%, respectively, and $CO_2$ emissions by 13.85% and 14.13% compared to CS and PI-S. However, TAC for EI-PI-S was 0.89% higher than PI-S. Despite this, the integrated and intensified WCO biorefinery emerges as a feasible option for SAF production, adhering to energy minimisation principles and improving economic performance.

**Keywords**: WCO biorefinery scheme, SAF, modelling and simulation, energy integration, process intensification

## INTRODUCTION

The aviation industry is increasingly under pressure to reduce its carbon footprint while also trying to recover from the crisis caused by the restrictions of the pandemic brought on by the SARS-CoV-2 virus. In this context, using renewable fuels has proven to be a promising and resilient alternative for the sustainable economic recovery of this sector, which faced its worst year in history in 2020 [1]. Currently, the price of renewable aviation fuel is not competitive compared to its fossil counterpart. One of the strategies to achieve its economic feasibility has been using biorefinery schemes based on residual raw materials, such as WCO. In this biorefinery scheme based on WCO, SAF is obtained as the main product [2]. Then, the separation zone was intensified to improve its economic and environmental competitiveness using the Rong-Errico methodology, achieving up to a 66.95 % reduction in reboiler heat duty through the intensified design [3, 4]. To further improve this biorefinery scheme, this study proposes the intensification of the ethanol recovery zone. Additionally, the energy integration of the scheme aims to utilise the energy from process streams while minimising reliance on external energy sources through the application of pinch point methodology [5]. This study seeks to reduce energy consumption in the

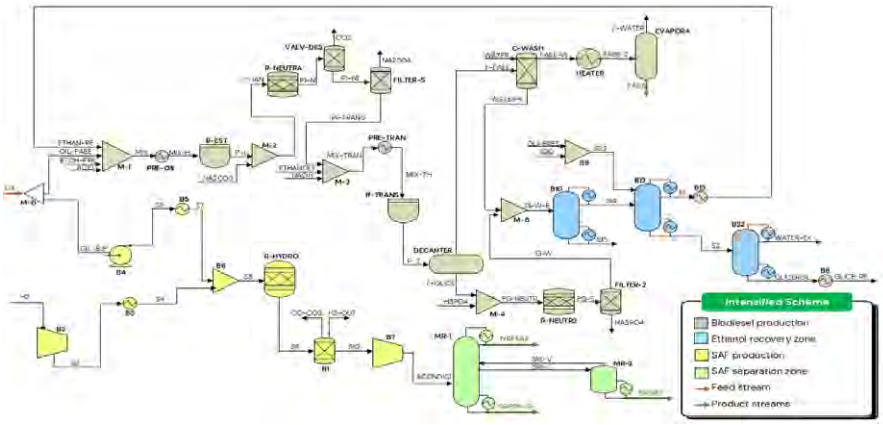

**Figure 1.** Intensified scheme developed by Carrasco-Suárez et al. 2022 [4].

biorefinery, which will contribute to the overall sustainability of the SAF production process.

## METHODOLOGY

The methodology adopted in this work centres on minimising energy consumption within the biorefinery framework by incorporating process intensification and energy integration tools. The following sections will discuss these energy efficiency approaches, alongside an evaluation of their effectiveness using economic-environmental indicators.

### Biorefinery of WCO

The biorefinery scheme developed after intensifying the SAF separation zone, served as the foundation for this work (Figure 1). It processes 2,004.88 kg/h of waste cooking oil (WCO), which consists of 94% triglycerides and 6% free fatty acids [4]. For more detailed information about the feedstock modelling and the base design of the WCO biorefinery, see [4]. The feed (OIL) is divided into two secondary streams, 50% (by weight) for each processing route; the first (OIL-FAEE) is destined for obtaining biodiesel, and the second (OIL-BJF) is to produce SAF.

Biodiesel is produced through two reactive zones in RBatch modules: esterification (R-EST) and transesterification (R-TRANS). The resulting stream (P-2) enters a decanter (DECANTER), producing two streams: F-FAEE (biodiesel) and F-GLICE (glycerol). The biodiesel is washed with a water stream (50% by weight) in the Extract module (C-WASH) to remove impurities. The washed biodiesel (FAEE-W) is dried in a Heater module (HEATER) and purified in a flash tank (EVAPORA) using the Flash2 module. Secondary products (ethanol, water, glycerol) are separated via a train of three RadFrac columns (B10, B12, and B22), with B12 employing glycerol as an extracting agent for recirculation in the biorefinery. The thermodynamic models used are NRTL and UNIFAC for the reactive zones and NRTL for secondary product recovery.

Regarding SAF production, the WCO enters a Pump module (B4) and a heat exchanger (B5) to condition the feed stream to 380 °C and 30 bar. A hydrogen stream at 10 bar enters a compressor (B2) and then to a heat exchanger (B3) to reach 30 bar and 380 °C. Next, both streams enter the hydrotreatment reactor (R-HYDRO), and its output (S10) is sent to a turbine (Compr module B7) to reduce pressure to 1 bar. The output stream (ACONDICI) containing 28 hydrocarbons is divided into three main products: naphtha (NAFTAS), SAF (BIOJET), and green diesel (GREEN-DI). SAF separation is achieved through a distillation train consisting of two columns (RadFrac modules MR-1 and MR-2), producing 306.12 kg/h of SAF with a recovery rate of 99.62% and representing 16.6% of the total products, with biodiesel being the most abundant at 50.1%. The conditioning and reaction zones use Peng-Robinson for thermodynamics, while the separation zone utilises BK10.

### Process Intensification on Separation Zones

Distillation is known for its low thermodynamic efficiency, a significant factor in energy consumption within biorefineries [6]. In this case, distillation accounts for 61.4% of the total energy consumed. This inefficiency requires exploring alternative methods, such as process intensification strategies, to optimise energy use and improve overall performance. Process intensification is a tool in chemical engineering that focuses on designing processes that are more compact, environmentally friendly, safe, and energy-efficient [7]. Using thermally coupled flows instead of traditional heat exchangers in distillation processes has demonstrated a reduction in energy consumption. This improvement enhances heat and mass transfer while meeting recovery and purity goals in distillation sequences [8].

## Intensification of the SAF Separation Zone

A systematic methodology developed by Rong and Errico has been implemented to improve the energy efficiency of the SAF, naphtha, and green diesel separation process, as illustrated in Figure 1. This approach reduced the reboiler heat duty by 66.95 % compared to the conventional one, resulting in a 3.07 % reduction in $CO_2$ emissions. Although the capital cost of the intensified biorefinery is 11.74 % higher than that of the conventional scheme, it offers operating costs that are 2.68 % and 8.13 % lower for steam and cooling water, respectively [4]. These results are promising, indicating that this biorefinery has the potential to meet energy demands sustainably, while significantly reducing emissions and energy requirements. Additionally, the intensification of the ethanol recovery zone could also lead to significant improvements. Thus, both strategies to achieve the complete intensification on the separation zones into the biorefinery scheme could be further improved by using an energy integration tool that utilises process streams and reactive energy zones as energy sources to meet all energy demands in the biorefinery [5].

## Intensification of the Ethanol Recovery Zone

The distillation train illustrated in blue in Figure 1 is designed to recover ethanol with a purity of 99.89%. This high-purity ethanol can subsequently be recirculated back into the biodiesel production process. This part of the biorefinery accounts for 57.7% of the total energy requirements. Thus, implementing energy-saving methodologies is essential for cost reduction, as decreased energy consumption significantly lowers operational expenses and enhances profit margins. Furthermore, such measures mitigate environmental impact by reducing greenhouse gas emissions. This approach is vital for establishing a long-term, viable, and resilient SAF production process, particularly as energy resources become increasingly scarce and expensive.

The conceptual principles of the Rong-Errico methodology were taken as the basis for reducing energy consumption in the ethanol recovery distillation process [3]. It is specifically designed for traditional distillation columns with a single condenser and reboiler, intended for non-azeotropic mixtures. Due to the formation of an azeotrope between ethanol and water, extractive distillation is necessary, utilising glycerol as the extracting agent. Therefore, the distillation train used to recover ethanol, as shown in Figure 1, falls outside the scope of the Rong-Errico approach; however, in order to address this challenge, the conceptual principles of the Rong-Errico methodology were used to enable the creation of intensified configurations.

In this case, a singular simple column configuration (D-SC) exists. The intensification process for this configuration commences with the generation of all possible original thermally coupled configurations (OTC) by substituting the heat exchangers linked to the submixtures S14 and S2 with thermal coupling streams, resulting in three distinct OTCs. These OTCs are the foundation for deriving thermodynamically equivalent structures (TES) by manipulating movable sections. Regarding OTC-2, section 5 cannot be relocated to column B12, as it is not a transport side column. In contrast, TES-1 and TES-3 incorporate a single-section transport side column (B12), while columns B10 and B22 maintain a simple column design. Consequently, ISC-1 and ISC-3 can be generated by omitting column B12 from the configurations.

The modifications to the original methodology for generating the seven intensified configurations involved using the feed stream S14 to define the rectifying and stripping sections in column B12. Additionally, to achieve the desired purity of the products, the feed stage location for stream S22 was modified, along with adjustments to operational parameters such as reflux ratio and mass flux of the thermal coupling streams. The D-SC achieves purities of 99.89% for ethanol, 85.83% for water, and 99.99% for glycerol. Among these configurations, OTC-2 is the only option that meets these requirements, while the other ones present convergence troubles. OTC-2 achieved the required purity specifications by adding glycerol to the top of column B12 to break the azeotrope and introducing thermally coupled flows at the bottom of the column for effective separation. In contrast, in other configurations, the thermally coupled flows in column B10 disrupted the separation process by mixing ethanol, water, and glycerol in the feed with the glycerol needed for column B12. This factor and heat duty savings in the condenser and reboiler were considered when determining the configuration to replace the conventional train. Consequently, OTC-2 was coupled into the biorefinery (Figure 2), which reduced heat duty by 8.17% for the condenser and 5.56% for the reboiler, compared to D-SC.

In the PI-S (Figure 2), designed after intensifying both distillation sequences, the energy requirements for heating and cooling were reduced by 3.10% and 11.81%, respectively, compared to the conventional scheme (CS). $CO_2$ emissions increased by 0.33%. This rise is attributed to the high heat duties in column B22, which has only four stages. Introducing thermal coupling streams (S2-V and S2-L) has negatively affected the column's energy efficiency and performance. With just four stages, the column requires a higher reflux ratio to achieve the necessary purity for glycerol and water. This, in turn, increases the heat duty of the reboiler by 2.76%, meaning the column must work harder to achieve effective separation.

## Energy Integration of an Intensified Biorefinery Scheme

Energy integration is a systematic approach designed to improve the energy efficiency of processes by

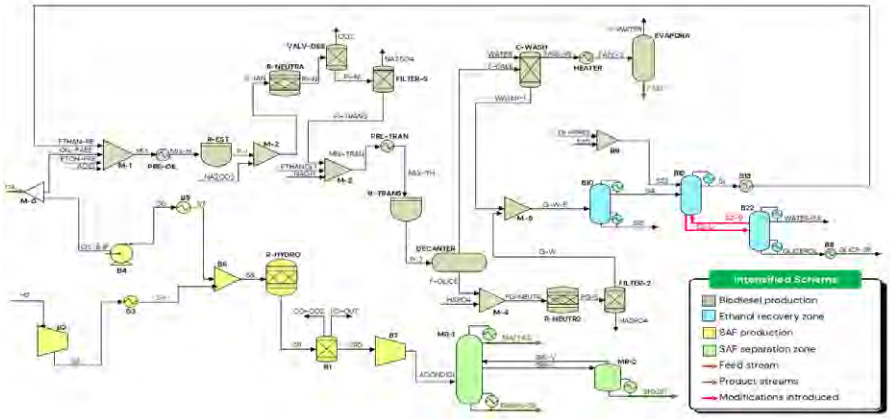

**Figure 2.** Intensified WCO biorefinery scheme

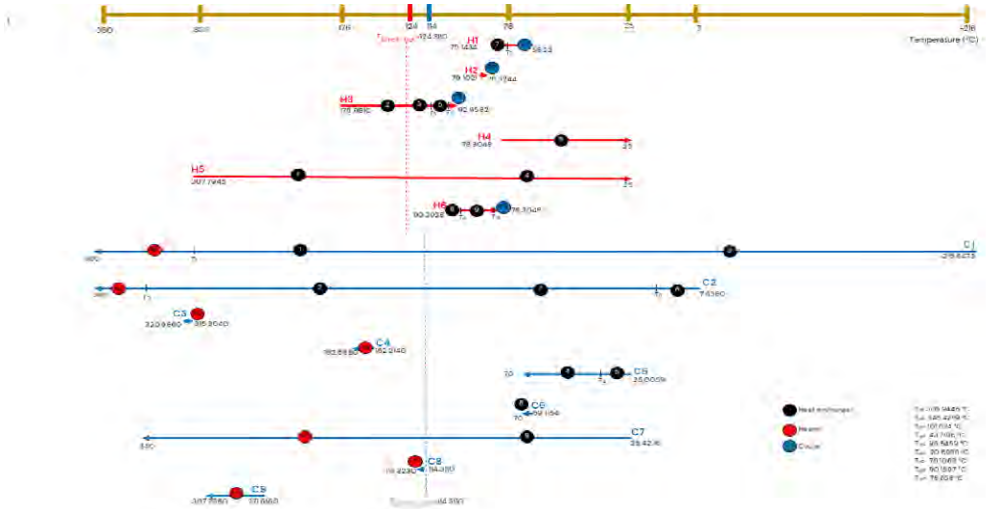

**Figure 3.** HEN designed for the intensified scheme

optimising energy use and recovery within a system. A key technique is pinch point analysis, which minimises energy requirements across the entire biorefinery process[9].

This technique was applied for energy integration of the PI-S, beginning with the collection of data on the energy requirements for both hot and cold process streams, including their temperatures and flow rates, from Aspen Plus V.10.0. This information was then visualised on a temperature-enthalpy (T-H) diagram, where a temperature difference (ΔT) of 10 °C was applied to adjust the temperatures of the hot streams. A heat cascade was employed to identify the pinch point, which was the optimal location for heat recovery, marked by the minimal temperature difference between the hot and cold streams. A heat exchanger network (HEN) was designed to maximise heat transfer around this pinch point while considering thermal constraints. This network aimed to significantly reduce energy consumption, resulting in cost savings and a lower environmental impact [10].

## Biorefinery assessment

The EI-PI-S was evaluated and compared with the CS and PI-S using economic-environmental indicators, defined from the energy and mass requirements of the process. These results quantify the energy performance and the $CO_2$ emissions from the process, as well as its profitability and efficiency. The indicators determined in this work are shown in Table 1.

# RESULTS

In this section are presented the results of energy integration and process intensification, energy efficiency strategies, applied on the WCO biorefinery. Based on the pinch point analysis, the pinch point temperature for hot streams was identified at 124.31 °C, while for cold streams, it was 114.31 °C, using a temperature difference (ΔT) of 10 °C. The calculated minimum heating and cooling requirements, determined through heat cascade analysis are 1126.40 kW and 441.02 kW, respectively.

**Table 1:** Economic-environmental assessment indicators.

| Indicator | Equation and description |
|---|---|
| Total annual cost (TAC) | $TAC\ \left(\frac{USD}{year}\right) = \frac{CC+0.18CC+0.61CC}{n} + OC$ (1)<br>This includes estimating capital (CC) by Aspen Plus and adjusting by CEPCI, as well as the operating costs (OC) and a period of recovery from the investment (5 years) [12,13]. |
| Energy indicator per total energy products (EI-P) | $EI-P\ = \frac{Invested\ energy\ for\ heating}{Energy\ provided\ by\ total\ products}$ (2)<br>It indicates the overall energy efficiency of the biorefinery. |
| Energy indicator per total products (EI-MP) | $EI-MP = \frac{Invested\ energy\ for\ heating}{Mass\ of\ main\ product}$ (3)<br>Similarly to EI-P, this indicator measures how effectively the energy input is converted into SAF, reducing reliance on external energy sources. |
| $CO_2$ emissions indicator per total products ($CO_2$-MP) | $CO_2-MP\ \left(\frac{ton\ CO_2}{kg}\right) = \frac{Total\ \ CO_2\ equivalent\ emissions}{Mass\ of\ main\ product}$ (4)<br>This metric provides insights into the environmental impact and quantifies the emissions relative to the total SAF mass, helping assess the carbon footprint. |

**Table 2:** Estimated indicators

| Scheme | % TAC savings | EI-P (kW/kW) | EI-MP (kW/kg) | $CO_2$-MP (ton $CO_2$/kg) |
|---|---|---|---|---|
| CS | - | 4.2919 | 12.5465 | 9.2918 |
| PI-S | -25.77 % | 4.1394 | 12.1580 | 9.3226 |
| EI-PI-S | -26.90 % | 4.0245 | 11.8202 | 8.0051 |

The designed HEN, shown Figure 3, uses the fewest heat exchangers to maximise savings in steam and cooling water consumption, as well as equipment costs. The energy savings achieved are 14.34% for heating and 31.06% for cooling, compared to the CS. The steam requirement for the EI-PI-S system was 0.67% higher than that of the CS and 0.13% higher than the PI-S. Similar to the PI-S, the ethanol recovery process is responsible for a 2.5% increase in emissions from column B10 in EI-PI-S. This increase occurs because column B10 handles the bulk of the three compounds from the feed, concentrating them into the liquid phase. As a result, higher reboiling energy is needed to generate the vapour phase required for separation, particularly for ethanol and water, which form an azeotrope and thus require additional energy for phase change. Conversely, the amount of cooling water used in the EI-PI-S scheme was reduced by 35.51% compared to the CS and by 8.53% compared to the PI-S.

The results from Table 2 indicate that implementing these methodologies contributed to energy savings and environmental benefits. By combining process intensification and energy integration strategies, the total energy invested is reduced, with the EI-P-S decreasing by 6.23% and the EI-MP decreasing by 5.79% compared to the CS.

Although the amount of vapour required in the EI-PI-S increased, the overall efficiency gains from energy integration led to a reduction in $CO_2$-MP by 13.85% when compared to the CS. The EI-PI-S demonstrates a 26.90% increase in TAC compared to the CS and a 0.89% increase compared to the PI-S.

This suggests that although the EI-PI-S reduces energy consumption and emissions, making it a promising alternative for sustainable biorefineries in the production of SAF, the costs of the equipment and raw materials outweigh the economic benefits gained from energy savings. This presents a challenge to the economic feasibility

of the EI-PI-S scheme, and achieving financial profitability remains a hurdle [11].

## CONCLUSION

In this work, the implementation of the pinch point analysis methodology in an intensified WCO biorefinery scheme to produce SAF was presented, achieving savings of 14.34 % and 31.06 % in heating and cooling requirements, respectively, compared to the conventional scheme. This energy-integrated scheme (EI-PI-S) was evaluated and compared with the conventional (CS) and intensified (PI-S) schemes, reporting savings across the proposed energy-environmental indicators. Thus, the production of SAF in this energetically integrated-intensified biorefinery scheme from WCO represents a promising alternative. Strategies are essential to tackle the challenge of cost competitiveness in biorefineries. Government initiatives and incentives, such as tax credits, grants, and subsidies, can significantly help reduce the capital and operational costs associated with biorefinery investments. Furthermore, promoting stakeholder collaboration is crucial for successfully deploying biorefineries.

## ABSTRACT

Dynamic or Programmable Catalysis is an innovative strategy to improve heterogeneous catalysis processes by modulating the binding energies (BE) of adsorbates on a catalytic surface. The technique enables the periodic favoring of different reaction steps, overcoming limitations imposed by the Sabatier Principle and allowing for higher overall reaction rates, otherwise unattainable. Previously, we implemented a simultaneous simulation approach using the algebraic modeling language Pyomo and the solver IPOPT to obtain cyclic steady state results for a unimolecular reactive system with up to four-order of magnitude increases in computational performance compared to the previously reported sequential approach. The flexibility of the method allowed for the investigation of the influence of forcing signal parameters on system behavior and provided a framework for waveform design. In this study, we use a hybrid framework that combines the sequential and the simultaneous simulation approaches to find the cyclic steady state of a more complex system, of ammonia synthesis, comprising 19 reversible elementary reaction steps. The framework allowed us to investigate sine wave parameters with approximately 220 times less computational effort compared to the sequential approach alone. With the parameters studied, our findings indicate that frequencies exceeding 1000 Hz and compressive strains greater than 2% can negatively impact the system performance. Future work will focus on expanding the model to include lateral interactions between molecules, using other waveform as forcing signals, and integrating systematic mathematical optimization approaches. These advancements pave the way to establishing a general framework for identifying optimal waveforms across diverse dynamic catalysis systems.

## INTRODUCTION

In a world facing pressing environmental challenges, disruptive and interdisciplinary solutions need to be explored. To navigate humanity toward sustainable scientific advancements, it is imperative to reinvent catalytic processes used to produce chemicals that are essential for the modern society. In this context, Dynamic or Programmable Catalysis [1] is a novel concept that has been capturing the attention of scientists in the catalysis field.

Research in heterogeneous catalysis has traditionally focused on selecting the ideal catalyst for a specific reaction, or designing the ideal active site within a catalyst, tied to advances of research in materials science and engineering. At its core, heterogeneous catalysis revolves around an important property of catalytic metals: the adsorption or binding energy (BE). Directly related to this property is the concept of the Sabatier Volcano [2, 3], which states that the ideal catalyst for a specific reaction is the one that binds the substrates with a “just-right” energy. Bindings that are too strong or too weak lead to prominent rate-controlling steps, reducing the efficiency of the catalytic process.

Dynamic Catalysis promotes oscillations of the binding energy throughout the duration of a catalytic

process. These oscillations would allow for faster chemical reactions, due to the periodic favoring of otherwise rate-controlling steps.

Figure 1 shows a representation we call the Extended Sabatier Volcano. The volcano-shaped curve in green represents the dependency of the overall reaction rate, commonly expressed as the Turnover Frequency (TOF), with the binding energy. The peak of this curve marks the balance or the compromise between otherwise rate-controlling steps, leading to the higher TOF value. The main goal of Dynamic Catalysis is to overcome the limitations associated to the volcano curve and obtain overall reaction rates that would be unachievable with conventional, or static, heterogeneous catalysis.

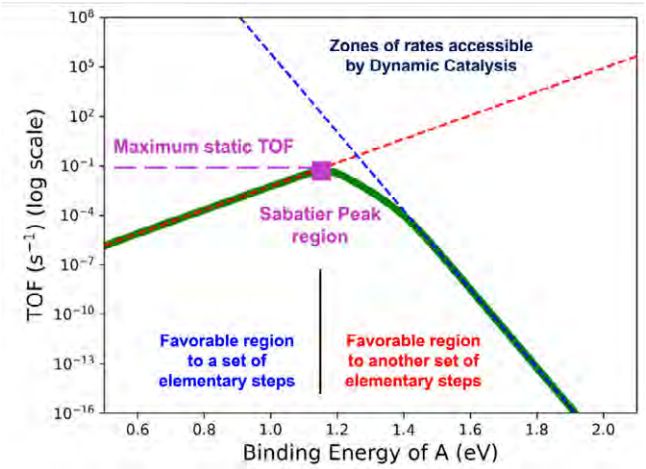

**Figure 1.** The Extended Sabatier Volcano. This is a conceptual figure; axes values are arbitrary and are used for illustration.

Since its introduction, Dynamic Catalysis has sparked significant research interest. On the computational front, researchers have explored several aspects of the concept: using general model reactions to investigate how binding energy (BE) oscillation parameters relate to activity response [1]; introducing conceptual ideas, such as supervolcanoes and molecular pumps derived from energy diagrams [4]; examining product selectivity and reaction pathways [5]; studying surface modulation through applied electric fields [6]; analyzing negative relationships between the BEs of reactants and products [7]; and applying BE modulation to loop reactions [8].

Other computational studies have focused on different simulation methodologies and optimization of forcing signals, including direct limit cycle solutions [9] and Gaussian kernel-based optimization of square wave parameters [10]. Additionally, rate enhancement and computational analysis of oscillation parameters have been applied to more realistic systems, electrocatalytic oxygen evolution reaction over metal oxides, incorporating both fixed overpotential and an additional arbitrary stimulus source [11]; and methane steam reforming under Ru(211) subjected to applied charge [12].

Experimental implementations of Dynamic Catalysis have also demonstrated rate enhancement due to dynamic oscillations. One study utilized pulsed light to control the rate of elementary steps in methanol decomposition [13], while another employed dynamic electrocatalytic modulation for formic acid decomposition [14]. Ongoing research efforts are dedicated to developing techniques and devices capable of inducing the necessary stimuli on catalytic surfaces to promote energetic fluctuations [15]. An interesting advancement is the “catalytic condenser”, a device that applies voltage to the surface, resulting in BE shifts of up to 0.2 eV [16–18]. We recognize that further experimental exploration is essential to validate the approach. Our goal is to have our computational frameworks leveraged to support experimentalists in developing methodologies for experimenting with real-life and industrially relevant reactive systems.

In this context, the present work builds upon our previous research on the simulation and of a unimolecular (“A-to-B”) dynamic catalytic system and the design of a forcing signal waveform [19]. The goal is to extend the framework to a more complex, intricate and industrially relevant system. Specifically, we draw on the work by Wittreich et al [20], who explored dynamic catalysis simulations for the synthesis of ammonia, one of the most important chemicals for modern society.

We use this broadly complex and detailed system as a case study to test and explore frameworks. Ultimately, our goal is to develop generalizable frameworks and tools for simulating dynamic catalysis processes and optimizing the waveform of the forcing signal. These frameworks would enable the identification of decision variables that yield the best outcomes in dynamic catalysis, paving the way for more effective catalytic systems.

The insights gained from results obtained with these frameworks are intended to guide experimentalists in developing techniques and devices for binding energy oscillations, as well as determining conditions for conducting experiments. We see this line of research as a foundational step toward the full application of dynamic catalysis. It lays the groundwork for extensive physical experimentation, progressing toward research on scaling up processes, and ultimately achieving widespread industrial implementation.

## METHODS

### Reactive System and Microkinetic Model

The reactive system for ammonia synthesis comprises 19 reversible reactions involving 16 chemical species. These reactions describe the adsorption and desorption of molecules to the catalytic surface, reactions

between adsorbates and their diffusion across the surface. The microkinetic model considers two distinct types of active sites on the surface, step and terrace sites. The compounds involved include the three gas-phase molecules, nitrogen, hydrogen and ammonia ($N_2$, $H_2$, $NH_3$, respectively), as well as six adsorbates on terrace sites and seven adsorbates on step sites.

In our previous work, we directly investigated the wave parameters of binding energy oscillations. In this study, the oscillation is of the stimulus source - compressive and tensile strain applied to the catalytic surface. The strain is represented by variations in the interatomic distances on the surface, which influence the d-band center of the atoms, leading to both physical and electronic rearrangements [21].

We developed our microkinetic model using Python and Pyomo based on the model developed by Wittreich et al [20] in MATLAB, using the data acquired and provided by the authors. This dataset includes results from energy calculations performed with Density Functional Theory (DFT) for a ruthenium-catalyzed system under three conditions: no strain, +4% compressive strain, and -4% tensile strain. The authors established linear scaling relationships with the data, enabling predictions beyond the specific parameters of the DFT calculations. A comprehensive and detailed description of the methodology used to generate the data is available in the Supporting Information of their publication [20].

The microkinetic model consists of thermodynamic and kinetic calculations to obtain a total of 38 rate constant ($k$) values, corresponding to the forward and reverse rates of each elementary step. Each applied strain value is linked to specific binding energy values, which in turn determine the rate constants. This mechanism explains the periodic favoring of different elementary steps: changes in the applied strain alter the rate constants, thereby influencing the rates at which individual steps occur.

The rate constants are parameters within the coupled system of Ordinary Differential Equations (ODEs) that describe the progression of the reaction over time, with the concentrations of all 16 compounds as the state variables. The complete list of reactions as well as the list of ODEs can be found in the Digital Supplementary Material.

## Sequential and simultaneous simulation workflow

By integrating Python and SciPy [22] with Pyomo.DAE [23] and the IPOPT solver [24], we developed a workflow to identify the cyclic steady-state behavior of the system under different forcing signal conditions and parameters. The unimolecular reactive system used in our previous study was small (four state variables) and simple enough that its solving process and run time were not significantly influenced by the initialization of the problem. However, in this ammonia synthesis system, we have observed that proper initialization is critical to the success of the simulation.

To address this, we developed a cascading framework consisting of the following steps: (1) performing a sequential simulation using Scipy's *integrate.solve_ivp* function until cyclic steady state; (2) using this solution as the initialization for a simultaneous simulation approach, employing the same forcing signal as in the sequential simulation; (3) progressively modifying the input conditions, while using the previous solution from the simultaneous simulation as the initialization for the subsequent iteration. Figure 2 presents a workflow block diagram illustrating the framework.

The sequential approach involves a simulation from initial conditions until cyclic steady state behavior for all the state variables, solving therefore an Initial Value Problem (IVP). Successful integration requires low tolerances and a small maximum step size, and the use of a solver that handles stiff problems, like Radau, LSODA or

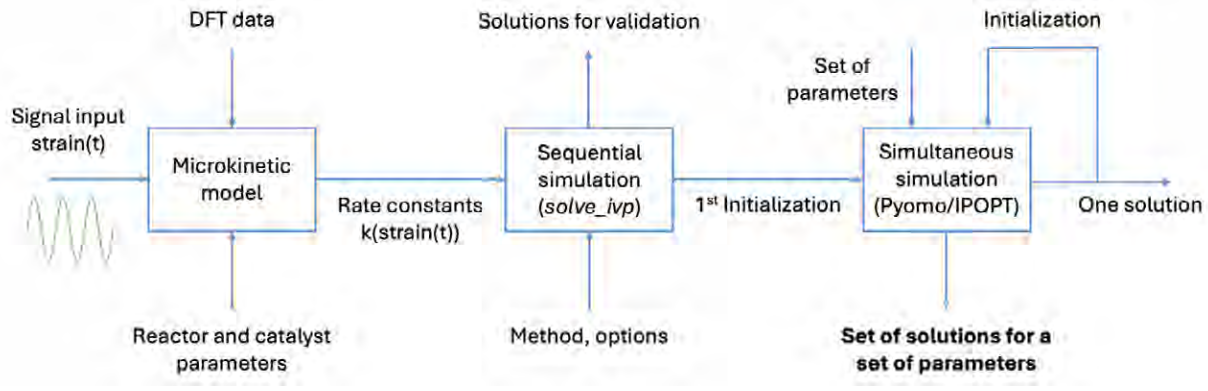

**Figure 2:** Workflow block diagram and systematic view of the simulation procedure.

BDF. Solving a sequence of simulations with this approach involves long computational run times.

The simultaneous simulation approach, in contrast, solves a Boundary Value Problem (BVP), using limit cycle or periodic boundary conditions. These conditions state that the initial and final points of a cycle need to have the same value, which defines the cycle steady state. The ODEs are automatically transcribed into algebraic equations using Pyomo.DAE and IPOPT then solves the square problem for all state variables at all discretized time points simultaneously, outputting a single cycle in the cyclic steady state for all variables [19].

As seen in later figures, the concentrations of the molecules in the reaction medium, which are the state variables, are generally very small, spanning several orders of magnitude - going from around $10^{-4}$ to $10^{-12}$ mol/cm$^3$. These units arise from the many thermodynamic and kinetic calculations that map data to rate constants. Even if the units were converted, the magnitude differences would persist. We explored various manual scaling strategies but found they did not significantly reduce the dependency on initialization or improve solver performance (e.g., reducing memory usage, enabling larger step sizes in the line search, or avoiding the need for restoration mode). However, we observed that scaling the time span (x-axis) had a noticeable impact on solver performance, though it still did not eliminate the dependency to a solid initialization.

In this paper, we focused on the parameters of a sine wave as the forcing signal for the oscillatory system: frequency, amplitude, and offset. The frequency dictates the number of cycles per second, while the amplitude and the offset values define the strain magnitude and its specific values, respectively. The use of strain values beyond those used to obtain the data (+4 and -4%) was done considering the linear scaling relationships can be extrapolated.

# RESULTS AND DISCUSSION

## Simulation framework outcomes

The simulation workflow, which combines initialization via sequential integration and a loop through parameters using the simultaneous approach, significantly reduced computational time compared to running a sequence of forward integrations for each parameter set. The initial single sequential simulation required 26 minutes to generate cyclic steady state results. Afterwards, the simulations for the almost 300 runs with the simultaneous approach were completed in under 10 minutes. Therefore, the total time required for our hybrid algorithm was of approximately 35 minutes. By comparison, if each of these runs had been performed sequentially, with each taking approximately 36 minutes, the total computational time would have been almost 220 times longer.

To validate the framework, several conditions were also simulated using the sequential approach, and the results were consistent with those obtained through the proposed workflow.

## Analysis of wave parameters and responses

The first parameter analyzed was the frequency of the forcing signal. The simulations depicted in Figure 3 were conducted with the default fixed amplitude of 0.04 and offset of 0, corresponding to a strain variation on the catalytic surface from -4% to +4%. From the figure, the average turnover frequency (avTOF) peaks around 500 Hz and declines for higher frequencies. While the absolute changes in values are small, the decrease in avTOF suggests that the rapid transitions between the high and low levels of the wave may not allow sufficient time for an elementary step to be favored in enough extent before the next switch occurs [4]. This result highlights the importance of selecting an appropriate forcing frequency, as operating at excessively high frequencies can also be energy intensive for the process.

Figure 4 was generated by fixing the frequency at 1000 Hz and varying the offset in values of 0.01, 0, and -0.01, individually, while simulating the system across different amplitudes ranging from 0.02 to 0.04. The blue points, representing an offset of 0.01, consistently show the lowest avTOF values for all amplitudes tested, indicating that applying high compressive strain is not favorable. For the default offset of 0, the results reveal an optimal amplitude near 0.024, while the default amplitude of 0.04 results in the lowest avTOF value within this configuration.

This result contradicts the intuitive conclusion drawn in our previous work: that higher amplitudes would lead to higher overall rates by reaching more extreme points of the Sabatier Volcano, where steps would theoretically be highly favorable. As observed for an offset of 0.01, the maximum avTOF occurs when the positive strain reaches the lowest value of 0.02, suggesting that applying excessive compressive strain may be detrimental to the efficacy of the system in achieving high reaction rates.

For an offset of -0.01, represented by the green curve, a maximum avTOF value similar to the one observed with an offset of 0 is achieved, reaching approximately 0.085 1/s for the amplitude of 0.03. The waveform corresponds to a strain oscillation ranging from -0.04 to 0.02. Once again, the analysis suggests that the maximum compressive strain should not exceed 2%. To improve the smoothness of this curve, we ran 100 iterations for this system, instead of 50, as for the others and lowered down the solver's tolerances.

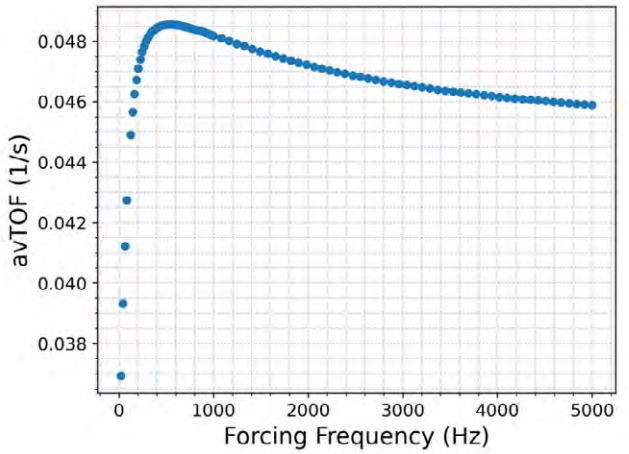

**Figure 3:** Comparison of avTOF results for different frequencies.

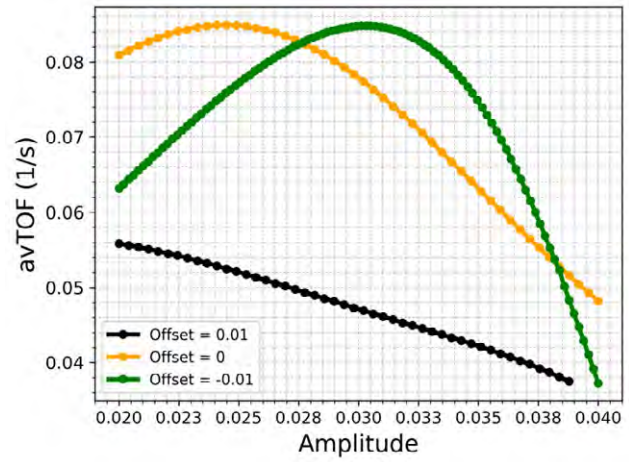

**Figure 4:** Comparison of avTOF results for different amplitudes and offsets - determining the range of strain oscillation.

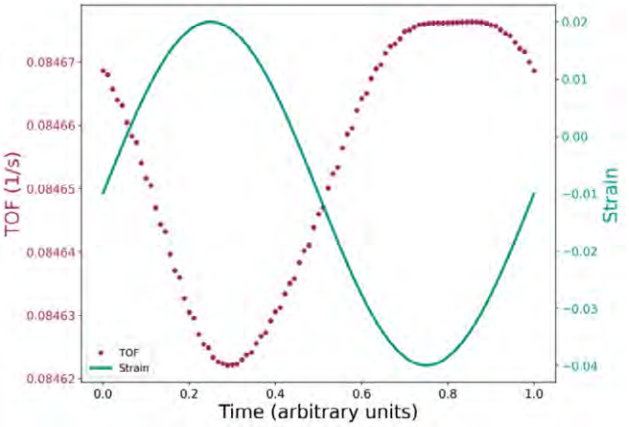

**Figure 5:** Sine wave forcing signal and turnover frequency response over the span of one cycle in cyclic steady state.

Figure 5 shows the shape of the sine wave and the TOF response for the case with higher avTOF for offset of -0.01, for one cycle in cyclic steady state. For this system, the TOF is calculated based on the concentration of reactants and products in the gas phase at each given moment. It is possible to see the mild delay in TOF response after the changes in direction by the sine wave. The first switch, around 0.3 in relative time, is rounder, and the next switch seems to stabilize in the higher value before going down. The causes for such difference are probably intrinsic to the responses of all the other species involved. Plots of the shapes for the concentration of all adsorbates can be found within the Digital Supplementary Material.

For comparison, the TOF of the static system, with no strain applied, is of 0.044 $s^{-1}$. As seen in figures 3 and 4, for some points the use of the oscillatory stimulus results in a lower overall rate than for the static case. This outcome underscores the importance of identifying the ideal wave parameters and carefully designing the forcing signal for dynamic catalysis systems.

As discussed in our previous work [19], analyzing the Extended Sabatier Volcano reveals important considerations for interpreting wave parameters optimality. According to different Sabatier Volcanoes in the literature [20, 26], ruthenium, the catalyst used in the working system, would be in the Sabatier Peak region, suggesting that oscillating symmetrically between either side of the volcano should be favorable. However, the shape of the volcano, which is highly influenced by the Bronsted-Evans-Polanyi relationship, must also be considered.

For instance, in the volcano shown in Figure 1 for the system discussed in our previous paper, the shape of the volcano led to an optimal range of binding energy values that is not symmetrically positioned on either side of the volcano. This observation highlights once again the need of computational investigations and the development of methods for simulating and optimizing input signals. The behavior of complex reactive systems is often non-intuitive and difficult to predict, emphasizing the importance of systematic exploration.

## CONCLUSIONS AND FUTURE WORK

In this work, we expanded on our previous research [19] and the contributions of Wittreich et al [20] to establish a structured and efficient way for simulating ammonia synthesis under Dynamic/Programmable Catalysis. Our approach combines an initialization strategy, based on forward integration results for a default system, with a looped simulation using a simultaneous approach to explore a range of sine wave parameters. The method has shown to improve the efficiency into simulating system with different parameters for forcing signal. Getting the same results solely with the sequential approach would take estimated 220 times more time.

This study represents a foundational step toward further modeling the system and refining the framework.

The next layer of complexity will involve accounting for lateral interactions between adsorbates on the catalytic surface. These interactions affect binding energies and thereby influence the entire dynamic system. With this consideration, the rate constants will depend not only on the applied strain but also on the concentrations of molecules - i.e., the state variables themselves - making the governing ODEs more intricate and their solutions more computationally demanding. To address this, we need to transition the current framework, which integrates Python and Pyomo, into a fully Pyomo-based framework. While this adaptation increases complexity, it will yield a more accurate and reliable microkinetic model by incorporating these essential interactions, which significantly influence the results of the simulations.

We will also extend this workflow to incorporate square wave forcing signals. Square waves, while increasing system stiffness due to their abrupt changes, have the potential for further enhancing the overall reaction rates [1, 4, 19]. From these results, we aim to optimize all wave parameters simultaneously to capture the interdependencies among them. This will require adapting the optimization frameworks from our previous work, particularly in terms of initialization strategies, to ensure convergence.

In parallel, we plan to apply this methodology to a different system, targeting formic acid decomposition (FAD). Like for the ammonia synthesis, the general reaction involves three molecules, but the reaction mechanism is complex and involves many molecules. In the case of FAD, it also involves competing reaction pathways, leading to undesirable products. Leveraging the insights gained from reproducing and adapting the microkinetic model of Wittreich et al [20], we will construct a model for the FAD system. An adjacent part of the work will be using machine learning potentials, trained within the Open Catalyst Project (OCP) [27], to generate input energy data. Our goal is to develop a comprehensive framework that integrates OCP data, microkinetic modeling, simulation, and waveform optimization, not only to enhance reaction rates but also to improve selectivity toward the desired products.

Ultimately, our intention is to develop a general framework for optimizing arbitrary waveforms as forcing signals for general dynamic catalysis reactions. We believe the results from this achievement will provide valuable guidance to experimentalists, enabling them to access the full potential of the promising technique of dynamic catalysis. Such advancements can pave the way for widespread implementation and realization of the benefits of the approach.

## DIGITAL SUPPLEMENTARY MATERIAL

Please access the GitHub repository for code used in this work: https://github.com/ccolomb2/dynamic_catalysis_NH3.git. The repository contains three notebooks that generate the figures presented and two csv files with data necessary to run the code.

## ACKNOWLEDGEMENTS

The authors thank Dr. Gerhard Wittreich for sharing MATLAB files used in previous work [28] and for relevant discussions around the concepts. We also thank Dr. Victor Alves and Laurens Lueg for insights into the work.

# Comparative Analysis of Conventional and Novel Low-Temperature and Hybrid Technologies for Carbon Dioxide Removal from Natural Gas

**Federica Restelli[a]* and Giorgia De Guido[a]**

[a] GASP - Group on Advanced Separation Processes & GAS Processing, Dipartimento di Chimica, Materiali e Ingegneria Chimica "G. Natta", Politecnico di Milano, Piazza Leonardo da Vinci 32, 20133 Milano, Italy

## ABSTRACT

Natural gas production is expected to increase, leading to the exploitation of low-quality reserves that contain high levels of acid gases, such as carbon dioxide. The aim of this work is to compare various innovative and conventional technologies for the removal of $CO_2$ from natural gas, considered as a binary mixture of methane and carbon dioxide, with $CO_2$ contents ranging from 10 to 70 mol%. The processes are simulated using Aspen Plus® V9.0 and compared in terms of energy consumption, which is evaluated through the net equivalent methane method. The results show that novel low-temperature and hybrid technologies, which combine distillation and physical absorption, are the most energy-efficient for $CO_2$ removal from natural gas with high acid gas contents, while conventional physical absorption processes are optimal for natural gas with low to moderate acid gas contents.

**Keywords**: natural gas, carbon dioxide removal, physical absorption, hybrid technologies, low-temperature distillation.

## INTRODUCTION

Global electricity consumption is projected to rise in the coming decades. To meet this growing demand sustainably, renewable energy sources and, among fossil fuels, natural gas are expected to see the most significant growth. As natural gas consumption increases, it will also become necessary to extract it from low-quality reserves, which often contain high levels of acid gases, such as carbon dioxide ($CO_2$) and hydrogen sulfide [1].

The aim of this work is to compare various innovative and conventional technologies for the removal of carbon dioxide from natural gas, considered as a binary mixture of methane and carbon dioxide. It first examines the performance of the physical absorption process using propylene carbonate (PC) as a solvent, along with a hybrid process in which it is applied downstream of low-temperature distillation. These results are, then, compared with previously studied technologies, including physical absorption with dimethyl ethers of polyethylene glycol (DEPG), low-temperature distillation, and hybrid processes that combine distillation and absorption [2]. The low-temperature distillation process considered here is the one described by Langé et al. [1]. It consists of two distillation columns operating at different pressures: the bulk $CO_2$ removal is performed in a high-pressure distillation column, typically operated at 50 bar such that $CO_2$ freeze-out is avoided, and the natural gas production at commercial grade is performed in a low-pressure column, typically operated at 40 bar (anyway lower than the critical pressure of methane).

The Fluor Solvent™ process, which uses PC as the solvent, was commercialized by Fluor in the early 1960s. Propylene carbonate is particularly advantageous, as noted by Bucklin and Schendel [3], when hydrogen sulfide is not present in raw natural gas. The bulk distillation + physical absorption finishing with PC is a new process that has been proposed for the first time in a patent by Xu [4]: no other references are in fact present in the literature about combined purification technologies for the natural gas purification in which propylene carbonate is involved.

The PC absorption process and the bulk low-temperature distillation + PC absorption process are

simulated using Aspen Plus® V9.0 [5]. The energy analysis is conducted using the net equivalent methane method. The processes are compared in terms of methane equivalent consumption, methane losses, and net produced purified methane, offering guidance on the optimal process based on the composition of the raw natural gas.

# METHODS

## Inlet and outlet stream conditions

The feed gas conditions are assigned in terms of temperature (35 °C), pressure (50 bar) and total flowrate (5,000 kmol/h). The raw natural gas is assumed to be a binary mixture of methane and carbon dioxide, having a $CO_2$ content ranging from 10 mol% to 70 mol%. When the $CO_2$ molar fraction is below 10 %, amine absorption is known to be a proven and cost-effective technology [1]. A $CO_2$ molar content of 70 % represents a sort of upper limit, indicating a reserve with an extremely low methane content [6].

The conditions for the purified gas are selected based on the requirements for pipeline network application. Therefore, the limit on the $CO_2$ content is set equal to 2 mol% [7]. The temperature of the purified natural gas is set to 25 °C, and the pressure is set to 50 bar, matching the operating pressure of the purification unit in the analyzed processes.

The $CO_2$ product stream is assumed to be injected underground for Enhanced Oil/Gas Recovery or sequestration and the specifications are assigned in terms of temperature (14.06 °C), pressure (50 bar) and maximum limit on hydrocarbons content of 2 mol%.

## Net Equivalent Methane method

The energy analysis is based on the "net equivalent methane" (NEM) method [8], which consists in the evaluation of the equivalent quantity of methane that must be burned to power a specific equipment piece. By using the same basis for the various types of energy, the NEM method allows a fair comparison between different processes. The energy requirements considered include: supplying electric power, heating above ambient temperature, and cooling below ambient temperature. Heating below ambient temperature and cooling above ambient temperature do not consume methane, as service water can be used to provide or remove heat, respectively.

### Supplying electric power

The gas compression and liquid pumping need electric power to be supplied. This electric power is assumed to be obtained by means of a methane-fired combined-cycle power plant. The amount of methane equivalent can be determined according to Eq. (1):

$$NEM = \frac{W}{\eta_{cc} \cdot LHV_{CH4}} \quad (1)$$

where $W$ indicates the mechanical power, $\eta_{cc}$ is the combined-cycle efficiency, assumed equal to 0.55, and $LHV_{CH4}$ is the lower heating value of methane, which is 50 MJ/kg.

### Heating above ambient temperature (> 25 °C)

The supply of heat to the process at temperatures higher than the ambient one is achieved through the use of low-pressure steam. The necessary amount of steam is provided by a boiler fed with methane: the equivalent methane flowrate consumed can be computed according to Eq. (2):

$$NEM = \frac{Q_{hot}}{\eta_b \cdot LHV_{CH4}} \quad (2)$$

where $Q_{hot}$ is the required thermal power, and $\eta_b$ is the boiler efficiency, assumed equal to 0.80.

### Cooling below ambient temperature (< 25 °C)

The removal of heat from the process at temperatures lower than the ambient one requires the use of a proper refrigeration cycle. This refrigeration cycle requires mechanical work to be operated, which is considered to be provided by a combined-cycle plant powered by methane. To calculate the amount of methane equivalent to the required mechanical duty, first it is necessary to compute the coefficient of performance (*COP*) of the refrigeration cycle from Eq. (3):

$$COP = \left(\frac{T_0}{T_f} - 1\right)^{-1} \cdot \eta_{II} \quad (3)$$

In Eq. (3), the term in brackets is the coefficient of performance of an ideal Carnot cycle, that is calculated knowing the temperature of the hot reservoir (the ambient temperature $T_0$ = 25 °C) and that of the cold reservoir (the final temperature reached at the outlet of the cooler, $T_f$). $\eta_{II}$ is the second law efficiency, which is defined as the ratio between the efficiency of the system and the theoretical maximum possible one. $\eta_{II}$ is assumed equal to 0.60.

By definition of the *COP*, the mechanical duty $W$ can be computed given the cooling duty, denoted as $Q_{cold}$, to be removed from the system (Eq. (4)).

$$W = \frac{Q_{cold}}{COP} \quad (4)$$

Therefore, the amount of equivalent methane can be determined according to Eq. (5):

$$NEM = \frac{Q_{cold}}{\eta_{cc} \cdot COP \cdot LHV_{CH4}} \quad (5)$$

# PROCESS SIMULATION

The processes are simulated using Aspen Plus® V9.0 [5]. Physical absorption is modelled with the "Acid gas:

physical solvents" property package, which exploits the PC-SAFT Equation of State (EoS). AspenTech suggests the use of this EoS for simulating physical absorption cleaning processes in the syngas and natural gas industry. To simulate hybrid processes, the flowsheet is divided into two sections. In the first one, related to bulk removal by low-temperature distillation, the Soave-Redlich-Kwong (SRK) Equation of State is selected, while the second section, which corresponds to the physical absorption and subsequent solvent regeneration, is modelled with the PC-SAFT EoS.

To be consistent with the results obtained by De Guido et al. [2], the same simplified assumptions for unit operations are applied: absorbers, distillation columns and heat exchangers provide no pressure drops; isentropic efficiency of compressors and pumps is set equal to the software's default value; the Efficiency Mode is used to simulate the absorption unit, assuming unitary efficiency for each stage. This simplified approach may result in an underestimation of energy consumptions. However, the primary goal of this work is to compare the processes relative to one another, rather than to provide an accurate estimate of methane consumption. Therefore, as long as the assumed values are applied consistently across all considered cases, the comparison remains valid.

After simulating the base configuration of the processes, energy-saving schemes, incorporating heat integration based on pinch analysis, are considered for each process.

## Propylene carbonate absorption process

The Process Flow Diagram (PFD) of the propylene carbonate absorption process is depicted in Figure 1.

The feed gas (FEED) is mixed with recycle streams from the regeneration section (vapors from FLASH-HP and FLASH-MP) and, then, cooled to a proper inlet temperature for the absorption column. To maintain a smooth temperature profile in the absorber, the inlet gas temperature is set equal to the temperature of the rich solvent stream exiting the bottom of the absorber minus 0.3 °C. The absorber has 10 stages: gas is fed at the bottom while propylene carbonate flows in counter-current from the top. It operates at 50 bar, with no assumed pressure drops inside the absorption tower.

According to Burr and Lyddon [9], the operating range for the propylene carbonate solvent is between -18 °C and 65 °C. For this simulation, the PC temperature is set to -15 °C, as reported by Freireich and Klooster [10] for a process in which the pressure of the absorber is 56.2 bar.

The solvent flowrate is determined to achieve a residual $CO_2$ molar content of 2 % in the purified gas.

Regeneration occurs through a series of three flashes at progressively decreasing pressures, with the first two being adiabatic. The pressure levels are chosen based on an example of a real plant reported by Mokhatab et al. [7]. Specifically, the pressure of the first flash is kept equal to 31.7 bar, and the pressure of the second flash is initially set to 13.1 bar, as in the reference example. However, the intermediate flash pressure may need some adjustments to meet the $CO_2$-stream purity requirements for reinjection. Results indicate that this adjustment is necessary when the feed molar $CO_2$ content is below 20 %. Above this threshold, the $CH_4$ molar fraction in the $CO_2$-OUT stream naturally becomes very low due to the reduced amount of methane processed. The last flash operates at atmospheric pressure. After conducting a sensitivity analysis, a pressure of 18 bar, as used by De Guido et al. [2] for absorption with DEPG

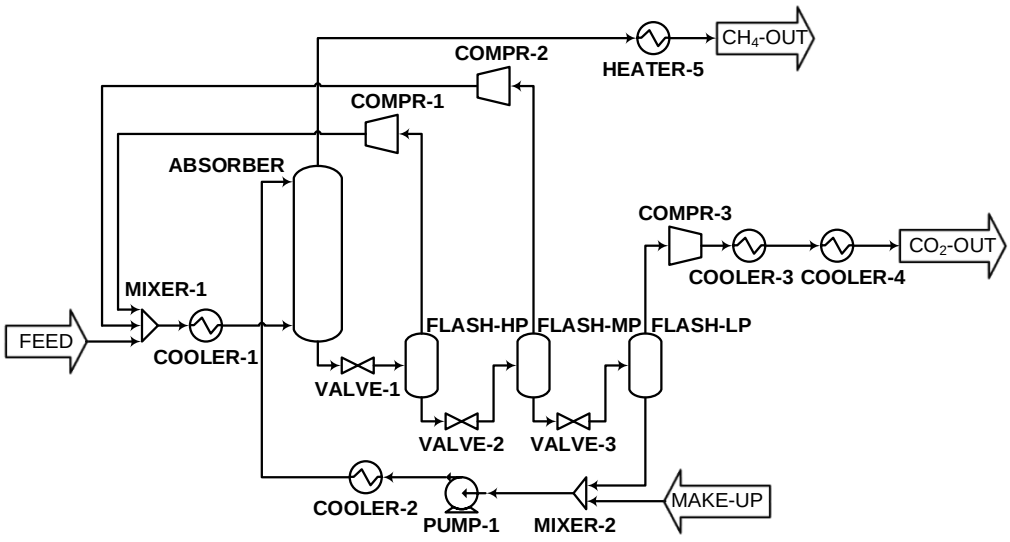

**Figure 1.** PFD of the propylene carbonate absorption process.

solvent, is adopted for the high-pressure vessel when the $CO_2$ molar content is below 20%, as this reduces methane consumption.

The vapor stream from the last flash can be used for reinjection purposes. Atmospheric flash vapors are recompressed to 50 bar in COMPR-3 and, then, cooled down to the bubble point temperature in a battery of two heat exchangers: COOLER-3 and COOLER-4. In the former, the $CO_2$ stream is cooled to ambient temperature (25 °C) using service water, while in the latter the final required temperature of 14.06 °C is reached employing a refrigeration cycle: decoupling these contributions is important, as only the duty related to the last cooler is considered in the energy consumption calculation.

Vapors from the first two flashes are recycled back to the absorber after being recompressed to 50 bar: this recycle is crucial because phase separation at high pressure generates a vapor stream with high methane content, and recycling helps minimize methane losses.

Since the maximum allowed residual $CO_2$ molar content in the purified gas is 2%, the regenerated solvent purity must be at least 98% to provide the necessary driving force for absorption. To ensure an adequate margin, the lean solvent molar purity is set at 98.5%. Solvent purity can be controlled by modifying the FLASH-LP duty.

Solvent losses occur with both $CH_4$-OUT and $CO_2$-OUT streams. Although these losses are small, they are significant enough to require a make-up stream to maintain the circulating solvent flowrate under steady-state conditions. After the introduction of the make-up stream, the regenerated solvent is pumped to 50 bar and cooled to -15 °C in COOLER-2, preparing it for re-entry into the absorber.

## Bulk low-temperature distillation + propylene carbonate absorption process

The PFD of the bulk low-temperature distillation combined with the PC absorption process is illustrated in Figure 2. The distillation unit treats the raw gas to reduce the $CO_2$ content to 20 mol%. The final gas purity is, then, achieved through PC absorption. This process is only simulated for $CO_2$ molar contents greater than 20 % since below this threshold, the process becomes a simple PC absorption operation, eliminating the need for hybrid technology.

The raw gas is expanded to 40 bar and cooled to its dew point in COOLER-6 before being fed into the distillation column (DISTILL-COL). In this column, the specifications are the number of theoretical equilibrium stages (20), the residual $CO_2$ molar fraction in the vapor stream exiting from the top (20 %) and the molar purity of the $CO_2$ product stream obtained at the bottom (99.99 %). The optimal feed tray location, for which the condenser duty is minimized, is immediately above the third tray from the top, independently from the feed composition. Such a high optimal feed location is justified considering that for methane a very rough separation is required (up to 20 mol% residual $CO_2$ in the top product), while at the bottom almost pure carbon dioxide must be obtained.

The separated liquid $CO_2$, with a purity of 99.99 mol%, is pumped to 50 bar and slightly heated to 14.06 °C in HEATER-7 using service water.

The partially purified natural gas is, then, compressed from 40 bar to 50 bar in COMPR-4 before

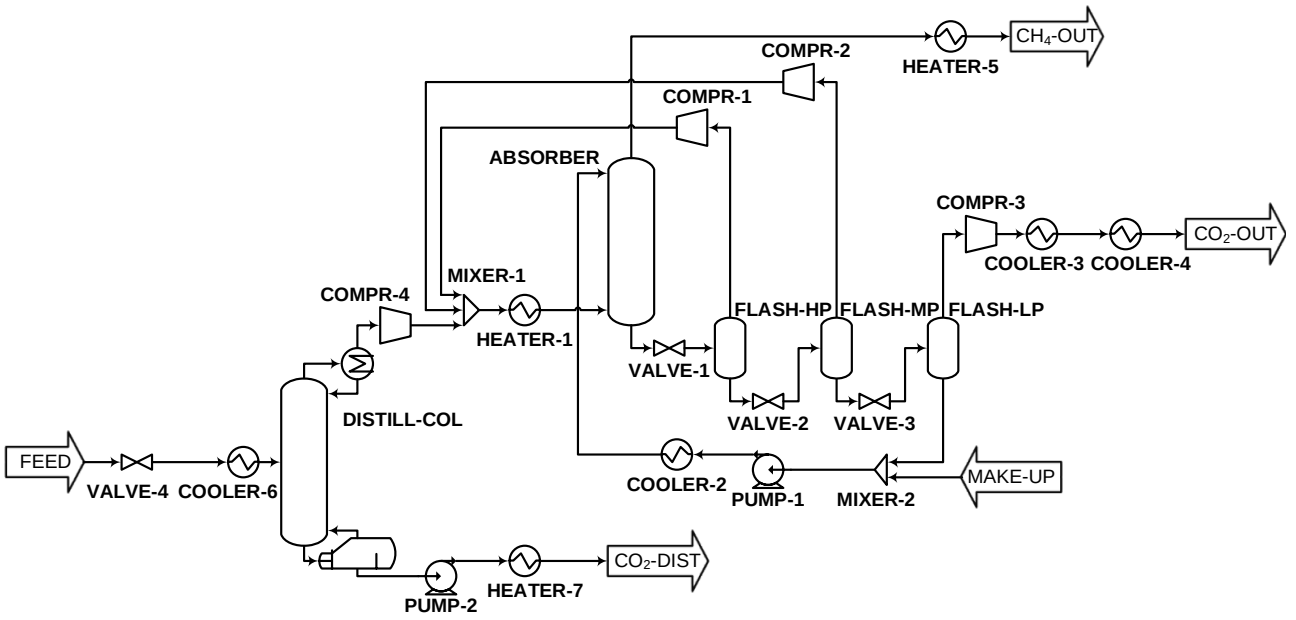

**Figure 2.** PFD of the bulk low-temperature distillation + propylene carbonate absorption process.

entering the absorption section. Absorption is carried out at 50 bar, with a PC feed temperature of -15 °C, consistent with the simple PC absorption process previously discussed. The compressed gas, containing 20 mol% residual $CO_2$, is mixed with vapor recycle streams from the first two flashes in the solvent regeneration section. The resulting stream is heated in HEATER-1 to reach the same temperature, as in the simple PC absorption process. In the absorber, the $CO_2$ content is reduced to 2 mol%.

The $CO_2$-rich solvent exiting the bottom of the absorber is sent to the regeneration section, which operates under identical conditions to those used for the simple PC absorption process when handling a feed stream with 20 mol% initial $CO_2$ content. Vapors from the last flash are recovered for reinjection purposes.

The regenerated lean solvent, with a molar purity of 98.5 %, is pumped back to 50 bar and cooled to -15 °C, preparing it for reuse in the absorption unit.

## RESULTS AND DISCUSSION

The results reported in the following are obtained by applying the NEM method to convert the energy consumptions, retrieved from process simulations, into methane consumptions. To enable a meaningful comparison among the investigated processes, optimized process schemes, incorporating heat integration based on pinch analysis, are considered.

The results in terms of NEM consumption and methane losses in the $CO_2$-rich streams obtained for the PC absorption process and its corresponding hybrid version, together with the technologies studied by De Guido et al. [2], are reported in Figure 3 and Figure 4, respectively. The methane losses in the $CO_2$-rich streams are expressed as a percentage of the methane fed.

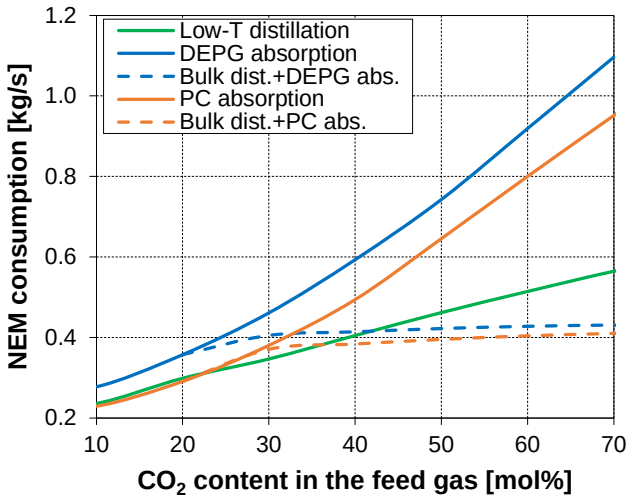

**Figure 3.** Comparison between $CO_2$ removal technologies in terms of NEM consumption.

Looking at Figure 3, it can be observed that physical absorption with PC solvent consumes less energy than with DEPG solvent across the entire range of $CO_2$ contents studied. It also performs slightly better than low-temperature distillation for $CO_2$ concentrations between 10 and 25 mol%. For $CO_2$ contents in the feed gas between 25 and 35 mol%, the process with the lowest energy requirements results to be the one based on low-temperature distillation. Above 35 mol% $CO_2$ in the feed gas, the hybrid process, where the finishing step is carried out using PC physical absorption, becomes more efficient.

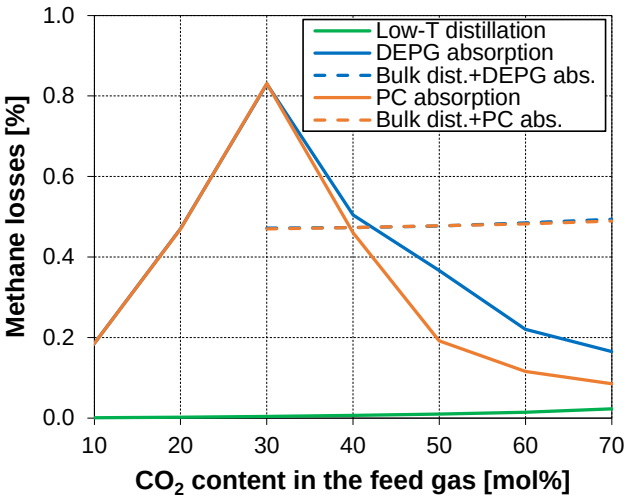

**Figure 4.** Comparison between $CO_2$ removal technologies in terms of methane losses.

From Figure 4 it is possible to notice that up to 30 mol% $CO_2$ content, the methane losses for the two physical absorption technologies considered are the same, due to the imposed specification of 2 mol% methane content in the $CO_2$ product stream. Above a $CO_2$ content in the feed gas of 30 mol%, the percentage of methane lost in this stream falls below the limit of 2 mol % and losses are related to the solubility of methane in physical solvents at atmospheric pressure, which is the pressure set in the last regeneration flash, and at the temperature reached in this non adiabatic flash, which is about 11 °C when PC is used as solvent, and 61 °C when DEPG is used. The propylene carbonate absorption process shows the lowest methane losses because methane's relative solubility in PC is less than in DEPG (0.038 *vs* 0.066 at 25 °C [9]) and due to the lower operating temperature of the FLASH-LP. It is also worth noting that, in the low-temperature distillation process, methane losses are essentially negligible due to the imposed specification on $CO_2$ product purity. For hybrid technologies, methane losses show a flat trend. The lost methane is almost independent of the $CO_2$ content in the feed gas, as the bulk separation is performed in the distillation

section, where a high-purity $CO_2$ stream is removed. Methane losses are similar for both PC and DEPG hybrid technologies.

Net purified methane is defined as the percentage of methane in the raw gas that exits the process in the sales gas, minus the amount of methane burned to operate the process. This parameter takes into account both the equivalent methane consumption, which is a measure of energy requirements, and methane losses, which depend on the nature of the separation process (distillation and/or absorption). Referring to the graph in Figure 5, the best process selection is indicatively:

- PC absorption or low-temperature distillation in the range 10 - 15 mol% $CO_2$;
- low-temperature distillation in the range 15 - 50 mol% $CO_2$;
- hybrid processes, with a slight preference for bulk low-temperature distillation + PC absorption, above 50 mol% $CO_2$.

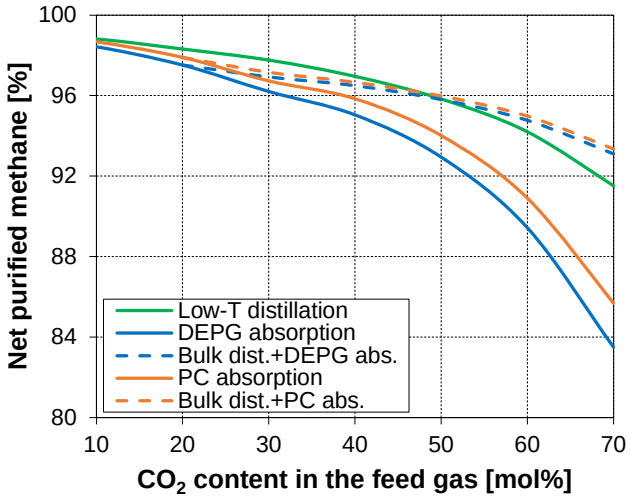

**Figure 5.** Comparison between $CO_2$ removal technologies in terms of net purified methane.

## CONCLUSIONS

The analysis carried out in this work is relevant to the upgrading of low-quality natural gas through $CO_2$ removal and underground storage, offering a climate change mitigation solution by utilizing methane, the cleanest fossil fuel, and securely storing $CO_2$. The focus is on identifying the most energy-efficient $CO_2$ separation technology for natural gas, which mainly contains methane and carbon dioxide, depending on the $CO_2$ content.

For moderate $CO_2$ contents, below 15 mol%, both physical absorption with propylene carbonate and low-temperature distillation are good options, with propylene carbonate outperforming other physical solvents (e.g., DEPG) due to lower $CH_4$ losses with the solvent. For higher $CO_2$ contents, from 15 to 50 mol%, low-temperature distillation is the most convenient process, in fact, by avoiding the use of a solvent, the energy requirements of the plant are less sensitive to the $CO_2$ content in the feed. For very high $CO_2$ concentrations (> 50 mol%), hybrid technologies are optimal, with the propylene carbonate-based process being the most efficient one.

## ABSTRACT

Temperature regulating in liquid tanks is critical in the chemical industry and conventionally relies on sensor feedback. However, due to the complex thermo-hydrodynamics, unsensed local temperatures can deviate from desired thresholds, underscoring the need for improved tank temperature modeling. The absence of internal thermal or flow data, however, poses significant challenges for the development and validation of effective control strategies. In this study, a virtual model for regulating liquid tank temperature was developed using computational fluid dynamics (CFD). Adaptions were made mainly by involving (1) a simple on-off mechanism of feeding based on a virtual sensor to achieve temperature within the acceptable range and (2) the imposition of unfavorable temperatures on the walls representing ambient influences. Leveraging this virtual system, several new cases were simulated. The simulation results highlighted pronounced temperature non-uniformity, with discrepancies exceeding 2°C between sensor readings and interior points, even leading to inefficiencies of regulatory mechanism. Additionally, the buoyancy was found to significantly influence the internal thermal distributions, and proper outlet position can help alleviate the temperature non-uniformity. Thus, the proposed CFD model serves as a reliable platform for generating comprehensive datasets to support temperature regulation studies in liquid tanks.

**Keywords**: Liquid tank, temperature regulating, CFD, thermal non-uniformity, stratification, buoyancy.

## INTRODUCTION

Liquid temperature non-uniformity is a widespread issue in the chemical industry and thermal management. For instance, maintaining minimal temperature differences within materials should be crucial, as emphasized by the pharmaceutical and food industries, which prioritize thermal uniformity during heating processes [1,2]. Moreover, uneven temperature distribution can cause discomfort for living beings in facilities such as public baths and aquariums.

However, it is impractical to install many physical sensors in the above facilities to measure local temperatures, and current temperature regulation systems often assume uniformity within the unit [3,4]. It is well-established that density variations caused by temperature differences can result in thermal stratification, where buoyancy drives less dense fluid upward. Consequently, sensed temperatures often deviate from actual internal values, leading to less effective control. Fortunately, recent studies have begun addressing this issue through soft-sensor development. Experimental research involving local temperature measurements and flow field visualization has been conducted [4,5]. However, experiments are labor-cost and limited by the availability of facilities.

Computational fluid dynamics (CFD) offers a powerful alternative by providing detailed internal temperature distributions to inform regulation systems. CFD excels at handling complex thermo-hydrodynamics by solving the

Navier-Stokes equations coupled with the energy equation. Control-integrated CFD models have been employed for over a decade to optimize air-conditioning control strategies, despite concerns about computational cost [6]. More recently, CFD has been combined with deep learning frameworks for indoor environmental control [7]. With advancements in computational hardware, CFD is poised to play an increasingly significant role in developing temperature regulation systems.

However, CFD is still underutilized for liquid temperature regulation. A CFD-based model can facilitate system design refinement with quantified insights into thermal field distributions but requires a highly adaptive interface for diverse industrial scenarios and considerable computational resources. Recently, water stratification was investigated thoroughly for energy storage, taking up to 18 days of computation per case [8]. Over the past decade, the open-source CFD software OpenFOAM has gained traction due to its fully adaptable framework, making it a valuable tool for customizing industrial processes. With the rapid expansion of data centers, advancing CFD-based temperature regulation becomes increasingly essential for improving product quality and energy efficiency in industries.

This study aims to bridge the above research gap by introducing the CFD method into the investigation of liquid temperature regulation in a tank. An original CFD model was developed using the OpenFOAM framework and validated against experimental data. The model was adapted as a virtual temperature regulation system, involving ambient temperature influences and integrated with a simple on-off control mechanism. Several regulation scenarios via heating and cooling were simulated and analyzed. The results demonstrated that thermal non-uniformity was well captured, revealing severe temperature discrepancies between interior locations and the virtual sensor. These discrepancies can even disable the regulatory mechanism under severe stratification conditions. The effects of outlet and sensor positions were also investigated in cooling scenarios. Our model enables an in-depth analysis of thermal stratification and regulatory performance, providing a foundation for optimizing system design and control strategies.

## MODELING

### Validation of the original CFD model

In a previous study [5], we encountered stratification issues in a water tank during the development of a soft sensor. Hot water (50 °C) was fed from the top side into a tank filled with cold water (10 °C) at a flow rate of 770 ml/min (or equivalent to 0.1889 m/s at the inlet), which exhibits complexity of natural and forced convections due to strong buoyant influences. Due to the similar main mechanisms existing in our following case study, this original case is suitable to examine our CFD settings. The solver buoyantPimpleFoam in OpenFOAM9 was adopted due to its capability to resolve transient thermo-hydrodynamics. The thermo-physical properties of water were assumed to be temperature-dependent, as described in reference [8], and the same formulations for density, heat conductivity, specific heat capacity, and viscosity were employed. The velocity of 0.1889 m/s was set at the inlet and the gauge pressure=0 Pa was set at the outlet.

Figure 1 (a) illustrates the original CFD model, which conforms to the experimental dimensions. Within the tank, the locations B1M (0.046 m, -0.046 m, 0.0635 m) and C3T (0 m, 0.092 m, 0.127 m) were monitored, consistent with reference [5] where temperature measurements were taken using thermocouples. For subsequent work, we also recorded temperature data from interior locations and a near-outlet sensor, making B1M and C3T suitable validation points. Hybrid mesh system is adopted, with 1.67 million grids in total. Hexa grids are dominant while unstructured grids are near the top to adapt inlet and outlet, as observed at the section X = -0.08 m. As shown in Figures 1(b) and (c), the CFD model results are consistent with experimental data.

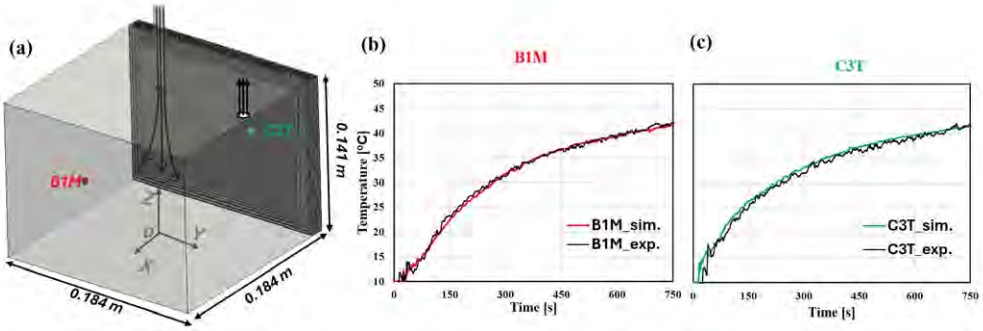

**Figure 1.** (a) The original CFD model used for validation, showing grid distribution at the section X = -0.08 m; temperature variations at (b) B1M and (c) C3T, comparing simulation results with experimental data.

**Table 1.** Case conditions

| Case no. | 1 | 2 | 3 | 4 | 5 |
|---|---|---|---|---|---|
| Target (initial) temperature [°C] | 25 | 20 | 45 | 20 | 20 |
| Fed temperature [°C] | 60 | 10 | 10 | 10 | 10 |
| Ambient temperature [°C] | 15 | 25 | 55 | 25 | 25 |
| Drain nozzle (/sensor) location | top | top | top | Middle | bottom |
| Simulated time [s] | 1200 | 1200 | 1200 | 1200 | 1800 |

*The flow rate is always 770 ml/min (or 0.1889 m/s at the inlet)*

## Adaption and control system integration

The model was adapted by installing the inlet tube on the side of the tank, as shown in Figure 2(a). The inlet velocity and tank size were inherited from the validated CFD model (Figure 1(a)). Hexa-dominant hybrid grids are still adopted with unstructured ones constructed near the side with the inlet and outlet. Another interior location, B2M (0.046 m, 0.046 m, 0.0635 m), was added for temperature monitoring. Notably, three optional outlet positions (diameter = 9 mm) were considered, with center coordinates as follows: top (0 m, 0.078 m, 0.127 m), middle (0 m, 0.078 m, 0.014 m), and bottom (-0.078 m, 0.078 m, 0.0635 m). Corresponding near-outlet sensors (sensorT, sensorM, and sensorB) were positioned 0.014 m from the outlet centerline. When the outlet was at the top or bottom, only half of the domain was simulated using symmetric boundary conditions to save computational cost.

Table 1 summarizes all cases in this study, and Figure 2(b) illustrates the boundary conditions for Case 1 as an example. Unlike the adiabatic wall conditions in the original model (Figure 1(a)), all tank sides were simplified to imposed ambient temperatures, except for the bottom (representing the ground), to simulate environmental influences. The initial tank temperature was set to the target value in all cases. Cases 1 and 2 can be taken as typical regulation scenarios via heating and cooling in winter and summer, respectively. However, regulation issues were identified in Case 2, leading to the design of Cases 3-5 for further analysis. Except for Case 3, the target temperatures were set at 25 °C for heating and 20 °C for cooling.

The on-off control mechanism was implemented using programmable boundary conditions in OpenFOAM via codeStream. The inlet velocity was set to 0.1889 m/s ("On") or 0 m/s ("Off") based on feedback from the virtual sensor. In the heating scenario, the control mechanism was defined as follows:

$$\begin{cases} \boldsymbol{Off},\ T_{sen} \in (T_{targ}+1, +\infty) \\ \boldsymbol{Remain}\ on\ or\ off,\ T_{sen} \in [T_{targ}-1, T_{targ}+1] \\ \boldsymbol{On},\ T_{sen} \in (-\infty, T_{targ}-1) \end{cases} \quad (1)$$

where the $T_{sen}$ represents the sensed temperature, and $T_{targ}$ denotes the target temperature for regulation. In the cooling scenario, the mechanism was reversed, with "On" and "Off" conditions switched in Eq. (1). To account for control system delays in real-world applications, the acceptable temperature range was set to $[T_{targ}-1, T_{targ}+1]$. To illustrate the regulatory mechanism, an additional sensor (sensor0) was embedded to record velocity magnitude at the inlet tube connection, as depicted in Figure 2(b). The temperature at sensorT and the velocity at sensor0 are shown in Figure 2(c), with data after 600 s omitted for brevity due to repetitive patterns. To reach target temperature at sensorT, the water (60 °C) supply was turned off when the temperature at sensorT reached 26 °C and resumed when it dropped below 24 °C, corresponding to "Off" and "On" states, respectively.

# RESULTS AND DISCUSSIONS

## Temperature non-uniformity issue

Significant temperature non-uniformity was observed in Case 1. As shown in Figure 3(a) and (b), the

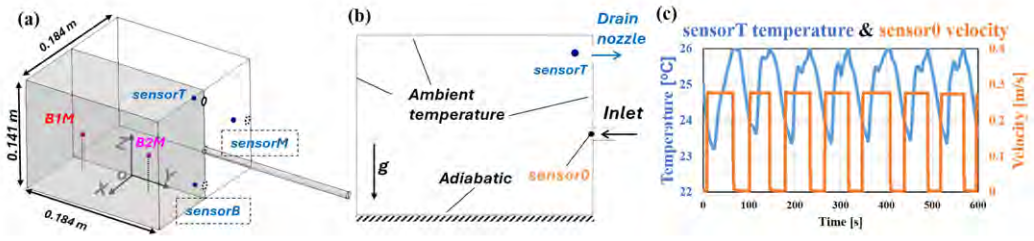

**Figure 2.** (a) Adapted CFD model with monitored points and optional outlet/sensor positions for case study; (b) I illustrations of boundary conditions; (c) the temperature at sensorT and velocity at sensor0 for Case 1.

temperatures at B1M and B2M began to oscillate steadily around certain levels after approximately 600 s. The calculated mean values between 600 s and 1200 s were 22.6 °C, 22.8 °C, and 24.9 °C at B1M, B2M, and sensorT, respectively. These results indicate temperature deviations at interior locations (B1M and B2M) of more than 2 °C from the target (25 °C), even though the control system maintained the sensor's temperature close to the target value. More seriously, as shown in Figure 3(c), at 835 s during the "on" state, temperatures below B1M and B2M were even lower, while some regions near the tank top exceeded 26 °C, further demonstrating stratification.

A more serious issue occurred in the cooling scenario (Case 2), where the regulatory mechanism operated abnormally due to the thermal stratification. As observed in Figure 4(a), the temperature at the sensor could not drop below the acceptable upper limit (21 ˚C) and failed to reach the off-triggering threshold (19 °C) throughout the simulation. Consequently, continuous cooling water feeding caused overcooling inside the tank. As shown in Figure 4(b), the mean temperature at B2M dropped to 17.9 ˚C after 900 s. Additionally, Figure 4(c) reveals that cooler regions persisted below B1M and B2M, indicating severe thermal non-uniformity.

## Analyses on the regulation failure

Stratification in the cooling scenario was characterized by weak mixing effects, which disabled the regulatory mechanism. As shown in Figure 4(c), velocity vectors beneath B1M and B2M (highlighted in red frames) displayed swirling patterns, indicating the difficulty in transporting cold water into regions of retained hot water above. Some upward convection near the wall (black frame) was observed but was insufficient due to heating from ambient temperatures 25 °C imposed on the wall. Consequently, the thermal mixing was weak in Case 2, preventing the "off" state from being triggered.

Buoyancy was found to dominate stratification formation during thermal regulation. Figure 5(a) and (b) present temperature distributions at the central section (X = 0 m) during the "on" state for Cases 1 and 2, respectively. Buoyancy deflected the fed flow along its direction. In Case 3, which shared identical absolute temperature differences with Case 1 ( $|T_{targ} - T_{fed}| = 35$ ˚C, $|T_{amb} - T_{fed}| = 45$ ˚C, $T_{fed}$ and $T_{amb}$ denote the fed and ambient temperatures, respectively), the stratification became more severe compared to Case 2. This ruled out temperature difference as the main factor for regulation failure and emphasized the stronger buoyant effects in Case 3, where greater density differences were present. Unfortunately, Case 3 also failed to trigger the "off" state. Buoyancy in Case 3 redirected the fed flow in the opposite direction of the outlet, contributing to stratification.

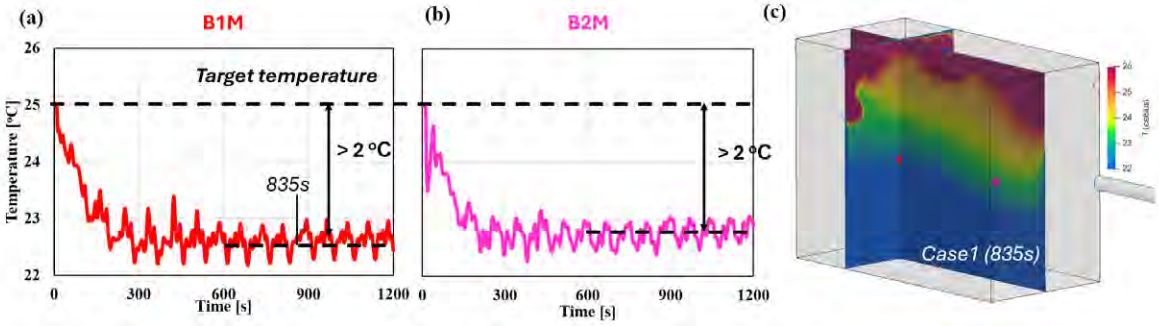

**Figure 3.** Case 1 results: temperature variations at (a) B1M and (b) B2M; (c) temperature contour at 835 s.

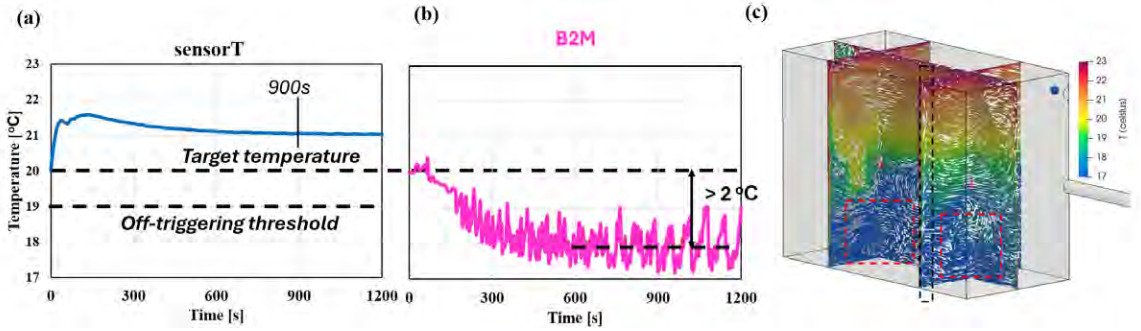

**Figure 4.** Case 2 results: temperature variations at (a) sensorT and (b) B2M; (C) temperature contour with velocity vectors at 900 s.

