To optimize the electrodialysis (ED) system, three RL algorithms (PPO, SAC, and A2C) were trained over 30,000 episodes, with one step per episode, under different reward scenarios. These included a single-objective reward function (F1) focused on salt removal (SR) and multi-objective reward functions (F2 and F3) incorporating SR and specific energy consumption (SEC). As shown in Figure 6, the A2C algorithm consistently outperformed PPO and SAC, achieving a reward exceeding 0.9 and 1.8 for single and multi-objective, respectively translating to >90% separation efficiency within the first 5,000 episodes for F1. Under multi-objective reward functions, A2C demonstrated faster convergence and higher rewards, further establishing its superior performance.

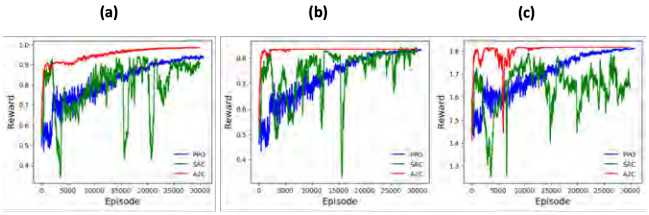

**Figure 6:** Mean reward improvement during the training process for different reward functions a) F1 b) F2 c) F3.

However, as shown in Figure 7, focusing on a single objective (F1) led to higher energy consumption (EC) as the controller prioritized maximizing SR without accounting for energy trade-offs. By contrast, the multi-objective reward functions (F2 and F3) enabled the controller to balance SR and EC simultaneously, achieving better overall system performance.

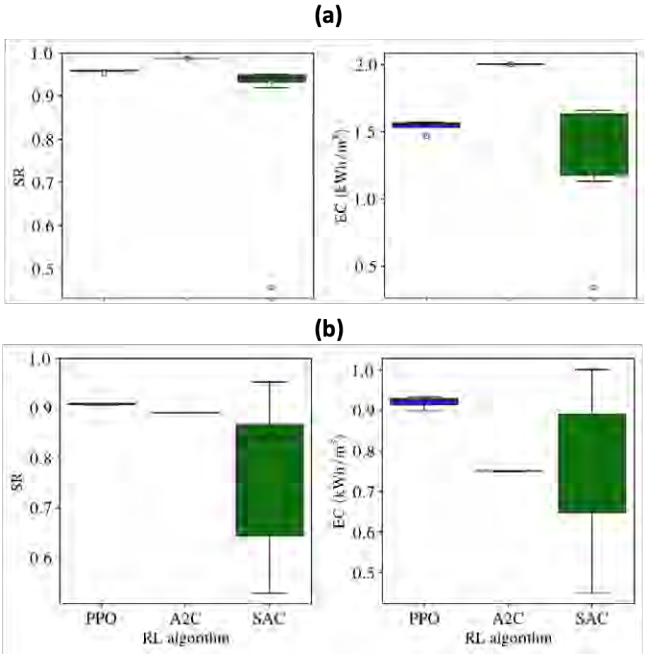

**Figure 7:** Boxplot of the RL-controller performance based on reward function a) F1 and b) F3.

**Table 3:** Statistics of the evaluated results.

| 6/23/2025 12:24:00 PMReward | Algorithm | SR | EC |
|---|---|---|---|
| F1 | PPO | 0.959 ± 0.002 | 1.545 ± 0.030 |
| | A2C | 0.988 ± 0.000 | 2.002 ± 0.000 |
| | SAC | 0.892+/- 0.153 | 1.329 ± 0.410 |
| F2 | PPO | 0.904 ± 0.003 | 0.877 ± 0.033 |
| | A2C | 0.892 ± 0.000 | 0.751 ± 0.000 |
| | SAC | 0.942 ± 0.037 | 1.353 ± 0.380 |

| | A2C | 0.892 ± 0.000 | 0.751 ± 0.000 |
| | SAC | 0.771 ± 0.143 | 0.772 ± 0.177 |

## 4. CONCLUSION

In this work, we have introduced reinforcement learning framework named “OptiDial” to optimize electrodialysis (ED) performance by balancing salt removal (SR) and specific energy consumption (SEC). The A2C algorithm demonstrated superior performance across both single and multi-objective reward functions, excelling in achieving high SR and low SEC simultaneously. Sensitivity to reward design highlighted the importance of multi-

objective optimization for real-world applicability. These findings underline the potential of RL-based approaches to effectively manage complex trade-offs in ED systems, paving the way for more efficient and adaptive desalination processes. While this study focuses on RL-based optimization, a direct comparison with nonlinear model predictive control (NMPC) is an important next step. We plan to explore this comparison in another publication, providing a deeper analysis of constraints, safety considerations, and performance trade-offs between RL and NMPC for ED control.

## ACKNOWLEDGEMENTS

We would like to thank U.S. Department of Energy, Office of Science, under the Office of Basic Energy Sciences Separation Science program under award no. DE-SC0022304 for the funding support.

## DATA AVAILABILITY

The datasets and code generated during this study are available at GitHub: https://github.com/Enthusiastic-Teslim/separationML. We adopted RL algorithms implemented in https://github.com/DLR-RM/stable-baselines3.

## APPENDIX

The section contains additional information from the manuscript.

## ABSTRACT

The transition to renewable energy sources, such as biogas, requires purification processes to separate methane from carbon dioxide, with adsorption-based methods being widely employed. Accurate simulations of these systems, governed by coupled PDEs, ODEs, and algebraic equations, critically depend on precise parameter determination. While traditional approaches often result in significant errors or complex procedures, optimization algorithms provide a more efficient and reliable means of parameter estimation, simplifying the process, improving simulation accuracy, and enhancing the understanding of these systems. This work introduces an Artificial Intelligence-based methodology for estimating the isotherm parameters of a mathematical phenomenological model for fixed-bed experiments. The separation of $CO_2$ and $CH_4$ is used as case study. This work develops an algorithm for parameter estimation for the system's mathematical model. The results show that the validated model has a close fit with experimental results.

**Keywords**: Adsorption, Optimization, Artificial Intelligence, Parameter Estimation

## INTRODUCTION

The need to reduce greenhouse gas emissions has driven the shift toward renewable energy sources such as biogas. However, to use biogas as a substitute for natural gas, it must undergo a purification process to separate methane from carbon dioxide. Adsorption-based separation processes are standard methods for biogas separation. Fixed-bed systems form the fundamental step for many separation processes in this context [1].

Parameter estimation is a usual step in developing mathematical models which affects not only the model prediction in itself, but also the future use of the model in process control and optimization.

By solving a system of coupled Partial Differential Equations, Ordinary Differential Equations, and Algebraic Equations, it is possible to accurately simulate fixed-bed units used in these processes [1, 2]. However, a rigorous simulation and, consequently, a better understanding of the intrinsic phenomena governing these systems, such as adsorption isotherms, film and particle mass transfer, energy transfer phenomena, among others, heavily depends on the parameter values [3]. These parameters can be estimated using well-known mathematical correlations or trial and error. However, these methods often introduce significant errors [4]. For a more accurate determination, an optimization algorithm can be employed to find the best set of parameters that minimize the difference between the simulation and experimental data, thereby providing a better representation and understanding of the real process.

Different optimization methodologies can be employed for this purpose. For example, deterministic methods are known for ensuring convergence to an optimal solution, but the starting point selection significantly impacts their performance [5]. In contrast, meta-heuristic techniques are often preferred for their adaptability and efficiency since they do not rely on predefined initial

conditions [6]. However, these approaches may not always guarantee finding the optimal solution for every problem.

Within the field of Artificial intelligence, Reinforcement Learning (RL) emerges as self-supervised technique. RL uses a trial-and-error algorithm, guided by rewards, to help agents learn optimal behaviors, mapping situations to actions to maximize long-term rewards [7]. RL excels at handling delayed feedback, where actions impact both immediate and future outcomes, enabling effective long-term planning. However, RL faces challenges in balancing exploration (seeking new optimal actions) and exploitation (using current knowledge to maximize rewards). Striking this balance is critical, as premature exploitation can lead to suboptimal solutions, while excessive exploration delays progress [8].

Recent advancements, including algorithms like Deep Deterministic Policy Gradient (DDPG), have expanded RL's reach by using deep neural networks for high-dimensional action spaces. This has driven success in multiple fields, including robotics, games, and industrial optimization by a more efficient management of delayed rewards and refining exploration-exploitation [9, 10].

This work introduces an AI-based approach for estimating adsorption isotherm parameters in the mathematical model of fixed-bed experiments for $CH_4/CO_2$ separation. Using a DDPG agent in a Reinforcement Learning algorithm, this methodology addresses the common limitations of deterministic methods by leveraging a deep neural network capable of balancing exploitation and exploration, aiming to optimize the fit between simulated results and experimental data by minimizing the error between the two datasets, thereby enhancing the accuracy and predictive capability of the model.

## MATERIALS AND METHODS

### Objective

Adsorption in a fixed bed unit can be described through a mathematical model that includes the mass, energy, and momentum balances that govern the process. Proper modeling of the equilibrium data is critical for effective process design. Using three different approaches, the main objective of this work is to determine the parameter set, $\theta$, of the Extended Langmuir isotherm (Equation 1) that, when incorporated into the mathematical model (available in [1]) for simulating the gas composition in fixed-bed experiments, enables accurate reproduction of experimental data, and achieves a close-to-optimal fit between simulated and experimental results.

$$q_i = q_{sat,i}\frac{b_i P_i}{1 + \Sigma_{1=1}^{n}(b_i P_i)} \quad (1)$$

### Experimental Dataset

This work used experimental data collected by Ferreira and colleagues [1] , using MIL-53(Al) as the adsorbent for the $CH_4/CO_2$ separation in fixed-bed experiments. The dataset comprises 17 breakthrough experiments conducted under varying feed composition and pressure (from 0.1 to 4 bar) conditions, all at constant temperature (303 K). The conditions can be consulted in Tabel SI.1. At the start of each breakthrough experiment, the column, initially filled with He, was fed with either pure gas or with a gas mixture of $CO_2$ and $CH_4$. Once the column reached saturation under the specified feed conditions the inlet stream was switched to helium at the same total flow rate to initiate the regeneration step. The dataset includes 7 experiments with pure $CO_2$, 7 with pure $CH_4$, and 3 with varying mixtures of $CO_2/CH_4$.

Since all experiments were conducted at the same temperature, the estimated parameters were $q_{sat,CO2}$, $q_{sat,CH4}$, $b_{\infty,CO2}$ and $b_{\infty,CH4}$. The parameters $b_{CO2}$ and $b_{CH4}$ can be calculated using Equation 2, based on a constant value of $(-\Delta H_i)$ obtained from the literature: 26000 J·mol$^{-1}$ for $CO_2$ and 18300 J·mol$^{-1}$ for $CH_4$ [11].

$$b_i = b_{\infty,i}\, exp\left(\frac{-\Delta H_i}{R_g T}\right) \quad (2)$$

Ferreira et al. [1] obtained the adsorption isotherms parameters through breakthrough experiments. The adsorbed amount of gas was calculated using breakthrough curve data from adsorption and desorption experiments. For adsorption, the area under the breakthrough curve was integrated and subtracted from the total gas fed into the column. For desorption, the area under the curve was directly integrated. Comparing both adsorbed amounts (adsorption and desorption), one can verify whether the mass balance closes. These values were normalized by dividing by the dry adsorbent mass, yielding the adsorbed amount per mass unit of adsorbent.

Subsequently, the Extended Langmuir Isotherm parameters were determined using the Generalized Reduced Gradient Nonlinear Solver by fitting the experimental data for adsorbed amounts to the Extended Langmuir Equation, using the partial pressures from each experiment. The parameters obtained can be consulted in Table 1 and were used as reference values for this work.

### Reinforcement Learning Algorithm

The RL setup requires defining: (1) the Environment, representing the system where actions are applied; (2) the Reward, which guides the algorithm's learning process; (3) the State, reflecting the environment's response to an action; (4) the Agent, the decision-making component of the RL algorithm; and (5) the Actions, indicating how the algorithm interacts with the environment.

The action represents how the RL agent affects the environment to maximize the reward. In this work, the action is the set of parameters, $\theta$, that needs to be

estimated. The action must be constrained between a lower ($Act_{min}$) and an upper bound ($Act_{max}$) and an initial guess must be given ($Act_0$).

The agent is the core of the RL algorithm, responsible for learning from past trials (exploitation) and exploring new possibilities (exploration) to maximize long-term rewards by deciding the next action to take. The selection of the best agent depends on the desired policy, observation space, action space, and learning process. For this project, since a deterministic policy is preferred over a stochastic one, both the observation and action spaces are continuous, and the objective function is too complex for a simpler Q-learning process so a deep neural network-based agent was chosen, a Deep Deterministic Policy Gradient agent was selected.

The tuning of the neural networks responsible for the agent is crucial, as their hyperparameters play a key role in balancing exploration and exploitation.

## Parameter Estimation

All the work was done on a computer with a processor 13th Gen Intel(R) Core (TM) i7-13700F 2.10 GHz, 32 GB of RAM and a graphic card NVIDIA GeForce RTX 4070.

The first approach tried replicating the method described in [1], replacing the used solver with the RL algorithm. This enabled the direct adjustment of the Extended Langmuir model for each experiment with the experimental values of $q_{CO2}$ and $q_{CH4}$, obtained after mass balance, as previously described.

In this approach, the Environment is defined as the calculation of the predicted $q_{CO2}$ and $q_{CH4}$ values for all experiments using Equation 1. The Action corresponds to the set of parameters to be applied in Equation 1, while the State represents the Mean Squared Error (MSE) between the calculated and experimental $q_{CO2}$ and $q_{CH4}$ values. In RL, the reward is typically designed to be maximized. However, since the objective is to minimize the error between experimental and simulated data, the Reward is defined as the negative of the MSE between the simulated and experimental results.

This entire approach was implemented in MATLAB. After the training, the parameter set that best minimized the MSE was used to simulate the 17 breakthrough experiments and the error between the experimental and simulated dataset was compared with the one obtained with the reference parameters.

The second and third approaches involved the direct adjustment of parameters based on the breakthrough curves simulations. The Environment is the simulation of the breakthrough experiments used for training, utilizing the parameter set provided by the agent in each trial. The simulations were conducted in the gPPROMS environment (Process Systems Enterprise, London, UK) and numerically solved using the orthogonal collocation on finite elements method, with second-order polynomials and 115 intervals, using the phenomenological model available at [1, 2]. The RL Algorithm was implemented in MATLAB.

As mentioned, RL algorithms typically aim to optimize a problem by maximizing the reward. Since the goal is to minimize the difference between experimental and simulated data, the reward is the negative of the error between the two datasets. The number of comparison points per experiment is denoted as $N_{\text{points}}$. Since this value varies across experiments, a weighting factor, $\omega$, is applied to normalize the MSE between experiments.

Equation 3 shows the objective function ($f_{obj}$) to be minimized and Equation 4 the Long-Term Reward ($\text{Rew}_{\text{LT}}$) that the agent aims to maximize. In these equations, $y$ corresponds to the molar composition of a determined component, $j$ represents the experiment number, $N_{exp}$ is the total number of experiments, $k$ is the time corresponding to the simulated and experimental points, $T$ is the total duration of the experiment, and $i$ represents 1 and/or 2 (depending on the type of experiment) corresponding to $CO_2$ and $CH_4$, respectively.

$$f_{obj} = \sum_{j=1}^{N_{exp}} \omega_j \left[ \frac{1}{N_{points,j}} \sum_{k=1}^{T} \left( \sum_{i=1}^{2} (y_{k,exp,i} - y_{k,sim,i})^2 \right) \right] \quad (3)$$

$$\text{Rew}_{\text{LT}} = \sum_{\text{trial}=1}^{\text{N}_{\text{trials}}} \text{Rew}_{\text{trial}} = \sum_{\text{trial}=1}^{\text{N}_{\text{trials}}} - f_{obj_{trial}} \quad (4)$$

To ensure consistency in the rate of change for each parameter across trials, the action generated by the agent is normalized in a range between -1 and 1. Before being sent to the environment, the action is re-normalized, converting it into a set of parameters suitable for simulating the experiments. This helps nullify the high difference in the order of magnitude between the parameters to be estimated.

To reduce computational effort, 6 experiments were selected from the dataset of 17. These included 2 experiments with pure $CO_2$, 2 with pure $CH_4$, and 2 binary experiments. The RL algorithm focused on maximizing the long-term reward for these 6 breakthrough curves during training by maximizing the reward function in each trial. Once the optimal $\theta$ was identified for these experiments, it was used to simulate the remaining experiments, and the objective function was evaluated across all experiments to assess the methodology's results.

The primary difference between approaches two and three lies in the range of the search for the optimal set of parameters, specifically in the range of the action. The first and second approaches aimed to improve the results obtained by the authors of the base article. To achieve this, a range of ±20% around the reference

values was used as the upper and lower limits for the action to be taken in each trial. The reference values served as the initial guess. The third methodology was implemented to assess the RL algorithm's ability to find the optimal set of parameters without prior knowledge of the system. In this case, a broader range of exploration was allowed for each parameter. The initial guess was set as the mean value of the action limits. The action limits for each approach can be consulted in Table SI.4.

# RESULTS

## Agent

A DDPG agent is an actor-critic RL agent that, using neural-networks, searches for an optimal policy that maximizes the expected cumulative long-term reward. The actor takes observations and returns the corresponding action that maximizes the long-term reward. The critic takes observations and actions as inputs and returns the corresponding expectation of the long-term reward.

The architecture and structure used are based on the one presented in [1], with some adaptations. The actor is a feedforward neural network with three fully connected layers. The first two dense layers have 256 neurons each, followed by ReLU activations. The final dense layer has 4 neurons, and its output is transformed using the Tanh activation function. The critic is a multi-input architecture with two neural network branches. Both input features through a fully connected layer with 256 neurons. The outputs of these branches are concatenated and passed through a ReLU activation, followed by a fully connected layer with 256 neurons and a subsequent ReLU activation. The agent uses an Ornstein–Uhlenbeck noise function to develop an exploration policy.

The hyperparameters were manually tuned following a sensitivity analysis, in which each of the main hyperparameters was varied within a specified search range. Although relevant, it was observed that hyperparameter manipulation within the selected tuning range had little impact on the algorithm's performance. Therefore, the agent was kept as small as possible without compromising its predictive capabilities. A more detailed description of the agent, as well as the process of hyperparameter tuning and selection, is provided in the SI.

## Parameters Estimation

On the first approach, 500,000 trials were used to estimate $\theta$. Despite the extensive number of iterations, the best parameter set only managed to reduce the error by 8% on the breakthrough curves compared to the reference parameters. Thus, while this methodology is more straightforward than the next two, it does not offer significant advantages to the standard approach, as it requires the same previous work, is more time-consuming and provides no meaningful improvements in accuracy.

For the second approach, the search for the optimal set of parameters was conducted over 350 trials, with the best result achieved at trial number 276. The obtained $\theta$ reduced the objective function by 26% for the training experiments and by 28% across all experiments. However, to achieve this result, all the manual work done in [1] to find the initial guess and a small margin of search must still be performed. This approach proved to be a valid methodology for achieving high accuracy, allowing for fine-tuning of the parameters, although exhaustive work is still required.

For the third approach, the search was done for 350 trials, with the best result achieved at trial number 119. The obtained $\theta$ resulted in a 15% reduction in the objective function for the training experiments and a 31% reduction in the objective function across the entire set of experiments, indicating a substantial improvement in the alignment between the simulated and experimental data. More significantly, this result demonstrates that the RL algorithm can map the surface area of the objective function and identify a function minimum, surpassing the derivative-based solver used in the reference work.

Table 1 summarizes the parameter sets obtained from each approach, the reference values used for process simulation, and the objective function obtained with each methodology. Table S.I.5 provides a more detailed analysis of the results. These results highlight the effectiveness of approach number 3. It resulted in the set of parameters that most significantly reduced the global error between the experimental and simulated datasets and was the only approach that improved the fit for the pure $CH_4$ experiments when compared to the reference work. Additionally, this methodology does not rely on all the previous work already done by the authors, like approach one and two, allowing a broad exploration of each parameter without prior knowledge of the system and, so, can be applied directly after experimental work.

**Table 1:** Reference and Estimated Parameters and objective function value obtained via Approach (Ap.) 1, 2 and 3

| $\boldsymbol{\theta}$ | Units | Ref. | Ap.1 | Ap.2 | Ap.3 |
|---|---|---|---|---|---|
| $q_{sat,CO2}$ | [mmol g$^{-1}$] | 6.38 | 6.76 | 7.65 | 6.46 |
| $q_{sat,CH4}$ | [mmol g$^{-1}$] | 7.38 | 6.87 | 6.48 | 6.86 |
| $b_{\infty,\mathrm{CO2}}$ | [Pa$^{-1}$] | 1.55 | 1.40 | 1.24 | 1.67 |
| $b_{\infty,\mathrm{CH4}}$ | [Pa$^{-1}$] | 8.07 | 8.87 | 9.68 | 8.74 |
| $\boldsymbol{f_{obj}}$ $(\times 10^3)$ | | 3.06 | 2.82 | 2.19 | 2.11 |

To evaluate the exploration behavior over trials, Figure SI.1 displays the action values assigned per trial in this approach. It demonstrates that the algorithm initially explores the entire parameter space. However, as iterations progress, it begins to focus more on a specific region,

prioritizing exploration in that area to identify a minimum. This underscores the algorithm's ability to explore the parameter space effectively while simultaneously learning to refine its search for optimal solutions.

When analyzing the evolution of the objective function over the trials (Figure 1), two main conclusions can be taken that coincide with the two main concepts of Reinforcement Learning. Firstly, a clear trend of reduction in the objective function emerges as the RL agent begins to learn. This demonstrates the agent's ability to leverage past experiences to maximize long-term rewards (exploitation). This learning process is further corroborated by the convergence observed in Figure SI.1 for all actions. Secondly, significant fluctuations in the objective function are still evident, even after numerous trials. These fluctuations can be attributed to the algorithm's continued exploration of the parameter space and the high sensitivity of the simulation to small parameter changes.

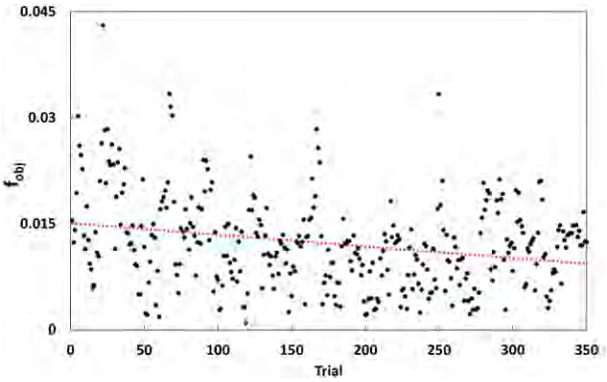

**Figure 1:** Evolution of the Objective Function Across Iterations: Objective function per iteration (•) and Trendline of the objective function (·····)

To assess the impact of these small fluctuations of the parameters set on the objective function, a sensitivity analysis was conducted. The 17 breakthrough experiments were simulated using the parameter set obtained on the third approach, adjusted by multiplication factors of ± 0.01, 0.1, 1, 5, and 10%. The objective function values for the full set of experiments, corresponding to each parameter set, are presented in Table SI.6.

This analysis is particularly relevant as it leads to several conclusions. Firstly, as mentioned previously, even small changes in the parameter set can result in significant variations in the objective function. For instance, decreasing the parameters by just 1% can increase the objective function by 38%. However, increasing all the parameters by the same 1% can reduce the objective function, demonstrating no straightforward correlation. This conclusion is supported by the results in Table SI.7, which presents the outcomes of a sensitivity analysis similar to the one described earlier. However, in this case, only a 1% variation was applied to each parameter individually. Even such a small change of 1% can lead to a 10% increase in the objective function.

This underscores the challenges faced by the RL algorithm in mapping the objective function surface, given its high sensitivity to minor parameter changes. Nonetheless, it also highlights the effectiveness of the algorithm in learning from past trials and converging toward an optimal region, as evidenced by Figure 1. These results also indicate that the best parameter set achieved with approach 3 does not correspond to the global minimum, as evidenced by better outcomes obtained after incrementing all parameters by 1%, 0.1%, and 0.01%. This was somewhat expected after analyzing Figure 1. While there is a clear trend of reducing the objective function across trials, the best result occurred at trial 119 out of 350. This suggests that the result was achieved more due to exploration than exploitation. Furthermore, since the RL algorithm did not immediately converge to the region of this trial, that area was not thoroughly explored, preventing further refinement of the result. This explains the presence of better outcomes near the identified optimum that were not found by the algorithm.

Finally, to evaluate the capability of the new set of parameters on predicting the adsorbed amount on every experiment, the Extended Langmuir Isotherms were plotted and the MSE values between the experimental (obtained in [1] after mass balance) and calculated (using both the reference parameters and those obtained from approach 3) $q_{CO2}$ and $q_{CH4}$ were determined (Table SI.8 ,Figures SI.2 and SI.3) . Although the new parameter set improves the fit between predicted and experimental adsorbed amounts for some experiments (especially for pure $CH_4$ experiments), it globally increases the MSE from $3.97\times10^{-3}$ to $5.87\times10^{-3}$. This leads to the conclusion that this methodology does not improve the precision of the model in predicting the adsorbed amount. However, the adjustment of the simulated breakthrough curves to the experimental data is still enhanced by the new parameter set (Figure SI.4), as previously discussed. This improvement can be attributed to the ability of the new parameters to compensate for inaccuracies in other parameters of the mathematical model. Thus, while the prediction of the adsorbed amount is negatively affected, the overall adjustment benefits from this compensation. This is another advantage of using a broad range of search.

To assess the algorithm's reproducibility, approach 3 was repeated. After 207 trials, the objective function was reduced by 7%. Although this result did not match the previous outcome (likely due to earlier success driven by exploration), it confirms that the RL algorithm reliably identifies a set of parameters for the Extended Langmuir Equation that accurately simulates fixed-bed experiments for $CH_4/CO_2$ separation. Additionally, the same trends observed in Figures 1 and SI.1 were visualized when repeating the methodology, highlighting the

capability to replicate the behavior of the training.

## CONCLUSIONS

This work introduces an AI-based methodology using Reinforcement Learning to estimate parameters in the mathematical model of gas-phase fixed-bed experiments for $CO_2$ and $CH_4$ separation and minimize the error between simulated and experimental breakthrough data.

Using the same DDPG agent, three approaches were tested. In the first, the RL algorithm replaced the traditional solver to determine Extended Langmuir isotherm parameters that best fit the experimental adsorbed amounts obtained from breakthrough curves. In the second and third approaches, the RL agent directly provided parameters for breakthrough curve simulations. The key difference lies in parameter exploration: the second approach used literature values as an initial guess with a limited search range, while the third treated it as a zero-knowledge problem, allowing wide parameter exploration without prior system knowledge.

While RL, like other meta-heuristic approaches, does not guarantee global optimality, it offers a flexible framework that adaptively explores and exploits the search space. By incorporating learning into the exploration process, RL can reduce the number of iterations typically required by standard meta-heuristic methods. Despite its simplicity and lack of manual work required after the experimental phase, the third approach delivered the best results. It reduced the global error between experimental and simulated data by 31% after just 119 iterations, when compared with the parameters obtained using the Generalized Reduced Gradient. The new set of parameters can compensate for misadjustments in other system parameters, which was not possible when obtaining the parameters by adjusting the Extended Langmuir Equation to only the adsorbed amount. Using RL as an optimization algorithm proved to be an efficient, reproducible, and highly effective method for parameter estimation. It exhibited strong iterative learning and thorough exploration of the objective function surface, successfully identifying a set of parameters that align the mathematical model with the experimental data.

# Engineering the Final Frontier: The Role of Chemical and Process Systems Engineering in Space Exploration

**Edwin Zondervan**

[a] Twente University, Drienerlolaan 5, Enschede 7522NB, the Netherlands. e.zondervan@utwente.nl

## ABSTRACT

Space exploration demands the integration of multiple scientific and engineering disciplines, with chemical engineering and process systems engineering playing pivotal roles. This paper examines their critical contributions to propulsion systems, life support mechanisms, and advanced materials essential for space missions. Recent advancements in chemical propellants and rocket fuels, illustrated by SpaceX and NASA missions, have significantly improved propulsion efficiency and safety. Chemical engineering is vital in developing air purification, water recycling, and bioregenerative life support systems, ensuring astronaut survival and mission sustainability. Additionally, creating heat-resistant, lightweight materials enhances spacecraft durability under extreme space conditions. Process systems engineering (PSE) complements these efforts by integrating, simulating, and controlling complex systems. PSE ensures reliable subsystem integration and uses predictive analytics and advanced modeling for mission planning and risk mitigation. Automation and control systems are essential for maintaining operations with minimal human intervention. The synergy between these fields is evident in in-situ resource utilization (ISRU) technologies, which extract and process local resources on extraterrestrial bodies, reducing reliance on Earth supplies and enhancing mission viability. Despite significant progress, challenges remain. Addressing harsh space environments, ensuring long-duration mission sustainability, and advancing energy sources and materials are ongoing research areas. This presentation underscores the indispensable roles of chemical and process systems engineering in overcoming space exploration challenges.

**Keywords**: Space exploration, chemical engineering, process systems engineering

## 1. INTRODUCTION

A few years ago, I read somewhere in a popular magazine about the *Mars Oxygen In-Situ Resource Utilization Experiment* (MOXIE). A project by NASA where a mobile reactor was landed on Mars. The equipment could capture carbon dioxide and convert it into oxygen. The start of a science fiction story! Such equipment could be used in terraforming (making Mars suitable for humans to live). The chemical engineer in me was also thinking about how such equipment had to be completely autonomous and that communication with Earth would lead to large delays (the average distance between Mars and Earth is 140 million miles). This probably required a big deal of *control systems engineering*. At that time, I was still working at Bremen University (Germany), and one of my colleagues, Lucio Colombi Ciacchi, was also thinking about how *chemical engineering* could be of importance in space exploration. He was reasoning that if men wanted to live on the moon or Mars, for that matter, shooting rockets with construction materials into space would be hard to impossible. In other words, materials should be locally produced. As a materials scientist, Colombi Ciacchi was especially interested in developing electrochemical processes to make metal alloys; see, for example, [1].

I also got back in touch with Volker Hessel, one of my former colleagues at Eindhoven University (the Netherlands), who moved to Australia and took up a new research direction. Hessel was very much interested in exploring how space conditions (e.g., vacuum, no gravity, extreme pressures/temperatures) affected and/or could be used to benefit the design of new pharmaceuticals [2,3].

**Figure 1:** Manufacturing equipment could be much lighter than on earth because of the moon's gravity. The first things you would want to make would be mining devices to speed up production. After that you would make the things you need for a power grid, including solar panels. You might also make robots that are remotely operated by humans on earth for general maintenance tasks. The last thing to produce would be rockets since they don't offer much for base expansion and self sufficiency. Heat shields are heavy so a rocket could launch off earth without one and then one made on the moon could be attached. Taken from [4]

You can imagine that my attention to this topic was caught, and I was looking around for possibilities to hook up or launch some projects that linked chemical engineering to space exploration. Figure 1 shows an artist's impression of how a lunar industrial site could look.

It turned out that there are not so many direct references to chemical engineering in space [5,6]. I found inspiration in a short chapter that Isaac Asimov wrote in 1989 in "*The Tyrannosaurus Prescription and 100 Other Essays*" [7]. Chapter 6 deals with the future of chemical engineering, where he concludes that "orbital chemical engineering" is a new and spacious branch of the field in which engineers deal with new situations and new problems. For sure, we can hope that finding new solutions will make the 21$^{st}$ century as different from the 20$^{th}$ as the twentieth is from Roger Bacon's 13$^{th}$!

When sharing my enthusiasm about this with my colleagues, I often was answered with frowning eyebrows and replies like, "Let us first try to find solutions for the problems we have on earth". When reaching out to students to probe if they would be interested in researching the topic, they'd politely thank me and preferred to stay with a more conventional topic.

Maybe a focus on solving Earth's problems is indeed more appropriate. But there already exists something like a space economy. In 2022, OECD countries spent 75 billion US dollars on space-based systems [8]. That means especially satellites. More than 100 countries have already managed to launch satellites into space. These satellites provide information on climate variables (e.g., methane emissions in landfills), and this data is used, of course, to monitor and control greenhouse gas emissions globally. Satellites also support our critical infrastructures on Earth (transport, energy, food supply, and law enforcement). Especially via communication and positioning instruments. Although most of the spending still comes from governments, more and more commercial space activities commence. In other words, space exploration also contributes to solving problems on Earth.

I got stuck with the question: What kind of problems might we encounter when doing space exploration, and what type of solutions could chemical engineering offer to such problems? It stayed with being a question until I submitted an abstract to the ESCAPE, which was accepted. Not hindered by any knowledge, the accepted abstract forced me to look into the matter, so here we go!

Space exploration is a paramount scientific and engineering pursuit that involves overcoming numerous challenges. Chemical and process systems engineering are critical in developing the technologies necessary for successful and sustainable space missions.

This paper explores the significant contributions of these fields to space exploration, focusing on propulsion systems, life support mechanisms, materials engineering, systems integration, simulation, automation, and in-situ resource utilization (ISRU).

## 2. CHEMICAL ENGINEERING IN SPACE EXPLORATION

### Role of Chemical Engineering

Chemical engineering involves the application of chemical processes and principles to create and optimize products and systems. In space exploration, chemical engineering is vital for developing propulsion systems, life support technologies, and advanced materials.

### Propulsion Systems

Propulsion systems are fundamental to space travel. Chemical engineers develop and optimize rocket fuels and propulsion technologies to enhance efficiency and safety. Innovations in chemical propellants, such as liquid hydrogen and oxygen, hypergolic fuels, and ion propulsion systems, have revolutionized space travel. Case studies from SpaceX and NASA missions illustrate these advancements' practical applications and benefits. For instance, SpaceX's Falcon 9 and NASA's Space Launch System (SLS) utilize advanced chemical propellants for higher performance and safety (You might think of hypergolic fuels or ion propulsion systems).

### Life Support Systems

Life support systems are essential for maintaining astronaut health and safety. Chemical engineers design air purification systems that remove carbon dioxide and other contaminants from the spacecraft environment.

Water recycling systems convert wastewater into potable water, ensuring a sustainable water supply. Bioregenerative life support systems, which include the cultivation of plants for food and oxygen production, have also been developed by chemical engineers. These technologies are critical for long-duration missions, such as those planned for Mars exploration. Figure 2 renders an impression of a life support system, see also [9], basically (re)cycling water, oxygen, and carbon dioxide, mining regolith (space rock), and then producing materials, food, medicine, and fertilizer.

### Materials Engineering

Materials engineering, a subset of chemical engineering, focuses on developing materials that can withstand the extreme conditions of space. Engineers create heat-resistant and lightweight composites and alloys for spacecraft construction. These materials must endure high radiation levels, temperature fluctuations, and mechanical stresses. Innovations in materials engineering enhance the structural integrity and durability of spacecraft, ensuring mission safety and longevity.

## 3. PROCESS SYSTEMS ENGINEERING IN SPACE EXPLORATION

### Role of Process Systems Engineering

Process systems engineering (PSE) focuses on designing, integrating, optimizing, and controlling complex systems. In space exploration, PSE is crucial for ensuring the reliability and efficiency of spacecraft systems.

### Systems Integration

Systems integration involves the seamless combination of various subsystems, such as power, life support, and thermal management. PSE ensures that these subsystems work together reliably and efficiently. Redundancy and reliability are critical as any subsystem failure can jeopardize the mission. PSE methodologies, including systems engineering principles and integration frameworks, are employed to achieve this goal.

### Simulation and Modeling

Simulation and modeling are essential tools in PSE. They provide a means to plan missions, assess risks, and

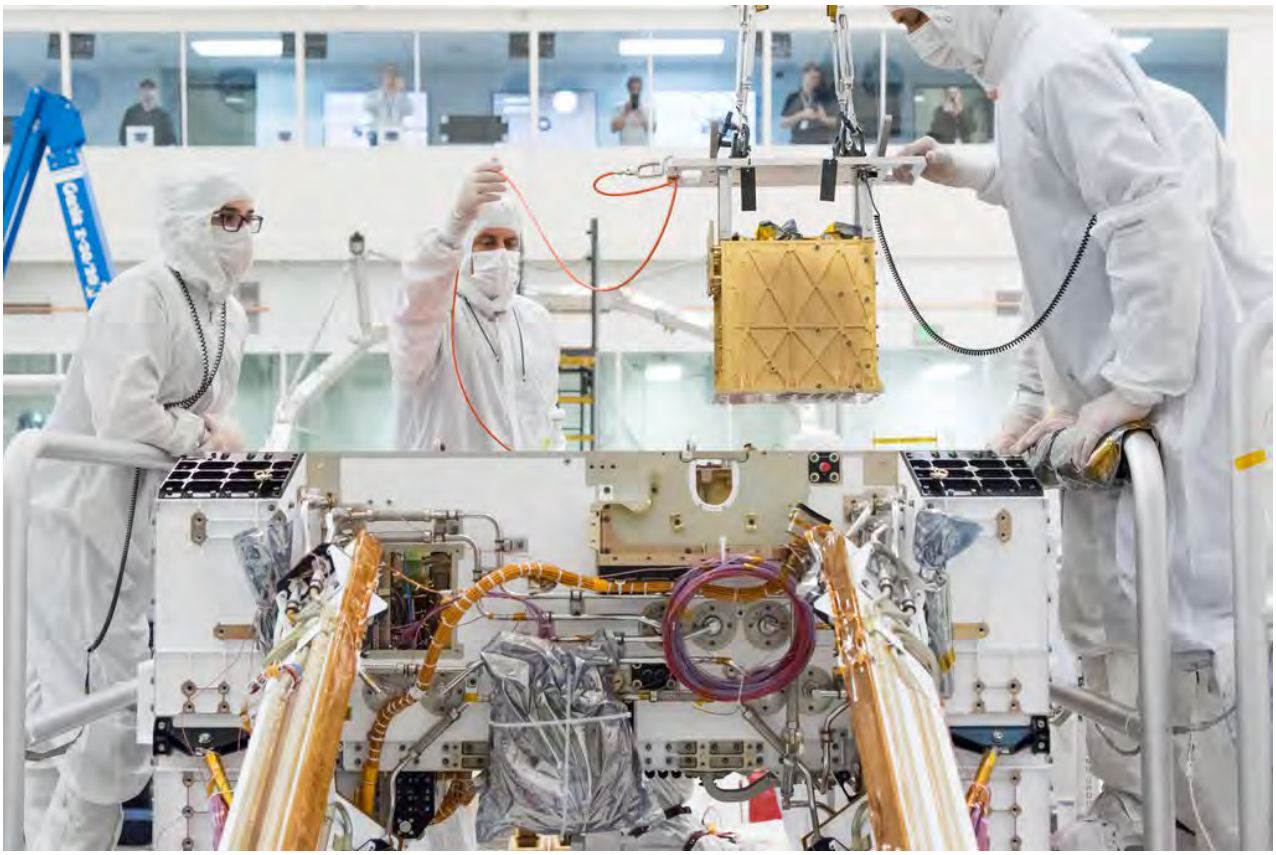

**Figure 3:** MOXIE (Mars Oxygen In-situ Resource Utilization Experiment) is lowered into the chassis of NASA's Perseverance in 2019. During the mission, MOXIE extracted oxygen from the Martian atmosphere 16 times, testing a way that future astronauts could make rocket propellant that would launch them back to Earth.
Credit: NASA/JPL-Caltec

optimize systems. Predictive analytics and advanced modeling techniques allow engineers to anticipate potential issues and develop effective mitigation strategies. For example, thermal modeling ensures that a spacecraft can maintain optimal temperatures in the harsh environment of space, while life support models simulate the long-term sustainability of air, water, and food systems.

### Automation and Control

Automation and control systems are critical for maintaining spacecraft operations and habitat environments with minimal human intervention. PSE develops automated control systems that manage various functions, such as navigation, thermal regulation, and life support. These systems enhance mission efficiency and reduce the risk of human error. Examples include automated docking systems used by the International Space Station (ISS) and autonomous rovers deployed on Mars.

## 4. SYNERGISTIC APPLICATIONS

### Combined Use in Life Support Systems

The integration of chemical and process systems engineering is particularly evident in life support systems. Chemical processes are used to purify air and recycle water, while PSE integrates these processes into a reliable and efficient system. Case studies, such as the ISS life support systems, demonstrate how these disciplines work together to ensure sustainability.

### In-Situ Resource Utilization (ISRU)

ISRU involves extracting and processing local resources on extraterrestrial bodies, such as the Moon and Mars, to produce water, oxygen, and building materials. Chemical engineering develops the extraction and processing techniques, while PSE integrates these processes into a coherent system. For instance, lunar regolith can be processed to extract oxygen, which can then be used for life support and propulsion. Efficient ISRU systems reduce reliance on Earth-supplied resources and enhance mission viability. With Figure 3, I am returning to my opening statement. Figure 3 shows MOXIE, the reactor that can convert captured carbon dioxide from Mars's atmosphere into oxygen. A lighting example of reactor engineering (chemical engineering) and automation and control (process systems engineering).

### Advanced Manufacturing and Repair

Advanced manufacturing technologies, such as 3D printing, are crucial for space exploration. These technologies enable the in-situ production of tools, spare parts, and even habitats using local materials. Chemical engineering develops the materials and processes for 3D printing, while PSE ensures the integration and reliability of these manufacturing systems. This capability is vital for long-duration missions where resupply from Earth is not feasible.

### Illustrative example: distillation on the Moon

NASA and other space agencies are making plans to develop ISRU technologies on the moon, including distillation. Distillation could be used to purify water (that is available in lunar ice) or extract oxygen, water or other byproduct after regolith is treated chemically (e.g. via hydrogen reduction, carbon thermal reduction or molten salt electrolysis). It might also be useful as part of a process to locally produce rocket fuels.

But distillation on the moon poses several (chemical engineering) challenges. For example:

- The Moon's gravity is about 1/6th of Earth's, which could affect the separation of liquids and vapors during distillation. However, this is a manageable issue with the proper equipment design;
- The Moon has no atmosphere, meaning distillation would need to occur in a pressurized, controlled environment to prevent liquids from boiling away instantly in the vacuum.
- Lunar temperatures range from extremely cold (-173°C at night) to very hot (127°C during the day). Distillation systems would need robust thermal insulation and temperature control to function effectively.
- Distillation requires energy to heat liquids. On the Moon, energy would likely come from solar panels or nuclear power sources, both of which are feasible but require careful planning.
- Equipment would need to be lightweight, durable, and capable of operating in harsh conditions. Transporting materials to the Moon is expensive, so efficiency is critical.

PSE can tackle lunar distillation challenges through a structured, holistic approach. It uses system modeling and simulation to predict performance and address low-gravity issues like phase separation.

PSE integrates distillation with power, water extraction, and life support systems for optimal resource and energy use. It optimizes designs to balance mass, efficiency, and reliability for lunar operations. Risk analysis identifies failure points and incorporates safeguards for harsh environments. Automated control systems enable real-time monitoring and adjustment, reducing human intervention.

And, PSE designs gravity-independent solutions using centrifugal force, capillary action, or pressure gradients. It also ensures sustainability and validates designs through microgravity and lunar simulations for reliable

performance.

## 5. CHALLENGES AND FUTURE DIRECTIONS

### Technical Challenges

Space exploration faces numerous technical challenges, including harsh environmental conditions, long-duration mission sustainability, and system reliability.

Engineers must develop technologies that can withstand high radiation, extreme temperatures, and mechanical stresses. Ensuring the durability and efficiency of life support systems, propulsion systems, and materials is paramount.

### Future Research Areas

Future research must address the development of new energy sources, advanced materials, and sustainable life support systems. Innovations in biotechnology, such as bioengineered organisms for life support, and the application of artificial intelligence (AI) in process systems engineering, hold promise for future space missions. AI can optimize system performance, predict failures, and enhance automation.

### Potential Breakthroughs

Potential breakthroughs include the integration of biotechnology and AI in space exploration. Bioengineered organisms could be used to produce food, oxygen, and other essential resources. AI-driven process systems could enhance the reliability and efficiency of spacecraft systems. These innovations could revolutionize space exploration, making long-duration missions more feasible and sustainable.

## 6. CONCLUSION

Chemical engineering and process systems engineering are indispensable for the success and sustainability of space missions. These fields contribute to the development of propulsion systems, life support technologies, materials, systems integration, simulation, automation, and ISRU. As humanity continues to push the boundaries of space exploration, innovations in these disciplines will be crucial in overcoming the challenges of the final frontier. The collaboration between chemical engineering and PSE will play a pivotal role in ensuring the success of future space missions, making it possible to explore and inhabit new worlds.

## ABSTRACT

The separation of 1,3-butadiene from $C_4$ hydrocarbon mixtures is a crucial step in the production of synthetic rubbers and plastics. Conventional extractive distillation methods using solvents, like N,N-dimethylformamide (DMF), have proven effective but presents significant health and environmental challenges. This study explores the feasibility of using propylene carbonate (PC) as a green solvent alternative for butadiene extractive distillation, leveraging its environmentally friendly properties and industrial compatibility. Simulations were conducted using Aspen Plus®, employing the Non-Random Two-Liquid (NRTL) model coupled with the Redlich-Kwong equation of state to describe phase equilibrium. Results indicate that PC integrates seamlessly into existing processes, achieving comparable operational stability and butadiene separation efficiency with minimal modifications. A significant design improvement was the elimination of the methylacetylene separation column in the PC process, which simplified the overall configuration and reduced cooling water requirements by approximately 43 tonnes per hour. This change resulted in a 0.4% reduction in utility costs. While PC's higher boiling point requires operational adjustments, such as the use of higher medium-pressure steam, the overall energy consumption was 3.7% lower than with DMF. These findings demonstrate that PC is a viable and sustainable alternative for butadiene recovery processes, offering economic, operational, and environmental benefits.

**Keywords**: 1,3-Butadiene, Extractive distillation, Green solvent, Propylene carbonate, Process simulation, Aspen Plus

## INTRODUCTION

1,3-Butadiene (butadiene) is a critical feedstock to produce synthetic rubbers and plastics, including styrene-butadiene rubber, polybutadiene rubber, and latex. It is primarily obtained as a by-product of steam cracking processes. However, its separation from $C_4$ hydrocarbon mixtures poses a significant challenge due to the close boiling points of the components within these mixtures. Conventional distillation requires an impractically high number of trays and high reflux ratios, making it unfeasible. Consequently, extractive distillation has become the primary technique for separating butadiene, leveraging the selective solubility and enhancement of relative volatility by using appropriate solvents that facilitate the separation process.

Commonly used solvents for extractive distillation include N,N-dimethylformamide (DMF), N-methyl-2-pyrrolidone (NMP) and acetonitrile. Each of these solvents offers distinct advantages and limitations [1-5]. Although highly successful in separating butadiene from other $C_4$ hydrocarbons, these solvents pose significant health and environmental risks. Their use has been linked to adverse human health effects, including skin irritation, liver damage and an increased risk of cancer. Additionally, these solvents might bioaccumulate in ecosystems, posing serious threats to wildlife habitats and species. Identifying and mitigating these risks is essential to ensure safer and more sustainable industrial processes [6,7].

The economic, health and environmental challenges associated with conventional extractive distillation solvents have driven growing interest in simulation-based studies to optimize the process. Simulation tools, like As-

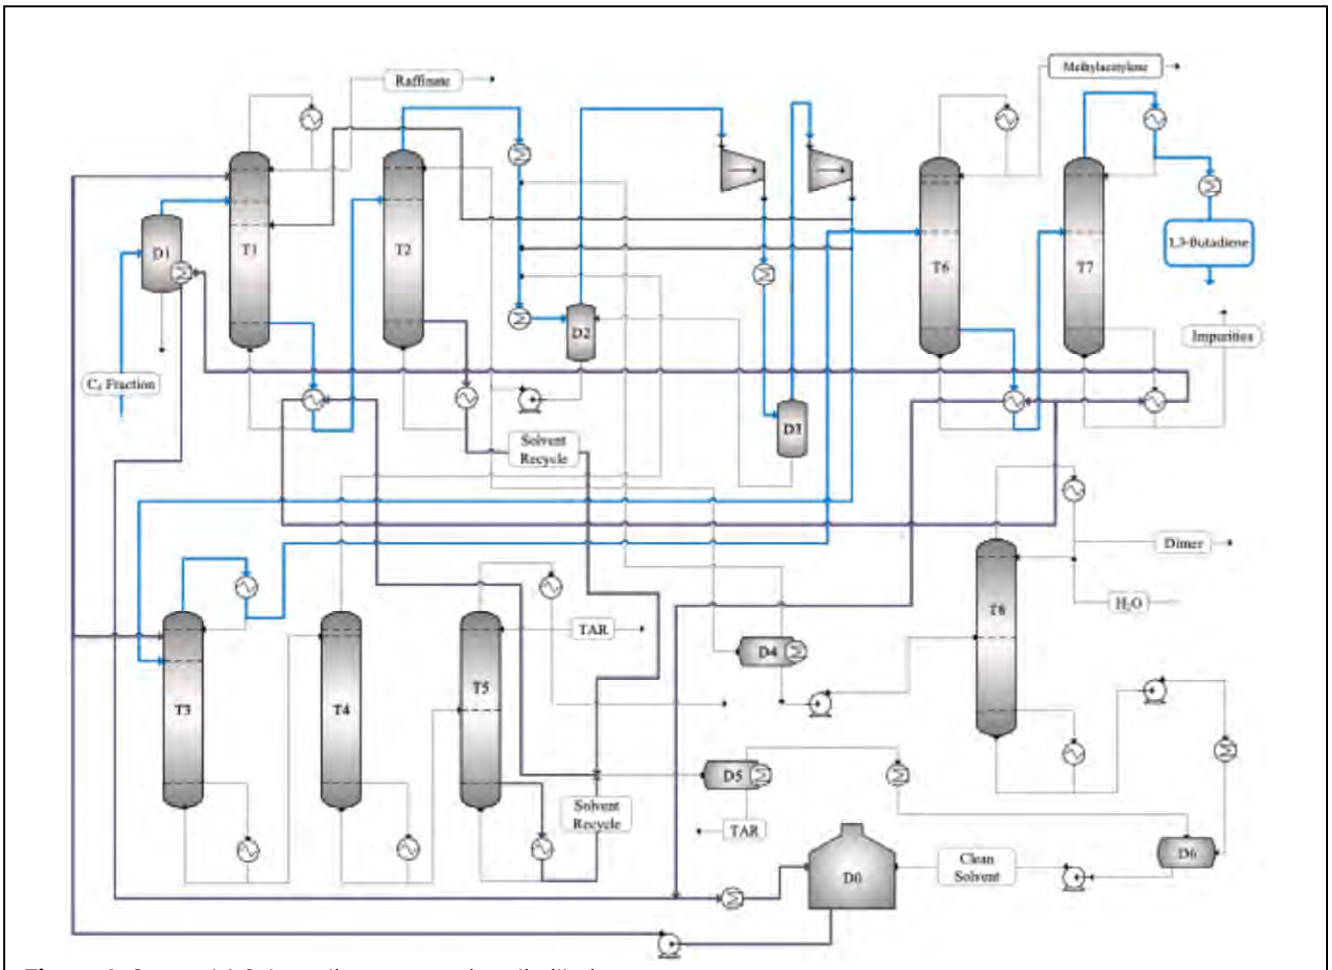

**Figure 1:** General 1,3-butadiene extractive distillation process.

pen Plus®, offer a robust framework for modeling extractive distillation processes, enabling the integration of mass and energy balances, phase equilibrium data, and complex distillation modeling. Advanced thermodynamic models, such as the Non-Random Two-Liquid (NRTL) model coupled with the Redlich-Kwong (RK) equation of state, are often employed to account for the non-ideal behavior of complex mixtures. These simulations not only facilitate accurate predictions of process behavior but also support the design and optimization of distillation columns and overall process efficiency. Previous studies have used computer-aided simulations to investigate the performance of conventional solvents, such as DMF, NMP, and acetonitrile, in extractive distillation processes for separating butadiene from crude $C_4$ mixtures [8,15].

Recent research has identified propylene carbonate (PC) as a promising green solvent for butadiene recovery, offering a viable alternative to conventional solvents like DMF and NMP, which may pose significant health and environmental risks [13]. While PC exhibits slightly lower selectivity, it provides an optimal balance between selectivity, cost-effectiveness, and industrial compatibility. Moreover, its favorable environmental, health, and safety (EHS) profile aligns with regulatory frameworks such as REACH (Registration, Evaluation, Authorization, and Restriction of Chemicals), which governs chemical use in the European Union. Additionally, the CEFIC (European Chemical Industry Council) emphasizes the need for sustainable and safer chemical alternatives, reinforcing the relevance of this study.

Building on these findings, this study aims to evaluate the feasibility of integrating PC into an existing butadiene recovery process with minimal modifications, ensuring that its adoption does not significantly disrupt current industrial operations or increase capital expenditures. A simulation approach using Aspen Plus® software is employed to model the extractive distillation process, comparing the performance of PC with the conventional DMF based process. Furthermore, the study assesses potential energy efficiency improvements, contributing to a more sustainable and economically viable butadiene production process.

Butadiene extraction is a multistep procedure that can be divided into four main sections (as it can be seen in Figure 1): first and second extractive distillation units, conventional distillation unit, and solvent purification

section. These stages work synergistically to achieve efficient butadiene separation while simultaneously enabling the recovery and reuse of the solvent. To improve process efficiency, the hot solvent from the bottoms of the stripping columns is integrated into a heat recovery circuit, where it is utilized to preheat subsequent distillation column streams. This heat integration significantly reduces total energy consumption.

In the first extractive distillation unit, the feed is introduced into the first column, where components with higher relative volatility than butadiene, such as 1-butene, are removed as overhead products. The bottom stream, enriched with butadiene and other less volatile components, including acetylene compounds, is directed to a stripper. In the stripper, hydrocarbons and impurities are separated from the solvent, producing a side stream containing purified butadiene and minor quantities of acetylene compounds. This side stream is subsequently fed into a second extractive distillation column, which removes remaining low-volatility impurities, achieving higher purity of 1,3-butadiene as the overhead product.

The conventional distillation section complements the process by refining by-products such as methylacetylene (propyne) and *cis*-2-butene. Additives, such as *tert*-butyl catechol (TBC) and silicone, are commonly employed to inhibit butadiene polymerization during the distillation process. However, due to the complexity and multiple pathways involved in polymerization mechanisms, its formation was not included in the current simulation. The so-called “popcorn” polymerization of butadiene, which occurs under specific reaction conditions in the presence of oxygen, remains a critical consideration. While this aspect was not addressed in the present study or in other similar studies, it represents a significant factor that should be incorporated into future analyses to ensure a more comprehensive evaluation of the process.

The final stage of the process involves solvent purification. A small fraction of the stripper’s bottom stream is directed to a distillation column for solvent recovery.

The feed composition plays a vital role in defining key process parameters. **Table 1** shows a representative feed composition stream, which was used in this simulation.

## Methodology

The process flow diagram (PFD) depicted in **Figure 1** illustrates a standard configuration for a butadiene extraction plant, showcasing the typical steps and equipment involved in the extraction process. The system was designed to process an average $C_4$ feed of 10,000 kg/h under normal operating conditions. Operating conditions and feed specifications were derived from typical industrial data, ensuring the simulation accurately mirrored realistic scenarios. The composition of the $C_4$ mixture and DMF solvent entering the first extractive distillation column is shown in **Table 1**.

**Table 1:** Composition of the fresh $C_4$ mixture and solvent.

| **$C_4$ mixture Component** | **wt%** |
|---|---|
| Propane | 0.03 |
| Propadiene | 0.03 |
| Methylacetylene | 0.02 |
| 1,2-Butadiene | 0.25 |
| 1,3-Butadiene | 44.98 |
| *cis*-2-Butene | 4.26 |
| *trans*-2-Butene | 5.41 |
| *iso*-Butene | 20.72 |
| 1-Butene | 13.67 |
| n-Butane | 4.98 |
| *iso*-Butane | 4.98 |
| Ethylacetylene | 0.09 |
| Vinylacetylene | 0.49 |
| n-Pentane | 0.09 |
| **DMF Solvent** | **wt%** |
| DMF | 97.00 |
| TAR | 2.50 |
| Dimer | 0.50 |
| Water | 0.00 |

The NRTL model, coupled with the RK equation of state, was selected as the thermodynamic framework to handle the complex, non-ideal behavior of the chemical systems involved. This combination is particularly effective for polar compounds, systems with strong molecular interactions, and highly non-ideal mixtures, such as those encountered in extractive distillation processes. Accurate vapor-liquid equilibrium (VLE) calculations were primarily based on binary interaction parameters obtained from the Aspen Plus® database. However, for certain pairs, where parameters were unavailable, the COSMO-RS (Conductor-like Screening Model for Real Solvents) model was employed. COSMO-RS, known for its accuracy in predicting molecular interactions, was utilized to estimate new parameters, ensuring robust and reliable VLE predictions for these systems [16]. Previous research has established the usefulness of COSMO-RS for estimating phase equilibrium parameters in extractive distillation systems, including its application to butadiene purification using polar solvents, where it offered reliable predictions of solution non-ideality and VLE behavior [17].

The integration of the new solvent into the simulation model began by closely aligning it with the existing DMF-based simulation. This approach minimized process modifications, ensuring a direct and reliable comparison of energy consumption in the subsequent analysis.

## Results

**Figure 2** presents the calculated temperature profile and the butadiene mass composition in the liquid for the first extractive distillation column (T1 in **Figure 1**). As expected, the temperature changes most rapidly at the top and bottom of the column and in the vicinity of the solvent feeding point and the $C_4$ fraction feeding point for the extractive distillation. Due to having a lower selectivity than DMF, PC simulation needed a solvent to feed ratio higher than DMF (6.8:1.0 for DMF and 7.6:1.0 for PC). Yet, PC showed a similar affinity behavior in the separation of butadiene, resulting in similar operational procedure.

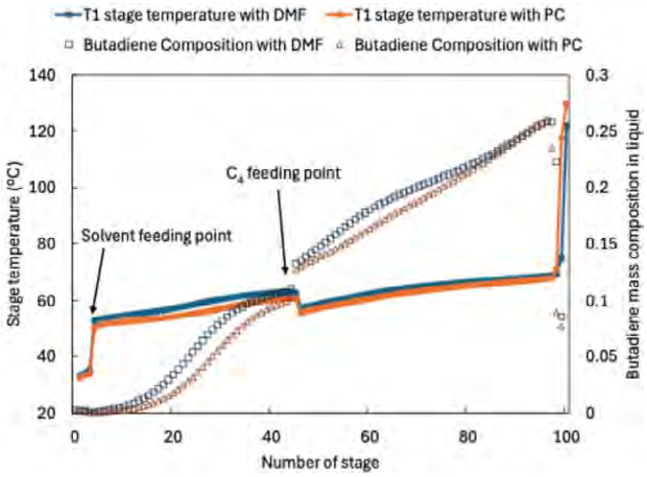

**Figure 2:** T1 stage temperature and butadiene composition for DMF and PC simulations.

The theoretical number of trays was determined by initially considering the actual number of trays in the distillation columns and systematically reducing them until significant differences in composition and temperature were observed between adjacent stages. This iterative approach ensured that only effective stages, which contribute meaningfully to the separation process, were included in the final design. If a stage exhibited negligible differences in these parameters compared to adjacent stages, it was deemed ineffective contributing little to the separation process. Such stages were excluded from the final design as they added unnecessary complexity to the simulation. This approach is particularly critical in complex systems, such as the one studied here, which involves multiple recycles and interconnected units (**Figure 1**). Reducing the number of ineffective stages helps to streamline the simulation, improving computational efficiency and model convergence. Moreover, removing non-contributing stages minimizes the potential for numerical instability, which is often a concern in simulations with extensive recycle loops and highly coupled systems. By ensuring that, only effective stages were included, and the simulation more accurately represented the operational behavior of the distillation columns, leading to more reliable results.

The implementation of PC as a solvent demonstrated that methylacetylene is insoluble in PC, thereby eliminating the need for column T6 (**Figure 1**) in the separation process. This significantly simplified the process design, as methylacetylene was effectively removed in the raffinate stream from the first extractive distillation column and directed towards other production facilities. In these facilities, methylacetylene may, for example, undergo hydrogenation, preventing adverse effects in subsequent process steps. This modification alone resulted in a 0.4% reduction in utility costs, primarily due to an estimated savings of 43 tonnes per hour in cooling water consumption.

A critical challenge associated with PC as a solvent is its high normal boiling point (242°C) compared to DMF (153°C). This requires operating at lower pressures (as low as -0.8 barg) to accommodate the thermal limitations of existing equipment. However, not all distillation columns in the process can operate under vacuum conditions. Specifically, the first stripper, responsible for separating the solvent from butadiene and acetylene compounds, cannot operate at reduced pressures due to operational constraints imposed by the positive displacement compressor downstream. In contrast, the second stripper (T5 in **Figure 1**) is capable of operating under these conditions, allowing for partial adaptation of the process to the use of PC.

Additionally, a conventional DMF-based process primarily relies on low-pressure (LP, 5 barg) and medium-pressure (MP, 12 barg) steam for heating. However, the implementation of PC required a higher hot utility, which was successfully met by employing higher medium-pressure steam (MP+, 18 barg). This adaptation was critical to avoid the use of high-pressure steam, thereby minimizing infrastructural modifications and maintaining the feasibility of the process. Additionally, PC showed similar behavior to DMF within the general solvent circuit, where hot solvent from the bottom of strippers was used to heat other column streams and equipment, as shown in **Figure 1** (blue line).

Overall, the transition to PC as a solvent demonstrated high compatibility with the existing butadiene plant configuration, achieving the desired separation performance (butadiene product 99.6 wt%) with minimal process modifications. In terms of utility consumption, PC required slightly higher electricity usage due to its higher solvent-to-feed ratio compared to DMF (**Figure 3**). However, despite using higher pressure steam, the total heat consumption in the PC simulation was 3.7 % lower than in the DMF process.

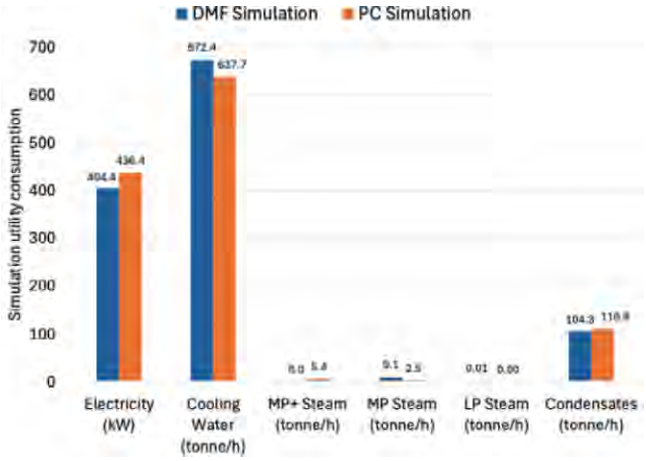

**Figure 3.** DMF and PC simulation's utilities consumptions.

**Table 2** highlights the key operational rates and ratios for the DMF and PC simulations, providing insight into their comparative performance within the same process framework. The data indicates that PC solvent values align closely with those of DMF, confirming that PC integrates seamlessly into the existing process configuration with minimal adjustments. Notable differences include a slightly higher solvent-to-$C_4$ feed ratio for PC, which compensates for its lower selectivity relative to DMF. Furthermore, the reflux-to-feed ratio in the downstream columns (T5 and T8) is lower for PC, contributing to reduced energy consumption in some sections of the plant.

Despite these differences, PC achieves similar operational stability and butadiene separation efficiency, illustrating its strong compatibility with the existing process. Moreover, the elimination of column T6 in the PC simulation, due to the insolubility of methylacetylene in PC, further simplifies the process and reduces operational complexity. Overall, these results underscore PC's potential as a viable and sustainable alternative to DMF, offering operational consistency with additional energy and process efficiency benefits.

## CONCLUSION

This study explored the use of PC as a green solvent alternative for the extractive distillation of butadiene, comparing its performance to the conventional DMF process. The results demonstrated that PC is highly compatible with the existing butadiene recovery configurations, requiring only minor process adjustments to achieve similar separation efficiency. Although PC exhibited slightly lower selectivity, necessitating a higher solvent-to-feed ratio, it maintained comparable operational stability and achieved the desired butadiene purity of 99.6 wt%.

Overall, PC proved to be a viable and sustainable alternative to DMF, offering notable operational, environmental, and economic advantages while minimizing the need for infrastructural modifications. Its implementation has the strong potential to enhance energy efficiency and reduce the environmental footprint of butadiene recovery processes. Future studies should focus on validating these findings under industrial-scale conditions and exploring the long-term stability and performance of PC in continuous operations.

## ABSTRACT

The electrification of chemical processes and carbon capture and utilisation represent two promising approaches to improve efficiency and decrease carbon emissions of the process industry. The development of electrolyzers has gathered momentum in the last decades, allowing for the possible introduction of renewable electrons into carbon dioxide-based chemicals manufacture. While the performance of the electrolyzers is subject to improvements driven by the experimental community, the generation of waste heat is unavoidable due to the electrical resistances and process inefficiencies within the electrochemical cells. The possibility of re-using this waste heat has not been investigated within the realm of carbon dioxide electrolyzers. Here we show the potential of upgrading this waste heat by means of a heat pump, for its utilisation in the downstream processing of formic acid obtained from carbon dioxide electroreduction. We found that the waste heat represents roughly 62% of the power input to the electrochemical cells and it can be upgraded from 35 °C to 112 °C to drive the extractive distillation of formic acid and water. For a system producing 25 kt/y of formic acid, this results in the electrification of 60% of the separation energy duty, yielding a decrease in carbon dioxide emissions of 39-58% for the downstream processing, while the addition of a heat pump has a payback period of ~4.4 years in the base case.

**Keywords**: Process Design, Carbon Dioxide, Electrification, Process Integration, Heat Pump

## INTRODUCTION

Several strategies can be deployed to reduce the environmental burden of manufacturing processes, specifically for chemicals. Among these strategies, of prime importance is the substitution of fossil inputs with renewable ones, whether it be electricity, biomass, or carbon dioxide. To enable this, productions based on electrolysis have significant potential, as they exploit renewable electricity to drive the reactions and allow for the conversion of carbon dioxide. Both experimental efforts and techno-economic assessments are directing the concerted development of the field of carbon dioxide electrolysis [1-2].

However, electrolyzers generate waste heat due to ohmic and kinetic losses, which are overcome through the application of an overpotential. Notably, heat management for electrolyzers remains under-explored, particularly when referring to the realm of low temperature carbon dioxide electrolysis. Conversely, the field of water electrolysis has seen some research in this [3], but, as hydrogen production lacks significant downstream processing, the possibilities of waste heat utilisation in the plant are limited.

This is not true for carbon dioxide electrolysis, especially when yielding liquid products relying on thermal separations. As the waste heat is at low temperature, it cannot be directly exploited to drive the separations. To tackle this obstacle, heat pumps can be employed to upgrade the waste heat to useful temperature levels, thus enabling heat integration and further diminishing the need for fossil fuels in the separation section of the plant. An additional challenge is represented by the typical room temperature operation of carbon dioxide electrolyzer currently developed at the lab scale. This would imply a very high temperature lift for the heat pump, thus diminishing its performance. However, recent literature shows that optimal operation would lie between 60 and 70 °C [4], which can be more readily exploited by a heat pump.

## PROBLEM STATEMENT

This study aims at assessing the potential of upgrading the waste heat from the electrolyzer via heat pump to drive the product recovery and purification processes. To showcase this, we have selected the production of formic acid, since it can be obtained with good performance through carbon dioxide electrolysis [5]. By designing the different parts of the process – electrolyzer stacks, separation processes, and heat pump – and combining them together, we have obtained a complete flowsheet for the integrated plant. This has allowed for the quantification of the reduction in the external load for the thermal separation and, consequently, of the carbon dioxide emissions of the process.

This work constitutes a proof of concept for the potential upgrade of waste heat from the electrolyzers, reporting preliminary results. The inclusion of a heat pump in the process is evaluated based on economics and environmental (carbon dioxide emissions) performance. However, the complete techno-economic assessment of the process, together with further heat integration and overall process optimization, are out of scope for this study.

## METHODOLOGY

A process to produce formic acid (HCOOH) from carbon dioxide and water comprises three main parts, as shown in the block flow diagram of Figure 1: the electrolyzer stacks, the formic acid-water separation and the heat pump. To support the design, we simulated this process at steady state using Aspen Plus®. Considering the formic acid market [6], the plant is sized to produce 25 kt/y of FA at 85 wt.%, with 100% utilisation based on 8000 h/y of operation.

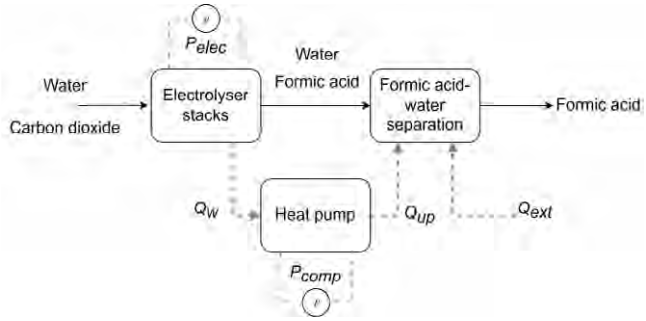

**Figure 1.** Block flow diagram for the process, highlighting the three sections in which the system can be broken down. The main material and energy flows are also displayed.

A three compartment electrolyzer, based on the set up of Yang et al. [7], is chosen, as it reduces the complexity of the process by yielding directly formic acid instead of the formate salt, obtained from the combination of the product and the cation of the electrolyte. To design the electrolyzer, we considered several trade-offs between major decision variables, namely the cell voltage, the current density, the faradaic efficiency and the product concentration in the outlet stream [8]. The current density determines, for a given production capacity, the electrolyzer size required, and its dependence on the cell voltage can be obtained by fitting experimental data [7]. The availability of experimental data up to 4 V for the polarization curve provides an upper limit to the investigated cell voltage ranges.

The waste heat $Q_W$ developed by the electrolyzers is calculated using in Eq. 1, where $i_k$ is the partial current for product $k$ ($i_k = FE_k\ i$, with $FE_k$ Faradaic efficiency for product $k$, and $i$ total current), $E_{cell}$ is the total cell voltage, and $E_{tn,k}$ is the thermoneutral voltage for product $k$ (i.e. the voltage such that the cell would have isothermal operation) [3]. The waste heat, together with the total power input to the cell $P_{cell}$, determines also the cell efficiency $\epsilon$, as expressed in Eq. 2.

$$Q_W = \sum_k i_k (E_{cell} - E_{tn,k}) \quad (1)$$

$$\epsilon = \frac{P_{cell} - Q_W}{P_{cell}} \quad (2)$$

The separation of formic acid from water is based on the work of Ramdin et al. [9], where it is carried out through extractive distillation with 2-methyltetrahydrofuran. Notably, this separation technology keeps the main reboiler temperature at 106 °C, which is key to enable a more efficient performance for the heat pump. Since the goal of this work is to demonstrate the potential of upgrading the waste heat, systematic improvements to the downstream processing are out of scope.

The selection of the heat pump technology is limited to the mechanically-driven ones in order to maximise the electrification of the process via the compressor power input. The investigation space is thus reduced to vapor compression and compression resorption heat pumps [10]. Due to the scope constraints of this work, the implementation of compression resorption heat pumps, which might result in higher efficiency, is deferred to future studies. We have analyzed the performance of different working fluids, with the goal of maximising the coefficient of performance ($COP$) of the system, as defined in Eq. 3, where $Q_{up}$ is the upgraded heat flow and $P_{comp}$ is the power input to the compressor.

$$COP = \frac{Q_{up}}{P_{comp}} \quad (3)$$

Simplified economics, based on the Total Annualised Costs ($TAC$, see Eq. 4) have been exploited for the design of the electrolyzer.

$$TAC = \mathrm{OPEX} + \frac{CAPEX}{lifetime} \quad (4)$$

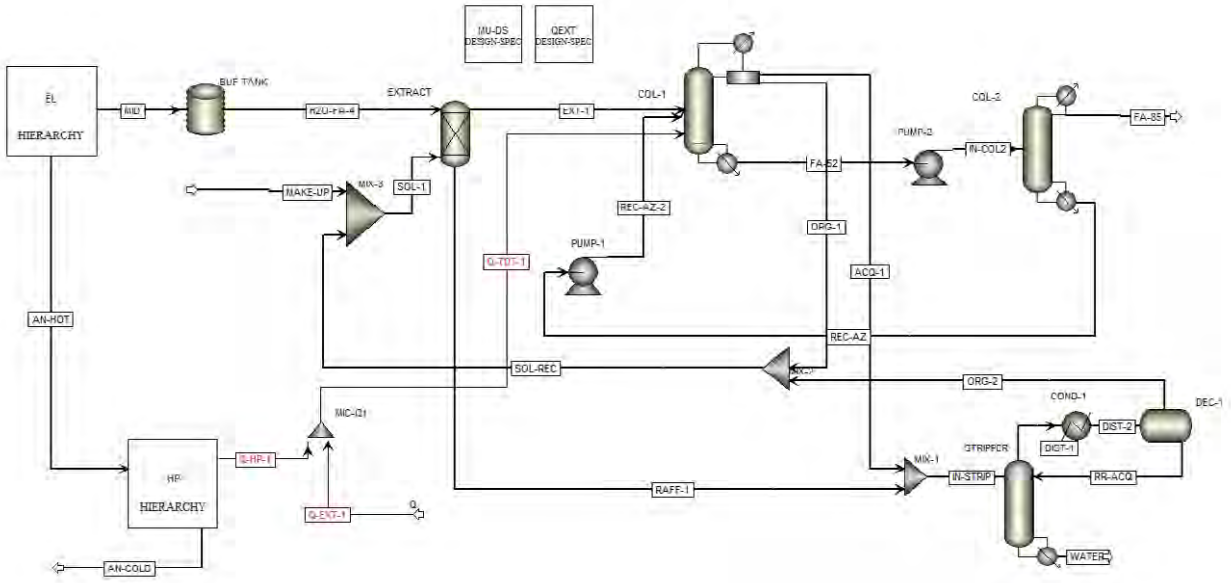

**Figure 2.** Aspen Plus® flowsheet for the process, showing the separation system and the two hierarchical blocks containing the electrolyzers and the heat pump models.

Moreover, the payback period for the heat pump has been calculated to evaluate the investment from an economic perspective (compressor and heat exchangers capital costs estimated according to [11]). Carbon dioxide emissions per unit product, based on the energy demand and its origin, provide support and context for the decisions on design and the benefits of upgrading the waste heat by means of the heat pump.

The Aspen Plus® implementation of the model rests on the choice of different thermodynamic packages for different parts of the flowsheet, namely: ELECNRTL for the electrolyzer stacks and balance of plant; UNIQUAC-HOC for the formic acid-water separation; and REFPROP for the heat pump, tailoring each of these models to the specific application. The REFPROP library contains several, fluid-specific models based on fundamental equations of state, as discussed in [12].

## RESULTS AND DISCUSSION

The flowsheet for the whole process, as developed in Aspen Plus®, is reported in Figure 2, which displays the downstream separation, while the electrolyzers and the heat pump are included in hierarchy blocks. The electrolyzer is modelled in Excel, which is embedded as a calculator block in the Aspen Plus® simulation, while the heat pump is modelled as a closed loop vapor compression system (evaporator, compressor, condenser, and expansion valve). The following sections present first the results for the electrolyzer design, followed by the heat pump selection and the heat integration in the process. Finally, simplified metrics to evaluate the carbon dioxide emissions and the economic performance of the design are described and discussed.

### Electrolyzer design

The design of the electrolyzer has been defined through an optimisation of the different trade-offs discussed in the previous section. The sensitivity of the cell voltage which allows to minimise the $TAC$, based on the electricity price and the electrolyzer cost, is shown in Figure 3.

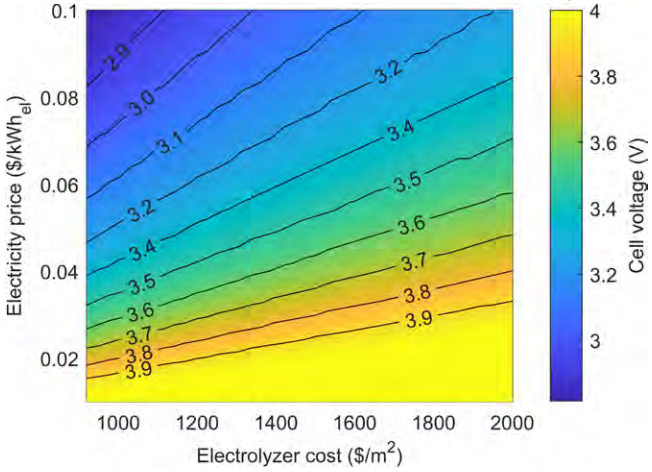

**Figure 3.** Cell voltage that minimises total annualised costs as a function of electrolyzer and electricity cost.

Cheap electricity (below 0.03 $/kWh$_{el}$) would favor operation at maximum voltages, regardless of the electrolyzer cost, because the current density, a function of the cell voltage, is pushed to higher values, resulting in smaller, and thus cheaper, reactors. This effect can also be observed at constant electricity price, with an increasing trend in the optimal voltage with higher electrolyzer prices, thanks to the inverse proportionality between cell voltage and electrolyzer area required. The capital costs

of the electrolyzer do not become dominant in the range considered (based on [13]), therefore the optimal operation is not found at lower voltages.

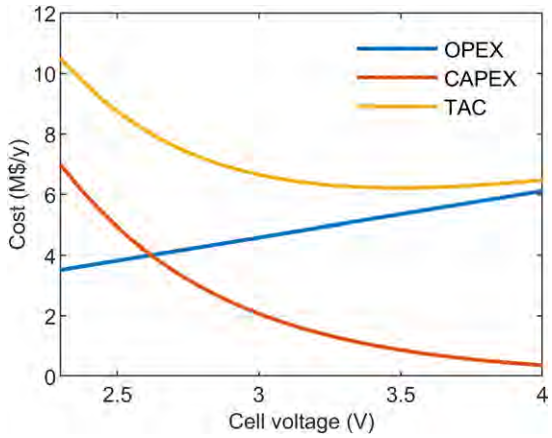

**Figure 4.** Trade-off between OPEX and CAPEX for the electrolyzer as a function of the cell voltage (electricty price: 0.05 $/kWh$_{el}$; electrolyzer cost: 1500 $/m$^2$).

For the base case values of 0.05 $/kWh$_{el}$ and 1500 $/m$^2$ for electricity price and electrolyzer cost, respectively, the trade-off between OPEX and CAPEX is displayed in Figure 4. The OPEX are linearly dependent on the cell voltage, for a given production capacity, while the CAPEX decrease with $E_{cell}$, since the current density rises, leading to smaller units. An optimum value of the cell voltage can be identified, as ~3.5 V, which corresponds to a current density of ~130 mA/cm$^2$. Table 1 summarizes the design variables chosen, as well as some relevant design parameters and process inputs.

**Table 1:** Main process design variables chosen, together with the carbon intensity of relevant energy sources. $FE$ is Faradaic efficiency. The subscript *th* and *el* distinguish between thermal and electrical energy.

| Stream | Value | Units of measure |
|---|---|---|
| Cell voltage | 3.5 | V |
| $FE$ (HCOOH) | 90% | (-) |
| $FE$ (CO) | 2% | (-) |
| $FE$ ($H_2$) | 8% | (-) |
| Product concentration (middle compartment outlet) | 10% | w/w |
| Electrolyzer lifetime | 5 | years |
| Electrolyzer temperature | 50 | °C |
| Carbon intensity MP steam | 237 | gCO2/kWh$_{th}$ |
| Carbon intensity electricity (grid, EU-27)[15] | 251 | gCO2/kWh$_{el}$ |
| Carbon intensity electricity (renewables)[16] | 19 | gCO2/kWh$_{el}$ |

The choice of the cell voltage determines also the amount of waste heat available for upgrading via the heat pump, according to Eq. 1. This effect is shown in Figure 5, which on the right y-axis reports both the total power input to the electrolyzers and the available waste heat as a function of the cell voltage, while the left y-axis shows the electrolysis cell energy efficiency (Eq. 2). This highlights how the design of the electrolyzer has cascade effects on the performance of the rest of the process, as the electrolyzer efficiency could be improved, but this would increase the demand for external energy inputs for the downstream separation in the integrated system. For the cell voltage chosen, ~8.3 MW of waste heat is obtained, while the cell operates at ~38% efficiency.

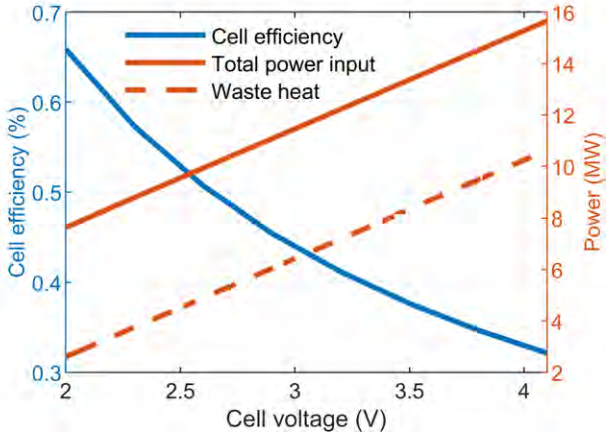

**Figure 5.** System trade-off showing the total power input to, and the waste heat developed by, the electrolyzers, as a function of the cell voltage. The cell efficiency vs. the voltage is also provided.

## Heat pump selection and heat integration

The waste heat available can be upgraded by means of a heat pump. The performance of the heat pump, measured by the $COP$, is strongly dependent on the temperature lift required, defined as the difference between the temperature of the upgraded heat and that of the waste heat. In our case, based on the electrolyzer operating temperature of 50 °C, electrolyte return temperature of 40 °C, and reboiler temperature of 106 °C, the temperature lift is 77 °C (35 °C to 112 °C).

After screening different working fluids, we have identified a vapour compression heat pump using HFO-1233zd and one using ammonia as a suitable candidates, due to their performance, appropriate critical temperature, and low global warming potential and ozone depletion potential [14]. Based on the conditions, the heat pump can reach a COP of ~2.8-3.1, employing compressors requiring ~4-4.5 MW$_{el}$, and leading to upgraded heat of ~12-13 MW$_{th}$ at the desired temperature. The results presented below are based on the ammonia case, as they are substantially the same for HFO-1233zd.

**Table 2:** Impact of different heat pump technologies and working fluid on the upgraded heat and on carbon dioxide emissions for the downstream processing (DSP). Note that the emissions do not represent the full carbon footprint of the product.

| Heat pump | Working fluid | COP | Electricity source | Carbon dioxide emissions DSP ($kgCO_2$/kg product) | Carbon dioxide reduction (%) |
|---|---|---|---|---|---|
| No | N/A | N/A | N/A | 2.55 | N/A |
| Yes | Ammonia | 3.06 | Offshore wind | 1.07 | -64% |
| Yes | Ammonia | 3.06 | Grid | 1.56 | -42% |

The reboiler heat duties for the azeotropic distillation and the vacuum distillation (COL-1 and COL-2 in Figure 2) are 13.5 $MW_{th}$ and 7 $MW_{th}$, respectively. Figure 6 summarizes the main energy flows among the three sections of the system: it is possible to observe that the upgraded heat covers the vast majority of the duty of the azeotropic distillation column (COL-1), leaving COL-2 to be supplied by external heat. The heat pump thus accomplishes the dual goal of providing cooling to the electrolyzer system, and delivering high temperature heat to the separation. Electricity constitutes ~70% of the energy inputs to the process, while the upgraded heat covers ~60% of the thermal duties.

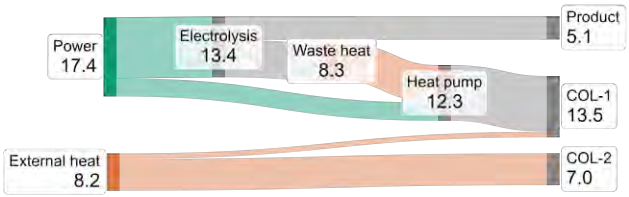

**Figure 6.** Sankey diagram displaying the energy flows (in MW) in the system. Electric energy is shown as green, while thermal energy is represented in orange.

## Emissions and economic metrics

Table 2 provides a comparison between the case of implementation of a heat pump versus a system in which the separation duty is fully provided via an external source (steam boiler with natural gas). The results show that the heat pump allows for significant improvements in the carbon dioxide emissions of downstream process, with a reduction of -58% when using fully renewable electricity (based on median offshore wind emissions [16]) and -39% when connected to a national grid (assuming the current average grid emissions for the European Union-27 [15]). This reduction in emissions results from a decrease in the primary energy input through the energy multiplying effect of the heat pump.

While the heat pump brings benefits from the environmental perspective regardless of the source of the electricity, economic considerations should not be overlooked for its widespread adoption. Therefore, we have calculated the payback period for the addition of the heat pump to the system, as displayed in Figure 7 for different scenarios of electricity and fuel prices. The figure shows that the investment is paid back in less than ~4.5 years, except for when electricity is expensive (0.09 $\$/kWh_{el}$). In this case, the investment is not attractive, as the additional electricity input to the system for the heat pump compressor does not offset the reduced primary energy demand. Furthermore, it can be observed that the system is sensitive to increases in the fuel prices, given that the payback period for scenario 4 (electricity price of 0.05 $\$/kWh_{el}$ and fuel price of 0.045 $\$/kWh_{th}$) is about half of that for scenario 1 (same electricity price, 0.03 $\$/kWh_{th}$ for fuel).

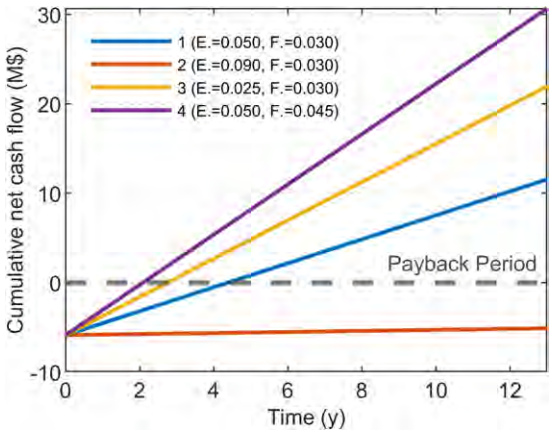

**Figure 7.** Cumulative net cash flow over a plant lifetime of 20 years for the investment in the heat pump, showing different scenarios based on the electricity (E.) and fuel (F.) price (reported in $\$/kWh_{el}$ and $\$/kWh_{th}$, respectively).

## CONCLUSIONS AND FUTURE WORK

This work shows how the waste heat from the electrolyzer can be upgraded for heat integration, thus reducing the need for external energy inputs for the separation of products. This type of assessment can be extended to other processes operating with electrolyzers and similar conditions, including those downstream of water electrolysis for hydrogen generation.

Moreover, the application of a multi-pronged

electrification strategy, in which renewable electrons are used to both drive reactions and the energy integration of the system, is demonstrated. This is key in the perspective of the reduction of carbon dioxide emissions, as it offsets the use of conventional heating media in the downstream separations by ~60% and increases electricity inputs to 70% of the total energy demand. Additionally, the economic performance of the heat pump would justify the increased capital investment, given that the payback period is a few years, with the exception of higher electricity prices.

These results justify future work on a detailed techno-economic assessment of the whole process, including a system-wide optimisation to find the best design and operating conditions under different sets of inputs (electricity price, renewable electricity availability, heat pump technology). Moreover, the potential for waste heat upgrade in other electrolysis-based processes merits further investigation.

# Optimization of Sustainable Fuel Station Retrofitting: A Set-Covering Approach considering Environmental and Economic Objectives

**Daniel Vázquez*, Raul Calvo-Serrano**

IQS School of Engineering, Universitat Ramon Llull, Via Augusta 390, 08017 Barcelona, Spain
* Corresponding Author: daniel.vazquez@iqs.url.edu.

## ABSTRACT

In this work, we propose a mixed-integer linear programming (MILP) model that optimizes economic and environmental objectives by retrofitting fuel stations for the case study of Spain. The model contains set-covering constraints that ensure that there is at least one retrofitted fuel station within a radius of 20 kilometers of each retrofitted fuel station. The results indicate that by retrofitting fuel stations to allow for electric vehicles, both economic and environmental objectives improve, while showing which power plants would be tasked with the increase in electricity production to satisfy the increased electric demand.

**Keywords**: Life Cycle Assessment, Supply Chain, Optimization, Renewable and Sustainable Energy, Technoeconomic Analysis

## INTRODUCTION

To improve the sustainability of the transport sector, there is a global tendency to promote more environmentally friendly modes of transportation, in alignment with the Sustainable Development Goals (SDGs), particularly SDG 13, which focuses on climate change action. This shift is essential given that the transport sector is one of the largest contributors to greenhouse gas emissions globally, and transitioning to cleaner transportation options is a critical step toward mitigating climate change. Electric vehicles (EVs), if powered by renewable energy, are a promising solution to reduce emissions significantly. In response to these developments, many countries are implementing policies and incentives to encourage the adoption of EVs, including subsidies for EV purchases, investments in charging infrastructure, and stringent emission standards for conventional vehicles. This trend has led to a surge in EV adoption, which may reduce the reliance on traditional fuel stations in the future. However, the existing network of fuel stations, strategically located and familiar to consumers, offers a unique opportunity to support the EV transition. Retrofitting these fuel stations into EV charging stations not only profits from their advantageous locations and existing infrastructure but also facilitates a smoother transition for current consumers [1].

We propose a mixed-integer linear programming (MILP) optimization model based on the set-covering problem to determine which fuel stations are best suited for retrofitting and to evaluate the impact of this conversion on economic and environmental objectives compared to a baseline scenario with no retrofitting. The set-covering approach ensures that the retrofitted stations can adequately serve EVs within a specified radius, addressing the limited range issue of current electric vehicles. These types of models are common in supply chain and energy systems modelling [2].

This methodology is applied to a case study in Spain, utilizing a comprehensive dataset of all existing fuel stations. Given the NP-hard nature of the set-covering problem, an initial filtering step is employed to reduce the problem's size. Subsequent optimization is performed under various assumptions, such as the source of electricity and local demands of transport usage, using bi-objective optimization techniques. The model aims to minimize economic costs and $CO_2$ equivalent emissions, employing a life-cycle assessment (LCA) framework [3].

The results indicate that retrofitting a relatively small fraction (~10%) of the fuel stations satisfies set-

covering constraints, ensuring sufficient coverage for EV users. Notably, even considering retrofitting costs, both the economic and environmental optima coincide in a full electrification of the vehicle float.

## PROBLEM STATEMENT

The objective is to model and optimize the economic and environmental impacts of retrofitting existing standard fuel stations into EV charging stations in Spain, compared to a baseline case where no retrofitting is allowed. Thus, part of the energy system of the country is also modeled through the locations and capacities of existing power plants. The problem can be summarized through the following bi-objective optimization problem (1).

$$\begin{aligned} &\min\ \{obj^{eco}(x,y), obj^{env}(x,y)\} \\ &s.t. \\ &h(x,y) = 0 \\ &g(x,y) \leq 0 \\ &x \in \mathbb{R}^n, y \in \{0,1\} \end{aligned} \tag{1}$$

where $obj^{eco}, obj^{env}$ represent economic and environmental objectives, $x$ represent continuous variables, $y$ represent Boolean variables, $h(x,y)$ indicate equality constraints, and $g(x,y)$ indicate inequality constraints. Boolean variables are required to include set-covering constraints and other logical requirements detailed in the modeling section. For the economic objectives we consider the total cost, and for the environmental objective, we use the global warming potential from the IPCC2021 method (GWP). The temporal scope is one year.

## OPTIMIZATION MODEL

### Sets

We will use three main sets to model the system, these being, the set of fuel stations that can be retrofitted, $s \in S$, the set of power plants that could provide electricity to the retrofitted fuel stations, $p \in P$, and the set of autonomous regions in Spain, $r \in R$.

We define subsets depending on the type of power plant, specifically, if they are wind-offshore ($P^{WO}$), coal ($P^{C}$), gas ($P^{NG}$), waste ($P^{W}$), biomass ($P^{B}$), hydropower ($P^{H}$), solar ($P^{S}$), oil ($P^{O}$), or nuclear ($P^{N}$). We define a multi-set, $GS_{s,r}$, which maps which fuel stations are in each autonomous region.

### Variables

The model includes the following continuous variables: $e_{p,s}^{RF}$ indicates the amount of electricity produced in power plant $p$ that will be sent to retrofitted fuel station $s$ [GWh], $e_p^{DE}$ refers to the electricity produced in power plant $p$ to satisfy the country's demand of electricity [GWh], $e_p^{TP}$ refers to the total amount of electricity produced in power plant $p$ [GWh], $e_r^{EC}$ refers to the electricity available in autonomous region $r$ to be used to charge electric vehicles, $e_s^{SEC}$ refers to the electricity available in fuel station $s$ to be used to charge electric vehicles, $d_r^{EC}$ refers to the amount of kilometers traveled using electric cars in autonomous region $r$ [$\times 10^3$ km], and $d_r^{NC}$ refers to the amount of kilometers traveled using conventional combustion engine cars in autonomous region $r$ [$\times 10^3$ km].

Regarding binary variables, we consider two. $w$ indicates if we activate or de-activate the set-covering constraints, while $y_s$ indicates if we retrofit fuel station $s$ ($y_s = 1$) or not ($y_s = 0$).

### Parameters

$D_{s,s'}^{SC}$, refers to a binary parameter that has a value of 1 if fuel stations $s$ and $s'$ are within a given distance valid for the set-covering problem, $D_{s,s'}^{S}$, refers to the distance between two fuel stations [$10^3$ km], $D_{p,s}^{PS}$ refers to the distance between each power plant and each station [$10^3$ km], $GWP_p^{PP}$ refers to the GWP of generating electricity in power plant $p$ [$\mathrm{tCO_2eq/GWh}$], $GWP^{EC}$ refers to the GWP of using an electric car without counting the fuel [$\mathrm{tCO_2eq}/10^3$ km], $GWP^{NC}$ refers to the GWP of using a standard car [$\mathrm{tCO_2eq}/10^3$ km], $\bar{E}_p$ refers to the maximum amount of electricity that power plant $p$ can produce [GWh], $E^{EC}$ refers to the required electricity for traveling using an electric vehicle [$\mathrm{GWh}/10^3\mathrm{km}$], $B_r^D$ refers to a demand of distance that must be fulfilled in each autonomous region $r$ [$10^3$ km], $B^E$ refers to the demand of electricity of the country, not counting inclusion of new electric vehicles [GWh], $C^{RF}$ refers to the cost of retrofitting a fuel station [M€], $C^{NC}$ refers to the cost of traveling using a standard vehicle [M€/$10^3$ km], and $C^{WO}$, $C^{C}$, $C^{NG}$, $C^{W}$, $C^{B}$, $C^{H}$, $C^{S}$, $C^{O}$, and $C^{N}$ refer to the levelized cost of each type of electricity [M€/GWh].

### Equations & Constraints

#### Objective functions

We consider both an economic and an environmental objective, calculated as shown in (2) and (3).

$$\begin{aligned} obj^{eco} = &\sum_{s\in S} C^{RF} y_s + \sum_{r\in R} C^{NC} d_r^{NC} + \sum_{p\in P^{WO}} C^{WO} e_p^{TP} + \\ &\sum_{p\in P^{C}} C^{C} e_p^{TP} + \sum_{p\in P^{NG}} C^{NG} e_p^{TP} + \sum_{p\in P^{W}} C^{W} e_p^{TP} + \\ &\sum_{p\in P^{B}} C^{B} e_p^{TP} + \sum_{p\in P^{H}} C^{H} e_p^{TP} + \sum_{p\in P^{S}} C^{S} e_p^{TP} + \sum_{p\in P^{O}} C^{O} e_p^{TP} + \\ &\sum_{p\in P^{N}} C^{N} e_p^{TP} \end{aligned} \tag{2}$$

$$\begin{aligned} obj^{env} = &\sum_{r\in R} d_r^{NC} GWP^{NC} + \sum_{r\in R} d_r^{EC} GWP^{EC} + \\ &\sum_{p\in P} GWP_p^{PP} e_p^{TP} \end{aligned} \tag{3}$$

The economic objective includes the cost of retrofitting plants, producing electricity required both for the country's demand and for the electric vehicles, and the cost of using standard combustion cars for traveling distances. The environmental objective includes the

emissions from the electricity production, the emissions of using standard combustion cars for traveling distances, and the emissions of electric vehicles for traveling distances, without counting the electricity itself to avoid double counting.

### Set-covering constraints

The set-covering constraints make use of the Boolean parameter $D^{SC}_{s,s'}$, to make sure that there each retrofitted fuel station has at least one another retrofitted fuel station at the stipulated distance. In this work, the stipulated distance is 20 km. We also allow the model to not retrofit any station at all, thus ignoring the set-covering constraints. For this, we use the following equations (4,5):

$$\sum_{s' \in S} D^{SC}_{s',s} \geq w \quad \forall s \in S \tag{4}$$

$$w \geq y_s \quad \forall s \in S \tag{5}$$

### Electricity balances

The total electricity produced in a power plant is given by (6).

$$e^{TP}_p = e^{DE}_p + \sum_{s \in S} e^{RF}_{p,s} \quad \forall p \in P \tag{6}$$

The electricity that can be used in a retrofitted fuel station is the amount that is sent from each power plant, subtracting a 3%/1000 km loss in transport (7).

$$e^{SEC}_s = \sum_{p \in P} e^{RF}_{p,s} \cdot (1 - 0.03 D^{PS}_{p,s}) \quad \forall p \in P \tag{7}$$

The aggregation of electricity produced for electric vehicles in an autonomous region is given by (8).

$$e^{EC}_r = \sum_{s \in GS_{s,r}} e^{SEC}_s \quad \forall r \in R \tag{8}$$

We also limit the amount of electricity that each retrofitted gas station can receive from non-dispatchable technologies (wind and solar) to a 40% of the total it receives (9), in order to at least simulate part of the availability problems that non-dispatchable technologies present.

$$\sum_{p \in (P^{WO} \cup P^{S})} e^{RF}_{p,s} \leq 0.40 \cdot \sum_{p \in P} e^{RF}_{p,s} \quad \forall s \in S \tag{9}$$

If a fuel station is not retrofitted, it cannot be used to fuel electric vehicles (10)

$$e^{RF}_{p,s} \leq \bar{E}_p \cdot y_s \quad \forall s \in S, p \in P \tag{10}$$

You cannot produce more electricity in a power plant than its maximum capacity (11)

$$e^{TP}_p \leq \bar{E}_p \quad \forall p \in P \tag{11}$$

A lower bound of 1 GWh is set to the electricity used to charge electric vehicles, so to ensure that all retrofitted stations are used to charge electric vehicles (12).

$$e^{SEC}_s \geq y_s \quad \forall s \in S \tag{12}$$

### Demand constraints

The demand of electricity of the country must be fulfilled notwithstanding the introduction of electric vehicles (13).

$$\sum_{p \in P} e^{DE}_p = B^E \tag{13}$$

To fulfill the transportation demand, we must specify how electricity is converted through kilometers in electric vehicles, using (14).

$$d^{EC}_r = e^{EC}_r / E^{EC} \quad \forall r \in R \tag{14}$$

The transportation demand is fulfilled through electric and non-electric vehicles (15).

$$B^D_r = d^{NC}_r + d^{EC}_r \quad \forall r \in R \tag{15}$$

### Domain of the variables

All continuous variables, except for $obj^{eco}, obj^{env}$, are positive real variables ($\mathbb{R}^+$). The objective function variables are real variables ($\mathbb{R}$). Variables $w$ and $y_s$ are binary variables ($\{0,1\}$).

## Data gathering and assumptions

For the geographical coordinates, enumeration, and label of the existent fuel stations in Spain, we use the API offered by the Spanish Ministry of Industry and Tourism[4], through GET requests. A total of 11,733 fuel stations were found in the original dataset. Due to the set-covering problem being NP-hard, we reduced the size of the dataset by filtering out the fuel-stations that do not belong to major companies in Spain in order to reduce the solving time. The reduced dataset contains 5,866 fuel stations.

We obtain the geographical coordinates, primary fuel, and capacities of the power plants from the World Resources Institute [5]. We assume 8,000 h of possible production of electricity per year for the power plants. We model intermittency through the assumption that only 40% of the electricity used in electric vehicles can come from non-dispatchable technologies (9).

To calculate the distance among the different fuel stations, as well as between power plants and fuel stations, we use Haversine equation. While this distance is the shortest distance between two points in the Earth, and due to that is not really the distance that vehicles would have to traverse between two fuel stations, we balance that through the fact that for the set-covering, a small limit of 20 km is set for two fuel-stations to be able to fulfill the constraint. Considering that electric vehicles have an autonomy of >200 km, we consider that this proximity between retrofitted fuel stations would be enough to ensure availability.

The cost parameters for the electricity are sourced from a work by the European Commission [6], and the amount of kilometers traveled in the country per autonomous region has been calculated from a Spanish

**Figure 1**. Map showing the location of the possible gas stations to retrofit, as well as the power plants available to produce the electricity required in them. The legend indicates the types of power plant and gas stations. The number between parenthesis indicates the number of plants/gas stations that are considered in the study.

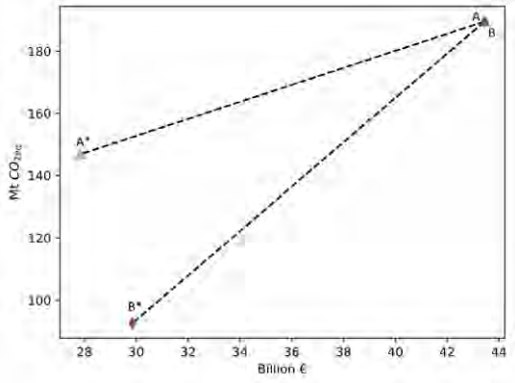

**Figure 2**. Results of the four optimization problems run. A and A* refer to the optimization of the economic objective without and with retrofitting, respectively. B and B* refer to the optimization of the environmental objective without and with retrofitting, respectively.

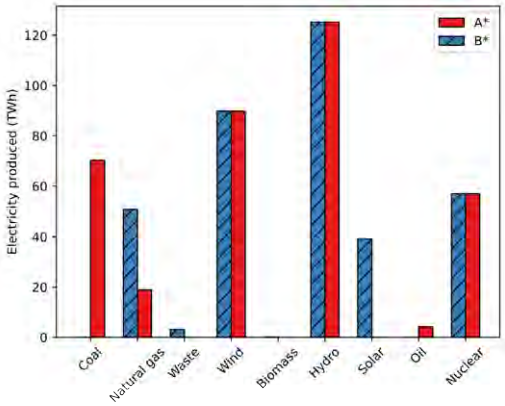

**Figure 3**. Electricity mix obtained for the economic optimum scenario (A*) and the environmental optimum scenario (B*).

newsletter [7], considering an average consumption of six liters of gasoline per 100 km traveled. The price of fuel for standard cars is considered as 0.771 €/l, without counting taxes. The cost of retrofitting a fuel station ($3,988,900) is sourced from the work of Feng and Khan [8], and does not consider on-site power storage. For the environmental impacts, we use the Ecoinvent database[9] 3.9.1 cutoff, using the IPCC2021 GWP method. For the case of electric cars, we take the GWP of the car subtracting the electricity needed to fuel it, since we are considering it in the model through equation (14).

In **Figure 1**, we show the location of each power plant and fuel station considered in this work.

## RESULTS AND DISCUSSION

We perform two optimizations per objective, for a total of four optimization runs. For each objective, we consider a scenario where we forbid retrofitting ($w \leq 0$) in order to obtain a comparison of how much the inclusion of electric vehicles modifies the results. The scenarios considered are therefore A and A*, where we optimize the economic objective without and with retrofitting, and B and B*, where we optimize the environmental objective without and with retrofitting. The results obtained are shown in Error! Reference source not found..

As shown in the figure, when we do not allow retrofitting in the model, both solutions (points A and B) are very close, changing only a bit the optimal electric mix obtained. However, when we allow retrofitting (points A* and B*), and thus, electric vehicles, both solutions immediately get better in both objectives. Compared to their base cases, A* improves 36% its economic objective and 22% its environmental objective, while B* improves 31%

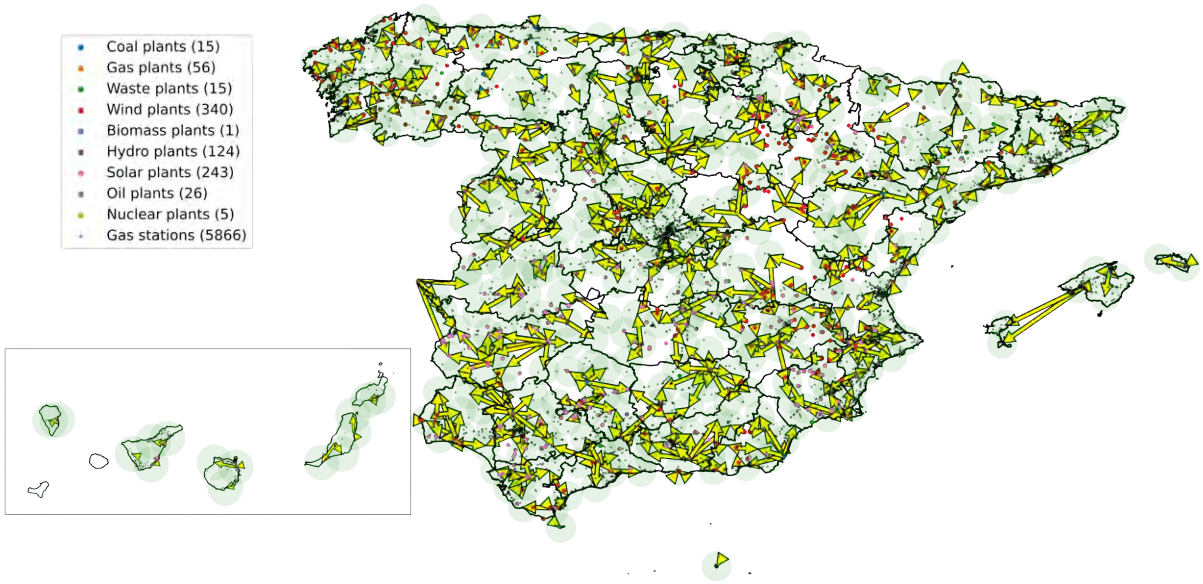

**Figure 4**. Economic optimum result (A*). Green circles indicate service area of each retrofitted station. Yellow arrows indicate from which power plant is electricity generated for each retrofitted fuel station.

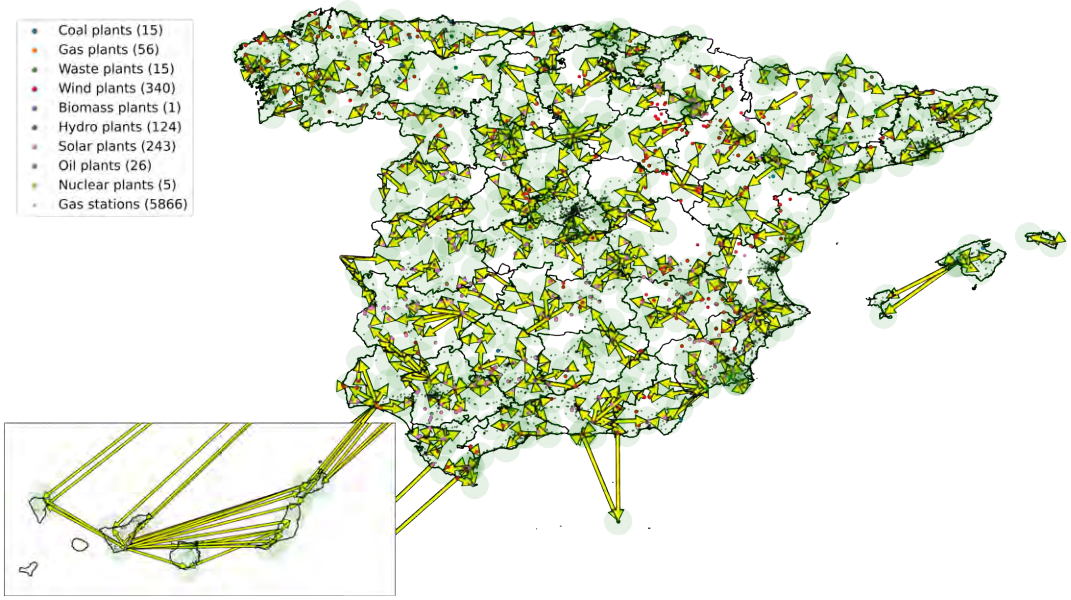

**Figure 5**. Environmental optimum result (B*). service area of each retrofitted station. Yellow arrows indicate from which power plant is electricity generated for each retrofitted fuel station.

its economic objective and 51% its environmental objective.

Notably, in both A* and B*, the model chooses to electrify the vehicle fleet completely, since that alternative is cheaper and more environmentally friendly than standard combustion vehicles, even with the cost of retrofitting the fuel stations needed.

Focusing on the scenarios where we allow retrofitting of fuel stations, the electric mix optimized to account for both the electricity demand of the country and the demand from the electric vehicles is shown in **Figure 3**.

While the electricity mixes are very similar, focusing on renewable energy available in the country with a low levelized cost of electricity, there certain differences between the environmental and economic optimums. While the economic optimum employs oil and coal, which are economic but contaminant, the environmental optimum uses solar and waste, as well as raising the use of natural gas, which while being a fossil fuel, has a lower GWP than that of coal and oil.

In **Figure 4** and **Figure 5** the supply chain results of the economic (A*) and environmental (B*) optima are

shown. It is important to mention that, in the model, certain electricity transport options which are currently not possible were not limited. For example, in the environmental optimum, there is transport from the mainland to the Canary Islands, which is not currently possible. However, it is noteworthy that even with losses that are proportional to the distance that electricity is transported, the model chooses to generate electricity in the peninsula and transport it to the islands. The number of retrofitted stations also varies between the solutions. For the economic optimum, 412 fuel stations are retrofitted, to fulfill the set-covering constraint. However, in the environmental optimum, this number rises to 477.

It is important to note that, due to data not being available, there was no upper limit to the number of cars that any fuel station can serve in a year. For a more precise model, an upper bound would need to be set to each fuel station that limits the amount of service that it can provide per year.

## CONCLUSIONS AND LIMITATIONS

The model shows that it is possible to reduce both the economic and environmental objective through an implementation of retrofitted fuel stations and electric vehicles. Specifically, the cost and GWP are reduced from 43.44 billion € and 189.55 million tonnes of CO2eq. to 27.83 billion € and 146.80 million tonnes of CO2eq. when minimizing the cost (scenarios A and A*), and from 43.44 billion € and 189.55 million tonnes of CO2eq. to 29.85 billion € and 92.57 million tonnes of CO2eq. when minimizing the cost (scenarios B and B*).

However, the results of this study must be taken as an ideal case due to the assumptions followed during its modeling. Namely, the consideration of steady state indicates that although Spain has enough electricity production capacity to satisfy a full electric fleet, electricity demand and production dynamics are not considered, hence assuming that the country has the instantaneous capacity required to provide electric energy at a given point in time.

In summary, future work will focus on the dynamic aspect of the model, including generation profiles of the different electricity technologies, as well as realistic upper limits for the service that each fuel station can provide at a given time.

## ABSTRACT

A comprehensive model has been developed to design heat exchanger networks integrated with organic Rankine cycles (ORCs) and heat pumps, aiming to optimize energy efficiency. The model focuses on two key objectives: first, using heat pumps to reduce dependency on external services by enhancing heat recovery within the system; second, utilizing ORCs to recover residual heat or generate additional energy. To achieve optimal performance, the model requires careful selection of fluids for both ORCs and heat pumps, and the determination of optimal operating temperatures for maximum efficiency. The heat exchanger network is designed to be flexible, with non-fixed inlet and outlet temperatures, while simultaneously optimizing the number and operating conditions of ORCs and heat pumps. This approach reduces costs related to external services, electricity, and equipment such as compressors and turbines. Ultimately, the model facilitates the design of a heat exchanger network that efficiently utilizes residual heat and integrates other energy streams, thus improving both operational efficiency and sustainability. It demonstrates the potential for incorporating ORCs into systems that manage various energy streams, extending beyond just residual heat.

**Keywords**: Electrification Strategies, Green Heat Integration, Low-Carbon Technology, Eco-Friendly Heat Recovery.

## INTRODUCTION

In recent years, the optimization of heat recovery networks has become a key focus in efforts to improve energy efficiency and reduce environmental impact in industrial systems. The integration of Organic Rankine Cycles (ORCs) and heat pumps into these networks offers a promising solution by recovering waste heat and converting it into usable energy, thereby reducing the reliance on external energy sources. However, the successful implementation of this approach depends on the careful selection of system components, including fluids for the ORCs and heat pumps, as well as the determination of optimal operating conditions. In this study, we explore several case studies that illustrate the potential of these technologies in different industrial settings, highlighting their impact on cost reduction, energy efficiency, and sustainability.

## CASE OF STUDY

### 1. Integration of Heat Recovery and Heat Pumps

A base case study was analyzed to illustrate the effectiveness of the proposed methodology. The process system included a hot stream (H1) and a cold stream (C1) with defined inlet and outlet temperatures (Table 1). This system has been previously studied by Holiastos & Manousiouthakis [1] to consider the introduction of heat pumps and heat engines. We assume that there are contracts with a utility plant that provided vapor in different conditions and prices as shown in Table 2. Prices are calculated using the approach proposed by Turton et al. [2] using gas natural prices from Eurostat [3].

**Table 1.** Process Streams Data

| Name | Tin [°C] | Tout [°C] | Fcp [MW/°C] |
|---|---|---|---|
| H1 | 106 | 176 | 0.52 |
| C1 | 146 | 76 | 0.32 |

**Table 2.** Utilities Streams Data

| Name | Tin [°C] | Tout [°C] | Cost [k$/MW·y] |
|---|---|---|---|
| LP Steam | 150 | 149 | 666,43 |
| MP Steam | 200 | 199 | 700,42 |
| HP Steam | 250 | 249 | 831,42 |
| Cooling Water | 20 | 25 | 23,5 |

## 2. Initial Results

In the base case, the total utility cost was calculated at **18,797.4 k$/y** without additional optimization. MP Steam was the primary utility with a consumption of 18.72 MW, followed by LP Steam at 8.08 MW and cooling water at 12.80 MW (Figure 1)

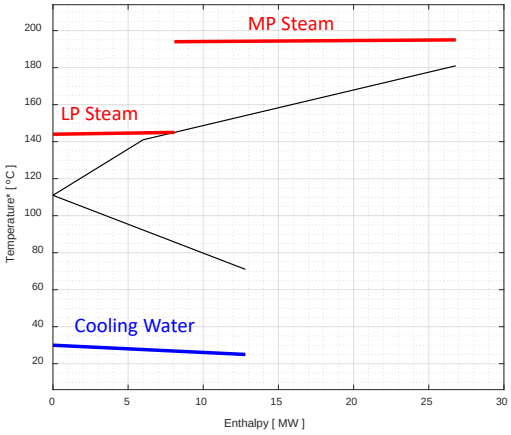

**Figure 1.** Analysis of Utilities on the Grand Composite Curve

## 3. Optimization with Re-Flashing:

The first optimization step involved re-flashing MP Steam (200 °C) into LP Steam (150 °C) (Figure 2). By recovering 2.246 MW of LP Steam, the utility cost was reduced by **1,496.8 k$/y**, representing a **7.96%** cost reduction. (Figure 3)

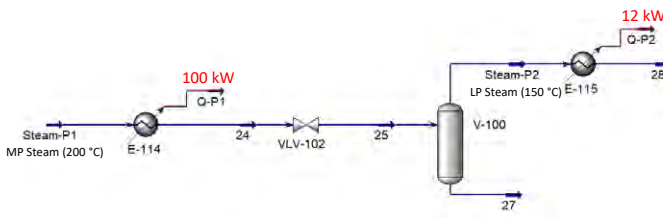

**Figure 2.** Re-flashing diagram in Aspen HYSYS.

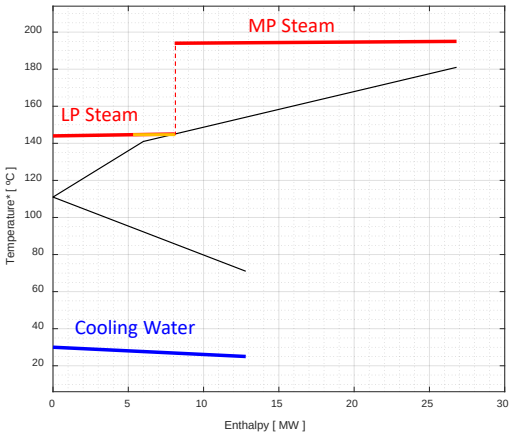

**Figure 3.** Analysis of Utilities on the Grand Composite Curve after re-flashing the MP Steam to LP Steam.

## 4. Optimization with Heat Pump:

A heat pump was introduced to enhance energy efficiency further to reduce the remaining LP Steam consumption (from 8.08 MW to 2.25 MW). The heat pump, operating between a hot stream at ~150 °C and a cold stream at ~90 °C, optimized using GAMS, required 1.259 MW of electrical work and contributed to recovering 5.83 MW of heat. This configuration reduced the total utility cost to **14,813.2 k$/y**, reducing additional costs while maintaining process requirements, representing a **21.02%** cost reduction. (Figure 4 and 5).

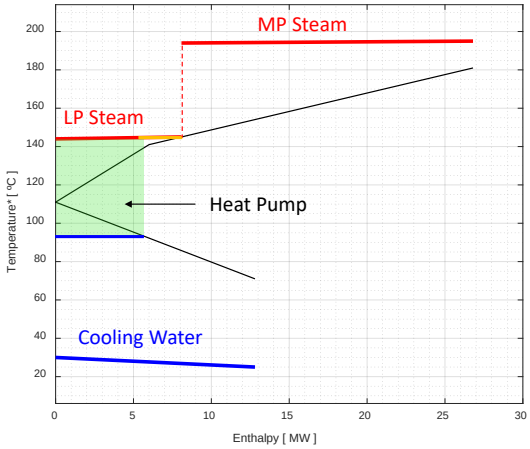

**Figure 4.** Analysis of Utilities on the Grand Composite Curve after re-flashing the MP Steam to LP Steam (the green section qualitatively illustrates how to add a heat pump)

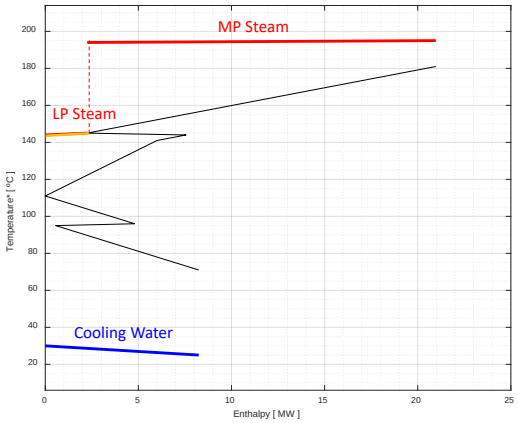

**Figure 5.** Analysis of Utilities on the Grand Composite Curve after adding the first heat pump.

For optimization in GAMS, the Pinch Location Methodology [4,5] was employed, enabling the calculation of utility costs for streams with variable temperature and/or flow rates. The heat loads associated with heat pumps or heat engines were correlated using second-order polynomials, with correlation coefficients exceeding 0.995 in all cases. The problem was solved to global optimality

This example demonstrates the proposed methodology's capability to integrate heat pumps and re-flashing processes, significantly improving heat recovery, reducing energy costs, and promoting system sustainability.

## 5. Integration of an ORC

Before incorporating the second heat pump, a simulation was performed to explore the integration of an Organic Rankine Cycle (ORC) below the pinch point. Under these conditions, the simulation indicates that approximately **0.70 MW** can be recovered using benzene as the working fluid.

While this amount of energy recovery is relatively small and does not appear to offer significant economic benefits, an interesting opportunity exists to enhance the ORC's performance. By extending the heat pump's operating range to higher values, the ORC can utilize the hot water generated by the utility system. This, however, comes at the expense of requiring additional cooling water.

For instance, by specifying an ORC capable of expanding to around **14 MW**, we obtain the configuration of Figure 6.

This example highlights the potential for combining heat pumps and ORCs to maximize energy recovery. Such an approach optimizes the utilization of thermal resources within the system, showcasing the flexibility and benefits of integrating ORCs in conjunction with other thermal management strategies.

Using the available data, it is possible to calculate the amount of hot water (in MW) generated from the saturated liquid after utilizing both MP and LP steam (Figure 7)

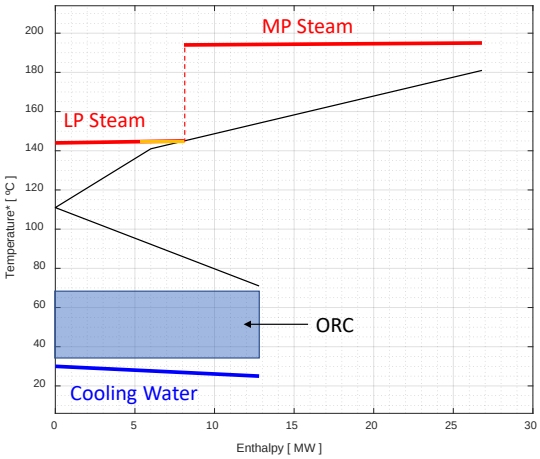

**Figure 6.** Analysis of Utilities on the Grand Composite Curve (the blue section qualitatively illustrates how to add an ORC)

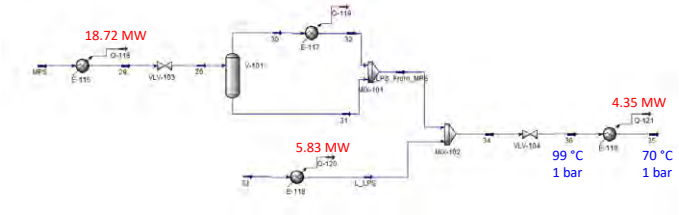

**Figure 7.** Simulation of the amount of hot water (in MW) generated from the saturated liquid in Aspen HYSYS.

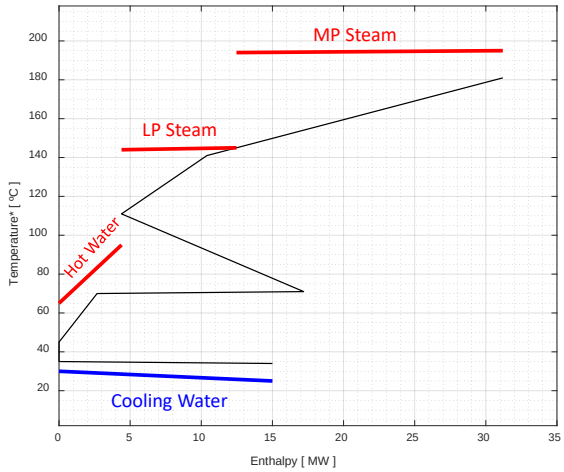

**Figure 8.** Analysis of Utilities on the Grand Composite Curve after adding an ORC.

As illustrated in the schematic, the system can recover 4.35 MW of hot water at 99°C (1 bar) and reduce it to 70°C (1 bar). However, with the extended ORC design, the recovery is limited to **approximately 0.85 MW**, which

is relatively low.

This configuration reduced the total utility cost to **17,840.4 k$/y**, reducing additional costs while maintaining process requirements, representing a **5.09%** cost reduction. (Figure 8)

## 6. Integration of an ORC after the heat pump.

This study evaluates the feasibility of implementing an Organic Rankine Cycle (ORC) operating between temperatures of approximately 65 °C and 40 °C. (Figure 9) Tests conducted with benzene as the working fluid have demonstrated feasibility within these temperature ranges. The system focuses on recovering approximately **8 MW** from residual streams, optimizing the energy utilization of the process.

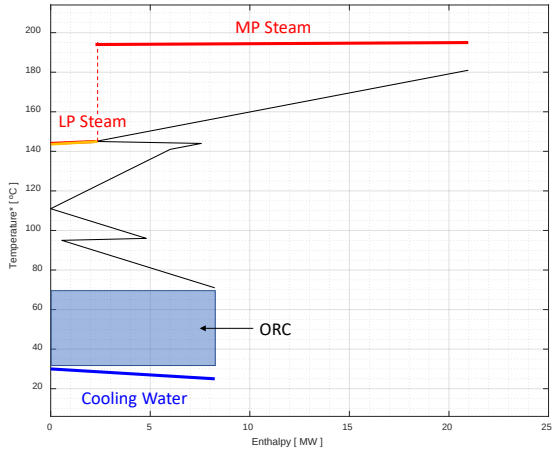

**Figure 9.** Analysis of Utilities on the Grand Composite Curve after adding the first heat pump (the blue section qualitatively illustrates how to add an ORC)

Additionally, it has been identified that by expanding liquid water from the condensation of low-pressure (LPS) and medium-pressure steam (MPS) to atmospheric conditions, up to **2.75 MW** of hot water can be generated. This recovered heat can be utilized as an additional thermal utility. (Figure 10)

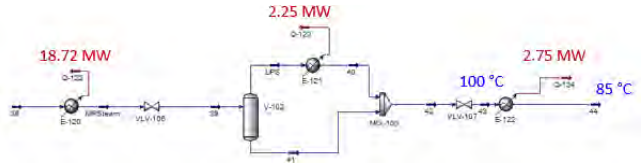

**Figure 10.** Simulation of the amount of hot water (in MW) generated from the saturated liquid in Aspen HYSYS.

Based on these findings, the implementation of an ORC with 10.3 MW thermal power in the condenser is proposed. Although this increases cooling water consumption, it generates **0.58 MW** of electricity (Figure 11). This approach represents a technically and economically attractive solution to maximize energy utilization in industrial processes through the integration of recovery and energy conversion technologies.

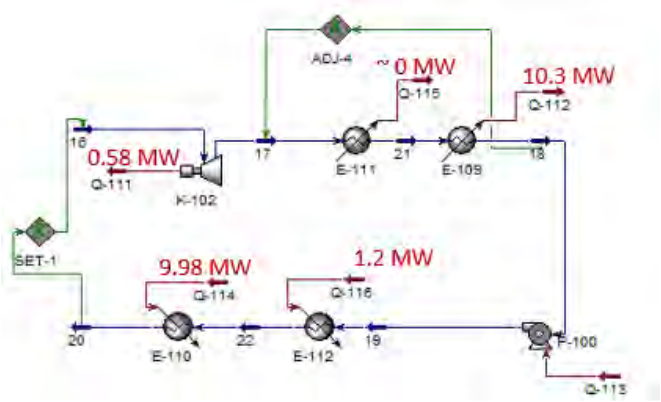

**Figure 11.** Simulation of the ORC in Aspen HYSYS.

By implementing this configuration, the total utility cost was reduced to **14,168.7 k$/y**, representing a **24.60%** decrease in costs while ensuring compliance with process requirements and limiting additional expenditures (Figure 12)

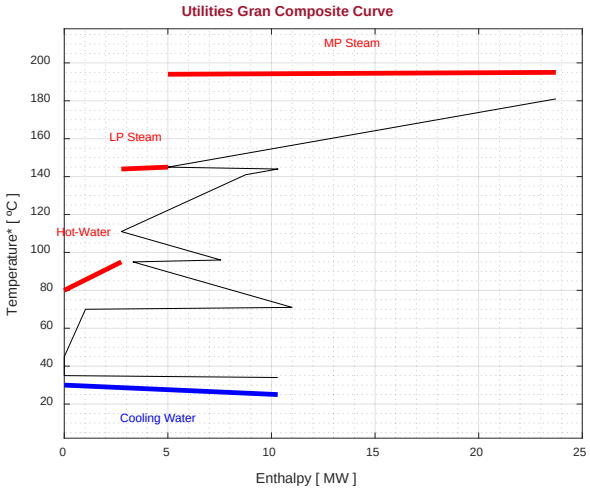

**Figure 12.** Analysis of Utilities on the Grand Composite Curve after adding a heat pump and ORC.

## CONCLUSION

In conclusion, the integration of Organic Rankine Cycles (ORCs) and heat pumps into heat exchanger networks presents a promising approach for improving energy efficiency and reducing operational costs. The optimization of both the internal and external energy flows within a system can significantly lower the reliance on external energy services, minimizing the overall energy consumption and reducing carbon emissions. This method shows great potential for industrial applications,

especially when considering the wide range of energy streams that can be recovered, such as residual heat, and used to generate power or preheat fluids.

However, there are practical limitations in applying this approach in real-world industry, particularly when it comes to selecting the right operating conditions for ORCs and heat pumps, as well as ensuring that the integration with existing systems is efficient. The modeling complexity can also increase as the number of variables grows, making it crucial to optimize not just the design but the operation of these systems in real-time.

Heat recovery, such as from steam, has a significant impact on the energy requirements of a utility system in an industrial plant. When a heat recovery strategy is implemented, the plant's energy system is affected as the amount of energy supplied externally to meet thermal demands is reduced. Specifically, heat recovery from steam can reduce the need for additional heat provided by conventional energy sources like natural gas or coal, which decreases the demand for fossil fuels and reduces the system's carbon footprint. However, this type of recovery can also affect the amount of energy the utility system must provide to maintain thermal balance in other areas of the process. For example, if recovered heat is used to preheat feed fluids to a distillation column or heat exchanger, the plant's heating system will require less energy to generate the necessary heat, but the pumping or generation systems may need to be adjusted to handle flow or pressure variations.

Therefore, it is essential to model the impact of heat recovery on the overall energy requirements of the utility system. It should be evaluated how this recovery influences the energy consumption of pumps, generators, or cooling units, and how different energy flows within the system are balanced to optimize consumption and minimize operating costs.

## ABSTRACT

Climate change, driven by increasing $CO_2$ emissions, necessitates innovative mitigation strategies, particularly for hard-to-abate industries. Carbon Capture and Utilization technologies offer promising solutions by capturing $CO_2$ from industrial flue gases and converting it into value-added products. Among capture methods, membrane separation stands out for its compact design, energy efficiency, and scalability. Following capture, $CO_2$ can be converted into chemicals like formic acid using electrocatalytic processes, enabling energy storage from renewable sources. This study proposes the design of an industrial demonstrator for a $CO_2$ recycling plant targeting hard-to-abate sectors such as textile and cement industries. The system integrates polymeric membranes for $CO_2$ capture and a 100 $cm^2$ electrochemical reactor for $CO_2$ electroreduction into formic acid. Experimental data from both stages are used to develop predictive models based on artificial neural networks (ANN), optimizing system performance. Case studies reveal that $CO_2$ concentration at the capture inlet significantly impacts plant design. For a textile plant with 3.5% $CO_2$ emissions, a four-stage membrane system is required, resulting in higher CAPEX and OPEX. Conversely, a cement plant with 12% $CO_2$ emissions requires only two stages to achieve the target $CO_2$ concentration of >75 %, reducing costs by over 60%. Sensitivity analysis highlights the critical role of inlet $CO_2$ concentration on the membrane area and system stages. The findings underscore the feasibility of modular membrane systems tailored to emission characteristics, paving the way for sustainable $CO_2$ recycling processes adaptable to various industries. This integrated approach offers a pathway to mitigate emissions while generating valuable chemical products.

## INTRODUCTION

Climate change has emerged as one of the most important challenges that society faces nowadays. Increasing anthropogenic $CO_2$ emissions is one of the main causes driving this phenomenon. In this sense, several strategies have been proposed to mitigate $CO_2$ emissions. Some of these are related to the use of renewable energy sources or improving energy efficiency. However, some industries inherently produce $CO_2$ as a by-product of their production processes, making conventional approaches insufficient to eliminate emissions. In such cases, alternative strategies must be explored, including Carbon Capture and Utilization (CCU) technologies [1].

Two stages are involved in this decarbonization approach. First, $CO_2$ is captured from industrial gas effluent. In the second stage, it is converted into value-added chemicals. To achieve efficient separation of $CO_2$ from industrial flue gas streams and prevent its release into the atmosphere, various capture technologies have been developed. These include absorption, adsorption, membrane capture, and cryogenic separation [2,3].

Among these technologies, membrane separation has garnered significant attention due to its compact

design, energy efficiency, simplicity, and ability to overcome selectivity limitations [4]. Additionally, the modularity of membrane systems enhances their scalability, making them a promising solution for industrial $CO_2$ capture. Polymeric membranes are particularly well-suited for separating $CO_2$ from other compounds in post-combustion streams, which typically contain $CO_2$, $N_2$, $O_2$, and traces of CO or NOx [5].

Once captured, $CO_2$ is directed to the conversion stage. In this context, the electroreduction of $CO_2$ ($ERCO_2$) into value-added products has emerged as one of the most promising $CO_2$ conversion processes, offering significant economic and environmental benefits [6]. This technology converts $CO_2$ into various chemical products, such as formic acid, methanol, and ethylene, via an electrocatalytic process that supplies an external voltage to generate electron flux between two electrodes. Furthermore, it enables the storage of energy from renewable sources in the form of chemical bonds [7].

Integrating these two stages presents a significant challenge for the industrial implementation of $CO_2$ recycling plants, where $CO_2$ is first captured and subsequently converted [1]. To address it, this work proposes the design of an industrial demonstrator for a $CO_2$ recycling plant. This system employs polysulfone membranes for $CO_2$ capture, followed by conversion into formic acid through $ERCO_2$ targeting the decarbonization of hard-to-abate industries such as textile or cement.

The study focuses on empirically modeling both the $CO_2$ capture and electroreduction systems using neural networks, resulting in an integrated predictive model for the entire $CO_2$ recycling process. This model aims to optimize the performance of the capture-conversion system, thereby paving the way for developing a sustainable process for $CO_2$ capture and its conversion into formic acid. Furthermore, the model is designed to adapt to the specific conditions and needs of different industries.

# METHODOLOGY

## Experimental set-up

Two experimental setups are used to provide the data required for constructing the empirical model for each stage. For $CO_2$ capture, hollow fiber membrane modules (Airrane, MCH-1006A) with an active area of 1822 $cm^{-2}$, 2000 fibers, and 110 µm thickness are utilized. The concentrated $CO_2$ is collected in the permeate, which is released at ambient pressure. Various operational variables are evaluated to determine the separation performance; i) pressure applied, ii) $CO_2$ inlet flow rate, and iii) $CO_2$ inlet concentration. Capture experiments are carried out at least twice using synthetic and real gas mixtures from two industrial sources (textile and cement). These flue gas sources differ in $CO_2$ concentration, reflecting the variability in industrial emissions.

For the conversion stage, a 5 $cm^2$ commercial lab-scale three-compartment electrochemical reactor (Dioxide Materials and Membranes International, Inc), consisting of a $Bi_2O_3$ cathode, an $IrO_2$ anode, with a central compartment formed by ion exchange resins (Amberlite), a CEM (Nafion) and an AEM (Sustainion). The reactor is fed with deionized water to the anode and central compartment, while humified $CO_2$ is supplied to the cathode. This is utilized to investigate the effects of key process variables. A factorial experimental design is implemented to analyze three operational parameters: (i) $CO_2$ inlet flow rate, (ii) humidity of the $CO_2$ feed, and (iii) applied current density, identified as critical variables [8]. Additional factors, such as the water flow rate into the central compartment and the anolyte inlet flow rate, are evaluated based on information from the literature [9]. To ensure robust input data for the model, all experimental tests are performed at least in duplicate.

## Model deployment

Two independent neural-network-based empirical models are developed using Neural Designer [10] (Artificial Intelligence Techniques, Ltd.). These models generate numerical expressions based on the input data collected during experimental work with the membrane modules and the commercial reactor. The input variables and their corresponding ranges are detailed in Table 1:

**Table 1:** Variables and value ranges for input variables in the Artificial Neural Network (ANN) models.

| Model | Variable | Range |
|---|---|---|
| Capture | Pressure (bar) | 3-6 |
| Capture | Inlet flowrate (ml $min^{-1}$ $cm^{-2}$) | 0.17-0.55 |
| Capture | $CO_2$ inlet concentration (%) | 0.5-35 |
| $ERCO_2$ | Central water flow rate (ml $min^{-1}$) | 0.12-0.17 |
| $ERCO_2$ | Current density (mA $cm^{-2}$) | 45-200 |
| $ERCO_2$ | Cathode water feed (g $h^{-1}$) | 0.5-3 |
| $ERCO_2$ | $CO_2$ flowrate (ml $min^{-1}$) | 1500-2000 |
| $ERCO_2$ | $CO_2$ concentration (%) | 75-100 |

## Case study

An optimization problem is proposed for the functioning of an industrial demonstrator plant, where the electrochemical reactor serves as the central element. In this case, the $CO_2$ capture process must be optimized to supply $CO_2$ under specific conditions to the 100 $cm^2$ electrochemical reactor. The critical variables of the reactor must also be optimized to maximize formic acid

production. The overall cost is established as the objective function to minimize, considering both the CAPEX and OPEX of the recycling plant.

$$OF = CAPEX + OPEX \quad (1)$$

$$CAPEX = (AreaR \cdot Rc + AreaM \cdot Mc)/5 \quad (2)$$

$$OPEX = Ecost + Ccost - FA \cdot FAp \quad (3)$$

In these equations, AreaR represents the reactor's geometric area ($m^2$), and AreaM refers to the total membrane area required for $CO_2$ capture ($m^2$). The respective costs, Rc (Reactor cost, 27,000 € $m^{-2}$) and Mc (Membrane cost, 5,500 € $m^{-2}$), are based on previous acquisition costs per square meter. Ecost and Ccost represent the energy cost from the conversion stage and the compression cost required in each separation stage, respectively. FA denotes the amount of formic acid produced, and FAp is its market price (4,100 € $t^{-1}$).

The CAPEX evaluates the cost of constructing the $CO_2$ recycling plant, taking into account both the membrane area required for $CO_2$ capture and the fixed cost of the 100 $cm^2$ reactor, annualized over 5 years. On the other hand, the OPEX includes the electricity cost (based on Spanish electricity prices) for the $ERCO_2$ process, the compression cost for the capture stage, and the savings associated with the formic acid produced, which can either be sold or used in industry.

The optimization problem is subject to constraints related to product quality, model, or process input requirements (as shown in Table 2). This leads to a constrained non-linear optimization minimization problem (MINLP), which is addressed using the General Algebraic Modeling System (GAMS, GAMS Development Corporation, Washington, DC, USA). A reduced gradient algorithm is employed to solve the MINLP, with the CONOPT solver used to obtain the optimal solution.

**Table 2:** Constrained variables of the case study optimization problem

| Constrain | Variable | Range |
|---|---|---|
| Model Capture | Pressure | 3-6 |
| Model $ERCO_2$ | Central water flow rate (ml $min^{-1}$) | 0.13-0.34 |
| Model $ERCO_2$ | Current density | 45-200 |
| Input $ERCO_2$ | $CO_2$ inlet concentration (%) | 75-100 |
| Input $ERCO_2$ | $CO_2$ flowrate (ml $min^{-1}$) | 1500-2000 |
| Product Quality | Formic acid concentration (g $L^{-1}$) | 80-130 |

Two industries are considered for the case studies: a textile plant, where the $CO_2$ content in the flue gas stream is 3.5 %, and a cement industry that emits 12 % of $CO_2$ in its post-combustion stream. Additionally, a sensitivity analysis regarding the $CO_2$ concentration in the inlet of the $CO_2$ capture is conducted to evaluate the economical viability of installing this $CO_2$ recycling plant in diverse industries with varying $CO_2$ emissions.

# RESULTS

## Model deployment

The $CO_2$ capture predictive model is developed using a machine learning approach, where experimental data is utilized to establish the architecture of the artificial neural network (ANN). As shown in Figure 2.a, the resulting ANN comprises several interconnected components: (i) a scaling layer to normalize input values, (ii) a perceptron layer that processes the inputs using a mathematical function derived from the experimental data, (iii) an un-scaling layer that restores the output values to their original dimensions, and (iv) a bounding layer that constrains the final output within the model's confidence intervals. The selection and optimization of neurons is performed through an iterative process designed to achieve the best possible alignment with the provided data, thereby constructing an accurate and efficient ANN. The neural network architecture comprises three neurons in the scaling layer, seven and two for the subsequent perceptron layers (with hyperbolic and linear activation functions), and two neurons in each un-scaling and bounding layer. As seen in Figures 1.c-d, the predictive model's adjustment for the two output variables achieves an $R^2$ value exceeding 0.99, demonstrating high accuracy.

The Gradient Boosting Variable Importance highlights the contribution of each input variable to the final output, effectively capturing the system's nonlinearities (Figure 2.b). For the permeate flow rate, the inlet pressure emerges as the most influential factor (0.544), followed by the inlet flow rate (0.332). In contrast, these variables have a negligible impact on the $CO_2$ outlet concentration, which is primarily determined by the inlet $CO_2$ concentration (0.964).

For the $CO_2$ conversion predictive model, a similar methodology is followed, as detailed in previous works [8]. Another input variable is introduced in this case: the inlet $CO_2$ concentration, which corresponds to the $CO_2$ concentration at the capture stage outlet. The target variable in this model is the formate concentration obtained. When analyzing the importance of each input variable with the Gradient Boosting Variable Importance, two input variables stand out as the most influential on the target variable, the current density and $CO_2$ inlet concentration.

The development of the ANN enables the creation of an empirical mathematical model that establishes the relationship between input and output variables. The

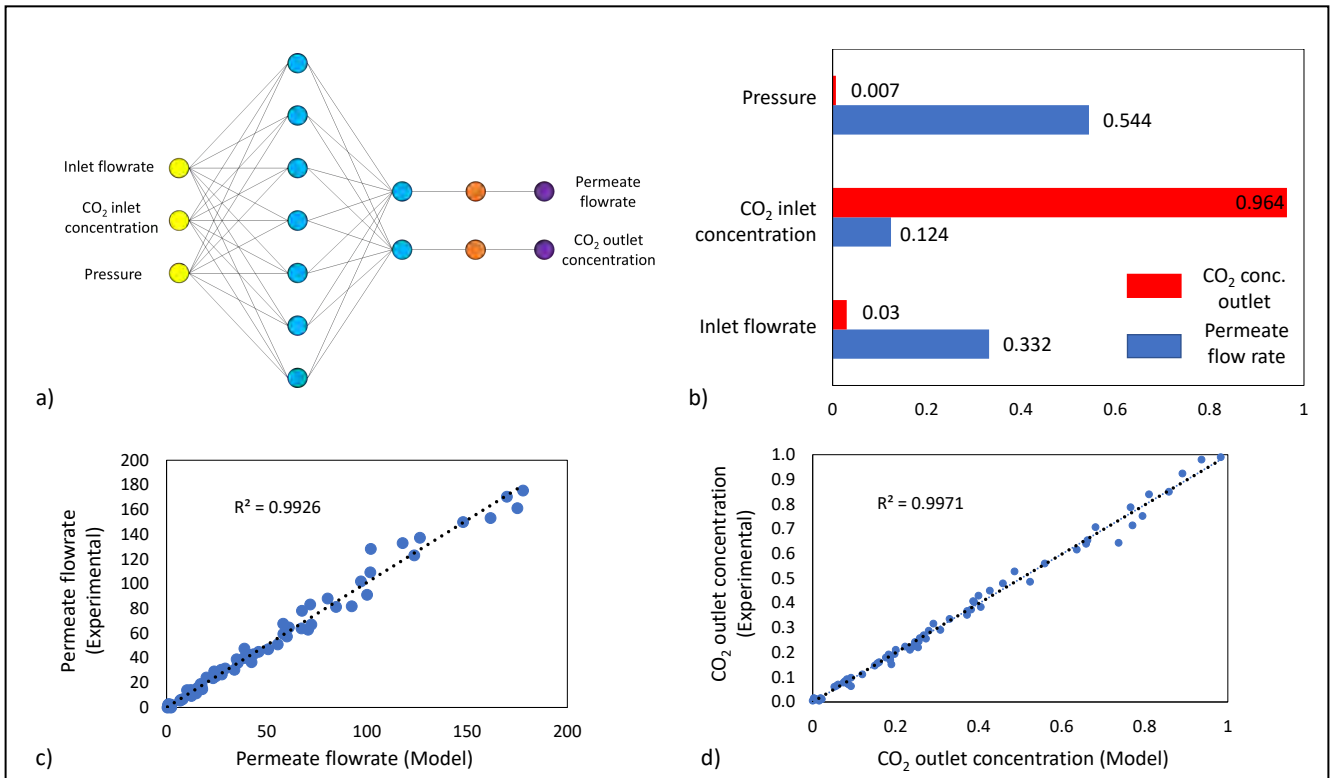

**Figure 1: a)** ANN architecture for the $CO_2$ capture predictive model using membranes, **b)** Gradient Boosting variable importance coefficient chart of the input variables regarding the two target variables of the model, **c)** Model adjustment to experimental data for the permeate flow rate, and **d)** Model adjustment to experimental data for the $CO_2$ outlet concentration.

mathematical expressions defining the ANN's architecture are manually derived and integrated as model equations within the optimization problem described below.

## Case Study

The optimization problem focuses on designing an industrial demonstrator for decarbonizing hard-to-abate industries. The system consists of two stages: $CO_2$ capture using polymeric membranes and $CO_2$ conversion to formic acid via $ERCO_2$. The design is centered around the $ERCO_2$ reactor, which has an active area of 100 $cm^2$.