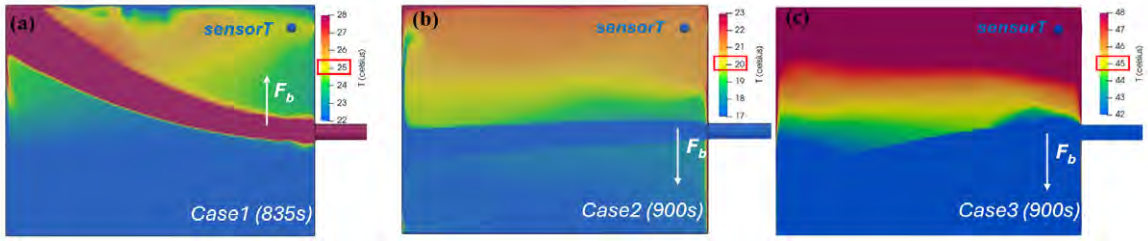

**Figure 5.** Temperature contours at the tank center (section at X = 0 m) for (a) Case 1 (835s) (b) Case 2 at 900 s and (c) Case 3 at 900 s. Framed values on legend indicate target temperatures for corresponding cases.

In contrast, buoyancy in Case 1 aided regulation by pushing fed water toward the outlet, enabling the sensor to detect variations effectively.

## Influences of the outlet position

To activate the "off" state, outlet positions and their corresponding sensors were varied. Cases 4 and 5, sharing identical initial, target, fed, and ambient temperatures with Case 2, positioned outlets in the middle and bottom of the tank, respectively. Notably, Case 4 required simulating the entire domain, unlike the half-domain simulations in other cases, due to symmetry breaking. As shown in Figure 6(a), the middle outlet in Case 4 failed to trigger the "off" state, with sensorM temperatures remaining above 19 ˚C even after 1200 s elapsed. In contrast, Case 5 successfully activated the on-off mechanism (see Figure 6 (d)), but its oscillation cycles (average more than 200 s) were longer than those in Case 2 (average less than 100 s). The simulation for Case 5 was extended to 1800 s to capture steady oscillation patterns while conserving computational resources.

Varying the outlet position cannot eliminate stratification, but it can alleviate non-uniformity severity. As demonstrated in Figure 6 (c), the stratification still exists in Case 4, although temperatures at B2M is nearly stable at the target level (see Figure 6 (b)). In Case 5, despite the mean temperature value at sensorB (Figure 6 (d)) is 20.1 °C between 900 s and 1800 s, the B2M's mean value is 22.1 °C, 2 °C higher than the target level (Figure 6 (e)). Among Cases 2, 4, and 5 (Figure 4(c), Figure 6(c), and Figure 6(f)), the top outlet in Case 2 resulted in the least severe stratification, while Case 5 showed the worst distribution, with over half the regions exceeding 22 °C (Figure 6(f)), despite normal regulatory operation. This can be attributed to the higher-temperature water being retained at higher locations, making it easier to discharge through a top outlet. Conversely, fed cold water tended

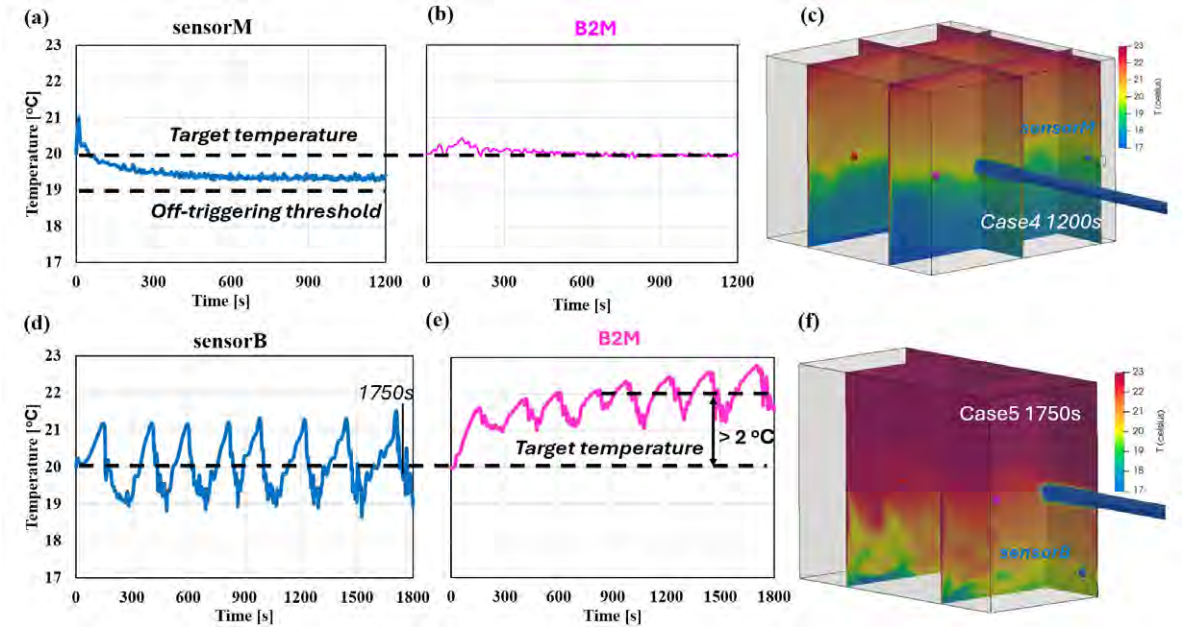

**Figure 6.** Temperature variations in Case 4 at (a) sensorM and (b) B2M; (c) temperature contour of Case 4 at 1200 s; Temperature variations of Case 5 at (d) sensorM and (e) B2M; (f) temperature contour of Case 5 at 1750 s.

to accumulate at lower locations, facilitating its exhaustion through a bottom outlet. Therefore, it is advisable to position the outlet on the side opposite to the buoyancy direction, while the resolving of regulation failure should resort to other strategies except for outlet positions.

### Modifications in future work

In summary, the temperature regulations in this study faced challenges due to stratification and abnormal operations. The single input fluid combined with an on-off control mechanism failed to achieve uniform temperature distribution at the target level. Future strategies can consider adding internal circulation procedure in the regulation mechanism (e.g., the thermo-on/off control in air-conditioning) or using our proposed dual-input systems [9]. Previous research on soft sensors may also provide solutions, particularly given the difficulties in increasing the number of internal sensors [4,5].

## CONCLUSIONS

A CFD-based temperature regulation model for a liquid tank was developed by adapting a validated CFD model. An on-off control mechanism was integrated with $\pm$ 1 °C relative to the target temperature as the acceptable limits. Both heating and cooling regulating scenarios were simulated to investigate the temperature non-uniformity inside the tank. The following conclusions were drawn: (1)buoyancy can induce thermal stratification, leading to interior temperature discrepancies exceeding the acceptable range relative to the target value; (2) thermal stratification can even disable the regulatory mechanism in cooling scenarios, as the conventional near-outlet sensor fails to drop below the "off" triggering threshold (acceptable lower limit) ; (3) Positioning the outlet on the side opposite to the buoyancy direction can mitigate (but not eliminate) thermal non-uniformity by facilitating the removal of retained water.

In summary, our virtual CFD model can provide detailed thermal field information during liquid temperature regulation, offering a controlled environment to explore the system improvement without experimental constraints. The insights gained from the thermal field analysis can guide the development of more effective temperature regulation designs and strategies.

## ABSTRACT

Mathematical modelling and simulation are pivotal components in process systems engineering. Focusing on polymerization process systems, identifying microscopic properties of polymers is highly sought after for advancing kinetic comprehension and facilitating industrial applications. Among various computational methods predicting polymeric properties microscopically, kinetic Monte Carlo (kMC) offers a stochastic framework to characterize individual polymer chains and track dynamic system evolution, providing mechanistic insights into complex polymerization kinetics. In this study, an accurately accelerated Superbasin-aided kMC model is developed for enhancing the kinetic understanding of the advanced photo-iniferter RAFT (PI-RAFT) polymerization. The contribution is twofold, presenting advancements in both the mathematical modelling techniques for complex dynamic process systems and the mechanistic understanding of photo-induced polymerizations. Leveraging the increased computational performance and the gained kinetic understanding, batch blending is examined as a viable approach to produce polymers with desired microscopic properties. This work bridges stochastic molecular simulations with scalable polymerization processes, laying groundwork for multiscale modelling in polymer engineering, and also the foundation for process design, control, and optimization.

**Keywords**: Modelling and Simulations, Multiscale Modelling, Polymers, Reaction Engineering, Acceleration.

## INTRODUCTION

Microscopic state variables for describing polymeric structure, including chain length distribution (CLD) and molecular weight distribution (MWD), directly influence the end-use functionalities of polymer products. Mathematical modelling methods for polymerization processes can be categorized into two types: the deterministic method solving mass balance equations and the stochastic simulation using the Monte Carlo (MC) method. For complex polymerizations, like the controlled radical polymerization (CRP) with reverse reaction pairs, it is challenging to derive a rigorous model and solve it with deterministic methods. Direct solution of the underlying ordinary differential equation systems is computationally infeasible due to memory resource limitations and model stiffness. These hurdles can be circumvented via coarse graining and order reduction for computational efficiency, albeit with a trade-off in applicability. In contrast, the kinetic Monte Carlo (kMC) method, based on Gillespie's [1] stochastic simulation algorithm, is conceptually straightforward to implement and insensitive to kinetics complexity, focusing on individual molecules.

In kMC simulations, the system states undergo continuous updates within an event-driven framework. Herein, an "event" refers to one occurrence of any reaction, which leads to the evolution of the system's state. The determination of which events happen is based on a set of probabilities derived from first-principle kinetic-based theory. These probabilities are calculated by evaluating the propensities for all reactions in a chemical system. Through determining events and meticulously

recording all ensuing changes resulting from these events, kMC simulations accurately portray the modelled process system. KMC simulations are straightforward to implement with simple rules; still, their application is limited due to computational inefficiency, particularly for polymerization process with intricate mechanisms.

Events with higher propensities are more frequently observed compared to those with lower propensities. When propensities exhibit significant differences in magnitude, a considerable number of trials must be executed and tracked for stochastic simulation to overcome inherent fluctuation errors and explore rare events with small propensities. For modelling polymerization systems with significant disparities in propensities, the adoption of the Superbasin strategy in stochastic simulation enables computational acceleration through appropriately scaling the propensity values of frequent events [2-3].

Photo-iniferter reversible addition-fragmentation chain-transfer (PI-RAFT) polymerization is a representative technique within the class of CRPs, valued for its ability to produce well-defined polymers in an environmentally friendly way [4]. A defining feature of PI-RAFT is the significant discrepancy in the rates of individual reactions, which involves both frequent and rare reactions. The frequent reactions ensure a controlled polymerization, yielding polymers of uniform chain lengths. Understanding polymerization kinetics and chain growth mechanisms is of great demand in both academia and industrial applications, with mathematical modelling being a viable tool for this purpose. However, challenges remain in accurately modelling the complex PI-RAFT mechanism, particularly with dual chain transfer agents (CTAs) involved, and under varying light irradiation conditions.

In this work, an accelerated Superbasin-aided kMC model is developed, which simulates PI-RAFT polymerization processes with microscopic resolution under different light irradiation conditions. The model successfully captures the full kinetic complexity of the PI-RAFT system, achieving a maximal computational speedup of approximately 50,000 times. Based on the gained accuracy and efficiency from the simulations, batch blending is subsequently investigated as an open topic to provide potential strategies for producing polymers with desired microscopic properties.

This study intents to open new possibilities for further advancements in online control, optimization, and multiscale integrate of dynamic polymerization processes. Specifically, the contributions of this work establish a methodological foundation for developing multiscale models that integrate microscopic insights with macroscopic reactor design. Such integration can be achieved through the developed kMC model by further leveraging techniques such as the computational fluid dynamics (CFD) and data-driven methods.

# METHODOLOGY

## Conventional kinetic Monte Carlo simulation

In the conventional kMC simulation, the reaction propensity for each reaction within the chemical system involving a total of *M* reactions is defined as:

$$R_\mu = k_\mu c_\mu, \forall \mu = 1,2,\dots,M \tag{1}$$

where $k_\mu$ is the kinetic rate constant of the $\mu^{\text{th}}$ reaction, and $c_\mu$ is the concentration of possible molecular sets related to the $\mu^{\text{th}}$ reaction. For a reaction described by:

$$\mathrm{A} + \mathrm{B} \xrightarrow{k_\mu} \mathrm{C} + \mathrm{D} \tag{2}$$

The corresponding sets $c_\mu$ is calculated as:

$$c_\mu = [\mathrm{A}] \cdot [\mathrm{B}] \tag{3}$$

where $[\,\cdot\,]$ represents the concentration of reactants. The probability $\mathbb{P}_\mu$ for the $\mu^{\text{th}}$ reaction to occur is derived by:

$$\mathbb{P}_\mu = \frac{R_\mu}{R_{SUM}} \tag{4}$$

where $R_{SUM}$ is the summation of propensities, given as:

$$R_{SUM} = \sum_{\nu=1}^{M} R_\nu \tag{5}$$

A uniformly distributed random number $rnd_1 \in U(0,1)$ is generated to determine which one reaction event to occurr at the moment based on the rule:

$$\frac{\sum_{\gamma=1}^{\mu-1} R_\gamma}{R_{SUM}} < rnd_1 \leq \frac{\sum_{\gamma=1}^{\mu} R_\gamma}{R_{SUM}} \tag{6}$$

Following the occurrence of the selected event, the molecular set concentration of each reaction is updated. The time between two consecutive events of the chemical system is evaluated by $\tau$, which is determined by:

$$\tau = \frac{\ln(1/rnd_2)}{R_{SUM}} = \frac{-\ln(rnd_2)}{R_{SUM}} \tag{7}$$

where, $rnd_2 \in U(0,1)$. The event selection and system evolution time iterate until a preset simulation step number or desired time is satisfied.

## Accelerated kinetic Monte Carlo simulation

As indicated by (4) and (6), the discrepancy in probability values results in a significant portion of computational effort being consumed by frequent events with high propensities. When frequent reversible events occur ceaselessly during a period of process time, the system is deemed to be trapped, which is called the kinetic trap phenomenon. The system escapes from the entrapment when a rare event occurs. During the entrapment, scaling the propensity of frequent events artificially narrows the occurrence probability gap between frequent and rare reactions. Furthermore, as evidenced by (7), the scaling operation increases the time intervals, reducing the number of simulation steps required to reach the desired time. Therefore, the Superbasin-aided kMC enhances

simulation efficiency. Compared to the conventional kMC, the execution of the Superbasin-aided kMC model involves three additional procedures: (i) identification of frequent and rare events; (ii) feasibility assessment for scaling; and (iii) implementation of the scaling operation.

The flowchart of simulations using the Superbasin-aided kMC model for dynamic PI-RAFT polymerization process considering varying light conditions is presented in Figure 1, wherein the steps corresponding to the conventional kMC are highlighted in blue, the steps corresponding to the Superbasin-aided kMC are highlighted in green. Furthermore, as the photodissociation reactions in PI-RAFT are sensitive to external light sources, the values of the kinetic constants are automatically adjusted in response to the light modulation in the simulations. A light-switch module is designed in this study to implement the varying light irradiation, with the corresponding steps marked in yellow in Figure 1.

## Key procedures in Superbasin-aided kMC model

Focusing on the modelling for the PI-RAFT process, the involved reversible reaction pairs in the form of:

$$\mathrm{E} + \mathrm{F} \xrightarrow{k_{forward}} \mathrm{G} + \mathrm{H} \tag{8}$$

$$\mathrm{G} + \mathrm{H} \xrightarrow{k_{reverse}} \mathrm{E} + \mathrm{F} \tag{9}$$

are classified as frequent events. When the corresponding forward and reverse reactions from a reversible pair exhibit similar propensity values, this reaction pair reaches equilibrium. The successive and abundant occurrences of the forward and reverse reactions from the equilibrium pair leads to a quasi-steady-state (QSSA) system. The molecular concentrations and propensities remain stable as the process moves forward during the QSS period. The occurrences of the other irreversible reactions are classified as rare events, which introduce significant fluctuations into the system.

Frequent events are further categorized as equilibrated or unequilibrated frequent events based on whether the corresponding reaction pairs have reached equilibrium. For a reaction pair $\upsilon$ out of the total $K$ pairs, if the forward and reverse reactions occur $N_f$ times, there is a confidence of $1-\delta_f$ in safely reaching equilibrium if the following rule is satisfied:

$$\left|n_{\upsilon,+} - n_{\upsilon,-}\right| \le \delta_f \cdot N_f, \qquad \forall \upsilon = 1,2,\dots,K \tag{10}$$

$$\eta_{\upsilon,+} + \eta_{\upsilon,-} \ge N_f, \qquad \forall \upsilon = 1,2,\dots,K \tag{11}$$

$$N_f = \left\lceil (\alpha-1)/\delta_f \cdot \ln(\delta_f) \right\rceil \quad \forall \upsilon = 1,2,\dots,K \tag{12}$$

where $n_{\upsilon,+}$ and $n_{\upsilon,-}$ record the occurrence numbers of the forward and reverse reactions over the last $N_f$

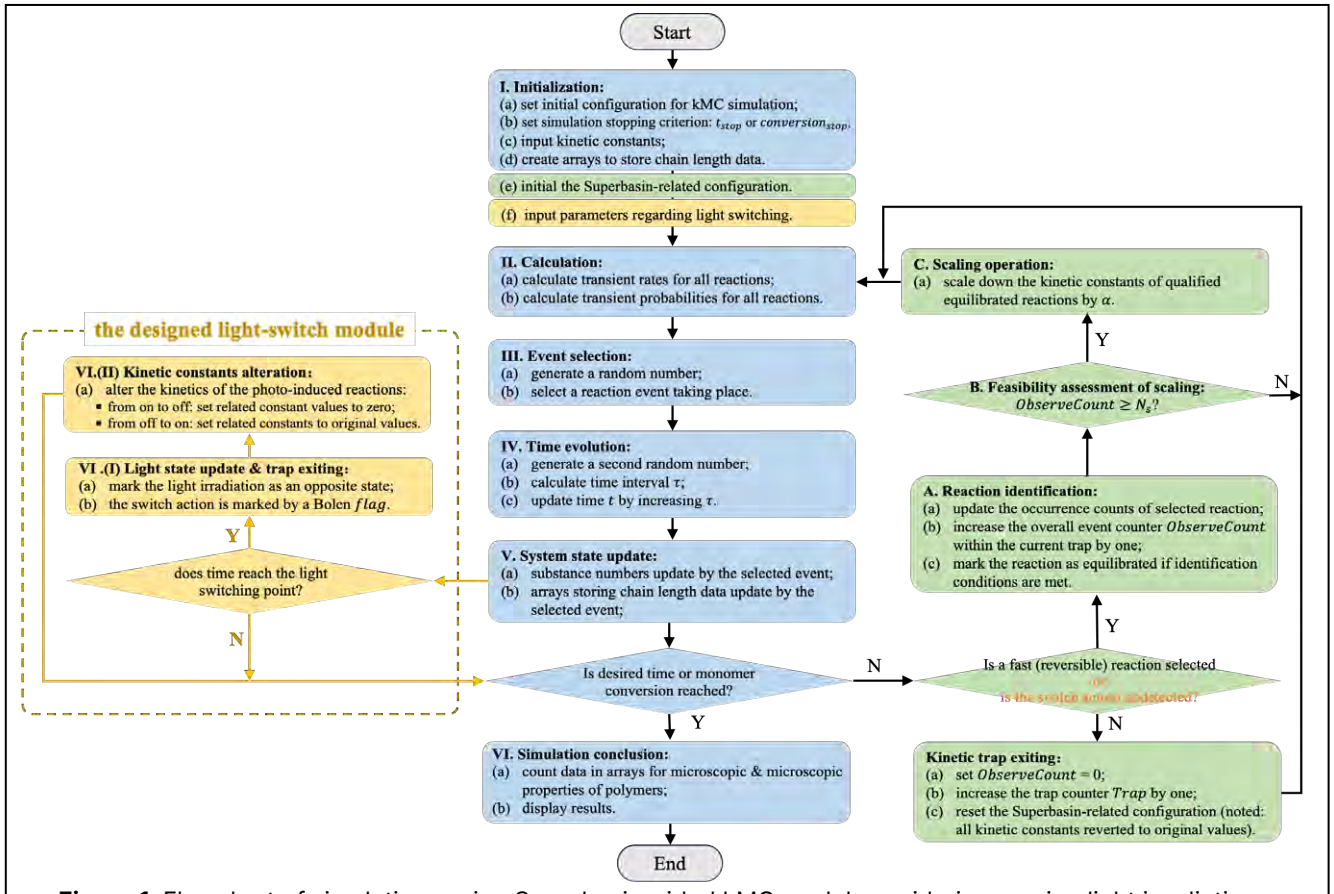

**Figure 1:** Flowchart of simulations using Superbasin-aided kMC model considering varying light irradiations.

reaction events for the reaction pair $\upsilon$. Term $\delta_f \cdot N_f$ calculates a threshold value for reaction identification. Variable $N_f$ is determined by (12) using scaling factor $\alpha$ and $\delta_f$. At the outset of the Superbasin-aided kMC model simulation, all frequent reactions are designated as unequilibrated.

Figure 2 presents the state transition during the Superbasin-aided kMC simulation, considering the complete feasible state space. Following the occurrence of a rare event, a frequent event causes the system to transition from the previous state $S_o$ into a kinetically trapped state $S_i$, as indicated by the leftmost yellow arrow in Figure 2. Two distinct regions comprise region $S_i$: the known ($S_k$) and unknown ($S_u$) regions. The occurrence of an equilibrated event shifts the current system into $S_k$ inside the trap, highlighted in the green area in Figure 2. The occurrence of an unequilibrated event shifts the current system into $S_u$ inside the Superbasin, highlighted in the gray area in Figure 2. A rare event drives the system's exit from the current trap, transitioning it toward $S_o$.

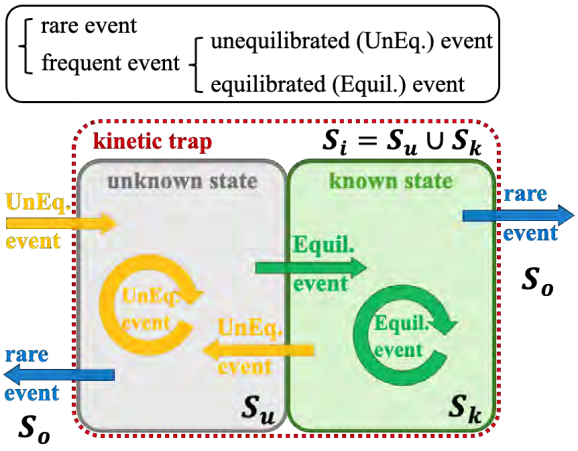

**Figure 2.** System state transformation within the complete possible state space resulting from the occurred reaction event.

When the number of reactions from an equilibrated frequent pair within the current kinetic trap exceeds $N_s$ times, a propensity scaling operation is applied with a confidence of $1 - \delta_f$. The propensity (equivalent to the transient rate) of the corresponding reaction is scaled by a user-defined factor $\alpha$:

$$R'_\mu = \frac{R_\mu}{\alpha},\ \alpha \geq 1 \tag{10}$$

The minimal observed occurrence number is derived as

$$N_s = \left\lceil -\chi \cdot \frac{\alpha - 1}{\delta_f} \cdot \ln(\delta_f) \right\rceil, \chi \geq 1 \tag{11}$$

where $\chi$ is a user-defined parameter determining the minimal observed occurrence number before scaling. For polymerization process modeling, it is critical to accurately capture higher dimensional information such as chain lengths and polymeric structures for individual polymers from diverse polymer species. Parameter $\chi$ facilitates the precise recording of the intricate information associated with polymers.

The scaling operation is applied simultaneously to both forward and reverse reactions of an equilibrated pair, which is recursive, leading to a cumulative effect on the propensity values of fast reactions during simulation. If a reaction pair has been scaled by $\alpha$ once and continues to meet the scaling criteria while within the current kinetic trap, it will undergo further scaling.

## PI-RAFT POLYMERIZATION MECHANISM

The kinetic mechanism of PI-RAFT with two CTA species, $TR$ and $XR$, is tabulated in Table 1. During the polymerization process, different types of CTAs influence the synthesis efficiency, uniformity of polymer chains, and microstructural properties of the resulting polymers. In Table 1, $R^*$, $M$, $T^*$, and $X^*$ denote primary radicals, monomers, and thiocarbonylthio radicals of $T$ and $X$, respectively. $D_n$, $P_n^*$, $TP_n^*$, and $XP_n^*$ represent dead polymers, radical polymers, and inactive polymers of $T$ and $X$ with chain lengths of $n$, respectively. $P_nTR$ and $P_nXR$ are one-arm adduct radicals of $T$ and $X$ with chain lengths of $n$, respectively. $P_nTP_m$ and $P_nXP_m$ are the two-arm adduct radicals of $T$ and $X$ with $n$ and $m$ on each arm. This mechanism involves six micromolecular reactants and eight polymer species, the latter possessing high-dimensional chain structure information that needs to be characterized and recorded in the simulation.

## RESULTS AND DISCUSSIONS ON ONE-SHOT SIMULATION

### Model Accuracy

The simulations were performed on a personal desktop computer with 32 GB RAM and Intel i7-10700 CPU using Python version 3. The initial concentrations of monomers and CTAs are 2 M and 0.04 M, respectively.

Figure 3 presents the Superbasin-aided kMC simulation results as black lines, the conventional kMC simulation results as gray dashed lines for MWDs and method of moments results as gray dashed lines for average information. The results obtained from different methods demonstrate good consistency. The simulated MWDs at 95% monomer conversion for diverse initial CTA concentrations are presented in Figure 3(a)-(b). The evolutions of average chain lengths are presented in Figure 3(c)-(d).

A lower initial feed of $XR$ results in a smaller length disparity of the resulting polymers, and the MWD shape is narrower. A higher $XR$ proportion leads to a faster polymer growth rate at the initial polymerization stage.

**Table 1:** kinetic mechanism for PI-RAFT with two chain transfer agents.

| Number | Reaction | Event type | Equation | Kinetic constant* |
|---|---|---|---|---|
| 1 | ini-propagation | rare | $R^*+M \rightarrow P_1^*$ | $k_{i,R}$=200 M·s$^{-1}$ |

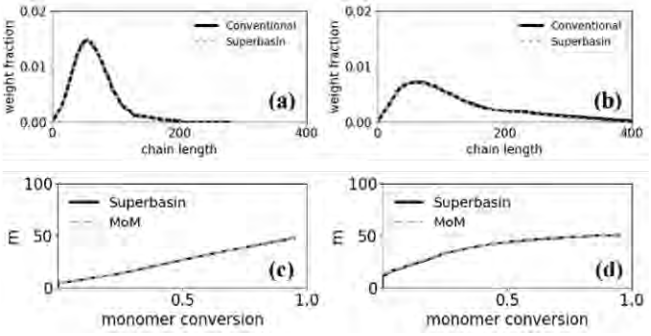

**Figure 3.** Simulated MWDs at 95% conversion and simulated dynamic average chain lengths using $[XR]$:$[TR]$=1:4 and $[XR]$:$[TR]$=4:1, respectively.

## Model Efficiency

The computational time for PI-RAFT processes to 95% monomer conversion with different initial feed ratios of CTAs is shown in Table 2. The developed Superbasin-aided kMC achieves a remarkable thousand-fold acceleration compared to conventional kMC. With a set of alternative user-defined parameters, the simulation has a 48961 times' acceleration from 12.1 days to 21.34 seconds, with a sight compromission on result precision.

**Table 2:** Comparison of computational time.

| Parameter | [XR]:[TR] | Speedup |
|---|---|---|
| $\alpha = 2, \chi = 5.12$ | 1:9 | 205 |
| | 1:4 | 467 |
| | 2:3 | 1182 |
| | 1:1 | 1772 |
| | 4:1 | 3379 |
| | 1:0 | 4729 |
| $\alpha = 1.16, \chi = 1.04$ | 1:0 | 48961 |

# RESULTS AND DISCUSSIONS ON BATCH BLENDING

## Blended molecular weight distribution

Batch blending is an alternative idea in producing polymers with desired microscopic features, which is examined in this study as a strategic approach in the context of PI-RAFT. A schematic representation of the batch blending is presented in Figure 4 to illustrate how the combination of polymers synthesized in distinct batches can achieve a target MWD profile.

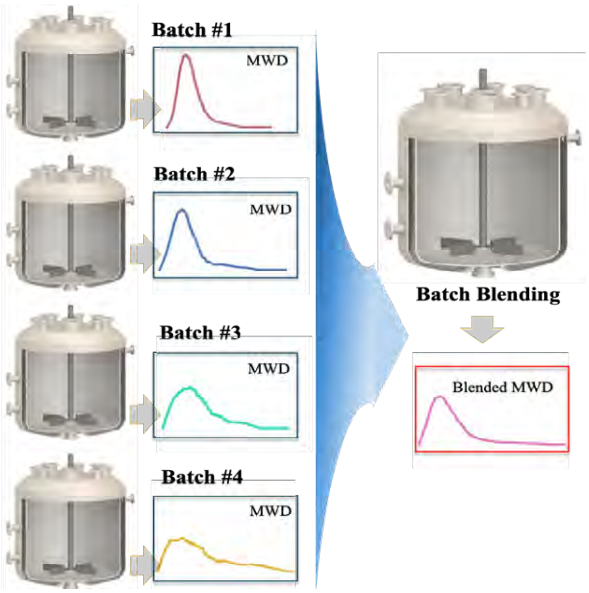

**Figure 4.** Scheme of batch blending.

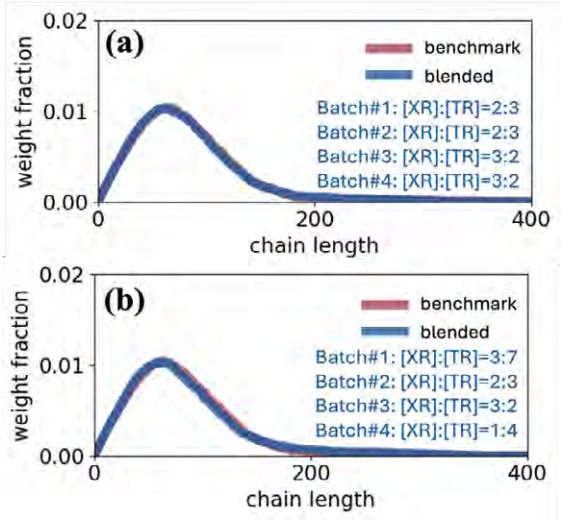

**Figure 5.** The blend MWDs and their comparison with the benchmark distributions (using [XR]:[TR]=1:1) obtained using Superbasin-aided kMC simulation.

The batch blending operation leverages the differences in MWD resulting from the use of varying CTA feeding policies across multiple batch reactors. Figure 5 presents the blended MWDs and their comparison with the benchmark distribution obtained using the feeding policy [XR]:[TR] = 1:1. The results clearly demonstrate the capability of batch blending to closely replicate the benchmark MWD, even with reduced $XR$ usage (with a 16% reduction), as shown in Figure 5(b).

### Prospects of batch blending

Batch blending has advantages in process and production quality optimization. By adjusting the CTA feeding policies in individual batch reactors, the blending operation allows for the achievement of desired MWD profiles without requiring additional polymerization steps. The ability to reduce the feeding of one type of CTA while maintaining target properties further contributes to resource conservation and cost savings. Moreover, with the computational efficiency of the Superbasin-aided kMC model, future studies can explore the effects of varying polymerization conditions, such as temperature, monomer concentration, and irradiation, to further enhance the versatility of batch blending.

## CONCLUSION

Simulating polymerization processes at the microscopic scale presents a significant challenge due to the complex structure of macromolecules. In this study, a Superbasin-aided kMC model was developed to capture microscopic polymeric properties in PI-RAFT processes. The proposed simulation method substantially reduces computational time from weeks to minutes, enabling more efficient exploration of inverse design, online control, and process and production optimization. Additionally, leveraging the efficiency of the simulation, batch blending is introduced as a promising approach to enhance production quality and process optimization. Specifically, one can expand the versatility of the developed Superbasin-aided kMC simulation and the batch blending approach in scale-up strategies and applications under continuous-flow processes for product quality optimization purpose, by combining CFD simulations and real-world data. Ultimately, this computational framework aims to bridge the gap between lab-scale mechanistic insights and industrial scalability in practical applications.

## ABSTRACT

This study presents the design and evaluation of a plantwide control (PWC) system for Formic acid (FA) production under unsteady green Hydrogen supply. Starting from a steady-state foundation in Aspen Plus V12, the system was prepared to handle variable inputs and was subsequently transitioned into Aspen Dynamics for real-time responsiveness. The two-level design methodology to build a PWC scheme, which is comprised of equipment-specific and plantwide controllers, effectively managed fluctuations in feed rates ranging up to ±20%, maintaining FA purity and production rate targets. Gradual SRAMP (sinusoidal ramp) adjustments of 1% per hour provided optimal stability. These results confirm the PWC system's effectiveness in maintaining production goals under the variability of throughput.

**Keywords**: Plantwide Control, Dynamic Simulation

## INTRODUCTION

The drive for sustainability is compelling the chemical industry to transition from conventional, non-renewable resources to renewable, green feedstocks. Formic acid (FA), which can be synthesized from green Hydrogen and captured carbon dioxide ($CO_2$), presents a promising approach for mitigating greenhouse gas emissions while also yielding a versatile chemical with widespread industrial applications. Nevertheless, the shift to renewable sources introduces new challenges—most notably, the variability in feed availability inherent to renewable sources. In response, maintaining stable production and product quality under these fluctuations has underscored the need for advanced control systems, with plantwide control (PWC) emerging as essential for operational reliability.

This work seeks to design an effective PWC system for a highly intensified FA production plant, targeting a stable production rate of FA with a purity of 85% by weight. The complete plant design can be seen in the previous work [1]. The main challenges for the PWC design include the COPure™ absorption system, the divided wall column and the 16 recycle streams within the plant.

To address these challenges, the approach taken first involved reinforcing the steady-state flowsheet's robustness within Aspen Plus V12. This required a comprehensive evaluation of sensitivity across process parameters and equipment to ensure flexibility in adapting to variations in feed flow rates.

With this foundation established, the focus shifted to transitioning the model into Aspen Dynamics for dynamic simulations. This conversion required incorporating additional equipment and pressure control elements to facilitate a pressure-driven simulation that reflects real operational conditions.

Following successful initialization in dynamic mode, a two-level design methodology for PWC system was developed. The first control layer focuses on equipment-specific control strategies but was found insufficient for handling significant variations in feed rates. Consequently, a second plantwide control layer was designed to manage throughput fluctuations and sustain product specifications across varying production capacities.

The final PWC configuration demonstrates that despite the complexities introduced by the DWC and multiple recycle loops, the designed control system maintains FA purity and production rates, even under ±20% throughput disturbances, confirming that PWC can play a critical role in stabilizing renewable-driven processes

with inherent variability in feedstock supply.

## PROCESS SIMULATION

### Process Description

The production process of formic acid (FA) is divided into two main sections [1]: the synthesis of carbon monoxide (CO) and its subsequent conversion to FA. The $CO_2$ feed is sourced from the CCUS network at 25 °C and 35 bar, while green hydrogen, supplied at 25 °C and 30 bar, is obtained from an electrolyzer (Figure 1).

In the first section, the reverse water-gas shift (RWGS) reaction converts $CO_2$ and $H_2$ into CO within a tubular reactor. The process operates at 1.2–1.4 bar, with temperatures ranging from 573–600 °C and a $H_2$:$CO_2$ molar ratio of 2.5. Following water removal, the reactor outlet undergoes chemical absorption (COPure™ technology) to isolate CO from unreacted feedstock and impurities. This involves selective chemisorption using a $CuAlCl_4$ complex dissolved in toluene, achieving a CO purity of 99% and a recovery rate of 98%. The CO-$CuAlCl_4$ complex is then dissociated in a stripper for further use.

In the second section, methanol is carbonylated with CO in a continuous stirred-tank reactor (CSTR) at a methanol-to-CO ratio of 5, under conditions of 40 bar and 80 °C. This process yields methyl formate (MF) with high selectivity, achieving moderate per-pass conversions of methanol (14.8%) and CO (74%). Excess methanol is separated and recycled via distillation. The hydrolysis of MF to FA occurs in two stages within packed flow reactors (PFRs). The first reactor operates at 18 bar and 120 °C, with MF reacting with water to produce FA and water, achieving a 10% conversion. The resulting FA acts as a catalyst for further hydrolysis in the second reactor, achieving a 30.5% per-pass conversion with 100% selectivity. The reactor outputs are distilled using a dividing wall column (DWC) to separate FA and water from unreacted methanol and MF, which are recycled. The FA-water mixture is then distilled at 3 bar to overcome the azeotrope, achieving the desired FA purity.

### Process Simulation

From the explained process, the aim of the work was

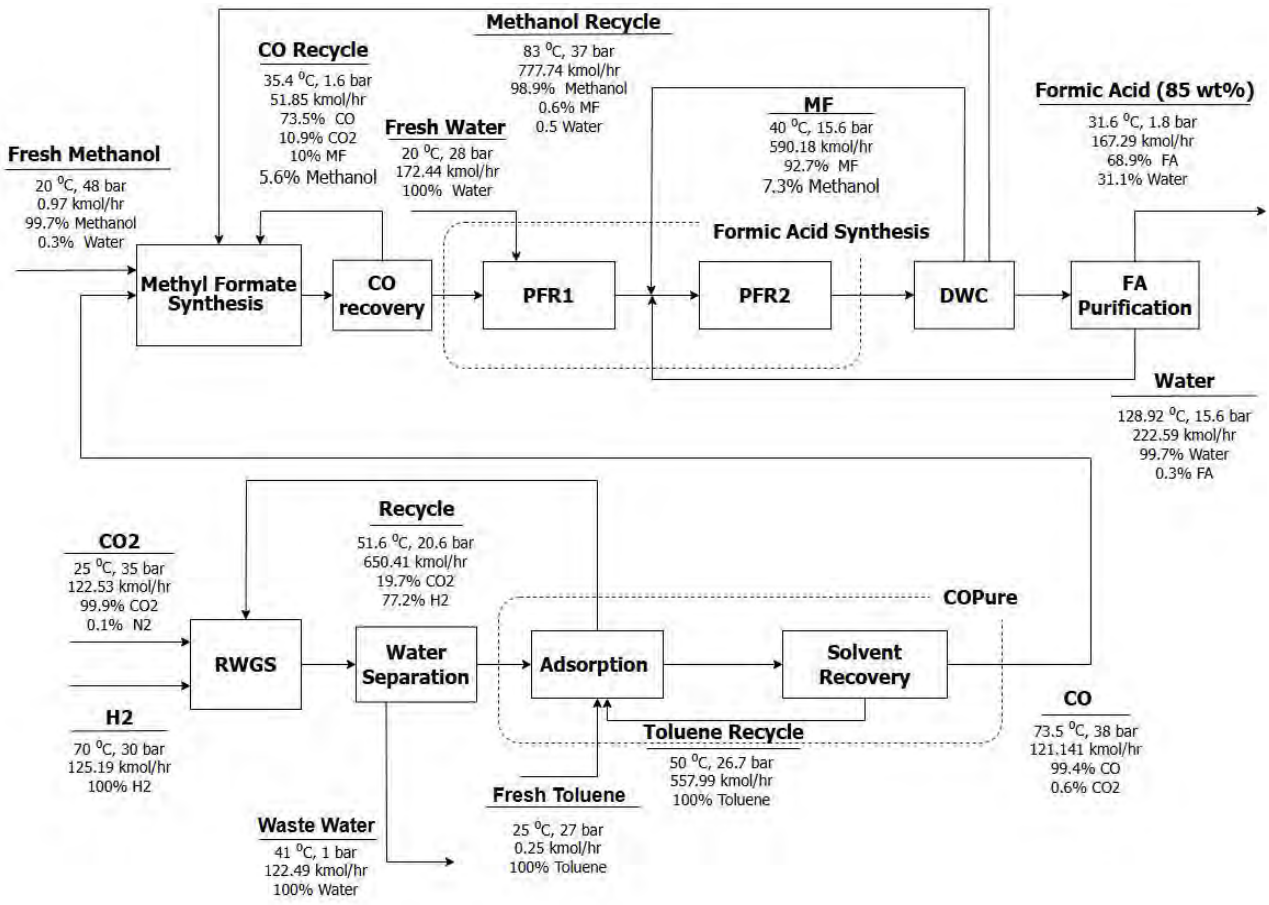

**Figure 1**. Process Block Flow Diagram

to design a PWC system, starting from the development of a robust steady-state model, simulated in Aspen Plus V12.

Two thermodynamic models were chosen to accurately capture the system's phase behavior across diverse conditions. The RWGS reaction and CO separation processes were simulated with the Peng-Robinson equation of state due to their high-pressure and non-polar components, while the UNIQUAC-HOC model was used for MF and FA production to account for complex liquid-phase interactions.

To enhance the simulation's stability and enable responsiveness to feed fluctuations, critical parameters were identified through sensitivity analysis, allowing the model to accommodate a range of operational conditions. Disturbances in feed composition and flow rates were evaluated, ensuring the process could achieve the desired FA purity and throughput across varied conditions. This steady-state simulation serves as the baseline model, supporting the design of a flexible and resilient dynamic model and the foundation for developing an effective plantwide control system in subsequent stages.

The most challenging aspect of achieving robust and flexible steady-state simulation involved the implementation of calculator blocks and flowsheet design specifications. Calculator blocks, along with DesignSpecs at both the flowsheet and equipment levels, were essential for manipulating key process variables to meet the desired product specifications and ensure mass balance closure across the process.

Achieving convergence across multiple disturbance scenarios in steady-state mode proved to be a valuable predictor of smooth operation during dynamic simulation, ultimately ensuring that the system could transition effectively to Aspen Dynamics for plantwide control analysis.

## PWC system Design and Dynamics Simulation

The Integrated Framework of Simulation and Heuristics Method (IFSH) has been widely used for plantwide control (PWC) design [2, 3]. Drawing inspiration from this approach, the methodology begins with defining the objectives of PWC. Plantwide disturbances are then analyzed, and the main throughput variable is identified. Based on these inputs, a two-level control scheme is developed to achieve the desired operational stability and efficiency.

The first control level focuses on stabilizing individual unit operations by implementing primary controllers for critical variables. For example, level control is essential in continuous stirred-tank reactors (CSTRs), where it directly impacts reaction rates. In flash operations and distillation columns, maintaining appropriate liquid levels is equally crucial. The liquid level in flash operations is regulated by adjusting the liquid outlet flow rate, while in distillation columns, the reflux drum and column base levels are controlled via distillate and bottoms flow rates, respectively. Reboiler and condenser temperatures are managed by manipulating their respective heat duties. Similarly, cooler and heater outlet temperatures are controlled by adjusting their thermal inputs. In process-to-process heat exchangers, the temperature on the cold side is regulated by modulating the flow of the hot side through the exchanger. Column and flash pressures are maintained by manipulating the overhead streams and flow controllers manage critical feed streams, including $CO_2$, $H_2$, water, toluene, and methanol.

To ensure optimal performance, a closed-loop autotune variation (ATV) test was conducted with a 1 to 10 percent change in the output range. Based on the outcomes of these tests, the Tyreus-Luyben [4] method was implemented to tune the parameters of the controllers in this first level of the control scheme. The Tyreus-Luyben method was applied primarily; however, in some cases, the Ziegler-Nichols [5] method was used.

These controllers ensure steady operation within each plant section, mitigating localized disturbances and maintaining unit-level stability. However, plantwide disturbance analysis revealed that this layer alone could not adequately address larger fluctuations, particularly those related to variable hydrogen supply. While individual units remained stable, the lack of coordination across sections hindered the system's ability to handle interdependencies effectively.

To manage broader disturbances, a second control level was introduced, focusing on overall production stability, quality targets, and material balance across the plant. This layer employs ratio and mass balance controllers to maintain critical system ratios and regulate material flows, particularly within recycle loops.

Several points of the plant required the implementation of these 2$^{nd}$ level controllers to achieve smooth operation. For example, an important aspect of the reactors is to maintain a constant mole ratio for the reactants. One of them is the ratio for $H_2$ to $CO_2$ entering the RWGS reactor which is dependent on the fresh $H_2$ stream flow. At the same time, a make-up stream of Methanol is adjusted based on the required ratio to CO entering the Methyl Formate synthesis reactor. Additionally, Formic Acid is produced in PFR2, for which the required fresh water is checked by a ratio controller at the inlet of the reactor. Continuing on the topic of ratio control, another highly important ratio controller is the one related to the Toluene solvent in the 1$^{st}$ section. The goal is to keep a constant ratio of gas/liquid entering the adsorption column during transitions, while also compensating for the loss of Toluene in other parts of the plant.

Other, more unique controllers have been implemented in the plant, such as the controller for a main path

valve and compressor in the 1st section, which affects the main path flowrate and consequently the recycle rate towards the RGWS reactor and therefore the extent of the reaction, with the purpose to keep a specific percentage conversion.

In a similar fashion, the conversion of the reaction in the Methyl Formate Synthesis reactor needs to be controlled and this is done by cascading the level controller of the CSTR, which in turn affects the outlet valve opening, the residence time and the conversion rate. For the same reactor, one of the recycle streams entering it is composed of primarily CO and it is controlled to have a specific flow ratio compared to the "fresh" CO entering the 2nd section. Moreover, this unreacted CO is mainly returned due to a flash separation after the CSTR and it is required that a specific percentage of CO exits as the recycle at the top, which is manipulated by the corresponding valve.

The most complicated controller to implement was the one related to methanol build-up in the 2nd section, which is explained in more detail later. Overall, the 2nd level controllers are essential for sustaining continuous, stable operations and achieving the desired purity of FA and separation efficiency, even under varying input conditions.

With the two-level control design methodology established, the transition to dynamic simulation was initiated. Key adjustments were made to ensure consistent pressure conditions, essential for pressure-driven operation throughout the plant. Control valves were configured to maintain a pressure drop of 2–3 bar, enabling precise flow rate control. Furthermore, controlled pressure differentials were introduced between equipment and across battery limits to drive fluid flow and regulate stream entry and exit effectively. Equipment with holdups, such as reactors, flash drums, reflux drum and sump of distillation columns, were sized to accommodate an inventory corresponding to at least 10 minutes of operation. Additionally, a length-to-diameter ratio of 2:1 was assumed [3]. These adjustments were crucial to ensure a stable and responsive dynamic model.

Figure 2 depicts the two-level control design methodology for the Dividing Wall Column (DWC) system. The DWC system is modeled using two RadFrac columns, one equipped with a reboiler and condenser and the other without, simulating the two chambers separated by a dividing wall within a single column. Four intermediate streams are included to represent the vapor and liquid exchange between the chambers. Additionally, pressure gradient equipment has been introduced between these streams to simulate a pressure gradient for modeling purposes [6].

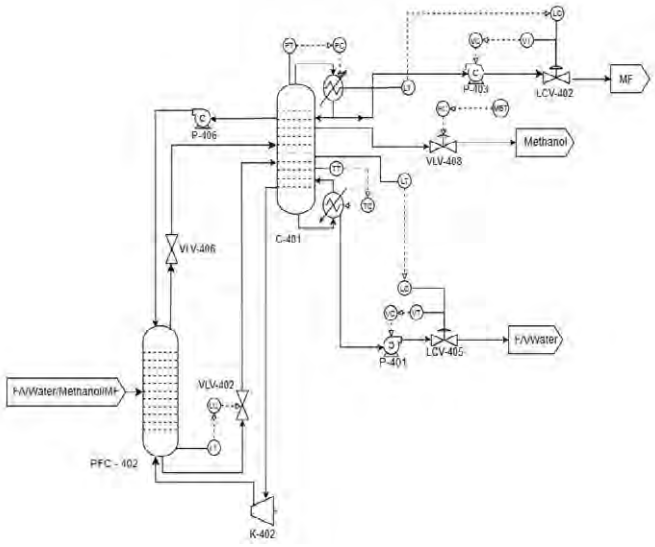

**Figure 2.** Designed PWC for the DWC

The first level of the control scheme for the DWC incorporates level, temperature, and pressure controllers to ensure stable operation. The levels in the reflux drum and the base of the right column are maintained by adjusting the distillate and bottoms flow rates, respectively. Similarly, the base level of the left column is regulated by controlling the liquid exiting from its bottom. Pressure control for the right column is achieved by manipulating the condenser duty, while the reboiler temperature is controlled by manipulating the reboiler duty. Considering the DWC as part of the overall process, the first level of control alone is insufficient to address plantwide operational challenges. This is where the second level of control becomes critical.

At this level, a mass balance controller is introduced to address methanol accumulation within the system. Methanol is the most difficult component to control, because it is consumed at the Methyl Formate Synthesis reactor and generated at the same time in the 2 PFR reactors (Figure 1). These 3 reactors lie in series along the main path of the process and they are also connected end-to-front through a recycle Methanol stream. Simultaneously, fresh make-up methanol enters the system and some of the methanol is purged from the recycle stream coming out of the CO recovery system. All these points of methanol generation and consumption need to be delicately balanced in order to keep its accumulation in the system at 0. The challenge in achieving that is apparent because of the interconnected nature of the plant. However, at a closer glance it can be seen that for a specific amount of CO entering the 2nd section, the fresh methanol is dynamically changed for a specific reactant ratio in the CSTR. As a consequence, the CSTR and PFR1 rates of change stay "locked in" while the purge stream and its contribution is relatively small in the methanol mass balance. This leaves PFR2 as the only variable to

manipulate in order to accomplish 0 accumulation rate. The only way to manipulate the rate of change in PFR2 is by influencing the recycle stream around the reactor composed of unreacted Methyl Formate. This is where the mass balance controller system BC and MBT enter the scene (Figure 2).

To start off, a separate system of logical blocks is used to monitor all the aforementioned points of methanol entry, exit, consumption, and generation across the process and calculates the rate of accumulation of methanol. Its output is used as a process variable in the mass balance controller and set to make it zero. The cascade controller dynamically adjusts the side-draw percentage of the middle stream exiting the DWC column and in continuation it affects the flow of the recycled Methyl Formate stream coming out of the top of the column. By doing so, the mass balance controller effectively minimizes methanol buildup, ensuring a stable material flow and supporting continuous, efficient operation of the process.

During varying throughput scenarios, relying solely on valve adjustments (distillate and bottom flow rates) is insufficient to maintain the levels in the drum and sump. To address this, two additional controllers were implemented to regulate the pump power upstream of the valves. These controllers increase the pump power as needed, providing additional head to the system and ensuring sufficient material flow out of the sump.

## RESULT AND DISCUSSION

To evaluate the performance and resilience of the designed plantwide control (PWC) system, dynamic simulations were conducted by introducing controlled disturbances to the $CO_2$ feed stream as the main throughput manipulator.

These disturbances ranged from a -20% decrease to a +20% increase in throughput flow rate, implemented through a SRAMP function within Aspen Dynamics. The SRAMP function was carefully configured to gradually adjust the $CO_2$ feed rate over a designated time period, thereby simulating fluctuations in green Hydrogen. By systematically varying the feed rate across this spectrum, the control system's ability to maintain consistent Formic acid (FA) production rates and purity levels under both positive and negative disturbances was thoroughly assessed. Each simulation scenario was monitored to capture key performance indicators such as stabilization time, integral absolute error (IAE), and relative absolute error (RAE) in order to assess the designed control scheme.

This approach provided comprehensive insights into how effectively the PWC system could manage and mitigate the impacts of unsteady feed conditions, ensuring operational stability and product quality despite throughput variations.

The analysis revealed that as the magnitude of feed disturbances increased, the time required for the system to transition from one steady state to another also escalated. It is important to note that steady state is achieved when the Relative Absolute Error (RAE) graph drops below 0.1% and remains within this boundary, indicating that the system has stabilized and deviations are effectively minimized. For instance, in simulations with smaller feed fluctuations, the system quickly adapted, achieving a new steady state within 16.7 hours for a +10% feed disturbance and 42.6 hours for a -10% disturbance. However, with larger changes, the time to stabilize increased, as the control system needed to accommodate more significant adjustments throughout the plant (Figure 3 and Figure 4) with transitions taking 33.7 hours for +20% and 59.5 hours for -20% disturbances. Kink points in Figure 3 are primarily due to the challenges of managing material within the recycle loops during capacity changes.

Figure 5 illustrates the FA purity error relative to the target value of 85 wt%, demonstrating that even under significant throughput variations of ±20%, the FA purity remains within a narrow 0.2% range. This error decreases by an order of magnitude for ±10% changes in throughput, indicating improved purity stability under less severe disturbances. However, the error associated with a throughput drop is slightly higher compared to a throughput increase. This variance is likely due to challenges in managing material within the recycle loops during capacity reduction, which may cause slight imbalances and affect the control system's ability to stabilize purity as efficiently. This behavior is further supported by Figure 4, which show that the stabilization time required for the simulation is longer in scenarios involving a throughput drop compared to those with a throughput increase.

To ensure stability and prevent the simulation solver from crashing, tests were conducted with a conservative feed disturbance rate of 1% per hour. Meaning that, while, Figure 6 to Figure 9 indicate that for moderate changes of ±5% or ±10%, this rate could be increased up to 2.5% per hour; the repercussions of doing so led to higher IAE and FA purity Error values, indicating a trade-off between response speed and error minimization. Importantly, a 2.5% rate is unsuitable for extreme 20% changes, as it caused instability in the solver, indicating a control limitation under more severe fluctuations.

Additionally, the relative absolute error and integral absolute error trend remains almost identical, when throughput is either increased or decreased by the same percentage, reflecting symmetrical control behavior for equivalent rises and drops in feed rates period of +10% change in throughput (moderate flow rate changes). This symmetry highlights the robustness of the control strategy in handling feed variability, ensuring consistent error response regardless of the direction of throughput change.

A comparative analysis between the dynamic and steady-state results for the extreme disturbance scenario, demonstrating that, despite deviations from steady-state targets, the plantwide control objectives were largely achieved. Specifically, the control system maintained the desired production rate and adhered to process constraints, even under the harshest fluctuations. When there is a +20% disturbance in the system, the product flow rate, the overall MF production, and the fresh Methanol flow rate deviate by +0.6%, -2.7%, and -1.1% from steady state, respectively.

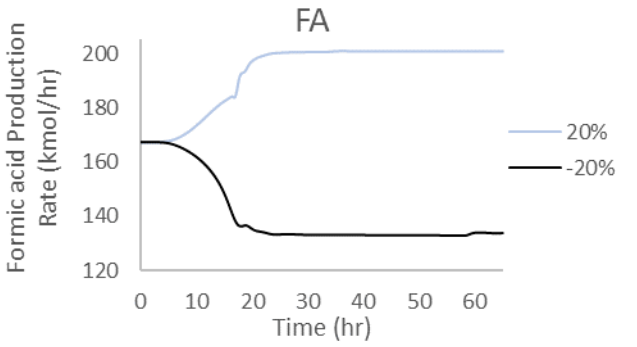

**Figure 3.** FA production rate for +20% and -20% change in throughput

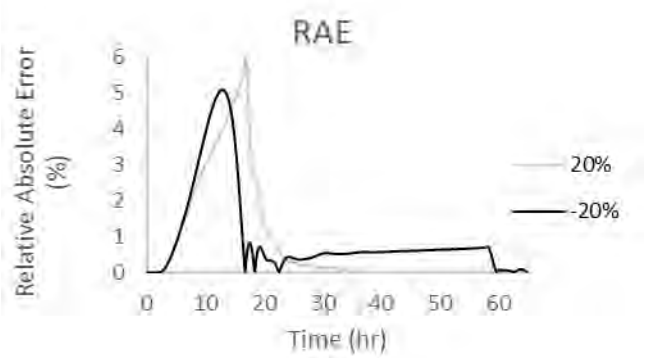

**Figure 4.** Relative Absolute Error (RAE) for +20% and -20% change in throughput

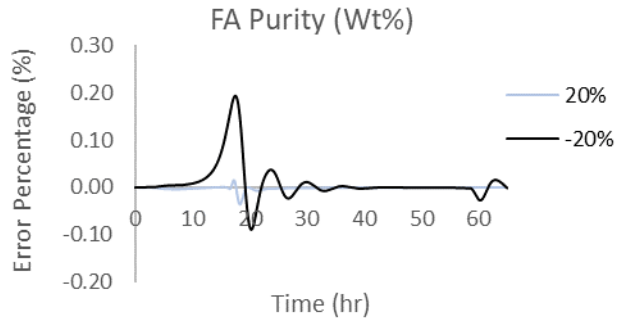

**Figure 5.** FA purity error relative to 85 wt% for +20% and -20% change in throughput

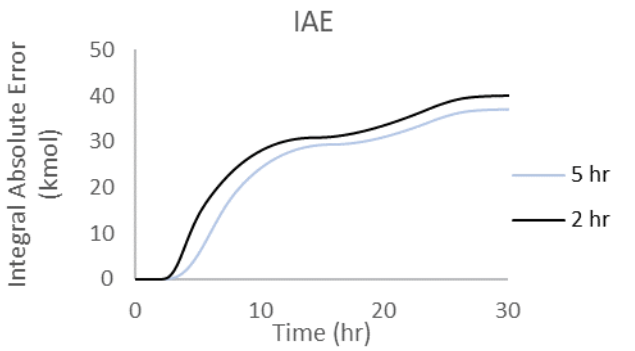

**Figure 6.** Integral Absolute Error (IAE) for 2 and 5 hr ramp period of -5% change in throughput

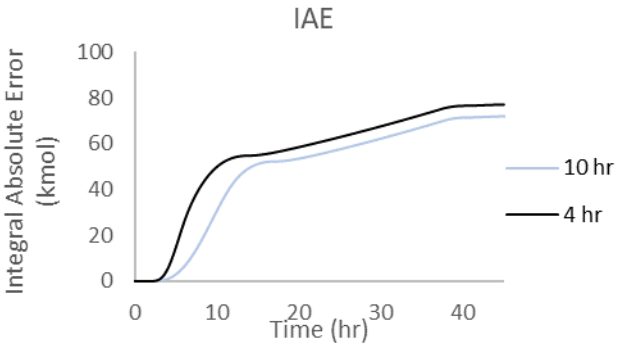

**Figure 7.** Integral Absolute Error (IAE) for 4 and 10 hr ramp period of -10% change in throughput

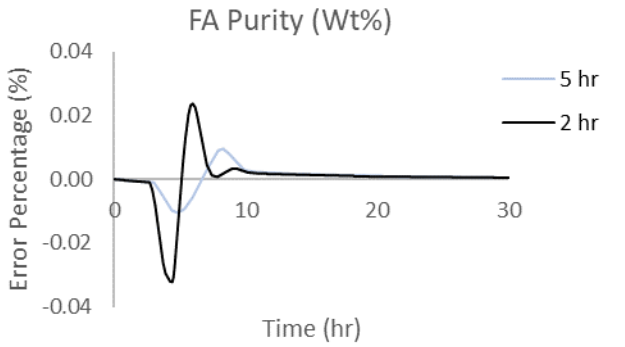

**Figure 8.** FA purity error relative to 85 wt% 2 and 5 hr ramp period of +5% change in throughput

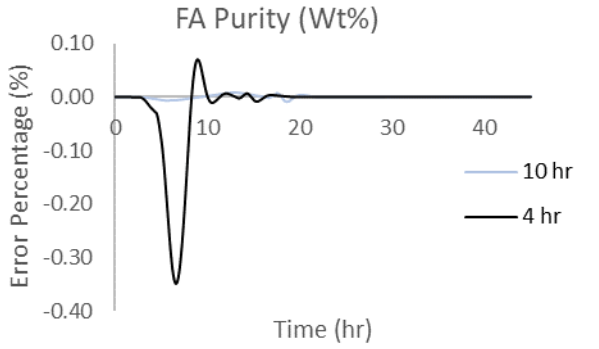

**Figure 9.** FA purity error relative to 85 wt% 4 and 10 hr ramp

Conversely, with a -20% disturbance, the product flow rate, the overall MF production, and the fresh Methanol flow rate deviate by -0.2%, -2.9%, and +1.9% from steady state, respectively. These results confirm the robustness of the PWC system in adapting to significant disturbances, ensuring stable Formic acid output and maintaining operational requirements within acceptable limits.

## CONCLUSION

The designed plantwide control (PWC) system effectively maintained Formic acid (FA) production rates and purity under variable feed conditions caused by unsteady green Hydrogen supplies. The results highlight the impact of the rate of feed changes on the overall control performance, with 1% throughput change per hour identified as a stable rate for maintaining system stability and performance. Despite the complexities of the process, including multiple recycle loops and the divided wall column, the PWC system ensured stable operations. Notably, the FA purity remained within a maximum of 0.2% deviation from the desired 85 wt%, even under the harshest feed flowrate changes of ±20%. The deviation of the FA flow rate in dynamic mode from the steady-state simulation for the +20% and -20% changes in throughput was +0.6% and -0.2%, respectively, further showcasing the robustness of the design. Overall, the evaluation of the PWC design of Formic acid under unsteady Hydrogen supply conditions proved the feasibility of the suggested PWC design on a conceptual level.

## ABSTRACT

This work presents a macroscopic, high-level representation of the interconnected nexus system, utilizing a resource allocation model to capture the interactions between the power and water subsystems. The model is employed to assess the system's performance under various external stressor impact scenarios, determining the thresholds at which the system can no longer maintain a continuous supply of functional services (i.e. power and water), which reveal the system's vulnerabilities. Resilience metrics are incorporated to interpret these results and characterize the nexus performance. The proposed methodology is generalizable, and its capabilities will be demonstrated through a case study on the energy-water nexus in the Gulf Cooperation Council region.

**Keywords**: Resilience, Energy, Water, Nexus

## INTRODUCTION

Energy and water are essential for societal progress and sustainability, necessitating robust management approaches to address economic, social, and environmental imperatives [1]. The demand for these vital resources rapidly evolves due to population growth, industrial developments, and external events such as climate change and instability. Consequently, the systems producing these resources are subject to multidimensional stressors and must be well-designed and operated to meet these dynamic demands [2]. Energy and water systems, commonly referred to as the Energy-Water Nexus, are interconnected through flows of water, electricity, and heat, which are fundamental to maintaining continuous operation and functional service supply [3]. While distinct in processes and infrastructures, they are highly interdependent, increasing the complexity of the system. Water is needed in energy production for cooling, while energy is essential for pumping, treatment, and desalination. This codependency has guided recent research to view these two systems as a coupled unity with two key directions: "water for energy" and "energy for water" [2,4].

The Gulf Cooperation Council region, GCC, is known for its abundance of energy resources, such as oil and natural gas, making it a global energy hub. However, it faces a severe scarcity of freshwater resources, ranking it among the world's most arid regions [5,6]. As a result, water solutions like desalination plants and wastewater reuse have become the primary strategies in these areas. Seawater desalination, a widely adopted process to address freshwater shortages, is a highly energy-intensive endeavor that requires continuous supplies of heat and/or power, depending on the technology used [7]. Currently, desalination plants account for the majority of the region's freshwater supply, with fossil fuel-based power plants providing the necessary energy input [8]. Wastewater treatment facilities further contribute to the nexus by supplying treated wastewater, primarily for greening, irrigation, and limited agricultural activities [9]. This complex interconnection of power plants, freshwater production plants, and wastewater treatment plants enables the exchange of material and energy resources to support domestic, industrial, and agricultural demands. However, this strong dependency between water and energy systems raises critical concerns about the resilience and sustainability of resource management in the region.

Interconnected Energy-Water Nexus systems face a variety of internal and external events that can disrupt

their operations. These disruptions may decrease the system's efficiency or lead to partial or complete production failure, preventing the system from meeting demand constraints [10]. Potential external factors that may disrupt the operational stability of the nexus include governance frameworks, suboptimal management approaches, resource constraints, and the impacts of climate change [11]. Extreme weather events, policy shifts, geopolitical tensions, or technical failures further intensify nexus vulnerabilities [12]. The inherent uncertainties associated with these events render these critical systems fragile and threaten the continuous provision of essential power and water services. Ensuring resilience to such disruptions is crucial as the unpredictability of these stressors jeopardizes system stability, increasing risks to infrastructure networks and resource security. Climate change, in particular, is one of the primary drivers of instability. Hence, enhancing resilience within the nexus is essential for adaptation [3]. A system's resilience is defined by its ability to withstand, adapt, absorb, and recover from disturbances while maintaining functional service delivery [13].

## Resilience Challenges within the Energy-Water Nexus

Many resilience assessments in energy-water systems focused on evaluating individual subsystems in isolation, limiting their ability to capture the cascading impacts between interconnected components [4,10]. Additionally, some studies rely on static resilience analyses, overlooking the temporal variations in supply and demand that influence real-world infrastructure performance [3]. Emerging research highlights the need for integrated approaches that optimize resource allocation in the energy-water nexus to improve system resilience [14,15]. Process system optimization provides a structured framework for modeling interdependencies and resource flows, enabling cost-efficient decision-making. Adopting these models to the energy-water nexus to represent the subsystems as resource integration networks allows for scenario-based testing and performance evaluation.

A key limitation of current resilience studies is the lack of dynamic modeling to track system behavior over time. Accordingly, introducing a temporal scale into the steady-state resource allocation can bridge this gap by capturing the dynamic behavior of power and water production, as well as fluctuating demands [16]. Resilience must be quantified through scenario analysis to identify deviations from operational targets and expose system vulnerabilities. Incorporating resilience principles into the process system optimization provides a structured decision-making tool for addressing potential disruptions at both design and operation stages [13].

Before implementing resilience planning strategies, it is essential to assess the performance of the existing system and evaluate its vulnerabilities. This pre-assessment allows for optimization-driven solutions tailored to system characteristics and constraints [17]. While such vulnerability assessments have been widely applied in transportation networks and energy supply chains, they remain underutilized in the water-energy nexus domain [18,19].

## Approach and Key Contributions

This study adopts a superstructure-based optimization approach to assess the resilience of an energy-water nexus system under disruption scenarios. The resilience assessment focuses on the measurable impacts of capacity losses on functional service delivery, helping to identify system vulnerabilities and inform resilience enhancement strategies. By simulating disruptions, this approach aids in designing optimal operational adjustments

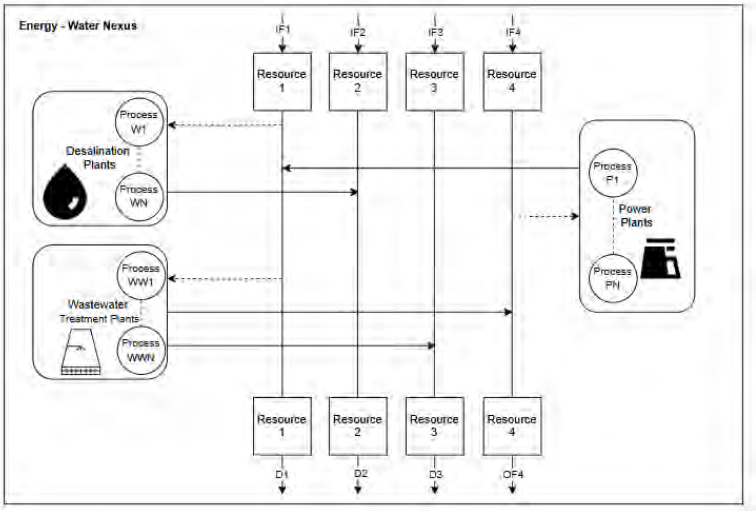

**Figure 1:** Shematic representation of the nexus superstructure

that minimize service interruptions and support system recovery.

To advance resilience modeling, this study introduces a resilience-driven optimization framework that:

- Integrates system-level scenario analysis to investigate cascading disruptions.
- Uses optimization-based resilience assessment to improve resource allocation.
- Incorporates time-dependent resource dynamics, capturing fluctuations in demand and production.
- Identifies key vulnerability thresholds to guide proactive mitigation strategies.

This quantitative approach provides a structured method for evaluating interdependencies and optimizing resource allocation under disruptions. By leveraging scenario-based stress testing, the framework offers actionable insights for policy and infrastructure planning.

# METHODOLOGY

## Energy-Water Nexus Resilience Optimization Framework

The proposed resilience-driven optimization framework integrates system modeling, resource allocation, and resilience quantification. The framework consists of three core stages:

- System Representation & Resource Allocation Modeling: This stage establishes the interconnections between power generation, desalination, and wastewater treatment systems. It defines the material and energy exchange pathways necessary for effective resource allocation and formulates resource balance equations to capture the interdependencies among the subsystems.
- Optimization & Operational Analysis: The second stage implements a cost-minimalization optimization model to balance supply and demand. It incorporates plant capacities, resource availability, and operational flexibility constraints to identify optimal operational configurations under stress scenarios.
- Resilience Assessment & Scenario Testing: The final stage introduces disruption scenarios ranging from partial to complete power losses to evaluate cascading impacts on the nexus. The Resilience

  Index and System Reliability are quantified metrics used to assess the system's performance under stress, revealing key vulnerability thresholds of the nexus.

## System Modeling and Optimization

The energy-water nexus system is represented at a macroscopic, high level in **Figure 1.** The system is modeled using a resource allocation model that captures the interactions between the main components: power plants, desalination plants, and wastewater treatment plants. These components are interconnected through resource lines, where main and auxiliary resources, including materials and energy, are exchanged within the physical constraints imposed by resource availability and plant capacities, adopting the method developed by Ahmed et.al [20]. The model has been advanced to incorporate a temporal scale, which is essential to reflect the dynamic behavior of the energy and water production systems, as well as the dynamic demands for functional services, following the model advances developed by Lameh et.al. and customizing it to the characteristics of the energy-water nexus [16]. The resource balance equation governing the model is:

$$IF(r,t) + \sum \varphi(r,p)CAP(p,t) + OF(r,t) = D(r,t) \quad \forall\, r \in R, p \in P, t \in T \tag{1}$$

Where $IF(r,t), OF(r,t), D(r,t) and\ CAP(p,t)$ are input resource flowrate, output resource flowrate, resource demand rate, and plant capacity respectively.$R, P and\ T$ are the sets of resources, processes and time periods respectively. $\varphi(r,p)$ is a factor that represents the ratio of resource production or consumption to the main resource produced by the process P. The resource allocation model is utilized in an optimization formulation that minimizes the total cost of the integrated system, accounting for components and resources capital and operation cost as given by the objective function:

$$Min\ (C_{CAPEX} + C_{OPEX} - R_{Total}) \tag{2}$$

Where, $C_{CAPEX}, C_{OPEX}, R_{Total}$ are the total capital cost, total operational cost, and total revenues, respectively. The aim is to meet water and electricity system demands at minimum cost. The incorporated subsystems are defined in the model on a technological basis (i.e., technologies for each type of production plant) and incorporate distinctive parameters for each type in terms of CAPEX, OPEX, and minimum and maximum capacities. These parameters are collected from peer-reviewed and reputable literature resources.

## Resilience Analysis

The system's performance is analyzed by observing the optimal solution of the optimization problem. It provides the most optimal operational load at which each production technology must be operated, revealing how much of the total capacity is utilized to meet the demand. The net balance of resources across the network is tracked to indicate the success or failure of the system

to meet the demand. A balance of zero ensures that a demand was met, while a negative balance indicates a shortage. In the later case, the model is directed to provide the needs through virtual, highly costed water and power reservoirs resulting in substantially high overall cost indicating system failure. The study focuses on revealing the nexus's vulnerability to potential losses of power production capacity as an impact of external stressors and how that impact cascades onto water and wastewater plants. Accordingly, disruption scenarios where the model is subjected to gradual losses of power production capacities, ranging from 0% to 100% power losses, are analyzed based on production technology type. This gradual reduction contributes to the loss of plant capacities that are associated with the technology under consideration.

A comparison between the demand variation over time and the system's output of water and electricity is conducted to reveal the system's bottlenecks. The resilience index and reliability of the system are evaluated in each scenario as metrics reflecting the resiliency level, according to the following equations:

$$RI = \frac{D - S_{Op}}{D} \quad (3)$$

$$SR\% = \frac{TD_{met}}{TS_{Op}} \times 100\% \quad (4)$$

where $RI$ is the Resilience index; $D$ is the demand for a functional service; $SR$ is the System reliability, reflecting the system's capability to meet the demand without failure; $TD_{met}$ is the total times the demand is met; and $TS_{Op}$ is the total times the system is operated.

## CASE STUDY

To demonstrate the method, an energy-water nexus system serving an arid region is investigated. The nexus comprises power generation facilities, desalination plants, and wastewater treatment facilities. The power plants produce both electricity and heat to meet external power demands and the needs of the desalination and wastewater treatment processes. The desalination plants generate potable water for domestic and industrial use, while the wastewater treatment facilities produce treated effluent to satisfy water demands for landscaping, irrigation, and limited agricultural activities in the region. The power production facilities incorporate three primary technologies: combined-cycle gas turbine with waste recovery (CCGT-CHP), open-cycle gas turbine (OCGT), and photovoltaic solar panels. The desalination plants employ thermal multi-effect desalination, multi-stage flashing, and reverse osmosis technologies. The wastewater treatment facilities range in scale from medium to large, utilizing secondary and tertiary treatment processes.

**Table 1** and

**Table 2** below summarizes the characteristics of the power plants, the featured nexus subsystem in this study, and the monthly demands for functional services. For demonstration purposes, disruption scenarios in which the production capacity of the dominant power generation technology is subjected to a loss percentage ranging from 0% to 100% are required to evaluate the nexus resilience and reliability to each of these impacts using the resource allocation model.

**Table 1** Power Generation Parameters

| Technology | CAPEX ($/MWh) | Max Capacity (TWh/yr) |
|---|---|---|
| CCGT-CHP | 10.7 | 77.6 |
| OCGT | 9.06 | 17.4 |
| PV | 7.5 | 3.07 |

**Table 2** Monthly demands of functional services

| Month | Power Demand (TWh) | Water Demand ($Mm^3$) | Treated Water Demand ($Mm^3$) |
|---|---|---|---|
| Jan | 2.96 | 52.0 | 11.0 |
| Feb | 2.66 | 47.7 | 10.4 |
| Mar | 3.43 | 54.1 | 12.3 |
| April | 3.98 | 55.9 | 15.7 |
| May | 4.82 | 58.0 | 17.5 |
| Jun | 5.45 | 57.4 | 18.5 |
| Jul | 5.86 | 58.5 | 18.3 |
| Aug | 6.35 | 60.2 | 18.4 |
| Sep | 4.48 | 34.0 | 17.4 |
| Oct | 4.02 | 33.7 | 17.3 |
| Nov | 3.25 | 30.7 | 15.1 |
| Dec | 2.76 | 29.6 | 14.0 |

## RESULTS AND DISCUSSION

The model was employed to examine the impact of losing varying proportions of the power production capacity associated with the predominant technology, the combined cycle gas turbine with waste heat recovery, denoted as T1 in **Figure 1**. This technology accounts for an average of 79% of the total power generation within the existing nexus system. The findings indicate that the nexus can tolerate up to a 20% loss of this technology's capacity, which is equivalent to a 16% reduction in the overall power production capacity of the nexus, while still being capable of meeting the demands for power, water, and treated wastewater effluent. This is demonstrated in **Figure 1(a)** where the resilience index of the system for all of the 3 subsystems involved maintains a value of 1. This is associated with an overall nexus reliability of 100% ensuring the nexus's ability to meet all the demands at all periods despite the impact of the external shocks by

relying on the remaining 84% of total capacity for power generation. As the loss percentage of this technology goes up to 40%, the integrated system succeeds in meeting the demands for both water and treated sewage effluent for all periods while it fails at delivering external power demands for the June to August period. This is reflected by a resilience index that drops to 0.975, 0.9, and 0.825 for these three months, respectively, as shown in **Figure 1(b)**. Alongside the massive loss of generation capacity, another main contributor to the declined system performance is associated with higher demand registered in these summer months. The overall nexus reliability registered for this scenario is 91.7%. **Figure 1(c)** reveals that the impact of losing 60% of T1 production capacity propagates to the water subsystem as reflected by the resilience index drop for this subsystem between the January and September period in addition to the system's inability to meet power demands in May to September. The observed differences in the failure frequencies between the two subsystems potentially hint at cost-based prioritization for power production over water desalination governed by the optimization algorithm, an interesting point that calls for further investigation. In **Figure 1 (d)** 80% loss of T1 led to insufficient power and water supplies for all periods except January and December, where water and power insufficiency altered, respectively bringing the nexus reliability down to 39%. At 100% loss of T1 capacity illustrated in **Figure 1 (e)**, the nexus system 79% of its power generation activities resulted in insufficient supplies of power and water at all periods with resilience indices below 0.6 for the associated subsystems and an overall reliability of 33%. The wastewater treatment subsystem maintained its resilience index at 1 in all scenarios, ensuring that the demand for treated sewage effluent was met. This may be attributed to the relatively lower power requirements and costs associated with the wastewater treatment processes.

## CONCLUSIONS

Using a resource allocation model within an optimization framework is a promising approach to guide decision-making for interconnected energy-water nexus systems. This method has demonstrated the ability to assess the system's resilience against quantified impacts of external stressors. In the examined case, the system could withstand up to a 21% loss of power production capacity before being unable to meet the demand for the interconnected subsystems' functional services. Furthermore, this method facilitates the analysis of each technology's contribution to the overall resilience scheme of the nexus. The optimization component ensures an optimal target is achieved as the system responds to a stressor impact, which may inform strategies that prioritize economic or environmental goals, depending on the set target. Consequently, this method can assist in

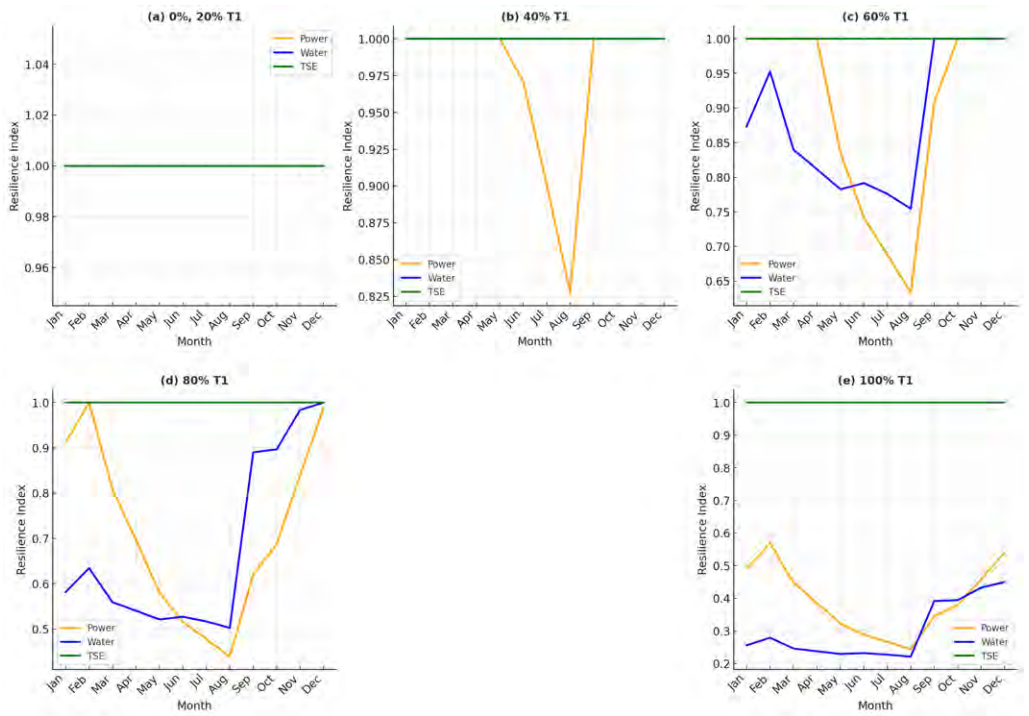

**Figure 1:** Resilience index of the energy-water nexus at various impacts of external stressors (a) 0%,20% T1 capacity loss (b) 40% T1 capacity loss (c) 60% T1 capacity loss (d) 80% T1 capacity loss (e) 100% T1 capacity loss

developing system hardening and emergency response plans to guarantee meeting all or prioritized demands from the nexus. These potential warrants further investigation in future work to help tailor strategies that enhance the resilience of the integrated nexus.

## ABSTRACT

The increasing need for Direct Air Capture (DAC) technologies is driven by the urgent global need to mitigate rising $CO_2$ levels due to climate change. In humid climates, DAC systems face challenges as high humidity increases the energy required for regeneration. This study introduces a novel DAC system integrated within an Air Handling Unit (AHU) that includes a silica gel wheel for air dehumidification before $CO_2$ capture, significantly enhancing physisorbent performance by optimizing conditions for $CO_2$ adsorption. This system, tailored for the AHU of Doha Tower, involves dehumidifying return air, subsequently cooling it for effective CO2 capture. The introduction of the silica gel wheel notably reduced the energy requirements by 81.5% for NbOFFIVE compared to configurations without dehumidification, and the thermal energy cost for NbOFFIVE when integrated with HVAC and silica gel is 70 USD/ $ton_{CO2}$, compared to 160 USD/ $ton_{CO2}$ for SBA-15 + TEPA used alone. Additionally, the thermal energy cost for the HVAC system was reduced from 430 USD/$ton_{CO2}$ to 303 USD/ $ton_{CO2}$. A technoeconomic analysis highlights these improvements as crucial for reducing operational costs and cutting capital expenditures by leveraging existing AHU infrastructure. Despite the higher initial cost of NbOFFIVE, the levelized cost for DAC using NbOFFIVE is estimated at 184 USD per ton of $CO_2$, making it economically advantageous compared to 208 USD per ton for SBA-15.

**Keywords**: DAC, HVAC, Dehumidification, Chemisorption, Physisorption

## INTRODUCTION

Recent data shows a steady increase in global surface temperatures, with a notable 1°C rise since the pre-industrial period, making 2023 the hottest year to date [1]. These changes reflect broader climate shifts that manifest in altered weather patterns and varied precipitation across regions, contributing to environmental strain [2]. Within this context, the built environment emerges as a major energy consumer, responsible for substantial $CO_2$ emissions, particularly from systems like air conditioning that dominate building electricity usage [3, 4]. With projected temperature increases, the demand for cooling is expected to surge, potentially creating a feedback loop that could exacerbate global warming [5].

Direct Air Capture (DAC) technologies represent a promising avenue for mitigating atmospheric $CO_2$ levels. Unlike conventional methods that target emissions at their source, DAC systems capture carbon directly from the air, highlighting their potential in comprehensive climate strategies [6]. However, DAC's effectiveness is tempered by current technological and economic limitations, as evidenced by the modest capacity of existing facilities like the Orca in Iceland [16]. Innovations in material science and system design remain pivotal for enhancing DAC's efficiency and affordability, with costs of carbon removal varying widely [7].

The effectiveness of DAC is heavily influenced by the choice of capture materials—adsorbents and absorbents [8]. Adsorbents, in particular, are advantageous due to their lower energy requirements for regeneration and significant CO2 adsorption capabilities [9]. Developments in materials such as MOFs and amine-functionalized silica have achieved notable $CO_2$ uptake efficiencies

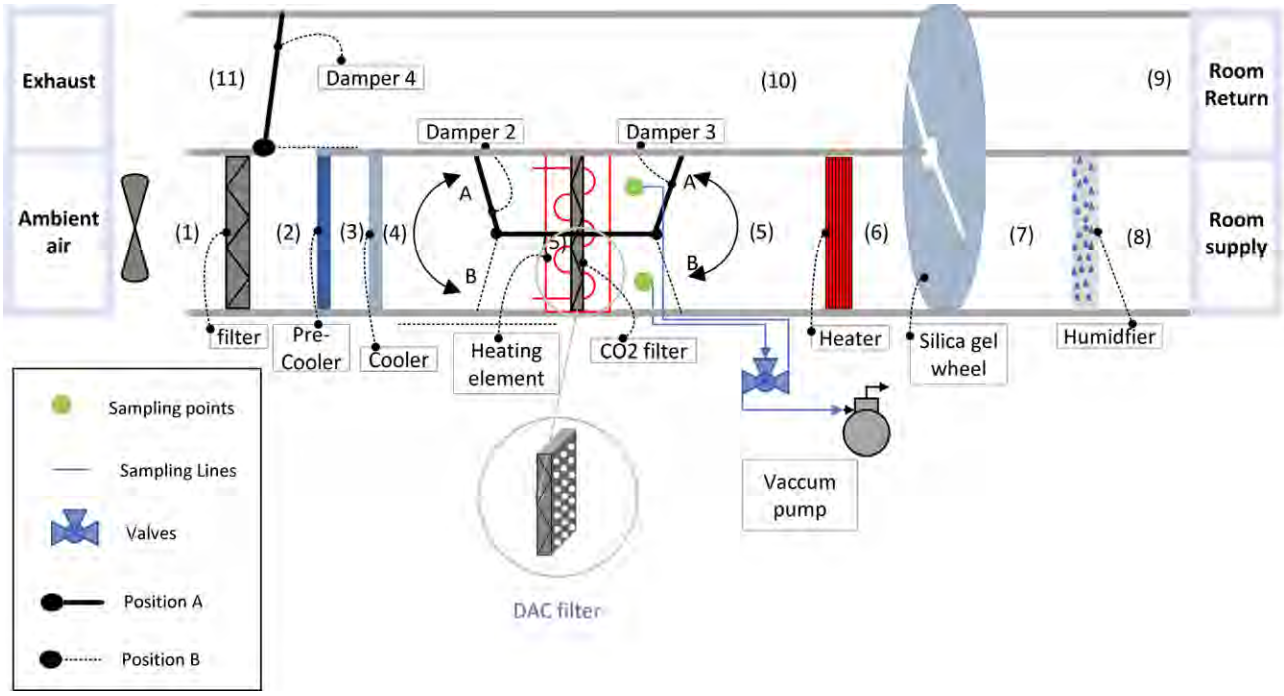

**Figure 1:** System diagram shows the Air handling unit compenents, DAC and silica gel wheel

under ambient conditions [10]. Yet, managing humidity remains a critical challenge, with innovations aimed at mitigating moisture to enhance system performance [11].