Two different scenarios are proposed for implementing the system: the case of the textile industry, the $CO_2$ concentration is 3.5 %, while for the cement industry, it rises to 12 %. This variation directly impacts the overall design of the $CO_2$ recycling plant, although both scenarios target the same product quality.

For the textile industry case, the optimal design for the capture stage involves four different membrane stages to achieve the required 75 % $CO_2$ concentration at the inlet of the $ERCO_2$ [11]. Four membrane separation stages are arranged in series, using the polymeric membrane modules employed in the experimental testing, as shown in Figure 2. The total membrane area is 27.7 $m^2$, operating at 3 bar pressure. The membranes feed the $ERCO_2$ with 1569 ml $min^{-1}$ of gas at a $CO_2$ concentration of 90.9 %. The $ERCO_2$ reactor operates at 200 mA $cm^{-2}$, producing 137.2 g $L^{-1}$ of formic acid. The system CAPEX is estimated at 30,524 € $y^{-1}$, with the membrane cost being the biggest contributor. On the other hand, the compression cost, primarily associated with the $CO_2$ capture stage is the main contributor to the OPEX. Ultimately, the total yearly cost for the recycling plant, representing the objective function, is calculated at 36440 € $y^{-1}$.

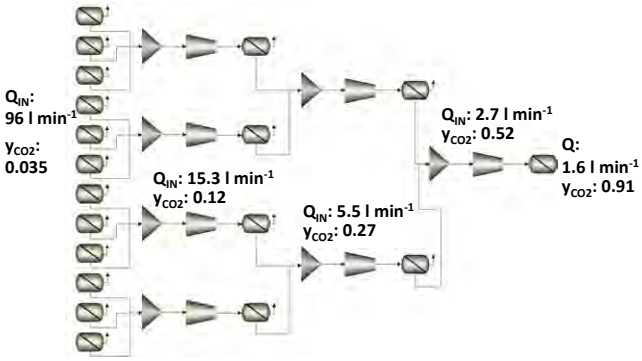

**Figure 2:** Schematic diagram for the capture stage of the $CO_2$ recycling plant for the textile industry case study.

As observed in the model evaluation, the $CO_2$ concentration in the flue gas at the capture inlet is one of the most impactful variables in achieving the desired $CO_2$

concentration at the outlet. In this sense, the next case study evaluates the cement industry, where the initial $CO_2$ concentration is 12 %. The optimal design for the $CO_2$ recycling plant in this case consists of 2 stages in series, as seen in Figure 3. The total membrane area is reduced compared to Case Study 1 to 8.2 $m^2$, and it achieves a $CO_2$ concentration of 95.9 % with a 1640 ml $min^{-1}$ flow rate. The $ERCO_2$ is operated at 200 mA $cm^{-2}$, resulting in a formic acid concentration of 130.27 g $L^{-1}$. The CAPEX is notably reduced to 9074 € $y^{-1}$, with the membrane cost is cut by 70 %. OPEX is also lower, as less gas volume is treated by the membrane modules, resulting in reduced compression costs. Overall, the total cost is 12,359 € $y^{-1}$, which is a 66 % reduction compared to the overall cost for the textile industry case, confirming the significant impact of the $CO_2$ inlet concentration on the overall $CO_2$ recycling plant design.

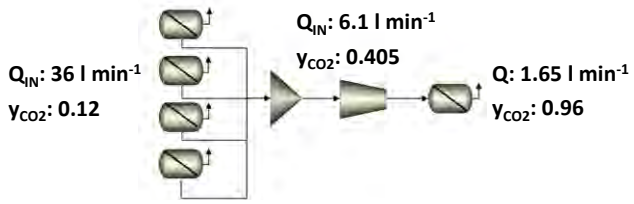

**Figure 3**: Schematic diagram for the capture stage of the $CO_2$ recycling plant for the cement industry.

One of the benefits of membrane separation for $CO_2$ capture is the system's modularity, which allows it to adapt to varying $CO_2$ concentrations at the capture in let. As observed in both case studies, the $CO_2$ concentration is a critical variable in the system's design to achieve the target $CO_2$ concentration before the $ERCO_2$. A sensitivity analysis is performed to determine the effect of this input variable in the membrane area required to achieve the target $CO_2$ concentration (>75 %). This analysis helps identify which emission sources are suitable for capture without oversizing the membrane system. It also serves as a preliminary estimate for evaluating other $CO_2$-emitting industries, such as biogas plants, thermal power plants, or large chemical plants.

A sensitivity analysis is carried out to evaluate the membrane area and the number of capture stages needed to achieve the target $CO_2$ concentration with different $CO_2$ concentrations at the inlet. As seen in Figure 4, as the inlet $CO_2$ concentration increases, the membrane area required decreases significantly. Notably, a small increase in concentration yields a substantial reduction in the membrane area when operating with highly diluted $CO_2$ streams. However, when the $CO_2$ stream is less diluted, increasing the concentration results in a smaller reduction in the total membrane area required.

The membrane area directly impacts the CAPEX of the system. Therefore, a higher $CO_2$ concentration in the inlet stream leads to lower capital investment for the $CO_2$ recycling plant. Additionally, the number of membrane stages decreases as the $CO_2$ concentration increases, affecting the OPEX, as fewer stages result in lower compression costs.

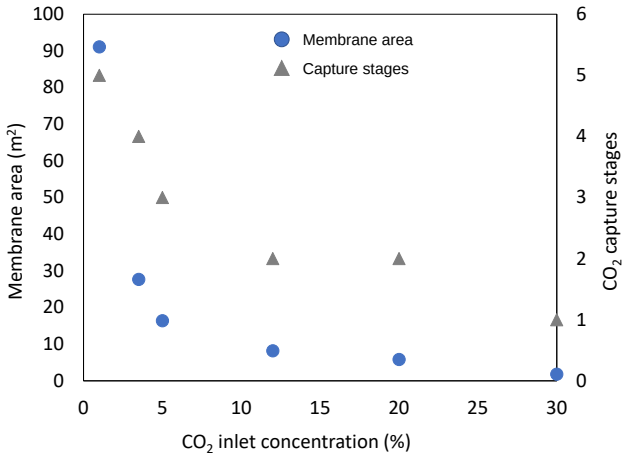

**Figure 4**: Sensitivity analysis results for evaluating the influence of the inlet $CO_2$ concentration on the membrane area and stages of the $CO_2$ capture system.

## CONCLUSIONS

The integration of $CO_2$ capture and conversion presents a viable solution for reducing emissions in hard-to-abate industries such as textiles and cement. This approach not only mitigates $CO_2$ emissions but also facilitates the conversion of captured $CO_2$ into value-added products like formic acid, offering economic and environmental benefits.

The $CO_2$ concentration of $_2$ in the inlet stream is a critical factor that significantly impacts the design and cost of the system. Higher $CO_2$ concentrations reduce the required membrane area and the number of capture stages, leading to lower capital (CAPEX) and operational (OPEX) expenditures. This underscores the importance of adapting the system design to the specific characteristics of each industrial emission source. The modularity of membrane systems makes them highly adaptable to varying $CO_2$ concentrations and emission profiles. Sensitivity analyses confirm that even small increases in inlet $CO_2$ concentration can drastically reduce the required membrane area, particularly in highly diluted streams. This adaptability makes the technology suitable for a wide range of industries, including biogas plants, thermal power plants, and chemical manufacturing facilities.

Overall, the proposed $CO_2$ recycling system offers a scalable and sustainable pathway for decarbonizing industrial processes. It demonstrates the potential to address climate change challenges while generating

economic value through the production of high-demand chemical products.

## ABSTRACT

To achieve long-term greenhouse gas neutrality in aviation, replacing fossil aviation fuels with Sustainable Aviation Fuels (SAF) from renewable sources is essential. A SAF production process from renewable hydrogen and carbon dioxide, was designed using Aveva Process Simulation, followed by comprehensive economical assessments. The designed process leads to an annual production of 37kt of SAF, with 97% of the molecules featuring a carbon chain length between 8 and 16. This output indicates a robust and targeted production capability. With an in-depth optimization of the methanol reactor, it was found that the profitability of the plant aligns with other SAF studies, demonstrating a Minimum Selling Price of Product of $2.46/kg after Heat Integration. In terms of economic profitability, the production of SAF using the methanol pathway appears to be an alternative to other SAF production pathways such as Fischer-Tropsch process but resides dependent on the evolution of $H_2$ production technologies, novel SAF production processes and environmental regulations. Despite this, the price remains higher than the current cost of fossil jet fuels, posing a competitive challenge.

**Keywords**: Alternative Fuels, Modelling and Simulations, Methanol, Technoeconomic Analysis

## INTRODUCTION

To limit global warming to 1.5°C, the Paris Agreement of 2015 established goals for reducing greenhouse gas emissions [1]. The transportation sector is a major contributor to emissions, and the aviation field is no exception, accounting for 2.5% of global emissions [2]. By 2025, SAF production will be predominant through the Hydrotreated Esters and Fatty Acids (HEFA) pathway, which will account for 99% of production (42.1 Mt). The HEFA process can reduce greenhouse gas emissions by up to 85% compared to fossil jet fuels, whereas Power-To-Liquid processes have the capability to achieve a 100% reduction [3]. One Power-To-Liquid pathway involves using renewable hydrogen and carbon dioxide to produce methanol, which can then be converted into SAF using the ExxonMobil process [4]. Although SAF production from $H_2$ and $CO_2$ is still under development, it is necessary to evaluate the economic potential of this process. This study explores the process design, optimization and economic viability of the production of SAF from $H_2$ and $CO_2$.

## MATERIAL AND METHODS

### Process Design

The production of SAF from $H_2$ and $CO_2$ consists of 4 main steps: methanol is first formed based on equation 1. Secondly it is turned into dimethyl ether and further to olefins through the Methanol-To-Olefins (MTO) process (equations 2 and 3). Olefins are then converted into longer olefins in the Mobil-Olefins-to-Gasoline-and-Distillate (MOGD) process (equation 4) and finally converted to paraffins through hydrogenation (equation 5).

$$CO_2 + 3\,H_2 \leftrightarrow CH_3OH + H_2O \quad (1)$$

$$2\,CH_3OH \leftrightarrow CH_3OCH_3 + H_2O \quad (2)$$

$$n\,CH_3OCH_3 \leftrightarrow 2\,(CH_2)_n + n\,H_2O \quad (3)$$

$$2\,(CH_2)_n \leftrightarrow C_{2n}H_{4n} \quad (4)$$

$$C_{2n}H_{4n} + H_2 \leftrightarrow C_{2n}H_{4n+2} \quad (5)$$

The process is modelled using the equation-based software Aveva Process Simulation 2024 (APS). The sizing of equipments is based on basic Chemical Engineering Principles and APS modelling assumptions. The process is designed with the following objectives: 37kt/year of kerosene with a purity of 91.3% of C8-C16 Hydrocarbons. The choice of quantity is based on the average value of kerosene from existing and future SAF production projects [5,6]. The purity is based on the percentage of non-desired products from the High Biofuel Blends in Aviation Final Report [7]. Additionally, Liquefied Petroleum Gas (LPG), gasoline and diesel are co-products of the process. Furthermore, Heat Integration (HI) was performed on the major hot and cold streams of the process with a heat duty higher than 200kJ/s.

## Sensitivity analysis

While the process of SAF production and its reactions are studied in the literature, the impact of key design parameters is often neglected, especially for the methanol formation reactor in a SAF production process. An in-depth sensitivity analysis was performed on the methanol reactor to optimize the conversion of reactants. Sensitivity analysis was performed on the temperature, pressure, and reactor design (diameter, length, number of tubes).

## Economical Assessment

The economical assessment was performed on the process for different scenarios. A Matlab script of a Discouted Cash Flow Rate (DCFR) model for Monte-Carlo simulations is used based on 7 input parameters: price of reactants ($H_2$ and $CO_2$), price of Kerosene Fixed Capital Cost (FCI), Working Capital (WC), Operational Cost (OPEX) and Income Tax Rate. The plant is located in Denmark with a lifetime of 20 years.

## Input parameters

### Fixed Capital Investment

The Fixed Capital Investment (FCI) includes the purchase of equipments and their installation. The price of a single piece of equipment is taken from APS 2024 and based on the Chemical Engineering Plant Cost Index (CEPCI) of 2022 (816.0) [8]. This library uses a factorial method considering the Lang factors for the cost of purchase and installation of equipments. The fixed capital cost is calculated using the following formula:

$$C_f = f_L * C_e \quad (6)$$

Where $f_L$ is the Lang factor and $C_e$ is the total delivery cost of all the major equipment items.

The Lang factor is already implemented in Aveva and set to $f_L$=*5.93* for the total capital investment which is the recommended value from Aveva for a fluids processing plant. The total capital cost is equal to the sum of the FCI and the working capital calculated directly from APS. This investment in cost is divided over the first two years.

### Operational Cost (OPEX)

The cost of operations includes the heating and cooling of the streams, the electricity furnished to the process and the cost of raw material and catalyst (assumed to be replaced every 2 years). The cooling of streams is assumed to be done with water or glycol while the heating is assumed to be from steam (low pressure at 160°C, medium pressure at 184°C and high pressure at 254° C) [9]. These costs include the operating costs to generate the utility and the price of the circulated cooling or heating system. Moreover, based on the Danish grid, the cost of electricity is taken as 0.095$/kWh [10]. Operational cost also includes the price of raw material. Finally, the economic assessment needs to take the price of products into account. The perturbation and distribution of reactant and kerosene prices are based on a list of current literature values. The lower, average and upper values are presented in Table 1.

**Table 1:** Lower, average and upper values used for the uncertainty analysis [11-13]

| Parameter | Lower value | Average value | Upper value |
|---|---|---|---|
| $H_2$ price ($/kg) | 1.27 | 3.00 | 10.13 |
| $CO_2$ price ($/kg) | 0.06 | 0.10 | 1.27 |
| Kerosene price ($/kg) | 0.86 | 3.25 | 6.06 |

## Output parameters

Five outputs parameters are studied with their uncertainty:

- The Return of Investment (ROI) is taken as the average of the annual net profit calculation divided by the total investment capital.
- The Payback Period (PBP) is obtained by dividing the FCI by the average of annual operating cash flow.
- The Net Present Value (NPV) is equal to the sum of present worth of annual cash flow of each year of the plant life.
- The Discounted Cash Flow Rate (DCFR) is the iterated discount rate corresponding to a NPV

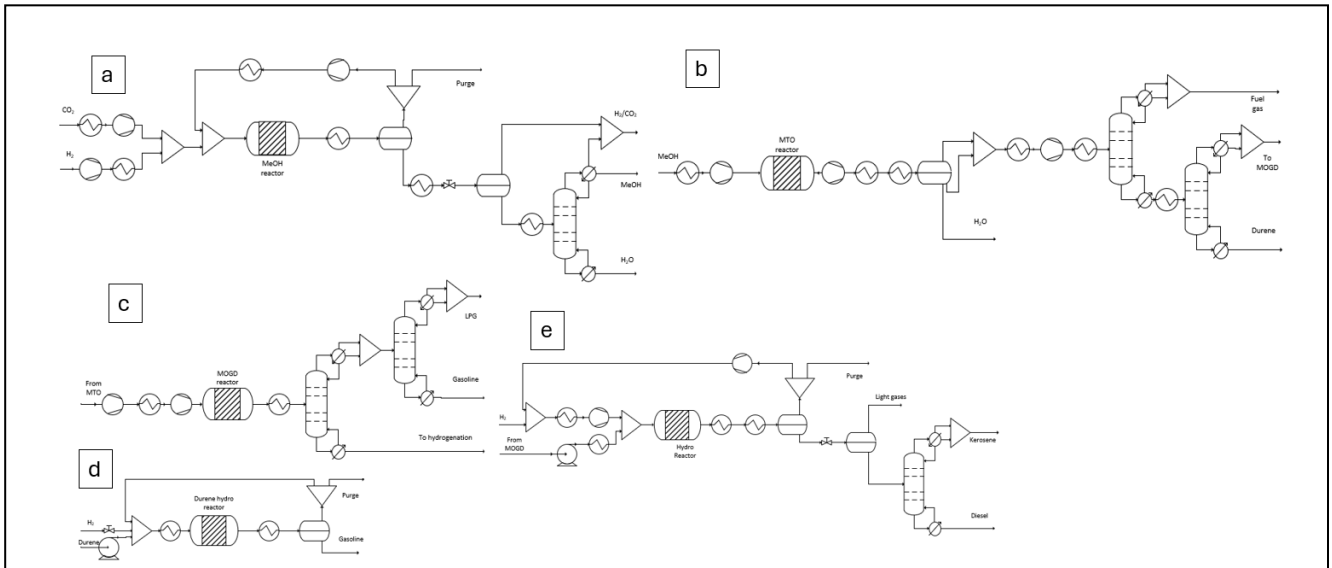

**Figure 1:** Complete process of the production of kerosene from $H_2$ and $CO_2$: Formation of methanol (a), Methanol-To-Olefins (b), Mobil-Olefins-To-Gasoline-and-Distillate (c), Durene Hydrogenation (d), Olefins Hydrogenation (e)

equal to zero.

- The Minimum Selling Price of Product (MSEP) is the price of SAF corresponding to an NPV equal to zero.

The Monte-Carlo simulations are done with 500 iterations and returns the average and standard deviation of each value. The perturbations and distributions for the Monte-Carlo Analysis are presented in table 2. For reactant and product prices, a lognormal distribution has been chosen to fit with the range of prices found in literature [11-13]. Additionally a Latin Hypercube Sampling function is applied to the input parameters to represent their distribution within the minimum and maximum values.

**Table 2:** Perturbation and distribution of inputs parameters for uncertainty and sensitivity analysis of the economical assessment

| Parameter | Perturbation (%) | | Distribution |
|---|---|---|---|
| FCI | -30 | +30 | Normal |
| WC | -20 | +50 | Uniform |
| $H_2$ price | -60 | +230 | Lognormal |
| $CO_2$ price | -40 | +1170 | Lognormal |
| Kerosene price | -70 | +90 | Lognormal |
| OPEX | -30 | +30 | Normal |

# RESULTS AND DISCUSSION

## Final process

The final process is presented in figure 1. In a boiling-water reactor, $H_2$ and $CO_2$ are first converted into methanol and water which are then separated in a distillation column. A kinetic model based on Froment et al. work is implemented [14] over a $Cu/ZnO/Al_2O_3$ catalyst. The second part from methanol to SAF is based on the conversion models from Ruokonen's work [11]. Four reactors are implemented using the zeolite catalyst HZSM-5: the conversion of methanol to olefins (b), the formation of higher olefins (c), the hydrogenation of durene to form a part of the gasoline (d) and the hydrogenation of olefins to form kerosene and diesel (e). Additionally, the ratio kerosene/reactants is based on Ruokonen's work [11] for a production of 37kt of kerosene for 66kt of $H_2$.

## Sensitivity Analysis

### Comparison with experiment

A Sensitivity Analysis was performed on the methanol formation reactor. First the kinetic model needs to be validated with experimental data. The $CO_2$ hydrogenation (equation 8) and Reverse Water Gas Shift (equation 9) are considered to model the methanol formation:

$$CO_2 + 3\,H_2 \leftrightarrow CH_3OH + H_2O \quad (8)$$

$$CO_2 + H_2 \leftrightarrow CO + H_2O \quad (9)$$

As the kinetic model from Froment et al. fits with the experimental data, the model implemented in Aveva Process Simulation is compared with the model implemented by Froment et al. [14]. This comparison is performed for a laboratory scale plug flow reactor with a feed composed of 4 mol% of CO, 82 mol% of $H_2$, 3 mol% of $CO_2$ and 11 mol% inert. The results are presented in Table 3.

The implementation on Aveva fits with the referenced model and therefore with the experimental data. The applied model can be the subject of further studies.

**Table 3:** Comparison of the component fraction at the outlet of the methanol reactor for the model implemented in APS and the model implemented by Froment et al. [14]

| Component | APS model | Froment et al. model |
|---|---|---|
| CO | 0.030 | 0.030 |
| $CO_2$ | 0.021 | 0.021 |
| $H_2$ | 0.801 | 0.801 |
| $CH_3OH$ | 0.023 | 0.023 |
| $H_2O$ | 0.011 | 0.011 |

## Key-design parameters

The key-design parameters of the methanol formation reactor are studied to optimize the carbon conversion to methanol. The initial design is based on the Luyben et al. model of the methanol formation [15]. The methanol formation reaction being exothermic, the reactor is modelled as tubular with an external utility to cool down the fluid. The diameter of the tubes is set as D=0.03675 m, the smallest diameter available, to maximize the heat exchange, with a heat transfer coefficient of 244 $kcalh^{-1}m^{-2}K^{-1}$ [15]. The volume is calculated from the Gas Hourly Space Velocity used in the literature GHSV=3.348 $kg/kg_{cat}/h$ [15]. Hence, for a number of tubes $N_t$=4000, the length of the reactor is L=4 m with a feed of 66kt/year of $H_2$ and 480 kt/year of $CO_2$. Moreover, the pressure drop inside the reactor is assumed to be equal to 1 bar.

The evolution of carbon conversion with the pressure inside the reactor is plotted figure 2. The carbon conversion is defined as the following:

$$conv = \frac{n_{in}(CO_2) - n_{out}(CO_2)}{n_{in}(CO_2)} \quad (10)$$

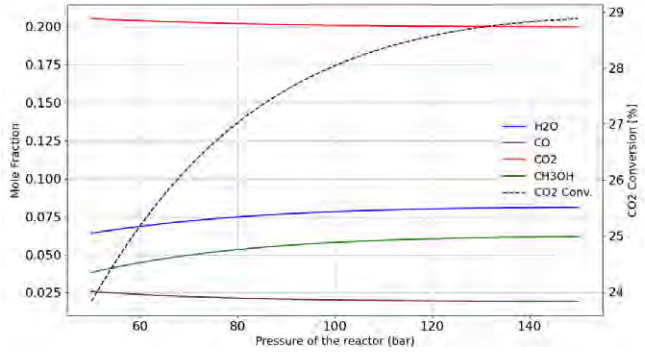

**Figure 2.** Evolution of the gas composition and the carbon conversion at the outlet of the methanol reactor with the inlet pressure at fixed temperature ($T_{feed}$=423.15K)

The carbon conversion increases with the pressure of the reactor. However, the conversion stabilizes after 150 bar. Hence, P=110bar is chosen to optimize the conversion while lowering the operational cost.

Additionally, the evolution of the carbon conversion is studied figure 3 with the variation of temperature. The carbon conversion increases with the temperature of the reactor until 540K before decreasing due to the main reaction of $CO_2$ hydrogenation being exothermic and the competitive reaction (Reverse Water Gas Shift) being endothermic.

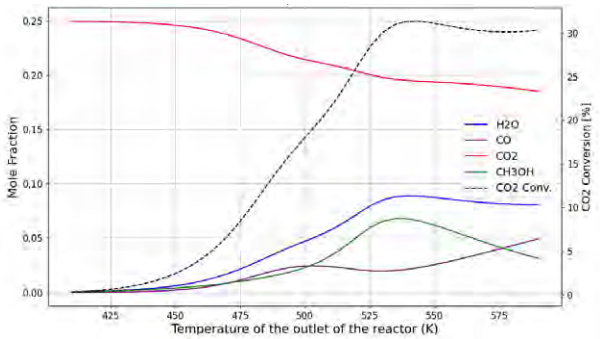

**Figure 3.** Evolution of the gas composition and the carbon conversion at the outlet of the methanol reactor with the outlet temperature (P=110bar, $T_{feed}$=423.15K)

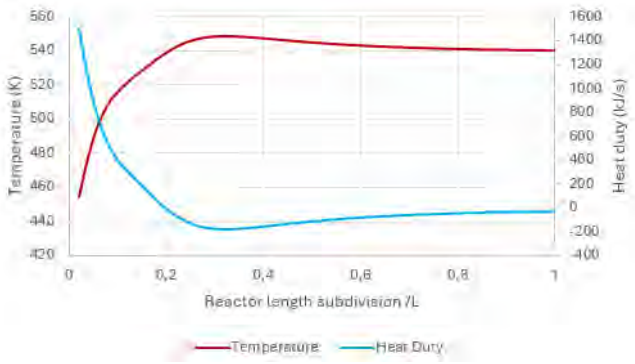

**Figure 4.** Evolution of the temperature and heat transfer duty inside the methanol formation reactor ($Duty_{tot}$=1465 kJ/s)

**Table 4:** Key-design parameters of the methanol formation reactor

| Parameter | Value |
|---|---|
| Pressure (bara) | 110 |
| $T_{out}$(K) | 540 |
| Number of tubes | 4000 |
| Diameter of the tubes (m) | 0.03675 |
| Length of the tubes (m) | 4 |
| Volume ($m^3$) | 17 |
| Catalyst | Cu/ZnO/Al2O3 |
| Catalyst mass (kg) | 15 054 |
| Catalyst volumic mass ($kg/m^3$) | 1 775 |

Consequently, the utility of the reactor is modelled to obtain an outlet temperature of the reactor equal to

540K. The evolution of temperature and heat transfer inside the final model of reactor is presented figure 3 while the final reactor design parameters are presented in table 4. All the parameters listed in Table 4 influence the final conversion, and their optimal values were determined through univariate analysis. However, an additional assessment considering their interdependencies could improve the optimization process.

### Heat Integration

The cumulative heats are presented in figure 5. As no pinch point exists, the heat exchangers are combined freely if heat is transferred from warm streams to cold streams (with threshold set to $\Delta T_{min}$ = 10K). The resulting optimization of cost after Heat Integration is presented in table 5.

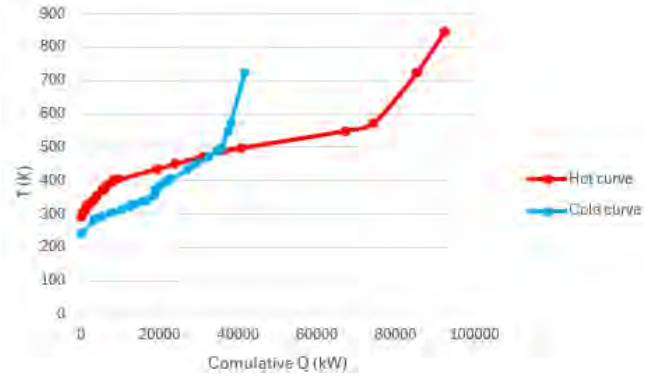

**Figure 5.** Cumulative heat of the hot and cold streams

**Table 5:** Reduction of duties and cost after HI

| | Duty reduction (kW) | Cost reduction ($million/year) |
|---|---|---|
| Cooling | 39 701 | 0.43 |
| Heating | 39 701 | 2.33 |
| **Total** | **79 401** | 2.76 |

## Economic Analysis

The economical analysis is performed for the overall process from the purchase of $H_2$ and $CO_2$ to the retailing of kerosene and its co-products. The mean value of the input parameters for the Monte-Carlo simulation are presented in table 5. The resulting distribution is plotted in figure 6 and 7 and matches with the expected distribution from table 2 for all 7 inputs parameters.

Figure 8 and Table 6 show the results of the economic assessment. The value of MSEP ($2.46/kg) fits with previously published values [11-13] but remain however higher than $0.68/kg the current price of fossil-based kerosene in Denmark [16]. Additionally, the purchase of hydrogen accounts for 78% of the total OPEX with an extremely wide range of price values (see Table 1). This results in a high standard deviation of all the output parameters.

**Table 6:** Mean Value of the input parameters for the economic assessment

| | $million | $million/year |
|---|---|---|
| FCI | 144.9 | |
| Working Capital | 22.6 | |
| **Total CAPEX** | 167.5 | |
| Utility | | 15.3 |
| Raw materials | | 249.1 |
| **Total OPEX** | | **264.4** |
| **Sales** | | **304.2** |

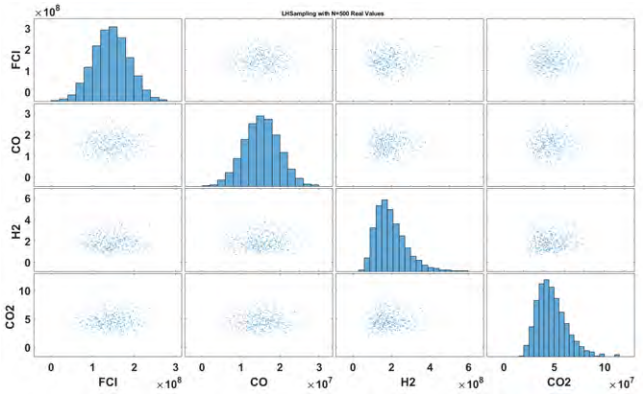

**Figure 6.** Real value distribution of the first 5 input parameters for the Monte-Carlo simulation

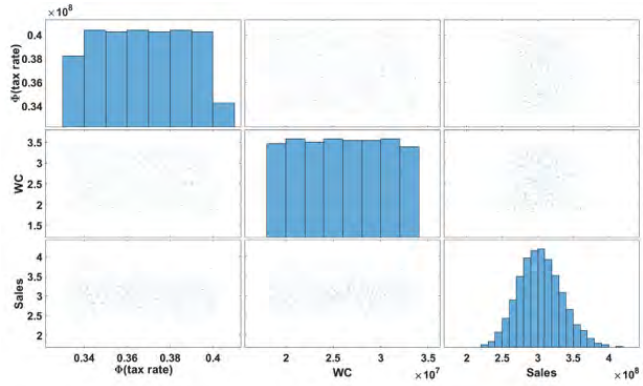

**Figure 7.** Real value distribution of the last 5 input parameters for the Monte-Carlo simulation

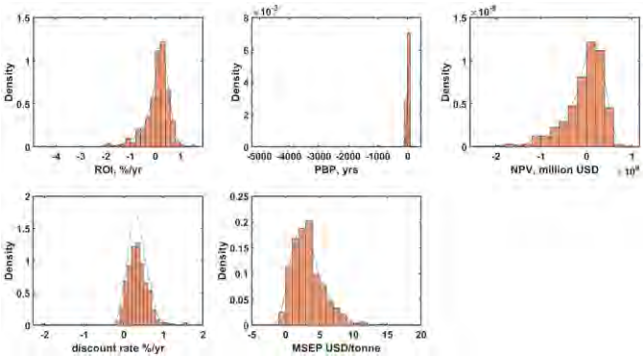

**Figure 8.** Density value of the ouput parameters of the Monte-Carlo simulation (N=500)

**Table 7:** Avearge and Standard Deviation of the ouput parameters of the Monte-Carlo simulation (N=500)

| | Average | Standard deviation |
|---|---|---|
| ROI (%/year) | 0.09 | 0.47 |
| PBP (years) | 5.87 | 50.52 |
| NPV ($million) | -50.5 | 448.2 |
| MSEP ($/kg) | 2.46 | 2.30 |

## CONCLUSION

The process design of SAF from $H_2$ and $CO_2$ appears to be a promising process for the development of alternative fuels. As the quantity of raw materials mainly impacts the final price of SAF, the conversion into methanol must be the subject of an in-depth study. A boiling-water reactor with V=17m³, P=110bara and $T_{out}$=540K is chosen for the final design.

While the Minimum Selling Price of the produced kerosene ($2.46/kg) falls into the range of previous techno-economic assessments, it remains non-competitive against fossil-based aviation fuels. Additionally, a significant sensitivity to the price of hydrogen leads to considerable uncertainty on the result. Hence, the economic viability of SAF is highly dependent on innovations in performance, cost-breakdown electrolyzer technologies along with governmental regulation on fossil-based kerosene usage. Finally, novel concepts for Sustainable Aviation Fuel (SAF) synthesis could potentially reduce aviation fuel production costs, opening pathways for more sustainable air transportation in the future.

# Assessing the Environmental Impact of Global Hydrogen Supply through the Lens of Planetary Boundaries

**Jesmyl-Elisa Cordova-Cordova[a], Carlos Pozo[a]***

[a] Departament d'Enginyeria Química, Universitat Rovira i Virgili, Av. Països Catalans 26, 43007 Tarragona, Spain

## ABSTRACT

Hydrogen is increasingly recognized as a crucial energy carrier for a low-carbon future. However, most studies on clean hydrogen production devote limited attention to the entire supply chain. This study evaluates the sustainability of 800 combinations of hydrogen production and transportation methods, comparing their environmental impacts against the geophysical limits defined by the Planetary Boundaries framework. Findings reveal that no supply chain alone can make the current economy sustainable, yet powering water electrolysis with bioenergy and carbon capture and storage can meet the $CO_2$-based planetary boundaries. The analysis also underscores the need for decarbonization efforts in the hydrogen transportation sector, as certain options could offset the benefits of clean hydrogen production.

**Keywords**: Life Cycle Analysis, Planetary Boundaries, Absolute environmental sustainability, Hydrogen

## INTRODUCTION

Most of current hydrogen production is centralized, with large-scale hydrogen plants, often located near natural gas reserves or industrial hubs, dominating global production. However, as global decarbonisation efforts accelerate and hydrogen is increasingly recognised as a crucial energy carrier for the transition to a low-carbon future, decoupling of production and demand become more likely. Regions with abundant renewable energy resources are positioned to produce green hydrogen at lower costs, while other industrialized regions have high hydrogen demand but limited local production capacity.

This potential paradigm shift is not yet reflected in the literature, where most research efforts still focus on hydrogen production alone. Few studies have examined the complete hydrogen supply chain, integrating both production and transportation. This leaves unanswered important questions about the real impact of large-scale hydrogen production, which can hamper a rapid transition towards a global hydrogen economy.

In addition, recent life cycle assessment (LCA) studies for hydrogen production and end uses are mostly limited to benchmarking alternatives. While these studies provide valuable insight regarding the best performing alternatives, they do not address the fundamental question of whether said options are sustainable in absolute terms.

To address this gap, we investigate the sustainability of different technologies for hydrogen production and transportation in a global context, comparing the impacts produced by multiple supply chain alternatives against the geophysical limits provided by the Planetary boundaries (PB) framework [1]. PBs are safe environmental limits within which humanity can operate to ensure the stability and resilience of Earth's systems. Each boundary is associated with quantitative limits on specific control variables that help monitor its state. Crossing these boundaries increases the risk of destabilizing critical processes that regulate the planet, potentially leading to irreversible environmental changes. Hence, comparing impacts of hydrogen supply chains against PBs is crucial to properly assess the potential consequences of adopting a hydrogen economy for the planet.

## METHODOLOGY

### Hydrogen Supply Chain Pathways

The present study evaluates the environmental performance of various hydrogen supply chains (i.e., production and transportation) options on a global scale. Specifically, we base our analysis on the 2021 hydrogen demand data provided by the International Energy

Agency (IEA) [2], which accounts for a total of 94 Mt. This demand is distributed across six regions: Europe (EU), China (CN), India (IN), the Middle East (ME), the United States (USA), and the Rest of the World (RoW).

We analyse 32 hydrogen production methods (see Figure 1a), including steam reforming using biogas or natural gas (Business-As-Usual (BAU)) as feedstock, as well as water electrolysis (WE) powered by various energy sources, such as bioenergy with carbon capture and storage (BECCS) or wind energy. We also explore the potential of producing hydrogen from waste materials, such as plastic waste, aluminium scrap, rice husks, and residues from other processes, using methods like gasification, aluminium combustion, or dark fermentation.

In addition, we model hydrogen transportation with the aim of understanding how the introduction of this activity would affect the Earth System in terms of PBs. This requires tracking (i) hydrogen state, and (ii) the transportation mean used of each alternative.

For the former, three options are considered: compressed hydrogen gas, liquid hydrogen, and hydrogen chemically bonded to another compound to form a stable liquid, the so-called Liquid Organic Hydrogen Carrier (LOHC). LOHCs are molecules that can absorb and release hydrogen through hydrogenation and dehydrogenation reactions, behaving as a storage media for hydrogen transportation. Hydrogen transportation as a LOHC can be addressed in two different ways. On the one hand, a linear transportation of the LOHC, which, upon dehydrogenation, results in the transportation of two compounds, hydrogen and the precursor of the corresponding LOCH, using the same transport. Alternatively, the precursor could be recirculated for reuse, reducing this way its overall consumption. This second option is considered for two compounds: dibenzyl toluene (DBT) and toluene.

For the transportation mean, hydrogen can be transported in any of the previous state-form alternatives. This can be done *via* pipeline, truck, and shipping. However, not all hydrogen state and transportation method combinations are viable. For instance, transporting liquid hydrogen *via* pipeline is highly energy-intensive due to the extreme cooling required to maintain its liquid state. Additionally, pipelines would require expensive insulation and frequent maintenance to prevent ice formation around pipes, valves, and vents. Therefore, this option is excluded. Similarly, compressed hydrogen *via* shipping is less feasible than liquid hydrogen, as the latter minimizes boil-off losses and requires less volume and weight. As a result, the three transportation means are available for all the LOHCs (i.e., 3·(5+2) = 21), but only two alternatives are considered for the other hydrogen-state forms (2·2 = 4).This results in a total of 25 transportation options, which, combined with the 32 production methods, yield a total of 800 alternative hydrogen supply chains. For simplicity, this study assumes that hydrogen production and transportation, over 500 km, occur within the same region where demand arises. However, a sensitivity analysis on transport distance is also performed to ascertain the potential influence of this parameter in the assessment.

## LCA and Planetary Boundaries

Next, the resulting 800 alternatives are assessed using the Planetary Boundaries-Life Cycle Impact Assessment (PB-LCIA) framework, an absolute environmental sustainability assessment (AESA) method, bridging conventional LCA principles with the concept of PBs. This requires following the four interconnected phases of the general LCA methodology.

In the first phase, the scope and goal of the study are defined. In this case, the goal is to quantify the absolute environmental sustainability level of different hydrogen supply chain alternatives, adopting an attributional approach with a cradle-to-gate perspective, i.e., considering processes from raw material extraction to hydrogen production and transportation. The functional unit is the annual hydrogen demand in 2021 for each region provided by the IEA, measured in million tonnes per year.

In the second phase, primary inputs and outputs — energy, raw materials, byproducts, and emissions— flowing in and out of the system (i.e., crossing its defined boundaries) are quantified. To this end, mass and energy balance information is gathered from previous studies. Then, this information is combined with the corresponding background activity data from ecoinvent v3.8 to calculate the so-called life cycle inventories (LCIs). This procedure was automated using the Activity Browser interface for Brighway2 open-source LCA software. In all cases, the “Allocation at the point of substitution” (APOS) system model was used.

Since hydrogen production and transportation are assumed to take place within the same region, the study accounts for location-specific environmental impacts. However, the regional classification in the ecoinvent v3.8 database does not align directly with the IEA regionalization, from which hydrogen demand data are sourced. To address this, distinct ecoinvent lumped regions (e.g., Rest of Europe (RER)) are used to model background activity impacts. When specific data for an activity is unavailable at the lumped-region level, data from a representative country within that region (e.g., Germany (DE)) are used instead. If no country-specific data are available, "Rest of the World" (RoW) data are used.

The third phase of the LCA involves assessing the damage produced by the LCIs in different environmental categories. In this case, ten control variables referring to eight Earth-System processes related to the PBs are considered. The PB-LCIA framework is used to express LCIs as impacts caused on the corresponding control

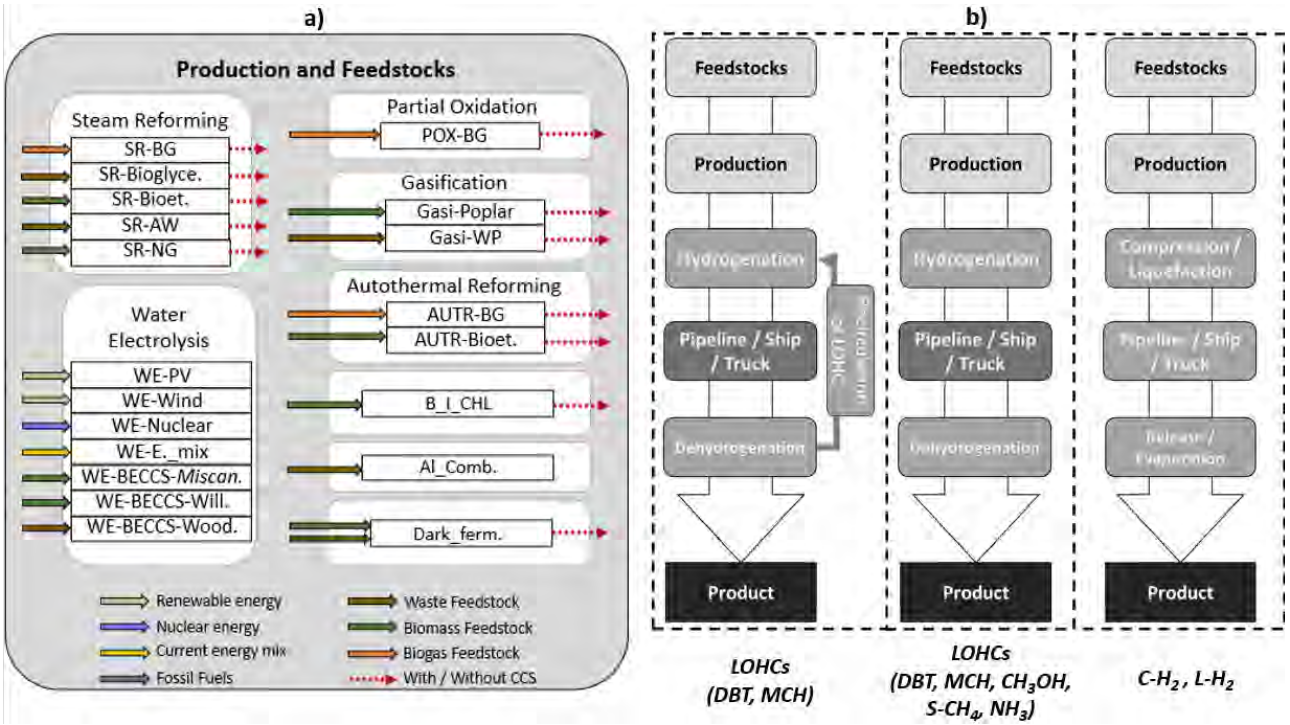

**Figure 1:** Panel (a) shows all the production alternatives studied and their main feedstocks, differentiated by colours. Panel (b) illustrates the three concepts considered for hydrogen transportation (from left to right): transportation as LOHC with precursor recirculation, transportation as LOHC with precursor delivery at destination, and transportation as hydrogen. CCS: carbon capture and storage; SR-BG: steam reforming from biogas; SR-bioglyce.: steam reforming from bioglycerol; SR-Bioet.: steam reforming from bioethanol; SR-AW: steam reforming from alcohol waste; SR-NG: steam reforming from natural gas; POX-BG: partial oxidation from biogas; Gasi-Poplar: poplar gasification; Gasi-WP: waste polymer gasification; AUTR-BG: autothermal reforming from biogas; AUTR-bioet.: autothermal reforming from bioethanol; B_I_CHL: biomass iron-based chemical looping; Al_Comb.: aluminum combustion; Dark_ferm.: dark fermentation; WE: water electrolysis; PV: photovoltaic; Wind: wind turbine onshore; E._mix: current energy mix; BECCS: bioenergy with carbon capture and storage ; Miscan.: Miscanthus; Will: willow; Wood: woodchips; LOHCs: liquid organic hydrogen carriers; DBT: dibenzyl toluene; MCH: methylcyclohexane; $CH_3OH$: methanol; S-$CH_4$: synthetic methane; $NH_3$: ammonia; C-$H_2$: compress hydrogen; L-$H_2$: liquid hydrogen.

variables by means of appropriate characterisation factors (CF). This can be expressed in mathematical terms as follows. The environmental impact caused by alternative $s$ on control variable $b$ ($EI_{b,s}$) is calculated with Eq. (1):

$$EI_{b,s} = \sum_{f} LCI_{s,f} \cdot CF_{b,f} \cdot FU \quad \forall\, b, s \tag{1}$$

where $LCI_{s,f}$ represents the quantity of elementary flow $f$ associated with the production and/or supply of one kilogram of hydrogen in alternative $s$, $CF_{b,f}$ is the CF translating the impact of one unit of elementary flow $f$ into control variable $b$, and $FU$ denotes the functional unit in consistent units (i.e., kilograms of hydrogen per year). CFs developed by Ryberg et al. [3] are employed for all the control variables studied expect for BII, for which the CFs by Galán-Martin et al. [4] are used.

In the fourth phase, results are interpreted, and recommendations are made. This is where the PBs framework demonstrates its full usefulness, as it provides quantitative limits to ascertain whether the activity under analysis can be deemed sustainable or not. To this end, results are compared against absolute limits derived from the PB framework, which defines the level to which principal Earth-system processes can be disturbed before triggering irreversible damage. We note that some Earth-system processes have clear thresholds beyond which critical changes would happen, while others do not. However, even when no precise tipping point exists, increasing stress can still lead to cumulative and potentially irreversible damage, triggering cascading effects on other systems. To address this, an uncertainty zone is defined around each control variable boundary, recognizing that the exact point of irreversible change is not always clear.

Additionally, the planet itself naturally contributes towards each control variables; this is called the natural background level (NBL). Hence, the available 'environmental budget' for human activities, the so-called safe operating space (SOS), is obtained by subtracting the

NBL from the corresponding threshold of the PB: here, the limit between the safe and the uncertainty zone.

On the other hand, PBs are defined at a global scale, but this study assesses only a single sector. To overcome this mismatch in scope, previous studies have employed downscaling methods, although this is a controversial approach that can yield varying conclusions depending on the specific downscaling methodology used. To avoid this, we simulate the global anthropogenic impact of the whole economy ($IMP^{GLO}$) that would result from replacing the BAU scenario for the hydrogen sector ($IMPT^{BAU}$) by each of the 800 alternatives for hydrogen production and transportation ($IMPT^{ALT}$).

$$IMP_{b,s}^{GLO} = IMP_{b}^{CUR} - IMP_{b}^{BAU} + IMP_{b,s}^{ALT} \quad \forall\, b, s \tag{2}$$

Here, $IMP_{b,s}^{GLO}$ provides the global impact of the whole economy on control variable $b$ after substitution of alternative $s$; $IMP_{b}^{CUR}$ corresponds to the current impact of the whole economy on control variable $b$; $IMP_{b}^{BAU}$ is the impact of the BAU scenario for hydrogen supply on control variable $b$; and $IMP_{b,s}^{ALT}$ is the impact of hydrogen supply alternative $s$ on control variable $b$.

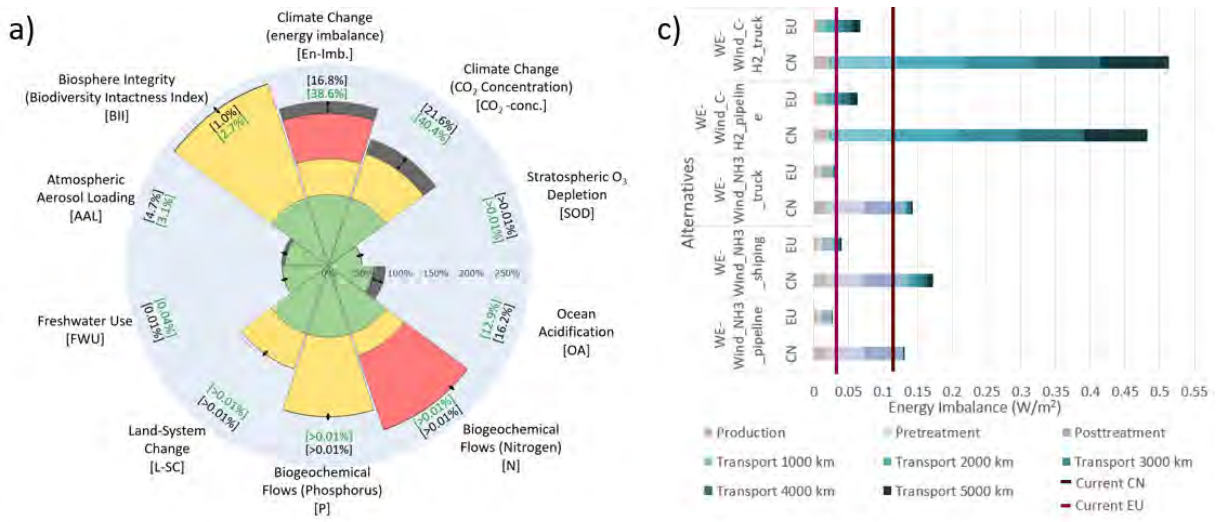
Finally, in order to ascertain whether a scenario is environmentally sustainable in absolute terms, the PB footprint (PBF) [6] is calculated by comparing the (predicted) global anthropogenic environmental impact $IMP_{b,s}^{GLO}$ with the SOS, as shown in Eqs. (3-4).

$$LT_{b,s}^{GLO} = \begin{cases} 0 \quad if \quad \dfrac{IMP_{b,s}^{GLO}}{SOS_b} < 1 \\ \dfrac{IMP_{b,s}^{GLO}}{SOS_b} \quad otherwise \end{cases} \quad \forall\, b, s \tag{3}$$

$$PBF_s = \frac{\sum_b LT_{b,s}^{GLO}}{|B|} \tag{4}$$

Here, the global level of transgression ($LT_{b,s}^{GLO}$) is given by the quotient between the global anthropogenic impact $IMP_{b,s}^{GLO}$ (for control variable $b$ under alternative $s$) and the $SOS$ for each control variable $b$ ($SOS_b$). PBs not transgressed after sector substitution, are assigned a $LT_{b,s}^{GLO}$ value of 0 is assigned, thus prioritising solutions that can meet multiple boundaries concurrently. Finally, the summation of the transgression level for each control variable $b$ (under alternative $s$) is divided by $|B|$, which corresponds to the number of control variables considered (ten in this study). This is equivalent to assuming equal weights regardless of the transgression level, i.e., all control variables are deemed equally important.

## RESULTS AND DISCUSSION



To provide some context, we start by analysing the current impacts of the global economy onto the PBs (Figure 2a). This is a relevant analysis since, arguably, already-transgressed boundaries should be prioritized when designing alternative systems and technologies. As can be seen in the figure, only four PBs are currently met: SOD, OA, FWU and AAL (see Figure 2 caption for acronyms). From the remaining control variables, four lie in the uncertainty zone (i.e., $CO_2$-conc., P flow, LSC and BII), while the other two are severely transgressed, reaching the high-risk zone.

Currently, hydrogen is responsible for more than 15% of the impacts incurred at global scale on $CO_2$-base control variables ( En-Imb., $CO_2$-conc., and OA, see black labels in the figure), while showing minor contributions (i.e., below 5%) to impacts on AAL and BII, and smaller than 0.01% in the remaining control variables. However, when hydrogen impacts are compared against the SOS (green labels), it can be seen that global hydrogen supply represents 39%, 40%, and 13% of the maximum impacts allowed at the global level in En-Imb., $CO_2$-conc., and OA, respectively. This reveals a concerning situation since it is hard to envision that the remaining economic sectors can successfully operate within the remaining SOS for these control variables. The situation is even more worrisome when considering that some of the PBs associated with these control variables have already been crossed at the global level (see Figure 2a). On the other hand, small contributions are observed towards the remaining control variables, all of them more strongly linked to other anthropogenic activities, mainly agriculture [5]. This situation might worsen in the coming years due to the expected increase in hydrogen demand.

We next turn our attention to the alternatives studied (Figure 2b), finding that only 205 out of the 800 hydrogen supply chains considered exhibit a lower PBF than the BAU scenario. As an example, the BAU scenario, predominantly based on steam reforming from natural gas, remains a better option than WE given that the current electricity mix is still largely based on fossil fuels.

There is no hydrogen supply chain that alone can make the current economy sustainable: additional efforts will be required from other sectors. The alternative with the lowest PBF (0.90) is WE-BECCS with Miscanthus, which meets the SOS limits for the $CO_2$-base control variables. However, growing biomass feedstock exerts increasing pressure on the Biodiversity Intactness Index (BII) due to land use impacts, though this boundary remains within the uncertainty zone (from 268% to 288% of the SOS). Additionally, biomass combustion contributes to NMVOC emissions, increasing pressure on the Atmospheric Aerosol Loading (AAL) boundary, but without exceeding the uncertainty zone (from 66% to 86%).

AI_Comb. emerges as a slightly better option production than WE with PV and wind turbines, primarily due to avoided impacts associated with aluminium scrap management. However, this effect shows asymmetric contributions across regions (results not shown owing to space limitation). Negative impacts (i.e., lower than zero)

b)

**Figure 2:** a) Analysis of the current situation. Current impacts of the whole economy are depicted against boundaries on the different control variables, with different colours depending on whether they lay within the SOS (green), in the uncertainty zone (yellow), or in the high-risk zone (red). The contribution from the hydrogen supply chain is highlighted with dark grey sectors, with black labels providing their contribution to current impacts. Green labels in the same panel show the share of the SOS by the current hydrogen supply chain. b) Level of transgression achieved by the global economy when replacing the BAU hydrogen supply chain by selected scenarios. Each row in the heatmap corresponds to a different alternative scenario, as described by the label of the first (hydrogen production) and second (transportation alternative) columns. Underlined values in the heatmap indicate that the impact on the control variable of this alternative is lower than the BAU scenario. The two last columns provide (from left to right) the PBF and the ranking of the alternative (from the lowest to the highest PBF). c) Impacts on the energy imbalance control variable of supplying current hydrogen demand in China and Europe over different distances with selected alternatives. Stacked bars breakdown the impacts by production, pretreatment, transportation mean (considering different potential distances), and posttreatment alternatives.

on $CO_2$-based control variables are achieved in all regions except in India, where the reliance on fossil fuels for electricity generation offsets the benefits of aluminium recycling.

Regarding transportation (Figure 2b), C-$H_2$ via pipeline is the most favourable option as it eliminates the need for conversion (e.g., hydrogenation-dehydrogenation reactions for LOHCs) or conditioning (e.g., liquefaction for L-$H_2$). For example, certain LOHCs such as DBT would transgress planetary boundaries like OA, while others like $CO_2$-concentration could shift from the uncertainty zone to the high-risk zone (results not shown). The AAL control variable also increase for all cases using LOHCs, specially for DBT, MCH, and $CH_3OH$. This is primarily due to the energy-intensive nature of pretreatment processes such as compression, liquefaction, and hydrogenation.

In $CO_2$-based control variables, as well as in BII, S-$CH_4$ and $NH_3$ alternatives show the highest contributions from post-treatment, highlighting this stage as a key bottleneck in these transportation pathways. Notably, if S-$CH_4$ and $NH_3$ were directly used as fuels (i.e., avoiding $H_2$ regeneration) their contribution from transport would almost be on pair with those from C-$H_2$ or L-$H_2$. In addition, this would have the added benefit of avoiding the need to update the transport infrastructure, as required for C-$H_2$. This suggests that S-$CH_4$ and $NH_3$ could serve as competitive alternatives to hydrogen in energy applications, providing comparable performance while reducing transport and infrastructure needs. This is only a viable

option in energy applications and not in cases where hydrogen is used as a chemical feedstock.

Finally, the largest contribution in the supply chain depends on the combination of production and transportation alternatives. For instance, in purple hydrogen (WE-nuclear), electrolysis contributions range from 0.5% to 37.5%, depending on the transportation method. Conversely, in alternatives such as WE-BECCS, the negative impacts from production are substantial enough to offset all positive transportation impacts. On the other hand, transport distance and regional factors are also crucial parameters. As an example (Figure 2c), we find that WE-wind combined with C-$H_2$ in China is a better alternative than BAU only for distances below 1,000 km, due to the energy required for hydrogen recompression every 250 km. For context, the breakeven distance for Europe is 2,500 km. Therefore, hydrogen decarbonization must be accompanied by simultaneous electricity mix decarbonization, which may follow different pathways and timelines across regions.

## CONCLUSIONS

Our results uncover the potential threats of maintaining the current hydrogen supply chain, which requires an excessive environmental budget: standalone, almost 40% of the Safe Operating Space in some control variables. Shifting Natural gas Steam reforming with Carbon Capture Storage or green hydrogen could reduce the damage to critical $CO_2$ control variables, leaving room for other hard-to-abate economic sectors to operate. However, decarbonisation efforts such as Water Electrolysis combined with Bioenergy with Carbon Capture Storage could still worsen Biodiversity Intactness Index or Nitrogen flows. In addition, recycling waste (e.g., aluminium scrap or plastic waste) to produce hydrogen can mitigate environmental burdens without jeopardising the Biodiversity Intactness Index (as Water Electrolysis combined with Bioenergy with Carbon Capture Storage does), or threatening the resources of critical materials required for the construction of electrolysers, photovoltaic panels, or wind turbines. Finally, when formulating policies for the hydrogen economy, these must also consider transportation means, as they could negate the efforts made in hydrogen production. Overall, this highlights the need to optimize hydrogen supply chains holistically.

## ABSTRACT

Reduction of greenhouse gas emissions is an important environmental element to actively combat the global warming and climate change. In view of reducing the $CO_2$ concentration from the atmosphere, the Direct Air Capture (DAC) options are promising technologies in delivering negative carbon emissions. The integration of renewable-powered DAC systems with the $CO_2$ utilization technologies can deliver both negative carbon emissions as well as reduced energy and economic penalties of overall decarbonized processes. This work evaluates the innovative energy- and cost-efficient potassium - calcium looping cycle as promising direct air capture technology integrated with various $CO_2$ catalytic transformations into basic chemicals / energy carriers (e.g., synthetic natural gas, methanol etc.). The integrated system will be powered by renewable energy (in terms of both heat and electricity requirements). The investigated DAC concept is set to capture 1 Mt/y $CO_2$ with about 75 % carbon capture rate. Up to 50 % fraction of the captured $CO_2$ stream will be then catalytically converted into the Synthetic Natural Gas (SNG) or methanol using the green hydrogen produced by the water electrolysis (using renewable power), the rest being sent to geological storage. As the results show, the integrated DAC - $CO_2$ utilization system, powered by renewable energy, has promising performances in terms of delivering negative carbon emissions, promoting the utilization of renewables and reducing ancillary plant energy consumptions.

## 1. INTRODUCTION

Combating the global warming and climate changes are matters of great importance globally. To achieve climate neutrality by 2050, several key technical options are envisaged such as increasing the share of renewable energy sources (e.g., solar, wind, biofuels etc.) to gradually replace the fossil fuels, large-scale implementation of the Carbon Capture and Utilization (CCUS) technologies, improving overall energy efficiencies of both production and utilization steps etc. The integration of renewable energy sources with the CCUS & DAC technologies is very promising in delivering negative carbon emissions as well as replacing the fossil energy for future low-carbon applications [1]. The negative carbon emission is a key environmental element for achieving the climate neutrality in order to balance the still remaining positive emission systems and the hard-to-decarbonize processes.

This work evaluates the innovative potassium - calcium looping cycle as DAC system integrated with various $CO_2$ catalytic transformations (e.g., synthetic natural gas, methanol etc.). Conceptual design, modelling and simulation, model validation followed by the energy optimization done by thermal integration analysis, were relevant engineering tools used to assess and optimize the mass and energy balances for quantification of the key

techno-economic and environmental performance indicators. As shown, the proposed integrated systems have promising performances (e.g., negative $CO_2$ emissions). However, significant technological developments are still needed to advance this innovative technology from the current state of the art to relevant industrial sizes as well as to improve the overall techno-economic indicators [2].

## 2. PLANT CONFIGURATION, DESIGN ASSUMPTIONS AND ENERGY INTEGRATION ANALYSIS

The innovative DAC system based on a potassium - calcium looping cycle involves the following technological steps with the correspondent chemical reactors [3]:

- Air contactor for $CO_2$ capture from air using an alkaline potassium hydroxide aqueous solution:

$$CO_2 + 2KOH \rightarrow K_2CO_3 + H_2O \;\; \Delta H = -95.8\ kJ/mole \quad (1)$$

- Causticization reactor for the carbonate precipitation and alkaline solvent regeneration:

$$K_2CO_3 + Ca(OH)_2 \rightarrow 2KOH + CaCO_3 \; \Delta H = -5.8\ kJ/mole \quad (2)$$

- Calcination reactor for the thermal release of captured $CO_2$ and sorbent regeneration:

$$CaCO_3 \rightarrow CaO + CO_2 \quad \Delta H = +178.3\ kJ/mole \quad (3)$$

- Slaker reactor for the hydration of quick lime (regeneration of causticization agent):

$$CaO + H_2O \rightarrow Ca(OH)_2 \;\; \Delta H = -63.9\ kJ/mole \quad (4)$$

Excepting the calcination of calcium carbonate (which requires a significant thermal energy consumption), the rest of involved chemical reactions are exothermic having a positive influence on overall plant energy consumption. The calciner is operated in oxy-combustion mode using biomass (renewable fuel). The overall configuration of the combined potassium - calcium looping cycle used for DAC purposes is shown in Figure 1.

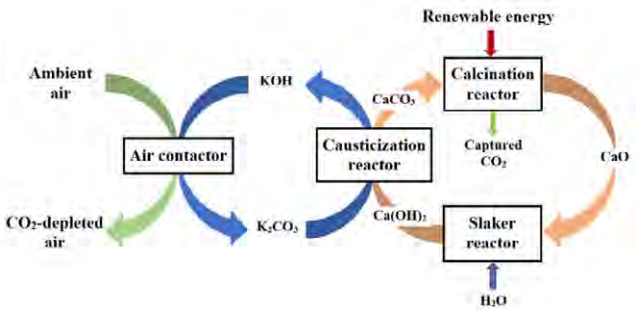

**Figure 1.** Innovative potassium - calcium looping cycles for the direct air $CO_2$ capture (DAC).

Up to 50 % ratio of captured $CO_2$ is then catalytically converted into Synthetic Natural Gas (SNG) or methanol using green hydrogen produced by renewable power water electrolysis [4]. The chemical reactions used in the $CO_2$ utilization concept are the following:

- SNG production (Sabatier process):

$$CO_2 + 4H_2 \leftrightarrow CH_4 + 2H_2O \quad \Delta H = -165\ kJ/mole \quad (5)$$

- Methanol production:

$$CO_2 + 3H_2 \rightarrow CH_3OH + H_2O \quad \Delta H = -49.8\ kJ/mole \quad (6)$$

Figure 2 presents the conceptual layouts of the SNG (left) and methanol (right) production plants using the captured $CO_2$ (from various industrial sources or DAC as the case of this work) and the green hydrogen (produced from the renewable-powered water electrolysis).

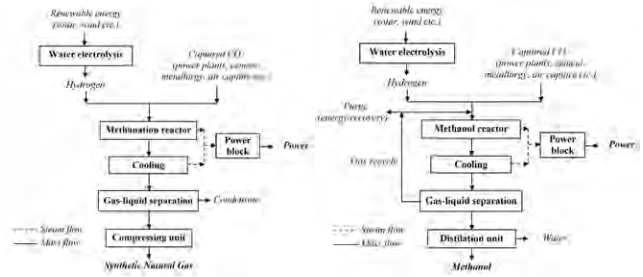

**Figure 2.** SNG (left) & methanol (right) production plants.

Table 1 presents the main design assumptions of the investigated innovative DAC - $CO_2$ utilization concepts.

To optimize energy efficiency, a detailed thermal integration analysis using the pinch methodology was performed for both DAC and $CO_2$ utilization main plant subsystems [5] (without considering the total site analysis). As an illustrative example, Figure 3 presents the correspondent hot and cold composite curves (HCC and CCC) for the sorbent calcination reactor within DAC plant which is showing a significant heat recovery potential (in form of steam generation - see the cold composite curve) from the available heat sources (hot process streams).

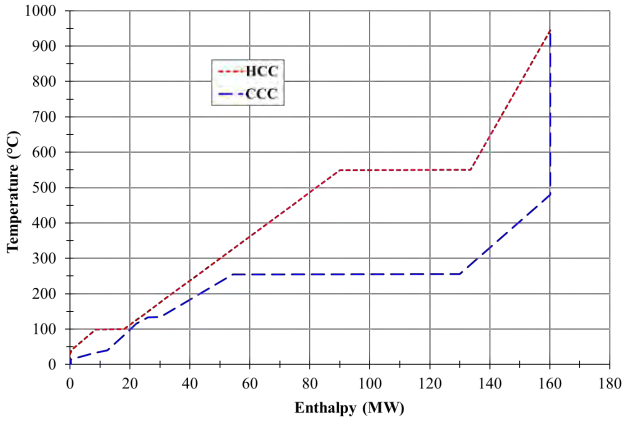

**Figure 3.** Thermal integration analysis of DAC calciner.

## 3. RESULTS AND DISCUSSIONS

The developed models for the combined DAC system and $CO_2$ utilization routes were validated by comparison to available industrial / experimental data. In this respect, the key performance indicators resulted from simulation results of main plant sub-systems were used. For instance, in relation with the involved chemical reactors, the following technical performance indicators were used: conversion rates of various chemical reactions, $CO_2$ capture and utilization rates, DAC calciner thermal duty and sorbent make-up ratio etc. Table 2 presents the comparison of experimental vs. simulated key performance indicators for the integrated DAC - $CO_2$ utilization systems [3-4,6]. As noticed, no significant differences were observed. Therefore, the developed models of integrated DAC - $CO_2$ utilization concepts are validated.

**Table 2:** Validation of developed DAC - $CO_2$ utilization systems.

| Key indicator | Experimental | Simulated |
|---|---|---|
| DAC $CO_2$ capture rate (%) | 70.00 - 75.00 | 75.00 |
| Thermal duty for sorbent regeneration (MJ/kg $CO_2$) | 4.50 - 5.25 | 4.80 |
| DAC sorbent regeneration rate (%) | 95.00 - 98.00 | 98.00 |
| Sorbent make-up rate (%) | 1.00 - 5.00 | 2.00 |
| Power consumption water electrolysis (kWh/kg) | 50.00 - 55.00 | 54.00 |
| $CO_2$ conversion rate for SNG plant (%) | 90.00 - 99.00 | 99.00 |
| $CO_2$ conversion rate for methanol plant (%) | 90.00 - 99.00 | 97.25 |

The overall assessment methodology used for the techno-economic and environmental evaluation as well as the used key performance indicators of the integrated $CO_2$ capture and utilization system were described in details in another paper [4]. For the DAC system, woody biomass was used in the calcination reactor under oxy-combustion conditions (the required oxygen was provided by an integrated cryogenic air separation unit). Considering the thermal operation of the DAC calcination reactor, the overall captured $CO_2$ stream is about 1.5 Mt/y covering both the $CO_2$ captured from air (1 Mt/y) and the $CO_2$ generated from the biomass oxy-combustion process (0.5 Mt/y). The process flow modeling and simulation was done using ChemCAD software [7] for all integrated DAC - $CO_2$ utilization concepts. Table 3 presents the most important techno-economic performance indicators of the evaluated renewable-based DAC system.

**Table 3:** DAC performance indicators.

| Key performance indicator | U.M. | Value |
|---|---|---|
| Captured $CO_2$ flowrate | t/h | 187.50 |
| Biomass input to calciner (pre-dried to 10 % moisture) | t/h | 35.70 |
| Oxygen input to calciner | t/h | 48.20 |
| Power output | $MW_e$ | 23.50 |
| $CO_2$ capture rate | % | 75.00 |
| Specific power consumption per captured $CO_2$ | kWh/t | 315.00 |
| Specific thermal energy per captured $CO_2$ | kWh/t | 1400.00 |
| Captured $CO_2$ quality specification | % vol. | 97.4 % $CO_2$, 2.58 % $N_2$ + Ar, 200 ppm $H_2O$ |
| Specific investment cost per captured $CO_2$ | €/t | 1022.10 |
| Operational and Maintenance (O&M) costs | €/t | 55.82 |

The levelized cost of captured $CO_2$ for the investigated biomass-based DAC concept is about 166 €/t. This calculated value is in line with other estimations presented in the literature (for the same high-temperature DAC technology and similar plant capture capacity) which ranged between 120 - 400 €/t [3,8]. Comparing with the current EU $CO_2$ prices of about 60 - 70 €/t [9], the investigated DAC technology has significantly higher values, but it is expected that in with the further decrease of renewable energy prices (e.g., green power), improving the technological and commercial expertise of DAC processes (to reduces capital and operational costs), the proposed technology will become economically viable.

To assess the overall influence of different cost components (e.g., capital and operational costs, biomass cost, interest rate, plant availability factor etc.) on the levelized cost of captured $CO_2$ for the evaluated DAC plant, a sensitivity analysis was performed. Figure 4 presents the sensitivity analysis for the evaluated biomass-based DAC concept. The analysis shows, somehow expected for these systems, that the DAC capital cost has the highest influence on the captured $CO_2$ cost followed by the interest rate and the plant availability factor.

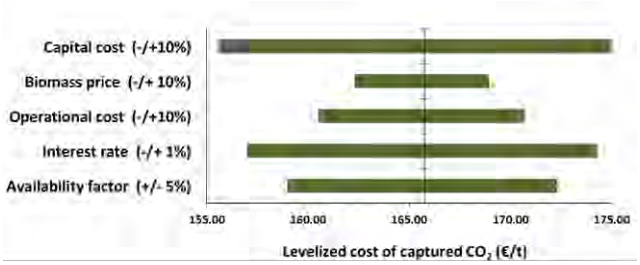

**Figure 4.** Sensitivity analysis of the levelized cost of captured $CO_2$.

In addition, the influence of $CO_2$ transport and storage cost was evaluated (see Figure 5). This key economic indicator is very important for any CCUS project. One can notice that the $CO_2$ transport and storage cost has an important influence on the overall DAC economics.

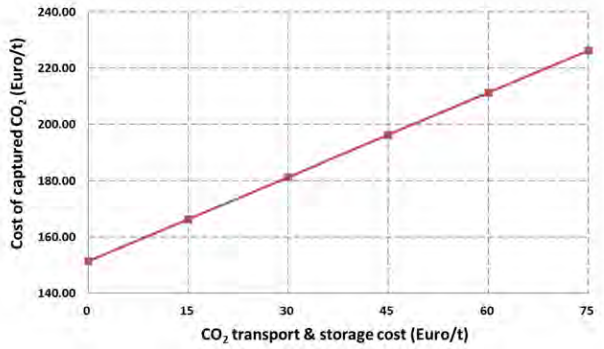

**Figure 5.** Influence of the $CO_2$ transporty and storage cost.

The cumulative cash flow analysis is a very important tool for evaluation of any project along its entirely life (construction, commissioning, operation and decommissioning). Figure 6 presents the cumulative cash flow analysis for the evaluated biomass-based DAC system.

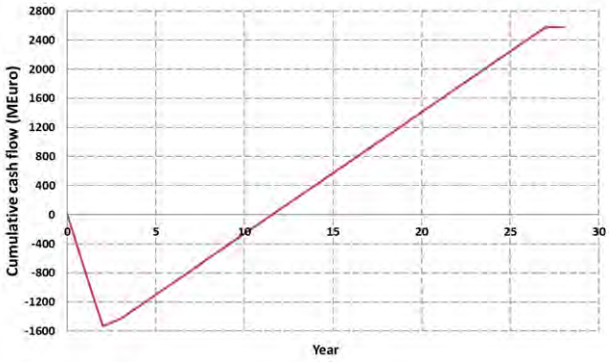

**Figure 6.** Cumulative cash flow analysis for the DAC concept.

Following the biomass-fuelled DAC plant, a relevant fraction of captured $CO_2$ (up to 50 %) is then catalytically transformed into SNG or methanol (MeOH) using green hydrogen produced from renewable-based water electrolysis. As for DAC concept, both $CO_2$ utilization technologies were modeled and simulated using process flow modeling software ChemCAD. The resulted mass and energy balances were then subsequently used for the overall techno-economic and environmental evaluation. Table 4 presents the main techno-economic performance indicators for the integrated DAC - $CO_2$ utilization options. From the technical and specific $CO_2$ emissions (at plant level), both $CO_2$ utilization options are very attractive. For

instance, both $CO_2$ and $H_2$ conversion rates are very high. In addition, the overall $CO_2$ emissions at the plant level are very close to zero. Considering the overall carbon value chain, the specific $CO_2$ emissions are negative for both investigated energy carriers / chemicals (not considering further utilization of SNG and methanol).

**Table 4:** Integrated DAC - $CO_2$ utilization routes key techno-economic performance indicators.

| Performance indicator | U.M. | SNG | MeOH |
|---|---|---|---|
| SNG / methanol thermal output | $MW_{th}$ | 500.00 | 70.00 |
| $CO_2$ conversion rate | % | 99.00 | 97.25 |
| $H_2$ conversion rate | % | 98.00 | 99.00 |
| Cumulative energy efficiency | % | 58.70 | 54.10 |
| Specific $CO_2$ emissions (at plant level) | kg/kg | 0.05 | 0.04 |
| Specific $CO_2$ emissions (for the overall chain) | kg/kg | -2.58 | -1.30 |
| Specific capital investment per SNG / MeOH output | €/t | 2160.25 | 640.10 |
| Operational and maintenance costs | €/t | 734.91 | 1065.89 |
| Levelized cost of SNG / MeOH | €/t | 1324.86 | 926.52 |

From the economic point of view, both SNG / MeOH production costs are higher than the corresponded fossil-based options [4,10]. For instance, the SNG price is about 25.3 €/GJ which is significantly higher than the historical natural gas prices (6 - 8 €/GJ) but somehow comparable with current EU natural gas price of about 12 - 13 €/GJ [11]. A sensitivity analysis was also performed for SNG plant to see the influence of various economic elements (e.g., capital cost, green hydrogen cost, operational cost, interest rate, electricity price etc.) on the SNG production cost. As Figure 7 shows, the most important influence is observed for the green hydrogen cost followed by the operational and maintenance cost.

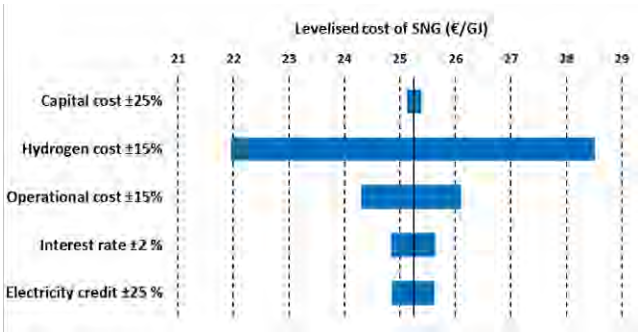

**Figure 7.** Sensitivity analysis of SNG production cost.

For the methanol case, a similar situation than the SNG case is observed, the methanol production price is about 400 - 600 €/t in case of fossil-based methanol [12-13] vs. about 926 €/t for this analysis (green methanol produced with air captured $CO_2$ and renewable energy sources). To assess the effect of $CO_2$ price / $CO_2$ emission tax on green methanol production cost, Figure 8 presents the variation of net present value (NPV). As can be noticed, the green methanol production from captured $CO_2$ can become economically viable (NPV zero or positive) at $CO_2$ emission cost of higher than 230 €/t (currently, this value is about 65 €/t, according to the European Union, Emission Trading System - EU-ETS [14]).

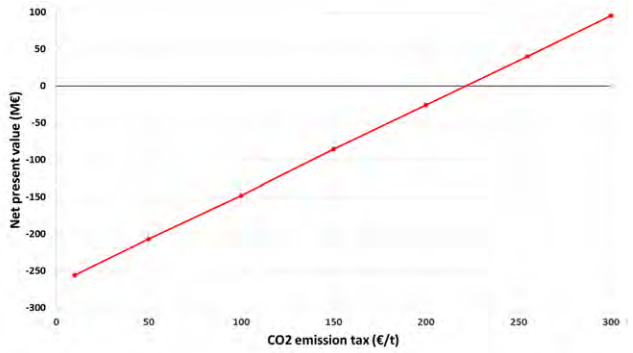

**Figure 8.** Net present value variation of methanol production cost vs. $CO_2$ price.

However, for both evaluated $CO_2$ utilization concepts, it is expected that the overall economics to be improved with expected reduction of the renewable energy prices, increase of $CO_2$ emission taxes as well as further technological improvements [15]. The presented analysis is emphasizing also the importance of developing renewable hydrogen supply chain in deployment of $CO_2$ utilization technologies [16]. It must be noted one strategically important aspect, namely the ability of the investigated green hydrogen $CO_2$ utilization concepts to tackle the inherent time variability of the solar and wind applications by producing storable chemicals that can be used either in energy applications and chemical processes [17]. In addition, the further technological developments (e.g., more efficient water electrolysis systems, improved mass and energy integration of DAC technology, better $CO_2$ utilization catalysts, process intensification etc.) will have a positive influence on economics of these processes.

## 4. CONCLUSIONS

The present work evaluated the techno-economic and environmental performances of an innovative renewable-based DAC system integrated with the $CO_2$ utilization routes to produce SNG and methanol. A wide range of process engineering tools (e.g., conceptual design, mathematical modeling and simulation, mass and energy process integration, techno-economic and

environmental assessment etc.) were used in the evaluation of the integrated DAC - $CO_2$ utilization concepts.

As the results show, the integrated DAC - $CO_2$ utilization systems, powered by renewable energy (biomass and renewable electricity), have promising technical performances in terms of delivering high energy efficiencies (54 - 59 %), negative carbon emissions for the overall value chain (- 2.58 to -1.3 kg/kg), boosting the utilization of renewable energy, reducing ancillary energy consumptions (e.g., for sorbent thermal regeneration), emphasizing the mass and energy integration potential etc. However, the economics of the investigated DAC - $CO_2$ utilization concepts is not yet fully viable in comparison to the current fossil-based similar systems (e.g., natural gas, fossil methanol) but several further developments (e.g., higher penetration of renewable-based hydrogen systems, improved processes and catalysts etc.) could significantly help to improve the economic indicators.

## ABSTRACT

The reduction and recovery of organic fraction of municipal solid waste is a major challenge for contemporary society. It requires the establishment of regional strategies with minimized environmental impact. This study employs life cycle assessment to evaluate the respective environmental performances of the current French system based on incineration, and those of alternative systems including (i) anaerobic digestion with composting and (ii) composting for biowaste treatment under different energy scenarios. The environmental impacts of Parisian biowaste are calculated by considering incineration technologies in the area, the French energy mix in 2022, the average European energy mix in 2022 and the projected French energy mix for 2030. The results show that the proportion of fossil-based sources in the energy mixes significantly influences the environmental performance of waste management systems. Energy mixes based in high-carbon fossil sources dependency tend to favour incineration-based processing systems. This is driven by the significant volume of credits allocated to the alternative energy produced from waste treatment. It is therefore essential for processing system design projects to account for planned changes in the energy mix in order to accurately assess the future impact of waste management strategies.

Keywords: Life Cycle Analysis, Biowaste, Circular Bioeconomy, Composting, Anaerobic Digestion, Energy Efficiency, Municipal Household Waste Management.

## INTRODUCTION

The significance of waste management in European legislation reflects the environmental challenges posed by the vast quantities of waste requiring treatment. Annually, more than 2 billion tonnes of municipal solid waste are generated, with 32-34% comprising the organic fraction of municipal solid waste (OFMSW) in Europe [1,2]. To address the critical need for sustainable management of organic solid waste, several studies [3–5] have examined the environmental assessment of various technological alternatives that can be mobilised for this purpose. Previous research has highlighted the sensitivity of the environmental performance of biowaste reprocessing technologies to energy mixes.

Slorach et al. [3] compared incineration, composting and anaerobic digestion technologies for food waste in the United Kingdom (UK). Their study showed better environmental performance for the anaerobic digestion treatment with a particular sensitivity of the results to the energy mix. They found out that when anaerobic digestion and incineration are credited with displacing wind or solar energy, both treatment options become net contributors to Global Warming Potential and Fossil Depletion, as the associated credits are lower compared to those for the grid electricity. As highlighted by Soimakallio et al. [4] differences in actual research questions, methodological choices, and data set selection have a significant impact on the outcomes of life cycle assessment (LCA) studies for energy systems. These inconsistencies make it challenging to compare the findings of various studies and may lead to uncertainties in the conclusions. These results were confirmed by Dastjerdi et al. [5] in a systematic review. The article states that one of the most investigated sources of uncertainty was the source of avoided electricity and assumptions for energy recovery.

The aim of this work is to assess the environmental performance of current and potential systems for

managing OFMSW in the Parisian region. To the best of our knowledge, the case of France has not been studied from this perspective. The scenarios evaluated are mainly incineration, composting, and anaerobic digestion with composting (AD-co). In the first part, the comparison of the French and European scenarios was evaluated. In the second part of this work, the influence of the energy mix planned in France for 2030 vs. that of 2022 on the environmental performance of the OFMSW treatment system was studied. Results aim to provide actionable insights to policymakers and waste management operators.

## METHODOLOGY

Figure 1 illustrates the perimeter of the data used in

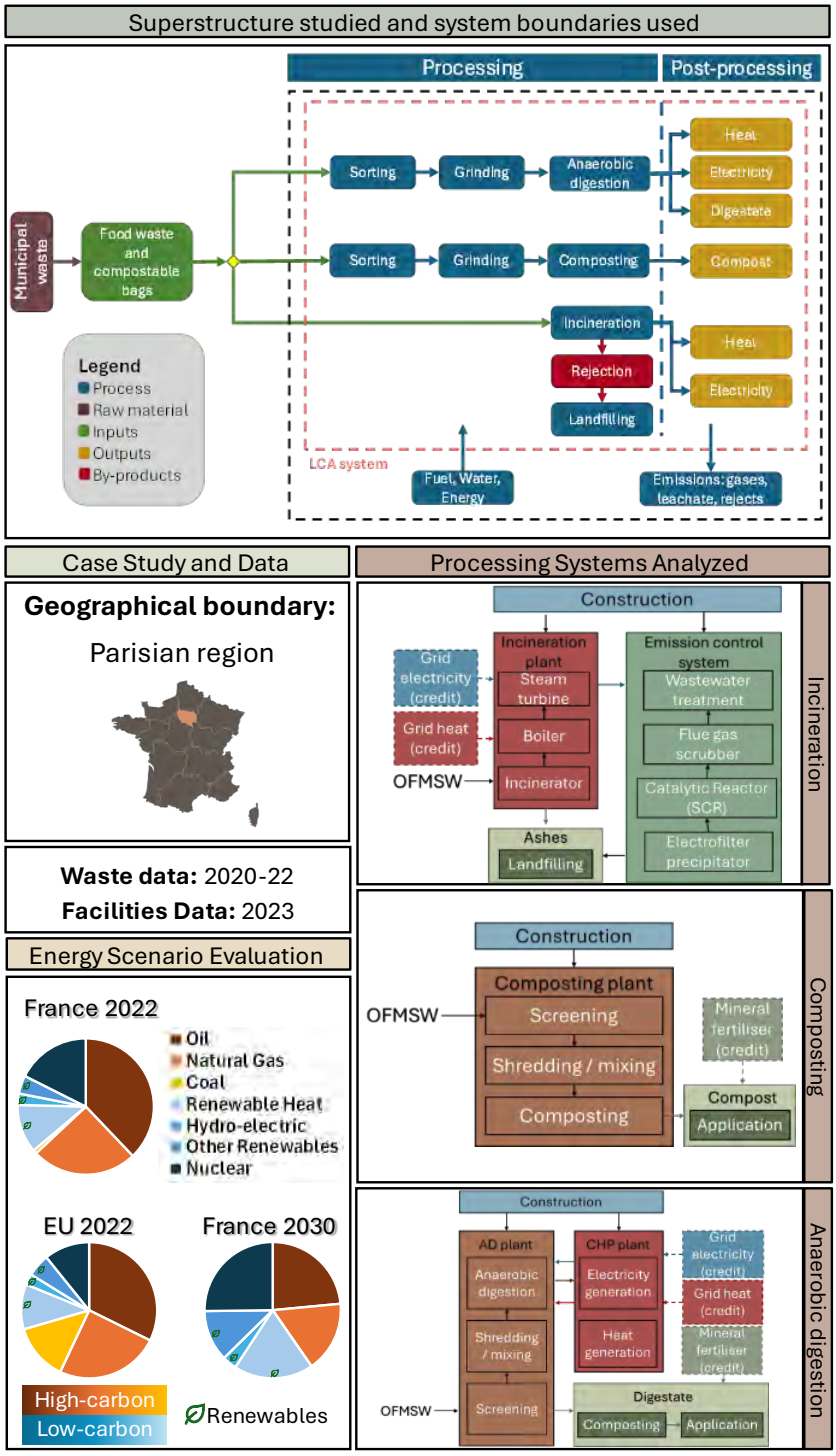

**Figure 1**. Schematic representation of the study boundaries and considered cases.

this study, including energy mix scenarios and the perimeters of the global system and sub-systems compared. LCA was conducted using the OpenLCA 2.3.1 software with the Ecoinvent 3.9.1 database. The four phases of LCA have been followed as standardized by ISO 14040/44. The functional unit was defined as the treatment of 1 kg of OFMSW. A review of recent publications [5-8] guided the selection of the 12 most relevant environmental categories for this field as shown in Figure 2. Impacts were normalized according to the highest absolute value per category for better visibility. The impact assessment method chosen is: ReCiPe (H) 2016 [6] (LCIA method 2.1.1).

For the analysis, three energy mixes were considered: i) France 2022 (current energy mix), ii) 2030 future scenario (projected energy mix), and iii) Average European Union (EU) energy mix in 2022 (as the comparison system). The details of these energy mixes are provided in the supplementary material (Tab. S1-3). To isolate the impact of the national energy grids, including the expected changes in the national energy grid for 2030, consistent process efficiencies have been applied throughout the study for the same technologies across all scenarios. This approach ensures that the analysis focuses solely on the influence of the different energy mix grids analysed. The Parisian OFMSW was characterised in terms of volume using data supplied by the operator, and its composition was established using literature data on composition [7]. A detailed description can be found in Tab. S4-5.

The incineration process of OFMSW was simulated using the modelling tools provided by Doka et al. [8]. After data collection, the detailed Parisian plant inventories have been summarized in Tab. S4 and used in the assessment. It is important to note that incineration facilities in Paris are highly optimized, including their dry ash treatment. The energy produced by incineration has been discounted from the LCA as a credit.

For the composting process, the inventory was retrieved from Lu et al. [9]. The compost has been allocated by means of substitution and the system is credited against the avoided production of mineral nitrogen (calcium ammonium nitrate), phosphate (diammonium phosphate) and potassium fertilizer. For that, the characterization of the compost composition was performed as proposed by Boldrin et al. [10] and detailed in Tab. S6. To credit the various fertilizer substitutions used in the study, the replaced quantity was calculated using Eq. S1-3.

For the anaerobic digestion process, the inventory was retrieved from the literature [11]. Using annual OFMSW production data for greater Paris, the required sizes for the AD-co and Combined Heat and Power (CHP) unit were calculated using the Ecoinvent inventory and scaled up with Eq. 1.

$$E_2 = E_1\left(\frac{C_2}{C_1}\right)^{0.6} \quad (1)$$

where:

$E_1$ environment impact of the smaller plant

$E_2$ environment impact of the larger plant

$C_1$ plant capacity of the smaller plant

$C_2$ plant capacity of the larger plant.

The produced biogas, without upgrade to biomethane, has been considered to be burned in a CHP unit. Its calorific value was credited for the energy displaced, and the digestate through Eq. S4-6.

## RESULTS AND DISCUSSION

The results clearly highlight the significant influence of the different energy mix grids on the environmental performance of waste treatment system.

Figure 2a and 2b illustrate the midpoint impact assessment of the studied technologies. These graphs were constructed by subtracting the environmental credits (avoided impacts) of each technology from their generated impacts. Figure 2a compares the midpoint impact assessment of the three technologies for the French (2022) and average EU (2022) energy grid mixes. Concerning fossil resource scarcity (FRS), the energy credits from displacement are sufficient to make incineration and AD-co net negative-impact processes under the studied grid mixes (60% fossil for France, 70% for the EU). This is due to energy production rates of 0.81 kWh/FU for incineration and 0.753 kWh/FU for AD-co. Incineration emerges as the best option, followed by AD-co, with a greater relative benefit in the EU context. Composting, which consumes resources like fuel and energy, does not gain sufficient offset from fertilizer displacement, resulting in a net environmental impact.

Aquatic environmental impacts, including freshwater ecotoxicity (FWEc), eutrophication (FWEu), and marine ecotoxicity (MEc), vary significantly across different contexts. In France, AD-co consistently performs best, while composting ranks as intermediate. Incineration exhibits the highest impacts due to the release of toxic compounds from combustion, flue gas washing, and phosphate emissions from fly ash. In the EU context, similar trends are observed for ecotoxicity. However, freshwater eutrophication improves substantially for incineration (-581%) and AD-co (-311%), which is attributed to the displacement of coal-based energy production.

For global warming (GW) it can be seen that incineration is the least polluting option, followed by AD-co and lastly, composting. For France and the EU, a difference of -12.16 and -13.72% is observed for incineration and anaerobic digestion respectively. It's important to point out that even if seemingly small, this difference in the impact for one kg when related to the annual production of 440kt in France creates a difference of 2 million

$CO_2$eq. saved per year for the incineration and 1.85 $CO_2$eq. for anaerobic digestion.

Human health impacts, measured through carcinogenic (HCT) and non-carcinogenic toxicity (HNCT) (1,4-DCB eq. and kg $NO_x$-eq.), show that AD-co consistently demonstrates superior performance, while incineration ranks lowest despite filtration systems, due to combustion-generated toxic compounds.

For ozone formation related impacts (OF-HH and OF-TE), composting presented the highest impact due to unfiltered $NO_x$ and NMVOC emissions, with the lack of biofilters resulting in direct atmospheric exchange of

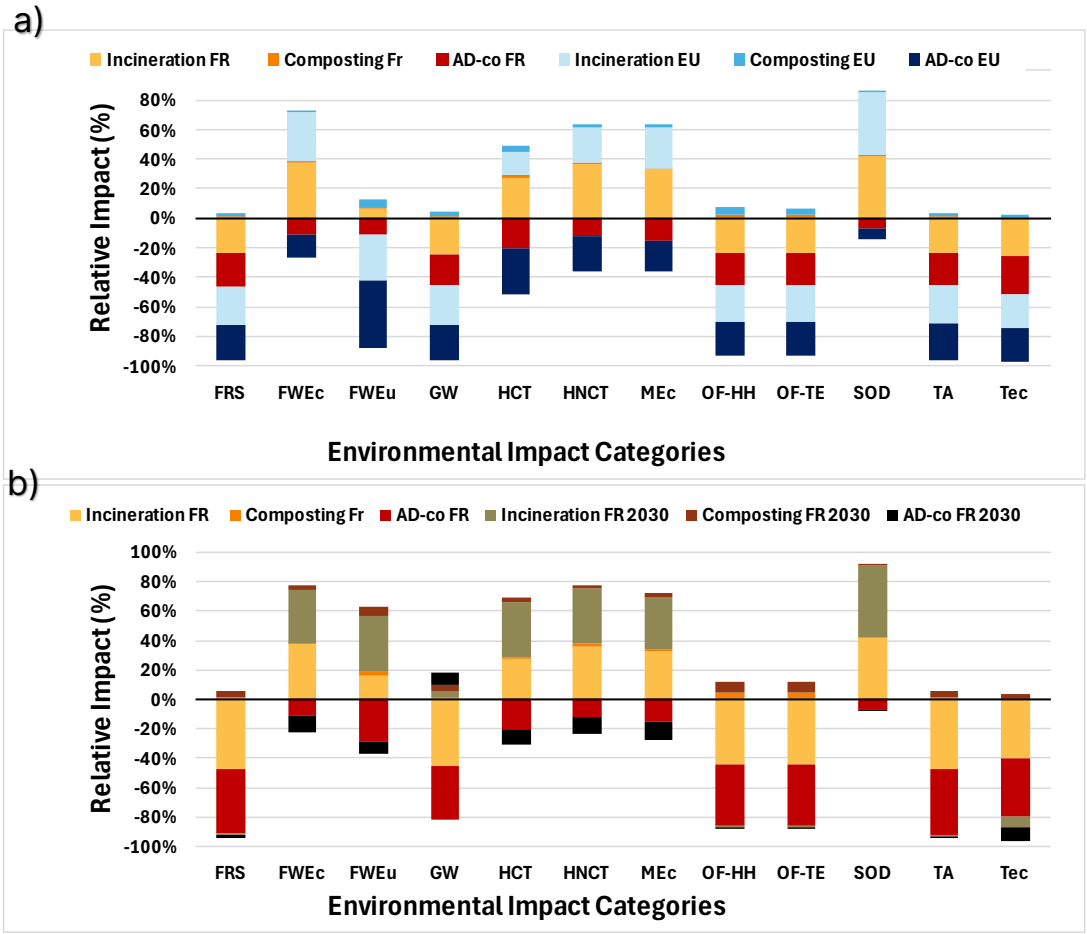

**Figure 2**. Environmental impacts with credits of the various processing technologies in the Parisian region a) using the French (2022) and European (2022) energy mix and b). using the current (2022) and projected French (2030) energy mix Terrestrial Acidification (TA), Global Warming (GW), Stratospheric Ozone Depletion (SOD), Ozone formation-Human health (OF-HH), Ozone formation-Terrestrial ecosystems (OF-TE), Human carcinogenic toxicity (HCT), Human non-carcinogenic toxicity (HNCT), Freshwater Eutrophication (FWEu), Freshwater Ecotoxicity (FWEc), Marine Ecotoxicity (MEc), Terrestrial Ecotoxicity (TEc) and Fossil Resource Scarcicity (FRS).

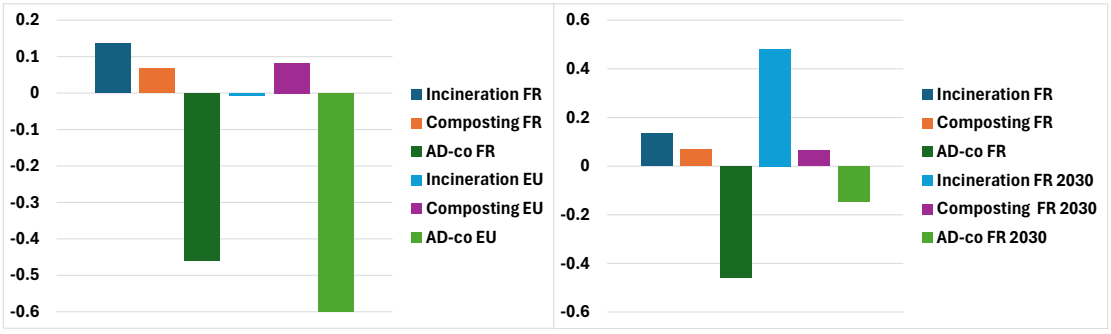

**Figure 3.** Environmental single score for different energy mix grids: a) France vs EU and b) France today vs 2030.

these compounds.

Regarding stratospheric ozone depletion (SOD) (kg CFC11-eq.), AD-co showed the least impact, with energy displacement creating environmental credits, while incineration's energy credits prove insufficient to offset continuous ozone-depleting compound production.

For terrestrial impacts, the analysis of acidification (TA) and ecotoxicity (TEc) (measured in kg $SO_2$-eq. and 1,4-DCB eq. emitted to industrial soil) reveals that composting demonstrates the highest impact, primarily due to fuel combustion during operations and energy production. Both AD-co and incineration benefit significantly from energy displacement credits, which effectively reduce their environmental impact in these categories.

Figure 2b present the comparison of the midpoint impact assessment of the three technologies with regards to the actual French energy mix grid and the 2030 horizon is shown. The reduction in high-carbon fossil fuel based technologies share from 60 % to 42 % drastically reduce the environmental credits of the three waste treatment technologies, revealing significant shifts in technology performance with the projected changes in energy mix composition. For fossil resource scarcity (FRS), the impact order changed, now Ad-co is the least impacting technology, followed by Incineration. The same results are found for freshwater ecotoxicity (FWEc), eutrophication (FWEu) and marine ecotoxicity (MEc). AD-co is the least impacting technology bringing credits; while composting and incineration result in higher environmental impacts. A slight reduction of -4 % to -14 % in the impact category of freshwater ecotoxicity is observed, primarily due to the increased share of energy co-generation using biogas. However, freshwater eutrophication and marine ecotoxicity show significant increases for incineration (130 % and 10.6 % respectively) and AD-co (70 % and 21 % respectively), linked to reduced energy displacement credits.

The global warming (GW) analysis for 2030 demonstrated perhaps the most dramatic shift, with a 108 % to 122 % relative increase for incineration and AD-co respectively. This shift transforms incineration from saving 16 million tonnes $CO_2$eq. to producing 1.38 million tonnes $CO_2$eq. annually, while AD-co shifts from saving 13.5 million tonnes $CO_2$eq. to producing 3 million tonnes $CO_2$eq.

Despite these increases, the analysis of human toxicity impacts shows that AD-co maintains its environmental advantage, even after experiencing a 46 % increase in human carcinogenic (HCT) and 7 % increase in non-carcinogenic toxicity (HNCT) impacts. Incineration follows a similar trend but to a lesser extent, with 37 % and 2 % increases respectively.

Fig. 3 presents the aggregated end-point environmental single score, they have been produced following ReCiPe 2016 [6] methodology. The analysis highlights how energy mix differences lead to varying technological preferences. In the EU context, with its higher fossil fuel dependency, AD-co emerges as the least impacting technology available, followed by incineration and lastly composting.

However, the French context, with its less carbon-based energy mix, shows a different trend: AD-co remains the preferred option, but composting becomes more favourable than incineration due to reduced energy displacement credits. This trend becomes even more pronounced in the 2030 scenario, where AD-co maintains its position as the least environmentally impacting system despite losing a significant share of positive impact. Composting emerges as a valuable alternative with relatively small environmental impact, and incineration becomes one order of magnitude more impacting than composting and two orders more impacting than AD-co.

## CONCLUSIONS

This study provides valuable insights into waste treatment technologies through two perspectives. In the context of Paris, the life cycle assessment demonstrated that anaerobic digestion with composting (AD-co) emerges as the most environmentally favourable option, followed by composting, with incineration showing the highest environmental impact. This hierarchy is maintained when the share of high-carbon sources in the energy mix is reduced. However, the decarbonisation of the mix increases the final impact of incineration and progressively reduces the interest of anaerobic digestion with composting.

The analysis of environmental impacts in different energy mix scenarios revealed a critical insight: the perceived advantages of WtE plants are largely artificial, created by avoided impacts in carbon-intensive energy contexts. As energy grids transition toward low-carbon renewable sources, this artificial benefit will decrease, highlighting the urgent need to shift toward alternative treatment systems like AD-co and composting. This relationship between waste treatment technologies and energy resources demonstrate how the environmental performance of waste management systems is intrinsically linked to the energy mix grid.

The specific impact assessment shows that AD-co consistently maintains its environmental advantage across different scenarios, while incineration's performance significantly deteriorates in lower-carbon energy contexts. For instance, in the 2030 scenario, AD-co remains the most environmentally sound option, despite reduced benefits from energy displacement, while incineration becomes notably less favourable, showing impacts two orders of magnitude higher than AD-co.

Based on these findings, some recommendations to the policymakers can be formulated: consider the projected changes in energy mix when planning long-term

waste management infrastructure, prioritize the development of AD-co facilities due to their consistent environmental benefits across different energy scenarios, and gradually transition away from incineration in regions with increasingly renewable energy mixes. Additionally, policymakers should consider incorporating composting facilities in their plans as complementary infrastructure to AD-co, particularly in areas with limited space or resources for AD-co implementation. Future studies should also consider technological advancements and various system configurations to provide a more comprehensive understanding of treatment options.

While these findings provide crucial environmental insights, it's important to recognize that a comprehensive assessment of waste processing systems must also incorporate economic and social dimensions to develop truly sustainable and practical solutions.

## ABSTRACT

Energy storage is essential for transitioning to a renewable system based on renewable sources. To meet this challenge, Power-to-X technologies are attracting more attention. This work explores converting the excess of electric energy obtained from wind or solar sources into hydrogen and then into methane leveraging existing natural gas infrastructure for easier storage and transport. The process involves two stages: Firstly, the methane production step using Power-to-X technologies during excess renewable energy periods and, secondly, the electricity generation step during high demand with $CO_2$ capture for reuse in methane synthesis, forming a closed carbon loop. In this way the Power-to-X process is integrated with repurposed combined cycle power plants (CCPPs) creating a Power-to-methane-to-power system. Two approaches are evaluated: oxy-combustion, which simplifies process $CO_2$ purification and air combustion, which needs a more complex $CO_2$ purification, such as amine absorption or PSA systems. The results show that ordinary combustion capturing $CO_2$ by amines is the most profitable process, especially when it is assumed that the oxygen produced by the electrolyzer is sold. For a CCPP with a nominal capacity of 400MW, the cost of electricity production ranges from 450 $/MWh to 490 $/MWh when the income from oxygen sales is neglected. If the oxygen produced can be fully absorbed by the market, the electricity production cost decreases to 250 $/MWh and 300 $/MWh.

**Keywords**: Process Design, Carbon Capture, Energy Storage, Hydrogen, Methane.

## INTRODUCTION

Renewable energy sources (RES) are transforming power systems and will be predominant in the years to come. For example, by 2030, an increase of more than 90% in the electricity generation from RES is expected with solar PV and wind being the leading technologies. However, these generation alternatives fluctuate according to the weather conditions, causing a paradigm shift from the current steady-state systems. Therefore, energy storage technologies will be required to ensure a stable power grid and the balance between electricity production and demand at every time. Different alternatives have been proposed, which can be classified as follows: mechanical, chemical, electrochemical, and electrical.

Among them, hydrogen is emerging as a highly attractive option. According to the current predictions, by 2050, the global demand for hydrogen could increase up to 585 Mtpa under a Net Zero scenario. However, some significant challenges are associated with hydrogen utilization highlighting the low volumetric energy density and the difficult storage conditions. Thus, for medium/long-term storage horizon, the use of hydrogen as such is not considered the most suitable option. Other chemicals produced from hydrogen have been proposed to overcome its issues. These options offer beneficial conditions in terms of volumetric energy density, storage and transport conditions, etc. allowing an effective deployment as grid-scale energy storage system. Among these chemicals, methane, methanol, and ammonia emerge as the most promising options. Although methane is a gas, with the difficulties associated with this phase, this component is attracting attention due to the possibility of using the existing natural gas infrastructure to handle this hydrogen carrier. This allows storage and transport of significant amounts of green methane to address the challenges associated with an energy system with a high

penetration of renewables. The use of methane as energy storage system involves two main steps. The first one is related to the production of methane using Power-to-X processes in time periods with high energy production. Subsequently, a second step is the back transformation into electricity with the possibility of capturing $CO_2$ to synthesize again methane as required.

In this field, Xiang et al. [1] evaluated the implementation of the carbon capture technology in a natural gas combined cycle power plant coupled with oxy-combustion. A simple condensation step is selected as $CO_2$ separation alternative due to the oxy-combustion conditions. An extended work including two $CO_2$ capture retrofits in natural gas power plants in presented by Strojny et al. [2]. In particular, amine absorption and calcium looping have been investigated. Other works have assessed the production of methane through $CO_2$ methanation. For instance, Blanco et al. [3] evaluated the potential implementation of Power-to-methane processes in the European Union using a life cycle assessment approach. However, a comprehensive analysis of the two stages to introduce green methane as energy storage has not yet been performed.

Therefore, in this work, a holistic process design analysis of the Power-to-methane-to-power is developed to be integrated as grid-scale energy storage system. Specifically, the integration of this technology with existing combined cycle power plants is proposed to repurpose current infrastructure, thereby reducing the capital costs associated with the energy transition. In the first stage, devoted to methane production, $CO_2$ (from carbon capture) is combined with green hydrogen produced from water electrolysis using renewable energy (wind and PV solar). This stage will take place in periods with high renewable generation (exceeding demand). The second stage is related to the production of electricity from the previously produced methane. This will take place during periods when renewable generation is not sufficient to meet demand. In this case, the existing combined cycles are evaluated by coupling carbon capture technologies. Two different approaches have been evaluated. Firstly, the use of oxy-combustion together with a simple carbon capture unit (condensation). A second option is to maintain the existing air combustion but with a more complex carbon capture technology (amines or pressure swing adsorption in this case). The captured $CO_2$ is stored to be used in the methanation section as required. Therefore, this comprehensive approach demonstrates the potential of green methane as an efficient solution for grid-scale energy storage, enabling the repurposing of natural gas-based infrastructure to support the transition to a sustainable energy system.

## PROCESS ANALYSIS

This work compares three methane combustion processes. The first two utilize conventional combustion (air-based combustion), which requires a carbon capture system due to the high nitrogen content in the exhaust gases. These processes differ in their carbon capture technology: one employs amine absorption technology, while the other uses PSA systems. The third process replaces air with pure oxygen (oxy-combustion), resulting in exhaust gases mainly composed of $CO_2$ and water.

The diagram of each process can be seen in Figure 1, Figure 2 and Figure 3.

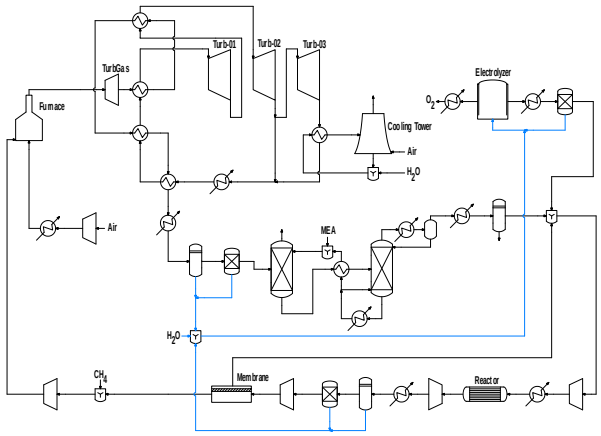

**Figure 1.** Process flow diagram of process using ordinary combustion and absorption as carbon capture system.

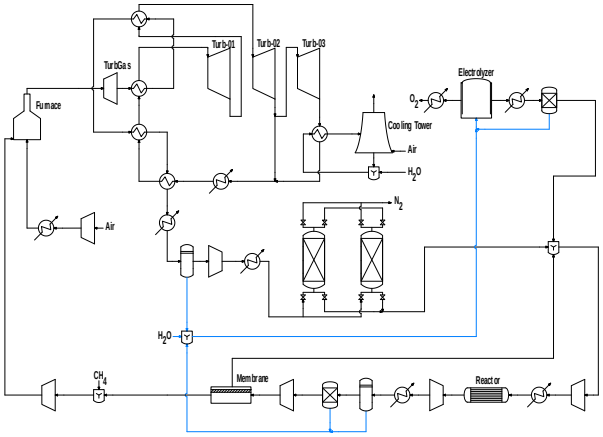

**Figure 2.** Process flow diagram of process using ordinary combustion and adsorption with PSA as carbon capture system.

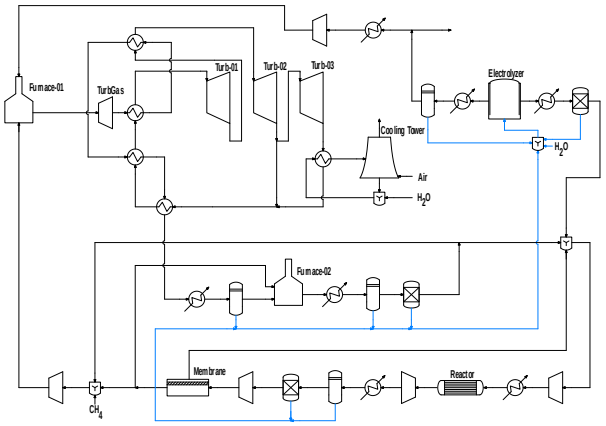

**Figure 3.** Process flow diagram of process using oxy-combustion.

## Process Description

The processes can be divided into four sections. 1) the combined cycle power plant where electricity is produced by burning methane. 2) The second one consists of capturing or purifying CO2. 3) The third one corresponds to renewable hydrogen production by an electrolyzer. 4) Finally, the reaction of H2 and CO2 to produce methane. The methane generated in this section is used as feed of the first. Thereby, the cycle can be closed. The different sections are described as follows.

### Combined Cycle Power Plant

The Combined Cycle Power Plant is composed of two thermodynamic cycles to maximize efficiency. The first one is the Brayton cycle, which takes place in a gas turbine and the second one is the regenerative Rankine cycle, which involves a system of steam turbines (high-pressure, medium-pressure, and low-pressure turbines). Although the reuse of existing CCPPs is proposed, they are also modeled to create a complete model.

The operation of a CCPP begins by introducing the feed, which has been previously conditioned, into the combustion chamber. The composition of the feed varies depending on the modeled processes, but the treatment is the same for all the cases: the feed stream must be compressed and its temperature adjusted to the required level. The combustion chamber is modeled as adiabatic where complete combustion is ensured by adding an excess of comburent. Moreover, an inert substance must be introduced with the comburent to prevent the furnace temperature from exceeding the critical limit of 1600 ºC and avoid material problems. For ordinary combustion the oxygen is already mixed with nitrogen from the air. However, in the case of oxy-combustion, pure oxygen is mixed with $CO_2$ from combustion exhaust gases to achieve the conditions required.

The gas turbine is modeled as a polytropic expansion process with an efficiency of 85%. After passing through the gas turbine, the exhausted gases, which still contain significant thermal energy, are utilized as a heat source for reheater and preheater in the regenerative Rankine cycle with reheating.

In the Rankine cycle, the steam exiting the low-pressure turbine is condensed using a water refrigeration cycle with a cooling tower. The performance of the tower is modeled using Mickey's method [4]. The increment of temperature is limited to 8-10 ºC following rules of thumb to ensure a proper operation. In the cooling tower, the water temperature is reduced by evaporating a fraction of the water so to compensate this lost make-up water is required. To calculate it, the air humidity and water temperature in the cooling tower must be considered.

In general, the equipment of CCPP is the same for all alternative processes, but the following subsections are different for each one.

### $CO_2$ Separation

The $CO_2$ separation section is designed to be integrated with existing CCPPs, creating a closed carbon loop to prevent emission into the atmosphere. Various treatments methods for the exhaust gases are proposed, including the following. When the methane is burned using air as the comburent the exhaust gases are composed mainly of $CO_2$, $H_2O$, a small amount of $O_2$ (as previously it was introduced in excess) and a large amount of $N_2$. Nitrogen acts as an inert component and must be separated from the $CO_2$ to enable a proper operation of methanation. To reach the $CO_2$ purification two technologies are evaluated: adsorption with PSA system and amine absorption system.

Adsorption with PSA system. The process flow diagram can be seen at Figure 1. The PSA columns use as adsorbent material zeolite 13 X [5]. This process is modeled using a Langmuir solid-gas adsorption isotherm. Mainly, the nitrogen can cross the bed while the $CO_2$ is captured. It can be assumed the small amount of oxygen in inlet gases is not trapped, since the adsorption capacity of zeolite 13 X for oxygen is minimal [6]. Then, the $CO_2$ is sent to the methane production section and the not captured gases ($N_2$, $H_2O$, $O_2$) are released into the atmosphere.

Amine absorption system. The process flow diagram is shown at Figure 2. This system consists of two columns. The first one is the absorption column where the exhaust gases from the gas turbine brought into contact with amine solution of 20 % monoethanolamine (MEA). The non-absorbed gases are released into the atmosphere. The amine solution rich in $CO_2$ is heated and sent to the second column or stripping column. Here the $CO_2$ is desorbed from the amine solution and a pure steam of $CO_2$ is reached. Then, the amine solution is mixed with fresh amine solution to make up for losses and refeed to

the first column. The model of this section is based on first principles and industrial data.

In contrast, the exhaust flue gases of oxy-combustion are only composed of $CO_2$, $H_2O$ and $O_2$. The flow diagram of this process can be seen at Figure 3. In this case the $CO_2$ must be also purified. The water is easily removed by condensation and the elimination of the oxygen is done by sending the gases to a second combustion chamber where extra methane is added to ensure the complete remotion of oxygen. The chamber combustion temperature is limited thanks to the large amount of $CO_2$ there is in the inlet steam. After this step, the humidity steam is reduced by condensation to reach a better operation of methane production.

### Renewable hydrogen production

The hydrogen is produced through water electrolysis and is the same for all alternative processes. Since it is proposed that the electricity used for electrolysis came from renewable energy sources such as wind or solar, the hydrogen produced can be considered green hydrogen. The water required for this operation is provided by the various drying operations throughout the system, minimizing the need for external water. Nowadays, several types of electrolyzers are available: Proton Exchange Membrane (PEM), Anion Exchange Membrane (AEM), Alkaline and Solid Oxide Ceramic (SOEC). Among them, PEM technology is selected due to the high purity of gases produced, its advanced commercial maturity and its short start-up time [7].

The electrolyzer generates two streams, one contains mainly hydrogen and the other contains oxygen. Both streams are subjected to a drying process to remove the residual water. The hydrogen stream is mixed with the $CO_2$ previously purified while the intended use of the oxygen depends on the analyzed process. The oxygen obtained under ordinary combustion process can be sold. However, the oxygen obtained under oxy-combustion process is used as a comburent in this process. In this way, the oxygen is completely integrated in the process.

### Methane production

The $CO_2$ stream, the hydrogen stream and the recirculation steam are mixed and compressed to reach the methanation reactor conditions. The methanation reactor is a fixed bed reactor with thermal control. A nickel-based catalysis is used. The reactions for methane production are shown below, eqs 2, 3, 4. The reactor behavior is modeled using equilibrium conditions. The typical temperature range is between 250 ºC and 400 ºC and the pressure is up to 20 bar [8].

$$CO + 3H_2 \rightleftarrows CH_4 + H_2O \quad (2)$$

$$CO_2 + H_2 \rightleftarrows CO + H_2O \quad (3)$$

$$CO_2 + 4H_2 \rightleftarrows CH_4 + 2H_2O \quad (4)$$

The outlet reactor stream is expanded into a gas turbine and cooled to remove water by condensation. As there is hydrogen in this stream, it is recovered and recirculated to the methane production by a membrane separation. Finally, the purified methane is sent to the CCPP combustion chambre, closing the cycle.

### Optimization procedure and Techno-economic analysis

The processes are modeled using mass and energy balances, thermodynamic equilibria, experimental data and rules of thumb and they are optimized to maximize the electricity production and minimize the energy consumption derived of the process. For this purpose, a NLP is solved for each of the suggested cases. The objective function is the same for all cases, see eq (1), and the objective is to maximize the electrical efficiency of the cycle. The problem is formulated as a MINLP, which is decomposed into three NLP. The first one modeled the process using ordinary combustion with absorption as the carbon capture technology. This model contains 1491 variables and 1279 equations. The second one also employs ordinary combustion but using adsorption with a PSA system for carbon capture, in this case 1045 variables and 1202 equations. Finally, the third one models the oxy combustion process, which contains 1379 variables and 1229 equations.

$$OBJ = Max\ (W_{generated} - W_{consumed}) \quad (1)$$

The capital cost of every piece of equipment is calculated with a function of a characteristic variable such as power for turbines or area for heat exchanges. This characteristic variable also indicates which option of equipment is the most suitable and if it is necessary to add a new unit because the capacity of the previous one is excesses. The investment cost is estimated from the unit costs using the factorial method [9]. To perform the scale-up analysis, the different Spanish CCPP capacities have been used. The Spanish CCPPs can be categorized into three distinct capacity ranges: 400 MW, 800 MW, and 1200 MW with small deviation. Each group of a CCPP typically has a capacity of 400 MW, which means that the different types of power plants usually comprise 1, 2, or 3 groups, respectively, although there are also groups with a capacity of 800 MW.

## RESULTS

The methodology has been applied to the Spanish CCPPs which are located in the peninsular territory, in total there are 30 plants. Figure 4 illustrates the evolution of electricity production cost for various groups of power plants when the oxygen generated as a byproduct during the electrolysis process is sold. Among the analyzed

processes, the most profitable is the ordinary combustion with absorption for carbon capture, followed by ordinary combustion process with PSA systems for carbon capture and finally oxy-combustion process.

A remarkable point of this figure is the significant impact of economies of scale on electricity production costs. Specifically, as the size of the groups of power plant increases, the production cost per unit of electricity decreases. Another important aspect is the important difference in electricity production costs between the ordinary combustion processes and the oxy-combustion process. For ordinary combustion processes, the electricity production cost ranges between 250 $/MWh and 300 $/MWh for CCPP groups with a nominal capacity of approximately 400 MW and between 90 $/MWh and 120 $/MWh for CCPP groups with a nominal capacity of around 800 MW. In contrast, the electricity production cost for oxy-combustion process is higher, approximately 470 $/MWh for 400 MW CCPP groups and 270 $/MWh for 800 MW CCPP groups.

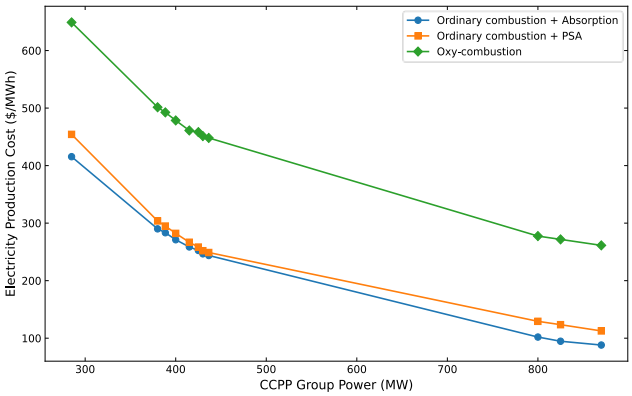

**Figure 4.** Comparation of electricity cost obtained with the different alternatives processes when the oxygen produced in the electrolyzer as subproduct is sold.

The reason for that big difference is due to the utilization of oxygen. In the oxy-combustion process, the oxygen produced during electrolysis is consumed completely for methane combustion, eliminating the option of selling it. In the ordinary combustion processes, it is assumed that all the oxygen generated as a byproduct is sold, which provides an additional revenue line that offsets the electricity production cost. This difference in oxygen utilization has a profound impact on the economic results of the processes, making the ordinary combustion configurations more cost-effective under these assumptions.

To take into account the effects of oxygen sales on electricity production costs, Figure 5 presents the costs under the assumption that the oxygen generated during the electrolysis process is not sold. In this scenario, the electricity production costs for the oxy-combustion process remain unchanged, as the oxygen produced in this process is already consumed entirely for methane combustion. However, the electricity costs for the processes based on ordinary combustion increase significantly, bringing them much closer to the costs of the oxy-combustion process. Without the additional revenue from selling oxygen, the cost advantage of these processes diminishes substantially. Figure 5 also shows an interesting trend for larger groups of power plants. Specifically, for groups with a nominal capacity exceeding 800 MW, the cost dynamics begin to change, and the oxy-combustion process emerges as the most profitable option. This suggests that, at larger scales, the oxy-combustion process offers significant economic advantages. However, only 7% of CCPP groups in Spain have a capacity higher than 800 MW, limiting the scope of this benefit.

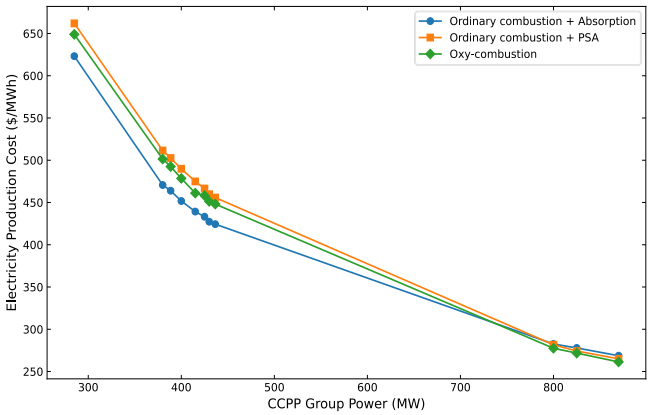

**Figure 5.** Comparation of electricity cost obtained with the different alternatives processes when any subproduct is sold.

The yields of this process have been calculated according to the following equations (5, 6, 7) and the results can be seen in Table 1.

$$\eta_{CCPP} = \frac{Power\ generated\ tubines\ CCPP}{LHV_{CH_4} \cdot F_{CH_4}} \quad (5)$$

$$\eta_{PtG} = \frac{LHV_{CH_4} \cdot F_{CH_4}}{W_{aux.met.} + W_{electrolyzer} + W_{carbon\ capture}} \quad (6)$$

$$\eta_{process} = \frac{Power\ generated}{Power\ consumed} \quad (7)$$

A typical CCPP usually achieves an efficiency ranging between 55% and 62% [10]. Processes based on ordinary combustion fall within this range, while the efficiency of the oxy-combustion process is lower. However, this trend is inverted when Power-to-Gas efficiency is analyzed. Although the oxy-combustion process requires the same hydrogen production as ordinary combustion processes, it eliminates the need for a carbon capture system, which improves the performance process. As a result, the best PtG efficiency results are achieved with oxy-combustion process (39.78%). The global efficiency of the processes analyzed is relatively similar, ranging

between 17.56% and 14.98%.

**Table 1:** Efficiencies of the processes.

| | Ordinary C. + Absorption | Ordinary C. + PSA | Oxy-combus-tion |
|---|---|---|---|
| $\eta_{CCPP}$ (%) | 65.39 | 65.65 | 43.28 |
| $\eta_{PtG}$ (%) | 32.56 | 34.06 | 29.68 |
| $\eta_{process}$ (%) | 18.14 | 20.88 | 11.65 |

## CONCLUSIONS

Different processes to integrate renewable energy with CCPP as energy storage systems are optimized and evaluated. The current CCPP could be part of this type of system by coupling the new sections of hydrogen production, carbon capture and methane production. Renewable energy (wind or solar) is employed to produce hydrogen by a PEM electrolyzer when there is an excess in the electric grid. Then it is mixed with CO2 purified to generate methane, which is again burned at the combustion chamber in the CCPP. The three processes are optimized and modeled using the first principles, thermodynamics equilibria, rules of thumb. Next, the cost estimation studies are performed and, finally, a scaling study using as base the capacity of the Spanish CCPP.

A large difference exists between the electricity production cost in ordinary combustion processes and oxy-combustion process. For a CCPP group with nominal power of 400 MW ordinary combustion processes reach a production cost of 250 -300 $/MWh and around 470 $/MWh for oxy-combustion processes. However, the difference is reduced when it is considered that oxygen cannot be sold, and the production cost is approaching the oxy-combustion ones.

The process global efficiencies are not particularly high (14.98% - 17.56%), but they demonstrate the potential of these technologies as a viable alternative for energy storage. This highlights the importance of future development and optimization of these processes to expand the number of options available for integrating renewable energy into the storage energy system.

## ABSTRACT

The aluminium industry emits approximately 1.1 billion tonnes of $CO_2$-eq annually, contributing about 2% of global industrial emissions. Decarbonization pathways aim to achieve net-zero emissions by 2050, but this requires making decisions today for technologies having lifetimes of 20 – 25 years, based on uncertain economic assumptions, particularly given the volatility of energy prices. Traditional price forecasting models often fail to anticipate major disruptions, such as the 2022 energy crisis. This work applies Monte-Carlo Analysis (MCA) to evaluate the financial stability of decarbonization pathways under energy crisis scenarios and report on the resilience of the alternative solutions. In the modelled secondary aluminium production facility, direct electrification is assumed for lower temperature furnaces of annealing heat treatments or preheating, while the study defines the decarbonization options based on the melter furnace technology, a key bottleneck in terms of load and viable technological alternatives with roof temperatures exceeding 1,000°C. In this study, four decarbonization pathways characterized by unique melting furnace solutions are analyzed, namely: an oxyfuel scenario using natural gas with carbon capture, a biomass-based approach relying on syngas, a hydrogen-based solution utilizing onsite electrolysis, and a plasma-based system with torches for melting. These options are compared to a natural gas baseline. Differences in electrification levels and reliance on imported energy sources result in varied economic resilience under price shocks that can occur during different times of the plant's life. Results obtained for a set of initial price levels at moderate or crisis energy price profiles revealed a more resilient oxyfuel scenario, followed by biomass utilization, and finally the all-electric scenarios utilizing either hydrogen or plasma. For instance, the oxyfuel option demonstrates a 54% probability of negative incremental Net Present Value (iNPV) with reference to the base case under both crisis and moderate price profiles. Conversely, the biomass scenario was found to have a 95-98% likelihood of economic loss under similar conditions while the all-electric solutions were at 100% likelihood of loss regardless of the initial price or profile. This is because electricity prices start at a higher baseline than combustible fuels and spike dramatically during crisis events. This analysis highlights the importance of considering energy price volatility and the need for diversified energy sources when developing decarbonization strategies for the aluminium industry.

## INTRODUCTION

Increasing global warming effects have urged heavy industries to actively reduce greenhouse gas (GHG) emissions, targeting net zero by 2050. The aluminium sector emits approximately 1.1 billion tonnes of GHG

annually, representing 2% of global industrial emissions [1]. The primary energy source for aluminium remelting furnaces is fossil natural gas; while rolling processes consume electricity whose embodied emissions depend on geographical location. Decarbonization strategies for aluminium include biomass gasification, power-to-gas, direct electrification of furnaces, and carbon capture. While most of these technologies have lifetimes of 20 – 25 years, decisions on their installment must be made during the early stages of design. Prices and future availability of utilities depend on many economic and geopolitical inter-related aspects. Another influencing value is the cost of continuing to emit GHG which could directly translate to an imposed carbon tax [2] or a defined social cost of negatively impacting the environment [3]. Hence, future uncertainty in energy prices must be accounted for in today's decisions.

Price forecasting models, while useful, are often inaccurate, failing to account for significant events like the 2022 energy crisis [4–6]. Historical data shows that predictions can significantly underestimate or overestimate actual prices due to unpredictable market factors. This is because the market is not only a function of demand and supply but is also dependent upon numerous geopolitical factors which are simply unpredictable in the long term. Nonetheless, prices are a major influencing factor on decision-makers' choices towards industry decarbonization, which necessitates the development of a systematic methodology to deal with such uncertainty.

Monte-Carlo analysis (MCA) is a stochastic mathematical technique for global sensitivity and risk or uncertainty evaluations. It is mainly used to quantify the simultaneous impact of various parameters on a performance indicator using hundreds of thousands of model inputs. One study used MCA to explore decarbonization strategies in the steel industry [7]. The authors used MCA to examine the effects of factors such as hydrogen prices, the investment costs of reduction furnaces, and associated emissions on the adoption of hydrogen in steel production. Their analysis identified hydrogen price as the most critical factor. Similarly, another study evaluated the impact of natural gas price uncertainty on the economic feasibility of offshore power hubs with carbon capture systems for Floating Production, Storage, and Offloading facilities (FPSOs). By generating stochastic price profiles, the researchers calculated incremental net present values (iNPVs) for various configurations and found that profitability was highly sensitive to operational delays, as longer delays increased the likelihood of losses due to opportunity costs and depreciation [8]. Similarly, MCA could be used in evaluating the economic stability of different decarbonization configurations developed for the aluminium industry. In this regard, this work adopts stochastic and deterministic methodologies to more accurately model the effect of energy price uncertainty, especially during times of economic crisis, on potential decarbonization pathways for secondary aluminium production. The work integrates Process Systems Engineering (PSE) methodologies by combining mixed-integer linear programming (MILP) with MCA to evaluate uncertainty in industrial energy systems. The developed framework provides a systematic approach for assessing economic risk in decarbonization pathways, offering a decision-support tool based on PSE principles for process optimization under uncertainty.

## METHODS

The methodology developed in this work starts by modeling a typical secondary aluminium production plant and a set of energy conversion systems associated with different decarbonization pathways within the OSMOSE platform [9]. Herewith, a MILP optimization approach is applied to generate a list of optimal system configurations under specified economic scenarios using a defined set of current energy price levels. Finally, MCA is performed to estimate the probability of each solution incurring higher costs than the base case over a 25-year lifetime, incorporating random price fluctuations and crisis-like price profiles. This hybrid deterministic-stochastic approach aligns with PSE methodologies, enabling more robust decision-making in the face of industrial uncertainties.

First, a typical secondary aluminium production process is modeled based on Novelis' production facility in Sierre, Switzerland, consisting of a cast house, and a rolling mill for subsequent treatment and coil rolling [10]. The process begins with preheating pure aluminium ingots to around 250°C in the preheater, to prevent explosion risks during melting, this step accounts for approximately 5% of the plant's total natural gas consumption. In the melter, where around 49% of the facility's natural gas is consumed, pure and scrap aluminium are melted at approximately 660°C and then superheated to 700°C. The holder furnace, which uses 4% of the plant's natural gas, acts as a buffer for the direct chill casting (DCC) process, where the aluminium solidifies gradually by dissipating heat into a water sink. The cast ingots undergo surface treatment before being sent to the pusher furnace for annealing, which consumes 25% of the plant's natural gas, followed by hot and cold rolling processes. Finally, the coils are subjected to further heat and chemical treatment in the annealing continuous line (ACL), which accounts for 17% of the natural gas consumption. While conventional facilities rely on fossil natural gas to fuel these furnaces, several decarbonization alternatives can be explored, utilizing diverse energy sources. This work evaluates several of these alternatives. A simplified schematic of the potential decarbonization options is presented in **Figure 1**. The energy conversion technologies and furnaces were modeled in detail using software tools

such as Aspen Plus®, supplemented by data from industrial system audits and commercial technology specifications. All optimized scenarios, except the base case, employ fixed electrification solutions for the preheating, annealing, and holding furnaces. Thus, the optimization focuses on the melter furnace, identified as the technological bottleneck in decarbonizing secondary aluminium production. The following scenarios define the range of solutions explored:

1. **Base Case:** This represents the current baseline operation of the plant, where all furnaces rely on fossil natural gas combustion.
2. **Oxyfuel CCS:** Implements an oxyfuel combustion system for the melter furnace, where natural gas is burned in oxyfuel burners, followed by post-combustion carbon capture and sequestration through transportation and injection. Oxygen for the process is supplied by an on-site air separation unit (ASU).
3. **Bio-Syngas:** Utilizes oxyfuel combustion of bio-syngas, a mixture of CO, $H_2$, and $CO_2$ gases, produced via on-site biomass gasification for the melter furnace. Oxygen is supplied using an on-site ASU.
4. **Hydrogen:** Employs air combustion of hydrogen in the melter furnace, with hydrogen generated on-site using a proton exchange membrane (PEM) electrolyzer.
5. **Plasma:** Adopts an electric aluminium melting solution using plasma torches for the melter furnace, with nitrogen plasma gas supplied via an on-site ASU.

This structured approach ensures that each decarbonization pathway addresses the specific challenges posed by the melter furnace while considering diverse energy resources and technologies.

Furthermore, MCA is applied to assess the economic feasibility of these defined decarbonization pathways for aluminium production compared to the natural gas-based baseline (Base Case). Two modes of price evolution are modeled: moderate price trends, representing natural market fluctuations, and crisis scenarios, simulating sudden price spikes followed by gradual recovery. An example of the generated price profiles is illustrated in Figure 2 (moderate trends) and Figure 3 (crisis scenarios).

**Table 1:** Initial energy prices and crisis mode multipliers

| Resource | Initial Price | Peak multiplier |
|---|---|---|
| Natural gas | 0.04 (€/kWh) | 7 |
| Electricity | 0.10 (€/kWh) | 3 |
| Biomass | 0.06 (€/kWh) | 3 |
| $CO_2$ tax | 100 (€/t$CO_2$) | N/A |

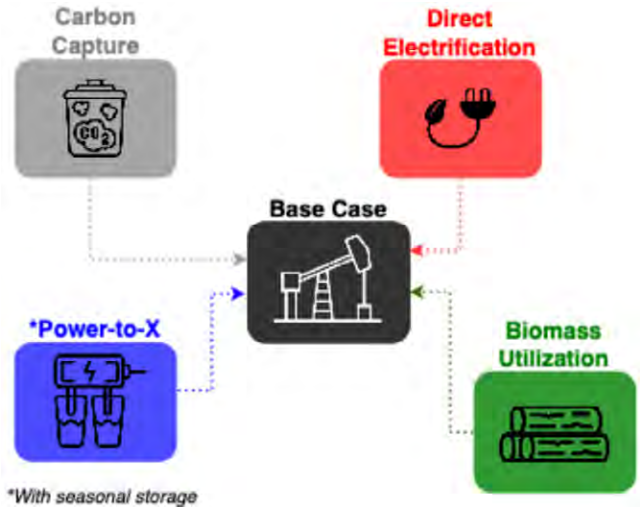

**Figure 1.** Simplified schematic of aluminium decarbonization scenarios investigated in this work.

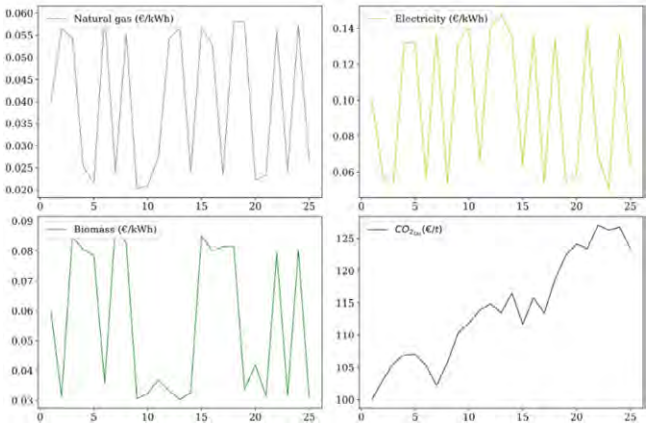

**Figure 2.** MCA sample of a set of stochastic energy price profiles over a lifetime of 25 years.

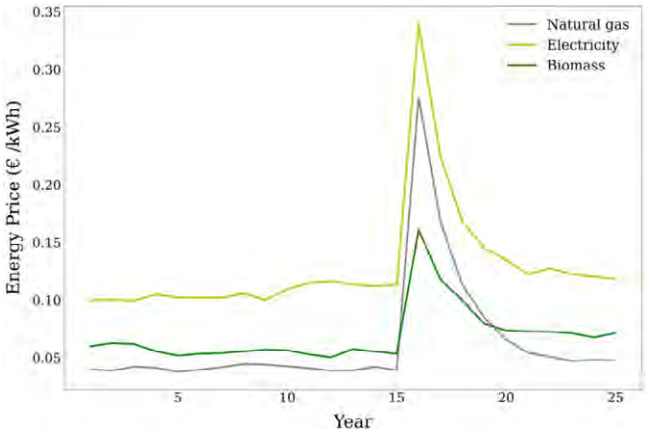

**Figure 3.** MCA sample of a set of energy price shock profiles over a lifetime of 25 years.

## Initial Price Trends and Profiles

The simulation begins by defining initial energy and commodity prices for key resources, as shown in Table 1.

Next, price evolution is modeled as follows:

1. **Moderate Price Trends:** Prices fluctuate annually based on a normal distribution with a 5% standard deviation around the previous year's price. These profiles represent natural market dynamics without major disruptions and are shown in Figure 2.
2. **Crisis Scenarios:** A random crisis year is selected between years 2 and 20. During this year, prices experience sudden spikes, defined by resource-specific peak multipliers. Prices then gradually stabilize post-crisis at levels 20% higher than the initial price. An example of these crisis-induced profiles is illustrated in Figure 3.

The price profiles in this study are generated using pseudo-random numbers sampled from statistical distributions implemented by Python's NumPy random number generator. The following equations provide more insight into how the profiles are generated:

- **Moderate Trends:**

$$P_y = P_{y-1} \cdot (1 \pm random\ variation) \quad (1)$$

In this case, the random variation is sampled from the range defined by `varin=(0.3, 0.5)`, representing deviations of 30% to 50% of the initial or previous year's price. This range ensures variability while maintaining realistic fluctuations in the moderate trend profiles. Additionally, for each resource price profile, a trend probability parameter ($P_{trend}$) determines the likelihood of following a predefined trend. In the current simulation, $P_{trend} = 0.5$, meaning there is a 50% probability that the price will follow the specified trend ("up," "down," or "none"). The remaining 50% of the time, prices deviate randomly, ensuring variability in the generated profiles.

- **Crisis Mode:**

o Pre-crisis:

$$P_y = P_{y-1} \cdot Normal\ (1, 0.05) \quad (2)$$

Smaller fluctuations in prices before the crisis are modeled using random multipliers sampled from a normal distribution $Normal\ (1, 0.05)$, which ensures prices fluctuate around the previous year's value with a mean of 1 and a standard deviation of 0.05, reflecting natural market variability.

o Crisis year:

$$P_y = P_{y-1} \cdot Peak\ multiplier \quad (3)$$

During the crisis year, prices experience sharp spikes, modeled using predefined peak multipliers (e.g., 7 for natural gas, 3 for electricity, and 2 for biomass).

o Post-crisis:

$$P_y = P_{y-1} - (P_{y-1} - P_{post-crisis}) \cdot Decline\ Rate \cdot Normal\ (1, 0.05) \quad (4)$$

After the crisis, prices gradually stabilize toward a defined post-crisis level, calculated as a fixed percentage above the initial price (e.g., 20% higher, as set in this simulation). The decline rate, set to 0.5, in this case, controls how quickly prices approach the post-crisis level.

## Cost Calculation and NPV Evaluation

For both modes, the Base Case and decarbonization scenarios are evaluated as follows for the defined parameters listed in Table 2:

1. **Annual Cost Profiles:**
   - o Resource costs (natural gas, electricity, etc.) are multiplied by respective consumption flows to calculate operational expenses (OPEX).
   - o Capital expenditures (CAPEX) are distributed as 60% in the first year and 40% in the second year.
2. **Net Present Value (NPV):**
   - o Total Expenditures ($TOTEX_y$) include CAPEX and OPEX for each year.
   - o Discounted cash flows are calculated using:

$$NPV = \sum_{y=1}^{N} \frac{TOTEX_y}{(1+i)^y} \quad (5)$$

   where $i = 6\%$ is the discount rate.
3. **Incremental NPV (iNPV):**
   - o $iNPV = NPV_{decarb} - NPV_{base\ case}$
   - o The likelihood of loss ($iNPV < 0$) is calculated over 10,000 Monte Carlo iterations.

**Table 2:** Simulation settings for both moderate and crisis modes

| Parameter | Value |
|---|---|
| Discount rate (i) | 6% |
| Plant lifetime (N) | 25 years |
| Annual Operating hours | 8,760 h |
| Monte-Carlo iterations | 10,000 |

By combining moderate and crisis price profiles, the approach quantifies the economic stability of decarbonization pathways, highlighting the influence of market volatility and extreme price shocks on incremental net present value. This dual-mode simulation provides a probabilistic framework for decision-making under uncertainty.

# RESULTS

First, the performance of the defined decarbonization routes is assessed relative to the Base Case. **Figure 4** illustrates the energy load distribution and the equivalent carbon footprint (including scope 1 and 2 emissions) for the various alternatives. Among the scenarios, the

Bio-Syngas route achieves the lowest carbon footprint, at approximately -2.80 $kgCO_2/tAl$, due to the net-negative impact of sequestering biogenic carbon used in the melter furnace. The all-electric options result in a footprint of around 30 $kgCO_2/tAl$, primarily driven by the indirect emissions associated with the electricity grid. In contrast, the Oxyfuel CCS scenario has slightly higher emissions, at approximately 55 $kgCO_2/tAl$, which is attributed to both indirect electricity emissions and loss of some direct $CO_2$ during furnace operation prior to capture.

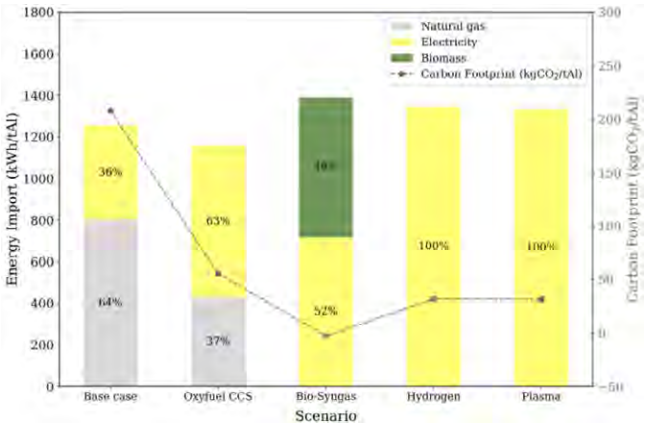

**Figure 4.** Energy load distribution and equivalent carbon footprint of aluminium decarbonization options.

Next, the iNPVs of the different scenarios are evaluated for both moderate and crisis price fluctuations over 10,000 Monte-Carlo samples and the resulting distributions are plotted in **Figure 5**. It is evident that moderate price fluctuations generally result in broader iNPV ranges than crisis price profiles while the average iNPV value for both modes is observed to be similar. The Oxyfuel CCS is the least economically volatile solution at a 54% likelihood of loss regardless or moderate or crisis modes, followed by the Bio-Syngas option at around 95-98% likelihood of loss. Both electrification solutions are significantly negative in terms of iNPVs with reference to the natural gas driven base case. With a 100% likelihood of loss quantifying the economic risk associated with complete electrification.

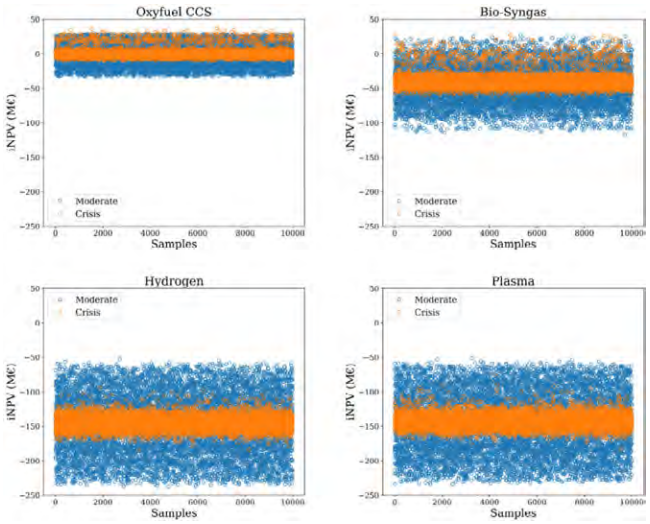

**Figure 5.** Resilience comparison of the decarbonization options in case of moderate or crisis price profiles.

To better understand the statistical distribution of iNPV results**, Figure 6** presents a box plot of iNPVs for the different decarbonization scenarios, highlighting the variability under moderate and crisis conditions. The boxes represent the interquartile range (IQR), while data points outside the whiskers, calculated as values smaller than Q1–1.5×IQR or larger than Q3+1.5×IQR, are considered outliers and plotted as dots. The outliers observed in the iNPV distributions, particularly under crisis scenarios, are closely linked to the timing of energy price spikes and their impact on operational costs. Both higher-than-average and lower-than-average outliers tend to occur when the crisis happens early in the project lifetime, specifically in Year 2. This timing coincides with a period where discounting effects are less pronounced, which intensifies the influence of energy price volatility on economic performance outcomes. The exact reasons for the dual behavior, positive and negative outliers, remain complex and may depend on several factors, including the severity of the spike, the recovery rate of energy prices, and other influential aspects. This result, however, highlights Year 2 as a critical period where energy price dynamics have an exaggerated impact on iNPV.

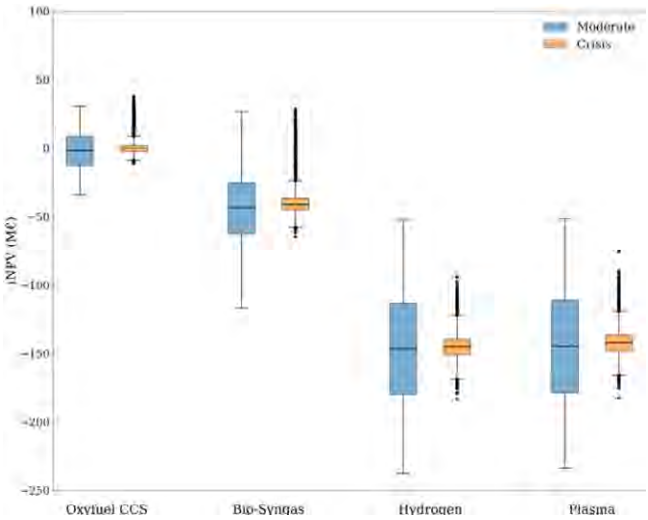

**Figure 6.** Box plot distribution of the likelihood of loss results for the decarbonization options.

Due to the apparent coupling of natural gas and electricity prices the economic risk for the Oxyfuel CCS solution seemed to remain constant at 54% for a fixed set of initial energy prices no matter the mode of energy price profiles (moderate or crisis). Hence, a sensitivity analysis over the likelihood of loss when varying initial prices of electricity and $CO_2$ tax was conducted following moderate price fluctuations. From **Figure 7**, it is seen that the breakeven initial $CO_2$ tax for this solution increases from around 170 €/t$CO_2$ for cheaper electricity (at an initial price of 0.1 €/kWh$_{EE}$) to 380 €/t$CO_2$ at double the initial electricity price following a directly proportional correlation.

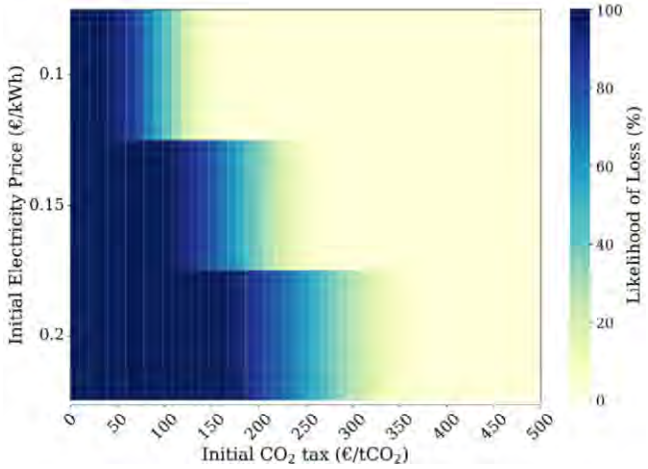

**Figure 7.** Economic risk of the Oxyfuel CCS configuration as a function of the initial values of $CO_2$ tax and electricity price.