In advancing our previous investigations where the integration of DAC within HVAC systems to optimize energy use and $CO_2$ capture in buildings were investigated [12-15]. We examine the technoeconomic aspects of employing a novel physisorbent, NbOFFIVE with silica gel, and compare its performance and cost-effectiveness to a setup using SBA-15 alone, without silica gel. Both scenarios utilize integration within HVAC systems, aiming to establish a comparative understanding of their viability and scalability in urban structures like Doha Tower. This analysis seeks to identify the most efficient and economically feasible solution for large-scale implementation in modern buildings.

## METHODOLGY

### System description

In the configuration shown in Figure 1, return air is first dehumidified by passing through the silica gel wheel at Point 9, which was experimentally proven in our previous work to desorb water without heating, thereby reducing costs associated with water desorption. Following dehumidification, this air is mixed with the required fresh air at Point 2. The mixture is then cooled by the cooling coil to reach the supply temperature of 12°C at Point 3. After cooling, the dry, cooled air enters the Direct Air Capture (DAC) unit at Point 3, where $CO_2$ is captured using NbOFFIVE, a physisorbent free of amines. This material choice not only eliminates the cost of water desorption from DAC but also removes functionalization cost, enhances stability and avoids interactions of amines with air.

This system does not employ full recirculation as studied in [13] which reduces the need for additional filtration to manage airborne particulates, as fresh air is continuously introduced. However, it captures about 50% of ambient $CO_2$ levels due to the filtering of recirculated $CO_2$, with only fresh air and emissions from indoor occupants and appliances contributing to the $CO_2$ load. This setup will be compared to an alternative where SBA-15-TEPA [15] is used without a silica gel wheel and positioned at the beginning of the return stream at Point 9, both integrated within an Air Handling Unit (AHU) in an HVAC system. The comparative analysis aims to evaluate the performance and economic aspects of using NbOFFIVE versus SBA-15.

### Space and AHU design

In designing the AHU setup for a standard office space in Qatar, we considered a room volume of 800 $m^3$ with 30 occupants, aligned with ASHRAE standards for space allocation and ventilation. The AHU is optimized to maintain thermal comfort and indoor air quality, addressing both sensible and latent cooling loads. Our calculations incorporated factors like occupant density, equipment heat gains, and external climatic conditions, with special consideration given to the interaction

between one external wall and the conditioned space. The required supply flow rate was calculated to effectively manage these loads, ensuring stable indoor conditions of 23°C and a specific humidity ratio, by balancing the heat contributions from occupants, equipment, and infiltration.

## Adsorbents analysis

The $CO_2$ and water uptake capacities for SBA-15 functionalized with TEPA were measured using a dynamic adsorption experiments. This chemisorbent, known for its high $CO_2$ capture capacity, was tested under both dry and humid direct air capture (DAC) conditions using a 3P mixSorb analyzer. The rigorous synthesis and detailed characterization of these materials are comprehensively documented in the literature [15]. In contrast, NbOFFIVE, a fluorine-functionalized physisorbent, demonstrates excellent thermal stability with a $CO_2$ capture capacity of 1.3 mmol/g at 298 K in dry conditions. However, under humid conditions, its performance is reduced. The $CO_2$ and water uptake for NbOFFIVE were calculated based on a model outlined in the referenced study, utilizing following equations [16]:

$$q^*_{CO2} = q_s . b . \frac{P_{CO2}}{[1+(b.P_{CO2})^{\omega}]^{\frac{1}{\omega}}} \quad (1)$$

Where $P_{CO2}$ is the $CO_2$ partial pressure. The parameters b and ω describe the affinity and heterogeneity which are function of adsorption temperature and reference temperature, respectively. $q_s$ represents the saturation loading and expressed in temperature dependent form as shown in equation (2). The parameters b and $\omega$ describe the affinity and heterogeneity.

The water isotherm data under equilibrium conditions were fitted using Guggenheim - Anderson - de Boer (GAB) model [16]:

$$q^*_{H2O} = \frac{C_m C_G K_{ads} x}{(1-K_{ads}x)(1+(C_G-1)K_{ads}x)} \quad (2)$$

Here, the relative humidity is represented by x, and Cm, Cg and Kads are fitting parameters.

## Energy calculations

In this study, the energy required for the Thermal Swing Adsorption (TSA) process was estimated by building upon the methodology outlined in our previous work [17]. This involved considering the mechanical work needed for $CO_2$ compression, the heat necessary for desorbing $CO_2$ and $H_2O$, and the energy to facilitate the thermal swing of the sorbent and its adsorbed components. The analysis excluded parasitic losses such as pressure drops and heat dissipation. Energy consumption for sorbent regeneration was quantified, including the power for the vacuum pump operation, calculated as

$$W_{comp} = \frac{R . T_{pump}}{\eta_{pump}} . \ln\left(\frac{P_{amb}}{P_{des}}\right) \quad (3)$$

The sensible heat required to raise the sorbent to the desorption temperature was expressed as

$$Q_{sens} = \left(\frac{c_{p_{sorb}}}{\Delta q_{CO2}} + c_{p_{CO2}} + c_{p_{H2O}} \left(\frac{\Delta q_{H2O}}{\Delta q_{CO2}}\right)\right) . (T_{des} - T_{ads}) \quad (4)$$

The heat inputs for desorption enthalpies of $CO_2$ and H2O were calculated and added to the total heat per mole of separated $CO_2$ (Equations 5 and 6).

$$Q_{des} = \Delta H_{H2O} \left(\frac{\Delta q_{H2O}}{\Delta q_{CO2}}\right) + \Delta H_{CO2} \quad (5)$$

$$Q_{Total} = Q_{des} + Q_{sens} + Q_{cooling} \quad (6)$$

Furthermore, the main components of the AHU, including precooler, cooler, heater, and fan, were modeled using the mass balance equation, the first and second laws of thermodynamics, with the energy balance for each component detailed in [18], represented by

$$\dot{m}_i \times h_i + \dot{Q}_i + \dot{W}_i = \dot{m}_o \times h_o + \dot{Q}_o + \dot{W}_o \quad (7)$$

## Technoeconomic analysis

The levelized cost is calculated using Equation 8, which accounts for capital expenditures (CAPEX), fixed operating costs ($OPEX_{fix}$), variable operating costs ($OPEX_{var}$), and the amount of $CO_2$ captured ($CO_{2,captured}$). The CAPEX includes the base costs of equipment required for the TVSA process in the DAC system, such as the vacuum pump, heat exchanger, heat pump, and the adsorbent filters, as well as the costs associated with equipment delivery and installation. The variable OPEX accounts for utility costs, including electricity requirements for heating, cooling, and vacuum generation. The fixed OPEX covers maintenance, labor, insurance, administrative expenses, and filter replacement costs. The Capital Recovery Factor (CRF), which is used to annualize the capital investment over the project lifetime, is calculated using Equation 9. It is derived from the interest rate and project lifetime.

$$LC = \frac{CAPEX.CRF + OPEX_{fix}}{CO_{2,captured}} + OPEX_{var} \quad (8)$$

$$CRF = \frac{i(1+i)^n}{(1+i)^n - 1} \quad (9)$$

where i is the discount rate (7%) and n is the project lifetime (20 years) [19].

Moreover, a sensitivity analysis is performed to examine the impact of varying discount rates and utility prices, primarily electricity, on the levelized cost of the DAC system.

# RESULTS

Figure 2a displays the thermal energy required for

five different cases concerning HVAC and DAC systems. The first two bars (A and B) represent the cooling load consumption of an HVAC system when operating alone and within an integrated system incorporating DAC and silica gel (as outlined in Figure 1). The significant decrease in energy from A to B demonstrates the efficiency improvement when HVAC is combined with silica gel, which aids in moisture control.

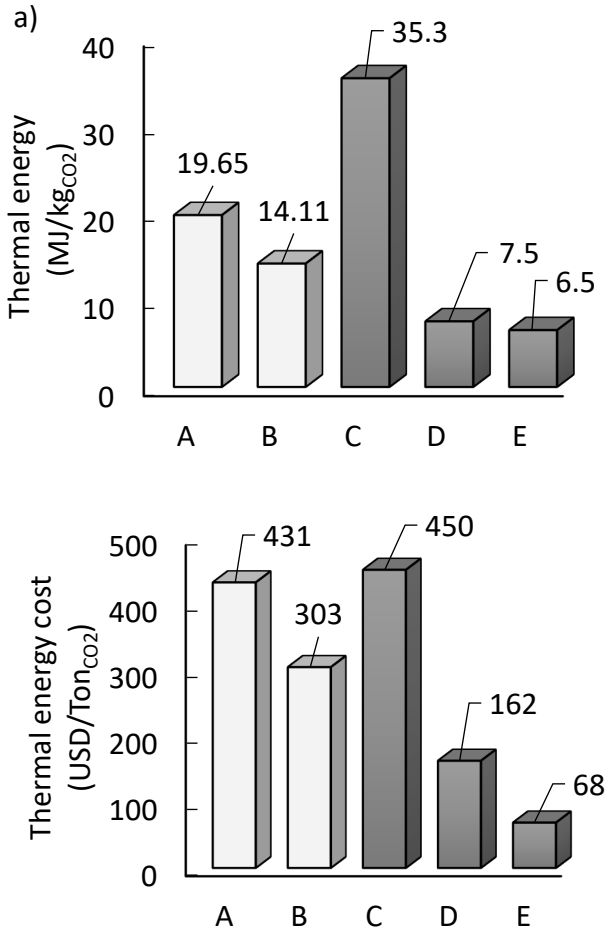

**Figure 2:** 2a) Thermal energy (MJ/kgCO2) and 2b) Thermal energy cost (USD/ $KgCO_2$ ) for (A) HVAC only, (B) HVAC within integration, (C) NbOFFIVE based DAC only, (D) SBA-15 + TEPA based DAC only, (E) NbOFFIVE based DAC within integration.

For bars C to E, it focus on DAC systems. The 'C' bar represents a DAC system using the physisorbent material NbOFFIVE, notable for its sensitivity to humidity, which explains its higher thermal energy consumption. Bar 'D' illustrates the thermal energy for a chemisorption-based DAC system using SBA-15 + TEPA, known for high $CO_2$ uptake efficiencies [15]. Finally, bar 'E' shows the reduced thermal energy consumption for an NbOFFIVE-based DAC system when integrated within the HVAC system incorporating silica gel wheel. This reduction highlights the effectiveness of integrating silica gel for moisture removal and leveraging the cooler air streams from the HVAC system, which significantly lowers thermal energy requirements, making it even more efficient than the SBA-15 + TEPA system.

Figure 2b correlates these thermal energies to their respective costs, normalized by the amount of $CO_2$ captured. The calculated costs incorporate the required electricity for a heat pump (assuming a COP of 2.6) and the local Qatari electricity rates (0.03 USD/kwh). This economic analysis further emphasizes the cost-effectiveness of integrated systems, particularly when using NbOFFIVE within an HVAC setup, due to the synergistic effects of reduced thermal loads and optimized energy use.

This detailed energy and cost analysis provides valuable insights into the selection of HVAC and DAC configurations, guiding towards choices that balance performance with economic feasibility in a climate-sensitive deployment scenario.

The levelized cost of the DAC system in this study is \$190 per ton of $CO_2$, which is within the range of \$88 to \$228 per ton of $CO_2$ estimated by the National Academy of Sciences (NAS) for DAC systems with solid adsorbents. Additionally, TVSA using a magnesium-based solid MOF sorbent has been reported to have a price range of \$60–\$190 per ton of $CO_2$[20].The sensitivity analysis indicates that the levelized cost of the DAC increases with a higher discount rate, reaching \$227 per ton of $CO_2$ at a 15% discount rate (Figure 3, a). Furthermore, utility prices significantly impact the levelized cost, with unsubsidized electricity prices in Qatar potentially driving the DAC's levelized cost up to \$306 per ton of $CO_2$ (Figure 3, b).

For SBA15 the levelized cost is 218 \$/ton $CO_2$. At a discount rate of 15% the cost gets higher to 251\$/ton $CO_2$ and at a high electricity cost of 0.14 \$/kWh the levelized becomes 438 \$/ton $CO_2$.

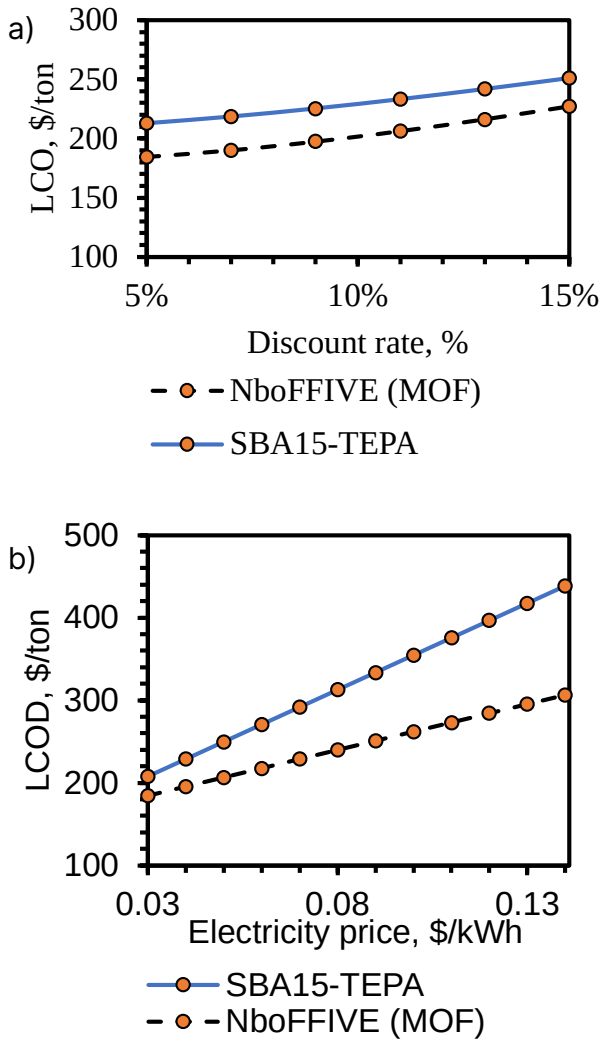

**Figure 3:** Effect of discount rate (a) and electricity price (b) on levelized cost of DAC.

### Conclusion

In conclusion, this study demonstrates the significant potential of integrating Direct Air Capture (DAC) technology within an Air Handling Unit (AHU) to effectively mitigate the challenges posed by high humidity in DAC systems. By incorporating a silica gel wheel for air dehumidification before $CO_2$ capture, the system tailored for the AHU of Doha Tower significantly enhances the performance of physisorbents like NbOFFIVE, reducing their energy requirements by 81.5% compared to traditional configurations. This integration not only leads to a substantial decrease in thermal energy costs—from 430 USD/tonCO2 to 303 USD/ton$CO_2$ for the HVAC system and from 160 USD/ton$CO_2$ to 70 USD/ton$CO_2$ for NbOFFIVE—but also notably lowers the levelized cost of DAC to 184 USD per ton of $CO_2$, offering an economic advantage over systems using SBA-15 + TEPA. Furthermore, this innovative integration allows for the utilization of an amine-free system, marking a significant advancement, particularly for indoor applications where health concerns are paramount. The technoeconomic analysis underscores the crucial role of leveraging existing AHU infrastructure to cut operational costs and capital expenditures, making this integrated DAC system a highly attractive solution for large-scale $CO_2$ capture in building environments.

## ABSTRACT

Demographic shifts and increased automation in chemical plants are reducing the experience and skill levels of plant operators. Therefore, BASF has implemented Operator Training Simulators (OTS) to allow operators to practice and improve their skills in this safe and controlled environment. The OTS consists of a dynamic model of the process, a control system and safety logics. This paper describes the learnings from using OTS at BASF, where they are used to train operators in process understanding, optimization, procedural training, and disturbance handling. Benefits include reduced training costs, minimized risks and improved efficiency. Also organizational guidelines are provided to ensure that the mentioned benefits are realized in industrial practice. Additionally, high-accuracy OTS models support HAZOP, debottlenecking, and optimization studies.

**Keywords**: Simulation, Optimization, Modelling and Simulations, Training Systems, Digital Twin, Dynamic Modelling

## INTRODUCTION

The chemical industry is characterized by complex processes and stringent safety requirements, making the training of operators a critical component for ensuring operational efficiency and safety. Traditional training methods, while effective to some extent, often fall short in providing hands-on experience and real-time decision-making skills necessary for modern plant operations.

Furthermore, a significant demographic shift and a surge in automation, has led to a decline in the experience and skill levels. This trend is further exacerbated by the fact that new operators are accustomed to different learning methods compared to their predecessors. Consequently, there is an urgent need for innovative training solutions to bridge the skills gap and ensure operational safety and efficiency.

*Operator Training Simulators* (OTS) (see, e.g., [1-3]) have become indispensable tools within BASF to address these challenges. OTS provide a realistic and immersive training environment where operators can practice and enhance their skills in a safe and controlled setting. Furthermore, the OTS system serves as a *digital twin* of the plant, allowing to test changes in control structure and perform optimisation process studies [4]. These OTS's simulate the dynamic behavior of the chemical plant with a *dynamic first principles model*, replicate the behavior of the *Distributed Control System* (DCS) system including the *Human Machine Interface* (HMI) and process controls and the safety logics, offering a comprehensive training experience.

In this paper, first the different types of OTS systems are discussed, followed by the technical details of how an OTS is set up. Third, insight is given in the way OTS's are embedded in the organization from a management perspective followed by some case studies. Operators trained with OTS exhibit improved problem-solving skills, faster response times, and a better understanding of process safety. Furthermore, the use of OTS has been linked to a reduction in operational errors and incidents, contributing to overall plant safety and efficiency. Finally, a summary is presented including lessons learned.

## TYPES OF OTS SYSTEMS

Industrial OTS systems consist of 3 distinct main parts as depicted in Figure 1:

- a detailed *dynamic model* which accurately describes the plant behavior.

- an emulation of (i) the *Distributed Control System* (DCS), comprising the process controls and logics, and (ii) the *Safety Interlock System* (SIS), comprising the separate safety system.
- a *Human Machine Interface* (HMI), displaying all sensor values on a process diagram and allowing the operator to interact with the process.

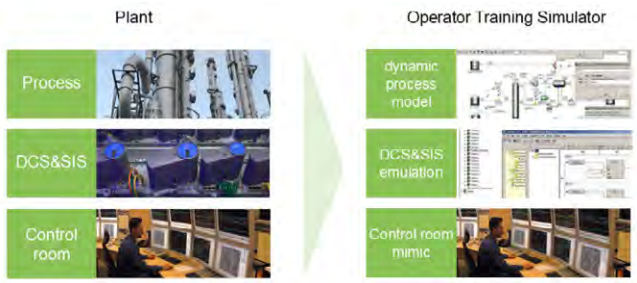

**Figure 1.** Components of an OTS system.

A distinction between 3 classes of OTS's can be made based how accurately the real plant is represented by the OTS and the way the above-mentioned components are implemented: (i)*High Fidelity* (HiFi) OTS, (ii) *Mid Fidelity* (MiFi) OTS and (iii) *Low Fidelity* (LoFi) OTS. Here is HiFi-OTS the most expensive and complex to implement while the other two are a less accurate representation of the plant, but at a significant lower implementation cost and complexity. Below, we will briefly discuss every type. Figures 2 and 3 summarize their features.

The **HiFi OTS** is distinguished by its highly detailed and realistic modeling, designed to closely replicate actual plant operations. This system facilitates comprehensive training, encompassing both the start-up and shut-down processes of the plant, as well as the management of random scenarios. The HiFi OTS employs components for the DCS that are virtually identical to those used in the actual DCS, ensuring that the training environment accurately mirrors the real control system. Furthermore, it features the same HMI as the real DCS, providing operators with a familiar and intuitive interface. The SIS within the HiFi OTS is also an exact replica of the real SIS, enhancing the realism and effectiveness of the training experience. Because this type of OTS matches closely the real plant, the OTS also serves as a digital twin allowing to, e.g., test DCS changes and perform plant optimization and safety studies. A HiFi-OTS is particularly advantageous for plants that experience infrequent shut-downs and where unplanned trips are exceedingly costly. In general, this OTS is considered for larger plants with typically more than 5000 IO's (Input/Output points). By providing a realistic and immersive training environment, the HiFi OTS enables operators to develop and refine their skills, thereby improving operational efficiency and safety.

The **MiFi OTS** is most suited for smaller plants which have more frequent shutdowns, are less complex and have less costly plant trips. For such plants, MiFi OTS offers a better balance between cost and functionality, making it a practical choice for enhancing operator training and plant performance. The development of MiFi OTS was primarily driven by the need to reduce the investment costs associated with a traditional HiFi OTS, thereby allowing a broader adoption across various plants and processes. By simplifying the OTS architecture, MiFi OTS achieves a significant cost reduction. It employs a simpler first principles model, which focuses on fundamental process dynamics rather than the precise replication of real plant behavior. As a result, MiFi OTS typically does not support plant start-up simulations, which are often complex and require much more modelling effort. One of the key cost-saving features of MiFi OTS is the elimination of the substantial expenses linked to the representation of the DCS system and the SIS system. Instead of relying on these complex and licensed systems, MiFi OTS integrates process controls, DCS logic, and SIS logic directly within the first principles model. This integration not only reduces costs but also simplifies the overall system architecture. The graphical interface of the DCS HMI is emulated using a multifunctional graphical software package, ensuring a user-friendly interaction that generally mimics the actual plant HMI environment. MiFi-OTS is generally envisioned for plants with 1000-2000 Input/Output (I/O) points, seeking a cost-effective and less complex OTS, while still enabling training of normal operations, standard scenarios and standard procedures.

**LoFi OTS** (or generic OTS) are designed around standard unit operations to train new operators during their initial weeks. They provide a foundational understanding of basic processes and procedures, aiming to enhance the competence and confidence of new hires.

At BASF Antwerpen, the focus is on MiFi OTS and HiFi OTS. These systems allow for plant specific training with higher effectiveness on different training levels. LoFi OTS is not used often within BASF Antwerpen due to the limited learning experience which is only relevant during the first weeks of onboarding. In this paper we will therefore further focus on HiFi OTS and MiFi OTS.

## BUILDING AN OTS

Different elements are needed to build an OTS. Depending on the type of OTS envisioned and the plant condition, the requirements can change slightly. As mentioned, we focus in this paper on the cases of MiFi and HiFi OTS.

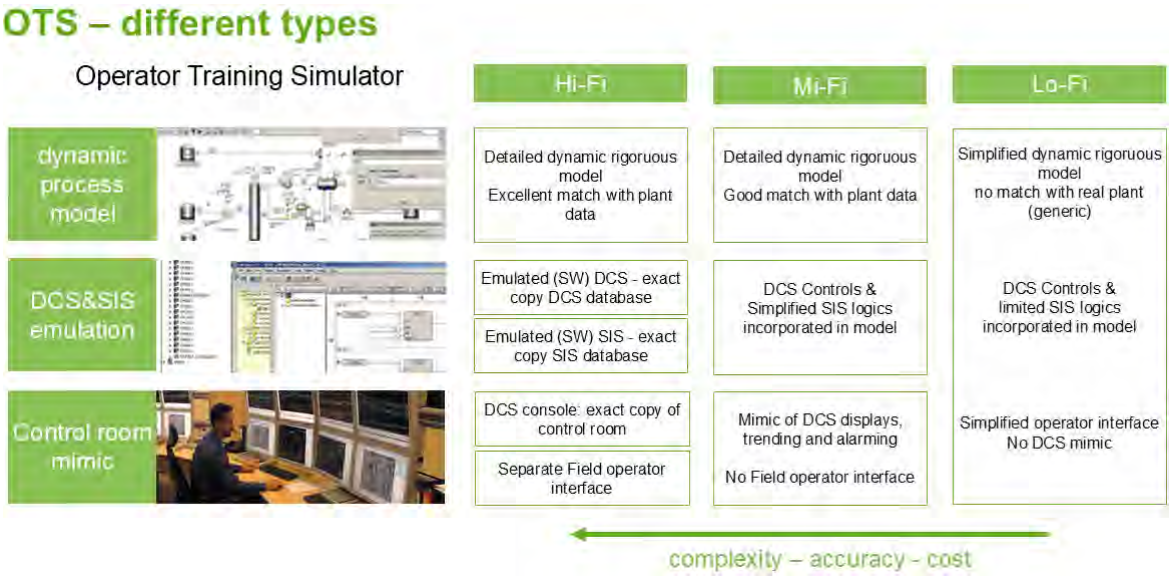

**Figure 2.** Different components of the various types of OTS systems.

| Type | Scope | Training | | | | | Testing | | Cost | |
|---|---|---|---|---|---|---|---|---|---|---|
| | | Training level | Understand process | Defined scenarios | Startup/S hutdown | Random scenarios | DCS/SIS changes | Process changes | Invest | Maintain |
| Hi-Fi | Whole plant (>5000 IO's) | Monitor<br>Operate<br>Master | ✓<br>✓<br>✓ | ✓<br>✓ | ✓ | ✓ | ✓ | ✓ | 1000k€ - 2000k€ | 5-10% |
| Mi-Fi | Section/small plant (250 – 5000 IO's) | Monitor<br>Operate<br>Master | ✓<br>✓<br>✓ | ✓<br>✓ | ✗<br>✗ | ✗ | ✓ limited | ✓ limited | 150k€ - 500k€ | 5-10% |
| Lo-Fi (generic) | Unit operation (<250 IO's) | Monitor<br>Operate<br>Master | ✓<br>✓<br>✓ | ✗<br>✗ | ✗<br>✗ | ✗ | | | 50k€ - 150€ | 5% |

**Figure 3.** Comparison between different types of OTS systems.

## REQUIRED INFORMATION

Different information is needed for the dynamic model of a plant. In view of the general plant set-up this includes (i) process flow diagrams (PFD) for the general plant lay-out (including the material and heat balances), (ii) Piping and Instrumentation Diagrams (P&IDs) for the over-all pipe connections and control design, (iii) equipment design sheets of all equipment (e.g., reactors, columns, tanks, heat exchangers, pumps, valves, compressors, sensors, ….) for the mechanical and thermal behavior, (iv) a scheme describing the relative heights of the different equipment. In view of the chemical and thermodynamical modeling this includes among others reaction kinetics, vapor-liquid equilibrium data. For HiFi OTS detailed information for all items is needed. For MiFi OTS, several aspects of can be simplified (e.g., linear valve curves, lumped kinetics and thermodynamics, and approximated thermal and kinetic equipment inertia). In view of process control functional descriptions of the different control structures are needed. When constructing an OTS, the dynamic simulations must be validated against plant data. Typically, this is performed section by section. For the brownfield OTS projects (where the plant already exists) this can be done against actual plant data. For greenfield OTS projects (where the plant is being constructed) it must be done against the (steady-state) simulation data that was gathered during plant design phase, more specifically the heat and material balance of each unit and stream.

In view of the HMI interface, there is a large difference between MiFi and HiFi OTS. For HiFi OTS the actual DCS configurations and faceplates are needed and have to available. Typically, the actual DCS system will be emulated. For MiFi OTS a selection of the actual DCS features has to programmed using DCS screenshots.

## Modeling and simulation tools

Different dynamic flowsheet simulators exist. At BASF Antwerpen the following ones are used: Aspen HYSYS (AspenTech) for MiFi OTS and DynSim (Aveva) and UniSim (Honeywell) for HiFi OTS. Apart from typical simulation aspects (mass and energy balances), the tools also have to include typical aspects for process control and process safety. This includes PID and possibly MPC controllers as well as alarming features and cause and effect schemes that guarantee the interlock and trip behavior of different equipment.

## Graphical tools

For MiFi OTS specific software is needed to create the HMI layer as the actual DCS screens and faceplates are not being emulated. Instead a mimic of the DCS displays is built covering most the most important functionality and information to be presented to the operator. At BASF Antwerpen the InProcess Infrastructure Suite IIS (InProcess) is used for this purpose.

## Software and hardware set-up

From an ICT point of view, a typical set-up of an OTS will be different for a MiFi and a HiFi OTS.

In Figure 4 a typical example of for the set-up of a HiFi OTS is given. This set-up comprises two virtualized servers hosting the different components of the process control and simulation network. These components are connected via ethernet to a switch. To this switch are also a NAS, the different operator stations as well as the instructor station connected.

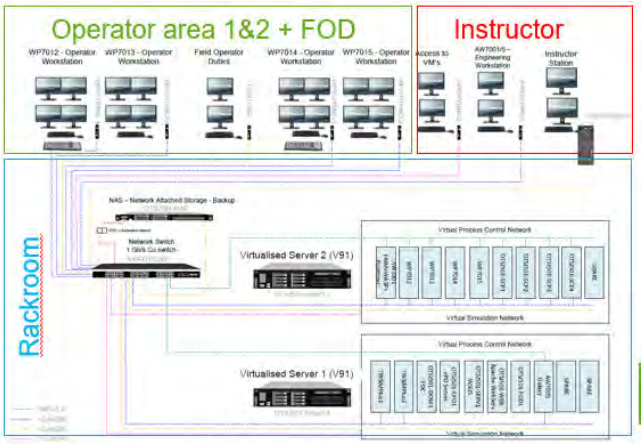

**Figure 4.** ICT components of a HiFi OTS system.

For MiFi OTS the ICT framework is simpler (see Figure 5). It comprises of a single server, where both the simulation and the HMI runs. This server is connected via the local network to an operator and an instructor station. The number of components for a MiFi OTS is low compared to the set-up of HiFi OTS .

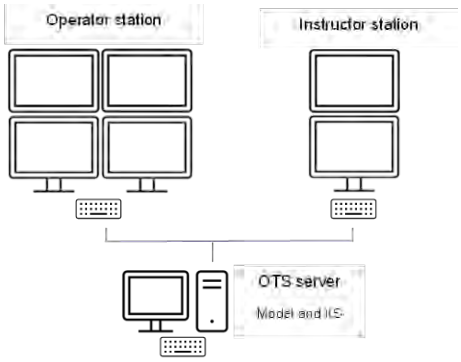

**Figure 5.** ICT components of a MiFi OTS system.

The operator working console should be mimicked as closely as possible in the training room. This means, for instance, that the operator should have sufficient screens to displays trends alongside the DCS screens. The typical quad-head setup is mimicked from the control room. Typically, in the training room there is a console for the trainer, who can interact with the simulation, e.g., by initiating different scenarios and disturbances. A picture of an OTS training room is presented in Figure 6.

**Figure 6.** View of an HiFi OTS training room.

# OTS TRAINING APPROACH

Continuous training of the operators is required to improve and maintain their skill level to assure correct operator actions in case of specific situations. OTS training has become an essential part of this continuous operator training journey within BASF.

Within BASF the skill level of operators is typically increased in three steps:

- *Monitor* level: the operator needs to be able to understand and interpret how the process is working. At this level the operator is not yet allowed to operate the plant/process from the DCS panel.
- *Operate* level: the operator is able to operate the plant from the DCS panel in normal conditions and he is able to act properly to reject smaller disturbances.
- *Master* level: the operator is able to handle the

process properly in all situations including bigger disturbances and full start-up/shut-down.

OTS is an effective training tool to reach the different skill levels mentioned above and/or to sustain the knowledge at the desired level as is depicted in Figure 3:

- *Monitor* level: basic process behavior, dynamic interactions in the plant/section can be explained and illustrated to the trainee on the OTS. The OTS is an ideal environment to explore the information displayed on and demonstrate the functionality of DCS (displays, PID faceplates, trends, alarm lists, control concepts, ...).
- *Operate* level: operators can train on the OTS how to handle the plant during, e.g., load changes or specific disturbances (e.g., smaller equipment failures) can be introduced on the OTS on which the trainee needs to respond in a correct and timely manner.
- *Master* level: the trainee can train full start-up and shut-down. Random disturbances can be introduced on OTS (equipment failures/trips) causing significant disturbances to be handled by the operator.

**HiFi OTS** systems can cover training to reach (or sustain knowledge at) all three levels mentioned above. In large, complex plants where an HiFi OTS is available, it is important to bring operators efficiently to a basic operating skill level but it is equally important to maintain and even deepen the skills of the more experienced operators (operate and master level). An evolution of the registered training of a HiFi OTS at BASF Antwerpen is depicted in Figure 7.

**MiFi OTS** systems are typically more limited in functionality (e.g. limited number of available scenario's). Consequently, they mainly focus on training towards the *monitor* and *operate* level. Typically, the plants/sections for which a MiFi OTS is available, have a smaller scope and lower complexity compared to plants where the choice is made for a HiFi OTS. In such a case (smaller scope, lower complexity plants) intensive training of operators on the *master* level is less crucial as well.

In most plants with an OTS a dedicated training instructor manages and coordinates all the training activities within the plant. The *training instructor* is *key for the success* and effectiveness of the OTS as training tool. In most BASF plants where an OTS is introduced we have a combination of training sessions on OTS performed by the instructor (typically during day time or depending on availability of the instructor) and training sessions without instructor (e.g., during night/weekend). *Instructor-led* training sessions are required to transfer knowledge in a consistent way to the trainees and to give them correct feedback on the actions taken on the OTS. *Instructor-less* training sessions allow the trainee to train on his own (e.g. repeat training sessions/scenarios performed with the instructor). *Instructor-less* training is in some cases supported by definition of kpi's (key performance indicators) to track the operator performance during the execution of a certain task on the OTS: kpi's can be defined as time or process criteria: achieve goals within time limit, while assuring not to exceed certain process parameters.

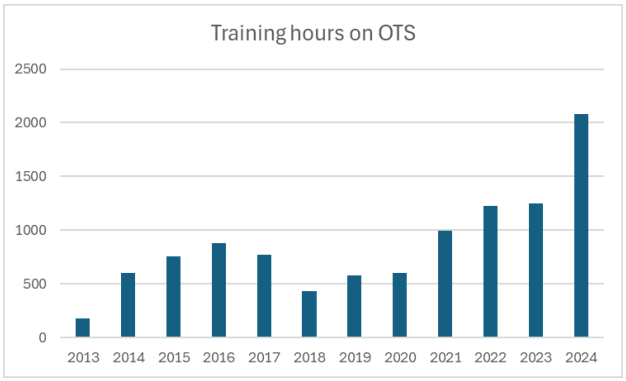

**Figure 7.** Registered training hours for a HiFi OTS at BASF Till 2022 only instructor-led trainings were registered.

## OTS AS A DIGITAL TWIN

The focus for an OTS application is training as described above. However, the rigorous dynamic plant model and the link with the control system (DCS/SIS) allows the OTS to be used for a broader range of applications ranging from process (control) optimization and design to safety studies. Below two examples are given of how OTS can be used as a digital twin to bring substantial benefits by supporting other activities besides training.

### "Parking lot" sequence for the steam cracker plant

For the steam cracker, i.e., the biggest and most complex plant at the BASF Antwerp site, a "parking lot" sequence concept has been developed. The aim of this sequence is to support the operator in case of a serious plant disturbance and to bring the plant quickly to a safe and stable state ("parking lot"). This allows a faster recovery to normal load and avoids a full trip of the plant. When the full "parking lot" sequence is activated around 150 variables (setpoints, valves, ...) are triggered to reach a desired position. The full concept was first implemented on the HiFi OTS to verify its correct operation. The HiFi OTS environment is used as an accurate digital twin allowing for full dynamic response evaluation of the plant in case the sequence is activated. In addition the operators were trained on the OTS on what to expect in case the sequence is activated. Only after these steps, the final version of the "parking lot" sequence was implemented on the real plant. This approach (validation and training on OTS first) assures a "first time right" implementation in the real plant and on top a very high

acceptance of the operators since they feel confident that the sequence and logics will work as expected. In the years the "parking lot" sequence has been implemented it was activated a couple of times working as expected. This allowed the plant to stabilize and recover to normal plant load quicky, minimizing production losses.

### Greenfield OTS: a digital twin for a new plant

Building an OTS for a greenfield plant (greenfield OTS) is especially beneficial to assure a smooth and efficient start-up of the plant due to different reasons.

The OTS can be used to train the operators extensively in order to improve and speed up significantly the understanding of the new process and how to handle it (e.g. start-up/shut-down) before the actual plant is started up. Having the OTS already available before the start-up of the plant will allow the start-up/shut-down procedures to be validated thoroughly and where required adjusted. Having the OTS available in this stage of the project allows as well to validate in detail the control concepts (DCS) and safety logics (SIS) in more detail compared to the typical FAT (factory acceptance testing) protocols applied for the DCS and SIS. The OTS allows full dynamic testing of the interaction of all the controls and logics in all different states of the process. The control concepts and logics can be improved based on the outcome of these detailed dynamic tests. Stable and dynamic behavior of the process is also related to the tuning of the PID controllers in the DCS. The OTS serves as digital twin and is the ideal test bank to provide appropriate initial values for the PID tuning. The PID parameters obtained during the testing and training on the OTS can be transferred to the life system before start-up. Sometimes conceptual design errors are identified during greenfield OTS projects that require equipment changes. An example from one of the greenfield OTS projects is the wrong sizing and positioning of an outlet nozzle on a drum not allowing to collect sufficient liquid in the drum to operate properly in all circumstances.

As illustrated above, the use of a greenfield OTS as a digital twin facilitates the early detection of all kinds of design errors (equipment, controls, procedures, …) which leads to a smoother start-up and significantly reduced start-up times. Due to the OTS training before start-up, operators are familiar with the procedures and feel much more confident to start up their greenfield plant.

## OTS MAINTENANCE

Plants are subject to modifications continuously, either to improve process efficiency or for safety reasons, equipment, piping, controls and logics are changed throughout the lifetime of a plant. Keeping the OTS aligned with the real plant is important for operators to experience the actual plant's state properly on the OTS. Training of operators on an outdated OTS system (OTS not fully in line anymore with the real plant) significantly reduces the effectiveness of the training. To avoid this degradation of the OTS training experience, regular maintenance on the OTS is required. The maintenance includes model changes (to reflect, e.g., equipment and piping changes) as well as control and logic changes (to reflect changes in DCS&SIS). Typically, maintenance is performed by a process control engineer (e.g., model changes, control and logics changes) together with the instructor (validating the applied changes in the OTS). The maintenance frequency depends on the number of plant modifications in the real plant but typically ranges from twice to once a year. Typical bigger maintenance activities on OTS are related to turn around (TAR) activities of the real plant in which major modifications are implemented on the real plant. Again, here the OTS can serve as the perfect test bank (digital twin) for changes to be applied during the TAR by implementing and testing the OTS relevant changes before the TAR takes place.

## CONCLUSION

OTS systems have become a vital tool for training starting as well as experienced operators within BASF. At BASF Antwerpen, the deployment of both High Fidelity (HiFi) and Mid Fidelity (MiFi) OTS has enabled to differentiate and tailor these training tools to different types of plants, enabling a wider adoption. The presence of a dedicated instructor is critical for the effective implementation and utilization of an OTS, ensuring consistent and impactful training. Furthermore, regular maintenance of an OTS is imperative to maintain the alignment with real plant conditions, thereby preserving its relevance and efficacy as training instrument. Beyond their primary training function, OTS also serve as a digital twins, facilitating the testing and validation of modifications in the DCS&SIS or the plant itself of both green/brownfield plants.

# Comparative Assessment of Aspen Plus Modeling Strategies for Biomass Steam Co-gasification

**Usman Khan Jadoon[a*], Ismael Díaz[a], Manuel Rodríguez[a]**

[a] Departamento de Ingeniería Química Industrial y del Medioambiente, Escuela Técnica Superior de Ingenieros Industriales, Universidad Politécnica de Madrid, Madrid, Spain

## ABSTRACT

The urgent need for sustainable energy drives the exploration of biomass and plastic waste co-gasification, a promising route for producing clean fuels and chemicals, reducing greenhouse gas emissions, and minimizing fossil fuel dependence. Modeling and simulation are vital for optimizing this process, particularly syngas yield, yet comparative studies on Aspen Plus modeling techniques for steam co-gasification are limited. This research addresses this gap by comparing three Aspen Plus strategies: thermodynamic equilibrium modeling (TEM), restricted thermodynamic modeling (RTM), and kinetic modeling (KM), for simulating the co-gasification of pine sawdust and polyethene (PE) with steam in bubbling fluidized bed gasifier (BFBG). The primary objective is to evaluate the effectiveness of each strategy in predicting the syngas composition under varying conditions. Three models were developed in Aspen Plus on the basis of each strategy, and their predicted syngas compositions were compared with published experimental data. A detailed sensitivity analysis was performed within the RTM framework to obtain optimized values of the approach temperatures to enhance predictive accuracy. The results showed that RTM provided the highest precision, with an average root mean square error (RMSE) of 0.0296, while TEM showed the lowest precision with RMSE of 0.1234. KM performed moderately with an RMSE of 0.0929. These findings demonstrate that RTM is superior for predicting the syngas composition for this co-gasification process, and its optimized solution presents a viable alternative when detailed kinetic data are lacking, thus reducing computational expense.

## INTRODUCTION

The escalating global climate crisis, coupled with concerns regarding energy security and dependence on finite fossil fuel resources, has spurred a critical need for the development and implementation of sustainable energy alternatives [1]. In this context, steam co-gasification of biomass and plastic waste in BFBGs emerges as a promising technology, offering a dual benefit of renewable energy generation and waste valorization. This thermochemical conversion process effectively transforms these feedstocks into syngas, a valuable intermediate product for producing clean fuels, sustainable aviation fuels, and various chemicals such as methanol, ethanol, and dimethyl ether. By utilizing renewable biomass sources and mitigating the environmental impact of plastic waste, steam co-gasification holds the potential to significantly reduce greenhouse gas emissions and lessen reliance on fossil-based energy systems [2]. Therefore, the precise analysis and optimization of this process are vital for its widespread adoption and contribution to a sustainable energy future.

In this regard, some researchers have explored high-temperature steam gasification to enhance $H_2$ production. For instance, Chang et al. (2011) reported that steam gasification of agricultural waste in a fluidized bed reactor at 1000 °C and an equivalence ratio of 0.2 yielded a maximum bio$H_2$ of 29.5%, CO at 23.6%, and $CO_2$ at just 10.9% [3]. Ahmed et al. (2009) compared pyrolysis and steam gasification of paper, varying temperatures from 400 to 700 °C for pyrolysis and 600 to 1000 °C for gasification [4]. Numerous experimental studies have been

published in literature show that steam gasification has the ability to produce the medium heating value of up to 16 MJ/Nm$^3$ and $H_2$ concentration in syngas up to 60% [5-7].

However, accurate modeling and simulation of thermochemical processes are indispensable tools for gaining a fundamental understanding of their behavior and for optimizing gasification performance. Specifically, for gasification, modeling is crucial in predicting syngas yield, composition, and process efficiency under varying operating conditions. Syngas, as the primary product of gasification, serves as a versatile building block for numerous energy and chemical applications, making a reliable prediction of its composition very important. This requires the development and comparative analysis of different modeling strategies, each with its unique capabilities and limitations.

Although various modeling techniques have been proposed in the literature for gasification processes, there remains a noticeable gap in comprehensive comparative assessments, particularly concerning different Aspen Plus modeling approaches for steam co-gasification of biomass and plastic waste. This gap highlights the need for further investigation to identify the most effective and accurate modeling strategies for this specific process. Recognizing the limitations mentioned above in the existing literature, this study focuses on a comparative evaluation of three distinct Aspen Plus modeling strategies: thermodynamic equilibrium modeling (TEM), restricted thermodynamic modeling (RTM), and kinetic modeling (KM) for simulating steam co-gasification of pine sawdust and polyethene in a bubbling fluidized bed reactor.

## METHODOLOGY

In this article experimental study was adopted from Pinto et al. (2002) for the pine and polyethylene (PE) co-gasification in BFBG by steam [5]. The reactor configuration is given in the article along with the ultimate and approximate analysis of the feedstocks. Modeling was carried out in 100% Pine, 10% PE and 90% pine mix, 40% PE and 60% pine, and 60% PE and 40% pine at varying temperature, while the steam-to-biomass ratio remains at 0.8kg/kg-feedstock. This study employed Aspen Plus V.14.0 to model the steam co-gasification process and predict syngas composition under various operating conditions, and both equilibrium and kinetic modeling strategies were implemented. In Aspen Plus platform all models began with the definition of biomass, PE, ash, and char as non-conventional components, using proximate and ultimate analyses from the ULTANAL and PROXANAL models, respectively. The built-in property database of Aspen Plus was utilized for the calculations, with the HCOALGEN and DCOALIGT models providing enthalpy and density data, respectively, based on biomass combustion and composition. Heat of combustion was derived from biomass combustion using the HCOALGEN model and elemental analysis, while density was determined using the DCOALIGT model, which is based on the IGT correlation and utilizes ultimate analysis data. The Peng-Robinson thermodynamic package with the Boston-Mathias function was chosen for its suitability in high-temperature gasification simulations.

### Equilibrium Modeling

Thermodynamic Equilibrium Model (TEM) and Restricted Thermodynamic Model (RTM). TEM, a non-stoichiometric approach, determines the equilibrium composition by minimizing Gibbs free energy, requiring only the elemental composition derived from ultimate analysis. This makes it computationally efficient and useful for preliminary assessments. However, TEM does not incorporate reaction kinetics or stoichiometric constraints, leading to discrepancies in syngas predictions, particularly in underestimating syngas composition.

RTM, a stoichiometric approach, improves upon TEM by incorporating temperature-dependent constraints on chemical equilibria. Real-world gasification processes often do not reach complete equilibrium due to kinetic limitations, and RTM accounts for this by restricting selected reactions to better match experimental conditions. By restricting reaction equilibria to temperatures above or below the actual reactor temperature, accounting for stoichiometric constraints. This approach is designed to provide a more realistic representation of the gasification process, since the reactions in the reactor may not necessarily reach the true thermodynamic equilibrium. By incorporating temperature-based constraints, it improves the accuracy of syngas composition predictions and other performance metrics. A similar approach was previously applied to air gasification by Jadoon et al., (2025) this study implemented strategy for the steam gasification to improve the precision for optimizing operating conditions and improving the overall efficiency of predicting the syngas composition [6].

In this study the Aspen Plus model developed by Acar et al., (2019) for gasification, was adopted, using both TEM and RTM [7]. Biomass and plastic waste were first decomposed in the RYIELD reactor (DECOMP) into constituent elements based on its ultimate and proximate analyses. Ash was then separated from the other components using a separator (SEP1). The elemental components were mixed with steam and then fed to an RGIBBS reactor. The gasifier (EQIL) simulates the TEM approach, while another reactor (R-GASI) models RTM. Syngas is then separated from other byproducts in separators (SEP2 for R-GASI and SEP3 for EQIL) as shown in Figure 1.

Following Acar et al. (2019), four key reactions

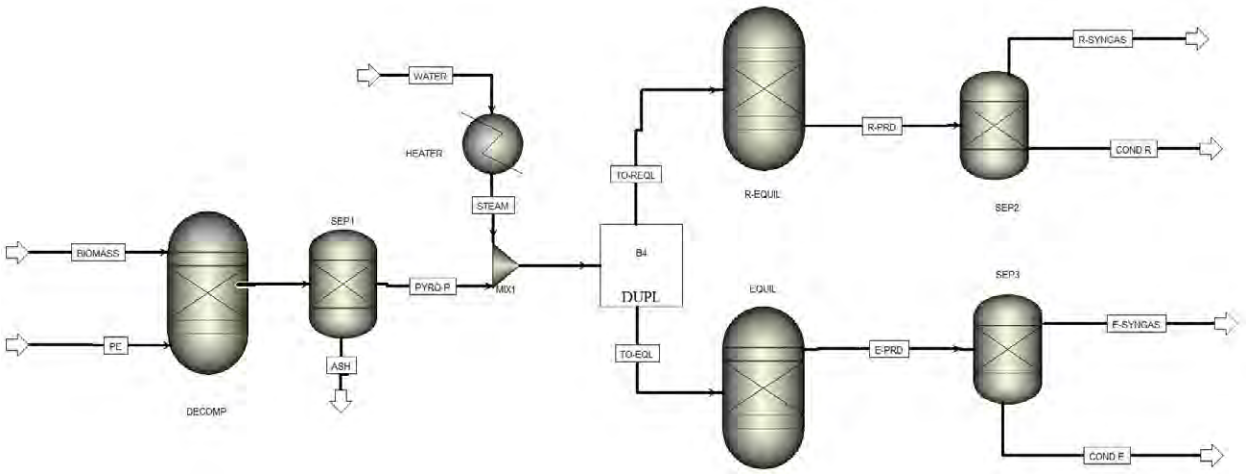

**Figure 1:** Process flowsheet of Equilibrium model

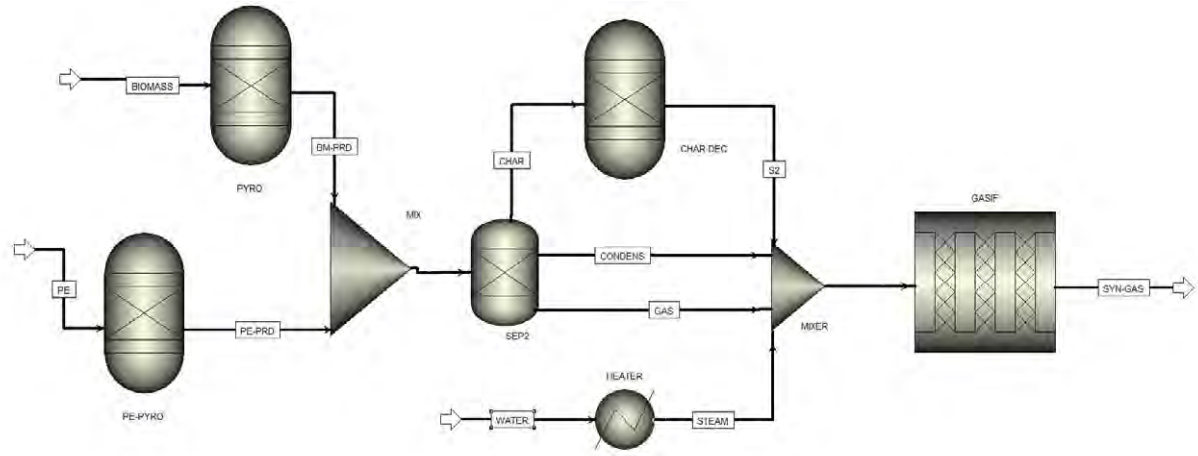

**Figure 2:** Process flowsheet of kinetic model

(listed in Table 1) were selected to constrain the chemical equilibrium within the RTM framework. A sensitivity analysis was performed for each of the 17 experimental instances by varying the approach temperature of individual reactions. Each sensitivity analysis consisted of 22,500 cases, and the case with the smallest absolute difference between experimental and predicted values was selected. The absolute difference between the molar fractions of the predicted and experimental syngas composition was calculated using Equation 1, where ME represents the minimum error, *e* is the experimental value, *p* is the predicted value, and *i* denotes the *i*-th case in the sensitivity analysis.

$$(ME)_i = |H_2^e - H_2^p|_i + |CO^e - CO^p|_i + |CO_2^e - CO_2^p|_i + |CH_4^e - CH_4^p|_i \quad (1)$$

Table 1: Reactions used in RTM

| No. | Reaction | ΔHr (kJ/mol) |
|---|---|---|
| R1 | $C + H_2O \rightarrow CO + H_2$ | 131 |
| R2 | $C + 0.5O_2 \rightarrow CO$ | -111 |
| R3 | $CO + H_2O \rightarrow CO_2 + H_2$ | -41.2 |
| R4 | $CH_4 + H_2O \rightarrow CO + 3H_2$ | 206 |

## Kinetic Modeling

A KM was developed within the Aspen Plus environment to simulate the co-gasification feedstocks, explicitly representing the complex thermochemical reactions occurring within BFBG. The model's flowsheet, depicted in Figure 2, utilizes several interconnected unit operation blocks. Initial decomposition of biomass in the RYIELD reactor (PYRO) was modeled using empirical equations from Neves et al. (2011) [8]. In contrast, plastic waste decomposition (PE-PYRO) was based on its ultimate and proximate analyses, reflecting the primary and secondary depolymerization processes that occur at high temperatures. The resulting pyrolysis products were then separated by a separator (SEP2) into gaseous, condensable, and char fractions. The char fraction was further decomposed into elemental carbon, sulfur (if present), and ash

within another RYIELD reactor (CHAR-DEC). These decomposition products were then combined with the gasifying medium in a mixer (MIX2) before entering the gasification reactor. A plug flow reactor was opted for modeling the final gasification process to convert the pyrolysis products and gasifying medium into syngas. Kinetic models use rate equations to quantify the rates of various chemical reactions that occur during gasification. The reactions and kinetic data used in the gasification step are given in **Table 2** and **Table 3** [9].

**Table 2:** Chemical reactions and rate expressions

| Reaction | Rate expression |
|---|---|
| $C + 0.5O_2 \rightarrow CO$ | $r_1 = k_1 \cdot \exp\left(\frac{E}{RT}\right)[O_2]^{0.78}$ |
| $H_2 + 0.5O_2 \rightarrow H_2O$ | $r_2 = k_2 \cdot \exp\left(\frac{-E}{RT}\right)[H_2][O_2]$ |
| $CO + 0.5O_2 \rightarrow CO_2$ | $r_3 = k_3 \exp\left(\frac{-E}{RT}\right)[CO][O_2]^{0.5}[H_2O]^{0.}$ |
| $C + H_2O \rightarrow CO + H_2$ | $r_4 = k_4 \cdot \exp\left(\frac{-E}{RT}\right)[C][H_2O]$ |
| $C + CO_2 \rightarrow 2CO$ | $r_5 = k_5 \cdot \exp\left(\frac{-E}{RT}\right)[CO_2]$ |
| $CH_4 + H_2O \rightarrow CO + 3H_2$ | $r_6 = k_6 \cdot \exp\left(\frac{-E}{RT}\right)[CH_4][H_2O]$ |
| $CO + H_2O \rightarrow CO_2 + H_2$ | $r_7 = k_7 \cdot \exp\left(\frac{E}{RT}\right)[CO][H_2O]$ |
| $C + 2H_2 \rightarrow CH_4$ | $r_8 = k_8 \cdot \exp\left(\frac{-E}{RT}\right)[H_2]$ |
| $C_{10}H_8 \rightarrow 7.38C + 0.275C_6H_6 + 0.94CH_4 + 1.235H_2$ | $r_9 = k_9.\exp\left(\frac{-E}{RT}\right)[C_6H_6O]^{1.6}[H_2]^{-0.5}$ |
| $C_6H_6 + 2H_2O \rightarrow 1.5C + 2.5CH_4 + 2CO$ | $r_{10} = k_{10}.\exp\left(\frac{-E}{RT}\right)[C_6H_6]^{1.3}[H_2O]^{0.2}[$ |
| $C_6H_6O + 3H_2O \rightarrow 4CO + 0.5C_2H_4 + CH_4 + 3H_2$ | $r_{11} = k_{11}.\exp\left(\frac{-E}{RT}\right)[C_6H_6O]$ |

**Table 3:** Kinetic parameters

| Reactions | k | E (J/mol) |
|---|---|---|
| $r_1$ | $5.70 \cdot 10^{11}$ | $5.50 \cdot 10^{4}$ |
| $r_2$ | $2.20 \cdot 10^{9}$ | $1.08996 \cdot 10^{6}$ |
| $r_3$ | $1.00 \cdot 10^{10}$ | $1.2599 \cdot 10^{5}$ |
| $r_4$ | 200 | $4.9887 \cdot 10^{4}$ |
| $r_5$ | 4.364 | $2.48123 \cdot 10^{5}$ |
| $r_6$ | $3.00 \cdot 10^{3}$ | $1.2471 \cdot 10^{5}$ |
| $r_7$ | $2.20 \cdot 10^{-2}$ | $3.473 \cdot 10^{4}$ |
| $r_8$ | $2.43 \cdot 10^{-4}$ | $1.30 \cdot 10^{4}$ |
| $r_9$ | $1.70 \cdot 10^{14}$ | $3.50 \cdot 10^{5}$ |
| $r_{10}$ | $2.00 \cdot 10^{16}$ | $4.43 \cdot 10^{5}$ |
| $r_{11}$ | $1.00 \cdot 10^{7}$ | $1.00 \cdot 10^{5}$ |

The syngas molar fraction predicted by each model is evaluated using RMSE, which measures the square root of the average squared differences between predicted and observed values. RMSE can be computed by equation 2.

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2} \quad (2)$$

## RESULTS AND DISCUSSION

Aspen Plus models utilizing TEM, RTM, and KM were developed to simulate steam co-gasification in a BFBG. For RTM, a detailed sensitivity analysis was conducted to align the syngas composition as closely as possible with experimental values. This analysis, performed using Aspen Plus's built-in sensitivity tool by changing the temperature for each reaction given in Table 1. The temperature limit for the reactions R3 and R4 are zero to 1000 °C and -1 to -500 °C, respectively. A total of 22,500 sensitivity instances were computed for each sensitivity analysis, and this analysis was performed for all seventeen experimental cases. The absolute error was calculated for every instance, and then minimum absolute error was determined using equation 1. The syngas composition corresponding to this minimum error was selected as the final syngas composition in RTM framework.

**Table 4**: RMSE of different Aspen Plus models

| | RTM | KM | TEM |
|---|---|---|---|
| $H_2$ | 0.0363 | 0.1705 | 0.2101 |
| CO | 0.0533 | 0.0953 | 0.1184 |
| $CO_2$ | 0.0208 | 0.0374 | 0.0365 |
| $CH_4$ | 0.0079 | 0.0682 | 0.1285 |
| Average | 0.0296 | 0.0929 | 0.1234 |

RMSE values for different modeling strategies—RTM, TEM, and KM—are presented in **Table 4**. These results highlight notable differences in the predictive performance of the models for co-gasification. RTM demonstrated the most favorable performance overall, achieving the lowest RMSE values across all outputs compared to the other models. The average RMSE for RTM is 0.0296, significantly outperforming TEM and KM, who's average RMSE values were 0.1234 and 0.0929, respectively.

Unlike the TEM model the RTM model accounts for kinetic constraints that influence reaction rates. This is particularly relevant in non-equilibrium conditions where factors such as heat and mass transfer limitations affect the reaction progress. Additionally, while the KM model includes kinetic mechanisms, its predictive capability is restricted by predefined reaction pathways and rate expressions that may not fully represent the complexities of co-gasification, especially for varying feedstock compositions. The RTM framework, by contrast, fine-tunes

reaction temperatures through sensitivity analysis, ensuring improved alignment with experimental data.

When examining individual syngas components, RTM consistently exhibited the lowest RMSE values. For CO, RTM achieved the lowest RMSE of 0.0533, followed by KM at 0.0953, while TEM performed poorly with RMSE values of 0.1184. A similar trend was observed for $CO_2$, where RTM had an RMSE of 0.0208, followed by KM at 0.0374 and TEM at 0.0365. For $CH_4$, RTM again excelled with the lowest RMSE of 0.0079 while KM and TEM have 0.0682 and 0.1285, respectively.

The predictions obtained from different models were analyzed and plotted to evaluate their performance. **Figure 3** illustrates the comparison between experimental and predicted $H_2$ values across various feedstock compositions. Among the models, the RTM demonstrates exceptional predictive accuracy, with blue data points closely aligning with the experimental values for all percentages of polyethylene (PE). The minimal error observed in RTM predictions underscores its reliability and effectiveness. In contrast, the KM model performs well for feedstocks containing 100% pine and mixtures with 80% pine + 20% PE, but its accuracy significantly deteriorates for feedstocks with 40% or 60% PE, where it tends to overpredict $H_2$ values. This decline in performance suggests that the KM model is less suitable for feedstocks with higher PE content. The TEM model, on the other hand, consistently overpredicts $H_2$ values across all feedstock compositions, likely due to limitations in Gibbs free energy estimations for syngas constituents, as highlighted by Ajorloo et al. (2022) [10].

**Figure 4** illustrates the prediction of CO in Aspen Plus model's environment in comparison to the experimental values. The RTM model again demonstrates strong predictive accuracy, with blue data points aligning closely with experimental values across all percentages of PE, reaffirming its robustness in predicting CO concentrations. The KM model provides reasonable predictions for feedstocks with low PE content, such as 100% pine and 20% PE. However, as the PE content in the feedstock exceeds 40%, the KM model begins to underpredict CO concentrations, indicating its limited applicability for feedstocks with higher PE proportions. In contrast, the TEM model shows improved accuracy in predicting CO for feedstocks with 40% or more PE, suggesting that its performance improves with increasing PE content. As the PE content is increasing, 40% and above, in feedstock the TEM prediction tends to accurately predict it.

For $CO_2$ predictions, depicted in **Figure 5**, the RTM model once again delivers the most accurate results. However, predictions by the TEM and KM models exhibit similar trends and complement each other, as evidenced by their comparable RMSE values in **Table 4**. This alignment suggests that both models can provide reasonable $CO_2$ predictions under certain conditions, though they remain less accurate than the RTM model.

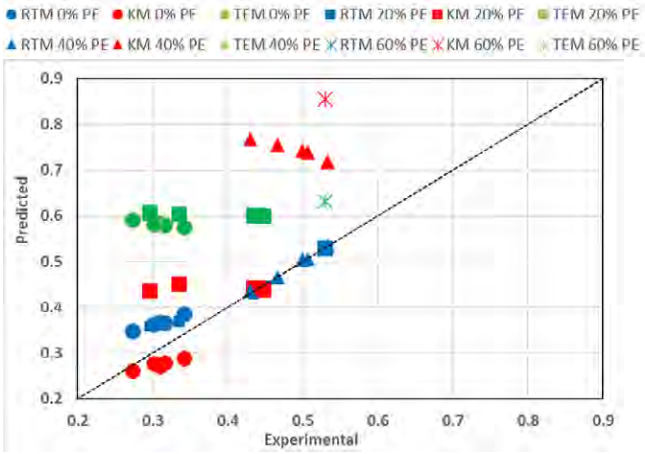

**Figure 3:** Experimental and Predicted mole fraction of $H_2$

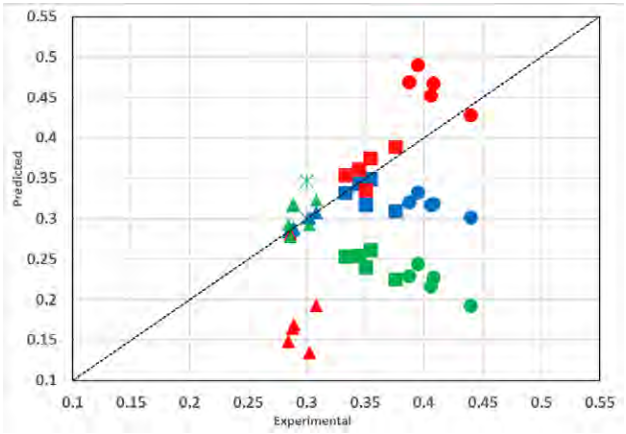

**Figure 4:** Experimental and predicted mole fraction of CO

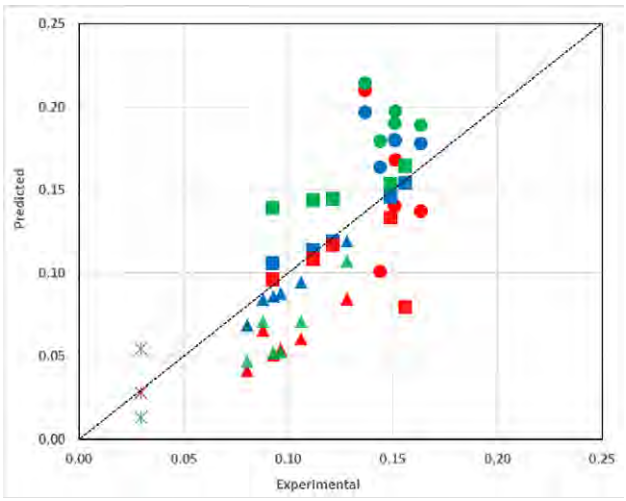

**Figure 5:** Experimental and Predicted mole fraction of $CO_2$

From the **Figure 6** $CH_4$ predictions further emphasize the superior performance of the RTM model, which consistently provides accurate results. In contrast, the

TEM model struggles significantly, often underpredicting $CH_4$ concentrations. The KM model performs adequately for feedstocks with low PE content, but its accuracy declines sharply as the PE proportion increases, resulting in poor predictions for higher PE feedstocks.

In this study the RTM model demonstrated exceptional predictive capabilities for molar concentration of $H_2$, CO, $CO_2$, and $CH_4$ across all feedstock compositions, making it the most reliable model overall. While the KM and TEM models exhibit some strengths in specific scenarios, their accuracy diminishes as the PE content in the feedstock increases, highlighting the importance of model selection based on feedstock composition.

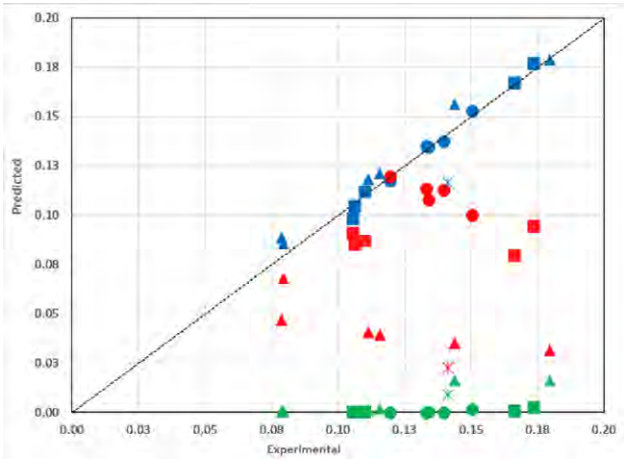

**Figure 6:** Experimental and Predicted mole fraction of $CH_4$

## CONCLUSIONS

Pine and plastic steam co-gasification offers a promising route for renewable energy production; however, accurately predicting syngas composition remains a significant challenge. This study provides a comprehensive comparative analysis of three modeling approaches—TEM, RTM, and KM—in a BFBG. Among these models, RTM demonstrated the highest accuracy in predicting syngas composition, with an average RMSE of 0.0296. In contrast, the TEM model showed the lowest performance consistently overestimated or underestimated syngas composition, with an RMSE of 0.1234, while the KM model exhibited intermediate performance with an RMSE of 0.0929. The KM model's performance notably declined as the proportion of PE in the feedstock increased, further limiting its reliability for feedstocks with higher plastic content. In comparison, RTM proved to be the most robust and accurate, making it a strong candidate for future research on syngas composition across different technologies and fuel mixtures, including agricultural, forestry, and municipal solid wastes with steam or steam-$O_2$ gasification.

## ABSTRACT

Proton Exchange Membrane (PEM) fuel cells are gaining traction in automotive applications due to their efficiency and environmental benefits, but they face challenges such as high costs, degradation rates, and limited hydrogen availability. To address these issues, novel operational methods have been developed, focusing on customized designs rather than traditional uniform configurations. These advancements include the variable temperature flow field, which maintains high relative humidity without external humidification by leveraging internally generated water and heat, and graded catalyst loading, which enhances current density distribution. Additionally, complex flow fields have been designed using 3D metal printing to mitigate liquid water accumulation. These innovations have shown significant performance improvements, particularly when combined, demonstrating a 260% increase in current density at 0.6 V. These advancements hold promise for overcoming the limitations of conventional PEM fuel cell designs and enhancing their viability for commercial applications.

**Keywords**: PEM fuel cells, Computational Fluid Dynamics, Variable Temperature Flow Field, Graded Catalyst Design, 3D Metal Printed Flow Field

## INTRODUCTION

Proton exchange membrane (PEM) fuel cells are steadily gaining momentum in automotive applications. Besides their formidable benefits such as low operating temperature, high efficiency, zero emissions and low noise, there are several drawbacks such as high price, unreliable degradation rates and very limited availability of hydrogen, as well as poor dynamic power output. To tackle these issues, we have developed several novel methods for operation of PEM fuel cells. There methods are based on designing the PEM fuel cell in a custom way to fit the application, instead of using uniform design with fully humidified reactants which is common practice. Throughout our research over a span of several years we have started to address the issue of liquid water accumulation and transport inside the cell, which is consequence of cell operating at the constant temperature with usage of fully humidified hydrogen at the anode and air at the cathode. The humidification of reactants was thought to be a necessity, since the proton conductivity of the Nafion membrane is directly proportional to its water content. However, since PEM fuel cell generates large quantities of water during operation at elevated current densities, using fully humidified reactants is detrimental to its performance since the generated water remains in liquid form and is unable to evaporate and thus accumulates in the diffusion layers and sometimes in the reactant channels, which causes uneven current density and heat transfer distribution. The first method we have developed to tackle these issues is variable temperature flow field, shown in references [1-3]. This method is based on usage of ambient air and dry hydrogen for feeding of the cell. High relative humidity is achieved by establishing and maintaining a precise temperature profile along the cell which in ensures almost 100% humidified reactant gases along the active area of the cell using water generated by the cell. To establish and maintain this specific

temperature profile coolant fluid is used. Coolant enters the cell at temperature of 30°C and gradually increases its temperature to 60°C while absorbing internally generated heat. Variable temperature flow field has shown that it is possible to achieve higher performance using this method and basically dry reactants contrary to the isothermal operation with fully humidified reactants, which indicates its potency towards the development for commercial applications. This method was further enhanced together with another method, which was developed by Xing et al. research group [4,5], utilizing graded catalyst loading which further enhances the current density distribution of the cell by controlling of the chemical rates of reaction along the active area of the cell. Graded catalyst design was combined with variable temperature flow field in [4] and compared to fully humidified isothermal operation. It was demonstrated experimentally that using variable temperature flow field combined with graded catalyst design leads to 260% increase in current density at 0.6 V which was astounding. Our research also focused in the direction of developing complex flow fields which utilize pressure gradients to expel the liquid water, which tends to accumulate near the cathode outlet. This method has also demonstrated that it is possible to achieve significant improvements in the performance at elevated current densities. We call these three methods - three critical advancements. They are described in more details in the continuation of this work.

## 1 CRITICAL ADVANCEMENTS

### Coolant Induced Variable Temperature Flow Field

Traditional Proton Exchange Membrane (PEM) fuel cell operation relies on maintaining an isothermal temperature profile across the cell, which necessitates external humidification systems to ensure high membrane water content. However, this conventional approach introduces increased system complexity, higher parasitic energy losses, and greater cost. The critical challenge in PEM fuel cell operation is maintaining optimal membrane hydration while preventing flooding that can block reactant transport pathways. Conventional isothermal approaches struggle to achieve the delicate balance between membrane hydration and preventing excess water accumulation in the gas diffusion layer (GDL) and catalyst layer (CL). This excess water can block oxygen transport to reaction sites, especially at higher current densities, leading to reduced performance. External humidification has been the standard solution but introduces significant system complications.

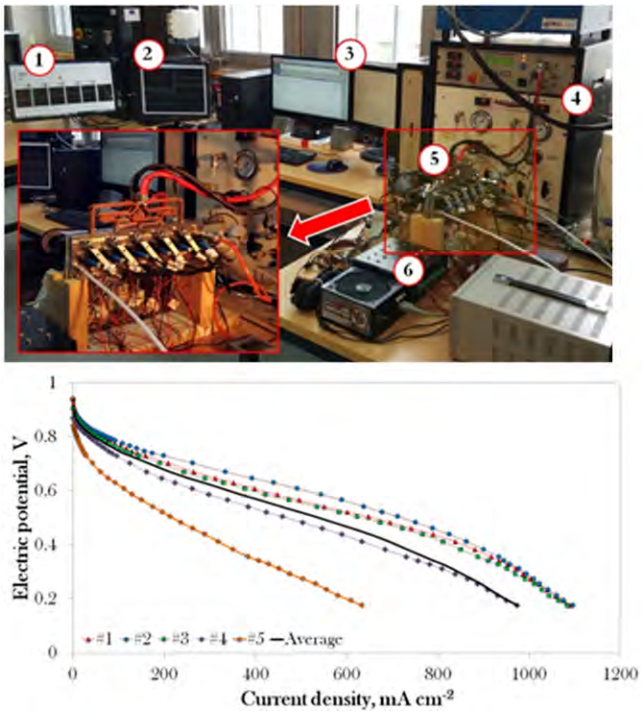

**Figure 1.** Experimental investigation of variable temperature flow field and polarization curves for each segment.

Željko Penga's innovative variable temperature flow field (VTFF) concept represents a significant advancement in addressing these challenges. The VTFF approach creates a controlled temperature gradient along the flow field by gradually increasing the coolant temperature as it passes through the PEM fuel cell. This strategic temperature management leverages internally generated water and heat to maintain relative humidity close to 100% along the entire flow field of both anode and cathode sides without requiring external humidification. The VTFF concept operates on the principle that water generated during fuel cell operation can be effectively utilized for internal reactant humidification when properly managed with a temperature gradient. By carefully controlling the temperature profile, the water vapor partial pressure can be maintained just below saturation pressure throughout the reactant channels. This prevents liquid water condensation while ensuring high membrane hydration, effectively addressing the dual challenges of membrane drying and electrode flooding that plague conventional designs. Penga validated this concept through extensive computational fluid dynamics (CFD) modeling and experimental testing using a custom-designed segmented PEM fuel cell setup, shown in Figure 1. The experimental apparatus provided critical insights into membrane water transport, temperature distribution on current collectors and inside channels, and current density distribution along the cell. This segmented approach allowed for precise monitoring of conditions at different

positions along the flow field, confirming the theoretical predictions of the VTFF concept. The experimental results demonstrated that PEM fuel cells operating with dry reactants under the VTFF concept achieved performance comparable to or better than conventional isothermal configurations with fully humidified reactants. Polarization curve comparisons revealed that the VTFF approach particularly excelled in reducing mass transport losses at higher current densities. This improvement stems from the VTFF's ability to maintain optimal hydration while preventing liquid water accumulation by evaporating generated water into the reactant streams. The most significant contribution of the VTFF concept is its ability to eliminate the need for external humidification while simultaneously enhancing high-current performance.

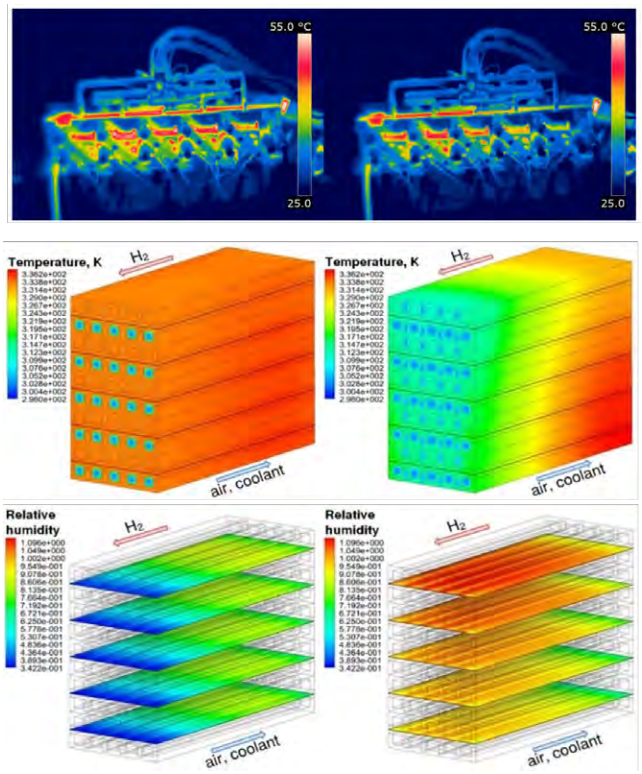

**Figure 2.** Isothermal (left) vs. variable temperature flow field (right) operation. Exp. vs. CFD results (above vs below) for temperature and relative humidity distributions.

By maintaining high relative humidity without condensation, the VTFF concept minimizes the problematic accumulation of liquid water that typically restricts reactant transport at higher current densities. This results in extended operational ranges and improved overall efficiency. Furthermore, the VTFF concept offers substantial system-level benefits, including reduced complexity, lower parasitic power losses, and decreased weight and volume requirements due to the elimination of external humidifiers. This makes the approach particularly valuable for mobile and portable applications where system simplicity and efficiency are paramount. The concept has been demonstrated to be applicable to PEM fuel cell stacks, as shown in Figure 2, further extending its practical utility for commercial applications.

## Variable Temperature Flow Field with Graded Catalyst Design

Traditional Proton Exchange Membrane (PEM) fuel cell designs typically employ a uniform distribution of functional components throughout the membrane electrode assembly (MEA), including consistent platinum catalyst loading, ionomer content, and porosity distributions. However, this uniform approach fails to account for the highly non-uniform distribution of current density, reactant concentration, and water content that naturally occurs during operation. This mismatch between uniform design and non-uniform operating conditions leads to suboptimal performance, excessive platinum utilization in low-activity regions, and heterogeneous degradation patterns. The cost of platinum-based catalysts remains a significant barrier to widespread PEM fuel cell adoption, with catalyst layers accounting for approximately 40% of the total system cost. Additionally, the durability issues stemming from non-uniform current distribution continue to impede commercial deployment. These challenges create a pressing need for more sophisticated design approaches that can optimize material utilization and performance simultaneously. Lei Xing's research has pioneered the concept of functionally graded porous electrode design, which strategically varies the distribution of key components along both through-plane and in-plane directions. This approach recognizes that different regions of the MEA experience vastly different local conditions during operation, requiring tailored properties to optimize performance. By creating spatial gradients of functional components such as platinum loading, ionomer content, and porosity, the graded design approach can significantly enhance performance while reducing material usage. The graded design strategy addresses the trilemma of performance, durability, and cost that has long challenged PEM fuel cell commercialization. For cells operated under varying loads, different regions require different catalyst activities and mass transport rates due to non-uniform reactant and product distribution. A rational graded design helps reduce precious material usage, improve overall cell performance, and achieve more uniform distributions of current density and heat generation.

A key innovation in Xing's work is the development of sophisticated hybrid modeling approaches that combine physics-based simulation with machine learning techniques. This methodology first establishes detailed multi-physics models that capture the complex interactions between electrochemical reactions, heat transfer, and mass transport. After experimental validation, these

models generate comprehensive databases that inform data-driven machine learning algorithms, creating powerful surrogate models capable of rapid multi-objective optimization. This hybrid approach overcomes the limitations of purely physics-based or purely data-driven methods. The physics-based foundation ensures accurate representation of fundamental processes, while the machine learning integration enables efficient exploration of vast design spaces that would be computationally prohibitive with traditional methods. This combination has proven particularly effective for optimizing multiple interconnected variables involved in graded electrode design. Xing's research has demonstrated significant improvements through graded catalyst designs, particularly in homogenizing current density distribution and enhancing performance at high current densities. By strategically varying platinum loading and gas diffusion layer porosity along in-plane directions, these designs achieve more uniform reaction rates and improved reactant transport to under-represented regions. The optimized graded designs have shown superior performance compared to uniform designs while using less platinum catalyst overall. Multi-objective optimization techniques have been employed to balance competing performance metrics such as maximum power density, platinum utilization efficiency, and current density homogeneity. These approaches have identified optimal grading profiles that represent the best compromises between different objectives, providing valuable design guidelines for practical implementation. The research has clearly established that properly designed graded structures can simultaneously address cost, performance, and durability challenges. By using a combination of variable temperature flow field and graded catalyst design, it was demonstrated that at 0.6 V the current density can be 260% higher when compared to isothermal operation with constant catalyst loading which is highly favourable for wide range of fuel cell applications because it addresses most of its current issues. The experimental rig where variable temperature flow field and graded catalyst design were used is shown in Figure 3.

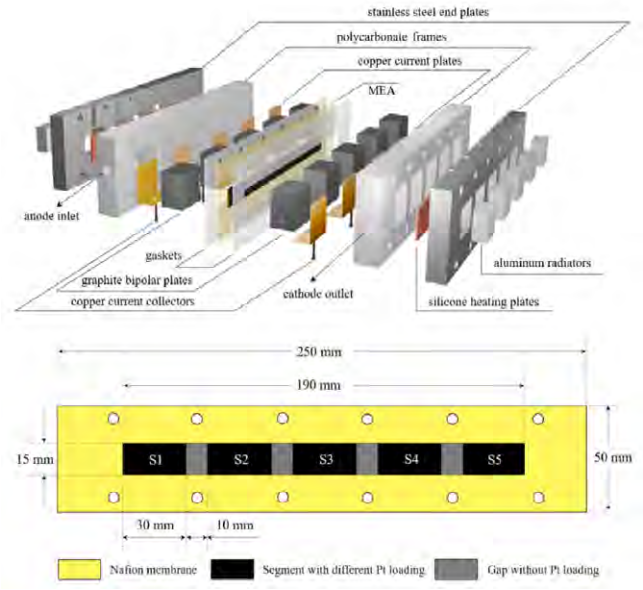

**Figure 3.** Segmented fuel cell with temperature control of each segment and segmented membrane-electrode assembly with different catalyst layer concentration on each segment.

## 3D Metal Printed Flow Fields

Conventional flow field designs in PEM fuel cells face significant challenges related to reactant distribution and water management, particularly in regions directly beneath the ribs of bipolar plates. These under-the-rib areas typically suffer from lower oxygen concentration and more severe water flooding than areas beneath the channels, creating performance bottlenecks that limit overall cell efficiency. The design of flow field geometry thus becomes critical for optimizing the balance between electrical conductivity and mass transport. Traditional manufacturing methods have imposed significant constraints on flow field designs, often limiting innovation to simple channel geometries that fail to address these under-the-rib transport issues. The emergence of advanced manufacturing techniques, particularly three-dimensional (3D) metal printing, has opened new possibilities for creating complex flow field geometries previously impossible to fabricate using conventional methods. Research by Penga, Xing, and colleagues has explored innovative flow field designs that leverage 3D metal printing capabilities to address under-the-rib transport limitations. These designs feature auxiliary channels equipped with through-plane arrayed holes strategically positioned to improve oxygen transport and water removal from under-the-rib regions. The auxiliary channels create additional pathways for reactant delivery and product removal, while the through-plane holes facilitate direct transport between the main channel and the electrode surface beneath the rib. These novel designs represent sophisticated modifications of traditional

serpentine and parallel flow field patterns. By integrating auxiliary structures without compromising the mechanical integrity or electrical conductivity of the bipolar plate, these designs achieve a careful balance between competing requirements. The number, placement, and dimensions of auxiliary channels and holes have been systematically optimized to maximize performance benefits while minimizing pressure drop penalties.

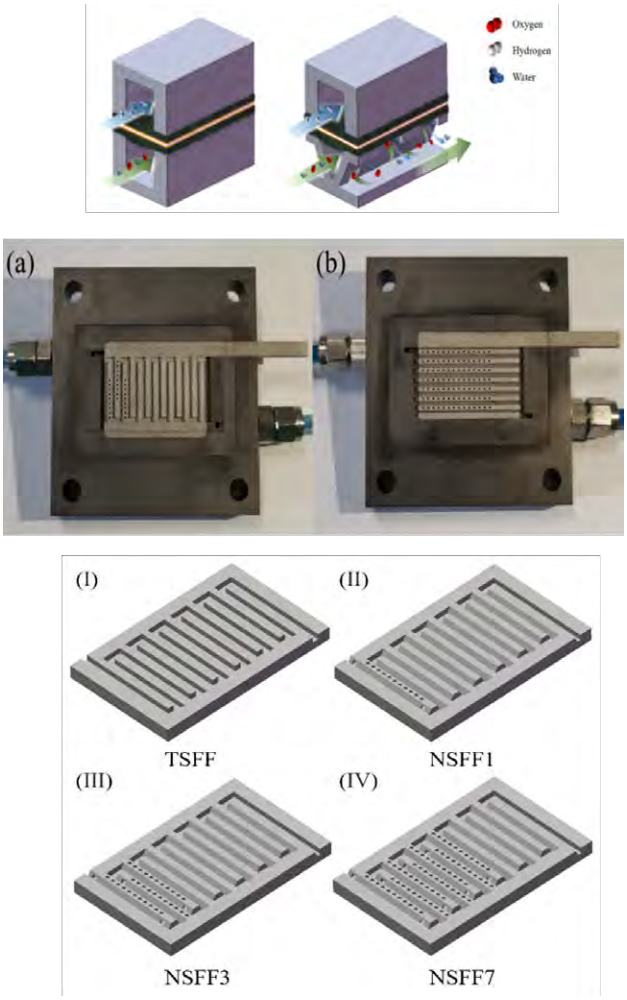

**Figure 4.** Isothermal (left) vs. variable temperature flow field (right) operation. Exp. vs. CFD results (above vs below) for temperature and relative humidity distributions.

The implementation of these complex flow field designs has been enabled by advances in 3D metal printing technology, as shown in Figure 4, which allows for the fabrication of intricate features with high precision. This additive manufacturing approach overcomes the limitations of traditional machining methods, enabling the creation of structures with internal passages, overhanging features, and precise dimensional control that would be difficult or impossible to achieve through conventional means. The 3D printing process for these flow fields involves selective laser melting of metal powders, building the structure layer by layer according to a digital design. This approach offers significant advantages in terms of design freedom,

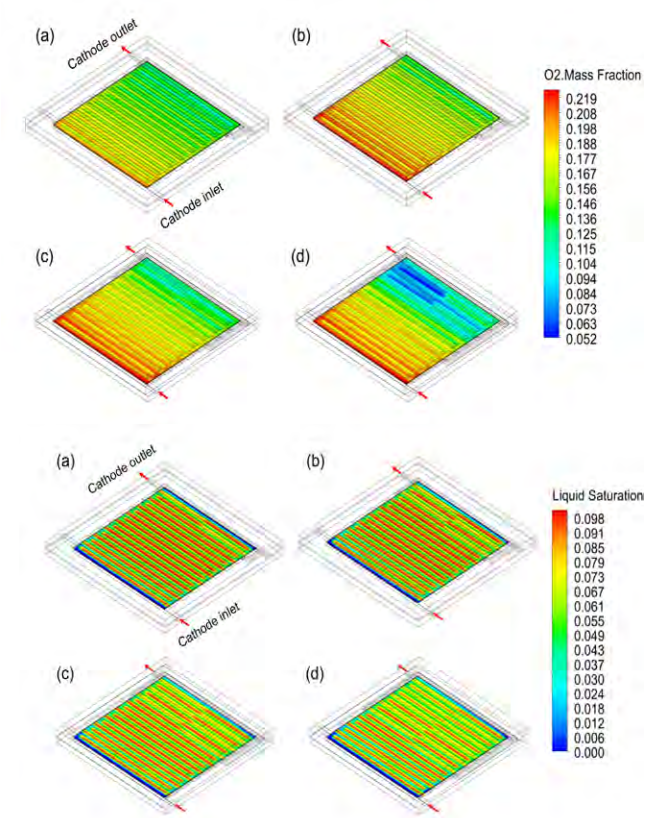

**Figure 5.** Isothermal (left) vs. variable temperature flow field (right) operation. Exp. vs. CFD results (above vs below) for temperature and relative humidity distributions.

The technology has reached sufficient maturity to produce functional bipolar plates with the required dimensional accuracy, surface finish, and material properties for practical fuel cell applications. Experimental and numerical evaluations, Figure 5, of the 3D printed novel flow fields have demonstrated significant performance improvements, particularly at high current densities where mass transport limitations typically dominate. Cells equipped with optimized auxiliary channel designs showed reduced ohmic resistance and enhanced mass transport capabilities compared to conventional designs. The performance gains were achieved through the improved oxygen supply and water removal from under-the-rib regions, preventing local flooding and reactant starvation. Perhaps most significantly, these novel flow field designs successfully address what the researchers describe as the "trilemma" of performance, pressure

drop, and manufacturability. Conventional designs typically force compromises between these competing factors, but the combination of innovative geometry and advanced manufacturing technology has enabled solutions that excel in all three dimensions. The optimal designs achieve enhanced performance without excessive pressure drop penalties, while the 3D printing approach makes their manufacture commercially viable.

## CONCLUSIONS

The innovations in variable temperature flow fields, graded catalyst designs, and 3D metal printed flow structures represent significant advancements in PEM fuel cell technology. Željko Penga's variable temperature flow field concept eliminates the need for external humidification while maintaining optimal membrane hydration and reducing mass transport losses. Lei Xing's graded catalyst approach optimizes material utilization and performance through strategic variation of functional components guided by sophisticated hybrid modeling. The collaborative work on 3D metal printed flow fields addresses critical under-the-rib transport limitations through novel geometries enabled by advanced manufacturing techniques. Together, these innovations address key barriers to widespread PEM fuel cell adoption by enhancing performance, reducing cost, increasing durability, and simplifying system design. The integration of these approaches offers a promising pathway toward more efficient, cost-effective, and commercially viable PEM fuel cell systems for a variety of applications, from transportation to stationary power generation. As these technologies continue to mature, they will likely play an increasingly important role in the transition to clean energy systems and contribute significantly to global decarbonization efforts. In this work, we have demonstrated that the performance of conventional PEM fuel cell designs—characterized by isothermal operation, constant catalyst loading, and standard flow field configurations—can be significantly enhanced through the application of our proposed methods. The integration of these approaches has the potential to enable the development of a novel class of PEM fuel cells, tailored in every aspect to meet specific application requirements. However, the combination of these methods introduces a vast array of input and output parameters, necessitating the development of an advanced AI model to guide and optimize this process, which will be the focus of our future research.

## ABSTRACT

Cell culture processes play a central role in the production of various therapeutic compounds. These processes are multiscale and highly complex, making them challenging to describe comprehensively using fully mechanistic models. In this study, we employ an integrated hybrid machine learning and first principles model to predict the viable cell density, product titer, and metabolite concentration profiles. We employ the concept of degree of hybridization, where we create a family of hybrid models each with increasing degree of process knowledge. Predictions from the feasible hybrid architecture were integrated with a genome scale metabolic model to evaluate the flux distribution of reactions related to the central carbon metabolism of the cell throughout the process duration. We demonstrate that the current approach not only reasonably predicts the bioprocess profile but also provides biologically relevant information that can uncover dynamics of intracellular metabolism which can open opportunities for new optimization strategies.

**Keywords**: Modelling and Simulations, Machine Learning, Hybrid Modelling, Metabolic flux distribution

## INTRODUCTION

Mathematical modelling of mammalian cell based biomanufacturing process is now at the heart of academic and industrial research due to quality-by-design standards[1] that are recommended by regulatory agencies as well as its potential in optimizing the processes driven by global sustainability demands[2]. Mechanistic (or knowledge-driven, first principles) and statistical (or data-driven) are two ends of a spectrum of modelling strategies. Knowledge-driven models are preferred when fundamental knowledge of the underlying process is available. But, construction of fully mechanistic models for bioprocesses is extremely challenging, as the knowledge available to describe the biology of the process is limited or too complex for practical applications[3]. Hence, conventional mechanistic models attempt to achieve a trade-off between the process knowledge they attempt to describe using the experimental data available and the computational complexity of a robust model.

On the other hand, data-driven models are preferred when there is limited understanding of the underlying process. Statistical and machine learning techniques are employed to infer non-linear relationships between process variables. While these models are often simple to generate and use, they often cannot extrapolate, and a large quantum of training data is required to adequately capture process dynamics.

An attractive combination of mechanistic and data-driven techniques to integrate the advantages of both approaches is being increasingly investigated over the past decades. Several architectures of hybrid models have been built which are described in detail in [4]. In our study, we use a serial architecture in which we establish a mechanistic backbone that is derived from the principle of conservation of mass and use a data-driven model to estimate the unknown parts of the equation. We investigate the concept of 'degree of hybridization'[5], [6] to identify the optimal level of process knowledge that can be described by the hybrid model. To achieve this, we construct a family of hybrid models with varying levels of process knowledge and evaluate their predictive capability.

A connection between macro-scale process model and microscale metabolic behaviour can provide scientific

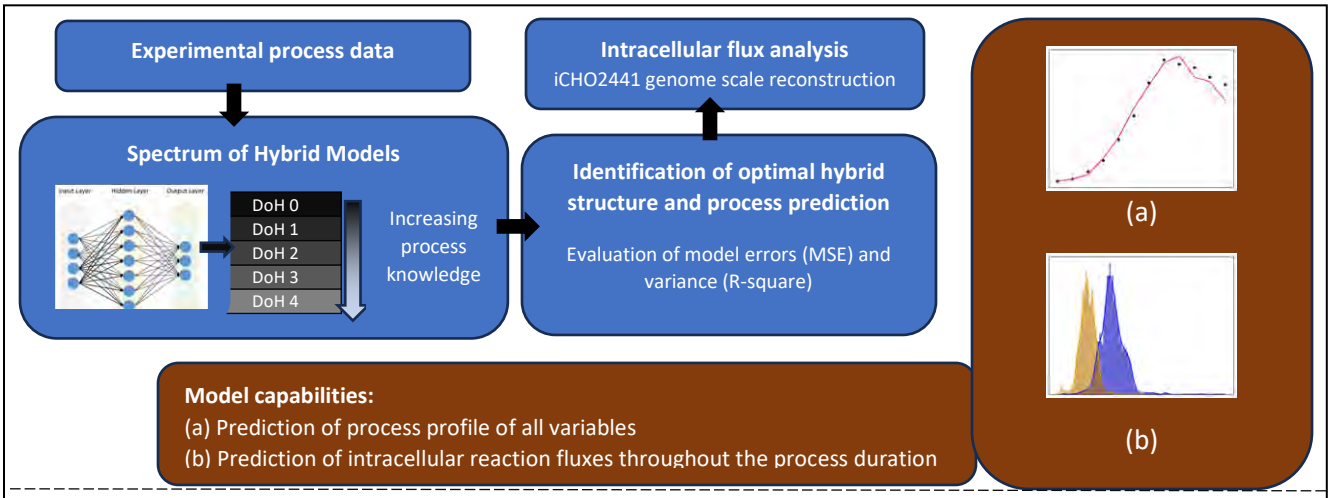

**Figure 1:** Hybrid modelling framework outline.

understanding of the biological process and uncover new strategies for optimization. Genome scale metabolic models are a mathematical representation of all known metabolic reactions for an organism and are a valuable tool to understand the interplay between various cellular pathways. Usually these models are expressed as an underdetermined system of equations and the flow of metabolites through the network is studied by optimizing the fluxes to achieve a 'cellular objective'[7], which results in an infinite solution space that satisfies the cellular objective as well as other enforced constraints that are determined through experimental and theoretical knowledge. Flux sampling is another powerful method that allows us to study the steady state distribution of fluxes throughout the feasible solution space without assuming a cellular objective[8] and as a result eliminates observer bias. In this study we harness the power of both hybrid process models and genome scale metabolic models to simultaneously model the process dynamics of CHO cell cultures and describe the intracellular behaviour that drives the observed process. The overall modelling framework is outlined in Figure 1. First, we demonstrate the concept of degree of hybridization and use it to determine the optimal level of process knowledge that accurately describes the process dynamics. Subsequently, we use the predictions of the hybrid process model to determine the distributions of important reactions belonging to the TCA cycle and pentose phosphate pathway of CHO cell metabolism using a recent genome scale reconstruction to study the intracellular behaviour throughout the fed-batch process. We demonstrate that the optimal hybrid model makes predictions that are not only accurate, but also biologically relevant. This framework can be a useful tool in building process monitoring tools and developing optimization strategies.

# METHODS

## Family of hybrid models

The family of hybrid models are constructed as described by Narayanan[5], where they define the degree of hybridization (DoH) as a measure of the process knowledge that is described explicitly by the mechanistic part of the hybrid model. This strategy was adopted to determine the optimal degree of hybridization that best describes the process dynamics of the cell culture under study. A family of 5 models with increasing degree of hybridization were constructed. The purely data-driven model (DoH =0) has no process knowledge incorporated and is tasked with predicting the process variables directly. The succeeding model (DoH=1) attempts to learn the rate of accumulation of the process variables, and the mechanistic part of the model calculates the value of the process variable at the next time step by integrating the system of differential equations. Here, the data driven part, a neural network, must learn to close the mass balance. The next hybridized model (DoH=2) is tasked with learning only the rates of production or consumption of the process variables, because the mechanistic model describes the mass balance through inflow and outflow rates of the process variables.

Further knowledge is added in the next model (DoH = 3) by encoding the proportionality of the reaction rates to the viable cell density. This allows the data-driven model to learn the specific reaction rates of the various process variables. The final model of this study (DoH = 4) incorporates the phenomenon of cell death, which is also modelled as a reaction proportional to the viable cell density. In all models, we employ only shallow neural networks as the data-driven part of the hybrid model. It is also assumed that the reactor is fully mixed with a homogenous cell population. Table 1 describes the model equations of the family of hybrid models.

## Datasets for modelling

| Degree of Hybridization (DoH) | Process knowledge described | Mechanistic model | Data-driven model |
|---|---|---|---|
| **0** | - | - | $[Z, Y_{t-1}, F] \xrightarrow[ANN]{} Y_t$ |
| **1** | Rate of accumulation | $\frac{d\boldsymbol{Y}}{dt} = \boldsymbol{\alpha}$ | $[Z, Y_{t-1}, F] \xrightarrow[ANN]{} \boldsymbol{\alpha}$ |
| **2** | Mass balance | $\frac{d\boldsymbol{Y}}{dt} = \boldsymbol{\beta} + \boldsymbol{F}_{in} - \boldsymbol{F}_{out}$ | $[Z, Y_{t-1}, F] \xrightarrow[ANN]{} \boldsymbol{\beta}$ |
| **3** | Cell specific reaction rate | $\frac{d\boldsymbol{Y}}{dt} = \boldsymbol{\gamma} * X_v + \boldsymbol{F}_{in} - \boldsymbol{F}_{out}$ | $[Z, Y_{t-1}, F] \xrightarrow[ANN]{} \boldsymbol{\gamma}$ |
| **4** | Cell specific reaction rates, growth and death rates | $\frac{dX_v}{dt} = \boldsymbol{\mu_g} * X_v - \boldsymbol{\mu_d} * X_v + \boldsymbol{F}_{in} - \boldsymbol{F}_{out}$<br>$\frac{d\boldsymbol{Y}}{dt} = \boldsymbol{\gamma} * X_v + \boldsymbol{F}_{in} - \boldsymbol{F}_{out}$ | $[Z, Y_{t-1}, F] \xrightarrow[ANN]{} \boldsymbol{\mu_g}, \boldsymbol{\mu_d}, \boldsymbol{\gamma}$ |

**Table 1:** Description of family of hybrid models explored in this study. In all hybrid structures, the data-driven part and mechanistic part are sequentially connected and the data driven part is tasked with learning a different phenomenon for each model. $\boldsymbol{\alpha}$ describes the rate of accumulation, $\boldsymbol{\beta}$ describes rate of production/consumption, $\boldsymbol{\gamma}$ describes cell specific reaction/growth rates, $\boldsymbol{\mu_g}$ is the specific growth rate, and $\boldsymbol{\mu_d}$ is specific death rate. *Z*: process conditions (feed concentrations of glucose and glutamine), *Y*: Response variables measured daily, *F*: Feeding profile and feed rate.

The dataset consists of 33 fed-batch shake flask cultivations that were collected and provided publicly by Bayer et al[9]. In brief, the cultivations were carried out with defined process conditions designed using Design of Experiments (DoE). The 4 important process conditions that were varied in the DoE were glucose concentration in the feed, glutamine concentration in the feed, rate of bolus feed, and the feeding profile. The cultivations were sampled once per day, the response variables (Viable and dead cell density, concentrations of glucose, glutamine, ammonia, lactate, and product) were analytically determined.

## Model training and evaluation

The family of hybrid models were constructed and trained in Python using the package PyTorch (2.5.1). The data driven part of the models had similar structure with only 1 hidden layer composed of 10 nodes activated by a *tanh* function. Of the 33 fed batch runs, 5 batches were set aside for testing and the rest were split into a ratio of 80:20 for training and validation after normalization.

The performance of the different models was compared using mean squared error for the test data:

$$MSEP = \frac{1}{N_time \cdot N_var} \sum_{i=1}^{N_var} \sum_{t=1}^{N_time} \left( C_{i,t}^{meas} - C_{i,t}^{pred} \right)^2$$

In addition, R-squared values were computed for each process variable in the test data for each model, to assess the ability of the model in capturing the variance in the dataset.

## Metabolic flux distribution

The metabolic flux analysis part of this multiscale framework is developed using iCHO2441, a genome scale metabolic model of Chinese Hamster Ovary cell[10]. Transport fluxes which carry metabolites in and out of the cell are determined by the hybrid process model described previously. The cell-specific reaction rates of glucose, glutamine, ammonia, and lactate are incorporated in the metabolic model as the transport fluxes. In addition, cell specific growth rate was also used to constrain the 'biomass transport flux'. The assumption of a pseudo-steady state results in equation (2):

$$\boldsymbol{S v_t} = 0, \tag{2}$$

$$\boldsymbol{v_t^{trans}} = \boldsymbol{r_i^{hybrid}}, \quad i \in \{Glc.Gln, Lac, Amm, Biomass\} \tag{3}$$

In equation (2), $\boldsymbol{S}$ corresponds to the stoichiometric matrix of the genome scale model, which is composed of the stoichiometric coefficient of every metabolite in every equation. $\boldsymbol{v_t}$ refers to the flux of every reaction at time **t**. This equation imposes the pseudo-steady state by ensuring that there is no intracellular accumulation of metabolites. The metabolic network is subject to the constraints imposed by equation (3) on the extracellular transport fluxes $\boldsymbol{v_t^{trans}}$, which correspond to the specific exchange reaction rates $\boldsymbol{r_i^{hybrid}}$ that are determined by the hybrid process model. Equation (2) and (3) will result

in infinite possible solutions for $\boldsymbol{v_t}$, as the number of variables is much higher than the number of equations in the model. Biologically, this means that the flow of metabolites can be re-routed in infinitely possible ways to satisfy the requirements of the cell. To study the solution space generated by equations (2) and (3), we perform uniform sampling of the solution space using an artificial centering hit-and-run sampling implemented in Python[11]. By generating 10000 samples of the metabolic network at each time step, we analysed the changes in the distribution of fluxes of reactions belonging to the central carbon metabolism (TCA cycle and Pentose Phosphate Pathway).

## RESULTS AND DISCUSSION

### Identification of optimal hybrid architecture

Figure 2 compares the predictive performance of the family of hybrid models in the test data set. The purely data driven model exhibits the lowest performance both in terms of mean squared error of the predictions and the coefficient of determination.

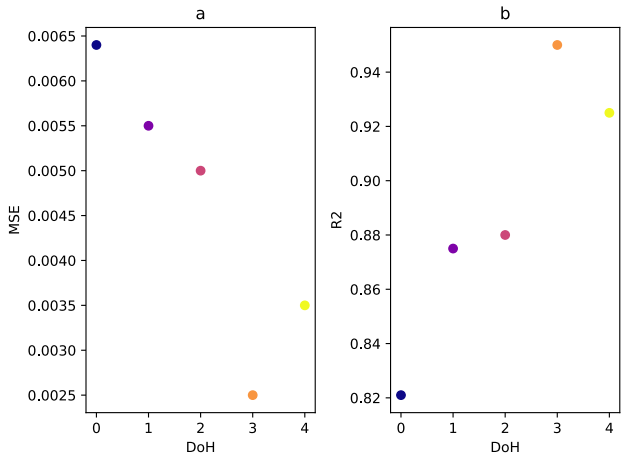

**Figure 2**: MSE (a) and coefficient of determination (b) of the family of hybrid models applied on the test data set. DoH=3 shows the best performance interms of least error ($2.5 \times 10^{-3}$) and highest R2 (0.95).

Addition of the first layer of process knowledge (DoH = 1) brings the MSE down by about 14% to $5.5 \times 10^{-3}$. This trend continues in the next two steps, where the MSE lowers to $5.0 \times 10^{-3}$ for the model with DoH = 2 and further down to a minimum of $2.5 \times 10^{-3}$ for the model with DoH = 3. Interestingly, the DoH=4 model does not follow this trend. Addition of process knowledge about cell death increased the MSE error of DoH=4 model to $3.5 \times 10^{-3}$. A similar trend is seen in the coefficient of determination (Fig 2B), where the highest R squared value is observed for the model with DoH = 3. It is important to note that despite the addition of further process knowledge from DoH =3 to 4, the predictive performance of the hybrid model decreases. This observation underlines the trade-off between the generalizability of the hybrid model and the degree of freedom imposed by the hybrid architecture. Based on these observations, DoH=3 was selected to be the optimal level of hybridization.

### Intracellular flux distributions

The selected optimal hybrid model provides biologically interpretable information in terms of cell specific uptake and secretions of Glucose, Glutamine, Lactate, and Ammonia. In addition, it is also able to describe the specific growth rate of the cells. The profile of the cell specific exchange fluxes predicted by the hybrid model for a test data set throughout its process profile is shown as illustrative example in Figure 4.

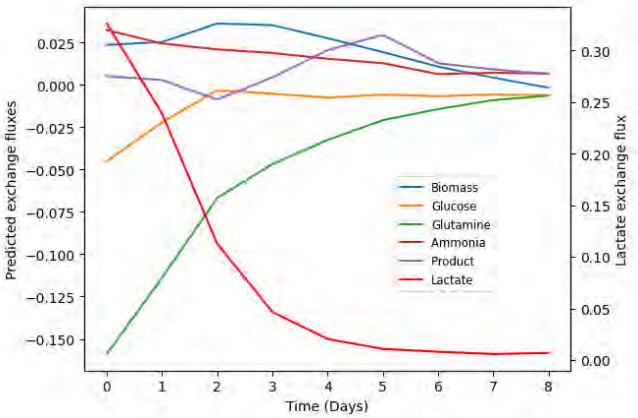

**Figure 4:** Cell specific uptake and secretion fluxes predicted by the hybrid process model. All fluxes except biomass are expressed in $mmol\,(10^6\,cells)^{-1}day^{-1}$. Biomass flux is expressed conventionally in $day^{-1}$ .

The exchange fluxes predicted by the hybrid process model describe a rapid proliferation/growth phase between days 1-3, and a production phase between days 4-7. In the growth phase, the cells have a high uptake rate of glutamine and glucose. As expected, the secretion flux of lactate is also high, to account for the ATP generation required to meet the cells energy demand. In the production phase, as secretion flux of lactate is low, the carbon flux is directed towards the product.

To understand the intracellular metabolism that underlies the observed process, a genome scale metabolic reconstruction of CHO cell was employed. This reconstruction, iCHO2441[10], has been reported to have improved intracellular predictive performance. By using the predictions from the hybrid model as constraints, 10000 points were sampled from the solution space generated by assuming a pseudo-steady state at each time step. The sampled fluxes were used to visualize the difference in cellular metabolism between the growth phase and the

stationary/production phase.

### TCA cycle

The distribution of fluxes of 2 important reactions belonging to TCA cycle is visualized in Figure 5. It is observed that the activity of reactions in the TCA cycle is higher in the production phase than in the growth phase.

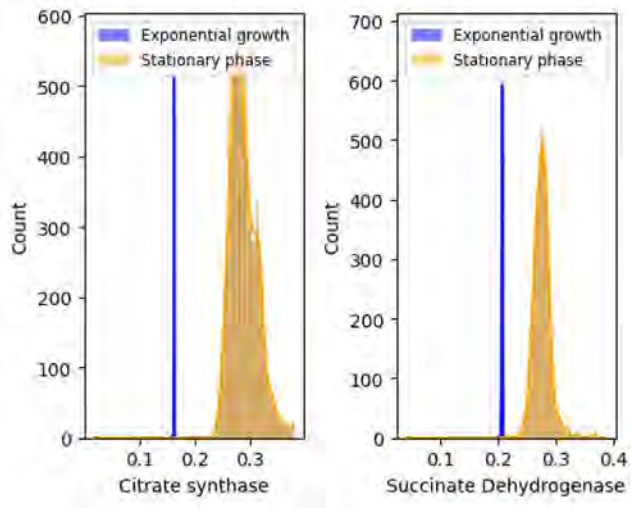

**Figure 5:** Distribution of fluxes of reaction in TCA cycle (in $mmol\ (10^6\ cells)^{-1} day^{-1}$).

This has been previously verified through experimental approaches through $^{13}C$ metabolic flux analysis[12]. In the growth phase, lactate production is preferred as it is faster but energetically less efficient route for ATP synthesis. But in the production phase, TCA cycle is favoured to generate ATP. A possible reason for this phenomenon is the inhibiting nature of the accumulated lactate[13].

Pentose Phosphate Pathway

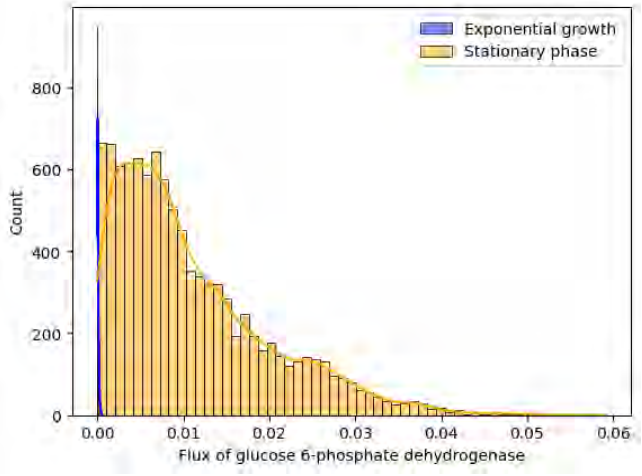

**Figure 6:** Distribution of flux of G6PDH reaction in the oxidative PP pathway in the exponential and stationary phase.

Oxidative pentose phosphate pathway (oxPPP) flux was significantly higher after the growth phase, while it was close to zero during the growth phase. The flux of glucose-6-phosphate dehydrogenase (G6PDH) increased during production phase even as the uptake fluxes of glucose and glutamine fell considerably when compared to the growth phase. The distribution of G6PDH is visualized in figure 6. This phenomenon of increased oxPPP activity during post growth phase has been reported previously[14]. It has been suggested that the increased flux towards PPP is a result of increased antibody production, which requires constant supply of NADH for protein folding[15].

## CONCLUSION AND OUTLOOK

In this study, we demonstrate that for the cell culture process described by the dataset, hybrid architectures work much better than purely data-driven models and that the introduction of fundamental process knowledge greatly improves the predictive capability of the model. By constructing a family of hybrid models with increasing degree of hybridization, we observe that the predictive accuracy of the hybrid model increases as long as the process knowledge introduced does not introduce a bias in the model. There exists a trade-off between the model parameters and the fundamental process knowledge to be added, as a more complex model needs more data points for robust training. In this case, a model with moderate degree of hybridization (DoH=3) was found to be the optimal model by comparing the error and predictive accuracy across the family of models. This model can efficiently learn the cell specific uptake/secretion/growth rates of the cell culture process, which aids in both macro-scale process monitoring as well as understanding of biologically relevant phenomena. While the hybrid process model shows good accuracy within the dataset, it will be interesting to test the capabilities of the model in extrapolating with respect to the process operating conditions. This

A cellular scale understanding of the cell culture process is achieved by employing a genome scale metabolic reconstruction of CHO metabolism constrained by the predictions of the hybrid model. By performing flux sampling, we capture the distribution of the entire feasible solution space of the metabolic network within these predicted constraints. This allows us to study the flux distribution without the assumption of metabolic objectives, which cannot be experimentally determined at most time steps. The captured flux distributions match well with previously available experimental data and provides a micro-scale understanding of the bioprocess. This hybrid framework opens avenues for further process optimization strategies by targeting cellular level processes; for example, a glucose feeding profile that directs carbon

flux towards the TCA cycle instead of the energetically inefficient lactate synthesis.

Overall, the outlined hybrid framework has the ability to combine data-driven techniques with fundamental process knowledge to simultaneously predict macroscale process profile and biologically relevant process information that can provide microscopic information about cellular behaviour. This strategy is particularly relevant for advanced modelling and simulation of cell cultures for process monitoring and optimization.

## ABSTRACT

Process simulation is essential for optimizing chemical processes, offering a cost-effective alternative to the experimental approach. This study presents a co-current hollow fibre membrane model for $CO_2$ separation, integrated into Aspen HYSYS® using the CAPE-OPEN standard. A one-dimensional boundary value problem (BVP) is solved through the shooting method, ensuring accuracy for complex gas separation processes. The unit is implemented in C++, facilitating interoperability, error handling, and optimization of key performance indicators like energy consumption and separation efficiency. Appropriate output variables are employed in the Aspen HYSYS® environment to enable direct sensitivity analysis and optimization within the process simulator. Results Sensitivity analysis results demonstrate that the co-current hollow fiber membrane unit improves methane recovery compared to a pressure swing water absorption (PSWA) column for biogas upgrading to biomethane. While membrane technology showed a 24% reduction in energy consumption for biomethane production, PSWA exhibits higher efficiency for biomethanol production. This study not only demonstrates the value of CAPE-OPEN standards in implementing custom unit operations but also lays the groundwork for future developments in process simulation using advanced mathematical modelling and optimization techniques.

**Keywords**: CAPEOPEN, Biogas, Modelling, C++

## INTRODUCTION

Sustainable process alternatives in the chemical industry have emerged to comply with the reduction of greenhouse gases (GHG). The main molecule to mitigate among GHG is $CO_2$. A valid mitigation strategy involves the substitution of thermal energy sources with renewable electrical ones, capture and storage technologies (CCS) and capture and utilization (CCU) technologies. Among carbon neutral sources, there is biogas: a mixture of gases produced by anaerobic digestion of either agricultural, animal or municipal waste. Composition is typically formed by 55-60 % of methane and 38-40 % of $CO_2$, with different amounts of impurities, depending on the feedstock [1]. The high tenor of methane allows for biomethane production or implementation in fuel production applications, as reported by many in the literature [2], [3], [4]. Membrane technology, particularly hollow fiber membranes, has gained increasing importance in industries for its energy efficiency, scalability, and suitability for applications in biogas upgrading, where either all or part of the total carbon dioxide is removed [5].

Process simulation is an essential tool for the design, control and optimization of chemical processes. It allows for detailed analysis of individual unit operations and entire processes under different operating conditions, providing a valid alternative to costly and time-consuming laboratory experiments, without risking any plant damage. While common unit operations are already implemented in the database of commercial process simulation software, non-conventional units can only be externally included as custom units. This work focuses on the implementation of a nonstandard co-current hollow fiber membrane unit for gas separation in Aspen HYSYS V11®, using C++ programming and the CAPE-OPEN (Computer Aided Process Engineering - Open Standard),

a standard that offers interoperability and communication between different process simulation software tools [6]. The procedure for integrating a custom unit in a process simulator begins with validating a suitable mathematical model found in the literature or derived from experimental data, which accurately describes the behaviour of the unit operation. The validated model is then integrated into a C++ code for CAPE-OPEN units, where the material port and parameter collection of the unit are also defined. Once implemented, the custom unit is applied in process simulation case studies to compare layouts and find optimal operating conditions.

# METHODOLOGY

## Solution-diffusion model

As a common practice in literature, the solution-diffusion model is implemented to predict gas permeation through the polymer membrane. The model implies gas separation through the membranes to occur according to both gas molecular size and gas-polymer interaction: the gas dissolves into the polymer, diffuses through it, and desorbs on the other side. The fundamental equation of the solution-diffusion model is Fick's law, which expresses the gas diffusion at a steady state of species i ($J_i$) through a polymeric membrane of thickness l as a function of its diffusivity ($D_i$) and its gradient of concentration ($c_i$), Eq. (1).

$$J_i = -D_i \frac{dc_i}{dl} \tag{1}$$

In an ideal system where solubility ($S_i$) is independent of concentration, Henry's law relates gas concentration to its solubility and pressure. Integrating Fick's law across the membrane thickness ($l$) yields total flux:

$$J_i = \frac{D_i S_i (x_i P_f - y_i P_p)}{l} \tag{2}$$

where $x_i$ is the retentate side mole fraction, $y_i$ is the permeate side mole fraction, $P_f$ is the feed side pressure and $P_p$ is the permeate-side pressure. Moreover, ($D_i \cdot S_i$) is the membrane permeability, which indicates how effectively the membrane allows gas to pass through. Permeance, defined as the ratio of permeability and thickness of the membrane, is used in modelling hollow fibre membranes.

## Mathematical model

Hollow fibre membranes allow for a compact configuration, where multiple fibres are bundled in a shell due to their small diameter (1 mm). This technology is one of the most diffused in the industry. Operation can be co-current or counter current, differing by the flow direction of the permeate flux direction. A co-current hollow fibre membrane modulus can be schematically represented as a horizontal cylinder with one closed end (**Figure 1**). The gas is fed on the shell side, where, by passing through the tiny hollow fibres, it is separated from the feed into a permeate and a retentate stream.

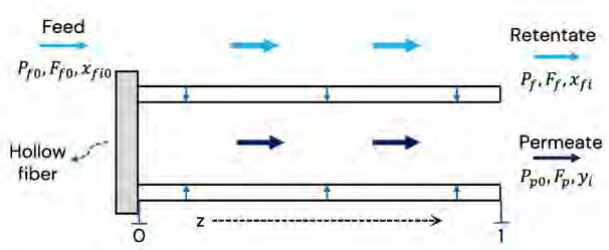

**Figure 1**. Simplified representation of a hollow-fiber co-current membrane.

The axial domain is normalized along the $z$ coordinate, and the following assumptions are taken under consideration:

- the model is one-dimensional;
- the Hagen-Poiseuille equation describes pressure drop on the permeate side;
- the pressure at the retentate side is constant and equal to the feed pressure;
- the gas presents laminar behaviour in both the retentate and permeate sides;
- properties and structure of the membrane are not influenced by pressure. Hence, permeances are assumed constant along the membrane;
- the unit is isothermal, thus no energy balance is needed to describe its thermal behaviour;
- the unit works at steady state conditions;
- membrane porosity does not oppose any resistance to the gas;
- no mixing occurs between permeate fluxes of different compositions along the length of the membrane.

Given the stated assumptions, the molar balance for the $i^{th}$ component along the membrane is expressed as reported in Eq. (3)

$$\frac{dF_{fi}}{dz} = -2\pi r_0 N_f L K_i \left(x_i P_f - y_i P_p\right) \tag{3}$$

where $F_{fi}$ is the molar is the feed side flowrate of the component, $N_f$ represents the number of fibres and is calculated as the ratio between the total membrane area $A$ and the external area of a single cylindrical fibre $2\pi r_0 L$. $K_i, x_i, y_i, P_f, P_p$ are, respectively, the permeance, the molar fraction and pressure feed and permeate side.

The pressure drop is described by the Hagen-Poiseuille equation Eq. (4), where R is the universal gas

constant, $r_{in}$ the inner radius of the hollow fibre, $\mu_m$ is the viscosity of the mixture and $F_p$ is the flowrate on the permeate side.

$$\frac{dP_p}{dz} = -\frac{8RTL\mu_m F_p}{\pi r_{in}^4 N_f P_p} \quad (4)$$

Appropriate boundary conditions are applied to both balances, Eq. (5) and Eq. (6), given the inlet feed flowrate $(F_{f0}, x_{f0})$ and downstream pressure $P_{p0}$.

$$\begin{cases} F_f(z=0) = F_{f0} \\ x_i(z=0) = x_{f0} \end{cases} \quad (5)$$

$$P_p(z=1) = P_{p0} \quad (6)$$

The mathematical problem to be solved is a so-called Boundary Value Problem (BVP), given the boundary conditions on different ends of the domain. The system is composed by the total number of molar components, NC+1 equations. A BVP can be solved by an iterative procedure that simplifies the problem to an Initial Value Problem (IVP) by guessing initial conditions and integrating to check if boundary conditions are met. If the error does not comply with the accepted tolerance $\varepsilon$, set equal to 1e-4, a new guess is given to the IVP. To ensure a decreasing trend in the total error, the initial guess is updated at each iteration by a relaxation factor $\alpha$, equal to 0.1 (Eq. (7)).

$$x_{j+1} = x_j - \alpha|error| \quad (7)$$

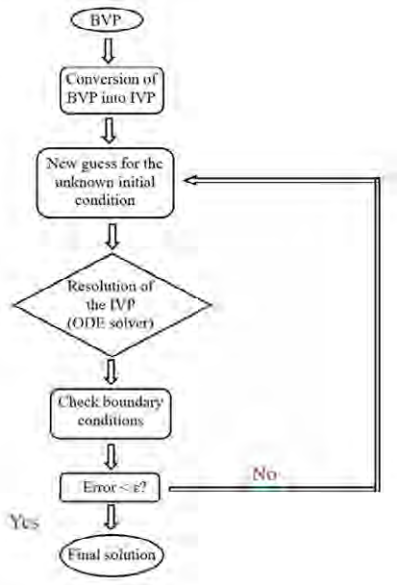

**Figure 2**-Scheme of the shooting methodology for the resolution of a boundary value problem.

The described method is commonly referred to as the *shooting method* [7], a scheme representation is reported in **Figure 2**. The mathematical model is first validated against data from the literature [8], [9], [10] in Matlab® and successively implemented in Aspen HYSYS®. It is highly relevant to provide feasible physical guesses to the unit to ensure convergence in the process simulator. For the validation results, experimental data were available to test, but for process operation, the choice is to consider the pressure higher at z=0, as pressure drops are present along the membrane.

$$P_p(z=1) = P_{p0} \quad (6)$$

A counter current implementation requires numerically to modify the boundary values. The permeate side would migrate in opposite direction from the feed, exiting at x=0. The assumptions stated are valid, the sign in front of Eq. (4) becomes a plus sign and the boundary condition for the permeate pressure becomes:

$$P_p(z=0) = P_{p0} \quad (9)$$

## Case studies in the simulation environment

The study investigates the application of the hollow fiber membrane in biogas processing, for its upgrading to biomethane (Case A), or partial $CO_2$ separation for methanol synthesis application (Case B). Both systems treat 24.5 kmol/h of biogas with 60% tenor of methane and 40% of carbon dioxide, supposing to collect it from pretreatment facilities where impurities such as $H_2S$, siloxanes or volatile components are removed. A block scheme diagram is reported in **Figure 3,** it shows both configuration unit operations.

Case A studies the production of biomethane for grid injection (purity of 98% and 13 bars according to Italian standards) by comparing a pressure swing water absorption (PSWA) column performance to a three hollow fibre co current membrane system at 20 bars [11]. In the latter configuration, the first membrane recovers most of the methane, the retentate is sent to a second membrane where the specifications for biomethane are met. A third membrane is necessary to further recover the methane present in the permeate P-2, as reported in

**Figure 4.**

In Case B, the stream undergoes a partial removal of $CO_2$ to prepare for methanol synthesis. The optimal operating conditions are reached with syngas with a stoichiometric ratio (SN) equal to 2, Eq. (8).

$$SN = \frac{y_{H_2} - y_{CO_2}}{y_{CO} + y_{CO_2}} \quad (10)$$

In this case, separation by membrane was achieved with a two-membrane setup [11]. Case A is only concerned by the $CO_2$ removal, while case B undergoes a steam reforming unit, which produces hydrogen and CO, that after condensation of water, enters the methanol synthesis reactors and purification by a two-distillation columns system. The reforming reactor operates at 900°C with a feed steam to carbon ratio of 3 and 15 bars. Methanol synthesis operates at 61 bars, 250 °C and with a 5% purge when recycling the unreacted syngas.

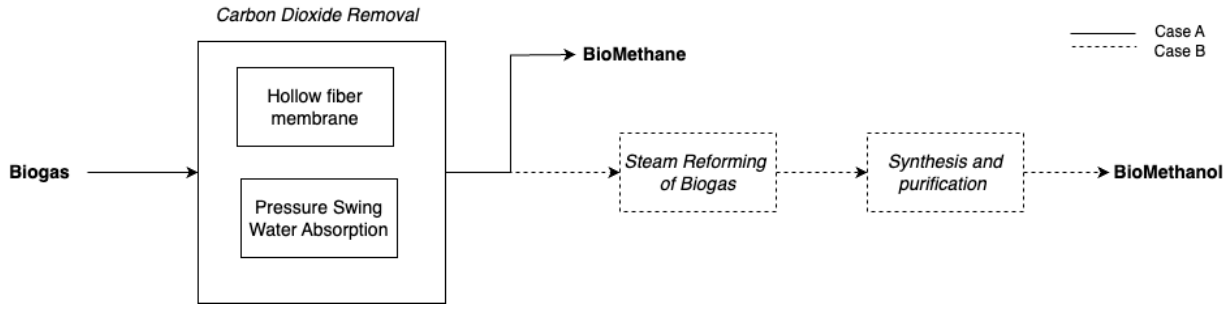

**Figure 3** - Block scheme for the case studies simulated in Aspen HYSYS®. Case A compares the carbon dioxide removal technologies for biomethane as the final product, while case B removes only partially CO2 to use the product for biomethanol production.

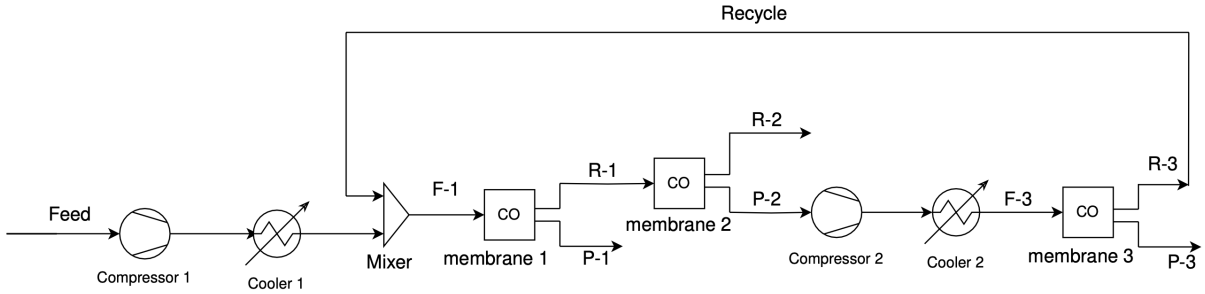

**Figure 4 -** Three membrane configuration for biomethane production from biogas.

**Table 1** - Membrane input parameters implemented in process simulations in Aspen HYSYS®

| Parameter | Unit | Case A | Case B |
|---|---|---|---|
| *L* | m | 4 | 2 |
| *A* | *m*2 | 800 | 90 |
| *rin* | *μ*m | 40 | 40 |
| $r_o$ | *μ*m | 100 | 100 |
| $xf,CO_2$ | - | 0.40 | 0.40 |
| $xf,CH_4$ | - | 0.60 | 0.60 |
| $K_{CO2}$ | mol/m$^2$/s/Pa | 7.86e-9 | 1.34e-8 |
| $K_{CH4}$ | mol/m$^2$/s/Pa | 6.77e-10 | 3.72e-10 |

**Table 2-** KPIs for the two case studies

| KPI | Formulation | Unit | Case A | | Case B | |
|---|---|---|---|---|---|---|
| | | | PSWA | Membrane | PSWA | Membrane |
| $EC_{bioCH4/bioMeOH}$ | $\frac{Q_{compr}+Q_{pumps}}{\dot{m}_{bioCH_4/bioMeOH}}$ | *kWh/kg* | 0.75 | 0.57 | 0.18 | 0.22 |
| $EC_{BG}$ | $\frac{Q_{compr}+Q_{pumps}}{\dot{m}_{BG}}$ | $kWh/kg_{BG}$ | 0.31 | 0.25 | 0.12 | 0.15 |
| $EC_{CO2}$ | $\frac{Q_{compr}+Q_{pumps}}{\dot{m}_{CO_2,out}}$ | $kWh/kg_{CO2}$ | 0.35 | 0.44 | 0.41 | 0.68 |
| $R_{bioCH4/bioMeOH}$ | $\frac{\dot{m}_{bioCH_4/bioMeOH}}{\dot{m}_{BG}}$ | $kg_{bioCH4}/kgBG$ | 0.41 | 0.43 | 0.68 | 0.66 |

Both scenarios are compared in terms of key performance indicators (KPI), reported in the results (**Table 2**), to evaluate which technology suits best each application.

The key steps of the implementation procedure include creating both material port connections (the feed, retentate and permeate ports) and parameter collections

(the main features to define the membrane unit), including the equations of the mathematical model and transferring data between the simulation environment and the custom unit.

The code is then compiled into a DLL (Dynamic Linked Library) file, which is registered in the Windows operating system to enable the use of its final version within Aspen HYSYS®. In particular, the input parameters to be provided by the user, and chosen for the cases under study, are reported in **Table 1**.

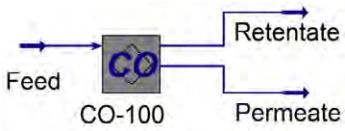

**Figure 5**-CAPEOPEN unit implemented in the process simulator

## RESULTS AND DISCUSSION

### Model validation

**Figure 6** shows both model results and experimental data in the three reference cases: the molar fraction of the species of interest in the permeate decreases when stage-cut increases and a maximum relative error lower than 14% demonstrates a good accuracy of the mathematical model. Further on, convergence is met after few iterations (in the order of 5), given a first guess from the available literature data.

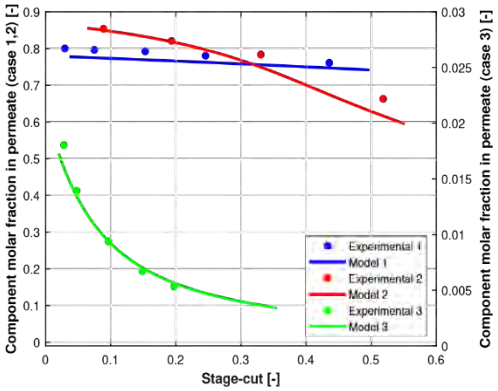

**Figure 6** - Model performance against the collected experimental data from the literature [8], [9], [10].

### Case studies result in Aspen HYSYS®

Once the mathematical model is validated, the co-current hollow fiber membrane unit can be integrated in Aspen HYSYS® using the CAPEOPEN Unit Operation in its "model palette" of the simulator, which is directly connected to a DLL. developed in C++.

The goal of the simulation is to find the most suitable operational unit for biomethane and biomethanol production from biogas. The implementation of the CAPEOPEN unit allows for carrying out a sensitivity analysis in the process simulator and obtaining reliable results. The most relevant results are summarized in **Table 2**. In Case A biomethane is the main product to be injected into the Italian national grid at 13 bars. The three-membrane system shows a lower methane slip when compared to the column, with a recovery term $R_{bioCH4}$ of 0.43 rather than 0.41, which has a strong impact if considering product revenues. Energy costs are evaluated directly from electrical demand from compressors and pumps (of water recirculation in the absorption column) given equal operating conditions. The membranes allow for lower costs in biomethane production, even if, to ensure low slip values, two compressors' stages are required between each recycle (**Figure 4**). The PSWA low efficiency is associated with the high amount of water and carbon dioxide recirculated in the system. Around 57 tons per hour of water are necessary to reach 98% purity in methane. The operating pressure is highly relevant in the PSWA, increasing its values strongly affects the $CO_2$ removal, for this case study a value of 21 bar is chosen after appropriate operational case studies.

The second application frames the CAPEOPEN unit in a complex process simulation from biogas to biomethanol composed by a steam reforming section, methanol synthesis section and finally, a purification section. Results are evaluated on the base of biomethanol rather than biomethane. In this case, the PSWA shows lower consumption as a lower amount of $CO_2$ must be separated to reach biomethanol synthesis optimal conditions, even if in this configuration the membranes can only take advantage of two units and one intermediate compression. The constraint provided is in fact to reach an SN value of 2±0.1.

Further on, the two-membrane layout allows for a slightly higher methane slip, reducing the recovery term and producing slightly lower methanol than the PSWA configuration. Another relevant aspect regards the operating pressure required by both configurations, the membrane require 30 bar to reach the specifics, while the PWSA is operated at 23 bars, to avoid an extra compression step before the reformer, which works at the same conditions. The choice of higher-pressure operation is due to the methanol synthesis necessary further compression step.

## CONCLUSIONS

In the study, a custom co-current hollow fiber membrane model for $CO_2$ separation was successfully developed and integrated into Aspen HYSYS® simulation environment using the CAPE-OPEN standard. The mathematical model was first validated against experimental data, demonstrating high accuracy with a relative error below 14%. Comparative case studies highlight the versatility of

the membrane unit in biogas upgrading applications, showing its capability to produce biomethane with reduced methane slip and lower energy costs compared to a column water absorption technology. For biomethanol production, the PSWA shows lower energy consumption and higher productivity, due to the low amount of CO2 that must be separated to reach an SN equal to 2 in the synthesis section. The simulations show the advantages of membrane technologies in biogas processing, including their adaptability to various product specifications and their ability to reduce operational energy demands. Additionally, the CAPE-OPEN framework has proven to be a powerful tool for integrating and optimizing novel unit operations within standard process simulation environments. It can be concluded that while membranes are more energy-efficient for high-purity biomethane production, a comprehensive comparison should also consider the cost associated with each layout, as membranes require higher maintenance but allow for compact systems. Further optimizations and evaluations can be carried out directly in the process simulator environment thanks to the CAPEOPEN output variables provided. The methods developed for co-current hollow fibre membranes can be applied to other custom unit operations in process simulation, offering versatility for future applications.

## ABSTRACT

The co-gasification of biomass and plastic waste offers a promising pathway for sustainable syngas production, necessitating precise prediction of its composition to optimize efficiency. This study compares the performance of Aspen Plus models, including the thermodynamic equilibrium model (TEM) and restricted thermodynamic equilibrium model (RTM), with machine learning (ML) techniques, focusing on the support vector regression (SVR) for syngas prediction during steam and air co-gasification. Aspen Plus simulations provided valuable mechanistic insights, while the ML model demonstrated superior predictive accuracy. The SVR, enhanced by principal component analysis (PCA), significantly improved performance, achieved $R^2$ values of 0.879 for $H_2$, 0.856 for CO, 0.859 for $CO_2$, and 0.744 for $CH_4$ on the testing dataset. It also outperformed other models in terms of RMSE, achieving exceptional precision for $CH_4$ (0.0087), CO (0.0193), and $H_2$ (0.0194). In contrast, RTM exhibited moderate accuracy with minimal deviations, while TEM showed the highest RMSE values across all predictions, indicating its limited reliability for real-world applications. This study advances gasification technologies by demonstrating the advantages of ML models, particularly SVR, in predicting syngas composition and supporting the global transition toward sustainable energy systems.

**Keywords**: Biomass, Aspen Plus, Modeling and Simulations, Plastic wastes, Syngas prediction

## INTRODUCTION

The transition to sustainable energy production necessitates the optimization of thermochemical conversion processes, with co-gasification of biomass and plastic waste emerging as a promising route for syngas generation. Accurate prediction of syngas composition is crucial for efficient process design and operation. Traditional modeling approaches, primarily thermodynamic equilibrium and kinetic models implemented in process simulation software like Aspen Plus, have served as the foundation for gasification studies. These models leverage fundamental principles of thermodynamics and reaction kinetics to simulate the complex interactions within the gasifier. However, they often struggle to capture the non-linearities and intricate phenomena inherent in these processes, especially when dealing with mixed feedstocks [1].

Machine learning (ML) is increasingly being explored as a complementary or alternative approach, offering the potential to enhance predictive accuracy. ML techniques, such as random forest, artificial neural networks (ANNs), and support vector machines (SVMs) can learn complex relationships directly from data, bypassing some of the limitations of purely mechanistic models [2]. ML's capacity to learn from high-dimensional data and capture non-linear relationships has made them a popular choice for modeling complex systems. Significant research has focused on both Aspen Plus modeling and ML-based modeling of gasification. For example, Aspen Plus studies often focus on the effects of different operating conditions such as temperature, air/steam to fuel ratio on syngas composition . ML studies, on the other hand, tend to concentrate on developing predictive models that are trained

using either experimental data or output from process simulation software [3]. The comparison of these two approaches and the exploration of their potential synergy, however, is less well-explored in the current literature.

While both Aspen Plus and ML techniques have individually contributed to understanding and predicting syngas production from gasification, the direct comparative analysis of these methods, particularly in the context of co-gasification, is lacking. This research directly addresses this gap by comparing the predictive performance of Aspen Plus models, TEM and RTM, and surrogate ML model, SVM, for the co-gasification of biomass and plastic waste, and exploring the advantages each technique bring. The novelty of this study lies in the integration of these approaches and offers a comprehensive comparison of their prediction accuracy in prediction of syngas compositions. While conventional gasification methods and simulation tools like Aspen Plus have been widely used to study biomass and plastic waste gasification, this study will also explore how ML model trained on experimental data can overcome limitations in mechanistic models for predicting syngas outputs [4]. This approach has the potential to contribute towards a more accurate and data-driven approach to design and optimization of co-gasification plants.

## METHODOLOGY

Experimental data on steam-$O_2$ biomass plastic gasification, based on a mixture of rice husk (RH), polyethylene PE, polyethylene terephthalate (PET), and tyres, was collected from the published articles by Brachi et al. (2014), Pinto et al. (2002), and Pinto et al. (2016) [5-7]. Experiments were performed on a bench scale with varying temperature and steam-to-biomass ratio. To conduct the ML model training, the eleven input features selected were ash, moisture, volatile matter, and fixed carbon from the proximate analysis. From the ultimate analysis, carbon, hydrogen, nitrogen, and oxygen were selected, and from the process variables, reactor temperature, steam-to-biomass ratio (S/B), and equivalence ratio (ER) were included. The dependent features are the molar fraction of the syngas composition $H_2$, CO, $CO_2$ and $CH_4$. The dataset consists of 40 rows with eleven input and four output features, so PCA was applied to reduce dimensionality before training the ML model to avoid possible overfitting. The data was then standard scaled, and 10-fold cross-validation was performed, splitting the data into an 80/20 ratio for training and testing purposes.

### Equilibrium Modeling

This study employed Aspen Plus V.14.0 to model steam co-gasification and predict syngas composition under various conditions, utilizing both equilibrium and kinetic modeling strategies. Biomass, PE, and char were defined as non-conventional components using proximate and ultimate analyses from the ULTANAL and PROXANAL models, with enthalpy and density data provided by HCOALGEN and DCOALIGT models, respectively, based on biomass combustion and composition. Ash was treated as inert, and the Peng-Robinson thermodynamic package with the Boston-Mathias function was selected for high-temperature gasification simulations. Two equilibrium models were used: the TEM, which minimizes Gibbs free energy to predict product composition but neglects reaction kinetics and often overestimates or underestimates syngas, and the RTM, which incorporates temperature-dependent constraints to better reflect real-world gasification by minimizing Gibbs free energy based on elemental composition without requiring detailed kinetic data.

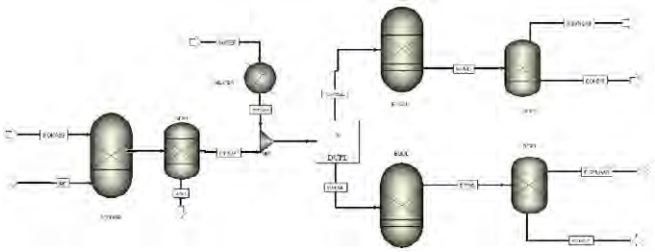

**Figure 1:** Aspen Plus modeling of TEM and TRM

In this study the Aspen Plus model structure developed by Acar et al., (2019) for gasification, was adopted, using both TEM and RTM [8]. Biomass and plastic waste were decomposed in a RYIELD reactor (DECOMP) into constituent elements based on ultimate and proximate analyses, with ash separated using a separator (SEP1). The components were mixed with steam and fed into an RGIBBS reactor, where the gasifier (EQIL) simulated the TEM approach and another reactor (R-GASI) modeled RTM. Syngas was separated from byproducts using separators (SEP2 for R-GASI and SEP3 for EQIL), as illustrated in Figure 1. Following Acar et al. (2019), four key reactions (Table 1) were used to restrict chemical equilibrium in RTM, and sensitivity analysis was conducted for each of the 40 experimental instances by varying the approach temperature of individual reactions, generating 22,500 cases per instance. The absolute difference between the molar fractions of the predicted and experimental syngas composition was calculated using Equation 1, where ME represents the minimum error, *e* is the experimental value, *p* is the predicted value, and *i* denotes the *i*-th case in the sensitivity analysis [9].

$$(ME)_i = |H_2^e - H_2^p|_i + |CO^e - CO^p|_i + |CO_2^e - CO_2^p|_i + |CH_4^e - CH_4^p|_i \quad (1)$$

**Table 1:** Reactions used in RTM

| No. | Reaction | ΔHr (kJ/mol) |
|---|---|---|
| R1 | $C + H_2O \rightarrow CO + H_2$ | 131 |
| R2 | $C + 0.5O_2 \rightarrow CO$ | -111 |
| R3 | $CO + H_2O \rightarrow CO_2 + H_2$ | -41.2 |
| R4 | $CH_4 + H_2O \rightarrow CO + 3H_2$ | 206 |

## Dimensionality Reduction

In order to address the curse of dimensionality and possible multicollinearity among the input variables and also to represent independent variables with minimal redundancy, PCA has been used, which can find feature components that have low and high variance in a given data set [10]. PCA is a multivariate technique that allows one to transform a series of correlated variables into a set of uncorrelated variables known as principal components (PCs). The PCs of a data set *x* are obtained by solving an eigenvalue–eigenvector problem. In this regard, the covariance matrix can be computed by equation 2. Where *n* is total number of samples in the data set and $\overline{x_i} = \frac{1}{n}\sum_{i=1}^{n} x_i$.

$$M_c = \frac{1}{n-1}\sum_{i=1}^{n}(x_i - \overline{x_i})(x_i - \overline{x_i})^T \quad (2)$$

## Machine learning

SVR is a powerful supervised learning algorithm based on the principles of Support Vector Machines (SVMs). Unlike traditional regression models, SVR aims to find a function that not only minimizes error but also avoids overfitting by balancing complexity and predictive performance. SVR achieves this by defining a margin of tolerance within which predictions are considered acceptable deviations from the actual data points. In SVR, the objective is to find a hyperplane that best fits the data points, allowing for some deviations. The SVR function can be expressed in equation 3, where w is weight vector, x is input feature vector, and b is bias term.

$$f(x) = [w, x] + b \quad (3)$$

## Performance Evaluation

The accuracy and reliability of the surrogate models were evaluated using Coefficient of Determination ($R^2$), RMSE, and Mean Absolute Error (MAE) for both training and testing datasets. $R^2$, as defined by Equation 4 measures how well the model explains variance in the target variable. RMSE, defined by Equation 5, quantifies the average prediction error with greater sensitivity to outliers. In addition, MAE, as described in Equation 6, provides a straightforward measure of overall error magnitude. These evaluation metrics were specifically applied to the molar fractions of syngas components—$H_2$, CO, $CO_2$, and $CH_4$—where $y_i$ is the observed value, $\hat{y}_i$ is the predicted value, $\overline{y}_i$ is the mean of the observed values, and *n* is the number of data points.

$$R^2 = 1 - \frac{\sum_{i=1}^{n}(y_i - \hat{y}_i)^2}{\sum_{i=1}^{n}(y_i - \overline{y}_i)^2} \quad (4)$$

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2} \quad (5)$$

$$MAE = \frac{1}{n}\sum_{i=1}^{n}|y_i - \hat{y}_i| \quad (6)$$

## RESULTS AND DISCUSSION

SVR with a radial basis function kernel was employed to develop a predictive model based on the eleven input features, utilizing MultiOutputRegressor to handle multiple output variables. The model was configured with an RBF kernel, a regularization parameter of 1.0, and an epsilon value of 0.1, which defines the margin of tolerance for error. The model's accuracy was assessed using $R^2$, RMSE, and MAE for both training and testing datasets. The results are summarized in **Table 2**, values in parentheses representing the test dataset. The results indicate that the SVR model performed well in capturing the variance in the training set, with $R^2$ values exceeding 0.78 across all outputs. However, a decrease in $R^2$ for the testing set shows overfitting.

**Table 2:** Performance matrix of train(test) based on real input features

| | $R^2$ | RMSE | MAE |
|---|---|---|---|
| $H_2$ | 0.894(0.652) | 0.022(0.040) | 0.016(0.030) |
| CO | 0.966(0.862) | 0.015(0.031) | 0.012(0.025) |
| $CO_2$ | 0.936(0.779) | 0.023(0.043) | 0.015(0.031) |
| $CH_4$ | 0.784(0.577) | 0.013(0.019) | 0.008(0.014) |

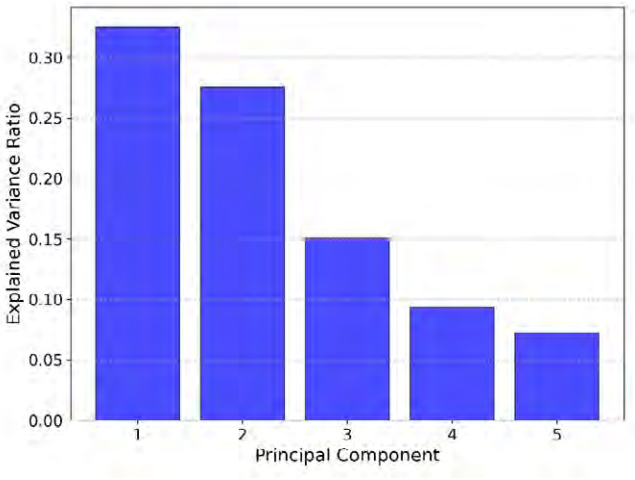

**Figure 2:** Explained variance for every PC

To address potential overfitting and improve model performance, PCA was applied to reduce the dimensionality of the input features while retaining essential information. The dataset, sourced from published studies, was first standardized using the Standard Scaler to

ensure uniform scaling across variables. PCA was then performed, and cumulative explained variance analysis showed that five principal components captured over 90% of the total variance. This transformation effectively simplified the data structure while preserving key patterns, allowing for a refined input representation for subsequent modeling steps. The cumulative explained variance, shown in **Figure 2**, further highlights the efficiency of PCA in retaining maximum information. The bars in the graph indicate that the first PC accounts for over 30% of the variance, the second PC captures approximately 28%, and the third PC retains around 15%, with the first three PCs collectively preserving more than 75% of the total variance. This finding provides a solid foundation for further analysis using the reduced dataset, ensuring computational efficiency without compromising data integrity. Elmaz et al., (2020) applied PCA to reduce input dimensionality in a downdraft biomass gasification study before training SVR, DTR, and MLP models for prediction [11].

**Table 3** presents the performance metrics ($R^2$, RMSE, and MAE) for each syngas component, with values in parentheses representing the testing dataset. These results are based on PCA-reduced input features, which significantly improved model performance. $H_2$ exhibits the highest $R^2$ values for both training (0.977) and testing (0.853), along with favorable RMSE and MAE values, indicating superior predictive accuracy. CO demonstrates comparable training performance ($R^2$ = 0.950) but surpasses $H_2$ in testing ($R^2$ = 0.878), suggesting improved generalization. While CO's training RMSE (0.0191) is lower than that of $H_2$ (0.0240), its other error metrics remain slightly below $H_2$. $CO_2$ and $CH_4$ show lower $R^2$ values in both training and testing datasets, with $CH_4$ exhibiting the lowest $R^2$ (0.744) for testing. However, $CH_4$ also has the lowest RMSE and MAE, indicating relatively small errors despite lower variance capture. The improvements observed in these results highlight the effectiveness of PCA in reducing dimensionality while preserving essential information, thereby enhancing the SVR model's predictive capabilities. The performance variations across syngas components may stem from differences in their formation mechanisms or disparities in the quality and quantity of available training data. Further investigation into these factors could refine model accuracy even further.

**Table 3:** Performance matrix of train(test) based on PCA reduced features

| | $R^2$ | RMSE | MAE |
|---|---|---|---|
| $H_2$ | 0.977(0.853) | 0.0240(0.038) | 0.016(0.029) |
| CO | 0.950(0.878) | 0.0191(0.035) | 0.014(0.027) |
| $CO_2$ | 0.942(0.805) | 0.0223(0.040) | 0.015(0.028) |
| $CH_4$ | 0.944(0.744) | 0.0135(0.018) | 0.008(0.013) |

*Performance matrix for SVR is given as train(test)

**Table 4** presents the predicted values from all models, clearly showing that SVR consistently outperformed the other techniques across all syngas components by achieving the lowest RMSE values. Among the predictions, the most accurate prediction by SVR was for $CH_4$, with an exceptionally low RMSE of 0.0137, signifying high precision. Similarly, SVR also demonstrated strong predictive performance for CO and $CO_2$, with RMSE values of 0.0197 and 0.0238, respectively. Although the RMSE for $H_2$ (0.0242) was slightly higher than that of RTM (0.0238), SVR still outperformed the remaining models by a considerable margin.

**Table 4:** RMSE values of different modeling techniques

| | RTM | TEM | SVR |
|---|---|---|---|
| $H_2$ | 0.0238 | 0.1971 | 0.0242 |
| CO | 0.0391 | 0.0911 | 0.0197 |
| $CO_2$ | 0.0539 | 0.1038 | 0.0238 |
| $CH_4$ | 0.0488 | 0.1125 | 0.0137 |

In comparison, the RTM showed commendable prediction accuracy, though not as precise as SVR. It achieved moderately low RMSE values for $H_2$ (0.0238), CO (0.0391), $CO_2$ (0.0539), and $CH_4$ (0.0488), making it a viable alternative in some scenarios. However, its performance for the $H_2$/CO ratio, with an RMSE of 0.2569, was less accurate compared to SVR. Conversely, TEM performed the weakest among the three techniques, with significantly higher RMSE values across all predictions. For example, the RMSE for $H_2$ was 0.1971, almost ten times higher than that of SVR, while the RMSE values for CO (0.0911), $CO_2$ (0.1038), and $CH_4$ (0.1125) further highlighted its lack of precision.

In this Study the predictions obtained from different models were analyzed and plotted to evaluate their performance. **Figure 3** illustrates the comparison between experimental and predicted $H_2$ values across various feedstock compositions and process variables. Among the models, the SVR demonstrates exceptional predictive accuracy, with green data points closely aligning with the experimental values for all the experimental values. The minimal error observed in SVR predictions underscores its reliability and effectiveness. In contrast, the RTM also performed well for the $H_2$ concentration above 35%. The TEM model, on the other hand, consistently overpredicts $H_2$ values across all feedstock compositions, likely due to limitations in Gibbs free energy estimations for syngas constituents, as highlighted by Ajorloo et al. (2022) [1].

The predictions of all models for CO against the experimental values are given in the **Figure 4**. Just like the predictions of H2 the SVR also has excelled in predicting the CO in this study. The SVR model consistently demonstrates superior predictive performance, with the predicted values (green points) closely matching the experimental results. The RTM model performs relatively well

in predicting CO values at lower concentrations but exhibits slight deviations at higher concentrations. Conversely, the predictions by TEM model are quite diverse as shown by the red points, reflecting potential inaccuracies in the equilibrium modeling of CO. This is also evident by the RMSE values from the **Table 4** where TEM has highest RMSE among other models.

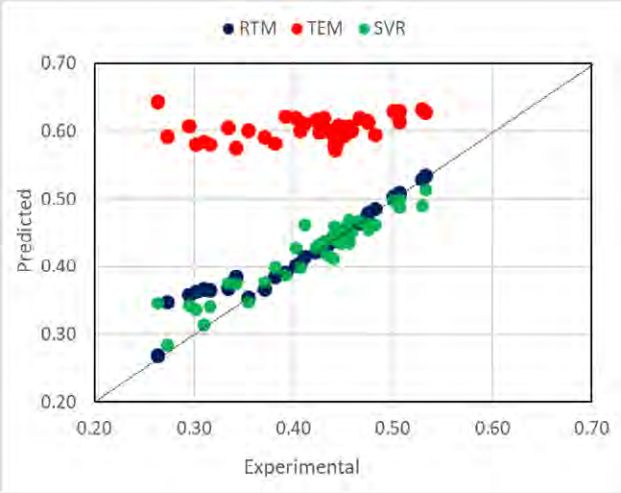

**Figure 3:** Experimental and predicted mole fraction of $H_2$

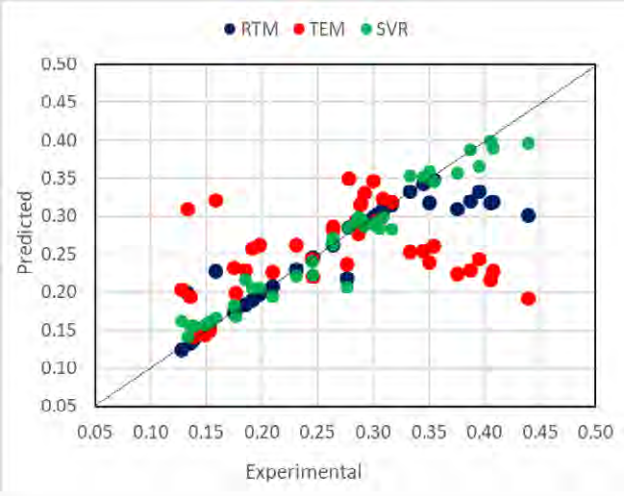

**Figure 4:** Experimental and predicted mole fraction of CO

Figure 5 and Figure 6 shows the predicted values by the models for CO2 and CH4 respectively. Similar to the predictions of $H_2$ and CO, the SVR model demonstrates excellent agreement with experimental data, as the predicted values align closely with the experimental results. On the other hand The RTM model shows reasonable accuracy for higher $CO_2$ concentrations but fails to maintain the same precision for predicting $CH_4$. The TEM model, however, systematically underpredict $CO_2$ values in Figure 5 and predictions for the $CH_4$ are quite lower below 1% even sometimes the predicted values for $CH_4$ are like $10^{-5}$ which raises serious question mark on the predictive accuracy and use of TEM for the real world scenario. SVR remained most accurate predicting model which shows that data based modeling outperforms the Aspen Plus, TEM and RTM, modeling strategy.

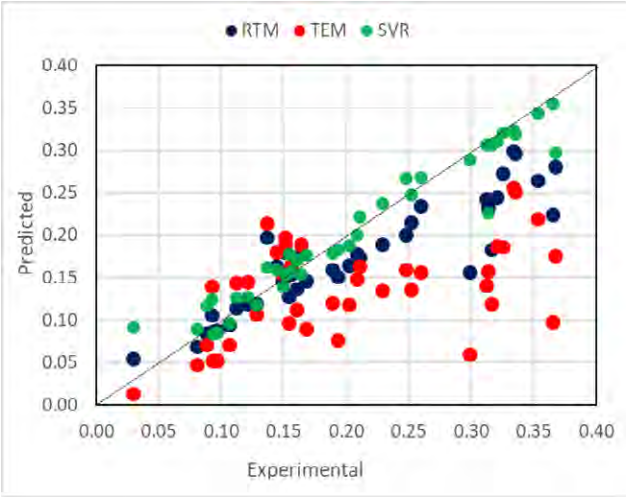

**Figure 5:** Experimental and predicted mole fraction of $CO_2$

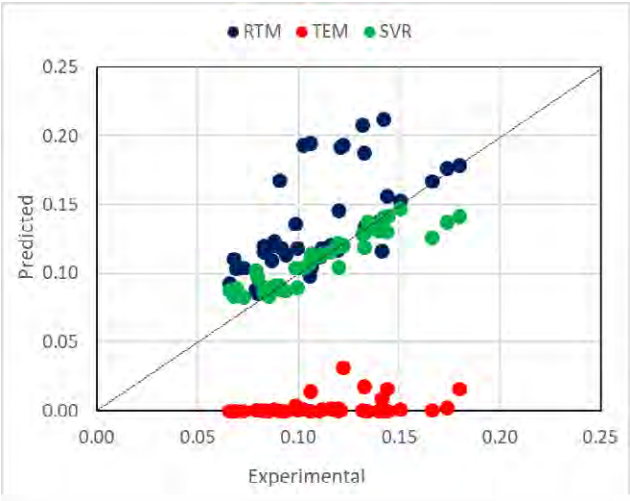

**Figure 6:** Experimental and predicted mole fraction of $CH_4$

## CONCLUSIONS

In this study, a comparative analysis of Aspen Plus models and machine learning techniques was conducted to evaluate their performance in predicting syngas composition during the co-gasification of biomass and plastic wastes. The results clearly demonstrate that the SVR, in accurately capturing the non-linearities of the gasification process. Without the use of PCA, the SVR model achieved high performance in training dataset, particularly for syngas components like CO and $CH_4$, with RMSE values as low as 0.0197 and 0.0137, respectively, across training and testing datasets. However, the application of

PCA to reduce the dimensionality of the input features resulted in substantial improvements in model accuracy. For instance, after applying PCA, the RMSE for $CH_4$ further decreased to 0.0135, while the $R^2$ for $H_2$ increased from 0.894 to 0.977 for training and 0.652 to 0.853 for testing, indicating better generalization.

While the SVR model with PCA consistently outperformed the other techniques across all syngas components, achieving notably low RMSE values, the RTM showed commendable accuracy, although not as precise as SVR. The RTM model achieved moderately low RMSE values for $H_2$ (0.0238), CO (0.0391), $CO_2$ (0.0539), and $CH_4$ (0.0488), but fell behind SVR in terms of predictive precision. The TEM model, on the other hand, performed the weakest, with significantly higher RMSE values for all components. For example, the RMSE for $H_2$ was 0.1971, almost ten times higher than that of SVR, underscoring the strength of SVR in handling non-linear relationships and high-dimensional data.

These findings highlight the importance of dimensionality reduction through PCA when applying machine learning to predict complex systems such as syngas composition. The superior performance of the PCA-enhanced SVR model, coupled with its ability to generalize better across different feedstock compositions and operating conditions, emphasizes its potential as a robust predictive tool in renewable energy technologies. Furthermore, this study underscores the potential of ML models to complement traditional mechanistic models like Aspen Plus, providing valuable insights into syngas production processes, thus advancing the transition toward more sustainable energy systems.

## ABSTRACT

This work presents a comprehensive multiscale model for Solid Oxide Fuel Cells (SOFCs), integrating microscale and macroscale simulations to analyze internal reforming and its impact on overall cell performance. The microscale model [1], [2] captures the intricate mass and charge transport phenomena at the pore scale of porous electrodes, resolving electrochemical reactions at the triple-phase boundaries and modeling chemical reactions at pore spaces. Simultaneously, the macroscale model provides a broader view of the entire cell's behavior by solving the same transport equations on a coarser computational mesh. The multiscale approach is particularly useful for addressing the challenges posed by simultaneous chemical and electrochemical reactions at the anode, which complicate the modeling of internal reforming. To overcome these challenges, a novel approach is introduced [3], spatially separating the regions of chemical and electrochemical activity in the pore scale domain by taking the electrochemical active layer thickness into consideration. The integrated multiscale model is applied to a complete internal reforming SOFC to explore how electrode morphology, particularly the use of gradient microstructures, influences cell performance.

**Keywords**: SOFC, Multiscale Model, Microscale Model, Internal Reforming, Gradient Microstructure

## INTRODUCTION

Fuel cells are electrochemical devices that convert the chemical energy of a fuel directly into electricity, heat, and water through a reaction with oxygen, typically without combustion. They are highly efficient, scalable, and environmentally friendly, making them suitable for various applications, including power generation, transportation, and portable energy solutions. Among the different types of fuel cells, the choice depends on factors such as operating temperature, efficiency, and fuel flexibility.

Solid Oxide Fuel Cells (SOFCs) are a type of high-temperature fuel cell that operates at temperatures between 600°C and 1000°C. They use a solid ceramic electrolyte to conduct oxygen ions from the cathode to the anode, where they react with a fuel—such as hydrogen, natural gas, or biogas—to generate electricity. SOFCs are known for their high efficiency, fuel flexibility, and ability to use waste heat for additional power generation in combined heat and power (CHP) systems [4].

To use hydrocarbon fuels like methane ($CH_4$) in SOFCs, a reforming process, such as steam reforming, converts them into hydrogen-rich gas. SOFC high operating temperatures enable internal reforming, which simplifies system design and improves efficiency but requires careful management to prevent carbon deposition and ensure stable operation.

Internal reforming can be categorized into indirect and direct methods. Indirect reforming places the reformer outside the fuel cell but in thermal contact, using SOFC-generated heat to drive the reaction and minimizing carbon deposition risks [5]. Direct reforming occurs within the anode, where fuel and steam react together, streamlining the system and boosting efficiency but demanding precise control of temperature gradients to

prevent material degradation.

SOFCs exhibit defining features across various length scales, from the microscale structure of the porous electrodes to the macroscale design of the entire system. To predict their performance, different types of models have been developed, each focusing on a specific length scale. Microscale models focus on reactions and mass transport processes within the porous anode and cathode. At the macroscale, models address the transport phenomena within a single cell. By combining these models, researchers can better understand and enhance the performance of SOFCs across all relevant scales.

The microstructure design of the porous electrodes plays a critical role in defining the performance of SOFCs. Electrochemical reactions primarily occur at the triple-phase boundary (TPB), where the electrolyte, electrode, and gas phase meet. A high TPB density is essential for maximizing reaction sites and enhancing performance. Additionally, the tortuosity of the porous structure significantly affects gas and ion diffusion [6]. High tortuosity can hinder mass transport by increasing the effective path length for reactants and ions, leading to concentration gradients and performance losses. Optimizing the microstructure to balance TPB density and tortuosity is crucial for achieving efficient gas diffusion, ionic conductivity, and overall cell performance.

A multiscale model combines the strengths of these individual models to assess SOFC performance more comprehensively. By integrating physics across different length scales, such a model can capture detailed electrochemical and transport processes at the microscale while also considering cell-level features at the macroscale.

In the current study, a direct internal reforming SOFC is modelled using a multiscale framework. The model solves transport, chemical reactions, and electrochemical reactions at the microstructure level and transport equations, and chemical reactions at the cell level, syncing information between these two scales. Different microstructure configurations—conventional, lattice, and fibrous—are tested for both the anode and cathode to evaluate the benefits of each design.

## METHODOLOGY

The methodology employs a multiscale framework that integrates two distinct models: a microscale model and a macroscale model. The microscale model focuses on the processes occurring within the porous microstructure of the electrodes. The macroscale model captures the transport behaviour at the cell level, addressing overall performance metrics. The computational domain is schematically shown in figure 1.

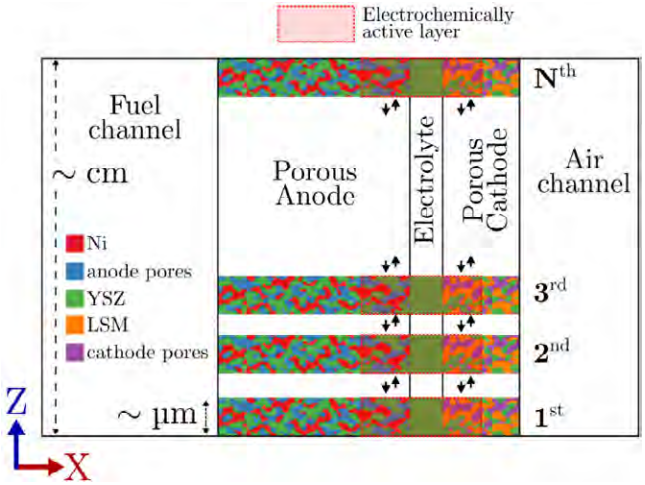

**Figure 1.** Schematic domain of the problem (microstructures and the entire cell)

Here only small "patches" of the microstructural domain are actually solved, as in the gap-tooth scheme [7,8] to reduce computational cost. The vertical arrows in fig 1 represent the fluxes between the microstructure patches.

To ensure consistency between the two scales, an iterative algorithm is employed. This algorithm minimizes discrepancies between the outputs of the microscale and macroscale models by iteratively adjusting parameters in the macroscale model. More specifically, the electrochemical reaction rates in the macroscale model are modified to better align with the detailed microscale predictions since there is a more fundamental definition for the kinetics of electrochemical reactions at the microscale. To describe the rate of electrochemical reactions at microscale we have used a lineal exchange current density, which is per length of TPB. Whereas for the macroscale model the kinetics of electrochemical reactions could only be described based on area or volume. Since electrochemical reactions are essentially heterogeneous and take place on the TPB lines in space (as opposed to a homogeneous reaction that take place in space) a lineal exchange current density is fundamentally more accurate than an area-averaged or volume-averaged definition.

By iterating between the models, the framework converges to a solution that harmonizes the behaviour across scales. This idea is explained in more detail in our recent work [2].

The convective and diffusive mass transport is dictated by the following equation:

$$\overbrace{\nabla \cdot \left(D_i^{\text{eff}} \nabla C_i\right)}^{\text{diffusive}} - \overbrace{\nabla \cdot (\vec{V} C_i)}^{\text{convective}} + S_i = 0 \qquad (1)$$

Here, $D_i^{\text{eff}}$ is the effective diffusivity of component $i$ into the gaseous mixture, $C_i$ is mass density of $i_{th}$ gaseous component, $V$ is fluid velocity. The term $S_i$ is the non-

linear source term that exists due to chemical and electrochemical reactions that consume or produce a particular component in the mixture. In the microscale model the convective term is disregarded due to the small pore sizes in the porous electrodes.
The ion conduction is modeled using this equation:

$$\nabla \cdot \left(\sigma_{\text{ion}}^{\text{eff}} \nabla \phi_{\text{ion}}\right) + S_{\text{ion}} = 0 \quad (2)$$

Here, $\sigma_{\text{ion}}^{\text{eff}}$ is the effective diffusivity of ions in the ion conductive material and $S_{\text{ion}}$ is the non-linear source term due to electrochemical reactions.

The two main chemical reactions considered for internal reforming are Steam-Methane Reforming (SMR) and the Water-Gas Shift (WGS) reaction. In SMR, methane reacts with steam to produce hydrogen and carbon monoxide: $CH_4 + H_2O \rightarrow CO + 3H_2$. The WGS reaction further converts carbon monoxide and steam into additional hydrogen and carbon dioxide: $CO + H_2O \rightarrow CO_2 + H_2$. These reactions are crucial for generating the hydrogen necessary for electrochemical reactions at the anode. The following equations describe the rate of SMR and WGS [9]:

$$r_{\text{SMR}} = k_{\text{SMR}} p_{\text{CH4}} \, exp\left(-\frac{E_{\text{SMR}}^{A}}{RT}\right) \quad (3)$$

$$r_{\text{WGS}} = k_{\text{WGS}} p_{\text{CO}} \left(1 - \frac{p_{\text{CO2}} p_{\text{H2}} / p_{\text{CO}} p_{\text{H2O}}}{K_{eq}}\right) \quad (4)$$

Here, $E_{\text{SMR}}^{A}$ is the SMR reaction activation energy, $k_{\text{SMR}}$ is pre-exponential factor of SMR. For WGS, $k_{\text{WGS}}$ is the reaction rate constant, and $K_{eq}$ is the equilibrium constant.

Modelling internal reforming presents a significant challenge when it comes to simultaneously simulating chemical and electrochemical reactions. These two processes occur in tandem, but their interplay complicates the formulation of the problem. One specific issue is the modelling of concentration overpotential, which is traditionally defined in terms of the bulk pressure of hydrogen. In the case of internal reforming SOFCs, if the hydrogen pressure at the inlet is zero, the concentration overpotential would theoretically become infinite, which is physically unrealistic and resulting in zero-division error. This presents a fundamental problem because it suggests an unbounded overpotential. To address this, we propose a solution that involves artificially separating the regions where electrochemical and chemical reactions occur.

In our model, the anode side of the microstructure is divided into two distinct zones: the region closer to the electrolyte, where electrochemical reactions dominate, is treated as an electrochemical-only zone, while the region farther away from the electrolyte, where chemical reactions dominate, is treated as a chemical-only zone. This separation allows us to avoid the unphysical infinite concentration overpotential by ensuring that each region is simulated with the appropriate reaction mechanism. This is schematically shown in Figure 2.

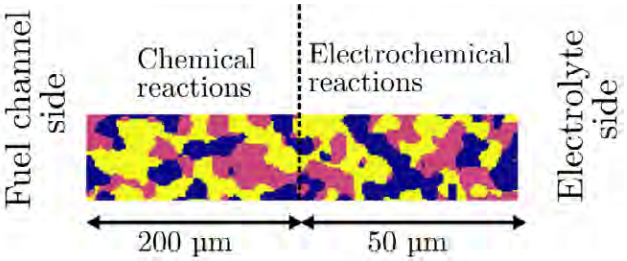

**Figure 2.** Separation of anode side into two regions

Electrochemical reactions are dominant in a very thin layer close to the electrolyte called the "electrochemical active layer". The length of this layer is reported to be smaller than $50\ \mu\text{m}$ [10]. The concept is that the rate of electrochemical reactions is negligible on the left side of Figure 2, while the rate of chemical reactions is negligible on the right side. Therefore, it is assumed that these negligible rates are effectively zero.

Different microstructure designs tested in this study are shown in Figure 3. The reasoning behind why each design is selected is further explained in our recent manuscript [11].

## RESULTS AND DISCUSSION

### Model Validation

The model is firstly validated against experimental measurements of Rogers et al.12]. The polarization curve is selected for the basis of the comparison, and it is shown in Figure 4. In this figure the experimental data points are shown with black dots, and results of the macroscale and multiscale models are shown with red and green lines, respectively. The red area shows the region where the polarization curve varies with a ±10% change in the calibration parameter of macroscale model.