## CONCLUSION

This study highlights the critical role of economic uncertainty and energy price volatility in shaping the viability of decarbonization pathways for secondary aluminium production. By combining Monte Carlo Analysis with mixed-integer linear programming, the work leverages PSE tools to provide key insights into the resilience of various technological configurations under moderate and crisis scenarios. The findings emphasize that decarbonization strategies heavily reliant on electricity are particularly vulnerable to price shocks, leading to a 100% likelihood of economic loss compared to the natural gas baseline. In contrast, the Oxyfuel CCS scenario exhibits greater economic resilience, maintaining a constant 54% likelihood of loss across both modes of price evolution, suggesting its potential as a transitional pathway. However, these conclusions must be taken with caution as they are heavily influenced by the low initial natural gas price of 0.04 €/kWh, mainly due to fossil subsidies, which currently makes it a more economically favorable energy source. If renewable electricity becomes significantly cheaper in the future, the relative economic performance of electrification-based solutions could improve, shifting the results of this comparative evaluation. This work provides a probabilistic framework to guide policymakers and industry stakeholders in navigating market uncertainties and emphasizes the importance of preparing diversified and adaptive decarbonization strategies.

## ACKNOWLEDGEMENTS

The authors would like to thank the Net Zero Lab consortium for funding this work in the context of the project goals of decarbonizing secondary aluminium production.

## ABSTRACT

Heat pumps play a crucial role in decarbonizing the chemical industry. The integration and sizing of heat pumps in chemical processes is a challenging task in multi-product chemical processes due to the fluctuating waste heat supply and heat demand. Integrating heat pumps may require a retrofit of the utility system. Mathematical optimization is a useful tool to tackle this challenge by enabling the analysis of correlation between relevant system parameters and equipment sizing. This study demonstrates the utilization of mathematical optimization and parameter studies for utility system equipment sizing addressing fluctuating heat supply and demand profiles.

**Keywords**: Energy Systems, Batch Systems, Optimization, Renewable and Sustainable Energy, Energy Storage

## INTRODUCTION

To achieve the goal of climate neutrality by 2045, Europe must cut down $CO_2$ emissions significantly [1]. This initiative directly impacts the chemical and pharmaceutical industries, which account for a substantial share of energy usage and related $CO_2$ emissions [2]. One potential approach to lower these emissions is the electrification of chemical and pharmaceutical processes, ideally powered by renewable electricity with a smaller carbon footprint, for instance, through the integration of heat pumps [3]. Pharmaceutical processes are often multi-product plants where heat is supplied using heating and cooling circuits. In these cases, heat is supplied centrally to the utility system. When integrating heat pumps, not only the correct sizing of the heat pump must be determined but also a possible retrofit of the utility system, additional components such as heat storages and backup systems and optimal operation must be considered. This results in a complex integration problem. Mathematical optimization is a method that can solve complex problems like the aforementioned. Different problem types have been solved in the context of utility system optimization for chemical processes. The scope of this paper is to give a brief overview of mathematical optimizations in different applications of utility systems. We further analyse optimal equipment sizing for a utility system in a multi-product plant with fluctuating waste heat supply and heat demand. By using mathematical optimization and parameter studies, we analyse the correlation between system parameters such as specific investment cost or heat profile characteristics and equipment sizing.

## LITERATURE REVIEW

The optimization of utility systems without the integration of heat pumps is a topic that has been extensively studied. A utility system should deliver mostly electricity and heat. Papoulias and Grossmann developed a MILP to minimize costs of a utility system that provides electricity and steam in the context of a chemical plant and to derive the optimal structure of equipment and operation [4]. Other work included nonlinear equations of cost functions and operational constraints, resulting in a MINLP for optimizing the utility system [5]. Mitra et al. optimized operation of an existing utility system under fluctuating electricity prices. Solving the resulting MILP requires precise knowledge of the flexibility parameters of the components. [6]

Several studies also optimize the design and

operation of utility systems including heat pumps with respect to minimizing costs. Bischi et al. linearized non-linear performance curves of equipment to minimize costs using a MILP [7]. Baumgärtner et al. developed a model for a low-carbon utility system incorporating heat pumps. By accounting for time-dependent emission factors, a MILP was employed to analyze the trade-off between economic and environmental impacts. [8] Prendl et al. examined the sizing and operation of a heat pump and heat storage within heat exchanger networks, aiming to minimize total annual costs using a MILP [9].

As previously mentioned, integrating heat pumps into chemical processes poses significant challenges. It may be worthwhile looking at different sectors which also implement heat pumps in their utility system to find possible analogies. One such sector is the residential sector where various methods for heat pump integration and equipment sizing are studied, including mathematical optimization. Molyneaux et al. solved the problem of choosing between centralized and decentralized heat pump integration for district heating in residential buildings using a multi-objective optimization. They compared different systems using multi-objective optimization regarding economic and ecological parameters. [10] Rinaldi et al. determined the optimal size of a system which includes photovoltaic, battery storage and a heat pump for residential buildings by minimizing the total cost. The heat pump enables the system to increase the utilization of electricity generated by the photovoltaic system. Furthermore, the heat pump can be operated flexibly to reduce operating costs, leveraging the building's thermal inertia, as heat only needs to be provided over the course of the day rather than at specific times. [11] Renaldi et al. also analyzed a residential heating system including a heat pump and a thermal storage, by minimising the total costs using a MILP. They considered flexible heat pump operation with upper and lower operating bounds for the heat pump. [12]

A few optimisation approaches compare the solution of mathematical optimization with rules of thumb. Alay et al. use a mathematical approach to optimize the design of a hybrid ground source heat pump for different case studies. The results of the optimization have been compared afterwards with an existing rule of thumb regarding the percentage of the total heat demand covered directly by the heat pump. It became evident that results of the optimisation could not confirm the rule of thumb but rather also vary in a range for different case studies. Furthermore, they highlighted that rules of thumb are often restricted to a specific sector, as general conditions, such as the ratio of cooling to heating, can vary significantly depending on the sector. [13] Fischer et al. examined existing heuristic sizing methods of thermal energy system components like heat pumps and heating storage depending on the operation mode of the heat pump (monovalent, monoenergetic and bivalent). They applied mathematical optimization to minimize total cost for different case studies in the residential sector, taking variable electricity prices into account and compared the results with the heuristic rules. They found sufficient agreement between the heuristic-based design and mathematical optimization approach. Moreover, they underline that the heat demand profile has the greatest impact on sizing. [14]

This further motivates investigating the impact of heat profiles on component sizing within other sectors, such as the chemical industry. In non-continuous chemical processes in particular, the heat demand profiles are not as characteristic as in the building sector and can therefore present an additional challenge for deriving sizing methods for heat pumps. In order for heat pumps to be integrated in chemical processes such as non-continuous processes, their flexibility parameters must be available. Sadjjadi et al. underline the importance of developing methods for sizing and operational strategies of large-scale heat pumps for industrial applications [15]. Part-load efficiencies are relevant to model the flexibility of heat pumps. However, Xu et al. point out that there is no uniform standard for part-load efficiency calculations of heat pumps [16]. Walden et al. used an approach to determine heat pump part-load efficiency by taking the individual component part-load efficiencies into account. They compared this approach to a standard approach which calculates the part-load efficiency by means of a degradation coefficient. [17]

This brief literature review illustrates that equipment sizing for processes requiring flexible operation, such as non-continuous chemical processes, presents a significant challenge. Mathematical optimization proves to be a valuable method to address this complexity, and to analyze the impact of fluctuating heat supply and demand profiles on equipment sizing and operation while incorporating the flexibility characteristics of components.

## PROBLEM STATEMENT

Using mathematical optimization in combination with robust parameter studies allows for the sizing equipment of a utility system and is applied to an application in a multi-product chemical process with resulting fluctuating waste heat supply and heat demand in this work.

To analyze the impact of fluctuating waste heat supply and heat demand, an exemplary scenario has been analyzed as depicted in Figure 1. This can be a typical energy supply system to multiple batch processes with fluctuating heat and cooling demand. Batch operated processes often require heating and cooling intervals following fixed patterns to produce the desired product. These patterns can vary for different products considering heating and cooling duties as well as their duration.

Additionally, batch plants can be multi-product plants without fixed production schedules which can lead to further fluctuations in heat supply and demand.

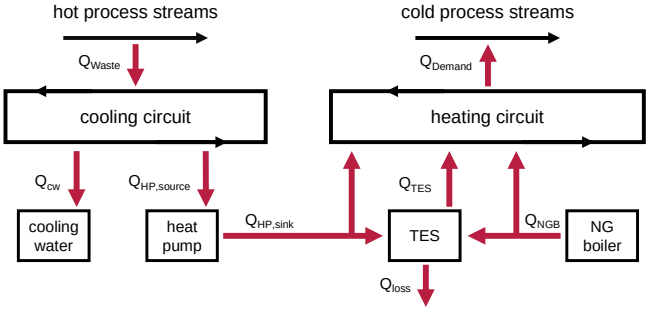

**Figure 1.** Schematic of the examplary utility system.

We assume a brownfield scenario for the chemical process side where heat is supplied to cold process streams using a heating circuit at a supply temperature of maximum 105 °C e.g. through thermal oil or steam. A cooling circuit is used to collect waste heat from the processes at a return temperature of minimum 25 °C e.g. through thermal oil or cooling water. We assume the holdup in the system to be in the range of 15 minutes. To ensure normal operation, the energy demand of the process system must be met by the energy supply for every 15-minute period. The necessary heating and cooling duties are supplied centrally to the heating and cooling circuits.

For the utility side, three technologies are available for a new investment. Firstly, a natural gas boiler which can be used to supply heat to the heating circuit by burning natural gas. Secondly, a vapor compression heat pump which can be used to upgrade waste heat from the cooling circuit to the heating circuit by using electricity to drive the compressor. Lastly, a thermal energy storage can be used to store thermal energy supplied by the natural gas boiler or heat pump and supply it to the heating circuit.

We use a synthetic profile with fluctuations around a mean to emulate a fluctuating heat demand and waste heat profile. The fluctuations are evoked by normally distributed random noise and small and large spikes with normally distributed random amplitude and time between spikes. These fluctuations are assumed to result from fluctuating heating and cooling demand from process streams which must be met by the different utility components. Although we assume a multi-product batch system on the process side, we assume the heating and cooling demand to follow similar patterns. Thus, the cooling duty profile differs from the heating duty profile only by assuming a lag of 15 minutes, as shown in the supplementary material.

## MODEL FORMULATION

The impact of fluctuating demand profiles on equipment sizing was examined using a MINLP to determine the minimum total annual cost. For this purpose, we used simple energy balance models that incorporate efficiency correlations and operational constraints for all components of the utility system. This reduces computational effort and allows for a general system comparison without technology specific characteristics. Including operational expenditure and investment cost allows for minimization of total annual costs. The equations used to model the utility system as well as underlying operational constraints are described in more detail in the following sections and in the supplementary material.

### MINLP

The MINLP formulation minimizes the objective function $c$ subject to sets of linear and nonlinear equality and inequality constraints, represented by $g$ and $f$, respectively. The decision variables include binary variables $x$ and continuous variables $y$.

$$\min_{x,y} c(x,y) \tag{1}$$
$$\text{s.t. } g(x,y) = 0$$
$$f(x,y) \leq 0$$
$$x \in \{0,1\}^m,\ y \in \mathbb{R}^n$$

The component and system constraints must be satisfied for each time interval $t$. Since energy supply and demand must be balanced in 15-minute intervals, this condition applies to every 15-minute timestep within the optimization time horizon of 48 hours.

### Heat Pump

We consider the heat pump (HP) to be a closed-cycle mechanical vapor compression HP. It can be operated with load flexibility concerning its sink duty $\dot{Q}_{HP,sink}(t)$ in a range of 40-100% of the nominal sink duty $\dot{Q}_{HP,sink,nom}$. A constant part-load efficiency is assumed by using a constant coefficient of performance (COP).

To account for operational constraints, we used minimum uptime and downtime constraints. We used binary variables to indicate startups and shutdown and summation constraints to ensure minimum uptime and downtime of the HP. Additionally, we added constraints on the time between load shifts of the HP to account for real world operational challenges during load shifts.

### Natural gas boiler

For the natural gas boiler (NGB), we used a simple model consisting of boiler efficiency ($\eta_{NGB}$) as well as the same operational constraints as for the HP. The duty of the NGB $\dot{Q}_{NGB}(t)$ is allowed to range from 20-100% of the

nominal duty $\dot{Q}_{NGB,nom}$. Again, we assume no decrease in efficiency during partial load.

The same operational constraints were applied for the NGB as for the HP. Binary variables indicate startup and shutdown of the NGB as well as load changes. Limitations for minimum uptime, minimum downtime and time between load changes were implemented analogically. This was done due to a lack of experimental data as well as the motivation to compare different heat supply system configurations instead of a detailed technological comparison. This also ensures that no unbiased preference is given to one component over the other. It follows that the primary distinction between the heat pump and natural gas boiler is the heat pumps supply of cooling duty and different efficiencies for heat supply.

### Thermal energy storage

The simple energy model for the thermal energy storage (TES) includes charging ($\eta_{TES,ch}$) and discharging efficiencies ($\eta_{TES,dis}$) to account for non idealities during charging and discharging. The energy level at the beginning and at the end of the time horizon of optimization is assumed to be 50% of the maximum storage capacity. Moreover, we assume an operating range of 0-100% of the nominal capacity of the TES ($C_{TES,nom}$). The charging and discharging rates of the TES are limited in correlation to the nominal TES capacity. Heat loss $\dot{Q}_{TES,loss}(t)$ to the environment was modeled as a linear efficiency of the actual storage level $C_{TES}(t)$ and efficiency factor $\eta_{TES,loss}$.

### System

The heat demand $\dot{Q}_{heating}(t)$ given by the fluctuating demand profile must be provided to the heating circuit by a combination of the three possible components HP, NGB and TES. Similarly, the waste heat $\dot{Q}_{cooling}(t)$ must be removed from the cooling circuit either by the HP or through cooling water $\dot{Q}_{cw}(t)$. It follows that the HP is limited by the waste heat supply.

### $CO_2$ emissions

As costs for $CO_2$-emission certificates are rising significantly and are expected to still rise in the future, we considered $CO_2$-emissions during operation of the HP and NGB, $e_{HP}(t)$ and $e_{NGB}(t)$ respectively. For the heat pump we used emission factors for electricity $EF_{CO_2,el}$ assuming the compressor is driven by electricity. Likewise, the emission factor of natural gas $EF_{CO_2,NG}$ was used for calculating the emissions of the NGB.

### Cost functions

The minimization of total annual costs (TAC) requires the consideration of operating expenditure (OPEX) as well as investment cost (CAPEX). We are assuming that all components are greenfield and use specific cost factors $f_{inv,i}$ for the HP, NGB and TES. We do not consider operating costs for the TES and only consider costs for $CO_2$-emissions, the required electricity of the heat pump, natural gas as well as costs for cooling water.

## CASE STUDIES

The MINLP has been solved in Python using Gurobi [18]. In the first case study (CS 1), current cost factors for equipment and operation have been used to find the optimal equipment sizing. The profile and cost parameters as well as operating limitations are shown in the supplementary material. Equipment sizing is significantly impacted by the economic parameters as well as the parameters affecting component flexibility. In the case of CS 1, the operational cost of the natural gas boiler combined with costs for cooling water are lower than the operational costs of a heat pump.

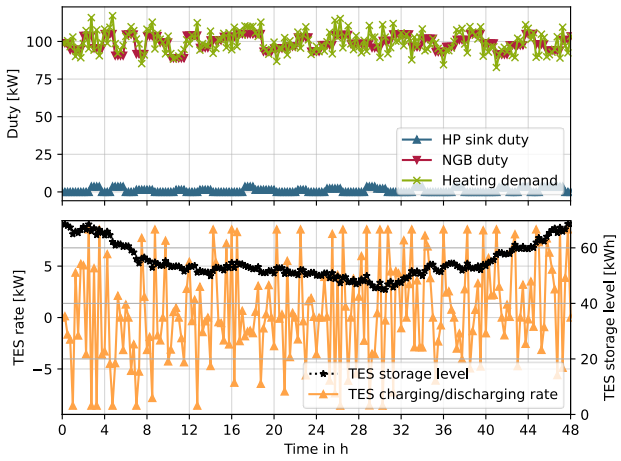

**Figure 2.** Operation and sizing results for CS 1.

Nevertheless, a small heat pump is used to improve the flexibility of the system as shown in Figure 2. NGB and HP are both constraint to a maximum of one load change per hour. With a fluctuating heat demand changing every 15 minutes, this results in heat surplus or heat deficit supplied by the NGB and HP. This mismatch of heat supply and demand can be reduced by shifting the load changes of the HP to time periods where no load shift is allowed for the NGB and vice versa. The remaining mismatch is met by charging and discharging the TES. This subsequently leads to the required storage size. The maximum allowable charging and discharging rates are a function of the nominal storage capacity. Thus, the required storage capacity is directly influenced by the fluctuating heat demand and the flexibility of the other components. In case of no restrictions on load changes of HP and NGB, no TES might be required. On the other hand, with fewer load changes allowed, the required storage capacity increases. Moreover, it is evident that the TES is operated such that the storage level is lower than the

starting and ending level. This is likely because the thermal energy loss is a function of the current energy stored in the energy storage. By reducing the energy stored in the storage, the energy loss is reduced.

In case study 2 (CS 2), we conducted a parameter study to determine the effect of varying specific HP investment cost on equipment sizing. As shown in Figure 3, for low specific investment costs, the heat pump is preferred over the natural gas boiler. The TES is used to buffer the supply and demand mismatch which result from load change restrictions of the HP. High specific investment cost led to a small HP design. This requires higher TES capacity to buffer the mismatch between heat supply and demand, because load changes of the HP only have a small contribution. In cases where the operational and investment costs of the HP exceed those of a NGB, the HP may nonetheless be favored due to its ability to provide cooling services. This characteristic contributes to a reduction in costs associated with cooling water consumption.

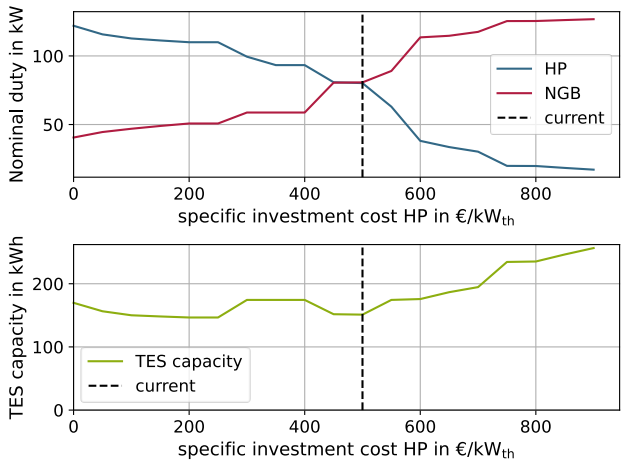

**Figure 3.** Impact of specific HP investment cost on equipment sizing.

To further examine the impact of different economic and profile parameters on equipment sizing, we conducted a parameter study in case study 3 (CS 3). The sensitivity parameter ranges are shown in the supplementary material. As depicted in Figure 4, there is a strong correlation between the standard deviation of the demand profile and the required capacity of the TES. For cases with restrictions on load shifts for the HP and NGB, the TES is required to buffer the resulting mismatch between heat supply and demand. For current price ratios of electricity to natural gas and lower investment cost of the NGB favor the NGB over the HP. The TES is required to buffer the mismatch between heat supply and demand resulting from load shift limitations of the NGB. As shown in Figure 4, for a price ratio of 1.5, the HP has lower operational costs and is therefore preferred over the NGB. With increasing standard deviations, the NGB and TES are utilized to buffer profile fluctuations. At a standard deviation of around 33, a new trend can be identified. The nominal heat duty of the NGB increases significantly and the required TES capacity is reduced. In profiles with standard deviations greater than 33, low waste heat supply and peaks in heat demand appear at the same time. In these cases, the HP can not be used to supply heat which requires the NGB and TES to buffer the mismatch. The NGB requires lower investment costs for the same output heat duty than the TES and is therefore preferred over the TES.

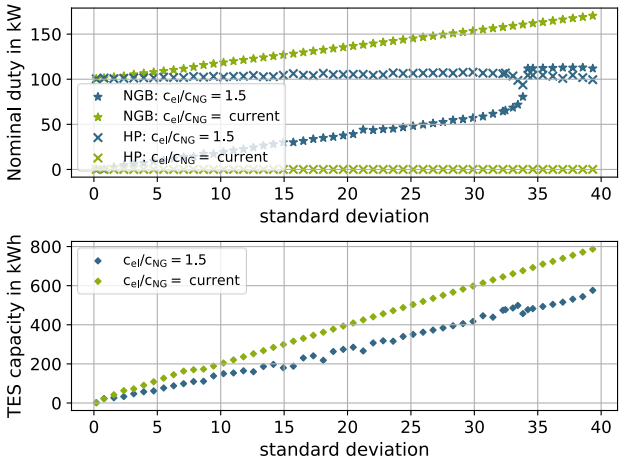

**Figure 4.** Correlation between the standard deviation of the demand profile and nominal TES capacity for different ratios of operating costs.

## CONCLUSION

In the present study, we analyzed the impact of fluctuating waste heat supply and heating demand in the context of chemical processes on utility equipment sizing. It is evident that equipment sizing is a complex task which is affected by many different aspects such as profile and cost parameters as well es equipment constraints. Parameter studies may support understanding the dependencies in a utility system and identifying economically feasible conditions. They can also help in identifying change points in optimal solutions e.g. for different degrees of fluctuations in the demand profile.

From our view, it is important to conduct further research on equipment flexibility parameters, since equipment sizing for fluctuating profiles is significantly dependent on equipment flexibility. Moreover, different types of profile fluctuations can be studied such as step profiles and seasonal profiles. Comparing statistical parameters of real-world profiles and synthetic profiles or combinations of synthetic profiles may help in qualitatively identifying the best combination and sizing of equipment.

## ABSTRACT

Hydrothermal liquefaction (HTL) has proven to be an appropriate technology for converting sewage sludge into a valuable resource for renewable energy generation. This study focuses on a prospective analysis of various technological scenarios for sewage sludge-to-fuel pathways via HTL, co-located with a wastewater treatment plant, in support of a circular economy perspective. Four technological foreground scenarios and three prospective background scenarios aligned with the Paris agreement's climate targets REMIND-SSP2-Base (projecting a 3.5°C temperature rise by the end of the century), PKBudg1150 (aiming to limit the rise to below 2°C), and PKBudg500 (targeting a cap below 1.5°C) are analyzed for sewage sludge-to-fuel conversion in 2030, 2040, and 2050. The superstructure problem of the possible combinations of the developed scenarios is solved using the P-graph studio which is based on the branch and bound approach. The goal of this study is to maximize the objective function (OF) by accounting the credits from avoided GHG emissions, the market value of recovered products, while subtracting operational costs and GHG emission penalties incurred during the biocrude production and upgrading processes. The optimal solution shows a potential OF equal to 858 €/ton of sewage sludge for Pkbudg500 under technological foreground scenario 2 by 2040. The P-graph approach demonstrates that HTL treatment of sewage sludge provides an alternative production pathway within the circular economy concept, capable of identifying optimal and near-optimal solutions for addressing trade-offs between future socio-economic policies and practical implementation for 2030, 2040, and 2050, which are often difficult to monetize.

**Keywords**: Prospective circular economy, integrated assessment models, shared socio-economic pathways, sewage sludge, hydrothermal liquefaction.

## INTRODUCTION

Sludge from wastewater treatment plants is a major source of urban waste and the circular economy approach has demonstrated its effectiveness in the waste-to-energy sector as a method to extract value from waste while minimizing fossil fuel consumption [1]. Transforming this sludge into fuels for the transportation sector via HTL can substantially support the renewable energy targets in Europe, presenting an eco-friendly and cost-effective solution over traditional waste management practices [2]. Regarding the market acceptance, the use of sustainable advanced biofuels produced from biocrude is viewed as essential in the shift towards renewable energy, offering a pathway to quick emission reduction while requiring minimal alterations to the existing fossil crude infrastructure [1,3]. As sustainability concerns continue to rise, environmental impacts are gaining increasing attention. Prospective life cycle assessment (pLCA) has emerged as a valuable tool for estimating future environmental performance by accounting for the advancement of current and emerging technologies. It considers both the foreground system e.g., improvements of the investigated technology, and the background systems

such as raw material and energy market developments [4]. Regarding the evolution of background systems, the integrated assessment model (IAM), based on shared socioeconomic pathways (SSPs), provides a framework for analyzing climate-related scenario outcomes [6]. One such IAM, the regional model of investment and development (REMIND), describes transformation pathways within the interconnected energy-economy-land-climate system [5]. Addressing climate change requires two key approaches: mitigation, which focuses on reducing greenhouse gas emissions, and adaptation, which involves adjusting economies and societies to meet climate goals [6,7]. Additionally, biogenic carbon removal is increasingly recognized as an essential aspect of mitigation and remains an important area for future exploration. This study employs the SSP2 narrative, known as the "middle-of-the-road" pathway, serving as a useful starting point for exploring solutions that integrate climate mitigation and adaptation while also addressing broader societal objectives throughout the 21st century [7,5,8,9].

The open source LCA tool, activity-browser (AB), modifies the Ecoinvent 3.9.1 database to align with socioeconomic and climate-oriented SSP projections, specifically REMIND-SSP2-Base, Pkbudg1150, and Pkbudg500, for the years 2030, 2040, and 2050 [10].

This study focuses on the conversion of sewage sludge into biofuel using the HTL process, as illustrated in Figure 1. Four distinct technological scenarios for converting sewage sludge to biofuel via HTL are analyzed, as detailed in Table 1. Despite the growing interest in HTL for biofuel production, there remains a gap in the literature regarding a comprehensive, prospective analysis that integrates both economic and environmental factors. The core of this study is the use of prospective assessment to identify the most suitable technological production pathway by considering the economic balance between future demand and the market value of products, alongside externality costs related to GHG emissions and future operating costs (OPEX). To address this, the P-graph framework, combined with prospective assessment, facilitates rigorous superstructure design and efficiently identifies optimal and near-optimal solutions for mid-to long-term scenarios [11,12,13].This approach offers a practical tool for decision-makers to assess trade-offs among technological options, accounting for future socio-economic policies and implementation goals for 2030, 2040, and 2050, which would otherwise be challenging to evaluate both economically and environmentally.

## MATERIALS AND METHODS

### Technological foreground scenarios

The HTL-based foreground system for sewage sludge valorization, shown in Figure 1, is analyzed across four scenarios as detailed in table 1. In scenarios 1 and 3, natural gas is used to heat the HTL unit, while biomethane is the heating source in scenarios 2 and 4, maintaining a temperature of 347°C [1,3,14]. This process converts sewage sludge into fractions by weight: 42% biocrude, 28% aqueous phase, 24% solids and ash, and small amount of gases [3,14,18]. The solid residues are assumed to be disposed of in a landfill. Other technological options involve recovering valuable nutrients, such as phosphorus, or producing a combined fertilizer product from these solids. While this could enhance sustainability and circular economy concepts, further research is needed to evaluate the technical and economic viability of this option, which is beyond the scope of the current study [3,14,18].

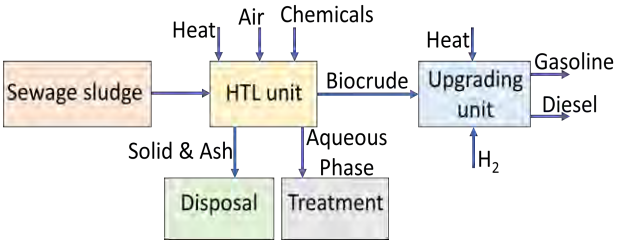

**Figure 1.** Sewage sludge to biofuel conversion via HTL process.

The aqueous phase treatment varies between scenarios. In scenarios 1 and 3, the aqueous phase, containing effluent water, dissolved organics, ammonia, and metal salts, is treated with lime to raise its pH to 11, releasing ammonia gas. This ammonia is then combusted catalytically in a thermal oxidation unit with a natural gas-air mixture [3,14,18]. In contrast, scenarios 2 and 4 employ dewatering to increase the organic content of the aqueous phase from 7.5% to 45% [3,14,18], followed by anaerobic digestion to produce biogas. After purification, the biomethane generated is used onsite in the HTL and biocrude upgrading units, with any surplus treated as an additional biomethane product. The hydrogen required for upgrading the biocrude differs across scenarios. In scenarios 1 and 2, hydrogen is generated via steam methane or biomethane reforming, while in scenarios 3 and 4, it is produced through electrolysis. The upgraded biocrude is ultimately converted into biogasoline and biodiesel as the primary products, with biomethane included as an additional product in scenarios 2 and 4. The production pathways for sewage sludge-to-biofuel are modeled using P-Graph studio to identify optimal configurations from both economic and environmental perspectives. The analysis evaluates four alternative technological pathways under various future scenarios spanning the years 2030 to 2050. The optimization goal is to maximize the objective function (OF), as defined in Equation (1) [12]. A cradle-to-gate approach is employed in this

study to conduct a prospective life cycle assessment (LCA), calculating both the greenhouse gas (GHG) emissions avoided by replacing fossil fuels and the GHG emissions generated during the hydrothermal liquefaction (HTL) process. In this analysis, sewage sludge is assumed to carry no environmental burden, as it originates from wastewater treatment plants (WWTP), where all associated impacts are already allocated. For the alternative approach to biofuel production via HTL, this study specifically examines non-biogenic emission sources, such as chemical inputs and energy consumption. The inputs for converting sewage sludge to biocrude via HTL, upgrading biocrude to biofuels, are detailed in Table 2 and illustrated in Figure 1. Comprehensive life cycle inventories (LCI) for these scenarios are based on data from Karka et al. (2024), Snowden-Swan et al. (2017) and Tews et al. (2014). For cradle-to-gate fossil fuel emissions, the study relies on a prospective LCI database accessed through the open-source software AB.

$$OF = GHG\ avoided\ emissions * C + MV\ product - OPEX - GHG\ emitted\ emissions * C \quad (1)$$

In Equation 1, the term 'OF' does not represent the monetary profit of the entity operating the sludge-to-biofuels facility. Instead, it denotes an objective function that integrates economic aspects (market value minus operational costs) and environmental factors (credits for avoided greenhouse gas emissions minus penalties for emitted greenhouse gases). Both components are monetized to formulate a unified single-objective problem, thereby avoiding the complexity of a bi-objective approach. In OF the term *GHG avoided emissions* refers to the greenhouse gas emissions avoided through the displacement of fossil fuels by biofuels. This is determined by multiplying the annual production of biofuels (e.g., tons of bio-gasoline per year) by the cradle-to-gate emission factor of the fossil fuel being replaced (e.g., tons of $CO_2$-equivalent per ton of fossil gasoline). These avoided emissions are then multiplied by the carbon tax *C*, measured in €/ton of $CO_2$-equivalent, to calculate the monetary credits for avoided emissions (€/year). Carbon tax values for 2030, 2040, and 2050 are sourced from the REMIND-SSP2-base, PKBudg1150, and PKBudg500 scenarios [5,15,17].

The term *MV product* is calculated as the revenue generated by biofuel production. This is obtained by multiplying the market price of the biofuel (€/ton), as predicted by the REMIND model for specific years and background scenarios, by the annual production volume (tons/year) for each technological pathway [15,17]. Operating costs *OPEX* include the annual expenses (€/year) associated with biofuel production, considering only the future costs of energy sources such as natural gas and electricity. These costs are derived from REMIND model projections for 2030, 2040, and 2050 under the REMIND-SSP2-base, PKBudg1150, and PKBudg500 scenarios. Material costs for inputs like lime or chemicals, listed in Table 2, are excluded due to insufficient data in the REMIND framework, which primarily focuses on energy-economy modeling [15,17].

The term *GHG emitted emissions* represent the cradle-to-gate greenhouse gas output generated during biofuel production (tons of $CO_2$-equivalent/year). These emissions are multiplied by the carbon tax (€/ton of $CO_2$-equivalent) to calculate emission penalties (€/year). Annualized capital costs are not included in this analysis, as their assessment would require a detailed technology learning framework, which is beyond the scope of this study.

## Data Collection

The data used in Equation 1, including avoided emission credits, market values of biofuels, operating costs, and emission penalties, is available in the GitHub repository [15]. For convenience, the repository can be accessed directly via this link:[https://github.com/safdar-abbas123/Availability-of-data-for-prospective-circular-economy?tab=readme-ov-file].

### Framework of scenarios' modelling using the P-graph software

The P-graph framework is a combinatorial optimization tool based on five core axioms [12,16]. These axioms establish the combinatorially feasible process structures within the P-graph software. Axiom 1 states that every product must be included in the structure. Axiom 2 specifies that a material has no ancestors in the structure only if it represents a raw material. Axiom 3 ensures that every operating unit in the structure is defined in the synthesis problem. Axiom 4 requires that each operating unit in the structure has at least one direct path leading to the final product. Axiom 5 dictates that if a material is part of the structure, it must either be an input to or an output from at least one operating unit in the system [12,16]. These axioms provide mathematically precise guidelines regarding the structural requirements of a problem [12,16]. They are particularly effective in narrowing the structural search space for optimization, allowing the focus to remain on analysing feasible configurations. Figure 2 illustrates the general P-graph structure used to optimize the sewage sludge system. In the first layer, sewage sludge is converted to biocrude via hydrothermal liquefaction (HTL), with heating for the HTL unit provided by either natural gas or onsite-produced biomethane. The second layer involves the upgrading of biocrude, with hydrogen supplied either from natural gas or biomethane through a steam methane reformer (SMR) or electrolysis. In the third layer, product recovery takes place. Four different technological foreground pathways and three prospective background scenarios are considered for the years

**Table 1.** Scenario description for sewage sludge to biofuel conversion via HTL process included in superstructure.

| Scenarios | Heating source in HTL Unit | $H_2$ source in upgrading Unit | Aqueous phase treatment | Products |
|---|---|---|---|---|
| Scenario 1 | Natural gas | SMR* | Thermal treatment | Gasoline, Diesel |
| Scenario 2 | Biomethane | SBMR** | Anaerobic digestion | Gasoline, Diesel, biomethane |
| Scenario 3 | Natural gas | Electrolysis | Thermal treatment | Gasoline, Diesel |
| Scenario 4 | Biomethane | Electrolysis | Anaerobic digestion | Gasoline, Diesel, biomethane |

SMR*: Steam methane reforming
SBMR**: Steam bio-methane reforming
Note: (Sources of these scenarios are mainly from Karka et al. (2024), Snowden-Swan et al. (2017) and Tews et al., 2014).

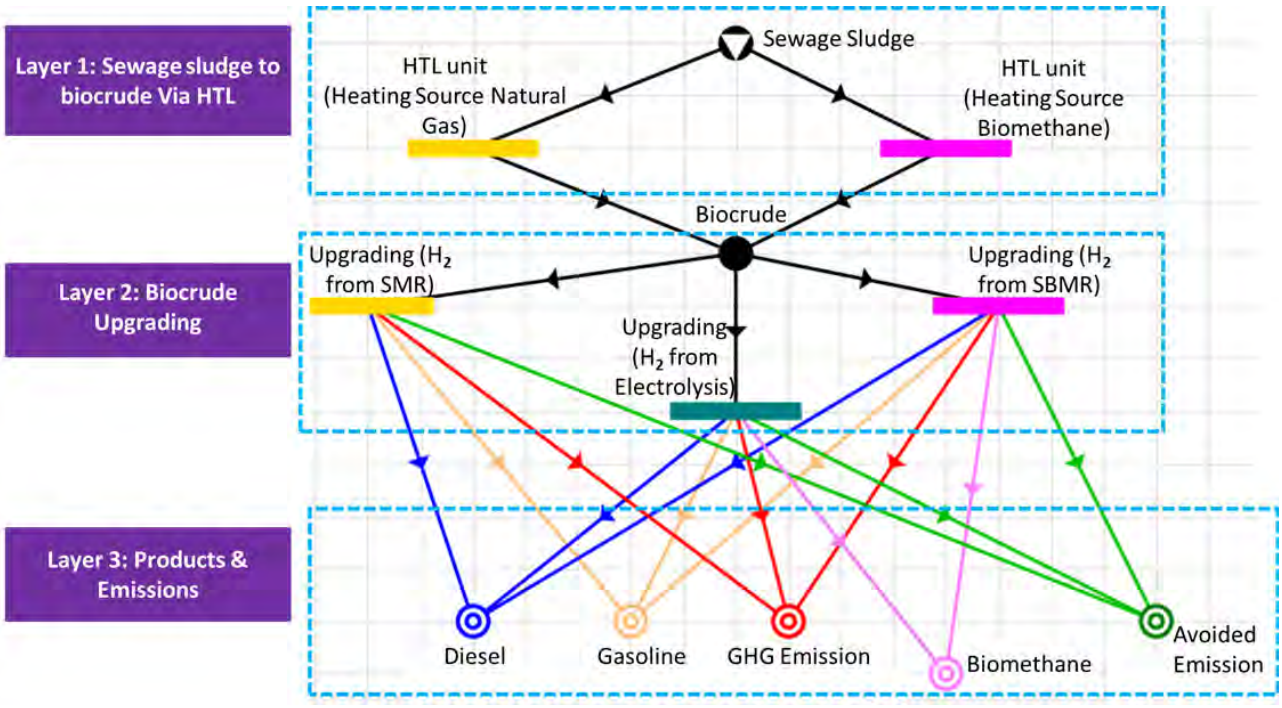

**Figure 2.** Generic model of sewage sludge to biofuel production using P-graphs: Layer 1 sewage sludge to biocrude via HTL; Layer 2 biocrude upgrading with $H_2$ sources from SMR, electrolysis, and SBMR; Layer 3 products and emissions.

2030, 2040, and 2050. A total of 36 scenarios are incorporated into a superstructure to find the optimal and near-optimal production pathways.

## RESULTS AND DISCUSSIONS

Figure 3 illustrates the optimal and near-optimal solutions for various technological production pathways, modelled using P-graph, across different prospective scenarios for the years 2030, 2040, and 2050. The optimal solution (Scen 2) achieves the highest OF of 858 €/ton of sewage sludge in 2040 under the optimistic REMIND-SSP2-Pkbudg500 scenario, which aims to limit global temperature rise to below 1.5°C. In this technological pathway, biomethane is used in HTL and the biocrude upgrading units. This pathway generates significant revenue from biofuel production (917€/ton of sewage sludge) and credits for avoided GHG emissions through the displacement of fossil fuels (200€/ton of sewage sludge). These benefits outweigh the associated costs, including penalties for cradle-to-gate non-biogenic GHG emissions, primarily resulting from material inputs, as shown in Table 2, during sewage sludge-to-biofuel production via HTL (-253€/ton of sewage sludge) and OPEX (-6€/ton of sewage sludge). The substantial objective function (OF) margin in this pathway is attributed to the optimal alignment of technology and market conditions, maximizing both environmental and economic performance.

**Table 2.** Material inputs for sewage sludge to biofuel conversion via HTL process.

| Material input | Processing unit | Amount |
|---|---|---|
| Dewatered sludge | HTL Unit | 4158 kg/hr |
| Air | HTL Unit | 4418 kg/hr |
| Natural gas or biomethane | HTL Unit | 221 m3/hr |
| Chemical organic | HTL Unit | 18.7 kg/hr |
| Electricity, medium voltage | HTL Unit | 160.4 kWh |
| Biocrude | Upgrading unit | 1767 kg/hr |
| Hydrogen | Upgrading unit | 96 kg/hr |

Note: (Sources of these material inputs are mainly from Karka et al. (2024), Snowden-Swan et al. (2017) and Tews et al., 2014).

The first near-optimal solution yields a slightly lower OF of 804 €/ton of sewage sludge, also in 2040 under the REMIND-SSP2-Pkbudg500 scenario. In this case, scenario 4 is used, where biomethane is utilized in the HTL unit, but electrolysis is employed for the biocrude upgrading unit. While this pathway generates the biofuel revenues (922 €/ton of sewage sludge) and identical avoided GHG credits (200 €/ton of sewage sludge), it incurs the GHG emission penalties (-267 €/ton of sewage sludge) and significantly increased OPEX (-51 €/ton of sewage sludge) due to the additional electricity use. These increased costs reduce overall OF profitability compared to the optimal solution.

Further reductions in OF are observed in the second and third near-optimal solutions, which use technological foreground scenario 2 as also the best solution but under different background scenario years. The second near-optimal solution, under the REMIND-SSP2-Pkbudg500 scenario for 2030, achieves a OF of 735 €/ton of sewage sludge. In this scenario, revenue from biofuel production is (781 €/ton of sewage sludge), and avoided GHG credits drop to (135 €/ton of sewage sludge), reflecting less favorable conditions compared to the optimal solution. Costs include GHG emission penalties (-170 €/ton of sewage sludge) and OPEX (-11 €/ton of sewage sludge). The third near-optimal solution, also using scen 2, occurs in 2050 under the REMIND-SSP2-Pkbudg500 scenario and achieves a OF of 728 €/ton of sewage sludge. Biofuel revenues is (765 €/ton of sewage sludge), while avoided GHG credits fall to (130 €/ton of sewage sludge). Associated costs include GHG emission penalties (-162 €/ton of sewage sludge) and OPEX (-5 €/ton of sewage sludge). The stack bar charts for these solutions demonstrate that the main drivers of OF are revenues from biofuel production and credits for cradle-to-gate avoided GHG emissions. Scenario 2 performs well under the REMIND-SSP2-Pkbudg1150 and REMIND-SSP2-Base scenarios; however, it achieves the highest objective function (OF) in REMIND-SSP2-Pkbudg500, as indicated by the optimal and near-optimal solutions shown in Figure 3.

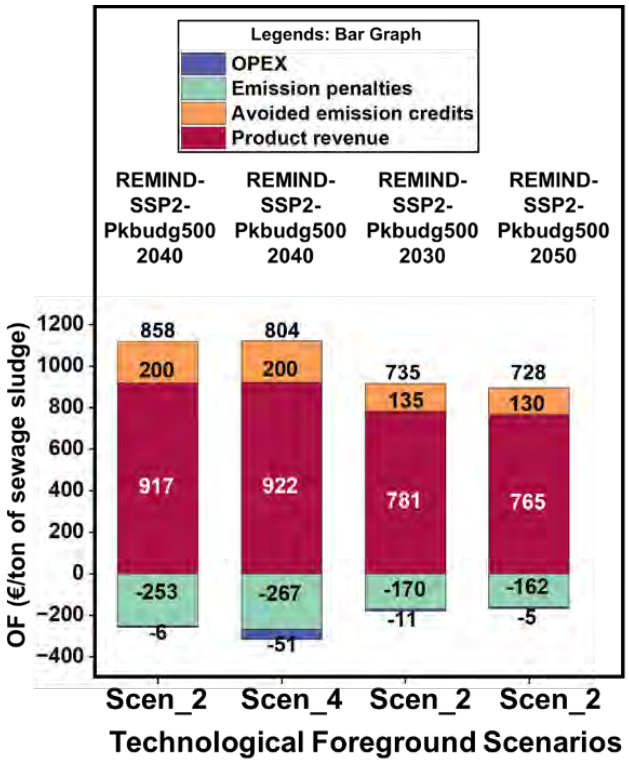

**Figure 3.** The set of optimal and near optimal solution of different technological foreground scenarios. The bar graph presents the optimal and near optimal solution achieved under the highly optimistic scenario REMIND-SSP2-Pkbudg500 for the year 2030, 2040 and 2050.

Despite costs like GHG emission penalties and OPEX, these revenue streams maintain OF profitability. The key driver for both optimal and first near-optimal solutions in the REMIND-SSP2-Pkbudg500 scenario is the higher biofuel market value in 2040, as outlined in GitHub repository [17]. This increase in biofuel prices significantly boosts revenue, making 2040 the most profitable year. However, biofuel OF are projected to decline in 2050, even under the highly optimistic REMIND-SSP2-

Pkbudg500 scenario, due to reduced demand as the transportation sector increasingly shifts towards electric vehicles and cleaner fuel sources, reducing the reliance on biofuels [5].

## CONCLUSIONS

The superstructure-based optimization of sewage sludge conversion to biofuel via HTL, using the P-graph framework combined with prospective assessments, offers valuable insights for circular bioeconomy approaches. The optimal and near-optimal solutions provide valuable guidance for stakeholders offering multiple technological production pathways under various socioeconomic scenarios for the years 2030, 2040, and 2050. The optimal solution recommends the conversion of sewage sludge to biocrude through HTL, followed by upgrading biocrude to biofuel, with biomethane being used in both stages. However, a key limitation of P-graphs is its reliance on predefined process structures, which restricts its ability to automatically explore alternative configurations outside the given set. For instance, the present study can be populated with more scenarios regarding the HTL aqueous phase treatment, alternative uses of sewage sludge, and biocrude upgrading product diversification. Despite this, the study illustrates the systematic development and assessment of scenarios, guiding future developments in waste-to-energy conversion and supporting long-term sustainability goals.

## ABSTRACT

In this paper, we present a systematic approach to quantify the safe operating window of a proton exchange membrane water electrolysis (PEMWE) system considering energy intermittency and varying hydrogen demand. The PEMWE model has been developed based on first principles, with the polarization curve validated against a lab-scale experimental setup. The impact of key operational variables is investigated which include voltage, inlet temperature, and water flowrate (utilized for both feed and system cooling). Emphasis is given on operating temperature, a safety-critical variable, as its elevation can pose significant hydrogen safety risks within both the electrolyzer cells and the storage system. The impact of temperature on process safety is quantified via a risk index considering the fault probability and consequence severity. Process operability analysis is employed to assess the achievability of a safe and feasible region for design and operations. This analysis provides a comprehensive framework to optimize PEMWE systems for enhanced operational flexibility and robust performance with application to modular hydrogen production using renewable energy sources.

**Keywords**: Operability Analysis, Risk Assessment, Water Electrolysis, Sustainable Hydrogen Production

## 1. INTRODUCTION

In recent years, the transition of the energy grid to hydropower, wind, and solar photovoltaics has gained significant attention. Renewable sources are at the core of energy transition and remain among the most critical factors in the process of industrial decarbonization. However, their output is intermittent with daily and seasonal variability, which may lead to fluctuations in energy supply [1, 2]. Advancements in electrolysis technologies, such as proton exchange membrane water electrolysis (PEMWE) systems, are critical in addressing the challenges of integrating renewable energy sources for hydrogen production [3, 4]. PEMWE stands out among other technologies (e.g., solid oxide electrolyzers and alkaline electrolyzers) due to its simplicity, reversible operation, higher current densities supported, and ability to supply highly pure hydrogen. These attributes make PEMWE a promising option for coupling with intermittent renewable energy sources, contributing to the decarbonization of various sectors such as transportation, industry, and power generation [5, 6]. Despite these advancements, significant research gaps remain in how to effectively characterize the operability of a PEMWE system. These include: (i) the lack of integrated performance analysis (and metrics) for PEMWE accounting for operability, safety, productivity, etc.; and (ii) the lack of a systematic approach to quantify the safe PEMWE operating window under conditions of energy intermittency and varying hydrogen demand.

To address these challenges, this work presents a systematic approach that integrates operability and safety analysis to quantify the safe operating window of a PEMWE system while ensuring high-efficiency hydrogen production. Section 2 provides a detailed PEMWE process description to motivate the research developments. Section 3 outlines the methods in terms of operability and risk assessment. Section 4 presents a case

study demonstrating the practical application and effectiveness of the methodology framework in enhancing PEMWE system safety and operability.

## 2. PEMWE CASE STUDY

### 2.1 Process Description

In this work, we consider the PEMWE system as conceptualized in Figure 1a. The PEMWE design and operations are based on the reference experimental setup given in Figure 1b [6, 7]. Specifically, water is supplied to the anode at a controlled temperature and flow rate, serving a dual purpose as both a reactant and a coolant. Within the anode, water moves through the diffusion layer to reach the catalyst site, where the anodic electrochemical reaction occurs as described in Eq. (1). During this reaction, water interacts electrochemically with electrons from the current to produce oxygen and hydrogen ions. The oxygen ions at the anode combine to form oxygen molecules, while the hydrogen ions diffuse through the membrane to the cathode, where pairs of $H^+$ ions combine to form hydrogen molecules as described in the cathodic reaction in Eq. (2). The oxygen and hydrogen molecules generated then exit the catalyst layer via the diffusion layer. The overall reaction is presented in Eq. (3).

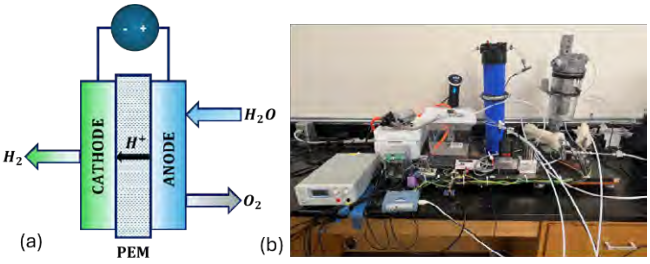

**Figure 1**: PEMWE system. (a) Schematic representation. (b) Experimental setup.

$$\text{Anode: } H_2O \longrightarrow \frac{1}{2}O_2 + 2H^+ + 2e^- \quad (1)$$

$$\text{Cathode: } 2H^+ + 2e^- \longrightarrow H_2 \quad (2)$$

$$\text{Overall Reaction: } H_2O \longrightarrow \frac{1}{2}O_2 + H_2 \quad (3)$$

### 2.2 Research Objectives

The manipulated variables for this PEMWE system are considered as: (i) makeup water flowrate – which is used for both feed inlet and system cooling, and (ii) voltage – reflecting the varying electricity availability considering the scenario of electrolyzer powered by renewable energy sources. Disturbance exists at the makeup water inlet temperature. To assess the PEMWE performance, the output variables are selected as $H_2$ production flowrate and power consumption. Temperature is the safety-critical variable to be further correlated with the process risk calculation. Temperature elevation can pose significant hydrogen safety risks within both the electrolyzer cells and the storage system.

Key research objectives of this work include:

- Model-based analysis to characterize the entire PEMWE safe and feasible operating region for input and output variables.
- Systematic identification of the optimal input operating region under disturbances, based on the desired level of outputs (maximum hydrogen production rates).

## 3. AN INTEGRATED OPERABILITY AND SAFETY OPTIMIZATION APPROACH

A methodology framework has been developed in our prior work to incorporate risk considerations into steady-state operability-based process design [8]. This section provides a brief overview on the key methods (i.e., process operability analysis and risk assessment), before applying the framework to study the PEMWE system in Section 4.

### 3.1 Process Operability Analysis

Process operability analysis is employed to quantify the achievability of a safe and feasible operating region at the early design stage. Several approaches have been proposed to tackle the challenges of feasibility and flexibility, including evaluating and integrating these factors within process design optimization and operations [9] and employing probabilistic identification of the design space [10]. The steady-state operability framework used in this study accounts for the impact of process design variables and varying operating conditions on the outputs to address the complexities of chemical processes [11, 12]. Figure 2 illustrates a schematic for performing a generalized steady-state operability analysis. This process starts by defining the input variables' upper and lower bounds, which define the Available Input Set (AIS). The process model, represented by $M$, is then applied to the AIS to determine the resulting output variables, which constitute the Achievable Output Set (AOS). Next, the Desired Output Set (DOS) is specified to include the target output values for the system. Through inverse mapping ($M^{-1}$), the input requirements needed to achieve the entire DOS region, if possible, are identified and referred to as the Desired Input Set (DIS). Additionally, by incorporating the Expected Disturbance Set (EDS), the AOS is adjusted to account for shifts across the specified range of disturbances, reflecting how these disturbances impact the achievable outputs. The feasible regions within DIS and DOS are labeled as DIS* and DOS*, respectively.

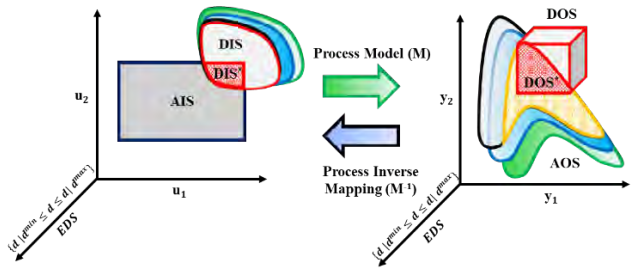

**Figure 2:** Schematic of the process operability concepts at steady-state.

## 3.2 Risk Assessment

The risk model can be established as a function of safety-critical variables in the process, inspired by the methodology described in [13]. Here, let $x$ represent these safety-critical variables, such as states. The risk index, $RI$, is defined in terms of the deviation of $x$ from the standard design or operating conditions, denoted by μ. Eq. (4) specifies $RI$ as the product of the fault probability, $P(x)$, and the consequence severity, $S(x)$. Additional insights into using $RI$ for real-time risk monitoring and management are provided in [14].

$$RI = P(x) \times S(x) \tag{4}$$

Fault Probability: The fault probability is determined using Eq. (5) for the case when $x \geq \mu$. The formulation incorporates a probability density function based on the mean (μ) and standard deviation ($\sigma$) of the safety-critical variables ($x$). This approach leverages the three-sigma rule ($\mu \pm 3\sigma$), meaning that roughly 99.7% of values are expected to lie within three standard deviations from the mean.

$$P(x) = \phi\left[\frac{x-(\mu+3\sigma)}{\sigma}\right] = \int_{-\infty}^{x} \frac{1}{\sqrt{2\pi}\sigma} e^{-\frac{[t-(\mu+3\sigma)]^2}{2\sigma^2}} dt, \quad \text{when } x \geq \mu \tag{5}$$

Consequence Severity: Eq. (6) is applied to measure consequence severity, which intensifies notably as the deviation of $x$ from three-sigma region increases.

$$S(x) = 100^{\frac{x-(\mu+\mu\sigma)}{x-\mu}}, \text{ when } x \geq \mu \tag{6}$$

# 4. PEMWE CASE STUDY: RESULTS AND DISCUSSIONS

This section presents the stepwise procedure to analyze the operability and safety of the PEMWE system.

## 4.1 First-Principles Process Modeling

The first-principles electrolyzer model provided in AVEVA™ Process Simulation is used in this case study. Modifications to the model are made to better align with the parameters of the experimental system (Fig. 1b). The polarization curve is a fundamental starting point in the study of PEMWE system, providing insights into the electrochemical performance of the cell under varying operating conditions. Table 1 provides the core electrochemical equations governing the PEMWE system, covering the open circuit voltage, activation overpotential, and ohmic overpotential.

In estimating the polarization curve, parameters with high impact on the stack's electrochemical behavior are carefully calibrated using experimental data. To ensure robustness, we conducted a sensitivity analysis to identify which parameters significantly affect the model's output and are well-represented by the experimental data. These include the exchange current densities for the anode ($i_{o,an}$) and cathode ($i_{o,ca}$). Table 2 presents both the design specifications and the estimated parameters for the PEMWE system. Table 3 presents the electrochemistry parameters. The optimal exchange current density values are determined to be $i_{o,an} = 3.62 \times 10^{-6}\ A \cdot cm^{-2}$ for the anode and $i_{o,ca} = 8.20 \times 10^{-6}\ A \cdot cm^{-2}$ for the cathode. Constants $\alpha_{an}$ and $\alpha_{ca}$, which represent the charge transfer coefficients for the anode and cathode, respectively, are adopted from literature values of 2 and 0.5. Figure 3 presents the polarization curve results, showing great agreement with experimental data.

## 4.2 Risk Modeling

Although the reaction is endothermic, heat is generated due to the Joule heating effect [6]. As a result, effective thermal management becomes crucial for safe PEMWE operation, as excessive heat buildup can lead to equipment failure and hazardous conditions. Applying high current densities increases electrolysis and heat generation, which risks damaging critical components like the membrane and electrodes or leads to a thermal runaway condition. Additionally, hydrogen is highly flammable. The leaks or improper handling can lead to explosive atmospheres.

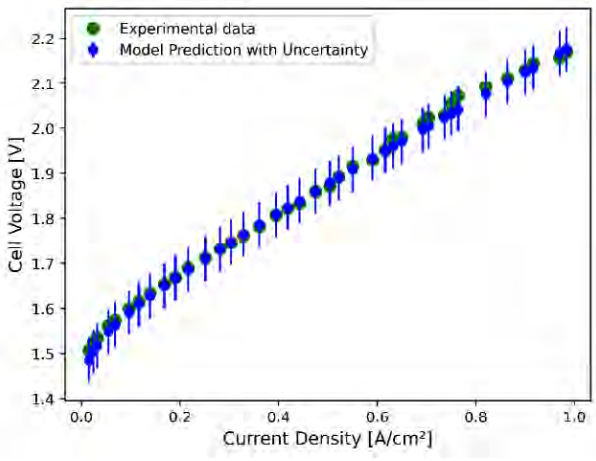

**Figure 3:** Parameter estimation results of the polarization curve.

**Table 1:** Electrochemistry equations of the PEMWE System.

| Electrochemistry | |
|---|---|
| **Open circuit voltage** | $V = E_{oc} + V_{act} + V_{\mathrm{ohm}}$ |
| | $E_{oc} = E_o + \frac{RT}{2\mathrm{F}} \ln \frac{p_{\mathrm{H_2}} p_{\mathrm{O_2}}^{0.5}}{p_{\mathrm{H_2O}}}$ |
| | $E_o = 1.229 - E_T(T - 298)$ |
| **Activation overpotential** | $V_{act} = \frac{RT}{\alpha_{an} F} \sinh \frac{i}{2i_{o,an}} + \frac{RT}{\alpha_{ca} F} \sinh \frac{i}{2i_{o,ca}}$ |
| **Ohmic overpotential** | $V_{\mathrm{ohm}} = \tau_m \frac{i}{\sigma_m}$ |
| | $\sigma_m = (M_a \lambda_m - M_b) \exp\left[M_c \left(\frac{1}{303} - \frac{1}{T}\right)\right]$ |

**Table 2:** Design and Estimated Parameters of the PEMWE System.

| Variable | Unit | Value |
|---|---|---|
| $\boldsymbol{P}$ | $Bar$ | 1.2 |
| $\mathbf{T_{in}}$ | ℃ | 20 |
| $\boldsymbol{\tau_m}$ | $\mu m$ | 254 |
| $\boldsymbol{A}$ | $cm^2$ | 50 |
| $\boldsymbol{N_c}$ | – | 4 |
| $\boldsymbol{\lambda_m}$ | – | 10.5 |
| $\boldsymbol{\alpha_{an}}$ | – | 2 |
| $\boldsymbol{\alpha_{ca}}$ | – | 0.5 |
| $\boldsymbol{i_{o,an}}$ | $A/cm^2$ | $3.62 \times 10^{-6}$ |
| $\boldsymbol{i_{o,ca}}$ | $A/cm^2$ | $8.20 \times 10^{-6}$ |

**Table 3:** Electrochemistry Parameters of the PEMWE System [13].

| Variable | Unit | Value |
|---|---|---|
| $\boldsymbol{E_T}$ | – | 0.0009 |
| $\boldsymbol{M_a}$ | – | 0.005114 |
| $\boldsymbol{M_b}$ | – | 0.00326 |
| $\boldsymbol{M_c}$ | – | 1268 |

In this study, the operating temperature is selected as the safety-critical variable, as its increase can pose significant risks to both the electrolyzer cells and the hydrogen storage system. The impact of temperature is quantified using the risk index previously presented, incorporating both fault probability and consequence severity to comprehensively assess safety risks. Figure 4 illustrates the risk quantification, with a mean temperature (μ) of $318.15\,K$ and a standard deviation ($\sigma$) of 5 K, defining the three-sigma range ($\mu + 3\sigma$) up to $333.15\,K$. Given a high-risk threshold temperature within this value, the calculated risk index of 0.5 underscores the need for urgent risk management.

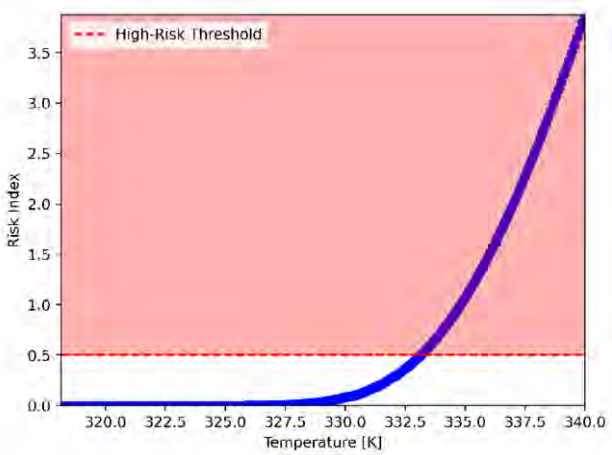

**Figure 4:** Risk evaluation

## 4.3 Operability and Safety Analysis – Forward Mapping

Forward mapping calculates the possible output space based on a given set of inputs (see Table 4). This analysis aims to provide valuable insights into how the system performs under varying conditions, such as fluctuations in renewable energy supply and demand-driven operations. The variables selected in this framework are designed to characterize these conditions. For example, makeup water is included as a manipulated variable as it serves as the raw material for hydrogen production and a key component of the system's cooling resources. Voltage is selected as the other manipulated variable to capture the impact of renewable energy source intermittency on system performance. The feed inlet temperature is considered as disturbance due to its potential variability, which may result from changes in ambient temperature or fluctuations in the cooling system.

**Table 4:** PEMWE System Input Variables.

| Input/Disturbance Variables | Physical Description | Available Range | Unit |
|---|---|---|---|
| $\boldsymbol{Q}$ | Makeup water | $0.01 - 1.2$ | $L/min$ |
| $\boldsymbol{T_{in}}$ | Voltage | $1.4 - 2.2$ | $V$ |
| $\boldsymbol{V}$ | Feed inlet temperature | $293.15 - 333.15$ | $K$ |

Figure 5a illustrates the space discretization employed based on the available input ranges. Figure 5b shows the corresponding outputs, which include hydrogen flow, outlet temperature, the ratio of hydrogen power (the power required by the electrolyzer per unit of hydrogen produced), and the risk index, as indicated in the

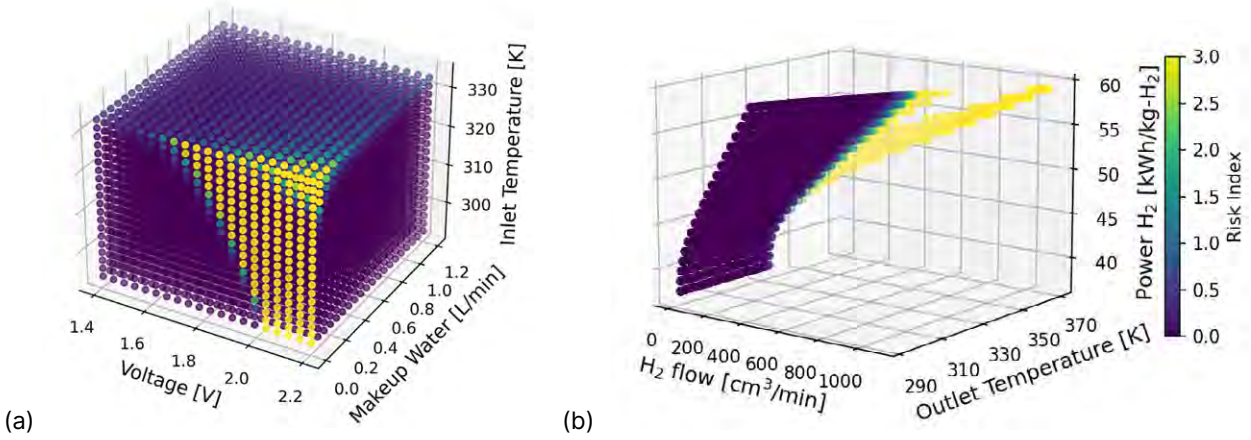

**Figure 5:** Forward mapping assessment for the PEMWE System. (a) Available input set (AIS). (b) Achievable output set (AOS).

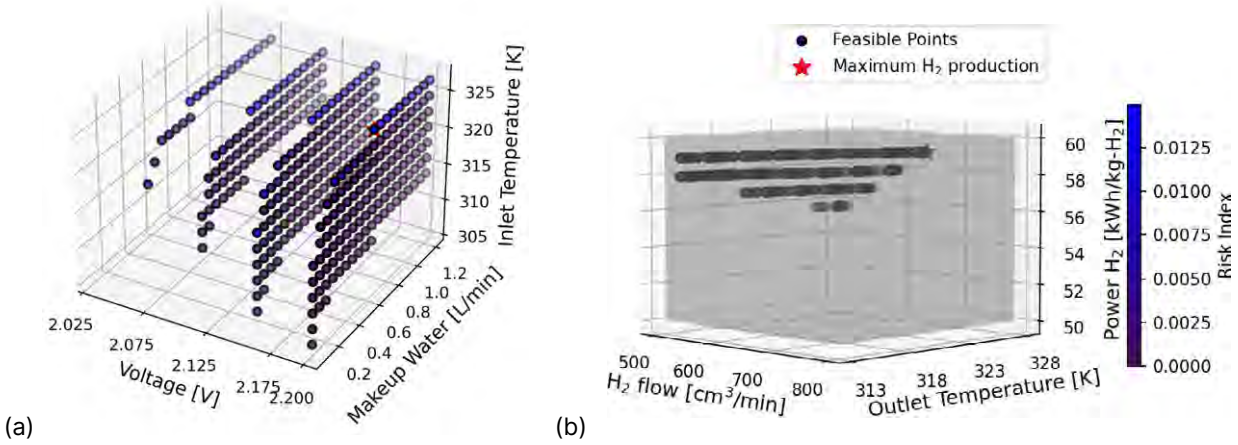

**Figure 6:** Inverse mapping assessment for the PEMWE System. (a) Feasible input set. (b) Feasible output set.

colormap. The high-risk region ($RI \geq 0.5$) results from a combination of inefficient cooling and elevated voltages in response to higher temperature disturbances, as depicted by the green-yellow regions in the colormap. This map enables to identify all possible configurations for the given high-risk scenarios, providing valuable insights for selecting set points in closed-loop operations. Notably, the achievability of these configurations is independent of the specific control law employed.

## 4.4 Operability and Safety Optimization – Inverse Mapping

Based on the entire operational space of the PEMWE system obtained via forward mapping, we further perform inverse mapping to evaluate whether the system can operate within a desired region. We identify the specific input conditions required to achieve the targeted hydrogen productivity while maintaining safety. Table 5 summarizes the target region for electrolyzer operation, derived from previous knowledge of the forward mapping results.

**Table 5:** PEMWE System Desired Output Set (DOS).

| Output Variables | Physical Description | Desired Range | Unit |
|---|---|---|---|
| $\boldsymbol{T_{out}}$ | Outlet temperature | $313.15 - 328.15$ | $K$ |
| $\boldsymbol{H_2\ Flow}$ | Hydrogen production | $500 - 800$ | $cm^3/min$ |
| $\boldsymbol{Power\ H_2}$ | Power $H_2$ | $50 - 60$ | $kWh/kg - H_2$ |

Figures 6a and 6b illustrate the feasible region from the input and output perspectives, respectively. Notably, within the feasible box, multiple points can be selected to achieve the desired target. The optimum point for

maximizing hydrogen production is identified as $T_{out} = 328.1\,K$, $H_2\,Flow = 650\,cm^3/min$, and $Power\,H_2 = 58.96\,kWh/kg - H_2$, with inputs of $Q = 0.63632\,l/min$, $V = 2.2\,V$ and $T_{in} = 326.83\,K$, which corresponds to a risk index of $0.01495$. This design not only achieves the highest hydrogen production but also adheres to the specified safety constraint ($RI < 0.5$).

## 5. CONCLUDING REMARKS

This work introduces a framework that integrates both forward and inverse mapping to optimize the operability and safety of PEMWE systems. Ongoing research is focused on implementing a multi-parametric model predictive controller (mp-MPC) to further enhance real-time control and safety performance based on the obtained regions from operability analyses.

## ABSTRACT

Endpoint indicators provide a concise representation of environmental impacts by aggregating multiple midpoint indicators into a single value. Traditional endpoint weighting systems, however, are often limited by biases introduced through panel reviews and a lack of robustness in scientific process models. Additionally, they typically fail to account for the preferences of key stakeholders, including industry, government, and the public. This work addresses these limitations by developing an endpoint indicator that incorporates stakeholder preferences and minimizes dissatisfaction. A multi-stakeholder optimization framework was formulated to achieve this goal, employing distance, downside risk, and conditional value at risk as objective functions. Stakeholder preferences were derived from emissions data for industry, federal spending on environmental issues for government, and public surveys for societal input. Results highlight regional variations in midpoint indicator weightings across Texas, California, Delaware, and the United States. Furthermore, the influence of public and government preferences reveals a prioritization of human health concerns over environmental impacts. This framework offers a novel approach to creating endpoint indicators that align with stakeholder priorities, promoting more inclusive and collaborative environmental decision-making.

**Keywords**: Life Cycle Assessment, Multi-Stakeholder Optimization, Risk Assessment

## INTRODUCTION

Life Cycle Assessment (LCA) is used to evaluate the environmental effects of products and processes. Several Life Cycle Impact Assessment (LCIA) methods such as TRACI and ReCiPE have been developed to quantify impacts[1, 2]. They employ midpoint indicators that relate the impact of an activity on specific environmental sectors. For example, kg $SO_2$-eq relates to acidification and kg N-eq for eutrophication in TRACI v2.1[2]. All environmental flows are measured relative to a basis, which serves as the primary causal factor. Additionally, ReCiPe also employs endpoint indicators that are a linear combination of midpoint indicators, with weights assigned based on relative physical impact.

Endpoint indicators aggregate relevant midpoint indicators to reflect broader societal impacts, such as human health, ecosystem quality, and resource depletion. While there is a physical basis for some of these endpoint indicators, their weights are mostly subjective and may not necessarily align with the interests of stakeholders. One example is the human development index (HDI) of the United Nations where three indicators (life expectancy, education index, and the income per capita) are grouped into the HDI with a fixed weight[3]. These weights can change between regions and the stakeholders' preferences.

Eco-Indicator 99 weighting for endpoint indicator was determined by a panel survey to weigh the importance of human life loss, extinction of plant species, and resource depletion[4]. The authors remarked that this panel is not necessarily reflective of society. The Institute of Environmental Science at Leiden University developed the CML method which does not provide endpoint indicators and states that any aggregation needs to be thoroughly explained[4]. The ReCiPe method provides three types of aggregation for endpoint indicators: individualistic, hierarchist, and egalitarian[5]. These

aggregations are based on Cultural Theory from the work of Thompson and are used to represent certain assumptions[5, 6]. The individualistic approach assumes a 20-year horizon with optimistic developments, the hierarchist approach aligns with current science over 100 years, and the egalitarian approach spans 1000 years with pessimistic assumptions and highest impact damages. The endpoint value varies based on the approach and assumptions made.

There are some limitations in the use of midpoint and endpoint indicators. The weighting for endpoint indicators is often done by an expert panel, which can result in biases and not accurately reflect stakeholder preferences[7]. In other instances when endpoint indicators are based on science modeling, the aggregation for different midpoint categories results in a loss of accuracy due to the lack of robustness of endpoint models[7].

In lieu of expert weighting or model-based aggregation, we propose an endpoint indicator that considers the environmental impacts important to stakeholders. By considering all stakeholders in the evaluation of the metric, we hope the framework would increase buy-in, particularly for policymaking. This metric is essential for setting policy that prevents burden-shifting between different environmental impacts. Consequently, a multi-stakeholder optimization approach with risk objective functions is formulated to develop an LCA endpoint metric. The multi-stakeholder framework allows for every perspective to be considered. Risk metrics are extensively used within the financial industry to minimize and mitigate extreme losses. In this context, they are used to minimize stakeholder dissatisfaction.

A data-driven, multi-stakeholder framework has been developed to enable the creation of LCA endpoint metrics that accommodate the diverse needs of stakeholders, including businesses, governments, and the public.