From figure 4, it is obvious that both the calibrated macroscale model, and multiscale model, are capable of explaining the polarization curve of the cell. However, the two models differ in terms of calibration requirements. The macroscale model requires calibration using experimental data, with the calibration parameter being the area-averaged exchange current density, which accounts for the overall electrochemical activity in the cell. In contrast, the multiscale model does not require such calibration. This is because it uses a more fundamental definition of exchange current density, namely the lineal exchange current density. As a result, the multiscale model offers a more fundamental approach without the need for calibration, while the macroscale model relies on fitting to ample experimental data to accurately represent the system's behaviour.

It is also important to note that the point of using a multiscale model is not to achieve a better match with experimental results for a given set of datapoints on the polarization curve. Rather, the goal here is to explore

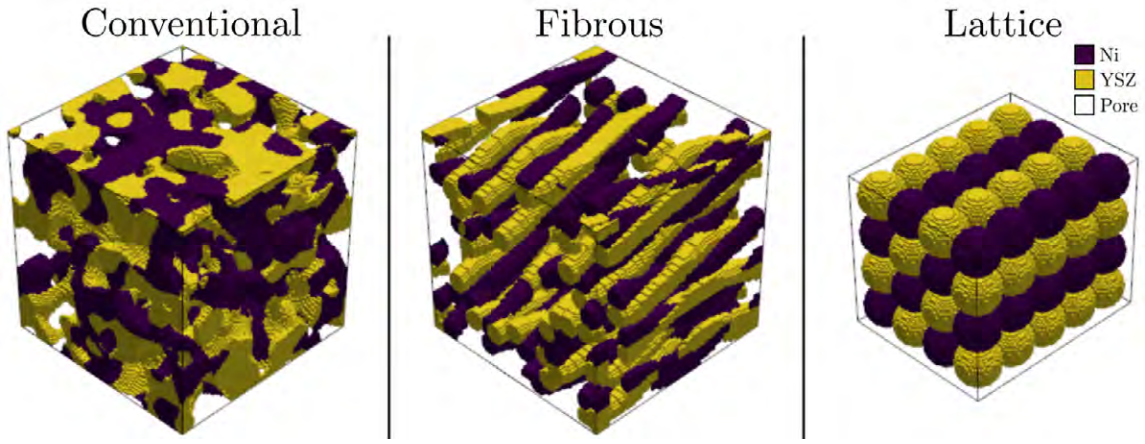

**Figure 3.** Different microstructure designs

different designs with varying microscopic and macroscopic features, especially for which no measured experimental data is available. This allows for the investigation of new designs and configurations that are not constrained by the existing experimental dataset.

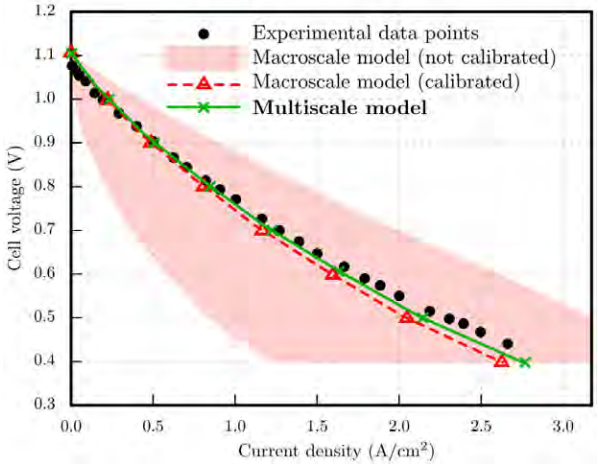

**Figure 4.** Polarization curve of different models compared with experimental measurements [9]

## Spatial Distribution of Field Variables Across the Anode

Variation of concentration of different components across the anode is shown in figure 5. This figure is for the case of conventional microstructure (refer to figure 2). Five different components exist in the gaseous mixture in the anode side.

At the anode inlet, only $CH_4$ and $H_2O$ have non-zero concentrations. Due to SMR, the concentration of $CH_4$ decreases monotonically toward the electrolyte side. Based on the chemical reactions, the concentration of $H_2O$ would be expected to decrease monotonically because it is consumed in both SMR and WGS. However, due to the production of $H_2O$ in the electrochemically active layer, its concentration levels off as it approaches this layer and then begins to increase. A similar explanation, but with the opposite reasoning, applies to the hydrogen concentration. Due to SMR and WGS, its concentration increases as it approaches the electrochemically active layer, only to level off and then decrease upon entering this layer.

To validate the assumption of a negligible chemical reaction rate near the electrolyte and a negligible electrochemical reaction rate in the remaining of the porous anode, these rates are compared in Figure 6, which is based on the case of a conventional microstructure. It can be observed that the rate of electrochemical reactions levels off after the first $50\ \mu m$ near the electrolyte. This occurs because the electrochemical activity becomes limited by the availability of reactants in this region. Similarly, the rate of the SMR reaction drops significantly as it approaches this region, which can be attributed to the limited availability of $CH_4$ approaching the electrochemically active layer.

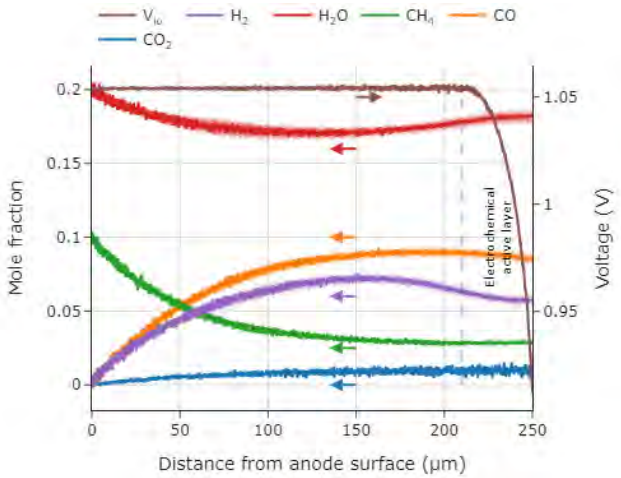

**Figure 5.** Concentration of different species across the anode

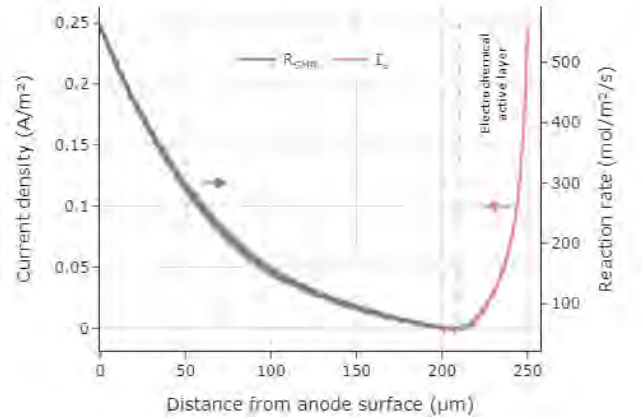

**Figure 6.** Comparison of electrochemical and chemical reactions rates

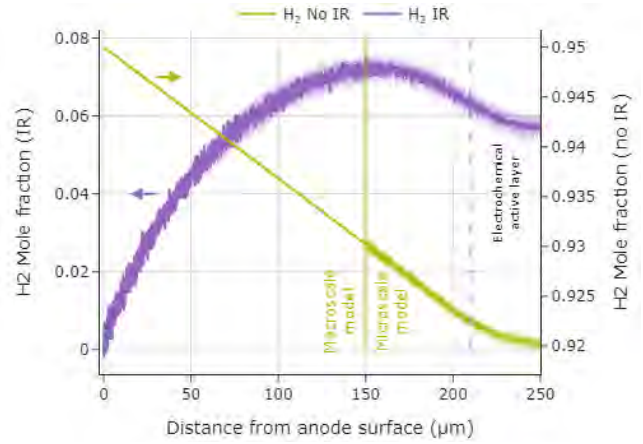

**Figure 7.** Evolution of hydrogen mole fraction across the width of the anode surface for the case of no IR and IR.

## Different Morphologies and Gradient Microstructures

Gradient microstructures are designed so that the volume fraction of the ion-conducting phase (YSZ, in this case) linearly decreases as we move further from the electrolyte. If the volume fraction of the ion-conducting phase behaves in the opposite manner, the resulting microstructure does not offer any benefits. This phenomenon is discussed in more detail in our recent manuscript [11]. Gradient microstructures have been synthetically generated using the framework discussed in our previous work [11] with $f_G$ being defined as $f_G = \frac{\overline{v_f^{\mathrm{YSZ}}} - v_f^{\mathrm{YSZ}}(x = x_{\mathrm{electrolyte}})}{\overline{v_f^{\mathrm{YSZ}}}}$.

The results in figure 8 shows the TPB density and current density of IR cell performing under $V = 0.4\ [V]$. The figure indicates that a microstructure with a stronger gradient of volume fraction leads to a greater reduction in TPB density. This occurs because, at both ends of a gradient microstructure, the volume fractions of the three phases deviate significantly from each other. Such imbalance makes the microstructure less optimal for TPB formation, as TPB density in conventional designs is maximized when the volume fractions of the three phases are nearly equal. While TPB density decreases as the gradient strength increases, the current density (a measure of the cell's overall performance) initially rises (in the $G^+$ region) before eventually declining (in the $G^-$ region). The decrease in current density in the $G^-$ region corresponds to the drop in TPB density. However, the initial rise in current density in the $G^+$ region, despite the reduction in TPB density, can be explained by improved ion conduction. This enhanced ion conduction promotes higher rates of electrochemical reactions at the remaining TPB sites, leading to better overall performance initially.

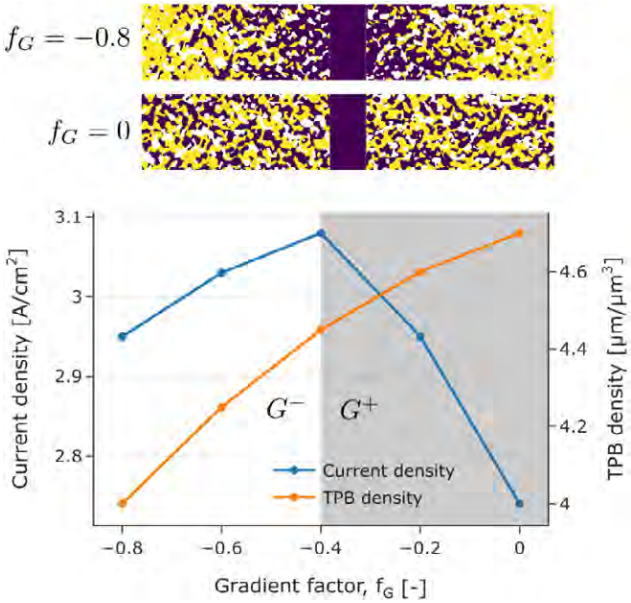

**Figure 8.** Performance of gradient microstructures

Different designs are tested for the microstructure of porous anode and cathode. Each design is tested for both sides of the cell—anode and cathode. In other words, the microstructural designs of the anode and cathode are assumed to be identical. To compare the performance of different designs, current density was measured at an operating voltage of 0.4 volts. Results indicate that the fibrous design increased current density by approximately 48%, from 2.74 A/cm² (conventional design) to 4.05 A/cm². In contrast, lattice structures significantly enhanced performance, increasing current density by roughly 4.4 times, from 2.74 A/cm² to 12.05 A/cm². It is important to acknowledge that the lattice structures depicted in Figure 3 represent a highly optimized theoretical design. Current state-of-the-art fabrication techniques cannot achieve the precise, highly ordered placement of nanoparticles required to realize these structures.

## CONCLUSIONS

This study employed a multiscale model to predict the performance of direct internal reforming solid oxide fuel cells, eliminating the need for calibration typically required with macroscale models. The model was used to evaluate various microstructure designs, including gradient microstructures, to assess their potential benefits. Results demonstrate the successful application of the multiscale model in predicting the polarization curve of a complete cell. Furthermore, the study revealed that certain gradient microstructures can outperform the counterpart non-gradient designs.

## ACKNOWLEDGEMENTS

The project is implemented within the framework of the National Recovery and Resilience Plan "Greece 2.0" and has been financed by the European Union (NextGeneration EU)

## ABSTRACT

This paper evaluates the thermodynamic efficiency of a newly synthesized large-scale pre-combustion $CO_2$ capture process using a novel ionic liquid (IL) 1-octyl-2,3-methylimidazolium thiocyanate [OMMIM][SCN] for blue $H_2$ production. In addition, the potential eco-toxicity of the selected IL was assessed using the ADMETlab 2.0 web tool. The results of these analyses were compared to those of an established IL 1-butyl-2,3-dimethylimidazolium bis(trifluoromethyl sulfonyl)imide [BMMIM][TF2N]. The eco-toxicity assessment confirmed that [OMMIM][SCN] is less environmentally toxic than [BMMIM][TF2N]. Thermodynamic analysis of the novel system shows the COOLER unit accounts for the highest energy demand; however, the [OMMIM][SCN] system demonstrates a 7.45% reduction in energy consumption in the COOLER unit compared to [BMMIM][TF2N]. The system experienced the highest exergy losses (irreversibilities) in the COOLER unit for [BMMIM][TF2N] (12982 kW) and in the flash separator unit for [OMMIM][SCN] (8256 kW). The thermodynamic efficiency was analyzed within a specified IL inlet temperature range (25°C – 75°C) and absorption pressure range (7 - 16 bar). The results show that the [OMMIM][SCN] system outperforms [BMMIM][TF2N] with higher IL inlet temperature but decreases at higher absorption pressure, while [BMMIM][TF2N] maintains constant energy efficiency. The exergy efficiency of the [OMMIM][SCN] system shows better performance across the studied conditions but decreases beyond the peak temperature range of 50–60°C. These findings highlight the potential of [OMMIM][SCN] as an excellent alternative solvent for pre-combustion $CO_2$ capture applications.

## INTRODUCTION

Hydrogen ($H_2$), a non-carbonaceous fuel abundant on earth in its oxidized form, has emerged as a promising pathway for deep decarbonization in various sectors, such as power generation and transportation [1]. However, the majority of the $H_2$ is produced from reforming fossil fuels, with steam methane reforming (SMR) accounting for 50% of the total production, without carbon capture, resulting in high $CO_2$ emissions (89.1 $gCO_2/MJ$) [2]. Blue $H_2$ is a viable solution with lower carbon intensity (22.4 $gCO_2/MJ$) and offers a feasible route to sustain reliance on fossil fuels [3]. Therefore, developing an economically viable and sustainable $CO_2$ capture system with a low environmental footprint is imperative. The pre-combustion $CO_2$ capture system has been widely explored in $H_2$ production units for its effectiveness in handling high-pressure streams with high $CO_2$ concentrations. In this context, solvent selection is essential for designing the $CO_2$ removal system by considering various factors, encompassing eco-toxicity, minimizing irreversibility, and increasing energy efficiency. Ionic liquids (ILs) have shown exceptional performance in reducing energy regeneration compared to conventional solvents such as Monoethanolamine (MEA), making ILs well-suited for pre-combustion applications [4]. Nevertheless, their tunability makes it challenging to synthesize the optimal IL from numerous possibilities.

This work conducts a comprehensive thermodynamic analysis of a newly synthesized pre-combustion

$CO_2$ capture process for large-scale $H_2$ production. The analysis aims to evaluate its energy and exergy performance and identify process irreversibilities. A novel IL 1-octyl-2,3-methylimidazolium thiocyanate [OMMIM][SCN], designed in our previous work using a predictive deep learning model [5], was utilized as a physical absorbent in this study (see **Figure 1**). The IL was defined in the simulation software Aspen Plus, following the integrated modified translation-rotation-internal coordinate (TRIC) system with the COSMO-based/Aspen approach developed in our previous work [6]. An eco-toxicity analysis was carried out using the ADMETlab 2.0 web tool [7] to evaluate the environmental suitability of [OMMIM][SCN]. Finally, the performance of [OMMIM][SCN] was compared to an established IL, 1-butyl-2,3-dimethylimidazolium bis(trifluoromethyl sulfonyl)imide [BMMIM][TF2N] to assess their relative effectiveness in the process and their environmental suitability.

**Figure 1.** Molecular structure of novel IL [OMMIM][SCN] [5]

# METHODOLOGY

## Eco-Toxicity assessment

The ADMETlab 2.0 web tool evaluated the selected ILs' eco-toxicity, leveraging its robust framework for accurate toxicity predictions. By providing the SMILES (Simplified Molecular Input Line Entry System) representation of the IL as input to the platform, the molecular structure is processed to predict different properties using the advanced quantitative structure-property relationship (QSPR) model. The platform assesses different endpoints, such as environmental toxicity. It evaluates carcinogenicity, eye and skin irritation, and respiratory toxicity. The results of the assessment are shown as numerical scores. These scores range from 0 to 1 and then are categorized using an empirical decision scale, as indicated in **Table 1**.

**Table 1**: Empirical decision score based on ADMETlab 2.0 framework [7].

| Empirical decision | Category |
|---|---|
| 0.0-0.3 | "Non-toxic" |
| 0.3-0.7 | "Slightly toxic" |
| 0.7-1.0 | "Toxic" |

## Large-scale pre-combustion $CO_2$ capture simulation

Following the TRIC system with the COSMO-based/Aspen approach, the novel IL [OMMIM][SCN] was successfully defined in the simulation software Aspen Plus V12 as a pseudocomponent. A steady-state large-scale pre-combustion $CO_2$ capture process was then developed, as depicted in **Figure 2**. This process was designed to capture 90% of the $CO_2$ and achieve an $H_2$ purity of 97%. It treats $H_2$ produced from a large-scale steam methane reformer (SMR), generating a 6.98x104 kg/h flow of syngas stream with the following compositions: 16.27% $CO_2$, 4.63% CO, 75.61% $H_2$, 3.05% $CH_4$, 0.24% $H_2O$, and 0.2% $N_2$. The syngas flow specifications were obtained from the IEAGHG report [8]. The proposed configuration comprises four main components: absorption columns, pumps, flash drums, heat exchangers, and compressors. The process specifications suggested by Hospital-Benito et al.[9], were used to develop the large-scale pre-combustion process in Aspen Plus. During the process development, the number of stages was adjusted and it was only 10 stages required to achieve the specified $CO_2$ removal target of (90%).

The syngas stream enters a flash separator (F-101) to separate the water content from the gas stream. The dry gas stream (S4) then enters a "RADFRAC" packed bed absorber column at 35°C and 26 bar, where the $CO_2$ is absorbed by the IL counter currently within the column. The stream "PURE $H_2$" exists from the column overhead, whereas the $CO_2$-rich stream (S6) leaves from the bottom of the column and enters the flash drum (F-102) to remove and recycle $H_2$ back to the absorber. Before the regeneration stage, the $CO_2$-rich stream (S8) is heated by a heat exchanger (HEATER) to a temperature suitable for effective separation. Then, the heated stream (S9) enters two flash separators arranged in series for the regeneration of IL, where the streams that contain mostly $CO_2$ leave the top of the flash columns (F-103 and F-104) and are combined via a mixer (M-102). The regenerated IL (S15) from F-104 is cooled via a heat exchanger (COOLER) and recirculated back (LEANIN) to the absorber.

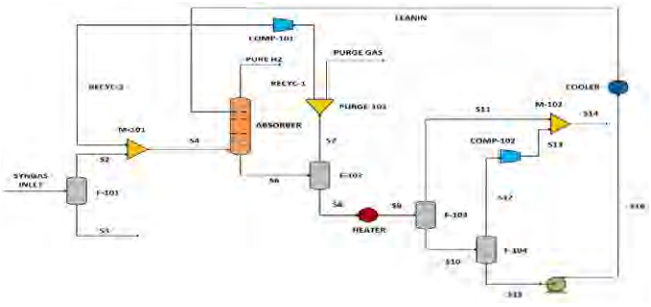

**Figure 2.** Large-scale pre-combustion $CO_2$ capture process scheme

## Energy and exergy analysis

Evaluating the thermodynamic efficiency via process system engineering aspects, such as energy and exergy, is essential for optimizing pre-combustion $CO_2$ capture and achieving maximum $CO_2$ capture efficiency and $H_2$ purity.

The energy-consuming equipment in the suggested process scheme includes heat exchangers, compressors, and flash separators. The equipment's energy duty (kW) values were obtained from Aspen Plus.

The overall thermal efficiency ($\eta$) of the $CO_2$ capture process can be evaluated using equation (1) [10]:

$$\eta = \frac{\sum \dot{Q}_{useful} + \sum \dot{W}_{out} + \sum \dot{m}_{useful} h_{useful}}{\sum \dot{Q}_{in} + \sum \dot{W}_{in} + \sum \dot{m}_{in} h_{in}} \quad (1)$$

Where $\dot{Q}_{useful}$ is the useful thermal energy output, $\dot{W}_{out}$ refers to the useful mechanical energy output, $\dot{Q}_{in}$ and $\dot{W}_{in}$ represent the total thermal energy and the mechanical energy inputs to the system, respectively, $\dot{m}_{useful}$ indicates the mass flow rate of useful products, specifically the pure $H_2$ stream, and the captured $CO_2$, $\dot{m}_{in}$ refers to the inlet mass flow rate, $h_{useful}$ and $h_{in}$ represent the enthalpy of useful and input streams, respectively.

The exergy flow rate $\dot{E}x$ of a material stream can be calculated using equation (2) [10]:

$$\dot{E}x = \dot{m}[(h_i - h_o) - T_o(s_i - s_o)] \quad (2)$$

$h_i$ and $s_i$ denote the stream's specific molar enthalpy and entropy in a certain state, $h_o$ and $s_o$ refer to specific molar enthalpy and entropy in the reference state ($T_o$ = 25°C, $P_o$ = 1 bar), and $T_o$ represents the reference temperature. The exergy destruction rate ($\dot{E}x_d$) can be calculated from the exergy balance equation of the main processing equipment as given by equation (3) [10]:

$$\sum \dot{m}_{in}\dot{E}x_{in} + Q_{consumption}\left(1 - \frac{T_o}{T}\right) + \dot{W}_{consumption} = \sum \dot{m}_{out}\dot{E}x_{out} + \dot{Q}_{generation}\left(1 - \frac{T_o}{T}\right) + \dot{W}_{generation} + \dot{E}x_d \quad (3)$$

Where the term $Q\left(1 - \frac{T_o}{T}\right)$ denotes the rate of exergy destruction associated with heat transfer. $\dot{E}x_{in}$ and $\dot{E}x_{out}$ refer to the inlet and outlet exergy flow rate mass, $\dot{E}x_d$ is the exergy destruction, $\dot{W}_{consumption}$ work consumed by the system, and $\dot{W}_{generation}$ generated by the system

The overall exergy efficiency of the proposed process configuration can be calculated using equation (4) [10]:

$$\varepsilon = \frac{\sum Ex(\dot{Q}_{useful}) + \sum \dot{W}_{out} + \sum \dot{m}_{useful} Ex_{useful}}{\sum Ex(\dot{Q}_{in}) + \sum \dot{W}_{in} + \sum \dot{m}_{in} Ex_{in}} \quad (4)$$

# RESULTS AND DISCUSSION

## Eco-toxic evaluation of selected ILs

The toxicity evaluation for both ILs, [OMMIM][SCN] and [BMMIM][TF2N], was conducted using the ADMETlab 2.0 web tool. The results of the assessment are summarized in Table 2. The toxicological profiles of IL [OMMIM][SCN] and [BMMIM][TF2N] differ noticeably. For instance, [OMMIM][SCN] is classified as slightly toxic for carcinogenicity (0.478), whereas [BMMIM][TF2N] is toxic (0.944), indicating a higher risk. However, despite these differences, both ILs exhibit high toxicity in respiratory effect, with [BMMIM][TF2N] demonstrating a slightly higher value (0.986) compared to [OMMIM][SCN] (0.882). Overall, the newly designed IL [OMMIM][SCN] shows less toxicity across multiple properties, suggesting that the IL is relatively safer and environmentally suitable.

**Table 2**: Probability of eco-toxicity assessment parameters

| Property | [OMMIM][SCN] | [BMMIM][TF2N] |
|---|---|---|
| **Carcinogenicity** | 0.478 (slightly toxic) | 0.944 (toxic) |
| **Eye Corrosion** | 0.257 (nontoxic) | 0.003 (nontoxic) |
| **Eye Irritation** | 0.434 (slightly toxic) | 0.032 (nontoxic) |
| **Skin Sensitization** | 0.156 (nontoxic) | 0.325 (slightly toxic) |
| **Respiratory Toxicity** | 0.882 (toxic) | 0.986 (toxic) |

## Thermodynamic analysis

The energy performance of the large-scale pre-combustion $CO_2$ capture process was analyzed, targeting a 90% $CO_2$ removal rate, and the results are shown in **Figure 3**. The COOLER demonstrates the highest energy demand for both ILs, with the [OMMIM][SCN] system requiring slightly less energy by 7.45% (33985 kW) than [BMMIM][TF2N] (36722 kW). On the other hand, the energy consumption associated with the HEATER, P-101, Comp-101, and Comp-102 is nearly identical for the two ILs. A noticeable difference is observed in energy demand for F-104, where [OMMIM][SCN], at 1080 kW, requires less energy than [BMMIM][TF2N] (2743 kW). In contrast, the total energy demand in F-102 (4785 kW) is slightly larger for [OMMIM][SCN] compared to [BMMIM][TF2N] (3748 kW).

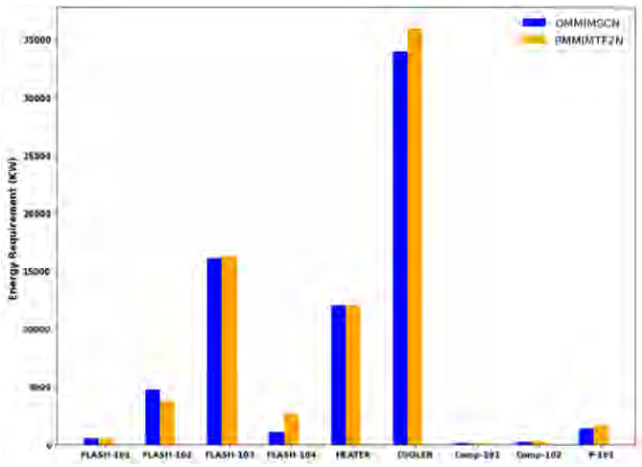

**Figure 3**. Comparisons of energy requirement for different equipment for both ILs.

Each unit's irreversibility (exergy loss) is calculated using equations (2) and (3), and the results are highlighted in **Figure 4**. The analysis shows that in the [BMMIM][TF2N] system, the COOLER component is the largest contributor to exergy loss, accounting for 47% (12982 kW) of the total exergy loss of the entire system. Conversely, the energy destruction in the [OMMIM][SCN] system is much lower (4690 kW), indicating that [OMMIM][SCN] operates with higher thermodynamic efficiency in the COOLER unit. In the separation stage (C-101), exergy loss in the [OMMIM][SCN] system is higher at 4048 kW compared to 2431 kW for the [BMMIM][TF2N] system. As for the regeneration stage, the exergy loss is greater in both units F-102 (1383 kW) and F-103 (8256 kW) in the [OMMIM][SCN] system compared to [BMMIM][TF2N], while [OMMIM][SCN] experiences less exergy loss in F-104, at 646 kW, than [BMMIM][TF2N] system.

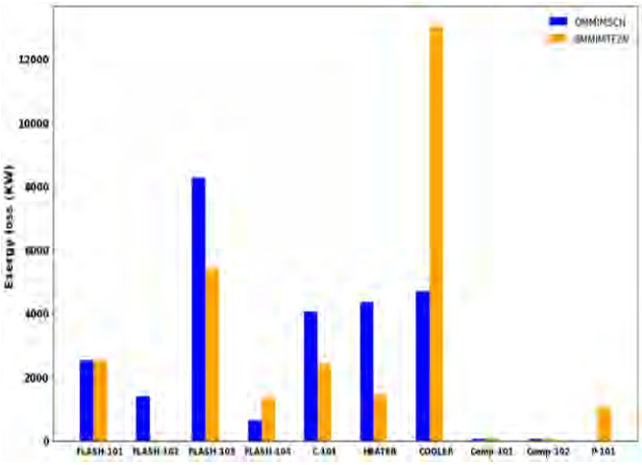

**Figure 4.** Exergy loss comparison across various equipment for both ILs.

## Parametric analysis

This section examines the impact of system parameters like the IL inlet temperature and absorption pressure on the thermodynamic efficiency of the proposed pre-combustion $CO_2$ capture process configuration. The effect was studied within the temperature range of 25°C to 75°C and pressure absorption range of 7 to 22 bar and 7 to 16 bar for energy and exergy efficiency, respectively.

### Effect of IL inlet temperature

Using equation (1), the total energy efficiency of the entire process was calculated within the specified temperature range, and the result is depicted in **Figure 5**. The system's energy efficiency decreases as the inlet temperature increases. The highest energy efficiency for both systems, [OMMIM][SCN] and [BMMIM][TF2N], occurs at 25°C. However, [OMMIM][SCN] demonstrates higher energy efficiency (91.2%) at 25°C than [BMMIM][TF2N] (90.6%). Additionally, the difference in energy efficiency between the two systems decreases across the temperature range, with the [OMMIM][SCN] system achieving higher energy efficiency. This trend continues throughout the temperature range, suggesting that the [OMMIM][SCN] system consumes less energy and, therefore, is more energy-efficient.

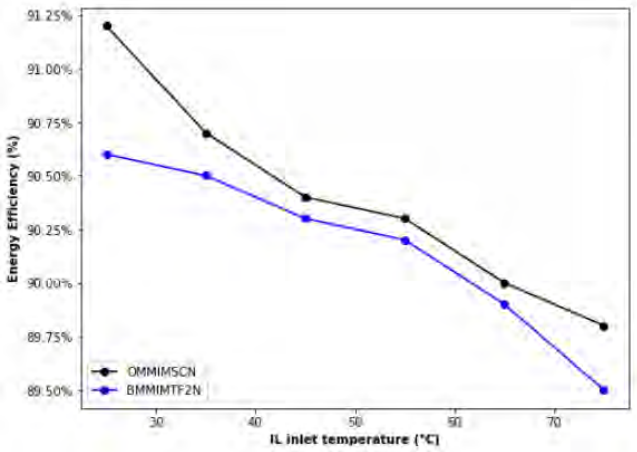

**Figure 5**. Effect of IL inlet temperautre on Energy Efficiecny (%).

Equations (2), (3), and (4) are used to calculate the overall exergy efficiency. **Figure 6** illustrates the exergy efficiency for both systems across the specified range for IL inlet temperature. As depicted from the graph, both IL systems demonstrate a significant increase in exergy efficiency as the temperature rises. The [OMMIM][SCN] system exhibited a higher exergy efficiency than [BMMIM][TF2N] throughout the temperature range, indicating that the [OMMIM][SCN] system experiences fewer irreversibilities. The maximum exergy efficiency occurs at 50-60°C, where [OMMIM][SCN] has slightly higher exergy efficiency (73.24%) compared to [BMMIM][TF2N]

(71.1%). Beyond this optimal range, the efficiency declines for both systems to around 57% at 75°C.

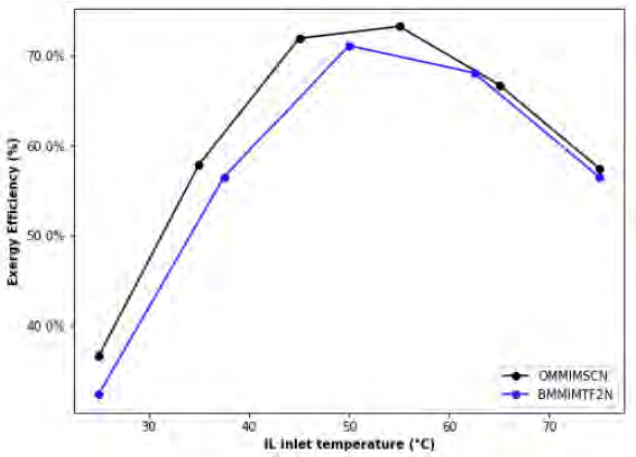

**Figure 6**. Effect of IL inlet temperautre on Exergy Efficiecny (%).

## Effect of absorption pressure

The impact of varying the absorption pressure on the overall energy efficiency was also calculated. As seen in **Figure 7**, the [OMMIM][SCN] system demonstrates a decline in efficiency as the pressure increases, whereas [BMMIM][TF2N] maintains energy efficiency close to 89.9% throughout the pressure range. While, [OMMIM][SCN] shows higher energy efficiency (91%) at 7 bar compared to [BMMIM][TF2N] (89.9%), the efficiency of [OMMIM][SCN] decreases by 1% within the limited pressure range of 10-16 bar. Given that physical absorption generally favors higher pressures for better $CO_2$ removal, [BMMIM][TF2N] is more suitable for higher absorption pressures.

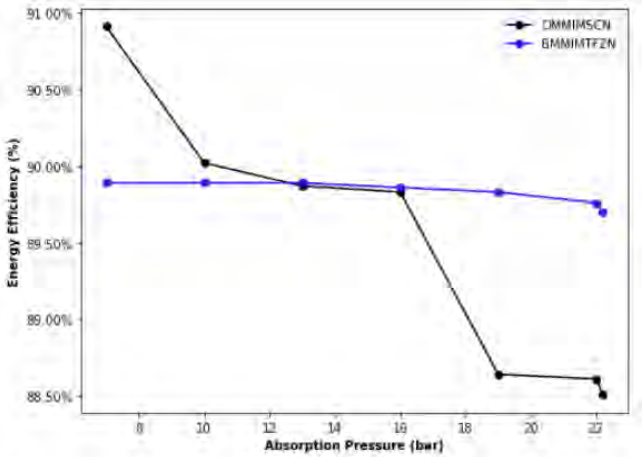

**Figure 7**. Effect of absorption pressure on Energy Efficiency (%)

Similarly, the parametric analysis was conducted to calculate the exergy efficiency within the specified pressure range. As illustrated in **Figure 8**, both IL systems experience a significant increase in efficiency as the pressure rises. The [OMMIM][SCN] system achieves higher efficiency across the pressure range compared to [BMMIM][TF2N], increasing from 25% to 37%. In contrast, the exergy efficiency for [BMMIM][TF2N] increases from 21% to 33%.

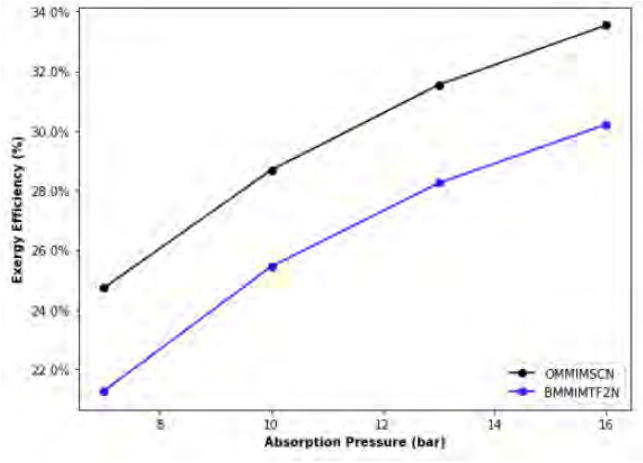

**Figure 8**. Effect of absorption pressure on Exergy Efficiency (%)

## CONCLUSIONS

This study evaluates the thermodynamic efficiency of a large-scale pre-combustion $CO_2$ capture process using two IL systems: novel IL [OMMIM][SCN] and established IL [BMMIM][TF2N]. Alongside the thermodynamic performance, the toxicity analysis of ILs using ADMETlab 2.0 was evaluated. The results indicate that [OMMIM][SCN] is less toxic across the studied properties, indicating that the IL is environmentally safer compared to [BMMIM][TF2N]. The results of the thermodynamic analysis conducted at a 90% $CO_2$ removal rate reveal that the highest energy consumption for both IL systems occurs at the “COOLER” units, while [BMMIM][TF2N] requires slightly more energy duty. Moreover, the “F-104” exhibits a larger energy demand in the [BMMIM][TF2N] system, whereas the energy consumption for [OMMIM][SCN] is marginally larger in “F-102”. Similarly, the exergy destruction results demonstrate that the “COOLER” in the [BMMIM][TF2N] contributes the highest system irreversibility. Conversely, [OMMIM][SCN] experiences higher exergy loss in F-102 and F-103 compared to [BMMIM][TF2N]. In terms of efficiency, the results highlight that the [OMMIM][SCN] system is more energy efficient when IL inlet temperature increases. However, its efficiency declines at higher absorption pressure, whereas the energy efficiency of the [BMMIM][TF2N] system remains constant. As for the exergy efficiency,

the [OMMIM][SCN] system shows higher exergy efficiency than [BMMIM][TF2N] throughout the studied temperature and pressure ranges. However, a decline in exergy efficiency is observed beyond the peak point temperature range of 50-60°C. This indicates that [OMMIM][SCN] exhibits better performance than established IL [BMMIM][TF2N], confirming its potential as a promising alternative for large-scale pre-combustion $CO_2$ capture process for blue $H_2$ production. However, while computational toxicity predictions using ADMETlab 2.0 provide valuable insights, experimental validation of [OMMIM][SCN] is crucial to evaluate its practical feasibility in industrial applications. In addition to toxicity assessment, further evaluation encompassing scalability and cost should be addressed to determine its large-scale implementation. Also, additional study is needed to optimize the [OMMIM][SCN] system to reduce irreversibility in process equipment and increase energy efficiency.

## ABSTRACT

Accurately predicting biogas production for real-time applications remains a challenge in anaerobic digestion (AD) due to the process's complexity and dynamic nature. While mechanistic models are essential for understanding and modelling AD processes, however they are highly non-linear and depend on detailed feedstock characterisation and parameter calibration. In contrast, data-driven models do not rely on predefined equations and rather use process data to capture the system's underlying dynamics. This study compares mechanistic and data-driven models for biogas prediction using lab-scale data. A state estimation framework with a rolling window was used for the mechanistic model, based on biomass and substrate concentrations with Haldane kinetics, achieved an accuracy of ($R^2$ = 0.91). A Long Short-Term Memory (LSTM) model with Bayesian Optimisation for hyperparameter optimisation, trained on the same data showed superior performance ($R^2$ = 0.93–0.98) and captured temporal dependencies inherent to the AD process. The LSTM model was further applied to industrial data, maintaining high accuracy ($R^2$ = 0.95–0.97) and demonstrating its scalability. Its strong predictive capabilities, combined with practicality for real-time applications, make it a promising tool for optimising operations in large-scale AD plants.

**Keywords**: Anaerobic Digestion, Mechanistic Modelling, Data Driven Modelling, Long Short-Term Memory

## INTRODUCTION

Anaerobic digestion (AD) is a biological process where microorganisms decompose organic matter in the absence of oxygen, producing biogas (primarily $CH_4$ and $CO_2$) and nutrient-rich digestate. This sustainable process supports waste management and renewable energy generation, aligning with global net-zero carbon emission goals [1]. Modelling AD is critical for optimising its performance and addressing its inherent complexity. Mechanistic models, such as the Anaerobic Digestion Model No. 1 (ADM1), simulate the biochemical and physicochemical processes in AD systems, offering detailed insights. However, these models often require extensive parameterisation where parameters can be difficult to identify uniquely along with high computational resources [2]. In contrast, simplified AD models focus on key system parameters which tend to be more identifiable and provide faster predictions but may compromise accuracy. Data-driven models from machine learning (ML) offer an alternative by capturing nonlinear relationships and dynamics directly from data [2]. Identifying the most suitable and accurate model for predictions is important to enhance system performance, enabling real-time control and decision-making for efficient AD operation.

Current approaches often prioritise either mechanistic accuracy or computational simplicity, limiting the ability to dynamically adapt to real-world scenarios. ADM1 remains widely used in AD modelling, but its application is constrained by insufficient measurements of state variables during AD operations [3]. Compared to physics-based models, ML has gained attention for advantages [4] including ease of implementation, generalisability, and faster execution times [5]. ML models can map inputs to outputs without requiring an understanding of underlying physical processes, making them particularly suitable for AD prediction and optimisation [6]. However, algorithms, such as Support vector machines and artificial neural networks, often struggle to capture sufficient information from sequential data to provide

accurate predictions [7]. The digester's performance is influenced by previous feeding where hydraulic retention time (HRT) is a crucial parameter affecting AD performance [6]. A Long Short-Term Memory (LSTM) network is a form of recurrent neural network (RNN), developed to solve the vanishing gradient problem of RNNs by retaining or discarding the data over long sequences. LSTMs excel due to their rapid learning capabilities and ability to retain long-term dependencies within sequential data, making them effective in improving the accuracy of biogas production predictions while considering HRTs [7-8]. LSTMs have demonstrated significant potential in AD with promising results, such as predicting biogas yields, optimising feed rates, process parameters and resulting in methane production enhanced by up to 25% [6-7]. [6] applied LSTMs on a wastewater site, while [7] applied LSTMs on limited food waste data which was extended using a synthetic minority over-sampling technique, however nobody has applied LSTMs on energy crops and waste co-digestion data from laboratory and Industrial plant with varying HRTs.

Therefore, this study compares a practical mechanistic model and a purely data-driven model with Bayesian optimisation for hyperparameter tuning for predicting biogas production using solid AD feedstocks at the laboratory level. The data-driven model's applicability is extended to industrial datasets, demonstrating its potential for real-time site-level predictions.

## METHODS

### Experimental Set-up and Data Collection

This study first uses a kinetic model proposed by [9] to simulate and fit parameters related to substrate degradation, biomass growth, and methane production. In a lab-scale AD system, experimental data were collected over time for various state variables, such as substrate concentration, biomass concentration, and biogas (methane) production. The lab-scale digester was fed with roughly 10% maize silage and 12% dried maize, 14% rye silage, 18% wheat grain, 25% pig slurry and 11% water in a % fresh weight basis, with the setup shown in **Figure 1**.

Experimental data was obtained from the laboratory from a small scale 5-liter AD reactor which mimicked an industrial site's operation using anaerobic co-digestion.

### Mechanistic Model Development

Interpreting the experimental data to predict system behaviour under different conditions for control and fast predictions across wider input space requires a simplified model. The model used simplifies the AD process by reducing it to two main state variables: substrate concentration ($ST$), biomass concentration ($XT$) and output of methane production ($Q$). By fitting the model represented in **Figure 2** to experimental data using optimisation techniques, the goal is to identify key kinetic parameters maximum specific growth rate ($\mu_{max}$), half-saturation constant ($K$), inhibition constant ($K_i$), substrate conversion coefficient ($k$), and methane production coefficient ($K_m$) , to accurately predict biogas production.

**Figure 1.** Semi-continuous AD experiment set-up.

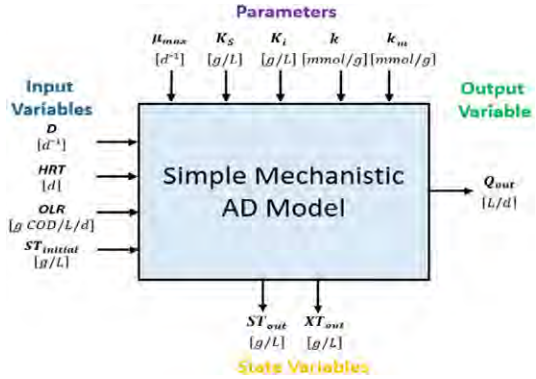

**Figure 2:** Simple Mechanistic AD Model Superstructure

The following steps outline the methodology used to model, simulate, and optimise the AD process in a lab-scale reactor using a simplistic mechanistic model. The model simulates the system's behaviour over time by integrating the differential equations which represent the mass balances for the substrate and biomass. The model parameters are optimised to minimise the difference between the model's predictions and the experimental data. The model uses a set of nonlinear differential equations to describe the interaction between these state variables, including substrate degradation and biomass growth as functions of substrate availability and microbial growth. The system of ordinary differential equations (ODEs) that governs the dynamics of the substrate concentration ($ST$), biomass concentration ($XT$), and methane production rate ($QT$). A rolling-window state estimation approach is used, instead of integrating the entire system from the initial to the final time. The rolling-window method divides the simulation horizon into sequential, overlapping segments. At each time step $t_i$, the state vector is re-initialised using the most recent measurements by setting $ST(t_i)$ and $QT(t_i)$ to their corresponding measured values while $XT(t_i)$ is propagated from the

previous prediction.

$$x(t_i) = \begin{bmatrix} ST(t_i) \\ XT(t_i) \\ QT(t_i) \end{bmatrix} \quad (1)$$

The rate of change of substrate concentration is represented by:

$$\frac{dST}{dt} = D \cdot (ST_{in} - ST) - k \cdot \mu \cdot XT \quad (2)$$

There are several growth rate equations available in literature such as Monod kinetics, first order kinetics, etc. For this model the specific growth rate ($\mu$) is modelled using Haldane kinetics, which accounts for both substrate saturation and inhibition:

$$\mu = \mu_{max} \frac{ST}{ST + K_S + \frac{ST^2}{K_i}} \quad (3)$$

The rate of change of biomass concentration is represented by:

$$\frac{dXT}{dt} = (\mu - D) \cdot XT \quad (4)$$

The methane production rate is calculated directly from the biomass concentration and the specific growth rate:

$$Q = k_m \cdot \mu \cdot XT \quad (5)$$

The objective function to be minimised is Sum of Squared Errors (SSE) between the model's predictions and the experimental data is defined as:

$$\text{Objective} = \sum_{i=1}^{n} \left(\frac{ST_{sim,i} - ST_{out,i}}{ST_{out,i}}\right)^2 + \sum_{i=1}^{n} \left(\frac{Q_{sim,i} - Q_i}{Q_i}\right)^2 \quad (6)$$

Where:

$ST_{sim,i}$: Simulated substrate concentration at time $i$
$ST_{out,i}$: Measured substrate concentration at time $i$
$Q_{sim,i}$: Simulated methane production rate at time $i$
$Q_i$: Measured methane production rate at time $i$
$n$: Number of data points

The integration over each small interval is performed using numerical solvers, yielding predicted states at $t_{i+1}$. Prior to the next integration step, the states are reset such that:

$$\begin{aligned} ST_{initial}(t_{i+1}) &= ST_{measured}(t_{i+1}) \\ XT_{initial}(t_{i+1}) &= XT_{measured}(t_{i+1}) \\ QT_{initial}(t_{i+1}) &= Q_{measured}(t_{i+1}) \end{aligned} \quad (7)$$

This approach reduces integration errors and offsets model mismatches by aligning the simulation with recent empirical data. A window size of 30 is the period during which new measurements replace older ones which was used based of average HRTs.

## Data-Driven Modelling Approach

### LSTM Model Development

Two LSTM neural networks were developed to predict total biogas production using input features from biogas plants and experimental data. The first model (LAB-LSTM) was applied to lab-scale reactor data of 150 sample points to evaluate performance on smaller datasets. The second (IND-LSTM) was applied to an industrial AD plant's historical data of 600 days to assess its capability for plant-level predictions. Feature selection was performed using Recursive Feature Elimination (RFE), which eliminates less relevant features based on model performance [6,8]. For the industrial case study, the top five parameters and any site-controllable variables were kept for control applications. Selecting the optimal hyperparameters is challenging for neural networks and trial and error can be long and expensive. Hyperparameters which were focussed on were LSTM units, batch size, epoch and learning rate (LR). The number of LSTM units determines the model's capacity to capture patterns, while batch size and learning rate balance computational efficiency and model accuracy. Epochs were adjusted to prevent overfitting, with training monitored to stop when validation loss increased. Bayesian Optimisation (BO) was employed for hyperparameter tuning, outperforming traditional methods like grid or random search by strategically minimising error through iterative adjustments [6-8]. The error measurement was performed using 5-fold cross-validation with the Mean Absolute Error (MAE) objective function to ensures a reliable evaluation of the model by averaging performance across multiple subsets of the data, reducing the risk of overfitting due to specific data splits. For each fold 80% of the data was used for training and 20% for testing. BO allowed for efficient exploration of parameter spaces, such as LSTM units (10-50), batch size (4-32), and LR (0.0001-1), ensuring a balance between performance and computational demands. The LSTM model predicts the next time step (t+1) based on a look-back window corresponding to the average HRT (t-average HRT) of 30 days. Since HRT represents the time required for feedstock to break down and produce biogas, this approach aligns predictions with the system's natural kinetics. Additionally, it enhances interpretability for operators and supports process optimisation by linking predictions to real-world process dynamics. In this study for all LSTM models, the number of iterations for the optimised hyperparameters was set to 25 to lower computational demands. All models were implemented using Python. Libraries included Pandas and NumPy for data preparation, Scikit-learn for feature selection and performance metrics, TensorFlow's `Keras` was for model development, and the `bayes_opt` library was used for hyperparameter tuning, and Matplotlib was used for data visualisation. The overall model architecture for the two LSTM models and optimised hyperparameters are outlined in **Table 1**.

**Table 1:** Model Architecture of each LSTM case study

| Model | Input Layer | LSTM Layer | | Output Layer | | Compilation | | Training Details | | |
|---|---|---|---|---|---|---|---|---|---|---|
| | Features | Units | Activation Function | Dense Layer | Activation Function | Loss Function | Optimiser | Epochs | LR | Batch Size |
| **IND** | Feedstock Quantities Tempera-ture, HRT, HLR, OLR & Stirrer Speeds | 24 | Hyperbolic tangent | Total Biogas | Linear | MAE | Adam | 70 | 0.003 | 14 |
| **LAB** | Feed, HRT & OLR | 35 | | Total Biogas Produc-tivity | | | | 100 | 0.005 | 10 |

# RESULTS AND DISCUSSION

## Performance Evaluation

To assess the accuracy of the model, the following error metrics are calculated:

a) Root Mean Squared Error (RMSE):

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(y_{sim,i} - y_{obs,i})^2} \quad (8)$$

b) Coefficient of Determination ($R^2$):

$$R^2 = 1 - \frac{\sum_{i=1}^{n}(y_{obs,i} - y_{sim,i})^2}{\sum_{i=1}^{n}(y_{obs,i} - \bar{y}_{obs})^2} \quad (9)$$

Where:

$y_{sim,i}$: Simulated value at time $i$

$y_{obs,i}$: Observed (measured) value at time $i$

$\bar{y}_{obs}$: Mean of the observed values

## Optimised Mechanistic Model

The parameter fitting was carried out using the Nelder-Mead method, which iteratively adjusts the parameter values to minimise SSE to a final value of 0.1204. After optimisation, the following parameters were obtained and shown in **Table 2**.

**Table 2:** Optimised Parameters from Mechanistic Model

| Parameter | Value | Unit |
|---|---|---|
| $\mu_{max}$ | 0.067 | 1/day |
| $K_S$ | 927 | g/L |
| $K_i$ | 265.5 | g/L |
| $k$ | 2796 | mmol/g |
| $K_m$ | 13.25 | mmol/g |

The model fits the experimental data shown in **Figure 3.**

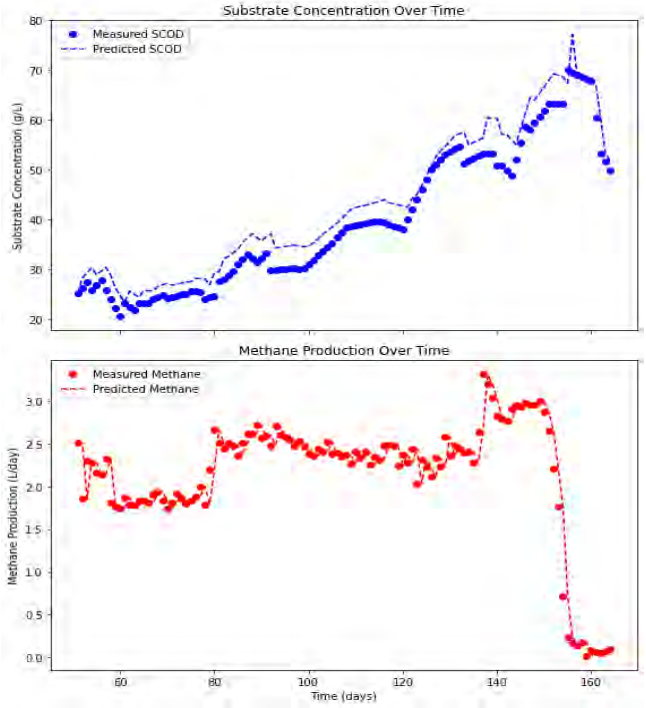

**Figure 3.** Substrate concentration and Methane production over time.

Mechanistic models rely on well-defined equations that represent the underlying biochemical and physical processes. However, these models are particularly sensitive to non-steady state conditions, as such variability may not be captured by the simplified model. The selected time points from the dataset used was days 50-162 where measurements of the substrate concentrations were made available. The optimised model was evaluated using RMSE and R2 values. The model fits the experimental data reasonably well, particularly for methane production. The RMSE and R2 values for substrate concentration (RMSE = 3.927, R2 = 0.87) and methane production (RMSE = 0.2089, R2 = 0.91) indicate that the model effectively captures the general trends in the data,

including both the dynamic nature of substrate degradation and methane yield over time. The model effectively captures oscillatory behaviour in substrate concentration, indicating it accurately reflects the dynamic relationship between substrate consumption and biomass growth. This is achieved using Haldane kinetics, which accounts for substrate inhibition, particularly at higher organic loading rates (OLRs).

This model is useful for early-stage predictions and lab-scale experiments, providing initial estimates for substrate concentration, biomass growth, and methane production. The model is flexible enough to incorporate key biological processes such as substrate inhibition and microbial growth, which are important at higher OLRs and help in planning and designing lab-scale experiments. This understanding aids in optimising processes, such as adjusting feed rates or HRTs, to maximise biogas yield.

## LSTM Results and Model Performance

The LAB-LSTM was developed using data from the lab scale AD reactor. For IND-LSTM, operation and feeding data from industrial partners where both LSTMs' capabilities to predict the total biogas produced was assessed. Since data-driven models do not require prior assumptions about the system's behaviour and can adapt to both steady and non-steady state conditions the entire dataset was used. The output is shown in **Figure 5**. The two LSTM models reveal consistent accuracy in predicting biogas production across different datasets and contexts. Each model, while designed with unique inputs and variable output, effectively captures the under-lying patterns in the AD process, showing their use in practical applications. Across both models, the $R^2$ values achieved in training and testing of 0.90-0.98 indicate strong predictive capabilities. This high level of accuracy shows that the models can effectively learn the relationships between the input features and their respective output variables, whether it is total biogas production or productivity. The close alignment between actual and predicted values in visual plots highlights the effectiveness of the models. **Figure 6** presents the error distributions of both models to provide further insights into model performance across different datasets.

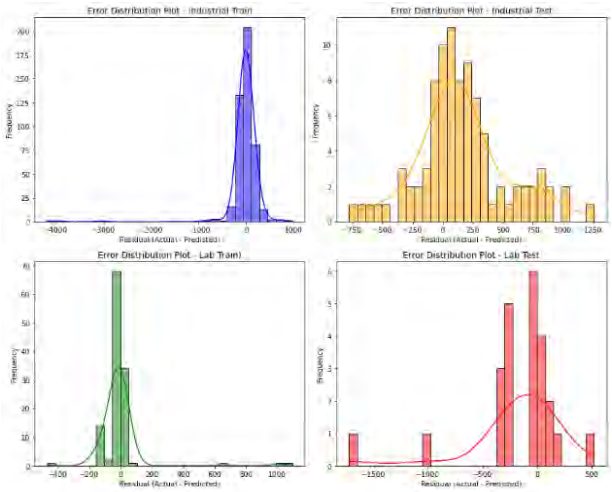

**Figure 6.** Model Error Distribution for Train and Test for Lab and Industrial Datasets.

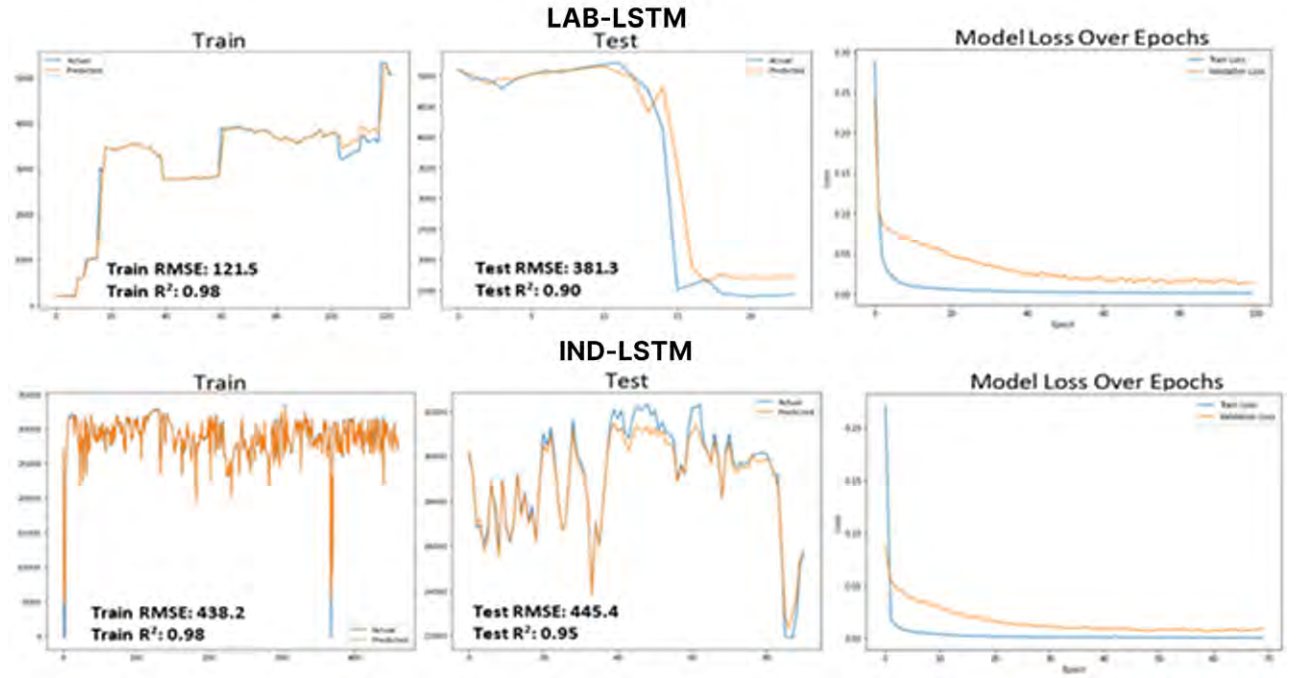

**Figure 5a-f:** Test, Train and Loss and Epoch plots of both laboratory scale data and industrial data LSTM Models.

The industrial dataset showed a near-normal residual distribution in training, indicating a well-fitted model, while the test set showed slightly higher variance, suggesting minor overfitting. In contrast, the lab-scale dataset had tightly clustered training residuals but a more skewed test distribution with higher variance, highlighting generalisation challenges. However, minor discrepancies, particularly during sharp changes, suggest a need for further refinement to improve responsiveness to dynamic transitions particularly on lab scale data which may be a result of the small dataset used.

## CONCLUSION

Both mechanistic and data-driven models demonstrated strong predictive capabilities for AD. The mechanistic model performed well at predicting substrate degradation and methane production in lab-scale systems with simpler feedstocks and OLRs, offering valuable insights for process control and early experimentation. However, enhancing the model with more advanced kinetics, additional states, and considerations for inhibitory factors such as ammonia, volatile fatty acids, and variables such as temperature and pH could improve its industrial applicability. The state estimation framework for the mechanistic model with the rolling window can also be explored further in future works. The use of Unscented Kalman Filter (UKF) can be explored and integrate integrated into the state estimation framework to enhance real-time prediction accuracy for the AD processes. Unlike the rolling-window approach, which relies on periodic re-initialisation from measurements, the UKF) continuously updates state estimates in real-time.

The LSTM models outperformed the mechanistic model across all datasets and scaling effectively to industrial datasets with higher $R^2$ values ranging between 0.90-0.98. While the LSTM model contains a larger number of trainable parameters compared to the first-principle model, this is necessary to capture complex temporal dependencies and non-linear interactions that are not explicitly represented in mechanistic equations. To mitigate the risk of overfitting, BO was employed to optimise the hyperparameters, ensuring a balance between model complexity and performance. LSTMs could be extended from predictions and be integrated into control systems for real-time monitoring and dynamic adjustments to parameters such as feed and loading rates, enhancing process stability and efficiency. Developing hybrid models that combine LSTMs with mechanistic approaches offers a promising forward direction. Such physics-informed models would integrate mechanistic constraints with LSTM's learning capabilities, providing accurate and interpretable results for improved decision-making and process optimisation.

## ABSTRACT

In the present paper, we come up with application of machine learning using data for flow visualization as a method for predicting unsteady flow patterns in oscillatory baffled reactors (OBRs). Application of the proper orthogonal decomposition (POD) is investigated for dynamic analysis of spatio-temporal data acquired by particle image velocimetry (PIV) to determine inputs and outputs for neural network model. It has demonstrated that three sets of modes and time-varying mode coefficients extracted by the POD could be useful for dynamic analysis and prediction of time-variant flow patterns in OBR. Also it is shown that decomposition of the time-series data for the mode coefficients by Fourier series expansion was effective for deriving reduced order model.

**Keywords**: Oscillatory baffled reactor, Proper orthogonal decomposition, Neural network model

## INTRODUCTION

An oscillatory baffled reactor (OBR) [1] is a type of flow reactor, and is generally structured with equally spaced baffles arranged inside a circular tube. In this reactor, the fluids in the reactor are mixed by periodically oscillating the fluids or the baffles. Tubular reactors and continuous stirred tank reactors (CSTRs) have been widely used as conventional flow reactors. Tubular reactor is a type of reactor in which the fluids flow continuously in one direction with reaction, and has a simple structure. However, it requires a large flow rate to sufficiently promote the mixing of the fluids, which results in a problem of consuming a lot of power. In addition, for long tube reactors that are applicable to slow reaction, there are limitations for implementation in terms of installation space and cost. On the other hand, CSTRs have the advantage that the fluids are sufficiently mixed in each stirred tank, but in order to attain a uniform residence time distribution, a large number of stirred tanks must be connected in series, which causes the system to become complicated.

OBRs are attracting attention for their process intensification effects, such as high mixing performance at low flow rates and long residence time due to the vortices generated by the interaction between the oscillating flow and the baffles. Due to high performances for mixing and mass transfer, the OBRs are applied to various process systems. For example, for applications of OBRs to gas-liquid reactions, the reaction efficiency could be enhanced by increase in the contact area between the gas and liquid that is caused by oscillating flow. For liquid-liquid reactions, OBRs could be applied to achieve uniform mixing of two phase flow. Also, for application of OBRs to solid-liquid reactions, it has been observed that oscillating flow between baffles performs well-dispersion of solid particles, which leads to intensification of the reaction process. Due to the above-mentioned process intensification effects, OBRs are being put to practical use in various industrial fields, such as fine chemicals, pharmaceuticals and biodiesel productions [2-3].

In design of the oscillatory baffled reactors, optimal reactor performance could be achieved through complex interactions among multiple design parameters. The design parameters for OBR are related to geometry of baffle, structure of reactor and operation for generation of oscillating flow, so that they influence flow pattern inside reactor. The design of the flow in OBR is evaluated by several dimensionless numbers, including the oscillatory Reynolds number), the Strouhal number (St), the velocity ratio and so on.

The oscillatory Reynolds number (Reo) [1] is an

index representing the mixing intensity inside the OBR, and is expressed by the following formula.

$$Re_o = \frac{2\pi f x_0 \rho d}{\mu} \quad (1)$$

where $f$ is the frequency of oscillation, $x_0$ is the amplitude of oscillation, $\rho$ is the density of the fluid, and $\mu$ is the viscosity of the fluid. When $Re_O \leq 250$, the flow is axially symmetric and is defined as laminar flow. In a case when $250 < Re_O < 2000$, the flow is in the transition region, and the flow where $Re_O \geq 2000$ is generally considered as turbulent. In our previous study for application of OBR to three-phase hydrogenation of 3-butyn-2-ol by using $Pd/Al_2O_3$ catalyst, OBR has demonstrated higher reaction performance than the conventional packed bed reactor (PBR), and at the same $Re_O$, OBR with lower amplitude attained higher conversion [4].

As shown Figure 1, it was considered that the difference in $f$ and $x_0$ influenced the flow pattern inside the reactor and behavior of the reaction process (e.g. conversion $X$) for a case when frequency and amplitude differ with the same $Re_O$. As a result of flow visualization, since the generation of vortices was remarkably observed in the vicinity of the loaded catalyst when the amplitude $x_0$ was smaller, it was thought that analysis and prediction of the time-dependent changes in the local circulating flow in the region between the baffles would lead to more efficient design of OBR.

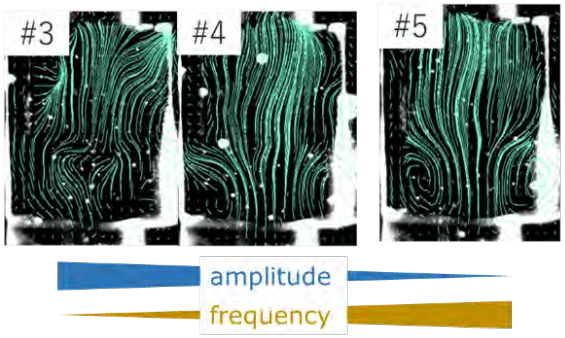

**Figure 1.** Comparison of streamlines that was obtained by PIV (#3: $x_0 = 15mm, X = 36.4\%$, #4: $x_0 = 10mm, X = 43.9\%$,#5: $x_0 = 5mm, X = 52.2\%$).

Although it is well known that computational fluid dynamics simulations [5-6] are effective in analysis and prediction of the flow patterns, there is a problem in that calculations for unsteady processes require a high computational load. Therefore, we came up with application of machine learning using data for flow visualization as a method for predicting unsteady flow patterns. In the present paper, we investigated methods for dynamic analysis of spatiotemporal data acquired by Particle Image Velocimetry (PIV) to determine inputs and outputs for neural network model.

# METHODOLOGIES

## Acquisition and analysis of flow visualization data

Figure 2 shows a schematic diagram of the oscillatory baffled reactor used in the flow visualization experiment using particle image velocimetry (PIV). The reactor is an acrylic tube type with an inner diameter of 26 mm. Baffles with a diameter of 25 mm and an opening area of 25% are placed in the reactor at equal intervals of 35 mm. The center part of the reactor tube with a length of 250 mm is covered by a rectangular vessel that is filled with water to eliminate distortion due to light refraction.

The flow rate of the steady flow was controlled by a plunger pump (FLOM, KP-22), and the oscillatory flow was generated from the bottom of the reactor using a syringe pump (Hamilton, PSD/6). Polyamide particles KP-050 (Kato Koken), which have a specific gravity almost the same as that of water, were used as tracer particles. The flow was visualized by irradiating the tracer particles with a green laser sheet formed by a PIV laser G2000 (Kato Koken). The motion of the tracer particles was recoded by using a high-speed camera (Kato Koken, k-8HD), and the obtained image data was analyzed by PIV software (Kato Koken, Flow Expert).

Table 1 shows operating conditions for acquisition of flow visualization data. Oscillatory Reynolds number $Re_O$, the flow rate of the steady flow $Q$, the amplitude of oscillation of syringe pump $x_0$, and the frequency of oscillation of syringe pump $f$ were changed in the present experiments.

## Application of the proper orthogonal decomposition (POD)

Recently, in the fields of computational fluid dynamics simulation, an approach that integrates the reduced order modeling (ROM) with machine learning technology has been investigated [7]. The major ROM techniques include the principal component analysis (PCA) and the proper orthogonal decomposition (POD) [8]. Application of the he ROM techniques can efficiently extract important information from phenomena by reducing the dimensionality of high-dimensional data, enabling accurate learning and highly accurate modeling of even highly nonlinear phenomena, enabling advanced prediction and analysis.

In the present paper, we investigate applicability of POD to reduced order modeling of spatiotemporal PIV data for OBRs. As mentioned above, POD is a modal decomposition method widely used in the field of fluid dynamics, which is used to efficiently reduce the dimensionality of huge amounts of data and extract the dominant structures in the flow field. POD is effective for analysis of unsteady flow, and is known as a method to clarify the essential characteristics of complex flow phenomena. POD calculates a spatially accommodating structure called "mode" based on a given data set, sorts the modes in order of contribution, and reduces the dimensionality of the data by selecting the dominant mode from the top.

In POD analysis, flow field data is decomposed based on the following formula.

$$\boldsymbol{q}(\boldsymbol{\xi},t)-\overline{\boldsymbol{q}}(\boldsymbol{\xi})=\sum_{j=1}^{r}a_j(t)\boldsymbol{\phi}_j(\boldsymbol{\xi}) \quad (2)$$

where $\boldsymbol{q}(\boldsymbol{\xi},t)$ is the time- and space-dependent flow field data, $\overline{\boldsymbol{q}}(\boldsymbol{\xi})$ is the time-averaged flow field data, $a_j(t)$ is the time-varying coefficient corresponding to each mode, $\boldsymbol{\phi}_j(\boldsymbol{\xi})$ is the spatial eigenmode, and $r$ is the total number of modes. In this decomposition, the spatial modes $\boldsymbol{\phi}_j(\boldsymbol{\xi})$ are obtained by solving the eigenvalue problem of the covariance matrix.

$$\boldsymbol{R}\boldsymbol{\phi}_j=\lambda_j\boldsymbol{\phi}_j \quad (3)$$

where $\boldsymbol{R}$ is the covariance matrix, and $\lambda_j$ is the eigenvalue indicating the contribution of each mode.

The covariance matrix $\boldsymbol{R}$ is defined as follows:

$$\boldsymbol{R}=\sum_{i=1}^{m}\boldsymbol{x}(\boldsymbol{t}_i)x^T(t_i) \quad (4)$$

The time-varying mode coefficients $a_j(t)$ represent the contribution of each POD mode at a particular time. The time-varying coefficients are calculated by the following equation:

$$a_j(t)=\langle\boldsymbol{q}(\boldsymbol{\xi},t)-\overline{\boldsymbol{q}}(\boldsymbol{\xi}),\boldsymbol{\phi}_j(\boldsymbol{\xi})\rangle \quad (5)$$

On the other hand, singular value decomposition (SVD) is sometimes used to calculate POD analysis, and is expressed as follows for a data matrix $\boldsymbol{X}$:

$$X=\boldsymbol{\phi}\sum\boldsymbol{\psi}^{\boldsymbol{T}} \quad (6)$$

where $\boldsymbol{X}$ is the data matrix, $\boldsymbol{\phi}$ is the left singular vector representing the spatial mode, $\sum$ is the singular value representing the contribution, and $\boldsymbol{\psi}$ is the right singular vector representing the time-varing coefficient indicating the temporal change of each mode.

# RESULTS AND DISCUSSION

## POD analysis of PIV data for OBR

Figure 3 shows time variation of streamlines that were obtained by PIV analysis when $Re_O$ was 762, $Q$ was 8.3 mil/min, and $x_O$ was 5 mm. It was observed that the flow pattern changes in this order: at the moment the oscillating flow became a push-out flow, vortices are generated on both sides of the lower part. The vortices then disappeared and the vertical flow occurred. At the moment when the flow became pull-out flow, vortices were generated on both sides of the upper part, and then the vertical flow was seen again. For the same oscillatory Reynolds number ($Re_O = 762$), when $x_O$ was 15 mm, it was seen that the vortices generated at the bottom and top moved up and down respectively, and the vortices remained. It was also observed that the axial symmetry of the flow was broken.

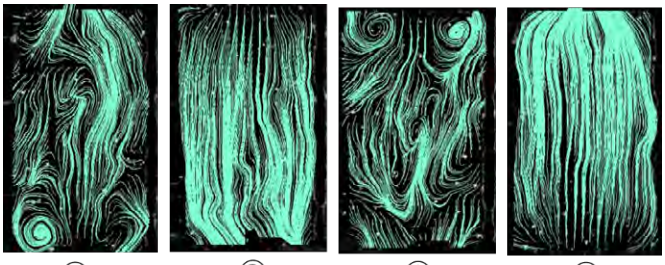

**Figure 3.** Time variation of streamlines that were obtained by PIV analysis.

As a result of POD analysis of the above-mentioned PIV data, the cumulative contribution of modes 1 to 3, which have the largest contribution, was about 80% (Figure 4 ). Figure 5 shows images of flow vectors that were reconstructed for three modes with the highest contribution which were selected from the more than 200 modes, for a case when $Re_O$ was 762, $Q$ was 8.3 mil/min, and $x_O$

was 5 mm. It was considered that the flow pattern for mode 1 represents profile of vertical flow and the flow pattern for mode 2 represents profile of generation of vortices in the upper and lower parts. Then Figure 6 plots change in calculated values of the time-varying mode coefficients $a_j(t)$. The trend in the time variation of $a_j(t)$ shows that POD could derive the reduced order model with characteristics of periodic changes in the flow pattern.

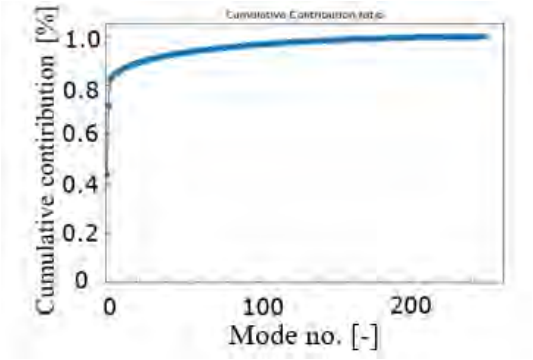

**Figure 4.** Variation of the cumulative contribution with increase in number of modes.

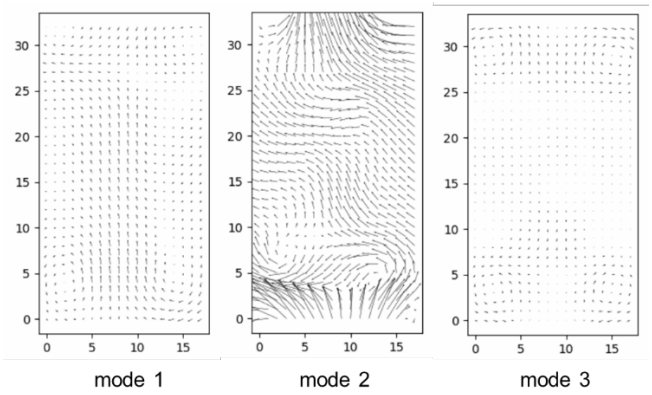

**Figure 5** Images of flows of vector fields that were reconstructed for principal three modes.

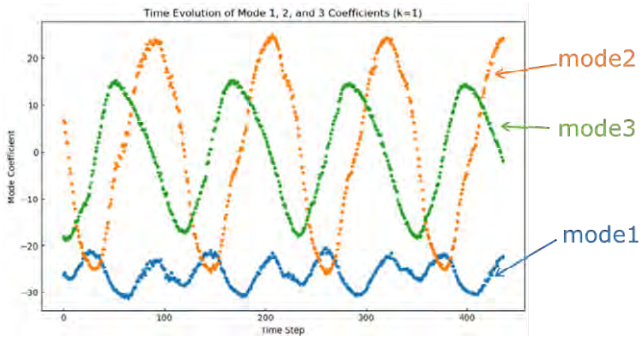

**Figure 6** Time-series plots for time-varying mode coefficients.

Cases that the profile of vertical flow was extracted as mode 1 were seen when the amplitude $x_O$ was larger. Even when the oscillatory Reynolds number $Re_O$ was small and the flow rate of the steady flow $Q$ was large, it was distinguished that the flows of vector fields for mode 1 showed profile of vertical flow. In addition, we analyzed the PIV data that were acquired by changing baffles with the different opening. When the baffle with small opening (16%) were used, it was experimentally observed position of generated vortices was upper part than cases of using the abovementioned baffles with 25% of opening. In application of POD analysis, the flows of vector fields with profile of generation of vortices in the upper and lower parts were extracted as mode 1, for case when the baffles with smaller opening.

## Application of neural network modeling for prediction of flows of vector fields in OBR

We developed the multi-layered neural network model with three outputs of mode 1 – 3 that were extracted above, by using the no-code AI analysis platform "Multi-Sigma" (AIZOTH Inc.). In the modeling, oscillatory Reynolds number, amplitude and frequency of oscillation of syringe pump, velocity ratio for oscillatory flow and local velocity vectors were set as inputs. When training was implemented by changing the number of hidden layers from 1 to 10 and the number of hidden nodes from 3 to 96. As shown in Figure 7, results with high predictive performance were obtained for the generation, size, and movement of vortices. On the other hand, poor predictive performance was observed when $Re_O$ was lower.

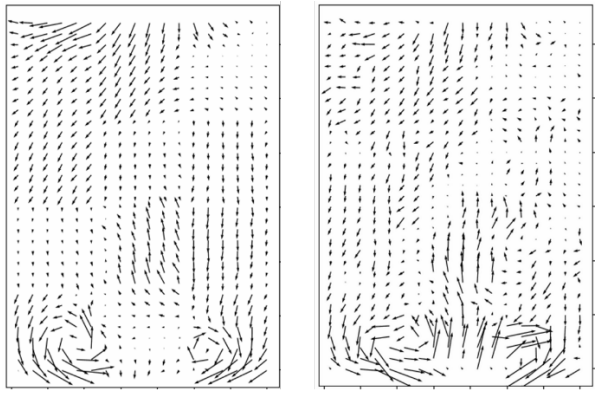

**Figure 7** Recall of flows of vector fields by using the trained neural network model.

Next, methods for prediction of time-varying mode coefficients for the above mentioned three modes were investigated. In order to reduce dimensionality of data for the mode coefficients, we investigated application of decomposition of the time-series data for the mode coefficients into periodic integrals by Fourier series expansion:

$$f(t) = \frac{a_0}{2} + \sum_{n=1}^{\infty}(a_0 \cos(nt) + b_n \sin(nt)) \quad (7)$$

Parameters $(a_0, a_1, \ldots, a_n b_1, \ldots, b_n)$ that were calculated by Eqs. (8) and (9) was used as outputs for multi-layered neural network model for prediction of the time-varying mode coefficients.

$$a_n = \frac{2}{T}\int_0^T f(t)\cos(nt)\,dt \tag{8}$$

$$b_n = \frac{2}{T}\int_0^T f(t)\sin(nt)\,dt \tag{9}$$

Combination of two types of neural network model for prediction of three mode (flows of vector fields) and for prediction of Fourier series expansion parameters related to the time-varying mode coefficients has demonstrated to show high predictive performance for time-varying streamlines in OBR.

While the proposed modeling approach has demonstrated the potential of black-box modeling for prediction of flow patterns, it was considered that the reliance on data-driven modeling without explicit physical insights may limit its generalizability across different reactor conditions. In future, it is necessary to focus on bridging machine learning models with first-principles approaches, ensuring a more interpretable and robust predictive framework for industrial OBR applications.

## CONCLUSIONS

In the present paper, we investigated application of POD for dynamic analysis of spatio-temporal data acquired by PIV to determine inputs and outputs for neural network model. It was demonstrated that three sets of modes and time-varying mode coefficients extracted by the POD could be useful for dynamic analysis and prediction of time-variant flow patterns in OBR. Also it was shown that decomposition of the time-series data for the mode coefficients by Fourier series expansion was effective for deriving reduced order model.

In future, we will apply this proposed method to machine learning modeling based on CFD simulation data to clarify its superiority over CFD simulation. Furthermore, by clarifying the correlation between the feature quantities extracted from the CFD simulation data and the structural parameters of the reactor, it is expected that the I/O structure of a machine learning model could ensure a more interpretable and robust predictive performance for a wider range of reactor conditions.

## ABSTRACT

Predicting the critical micelle concentration (CMC) of surfactants is essential for optimizing their applications in various industries, including pharmaceuticals, detergents, and emulsions. In this study, we investigate the performance of graph-based machine learning models, specifically Graph Convolutional Networks (GCN), Graph Attention Networks (GAT), and a graph-transformer model, PharmHGT, for predicting CMC values. We aim to determine the most effective model for capturing the structural and physicochemical properties of surfactants. Our results provide insights into the relative strengths of each approach, highlighting the potential advantages of transformer-based architectures like PharmHGT in handling molecular graph representations compared to traditional graph neural networks. This comparative study serves as a step towards enhancing the accuracy of CMC predictions, contributing to the efficient design of surfactants for targeted applications.

**Keywords**: Graph Neural Networks, Critical Micelle Concentration, Surfactants, Machine Learning, Molecular Property Prediction.

## INTRODUCTION

Surfactants are versatile chemical compounds utilized across various industries, including cosmetics,(*1*) pharmaceuticals, detergents,(*2*) and enhanced oil recovery.(*3*) Their unique amphiphilic structure, containing both hydrophilic and hydrophobic components, enables them to interact with immiscible phases by reducing interfacial tension.(*4*) A key property influencing surfactant behavior is the critical micelle concentration (CMC), defined as the minimum concentration at which micelles begin to form spontaneously.

Traditional methods for CMC determination, such as surface tension measurements(*5, 6*) and fluorescence spectroscopy,(*7*) while accurate, are time-consuming and require specialized equipment. Computational approaches, including quantitative structure-property relationship (QSPR) models(*8*) and molecular dynamics simulations,(*9*) offer alternatives but face limitations in accuracy or computational efficiency. Recent advances in graph-based neural networks present promising opportunities for molecular property prediction, offering potentially faster and more accurate predictions while capturing complex structure-property relationships.

This study compares three graph-based deep learning architectures—PharmHGT, GCN, and GAT—for predicting LogCMC values. We aim to evaluate their relative strengths in capturing molecular features and their potential for accelerating surfactant design and optimization.

## METHODOLOGY

### Model Architectures

#### PharmHGT Model

Our work adapts the Pharmacophoric-constrained heterogeneous graph transformer (PharmHGT) architecture, originally developed by Jiang et al.(*10*) for molecular property prediction, to specifically address the unique challenges of surfactant modeling and LogCMC prediction. While maintaining the core heterogeneous graph architecture of PharmHGT, we introduce several key modifications to handle surfactant-specific characteristics such as amphiphilic structure, head group chemistry, and tail group interactions.

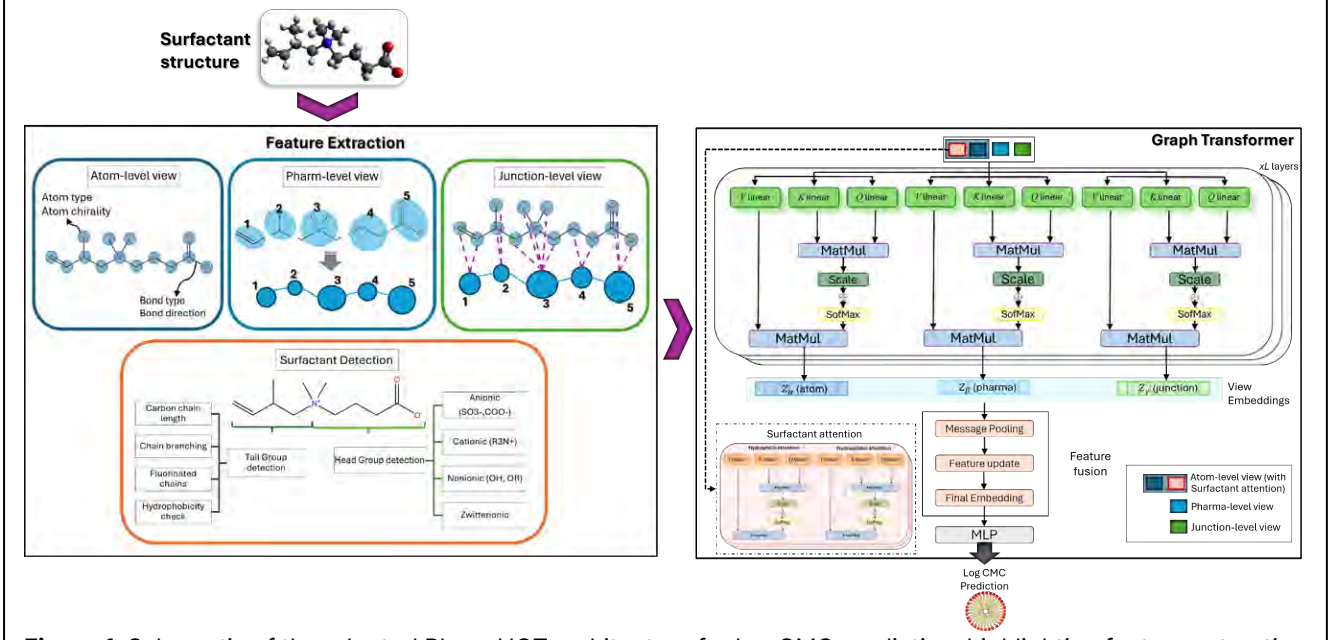

**Figure 1:** Schematic of the adapted PharmHGT architecture for LogCMC prediction, highlighting feature extraction (atom-level, pharmacophore-level, and junction-level), the surfactant detection module, attention mechanisms, and hierarchical feature fusion.