## METHODOLOGY

In this work, we consider the use of the following TRACIv2.1 midpoint indicators: acidification, ecotoxicity, climate change (GWP), human health (cancer and non-cancer), particulate matter (PM), smog formation, and ozone depltion. An endpoint indicator is a linear combination of the midpoint indicators as shown in equation 1, where $EP$ is the endpoint indicator value, $p_j$ is the weight for midpoint indicator *j,* and $f_j$ is the impact of midpoint indicator $j$.

$$EP = \sum_j p_j f_j \quad (1)$$

The main contribution of this work is to provide a method for determining the weighting factors of the midpoint indicators that will satisfy the needs of multiple stakeholders. To do so, first the stakeholder preferences are generated from data. A multi-stakeholder optimization function is generated to determine the optimal weighting function that minimizes stakeholder dissatisfaction.

### Stakeholder Preference Generation

There are three stakeholders: Industry, Public, and Government. For the public preferences, the results from a Gallup poll surveying 1,016 adults living in the United States were used[8]. Human health indicators and the remaining environmental indicators were split based on the number of correspondents who indicated that healthcare was a problem they worried about a fair amount or more. The remaining environmental indicator preferences were determined similarly by correlating responses with indicators. For the government preferences, the EPA 2024 Fiscal Year budget was used[9]. The EPA has strategic goals that were correlated with midpoint indicators. The preferences were generated as the fraction of money allocated to each strategic goal. For any indicators that are broken down into additional sub-indicators, such as Ecotoxicity, the weights are allocated uniformly.

For industry stakeholders, their preferences are built based on midpoint indicator impacts as calculated by their point-source air emissions. The point source air releases are obtained from the National Emissions Inventory (NEI), which contains information on point source emissions for every state in the United States[10]. The NEI consists of criteria air pollutants/precursors (CAPs), hazardous air pollutants (HAPs), and greenhouse gas emissions (GHGs). Point sources are facilities that have a large number of emissions from a fixed point. The NEI also reports nonpoint, on-road, nonroad, and fire sources. These alternative sources are smaller in magnitude than the point sources and are harder to attribute a stakeholder to. Consequently, only point sources from the NEI are used in this analysis. The NEI labels all point source data into facility types, which will serve as the basis for the industrial stakeholders. After the emissions for each pollutant type are identified, the midpoint impacts are calculated using the characterization factors from TRACIv2.2[11]. For substances in the NEI that are not found in the TRACI database, surrogate molecules are used as needed. Note that eutrophication is not considered in the optimization. Eutrophication can be calculated according to the spatial characterization factors provided by Henderson et al.; however, this consists of water emissions which can theoretically be determined by the national phosphorus inventory and national nitrogen inventory[12-14]. However, the water inventories do not have information on individual point sources. Therefore, we cannot attribute these emissions to any single stakeholder, and they are on a different basis than the air

emissions.

The stakeholder preferences are calculated from the midpoint impact values in the following way. Consider the matrix with elements $a_{i,j}$ where $i$ is the stakeholder and $j$ is the impact factor. The first transformation normalizes each column with respect to the total midpoint impact value, i.e. $a^1_{i,j} = \frac{a_{i,j}}{\sum_i a_{i,j}}$. The second transformation consists of normalizing each row with respect to the total TRACI impact across all impact categories, i.e. $a^2_{i,j} = \frac{a^1_{i,j}}{\sum_j a^1_{i,j}}$. We assume that if each stakeholder were to make an endpoint indicator as outlined in equation (1), then their desired weighting, $p_j$, will be proportional to their respective midpoint impacts. Therefore, we consider the preferred weightings for stakeholder $i$, $p_{i,j}$, to be equivalent to $a^2_{i,j}$. The preferred stakeholder weightings serve as parameters in our multi-stakeholder optimization problem.

## Multi-Stakeholder Model Formulation

There are three optimization objectives considered in the work, corresponding with Euclidean distance (ED), Conditional Value at Risk (CVaR), and downside risk (DSR) approaches. The three objective functions are different measures of stakeholder dissatisfaction, which should be minimized.

The Euclidean distance approach is equivalent to minimizing the sum of the stakeholder dissatisfaction. The distance approach minimizes the following objective function:

$$ED = \Sigma_s \Sigma_j k_s \left(p_{s,j} - p_j^*\right)^2 \qquad (2)$$

where $p_{s,j}$ is the preference for midpoint indicator$j \in J$ of stakeholder $s \in S$, $p_j^*$ is the optimum preference for midpoint indicator $j$, and $k_s$ is the stakeholder coefficient. The stakeholder coefficient is used to normalize the weighting between the industry, public, and government sectors. This is required because there are many industry stakeholders and only one public and one government stakeholder considered in this work. The goal of the distance approach is to simply minimize the sum of Euclidean distances between all stakeholders and the optimal preference.

In the CVaR approach, the expected dissatisfaction of the top c% dissatisfied stakeholders is minimized. $c$ is an arbitrary cutoff value, which is selected as 2.5 in this work. This objective function attempts to reduce the dissatisfaction of the stakeholders who will be most affected by the new endpoint metric[12]. The Conditional Value at Risk approach minimizes the following objective function:

$$CVaR = \frac{1}{(1-c)|S|} \sum_{s \in S} \psi_s + VaR \qquad (3)$$

where $\sum_j \left(\left(p_{s,j} - p_j^*\right)^2 - VaR\right) \leq \psi_s$ and $\psi_s$ is the amount of dissatisfaction above the VaR. , $p_{s,j}$ is the preference for midpoint indicator$j \in J$ of stakeholder $s \in S$ and $p_j^*$ is the optimum preference for midpoint indicator $j$. Both $\psi_s$ and $VaR$ are positive continuous variables. The Value at Risk, VaR, which represents $(1-c)$ percentile of dissatisfaction.

Downside Risk specifies a specific dissatisfaction level $L$. All stakeholder dissatisfaction greater than L is summed into the metric. The objective minimizes all stakeholder dissatisfaction above a specific level. The downside risk is given the following objective function:

$$DSR = \Sigma_s \phi_s \qquad (4)$$

where $\sum_j \left(\left(p_{s,j} - p_j^*\right)^2 - L\right) \leq \phi_s$ and $\phi_s$ is the amount of dissatisfaction above L, $p_{s,j}$ is the preference for midpoint indicator $j \in J$ of stakeholder $s \in S$ and $p_j^*$ is the optimum preference for midpoint indicator $j$.

The full optimization problem is formulated as follows:

$$\min f\left(p_j^*\right) \qquad (5)$$
$$s.t.\ \sum p_j^* = 1$$

where $f(p_j^*)$ corresponds to the corresponding objective function and $p_j^*$ are positive continuous variables corresponding to the ideal endpoint indicator weightings, that sum to 1. Additional inequalities are required for the CVaR and DSR approaches and are added as needed.

# CASE STUDY DESCRIPTION

The optimization problem was formulated and solved in Excel as an NLP using the Excel Solver plug-in with the GRG Nonlinear method. All computations were performed on a Mac M1 Pro @ 3.2 GHz CPU and 16.0 GB of RAM. The case study considers solving for endpoint indicator weights using the three objective functions described above. First, the state of Delaware is studied in depth. The endpoint indicators, risk by sector, and a sensitivity analysis on risk level are performed. To assess the effect of geography, the differences between the weightings are calculated from data for Texas, California, and Delaware, as well as the entire United States. These states were chosen as Texas and California have the largest GDP and large manufacturing sectors, while Delaware is a smaller state with manufacturing capacities. This is compared against the United States in aggregate. These results do not consider the effect of the public and of the government as stakeholders in the model. Finally, the effect of non-industry participants is considered by

increasing the stakeholder coefficients for these entities.

## RESULTS

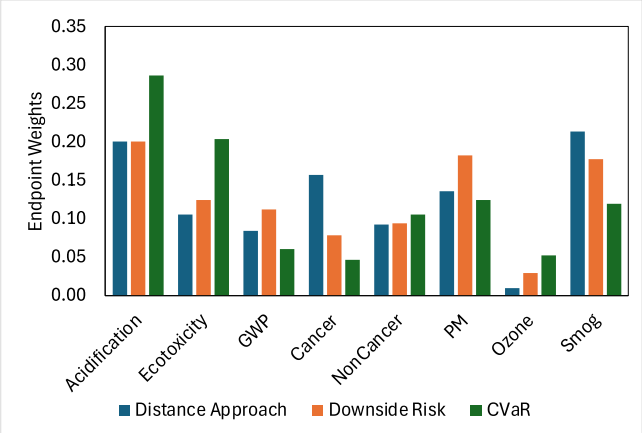

**Figure 1.** Endpoint indicator weights for the distance, downside risk (L = .15), and CVaR (c = 2.5%) objective functions for the state of Delaware.

The weights for the state of Delaware using distance, downside risk, and CVaR are obtained solving the optimization problem given in Equation 5. The resulting values $p_j^*$ are presented in Figure 1. The CVaR approach has higher weighting for acidification, ecotoxicity, and ozone depletion compared to the downside risk and distance approaches. CVaR has lower weighting for global warming potential (GWP), cancer, and smog. The downside risk approach with a dissatisfaction level of 0.15 has weights in between the distance approach and CVaR for a majority of indicator values. This effect is due in part to the low risk tolerance and medium risk tolerance set for CVaR, and downside risk, respectively. Additionally, the distance approach does not consider risk and therefore has the highest risk tolerance. Global warming potential and particulate matter (PM) are exceptions where downside risk has higher weighting.

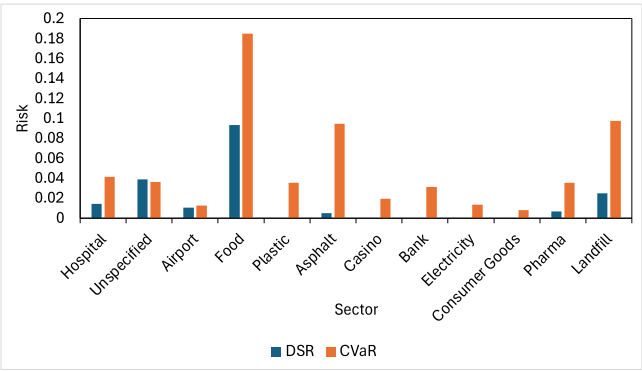

**Figure 2.** Risk levels for the downside risk and CVaR approach for unsatisfied sectors for the state of Delaware

There are 23 sectors considered in Delaware. At the prescribed dissatisfaction level, there are a number of sectors with dissatisfaction levels above the enforced limit. This is equivalent to risk. In the downside risk approach, there are 7 unsatisfied stakeholders with dissatisfaction levels above the dissatisfaction limit. In the CVaR approach, there are 12 unsatisfied stakeholders. The sectors' risks are shown in Figure 2. The lower risk tolerance in the CVaR approach accounts for the higher number of stakeholders and higher overall risk per sector compared to the downside risk approach.

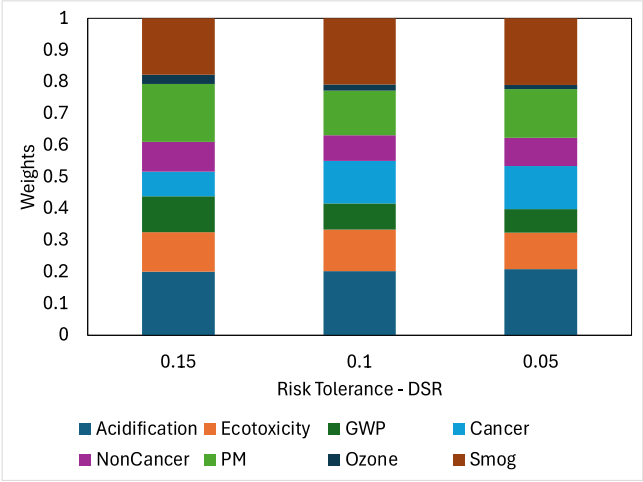

**Figure 3.** Endpoint indicator weights as a function of risk tolerance level for downside risk in the state of Delaware

A sensitivity analysis was performed on the risk tolerance level to understand the impact on endpoint indicator weights as shown in Figure 3. Decreasing the risk tolerance level results in smog, and cancer weights to increase. In contrast, global warming potential, particulate matter, and ozone decrease. Particulate matter and smog have the greatest contribution towards the total dissatisfaction. For particulate matter, there are two stakeholders with high dissatisfaction, food and asphalt. In contrast, smog affects a larger number of stakeholders but with relatively lower levels of dissatisfaction. Adjusting the weight of smog will result in higher cumulative stakeholder satisfaction than for particulate matter. For ecotoxicity, 0.1 relative to 0.15 risk tolerance has higher weights; however, 0.05 relative to 0.15 has a lower risk tolerance. The weighting for ecotoxicity is summed from several sub-indicators consisting of air, water, and soil emissions to water, resulting in no clear trend. When the risk tolerance was set above 0.2, there was no risk. Because there is no unique solution in this case, those results are omitted as there are multiple solutions.

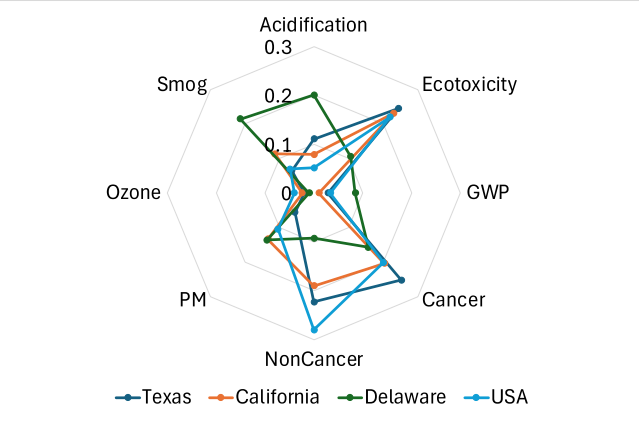

**Figure 4.** Endpoint indicator weights for Texas, California, Delaware, and the entire United States of America using the Euclidean distance approach

The endpoint indicator weights were calculated for Texas, California, Delaware, and the entire United States as a whole, as shown in Figure 4. The results reveal distinct regional variations in environmental impacts across Texas, California, Delaware, and the United States as a whole. Particulate matter impacts were notably lower in Texas compared to other regions. Delaware exhibited the lowest ecotoxicity values but had the highest acidification and smog endpoint weights. While ozone depletion and global warming potential carried relatively smaller weights across all regions, Delaware recorded a higher GWP weighting compared to the other states. Notably, the United States aggregated values were generally lower than those of individual states across most indicators, with the exception of non-carcinogenic effects, which were higher in the national assessment. These results highlight the spatial heterogeneity of environmental impacts and the importance of location-specific considerations in chemical engineering applications and policymaking.

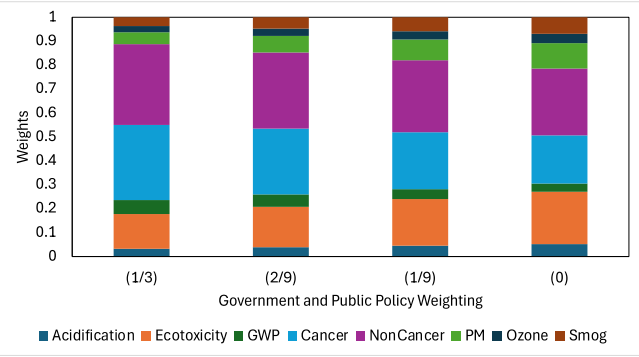

Figure 5. Endpoint indicator weights as a function of government and public policy stakeholder influence for the United States using the Euclidean distance approach

Figure 5 highlights the impact of varying public and government influence on endpoint indicators coefficients as determined using the Euclidean distance approach. As the influence of public and government preferences increases, the emphasis on cancer and non-cancer health risks increases significantly. This trend reflects the strong prioritization of these indicators, as supported by EPA spending and public survey data—92% of EPA spending is allocated to protecting public health and ensuring safe drinking water[9]. Similarly, the weighting of GWP rises with greater public and government influence, while the importance of other categories diminishes. Under the scenario with one-third weighting, each for the government and public, cancer and non-cancer health indicators account for 65% of the total weight. Even without government and public policy intervention, these indicators remain the most significant, representing 48% of the weight. This somewhat unexpected result underscores the dominant influence of regulatory compliance and societal priorities, which favor human health outcomes over broader environmental emissions.

## CONCLUSIONS

This work formulated a multi-stakeholder optimization problem to determine optimal midpoint indicator weightings for the creation of an endpoint indicator that minimizes dissatisfaction between all stakeholders. The Euclidean distance, downside risk, and conditional value at risk objective functions were minimized to do so. Industry, government, and public environmental impact preferences were generated from national emissions data, EPA funding, and public opinion data, respectively. The framework develops a unifying metric that can facilitate collaboration among stakeholders, promoting collective action towards environmental protection. It must be noted that the preference generation procedure in this work results in an inherently dynamic endpoint indicator. Emissions data, EPA fiscal budgets, and public opinion are constantly changing with time. The multi-stakeholder approach aims to minimize dissatisfaction between all stakeholders which optimizes agreement at the present time period. In context of policymaking, time inconsistency refers to the tendency for the optimal solution to any policy problem will be unlikely to remain the optimal solution throughout time, requiring new policies to be created. This is, in part, due to the dynamic nature of people's preferences.

Future work will focus on integrating this framework into policy-driven optimization models, such as cap-and-trade systems, where midpoint indicator impacts can be exchanged among stakeholders. This model will develop a pareto frontier of profits and environmental impacts with the goal of encouraging synergies between stakeholders via the novel endpoint indicator. Additional efforts will include refining the methodology for

determining preferences for midpoint indicators and tailoring the framework to capture regional variations by developing state-specific preferences. These advancements aim to further enhance the applicability and impact of this approach in fostering sustainable decision-making and environmental stewardship.

## ABSTRACT

This study optimizes the Sustainable Aviation Fuel Supply Chain Network (SAFSCN) in the Czech Republic, using wheat straw as feedstock. It integrates geospatial data, transportation logistics, and economic feasibility, applying mixed-integer linear programming (MILP) to optimize pyrolysis plant locations and minimize costs. Sensitivity analysis varied wheat production growth by ±0.1% and ±0.2%. Results confirm Sustainable Aviation Fuel (SAF) production is technically and economically viable, with costs projected to decline up to 30.64% and revenues rising 49.07% from 2030 to 2050 due to technological advancements, improved logistics, and economies of scale. The findings underscore the critical role of SAF in achieving EU aviation decarbonization targets and highlight the importance of efficient supply chain planning for scaling SAF production.

## INTRODUCTION

The EUROCONTROL main report [4] outlines long-term forecasts for flights and $CO_2$ emissions across three scenarios—low, base, and high. In the base scenario, Europe's aviation sector is expected to grow significantly, with flights increasing by 44% from 2019 levels, reaching 16 million annually by 2050. This growth in flights will drive a corresponding rise in fossil fuel demand, resulting in millions of gigatons of $CO_2$ emissions from aviation. According to Wang et al., renewable aviation fuel holds the highest potential for reducing $CO_2$ emissions, while biomass is the only renewable energy source capable of capturing $CO_2$ emissions. This makes biomass-based fuel production a promising option for achieving a net-zero carbon balance through $CO_2$ fixation via photosynthesis [18]. Similarly, Martinez-Valencia emphasizes that the production of renewable fuels is critical for global efforts to reduce greenhouse gas emissions [11]. This aligns with the Eurocontrol report, which identifies scaling up the production, distribution, and use of Sustainable Aviation Fuels (SAFs) as a key strategy to help the aviation industry achieve net-zero $CO_2$ emissions by 2050. In the base scenario, SAFs are projected to contribute 41% of the necessary emission reductions. While there is no single solution, the long-term impact of SAF scaling is expected to be the largest, with operational improvements providing more immediate benefits, alongside contributions from governments and regulators [4]. To address the growing $CO_2$ emissions from aviation, the European Union introduced the ReFuelEU Aviation Regulation, which aims to reduce greenhouse gas emissions by promoting SAF usage. Starting in 2025, aviation fuel suppliers will be required to provide a minimum SAF blend of 2% at EU airports, with this percentage increasing over time. By 2030 and 2050, the required SAF blend is expected to reach 6% and 70%, respectively, with 35% of this coming from synthetic aviation fuels (e-fuels). This regulation is projected to cut $CO_2$ emissions by more than 60% by 2050 compared to 1990 levels, playing a crucial role in the EU's broader decarbonization efforts [7]. The Renewable Energy Directive II (RED II) provides a comprehensive

framework for promoting renewable energy in the EU, with a focus on advanced biofuels (second-generation biofuels), which are derived from non-food feedstocks such as straw, nut shells, and husks. This distinction helps reduce competition with food crops and mitigates the risk of indirect land-use change [6]. Currently, Sapp's research on seven certified processes under ASTM D7566 allows up to 50% SAF blends with fossil jet fuel [15]. SAFs must ensure low lifecycle carbon emissions, renewability, and sustainability, avoiding competition with food production, ecosystem harm, and deforestation, while also being economically viable. Masum et al. highlight the importance of developing an efficient supply chain for large-scale SAF production and distribution. A comprehensive approach involves key elements like feedstock availability, optimization of production pathways by exploring technological options, assessing infrastructure and logistics for transporting feedstocks to pyrolysis plants and bio-oil to refineries, and ultimately utilizing Supply Chain Optimization Modeling. Mixed-integer linear programming (MILP) models can simulate and optimize the supply chain over time, aiding decisions on facility locations, transportation routes, and inventory management to minimize both costs and environmental impact [12].

Our study presents a comprehensive approach to optimizing a Sustainable Aviation Fuel Supply Chain Network (SAFSCN), with a focus on the Czech Republic.

## METHOD

This study outlines a SAF supply chain network, with the process divided into four stages. In Stage 1, geospatial data including wheat production and developed area data (2002-2023) from the Czech Statistical Office [1], administrative boundaries (Nomenclature of Territorial Units for Statistics - NUTS 3) provided by the EUROSTAT website [2], road distances between regions cities (point in the map) and refineries, Direct Normal Irradiance (DNI) data from SOLARGIS [17], and the locations and capacities of existing refineries are gathered. For this study, wheat straw is chosen as the feedstock for SAF production, aimed at replacing a portion of Jet A-1 fuel. In Stage 2, the methodology followed for the wheat straw estimation was first to calculate the dry matter production of wheat which is 90% [10]. Then, the yield (production/developed surface) was calculated for each year and the straw quantification estimation was calculated by using the residues-to-product ratio (RPR) empirical function by Scarlat et al., 2010 as reported by Karan & Hamelin [10, 16]. The RPR is as follows:

$$RPR = -0.3629*\ln(Y)+1.6057\ 0.28 \quad (1)$$

where Y is the Yield, and this function derived best-fit logarithmic function curves for RPR by plotting the values for RPR and crop yield based on data available in the literature. This approach determines the theoretical potential of straw production, by using the following formula as reported in the Karan and Hamelin study [10]:

$$\text{Straw Production} = \text{RPR} * \text{Yield} * \text{Surface area} \quad (2)$$

For estimating available straw production, it is important to take into account crucial parameters such as the removal rate of residues from the terrain and the amount that is used in competitive uses. Removal rates must be sustainable in order to protect soil quality, biodiversity, and erosion control, and in this study, the sustainable removal rate of wheat and rye residues is 40% [17], and the amount of straw needed for animal bedding is 16% of the collectable crop [14]. The formula that was followed to calculate the available potential straw production is as follows:

$$\text{Available residues} = \text{Theoretical potential (dry matter)} - \text{Removal rate \%} - \text{Competitive uses \%} \quad (3)$$

This approach is based on the approach mentioned by Elbersen et al. [3] and has been applied to the AdvanceFuel Horizon Project [8]. Using the historical data, forecasting of feedstock for the short-mid term (2030) and long term (2050) was performed by applying the 'Commission' method. In this method, the production area of wheat was forecasted based on the annual growth percentage of these crops given in Agricultural Outlook 2023-35 [2]. For the crop period 2013-2023, the annual growth percentage of soft wheat was 0.1% for the period of 2013-2023 and 2023-2035. This growth rate was applied to project wheat production areas for 2030 and 2050. Crop production was then estimated by multiplying the projected production areas by the average yield of these crops, which was derived from a historical dataset spanning 22 years. For this study, a sensitivity analysis was conducted by varying the annual growth rate (AGR) of wheat production within a range of ±0.1% and ±0.2% from the historical data. This approach accounts for potential fluctuations in productivity due to factors such as climate variability, thereby enhancing the robustness of the results.

In the present study, an initial quantitative assessment of SAF production was conducted based on the availability of feedstock, as outlined above. The calculations followed the material flow from dried feedstock to the final SAF product, utilizing a system coupling fast pyrolysis with solar energy, as proposed in the CIRCULAR FUELS project and presented in Figure 1 [9].

The SAF demand was forecasted for 2030 and 2050, considering the required minimum SAF blending

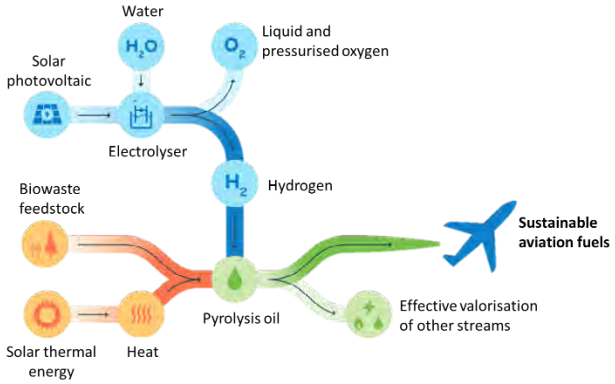

**Figure 1.** The Circular Fuels project process shows the conversion of renewable feedstock to sustainable aviation fuel (CIRCULAR FUELS).

targets of 6% by 2030 and 35% (with 70% of SAF, including at least 35% synthetic aviation fuels or e-fuels) by 2050, as outlined in Annex IX of the ReFuelEU Aviation regulation [7]. The Jet A-1 supply projections for 2030 and 2050 are based on EUROCONTROL's main report, using the base case scenario, which predicts a 14% increase in flight activity over 2019 levels by 2030 and a 44% increase by 2050 [4]. The analysis then assessed whether the SAF quantities required to meet the ReFuelEU regulation targets for 2030 and 2050 would be sufficient to satisfy demand. In Stage 3, potential sites for the pyrolysis plant are identified by calculating a trade-off score that balances feedstock capacity and DNI. First, the transportation cost of feedstock is calculated and normalized for different regions, taking into account straw availability and a distance constraint of up to 150 km. Then, a combined score function is applied to compute a trade-off score, incorporating the two normalized factors: transportation cost and DNI. This function helps assess how transportation costs and solar energy potential contribute to the overall system performance, allowing for a balanced decision. The weights used for this evaluation were 0.7 for transportation cost and 0.3 for DNI. The function operates by multiplying the normalized transportation and DNI scores by their respective weights, and then summing them to obtain the final trade-off score. This score, which ranges from 0 to 1 (assuming normalized scores between 0 and 1), provides an integrated metric where 0 represents the least favorable scenario (either high transportation costs or low solar potential) and 1 indicates the optimal combination (low transportation costs and high solar potential).
The combined score is calculated as:

$$\text{Combined score} = (\text{weight transport} \times \text{transportation normalized}) + (\text{weight DNI} \times \text{DNI normalized}) \quad (4)$$

For the final selection of plant sites, a two-thirds capacity constraint was implemented to ensure that each selected plant receives a minimum amount of straw to maintain operational efficiency. By enforcing this threshold, the algorithm avoids underutilized plants and prioritizes locations with sufficient biomass supply.

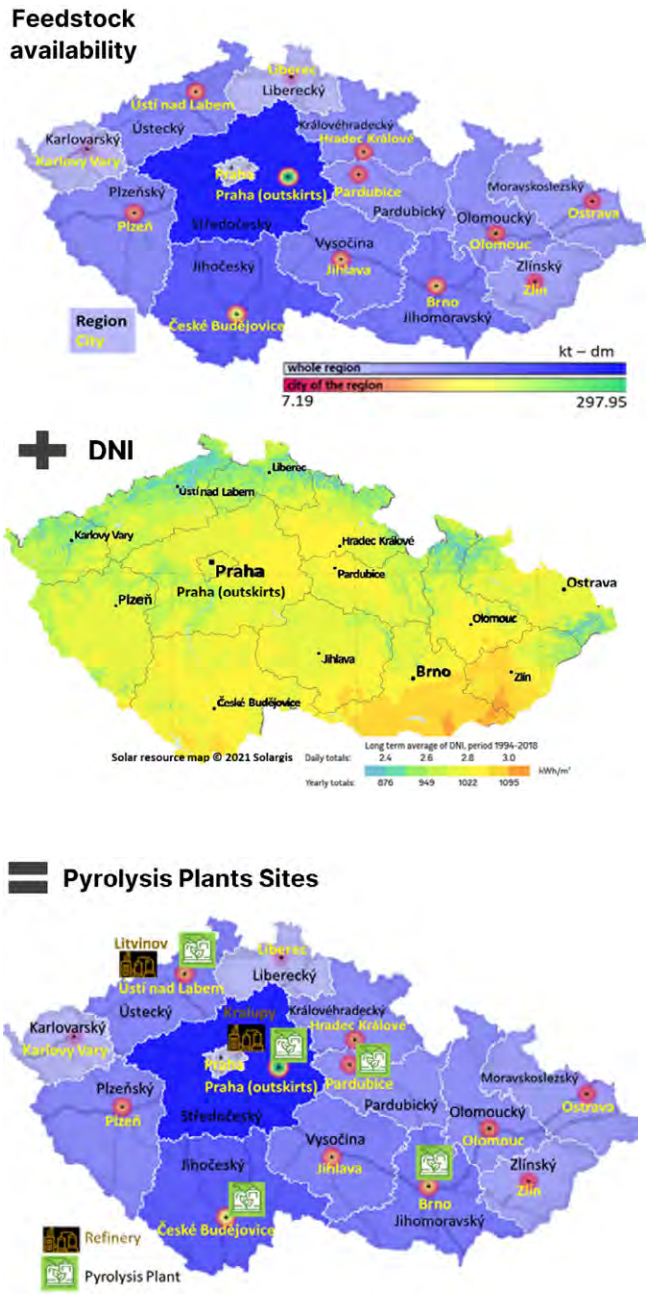

**Figure 2.** Selected pyrolysis plant sites, by using a trade-off score between feedstock capacity and DNI for 2030.

Mennicken et al. reported that when calculating transportation costs in Europe using straight-line distances, it is recommended to apply a correction factor (detour index) ranging from 1.1 to 1.3. In this study, a correction factor of 1.1 was applied [13]. In Stage 4, the supply chain network model was run to provide the optimal allocation of feedstock to the potential pyrolysis plant sites and bio-oil to the nearest refinery. Finally, the OPEX,

CAPEX breakdown, Revenues per site, and SAF replacement satisfaction in 2030 and 2050 were calculated.

## Supply Chain Network Model

The model in this study represents a three-stage supply chain for converting feedstock into SAF. It begins with straw collection from the regions, then transported to a storage facility where it is stored until needed for processing, which is located in the plant site area. The available straw of each region is transported to one plant site only. At the plant site, the feedstock undergoes initial treatment processes to prepare it for pyrolysis. Solar energy is utilized to support sustainable operations at the plant. In the pyrolysis plant, a wastewater treatment plant is located for treating the aqueous phase, where the purified water is used in the electrolysis. The pyrolysis plant includes two upgrading steps to begin refining the pyrolysis oil. Following the upgrading process, the resulting bio-oil is transported to the nearest refinery, where it undergoes further processing in a distillation column to produce biofuels, including SAF, biodiesel, and biogasoline. Each stage of the supply chain is interconnected through truck transportation, with transportation costs calculated in both directions. A 30% discount is applied to return trips. For this study, a plant capacity of 300 kt was assumed. It is assumed that the available straw in each region is concentrated at the regional city center to facilitate the calculation of distances. The plant sites are established in regions with the highest combined scores and are designated according to the names of these regions.

The objective function seeks to minimize the total costs, which include feedstock, transportation, storage, operational, and capital expenditure costs associated with pyrolysis plants, while accounting for the revenue generated from biochar and SAF.

### Index Sets:

R = {r|region in the country}

RF = {rf| refinery in the county}

### Decision Variables:

$X_r$ = 1 if r has a plant, otherwise 0

$Y_{r,r'}$ = 1 if the straw is transported from region r′ to plant in region r, otherwise 0.

$Z_{r,rf}$ = 1 if HDO from r is transported to rf; otherwise, 0.

### Parameters:

$DNI_r$ = Direct Normal Irradiance at a region

$S_r$ = biomass availability in a region

$S_p$ = available straw in a plant

$TC_{r,r'}$ = Full-truck transport cost per km with TC capacity

TC = Truck capacity (tn)

$CT_{r,r'}$ = Transportation cost per km per tn ($TC_{r,r'}$ / TC)

$D_{2,r,r'}$ = Two directions distance between r and r′ ϵ R

BD = Bulk density of biomass (kg/m³)

SC = Storage and loading cost per m³

CAP = Maximum straw processing plant capacity (kt)

$CAP_{rf}$ = Maximum refinery capacity (bbl)

$TC_{r,rf}$ = Transportation cost per km of a full tanker truck with TTC capacity

TTC = Tanker truck capacity (gallons)

$CT_{r,rf}$ = Transportation cost per km per bbl ($TC_{r,rf}$ / TTC*α)

$D_{2,r,rf}$ = Two directions distance between regions r and rf ϵ R

HDO = bio-oil (bbl)

α = Convector factor from gallons to barrels

γ = Conversion factor for SAF

δ = Conversion factor for HDO

Biochar and SAF selling price (€)

### Objective function:

$$min[\sum_{r,r' \in R, r \neq r'} r, r' Yr, r' * S_r * D_{2r,r'} * CT_{r,r'} + \sum_r BD * S_p * SC + \sum_{r,rf} Z_{r,rf} * HDO_r * D_{2,r,rf} * CT_{r,rf} + \sum_r (OPEX + CAPEX)] - \sum_r (Biochar\ revenues + SAF\ reveneues)] \quad (5)$$

### Constraints:

Feedstock Supply: $S_{min}*Y_r \leq \sum_r X_r*S_r \leq S_{max}*Y_r, \forall r$ (6)

Region Supply: $\sum_r X_r \leq 1, \forall r$ (7)

*Ensures that each region supplies biomass to only one plant.*

Straw Utilization: $\sum_r S_p \leq \sum_r S_r$ (8)

*Ensures the straw used in all plants does not exceed the total straw supply.*

Straw Allocation: $\sum_r Y_{r,r'} * S_r \leq CAP, \forall r$ (9)

*Ensures that the allocation of straw from each region to a plant does not exceed the plant's capacity.*

Trade-off Score: $X_r$ * Combined score ≥ Tmin (10)

Two-Thirds Plant Capacity: $S_r \geq 2/3 * Smax, \forall r$ (11)

Transportation Distance: $D_{r,r'} \leq 150, \forall Y_{r,r'}=1$ (12)

*Ensures transportation distances do not exceed 150 km for regions where biomass is transported.*

SAF Production: $\sum_r \gamma * S_p \geq$ SAF DEMAND (13)

*Ensures that the total SAF production meets the demand.*

HDO Refinery Capacity: $\sum_r \delta * S_p \leq \sum_{rf} CAP_{rf}$ (14)

*Ensures that the HDO produced at all plants does not exceed the total refinery capacity.*

Refinery Transportation: $\sum_{rf} Z_{r,rf} = 1, \forall p$ (15)

*Ensures that each region where a plant is located sends its produced HDO to exactly one refinery.*

Solar Collector Energy Production: energy produced by solar collectors must meet or exceed the daily thermal energy requirement for the pyrolysis process.

num collectors needed * energy per collector per day kWh ≥ total thermal energy kWh per day (16)

*The installed electrolyzer and PV systems must be sufficient to meet the hydrogen production demand.*

electrolyzer capacity kW ≥ ($H_2$ needed per year / operating hours per year) (17)

pv capacity kW ≥ [($H_2$ needed per year * production efficiency)/operating hours per year] (18)

## RESULTS

By executing the Supply Chain Network Model code in Python, the optimal locations for the pyrolysis plant in 2030 and 2050 for all the cases (AGR ±0.1% and ±0.2% from the historical data) and bio-oil transportation to the nearest refinery are presented in Figure 3.

In the short to mid-term (2030), the model does not exhibit sensitivity, as it selects the same plant sites. However, in the long term (2050), the model demonstrates sensitivity by selecting different plant sites. In all scenarios, the plant sites in Praha (outskirts) and České Budějovice are consistently chosen. Additionally, the results indicate a well-optimized and scalable pyrolysis-based SAF production system with high straw utilization (94–100%) across all cases, as presented in Table 1.

Refinery capacities remain sufficient to handle bio-oil production, supporting seamless integration into existing fuel infrastructure.

Despite fluctuations in biomass availability, SAF production consistently meets 6% and 35% of Jet A-1 fuel demand for 2030 and 2050 respectively, highlighting supply chain resilience.

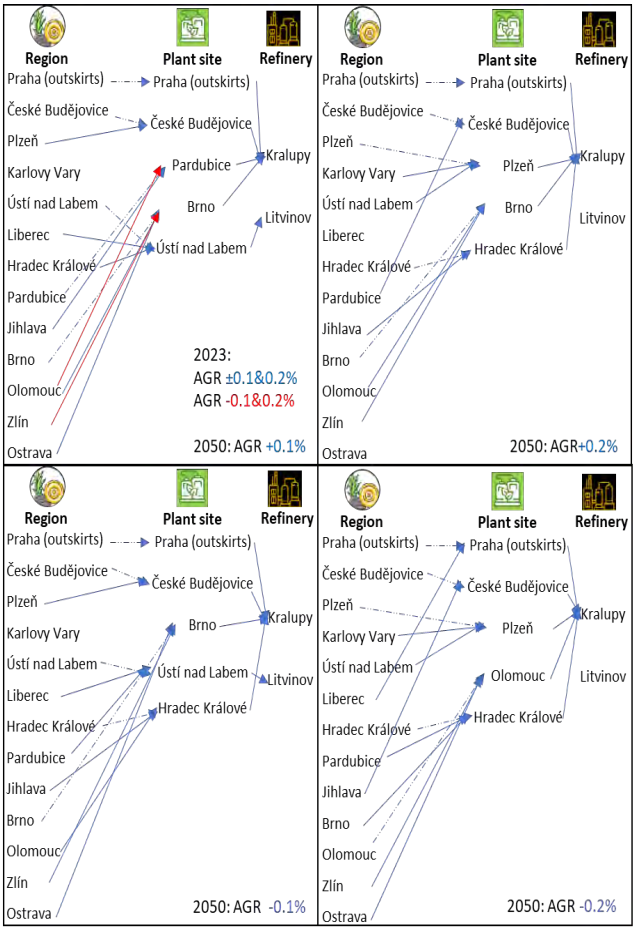

**Figure 3.** The three-supply chain network for 2030 and 2050. The dashed lines do not represent straw transportation but rather indicate that the straw from a region is utilized at the plant site located within the same region.

**Table 1:** Estimated wheat straw utilization and SAF production plant in 2030 and 2050 for all the cases.

| | Straw Utilized % | | SAF produced (kt) | |
|---|---|---|---|---|
| | 2030 | 2050 | 2030 | 2050 |
| AGR+0.1% | 94.4% | 94.4% | 199.05 | 202.1 |
| AGR -0.1% | 98.6% | 98.5% | 204.3 | 200.1 |
| AGR+0.2% | 94.4% | 93.7% | 200.1 | 205.2 |
| AGR -0.2% | 98.5% | 100% | 202.5 | 197.4 |

Total cost shows a downward trend over time, suggesting improved cost efficiency due to technological advancements. Specifically, in 2030 cases the economic feasibility is maintained, with total costs ranging from €755M to €884M, while biochar and SAF revenues contribute up to €214M, while in 2050 cases the total costs vary between €542M and €613M, while biochar and SAF revenues contribute up to €319M, ensuring economic feasibility. Praha (outskirts) consistently emerges as the most economically viable plant site location for all the cases. Solar collectors play a crucial role in meeting heat

demand, reducing external energy dependence, and ensuring sustainability.

Overall, the analysis confirms that the current strategy is robust, adaptable, and viable for long-term SAF production, while also highlighting a cost-effective approach with strong long-term profitability and energy security.

## CONCLUSION

This study confirms that SAF production in the Czech Republic is both technically and economically viable. The total costs are projected to decline by up to 30.64% from 2030 to 2050, while revenues are estimated to increase by approximately 49.07% over the same period. Strategic site selection based on feedstock availability, transportation costs, and solar energy potential enhances efficiency, with Praha outskirts emerging as a key production hub. CAPEX and OPEX (total cost) estimates show declining costs over time, especially with advancements in solar collectors and energy efficiency improvements.

The results align with EU decarbonization goals, demonstrating that SAF, supported by optimized supply chain networks, can play a pivotal role in reducing aviation emissions. Continued investment in SAF infrastructure, technological advancements, and regulatory support will be essential to ensuring a sustainable and cost-effective transition to greener aviation fuels.

## ABSTRACT

Decarbonizing industries could significantly increase electricity demand, necessitating strategic grid expansion. This study evaluates the impact of decarbonizing the Pulp and Paper Sector under four 2050 scenarios: carbon capture, biomass-based, direct electrification, and indirect electrification. A bottom-up approach is employed to estimate 2020 final energy demand by heat grade and subsector. Both final and primary energy demand systems are modeled, accounting for the efficiencies of end-use technologies and primary energy transformation processes. The analysis compares primary renewable energy demand (electricity and biomass) normalized per ton of equivalent $CO_2$ avoided against a business-as-usual scenario. It also considers the requirements for wood residues, organic waste, and $CO_2$ storage. The carbon capture scenario, while low in electricity demand, requires significant organic waste for renewable natural gas production and 2.6 Mt of $CO_2$ storage to offset direct and indirect emissions, making it the least feasible due to uncertainties around carbon storage in Quebec. Among the remaining scenarios, the direct electrification stands out by offering the lowest primary energy demand. It combines heat pumps with electric boilers for steam production and lime kilns are converted to a plasma-based solution. The study also includes a sensitivity analysis highlighting the potential of energy efficiency measures to ease the burden of decarbonization.

**Keywords**: Decarbonization, Energy Conversion, Modelling and Simulations, Planning, Carbon Capture, Pulp and Paper

## INTRODUCTION

Achieving net-zero emissions by 2050 will require significant adaptations in industries, increasing pressure on electric grids. Forecasting industrial energy demand is important for electric utilities and requires a deep understanding of each sector. In Quebec, Canada, the pulp and paper sector (PPS) may need to make major adjustments to reduce GHG emissions from fossil fuel combustion, which accounted for 12% of total industrial emissions in 2020. The PPS has several abatement solutions to choose from, including installing carbon capture units, shifting to sustainable natural gas, increasing biomass use, electrifying process heat, or using hydrogen for indirect electrification.

Besides these solutions, which can be combined, the PPS could further contribute to the energy transition. The chemical and semi-chemical pulp subsector emits significant biogenic $CO_2$ from the combustion of residual liquor and lime regeneration. This biogenic $CO_2$ could be used to produce synthetic fuels and/or generate negative emissions to offset unavoidable GHG emissions [1]. These pathways are known as Bioenergy with Carbon Capture and Utilization (BECCU) and Bioenergy with Carbon Capture and Storage (BECCS). The possibility of contributing to BECCU and BECCS, along with the existing biomass supply chain value and the fact that most of the sector's GHG emissions can be easily abated with existing solutions, the PPS is well-positioned to play a key role in decarbonization. Therefore, multiple decarbonization scenarios for the PPS should be evaluated, particularly regarding their impact on electric grids.

This study explores scenarios involving the adoption of different end-use technologies to achieve net-zero emissions by 2050. Key performance indicators assess the impact on the electric grid and biomass resources. The study aims to provide insights based on a bottom-up approach to guide electric system capacity expansion.

## METHODOLOGY

The methodology relies on publicly reported GHG emissions data [2]. Using a bottom-up approach, the final energy demand for low, medium, and high-grade heat is estimated for 2020 for two subsectors: semi-chemical and chemical pulp mills, and other categories. Low-grade heat is required for pulp bleaching, medium-grade heat for washers and evaporators, and high-grade heat for lime kilns. To estimate the evolution of energy demand, a useful energy approach is employed in the Low Emissions Analysis Platform (LEAP), considering an annual growth rate of 1% and the efficiencies of current and alternative end-use technologies. Based on energy demand, the software estimates primary energy demand, considering transformation process efficiencies.

### Scenarios

A business-as-usual (BAU) scenario serves as a baseline, with four simplified scenarios modelled using constant useful energy. The end-use technologies per subsector and heat grade are illustrated in Figure 1. The first scenario, the carbon capture (CC) scenario, involves minimal adaptation of end-use technologies, relying on carbon capture and storage to achieve net-zero. A blend of 20% renewable natural gas (RNG) and 80% natural gas replaces natural gas. RNG is produced from organic waste, including food, agricultural, livestock residues, landfill sites, and wastewater. Light fuel oil and heavy fuel oil are replaced with liquefied gas blend. The carbon capture units are directly installed as post-combustion equipment on boilers and lime kiln to offset emissions from burning natural gas.

The subsequent scenarios involve significant adaptations of end-use technologies, converting them to biomass-based, direct electrification, and/or indirect electrification technologies. For low- and medium-grade heat, heat pumps (HPs) and high-temperature heat pumps (HTHPs) are prioritized, as they can effectively upgrade waste heat to produce hot water and steam. The proportion of process heat that can be supplied by heat pumps depends on factors like location, timing, temperature and flow rate of both waste and process heat streams. Marina et al. [3] estimated that heat pumps could supply up to 69% of process heat below 200°C in European PPS, though excluding (Semi-) Chemical Pulp Mills. For the entire sector, up to 65% is set for low- and medium-grade heat. Since recovery boilers already provide steam, HTHPs supply 45% of medium-grade heat in (Semi-) Chemical Pulp Mills. A sensitivity analysis complements the results to account for uncertainties. For the biomass-based (BIO) scenario, efficient bark boilers supply the remaining heat, with enhanced efficiency from crushing and drying processes using low-grade waste heat. For the direct (DE) and indirect (IE) electrification scenarios, electric boilers provide the remaining heat. For high-grade heat, a gasified biomass lime kiln is selected in the BIO scenario, though alternatives like torrefied biomass, pulverized wood or lignin exist [4], with gasified biomass being widely adopted in Finland [1]. For the DE scenario, an electrified plasma calcination process is selected [5], and for the IE scenario, a hydrogen-fired lime kiln is selected. Finally, while adoption of end-use technologies is not constrained by regional electric capacities, but wood residues are limited to current availability.

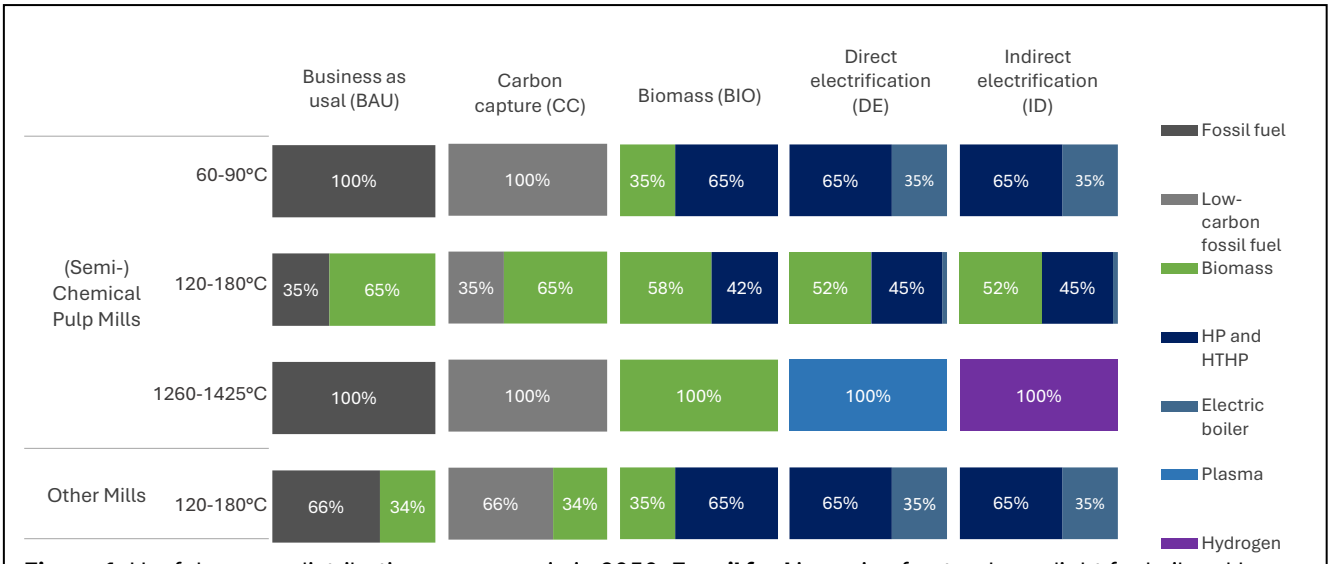

**Figure 1:** Useful energy distribution per scenario in 2050. **Fossil fuel** is a mix of natural gas, light fuel oil and heavy fuel oil. **Low-carbon fossil fuel** is a mix of natural gas, renewable natural gas and liquified natural gas blend. **Biomass** is a mix of residual liquor, wood bark and decentralized biogas. **HP, HTHP** and **EB** refer to heat pump, high temperature heat pump, and electric boiler.

## Final energy demand

The final energy demand system includes both current and alternative end-use technologies. For low and medium-grade heat, current technologies are fossil fuel-fired, bark, and recovery boilers, while alternatives include efficient bark boilers, electric boilers, HPs, and HTHPs. For high-grade heat, the current technology is a fossil fuel lime kiln, while alternatives include gasified biomass, plasma-based solution, and hydrogen. Efficiencies and auxiliary energy requirements are listed in Table 1, using a low heating value (LHV) of 19 MJ/kg for wood residues. The final energy demand system also includes carbon capture technology, with an efficiency of 95% and energy requirements of 333 $kWh_{el}$/t for capture and conditioning with a membrane separation technology Zanco et al. [6]. This simplified approach may differ for lime kilns due to variations in $CO_2$ concentration and scale [7, 8].

Direct emissions are estimated by LEAP, following the IPCC AR5. Quebec's electricity grid, mainly powered by renewables, has a GHG emissions intensity of about 0.3% of Europe's average in 2023 [9, 10]. Emissions from imported non-renewable electricity are small, but by 2050, all imports are assumed to be 100% renewable.

**Table 1:** End-use technologies parameters

| End-use technology | Efficiency | Auxiliary energy requirements |
|---|---|---|
| Low and medium-grade heat | | |
| Boiler | | |
| Fossil fuel | 75%[11] | N/A |
| Bark | 70%[11] | N/A |
| Recovery | 65% [12, 13] | N/A |
| Bark (efficient) | 80% [14] | Crushing: 32 $kWh_{el}$/t[1] |
| Electric | 99%[11] | N/A |
| Heat pump | | |
| HP | 300%[3] | N/A |
| HTHP | 250%[3, 15] | N/A |
| High-grade heat | | |
| Lime kiln | | |
| Fossil fuel | 53%[16] | N/A |
| Gasified biomass | 41%[4] | Drying: 465 $kWh_{th}$/t[4] Grinding: 278 $kWh_{el}$/t[4] |
| Hydrogen | 56%[4] | N/A |
| Plasma-based | 55%[16] | N/A |

[1]Electric consumption of a bark crusher per dry ton of pine wood residues, based on vendor data.

## Primary energy demand

The primary energy demand system includes centralized energy solutions such as natural gas, gas blend with RNG, liquefied gas blend, 100% renewable electricity, and green hydrogen. For the liquefied gas blend, energy for liquefaction, truck transport, and fugitive emissions are neglected due to data limitations, though it represents only 2% of final energy demand in the CC scenario. Green hydrogen is produced using alkaline electrolysers, with liquefaction and transport by trucks for storage and distribution. Decentralized energy solutions like wood residues, residual liquor, biogas from wastewater streams, are also included. Transformation processes and distribution efficiencies as well as fugitive GHG emissions are listed in Table 2. Fugitive emissions for natural gas are relatively low and have been estimated at 0.93%(vol.) by the CIRAIG [17], while those for RNG are considered negligible. The primary energy demand system also includes direct air capture technology, with an energy requirement of 2514 $kWh_{el}$/t [18], to offset the fugitive emissions of natural gas.

**Table 2:** Transformation processes and distribution parameters

| Energy produced | Requirements | Primary energy |
|---|---|---|
| Green hydrogen | 1.37 $kWh_{in}/kWh_{out}$ [19] | Renewable electricity |
| RNG[1] | 1.47 $kWh_{in}/kWh_{out}$ 0.05 $kWh_{in}/kWh_{out}$ | Organic waste Renewable electricity |
| **Energy distributed** | **Efficiency** | **GHG emissions** |
| Renewable electricity | 93%[20] | - |
| Natural gas | 96%[17, 21] | 13.5 $g_{CO2eq}/MJ_{consumed}$[17] |
| Green hydrogen | 95%[22] | 11.6 $g_{CO2eq}/g_{H2leaking}$[23] |
| Natural gas blend | 96%[17, 21] | 10.8 $g_{CO2eq}/MJ_{consumed}$[17] |

[1]The organic waste requirements are based on a theoretical assessment, assuming 50% average carbon content, a LHV of 5.55 kWh/kg, and a carbon conversion fraction of 0.85. The electricity requirement was estimated at 5% of the product's LHV.

## Key performance indicators

Resource indicators, along with the reduction of GHG emissions, differences in biomass demand and $CO_2$ storage requirements, are calculated for each scenario. The GHG Performance Indicator (GPI) assesses the marginal renewable energy - electricity, biomass, or both - required per ton of GHG emissions avoided, as expressed in Equation 1. This indicator is evaluated by heat grade, subsector, and globally, relative to the BAU scenario.

$$GPI_i = \frac{E_i - E_{i,baseline}}{GHG_{baseline} - GHG}, \quad (1)$$

where E is the primary energy demand in MWh, GHG is the 100-year GWP emissions in ton of equivalent $CO_2$, i is the resource of interest (electricity, biomass or total).

## RESULTS AND DISCUSION

The sector's thermal energy consumption in 2020 is estimated at 23 $TWh_{th}$, and its distribution by usage is illustrated in Figure 2.

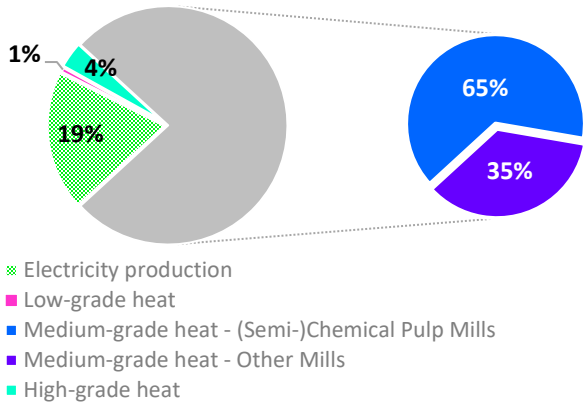

**Figure 2.** Distribution of the thermal energy consumption by usage.

Most consumption is attributed to steam used in various processes, with the remainder used for low- and high-grade heat in processes and on-site electricity production. The main fuels consumed in the (Semi-) Chemical Pulp Mills are residual liquor (63%), natural gas (25%), and wood residues (9%). For the Other Mills, the main fuels are natural gas (52%) and wood residues (37%). The use of gas directly fired in Through Air Dryers is neglected, slightly overestimating steam consumption. It is assumed that electricity production is fueled by wood residues and residual liquor.

### Resource analysis

Figure 3 illustrates the marginal primary energy demand for each scenario and its breakdown by source. All scenarios achieve a 98-99% reduction in 100-year GWP direct emissions and a 96-100% reduction in indirect emissions. Residual GHG emissions result from the combustion of large amounts of biomass - wood residues and residual liquor – emitting biogenic methane and nitrous oxide. Only the CC scenario requires $CO_2$ storage, with 2.2 Mt to offset direct emissions and 0.4 Mt for indirect emissions.

The CC scenario requires more energy due to electricity needed by the carbon capture technology and RNG production, along with about 3.2 TWh of organic waste for RNG production. The other scenarios are fossil-free and more efficient than the baseline, but they required additional electricity, mainly for direct electrification. The DE and IE scenarios, the adoption of direct electrification technologies releases 4.7 TWh of wood residues that were used in bark boilers. Lastly, the IE scenario requires an additional 0.6 TWh for electrolysis to supply five lime kilns.

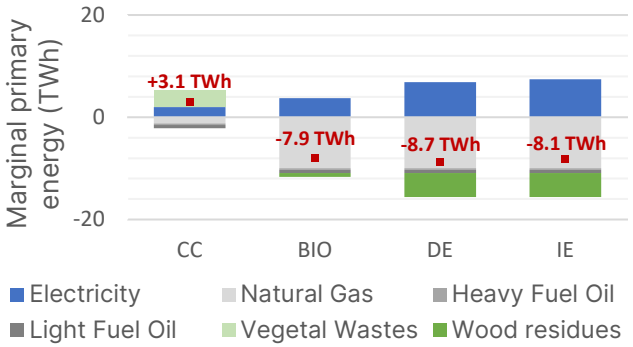

**Figure 3.** Marginal primary energy (red square) and its breakdown per source compared to the baseline.

The total, electric and biomass GPIs are reported in Table 3. The DE scenario have the highest biomass GPI, but with a relatively high electric GPI. Overall, the total GPI is the lowest, meaning that the DE can decarbonized effectively the PPS.

**Table 3.** Total, electric and biomass GPI in MWh/t per scenario.

| | CC | BIO | DE | IE |
|---|---|---|---|---|
| $GPI_{total}$ | +2.0 | +1.1 | +0.6 | +0.9 |
| $GPI_{electric}$ | +0.7 | +1.4 | +2.6 | +2.8 |
| $GPI_{biomass}$ | +1.2 | -0.3 | -1.9 | -1.9 |

To better understand what influences the GPIs, the total, electric and biomass GPI are breakdown by heat grade and subsector in Figure 4.

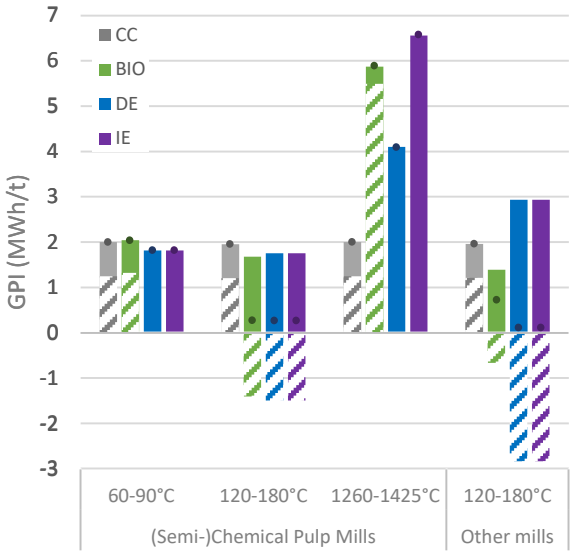

**Figure 4.** GHG performance indicator for electricity (solid bars), biomass (hatched bars) and total (dot).

The highest total GPI is for high-grade heat, reflecting that the usage is harder to abate than the others. The

CC scenario achieves the lowest total GPI, but $CO_2$ storage remains uncertain and the organic waste resource used to produce RNG is also limited - 25% of it is used in the CC scenario, based on the 2021 Quebec biomass inventory [24]. Therefore, the CC scenario's decarbonization solutions should be reserved for hard-to-abate industrial applications and residual emissions. The DE scenario ranks second, but it has the highest electric GPI across all heat grades and subsectors. The BIO scenario, relying mainly on wood residues, ranks third, with the lowest electric GPI and no need for additional biomass, as wood residues are redirected from steam production via HTHPs.

## Sensitivity analysis

The sensitivity of three uncertain variables on the GPI is assessed in Table 4 using a one-at-a-time technique with lower and upper bound for each variable:

1. The proportion of heat provided by heat pumps, with bounds of 25% and 85%.
2. The reduction in energy demand from energy efficiency measures (EEMs), excluding heat pumps, with bounds of 10% and 20%. EEMs are apply to electricity for equipment (lighting, motors, compressors, etc.) and steam demand in (Semi-) mChemical Pulp Mills only.
3. The proportion of RNG in the gas blend, with bounds of 10% and 20%, including the change in natural gas fugitive emissions.

**Table 4**: Sensitivity analysis of variables on the GPI.

| **Scenarios** | **$\Delta GPI_{electric}$ (%)** | | **$\Delta GPI_{biomass}$ (%)** | |
|---|---|---|---|---|
| | LB | UB | LB | UB |
| 1. Proportion of heat from HP and HTHP vs boilers | | | | |
| | 25% | 85% | 25% | 85% |
| BIO | OB | +13% | OB | -185% |
| DE | +40% | -9% | - | - |
| IE | +36% | -9% | - | - |
| 2. Reduction of electricity and steam consumption | | | | |
| | 10% | 20% | 10% | 20% |
| CC | -18% | -19% | -18% | -51% |
| BIO | -16% | -19% | 45% | 324% |
| DE | -12% | -24% | - | - |
| ID | -11% | -22% | - | - |
| 3. Proportion of RNG in the gas blend | | | | |
| | 10% | 30% | 10% | 30% |
| CC | +7% | -7% | -50% | +50% |

OB: Out of bounds

The sensitivity analysis results provide valuable insights: EEMs and waste heat recovery with heat pumps could significantly reduce additional electricity and limit unnecessary grid expansion. EEMs cutting steam and electricity demand of electric equipment by 10% and 20% could reduce additional electricity demand by 11%-18% and 18%-24%, respectively, depending on the scenario. EEMs should be implemented before or alongside electrification of process heat to reduce decarbonization's burden. They must also align with the chosen decarbonization pathway for effectiveness. Heat pump adoption is crucial in limiting electric demand. If heat pumps provide 25% of the process heat, additional electricity increases by 40% for the DE scenario, while providing 85% of the heat reduces additional electricity demand by 9%. These differences highlight the importance of characterizing the potential of heat pumps to minimize the capacities of electric boilers as much as possible.

The sensitive analysis shows that the proportion of RNG represents a trade-off between the organic waste demand and $CO_2$ storage requirements, both limited resources. At 30% RNG, organic waste demand rises to 37% of the available resource in Quebec for 2021. At 10% RNG level, $CO_2$ storage requirements to offset indirect emissions rises by 13% due to natural gas fugitive emissions.

# CONCLUSION

This study provides a comprehensive analysis of the decarbonization pathways for the PPS and their impact on resource in Quebec. The results indicate that while all scenarios lead to 98-99% reductions in GHG emissions, the strategies employed have varying levels of efficiency. The CC scenario is notable for its low electricity demand and costs but requires uncertain $CO_2$ storage and large amounts of organic waste for RNG production. Carbon capture and RNG should be reserved for the hardest-to-abate applications among all industries. Further work is needed to determine whether the lime kiln falls into this category. The DE scenario, with a total GPI of 0.6 MWh/t, uses the least combined electricity and biomass to avoid one ton of $CO_2$. The sensitivity analysis highlights key variables like EEMs, heat pump integration, and the proportion of RNG in gas bend. EEMs and heat pumps are critical for minimizing grid expansion, and aligning EEMs with decarbonization pathways is vital for an effective energy transition. Future research should focus on cost-effectiveness assessments and expanding the model to optimize resource allocation across Quebec's major industries.

## ABSTRACT

Methanol and ammonia are key energy carriers in a decarbonized society. This study assesses their use in power generation via two pathways: direct utilization as green fuels in fuel cells or as hydrogen carriers. Using these chemicals as hydrogen carriers achieves higher efficiencies (around 40%) due to the maturity of hydrogen fuel cells, resulting in electricity costs around 700 €/MWh compared to 1200 €/MWh for direct utilization. While hydrogen offers lower electricity production costs, efficiency advancements in methanol and ammonia fuel cells could enhance their competitiveness. Additionally, for scenarios involving transportation and power generation, methanol and ammonia prove economically viable, particularly for distances exceeding 3000 km. Consequently, both are crucial for addressing hydrogen-related challenges in the new renewable energy systems.

**Keywords**: Process Design, Energy Storage, Hydrogen, Fuel Cells, Methanol, Ammonia

## INTRODUCTION

The energy sector, responsible for around 75% of greenhouse gas emissions, requires a significant shift to achieve global climate goals. The integration of renewable energy sources, particularly wind and solar, is expected to increase substantially in the coming years. However, these technologies face challenges mainly related to their variability, which could disrupt grid stability. Additionally, sectors like heavy transport, shipping, and industrial heating are difficult to electrify directly. In this context, hydrogen is emerging as a promising solution to address these issues due to its versatility and potential to decarbonize hard-to-abate industries.

According to Bloomberg [1], hydrogen and its derivatives could reduce up to one-third of global emissions, with a projected capacity to meet 24% of global final energy demand by 2050. Hydrogen's challenges, such as low volumetric energy density and complex storage conditions, have led to the exploration of hydrogen-derived products with methanol and ammonia being the most prominent. These chemicals offer easier storage and transport options and are gaining attention for use in energy storage, power generation, and as alternative fuels in sectors such as maritime transport and aviation.

Ammonia and methanol can be used for different applications through two approaches: as green fuels or as hydrogen carriers [2]. When used as green fuels, they are synthesized from green hydrogen and directly utilized in end-use sectors. Alternatively, they can function as hydrogen carriers, simplifying the storage and transport of hydrogen. In this case, methanol and ammonia are first synthesized, then decomposed or reformed to release hydrogen for final applications. In this last option, methanol steam reforming and ammonia decomposition emerge as the key technologies for hydrogen production from these two liquid carriers.

For power generation, methanol and ammonia can be used in two pathways. The thermochemical approach involves combusting methanol or ammonia, mainly, in gas turbines, sometimes requiring co-fuels to stabilize combustion. Alternatively, electrochemical methods employ methanol or ammonia in fuel cells, known as Direct Methanol Fuel Cells (DMFC) and Direct Ammonia Fuel Cells (DAFC). While promising, these technologies face energy efficiency challenges today that require further research.

Another option is using methanol and ammonia as intermediaries to generate hydrogen, which is then used in hydrogen fuel cells. This approach benefits from the higher efficiency of hydrogen fuel cells but introduces added process complexity, energy losses, and costs.

Research has mainly focused on optimizing catalysts and reactor designs for processes like methanol reforming and ammonia decomposition, as well as improving fuel cell materials and configurations. However, there is limited comprehensive analysis from a process system engineering perspective of these X-to-Power alternatives using fuel cells. Therefore, this work addresses the gap by systematically evaluating five process alternatives: direct methanol and ammonia fuel cells, methanol reforming and ammonia decomposition coupled with hydrogen fuel cells, and direct hydrogen use in fuel cells. A technical and economic evaluation is performed, introducing detailed reactor modeling, to provide comprehensive insights into the deployment of this power generation technology.

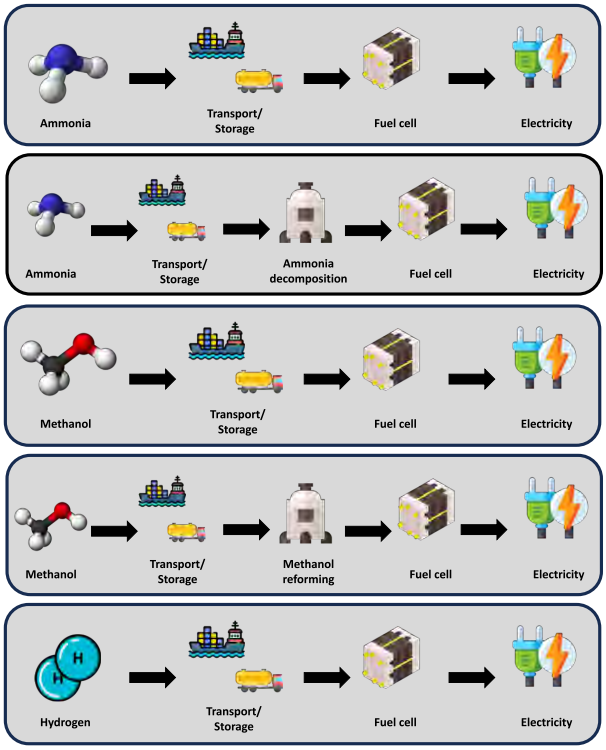

**Figure 1:** Overview of the analyzed alternatives [3]

## PROCESS ALTERNATIVES

This study evaluates two distinct methods for utilizing methanol and ammonia in power generation with fuel cell technology. The first approach directly introduces these compounds into fuel cells, while the second uses them as hydrogen carriers. In the latter option, hydrogen is generated from methanol or ammonia before being fed into a fuel cell. A third alternative is also examined, where hydrogen is directly utilized as a fuel for comparative purposes. A schematic representation of these approaches is provided in Figure 1.

### Methanol based alternatives

The first method involves the direct use of methanol in a direct methanol fuel cell (DMFC), which operates with an aqueous methanol solution (1 M) and air. In the DMFC, methanol reacts at the anode to produce carbon dioxide, protons, and electrons, while oxygen at the cathode reacts with protons to form water according to the following reactions.

$$CH_3OH + H_2O \rightarrow CO_2 + 6H^+ + 6e^- \quad (1)$$

$$6H^+ + 6e^- + \frac{3}{2}O_2 \rightarrow 3H_2O \quad (2)$$

The system operates at a temperature of 333 K under atmospheric pressure. Effluents from the DMFC are processed to separate carbon dioxide, water, and methanol. Gaseous $CO_2$ can be recycled to methanol synthesis, while water and methanol are reintegrated into the fuel cell feed. The cathode effluent undergoes similar separation to recycle water and adjust methanol composition.

In the second alternative, methanol is reformed to produce hydrogen, which is then fed into a solid oxide fuel cell (SOFC). The reforming process involves steam reforming of methanol in a fixed-bed, adiabatic, catalytic, membrane reactor, producing hydrogen, carbon dioxide, and small amounts of carbon monoxide. $Cu/ZnO/Al_2O_3$ is the selected catalyst due to its favorable catalytic activity, rapid kinetics, high selectivity, and cost-effectiveness. The following reactions are involved in the methanol steam reforming unit:

$$CH_3OH + H_2O \rightleftharpoons CO_2 + 3H_2 \quad (3)$$

$$CO + H_2O \leftrightharpoons CO_2 + H_2 \quad (4)$$

$$CH_3OH \leftrightharpoons CO + 2H_2 \quad (5)$$

The process operates at 600 K and 10 bar with a steam-to-methanol ratio of 1.5. A Pd-Ag membrane separates hydrogen from the reforming mixture, and the remaining stream is further processed. To maintain the endothermic reforming reactions, heat is supplied through intermediate heating stages (interheaters between adiabatic reaction stages). This involves burning a fraction of methanol and utilizing the flue gases for heating.

Hydrogen generated is then introduced into an SOFC, which operates at 800°C. This technology has been selected for its high level of efficiency, exploiting the high temperature of the hydrogen obtained in the reforming stage. The high-temperature outlet gases are used to heat the incoming streams, and the remaining energy is utilized in an organic Rankine cycle (ORC) to maximize energy recovery. Refrigerant R134a is selected as

working fluid in this work. The SOFC has an electrical efficiency of 60%, and its fuel utilization ratio is set at 80%.

## Ammonia based alternatives

The first alternative explored with regards to ammonia utilization is the direct ammonia fuel cell (DAFC). In this study, an alkaline membrane fuel cell has been selected since it allows operation at low temperature. Ammonia reacts at the anode to produce nitrogen, water, and electrons, while oxygen reacts at the cathode to form hydroxyl ions. The following reactions take place in the DAFC unit:

$$2NH_3 + 6OH^- \rightarrow N_2 + 6H_2O + 6e^- \quad (6)$$

$$3H_2O + 6e^- + \frac{3}{2}O_2 \rightarrow 6OH^- \quad (7)$$

The process operates at 368 K under ambient pressure, with air at 50% relative humidity. A fraction of the ammonia permeates the anion exchange membrane (referred to as crossover), undergoing oxidation at the cathode to produce nitrogen oxide (NO). A selective catalytic reduction (SCR) unit is used to remove nitrogen oxides from the cathode effluent. The anode effluent, primarily ammonia, water, and nitrogen, is cooled to separate and recycle ammonia.

In the second ammonia-based method, ammonia is decomposed in a fixed bed, adiabatic, catalytic membrane reactor to produce hydrogen, which is then fed into a SOFC. The reaction is endothermic, requiring high temperatures (900 K) and a pressure of 10 bar. $Ni/Al_2O_3$ is the selected catalyst due to its economic advantages and satisfactory performance. The following reaction is performed in the ammonia decomposition process:

$$2NH_3 \leftrightharpoons N_2 + 3H_2 \quad (6)$$

To enhance the performance of the decomposition reaction, a Pd-Ag membrane separates hydrogen in situ, improving equilibrium conditions. A sequence of four reactors along with their respective heat exchangers has been implemented to supply the required energy for the reaction. A fraction of ammonia is combusted to provide the necessary energy in the decomposition section. Hydrogen produced is heated and introduced into the SOFC, similar to the methanol reforming case. Waste heat from the SOFC is also used in an ORC to improve the energy efficiency of the overall process.