While the original PharmHGT framework was designed for capturing pharmacophoric structures through heterogeneous graph representation, we found it initially struggled to recognize the unique molecular structures of surfactants due to their unique amphiphilic nature and the interactions between hydrophilic and hydrophobic regions. However, the framework's underlying architecture for heterogeneous graph learning provided a valuable foundation. Our adaptation enhances this framework by incorporating surfactant-specific features and attention mechanisms, enabling it to effectively capture the distinct functional regions that significantly influence surfactant properties.

The adapted PharmHGT represents surfactants as heterogeneous graphs $G = (V, E)$, where $V$ is the set of nodes representing molecular components (e.g., atoms or functional groups) and $E$ is the set of edges representing chemical bonds or interactions. Node types are mapped using $\phi: V \to O$, and edge types are mapped using $\psi: E \to P$. This representation integrates three complementary views of the molecular structure:

The atom-level view ($G_\alpha$), which captures atomic features such as atomic number, chirality, and bonding patterns. Additionally, it encodes surfactant-specific information, such as whether an atom belongs to a hydrophilic head group or hydrophobic tail group.

The pharmacophore-level view ($G_\beta$), which focuses on functional groups and their interactions, especially tail-head relationships. Pharmacophoric features are derived using MACCS keys and chemical feature detection.

The junction-level view ($G_\gamma$), which combines atom-level and pharmacophoric information to provide a comprehensive molecular representation.

These three complementary views are illustrated in Figure 1 in the feature extraction section, which provides an overview of the adapted PharmHGT model and its surfactant-specific enhancements.

The model employs a multi-head attention mechanism to dynamically learn the importance of different molecular features across atom-level, pharmacophore-level, and junction-level views. The attention mechanism is mathematically expressed as:

$$Attention(Q, K, V) = \sum_{p \in P} \Omega_p \cdot \sigma\left(\frac{Q_p K_p^T}{\sqrt{d_k}}\right) \cdot V_p \qquad (1)$$

where Q, K, and V are the query, key, and value matrices; $\Omega_p$ is a learnable weight matrix specific to view p; and σ represents the SoftMax function. This mechanism prioritizes interactions unique to surfactants, such as those between hydrophilic head groups and hydrophobic tail regions, achieved through dedicated attention modules. Feature propagation through the graph is governed by a multi-view message-passing framework (MVMP), expressed as Eq. 2:

$$M^{(t)}(X_v) = \sum_{u \in N(v)} Attention\left(H^{(t-1)}(X_v)W_Q, H^{(t-1)}(X_u)W_K, H^{(t-1)}(X_u)W_V\right) \qquad (2)$$

where $M^{(t)}(X_v)$ is the updated feature of node v at

step t; $N(v)$ represents the neighbors of node v; $H^{(t-1)}(X_v)$ is the feature of v from the previous step; and $W_Q$,$W_K$,$W_V$ are learnable projection matrices. The MVMP framework integrates attention mechanisms to dynamically aggregate and prioritize molecular interactions, effectively capturing the diverse structural and functional relationships unique to surfactants.

After integrating surfactant-specific features into the atom-level embeddings, the model combines all structural views (atom-level, pharmacophore-level, and junction-level) through a hierarchical Readout Attention mechanism:

$$Z_{\gamma\beta} = ReadOutAttention(Z_\gamma, Z_\beta) \quad (3)$$

where $Z_\gamma$ and $Z_\beta$ are the feature embeddings from the junction-level and pharmacophore-level views, respectively. The resulting embedding $Z_{\gamma\beta}$ is further integrated with atom-level features using Eq. 4:

$$Z = ReadOutAttention(Z_\alpha, Z_{\gamma\beta}) \quad (4)$$

where Z_α is the atom-level embedding. Finally, the LogCMC prediction is obtained through a multi-layer perceptron (MLP), expressed as Eq. 5:

$$\hat{y} = MLP(Z) \quad (5)$$

### GCN Model

Our GCN architecture consists of two graph convolutional layers followed by a three-layer fully connected regression network as we defined in our previous work.(*11*) The model processes molecular graphs by iteratively updating node features based on their local neighborhood information.(*11, 12*) Each node's feature vector encodes atomic properties and surfactant-specific characteristics. The first convolutional layer maps input features to a hidden representation, while the second layer refines these representations. A global mean pooling operation then aggregates node-level features into a graph-level representation, which is processed through the regression network for final prediction. This architecture effectively captures local molecular structure and chemical bonding patterns while maintaining computational efficiency.

### GAT Model

The GAT architecture enhances the basic graph neural network framework by incorporating attention mechanisms that dynamically weight the importance of different atomic interactions.(*13*) Our implementation uses a dual-layer architecture with four attention heads in the first layer and a single consolidating head in the second layer. This multi-head attention allows the model to capture different aspects of molecular structure simultaneously. Each attention head computes importance weights for neighboring atoms, enabling the model to focus on the most relevant structural features for LogCMC prediction. The model combines local atomic features with global molecular context through a series of attention-weighted transformations, followed by a global pooling operation and regression layers.

### Data and Implementation

Our study utilized two carefully curated datasets of surfactants compiled from literature sources.(*14-19*) Data1 consists of 285 non-ionic surfactants, providing a focused dataset for evaluating model performance on a single surfactant class. Unlike Data1, Data2 encompasses 365 surfactants with a broader chemical diversity: 285 non-ionic, 35 cationic, 34 anionic, and 11 zwitterionic surfactants. This diverse dataset enables the assessment of model generalization across different surfactant types.

For molecular representation, we used RDKit(*20*) to generate comprehensive feature sets for each surfactant. Atomic features included atomic number, formal charge, hybridization state, aromaticity, and surfactant-specific properties such as head/tail group identification. Bond features captured bond type, conjugation, and ring membership. For the PharmHGT model, additional pharmacophoric features were extracted using MACCS keys(*21*) and chemical feature detection.

In creating the regression models, we adopted the PyTorch(*22*) for neural network components and the Deep Graph Library (DGL)(*23*) for efficient graph operations. For model training and evaluation, we systematically divided the available experimental datasets (containing the chemical structure and their corresponding logCMC values) into training (70%), testing (20%), and validation (10%) sets, maintaining the consistent distribution of surfactant types across splits. Hyperparameter optimization was conducted using Optuna, running 100 trials per model. Table S1 in the digital supplementary material presents the optimal hyperparameters for each model-dataset combination. All models were trained using early stopping with patience ranging from 20-40 epochs (monitoring validation loss without improvement) to prevent overfitting while ensuring convergence. Data splitting was performed using stratified random sampling to maintain a consistent distribution of surfactant types across training, testing, and validation sets. (see Table S2 in the digital supplementary material)

## RESULTS AND DISCUSSION

We evaluated the performance of PharmHGT, GCN, and GAT models on two distinct datasets (Data1 and Data2) using root mean square error (RMSE) and mean absolute error (MAE) as primary metrics. The comparative analysis reveals notable differences in predictive capabilities across model architectures and dataset compositions.

For Data1, which consists exclusively of non-ionic

surfactants (n=285), all three models demonstrated strong predictive capabilities, albeit with varying degrees of accuracy. As shown in Table 1, the PharmHGT model achieved the highest performance, with a test MSE of 0.090 and MAE of 0.207, followed by the GCN model (MSE: 0.238, MAE: 0.340) and the GAT model (MSE: 0.314, MAE: 0.369). Notably, the training metrics in Table 1 indicate strong learning capacity across all models, with PharmHGT showing the lowest training MSE (0.017) and highest training $R^2$ (0.990).

The superior performance of PharmHGT can be better understood by examining the structural complexity of Data1. Despite focusing solely on non-ionic surfactants, Data1 exhibits considerable structural diversity at both atomic and pharmacophoric levels. Quantitative diversity analysis reveals five unique atom types (C: 72.55%, O: 25.64%, N: 0.92%, F: 0.59%, S: 0.31%) with significant variance in key atom features (mean-variance: 0.036). At the pharmacophoric level, molecules contain a wide range of functional fragments (1-84 per molecule, average: 9.14±10.24) with varied fragment sizes (1-22 atoms, average: 3.38±3.68). Feature similarity analysis identifies multiple distinct structural clusters, indicating that the dataset encompasses diverse molecular scaffolds despite focusing on non-ionic surfactants. This structural complexity particularly benefits PharmHGT's heterogeneous graph representation, which better captures the varying importance of different structural features compared to the more uniform approaches of GCN and GAT.

**Table 1**: Model Performance on Data1 (Non-ionic Surfactants)

| Model | MSE | | $R^2$ | | MAE | |
|---|---|---|---|---|---|---|
| | Train | Test | Train | Test | Train | Test |
| GAT | 0.075 | 0.314 | 0.955 | 0.845 | 0.158 | 0.369 |
| GCN | 0.042 | 0.238 | 0.974 | 0.883 | 0.091 | 0.340 |
| PharmHGT | 0.017 | 0.090 | 0.990 | 0.943 | 0.098 | 0.207 |

Figure 2 presents scatter plots comparing predicted versus experimental values for all three models on Data1 in the top row. The PharmHGT model exhibits the tightest clustering around the diagonal line ($R^2$ = 0.943), indicating superior prediction accuracy across the full range of CMC values. The GCN model shows good correlation ($R^2$ = 0.883), while the GAT model demonstrates slightly lower but still substantial predictive power ($R^2$ = 0.845). Both models show increased scatter at extreme CMC values compared to PharmHGT. The outlier non-ionic surfactants in Figure 2 feature: (1) extreme ethoxylation patterns (very short or very long chains), (2) highly branched hydrophobic tails, and (3) atypical oxygen atom distributions throughout the molecule rather than concentrated in head groups. PharmHGT's superior handling of these challenging structures (reducing prediction error by up to 31% compared to GAT) demonstrates the advantage of heterogeneous graph representation and transformer-based attention mechanisms for capturing complex structure-property relationships in surfactants with

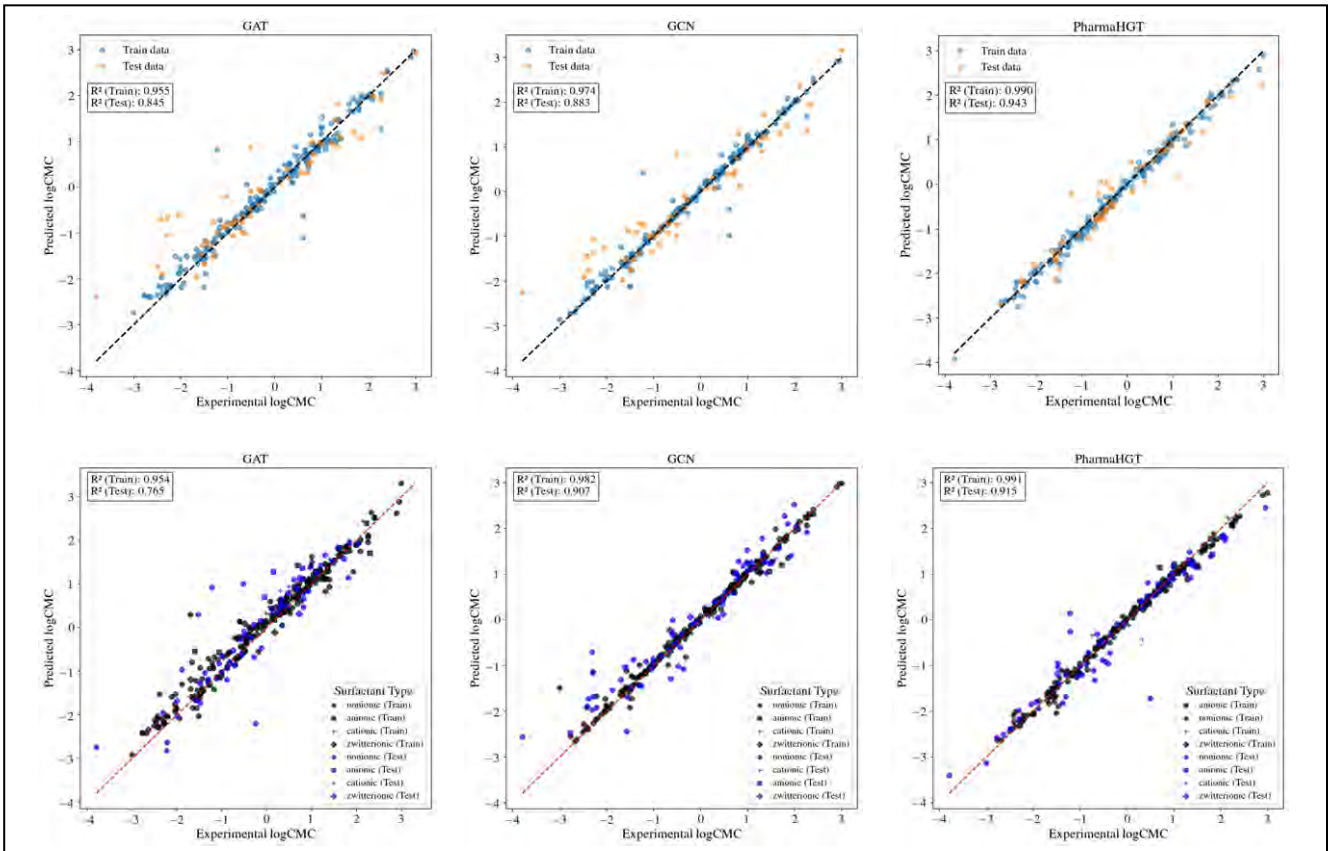

**Figure 2:** Scatter Plots of Predicted Vs. Experimental LogCMC Values for the top row representing Data Set 1 and the bottom row representing Data Set 2.

unconventional features.

The more diverse Data2 dataset (n=365), containing a mixture of non-ionic, cationic, anionic, and zwitterionic surfactants, presented a more challenging prediction task. As detailed in Table 2, the performance differences between models became more pronounced. The PharmHGT model maintained robust performance (MSE: 0.171, MAE: 0.250), demonstrating effective handling of diverse surfactant types. The GCN model showed comparable performance (MSE: 0.182, MAE: 0.307), while the GAT model exhibited higher prediction error (MSE: 0.318, MAE: 0.369). The training metrics in Table 2 reveal particularly strong learning capacity for both PharmHGT (training MSE: 0.014, $R^2$: 0.991) and GCN (training MSE: 0.027, $R^2$: 0.982), suggesting effective feature extraction from the more complex dataset.

Figure 2 illustrates the prediction performance on Data2 through scatter plots in the bottom row. The PharmHGT model maintains a strong correlation ($R^2$ = 0.915) despite the increased chemical diversity. The GCN model shows similar performance ($R^2$ = 0.907), while the GAT model ($R^2$ = 0.765) shows more substantial scatter across surfactant types. All models display some deviation from the ideal prediction line for surfactants with extreme LogCMC values, though this effect is least pronounced in the PharmHGT predictions.

**Table 2**: Model Performance on Data2 (Mixed surfactants)

| Model | MSE | | $R^2$ | | MAE | |
|---|---|---|---|---|---|---|
| | Train | Test | Train | Test | Train | Test |
| GAT | 0.078 | 0.318 | 0.954 | 0.765 | 0.190 | 0.369 |
| GCN | 0.027 | 0.182 | 0.982 | 0.907 | 0.083 | 0.307 |
| Pharm HGT | 0.014 | 0.171 | 0.991 | 0.915 | 0.080 | 0.250 |

Tables 1-2 report results from a single stratified random split (70/20/10) with fixed random seeds to ensure reproducible partitioning. To evaluate the impact of model configuration on performance, we first assessed all models with identical default parameters on the same data split, then performed systematic hyperparameter optimization using Optuna (100 trials per model). Notably, PharmHGT with default parameters ($R^2$ = 0.925 on Data1) outperformed both GCN and GAT even before optimization ($R^2$ = 0.862 and 0.814 respectively), demonstrating

that its superior performance is not merely an artifact of hyperparameter tuning. While performance may vary slightly with different splits, the consistent ranking of models across both default and optimized configurations confirms the robustness of our findings with respect to data partitioning and parameter selection.

### Analysis of Model Strengths

Based on the two dataset types studied in this work, it was discovered that PharmHGT performs better than GCN and GAT and the GAT model showing the least accuracy. The PharmHGT model's superior performance can be attributed to its sophisticated architecture that combines transformer-based attention mechanisms with heterogeneous graph representation. Its consistent performance across both datasets suggests effective capture of both local molecular features and global structural patterns. The GCN model showed robust performance, particularly on Data2, where it achieved comparable results to PharmHGT. This suggests that its message-passing mechanism effectively captures essential molecular features for LogCMC prediction. Lastly, the GAT model's performance revealed limitations in handling diverse surfactant types, with accuracy decreasing notably for the mixed surfactant dataset. This suggests that simple attention mechanisms may not fully capture the complex interactions present in diverse surfactant systems.

## CONCLUSION

In this study, we conducted a comprehensive comparison of three graph-based deep learning architectures (PharmHGT, GCN, and GAT) for predicting LogCMC values of surfactants. Our investigation using two distinct datasets, one focused on non-ionic surfactants and another encompassing diverse surfactant types, revealed several important findings about the capabilities and limitations of each architecture.

The PharmHGT model demonstrated superior performance across both datasets, achieving the highest prediction accuracy ($R^2$ = 0.943 for non-ionic surfactants and $R^2$ = 0.915 for mixed surfactant types) and the most consistent generalization behavior. The model's ability to maintain high accuracy when transitioning from non-ionic to mixed surfactant types (with only minimal performance degradation) highlights its robustness in handling diverse molecular structures. This effectiveness stems from its sophisticated architecture that combines transformer-based attention mechanisms with heterogeneous graph representation.

The GCN model showed surprisingly strong performance, particularly for the mixed surfactant dataset where it achieved results comparable to PharmHGT ($R^2$ = 0.907). This suggests that well-designed message-passing mechanisms can effectively capture the essential molecular features governing surfactant behavior. The GAT model, while performing adequately for non-ionic surfactants ($R^2$ = 0.845), showed limitations in handling the increased complexity of mixed surfactant types ($R^2$ = 0.765), indicating that simple attention mechanisms may not fully capture the complex interactions present in diverse surfactant systems.

Future work could explore several promising directions. First, the models could be extended to predict additional surfactant properties beyond LogCMC, such as surface tension or aggregation numbers. Second, the architecture could be modified to incorporate explicit handling of environmental factors such as temperature, pH, and ionic strength, which significantly influence surfactant behavior. Finally, the strong performance of these models suggests potential applications in inverse design problems, where the goal is to generate novel surfactant structures with desired properties.

## DIGITAL SUPPLEMENTARY MATERIAL

The digital supplementary material includes Table S1 detailing optimal hyperparameters for all models (batch size, learning rate, hidden units, epochs, and model-specific parameters); Table S2 showing Hyperparameter Ranges for GAT, GCN, and Graph Transformers. This information supports findings regarding model optimization, reproducibility, and result robustness. The supplementary material is available at https://psecommunity.org/LAPSE:2025.0036v1.

## ABSTRACT

The escalating urgency to address climate change has driven carbon capture (CC) technologies into the spotlight, particularly for large-scale emitters, which benefit from economies of scale. However, small-scale emitters account for a significant share of $CO_2$ emissions, yet such applications remain largely overlooked in the literature. While CC cost is often used as a key performance indicator (KPI) for CC technologies, the lack of standardized cost estimation methods leads to inconsistencies, complicating comparisons, and hindering the deployment of CC systems. This study addresses these challenges by developing flexible short-cut correlations for selected CC technologies, providing estimates of the total equipment cost (TEC) and energy consumption specific to small-scale applications across various $CO_2$ inlet concentrations (mol%) and capture scales (10 – 100 kt/y). The flexibility of the correlations enables the integration of various cost estimation methods available in the literature and case-specific assumptions (e.g., utility prices), enhancing their consistency and applicability across various scenarios. This approach provides decision-makers with a practical yet simple method for assessing the technical and economic viability of CC systems without conducting extensive simulations or detailed techno-economic assessments (TEAs). Ultimately, this work aims to improve the accessibility of CC technologies for small-scale industries, facilitating their broader application and contributing to the overall goal of reducing greenhouse gas emissions across various sectors.

**Keywords**: Carbon Capture, Technoeconomic Analysis, Short-cut correlations, Small-scale capture

## 1. INTRODUCTION

Carbon capture (CC) is crucial for achieving net-zero emissions and mitigating climate change. Despite its critical importance, the current deployment of CC technologies remains insufficient to meet the climate target, indicating an urgency to increase the number of CC applications [1]. Emission sources vary significantly in capture scale, with large-scale emitters benefiting from economies of scale, while smaller-scale applications are often neglected. However, to reach net-zero emissions, CC applications at various emission levels are necessary [2].

While many studies on CC technologies highlight capture cost as a key performance indicator (KPI), there is currently no standardized method in the literature to estimate the cost of CC [3, 4], leading to inconsistencies and incomparable results. This makes it challenging for decision-makers to fairly compare and identify suitable CC options based on the literature results, holding back the deployment of CC units. In addition, conducting detailed simulations and Techno-Economic Assessments (TEAs) to identify viable capture options across various scenarios can be time-consuming and requires significant effort.

To address the aforementioned challenges, this work develops short-cut correlations describing the total equipment cost (TEC) and energy consumption of selected CC technologies for small-capture scale applications. This will allow exploration of the role of CC in small-scale industries and offer a practical means of evaluating the technical and economic viability of various CC systems. Heat integration is not considered due to case-specific waste heat availability.

The goal of this paper is to provide an efficient approach for decision-makers to estimate the cost of CC

without the need for extensive simulations and detailed TEAs while ensuring consistent assumptions and cost estimation methods are applied across comparison studies. Also, the correlations are flexible, allowing for various cost estimation methods and case-specific assumptions to fine-tune the analyses for various scenarios.

## 2. MODELLING

In this paper, Aspen Plus models were developed to study chemical absorption and membrane separation processes which are among the promising CC technologies available today for small-scale applications [2]. The system boundary includes capturing units and $CO_2$ compressions as presented in Figure 1. Data related to pretreatment, transportation, and sequestration or utilization are excluded from the current study.

While $CO_2$-containing gases often include impurities like $NO_x$ and $SO_x$, it is assumed that the inlet feed gas is free from these impurities. The flue gas temperature is maintained at 170°C to avoid condensation of acid gases. Typically, flue gases contain between 5.5% and 15% $H_2O$ [5] and this study uses a default value of 11% $H_2O$. The common range for $O_2$ content is 2-8%, and this study adopts a value of 6.4%, with the remainder of the feed gas assumed to be $N_2$. A capture rate of 90% was attained across various $CO_2$ concentrations (5–70 mol%) and feed gas flow rates (corresponding to capture scales between 10 and 100 kt/y), with the minimum purity of the $CO_2$ product stream established at 95% or higher. Heat integration is not covered in this study due to the availability and characteristics of waste heat is highly case-specific. However, one of the outcomes of this research is to evaluate energy needs, which could be beneficial for future heat integration studies. The captured $CO_2$ is compressed to 150 bar for transportation through a multi-stage compression system (3 compressors plus a pump) equipped with intercoolers [6].

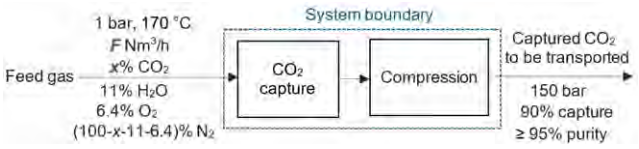

**Figure 1.** System boundary for $CO_2$ capture technologies

### 2.1 Chemical absorption process

Monoethanolamine (MEA) process is one of the widely studied capture technologies where lean solvent (30 wt.% in water) selectively absorbs $CO_2$ from flue gases and is then sent to the stripper for regeneration (100-140°C at 1 atm). In Aspen Plus, the electrolyte-NRTL thermodynamic package, in conjunction with the ideal gas law, is employed, and the design of the absorber is executed first using equilibrium calculations, subsequently changed to rate-based calculations to accurately model both equilibrium and kinetic reactions occurring within the absorber. A design specification was used to attain a 90% capture rate by adjusting the necessary reboiler duty in the stripper. For the compression loop, the Peng Robinson property package was used. This study employs vendor estimates from the paper of Nwaoha et al. for equipment cost estimation [7]. Other process parameters and cost data as well as detailed validations are presented in the work of current authors [8].

### 2.2 PolyActive membrane

Membrane CC represents a beneficial alternative technology compared to conventional solvent methods. A membrane separates gas mixture based on varying permeation rates. Membrane separation operates on partial pressure principles and is most effective with high-pressure gas streams [9]. Current advancements indicate that polymeric membranes dominate commercial membrane CC applications and the PolyActive membrane is selected in this study. This paper adopts a two-stage membrane system [9] to achieve enhanced capture rate and product stream purity.

Aspen Custom Modeller (ACM) was used to create a cross-flow membrane module, which was integrated into Aspen Plus as a block component. The process was assumed to be isothermal with negligible pressure drop, ideal gas behavior, and constant permeabilities. The module was divided into 100 cells, where feed conditions were set at the first cell inlet. The retentate ($F_{Ret,k}$) serves as the feed for the subsequent cell, while the permeate ($F_{perm,k}$) is combined with other streams and exits through the last cell. Mass balance calculations are conducted for each cell to determine the permeate flow rate and compositions as described in Equations 1 and 2.

$$F_{Ret,k-1} = F_{Ret,k} + F_{perm,k} \quad (1)$$

$$F_{Ret,k-1} \cdot ZRet_{comp,k-1} = F_{Ret,k} \cdot ZRet_{comp,k} + F_{perm,k} \cdot Zperm_{comp,k} \quad (2)$$

where $ZRet_{comp,k}$ and $Zperm_{comp,k}$ are the molar fractions of each component in each cell for retentate and permeate streams respectively. The permeances [$Nm^3m^{-2}h^{-1}bar^{-1}$] of the PolyActive membrane as well as other process and economic parameters are summarized in the supporting document, Tables S1–S2.

## 3. METHODOLOGY FOR CORRELATION DEVELOPMENT

This study aims to evaluate the performance of selected CC technologies, specifically MEA and the Polymeric membrane systems, under varying $CO_2$ concentrations ($x_{co_2}$, mol%) and flow rates ($F$, $Nm^3/h$). To overcome the limitations of literature-based cost comparisons

which are often fixed at specific flue gas characteristics and a selected CapEx/ OpEx estimation method, a flexible correlation is developed [8]. The correlation format of Equation 3 was adopted from the work of Hasan et al. [5] and various CapEx estimation methods can be applied to the TEC (total equipment cost) obtained from this correlation. A summary of the CapEx/ OpEx estimation method applied throughout this study is presented in Table S3, in the supporting document.

$$\text{TEC [M€]} = \alpha + (\beta \cdot {x_{co_2}}^{n} + \gamma) \cdot F^{m} \quad (3)$$

$$\text{Energy requirement} = \alpha \cdot e^{n x_{co_2}} + \beta \cdot e^{m x_{co_2}} \quad (4)$$

Where $\alpha$, $\beta$, $\gamma$, $n$ and $m$ are fitting parameters and to develop these parameters, several steps were followed: (1) a validated Aspen Plus model [8] was assessed across various $CO_2$ concentrations and feed gas flow rates generated from the Latin Hypercube Sampling (LHS) at a 90% capture rate; (2) these data points were connected to an Excel-based cost model to evaluate the TEC and specific energy consumptions; (3) results from the Excel model were imported to Matlab for multivariable regressions. The data points used in the correlation development can be found in the supporting document (Tables S4 and S5). The specific energy consumptions were found to be independent of capture scales [8], leading to a correlation format (Equation 4) based on the $CO_2$ inlet concentration only.

# 4. RESULTS AND DISCUSSION

## 4.1 Correlations for CC processes

The developed correlation parameters are presented in Table 1. These correlation results can be used to estimate capture costs relative to $CO_2$ concentrations and flue gas flow rates within defined ranges. The rule of six-tenths can be utilized for the TEC estimations beyond these boundaries.

In the PolyActive systems, the total membrane area showed a linear correlation with fixed $CO_2$ inlet concentration. To minimize inconsistencies in cost scaling, the specific membrane cost [€$_{2023}$/t] is separated from other membrane TEC. Therefore, the TEC correlation parameters in Table 1 solely reflect the aggregate process equipment costs, without the total membrane cost. A separate correlation was developed for the membrane cost [€/t] as a function of $CO_2$ inlet concentration, following a power law due to economies of scale.

$$\text{TEC}_{PolyActive}\left[\frac{€}{t}\right] = 2.6726\left(x_{co_2}\right)^{-1.298} \quad (5)$$

## 4.2 Correlations for $CO_2$ compressions

The specific TEC of the compression loop depends on the capture scale ($S$, in t/h) as the flue gas $CO_2$ concentration does not affect the $CO_2$ product stream. Equations 6 and 7 present the developed correlations for each CC technology.

$$\text{TEC}_{Comp,\ MEA}\left[\frac{\text{M€}}{\text{t/h}}\right] = 0.3957\ (S)^{-0.602} \quad (6)$$

$$\text{TEC}_{Comp,\ PolyActive}\left[\frac{\text{M€}}{\text{t/h}}\right] = 0.4634\ (S)^{-0.642} \quad (7)$$

Also, the electrical and cooling duties of the compression loop for MEA and PolyActive membrane are presented in Table 2 below. For MEA, the purity of the product stream stayed ≥ 99% and therefore, the specific energy consumptions across the $CO_2$ inlet concentrations and capture scale remained constant.

**Table 2:** Energy consumptions of the compression loops

| Compression Loop for: | Electrical duty [kWh/t] | Cooling duty [GJ/t] |
|---|---|---|
| MEA | 87.56 | 0.594 |
| PolyActive | 106.53[*] | 0.613[*] |

[*] The table lists average energy consumption for the PolyActive membranes at ≥ 95% purity.

**Table 1:** Correlation parameters for estimating the performances of small-scale $CO_2$ capture (10-100 kt/y)

| Process | $\alpha$ | $\beta$ | $\gamma$ | $n$ | $m$ | $x_{co_2}$ [mol%] | $F$ [1000 Nm³/h] |
|---|---|---|---|---|---|---|---|
| | | | | TEC [M€$_{2023}$] | | | |
| MEA | 1.0160 | 1.3364 | -0.0123 | 0.4486 | 0.7022 | $5 \le x_{co_2} \le 50$ | $1.30 \le F \le 128.80$ |
| PolyActive | 5.3843 | 0.0071 | 0.8840 | -0.8785 | 0.4915 | $5 \le x_{co_2} \le 70$ | $0.92 \le F \le 128.80$ |
| | | | | Specific Cooling Duty $\left[\frac{GJ}{t_{co2}}\right]$ | | | |
| MEA | 9.0860 | 2.8623 | — | -31.5148 | 0.2572 | $5 \le x_{co_2} \le 50$ | $1.30 \le F \le 128.80$ |
| PolyActive | 21.1248 | 3.3077 | — | -22.9241 | -1.9204 | $5 \le x_{co_2} \le 70$ | $0.92 \le F \le 128.80$ |
| | | | | Specific Reboiler Duty $\left[\frac{GJ}{t_{co2}}\right]$ | | | |
| MEA | 1.6315 | 3.5678 | — | -38.4307 | -0.0199 | $5 \le x_{co_2} \le 50$ | $1.30 \le F \le 128.80$ |
| | | | | Specific Electrical Duty $\left[\frac{kWh}{t_{co2}}\right]$ | | | |
| MEA | 9.4061 | 2.2475 | — | -21.6650 | -1.2483 | $5 \le x_{co_2} \le 50$ | $1.30 \le F \le 128.80$ |
| PolyActive | 1227.2 | 263.27 | — | -18.9830 | -0.9304 | $5 \le x_{co_2} \le 70$ | $0.92 \le F \le 128.80$ |

In this work, average values are presented in Table 2 when the purity is ≥ 95% as a simplified approach to estimate the energy consumption.

## 4.3 Correlations and relative errors

The relative errors between the correlation results and the data points obtained from detailed TEAs for the selected CC technologies are presented in Table 3.

**Table 3:** Relative errors of the capture technologies

| MEA | Average relative error [%] | Min/ Max relative error [%] | $R^2$ |
|---|---|---|---|
| TEC | 4.28 | 0.014/ 8.50 | 0.975 |
| Reboiler duty | 0.12 | 0.002/ 0.40 | 0.996 |
| Electrical duty | 2.87 | 0.03/ 8.59 | 0.997 |
| Cooling duty | 1.38 | 0.19/ 7.54 | 0.997 |
| **PolyActive** | | | |
| TEC | 1.90 | 0.004/ 4.92 | 0.999 |
| Electrical duty | 2.57 | 0.42/ 8.77 | 0.999 |
| Cooling duty | 3.95 | 0.24/ 8.67 | 0.999 |

Given the scarcity of real CC project data for small-scale applications in the public domain, it is important to clarify that these errors do not represent the uncertainty of a real CC unit but rather deviations between the correlation and TEA data used in this study. For CapEx/ OpEx, uncertainties as high as 10 to 20% are common during a process scale-up [5] and therefore, the average error as well as the maximum errors depicted in the correlations can be considered within the expected variations. Correlation development is iterative and more data points can be added to improve the correlation results. The validity of the developed correlations is demonstrated through the case studies.

## 4.2 Case study

### 4.2.1 Cement industry CC (20.5 mol%, 111 kt/y)

In this section, correlations from this study are applied to case studies presented by IEAGHG [2], starting with a small-scale cement plant. The CapEx estimation method used in the case study is presented in the supporting document. Key assumptions and input data are presented in Table 4. Note that natural gas is used to generate steam required by the MEA process while for the PolyActive membrane, no steam is required. Detailed breakdowns of the MEA capture cost retrieved from IEAGHG [2] as well as the correlation results for the MEA and PolyActive membranes are presented in Figure 2. CapEx is one of the dominant factors and accounts for close to 50% of the capture cost for small-scale application. Comparing the MEA correlation CapEx to the literature value, a difference of 6% was observed while the NG fuel costs showed a deviation of 5%. In the case of electricity costs, the report extracted electrical energy consumption from a coal-fired power plant case study treating a flue gas at 4.1 mol% $CO_2$ concentration without conducting a detailed simulation. As indicated in Table 8, the flue gas considered in this case study has a high

**Table 4:** Case study process/ economic inputs and assumptions [2] for the small-scale cement plant

| Parameters | Values | Parameters | Values |
|---|---|---|---|
| $CO_2$ concentration | 20.5 mol% | Operating hours | 7451 h/y |
| Capture scale | 111.3 kt/y | CEPCI (2024 April) | 799.5 |
| Process lifetime | 25 y | Electricity | 132.31 $/MWh |
| Discount rate | 10% | Natural gas (NG) price | 22.82 $/MWh |

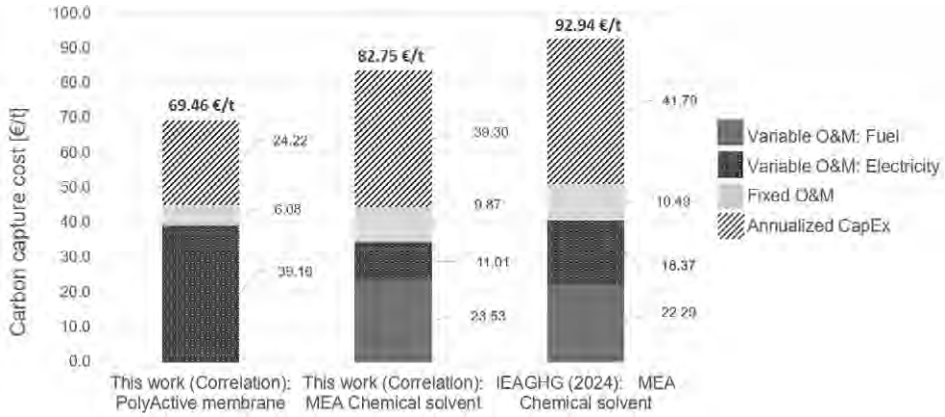

**Figure 2.** Detailed breakdown of carbon capture and compression cost [€/t]: Case study 1

concentration of 20.5 mol%. At low $CO_2$ concentrations (e.g., 4.1 mol%), high flue gas volumes will pass through a blower and more power will be required. Also, the study reported 1.58 $MW_{el}$ for the compression of $CO_2$ product which is higher than the power consumption considered in this study (1.11 $MW_{el}$), but no details about product compression was given. In addition, higher solvent pump power consumptions were considered in the literature by accounting for pressure drop in pipelines (a pump head of 10 bar) which was not considered in this study. These differences in the assumptions lead to a deviation of 45% in electricity costs. Overall, the MEA correlation showed a capture cost of 82.75 €/t with a difference of 11% compared to the reported value which is within the expected deviation defined by AACE [10]. Assuming more accurate power consumptions were applied in the literature result, the difference in capture costs for MEA process could be even lower which shows a good applicability of the correlations.

The capture cost obtained using the PolyActive correlations was found to be 69.46 €/t which is lower than the MEA process. This is possible since the membrane process can be less CapEx intensive and more cost-effective at high $CO_2$ concentrations. Also, membranes are well-suited for small-scale applications due to their modularity. However, 56.3% of the capture cost arises from the electricity cost and therefore, sources of electricity will be an important criterion to be considered.

### 4.2.2 Energy from Waste (EfW) (10 mol%, 90 kt/y)

An EfW plant with a capture scale of 90 kt/y was considered in the second case study where process parameters and assumptions are outlined in Table 5. The EfW plant without a CC unit produces 7.7 $MW_{el}$ and 8.1 $MW_{th}$. Note that NG cost is not considered since all the steam needed for solvent regeneration is assumed to be supplied by the steam turbine from the EfW plant. Based on this, a steam turbine loss of 3.89 $MW_{el}$ was assumed in the literature [2] and applied in the correlation results as well. Since the EfW plant produces electricity, a wholesale electricity price of 56.85 $/MWh was retrieved from the literature [2] and applied in this case study. The detailed breakdowns of capture costs are shown in Figure 3.

As observed in the first case study, the CapEx is the main contributor to the capture costs (54% for the literature MEA results and 59% for the MEA correlation result). For the annualized CapEx, a difference of 12% was observed between the correlations and the literature, while for the electricity cost, a difference of 22% was observed. As explained in Section 4.2.1, much higher power consumption for the compression loop and the solvent pumps are used in the literature [2]. Overall, a capture cost of 82.92 €/t was obtained from the MEA correlations with a difference of 3.54% compared to the literature value of 79.98 €/t. In the case of the PolyActive membrane, a capture cost of 71.48 €/t was obtained using the correlations with the same assumptions, which is a cheaper CC option than the conventional MEA CC in the EfW case as well.

**Table 5:** Case study process/ economic inputs and assumptions [2] for EfW process

| Parameters | Values | Parameters | Values |
|---|---|---|---|
| $CO_2$ concentration | 10.0 mol% | Operating hours | 7451 h/y |
| Capture scale | 90.0 kt/y | CEPCI (2024 April) | 799.5 |
| Process lifetime | 25 y | Electricity | 56.8 $/MWh |
| Discount rate | 10% | Natural gas (NG) price | NA |

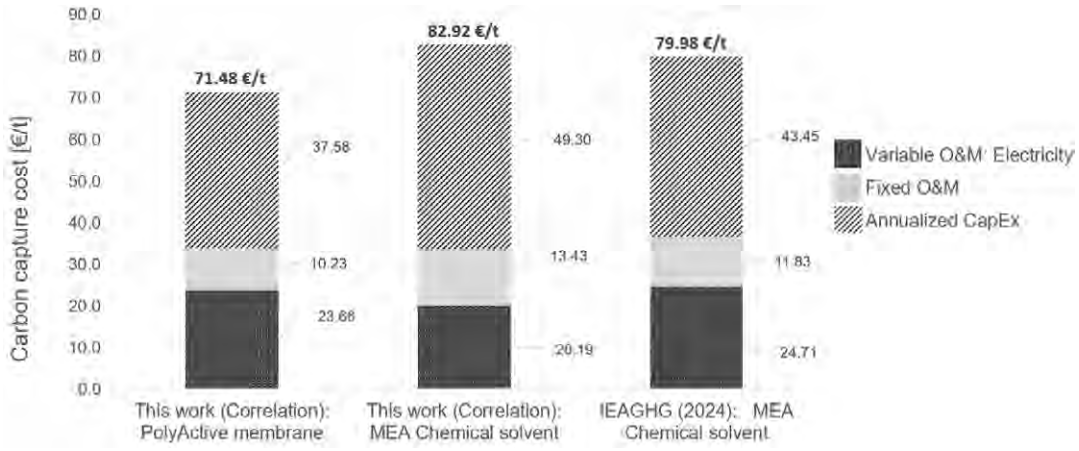

**Figure 3.** Detailed breakdown of carbon capture and compression cost [€/t]: Case study 2

## CONCLUSION AND PERSPECTIVES

In this paper, small-scale correlations for the MEA and the PolyActive membrane CC technologies are developed and the applicability is demonstrated in the case studies. These correlations can be applied across various $CO_2$ inlet concentrations (between 5 and up to 70 mol%) and capture scales (10-100 kt/y). Also, a consistent CapEx/ OpEx estimation method can be applied throughout the comparison studies to minimize discrepancies. More importantly, case-specific utility costs can be applied to the correlation results to fine-tune the capture costs depending on the considered case studies. As a benchmark CC process, MEA correlations are presented in this work which is one of the well-suited CC options for large-scale applications. However, small-scale CC processes are CapEx intensive due to the absence of economies of scale, leading to higher costs per ton of $CO_2$ captured. Therefore, technologies with a lower CapEx intensity (e.g., membranes) will have higher potential for small-scale emitters. Also, modularity and installation area of technologies will be crucial KPIs for small-scale applications due to often limited space availabilities. In the perspectives, new emerging technologies such as advanced chemical absorption or cryogenic CC can be studied to enrich small-scale CC applications in the literature.

Overall, these easy-to-use small-scale correlations are envisioned to assist with decision-making processes for small-scale CC and improve deployment of CC units by providing a framework to fairly compare various CC technologies.

## ABSTRACT

Integrated Carbon Capture and Conversion (ICCC) technologies offer an efficient alternative to conventional Carbon Capture, Utilization, and Storage (CCUS) methods by simultaneously capturing and converting $CO_2$ into value-added chemicals. Dual-function materials (DFMs) are particularly promising due to their capability to integrate adsorption and catalysis in a single step, thereby reducing both energy consumption and associated costs. This study models the dynamic behavior of $CO_2$ adsorption within a laboratory-scale packed-bed reactor employing DFMs. The mathematical model incorporates momentum, mass, and heat transfer equations, implemented using COMSOL Multiphysics v5.6, and evaluates various axial dispersion models (ADMs) and mass transfer coefficients (MTCs). The results indicate that the Rastegar-Gu ADM, combined with an MTC of $8.3 \times 10^{-2}$ $s^{-1}$, provides the most accurate representation of breakthrough and saturation times, as well as the total quantity adsorbed. Furthermore, relative errors associated with this model are consistently lower than those observed in alternative models. These findings offer valuable insights for the scaling-up of ICCC technologies, underscoring the significance of precise Computational Fluid Dynamics (CFD) simulations in advancing sustainable $CO_2$ capture and conversion solutions.

## INTRODUCTION

ICCC technologies represents an advancement over conventional CCUS methods[1]. The ICCC technologies are based on the *in-situ* conversion of the captured carbon into high-value chemical products, such as methane and methanol, thus eliminating the need for costly compression and transport processes [1]. Among these technologies, DFMs emerge as a promising solution, facilitating the integration of $CO_2$ adsorption (capture) and methanation (conversion), while simultaneously reducing energy consumption [2].

However, there remains a gap between the research and development of DFMs and their industrial implementation [1, 2]. As a result, both numerical simulation and CFD are pivotal in the optimal design and scale-up of these processes.

In the context of carbon dioxide adsorption, the numerical simulation incorporates the three primary transport phenomena – momentum, mass and heat transfer- coupled with equilibrium and kinetic adsorption models [3]. This approach is suitable for a range of adsorbent materials and their modifications [4]. Additionally, numerical simulation offers a rigorous framework for the design and optimal mathematical description for cyclic carbon capture processes, such as Pressure Swing Adsorption (PSA) and Temperature Swing Adsorption (TSA) [5].

The dynamic behavior of the adsorption column is typically described by a “breakthrough curve”. This curve is generated as the mass transfer zone advances through the column and reaches the exit [6]. The shape of the mass transfer zone and, consequently the breakthrough curve, depends on the isotherm model, axial dispersion model, and mass transfer model [7].

Both the axial dispersion coefficient and the mass transfer coefficient are key parameters influencing the adsorption dynamic behavior [8]. Axial dispersion arises from turbulent mixing and molecular diffusion [4, 6]

The mass transfer coefficient reflects the rate at which the adsorbate is transferred from the gas phase to the solid phase within the particles. It may also account for the resistance effects associated with diffusion into the solid materials [6].

In this study, the dynamic behavior of carbon dioxide adsorption from a nitrogen mixture using a $Ru/Na_2O_3/Al_2O_3$ DFM in a laboratory-scale packed bed is simulated using COMSOL Multiphysics v5.6. The momentum, mass, and heat transfer phenomena are modeled and integrated through various physics modules. Furthermore, several axial dispersion models (ADM) and mass transfer coefficients (MTCs) are evaluated.

## MATHEMATICAL MODELS

This section presents the formulation of the mathematical model. It outlines the assumptions, the geometry implemented in the software, and the physics modules, along with the equations utilized.

### Assumptions

For simplicity, several assumptions have been made regarding the mathematical model. First, it is assumed that only carbon dioxide is adsorbed onto the DFM, and the linear driving force model is implemented to account for mass loss. Additionally, the gas mixture is considered ideal. Finally, the energy balance model is assumed to be homogeneous.

### Geometry

To replicate the experimental system, a one-dimensional geometry was created in COMSOL along de *x*-axis. Two subdomains were defined: quartz wool and DFM. Figure 1 illustrates the final geometry implemented in the CFD model, while Image 1 depicts the laboratory-scale reactor used in the experiment.

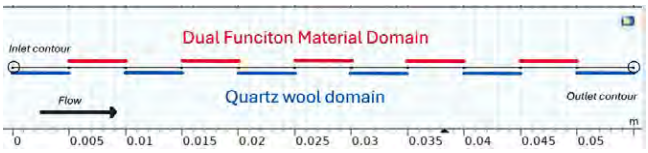

**Figure 1**. One-dimensional geometry employed in COMSOL.

**Image 1**. Laboratory-scale DFM packed reactor employed.

## Governing transport phenomena equations

### Momentum Balance

For the momentum balance, Darcy's *Law* physics module was implemented. This module includes both the continuity equation and the Darcy's law equation for pressure drop. The equation is expressed as follows:

$$\frac{\partial(e_{cat}\rho_f)}{\partial t} + \frac{\partial}{\partial x}\rho_f u = 0 \quad (1)$$

$$u = -\frac{\varkappa}{\mu}\frac{\partial P}{\partial x} \quad (2)$$

Where: $u$ is the Darcy velocity (m/s), $e_{cat}$ is the DFM porosity, $\rho_f$ and $\mu$ represent the gas phase density (kg/m$^3$) and viscosity (Pa·s), respectively. Finally, $\varkappa$ is the permeability (m$^2$), which was calculated using the integrated Kozeny-Carman equations and $P$ is pressure (Pa).

### Mass Balance

The Mass balance equations were modeled using *transport of diluted species* physics modules. The equation is expressed as follows.

$$\frac{\partial C_i}{\partial t} - D_L\frac{\partial^2 C_i}{\partial x^2} + u\frac{\partial C_i}{\partial x} = \mathrm{R}_i \quad (3)$$

Where $C_i$ denotes the gas phase concentration of each species (mol/m$^3$), $D_L$ represents the axial dispersion coefficient (m$^2$/s), and $\mathrm{R}_i$ refers to the reaction or sink term (mol/m$^3$·s).

### Adsorption term

To simulate the adsorption phenomenon, the linear driving force equation was implemented as a *domain ordinary differential equation* module, applied exclusively to the DFM subdomain.

$$\frac{\partial q}{\partial t} = k(q_e - q) \quad (4)$$

In this equation, $q$ represents the quantity of carbon dioxide adsorbed onto the solid material (mol/kg), $q_e$ is the equilibrium quantity (mol/kg), and $k$ is the mass transfer coefficient (1/s).

Thus, the mass balance for carbon dioxide is expressed as follows:

$$\frac{\partial C_{CO_2}}{\partial t} - D_L\frac{\partial^2 C_{CO_2}}{\partial x^2} + u\frac{\partial C_{CO_2}}{\partial x} = -\frac{1-e_{cat}}{e_{cat}}\rho_s\frac{\partial q}{\partial t} \quad (5)$$

For nitrogen, $\mathrm{R}_i$ is equal to zero.

### Adsorption equilibrium

The Langmuir isotherm model was used to represent the equilibrium quantity (equation 6). To ensure an accurate depiction of these phenomena, the model was fitted to experimental data obtained with a Micromeritics ASAP 2020+ at pressures up to 760 mmHg and 320 °C for $Na_2O/Al_2O_3$, a precursor to DFM. Table 1 presents the obtained parameters values.

$$q_e = \frac{q_{sat}K_L P_{CO_2}}{1+K_L P_{CO_2}} \quad (6)$$

**Table 1:** Langmuir isotherm model parameters.

| Stream | Description | Value |
|---|---|---|
| $q_{sat}$ | Saturated quantity | 0.193 mol/kg |
| $K_L$ | Equilibrium constant | $73x10^{-5}$ $Pa^{-1}$ |

## Energy Balance

The energy balance was modeled using the *heat transfer on porous media* physics module. The equation is expressed as follows:

$$A_c(\rho C_p)_{eff}\frac{\partial T}{\partial t} + A_c\rho_f C_{p,f} u\frac{\partial T}{\partial x} - A_c k_{eff}\frac{\partial T^2}{\partial x^2} = Q_{ads} \quad (7)$$

Where: $T$ is the system temperature (K), $A_c$ the cross-sectional area ($m^2$), $k_{eff}$ represents the effective heat transfer coefficient (W/m·K), and $Q_{ads}$ denotes the heat of adsorption ($W/m^3$).

## Boundary conditions

The equations for the boundary conditions at the boundaries of the geometry (Figure 1) are expressed as follows:

$$\boldsymbol{n}\cdot(\rho_f u) = \rho_f U_0 \quad (8)$$

$$\boldsymbol{n}\cdot\left(-D_L\frac{\partial C_i}{\partial x} + uC_i\right) = \boldsymbol{n}\cdot(uC_{i,0}) \quad (9)$$

$$-\boldsymbol{n}\cdot\left(-A_c k_{eff}\frac{\partial T}{\partial x}\right) = A_c\rho_f\Delta H(\boldsymbol{n}\cdot u) \quad (10)$$

Equations (8-10) represent the Danckwerts form for the inlet conditions for the momentum, mass, and energy balance, respectively. Here, $U_0$ is the initial Darcy velocity, $C_{i,0}$ the initial concentration of each gas in the inlet mixture (calculated using ideal gas equation), and $\Delta H$ the sensible enthalpy (KJ/mol) [9]

$$\boldsymbol{n} * (\rho_f u) = p_0 \quad (11)$$

$$\boldsymbol{n} * \left(-D_L\frac{\partial C_i}{\partial x}\right) = 0 \quad (12)$$

$$-\boldsymbol{n} * \left(-A_c k_{eff}\frac{\partial T}{\partial x}\right) = 0 \quad (13)$$

On the other hand, equations (11-13) describe the outlet boundary conditions. Here, $p_0$ represents the barometric pressure at the outlet, defined as zero. This condition ensures that *Darcy's Law* physics module calculates the barometric pressure drop [9].

## Initial values

The initial values for each of the main transport equations are presented as follows:

$$p_{t=0} = p_{op} \quad (14)$$

$$C_{CO_2,t=0} = 0 \qquad C_{N_2,t=0} = \frac{p_{op}}{R*T_{op}} \quad (15)$$

$$q_{CO_2,t=0} = 0 \quad (16)$$

$$T_{t=0} = T_{op} \quad (17)$$

Where: $p_{op}$ is the initial barometric pressure and $T_{op}$ is the initial temperature.

## Mixture properties calculation

The mixture properties, including density, viscosity, heat capacity and thermal conductivity, were calculated using a thermodynamics module. Each property was modeled as a function of temperature, pressure, and molar composition. However, to reduce computational time, these calculations were based on the inlet mixture compositions and a constant inlet barometric pressure.

## Computational aspects

As previously mentioned, COMSOL Multiphysics v5.6 CFD software was used. A mesh of ninety-nine (99) elements was created in conjunction with the one-dimensional geometry. A dynamic study was conducted from 0 to 540 seconds. MATLAB was employed as complemented software to perform various calculations.

# METHODOLOGY

## Axial dispersion coefficient models

Several models were evaluated to identify the most suitable for representing the dynamic behavior of the adsorption process. These models, along with their respective equations, are presented in the table below:

**Table 2**: Axial dispersion models evaluated.

| Model | Equation |
|---|---|
| No model (NM) | $D_L = D_m$ |
| Wakao-Funazkri (WF)[6] | $D_L = \frac{D_m}{e_{cat}}(20 + 0.5ScRe)$ |
| General model (GM) [6] | $D_L = 0.7D_m + 0.5dp_{cat}u$ |
| Rastegar-Gu (RG) [4] | $D_L = \frac{d_{p,cat}u}{Pe_z}$ <br> $\frac{1}{Pe_z} = \frac{0.7D_m}{Lu} + \frac{d_{p,cat}}{L}\frac{e_{cat}}{0.18+0.008Re^{0.59}}$ |

## Mass transfer coefficient constants

Table 3 represents a list of evaluated mass transfer coefficient (MTC) constants.

**Table 3:** Mass transfer constants evaluated.

| Reference | Value |
|---|---|
| [10] | $2.2\cdot10^{-2}$ [1/s] |
| [11] | $6.7\cdot10^{-2}$ [1/s] |
| [11] | $8.3\cdot10^{-2}$ [1/s] |

The evaluation of both axial dispersion models (ADM) and mass transfer coefficient constants (MTC) were performed simultaneously by pairing each model

with its MTC. As a result, twelve tests were conducted, divided into three sets of simulations.

**Table 4**: Sets of simulations performed.

| Set | Description |
|---|---|
| A | $k = 2.2 \cdot 10^{-2}$ [1/s]; with all ADM evaluated. |
| B | $k = 6.7 \cdot 10^{-2}$ [1/s]; with all ADM evaluated. |
| C | $k = 8.3 \cdot 10^{-2}$ [1/s]; with all ADM evaluated. |

## Breakthrough and saturation times

Two key design parameters for adsorption columns are the breakthrough $t_b$ and saturation time $t_s$. These parameters correspond, respectively, to the time when the mass transfer zone reaches the end of the column and the time when the column is fully saturated or in equilibrium with the flowing gas [12].

These parameters will be compared to verify that the mathematical model can be extrapolated to the design and optimization of an industrial scale reactor.

## Total quantity adsorbed

In addition to the $t_b$ and $t_s$ parameters, the total quantity adsorbed ($q_{total}$) is considered to assess the mathematical model and its relevance. Equation 18 presents the mathematical formula for its calculation [12].

$$q_{total} = \frac{F_{op} C_{i,in}}{m_{cat}} \int_0^{t_s} 1 - \frac{C_{i,out}(t)}{C_{i,in}} \partial t \quad (18)$$

Where: $F_{op}$ is the volumetric flow (m³/s), $\frac{C_{i,out}(t)}{C_{i,in}}$ represents the breakthrough curve, and $m_{cat}$ is the total mass of DFM inside the reactor (kg). To facilitate the rapid calculation of $q_{total}$, the breakthrough curve data for each run were first fitted to the Thomas model, as shown in Equation 19.

$$\frac{C(t)}{C_i} = \frac{1}{\exp\left(\frac{k_T q_T m_b}{F_{op}} - k_T C_i t\right) + 1} \quad (19)$$

By using the non-linear fitting tools in MATLAB, the values of $k_T$ and $q_T$ were determined. Subsequently, numerical integration was performed.

# RESULTS

## Breakthrough and saturation time

The breakthrough and saturation times obtained from the experimental set are presented in Table 5, while the results for each simulation set are shown in Tables 6-8.

To assess the accuracy of the simulation results, the relative error (RE) was calculated by comparing the simulated data with the corresponding experimental measurements. This comparison offers a quantitative evaluation of the model's predictive capability and underscores its potential reliability under the tested conditions.

**Table 5:** Experimental breakthrough and saturation times.

| Set | $t_b$ (min) | $t_s$ (min) |
|---|---|---|
| Experimental | 3.27 | 4.32 |

A comparison between the simulation results without the implementation of the ADM and the general model shows that the breakthrough and saturation times are closely aligned, both displaying similar trends of decreasing relative error as other mass transfer coefficient constants (MTC) are evaluated.

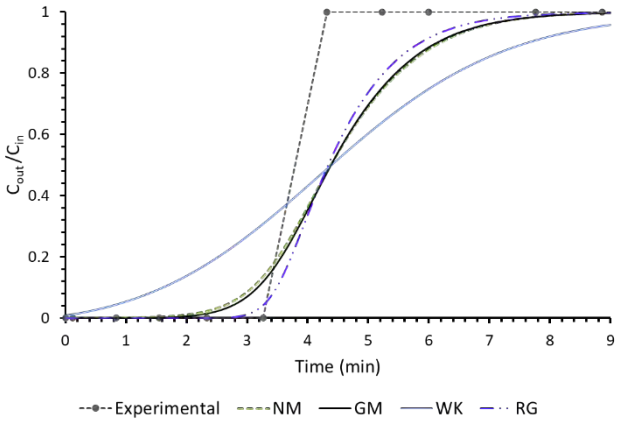

**Figure 2.** Axial dispersion model comparison. Set A

**Table 6:** Breakthrough and saturation times. Set A.

| ADM | $t_b$ (min) | RE $t_b$ (%) | $t_s$(min) | RE $t_s$ (%) |
|---|---|---|---|---|
| No Model | 1.08 | 66.9 | 8.16 | 89.0 |
| General Model | 1.32 | 59.6 | 8.15 | 88.8 |
| WK | 0.017 | 99.5 | 11.1 | 157.1 |
| RG | 2.53 | 22.6 | 7.72 | 78.8 |

In contrast, the Rastegar-Gu model demonstrates a significant improvement over the previously discussed models. The application of this model results in more closely spaced breakthrough and saturation times, leading to a steeper breakthrough curve. This corresponds to a shorter mass transfer zone, a characteristic that must be accurately represented in a DFM-packed bed, as observed in the experimental breakthrough curves (Figure 2-4). Furthermore, the Rastegar-Gu model consistently exhibits the lowest relative error for both breakthrough and saturation times across all three simulation sets, offering superior predictive capability under the evaluated conditions.

The application of the Wakao-Funazkri model

results in a broader breakthrough curve, characterized by breakthrough times of less than 0.20 minutes and saturation times exceeding 9 minutes. Moreover, this model shows significantly high relative errors, approaching 100% when compared to experimental data. These results suggest that the model lacks the precision required to accurately represent the dynamics observed in the experimental setup.

From a different perspective, the use of mass transfer coefficient constants of $6.7 \cdot 10^{-2}$ $s^{-1}$ and $8.3 \cdot 10^{-2}$ $s^{-1}$ leads to a significant reduction in the relative error associated with both breakthrough and saturation times. For example, for the general model, the relative error in saturation time is reduced by half, as observed in the simulation without an implemented model. Moreover, the relative error for breakthrough times decreases substantially by nearly one-third for the case without any model implemented and by one-sixth for the general model.

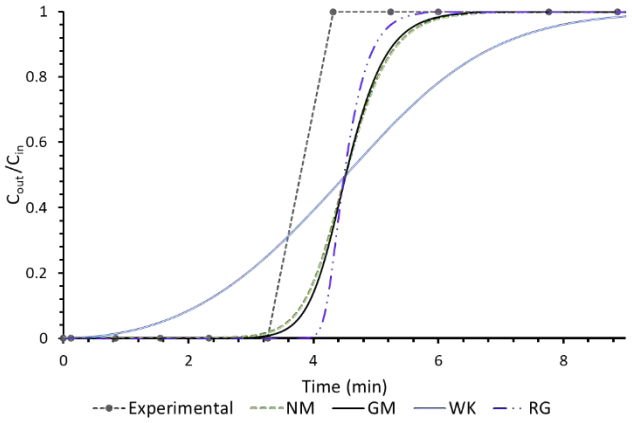

**Figure 3.** Axial dispersion model comparison. Set B

**Table 7:** Breakthrough and saturation times. Set B.

| ADM | $t_b$ (min) | RE $t_b$ (%) | $t_s$(min) | RE $t_s$ (%) |
|---|---|---|---|---|
| No Model | 2.48 | 24.1 | 6.30 | 45.9 |
| General | 2.75 | 15.8 | 6.13 | 42.0 |
| WK | 0.12 | 96.3 | 9.33 | 116.1 |
| RG | 3.88 | 18.8 | 5.58 | 29.3 |

The most favorable results are obtained with a mass transfer coefficient constant of $8.3 \cdot 10^{-2}$ $s^{-1}$, combined with the Rastegar-Gu axial dispersion model. This combination demonstrates superior consistency, yielding comparable reductions in relative error for both breakthrough and saturation times.

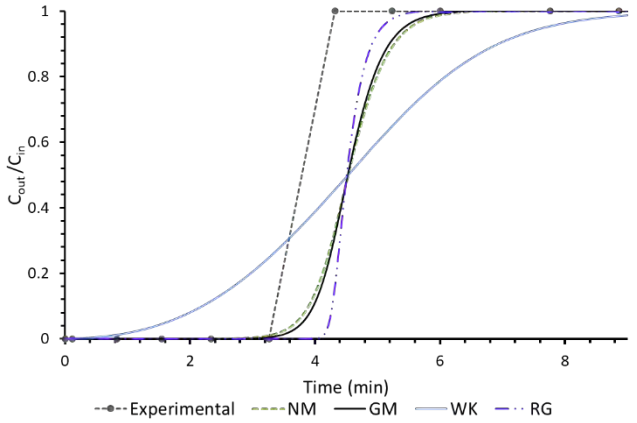

**Figure 4.** Axial dispersion model comparison. Set C

**Table 8:** Breakthrough and saturation times. Set C.

| ADM | $t_b$ (min) | RE $t_b$ (%) | $t_s$(min) | RE $t_s$ (%) |
|---|---|---|---|---|
| No Model | 2.67 | 18.3 | 6.08 | 40.8 |
| General | 2.93 | 10.3 | 5.93 | 37.4 |
| WK | 0.18 | 94.5 | 9.20 | 113.1 |
| RG | 4.03 | 23.4 | 5.42 | 25.6 |

## Total quantity adsorbed

**Table 9:** Experimental total quantity adsorbed.

| Set | $q_{total}$(mmol/g) |
|---|---|
| Experimental | 0.1645 |

The results for $q_{total}$, representing the total quantity adsorbed are presented in Table 9 for the experimental data and in Table 10 for each set of simulation runs. Due to the high relative errors observed, the Wakao-Funazkri axial dispersion model was excluded from the evaluation of $q_{total}$. This decision highlights the model's limitations in accurately representing the adsorption dynamics under the tested conditions, rendering it unsuitable for further analysis in this context.

**Table 10:** Results for the total quantity adsorbed for every set of runs.

| Set | A | B | C |
|---|---|---|---|
| ADM | | $q_{total}$(mmol/g) | |
| No model | 0.1894 | 0.1926 | 0.1929 |
| General | 0.1893 | 0.1926 | 0.1929 |
| Rastegar-Gu | 0.1883 | 0.1920 | 0.1925 |

**Table 11:** Results for the relative error, comparison between experimental and simulated $q_{total}$.

| Set | A | B | C |
|---|---|---|---|
| **ADM** | | Relative error (%) | |
| No model | 15.12 | 17.12 | 17.30 |
| General | 15.16 | 17.10 | 17.28 |
| Rastegar-Gu | 14.46 | 16.75 | 17.04 |

For all three simulation sets, the total quantity adsorbed exhibits only minor variations, with relative errors consistently around 15%. Regarding breakthrough and saturation times, the general model shows no significant improvement compared to simulations conducted without an implemented model. However, the Rastegar-Gu model remains the best option. In contrast to the behavior observed for breakthrough and saturation times, the relative error for $q_{total}$ increases in simulation sets B and C. Despite this, the combination of the Rastegar-Gu axial dispersion model and a mass transfer coefficient constant of $8.3 \cdot 10^{-2}$ $s^{-1}$ still provides the most accurate results in this context.

## CONCLUSION

This study compares various axial dispersion models and mass transfer constants used in the mass balance model of a packed-bed adsorption column. Additionally, it provides valuable insights into the CFD simulation of the carbon dioxide adsorption process utilizing DFMs. The general model does not demonstrate significant improvement, as its results are comparable to those obtained from the simulation set where no axial dispersion coefficient model was applied.

The findings indicate that the Rastegar-Gu axial dispersion model, combined with MTC of $8.3 \cdot 10^{-2}$ $s^{-1}$, provides an effective approach for accurately replicating the adsorption behavior of DFMs. These results represent a crucial starting point for the design, optimization, and scaling of dual-function reactors, facilitating their further development in $CO_2$ capture and utilization technologies.

## ACKNOWLEDGEMENTS

## ABSTRACT

As demand for long and accurate molecular simulations increases so too does the computation demand. Beyond using new, enterprise scale processor developments - such as the ARM neoverse chips – or performing simulations leveraging Graphics Processing Unit compute, there exists a potentially faster and more power efficient option in the form of custom hardware. Using hardware description languages it is possible to transform existing algorithms into custom, high performance hardware layouts. This can lead to faster and more efficient simulations but compromises on the required development time and flexibility. In order to take the greatest advantage of the potential performance gains, the focus should be on transforming the most computationally expensive parts of the algorithms. When performing molecular dynamics simulations in a polar solvent like water, non-bonded electrostatic calculations dominate each simulation step, as the interactions between the solvent and the molecular structure are calculated. However, simply developing a non-bonded electrostatics co-processor may not be enough, as transferring data between the host program and the Field Gate Programable Arrays itself incurs a significant time delay. For any changes to be made, competitive to existing calculation solutions, the number of data transfers must be reduced. This could be achieved by simulating multiple time-steps between memory transfers, which may impact accuracy, or performing more calculations in the custom hardware.

## INTRODUCTION

Molecular dynamics is the process of simulating molecular interactions at an atomic level, this allows researchers to divine information from chemical mechanisms that cannot be easily observed or measured. Depending on the configuration, simulations can be used to determine the reaction specific parameters such as the activation and Gibbs free energy of complex or expensive experimental processes in a way that may not be obtainable in a lab. As the simulations comprise of many bound and free atoms, the workloads are a prime candidate for parallelisation as the simulation space can be divided up into smaller chunks. This allows for the simulations to be run in supercomputers, which may have thousands of nodes, rather than just a few very fast machines. The majority of the simulations are run using either Central Processing Units or using Graphics Processing Units either as co-processors to the CPU or self-contained. CPU based calculations can be offloaded across one node by running multiple threads or across many nodes by utilising libraries like OpenMP. Simulations on a GPU backend are more complex, as they require the node to communicate and synchronize data especially if the simulation is running on a single-node, multi-GPU system, or on multi-node, multi-GPU systems. This also introduces the problem of communications latency between the co-processor – in this case, the GPU – and the host which must be taken into account when running very large scale or long simulations. This communications latency can be eliminated by performing all of the calculations within the GPU, which has been developed by AMBER using the PNEND backend. Whilst coming at the cost of scalability, as this method lacks inter-node communication, calculations are performed fast enough for that to be of limited benefit.

The CPU and GPU are not the only hardware available, however, Field Programmable Gate Arrays (FPGAs) are available for commercial purchase. They allow developers to design, prototype and deploy custom hardware layouts to chips in order to perform calculations in a time defined and massively parallel way. Designing a standalone FPGA molecular dynamics solver is outside the scope of this work, and has already been achieved though it did not act as a co-processor to an existing molecular dynamics program [8, 7, 9]. The aim here is to determine, for large simulations involving the In-Vitro Transcription (IVT) process, what parts of the simulation would be best handed off to a custom hardware environment.

## Molecular Dynamics

There are two varieties of Molecular modeling, molecular dynamics and quantum dynamics. Both have their distinct advantages and disadvantages. Quantum Dynamics is the most computationally demanding, with it realistically being limited to small molecules, but provides the most information and most accurate capture of real phenomena. Molecular dynamics on the other hand can be used to simulate large systems with reasonable accuracy in timescales of nano and microseconds. It achieves this by abstracting the difficult calculations performed by QM systems, into lookup tables which can be later adjusted to better replicate experimental results for the research area the force field has been tuned to. Prominent force-fields are both CHARMM-39 and AMBER, with both being tuned for bio-molecules and their associated structures [12]. The sometimes-extensive parameterisation into these force fields represents a major drawback to molecular simulations, as optimised force-fields struggle to accurately model molecular behaviour outside of the target domain [1]. Approaches exist that both attempt to mitigate this and to increase the scope of molecular simulations by allowing for non-ground state simulations, with the methods allowing for good accuracy whilst maintaining reasonable calculation speeds [2]. Many other abstractions are made to MD simulations to make them more performant, one of the most prominent is the treatment of solvents in large simulation domains. Due to the nature of a solvent, its presence within the simulation is typically the dominant force, and without further abstractions or clever modelling methods - such as periodic boundaries, the simulation of the solvent can take up a large portion of the compute time taken to simulate each timestep. In simulation domains that use Particle Mesh Ewald (PME), the number of atoms scales in line with Equation 1. Where N is a real number of elements within the simulation and where the equation models the growth in compute complexity for N.

$$Cost(N) = \mathrm{N}\log(\mathrm{N}) \tag{1}$$

Because the solvent particles are not numerous, it is necessary to simplify the structure and define the number of electrostatic interactions, with the most common water solvent model being TIP3P, which has a fixed charge and 3 polar interaction sites [4]. Even with this abstraction, when simulating large biomolecules, establishing periodic boundaries may only have a limited effect on the number of solvent molecules. An alternative is to replace the individual solvent molecules with a continuum dielectric model which is sampled to generate the electrostatic forces, These implicit solvent models can offer significant performance benefits, up to 100 times faster for specific simulations with the AMBER implementation of Generalised Born (GB) [10]. Despite the improvements in simulation speed, the scaling of strict GB computation complexity is worse than that for explicit methods, Equation 2. Where *n* is the real number of elements within the simulation solvent.

$$Cost(n) = n^2 \tag{2}$$

Despite the worse computational complexity implicit simulation methods can sample the solvent space faster. Though this faster simulation speed becomes more prominent when compared against explicit models with large solvent volumes. Using GB models also increases the design considerations of the simulation, as just as not all force-fields will produce accurate results, not all GB models are able to produce the same results in different simulation environments [3]. In addition, in order to facilitate the fast conformal sampling desired the collision frequency of the solvent is reduced, meaning that using implicit models necessitates the loss of viscosity modelling [10].

## Simulation Hardware

The majority of modern simulations are no longer performed on the CPU, both because of an increase in complexity and because there are alternative calculation methods in the form of consumer and datacenter GPUs which offer significantly better parallel performance. Instead, CPUs are used to orchestrate the management of the processes, and in multi-node simulations, to handle internode communication. There are two primary methods of GPU integration, the standalone method discussed already, AMBER PNEND manages all of the simulation steps on the GPU. Alternatively, the CPU will correlate and propagate the simulation timesteps, whilst the GPU performs all of the calculations on the data. This method is beneficial as it allows for the coordination of more resources, with simulations being able to be performed over multi-nodeGPU systems, though has a significant drawback in that the data is not available instantly. The primary method for connecting CPU and GPU systems is the PCIe bus, which has a non-trivial multi mi-

crosecond latency [13], especially between complex devices. This connection lag becomes more problematic as GPUs become more powerful, essentially meaning that devices are sitting idle for longer, increasing the amount of time required to run the simulation. New hardware designs such as Heterogeneous System Architecture can be used to mitigate this latency, which allows both devices to have a unified memory pool, eliminating the need to transfer the data. Other GPU bound processes also experience this problem, and other Host-Device communication protocols exist, which have lower latencies, such as NVLink for use in SXM socket GPUs.

As might be expected from CPUs, they are designed for general purpose compute tasks, GPUs whilst being specifically tuned for graphics operations, at least originally, are capable of doing a great many things. Though when performing computational work, the specific area of interest is typically the floating point mathematical operations they can carry out in parallel. This means that only a section of each chip will be operating, whilst the entire chip is powered on and operating. This presents a problem, as the throughput of the chip is limited by the number of physical compute cores and the operating speed of the chip. Increases in the chip speed lead to higher power consumption, including powered on components, such as memory banks, that are not being used. Additionally, in order to focus on Artificial Intelligence workloads like training and inference, manufacturers are reducing the amount of single and double precision floating point computing to dedicate more chip space to half and float8 workloads, though there are ways to recover some of this loss, and it is more prevalent in consumer grade chips [5].

In cases where standalone or co-processor GPU workloads are not supported, CPUs need to be used, at a significant performance penalty. This can be mitigated by using high core count chips, such as the Neoverse series of ARM chips, which are capable of scaling to 128 individual cores and performing 16 Fused Add Multply operations per cycle [6].

Instead of taking the general purpose approach to hardware, it is possible to use FPGAs, which sit in between the general purpose hardware solutions and completely custom Application Specific Integrated Circuits (ASICs), a category which both CPUs and GPUs fall into. As discussed earlier they allow for the design and implementation of custom hardware designs, which can be entire algorithms and allow for complete flexibility in their implementation; at least within the bounds of the FPGA manufacturer. The designs are typically limited in speed to the MHz range, which when compared to modern CPU and GPUs appears to be a significant performance reduction. FGPA designs are specific to the desired task, minimising the amount of general purpose overhead the chips must perform, and the large number of onboard components allows for them to maintain many data processing pipelines, which encourages parallel operation. Having the physical program laid out in the hardware allows for data to be processed at every step along it, rather than just at the instruction pointer like in a CPU. As well as MD solvers for FGPAs as mentioned earlier, solvers have also been created for ASICs, in the form of ANTON and MDGrape [14, 15]. With the FPGA hardware solutions holding their own against contemporary GPU hardware and the ASIC solutions capable of performing multi microsecond simulations per day. However, ASIC development costs are extraordinarily high, being in the region of Millions of USD, which places them out of the scope of many developers. In addition to this cost, because of the fixed nature of the designs, hardware must be extensively tested to ensure there are no bugs, with this verification typically being performed in FPGA based hardware. Both custom hardware solutions have significant efficiency benefits over complete GPUs however, which can consume up to 500W. This can be a critical factor, especially if simulations are being performed over a significant length of time, and helps to reduce the overall cost of the simulations, as whilst both custom solutions have a higher setup cost, the running costs can be significantly less.

## SIMULATION

Molecular Dynamics is a very capable tool for investing bio-molecules, as they are typically very complex and consequently reactions are not well understood. This is why simulation techniques must be implemented to investigate what cannot be observed directly. As such predicting protein physical properties and interactions with other molecules are important problems to the development of better healthcare. Whilst also being difficult to observe, some interesting but complex processes are also very expensive to investigate. One of these being mRNA, which even in research grade environments can easily consume USD$10,000 to USD$100,000 in materials over a set of experiments. mRNA investigation has gained significant traction after the pandemic, due largely to the fact that it uses the bodies own protein synthesis mechanisms to deliver the designed biological payloads, whether these be vaccines or therapeutic payloads. The process of mRNA manufacturing is an area of intense development, and in many cases determining specific reaction kinetics, such as the Activation Energy, Gibbs Free Energy and reaction coordinate diagrams would allow for the production of better higher order models. Which in turn would allow for experiments to be planned to both corroborate results and plot out the manufacturing space.

T7RNA transcriptase is a relatively large protein, and

the DNA molecular structures and mRNA chains are long, which prevents the use of tight periodic boundaries within the simulation. Not all of the reactions that involve these species are appropriate, the interaction of covalent bonds cannot be modeled using MD, and instead a mixed QM/MD approach must be used. Simulations that break ionic bonds however, are not restricted. This leads to the use of large solvent volumes which must be solved for each timestep. If a correlation between the simulation temperature and the Gibbs free energy was desired then an explicit solver would need to be used. Though in the case of the reaction coordinate diagram, a faster implicit solver could be used. Knowing that it is likely that the simulation run time will largely be dominated by electrostatic forces, the electrostatic interaction algorithm could make an impactful first target for transition to a FPGA based co-processor.

## Approaching electrostatic interactions.

In order to take advantage of the hardware co-processor being a part of the system, both the general purpose electrostatic algorithm, which supports both the explicit solvent model and inter-atomic electrostatic interactions, and the implicit solvent model should be implemented. As discussed previously, the hardware designs take up physical space on the FGPA, this is in antithesis to how CPUs work, which operate on information at the instruction pointer and is not dissimilar to how GPUs are designed, though the embedded pipelines tend to be more general. In order to take the greatest advantage of the physical nature of the design, most FGPA designs operate like pipes, taking data and using the design to transform it into the desired output, which allows for more data to be processed at a time. The downside of the physical layout is that there are finite resources available onboard, and increasingly complex pipelines reduce the number that can be fit in parallel onboard, which in turn reduces the calculation throughput.

### Designing

Since the idea is to use this as a co-processor to assist in calculations being performed on a host, it makes sense to convert parts of an existing simulation program to ensure maximum compatibility. This also allows for comparisons to be made between the co-processor and original code, to help eliminate any calculation drift or bugs that were introduced in the transfer. It is possible to convert the existing code almost directly into a Hardware Description Language (HDL) through a process known as High Level Synthesis (HLS). Though this approach is almost entirely automated, it can struggle to develop performant designs both due to the existing code semantics being designed for a general purpose architecture. The most performant option would be to port the algorithms by hand to HDL, which would allow for them to be tightly coupled to the physical resources onboard the FPGAs as it allows for complete control over the physical hardware implementation. This process is very labour intensive and requires all of the support infrastructure to be instantiated manually, such as the memory controllers. Though most importantly, especially so for long, mathematically intensive algorithms, it would require that all of the floating point units be designed and linked up by hand.

### Mitigation

Laying out the structure of the floating point operations manually in the hardware represents a significant amount of work, not only does it involve instantiating the hardware, but also determining how the data will flow through it. In order to do this in a scalable way, a semi-supervised automation approach is suggested as it would be easier to manage than a fully automated approach that would inherit the same problems as HLS. In this semi-supervised approach, the algorithm would be broken down into a graph representation, where nodes represent individual calculation steps, and the connections between them the flow of the data.

Once the pipeline is in this format, the physical layout can be organised by a series of optimisation algorithms, which determine where the most low-latency operations would be required, and where calculations are able to take longer to resolve. Once the fast and slow data paths have been determined, the configuration of the nodes can be transformed into instantiated floating point units, before being placed onto the FPGA fabric. This approach allows for designs to be optimised by configurable constraints, which supports flexible designs without having to rewrite large sections of the hardware design.

## CONCLUSION

Both FPGA and ASIC solutions are very competitive against modern hardware when running in stand-alone configurations, and will likely compare well in comparison to co-processor designs as they are all equally limited by the latency of the PCIe bus. Even outside of a speed comparison, FPGA solutions are more energy efficient than the alternatives making them a compelling choice. Though compared to stand-alone solutions an electrostatic co-processor is limited, it could potentially be beneficial for large solvent volumes within transcription simulations, and further developing a semi-supervised process for designing floating point algorithms would be helpful when expanding the design to become a self-sufficient solution.

## ABSTRACT

The deployment of $CO_2$ capture technologies at a large scale will largely benefit from the knowledge acquired during pilot testing. A mobile $CO_2$ capture pilot unit is currently being designed at the University of Liège. Here, the pilot plant is introduced, and the column sizing results are presented. The sizing was performed with a process model built in Aspen Plus. Overall, the pilot installation is expected to serve for process model validation, data collection and technology de-risking while assisting Belgian industries in their transition towards carbon neutrality.

**Keywords**: CO2 capture, MEA, pilot, ASPEN PLUS

## INTRODUCTION

As the European Union accelerates its efforts to decarbonize society, pilot installations play a pivotal role in validating both emerging and established technologies within the field of carbon capture (CC) [1]. Numerous CC pilot projects have been carried out in European countries such as the Netherlands, UK, Norway, Poland, Germany, Denmark, and Switzerland. This extensive testing has yielded parametric studies, validation of steady state and dynamic models, characterization of process emissions, determination of solvent corrosion behavior and degradation, comparison of different solvents, testing of different analytical tools, improved process modifications, and studies on control strategies [2,3]. Nevertheless, the high uncertainty across the whole $CO_2$ value chain prevents the large-scale deployment of such technologies.

Currently, supported by the European Union's Recovery and Resilience Facility, the Products, Environment, and Processes (PEPs) group at the University of Liège (ULiège) in Belgium is leading the construction of several key pilot installations, including a mobile $CO_2$ capture pilot plant, a $CO_2$-to-kerosene conversion unit, and a direct air capture (DAC) test bench.

The mobile $CO_2$ capture pilot plant will utilize chemical absorption to capture about 1 ton of $CO_2$ per day. The unit has been designed to operate with the benchmark solvent monoethanolamine (MEA). However, other solvents such as carbonates can be employed too. As shown in Figure 1, the installation is housed within three 20-foot shipping containers to support easy transport and deployment at various industrial locations. Two adjacent maritime containers enclose most of the process equipment as well as part of the electric cabinets. From these containers protrude the main columns. To render the unit more flexible, it comprises a gas pretreatment section that includes dust, $NO_x$, and $SO_x$ removal by bag filters, selective catalytic reduction, and alkaline scrubbing, respectively. These pretreatment steps are crucial to ensure the long-term performance of the unit by mitigating solvent degradation [1]. The plant is fully electrified, and its maximal power consumption is estimated to be 100 kW. Moreover, a heat pump is integrated into the system to enhance energy efficiency by recovering heat from the condenser and upgrading it for reboiler use. The automation and control system are centralized in the third container. The unit features a high degree of automation for remote and extended operation. This level of automation supports continuous data collection, which is essential for validating computational models and applying advanced control strategies, such as

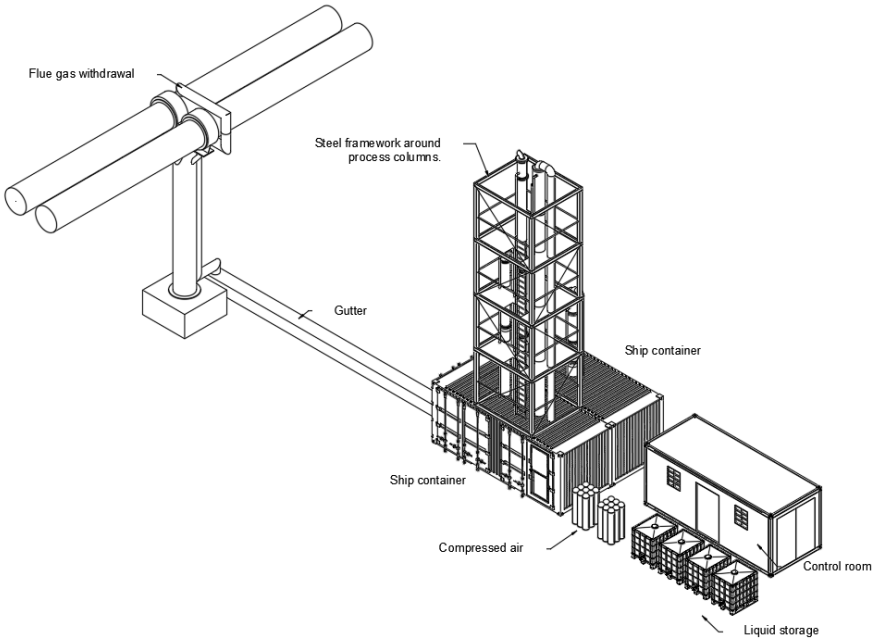

**Figure 1.** 3D plan of the $CO_2$ capture unit and its connection to the flue gas pipelines of the central heating station of the Sart-Tilman campus.

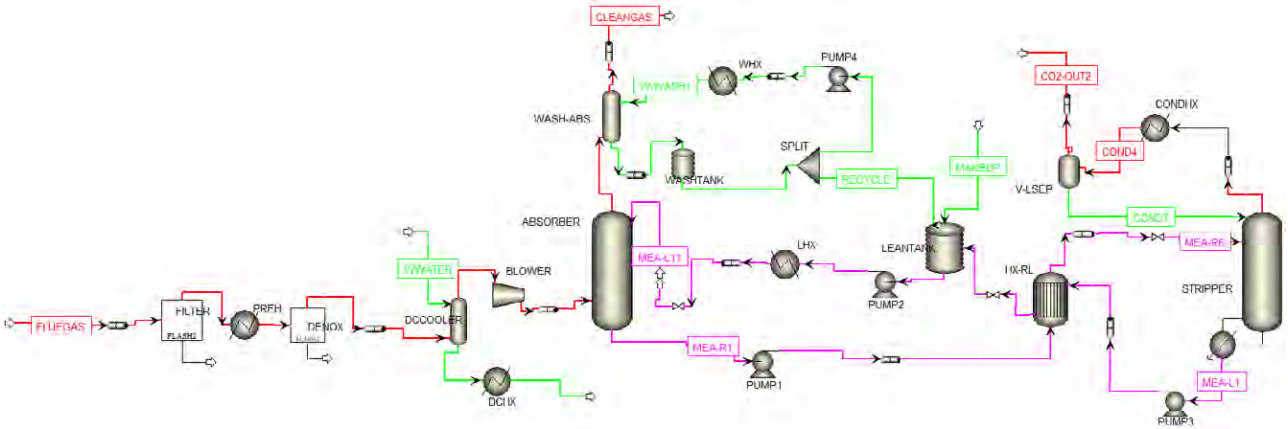

**Figure 2.** $CO_2$ capture pilot model in Aspen Plus.

machine learning algorithms [4,5]. Extended operation provides critical information to test solvent stability, understanding corrosion behavior, and refining steady state and dynamic process models—key factors for scaling up CC technology.

Commissioning and the first experimental campaigns are expected to take place at the central heating station at the Sart Tilman campus of ULiège in early 2026. Here, the pilot plant will treat a slipstream of the flue gases produced by a 7 $MW_{th}$ biomass cogeneration unit. All details of the unit, including the simulation files, PFD, P&ID, 3D plans, HAZOP tables and equipment, accessories, and instrumentation specifications will be made available after the commissioning and first experimental tests to facilitate the quick deployment of similar installations.

This work aims at introducing the model used to design the pilot and the main sizing results.

## MODEL DESCRIPTION

A model was built in Aspen Plus V11 to perform the basic engineering, see Figure 2. The thermodynamic model was set as the standard ENRTL-RK method [6]. Direct contact cooler, absorber (absorption and washing sections), and stripper (desorption and washing sections) were simulated using Rate-based modeling [6]. To simulate the reaction of $CO_2$ with the solvent, the following set of reactions were considered [6].

$$CO_2 + MEA + H_2O \rightarrow MEACOO^- + H_3O^+ \quad (1)$$

$$MEACOO^- + H_3O^+ \rightarrow CO_2 + MEA + H_2O \quad (2)$$

$$CO_2 + OH^- \rightarrow HCO_3^- \quad (3)$$

$$HCO_3^- \rightarrow CO_2 + OH^- \quad (4)$$

$$MEA + H_3O^+ \leftrightarrow MEAH^+ + H_2O \quad (5)$$

$$HCO_3^- + H_2O \leftrightarrow CO_3^{2-} + H_2O^+ \quad (6)$$

$$2H_2O \leftrightarrow H_3O^+ + OH^- \quad (7)$$

Reactions 1-4 are kinetic reactions whereas the rest are fast enough to consider them equilibrium reactions. Two different sets of values of the pre-exponential factors and activation energies were used for the absorber and stripper [6]. Some parameters of the rate-based model were tuned following the recommendations from [7] while the rest were left with the default values. A discretized film was only considered for the liquid phase. The number of discretization points was 5, whose thicknesses were fixed with a discretization ratio (ratio of film thickness between two adjacent discretization regions) of 10. Segments closer to the gas-liquid interface are thinner. The selected type of discretization option is geometric as it is expected to provide a better reproduction of $CO_2$ concentration profiles in the reactive film with fewer points. The reaction condition factor was 0.9 because of the fast reaction rate between $CO_2$ and MEA. The flow model was set to mixed to improve conversion.

The washing section of the absorber was modeled separately. Despite being inside the same vessel, this is consistent with the actual process as the washing section features a liquid collector with total draw-off to avoid mixing washing water and solvent inside of the absorber. On the other hand, the washing section of the stripper is modeled in the same block because of the presence of a collector-distributor above the first desorption bed. Both absorber and stripper were modeled using 20 stages while the direct contact cooler and the absorber washing section with only 10.

To facilitate conversion, the solvent loop is broken in the model. Consequently, the lean solvent loading fed to the absorber was fixed to the optimal value (determined by a sensitivity analysis using Equilibrium-based modeling) and a Design Spec (DS) was utilized to vary the lean solvent flow rate to achieve a given capture rate (usually 90%). Another DS was introduced to vary the reboiler duty of the stripper so that the amount of $CO_2$ recovered matches that captured in the absorber. Similarly to [8], the water balance in the solvent loop was kept by varying the temperature of the water fed to the washing section of the absorber. Thanks to these three DS, the composition of the lean solvent at both sides of the broken loop was very similar.

The model also includes most of the process pumps, piping, and gas filters. Due to the limited temperature of the gases fed to the pilot, an electric gas heater is going to be installed to ensure the effectiveness of the SCR filters. Finally, the $CO_2$ purification and compression sections are excluded from the model because they are not currently present in the pilot design.

## MODEL VALIDATION

Firstly, the reliability of the thermodynamic model was challenged by examining the prediction of the $CO_2$-MEA-$H_2O$ equilibrium at temperatures relevant for the absorber and desorber. As shown in Figure 3, the model provided an accurate determination of the $CO_2$ loading in MEA solutions in the required temperature range.

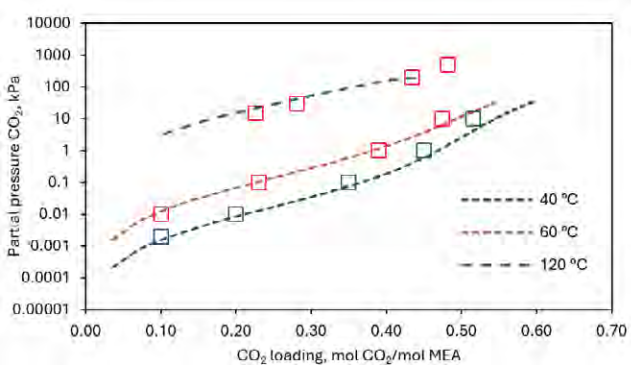

**Figure 3.** Validation of $CO_2$-MEA-$H_2O$ equilibrium. Experimental data (□) was obtained from [9].

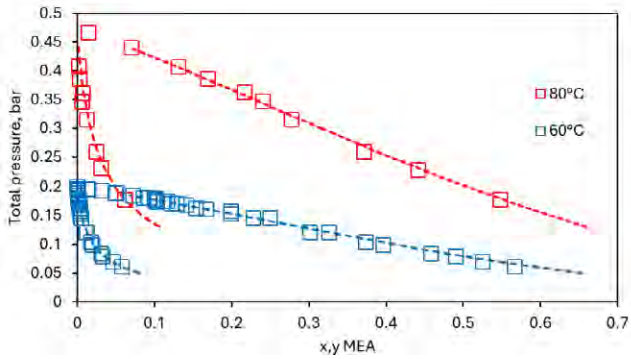

**Figure 4.** Validation of the MEA-$H_2O$ VLE equilibrium. Experimental data (□) was retrieved from [10,11].

MEA emissions are a concern from both an economic and safety point of view. Amine losses must be compensated by an MEA make-up stream. Additionally, MEA is a hazardous chemical for human health. The main points of solvent emission in the plant are the gaseous streams leaving the top of the absorber and stripper. A common solution to tackle the emissions is to install a water-wash section and a demister on the top of both columns. Experimental data from the MEA-water vapor-liquid equilibrium (VLE) was validated with the simulation tool before addressing the sizing of washing sections. Two temperatures were examined, 60 and 80°C. For both, there is a good agreement between the

experimental data and the model, see Figure 4. To further evaluate the capacity of the simulator to predict the emissions of the absorber and stripper, a literature survey has been conducted to identify MEA emission data from pilot plant installations. Measurements of total emitted MEA (in the form of vapor MEA, entrained droplets, and aerosols) were performed at the TNO's $CO_2$ capture pilot plant [12]. The MEA emission values were around 407-466 mg/STP $m^3$ (dry gas) right after the absorber. A water wash step and a conventional demister can reduce the total emissions to about 46%. A Brownian Demister Unit was necessary to further diminish the emissions to ~99%. From the total emissions encountered at the absorber outlet (before the water washing), it is expected that about 200 mg/STP $m^3$ are due to vapor MEA (gas temperature 30-40°C). This value is in the same range as the experimental volatility data when applied to the absorber top conditions, i.e., a concentration of vapor MEA of 285 mg/$Nm^3$ (50°C, 0.25 mol $CO_2$/mol MEA for the lean solvent loading) [13]. It is difficult to validate the data from the TNO's $CO_2$ capture pilot plant as the lean solvent loading is not provided and certain data must be traced from different documents. Nevertheless, a few simulations indicated that the predicted vapor MEA emissions on top of the absorber are in the same range.

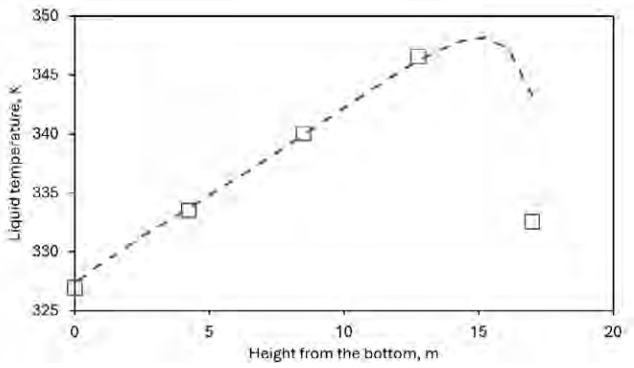

**Figure 5.** Validation of temperature profile in the absorber. Experimental data (□) was obtained from [15].

**Table 1:** Validation of absorber outputs. Data from [14].

| | Experimental | Model |
|---|---|---|
| $pCO_2$ in, kPa | 2.69 | 2.62 |
| $pCO_2$ out, kPa | 1.13 | 1.22 |
| Rich loading, mol/mol | 0.40 | 0.40 |
| T gas out, °C | 54.4 | 54.5 |

The capacity of the model to predict the behavior of the absorber was evaluated by comparing experimental data from pilot installations to simulated results. Two sets of data were utilized for the validation: Run 12 by Tobiesen et al. at Gløshaugen pilot (SINTEF-NTNU), Norway [14] and Run 1-A2 by Razi et al. at the large-scale Esbjerg CESAR pilot plant, Denmark [15]. Particularly, the absorber outputs and the temperature profiles along the column. The data shows the typical temperature bulb in the absorber temperature profiles caused by the exothermic $CO_2$ absorption.

Similarly, for the desorption unit, the simulation was validated employing data from two different installations: Run 1 by Tobiesen et al. at Gløshaugen pilot (SINTEF-NTNU), Norway [4], and Run 47 by Dugas at the pilot plant from the University of Texas at Austin [16]. The data from the latter pilot was retrieved from [7].

As portrayed in Figures 5 and 6 and Tables 1 and 2, the model was able to reproduce the experimental results to a certain extent. Increasing the number of column segments, the number of liquid thin film discretization points or changing the flow model did not improve the results significantly, indicating that the uncertainty could be coming mainly from the reliability of the kinetic data or the quality of the inputs for the modeling validation.

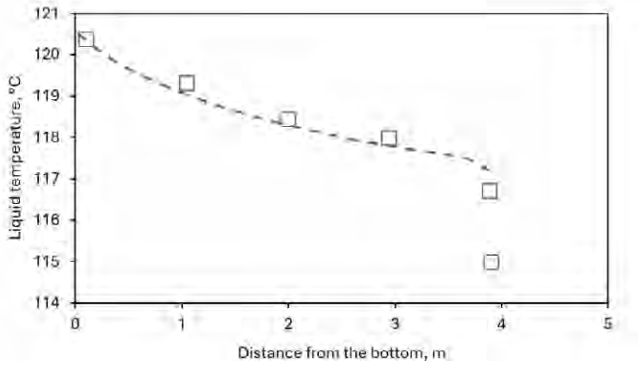

**Figure 6.** Validation of temperature profile in the stripper. Experimental data (□) was obtained from [4].

**Table 2:** Validation of stripper outputs. Data from [7].

| | Experimental | Model |
|---|---|---|
| $CO_2$ product, kg/h | 92 | 101 |
| Lean loading mol/mol | 0.29 | 0.24 |

Because of the limitations on data availability, validation results were obtained by modeling standalone equipment instead of the complete flowsheet. However, the latter was employed for the results discussed in the following sections.

## COLUMN SIZING

Packed columns typically operate in the range between 30-80% of the gas flooding velocity. The range of flue gas flow rates fed to the absorber was determined based on the desired capture scale (1 ton $CO_2$/day) and the $CO_2$ concentration encountered in the fumes produced by the biomass boiler of the Sart Tilman campus (about 10%$_{V\ dry}$). Considering the design (maximum) flue gas flow rate, 360 kg/h, and the available ASME pipes,

the absorber diameter has been fixed to 0.25 m allowing the column to operate at a flooding capacity between 50-85% in a broad range of solvent flow rates, 300-1000 kg/h. The gas flow rate could be varied between 180-360 kg/h without flooding the column (780 Kg/h solvent). Note that the flooding conditions are default parameters in Aspen Plus. The diameter of the stripper is equal to the absorber. In this regard, the stripper is oversized. However, this guarantees a larger flexibility of the vessel and the possibility of operating it under a slight vacuum.

To determine the required absorber height, the lean solvent concentration has been set to 5%$_w$ $CO_2$ (~0.23 mol $CO_2$/mol MEA) which is close to the optimum observed in the literature [17,18]. With the specified lean solvent conditions, a smaller column height can deliver the same performance at the expense of higher solvent flow rates than a taller one. Since the amount of solvent affects the reboiler duty, larger columns would lead to lower energy requirements in the stripper. Thus, there is a trade-off between CAPEX and OPEX. Similarly, a shorter stripper would require more energy to regenerate the solvent. The required packing height in both absorber and stripper was estimated by a sensitivity study. As shown in Figure 7, increasing the packing height reduces the specific reboiler duty. However, once a certain value is attained, further increases only lead to marginal improvement. Although it was not considered in the model, in practice, to limit the overall height of the pilot, the required packing in the absorber was distributed in two vessels. Thus, there are two absorbers connected in series in the pilot unit. The desorber height influences the required reboiler duty mildly, see Figure 8. As indicated in the figure, the diminution in energy consumption becomes marginal after 5 m of height.

In the model, the packing of both columns was the commonly employed Sulzer Mellapak™ 250.Y [6].

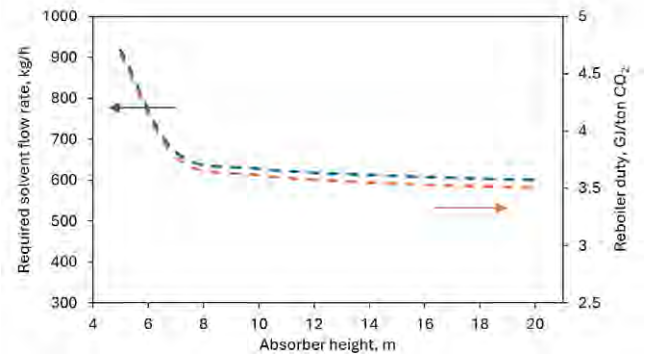

**Figure 7.** Effect of packing height in the absorber column on the specific reboiler duty.

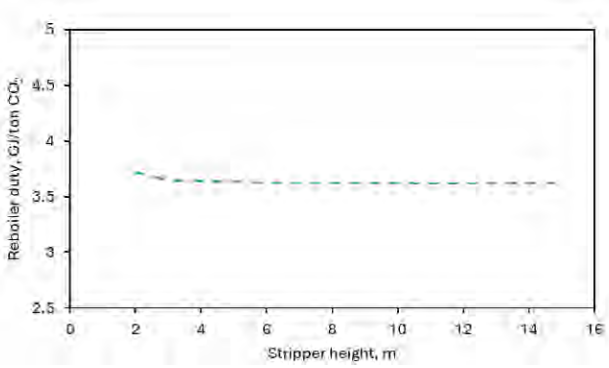

**Figure 8.** Effect of packing height in the stripper column on the specific reboiler duty.

At the top of the second absorber is the washing section which has the same diameter. The washing section fulfills two objectives: to control the water balance and to reduce MEA volatile emissions. As shown in Figure 9, both washing water temperature and flow rate can be used to keep the water balance. On the other hand, the packing height was determined using a sensitivity analysis on the recovery of volatile MEA, see Table 3. As indicated in the table, the washing water temperature and flow rate have a minor effect in comparison to the packing height.

For the stripper washing section, since the amount of volatile amine in the $CO_2$ product was fairly small after the condenser, the packing height was kept to 1 m.

**Table 3:** Sensitivity analysis on the recovery of volatile amine (%) by the water washing section on top of the absorber.

| | | Packing height, m | | | |
|---|---|---|---|---|---|
| **Water temperature, °C** | **Water flow rate, kg/h** | 0.5 | 1 | 1.5 | 2 |
| 30 | 1000 | 75.9 | 87.1 | 92.0 | 95.4 |
| 40 | 1000 | 75.7 | 87.0 | 91.9 | 94.5 |
| 40 | 500 | 75.0 | 96.5 | 91.6 | 94.2 |

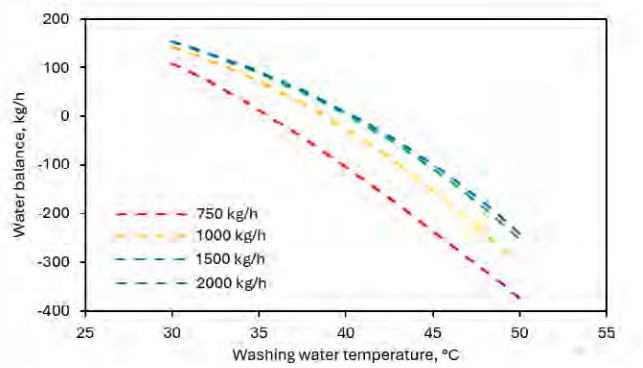

**Figure 9.** Water balance as a function of washing water flow rate and temperature in the washing section of the absorber.

## CONCLUSIONS

A 1 ton/day $CO_2$ mobile capture pilot is being designed at ULiège, Belgium. The main process equipment, notably the columns, have been sized utilizing a model built in Aspen Plus. From a sensitivity study, it was determined that the required absorber and stripper packed bed heights. Beyond those points, further increments in height did not cause a significant reduction in the reboiler duty. The effect of increasing the height is more marked for the absorber. The washing section of the absorber was set to ensure substantial recovery of volatile amines. Cooling washing water flow rate and temperature had minor effects on the separation. Being less relevant, the washing section of the stripper was shorter. Ongoing work will provide more details about the basic and detailed engineering of this project. Moreover, the models will be validated after the first experimental campaigns.

## ACKNOWLEDGEMENTS

The authors want to thank the organizations who are supporting this project and the coauthors of the present paper. In particular, the European Union Recovery and Resilience Facility is supporting the experimental developments. ## ABSTRACT

Process Systems Engineering (PSE) provides the advanced conceptual framework and software tools to formulate and optimise well-considered integrated solutions that could accelerate the sustainability transition within the industrial sector. The landscape of advanced PSE is poised to undertake a considerable transformation with the rise in popularity of open-source and script-based software platforms with predictive modelling capabilities based on modern mathematical optimization techniques. This paper highlights three leading equation-based platforms—IDAES[1], Modelica[2], and GEKKO[3] — that are increasingly utilised for the modelling, simulation, and optimisation of complex systems within the advanced PSE domain, alongside the strengths and limitations of each approach. Following this, we present a framework through which emerging techniques within the domain of Software Engineering could be leveraged to address these limitations, with a vision of improving the accessibility and flexibility of complex modelling tools for industrial partners.

**Keywords**: Pyomo, Industry 4.0, Process Design, Simulation, Process Synthesis

## INTRODUCTION

Process Systems Engineering (PSE) emphasises the ability to appropriately model, analyse, and optimise systems that relate to the design, retrofit, and operation of processes throughout its life cycle. Chemical plants often comprise multiple interacting processes, each of which involves complex, non-linear dynamics. Accurate models are necessary to establish the economic viability and chemical feasibility of processes of a plant and any changes. This is particularly relevant when considering the increase in global regulation requiring adherence to specific targets for greenhouse gas emissions and pollution reduction and the integration of renewable energy.

From the inception of PSE as a field of study, mathematical models often based on first-principles relationships have been developed to capture the complex interactions within unit operations and between components of plants. Relationships can also be data-driven using classical regression or modern machine learning methods, such as physics-informed neural networks (PINN) [1-2]. These models form systems of equations involving

[1] https://idaes.org/
[2] https://modelica.org/
[3] https://machinelearning.byu.edu/

integer variables, continuous variables, convex/non-convex relationships, and so on, that can be simultaneously solved to find the simulated solution (DOF=0) or optimal (and near-optimal) solution (DOF>0).

The PSE modelling approach is now well established and continues to progress with new advancements. Of particular note, several solvers have been developed specifically to solve formulated mathematical modelling problems, with both open source (e.g., IPOPT) and commercial solutions (e.g., BARON, Gurobi) accessible to researchers and industry [3]. These solvers represent verified programmes that enable practitioners to focus more on developing representative models, and less on the mechanics of how they are solved.

In a further step, Algebraic Modelling Languages (AML)s have also emerged to facilitate the faster development of models through systematic methods for expressing the equations using familiar mathematical notion and language. GAMS in the 1970's pioneered this level of abstraction, creating a comprehensive framework for capturing algebraic expressions. Similar open-source libraries built within modern programming languages are now seeing an upswing in use [4]. Of particular focus within this paper are the IDAES, Modelica, and GEKKO frameworks, each of which adopts an object-oriented approach to define properties and behaviours of modelled components, although with differing levels of abstraction [4-8]. To this end, IDAES and GEKKO are developed as open-source packages within Python, with components following a class structure that allows for the complex development of a system through the creation of modelled objects. In contrast, Modelica utilises a stand-alone language that follows the Modelica language specification.

The advance of AMLs has increased the accessibility of mathematical modelling, as demonstrated by the broad range of libraries developed within the Modelica community. However, broad adoption of such approaches is still limited by learning curve required to gain familiarity with the axioms and syntax of each respective framework, as well as broader experience in formulating models well suited to optimisation and proficiency with programming languages. Models are also constrained by the computational resources that are available to the solver.

At the opposite end of the abstraction spectrum lies process simulators such as Aspen Plus, Aspen HYSYS, gPROMS, CadSIM, DW Sim, and many more. Each of these simulators provide a "drag and drop" approach to adding/removing/modifying operations to a flowsheet while in the background models are being generated and solved. Advanced users can customise nearly all aspects of the flowsheet but not the mathematical model. Furthermore, once a complex flowsheet is built, there is no possibility to export the mathematical model to form a light-weight representation that could be solved independently.

In this paper, we discuss the IDAES, Modelica, and GEKKO frameworks and propose that advances within the domain of Software Engineering can be leveraged to better address current deficiencies in abstraction, computational resourcing, and modern software application development practices. Nearly all simulators predate modern software engineering practices (e.g., only DW Sim has an interactive web-based platform). As a result, their adoption of such practices and advances are constrained. To this end, we present a framework through which complex modelling capabilities can be enhanced and integrated into a unified and accessible software tool that follows a modular architecture, allowing for the integration of individual capabilities, developed as stand-alone modules, into a central system. This framework has a focus on User Experience (UX) based design, with data structures that are obscured from the user behind a UI, allowing for information to be stored in a standardised form that can be filtered for use across multiple analysis modules. Significantly, this framework leverages containerisation and cloud orchestration technologies to improve accessibility and performance by removing conflicts that arise when producing software solutions for heterogeneous hardware configurations and Operating Systems.

## MATHEMATICAL OPTIMISATION FRAMEWORKS

The frameworks explored within this paper are free-to-use and have established their capacity for the modelling, analysis, and optimisation of complex systems via the formulation of mathematical models created via an abstract AML syntax that are then passed to open source and commercial solvers. While the specifics of how this is accomplished differs between frameworks, as does the domain focus and accessibility model, there are strengths and limitations that are common across all approaches and speak to the broader need to improve accessibility and extendibility such that the benefits of mathematical models can be fully leveraged by those within the chemical process engineering domain.

IDAES and GEKKO are standalone packages, with modelling components developed within the Python programming language. GEKKO utilises its own AML formulation to achieve this, while the IDAES Core Modelling Framework (IDAES CMF) is built on top of Pyomo, a general-purpose Python AML. As Python packages, the creation of models within GEKKO and IDAES is achieved via the instantiation of defined classes as modelling objects. Models are specified as high level objects, from which complex behaviours can be captured through the incorporation of defined constants, parameters, and variables.

The intra-connectivity of models is established by relating model components through connections, intermediates, and equations in the case of GEKKO and arcs, expressions, and constraints in the case of IDAES. Once defined, models are optimised for a given objective function [9-11,6,8].

Modelica in contrast utilises its own language with a standardised approach for defining variables and behaviour. There are inherent trade-offs between these approaches. On the one hand, a proprietary syntax like that developed for tools within the Modelica framework ensures the consistency of modelled components and the compatibility of analysis techniques. Conversely, the Python based approach of IDAES and GEKKO presents a lower barrier to entry for users who are already familiar with the underlying syntax and concepts within Python as a higher level programming language, while also retaining the ability to integrate broader functionality within the Python ecosystem into the modelling process.

A key distinguishing feature between the frameworks is the primary use cases that they support. GEKKO is intended primarily for the dynamic optimisation and control of linear and non-linear systems, with an APMonitor executable providing solving capabilities. Specific libraries can be imported into GEKKO to extend this base functionality to incorporate Deep Learning and Machine Learning, as well as a chemical library that defines a flowsheet class, chemical compounds and thermodynamic properties. The relationship between GEKKO and its chemical library extension is somewhat analogous to that of IDAES and Pyomo, with Pyomo as a domain agnostic optimisation package and IDAES as a standalone library that leverages Pyomo capabilities to model problems within the domain of chemical engineering [12]. A core difference is that as a standalone modelling package, IDAES is much more feature-rich and comprehensive, with the core library providing capabilities to model unit operations and properties within chemical processes [8]. Specific libraries are also available for domain specific processes such as power generation, materials processing, and water purification, as well as further modelling extensions that support surrogate modelling and parameter estimation approaches and the incorporation of deep learning models trained through standard frameworks such as PyTorch and Keras [13]. As a well-established stand-alone modelling language, the ecosystem that has developed around Modelica is broad. Modelica has thus emerged as a framework for use in simulation of multi-domain dynamic systems, with libraries adhering to the Modelica specification released under both open source and commercial licences. This reflects the core strength of Modelica, being the ability to integrate dynamics across multiple domains into a single model for a given system [5,7,14].

While there are specific applications for which each framework is well suited - real-time optimisation and control for GEKKO, chemical process systems for IDAES, and multi-domain system modelling for Modelica – there are broader strengths and limitations that are applicable to all EOM frameworks. An obvious strength is the comparative performance of mathematical modelling approaches vs traditional simulation, due largely to the commercial and open source solvers that are available for computing solutions for well formulated models [3]. This is particularly relevant when considering the non-linear relationship between model complexity and solution space, for which the solving performance of traditional first principles based simulation engines becomes a clear bottleneck [15]. More significantly for chemical process engineering is the degree of customisation and extensibility that is available to an end user through mathematical modelling. Within traditional simulation engines, users are generally unable to access the expressions that govern the behaviour of modelled components. Furthermore, it is challenging to define and integrate new components. In contrast, using an AML it is possible to build new unit operations or property packages to suit the individual needs of a modelled system. This is exemplified within IDAES through their modular property package and reaction frameworks, as well as their generic *UnitModelBlockData* class, each of which can be implemented with custom configurations. In cases where dynamics are unknown for a given component within a system, surrogate models can be developed through machine learning techniques to capture the desired behaviours [16].

Common underlying limitations for all frameworks can broadly be captured under the scope of usability, accessibility, and extendibility. While the adoption of programming language-like syntax has greatly improved the usability of EOM frameworks, users are still faced with a steep learning curve to master the syntax and implementation of each AML, as well as the broader concepts and logic associated with the use of programming languages and environments. This is particularly challenging when considering IDAES wherein multiple layers of inheritance are implemented on top of base Pyomo classes, requiring a high degree of familiarity with the underlying source code to gain the full benefits. Furthermore, upon mastering the syntax and concepts of each AML, there is still a significant effort required to ensure that models are adequately specified with the correct number of degrees of freedom and can be initialised [17]. This limitation is recognised, with frameworks implementing approaches to abstract away the complexity of the underlying AML behind a User Interface (UI). In the case of GEKKO and IDAES this is limited to visualising and manipulating flowsheets after they have already been defined programmatically, although IDAES has also taken steps to provide users with Command Line Interface (CLI) diagnostics [17]. Modelica has open source and commercial tools to

provide a UI, however the open source UI of OpenModelica is somewhat unintuitive and outdated, while access to commercial versions is naturally constrained by cost. This issue of commercial vs open source development is also a core consideration for accessibility and extendibility. While the Modelica language specification has contributed to the development of an ecosystem of analysis packages, the creation of multi-domain models is predicated on the willingness and ability of the end user to pay for each of the commercial libraries that they require. Furthermore, to gain the best user experience when using these libraries, further costs must be borne to access relevant commercially developed UIs. Consequently, while the established nature of Modelica as a framework and its standardisation as an AML contributes to its extendibility, accessibility and collaboration is limited by its inherent commercial realities. GEKKO and IDAES are less established as frameworks but are entirely open source in their development, meaning that functionality is well suited to customisation and extension for user specific cases. Furthermore, the Python based nature of GEKKO and IDAES means that they are inherently compatible with other libraries that exist within the Python ecosystem, which is immense.

As a result of these observations, there is clear scope for the development of a generalised and intuitive, user experience-driven platform that is framework agnostic. Such an approach would provide the usability benefits of traditional process simulators, while retaining the extendibility and performance provided by mathematical frameworks. There are clear benefits that would result from such development, foremost of which is the ability to leverage the strengths of each framework and compare the resultant analysis for a given model. This benefit is not limited to EOM frameworks, as data within such a platform could be stored in a traditional database rather than existing explicitly within the context of any individual AML. Consequently, further forms of analysis that are not EOM based (such as Pinch Analysis or Heat Exchanger Network synthesis) could be performed on the same data, allowing for greater access to and integration of insights from such techniques. This would be of great benefit to chemical engineers seeking to design or analyse processes, as it would remove a lot of the time that is spent manually creating models across different frameworks and updating each with the results of another, as is the case in the current status quo.

## FRAMEWORK FOR A COMPREHENSIVE PLATFORM

There are two broad classes of problems that present bottlenecks to the uptake of robust equation-based modelling techniques: usability and compatibility. The modelling frameworks explored within this paper are all reliant on the user's familiarity with programming languages and development environments. Furthermore, each framework has its own respective axioms and syntaxes, with sophisticated capabilities inaccessible without significant legwork on the part of the user. This has contributed to the lack of extensive adoption of such frameworks outside of the research space.

Compatibility challenges extend beyond the scope of equation-based modelling, reflecting an issue that is more fundamental to modelling and optimisation in general: multiple forms of analysis and degrees of abstraction are often desirable, and it is difficult to integrate the insights from one approach into the formulation of another without considerable effort on the part of the end user. We propose a solution to these issues in the form of a comprehensive platform developed along software engineering methodologies.

### Addressing Usability Concerns

The fundamental issue at the core of usability challenges is the barrier to entry presented by the complex and abstract nature of modelling frameworks and syntax, as well as the inherent challenges in debugging models and interpreting results. We propose that to address this, a UX-focused UI should be developed independently from any single modelling framework. Interfaces should also be designed with a view of integrating further analysis and modelling functionality in the future, ensuring that the final solution does not suffer from the clutter that is associated with frequent retroactive additions. To this end, the design process should begin with initial consultation with intended users to elicit functional requirements and identify pain points with existing approaches, from which multiple draft prototypes should be developed to capture functionality and workflows. These steps should be repeated to select and refine the implementation, following which components should be developed from final prototypes.

The separation of concerns between front-end UI and backend data structures and modelling logic is part of a higher-level modular architecture that is a core feature of this framework. The modular components fall into the following three categories: front-end UIs, analysis, and data structures and APIs. UIs and analysis modules are developed independently of each other. The Front-end should have a focus on intuitive design and data interpretation, while analysis modules should be standalone packages. The link between front and back-end elements is established through a final module, which defines data structures and APIs.

Data structures can capture an exhaustive amount of information about a given system component beyond the scope of any individual modelling framework or form of analysis and can be informed by live sensor data. As further functionality is integrated into the platform,

additional properties can be added to the existing data structures as required, with new APIs managing the communication between the new module and the database. It is thus possible to retroactively integrate new features or properties without breaking existing models. Model data can also be filtered to display different abstractions or engage in multiple analysis functionalities, with each of them manipulating and modifying a shared data source, providing the user with a level of control over the detail and complexity of the UI, allowing for use by both basic and advanced users.

A modular architecture is further beneficial for maintaining code as modifications to the functionality of one module will not break the functionality of another. This supports a 'plug and play' approach for developing additional functionality. Each module is developed as a standalone package with a defined set of required parameters and accompanying tests to verify functionality. Database migrations are applied to integrate new properties into models, with UI components developed to manage interactions with the new module and an API layer developed to facilitate the communication of data between the database and the module.

## Leveraging Cloud Computing Strategies

The outlined modular architecture is well suited to deployment across a distributed system in the form of a microservice architecture [18]. This is achieved through a containerisation approach, which packages a process alongside its dependencies into a lightweight container image. Container images also define an Operating System (OS) that is required for the process, enabling processes with different OS requirements to run on the same system. In a microservice architecture, a complex application is separated into its constituent modular elements, each of which is then packaged as a containerised process. Containerisation has several benefits compared to more traditional monolithic application architectures [19]:

- Resource utilisation can be handled at a more granular level as each containerised process has its own respective allocations.
- The number of replicas for a containerised process can be increased or decreased. Requests can be handled by any replica.
- The impact of any given process failing is greatly reduced. functional replicas will automatically take up the jobs assigned to a failed container. Furthermore, containers can be quickly recreated as needed.

Kubernetes is a container orchestration platform that facilitates the management of containerised applications across a cluster of networked computational resources by encapsulating them within a higher-level "pod". This is achieved through a self-adaptive approach that leverages a control approach to match the running state of the application to an expected state. In practice, this means that Kubernetes allows for self-healing behaviour, wherein failed processes are automatically restarted, and autoscaling, where the number of container replicas for a given process will automatically increase and decrease in response to dynamic demand. A microservice architecture deployed to a Kubernetes cluster is visualised within figure 1.

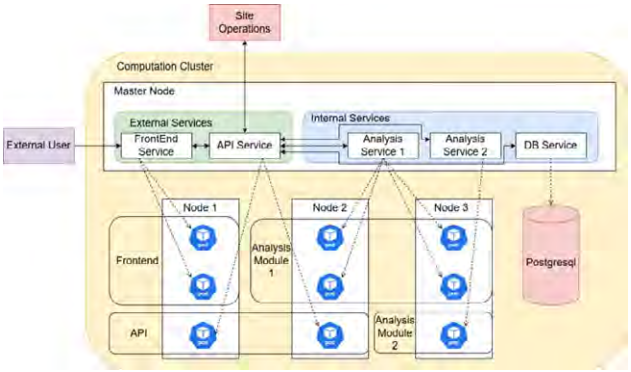

**Figure 1:** Microservice architecture deployed on Kubernetes.

As data is created or modified within the front-end, information is created or updated within the linked database. Upon engaging analysis functionalities, API calls extract relevant information from the database and send it to the relevant module. The results of the analysis are then returned to the database and displayed within the associated UI component. All interactions between a user and data within the platform are managed via UI components, with the actual data handling managed through APIs.

The integration of Kubernetes allows for an economic model that supports simultaneous commercial and open access releases, without limiting accessibility to core functionality. This can be achieved through the release the end software as a standalone containerised application that can be run on a local machine, or the release of standalone modules that could be integrated into other custom software. Conversely, more advanced users that wish to collaborate with others over shared models or require additional access to computational resources for parallel analysis could pay for access to the Kubernetes version, which is hosted externally. Such a financial model would support the continued development and maintenance of the software, while also ensuring that libraries remain open source and core capabilities are accessible.

## Key Directions for Future Research and Development

To adequately fulfil the vision that our presented

framework represents, the software platform must achieve the following outcomes:

- UI development should center around user experience, with primary consideration given to intuitive workflows.
- The platform should be agnostic with regard to modelling frameworks. Backend analysis modules should be able to automatically generate, export, and solve models using a framework chosen by the user.
- It should be freely available for research and development, with modules released as standalone, open source packages.
- It should leverage cloud computing paradigms such as containerisation to achieve optimal performance through scaling actions and avoid conflicts of OS or hardware configurations.

We envisage that such a platform would naturally fill a gap within the existing modelling ecosystem, improving accessibility to such tools and potentially extending in future to include multi-domain level analysis through the integration of additional modules.

## CONCLUSIONS AND FUTURE VISION

This paper has outlined the development of abstracted modelling within the process engineering domain, from initial verbose mathematical models to modern process simulation software and mathematical modelling frameworks. Three mathematical frameworks were chosen for their relevance to the chemical process engineering domain, as well as their individual implementation. Strengths and weaknesses for each framework were outlined, establishing advantages of mathematical modelling for performance and customisation while also highlighting the usability concerns associated with the steep learning curves required to gain proficiency. We then presented a framework through which the strengths of traditional process simulators can be combined with the powerful functionality of equation-oriented modelling via the adoption of modern software engineering concepts and methodologies for the development of a comprehensive software solution that allows for the integration of independent modules behind a single UI.

The vision we present for a software solution that follows the implementation path of our proposed framework is that of a centralised, comprehensive platform that serves as an intuitive interface through which users can access complex functionality. This platform would greatly contribute to the accessibility of advanced modelling capabilities by removing the requirements of familiarity with AML syntaxes and programming environments. Furthermore, the abstract nature of the data structures within this platform would also contribute to the integration of multiple disparate forms of analysis into a single shared knowledge base, greatly increasing the ability for engineers to integrate insights from multiple sources into a single model.

## ABSTRACT

This study focuses on enhancing heat and shaft power integration within existing nitric acid production processes to optimize waste heat recovery and identify opportunities to improve process efficiency. A digital twin of the operational plant is utilized, which features a dual-stage pressure nitric acid production process with a capacity of 50 tons/h of $HNO_3$ (100% equivalent). The authors conducted a simultaneous analysis of the thermal energy potential and the expansion capacity of tail gases to effectively fulfil the primary process's heating, cooling, and power requirements while increasing steam generation through waste heat recovery, all without compromising plant throughput. The proposed process modifications lead to a 23.8% reduction in cooling water usage and a 35.6% decrease in $CO_2$ equivalent emissions while achieving a 13.1% increase in steam generation. These utility savings culminate in a 10.2% enhancement in plant throughput.

**Keywords**: Energy Efficiency, Heat Exchanger Network, Modelling and Simulations, Process Synthesis.

## INTRODUCTION

Ammonia production contributes approximately 1.8% of global annual $CO_2$ emissions, equivalent to 439 million tons of $CO_2$ [1]. Nitric acid is produced through three well-established methods, with ongoing process improvements focusing on reducing nitrogen oxides ($NO_x$) in tail gases and enhancing productivity and energy efficiency. The mono-pressure process has been extensively studied; for instance, optimizations conducted in the ProSimPlus environment have led to a 55% reduction in NOx emissions and an 18% increase in productivity. However, this method necessitates cooling water at 5 °C, which requires additional energy for cooling [2]. A significant area of research remains centred on reducing nitrous oxide emissions in tail gases [3]. Recently, Clariant reported a reduction of $N_2O$ emissions by 690 kilotons per year of $CO_2$ equivalent using a new catalyst [4]. Catalyst ageing seriously challenges operating costs and $N_2O$ emissions, prompting extensive research efforts [5]. An exergy destruction analysis conducted on Ostwald-based plants indicated a high potential for improving energy efficiency [6]. Exergy analysis has been utilized for environmental impact assessments [7] and has subsequently been enhanced by sustainability evaluations, resulting in a 3% improvement in exergy efficiency through adjustments in compressor pressure [8]. Simulations of nitric acid plants have primarily focused on identifying optimal process parameters [9] and have been conducted using Aspen HYSYS [10] and Aspen Plus [11] commercial software to explore process parameter modifications and increase the concentration of final products. Some researchers have also implemented a pinch-based approach to improve nitric acid plants' heat exchanger network, highlighting a potential utility savings of 14%, excluding specific process changes and utilities [12].

Despite extensive research focused on optimizing nitric acid production processes, there remains a notable deficiency in the investigation of plants employing a dual-pressure method. Furthermore, energy consumption and emissions challenges continue to pose significant issues as society shifts towards circular production and consumption models. This study presents the findings from an investigation into dual-pressure nitric acid production through simulations of an existing facility. It analyzes energy and emission savings potential by integrating heat

and shaft work power. The theoretical potential and specific process modifications are examined using a simulation model, and the economic viability of these enhancements is also assessed.

## MATERIALS AND METHODS

The approach employed in this study is based on simulating the existing processes of a dual-pressure nitric acid plant coupled with a thermodynamic analysis of energy utilization. This approach aims to identify process modifications that can enhance the plant's overall performance. The integration of simultaneous thermal and shaft work power is evaluated while adhering to the existing equipment's constraints and the proposed solutions' economic viability. A comprehensive workflow outlining this approach is shown in Fig. 1.

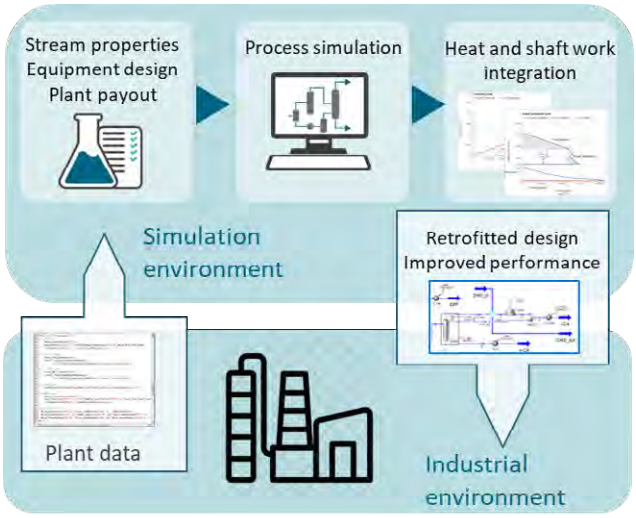

**Figure 1.** General workflow of the proposed method.

The investigated nitric acid plant was simulated utilizing UniSim Design software [13], and the simulation process flow diagram (PFD) is shown in Fig. 2.

### Simulation model set-up:

Materials are ammonia, air (feedstock), and nitric acid with a concentration of 60%wt in water (product). Fluid packages are extended NRTL and PRSV [14].

#### Chemical reactions

Ammonia conversion (conversion)

$$4NH_3 + 5O_2 \rightarrow 4NO + 6H_2O \ (-227 \ \frac{MJ}{kmole \ NH_3}) \quad (1)$$

$$4NH_3 + 3O_2 \rightarrow 2N_2 + 6H_2O \ (-317 \ \frac{MJ}{kmole \ NH_3}) \quad (2)$$

$$2NH_3 + 2O_2 \rightarrow N_2O + 3H_2O \ (-276 \frac{MJ}{kmole \ NH_3}) \quad (3)$$

Cooling and absorption of $NO_x$ (equilibrium)

$$2NO + O_2 \rightleftarrows 2NO_2 \ (-56.6 \frac{MJ}{kmole \ NO}) \quad (4)$$

$$2NO_2 \rightleftarrows N_2O_4 \ (-29.3 \frac{MJ}{kmole \ NO_2}) \quad (5)$$

$$3NO_2 + H_2O \rightleftarrows 2HNO_3 + NO \ (-12.7 \frac{MJ}{kmole \ NO_2}) \quad (6)$$

$$3N_2O_4 + 2H_2O \rightleftarrows 4HNO_3 + 2NO \ (33.3 \frac{MJ}{kmole \ N_2O_4}) \quad (7)$$

Tail gas treatment (catalytic)

$$2H_2 + O_2 \rightarrow 2H_2O (-484 \frac{MJ}{kmole \ O_2}) \quad (8)$$

$$2N_2O \rightarrow 2N_2 + O_2 \ (-81.6 \frac{MJ}{kmole}) \quad (9)$$

$$CH_4 + 2O_2 \rightarrow 2H_2O + CO_2 (-802 \frac{MJ}{kmole \ N_2O}) \quad (10)$$

$$CH_4 + 2NO_2 \rightarrow N_2 + 2H_2O + CO_2 \ (-435 \frac{MJ}{kmole \ NO_2}) \quad (11)$$

$$CH_4 + 4NO \rightarrow 2N_2 + 2H_2O + CO_2 \ (-291 \frac{MJ}{kmole \ NO}) \quad (12)$$

$$2CH_4 + 3O_2 \rightarrow 2CO + 4H_2O \ (-519 \frac{MJ}{kmole \ CH_4}) \quad (13)$$

$$CO + H_2O \rightarrow CO_2 + H_2 \ (-41.4 \frac{MJ}{kmole \ CO}) \quad (14)$$

$$NO + H_2 \rightarrow NH_3 + H_2O \ (-378 \frac{MJ}{kgmole \ NO}) \quad (15)$$

#### Specific variables

- $CO_2$ emission (Nat. gas) is 0.201 kg/kWh;
- $CO_2$ emissions of electricity (nat. gas) is 0.490 kg/kWh;
- nat. gas price is 0.110 €/kWh;
- calorific of natural gas is 42,000 kJ/m$^3$;
- electricity price is 0.24 €/kWh;
- nitric acid price is 0.23 €/kg;
- interest rate is 10%; project lifetime 5 years.

The following utilities are used: steam (2.2 MPa), electricity, cooling water, natural gas (97.4% $CH_4$, 2.6% $N_2$), and $N_2/H_2$ mixture (75% $H_2$, 25% $N_2$).

#### Process units' simulation methods

- Ammonia conversion: conversion reactor;
- Cooling: chemical equilibrium and heat transfer;
- Heat exchangers: sizing-based rating;
- Absorbers: rate-based radfrac model;
- Rotating units working curve-based rating.

The main modelling assumptions are feedstock flow rate is constant, heat losses not accounted, steady-state simulation mode, pipe pressure drop is not considered.

### Heat and shaft work power integration

The energy utilization efficiency in the simulated nitric acid production facility is evaluated in terms of thermal energy and mechanical power output. As detailed in work [15] and refined by various researchers, a systematic graphical methodology is implemented to identify

opportunities for optimizing heat recovery within the current process. This approach also aims to improve mechanical power generation, as suggested by Varbanov et al. [16], through strategic modifications to the process. The method leverages the thermodynamic potential of tail gas to produce mechanical power, which is subsequently harnessed for compressor operations. The proposed enhancements are scrutinized against the operational constraints of turbines and compressors. The maximum energy recovery potential is quantified while ensuring the plant maintains a consistent output level in alignment with the established baseline scenario. The analysis of capital costs for heat exchangers is conducted following the guidelines in [17]. In contrast, the capital costs for steam turbines and system upgrades are assessed according to results in [18], incorporating factors related to materials, pressure, and temperature. The integrated solution developed is evaluated for its capacity to enhance plant throughput by optimizing nitric acid production while adhering to the performance limitations of the existing equipment and the realized energy savings. The results from this analysis are contrasted with the baseline scenario, with particular emphasis on key performance indicators relevant to the plant's operation.

## CASE STUDY

The nitric acid production process under investigation commences with the catalytic conversion of ammonia to nitrogen monoxide through the oxidation of ambient air at low-pressure conditions. The resulting nitrogenous gases are directed to a waste heat recovery system, where steam is generated at a pressure of 4 MPa. Following this, the $NO_x$-rich gas is cooled using cooling water before entering a gas washer, where it is treated to eliminate by-products via the condensation of nitric acid. Upon washing, the $NO_x$-containing gas is subjected to high-pressure compression and subsequently routed into an absorption unit, where nitrogen oxides are absorbed by demineralized water, producing nitric acid. Thermal energy from gas cooling and absorption processes is recovered using cooling water in the main absorber and associated heat exchangers. The resulting nitric acid is funnelled to a purge column, where nitrogen oxides are purged, producing a final product with a concentration of approximately 60% (mass).

**Table 1:** Mass balance of the simulated nitric acid plant.

| | |
|---|---|
| **Feed streams (kg/h)** | |
| Ammonia | 14,801 |
| Air to conversion | 261,850 |
| Water to absorption | 18,742 |
| Feed water | 74,800 |
| Natural gas to fire heater | 1,140 |
| Air to fire heater | 22,237 |
| $N_2/H_2$ mixture to gas treatment | 80 |
| Steam-to-gas treatment | 10,000 |
| Natural gas to gas treatment | 1,280 |
| Steam to turbine (2 MPa) | 31,400 |
| Total | 436,331 |
| **Product streams (kg/h)** | |
| Nitric acid (final product) | 88,094 |
| Steam (4 MPa) | 64,134 |
| Boiler purging | 10,666 |
| Cooling air to turbines | 5,075 |
| Condensate | 31,400 |
| Total | 436,331 |

The tail gas that leaves the absorber is conveyed to a gas treatment unit designed to reduce $NO_x$ emissions and capitalize on the energy potential for operating oxygen and nitrogen gas compressors. The PFD for the simulation and the corresponding mass balance are

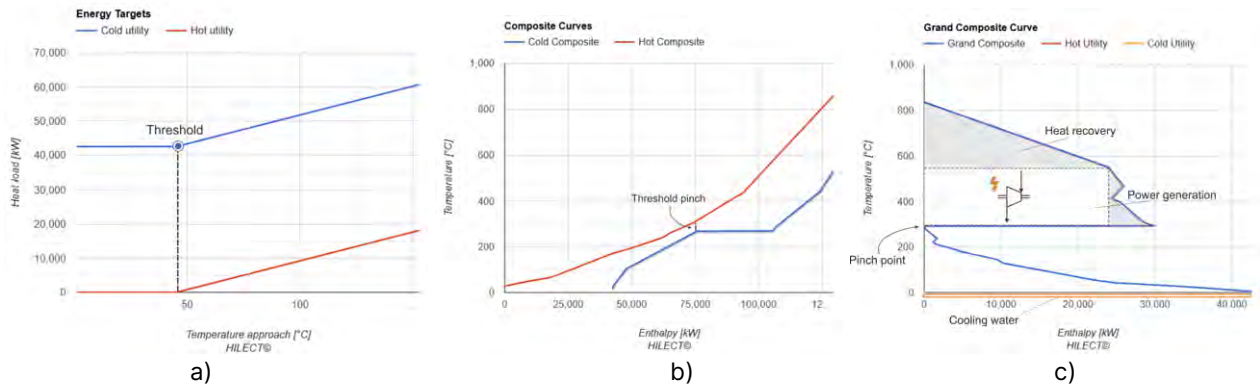
| $HNO_3$ concentration (%mass.) | 59.20 | 59.17 |
| Plant yield (t/h 100% $HNO_3$) | 51.90 | 52.12 |

## RESULTS AND DISCUSSION



### Energy performance

The analysis of the energy performance of the nitric acid plant revealed significant potential for energy savings that can be incrementally achieved by enhancing heat recovery within the existing process. The thermodynamic potential for energy savings reaches up to 18.1 MW for both cooling and heating applications, which can be realized by optimizing the heat recovery network. The relationship between energy savings and the minimum temperature approach is illustrated in Fig. 3a. A bottleneck inhibits further energy reductions, which the threshold pinch point can explain. This threshold pinch point is identified at a minimum temperature difference ($\Delta T_{min}$) of 46 °C, as shown in Fig. 3b. However, this bottleneck can be mitigated by the addition of steam generation at 2.2 MPa, necessitating an increase in the heat transfer area and a revamp of the existing network. Additionally, there exists further cogeneration potential within the investigated plant, with a theoretical power production potential of 4.5 MW, as illustrated in Fig. 3c. The realization of the identified energy efficiency potential necessitates an upgrade of the process through the retrofitting of the feed water heater, waste heat recovery unit, and heat exchanger associated with tail gas treatment. To fully exploit the $NO_x$ gas's heat recovery potential and preheat the untreated tail gas, two new heat exchangers are required to replace the existing gas coolers. Additionally, a new steam turbine is necessary to capitalize on the cogeneration potential of the waste heat unit, assuming a polytropic efficiency of 69% for the new turbine, which is pertinent for mid-sized units [19].

The simulation of the retrofitted process flowsheet facilitates the assessment of the potential increase in plant throughput resulting from the conservation of energy resources. In addition to energy savings and enhanced throughput, the retrofitted process design contributes to a reduction in harmful emissions. This is achieved by lowering natural gas consumption for the fire heater of the tail gas treatment unit, reducing cooling water requirements, and increasing the efficiency of the cogeneration facility. The process flow diagram (PFD) of the retrofitted system, reflecting the increased yield, is provided in Fig. 4, and the key performance indicators of the process are detailed in Table 3.

### Process electrification and low-grade heat

The utilization of the energy-saving potential within the nitric acid plant demonstrates that all heating requirements can be internally satisfied, while any surplus heat necessitates additional cooling capacity. This cooling demand is met by the cooling water cycle, which is powered

a) b) c)

**Figure 3:** Graphical interpretation of energy targets for analysed nitric acid, threshold $\Delta T_{min}$=46 °C: a) energy targets; b) composite curve; c) grand composite curve.

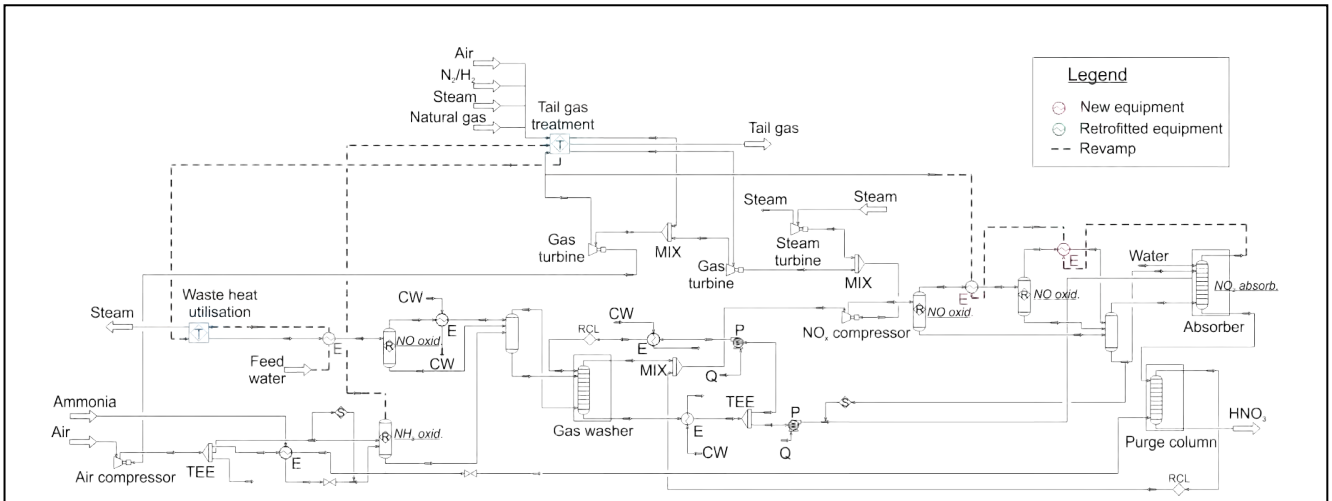


**Figure 4:** Simulation PFD of retrofitted dual-pressure nitric acid plant. A – adjust of parameters; CW – cooling water; E – heat exchanger; MIX – stream mixer; TEE – stream splitter; P – pump; Q – power; R – reactor; RCL – process recycle; S – parameter set; T – sub-flowsheet.

by electricity. However, the combustion of natural gas and a nitrogen/hydrogen ($N_2/H_2$) mixture continues to be employed for tail gas treatment. To facilitate a transition towards a fully electrified process with energy surplus capabilities, further investigation into the electrification of this part of the process is required. Despite the aforementioned process updates, there remains potential for further improvements within the investigated plant. According to the targeting procedure, a total of 42.6 MW of heat must be dissipated from the process through cooling. As illustrated in Fig. 3c, the temperature profile indicates that approximately 20 MW of this thermal energy can be utilized for district heating or other applications, with the remainder being addressed by the cooling water system. A thorough analysis of the effective utilization of this potential is warranted to capitalize on all available opportunities fully.

### Main limitations and future works

Future investigations may concentrate on the two previously mentioned issues and further alleviate the bottleneck associated with tail gas treatment caused by environmental regulations. Additionally, an analysis of the plant's operational lifespan in relation to the benefits of retrofit design should be conducted to assist plant owners in making informed decisions regarding the retrofitting of existing facilities. Moreover, the impact on the global fertilizer supply chain and other commodities should also be examined. The primary limitation to consider is the existing equipment design and plant layout, which significantly constrain any process updates or theoretical advancements. Furthermore, these types of processes typically have a limited operational lifespan, necessitating a trade-off decision between extending the facility's lifetime or investing in new structures.

**Table 3:** Main results of the nitric acid plant retrofit.

| Performance indicator | Base case | Improved process |
|---|---|---|
| Natural gas, $m^3/h$ | 3,528 | 2,239 |
| Cooling water, $m^3/h$ | 7,253 | 5,529 |

| Increased capacity, €/y | - | 9,995,800 |
| Payback period, y | - | 0.57 |

## CONCLUSIONS

The research findings highlight that existing dual-pressure plants still possess significant energy recovery potential. This potential was evaluated by developing a simulation model based on the actual operational processes of the plant, which was subsequently assessed and updated to integrate thermal energy and shaft work power effectively. Energy targets were established, and corresponding process modifications were proposed and simulated to validate the feasibility of these updates.

The primary outcome indicates that plant capacity can be enhanced by 10.2% through the debottlenecking of the energy system and improved utility efficiency. An analysis of capital expenditure recovery revealed a payback period of 7 months, assuming a 10% interest rate and a project lifespan of 5 years. Furthermore, the

environmental impact of the existing plant can be reduced by approximately 26.1 kt$CO_2$ per year. The results of this study are valuable for assessing the decarbonization potential within the fertilizer industry and for facilitating the electrification of existing processes during the transition to new sustainable chemical processes.

## ABSTRACT

In this research, a chemical looping scheme is combined with dry reforming of natural gas in a novel microwave reactor to produce industrial quantity of methanol. Simulation results show that the chemical looping scheme can produce all the hydrogen required by the methanol reactor as well as a significant portion of the carbon dioxide required for the syngas reactor. A heat exchanger network is developed to substantially reduce the hot and cold utility usage. A technoeconomic analysis indicates a significant positive net present value along with a substantial reduction in carbon dioxide emissions as well as a reduction in energy consumption.

## INTRODUCTION

Methanol is valued for its versatility as a feedstock and energy carrier. As a key component in producing formaldehyde, acetic acid, and methyl tert-butyl ether (MTBE), it supports a wide array of industries, including plastics, textiles, and automotive. Methanol also plays a growing role in renewable energy solutions, such as biodiesel production and as a hydrogen carrier for fuel cells. Global demand for methanol estimated to be $41.91 billion by 2026 [1], driven by expanding applications in petrochemicals and clean energy technologies. As global efforts toward sustainability intensify, methanol's importance as a low-carbon fuel alternative is set to rise. While methanol can be produced from different feedstocks, the most common feedstock is natural gas, primarily because it is available in abundant quantities at a cost-effective price [2]. In this process natural gas (primarily methane) is reformed into synthesis gas (syngas), a mixture of carbon monoxide, carbon dioxide, and hydrogen via steam methane reforming (SMR), where natural gas reacts with steam at high temperatures (700–1,000°C) and in the presence of a nickel-based catalyst. Alternatively, autothermal reforming (ATR) or partial oxidation can be used, especially in large-scale plants. The resulting syngas is then passed through a methanol synthesis reactor under high pressure (50–100 bar) and moderate temperatures (200–300°C), where it reacts over a copper-based catalyst to form methanol. The crude methanol is subsequently distilled to remove water and other impurities, yielding high-purity methanol. This process accounts for the majority of global methanol production, leveraging natural gas as a cost-effective and abundant feedstock. However, this process is highly energy intensive and contributes to greenhouse gases (carbon dioxide) to the atmosphere. As a result, there is significant interest to explore alternative pathways for methanol production that are more energy-efficient and environmentally sustainable.

One promising method is the microwave-assisted conversion of natural gas to methanol via dry reforming. This method uses electromagnetic waves to activate the natural gas molecules and create reactive species that can react with oxygen or carbon dioxide to form methanol. The advantages of this method include operation at lower temperatures and pressures, reduced number of

process steps, enhanced selectivity, and yield of methanol, and the utilization of carbon dioxide as a raw material [3]. However, dry reforming requires a source of hydrogen and it important to consider the energy cost and environmental impact of hydrogen production when considering dry reforming of methane as an alternative route for producing methanol.

In this paper, we explore the use of a chemical looping scheme that produces two separate streams of hydrogen and carbon dioxide that are then utilized in the production of methanol via dry reforming. The overall objective of this research is to develop a simulation model of a novel decarbonized microwave-assisted dry reforming process integrated with chemical looping for methanol production. Specifically, three key objectives are pursued: (1) investigate the impact of replacing the conventional syngas reactor with a microwave reactor for dry reforming of methane, (2) explore the feasibility of utilizing chemical looping for utilizing methane to produce the required hydrogen for methanol production, and (3) conduct a techno-economic analysis to evaluate the viability of the integrated process.

## REACTION CHEMISTRY AND REACTOR DESIGN CONSIDERATIONS

The current industrial approach to produce methanol involves steam reforming of methane to produce syn gas followed by catalytical conversion of syn gas to methanol [4]:

$$CH_4 + H_2O \rightarrow CO + 3H_2 \quad (1)$$

Some of the carbon monoxide reacts further with steam to form carbon dioxide via the water-as shift reaction:

$$CO + H_2O \rightarrow C0_2 + H_2 \quad (2)$$

An alternative method to produce syn gas is via methane dry reforming (MDR), Which uses carbon dioxide as a reactant, making advantageous for reducing greenhouse gas emissions [5]. The MDR reaction can be represented by the following equation:

$$CH_4 + CO_2 \leftrightarrow 2CO + 2H_2 \quad (3)$$

The MDR reaction is thermodynamically favorable at high temperatures (800-1000 °C) and low pressures, but it requires a suitable catalyst to overcome the kinetic limitations and avoid the formation of carbon deposits. Once syn gas is produced, it is possible to utilize this intermediate to produce methanol [4]:

$$CO + 2H_2 \leftrightarrow CH_3OH \quad (4)$$

The hydrogen to carbon monoxide ratio needs to be adjusted to a 2:1 ratio. Typically, the dry reforming process does not produce sufficient hydrogen, and so additional hydrogen needs to be added to the feed stream of the methanol reactor. This provides the motivation to utilize a chemical looping reactor system that converts methane and steam into separate streams of hydrogen and carbon dioxide. The hydrogen is sent to the methanol reactor feed, and the excess carbon dioxide is recycled back to the syngas reactor for dry reforming.

## PROCESS MODELING

### Methodological Framework

This research is divided into the following sections: (1) steady-state model development, (2) heat exchanger network (HEN) design, and (3) techno-economic analysis. In the first step, a comprehensive process model is developed for the integrated microwave-assisted dry reforming (MDR) and chemical looping processes, followed by methanol synthesis and product purification. The purpose of incorporating chemical looping is to generate additional hydrogen, compensating for the lower stoichiometric ratio ($H_2$ - $CO_2$) / (CO + $CO_2$) produced in conventional dry reforming. The goal is to achieve the target ratio of 2, which is optimal for methanol synthesis. Chemical looping provides a steady hydrogen source through an indirect oxidation process, using metal oxides to facilitate controlled oxygen transfer and ensure the required stoichiometric balance. Key process information, reaction kinetics, and operating conditions are taken from recent studies on chemical looping and microwave-assisted MDR5, with feed specifications aligned with the commercial Natgasoline process [4]. The steady-state simulation, developed in Aspen Plus v11, includes syngas production, methanol synthesis, and product purification. Next, a detailed HEN is designed using Aspen Energy Analyzer (AEA) v11.0 software. The HEN design targets energy optimization by creating a network that maximizes heat recovery and minimizes utility consumption. This configuration balances utility costs with capital. The resulting HEN grid meets targeted utility requirements, capital constraints, and optimal surface area, enabling efficient heat integration both in the microwave-assisted and chemical looping processes. Finally, a techno-economic analysis (TEA) is conducted using Aspen Process Economic Analyzer (APEA) v11 to account for capital and operating costs based on the Aspen Plus simulation specifications. Key economic indicator such as net present value (NPV) is calculated to evaluate the profitability of this novel methanol production process.

Figure 1 shows a schematic of the novel microwave-assisted dry reforming process. While the process development closely follows the flowsheet that is utilized commercially at Natgasoline LLC, two major changes are made to the process. First, the steam is replaced by carbon dioxide in the feed to the syn gas reactor and

secondly, an additional hydrogen stream, which is produced by chemical looping, is added to the inlet of the methanol reactor to have the correct carbon monoxide to hydrogen ratio. The carbon dioxide produced via chemical looping is recycled to the syngas reactor feed. In addition, there is a change in the process equipment where the conventional multi-tubular syn gas reactor is replaced by a microwave reactor. The separation train of distillation columns are essentially the same type as those found in the Natgasoline process; however, since the flow rates of some of the gaseous components are different, these distillation columns are sized appropriately. The final product stream is 14,201 lbmol/h of 99.9% pure methanol, which is the same as that produced via the conventional Natgasoline process.

## ASPEN PLUS Modeling

The methanol production process is modeled in two integrated subplants: Subplant 1, which handles hydrogen generation through chemical looping, and Subplant 2, where syngas is synthesized using a microwave reactor, supplemented by the $H_2$ stream from Subplant 1. The thermodynamic package RK-SOAVE is used for the syngas part while NRTL is used for the methanol production part and PENG-ROBINSON is used for the chemical looping. In Subplant 1, the chemical looping process is configured as a three-reactor, countercurrent setup to enable hydrogen production and $CO_2$ capture, based on the conditions outlined in the work of Riley et al [5]. The looping system uses $CaFe_2O_4$ as an oxygen carrier, which alternates between oxidized and reduced forms to facilitate methane and steam conversion in a controlled series of reduction and oxidation cycles. Process feed conditions and specifications for this setup are summarized in Table 1. Conditions such as temperature, pressure, and gas flow rates, are adapted from Riley et al. [5], but are further adjusted to meet the specific $H_2$ demand of our methanol synthesis setup.

The chemical looping system operates as follows: Natural gas is introduced into the fuel reactor (FR) to react with the oxidized $CaFe_2O_4$, producing $CO_2$ and $H_2O$ while reducing the oxygen carrier. This stage is conducted at elevated temperatures, allowing efficient conversion of methane into products that can be further processed. In the air reactor (AR), the reduced $CaFe_2O_4$ is re-oxidized by reacting with air, regenerating the oxygen carrier. In the steam reactor (SR) the re-oxidized $CaFe_2O_4$ interacts with steam, producing $H_2$ and $H_2O$. The operating conditions for each reactor in the chemical looping process are shown in Table 2. The $H_2$ generated in this stage is directed to Subplant 2 to supplement the syngas stream, achieving the necessary $H_2$ ratio for methanol synthesis. In Subplant 2 the methanol production process utilized in this research is modeled similarly to the commercial setup at Natgasoline LLC, with adjustments to the syngas production, feed conditions, and reactor configurations [6]. The syngas feed for methanol synthesis is through a microwave-assisted dry reforming reactor, where methane ($CH_4$) and recycled carbon dioxide ($CO_2$) are converted into a syngas stream. This process is conducted at 800°C and 1 bar and is modeled as a stoichiometric reactor. The $H_2$ ratio in the syngas is optimized by supplementing it with hydrogen generated from the chemical looping process in Subplant 1. The operating specifications for the microwave-assisted syngas production are provided in Table 2. The conditioned syngas is then compressed to approximately 76 bar and distributed across two parallel methanol synthesis reactors, each operating at 254°C and 76 bar. Here, CO and $CO_2$ undergo hydrogenation in the presence of a Cu/Zn-based catalyst to produce methanol and water. The product gas from reactors is then preheated by exchanging heat with the reactor feed stream before undergoing a final conversion step in an additional reactor operated

| R-4 | 2 | | 220 | 71 |

at 220°C and 71 bar. This additional reactor stage helps maximize methanol yield by enhancing the conversion of residual CO and $CO_2$. The reactor outlet gas, containing methanol, water, and unreacted gases ($H_2$, CO, $CO_2$, $CH_4$, and inert gases like $N_2$), is directed to a separator, where crude methanol is separated at 40°C and 67 bar. A portion of the unreacted gases is recycled back to the reactors to improve process efficiency, while a portion is purged.

The purification of crude methanol is achieved through a series of steps involving a flash tank and three distillation columns. First, crude methanol is depressurized in the flash, allowing off-gas, which mainly consists of $CO_2$, $H_2$, and $CH_4$, to be vented. The liquid phase is directed to the first column for initial purification. This column separates residual $CO_2$ and trace gases, which are flared, while the methanol-rich bottom stream is pumped into the second column for further separation. Here, methanol of approximately 99.99% purity is collected as the distillate, while the remaining mixture of methanol and water proceeds to the third column, where the final methanol product with a purity of 99.99 mol% is produced. The data from the steady-state simulation in Aspen Plus was imported to Aspen Energy Analyzer (AEA) v11 to design and optimize the Heat Exchanger Network (HEN) for maximum energy recovery. The HEN was designed separately for each subplant, with a larger HEN configuration applied to the microwave-assisted dry reforming process in Subplant 2 and a smaller HEN configured for the chemical looping process in Subplant 1.

## RESULTS

The steady-state simulation results for the integrated chemical looping and microwave-assisted reforming process demonstrate effective syngas production, hydrogen supplementation, and methanol synthesis, achieving high efficiency and purity. In Subplant 1, the chemical looping process is configured to produce a hydrogen stream of 22,299 lbmol/h, meeting the precise hydrogen requirement for the syngas production in Subplant 2. The chemical looping configuration also produces 7,163 lbmol/h of carbon dioxide. However, the syngas production reactor in Subplant 2 requires 9,746 lbmol/h of carbon dioxide. This additional amount of carbon dioxide (2,583 lbmol/h) has to be purchased separately or obtained from a separate decarbonization campaign in another part of the chemical plant. In Subplant 2, the microwave-assisted dry reforming reactor achieved a methane conversion rate of 97%. The resulting syngas composition is 40.3% $H_2$, 41.5% CO, 17% $CO_2$, and 0.57% $CH_4$, with an $H_2$ ratio of 0.971. This ratio is then optimized by supplementing the syngas with the hydrogen stream from Subplant 1 to achieve the ideal stoichiometric conditions for methanol synthesis. Moreover, the microwave-assisted dry reforming process reduced natural gas feed requirements by 12% and steam feed

consumption by 6%, demonstrating the process's enhanced resource efficiency compared to conventional methods. The methanol produced reaches 14,201 lbmol/h with a high purity of 99.9%, aligning with commercial methanol production rate and quality. The process overall achieves a net $CO_2$ utilization rate of -1,117 lbmol/h, indicating that it consumes $CO_2$ rather than emitting it. Compared to a baseline emission rate of 575 lbmol/h in conventional steam reforming processes, this setup achieves a $CO_2$ emission reduction of 294.3%. This reduction highlights the environmental benefits of integrating $CO_2$ into the process, furthering the goal of sustainable and decarbonized methanol production. The HEN design employed a mixed-integer linear programming (MILP) approach to achieve optimal heat recovery, thus, the utility requirements showed substantial reductions: Hot utility demand dropped from 2923 MMBTU/hr to 478 MMBTU/hr, representing an 83.6% reduction. Cold utility demand decreased from 3968 MMBTU/hr to 1482 MMBTU/hr, achieving a 62.7% reduction. The integration of HEN not only reduces operational costs but also aligns with decarbonization goals by lowering the environmental impact through reduced energy consumption.

Capital costs for standard equipment items were estimated by mapping the equipment items from the Aspen Plus plant-wide model to Aspen Process Economic Analyzer (APEA) V11. Costs for the microwave-assisted reactor (MW-reactor) was estimated separately as quoted equipment in APEA, broken down into the magnetron (including other electrical ancillaries) and pressure vessel. The magnetron cost, including electrical ancillaries, accounts for components such as the cavity, generator, controls, transformers, switches, installation, and setup, obtained from a vendor based on the power (kW) rating. The pressure vessel cost was estimated using correlations from Turton et al [7]., considering the material of construction and operating pressure. Additional costs, such as assembly, commissioning, and markup, were accounted for with escalations, given the novel state of MW-assisted reactor technology. Utilities such as electricity, cooling water, steam, and flow rates of raw materials were obtained from the Aspen Plus process model. The economic analysis of the proposed methanol production process shows that the integrated process achieves a TCI of $515.68 million, annual operating costs of $486.13 million and a combined NPV of $1439 million. The integrated design leverages the strengths of both subplants, offering significant economic potential through high methanol production and $CO_2$ utilization.

An additional amount of carbon dioxide (2,583 lbmol/h) is required to operate the syngas reactor, and this carbon dioxide cost can affect the NPV. The economic analysis presented in Table 3 assumes a cost of carbon dioxide as $38.59/ton. To assess the impact of key cost variables on the operating expenses (OPEX), a sensitivity analysis was conducted on electricity price (ranging from 0.01 to 0.12 cents/kWh) and methane price (ranging from 0.1 to 2 $/MMBtu).

**Table 3:** Economic Summary for Integrated Process.

| Parameter | Integrated Process |
|---|---|
| Total capital cost ($MM) | 515.68 |
| Total Operating Cost ($MM/year) | 486.13 |
| Raw Material Cost ($MM/year) | 162.25 |
| Utility Cost ($MM/year) | 279.14 |
| Methanol Production (lb/year) | $3.99x10^9$ |
| NPV ($MM) | 1,439 |

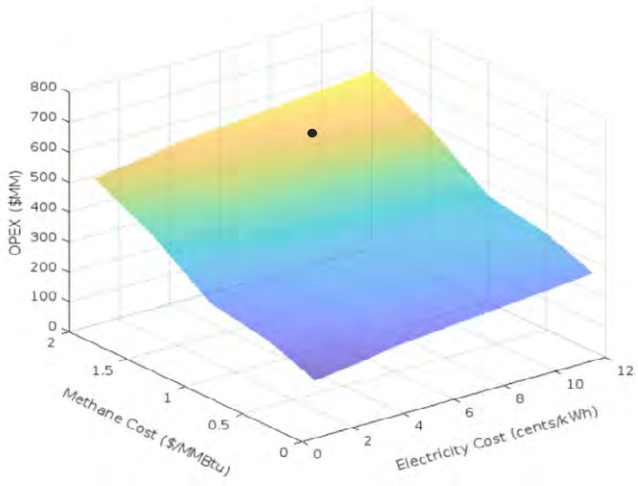

**Figure 2.** Sensitivity Analysis of OPEX to Electricity and Methane Costs

Figure 2 shows that OPEX increases with both electricity and methane costs, with a stronger sensitivity observed toward methane pricing. The lowest OPEX value, $160.84 MM, occurs at the lowest electricity and methane cost combination, whereas the highest OPEX, $592.20 MM, corresponds to the most expensive conditions. The black marker in the plot highlights the current cost scenario (electricity = 8.72 cents/kWh, methane = $1.8/MMBtu), which results in an OPEX of $486.13 MM. The findings emphasize that while both variables impact operational costs, controlling methane costs presents the most effective strategy for cost optimization in the proposed process.

## CONCLUSION

Current industrial practice for methanol is very energy intensive and produces a large amount of carbon dioxide. The use of a novel microwave-assisted conversion of natural gas to methanol via dry reforming has the potential to reduce energy costs and reduce carbon dioxide

emissions. However, this method requires the use of hydrogen. It is shown via simulation studies in this research that the hydrogen required for methanol production can be generated via chemical looping. Furthermore, chemical looping also produces a pure stream of carbon dioxide that can be utilized in the dry reforming step. Technoeconomic analysis indicates that this integrated plant has the potential to be profitable.

While the use of microwave reactors is promising and moves the chemical industry in the direction of electrification of process energy, further research is needed to make commercial-scale microwave reactors at a price comparable to traditional jacketed reactors that operate using hydrocarbon combustion. The scale-up of microwave reactors using multiple units of pilot-scale equipment and the effect of reactor cost on the manufacturing cost of methanol is being evaluated [8]. Another factor under consideration is the stability of the catalyst under microwave conditions, which is an area of active research [9]. While chemical looping is shown to be feasible for producing the necessary hydrogen for dry reforming, this method requires the transport of solids, which require special pneumatic handling techniques for smooth long-term operation. These issues, along with a quantitative comparison with current industry methods will be addressed in a future publication.

## ABSTRACT

In this research, a novel process is developed that utilizes low density polyethylene from plastic waste to produce ethylene. In this process, waste polyethylene is reacted in a microwave reactor to produce ethylene. A conceptual flowsheet based on this reactor is developed in the ASPEN Plus environment. Heat integration tools are utilized to reduce the hot and cold utilities used in this process. This novel design is compared with the conventional process of making ethylene from ethane via cracking. A technoeconomic analysis is conducted to demonstrate the economic feasibility of this process.

**Keywords**: Ethylene, Process Design, Process Development

## INTRODUCTION

Plastics are used in a wide variety of products and have displaced other materials – such as wood, metal, and glass – that were previously used for applications that plastics are currently used. The worldwide annual production of plastics has increased nearly 200-fold to 400.3 million metric tons in 2022 from 2 million metric tons in 1950 [1]. While plastic products have a service-life of around 10 years, plastics can take up to 500 years to decompose, depending on their composition and disposal. Most of the plastic waste generated is either landfilled or incinerated. It takes a long time for landfilled plastic waste to degrade, and incinerated plastic waste generates harmful air pollutants. Mismanaged plastic waste is mainly disposed of at illegal dumpsites or burned in open pits, while a considerable amount also leaks into rivers and oceans. From 1970 to 2019, an estimated 30 million metric tons of plastics have accumulated in the ocean, while more than 100 million tons have accumulated in rivers and lakes [1]. Such large amounts of plastic waste pollution in waterways can have a devastating impact on marine life and ecosystems.

In this research, a novel process is developed in which waste low-density polyethylene (LDPE) is converted into ethylene using a microwave reactor. A conceptual flowsheet for this reactor-based process is developed in the ASPEN Plus environment that is at industrial-scale. Heat integration tools are applied to optimize the use of hot and cold utilities in the process. This innovative design is compared with the current industrial production method of ethylene via ethane steam cracking to evaluate the cost constraints of the microwave reactor.

## PRODUCTION OF ETHYLENE

While ethylene was traditionally produced via steam cracking of petroleum (naphtha) at 800–900°C (1,470–1,650°F), followed by separation to isolate ethylene from the resulting gas mixture, there is an increasing trend to use ethane, derived from natural gas, to produce ethylene via steam cracking [2]. Ethane forms a major component of natural gas liquids (NGL) that is obtained from shale gas while purifying methane. This NGL feed stream is pre-heated by a heat exchanger, mixed with steam, and then further heated to its incipient cracking temperature (500°C to 680°C). At this point, it enters a reactor (typically, a fired tubular reactor) where it is heated to cracking temperatures, 750°C to 875°C. After cracking reaction, cracked gas mixture leave the furnace at 750°C to 875°C. The gases must be cooled immediately in the quench tower to preserve the current composition of the gas and prevent undesirable side reactions. After the

cracked gas mixture has been cooled in the quench tower and compressed, it is sent to the fraction section at a pressure of 464 to 551 psi (32-38 bar) for further separation into different products and fractions at specified qualities. This is done through a series of distillation columns and results in the separation of ethylene from the unreacted ethane, as well as the side products propylene, hydrogen and methane. Steam cracking of ethane is an energy intensive process due to the high reaction temperature (> 800°C). Furthermore, this process generates a significant amount of greenhouse gas (GHG) emissions and utilizes a non-renewable hydrocarbon feed resource. The process generally results in approximately 1.2 to 1.6 tons of $CO_2$-equivalent ($CO_2e$) per ton of ethylene produced [2,3].

The availability of a large amount of plastic waste provides the motivation to develop technologies to convert this waste product to ethylene instead of using ethane from non-renewable sources to produce ethylene. Tertiary recycling uses chemical and thermochemical methods to recover various components of waste plastic into monomers or fuels. This type of recycling is called “upcycling” as the waste plastic is converted back to monomeric forms of molecules that can be further processed into useful forms (polymeric or otherwise). The depolymerization process involved in upcycling of plastics can be enhanced by the use of catalysts, which promote deep cracking of primary products and accelerate the breaking of C–C and C–H bonds, resulting in high yields of liquid products with enhanced combustion performance and high-quality fuel production in a shorter time and at lower temperatures (280–500°C) compared to pure pyrolysis [4]. The products from catalyzed depolymerization processes include a mix of gasoline hydrocarbons (C5-C12), aromatics, light olefins, and other chemical feedstocks. Suitable catalysts and process conditions can be chosen for commercial applications to target the recovery of specific desired products.

The depolymerization process requires energy and different forms of thermal energy can utilized. The efficiency of this thermal energy utilization can vary significantly depending upon the type of energy. There is current interest in the use of microwave heating as a source of energy for depolymerization reactions. Microwave is a form of electromagnetic wave with perpendicular oscillating electric field and magnetic field that result in heat generation via (1) dielectric heating, (2) Joule heating, and (3) inductive heating. Compared with traditional hydrocarbon-based jacketed reactors as well as more novel resistive-heating reactors, microwave heating provides advantages in utilization efficiency, rapid heating, and lower bulk temperatures during reaction. For instance, it has been shown in laboratory-scale experiments that microwave-enhanced ethane catalytic cracking can produce the same conversion of ethane as conventional thermally heated cracking at an average temperature that is 150-200°C lower [5,6].

This provides the motivation to develop a process that utilizes polyethylene as a feed source in a microwave reactor to produce polymer-grade ethylene.

## PROCESS MODELING

### Conventional Production of Ethylene via Ethane Steam Cracking

A process simulation model is developed for the conversion of ethane to ethylene based on current industry practice [7]. This model is used as a basis of comparison for studying the advantages and disadvantages of the novel microwave-enhanced process for producing ethylene from LDPE. Ethylene is produced via thermal steam cracking of ethane gas. A process flow diagram based on industrial practice is shown in Figure 1.

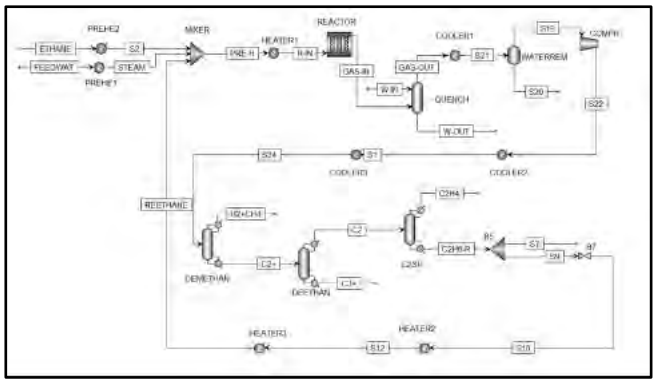

**Figure 1**: Process Flow Diagram for Ethane Cracking

The feed to the production process is ethane gas that comes from an ethane gas pipeline. Fresh ethane gas is fed into the process at a rate of 149 tons/h. The ethane gas is mixed with 50 tons/h of process steam to achieve a steam to hydrocarbon ration of 0.33 by mass and passed through the thermal stream cracking reactor at inlet conditions of 700 °C and 3.2 bar. The reaction conditions are 840 °C and 3.2 bar in the reactor. Under these conditions, the thermal steam cracking reaction occurs in the absence of a catalyst, converting the ethane feedstock into a gas mixture containing primarily ethylene, methane, hydrogen, and residual ethane. The exit gases from the reactor are cooled and sent through a flash unit to remove water. The organic vapors are compressed and sent through a series of three distillation columns. The top product of the last column is polymer-grade ethylene.

A simulation model is developed in ASPEN Plus v11 for this process. The feed specifications are listed in Table 1. The reaction kinetics [7] used in this model are shown in Table 2 and the reactor specifications are shown in Table 3. The Grayson thermodynamic property

model is used for this module. The flash unit and the three distillation columns utilize the Soave-Redlich-Kwong thermodynamic property model and rigorous modeling tools are used (e.g. RADFRAC) to model these separation units.