## Hydrogen based alternative

In the final alternative, hydrogen is directly fed into a SOFC. The process is similar to the hydrogen utilization stages of methanol and ammonia as hydrogen carriers. Hydrogen is preheated to 800°C, and the high-temperature SOFC exhaust gases are used, in a first stage, to heat the inlet streams and, finally, for energy recovery via an ORC.

## Solution Procedure

A detailed 1-D differential equation model is included to evaluate the performance of the reactor units (ammonia decomposition and methanol steam reforming). With this information, all alternatives are modeled using a nonlinear programming (NLP) approach in GAMS, optimizing system operation under an economic objective function. Mass and energy balances, equilibrium conditions, detailed 1-D differential equation models, etc. are used to represent the different units involved. Capital (CAPEX) and operating (OPEX) costs are estimated using established correlations for the chemical industry. For the calculation of the operating cost, the main inlet parameter is the cost of the fuel. For methanol, the baseline price is set to 1200 €/t, for ammonia, 1060 €/t and, for hydrogen, 5 €/kg. All cases are modeled for a fuel cell with a power capacity of 1 MW. In addition, an integrated assessment of the transportation of these chemicals and their subsequent transformation into power (using the proposed alternatives) is performed. To compute the transportation cost for each chemical, an average value is taken from the literature for the different alternatives.

# RESULTS AND DISCUSSION

The result section presents the key operating variables for four analyzed alternatives that utilize ammonia and methanol as hydrogen carriers, along with a baseline scenario using hydrogen directly in a fuel cell.

**Table 1:** Main operating variables for power production using methanol/ammonia as hydrogen carriers.

| Variables | Methanol | Ammonia |
|---|---|---|
| % inlet fuel to combustion | 22.5 | 25.5 |
| % $H_2$ recovery in the membrane | 78.8 | 96.1 |
| Final reactor conversion (%) | 97.3 | 97.5 |
| kg $H_2$ /kg fuel | 0.11 | 0.12 |
| Net power (kW) | 1106 | 1108 |
| Energy efficiency (%) | 35.8 | 42.3 |
| Energy yield (kWh/kg) | 2.00 | 2.18 |

Both methanol reforming (600 K) and ammonia decomposition (900 K) are endothermic reactions requiring significant heat input. To achieve standalone operation, a fraction of the fuel (20–25%) is combusted to meet these thermal requirements. Ammonia decomposition demands more fuel combustion due to its higher operating temperature (as shown in Table 1). The reactor configuration based on a multibed reactor ensures nearly complete conversion of methanol and ammonia (around 97% in both cases). However, hydrogen recovery varies between processes attributed to differences in permeability and partial pressures in the membrane. Consequently,

the hydrogen yield is 0.11 kg $H_2$/kg methanol (58% of maximum potential) and 0.12 kg $H_2$/kg ammonia (67% of maximum). This operating results directly influence the energy efficiency of the process. Methanol-based systems achieve 36% efficiency, while ammonia-based systems reach 42%, mainly due to the better performance in the production of hydrogen from ammonia.

**Table 2:** Main operating variables for power production using methanol/ammonia/hydrogen as green fuels.

| Variables | Methanol | Ammonia | Hydrogen |
|---|---|---|---|
| Net power (kW) | 1000 | 885.7 | 1000 |
| Energy efficiency (%) | 26.5 | 16.8 | 52.9 |
| Energy yield (kWh/kg) | 1.46 | 0.86 | 17.6 |

Methanol and ammonia can also be used directly in fuel cells. The fuel cell efficiencies achieved are 23.3% for methanol and 15% for ammonia (reaching the global efficiencies of Table 2). These efficiencies are significantly lower than those of hydrogen fuel cells (60% of the selected SOFC). The overall energy efficiency of the process (including other units apart from the fuel cell) is 26% for methanol, 17% for ammonia, and 53% for hydrogen. Therefore, despite the more complex processes in hydrogen carrier alternatives, they remain competitive due to the lower efficiencies of the current DMFC and DAFC technologies.

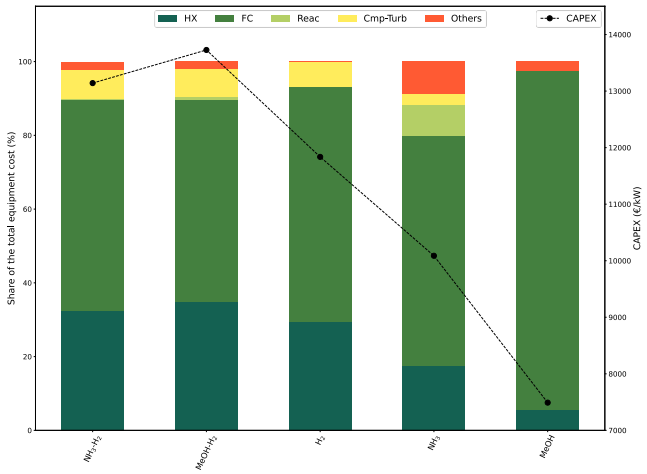

**Figure 2.** Total CAPEX and its distribution [3]

A systematic economic evaluation of the proposed alternatives has also been performed. The CAPEX for the systems studied ranges from 7,000 to 14,000 €/kW (as shown in Figure 2). Processes employing methanol or ammonia as hydrogen carriers exhibit higher investment costs compared to direct fuel cell technologies, mainly due to the added complexity introduced by methanol reforming or ammonia decomposition. Among these, the DMFC represents the least capital-intensive option, as it operates with minimal additional equipment beyond the fuel cell. However, alternatives with lower CAPEX have reduced energy efficiencies according to Tables 1 and 2, presenting a trade-off that becomes evident in the operating costs, as discussed below. The distribution of CAPEX shows that the fuel cell unit accounts for the majority of the investment, ranging from 55% to 92% of the total cost. Heat exchangers also constitute a significant portion of CAPEX in methanol reforming and ammonia decomposition processes, given their critical role in managing the thermal demands of these systems.

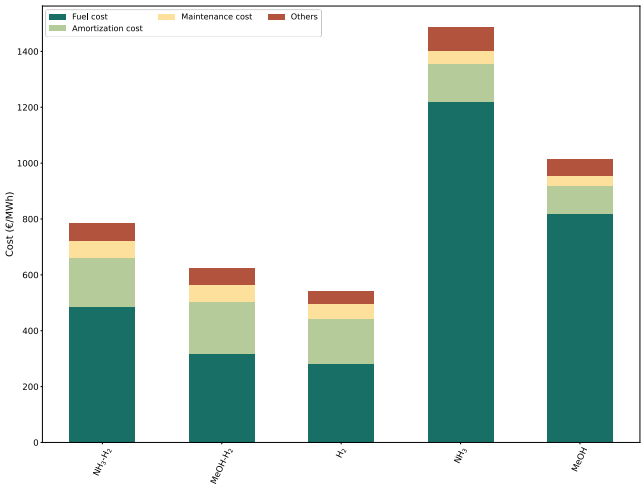

**Figure 3.** OPEX of the different alternatives with its breakdown [3]

When compared to other power generation technologies, the CAPEX for methanol and ammonia fuel cell systems is considerably higher. For instance, renewable technologies like PV panels (810 €/kW), onshore wind turbines (1178 €/kW), biomass-based systems (1998 €/kW), and concentrated solar power (3950 €/kW), as well as traditional sources like natural gas combined cycle plants (924–1386 €/kW) and nuclear plants (6470–7394 €/kW), all show significantly lower CAPEX. The elevated capital costs of methanol/ammonia fuel cell systems arise from two main factors: the high cost of fuel cells, which are still maturing and expected to become more affordable, and the lack of economies of scale due to their relatively small-scale application (in this study 1 MW capacity).

Figure 3 presents the operational costs for the analyzed alternatives. In contrast to CAPEX, the OPEX of systems using methanol/ammonia as hydrogen carriers is lower than that of direct ammonia or methanol fuel cell systems. For hydrogen carrier-based configurations, the OPEX is approximately 500–800 €/MWh, whereas for direct ammonia or methanol usage, the OPEX ranges from 1000–1500 €/MWh. The higher energy efficiency of

hydrogen carrier alternatives offsets their increased CAPEX, leading to comparatively lower operating costs. Fuel costs dominate the OPEX, especially for systems where methanol or ammonia is directly used as green fuels, contributing over 80% of total operational expenses. Thus, the reduction of the production cost of green methanol and ammonia will be a critical driver for the broader adoption of these power generation pathways.

Compared to current electricity generation costs, methanol and ammonia systems are more expensive. For example, renewable systems such as solar PV (60–100 €/MWh), onshore wind (40–80 €/MWh), and biogas (90–170 €/MWh) are more cost-effective. However, methanol and ammonia are employed as energy carriers/storage systems, involving the chemical production and the back transformation into electricity, which inherently leads to higher costs. When viewed as energy storage options, methanol and ammonia offer competitive costs compared to other storage technologies. For instance, pumped hydro costs range from 185–278 €/MWh for short-term applications but escalate to 2778–3704 €/MWh for seasonal storage. Similarly, battery storage costs range from 370–556 €/MWh for short-term and 37037–41667 €/MWh for seasonal applications [4].

In addition, a sensitivity analysis is performed for two critical parameters: fuel cell energy efficiency and the price of methanol/ammonia. Hydrogen fuel cells currently achieve approximately 60% efficiency, while direct ammonia and methanol fuel cells achieve around 15% and 25%, respectively. These efficiency differences significantly affect economic performance. Hydrogen fuel cells, being more developed, are expected to see moderate improvements (up to around 80%). However, direct methanol/ammonia fuel cells are in earlier stages of development, with potential for significant efficiency gains. The economic performance of the proposed system is analyzed under different energy efficiency scenarios showing the results in Figure 4. For direct methanol fuel cells, achieving an efficiency of 47% would make them competitive with systems based on methanol reforming and hydrogen fuel cells. Similarly, direct ammonia fuel cells would need to reach 43% efficiency.

Fuel cost is a dominant factor in the overall electricity cost, as indicated in Figure 3. Green methanol and ammonia prices vary widely, influenced by production methods. Future projections estimate prices of 231–583 €/t for methanol and 285–350 €/t for ammonia by 2050 [5]. If methanol and ammonia prices drop below 400 €/t, electricity costs could range between 400 and 600 €/MWh, narrowing the gap between direct and hydrogen-based systems. Direct methanol systems, in particular, could become more economically competitive, potentially outperforming hydrogen-based alternatives.

The previous results are circumscribed to the process itself. At this point, hydrogen as such shows the best economic performance with the lowest operating cost. However, the main limitations about the use of hydrogen come from its storage and transport conditions.

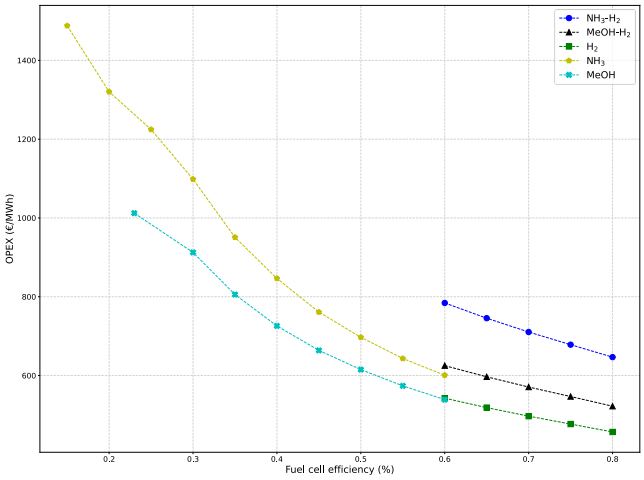

**Figure 4.** Operating cost versus fuel cell efficiency [3]

For shorter distances, the percentage of the transportation cost in the total cost remains low in all cases. Therefore, as hydrogen shows the best operating cost in the transformation stage, this is the technology with the best global performance. In the case of rail transport or shipping, hydrogen transport is not considered due to the difficulties associated and the lack of data for these alternatives. As distance increases, the transport costs associated with hydrogen experiments notably increase, higher than in the case of methanol or ammonia. For example, when transported by truck over 3000 km, the transportation cost represents around 70% of the total cost for hydrogen. Consequently, the total cost of the system exceeds the cost values associated with ammonia and methanol. In the case of truck transport, the transition point is around 400 km, where the use of methanol as hydrogen carrier is recommended. Regarding pipelines, the hydrogen transportation cost is significantly lower than the case of truck, shifting the transition point to around 3000 km. Hence, methanol and ammonia demonstrate great potential in applications where transportation and/or storage is critical.

## CONCLUSIONS

A systematic evaluation compares methanol and ammonia as green fuels or hydrogen carriers for electricity generation via fuel cells. Ammonia and methanol as hydrogen carriers demonstrate superior technical and economic performance today, with overall energy efficiency of 35–40% compared to 15–25% for direct alternatives. This efficiency translates to lower operating costs (600–800 €/MWh). While hydrogen fuel cells

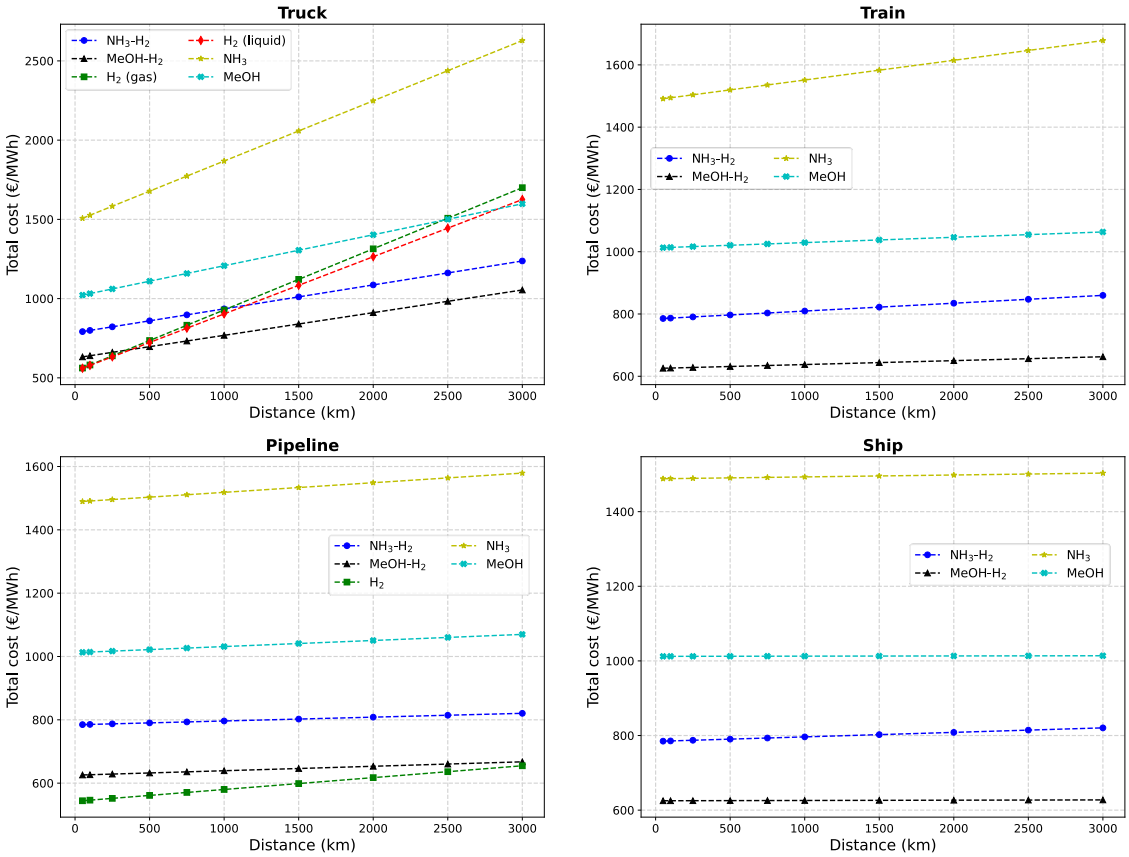

**Figure 5:** Total cost of transportation and power production [3]

exhibit higher efficiency in power generation, transportation costs favor methanol and ammonia, particularly for long distances. With potential efficiency improvements for direct alternatives, methanol and ammonia are positioned as critical solutions for long-term energy storage and transportation challenges.

## ABSTRACT

Hydrogen is a key element in the global transition toward a low-carbon economy, with green hydrogen offering significant potential to decarbonize industries and energy systems. This study focuses on designing and optimizing a green hydrogen supply chain (HSC) for the state of Bahia, Brazil, using a deterministic Mixed-Integer Linear Programming (MILP) model. The model evaluates 24 scenarios combining production sites, storage technologies, transportation methods, and energy sources, minimizing the Total Sustainable Cost (TSC). The TSC integrates financial and environmental costs, monetizing $CO_2$ emissions using international carbon pricing. Results indicate that economies of scale play a critical role allowing the minimization of the financial costs while achieving lower greenhouse gas (GHG) emissions compared to other scenarios. The study emphasizes the importance of aligning production strategies with regional renewable energy resources to enhance both cost-effectiveness and sustainability. Future research should incorporate stochastic approaches to address uncertainties in hydrogen demand, energy availability, and market dynamics.

**Keywords**: Green Hydrogen Supply Chain, Optimization, Brazil Case Study, Environmental Concerns, Scenarios Analysis

## INTRODUCTION

The rising greenhouse gas (GHG) emissions have led to a significant shift in energy production, distribution, and consumption. To facilitate this transition—replacing fossil fuels with renewable sources—it is essential to understand the role of energy storage in the supply chains (SC) of the future energy mix [1]. In this setting, Hydrogen is an energy carrier with significant potential to decarbonize key sectors. The optimization of hydrogen supply chains (HSC) has gained considerable attention from the Process Systems Engineering (PSE) community over the last decade [2]. Several studies address SC uncertainty, while others use capacitated facility location problem models based on deterministic data. Although deterministic models offer a solid foundation for SC design, they do not account for uncertainties and imperfect information about future business environments, limiting their capacity to predict performance in varying scenarios [3-4].

In this context, Brazil emerges as a relevant player in green hydrogen production due to its abundant wind and solar resources. However, the deployment of a complete SC is necessary to produce, transport, store, and distribute this low-carbon fuel [5]. This work explores these challenges and develops a deterministic approach to design and plan a green hydrogen supply chain (GHSC) for the Brazilian State of Bahia.

## PROBLEM STATEMENT

As a deterministic capacitated facility location problem, this work aims to design optimal investments in the GHSC to meet the demand of Bahia's oil refinery, according to the superstructure in figure 1. The demand cluster requires 200 MW (29 kt/year) of hydrogen, according to a previous study developed at SENAI-CIMATEC [6].

**Given:**

(i) A predefined hydrogen demand $D_j$ for $j = 1$ (representing the refinery).

(ii) Possible facility locations (7 locations in Bahia).

(iii) Scenarios involving energy sources (solar, wind, or grid), storage options (liquefied or compressed), and transportation methods (trucks or pipelines).

**Determine the optimal:**

(i) Hydrogen production plant locations and capacities $x_i$.
(ii) Storage and transportation methods for each production plant.
(iii) Energy sources used at each production plant.

**Objective:** Minimize the Total Sustainable Cost (TSC), which is the sum of financial and environmental costs. The environmental cost is represented as a weighted function of $CO_2$ emissions, monetized using the international carbon credit price.

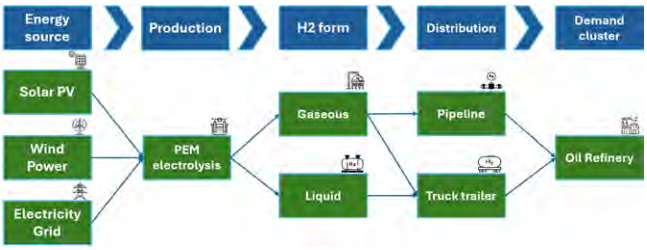

**Figure 1**: Model superstructure.

## METHODOLOGY

The cost and emissions data were obtained using the Decision-Making Model for Hydrogen (DMMH2) software developed by SENAI-CIMATEC University [7]. This software calculates the Levelized Cost of Hydrogen (LCOH) across all stages of production, storage, and transportation for different production scales, incorporating inputs such as capacity availability for wind and solar plants, as well as electricity prices for grid-powered plants. Emissions data are also considered. The model estimates annual costs based on a comprehensive database that includes both literature sources and supplier data [8].

The capacity factors for renewable energy generation at each site are derived from historical data provided by the National Electric System Operator (ONS) for the year 2024. Regarding $CO_2$ emissions, fugitive hydrogen emissions were not considered in this study. Instead, emissions were estimated based on life cycle assessment (LCA) data available in the literature for each stage of the supply chain, including PEM electrolysis, gaseous and liquid storage, as well as transportation via trucks and pipelines.

Distances (in kilometers) between the production plants and the demand point were included for both pipelines and trucks. These were calculated using Google Earth (with a 5% safety margin to account for potential deviations in pipeline routing) and Google Maps for road-based transportation routes, Figure 2 indicates the localization of each possible hydrogen plant (1 to 7) and the demand point (A) for the study case. Additionally, the analysis assumes the construction of new hydrogen pipelines, incorporating their associated costs into the model.

Capacity factors for wind and solar power plants were obtained from the Brazilian National Electric System Operator [9]. The capacity factors were regionally specific and calculated based on the locations of wind and solar plants near the hydrogen production sites. Table 1 summarizes the location, primary energy source, and distances between production plants and the demand point and average capacity factor. Figure 3 presents the monthly capacity factor.

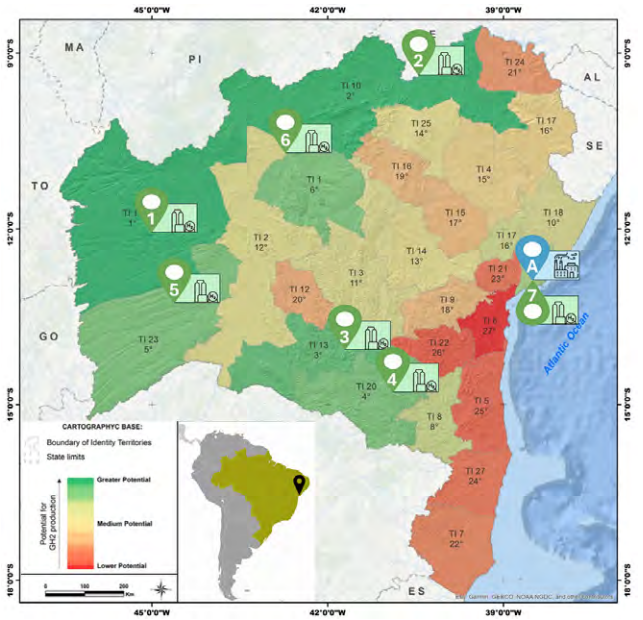

**Figure 2:** Geographic Map of Hydrogen Production Plants and Demand Points in Bahia.

The optimization problem incorporated these data inputs to evaluate 24 scenarios (7 potential plant locations, 2 storage technologies, and 2 transportation methods), with each scenario representing a different logistical and renewable energy availability. Table 2 provides additional information, such as electricity prices, carbon emissions prices, operational hours, and other relevant parameters.

These inputs directly feed into the Mixed-Integer

| Operating Hours | 8000 h/year | DMMH2 default |
| Cylinder Type | Type I | DMMH2 default |
| Pipeline Type | 20" 100% H2 | DMMH2 default |
| Plant Capacity Factor | 100% | DMMH2 default |
| WACC | Brazil: 0.089 | DMMH2 default |

Linear Programming (MILP) model, described in section "Mathematical Modelling", where the regression data ($A_i$, $B_i$, $C_i$, $D_i$) are used to calculate the TSC for each scenario. This integration ensures that the optimization process accounts for both economic and environmental considerations. The regression coefficients were derived using Microsoft Excel's "SLOPE" function, which determines the slope of the linear regression line, and the "INTERCEPT" function, which calculates the corresponding intercept. These calculations were performed using cost and emissions data extracted from the DMMH2 software.

## OPTIMIZATION FRAMEWORK

### Problem Description

The optimization aims to minimize the TSC of the GHSC. This is achieved by determining the optimal locations, energy sources, storage, and transportation methods to supply the full hydrogen demand of Bahia's oil refinery. Each scenario $i$ is defined by:

- One energy source (solar, wind, or grid).
- One storage technology (liquefied or compressed hydrogen).
- One transportation method (truck or pipeline).

### Mathematical Modelling

The sustainable cost for each scenario is given by the scalarization function:

$$min\ TSC = \sum_{i=1}^{n} SC_i(x_i) \quad (1)$$

$$SC_i(x_i) = TC_i(x_i) + E_i(x_i) \quad (2)$$

where:

- $TC_i(x_i) = A_i x_i + B_i$: Total financial cost as a function of decision variables $x_i$.
- $E_i(x_i) = C_i x_i + D_i$: Environmental cost, where $w$ is the weight given to emissions.
- $A_i, B_i, C_i, D_i$: Regression parameters for each scenario $i$.

**Constraints:**

- Hydrogen production from all selected plants must equal the refinery's demand:

$$\sum_i x_i = D_j,\ \forall j = 1\ ;\ D_j = 200\ MW \quad (3)$$

- Hydrogen production is an integer variable:

$$x_i \in \mathbb{Z}^+,\ \forall i \quad (4)$$

- Hydrogen production is constrained by its maximum capacity and is dependent on whether the plant is selected:

$$x_i \leq 200 Y_i,\ \forall i \quad (5)$$

  - Binary decision variables $Y_i$ indicate whether a specific scenario is selected:

$$Y_i \in \{0,1\},\ \forall i \quad (6)$$

This model was implemented using Python due to its flexibility and the availability of robust libraries for mathematical programming. The formulation of the MILP problem was conducted using Pyomo. For solving the optimization problem, GLPK was selected as solver, given its efficiency in handling large-scale MILP problems and its advanced features for parameter tuning and performance improvement. The solver configuration included default precision settings, with adjustments made to the time limit to ensure computational feasibility while maintaining the accuracy of the results. This computational framework facilitated the integration of regression data and allowed for efficient scenario evaluation across all 24 cases.

## RESULTS & DISCUSSION

The results obtained are presented in Table 3. The minimization of the Total Sustainable Cost (TSC) revealed only one viable scenario, scenario 8, characterized by maximum production capacity. This outcome is attributed to the economies of scale inherent in hydrogen production, where increasing production capacity significantly reduces financial costs. Consequently, the cost equations consistently achieve their minimum value at 200 MW.

Scenario 8, with a TSC of USD 5.88/kg $H_2$, was identified as the optimal solution. It features a plant located in Juazeiro, a region with high wind energy potential, and utilizes gaseous hydrogen distributed via pipeline. This configuration benefits from reduced financial costs due to the favorable wind energy profile of the location.

A sensitivity analysis (Figure 4) varying the demand constraint reinforces this finding. For most demand scenarios, Scenario 23 emerges as the optimal solution in terms of TSC, except for the 200 MW capacity case, where Scenario 8 remains the best option.

Figure 5 provides a snapshot of the results. While Scenario 23 demonstrates the lowest Levelized Cost of Hydrogen (LCOH), it shares the same hydrogen form and distribution method (Liquefied and pipeline) as Scenario 8 but differs in plant location (S. Francisco do Conde) and primary energy source (Grid). However, Scenario 8 achieves significantly lower GHG emissions than Scenario 23, highlighting the trade-off between financial and environmental considerations, and the considerable difference at TSC.

The results underscore the impact of economies of scale on GHSC optimization. By prioritizing maximum production capacity, the model leverages cost advantages that make large-scale production the most financially viable option. However, the practical implementation of such solutions remains challenging, requiring substantial investments in infrastructure and technology, particularly concerning the construction of new pipeline networks.

Furthermore, the comparison between Scenarios 8 and 23 highlights the importance of considering both financial and environmental metrics. While Scenario 23 minimizes LCOH, its reliance on electricity from the grid results in higher GHG emissions, emphasizing the environmental trade-offs of different SC configurations.

Additionally, scenarios relying on grid electricity exhibited significantly higher LCOH values due to the elevated electricity prices in Brazil. Despite these variations, the hydrogen cost ranges presented in this study align with values reported in the literature [12,13] for optimal configurations. This work reinforces the importance of evaluating the hydrogen supply chain (HSC) within specific production and usage contexts, providing valuable insights for guiding the development of the hydrogen market while reducing uncertainties from project planning to physical deployment.

## CONCLUSION

This study develops a deterministic MILP model to optimize the HSC for Bahia, focusing on supplying 200 MW of hydrogen to its oil refinery. The model evaluates 24 scenarios involving combinations of production sites, storage technologies, transportation methods, and energy sources, aiming to minimize the TSC, which integrates financial and environmental metrics. The results highlight the importance of economies of scale in reducing the financial costs of hydrogen production. The

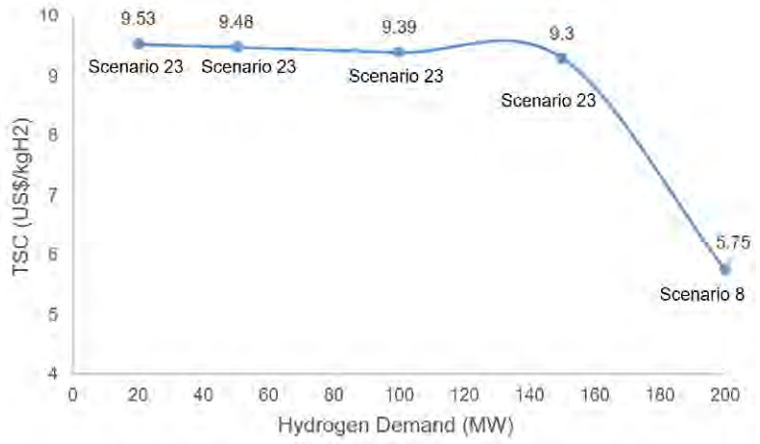

**Figure 4:** Sensitivity analysis.

**Table 3**: Study Case Results.

| Scenario | TSC (US$/kgH2) | Plant Capacity (MW) | Plant location | Energy source | H2 Form | Distribution |
|---|---|---|---|---|---|---|
| 8 | 5.75 | 200 | Juazeiro | Wind Power | Gaseous | Pipeline |
| 23 | 9.2 | 200 | São Francisco do Conde | Grid | Gaseous | Pipeline |

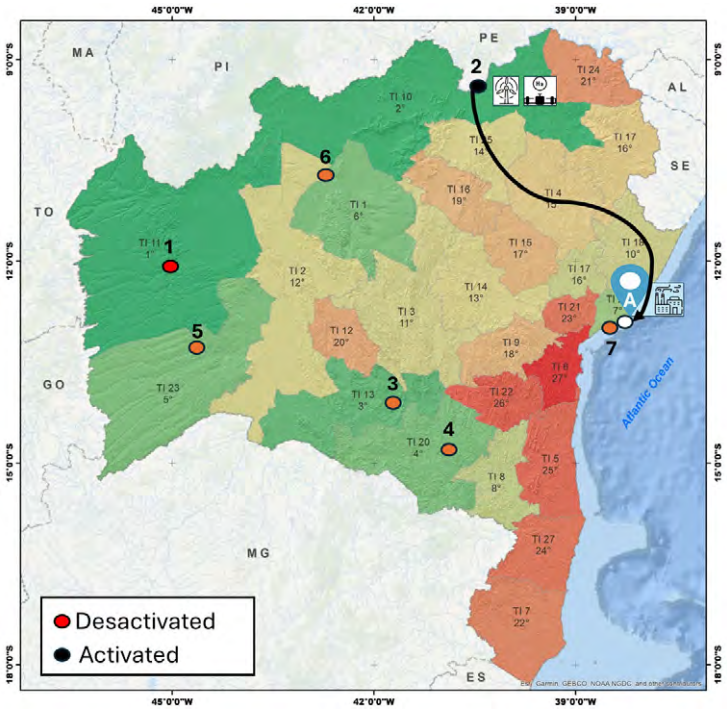

**Figure 5:** Result Snapshot.

optimal scenario identified a production plant located in a region with high wind energy potential, leveraging renewable energy to achieve cost-effectiveness and sustainability. However, trade-offs between financial and environmental metrics were observed, demonstrating the need for balanced decision-making to meet both economic and decarbonization goals.

Future research should address uncertainties in

HSC design, enhancing resilience to market and operational variability while advancing decarbonization strategies. Moreover, the integration of multi-objective optimization could provide more robust solutions, accounting for variations in renewable energy availability, hydrogen demand, and carbon pricing. Expanding the analysis to include sector coupling, such as heat and power integration, may further enhance the practical application and sustainability of GHSCs. Additionally, exploring parameter sensitivity and socio-political factors would enhance the robustness and relevance of the study.

## ACKNOWLEDGEMENTS

# Design of a policy framework in support of the Transformation of the Dutch Industry

**Jan van Schijndel[a]*, Rutger de Mare[a], Nort Thijssen[a] and Jim van der Valk Bouman[a]**

[a] QuoMare, Kampenringweg 45A, Gouda 2803PE, The Netherlands

## ABSTRACT

In 2022 the Dutch Energy System used some 2700 PJ of energy. Some 86% of its input was natural gas, crude oil and coal. The other 14% were renewables. A network of power-generation units, refineries and petrochemical complexes converted fossil resources into heat (700 PJ), power (400 PJ), transportation fuels (500 PJ) and chemicals (400 PJ). Some 700 PJ were lost due to conversion and transport. $CO_2$ emissions were 160 Mt in 2022 of which 65 Mt by industry and 30 Mt by mobility. Transformation of this system into a Net Zero $CO_2$ system calls for replacement of fossil resources by renewable heat, power and carbon. Decarbonisation of heat & power for residential and mobility is well underway at the moment. However, decarbonisation of industry and recarbonisation of shipping & aviation fuels, as well as recarbonisation of feeds for chemicals, is hampering progress. This paper concludes that current policies, predominantly based on trading $CO_2$ emission certificates (ETS) is insufficient for industry to justify investment decisions. A carbon tax of 100 €/t $CO_2$ on top of ETS prices (currently some 70 €/t $CO_2$) is still insufficient for viable business cases. This paper shows that a combination of mandated production volumes for renewable fuels supported by opex subsidies, investors' willingness to accept lower costs of capital, off-takers' willingness to pay higher prices for green products and producers' willingness to accept lower returns on their investment, may drive industry towards viable business cases. Financial support comes from government through their return of extra $CO_2$ tax income and income from sales of ETS certificates to producers, off-takers and investors (risk mitigation assurances). This paper shows how QuoMare's TDES (Transformation of the Dutch Energy System) is deployed to outline a policy framework that provides robust incentives to industry to invest in decarbonisation and recarbonisation projects.

**Keywords**: Mixed-Integer Multi-Period Linear Programming, Decision Support System, Optimal Policy Making

## INTRODUCTION

In 2022, the Dutch energy system emitted some 160 Mt $CO_2$: 20 Mt $CO_2$ by residential, 30 Mt $CO_2$ by mobility, 20 Mt $CO_2$ by agriculture (mostly $CO_2$ equivalents due to $CH_4$ & $N_2O$ emissions), 25 Mt $CO_2$ by electricity producers and 65 Mt $CO_2$ by industry [1].

The larger industrial $CO_2$ emitters are: Tata Steel (12 Mt $CO_2$), fertilizer producers Yara & OCI (6 Mt $CO_2$), refineries (18 Mt $CO_2$), naphtha crackers (6 Mt $CO_2$) and the chemical industry (23 Mt $CO_2$). These $CO_2$ emissions are classified as scope-1 & scope-2 emissions. Refineries produce 10 Mt transportation fuels that yield the 30 Mt $CO_2$ mobility emissions mentioned above. From a refinery point of view these $CO_2$ emissions qualify as scope-3 emissions.

Scope-1 and scope-2 $CO_2$ emissions need to be decarbonised. Recarbonisation of fuels will address scope-3 $CO_2$ emissions. In a fossil free scenario, cracker feedstocks face a similar recarbonisation challenge.

This paper shows that decarbonisation and recarbonisation are lacking economically viable business cases. Hence, the challenge is to design a policy framework that supports the energy transition stakeholders (producers, product off-takers, investors and government) to build viable business cases for the transformation of the Dutch industry. This paper outlines how such a framework can be developed by using network

optimisation principles with dedicated focus on the petrochemical sector (refineries, crackers, chemical industry). This paper builds on the TDES functionality presented at ESCAPE34, Florence, June 2-6, 2024 [2].

## DECARBONISATION ECONOMICS - GENERAL

### Tata Steel

Tata Steel operates two Blast Furnaces (BF's) and is evaluating the economics to replace these BF's by two Direct Reduction of Iron (DRI) facilities to eliminate its 12 Mt/a $CO_2$ emissions. DRI can be done by either $CH_4$ & CCS or by $H_2$. The DRI - $H_2$ option calls for an investment of 6 bln € (assuming a capital intensity of 850 € per ton of steel) and 0,5 Mt/a of green $H_2$ (variable opex of 2.5 bln €/a assuming @ 5000 €/ton $H_2$).

### Fertilizer manufacturing (OCI & YARA)

Decarbonisation of 3 Mt/a $NH_3$ production by $H_2$ calls for 0,5 Mt/a green $H_2$ to avoid 6 Mt/a $CO_2$ emissions. The corresponding electrolyser investment is 3 bln € and calls for 25 TWh electricity @ 80 €/MWh (2 bln €/a).

### Refineries

Crude intake by the Dutch refineries is currently some 52 Mt/a with reported $CO_2$ emissions of 18 Mt/a. It is assumed that these $CO_2$ emissions can largely be removed by Carbon Capture & $CO_2$ Storage (CCS) in the North Sea @ capital intensity of 500 € per ton $CO_2$ (9 bln €) and variable opex of 100 €/ton $CO_2$ (1,8 bln €/a).

### Naphtha crackers

The main feedstock for the Dow, Shell and Sabic crackers in the Netherlands is naphtha with some 4 Mt/a of ethylene and some 6 Mt/a of other lower olefins & aromatics as output. The cracking furnaces are fired by the $CH_4$ product stream (2 mln t/a), resulting in some 6 Mt/a $CO_2$ emissions. These emissions can be eliminated by ATR (Auto Thermal Reforming) of $CH_4$ into $H_2$ & $CO_2$ combined with CCS. The ATR-CCS capex is estimated at 3.7 bln €. Variable opex of 1.05 bln € is for the additional intake of steam, oxygen and natural gas for the reformer and utilities to capture and sequester $CO_2$.

### Chemical Industry

Olefins and aromatics are upgraded into industrial chemicals and polymers. Some 8,4 Mt/a $CH_4$ is consumed for the production of (high temperature) heat and power. The resulting 23 Mt/a of $CO_2$ emissions can be avoided by a combination of industrial heat pumps & e-boilers (20 TWh E-power @ 80€/MWh) and 1 mln ton/a $H_2$ firing (@ 5000 €/ton $H_2$) to meet the high temperature requirements. Capex for heat-pumps & boilers is estimated at 1.1 bln €.

### Break Even $CO_2$ Emission Trading Scheme (ETS) Prices

Total Annualised Costs (TAC's) have been calculated to test the economic viability of decarbonisation technologies discussed above. TAC is the sum of costs of capital (on annuity basis, but for simplicity sake set at 6% of capital expenditure), fixed opex for operations and maintenance (set at 4% of capex) and variable opex being feedstock costs and utility costs. The Break-Even ETS price is the price to be paid for an ETS certificate to match the TAC per ton of $CO_2$ to be captured. From the Break-Even ETS prices summarised in Table 1 below, it may be concluded that apart from CCS to remove and store $CO_2$ ex refinery furnaces, other technologies lack a solid business case to justify implementation. The projected $CO_2$ price of 220 €/ton by 2050 for ETS certificates (Figure 1) is simply too low. ETS certificate pricing is expected to increase from 70 €/ton $CO_2$ in 2025 to some 220 €/ton $CO_2$ in 2050 based on supply-demand unbalances for ETS certificates as predicted by TNO [5].

**Table 1:** Summary Break-Even ETS prices

| | TATA Steel | OCI & YARA | Refineries | Crackers | Chemicals |
|---|---|---|---|---|---|
| CO2 emissions 2022 (Mt/a) | 12 | 6 | 18 | 6 | 23 |
| | | | | | |
| Decarbonsation technology | DRI - H2 | H2 | CCS | ATR - CCS | E & H2 |
| Capex (bln €) | 6,0 | 3,0 | 9,0 | 3,7 | 1,1 |
| Cost of Capital (bln €/a) | 0,36 | 0,18 | 0,54 | 0,22 | 0,07 |
| Fixed Opex (bln €/a) | 0,24 | 0,12 | 0,36 | 0,15 | 0,04 |
| Variable Opex (bln €/a) | 2,50 | 2,00 | 1,80 | 1,05 | 6,60 |
| TAC (bln €/a) | 3,10 | 2,30 | 2,70 | 1,42 | 6,71 |
| | | | | | |
| Break Even ETS price (€/ton CO2) | 258 | 383 | 150 | 237 | 292 |

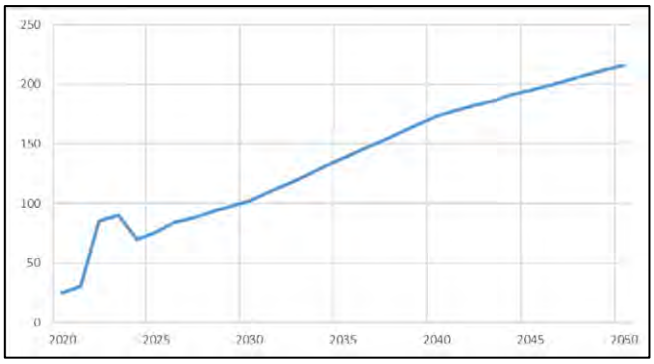

**Figure 1:** Projected cost ETS certificates in €/ton $CO_2$

## RECARBONISATION ECONOMICS - GENERAL

Recarbonisation projects for the production of renewable transportation fuels and feeds for the naphtha crackers will also be difficult to justify economically. As an example, the economics for the production of biomethanol are outlined in Figure 2 below. Typically, methanol prices range between 400 €/ton and 500 €/ton. The example shows that a Break-Even Value of 770 €/ton

methanol would be needed for a Return on Investment (ROI) of 0% and some 900 €/ton to deliver an ROI of 5%. ROI is the ratio between annual Net Income After Tax (NIAT) and project investment (capex) and a key-indicator for the profitability of a capital project.

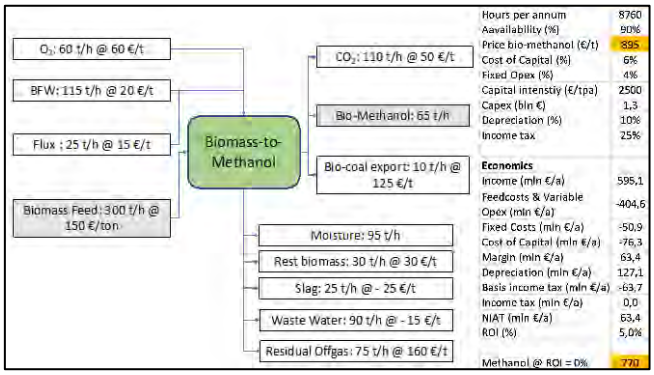

**Figure 2**: Biomass To Methanol Economics

## TDES & INDUSTRY TRANSFORMATION SCOPE

Transforming the Dutch industry sector into a system that is largely based on renewable energy resources in an economically viable manner, requires a systemic analysis of a large set of decarbonisation and recarbonisation investment options. To this end, QuoMare developed TDES (Transformation Dutch Energy System).

TDES is an optimisation methodology based on an MP-MILP (Muli-Period Mixed Integer Linear Programming) algorithm that evaluates a set of decarbonization & recarbonisation investment options (integer variables) on a year-to-year basis from today towards 2050, together with unit capacities (continuous variables) and subject to various constraints (like $CO_2$ reduction targets, availability of resources and product demand). The objective is to determine a lowest cost transformation pathway.

The combined decarbonisation & recarbonisation challenge and option space for petrochemicals is outlined in Figure 3.

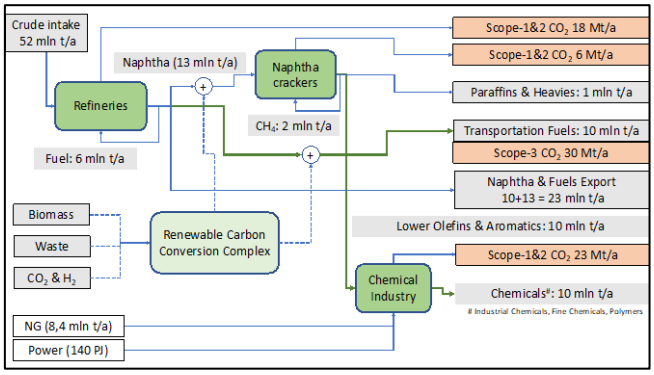

**Figure 3:** Decarbonisation & Recarbonisation Petrochemicals

To address the 47 Mt $CO_2$/a scope-1 & scope-2 decarbonisation challenge for petrochemicals, TDES may select technologies based on electrification (heat pumps, e-boilers), carbon capture & storage (CCS) or burning $H_2$ rather than $CH_4$.

To address the 30 Mt $CO_2$/a scope-3 recarbonisation challenge for petrochemicals, TDES has access to a portfolio of process technologies converting renewable carbon from biomass, waste and $CO_2$ into transportation fuels and feeds for chemicals. Process technologies modelled in TDES as per Figure 4 below include fermentation, hydrogenation, reforming, torrefaction, and gasification of biomass & waste streams into syngas. Renewable syngas can also be produced by the RWGS (Reverse Water Gas Shift) technology: reactivating $CO_2$ with green $H_2$ into CO & $H_2O$. Syngas is subsequently converted through either Fischer-Tropsch synthesis or methanol synthesis into transportation fuels and cracker feedstocks. Pyrolysis of recycled plastics is another route to produce renewable cracker feedstocks.

TDES is based on QuoMare's proprietary TEACOS framework (Techno-Economic Analysis of Complex Option Spaces). See below.

Please find below some comments on TDES validation, uncertainty & constraint analysis and broader concept applicability.

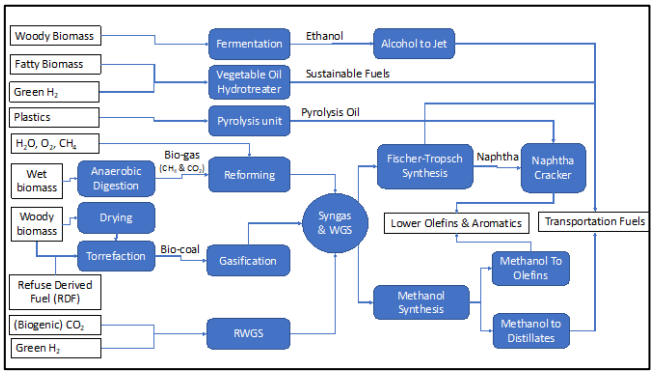

**Figure 4:** Superstructure Renewable Carbon Conversion Complex

TDES has been validated through various studies with institutions in the Netherlands: Institute for Sustainable Process Technology; Sustainable Industry Laboratory of University of Utrecht; Department of Economic Affairs of the Dutch Government.

TDES uses the Monte-Carlo functionality to address both parameter uncertainties and to evaluate scenarios in a systematic manner. This combination supports so-called "no-regret investment decisions". Likewise, also policy uncertainties are addressed by a structured Monte-Carlo and scenario analysis.

While TDES identifies economically viable transformation pathways within given set of constraints like feedstock availabilities, throughput capacities and product demand, TDES simultaneously also acknowledges

potential barriers to conversion technology implementation, such as technological readiness levels (TRL), supply chain limitations like mode-of-transport, and societal acceptance issues (e.g. no onshore windmills in a particular region).

Although TDES is specific to the Dutch context, it can easily be adapted to other countries or regions as TDES is 100% data driven. Heat, power and carbon demand data by residential, mobility, agriculture and industry sectors (production of steel, fertilizers and chemicals) are combined with yields and expense data of the conversion units to calculate feedstock and utility requirements. This clearly enhances the broader concept applicability.

## TEACOS

TEACOS is an optimization framework based on Multi-Period Mixed-Integer Linear Programming [3]. TEACOS has four general building blocks, as shown below.

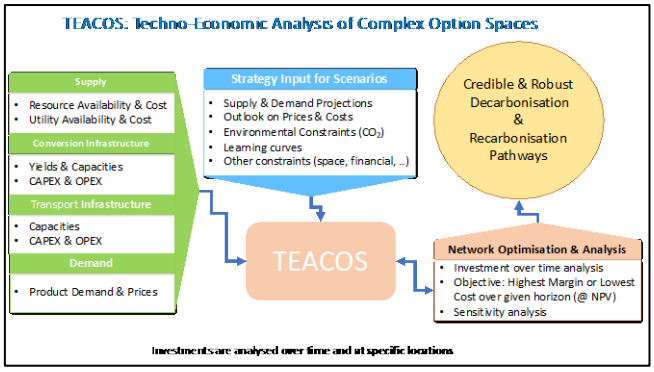

**Figure 5:** High level overview of TEACOS

These building blocks together represent a classical supply or value chain with temporal and spatial granularity: both location and timing aspects are included. TEACOS can either maximize the Net Present Value (NPV) of the supply chain margin or minimize the NPV of supply chain costs, both over the time horizon imposed, meanwhile respecting boundary conditions and environmental constraints. Sensitivity analyses by the Monte-Carlo functionality demonstrate the robustness of transition pathways and detect tipping points to understand the relative attractiveness of the investments over time. The mathematics (MP-MILP) behind TEACOS and its deployment have been described in a decarbonisation study for the industrial cluster of the Port of Rotterdam [4].

## DESIGN OF A POLICY FRAMEWORK

The Dutch government is well aware of the lack of economically viable business cases limiting progress towards the Net Zero $CO_2$ target in 2050. In principle, government has 3 degrees of freedom: imposing mandates, levy/charge additional $CO_2$ taxation and providing subsidies. However, such an approach is rather directive and collaboration with industry & infrastructure companies is probably more effective.

To this end, government is engaging with key industry partners (including TATA Steel, OCI & YARA and the petrochemical sector) with the aim to conclude tailor-made decarbonisation and recarbonisation agreements ("Maatwerk Afspraken" in Dutch).

Obviously, the Dutch government is key stakeholder in this process due to their commitment to deliver $CO_2$ reduction targets agreed upon within the European Community (55% reduction in 2030 and 100% reduction in 2050, both relative to the Dutch reference emission of 220 Mt $CO_2$ in 1990). Apart from the Dutch government and their industrial partners, there are two other important stakeholders: product off-takers and investors.

Figure 6 below shows how these stakeholders may work together to develop viable business cases.

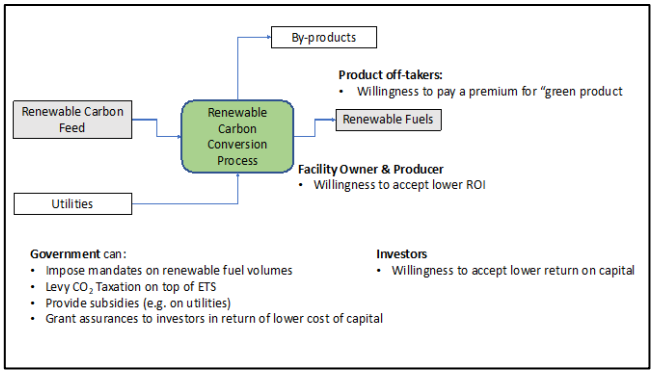

**Figure 6:** Stakeholder Analysis & their degrees of freedom

Product off-takers may be willing to pay a price premium for decarbonised and/or recarbonised products, which entitles them to market "green products". Investors' willingness relates to accepting a lower return on their investment by demanding a lower WACC (Weighted Average Cost of Capital). This usually comes with the requirement that the Dutch government provides them with sufficient assurances that reduce/minimize their risk of "losing" their investment. Producers contribute to a viable business case by accepting a lower Return on Investment (ROI): 5% rather than 10%.

Apart from imposing mandates on the production of renewable transportation fuels, the Dutch government has tax measures to play with. They may decide to impose an additional $CO_2$ tax on top of the $CO_2$ price to be paid for ETS certificates. Government may also grant income tax waivers or tax-holidays for producers. Another degree of freedom is the provision of subsidies on process utilities lowering operating expenses like costs of power, Natural Gas and CCS entrance fees.

As TDES selects those options that minimise the net present value of accumulated system costs over the 2020-2050 time-horizon, post-processing is needed to identify economically viable conditions for industry. The policy framework outlined above together with TDES results is used to find that combination of price premia, WACC reductions and subsidies that will bring decarbonisation and recarbonisation projects over time (2025 – 2050 horizon) sufficiently into "the money" within constraints imposed: $CO_2$ reduction targets; availabilities of renewable feeds; and mandates on renewable transportation fuels.

In the decarbonisation space, the Dutch government is clearly in the lead in view of the scope-1 and scope 2 $CO_2$ reduction ambitions. They orchestrate how their ETS-1 income (some 10 bln € per year with ETS certificates valued at 150 €/ton) can be redistributed as subsidies to the various industry segments, to create a viable business case in combination with price premia.

In case of recarbonisation, the Dutch government facilitates and supports industrial initiatives in getting recarbonisation projects towards Final Investment Decisions (FID) with a budget of some 4,5 bln € (30 Mt/a $CO_2$ scope-3 emissions @ 150 €/ton).

## DEPLOYMENT POLICY FRAMEWORK - RESULTS

### Outcome decarbonisation analysis

Table 2 below shows the results of the TDES decarbonisation optimisation. The table captures the situation in 2050. In case of TATA, the DRI option with $H_2$ has been chosen. For OCI & YARA, both green and blue $H_2$ have been included in the option space. For the refineries, blue $H_2$ has been shown to be less attractive than CCS. For the crackers, upgrading the $CH_4$ product stream through ATR into blue $H_2$ with $CO_2$ captured and stored proved the better decarbonisation option compared to electrification of the cracking furnaces. Most of the lower heat requirements of chemical production units can be met by industrial heat pumps and e-boilers with 1 Mt/a of $H_2$ to satisfy high temperature demand.

The benefits entry is based on the avoidance of buying ETS certificates @ 150 €/ton $CO_2$ plus extra revenues for green products. Within the stakeholder frame, product premia assumptions have been made for the off-take of green steel (50 €/ton) and ammonia (120 €/ton); government subsidies have been assumed for utilities: a renewable power discount of 40 €/MWh for power needed for $H_2$ production (partly reflecting the compensation for high electricity network costs in the Netherlands), a discount of 30 €/ton for $O_2$, a discount of 75 €/ton for NG and a discount of 25 €/ton $CO_2$ on the $CO_2$ feed-in tariff. Furthermore, investors are assumed to be willing to lower their fees for lending capital by 2% in absolute terms backed by government risk assurance terms (WACC of 4% rather than typically 6%).

This results in Net Income After Tax (NIAT) improvements for all industry partners bringing the ROI at/above the 5% threshold.

The reference NIAT entry refers to the NIAT without the benefits from variable opex subsidies, premia from green products, tax holiday and lower cost of capital.

The "zero-sum" section shows how each stakeholder may contribute to a sufficiently attractive decarbonisation project. The negative values are the off-takers, investors and government contributions: off-takers pay a premium for green, investors accept a lower return on capital they lend and government provide subsidies. Together they provide a margin improvement that turns the reference NIAT positive with an ROI above the 5% threshold the manufacturing stakeholder is willing to accept.

**Table 2:** Decarbonisation outcome

| | TATA Steel | OCI & YARA | Refineries | Crackers | Chemicals |
|---|---|---|---|---|---|

### Outcome recarbonisation analysis

TDES shows that the HVO (Hydrotreatment of Vegetable Oil), WPO (Waste Plastics to Oil), BTL (Biomass To Liquids) and PTL (Power to Liquids) processes deliver the best configuration for the recarbonisation of cracker feedstocks and transportation fuels. The basis for this TDES optimisation are constraints imposed on the production of renewable fuels mandated by the EU for aviation (Sustainable Aviation Fuel, SAF) and for shipping (Sustainable Marine Gasoil, SMG) as per Table 3 below. The availability of renewable feedstocks listed in Table 4 is another set of constraints used by TDES to determine

the best combination of renewable feeds and processes to deliver renewable transportation fuels (7,5 Mt/a in 2050) and renewable cracker feeds (3,8 Mt/a pyrolysis oil ex WPO-unit). Table 4 lists envisaged feedstock availabities in 2050 on the basis of a conversion efficiency (thermal efficiency) of 70% for lipids, ligno and RDF (Refuse Derived Fuel) and 75% for plastics.

**Table 3:** Renewable share as mandated by ReFuelEU for aviation fuels & FuelEU for shipping fuels

| | 2030 | 2040 | 2050 |
|---|---|---|---|
| Bio-based SAF (Mt/a) | 0,25 | 1,25 | 2,00 |
| E-SAF (Mt/a) | 0,05 | 0,50 | 1,50 |
| Total SAF (Mt/a) | 0,30 | 1,75 | 3,50 |
| Bio-based SMG | 0,10 | 1,50 | 4,00 |
| Total renewable fuels (Mt/a) | 0,40 | 3,25 | 7,50 |

**Table 4:** Feedstock availabilities (Mt/a)

| | LHV (GJ/ton) | 2030 | 2040 | 2050 |
|---|---|---|---|---|
| Lipids | 30 | 4,0 | 5,0 | 6,0 |
| Plastics | 40 | 1,3 | 2,7 | 5,0 |
| Lignocellulose | 12 | 2,0 | 2,4 | 7,0 |
| RDF | 25 | 0,5 | 1,0 | 2,0 |
| Biogenic $CO_2$ | 0 | 1,3 | 3,2 | 6,3 |

Table 5 below shows the ROI target of 5% is attained by the optimal combination of price premia and opex subsidies. The "zero-sum" analysis shows the importance of government-industry partnering. Reference prices are based on a crude oil price of 80 $/bbl with product-crude spreads assumed for naphtha, kero and gasoil of 20 $/bbl, 10 $/bbl and 5 $/bbl respectively, with corresponding bbl-factors of 8,3 bbl/ton, 8,4 bbl/ton and 7,5 bbl/ton respectively.

Note that Table 5 shows that in 2050 only 75% of the 10 Mt/a target renewable fuel volume (50/50 split over SAF/SMG) is realised. This is in accordance with the mandates imposed and availabilities of renewable feed volumes, but insufficient for the Net Zero $CO_2$ goal in 2050. Hence, additional volumes of $CO_2$ removal or negative emissions are needed as compensation.

Furthermore, note that product price premia to bring projects for producers into the money are significant: some 40% – 55% on top of the reference price for HVO & BTL fuels and even 150% for SAF from the PTL process. It will be difficult for producers to conclude long-term offtake agreements needed for FID based on those premia. Hence, assuming an ETS-2 $CO_2$ price of 150 €/ton by 2050 and the replacement of 7,5 Mt/a fossil fuels by renewables, the ETS-2 budget of some 3.4 bln €/a can be redistributed as opex subsidies to producers (1,8 bln €/a) and compensation to off-takers (1,6 bln €/a) to limit their contribution to the transportation fuels recarbonisation challenge. On average, the 1.6 bln €/a would lower price premia by some 200 €/ton. However, this would still be insufficient to attract PTL investments for production of E-SAF.

**Table 5:** Recarbonisation status by 2050

| | HVO | WPO | BTL | PTL |
|---|---|---|---|---|
| Capacity (Mt/a) | 3,2 | 3,8 | 2,3 | 2,0 |
| Investment (bln €) | 3,2 | 5,7 | 6,9 | 4 |
| | | | | |
| Reference Price (€/ton) | 755 | 839 | 640 | 755 |
| Premium (€/ton) | 285 | 0 | 345 | 1148 |
| Product Price (€/ton) | 1040 | 839 | 985 | 1903 |
| | | | | |
| Income (bln €/a) | 3,33 | 3,19 | 2,26 | 3,81 |
| Feedstock & Variable Opex (bln €/a) | 3,18 | 2,53 | 1,46 | 4,43 |
| Variable Opex subsidies (bln €/a) | 0,27 | 0,31 | 0,09 | 1,14 |
| Fixed Costs (bln €/a) | 0,13 | 0,23 | 0,28 | 0,16 |

## SUMMARY & CONCLUSIONS

Based on 2022 $CO_2$ emission data, the Dutch industry is facing a $CO_2$ decarbonisation target of 65 Mt/a. In addition, the envisaged domestic offtake of 10 Mt/a fuels for aviation and shipping sets a longer term recarbonisation target of 30 Mt/a of $CO_2$.

Within the current scheme of $CO_2$ reduction policies, largely driven by the Emission Trading Scheme, both decarbonisation and recarbonisation project options are insufficiently competitive relative to "business as usual": they do not result in attractive business cases, e.g. with a Return of Capital (ROI) of 10%. $CO_2$ emission Break Even values range between 150 €/ton and 380 €/ton for decarbonisation projects (delivering an ROI of 0%).

A policy framework is presented that builds on the TDES decarbonisation and recarbonisation results for the Dutch industry over the 2025-2050 time horizon. These

results are obtained within set of constraints imposed on the MP-MILP problem: $CO_2$ reduction targets, mandated production of renewable fuel volumes and given availiablities of renewable feedstocks. This policy framework allows industry and government to jointly explore and agree how their degrees of freedom (opex subsidies, price premia, lower WACC) contribute to the development of economically viable business cases for industry with an ROI of 5% (typically an ROI of 10% would be needed for industries to take a FID).

Decarbonisation of the Dutch industry calls for an investment of some 23 bln€ over the 2025-2050 timeframe. This is equivalent to 350 €/ton $CO_2$ avoided. Corresponding Total Annualised Cost average out at some 16 bln €/a, equivalent to 250 €/ton $CO_2$ avoided. Some 6,5 bln€/a opex subsidies are needed together with 1 bln€/a price premia and lower costs of capital to turn decarbonisation industry projects viable for an ROI of 5%. Part of the ETS-1 revenues of some 10 bln€/a would cover funding.

The mandated recarbonisation of 7,5 Mt/a aviation and shipping fuels by 2050 calls for an investment of some 14 bln € (some 625 €/ton $CO_2$ avoided). Corresponding Total Annualised Cost are some 10 bln €/a (some 450 €/ton $CO_2$ avoided). Significant price premia of some 530 €/t on average on top of the average fuel price of 720 €/ton together with opex subsidies of some 1.5 bln €/a are needed for an ROI of 5%. ETS-2 revenues of 4,5 bln € (30 Mt/a @ 150 €/ton) are insufficient to compensate the 5,5 bln €/a for price and opex support. The economics of the PTL process producing E-SAF is the main contributor to this unbalance.

The extension of TDES with this policy framework provides a powerful tool supporting government-industry discussions in an interactive and transparent manner. on the so-called “Maatwerk” agreements as to arrive at economically viable cases for industry to meet their 95 Mt/a CO2 reduction target.

The TDES functionality is currently being extended to cover European policies related to CBAM (Carbon Border Adjustment Mechanism policy imposing $CO_2$ taxes on fossil-based imports from outside Europe), PPWD (the Plastic & Paper Waste Directive addressing impact on volume and pricing of plastics & paper recycling as circular feedstocks for naphtha crackers) and the Clean Industrial Deal (policies that aim to compensate for high electricity distribution network costs and high energy prices in general).

## ABSTRACT

This study designs a green hydrogen supply chain for Portugal, focusing on minimizing both economic costs and water stress. The research uses a multi-objective simulated annealing algorithm to address the trade-offs between the two objectives. The process of producing hydrogen via electrolysis is highly water-intensive, posing a challenge in water-scarce regions like southern Portugal. The study considers Portugal's uneven water distribution, renewable energy availability and, different hydrological conditions across districts. An aggregate indicator, Water Stress Index (TWSI), quantify the pressure on water resources covering all the Portugal´s districts in a single score. This study explores four scenarios, a baseline scenario, a green hydrogen scenario using only renewable energy, drought conditions, and increased demand in major cities with drought conditions. The quasi pareto front illustrates the trade-offs between supply chain cost and TWSI, enabling decision-makers to select solutions tailored to local priorities. The findings highlight the importance of adaptable and robustness infrastructure to overcome both environmental and demand challenges.

**Keywords**: Green hydrogen supply chain, multi-objective, simulated annealing, water stress.

## INTRODUCTION

As the world pursues solutions to reduce carbon emissions and combat climate change, green hydrogen has emerged as a critical component of the clean energy transition. Produced through renewable energy-powered electrolysis, green hydrogen is a versatile and emissions-free fuel that offers a pathway to decarbonize hard-to-abate sectors such as heavy industry, transportation, and energy storage. Countries like Portugal, with rich renewable resources, are well-positioned to lead in green hydrogen production. However, the process of producing hydrogen via electrolysis is highly water-intensive, presenting challenges in water-scarce regions, particularly in southern Portugal where droughts are common.

Current research on green hydrogen supply chains (HSC) has largely focused on optimizing economic objectives, such as production cost minimization, while addressing safety and environmental impact through mixed integer linear programming (MILP) approaches [1]. The author explored multi-objective approaches, considering the trade-off between cost and sustainability goals, considering the global warming potential (GWP). The results have shown how hydrogen supply chains can achieve economic efficiency alongside some environmental benefits. In 2019, Câmara, et al. [2] used multi-objective, multi-period, stochastic, MILP model to design and plan an HSC considering uncertainty over the availability of primary energy sources.

The aim of this study is to design a green hydrogen supply chain, applied to Portugal, considering economic and water stress minimization, using multi-objective Simulating Annealing. A quasi pareto front is characterized showing the trade-off between both objective functions. Four scenarios are explored, with disruptive aspects (e.g. water scarcity, increase urban demand) to illustrate how the hydrogen supply chains can overcome the strain on water resources while meeting economic targets and satisfy the demand, highlighting the robustness of the Portuguese supply chain, and offering insights for

sustainable hydrogen production. This study aims to support policymakers and industry leaders in building a robust, efficient hydrogen infrastructure for Portugal that aligns with both economic and environmental objectives.

## The Problem

Portugal's hydrological landscape is marked by uneven water distribution across its regions, which presents specific challenges for green hydrogen production due to the highwater consumption of the electrolysis process. Portugal is divided into eight main hydrographic regions (HRs), each with distinct levels of water availability influenced by regional precipitation patterns and water basin characteristics. The water availability in each district was estimated considering the hydrological availability for each district, along with the values of the monthly and annual standard deviation. The uneven distribution of water resources requires careful planning to avoid exacerbating water stress, particularly in areas where drought and low precipitation levels already impact local water availability. Portugal's water resources are further influenced by the presence of Strongly Regulated Flows (SRFs) in certain river basins. Those allows to stabilize water supplies by controlling flow rates through dams and reservoirs. While SRFs can offer greater water stability, they also introduce constraints that must be integrated into hydrogen production to ensure sustainable water management.

Electrolysis is characterized by its reliance on water and electricity. Through electrolysis, water is split into hydrogen and oxygen using an electric current, if renewable sources are used the process is emissions-free. The average water consumption for hydrogen production via electrolysis is estimated between 10 to 22 liters of water per kilogram of hydrogen produced. In this study is used 16 liters/kilogram as a mean value, allowing the comparison of hydrogen production strategies across regions with different levels of water availability.

The availability of renewable energy sources also plays a critical role in ensuring that hydrogen production remains sustainable. Portugal's solar, wind and hydro energy outputs, are very different among each district. Producing hydrogen with grid electricity, or a mix of renewable and non-renewable sources, would reduce the overall environmental benefits of the supply chain, making it essential to focus on maximizing hydrogen produced with dedicated renewable sources.

## Model

A multi-objective Simulating Annealing is known, for handling complex problem and computational burden. This meta-heuristic mimic the physical process of annealing metals, where a material is heated and then gradually cooled to reach a stable, low-energy configuration. The gradual cooling allows the model to explore the solution space extensively and avoid local optima. In this work, a multi-objective Simulated Annealing algorithm (MOSA) is developed. The MOSA follows several steps, Figure 1. Two objectives' functions area used: the total cost of the supply chain, followed by the water stress index. The aim is to minimize the hydrogen supply chain design cost, ensuring the hydrogen production is economically feasible, and simultaneously minimize the environmental impact on water resources, which are particularly scarce in Portugal's southern regions.

**Total Costs:** Which stand, respectively, for Production Plants Capital Cost (PPCC), Biomass Transportation Cost, (BTC), Primary Energy Sources Cost (PESC), Hydrogen Transportation Cost (HTC) and Hydrogen Refuelling Stations Capital Cost (HRSCC).

$$Minimize\ TCSC = PPCC + PESC + HTC + HRSCC \quad (1)$$

**Water Stress Index:** Given Portugal's regional disparities in water availability, minimizing water stress is essential to ensure that hydrogen production does not exacerbate local water scarcity. The water stress metric used in this model is based on the Water Stress Index (WSI), an environmental assessment tool that quantifies the pressure on water resources, [3]. The WSI for each district is calculated by adjusting the water withdrawal-to-availability ratio (WTA) considering hydrological characteristics. Instead of optimizing the WSI of each district individually, the model employs an aggregate objective function to consolidate all district-level WSI values into a single representative metric: the Total Water Stress (TWS). Achieved by computing the geometric mean of the WSI values across all districts, ensuring a balanced and holistic evaluation of water stress at a regional level. The TWS provides a single metric that guides decision-making towards minimizing the overall impact on water resources across Portugal.

$$\text{Minimize } TWS = \left(\prod_{i=1}^{n} WSI_i\right)^{\frac{1}{n}} \quad (2)$$

The model generates a quasi pareto front, capturing the trade-offs between TWS and Cost, providing decision-makers with information to evaluate and select solutions that best align with regional resource availability, economic constraints, and sustainability goals, ensuring a flexible and informed approach to water resource management. E.g. In water-scarce regions, water conservation may be prioritized, while in water-abundant areas, cost reduction could prevail.

# CASE STUDY: HYDROGEN SC IN PORTUGAL

The case study designs a hydrogen SC in Portugal to meet district demand while minimizing costs and water stress.

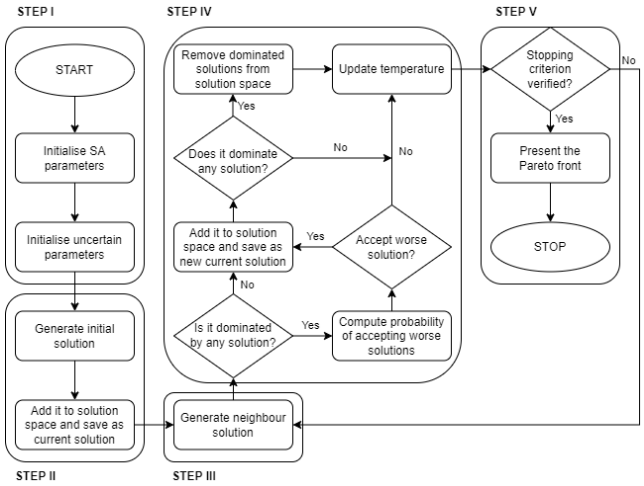

**Figure 1.** Multi-objective simulated annealing.

The study is set in mainland Portugal, considering the different hydrological conditions across eighteen districts, its characterization available in Figure 7 and delineated with a lighter line in all Portugal's figures**.** The electrolysis is the method for hydrogen production, because is the most used and is water-intensive process. The renewable energy sources (wind, solar, and hydro) as primary energy sources (PES) to produce energy for electrolysis, is considered, alongside grid power. Demand is estimated considering the population of each district and satisfied by hydrogen at Hydrogen Fueling Stations (HFS). The model integrates TWS to assess the environmental impact of water consumption, considering the presence of Strongly Regulated Flows (SRFs). The exportation and importation of hydrogen between district is allowed, only after its own demand satisfied. Higher producer of hydrogen may export hydrogen for districts with low production to face its demand. A MOSA algorithm is used to make the trade-off between both objective functions. The characterization of quasi pareto front allows decision-makers to select design of HSC that best fit their priorities. To evaluate the hydrogen SC robustness, four scenarios were developed. Each scenario represents different conditions for hydrogen production and distribution.

**Scenario A - Baseline** scenario exploring the trade-offs between cost and water stress.

**Scenario B - Green Hydrogen Supply Chain** focus on a green hydrogen SC powered only by renewable energy sources (wind, solar, hydro), excluding grid power.

**Scenario C - A drought scenario**, reduce the water availability by 10% of the baseline.

**Scenario D - Increased Demand in Major Cities** (Porto and Lisboa) combined with the water scarcity of scenario C.

Data: The model uses data on water runoff, water availability per district, renewable energy production by district, and hydrogen demand by district.

Multi-objective approach with objective functions: Economic) The model minimizes the total supply chain cost: production plants capital costs, primary energy source costs, hydrogen transportation costs, hydrogen refuelling stations capital costs; Total Water Stress) The water stress function is characterized by the calculation of two step: 1) the raw ratio of water use to availability and adjusts for regional factors using the variation factor and the presence of SRFs; 2) the resulting water stress index is aggregated into a single value (TWS) using the geometric mean.