**Table 1**: Feed Specifications for Ethane Cracking

| Component | Ethane | Steam | Initiator |
|---|---|---|---|
| Pressure (bar) | 3.21 | 3.21 | 2,010.00 |
| Temperature (°C) | 700.00 | 700.00 | 0.00 |

**Table 3**: Ethane Cracking Reactor Specifications

| Reactor Specifications | |
|---|---|
| Pressure (bar) | 3.2 |
| Temperature (°C) | 840 |
| Length (m) | 10.5 |
| Diameter (m) | 0.085 |
| No. of Tubes | 240 |
| Heat Duty MW | 132.81 |

The product gas from the reactor unit is 40.35 mol% ethylene, 41.75mol% hydrogen, 3.97 mol% methane, 11.67 mol% unreacted ethane and with slight impurities of other products. The results closely align with the industrial data available in literature [8] as shown in Table 4. The outlet gas of the cracking reactor is cooled down to 10 °C with the help of a quench tower. The condensed water vapor is separated from the bottom in a flash separator. Vapor products from the flash separator are compressed to 8 bars and then cooled down to -100 °C. This stream is sent to the demethanizer column where methane and hydrogen are separated as top products.

**Table 4**: Comparison of Simulation with Industrial Data

| Main Products | Product Yield [mol %] | | |
|---|---|---|---|
| | Simulation | Industrial Data | % Diff. |
| $H_2$ | 37.47 | 36.49 | 2.69 |
| $CH_4$ | 4.75 | 8.42 | 43.59 |
| $C_2H_4$ | 34.41 | 33.07 | 4.05 |
| $C_2H_6$ | 19.89 | 18.86 | 5.46 |

The bottom products are sent to the deethanizer column, where ethane and ethylene flow out of the top of the column while the remaining (undesired) products are separated from the bottom of the column. Finally, the top product stream is sent to the final column where ethylene is separated as the top product from ethane. The purified ethylene (99.97mol%) is recovered at 8 bar and -58.4 °C. The unreacted ethane is recovered from the bottom of the column and recycled back to the feed stream. The columns specification for ethylene separation are listed in Table 5.

**Table 5:** Column Specifications

| Tray Type | Sieve | Sieve | Sieve |
| Column Diameter (m) | 3.3 (2-4) | 3.1 (2-9) | 4.5 (2-26) |
| | 3.5 (5-10) | 3.5 (10-23) | 3.6 (27-49) |

Figure 2 shows the temperature and composition profiles of ethane and ethylene in the final distillation column. Since the reactor outlet matches industrial data closely and the final product results in polymer-grade ethylene, this simulation model is of high-fidelity and can be used in a technoeconomic analysis to compare with the economics of producing ethylene via a novel microwave process that utilizes LDPE.

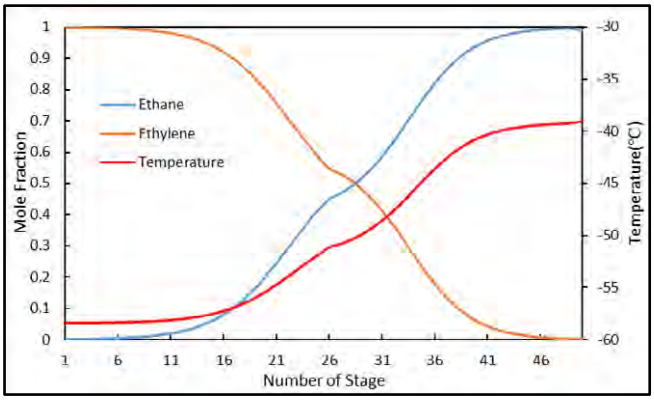

**Figure 2**: Temperature and Composition Profiles for Ethylene and Ethane in column C2SPLIT

## Microwave Enhanced Catalytic Conversion of LDPE to Ethylene

The focus of this section is the development of an ASPEN Plus simulation for the microwave-enhanced process to convert LDPE to ethylene. The objective is to match the same ethylene production as the conventional ethane cracking process in terms of quantity as well as product purity. A process flow diagram of the microwave process under consideration is shown in Figure 3. The reactor in the conventional process is replaced by a microwave reactor and a suitable distillation train is designed to recover the ethylene.

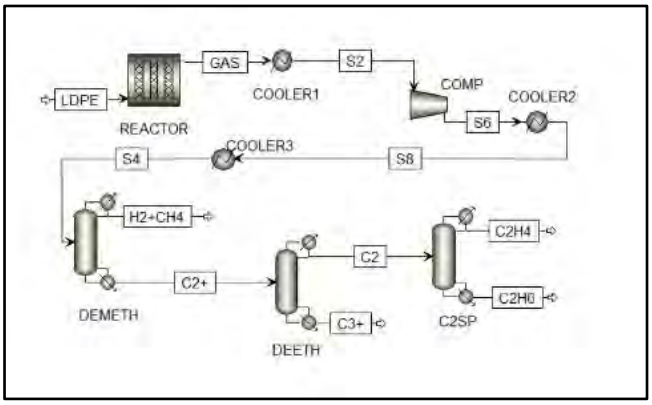

**Figure 3**: Flow Diagram of Microwave Enhanced Process for Converting LDPE to Ethylene

Preliminary data from laboratory-scale microwave reactor experiments [9] indicates that the product composition of the reactor under microwave heating with LDPE as feed is not the same as the product composition of conventional heating with ethane as feed as shown in Table 6. In particular, the microwave reactor produces a significant amount of propylene, which is also a valuable product, in addition to ethylene. This implies that the separation train specifications for the microwave process will be different from that of the conventional ethane-to-ethylene process. If propylene is included as a target product, additional costs for distillation to recover propylene, as well as the associated profits, will need to be considered. If the cost of recovering propylene is not competitive, it is necessary to redesign the microwave reactor to produce more ethylene and less propylene.

**Table 6:** Reactor Outlet Composition

| Gas components (ton/h) | $LDPE/N_2$ | Ethane |
|---|---|---|
| | MW | Conventional |
| | 400°C | 840°C |
| Hydrogen | 2.06 | 6.05 |
| Methane | 16.58 | 6.10 |
| Ethylene | 77.29 | 77.29 |
| Ethane | 16.21 | 47.90 |
| Acetylene | 0.09 | 0.00 |
| Propane | 8.42 | 0.99 |
| Propylene | 54.37 | 7.87 |
| C4 and higher | 39.15 | 2.81 |

In the novel microwave process, it is necessary to determine the feed rate of LDPE as well as the separation train design that results in the same amount of polymer-grade ethylene as the conventional process (77 tons/h). This allows for a comparison of capital cost, operating cost and life-cycle cost for the two processes. It was determined that a feed of 214 tons/hour of LDPE was required to produce the required amount of ethylene (77 tons/h) in the microwave reactor. The reactor is modeled as a yield reactor that has the same outlet composition as shown in Table 6. The reactor is assumed to operate at a temperature of 400 °C and a pressure of 1 bar. The outlet of the reactor is cooled and sent to a demethanizer column, followed by a deethanizer column, and finally to an ethylene column, similar to the separation process used in conventional ethane steam reforming product separation. In addition, an extra column is designed to recover propylene. The columns specifications for this process are listed in Table 7. Figure 4 shows the temperature and composition profile of ethylene from the C2 splitter.

## ECONOMIC EVALUATION

Aspen Energy Analyzer (AEA) V11 is used to develop and optimize a HEN for both the conventional as well as the novel process. The software employs a pinch analysis technique in the optimization algorithm to compute overall matches with heat load, surface area and cost target. The objective function of the HEN is to minimize utility cost, which is formulated as a mixed integer linear programming (MILP) problem. The solution consists of the

best set of matches rather than a single match.

**Table 7**: Column Specifications for Microwave Enhanced Process

| | Columns | | |
|---|---|---|---|
| | **DEMETHAN** | **DEETHAN** | **C2SPLIT** |
| Purpose | Distillation | Distillation | Distillation |
| No. of Stages | 15 | 24 | 60 |
| Feed Stage | 6 | 10 | 31 |
| Feed Temperature (°C) | -100 | -40.85 | -54.52 |
| Pressure (bar) | 8 | 8 | 8 |
| Reflux Ratio | 0.74 | 0.47 | 2.39 |

| | 2.6 (5-10) | 3.2 (10-23) | 3 (31-59) |

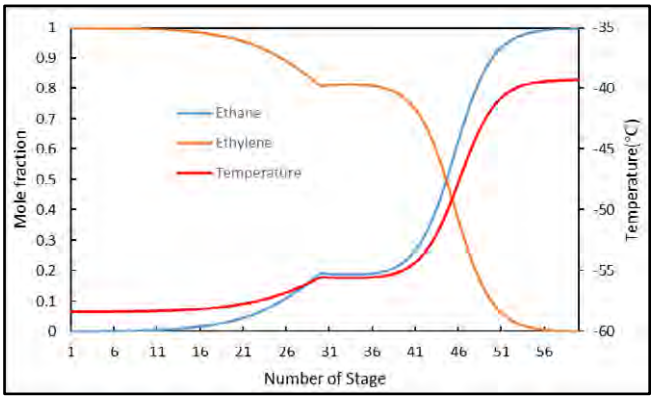

**Figure 4**: Temperature and Composition Profiles for Ethylene, Ethane in C2 splitter

Capital costs for standard equipment items were estimated by mapping the equipment items from the Aspen Plus plant-wide model to Aspen Process Economic Analyzer (APEA) V11. Costs for the microwave-assisted reactor (MW-reactor) was estimated separately as quoted equipment in APEA, broken down into the magnetron (including other electrical ancillaries) and pressure vessel. The magnetron cost, including electrical ancillaries, accounts for components such as the cavity, generator, controls, transformers, switches, installation, and setup, obtained from a vendor based on the power (kW) rating [10]. The pressure vessel cost was estimated using correlations from Turton et al [11]., considering the material of construction and operating pressure. Additional costs, such as assembly, commissioning, and markup, were accounted for with escalations, given the novel state of MW-assisted reactor technology. Utilities such as electricity, cooling water, steam, and flow rates of raw materials were obtained from the Aspen Plus process model.

A comparison of capital cost, operating cost, and utility cost between conventional steam reforming and microwave-enhanced LDPE upcycling (excluding the reactor component) is conducted as shown in Table 8. The objective of this comparison is to estimate the cost constraints of the microwave reactor necessary to ensure that the microwave-enhanced LDPE upcycling process is economically comparable to the conventional ethylene production process.

**Table 8**: Comparison of Capital and Operating Costs

| Scenario | Capital Cost (USD/Year) | Operating Cost (USD/Year) | Utility Cost (USD/Year) | Product |
|---|---|---|---|---|
| Conventional Ethane Steam Reforming | 36,557,700 | 48,770,700 | 42,463,100 | Ethylene |
| LDPE Conversion (MW/ excluding reactor) | 18,313,500 | 5,063,400 | 2,921,440 | Ethylene |

Currently a microwave reactor at industrial scale is not available for the proposed LDPE microwave enhanced conversion process and hence it is difficult to estimate its cost accurately. A rough estimate the microwave reactor cost based on magnetron price and reactor materials can be used as a first step. The LDPE feed rate of 214 ton/h is required to meet the ethylene production rate of 77 ton/h to match the ethylene production in the conventional ethane-to-ethylene process. The overall cost of the microwave reactor systems depends on the number of magnetron units needed to generate the necessary power requirement. As the batch time lowered down, the magnetron cost declines proportionally. When the batch time is 10 minutes, the magnetron cost is approximately $11 million as shown in Table 9. As this time is lowered, the cost of the microwave reactor systems falls further. Table 9 shows that if the batch time for the microwave-enhanced LDPE conversion process is reduced to less than 10 minutes, it has the potential to be competitive with conventional ethylene production.

**Table 9**: Cost Estimation of Microwave Reactor

(Magnetron Power: 100kW/module, Magnetron Price: 113872.82$/module, Power Needed: 66921420.69W)

| Batch time(min) | 0.5 | 1 | 2 | 5 | 10 |
|---|---|---|---|---|---|
| Batch volume($m^3$) | 8.45 | 16.89 | 33.79 | 84.47 | 168.94 |
| Microwave reactor power | 557678.51 | 1115357.01 | 2230714.02 | 5576785.06 | 11153570.11 |
| Magnetron needed(unit) | 5.58 | 11.15 | 22.31 | 55.77 | 111.54 |
| Total cost of Magnetron ($) | 683,236.92 | 1,366,473.84 | 2,732,947.68 | 6,376,877.92 | 12,753,755.84 |

## CONCLUSION

Simulation of industrial-scale production of ethylene via two distinct routes, ethane steam cracking and polyethylene upcycling, were considered. While the product compositions at the reactor outlet differ between the two processes, the feed rate of the reactants has been

adjusted to achieve the same ethylene production capacity. The novel microwave-enhanced process demonstrates the potential to produce both ethylene and propylene. The economic viability of using microwave reactors for LDPE conversion depends on the balance between the high efficiency and selectivity of the process against capital and operating costs. Technoeconomic analysis indicates that this integrated plant has the potential to be profitable.

## ABSTRACT

Bipolar membrane electrodialysis are receiving the attention of the research community in the last years because they can help the electrification and the spread of direct air capture systems. In this work, a mathematical model of a bipolar membrane electrodialysis cell for carbon dioxide recovery is carried out in order to find the most significant parameters on efficiency through a global sensitivity analysis. The electrochemical cell can be integrated into an absorption column capturing carbon dioxide from the air. Results show that the most important parameter over all investigated figures of merit (specific energy consumption, costs, carbon dioxide desorption efficiency, potassium transport number, removal ratio of potassium cation and carbon) is the potassium cation concentration in the rich solution feeding the cell. A trade-off between energy efficiency, process speed and operational cost is suggested. Future research should be conducted in order to apply the global sensitivity analysis to the overall integrated system considering the whole carbon cycle between the bipolar membrane electrodialysis and absorption column.

## INTRODUCTION

Global warming and climate change are two critical and current global challenges, due to continuous greenhouse gas (GHG) emissions that characterize the history after the industrial revolution. After the pandemic period, carbon dioxide ($CO_2$) emissions (one of the most important and abundant GHG in the earth atmosphere today) started rising again to a value of 37.79 billion ton on 2023 [1]. There is simultaneously an increase of temperature due to the trapping role of $CO_2$, so that the Intergovernmental Panel on Climate Change (IPCC) decided to restrict the global average temperature increase to within 2 °C above preindustrial levels [2].

The achievement of this objective will not be easy, as it will require a drastic reduction in $CO_2$ emissions by 2030 and net zero emissions by 2050 [3].

Within this context, it is becoming increasingly imperative to invent not only efficient but also cost-effective technologies for controlling and reducing the atmospheric $CO_2$ concentration. So that, in addition to the conventional capture of $CO_2$ from flue gases and industrial processes, new solutions to capture $CO_2$ from the air have been proposed and investigated among the literature and new emerging companies, during the last decades. It is evident that, direct air capture (DAC) technology is one of the most important process to achieve negative $CO_2$ emissions. The annual capture of $CO_2$ should reach more than 85 Mton in 2030 and more than 980 Mton in 2050 in order to control the 13% of global $CO_2$ emissions by 2050 [4].

Absorption, adsorption, ion exchange resin, mineral carbonation, membrane, photocatalysis, cryogenic separation, electrochemical approach and electrodialysis approaches have discussed and presented in the literature as potential alternative to this mentioned capture solution [4, 5, 6, 7]. Each reported technology has disadvantages and advantages and a defined value of technology readiness level (TRL) [8]. Among DAC companies, it is possible to find the main known and important such as Climeworks and Global Thermostat (based on adsorption), Carbon Engineering (based on absorption), Mission

Zero Technology (based on bipolar membrane electrodialysis (BPMED)) [8].

The BPMED is receiving a greater attention as a DAC technology in the last year, because it is based only on the use of electrical energy with the advantages to be modular, work in an isotherm modality, desorb $CO_2$ at an ambient or higher pressure and with the minimum efficiency losses compared to a temperature or pressure swing adsorption solution, if renewable energy is used.

In particular, a BPMED stack is used to regenerate the hydroxide based-solved (mostly NaOH or KOH water solution) coming from an absorption column and capturing $CO_2$ from the air [9]. In this way, it is possible to recycle the solvent to the column and release the captured $CO_2$ for its storage or utilization.

$CO_2$ separation through BPMED has already been analyzed in the literature with mathematical models [4, 9, 10, 11, 12] and experimental works [13] find a cost even higher than 1000 \$/ton$CO_2$ and energy consumption up to 1451 kJ/mol$CO_2$ in not optimal operating conditions.

A high separation cost is due to a high membrane cost, large electricity consumption, and uncertainties on the lifetime of the materials [9]. For this reason, the process optimization through the use of a mathematical model is therefore useful to support design and development through the identification of the best operating conditions and parameters along with a Global Sensitivity Analysis (GSA) with the aim of suggesting significant operating parameters on costs, energy consumptions and efficiency.

In this research, a mathematical model for a BPMED capturing $CO_2$ from the air is proposed to conduct a GSA to identify the most effective parameters for total costs and energy consumptions alongside with others figures of merit, as the considered Key Performance Indicators (KPIs).

# MODELLING

## Description of the technology

The scheme of the analyzed BPMED system is reported here and shown in Figure 1. The single cell has an acidic and alkaline compartment separated by a cation exchange membrane (CEM) in addition to a bipolar membrane for water dissociation. The acidic side is feed by a rich solution of carbonates and bicarbonates coming from the DAC absorption column. Here, the influx of protons ($H^+$) produced from the electro-dissociation of water inside the bipolar membrane reduces the pH, converting the carbonate ions to dissolved carbon dioxide. At the same time, $K^+$ ions are transported across the CEM to the alkaline compartment. $CO_2$ is finally recovered in a knock-out vessel, where an expansion induces a drastic reduction in solubility. On the other hand, the liquid stream, which is very diluted in KOH and $CO_2$, is fed to the alkaline compartment, where it receives the influx of $K^+$ from the acidic compartment and $OH^-$ from the bipolar membrane. The alkaline hydroxide solution is then regenerated and can be recycled in the absorption column.

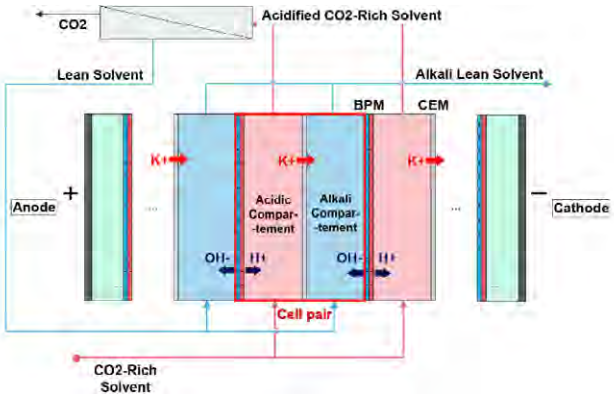

**Figure 1** Scheme of the investigated BPMED

In this work, a mathematical model for the BPMED unit inside the capture process is developed.

## Mathematical models

A model based on gas–liquid equilibria and mass balances has been carried out in MATLAB to evaluate the performance of the BMED-CEM system, considering the following assumptions: well-mixed compartments, ideal membrane behaviour without interfacial perturbations at its surface, absence of transport for neutral species through the membranes, steady-state conditions [11]. The liquid solution is described by the acid-base equilibrium equations for $H_2CO_3$, $HCO_3^-$, $CO_3^{2-}$ and $H_2O$ in addition to the electroneutrality of the solutions. In the acidic side, the liquid solution is in equilibrium with the gas phase (pure $CO_2$) with an absolute pressure of 0.6 bar so that the dissolved $CO_2$ concentration ($H_2CO_3$) can be estimated by the Henry's Law. In the alkaline compartment, there is no exchange of $CO_2$ with other parts of the system, so that the total concentration of $H_2CO_3$, $HCO_3^-$, and $CO_3^{2-}$ remains the same as in the acidic solution. In order to define the $K^+$ concentration in the acidic compartment the following correlations are used and linked to equilibrium equations (Eqs. 1-2) [11]:

$$J_{tot} = J_{k^+} + J_{H^+} = \frac{i}{F} \quad (1)$$

$$J_{k^+} = \frac{V_{rich}}{A_m} \times ([k^+]_{rich} - [k^+]_{acid}) \quad (2)$$

with $J_{tot}$ the total flux of cations ($K^+$ and $H^+$) across the CEM (mol/s•m$^2$), $J_K$+ and $J_H$+ the flux of $K^+$ and $H^+$ across the CEM respectively (mol/s•m$^2$), $V_{rich}$ the volumetric flow rate of rich solution (L/s), $A_m$ the CEM area (m$^2$), i the current density (A/m$^2$) and F the Faradaic constant (96485 C/mole-). Similarly, the amount of desorbed $CO_2$ ($J_{CO2}$ in mol/s•m$^2$) is evaluated by the following equation (see Eq. 3) [11]:

$$J_{CO2} = \frac{V_{rich}}{A_m} \times ([C_t]_{rich} - [C_t]_{acid}) \quad (3)$$

With $Ct_{rich}$ and $Ct_{acid}$ the total carbon concentration in the rich and acidic solutions.

The following figures of merit (removal ratio of $K^+$ ($R_{k+}$ in Eq. 4), removal ratio of carbon ($R_{ct}$ in Eq. 5), potassium transport number ($t_{k+}$ in Eq. 6), $CO_2$ desorption efficiency ($\eta_{CO2}$ in Eq. 7)) are considered to evaluate the efficiency of the electrodialysis process [11]:

$$R_{k^+} = \frac{[k^+]_{rich} - [k^+]_{acid}}{[k^+]_{rich}} \quad (4)$$

$$R_{C_t} = \frac{V_{CO2,g}}{V_{rich} \times [C_t]_{rich} \times V_m} \quad (5)$$

$$t_{k^+} = \frac{V_{rich} \times ([k^+]_{rich} - [k^+]_{acid}) \times F}{i \times A_m \times N} \quad (6)$$

$$\eta_{CO2} = \frac{V_{CO2,g} \times F}{i \times A_m \times N \times V_m} \quad (7)$$

With $V_{CO2,g}$ the $CO_2$ flow rate exiting the regeneration stage (L/s), $V_m$ the molar volume of $CO_2$ in standard conditions (22.4 L/mol), N the number of cell pairs.

It is possible to define, in addition, the carbon loading as the ratio between the total carbon concentration in the solution coming from the absorption column and the $K^+$ concentration in the same solution.

On the other hand, the load ratio is defined as the fraction electrical current to moles of $K^+$ ions supplied to the system (see Eq. 8) [11]:

$$L_{k^+} = \frac{i \times A_m \times N}{V_{rich} \times [k^+]_{rich} \times F} \quad (8)$$

In our model, at a fixed value of $K^+$ concentration, from Eq.8, we found the value of $V_{rich}$ that is able to provide the minimum positive value of load ratio. In this way the system equation is well determinate.

## Energy consumption

The specific energy consumption of the process is evaluated according to the following equation (Eq. 9) [11]:

$$SEC = \frac{U_{cell} \times i}{J_{CO2}} \quad (9)$$

With $U_{cell}$ the potential drop over N cell pairs calculated as (see Eq. 10):

$$U_{cell} = (N + 1) \times U_{BPM} + N \times U_{CEM} + N \times U_{ohmic} \quad (10)$$

where $U_{BPM}$ and $U_{CEM}$ are related to the overall potential drop over the bipolar membranes and CEMs while $U_{ohmic}$ considers the voltage for acidic and alkaline solutions. Their correlations are reported in the work of Castano et al. [11] taking into account the formation of $CO_2$ gas bubbles in the acidic solution.

## Economic analysis

A simple economic analysis has been performed for the BPMED stack system. The capture cost ($/ton$CO_2$) is provided by the following correlation (see Eq. 11) [9]:

$$Capture\ cost = \frac{TOC \times CRF + C_{O\&M}^{fix} + C_{O\&M}^{var} \times h_{eq}}{F_{CO2} \times h_{eq}} \quad (11)$$

with TOC as the total overnight cost, $F_{CO2}$ the overall captured flow rate ($J_{CO2} \bullet A_m$), CRF the capital recovery factor, $h_{eq}$ the plant ability. The TOC is evaluated as 2.6 times the bare erected cost (BEC) equal to 233 $/m$^2$, the fixed cost is a percentage of TOC (4.5%) while variable costs are evaluated considering a price for electricity, BPM and CEM respectively of 0.06 $/kWh, 750 $/m$^2$ and 75 $/m$^2$ [9-10].

## Global sensitivity analysis

A GSA has been conducted by quantifying the overall uncertainty in the KPIs of interest (specific energy consumption, capture cost, $CO_2$ desorption efficiency, removal ratio of $K^+$ and carbon, potassium transport number) and by simultaneously varying all of the uncertain factors through their entire range. The uncertain factors assume an uniform distribution, as reported in Table 1.

**Table 1.** Definition of uncertainty parameters in the GSA

| Uncertainty parameter | Lower bound | Higher bound |
|---|---|---|
| Current density (A/m$^2$) | 150 | 1000 |
| $K^+$, Rich concentration (M) | 0.5 | 2 |
| Membrane area (m$^2$) | 0.008 | 0.012 |
| Number of cell pairs | 3.2 | 4.8 |
| $CO_2$ partial pressure in the gas phase (bar) | 0.3 | 0.9 |

The GSA is conducted using the software Sobol-GSA, which constructs high dimensional model representation (HDMR) surrogates by drawing 1000 Sobol samples [14] from the uncertainty distribution and reevaluating the process model, then estimates total-order Sobol sensitivity indices [15] for each KPIs. The mentioned indices are evaluated in order to consider also interactions among parameters.

# RESULTS AND DISCUSSION

The developed mathematical model has been validated with data reported in Castano et al. [11]. The GSA provides 1000 values of input operating parameters reflecting on the distribution of the considered figures of merit and energy consumption and costs as reported in Figure 2. In Figure 2a, values of specific energy consumption are comparable with those reported in the literature [11] as well as for costs [9,10] in Figure 2b. Low values of $CO_2$ desorption efficiency in Figure 2c are due to the high load ratio caused by DAC operation or to a quite weak pH swing (driving force). Values of carbon removal ratio (Figure 2d), potassium removal ratio (Figure 2e) and

potassium transport number (Figure 2f) are similar to that reported in the literature [11].

Total-order Sobol sensitivity indices are evaluated and reported in Table 2: values higher than 5% suggest that the considered input is significant for the analyzed output [16].

The main specific energy consumption drivers seem to be the potassium cations concentration and the number of cell in the BPMED stack.. The cation concentration on rich solution has the highest impact on this response.

For the total cost, current density, $K^+$ concentration in the rich solvent and number of cell pairs are significant. The current density has the highest impact on costs while the number of cell pairs has the lowest impact on economy.

Minimal costs and energy consumptions are obtained at low potassium concentration. At lower current density, the system may experience lower losses due to reduced heat generation, less resistance in the system, and more efficient ion transport.

The concentration of $K^+$ in the feed and number of cells significantly affect the $CO_2$ desorption efficiency with a more effect for the cation concentration.

The concentration of $K^+$ cation in rich solvent is significant for the carbon and potassium removal ratio. The same input in addition to the number of cells significantly affect the potassium transport number. Here the number of cell pairs has a lower effect compared to the potassium concentration in the feed.

From the results, it is evident that membrane area does not affect the analyzed KPIs. This can be explained by the fact that the considered range values for the membrane area is not wide enough to be significant on cost or energy consumption, as reported in Sabatino et al. (2020). Moreover, as the $CO_2$ partial pressure does not affect each of the considered output, lower operating pressure are preferred to reduce costs and energy consumptions.

It is possible to see that the $K^+$ concentration is affecting all analyzed outputs and in a higher measure the carbon removal ratio. On the other hand, $K^+$ concentration has a lowest effect on the potassium transport number.

It is important to underline that these results are obtained considering a single electrodialysis cell not integrated into an absorption column so that the potassium cation concentration is fixed a priori and it is not a result from the absorption unit where the chemical absorption of $CO_2$ occurs. For this reason, values of load ratio higher than that reported in the literature in Castano et al. [11] are obtained in our results, as reported in Figure 3 where the potassium removal ratio as a function of load ratio is shown with $K^+$ concentration as parameter.

These results suggest that the optimal operation of the electrodialysis cell can be obtained only with an optimal operation of the absorption column that provides the optimal potassium concentration in the rich solution able to maximize efficiency and minimize costs.

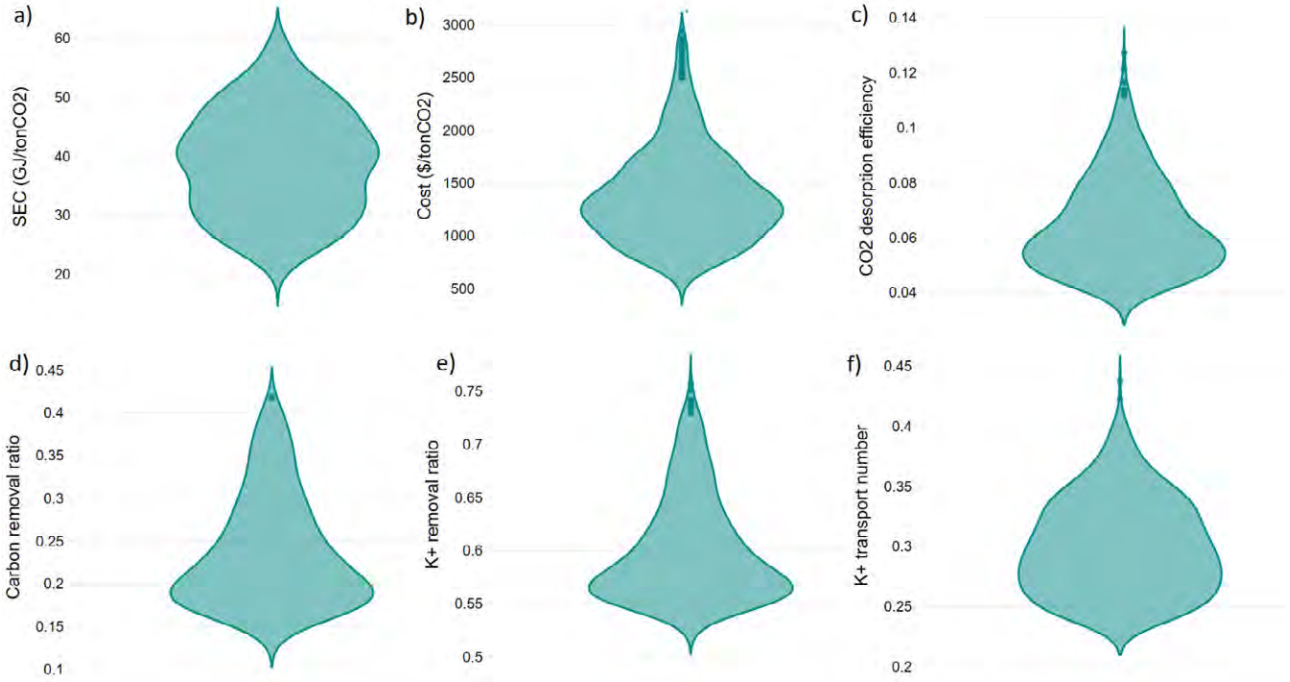

**Figure 2:** Distribution of a) SEC; b) Cost; c) $CO_2$ desorption efficiency; d) Carbon removal ratio; e) Potassium removal ratio; f) Potassium transport number.

**Table 2** Results of the Total-order Sobol sensitivity indices

| | SEC ($GJ/tonCO_2$) | Cost ($/tonCO_2$) | $\eta_{CO2}$ | $R_{CO2}$ | $tn_{K^+}$ | $R_{K+}$ |
|---|---|---|---|---|---|---|
| Current density ($A/m^2$) | 0.0003 | 0.4910 | 0.0001 | 0.0001 | 0.0000 | 0.0001 |
| $[K^+]_{rich}$ (M) | 0.8589 | 0.4597 | 0.8250 | 0.9976 | 0.2067 | 0.9817 |
| Membrane area ($m^2$) | 0.0005 | 0.0003 | 0.0002 | 0.0002 | 0.0000 | 0.0001 |
| Number of cell pairs | 0.1404 | 0.0732 | 0.1819 | 0.002 | 0.7960 | 0.0012 |
| $CO_2$ partial pressure in the gas phase (bar) | 0.0043 | 0.0021 | 0.0043 | 0.0002 | 0.0005 | 0.0196 |

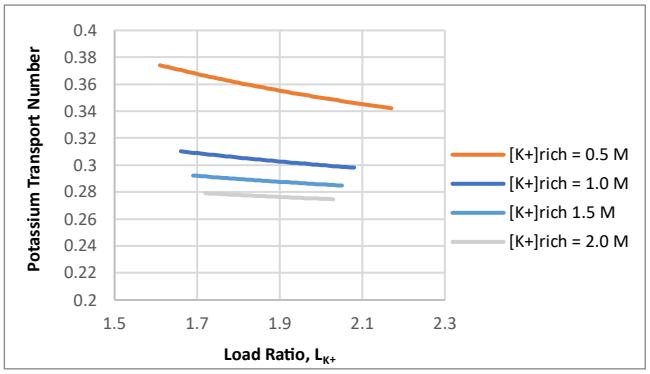

**Figure 3.** Potassium transport number as a function of load ratio and potassium concentration as a parameter

The optimization results interestingly highlight the trade-off between energy efficiency, process speed, and operational costs. Lower process costs are obtained at a higher current intensity due to an improved membrane utilization, the system operating at a more optimal voltage and current conditions. This may reduce the need for more frequent membrane replacements or over-sizing of the system, which can reduce long-term operational costs. Moreover, although higher current densities lead to higher specific energy consumption and lower efficiency, they can reduce overall costs by increasing the production rate or reducing the time required to process a given amount of $CO_2$. This faster operation could mean lower fixed costs for labour, equipment, and maintenance per ton of processed $CO_2$.

## CONCLUSIONS

This work analyzes the performances of a BPMED system for an absorption DAC. In particular a mathematical model has been developed considering equilibrium equations and material balances. In this way, a GSA is carried out to find significant parameters on the main figures of merit. Results show that the main important factor is the potassium concentration in the rich solvent affecting energy consumption, cost, $CO_2$ desorption efficiency, potassium and carbon removal ratio and potassium transport number.

A trade-off between energy efficiency, process speed, and operational costs could be achieved to have to optimal operating conditions.

In future research, an overall integrated system considering the absorption column and the cell must be considered for a better analysis.

## ABSTRACT

An intensified approach to γ-valerolactone (GVL) production is achieved using a reactive distillation column. Conventional methods require multiple units, leading to high energy consumption, costs, and limited scalability. The proposed technology integrates reaction and separation into a single unit, enhancing process efficiency for biomass-derived chemicals. A multiobjective optimization framework balances economic, environmental, and operational goals, reducing total annual cost (TAC) by 43% and environmental impact (EI99) by 45% compared to conventional processes. Additionally, energy consumption drops by 63%, while GVL production increases by 25%, highlighting the potential of reactive distillation for improved efficiency and sustainability.

**Keywords**: Process Intensification, Optimization, Distillation, Life Cycle Analysis, Biomass

## INTRODUCTION

The rise of Industry 4.0 is transforming manufacturing through digital integration, automation, and smart systems, fostering sustainability and efficiency [1]. Traditional biofuel production, such as bioethanol and biobutanol, faces challenges in cost and energy efficiency, prompting a shift towards high-value bio-based chemicals like γ-valerolactone (GVL) [2]. GVL, derived from levulinic acid via catalytic hydrogenation, serves as a green solvent, biofuel additive, and precursor for biofuels [2]. Despite its potential, conventional GVL production methods are energy-intensive and costly, requiring high pressures and temperatures, limiting scalability [2-3]. Process Intensification (PI) offers a solution by integrating chemical reactions and separation, reducing energy consumption and enhancing efficiency [5]. Reactive distillation, which combines reaction and distillation into a single unit, has successfully improved processes like biodiesel production, reducing energy use by 40% [6]. This study proposes a sustainable, intensified approach to GVL production using reactive distillation, compared with conventional methods under a multi-objective optimization framework evaluating total annual cost (TAC) and environmental impact [7]. This novel strategy aligns with Industry 4.0 and sustainability goals, enhancing GVL production efficiency and viability.

## PROBLEM STATEMENT AND CASE STUDY

Biocompounds derived from renewable biomass present a sustainable alternative to petrochemical-based products. However, conventional production methods are highly energy-intensive, often diminishing their environmental advantages. Typical processes involve multiple stages, including feedstock pretreatment, chemical or biochemical conversion, and product purification. Each stage contributes significantly to energy demand, with steam explosion consuming up to 15% of the total process energy, fermentation requiring 10-15%, and distillation accounting for 35-40% in ethanol production [7].

To address these inefficiencies, Process Intensification (PI) has emerged as a promising strategy,

integrating multiple unit operations to enhance mass and heat transfer, reduce equipment size, and minimize energy consumption. By leveraging PI, biocompound production can achieve improved economic feasibility and environmental performance [8].

In the case of γ-valerolactone (GVL) production, catalytic hydrogenation of levulinic acid (LA) has been widely studied [8]. demonstrated that a Cu–$ZrO_2$ nanocomposite catalyst achieves over 90% selectivity under optimal conditions (473 K, 3–4 MPa $H_2$ pressure), with excellent recyclability and low metal leaching, making it suitable for industrial applications. Later, [7]. implemented this process in a multi-product biorefinery, producing GVL alongside levulinic acid, furfural, and hydroxymethylfurfural using conventional reaction and separation technologies. However, their study revealed that GVL production accounted for 41% of the total energy demand of the process, highlighting a need for further optimization.

This study proposes the integration of a reactive distillation column as an intensified alternative to replace conventional reactor-separation schemes. By merging reaction and separation into a single unit, energy consumption is reduced, operational efficiency is enhanced, and process sustainability is improved. The proposed intensified process will be systematically compared against its conventional counterpart using multi-objective optimization, evaluating total annual cost (TAC) and environmental impact (EI99) as key performance indicators. The conceptual approach for process intensification applied to GVL production is illustrated in Figure 1.

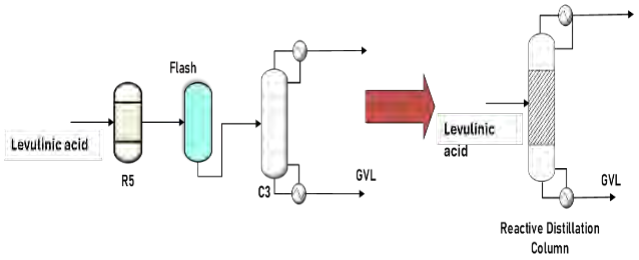

**Figure 1:** Process intensification applied to GVL production.

## PERFORMANCE ASSESSMENT

### Economic and Environmental Evaluation

A multi-objective optimization framework is used to evaluate both economic and environmental performance. The total annual cost (TAC) [9]. and environmental impact (EI99) [1]. serve as key indicators:

TAC Calculation:

$$TAC\ (\$/y) = \frac{\sum_{i=1}^{n} C_{TM,i}}{n} + \sum_{j=1}^{n} C_{ut,j} \qquad (1)$$

where TAC represents the total annual cost, CTM stands for the capital cost of the plant, n signifies the payback period, and $C_{ut}$ represents the utility cost.

Environmental Impact Evaluation (EI99):

To ensure a robust assessment, the system boundaries were carefully defined to encompass the entire life cycle of the process, from raw material input to product output. The analysis considers both direct and indirect environmental impacts associated with the production and operation of the proposed technology. Specifically, it includes the environmental footprint of the materials used for equipment construction, the energy required for heating, and the utilities needed for process operation. In particular, the impact of steel used for the fabrication of the equipment is incorporated into the analysis, considering its extraction, processing, and eventual disposal. Additionally, the steam utilized for process heating is accounted for, as it represents a major contributor to energy consumption. The evaluation also includes the electricity required for pumping operations, which reflects the indirect energy demand necessary for fluid transport and process continuity.

$$EI99 = \sum_b \sum_d \sum_{k \in K} \delta_d \omega_d \beta_b \alpha_{b,k} \qquad (2)$$

Here, $\beta_b$ denotes the total quantity of chemical b released per unit of reference flow due to direct emissions, $\alpha_{b,k}$ represents the damage caused by category k per unit of chemical b released into the environment, $\omega_d$ is the weighting factor for damage in category d, and $\delta_d$ is the normalization factor for damage in category d. This approach considers the impact of steel used for construction, steam used for heating, and electricity used for pumping.

## METHODOLOGY

### Kinetic Parameter Determination

The kinetic model for GVL production was developed using experimental data from [8]. with reaction kinetics adapted for a Cu–$ZrO_2$ catalyst. The catalyst parameters were optimized using the kinetic parameter estimation framework proposed by [9]. The process follows a two-step hydrogenation reaction: first, hydrogen peroxide decomposes into hydrogen and carbon dioxide. Then, levulinic acid undergoes hydrogenation in the presence of hydrogen gas, yielding γ-valerolactone (GVL) and water. Finally, an intramolecular cyclization step completes the formation of GVL, a high-value bio-based chemical with diverse industrial applications:

$$CH_2O_2 \rightarrow H_2 + CO_2 \qquad (3)$$

$$C_5H_8O_3 + H_2 \rightarrow C_5H_8O_2 + H_2O \qquad (4)$$

### Process Simulation and Modeling

The intensified alternatives were developed based on the optimization of the conventional GVL production process. The previously reported scheme [7]. was replicated to ensure a fair comparison, as detailed in Table 1 and illustrated in Figure 2, which highlights the key process stages. At the inlet of reactor R5, the feed stream rich in levulinic acid undergoes conversion, primarily yielding γ-valerolactone (GVL). The Aspen Plus process simulator was used to model both conventional and intensified processes, ensuring accurate process representation. Thermodynamic modeling was performed using the Non-Random Two-Liquid (NRTL) model for phase equilibrium, providing reliable predictions of separation efficiencies and component interactions.

**Table 1:** Design parameters conventional design [7].

| Column C3 | Value | Reactor R5 | Value |
|---|---|---|---|
| Stages | 39 | Flow rate (l/min) | 12.188 |
| Feed Stage | 22 | Volume ($m^3$) | 0.731 |
| Reflux ratio | 0.039 | Diameter (m) | 0.677 |
| Distillate flow (kmol/h) | 7.296 | Pressure (kPa) | 101.32 |
| Diameter (m) | 0.992 | Temperature (°K) | 473 |
| Condenser Duty (Watt) | 91280 | | |
| Reboiler Duty(Watt) | 138022 | | |
| Height (m) | 22.55 | | |

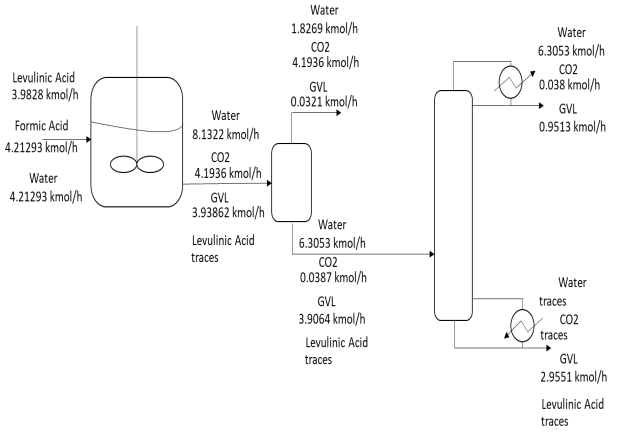

**Figure 2:** Mole balance of the conventional technology for GVL production.

## Reactive Distillation Design and Optimization

The optimization of the reactive distillation column design combines empirical heuristics with a hybrid optimization approach, integrating Aspen Plus with Differential Evolution with Tabu List (DETL) [12]. This method effectively handles nonlinear, nonconvex processes by preventing the re-evaluation of previously assessed points, enhancing search efficiency. The objective function minimizes both total annual cost (TAC) and environmental impact (EI99), ensuring an optimal balance between economic and environmental performance.

The design process starts with defining key parameters such as column dimensions, catalyst type, number of stages, and feed conditions, which are initialized using empirical rules and refined through Aspen Plus simulations. To ensure feasibility, the operating conditions of reaction and separation must align. Factors such as temperature, pressure, and relative volatility are critical, as mismatches between reaction kinetics and separation efficiency can compromise performance [11].

The multi-objective optimization integrates Aspen Plus with Excel via Dynamic Data Exchange (DDE). The DETL algorithm, implemented in Visual Basic, iteratively adjusts decision variables (e.g., reflux ratio, reboiler duty, and feed stage locations) based on process simulations. Optimization parameters include 200 individuals, 1000 generations, a tabu list size of 50%, a tabu radius of $1\times10^{-6}$, and crossover/mutation rates of 0.8 and 0.6, derived from previous studies [12]. The objective function minimizes both TAC and EI99:

$$Min(TAC, EI99) = f(N_{tn}, N_{fn}, R_{rn}, F_{rn}, R_{sn}, D_{cn}) \quad (5)$$

$$\text{Subject to } \vec{x_m} > \vec{y_m}$$

where $N_{tn}$ is the total number of column stages, $N_{fn}$ is the feed stages in the column, $R_{rn}$ is the reflux ratio, $F_{rn}$ is the distillate/bottoms flux, $R_{sn}$ is the reactive stages, and $D_{cn}$ is the column diameter. $y_m$ and $x_m$ are the vectors of both obtained and required purities for the $m_{th}$ components, respectively. The minimum purity targets were fixed as 98.5 %wt for GVL.

Decision variables such as reflux ratio, reboiler duty, feed stage locations, and catalyst distribution are identified and optimized with respect to a multi-objective function that incorporates economic, environmental, and operational goals (See Table 2).

**Table 2:** Decision Variables in the multi-objective optimization problem

| Variable | Type | Search Range |
|---|---|---|
| Number of Stages | Discrete | 5-100 |
| Feed Stages | Discrete | 4-99 |
| Reactive stages range | Discrete | 4-99 |
| Reflux Ratio | Continuous | 0.1-5 |
| Bottoms Rate | Continuous | 3.5 - 4 (kmol h-1) |
| Diameter | Continuous | 0.9-5 (meters) |

## RESULTS AND DISCUSSION

### Kinetic Model Validation

**Figure 3** shows a strong correlation between experimental and predicted outflows in the reactor, with a **99.9% GVL yield**. The close agreement between red (experimental) and blue (predicted) bars across all components validates the kinetic model's accuracy, confirming its reliability for process optimization.

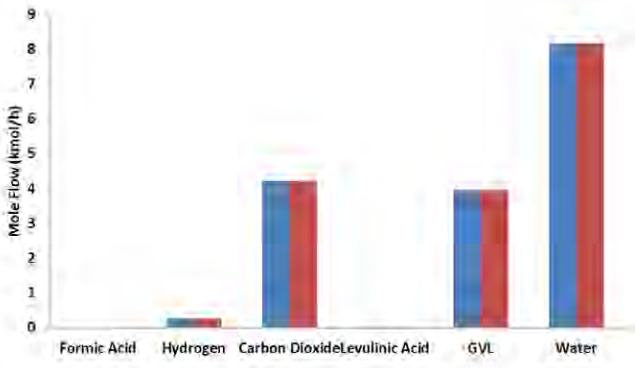

**Figure 3:** Experimental (red) and predicted (blue) outflows in the reactor

**Table 3** presents the kinetic parameters for key reactions in GVL production. The decomposition of **formic acid ($CH_2O_2 \rightarrow H_2 + CO_2$)** has a high rate constant and activation energy, indicating a fast, energy-intensive step. In contrast, the **hydrogenation of levulinic acid to GVL** occurs at a slower rate, suggesting it is the limiting step. These findings emphasize the need for optimized catalysts and conditions to enhance conversion efficiency

**Table 3:** Caption for the table. Multi-line table captions will be fully justified. The style is **PSE_TableCaption**.

| Reaction | k | E (cal/mol) |
|---|---|---|
| $CH_2O_2 \rightarrow H_2 + CO_2$ | 29513.430 | 3399.005 |
| $C_5H_8O_3 + H_2 \rightarrow C_5H_8O_2 + H_2O$ | 552.581 | 1703.585 |

### Process Optimization and Comparison

Reactive distillation column for GVL production was optimized using Differential Evolution with Tabu List (DETL), minimizing total annual cost (TAC) and environmental impact (EI99). The Pareto front (Figure 4) highlights designs that meet GVL purity constraints, demonstrating the trade-off between economic and environmental objectives.

Reducing equipment costs favors smaller, compact designs, but these require higher reflux ratios or reboiler duties, increasing operational costs. Conversely, minimizing steel usage reduces environmental impact but can lead to higher energy consumption. The optimal design, marked in Figure 4, balances TAC and EI99, ensuring an efficient and sustainable reactive distillation process.:

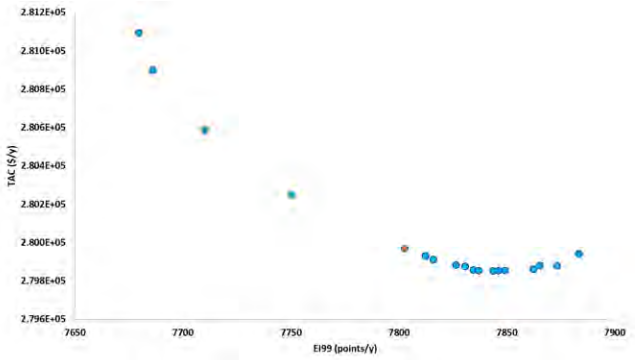

**Figure 4.** Pareto front for the reactive distillation column for GVL production.

A Pareto front analysis identified optimal designs that balance total annual cost (TAC) and environmental impact (EI99), demonstrating the advantages of the intensified process over the conventional approach. The intensified design achieved a 43% reduction in TAC, a 45% decrease in EI99, and a 63% reduction in energy consumption, while increasing GVL production by 25%. Compared to the conventional process, these improvements highlight the effectiveness of integrating reaction and separation into a single unit, significantly enhancing efficiency and sustainability.

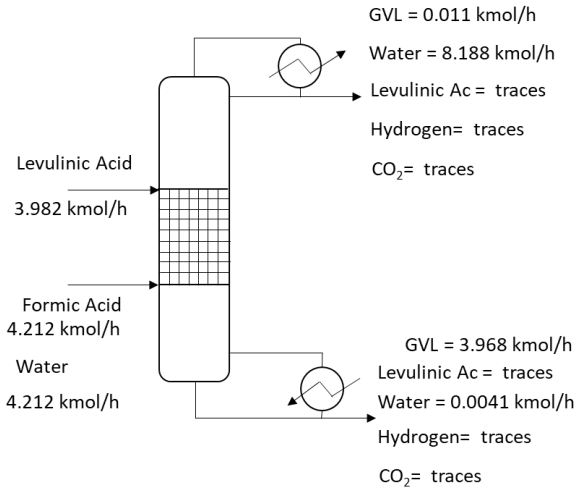

**Figure 5:** Flowsheet of the reactive distillation column.

Figure 5 presents the complete flowsheet of the intensified process, emphasizing the integration of reaction and separation within a single unit to enhance efficiency and sustainability. When contrasted with the Pareto front shown in Figure 4, the optimized design achieves a significant reduction in total annual cost (TAC) and environmental impact (EI99). The highlighted optimal point in the Pareto front confirms that the intensified

process configuration successfully balances economic and environmental objectives, reinforcing the advantages of reactive distillation over conventional multi-unit approaches.

**Table 4:** Optimal design parameter of the reactive distillation for GVL production.

| Reactive Column | | | |
|---|---|---|---|
| Number of stages | 12 | Distillate flowrate (kmol h-1) | 12.64 |
| Reflux ratio | 0.322 | Condenser duty (kcal h-1) | -15.66 |
| Feed stage | 5 and 9 | Reboiler duty (Watt) | 9.89 |
| Reactive stages | 5 to 9 | Operative pressure (kPa) | 101.32 |
| Hold Up (cum) | 0.668 | GVL production (kmol/h) | 3.968 |

Table 4 presents the complete flowsheet of the intensified process, emphasizing the integration of reaction and separation within a single unit to enhance efficiency and sustainability. This optimized design, when contrasted with the Pareto front in Figure 5, demonstrates a substantial reduction in total annual cost (TAC) and environmental impact (EI99). The highlighted optimal point in the Pareto front confirms that the intensified configuration effectively balances economic and environmental objectives. The key design parameters, such as the number of stages, reflux ratio, and reboiler duty, were optimized to maximize GVL yield while minimizing energy consumption. This reinforces the advantages of reactive distillation over conventional multi-unit approaches, offering a more sustainable and cost-effective alternative for GVL production.

The results clearly demonstrate the advantages of process intensification in γ-valerolactone (GVL) production. As shown in **Figure 6**, the intensified process significantly reduces Total Annual Cost (TAC) and environmental impact (EI99) while maintaining a lower heat duty compared to the conventional approach. This indicates improved energy efficiency and economic feasibility. Furthermore, **Figure 7** illustrates the molar composition profile along the reactive distillation column, where levulinic acid is effectively converted into GVL, with water as a major byproduct. The presence of formic acid and carbon dioxide suggests minor side reactions, while hydrogen formation in intermediate stages aligns with catalytic hydrogenation mechanisms. Overall, these findings validate the effectiveness of reactive distillation in optimizing GVL production, offering a more sustainable and cost-efficient alternative to conventional multi-unit processes.

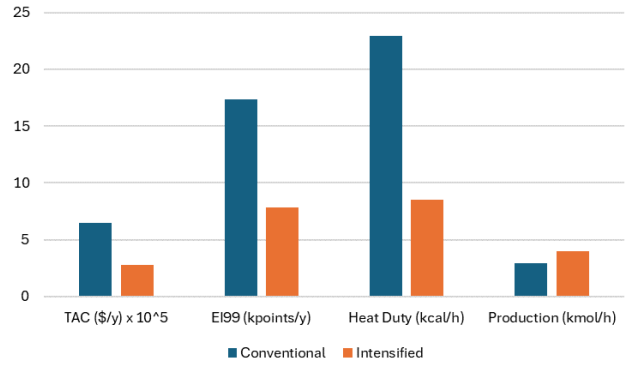

**Figure 6:** Comparison of the performance of technologies in GVL production

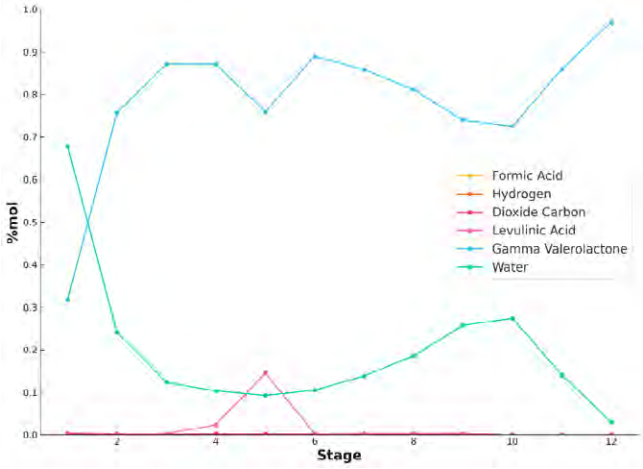

**Figure 7:** Molar composition profile at the reactive distillation column for GVL production

## CONCLUSION

This study introduces an intensified reactive distillation process for γ-valerolactone (GVL) production, significantly improving efficiency over conventional methods. By integrating reaction and separation in a single unit, energy consumption is reduced to 37% of the traditional process, enhancing sustainability. The approach aligns with Industry 4.0 principles, emphasizing process integration, automation, and resource efficiency, demonstrating its potential to drive economic and environmental benefits in modern industrial practices.

## ABSTRACT

Oxidation of arabinose to arabinoic acid is an innovative way to valorize local biomass to a high add value product. Previously done experiments on oxidation of arabinose to arabinoic acid with molecular oxygen were used to determine the optimum reaction conditions, scale-up the process and analyse the techno-economic aspects. These results were utilized to analyse the environmental impact of the scaled-up process during its lifetime using the life cycle assessment (LCA) methodology. SimaPro software combined with the impact assessment method IMPACT 2002+ were applied. The results revealed that heating seems to be the largest contributor to the environmental impact even if the reaction is performed under rather mild conditions (70°C). This highlights the importance of reducing the energy consumption via efficient heat integration.

**Keywords**: Catalyst, LCA, Biomass

## INTRODUCTION

The global transition toward sustainable chemical processes has underscored the importance of assessing the environmental impacts of emerging industrial technologies. One such process, the catalytic oxidation of arabinose to arabinoic acid, has gained attention for its diverse applications in the pharmaceutical, cosmetic, and food industries due to the functional properties of arabinoic acid as a platform chemical [1, 2].

Gold-based catalysts have been shown to be effective in achieving high sugar conversion and sugar acid selectivity under optimal conditions, especially in a slightly basic environment [3]. However, the environmental impact of scaling up this process needs to be carefully investigated. This is especially true with respect to energy-intensive operations such as heat generation and wastewater treatment.

Life Cycle Assessment (LCA) is a well-established framework for evaluating the environmental performance of chemical processes by systematically analyzing their impact across categories such as human health, ecosystem quality, climate change, and resource use. The IMPACT 2002+ methodology, a widely recognized LCA framework [4], integrates midpoint and endpoint impact categories, enabling a detailed analysis of environmental trade-offs associated with chemical processes. By applying this methodology, the present study aims to evaluate the environmental impact of catalytic oxidation of arabinose to arabinoic acid, focusing on critical hotspots such as heat generation and wastewater treatment.

This research employs a large-scale process model designed in Aspen Plus to simulate the production of arabinoic acid, offering insights into energy consumption, material flows, and waste streams. Specifically, the study investigates the contributions of heat generation and wastewater treatment to the overall environmental footprint of the process, identifying opportunities for optimization and mitigation. The results will pave a way for developing strategies for reducing emissions, minimizing resource depletion, and improving the sustainability of arabinoic acid production, thereby contributing to the broader goal of sustainable industrial chemistry and process technology.

## METHODOLOGY

### Oxidation of Arabinose

The selective oxidation of arabinose over gold

catalysts has been studied extensively to optimize reaction conditions. The process was carried out isothermally at atmospheric pressure in a semi-batch mode, with variations in temperature, pH, and catalytic properties to achieve the best results.

The primary product, arabinoic acid, is obtained via the intermediate arabinolactone. This final product, the sugar acid, and its derivatives are valuable compounds finding applications in the cosmetic, food, and pharmaceutical industries, offering a competitive price and versatility. Figure 1 illustrates the reaction pathway, highlighting the transformation of arabinose to arabinoic acid via arabinolactone.

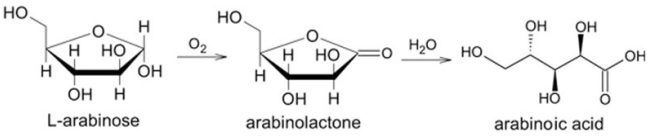

**Figure 1.** The reaction scheme for selective catalytic oxidation of arabinose (adapted from [5]).

The experimental studies reported in [6, 7] demonstrated that in acidic media, the reaction resulted in only 23% conversion of arabinose after 200 minutes, with 46% selectivity towards the desired product, arabinoic acid. Significant amounts of the intermediate compound, arabinolactone, were formed under these conditions. In contrast, slightly basic conditions (pH 8–9) led to the complete conversion and total selectivity for arabinoic acid within the same time frame. The temperature elevation was observed to enhance reaction activity but also promoted formation of the undesired byproducts.

Utilization of a continuous reactor can be challenging because the pH control is not easy, however, it was shown in [8] showed that continuous sugar oxidation could be carried out in a plug-flow reactor without the need for a pH control alongside the whole reactor. Moreover, it was reported that selectivity in the plug-flow reactor was similar to that in the batch reactor, 94% and 99%, respectively.

## Process Design and Modeling

Process design and modeling were conducted in Aspen Plus V11, following the methods used in similar studies previously [9–11]. As the properties of some compounds were not available in the Aspen database, Aspen Properties module was used to estimate the required parameters. The Peng-Robinson equation of state (EoS) was applied to calculate the phase equilibrium [13]. The reactor was modeled using Aspen PFR blocks, in accordance with Ranade et al. [12], who applied plug flow models for trickle bed reactors. Arabinoic acid properties, unavailable in the database, were added via the user-defined compound wizard after their estimation with the Joback method [13], while other parameters were computed with Aspen Properties. The developed flowsheet is

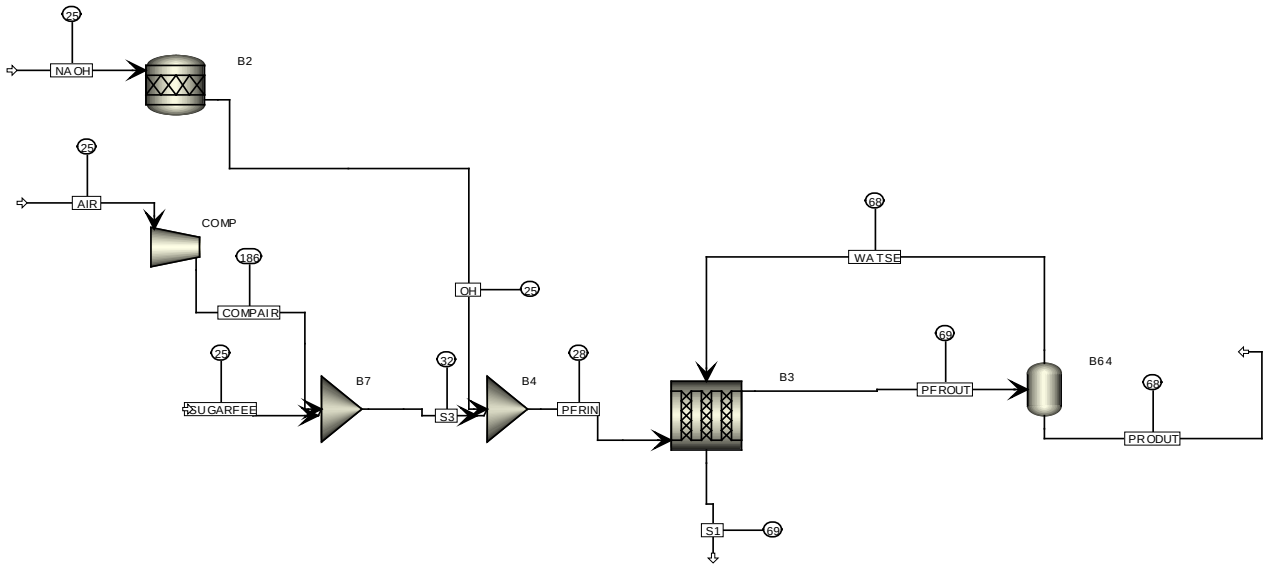

**Figure 2.** Flowsheet of arabinoic acid production via catalytic oxidation of arabinose

presented in Figure 2.

## Goal and scope

The goal of this study is to investigate the environmental impact of the catalytic oxidation of the arabinose sugar on a supported gold catalyst. This assessment is based on the data generated from the large-scale process model developed using Aspen Plus [10]based on the experimental results generated in laboratory scale [6, 14–16]. In this study, the annual processing capacity of 10 kt of arabinose solution (30 wt%) was considered. The functional unit was taken as 1 kg of arabinoic acid solution (30 wt%). The system boundaries followed a cradle-to-gate approach. SimaPro software was used for this work.

## Life Cycle Inventory and Life Cycle Impact Assessment

The life cycle inventory (LCI) data for the system (i.e. chemicals, energy, reactants' consumption) consists of the mass, heat balance, and energy consumption from the simulations using Aspen Plus. The details are reported in our previous publication [10].

Life Cycle Impact Assessment (LCIA) is a phase in the Life Cycle Assessment process where the potential environmental impact associated with a product or process is evaluated. The impact assessment was performed using the impact 2002+ method, originally developed in [4].

# RESULTS AND DISCUSSIONS

Figure 3 highlights the environmental impact of arabinose oxidation across four damage assessment categories: Human Health, Ecosystem Quality, Climate Change, and Resource Use, with contributions from specific sources represented as stacked bars.

Heating used in the process emerges as a major contributor to negative impacts in all categories. In the Human Health category, industrial heat processes significantly affect health outcomes, primarily due to emissions and resource-intensive operations. Similarly, for Climate Change, heat generation from industrial sources is the dominant factor driving adverse impacts, reflecting high greenhouse gas emissions associated with these processes. In Resource Use, the production and use of heat in industrial activities lead to substantial resource depletion, further emphasizing its environmental burden. Conversely, the impact of heat-related processes on Ecosystem Quality is relatively minor, though still present.
Wastewater treatment processes generally have a mixed impact. In the Human Health category, they show a slight mitigating effect, likely due to their role in reducing pollutants that would otherwise harm human populations. Similarly, in the Climate Change category, wastewater treatment contributes modestly to mitigating greenhouse gas emissions, though its overall impact is small compared to industrial processes like heat generation.

However, in the Resource Use category, wastewater treatment has a slightly negative impact, most likely due to the energy and materials required for facility operation. The effects on Ecosystem Quality are minimal, indicating that the wastewater treatment has a limited but generally a positive role in addressing ecosystem-related concerns.

The analysis, conducted using the IMPACT 2002+ methodology, underscores the significant role of heat generation in driving environmental and health impacts,

particularly in resource use and climate change. This highlights an urgent need for improving the energy efficiency, adopting renewable energy sources for heat generation, and exploring alternative, lower-impact materials in industrial processes to mitigate these effects. Prioritizing these strategies can significantly reduce the environmental footprint of heat-related activities.

## CONCLUSIONS

The obtained LCA results show that heat generation is the leading cause of environmental impact across all the major categories, especially resource use and climate change. This emphasizes the urgent need to transition to more energy-efficient systems and integrate renewable energy sources into industrial processes. Heat integration and optimization also play an important role in reducing the energy consumption, thus decreasing greenhouse gas emissions and improving the overall process efficiency.

Wastewater treatment, while essential for mitigating pollution and safeguarding public health, also presents opportunities for further optimization. Enhancing the energy efficiency of treatment systems and integrating renewable energy, such as solar or wind power, into their operation can help offset the environmental burdens associated with these processes.

## ABSTRACT

Steel mill off gas fermentation presents a promising green alternative to petrochemical isopropyl alcohol (isopropanol, IPA) and acetone production while potentially reducing greenhouse gas emissions. A pilot-scale study stated negative global warming potential (GWP) at 85% gas conversion and 90% product selectivity. However, industrial-scale plant design including detailed techno-economic assessment (TEA) and life cycle assessment (LCA) remain undescribed. Therefore, this study modelled a heat-integrated 47.5 kton/ year gas fermentation process to IPA and acetone, based on pilot-scale data. The downstream processing was designed using vacuum distillation and heat-pump integrated (extractive) distillation to purify the 50 $g_{product}$/ L broth with biomass and acetate as byproducts, to obtain 41.8 kton/ year of 99.6 wt. % IPA and 5.64 kton/ year of 99.0 wt. % acetone. Notably, no steam is consumed and 2.6 MWh of electricity is generated by utilising the energy from the steel mill off gas. The estimated unit production cost (UPC; 0.57 \$/$kg_{product}$) is significantly below market prices (1.65 \$/ $kg_{IPA}$ and 1.45 \$/ $kg_{acetone}$). Moreover, the cradle-to-gate LCA gave GWPs of -1.42 $kg_{CO2-eq}$/ $kg_{IPA}$ and -1.25 $kg_{CO2-eq}$/ $kg_{acetone}$, mainly due to avoided steel mill emissions. Other environmental impacts studied were also lower than for petrochemical production. Only the freshwater use is higher (70 L/ $kg_{IPA}$ and 62 L/ $kg_{acetone}$) compared to petrochemical production (16 L/ $kg_{IPA}$ and 28 L/ $kg_{acetone}$). Future research should study the impact of IPA and acetone selectivity and titer on the economic and environmental sustainability of steel mill off gas fermentation to IPA and acetone.

**Keywords**: Syngas fermentation, Isopropanol, Techno-economic assessment (TEA), Life Cycle Assessment (LCA), Product selectivity, Vacuum distillation, *Clostridium autoethanogenum*

## INTRODUCTION

Syngas fermentation of steel mill off gas can provide both (1) a sustainable alternative to petrochemical isopropyl alcohol (isopropanol, IPA) and acetone production and (2) reduce greenhouse gas emissions from the steel industry. Syngas fermentation using *Clostridium autoethanogenum* can convert the energy-rich steel mill off gas (50% CO, 10% $H_2$, 20% $CO_2$, 20% $N_2$) to ethanol on an industrial-scale [1]. Recently, a 120 L pilot producing mainly either isopropyl alcohol (IPA), or acetone or a mixture of both was published [2]. Liew *et al.*, (2022) even claimed negative global warming potential (GWP) for the production of IPA and acetone from steel mill off gas. However, the industrial-scale plant design and its potential techno-economic and environmental performance is yet unknown. Therefore, this study aims to design and model an economically and environmentally sustainable industrial-scale syngas fermentation to produce 47.5 kton/year of >99 wt. % isopropyl alcohol and acetone. Previous work has modelled the syngas fermentation to IPA at a 46 kton/year scale and described the dilution rate, volumetric mass transfer of CO, product selectivity and gas conversion as key sustainability parameters [3]. Besides, an eco-efficient downstream processing has been modelled and described for a gas fermentation

broth containing an IPA and acetone mixture [4]. This study fully-integrates the upstream and downstream process design including heat integration and wastewater treatment (anaerobic digestion, CHP and water recycle). Then a techno-economic assessment (TEA) and life cycle assessment (LCA) were performed. Not only considering GWP but also assessing stratospheric ozone depletion, fine particulate matter formation, freshwater eutrophication, marine eutrophication, human carcinogenic toxicity, land use, and freshwater use.

# METHODS

## Process modelling

The process was modelled in Aspen Plus V12.0 for a total production of IPA and acetone of 47.5 kton/y (see Figure 1). Whereas, the gas fermentation was modelled as previously described [3] using the 120 L pilot data [2], with adaptation of the (optimistic) CO volumetric mass transfer rate to 14.9 g/L/h. A CO volumetric mass transfer up to 8.5 g/L/h was deemed feasible for ethanol [5] at a lower overhead pressure (1.1 bar vs 1.4 bar). Additionally, IPA decreases the bubble size already at lower concentrations [6]. This resulted in a product titer of about 50 g/L, which can give a ~33% lower biomass growth rate [7]. The downstream processing was modelled based on [4]. Vacuum distillation was employed to capture volatile products while recycling the broth back to the fermenter. The product stream was further purified using heat pump-assisted distillation, incorporating heat integration from the hot steel mill off-gas. Additionally, Combined Heat and Power (CHP) generation and wastewater treatment with recycling were implemented [8]. All decisions during process design were made to minimise energy requirements.

## Techno-economic assessment (TEA)

The techno-economic assessment was performed according to the National Renewable Energy Laboratory (NREL) methodology to determine the capital expenses (CAPEX) and operating expenses (OPEX) [9]. The CAPEX includes the equipment and installation costs as well as indirect costs for home office and construction, field expenses, proratable expenses, project contingency, working capital, site development, additional piping, warehouse and initial water and solvent costs. The installed costs for the equipment, except the bioreactor was determined according to [10], [11] and using the Marshall & Swift cost index value of 1773.4 (end of 2021). Whereas the bioreactor (external-loop gas lift reactor) installed costs were determined based on a direct quotation, a scaling factor of 0.60, an installation factor of 2.00 [9], and a Chemical Engineering Plant Cost Index (CEPCI) of 800.3 (2024). In principle, the assessment was done for a plant located in the US. The assumed plant lifetime was 10 years.

For the OPEX, the costs for the steel mill off gas were assumed 14.64 $/ton based on low-pressure steam costs (7.78 $/GJ) for replacing the otherwise captured heat from flaring (38% efficiency) and the CHP costs were assumed 2.1 $/MWh (2024) [12]. The costs of wastewater treatment for recycle was done using data from [8]. The unit production costs (UPC) were calculated in US$ per kg of product (isopropyl alcohol or acetone) and the profit margin was calculated based on the market prices (1.65 $/ $kg_{IPA}$ and 1.45 $/ $kg_{acetone}$).

## Life cycle assessment (LCA)

The Life Cycle Assessment was performed cradle-to-gate (see Figure 1) using the ReCiPe 2016 Midpoint Hierarchical method (V1.04) and the US life cycle impacts from the Ecoinvent database V3.11. Including scope 1, 2, and 3 emissions. The assessed midpoint indicator categories are: (I) Global warming potential (GWP in $kg_{CO2\text{-}eq}$/ $kg_{product}$), (II) Stratospheric ozone depletion (SOD in $kg_{CFC11\text{-}eq}$/ $kg_{product}$, (III) Fine particulate matter formation (FPMF in $kg_{PM2,5\text{-}eq}$/ $kg_{product}$), (IV) Freshwater eutrophication (FWE in $kg_{P\text{-}eq}$/ $kg_{product}$), (V) Marine eutrophication (ME in $kg_{N\text{-}eq}$/ $kg_{product}$), (VI) Human Carcinogenic Toxicity (HCT in $kg_{1,4\text{-}DCB\text{-}eq}$/ $kg_{product}$), (VII) Land use ($m^2_{crop\text{-}eq}$/ $kg_{product}$), and (VIII) Freshwater use ($m^3$/ $kg_{product}$).

The environmental impacts are economically allocated to IPA and acetone based on their market price. Besides, production of other byproducts (i.e., biomass as a feed and electricity generation) is accounted for using substitution.

# RESULTS AND DISCUSSION

## Process

IPA and acetone are produced from the hot steel mill off gas (syngas) through gas fermentation (see Figure 1) at a capacity of 5,278 $kg_{IPA}$/h of 99.57 wt. % IPA and 706 $kg_{Ac}$/h of 99 wt. % acetone. After the gas fermentation followed the broth and the volatile products are separated and purified through vacuum distillation (C1), acetone distillation (C2), pre-concentration (C3), and extractive distillation with ethylene glycol (C4 and C5). The heat pump integration of the distillation columns and the utilisation of the heat from the syngas feed showed that the process at a CO conversion of 85%, product selectivity of 90% and a product titer (IPA + acetone) of about 50 g/L is utilising no steam and producing net 2.6 MWh of electricity. Whereas, Liew *et al.* [2] reported ~5 $MJ_{electricity}/kg_{product}$ for both products and for IPA the need for 6.28 $MJ_{steam}/kg_{IPA}$. Thus, the modelled process is more energy efficient than the model used for the 120 L pilot [2], possibly due to the optimistic CO volumetric mass transfer rate of 14.9 g/L/h resulting in a 50 g/L product titer in

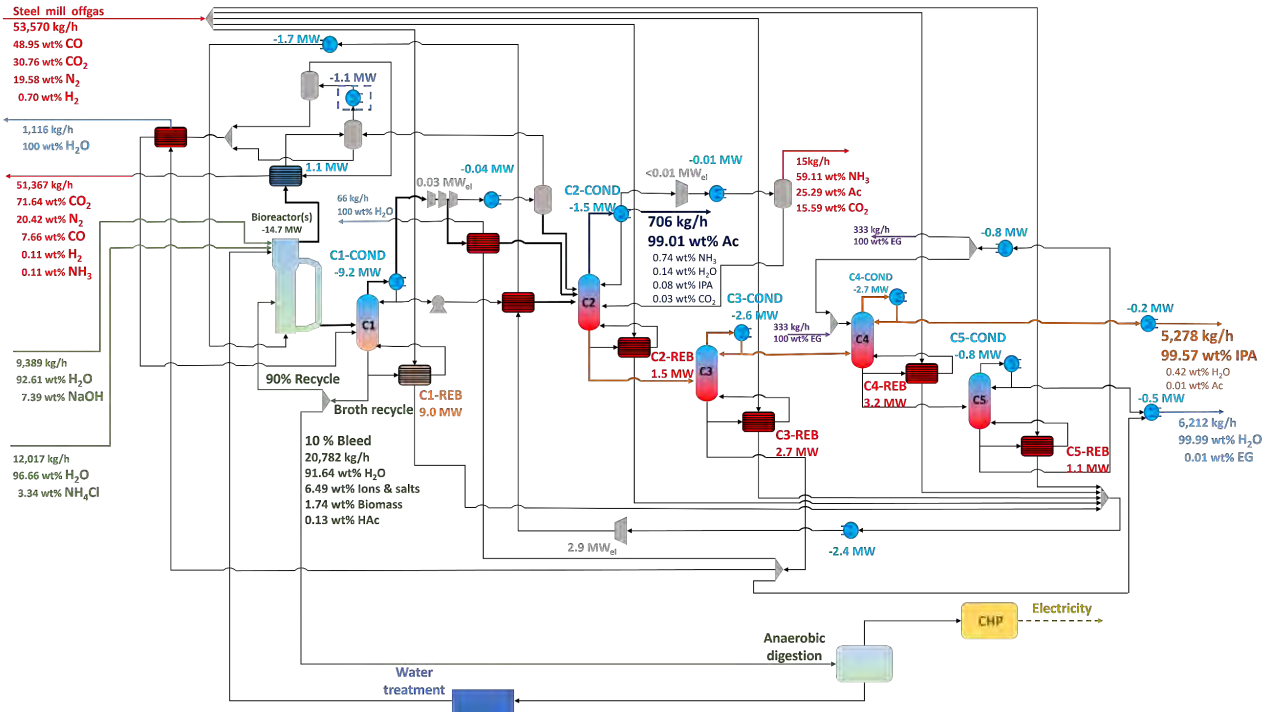

**Figure 1:** Overview of the 47.5 kton/year syngas fermentation (41.8 $kton_{IPA}$/y, 5.64 $kton_{acetone}$/y). The green inflows to the bioreactor are the pH control and nitrogen source, whereas the red in- and outflows are the gas streams. The inflowing syngas (at 1373 K/ 1100 °C) is used for heat exchange before it is compressed (3.84 bar) and fed to the bioreactor. Multi-stage heatpump integrated distillation is used to obtain 99.01 wt. % Ac (C2, dark blue) and 99.57 wt. % IPA (C4, orange). First the broth is separated from the volatile products (C1) by vacuum distillation. Followed by acetone distillation (C2), pre-concentration of IPA (C3), extractive distillation of IPA with ethylene glycol (EG) (C4), and EG recovery (C5). The anaerobic digestion, combined heat and power generation (CHP), and water treatment to demiwater are included within the system boundaries for the economic and environmental assessment.

combination with the energy-efficient DSP design.

## Techno-economic assessment (TEA)

### Capital Expenses (CAPEX): Bioreactor as main cost component and minimal expenses for the distillation columns

The NREL method [9] gave a factor of 1.84 for the modelled syngas fermentation process to get to the CAPEX of 103.7 M$, from the total installed equipment costs (56.3 M$, see Figure 2A). At a plant lifetime of 10 years, the **CAPEX** is about **0.22 $/kg$_{product}$**. The total installed equipment costs are dominated by the bioreactor costs (57.9%, see Figure 2A) which were estimated to have a working volume of 565 $m^3$ [5]. Besides the bioreactor, the compressors (17.8%) and the combined heat and power generation (CHP, 13.4%) contribute most to the total installed equipment costs. 38% of the compressor CAPEX are to compress the gas feed to 3.84 bar before fermentation. Whereas, all distillation columns only make up 5.5% of the CAPEX, because of separating the volatile products directly from the broth through vacuum distillation [4]. This reduces the mass flow to the distillation columns by 88.4%.

### Operating Expenses (OPEX): Minimised through heat integration of the hot steel mill off gas

The **OPEX** (see Figure 2B) are only 16.82 M$/y, which is **0.35 $/kg$_{product}$**. Traditional fermentation processes have OPEX dominated by feedstock expenses. However, the use of the steel-mill "waste" off-gas only contributes 0.04% to the OPEX. The steel mill off gas costs were assumed based on the otherwise obtained heat from flaring. In addition, no consumption of heat utilities and the net generation of 2.6 MWh electricity greatly reduce the OPEX. Moreover, the efficient recycle of the broth and components due to vacuum distillation allows for 90 % broth recycle as well as efficient downstream processing of the products. Therefore, typically minor expenses like labour and pH control together contribute to 67% of the OPEX.

### Overall economics

The estimated **unit production costs (UPC)** are only

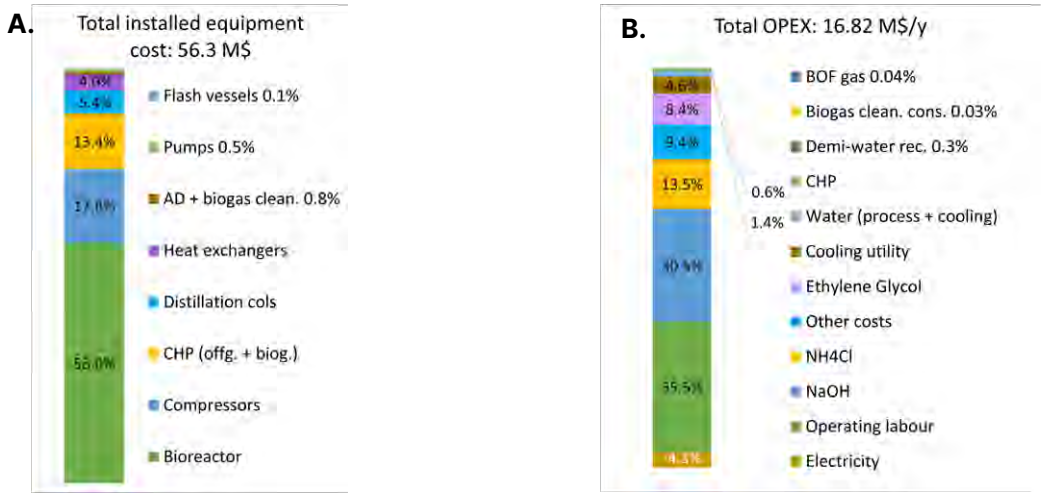

**Figure 2:** Economic assessment of the modelled syngas fermentation to 47.5 kton/y of isopropyl alcohol and acetone process. The calculated CAPEX is 103.7 M$ assuming a plant lifetime of 10 years of which 54.3% is the total installed equipment costs (A), the operating expenses are 16.82 M$/year (B). The excess energy produced from the CHP is assumed to be sold as electricity to the grid. AD is anaerobic digestion, CHP is combined heat and power generation, and BOF gas is the steel mill offgas (basic oxygen furnace gas) from the steel mill.

**0.57 $/kg$_{product}$** (isopropyl alcohol or acetone). whereas the market price for these products is 1.65 $/kg$_{IPA}$ and 1.45 $/kg$_{Ac}$ [13]. This leaves a margin between the production costs and the 2024 market price of 1.08 $/kg$_{IPA}$ (65.6%) and 0.88 $/kg$_{Ac}$ (60.8%), respectively. Thus, having an estimated **margin** of **over 60%** using the modelled, heat-integrated, gas fermentation process. Moreover, when the biomass byproduct is not anaerobically digested but sold as an animal feed, the overall UPC decreases with an additional 8.8% (0.05 $/kg$_{product}$).

## Cradle-to-gate life cycle assessment (LCA)

### The global warming potential can be net zero when considering the converted steel mill off gas as prevented emissions

The cradle-to-gate LCA gave net zero GWP for IPA and acetone production, when considering it as preventing the steel mill off gas related emissions (see Figure 3 & Table 1). The environmental impacts are economically allocated to the products and gave GWPs similar to the pilot-scale study [2] (see Figure 3). However, the results for acetone of Liew *et al.* [2] are on the high acetone selectivity (~85%), whereas this study uses high IPA selectivity with only 12 wt. % acetone produced. Besides, comparison of the GWPs from this study to the petrochemical IPA and acetone production indicates a potential GWP reduction of 160% for IPA and 147% for acetone. Still, the GWP is dependent on the mitigated $CO_2$ emissions by converting steel mill off gas into IPA and acetone. Additionally, utilising both the latent energy of the steel mill off gas before gas fermentation and combusting the residual off gas enables lower GWPs because of zero steam consumption and net electricity production (see Table 1). Additionally, the gas fermentation process prevents the direct use of fossil fuels for IPA and acetone production.

**Table 1:** Global Warming Potential (GWP) contributions for the modelled syngas fermentation to 47.5 kton-$_{prod}$/year of >99 wt. % isopropyl alcohol (IPA) and acetone (Ac).

| | **Isopropy alcohol** ($kg_{CO2\text{-}eq}/kg_{IPA}$) | **Acetone** ($kg_{CO2\text{-}eq}/kg_{Ac}$) |
|---|---|---|
| Process emissions | 7.64 | 6.70 |
| Heat replacement | 0.636 | 0.558 |
| NaOH | 0.147 | 0.129 |
| Ethylene Glycol | 0.120 | 0.105 |
| NH4Cl | 0.090 | 0.079 |
| Water | 0.069 | 0.061 |
| NaCl | $8.87x10^{-4}$ | $7.79x10^{-4}$ |
| Steam | 0.000 | 0.000 |
| Electricity (produced) | -0.255 | -0.224 |
| CO2 prevented from flaring | -9.86 | -8.66 |
| **Total** | **-1.42** | **-1.25** |

## Other environmental impacts most relevant to fermentation processes

Comparison of the modelled syngas fermentation process with conventional petrochemical production (see Table 2) also gave lower impacts for the stratospheric ozone depletion, marine eutrophication human carcinogenic toxicity. In addition, the calculated fine particulate