Parameters: The MOSA parameters are tuned through experimentation, considering factors like number of iterations, initial temperature, cooling rate, and final temperature.

## Results and Discussion

The research provides a comprehensive analysis of the challenges and trade-offs in designing a sustainable green hydrogen supply chain in Portugal. The use of a multi-objective optimization model, combined with scenario analysis, offers valuable insights for decision-makers in the energy sector. The study underscores the importance of considering both economic and environmental factors in the development of a robust and efficient hydrogen infrastructure.

Given the extensive number of solutions in the quasi pareto fronts, obtained for each scenario, Figure 6, four representative solutions were selected from each scenario to characterize their outcomes. These solutions are even distributed along the quasi pareto front.

A deeper understanding the SC dynamics each solution was analysed considering: the hydrogen SC design and transportation network, Figures 2-5; district classification as importer/exporter, Table 1 and Figures 2-5; PES portfolio consumption, Table 2. The hydrogen transportation network, Figures 2-5. In each scenario a deeper analysis is taken considering the fours solutions along the respective quasi pareto front.

**Scenario A**: The quasi pareto front, Figure 6, shows a clear trade-off, where lower water stress is achieved at the expense of increased costs. Viana do Castelo, Guarda, and Lisboa are the key exporter regions, producing more hydrogen than their local demand, as in Figure 2. The transportation network changes across the four solutions (being network of the two solutions on the right-hand side of the curve the same), but these three regions remain consistent exporters, Table 1. Initially, Viana do Castelo and Guarda export to several districts, but Lisboa becomes the dominant exporter in the later solutions, shown the wider arrow in Figure 2. The portfolio of primary energy sources is shown in Table 2. A low use in hydropower across the solutions, at expense of a higher grid power consumption.

**Scenario B**: Costs are generally lower than in

scenario A, but the Total Water Stress (TWS) is higher, Figure 6. This is due to the increased reliance on hydropower, Table 2. Bragança, Viseu, Coimbra, Santarém, Portalegre, and Évora become key exporters, with Bragança being the largest. Viana do Castelo and Faro become self-sufficient, producing only enough hydrogen to meet their own demand, Table 1. The transportation network shifts to accommodate the new exporters. The network design has two main topologies, Figure 3, and Bragança becomes a major supplier. The primary energy resources portfolio, shown in Table 2, denotes higher percentage of hydropower, which is related with the increase of TWS, Table2.

**Table 1:** District classification as importer (I), exporter (E) or self-sufficient (S) for each scenario.

| | Scenario | | | |
|---|---|---|---|---|
| | **A** | **B** | **C** | **D** |
| Viana do Castelo | E | S | I | I |
| Braga | I | I | I | I |
| Porto | I | I | I | I |
| Vila Real | I | I | I | E |
| Bragança | I | E | I | E |
| Aveiro | I | I | E | I |
| Viseu | I | E | I | I |
| Guarda | E | I | I | E |
| Coimbra | I | E | I | I |
| Castelo Branco | I | I | I | E |
| Leiria | I | I | E | E |
| Santarém | I | E | I | I |
| Portalegre | I | E | I | E |
| Lisboa | E | I | I | I |
| Setúbal | I | I | I | I |
| Évora | I | E | E | I |
| Beja | I | I | I | E |
| Faro | I | S | I | I |

**Scenario C**: Both the total cost and TWS are significantly higher compared to the baseline scenario, illustrating the impact imposed by limited water availability, Figure 6. Aveiro, Leiria, and Évora emerge as key exporters, with Leiria being the largest producer. Only in the solution on the right-hand of the quasi pareto front (solution IV), Viana do Castelo, Braga and Lisboa become self-sufficient, until then are importers district. The transportation network shows Leiria playing a major role in supplying a wide range of districts, Figure 4. There's a slight increase in the use of grid electricity, while the use of hydropower also increases, Table 2.

**Scenario D:** The quasi pareto front shows a substantial increase in both cost and TWS compared to all other scenarios, Figure 6. Vila Real, Bragança, Guarda, Castelo Branco, Leiria, Portalegre, and Beja are exportes, beeing Vila Real and Portalegre the larger, ones. Slight changes are shown in transportation network as we progress towards higher costs, Figure 5. The primary energy sources portfolio shows a high user of wind power, followed by the grid, hydro and finally solar, Table 2.

The analysis of previous scenarios highlights the impact of its characteristics in the hydrogen supply chain designs. For instance, in Scenario C, the networks emphasize reducing water stress by relocating production away from drought-affected regions, even if this increases the overall costs. In Scenario D, the networks illustrate how increased urban demand reshapes the supply chain, with production hubs shifting more attention to Lisbon and Porto to optimize logistics.

The Figures 2 to 5 offer a visual representation of the trade-offs captured by the quasi pareto front and demonstrate the model's flexibility in addressing complex, multi-objective optimization challenges in Portugal's green hydrogen supply chain design.

To better understand the trade-off between total supply chain cost and water stress, a deeper discussion and guidance will be conducted.

## DISCUSSION AND GUIDANCE

The restrictions on grid power access in Scenario B demonstrated the model's capability to maximize green hydrogen production, with wind accounting for over 50% of the primary energy source portfolio, followed by hydro and the remaining share from solar (Table 2). However, despite a similar cost distribution, the model did not achieve a lower water stress level compared to the baseline scenario. These findings suggest that while prioritizing green hydrogen production is feasible, it requires careful water management in water-scarce regions, as TWS cannot be reduced to the same extent as in the baseline scenario.

Furthermore, under drought conditions, the model efficiently redistributed production to regions with more stable water supplies, as observed in Scenario C, thereby mitigating the severe impact on production costs. The trade-off between cost and water stress led to increase reliance on grid energy to off-set drought effects.

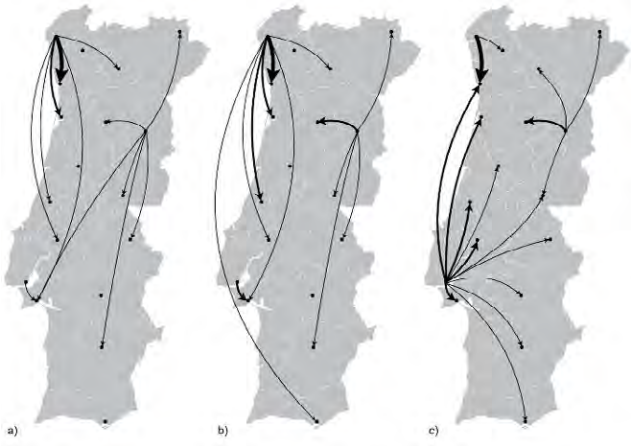

**Figure 2.** Scenario A. a) Transportation network for solution I. b) Transportation network for solution II. c) Transportation network for solutions III and IV.

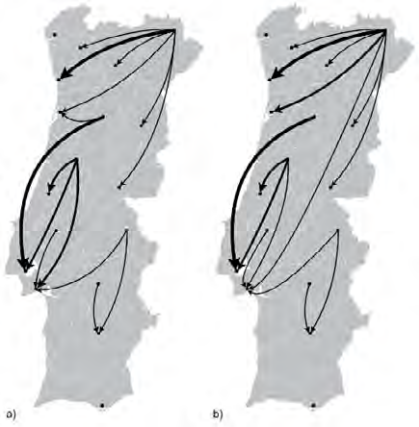

**Figure 3.** Scenario B. a) Transportation network for solution I. b) Transportation network for solutions II, III, IV.

Scenario D was the one that stood out from the rest, as shown in Figure 6. This scenario must overcome simultaneously the water scarcity and increase in demand. As result, has shown higher costs and higher water stress indicator. This analysis highlights how increasing demand, particularly in resource-constrained urban areas, puts significant pressure on the hydrogen supply chain. It underscores the urgent need for adaptable and robust infrastructures able to handle both environmental, economic challenges and demand fluctuations. Notably, most of the hydrogen produced was green, likely due to the higher overall TWS.

Regardless of the scenarios, the structure (design) of the hydrogen distribution chain remains robust. However, there is a noticeable variation in the amount of hydrogen produced in each district, along with a different utilization of the portfolio of primary energy sources.

## CONCLUSIONS

The work presented focuses on designing a green hydrogen supply chain in Portugal, considering the trade-offs between economic efficiency and water sustainability. The study uses a multi-objective simulated annealing algorithm to minimize both the total supply chain cost and the environmental impact on water resources, mainly in the water-scarce southern regions of Portugal. Lower water stress is generally achieved at the expense of increased costs. The quasi pareto fronts provide to the decision-makers with a framework to select solutions based on local priorities under different scenarios. The research highlights the significant impact of water availability on the hydrogen supply chain. Drought conditions (scenario C) lead to significantly higher costs and water stress. The model adapts by shifting production to regions with more stable water supplies, though this increases costs. Restriction to renewable energy sources (scenario B), lead to generally lower costs, but water stress is higher due to increased reliance on hydropower. This highlights the need for careful water management even when prioritizing green hydrogen production. The model demonstrates its ability to reallocate production and adjust the consumption of primary energy sources in response to varying conditions, such as drought, increased demand or both, which puts significant pressure on the hydrogen supply chain, leading to higher costs and water stress. This emphasizes the need for adaptable infrastructure capable of handling both environmental challenges and demand fluctuations.

## ABSTRACT

A transition to low-carbon fuels is integral in addressing the challenge of climate change. An essential transformation is underway in the transportation sector, one of the primary sources of global greenhouse gas emissions. The electrofuels that represent methanol synthesis via power-to-fuel technology have the potential to decarbonize the sector. This paper outlines a critical comprehensive life cycle assessment for electrofuels, with this study focusing on the production of synthetic methanol from renewable hydrogen from water electrolysis coupled with carbon from the direct air capture (DAC) process. This study has provided a comparison of the environmental impacts of synthetic methanol produced from grids of five regions (India, the US, China, Switzerland, and the EU) with conventional methanol from coal gasification and natural gas reforming. The results from this impact assessment show a high dependency of environmental scores on the footprint of the grid. Switzerland, with its limited usage of fossil fuels in grid electricity, has shown the least environmental damage in most of the impact categories in comparison to more non-renewable grids like India and China. Interestingly, conventional methanol has proved to be more environmentally friendly when compared with non-renewable grids like India and China in most of the impact categories.

## INTRODUCTION

The drive for reducing greenhouse gas (GHG) emissions has resulted in a global focus on sustainable fuels, with synthetic methanol among other potential alternatives to fossil fuels. Synthetic methanol combined with hydrogen ($H_2$) and carbon dioxide ($CO_2$) can be a pathway for decarbonizing the transportation and chemical feedstock production sector. Sustainable methanol paths rely on hydrogen generation by alkaline electrolysis and $CO_2$ capture through direct air capture (DAC) technologies. At the same time, fossil fuels demonstrate their continued relevance to world economies, and despite global endeavors to slash emissions, those typical mitigation methods are falling short of the ambitious targets set by the Paris Agreement. Synthetic fuel production is a promising avenue of study to fill this gap when paired with net carbon-negative technologies like DAC [1]. With ubiquitous $CO_2$-scrubbing technology, concentrated $CO_2$ streams are achievable for fuel production. Carbon dioxide is hence considered a renewable feedstock since it is non-depleting [2], [3], [4]. However, extraction and refining of the isolated carbon dioxide stream requires a significant amount of energy, which can further contribute to environmental damage scores. Hence, it can be stated that carbon capture and utilization (CCU) methods do not explicitly yield the environmental benefits one might assume, necessitating careful assessment. This often stems from the fact that these processes generally require substantial input energy. A detailed life cycle assessment (LCA) will be essential for elucidating the environmental footprints of synthetic methanol and discovering sustainable production pathways.

The studies at carbon capture plants combined with renewables for methanol manufacture present an intentional approach to reduce GHG emissions and

transition to sustainable production of chemicals. The studies [5], [6] analyze the economic and environmental performance of DAC and its environmental guide in the field of methanol production. In the work by [7] more of these arguments are fleshed out by comparing power-to-fuel and power-to-DAC approaches and providing evidence for the efficiency of DAC to facilitate climate change mitigation in Ireland. Biernacki et al. [8], who also consider the environmental impacts of using renewable electricity to produce methanol, further demonstrate the integration of renewable energy into the chemistry industry. Through a detailed assessment of CCU technology development, the research by [9] emphasizes that life cycle assessment (LCA) is fundamental to maximizing these technologies for environmental and economic sustainability. The research publications [10], [11], [12], [13] have examined green methanol production from $CO_2$ and renewable hydrogen, highlighting the significance of process design and the use of renewable energy sources in fuel production.

The literature thus far has much interest in the LCA of synthetic methanol and its precursors. However, most of these studies are too geographically limited, neglecting to model changes in grid mixes and lacking sufficient attention to the co-optimization of end-use electricity use. Most importantly, the differences in the carbon intensity of the electricity grid between countries and the resulting variability in environmental impacts remain largely unaddressed.

The present work can contribute to overcoming the existing research gaps by providing a detailed cradle-to-grave LCA of synthetic methanol and emphasizing the evaluation of electricity sources used for hydrogen production from alkaline electrolysis. This research analysis focuses on the impacts of electricity grids of five large-scale regions, namely India, China, Switzerland, Europe, and the USA, representing a wider range of electricity grid carbon intensities. Combining Aspen Plus modeling for process-level simulations with region-specific LCA data, this research depicts the regional environmental trade-offs related to electricity utilization depending on the grid. Moreover, this study seeks other routes for reducing ecological footprints, such as renewable energy incorporation and optimized electrolysis performance.

This work is significant because it features both the methodological rigor of high-resolution integration of Aspen Plus process simulations with geographically explicit LCA and the scenario-based assessment of regional electricity grids, yielding actionable insights for policymakers and industrial stakeholders. Instead of generalizing a single electricity input or assumed constant, this research serves as a dynamic model of grid mixes to enable a more realistic evaluation of the environmental viability of synthetic methanol.

This study is critical in closing urgent knowledge gaps in the literature. This work leverages advanced modeling and assessment tools to help inform sustainable energy pathways and aid in the decision-making for the low-carbon transition.

## METHODOLOGY

The methodology for assessing the environmental sustainability of synthetic methanol production combines process simulation, life cycle assessment (LCA), and comparative analysis. Hydrogen from alkaline electrolysis and subsequent conversion to methanol through hydrogen and $CO_2$ was modeled in Aspen Plus for process simulation and energy balance calculations. Parameters like electrolyzer operations, energy requirements, and process operations efficiency were specifically modeled to simulate hydrogen production in Aspen Plus.

The carbon dioxide used for methanol manufacturing was obtained from direct air capture (DAC) technologies. Plant data for DAC was imported from several literature sources ([14], [15], [16]), which allowed us to quickly disaggregate energy usage, material requirements, and $CO_2$ capture efficiencies. Using the LCA methodology, the above inputs were parametrically modeled to account for realistic operating situations, allowing for a comprehensive analysis of DACs' contribution to the overall environmental footprint.

Life cycle assessmentAn LCA was conducted following the ISO 14040 and 14044 frameworks using the SimaPro 9.6.0.1 software and various Ecoinvent databases. A cradle-to-grave system boundary was defined, including all stages from raw material extraction and energy inputs through methanol production and final use. Environmental impacts were evaluated using the ReCiPe 2016 impact assessment method with GWP, fossil resource depletion, and other impact categories of interest. The electricity consumption for hydrogen production has been modeled under five regional grid scenarios, i.e., India, China, Switzerland, Europe without Switzerland (EU), and the United States of America (USA) using the Ecoinvent database for country energy mix. The above geographical areas were chosen to capture a wide range of carbon intensity of the electricity grid, from coal-heavy grids to high-renewable generation grids across the globe.

The results from the LCA were contextualized by evaluating the LCA outcomes for synthetic methanol against conventional methanol production pathways, namely coal gasification and natural gas reforming. All these conventional pathways data were obtained from the Ecoinvent database in SimaPro to ensure consistency and comparability. Combining Aspen Plus simulations with region-specific life cycle assessment (LCA) enabled a high-fidelity examination of the environmental trade-offs of synthetic methanol production. This study draws

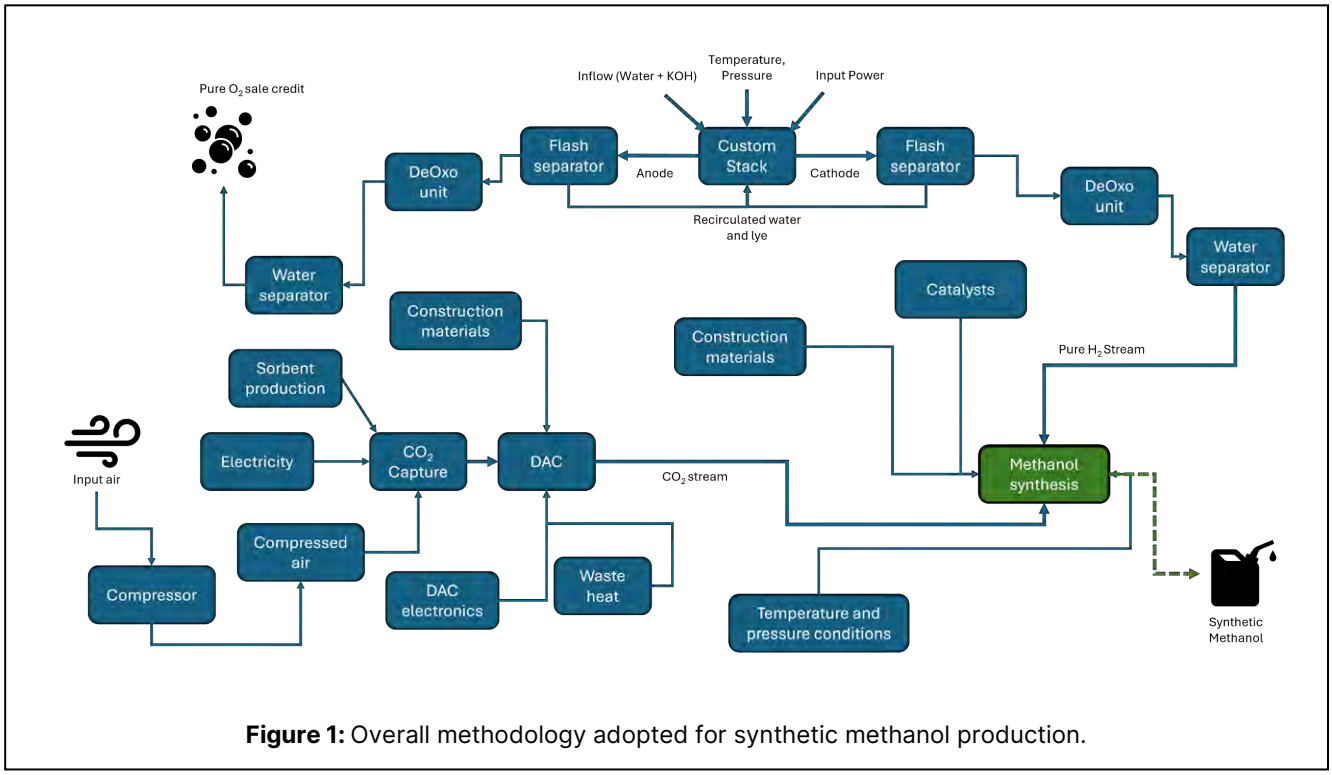

**Figure 1:** Overall methodology adopted for synthetic methanol production.

on available DAC data from credible literature sources and compares the results across regional grid scenarios and conventional production pathways to inform comprehensive insights into the potential for decarbonization and the hazards associated with transitioning to sustainable methanol production. The overall production methodology is depicted in Figure 1.

## Hydrogen production

The hydrogen production for this study has been modeled as a 500 kW electrolyzer in Aspen Plus, along with various balance of plant components. The hydrogen production modeling aims to obtain a purity greater than 99.99% to make industrially suitable hydrogen. As shown in Figure 1, the stack has been custom-modeled using the Aspen Custom Modeler at 25 bars of pressure and at a temperature of 75°C. This work has significantly used the semi-empirical polarization curve model developed by Sánchez et al. [17], [18] to generate a customized model for an alkaline electrolyzer stack in the Aspen Custom Modeler. This model has robustly described the electrochemical behavior of the alkaline water electrolyzers, incorporating critical resistive, kinetic, and thermodynamic phenomena for hydrogen production.

The Aspen Plus model is focused on efficiency and environmental effects, simulating the combined alkaline electrolysis for hydrogen production. Water and a lye solution are electrolyzed at the system's cathode and anode, producing hydrogen and oxygen molecules. This approach recycles the leftover water and lye produced at the two electrodes back to the stack (B1) to minimize the waste of resources and to maintain permanent operation. During recirculation, the recirculating streams are cooled using two shell-and-tube heat exchangers (IC-R1 and IC-R2) to maintain ideal operating temperatures for the stack to enhance system performance.

A de-oxygenation kinetic reactor unit operates on the cathode side to remove any oxygen impurities from the hydrogen product stream. This reactor facilitates the controlled reaction of surplus hydrogen and oxygen impurities to create water. This process creates high-purity hydrogen at 99.9958% purity that has high industrial utilization after extraction from the water stream. For oxygen purification at the anode side, a similar purification process is implemented via oxygen extraction as a product for real-world use. This recovery not only provides a potential financial benefit by valuing the by-product oxygen, but it also reduces the environmental impacts associated with the oxygen production processes, aligning with sustainable and resource-efficient concepts.

The model results show that approximately 59 units (kWh) of electricity are required to produce 1 kg of pure hydrogen. Similarly, 9.3 kilograms of makeup water is required to produce one kilogram of pure hydrogen.

## Carbon capture

This analysis's DAC plant construction and operating data are based on Climeworks' work [14]. The carbon capture is based on the temperature-vacuum swing adsorption method. The plant's capacity is four kilotons (kt) $CO_2$ per year with an operational life of 20 years. The plant's construction is divided into collector, processing,

land requirement, and hall and tank units. The land requirement for this 4-kt/year plant is taken as 1045 $m^2$. The LCI also considers the materials required to manufacture, operate, and maintain DAC systems. The existing plant comprises eight collection containers, each containing six $CO_2$ collectors and a processing unit. The materials are procured and processed according to industry requirements, including steel, stainless steel, aluminum, copper, concrete, insulation, and polymers. Considering global recycling rates (e.g., 70% for copper and 85% for steel), the LCI includes recycling rates for key metals, such as copper, steel, and aluminum. Plastics and insulation hand disposed of in landfilling or waste incinerator techniques are examples of non-metallic materials. For conventional production, end-of-life scenarios are considered to avoid burdens, accounting for the environmental credit through co-generated heat and energy in the waste treatment. The energy requirements for this plant have been fulfilled by waste heat from chemical industries and electricity. The waste heat requirement has been taken as 1.55 MJ and 0.55 kWh of electricity for extracting 1 kilogram of $CO_2$ [15], [16], [19]. The sorbent type for carbon capture was taken as zeolite powder. The solid low-temperature sorbent consumption requirement was 0.788 g/kg of $CO_2$ captured [19].

### Methanol production

Several interconnected procedures are used in the $CO_2$ hydrogenation process to produce methanol, increase productivity, and reduce environmental effects. A low-temperature powder sorbent DAC system is used to capture $CO_2$ at the start of the process. The methanol production for this study is based on research done by [20]. For every kilogram of methanol produced, the process consumes 1.446 kg of $CO_2$, 0.208 kg of $H_2$, and 2.173 kWh of electricity. The product is 1 kg of 95.3% pure methanol [20]. In the synthesis of methanol, the streams of $CO_2$ and $H_2$ are compressed and heated to 6.5 MPa and 210°C, respectively, before being fed into an adiabatic fixed-bed catalytic reactor with a Cu/Zn/Al catalyst installed based on the Aspen model by [20]. The reaction produces water and methanol; unreacted gases are recycled to increase conversion efficiency. However, during the separation process, there are minor losses of $CO_2$ (36.32 kg/h) and $H_2$ (9.64 kg/h). The purification process involves treating about 281 kg of water every hour, and a distillation column refines the resulting methanol stream.

## RESULTS, DISCUSSION, AND CONCLUSIONS

The underlying energy mix in each location drives notable trends in the Life Cycle Impact Assessment (LCIA) results for methanol production across different energy grids. In addition to traditional production techniques like coal gasification and natural gas reforming, the comparison covers the United States, Switzerland, India, the European Union, and China grids. Particulate matter generation, ionizing radiation, ozone depletion, global warming potential, and other essential impact categories were assessed. The observed differences in environmental impacts can be explained by the energy grid performance of each region, which reflects the proportion of nuclear, renewable, and fossil fuels in its electricity generation portfolio.

Compared to the grids in the United States, Switzerland, and the European Union, the global warming potential (GWP) of the Chinese and Indian grids is significantly more enormous. For instance, the Chinese grid records 11.51 kilograms $CO_2$ eq per kilogram of methanol, whereas the Indian grid displays 15.93 kg $CO_2$ eq. On the other hand, the Swiss grid exhibits a net carbon sequestration effect, with a negative GWP of -0.97 kg $CO_2$ eq. The negative values indicate the avoided emissions due to the sale of purified oxygen. This discrepancy can be linked to China's and India's heavy reliance on coal and other fossil fuels, which raise $CO_2$ emissions significantly when energy is generated. Coal makes up more than half of the electrical mix in China, and in India, it makes up around 70%. Conversely, Switzerland's energy mix is primarily composed of nuclear and hydroelectric power, which are nearly carbon-neutral and account for its negative GWP numbers.

Across all grids, stratospheric ozone depletion is typically minimal, but it is marginally higher in areas where a significant portion of fossil fuels are used. The Swiss grid reports 0.000002 kg CFC11 eq, while the Indian grid displays the highest amount at 0.000005 kg CFC11 eq. Though in small proportions compared to past emissions from refrigerants and aerosols, burning fossil fuels emits chlorinated chemicals that can damage the ozone layer. Switzerland contributes very little to ozone depletion because of its emphasis on clean energy sources, primarily hydropower and nuclear energy [21].

Impacts of ionizing radiation differ significantly; the EU grid has the second-highest figure at 2.84 kBq Co-60 eq, while the Swiss grid has the highest at 3.57 kBq Co-60 eq. Since ionizing radiation is released during the extraction, processing, and disposal of nuclear fuel, this pattern is consistent with the high percentage of nuclear power in Switzerland and the EU. On the other hand, because of its restricted use of nuclear energy, the Indian grid exhibits far lower ionizing radiation at 0.23 kBq Co-60 eq. There are noticeable differences in the creation of particulate matter and ozone, two processes that affect air quality and human health. The highest ozone generation values are seen in the Chinese and Indian grids, with the Chinese grid recording 0.03754 kg NOx eq and the Indian grid recording 0.04195 kg NOx eq. Similarly, the Indian grid has the largest particle matter generation

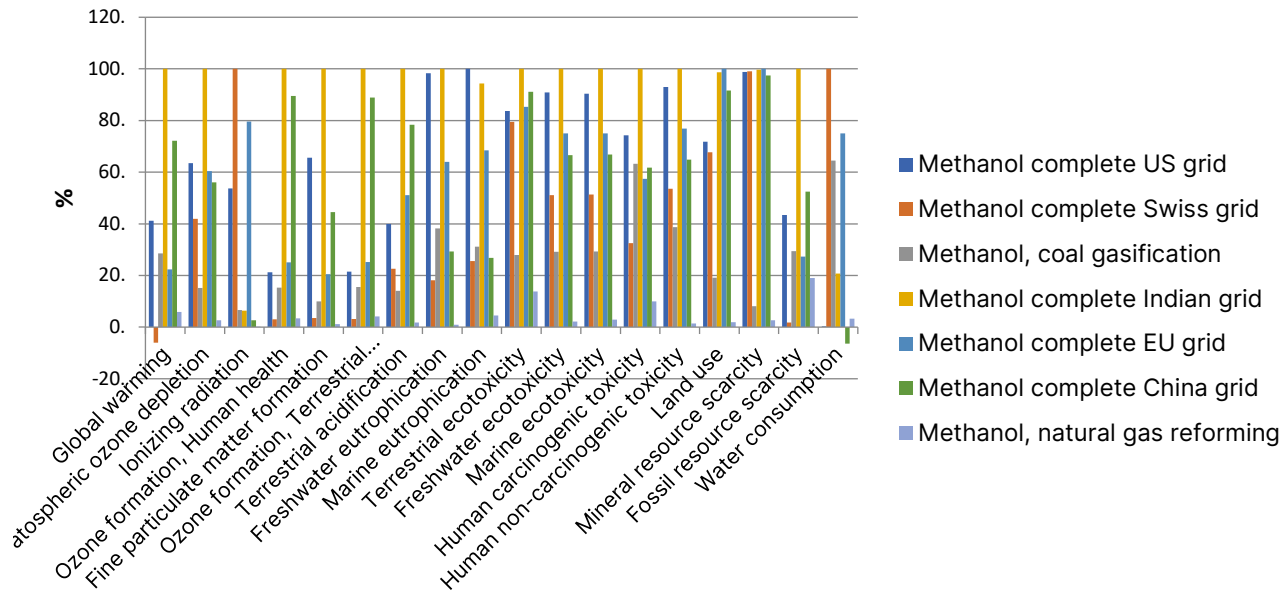

**Figure 2:** Life cycle impact results for synthetic and conventional methanol compared across various grids.

(0.04575 kg PM2.5 eq). These outcomes are caused by nitrogen oxides (NOx) and fine particles released while burning coal and other fossil fuels. With 0.00126 kg NOx eq for ozone formation and 0.00159 kg PM2.5 eq for particulate matter formation, the Swiss grid, on the other hand, has the lowest values in these categories because of its clean energy mix. An overall comparison of all the impact categories for various region-based grids for synthetic methanol and conventional methanol (natural gas reforming and coal gasification) is depicted in Figure 2. The significant impact that energy mixes have on environmental effects is highlighted by the comparative Life Cycle Impact Assessment (LCIA) for methanol production across several energy grids. Due to their carbon-intensive energy generation, grids that rely heavily on coal and other fossil fuels, like those in China and India, have far higher global warming potential (GWP), ozone formation, and particulate matter formation. On the other hand, networks that use cleaner energy sources—such as Switzerland's combination of nuclear and hydroelectric power—achieve low or even negative GWP values, which indicates net carbon sequestration. Furthermore, the effects of ionizing radiation and stratospheric ozone depletion correspond with the frequency of nuclear power and fossil fuel burning, respectively, in local grids. These results highlight how important it is to switch to low-carbon and renewable energy sources to lessen the adverse environmental effects of methanol production, especially in areas that rely significantly on coal and other fossil fuels.

## ABSTRACT

The use of waste heat from electrolysis can significantly increase process efficiency. Alkaline and PEM electrolyzers, the most mature technologies, produce low-temperature waste heat. Most studies focus on using this waste heat for low-temperature applications like district heating. Alternatively, this waste heat can be upgraded to a temperature that can be usable in the chemical industry, e.g., for steam generation. The combination of an alkaline electrolyzer with a heat pump has been recently investigated to supply both hydrogen and medium-temperature heat. Optimizing electrolyzers for both hydrogen and heat production (combined design) has been shown to have advantages over optimizing for hydrogen only and upgrading the waste heat a posteriori (separate design). However, the effects of electrolyzer pressure and hydrogen compression were not considered, and it remains unclear if similar benefits apply to PEM electrolyzers. This work further analyzes the combined system (i.e., electrolyzer with a heat pump) by including hydrogen compression and comparing alkaline and PEM electrolyzers. The results show that designing with waste-heat utilization in mind benefits both alkaline and PEM at low and high pressures. The combined design allows up to 10% cost reduction and up to fourfold reduction in $CO_2$ emissions compared to the separate design. However, this benefit is constrained by the maximum achievable current density, particularly for PEM. Despite this limitation, the combined system can effectively supply hydrogen and heat across various energy price scenarios, making it a promising solution for hydrogen supply and industrial electric heating.

**Keywords**: Hydrogen, Electric heating, Energy, Modelling, Optimization

## INTRODUCTION

Waste-heat recovery from alkaline and PEM electrolyzers has been widely studied for low-temperature heat applications (below 100°C), like district heating [1]. However, upgrading electrolyzer waste heat to meet medium-temperature heat demand (e.g., up to 200°C) is less explored, despite recent advancements in heat pump technologies that enable reaching these temperature levels [2]. Moreover, waste-heat utilization is usually added a posteriori after optimizing the electrolyzer for hydrogen production only, which may limit its benefits.

In our previous work [3], we recently explored the advantages of designing an atmospheric alkaline electrolyzer for waste-heat utilization, optimizing for both hydrogen and heat production. This new design approach provided further benefits over using the waste heat a posteriori. Additionally, upgrading waste heat to higher temperatures via heat pumps was found to be preferable over direct use at lower temperatures (e.g., district heating) when heat at both temperatures is required.

However, this previous study did not consider the effects of electrolyzer pressure or the integration with downstream processes: In most industrial applications, hydrogen is required at high pressures (e.g., up to 250 bar for chemical synthesis [4]), requiring a compression step and thus increasing cost and energy demand. Moreover, the same analysis should be extended to PEM electrolyzers, another well-established technology that is drawing increasing interest thanks to its potential for flexible operation.

In this work, we thus further investigate the potential

of combined systems to supply both hydrogen and medium-temperature heat. To address the aforementioned shortcomings, we analyze the impact of electrolyzer operating pressure, incorporate hydrogen compression, and compare alkaline and PEM electrolyzers.

## SYSTEM DESCRIPTION

The combined system consists of three main units, i.e., a water electrolyzer, a multi-stage compressor with intercooling and a heat pump. The electrolyzer is composed of 26 modules, each one capable of producing 72 kg/h of hydrogen [3]. The hydrogen is subsequently compressed to the required pressure in the multi-stage compressor. Finally, a closed-loop compression heat pump is used to upgrade the electrolyzer waste heat to a higher temperature level. Potential working fluids for achieving the target temperature lift include $CO_2$, argon, and air.

Such a combined system is able to supply around 1.9 t/h of hydrogen at 75 bar (suitable for methanol production [4]) and heat at 120°C (capable of producing low-pressure steam [2]), thus being an alternative to other electric heating technologies, such as direct electric boilers or air-source heat pumps.

For low-pressure (LP) electrolysis (alkaline and PEM at 1 bar), a multistage compressor with 5 stages is used, whereas for high-pressure (HP) electrolysis (PEM at 30 bar), a single-stage compressor is used. Intercooling to 35°C is considered between stages and before and after the compression step.

## METHODOLOGY

### Model

The backbone of the mathematical model is based on our previous work [3], which includes the polarization curve of an alkaline electrolyzer, the thermal model of the electrolyzer stack, and the efficiency-based model of different electric heating technologies (heat pump and direct electric boiler). The heat pump, operating at 40% of the maximum COP (i.e., Carnot cycle), achieves COP values ranging from 2.2 to 5.2.

For this work, the polarization curve [5] and Faraday efficiency [6] of a PEM electrolyzer and a multi-stage compressor model based on a fixed isentropic efficiency per stage are added. The molar enthalpies and entropies are computed using data from the CoolProp library [7]. Therefore, the effect of the pressure is captured in the electrolyzer and the compression stage.

### Performance evaluation

The performance is evaluated according to two indicators: the levelized cost of hydrogen (LCOH) and the net $CO_2$ emissions ($NetCO_2$).

The LCOH (Equation (1)) evaluates the total hydrogen production expenses over the system's lifetime (20 years) considering revenue from heat sales. Electrolyzer investment costs are taken from Cooper et al. [8], and replacement costs at the end of the tenth year are considered. Electricity and heat prices are based on the average EU-27 prices (2016-2020) [9]. The rest of model parameters are taken from our previous work [3].

$$\mathrm{LCOH} = \frac{\mathrm{CAPEX} + \sum_{j=1}^{N} (\mathrm{OM} + \mathrm{OPEX} - \mathrm{SALES}) \cdot (1+i)^{-j}}{\sum_{j=1}^{N} (m_{\mathrm{H_2}}) \cdot (1+i)^{-j}} \quad (1)$$

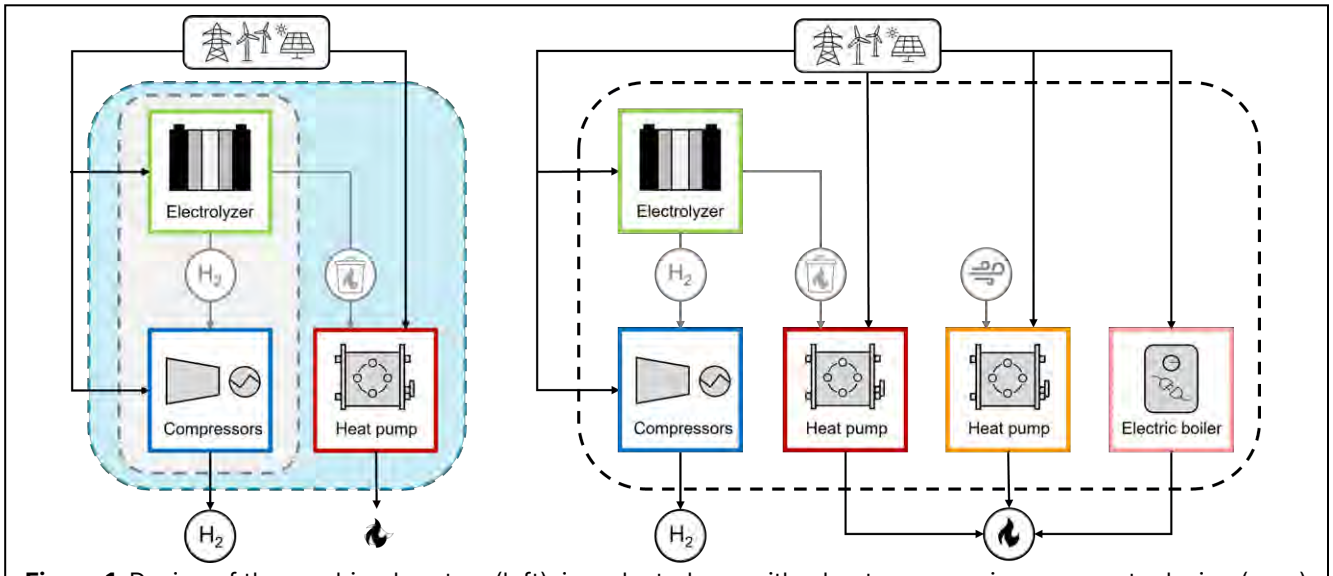

**Figure 1.** Design of the combined system (left), i.e., electrolyzer with a heat pump, using a separate design (gray) and a combined design (blue), and superstructure diagram of the hydrogen and heat supply network (right). The indicated areas refer to the system boundary considered in the optimization. The circled outputs are fixed.

The $NetCO_2$ (Equation (2)) accounts for the emissions due to electricity consumption of the different units *u* (i.e., electrolyzer, compressors, etc.) and the emissions avoided due to the heat output from electric heating technologies (i.e., heat pump and direct electric boiler), which is assumed to replace heating via natural gas.

$$\mathrm{NetCO_2} = \frac{\mathrm{Em_{ele}}(\sum_u P_u) - \mathrm{Em_{gas}}(\sum_u Q_u)}{m_{H2}} \quad (2)$$

For simplicity, the cooling requirements in the compression unit are excluded from the evaluation as they are small compared to those of the electrolyzer (up to 14% of the waste heat). However, the higher temperature level of the heat from compressor intercooling (140-150°C) makes it a potentially valuable additional heat source, which could further enhance system efficiency.

## System design and optimization

We compare the conventional separate design of the combined system, i.e., a posteriori coupling (see Figure 1 left, gray box), with the combined design approach that explicitly incorporates waste-heat utilization (blue box). In both design approaches, we optimize the system for both cost and emissions.

Additionally, we use a superstructure optimization problem to determine the optimal hydrogen and heat supply network, considering various electric heating alternatives, namely air-source heat pumps and direct electric boilers (see Figure 1 right). A hydrogen-to-heat demand ratio of one is considered, where the hydrogen energy content is computed using the higher heating value (HHV).

The electrolyzer optimization variables and the main model parameters are given in Table 1 and Table 2, respectively. Note that the COP of the heat pump is determined by the electrolyzer operating temperature and the sink temperature [3].

**Table 1:** Electrolyzer optimization variables.

| Variables | Alkaline | PEM |
|---|---|---|
| Temperature | 50-90°C | 50-90°C |
| Current density | 0.2-1 A $cm^{-2}$ | 0.5-3 A $cm^{-2}$ |

**Table 2:** Summary of the main model parameters.

| Variable | Value |
|---|---|
| Compressor isentropic efficiency | 0.8 |
| Electric boiler efficiency | 0.98 |
| Discount rate | 5% |
| O&M | 2% of the CAPEX |
| Operating hours | 8000 h/y |
| Electricity price | 79.2 €/MWh |
| Heat price | 30.7 €/MWh |
| Electricity emission factor | 0.164 kg/MWh |
| Heat emission factor | 0.244 kg/MWh |

# RESULTS AND DISCUSSION

## Designing for waste-heat utilization

### Optimal combined system designs

The performance of combined systems optimized using the different design approaches are shown in Figure 2. The results are consistent with our previous work on atmospheric alkaline electrolyzers only [3]: also for LP and HP PEM electrolyzers, the separate design leads to suboptimal solutions, whereas the combined design allows optimal trade-offs between cost and emissions, depending on the heat output of the system.

In terms of the electrolyzer operating conditions, the combined design leads to more compact electrolyzers with higher current densities, because the additional waste heat can be valorized. Moreover, operating at a higher pressure increases the optimal current density.

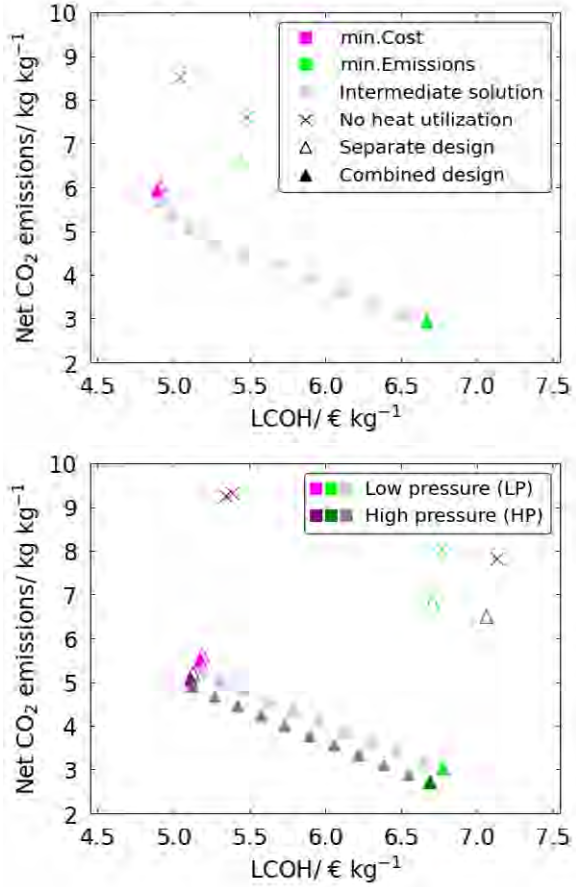

**Figure 2.** Trade-off between levelized cost of hydrogen (LCOH) and net $CO_2$ emissions for the combined system with alkaline (top) and PEM (bottom) electrolyzers. Both cost and emissions are given per kg of hydrogen and consider sales revenues and avoided burden, respectively, for the generated heat.

When minimizing costs, the combined systems

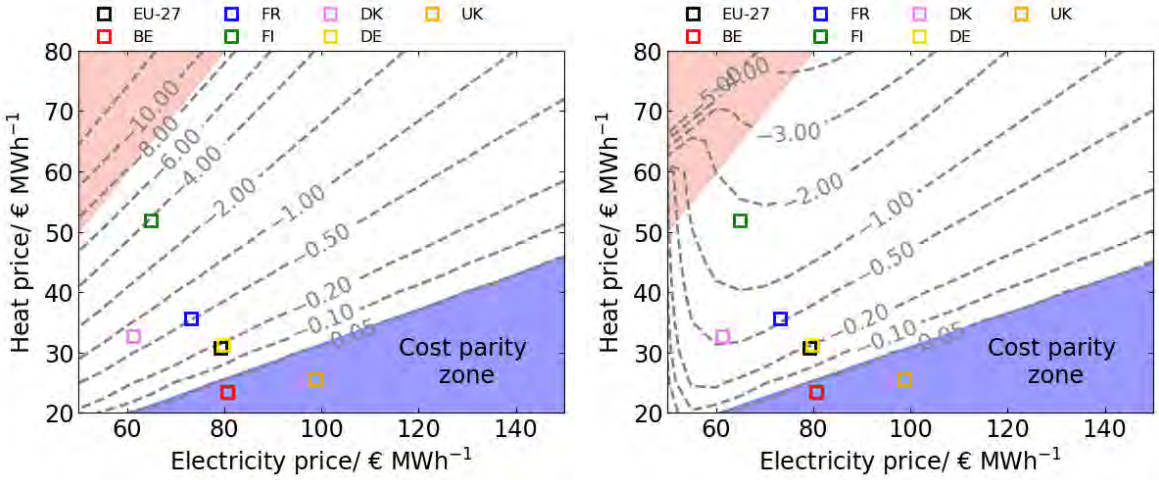

**Figure 3.** Percentage cost reduction of the combined design over the separate design of the combined system based on alkaline (left) and HP PEM (right) at different energy prices. The blue area indicates the area where both designs have the same cost. The red area indicates an area of unlikely price combinations, in which the heat price is higher than the electricity price. The squares indicate average price in different EU countries in 2016-2020 [9].

based on PEM are more expensive than those based on alkaline, mainly due to their higher CAPEX. Remarkably, HP PEM allows lower cost than LP PEM because (i) the increase in CAPEX due to the pressure factor of 1.2 is offset by an 80% reduction in compression costs (saving nearly 40 M€), and (ii) the higher waste heat available resulting from operation at higher current density is valorized via the heat pumps.

When minimizing emissions, the combined designs allow significant emission reductions but are generally more expensive than the separate designs (filled vs. unfilled green triangles). This is because in the separate designs, the optimizer selects an electrolyzer with the highest efficiency in terms of electricity consumption (highest temperature and lowest current density), significantly reducing the electrolyzer OPEX in exchange of a slight increase in CAPEX. However, for HP PEM, the increase in CAPEX is substantially higher due to the pressure factor, making it more expensive than in the combined design.

### Cost benefits over a posteriori coupling

The observed benefit of combined design over separate design holds across various energy price scenarios, especially when electricity prices are low and heat prices are high (see Figure 3). This is evident in the alkaline system, where straight contour lines are observed. However, for PEM systems, curved contour lines appear due to the upper bound on current density.

The higher the current density in the combined design compared to the separate design, the higher the benefit. For alkaline, optimal current densities are typically achieved in the middle of the allowable current density range. In contrast, for PEM, the optimal current densities often reach the upper bound, limiting the system's heat output and, consequently, the heat sales. This limitation is more pronounced in the HP PEM system, where higher current densities are required (Figure 3 right). This suggest that to fully unlock the potential of waste-heat utilization from electrolysis, even higher achievable current densities would be desirable.

### Emission benefits over a posteriori coupling

The analysis across various $CO_2$ emission factors show similar results: The combined design outperforms the separate design, especially at low electricity emission factors and high heat emission factors (up to fourfold reduction). While designing with waste-heat utilization in mind offers limited advantages at low heat emission factors (e.g., heat from biomass), heat is currently still mainly supplied by fossil sources like natural gas. Thus, the combined design remains beneficial in most current scenarios.

## Hydrogen and heat supply networks

### Optimal supply networks

The cost-optimal hydrogen and heat supply networks to supply a methanol production process and generate steam are depicted in Figure 4. The combined system is the main heat supplier in all the optimal networks, which showcases the potential of the system to contribute to industrial electric heating.

There are no significant differences between the different electrolyzer systems. In all optimal combined systems, the electrolyzer operates at the highest temperature and current density allowed. The slight discrepancy in the amount of heat supplied is due to the different polarization curve (alkaline vs. PEM) and the different

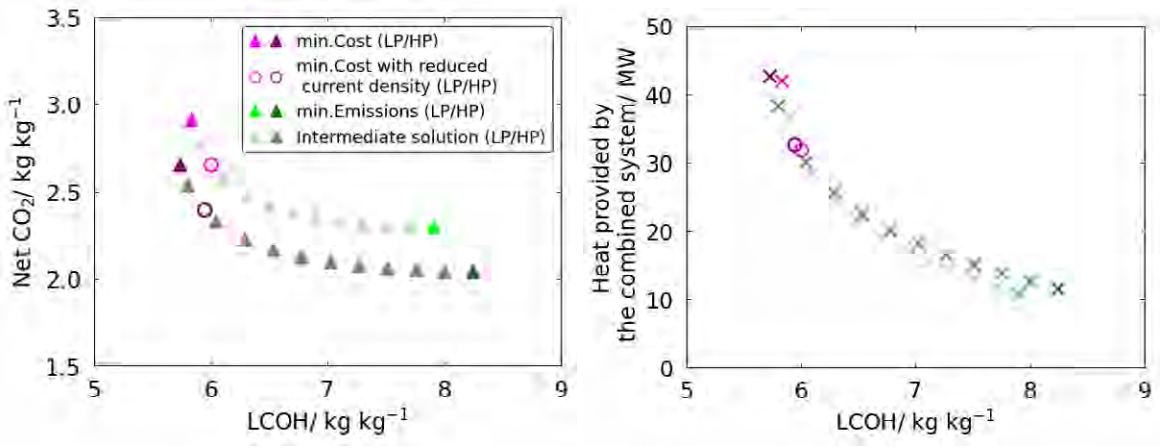

**Figure 5.** Optimal hydrogen and heat supply networks based on PEM: Pareto front (left) and heat contribution of the combined system in the Pareto-optimal solutions (right).

operating pressure (LP vs. HP).

The air-source heat pump supplies the remaining heat. This technology is preferred over the direct electric boiler for better efficiency and cost advantages from economies of scale.

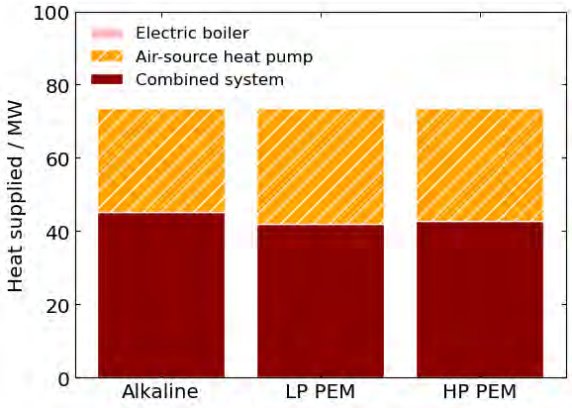

**Figure 4.** Cost-optimal heat supply networks when using different electrolyzers.

In this work, different heat pumps are considered for each heat source. However, utilizing a heat pump with multiple heat sources (e.g., waste heat, compressor intercooling, and ambient air), could further enhance efficiency, reduce reliance on a single heat source, and increase process reliability. Nonetheless, a cost analysis is necessary to ensure an effective heat supply.

## Contribution of the combined system

The cost of the supply network is significantly affected by the amount of heat supplied by the combined system (see Figure 5). While reducing its heat output (i.e., decreasing current density) can lower the net emissions, it also substantially increases costs.

The cost reduction potential compared to the minimum emissions solution depends on the upper bound of the current density. When considering a reduced upper bound of current density (0.7 A/cm2 for alkaline and 2 A/cm2 for PEM), the cost-optimal solutions result in a higher minimum cost (unfilled circles in Figure 5). Therefore, further advances in electrolyzer development to operate at higher current densities are desirable.

## Sensitivity analysis

A sensitivity analysis is conducted to assess the impact of electrolyzer investment costs and energy prices (i.e., electricity and heat) on the optimal supply network design and cost. The combined hydrogen and heat supply network is re-optimized for each parameter value.

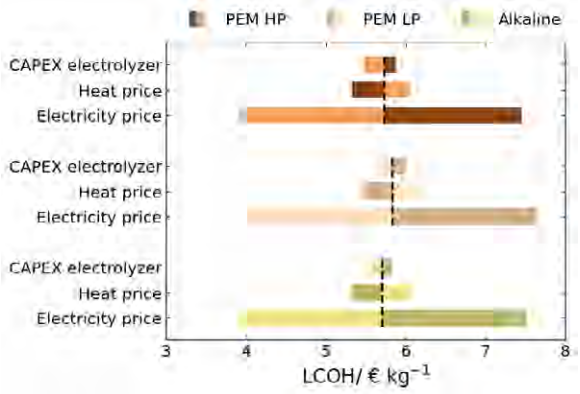

**Figure 6.** Influence of ±30% changes in the electrolyzer CAPEX, heat price and electricity price on the optimal levelized cost of hydrogen.

The optimal combined system design remains unaffected by these parameters, indicating the robustness of the system across a wide range of scenarios. Nonetheless, the resulting cost varies depending on the specific

parameter being considered (see Figure 6).

Electricity price has the biggest impact due to the high contribution of OPEX in the cost breakdown. Conversely, investment cost has the lowest influence because of the lower contribution of CAPEX.

The influence of electricity and heat prices is similar across the three electrolyzer systems. However, the investment cost has a greater influence on PEM compared to alkaline systems, as PEM are more expensive.

## CONCLUSIONS

The combined system, i.e., electrolyzer with a heat pump, was analyzed for supplying hydrogen to a methanol production process while producing heat suitable for steam production. Waste-heat upgrading from alkaline and PEM electrolyzers offer similar benefits, with the choice depending on the hydrogen needs. Alkaline electrolyzers are cost-effective for large-scale production, while PEM electrolyzers, despite higher upfront costs, provide higher hydrogen purity and flexibility.

Optimizing electrolyzers for both hydrogen and heat production is more beneficial than using the waste heat a posteriori from an electrolyzer optimized solely for hydrogen production. This new approach leads to more compact electrolyzers with higher current densities, reducing costs by up to 10% and $CO_2$ emissions by four times. Therefore, increasing the maximum achievable current densities can improve waste-heat utilization. The effect of the electrolyzer operating pressure is not significant, as the increase in CAPEX is offset by the reduced compression requirements (about 80% cost reduction).

The combined system is always selected over alternative electric heating technologies in the optimal hydrogen and heat supply networks. Notably, its optimal design remains consistent despite uncertainty in electrolyzer investment cost and energy prices, with electricity price having the biggest impact. Conversely, electrolyzer investment cost has the lowest impact, being higher for PEM than for alkaline.

Further research can investigate the detailed coupling of electrolyzers and heat pumps using flowsheet models. This analysis will help retrofit existing electrolyzer installations and contribute to the optimal waste-heat utilization of future energy systems.

## ABSTRACT

One of the proposed strategies to reach net-zero goals is the diversification of a country's energy mix and transition to technologies that favour the mitigation of greenhouse gas emissions, while decreasing dependency on conventional fuels. This work presents a mathematical model that describes key production routes for two proposed energy transition vectors, biomethane and hydrogen, expressed as a Mixed-Integer Linear Problem (MILP). The supply chain is optimized with the objective of maximizing the profits from the global supply chain. The problem is formulated as an allocation problem, with production distributed between biomethane and hydrogen markets. The case study focuses on a region in Mexico where second-generation biomass for biogas production is abundant, while hydrogen is produced from biomethane using steam methane reforming. The results highlight the importance of balancing resource allocation in shared supply chains. With a production ratio of 60% biomethane and 40% hydrogen, a Levelized Cost of Hydrogen (LCOH) of 2.07 €/kWh and a Levelized Cost of Biomethane (LCBM) of 0.17 €/kWh are obtained, resulting in total hydrogen and biomethane production of 12,563 GWh/year and 72,374 GWh/year, respectively.

**Keywords**: Optimization, Environment, Hydrogen, Renewable and Sustainable Energy, Supply Chain

## 1. INTRODUCTION

A country's energy consumption is closely linked to its economic growth. Despite efforts to reduce greenhouse gas emissions by integrating green technologies to meet energy demands, energy consumption remains heavily reliant on fossil fuels. On a global scale, oil and gas production is projected to increase by 27% and 25% by 2030 [1]. According to the findings of the Intergovernmental Panel on Climate Change (IPCC) in 2018, limiting global temperature rise to no more than 1.5°C requires nations worldwide to achieve net-zero emissions by 2050 [2]. To reach this goal, different pathways have been proposed, which include the use of various technologies to decarbonize hard-to-abate sectors [3]. These sectors, which account for 30% of global emissions, encompass industry applications such as cement, plastics, and steel, as well as heavy-duty transport. Among the proposed technologies for decarbonization, biomethane and hydrogen have emerged as promising solutions, supported by the extensive research into their production technologies and associated limitations. Biogas is obtained from organic waste, and its process occurs naturally in landfills when it decomposes and produces methane, which is twenty times more damaging to the atmosphere than carbon dioxide [4]. Hydrogen production is currently dominated by steam methane reforming (SMR) using natural gas. Since SMR is a well-established technology, using biomethane obtained from biogas offers an attractive alternative for hydrogen production [5]. The use of biomass for methane and hydrogen production fosters a circular economy by reincorporating waste into the value chain [6], significantly reducing greenhouse gas (GHG) emissions. Waste-to-energy systems provide dual benefits: improved waste management and enhanced energy security, as the production and consumption of the resulting product can be located within the same geographic region. To address some of the challenges that arise from the network design of these technologies, various approaches have been proposed.

For instance, the application of a multi-objective optimization approach for biogas supply chains that considers the upgrading of biogas to biomethane reduces environmental impact and enhances applicability to different end-users. However, this also leads to higher production costs [7]. Additionally, some studies have considered inorganic waste sources to obtain a range of products in addition to electricity, such as syngas [8], incorporating the minimization of GHG emissions. A key advantage of biogas production is its feedstock flexibility, making it a more reliable energy source compared to the inherent variability of wind and PV energy [9]. In parallel, there is extensive research on hydrogen supply chains [10-12], which determines key components for the optimal supply chain design (energy source, production technology, storage, transportation, end-use). For green hydrogen production, the prominent technology used is electrolysis, relying on electricity production from renewable energy sources (RES). However, production costs and availability are highly dependent on the geographical region. Some frameworks have been developed to integrate dual product demands within a single supply chain network, such as hydrogen and methane through Power-to-Hydrogen (which transforms energy into hydrogen) and Power-to-Methane concepts (which produces methane through methanation) [13]. These approaches aim to provide fuel supply at a lower carbon-cost, while mitigating the impact from RES fluctuations. In the present study, biomethane and hydrogen are considered as products from a shared supply chain, which uses second generation waste as biomass source, a strategy particularly relevant to avoid the use of energy crops. Biogas is produced through anaerobic digestion and subsequently upgraded to biomethane. Hydrogen is generated via SMR, with biomethane being allocated between market demand and hydrogen production based on a specified distribution ratio. The interdependency of these products is analysed using a techno-economic approach through a set of equations that consider resource allocation and distribution, as well as cost constraints.

### 1.1 Methodology

The framework for the techno-economic assessment for biomethane and hydrogen production consists of three steps. First, the potential biomethane and hydrogen markets are analysed, considering the demand for each product. In the case of biomethane, its use in the domestic sector and electricity production sector is considered. Two hard-to-abate sectors are identified for hydrogen: the heavy-duty transport sector and the steel sector. The second step comprises the formulation of the mathematical model, which is based on the superstructure shown in **Figure 1**. Finally, the supply chain is optimized considering the maximization of global profits as the objective function.

The mathematical model incorporates mass balance equations in a steady-state configuration. The supply chain considers the following echelons: biomass is obtained from location ***f*** and processed into biogas using technology ***j*** in location ***l***. Biofertilizer is obtained as a by-product and can be sold in demand market ***q.*** Biogas is upgraded using technology ***k*** in location ***m***. The upgraded biogas, or biomethane, is sold at demand market ***p***. Biomethane that is not sent to the demand market ***p*** is used to produce hydrogen, which is produced using technology ***r***. As this results in gaseous-state hydrogen, a liquefaction step is needed, using technology ***lq***, to store liquid hydrogen in storage tank ***s*** and to be able to transport it in liquid form to location ***h***, where it is regasified to be distributed through the refuelling station ***rf***. The mathematical model is formulated as a mixed integer linear programming model (MILP). Since this is a preliminary assessment, uncertainty in the process was not considered. The supply chain is modelled as an allocation problem, where a percentage of the obtained biomethane will be sold to the demand market and the other percentage is used to produce hydrogen.

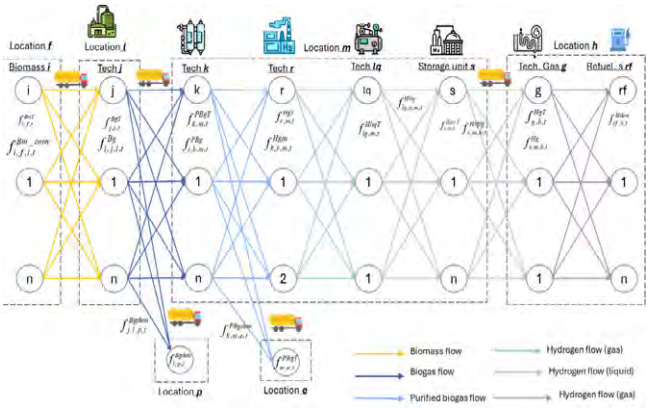

**Figure 1.** Proposed superstructure for the biomethane and hydrogen supply chain.

## 2. MATHEMATICAL MODEL

### 2.1 Biogas and Hydrogen Production

The total amount of biomethane ($f_{k,m,t}^{PBg_T}$) using technology ($k$) at location ($m$) must be equal to the sum of biogas from every biomass source ($i$) purified at location ($m$) using technology ($k$). It should also be equal to the amount of biomethane ($f_{k,m,p,t}^{PBg_market}$) needed to satisfy market ($p$) and the amount of biomethane allocated for hydrogen production ($f_{k,m,t}^{BgH}$).

$$f_{k,m,t}^{PBg_T} = \sum_i f_{i,m,k,t}^{PBg}, \forall (k \in K, m \in M, t \in T) \quad (1)$$

$$f_{k,m,t}^{BgH} = x \sum_i f_{i,m,k,t}^{PBg} \forall (k \in K, m \in M, t \in T) \quad (2)$$

$$f_{k,m,t}^{PBg_T} = \sum_p f_{k,m,p,t}^{PBg_market} + \sum_i f_{i,m,k,t}^{BgH}, \forall (k \in K, m \in M, t \in T) \quad (3)$$

The balance in the storage unit STOR of type s in location m at time *t* is given by the difference between the flows that go into the storage unit and the mass flows leaving the storage unit.

$$STOR_{s,m,t} = STOR_{s,m,t-1} + \sum_{lq} f_{lq,s,m,t}^{Hliq} - \sum_h f_{s,m,h,t}^{Hlqrf} \quad \forall (s \in S, m \in M, t \in T) \quad (4)$$

To make sure that the liquid hydrogen flow to and from the storage unit u at production site m during time t is within the storage unit capacity limit, the following restriction is applied:

$$SCap_{s,m,t}^{\min} \cdot \gamma_{s,m}^{s} \leq STOR_{s,m,t} \leq SCap_{s,m,t}^{\max} \cdot \gamma_{s,m}^{s} \quad (5)$$

$SCap_{s,m,t}^{min}$ and $SCap_{s,m,t}^{max}$ represent the minimum and maximum storage capacities for the storage tank type *s* at location *m* in time *t*.

## 2.2 Economic objective

The total profit (*Pft*) considers the revenue (*T_Rev*) obtained from sales for each product minus the total costs from the supply chain, which include fixed costs (*T_FC*), variable costs (*T_VC*), and transport costs (*Tr_C*).

$$Profit = Total_{Revenue} - Total_{Costs} \quad (6)$$

The fixed costs (*FC*) for each process *X* involved in the supply chain are calculated by multiplying the annualization factor *K* by the parameter *C*F and the binary variable y, which dictates whether the process technology *X* will be installed or not.

$$FC[processX] = KX_{x,t} \cdot CF_{x,t} \cdot y_{x,t} \forall t \quad (7)$$

The annualization factor K is calculated as follows:

$$k_{x,t} = \left[\frac{(1+\alpha_x)^n \cdot \alpha_x}{(1+\alpha_x)^n - 1}\right] \quad (8)$$

In this expression, *x* refers to the production technology, *α* is the discount rate set at 10%, and *n* is the plant lifetime (20 years). The variable costs are computed by the product of the parameter *VC* by the mass flow relevant to the conversion process at each stage. For instance, considering the SMR process, the parameter $VC_{m,r,t}^{ref}$ is multiplied by the mass flow $f_{k,m,r,t}^{Hgas}$ , that is used for hydrogen production.

$$VC^{ref} = \sum_k \sum_m \sum_r \sum_t CV_{m,r,t}^{ref} \cdot f_{k,m,r,t}^{Hgas} \quad (9)$$

Transport costs consider fuel, labour, and maintenance costs, multiplied by the demand flows, taking into account the distance between the production site and the demand market. The total costs are the sum of the fixed, variable, and transport costs.

$$TotalCosts = Total_{FC} + Total_{VC} + Total_{TR} \quad (10)$$

Finally, the levelized costs for biomethane and hydrogen respectively LCOH and LCBM are calculated as follows:

$$LCOH = \frac{Total\ hydrogen\ production\ costs}{Annual\ hydrogen\ production} \quad (11)$$

$$LCBM = \frac{Total\ biomethane\ production\ costs}{Annual\ biomethane\ \ production} \quad (12)$$

The mathematical model is expressed as a Mixed-Integer Linear Problem (MILP). This was solved using CPLEX 22 within the GAMS environment. The model consists of 83 blocks of equations and 70 blocks of variables. The supply chain is optimized with the objective of maximizing the profits from the global supply chain. The problem is expressed as an allocation problem, with production distributed between biomethane and hydrogen markets.

# 3. CASE STUDY

The mathematical model is applied to a case study in Mexico, focusing on the country's central region. The states selected play a significant role in the agricultural sector, resulting in a high availability of residues that can be used as feedstock for biogas production. For market demands, biomethane is considered a substitute for natural gas in energy production. Regarding hydrogen, market trends in Mexico highlight its potential to decarbonize the heavy-duty transport sector and some hard-to-abate industries, such as steel and ammonia production. In this case study, the heavy-duty transport sector was considered. GHG emissions from road transportation in Mexico contribute to 34% of the total emissions [14]. With current tendencies suggesting increased investment in the industry sector in the country, this number is expected to grow even further.

# 4. RESULTS

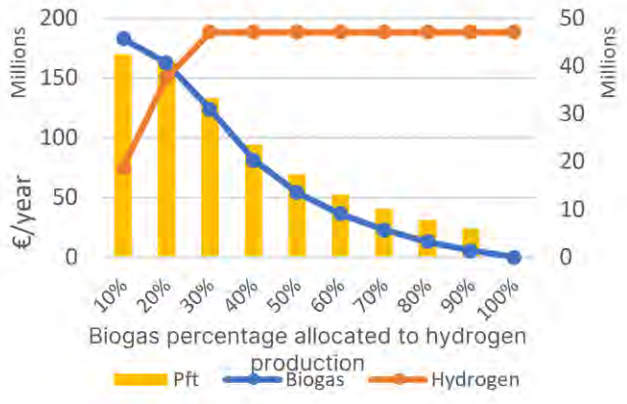

**Figure 2.** Revenue per product

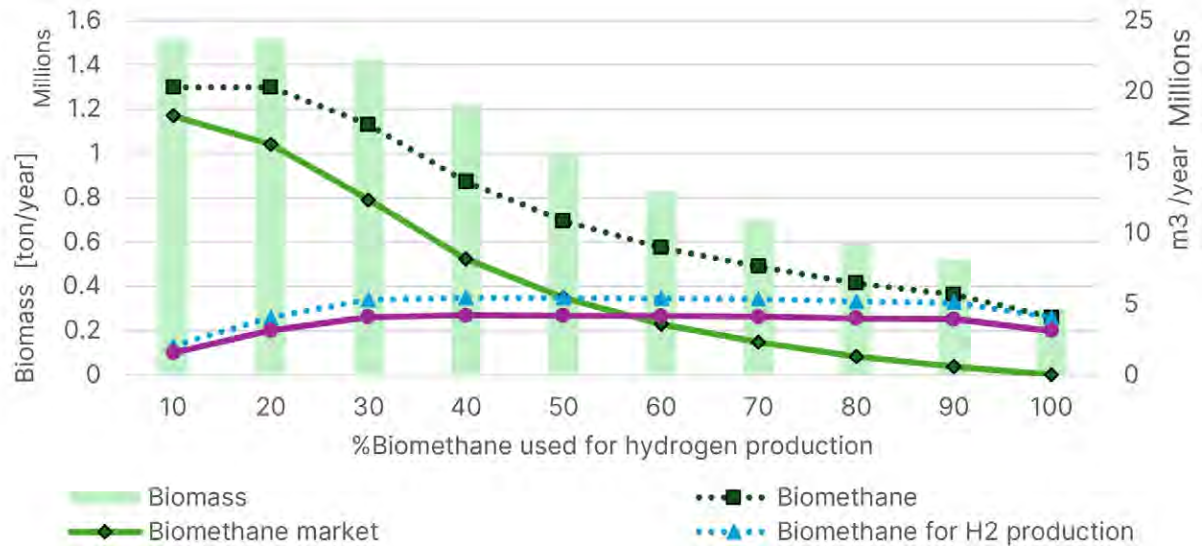

**Figure 3.** Impact of Biomethane Allocation on Hydrogen and Biomethane Production.

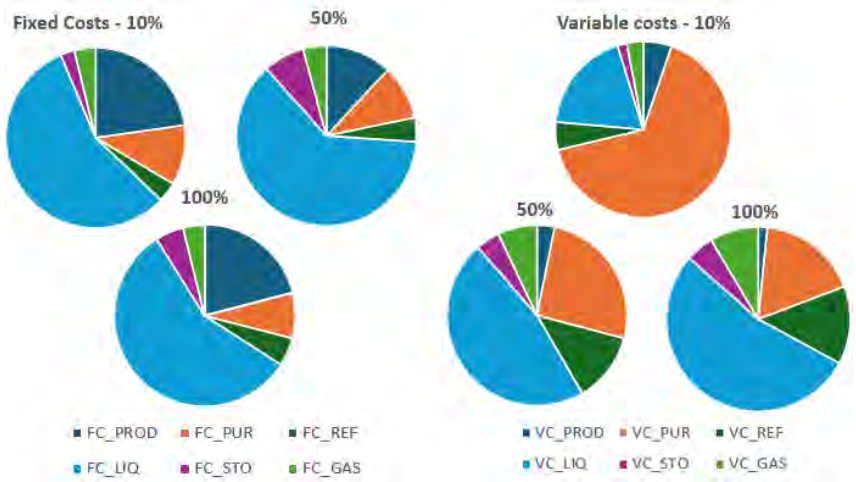

**Figure 4.** Share of Fixed and Variable costs.

**Figure 2** illustrates a clear trend, showing the profit for each allocation scenario. As the quantity of biogas allocated to hydrogen production increases, profits decrease significantly. Biomethane revenue decreases as the amount of biomethane allocated for hydrogen production rises, which aligns with the concept of economy of scales. This concept refers to the cost advantages with the increase in production. However, hydrogen revenue remains constant, from 30% of biomethane allocation for hydrogen production onwards. The main reason for this trend is the inflated cost of hydrogen production, specifically, its liquefaction, which is a crucial step needed to store and transport from the production site to refuelling stations.

This is further demonstrated in **Figure 3**, which shows that with a higher percentage of biomethane being used for hydrogen production, the overall of biomass required for the supply chain is adjusted to maintain profitability. This decrease helps in controlling costs associated with hydrogen production. As it can be observed in **Figure 4**, when hydrogen is produced from 10% biomethane, the fixed costs for the liquefaction technology take up more than half of the overall capital costs. This contribution remains constant up to the point where all biomethane is used to produce hydrogen. Yet, in terms of operational costs, the main contributor is the cost from upgrading biogas to biomethane. As hydrogen production increases, these costs become negligible compared to those associated with hydrogen liquefaction.

**Figures 5 and 6** present the levelized costs in terms of energy, considering that 1 $m^3$ of biomethane and 1 $m^3$ of hydrogen gas have a Low Heating Value (LHV) of 10 kWh/$m^3$ [15] and 3 kWh/$m^3$ [16], respectively. Under these assumptions, the highest LCBM for this supply chain reaches 1.04 €/kWh, while the highest LCOH amounts to 5.06 €/kWh. In **Figure 5**, an exponential trend

is noticeable from allocating 40% to the biomethane market onwards. Since the revenue from biomethane is higher than that from hydrogen, the optimization strategy seeks to limit its production. Considering the LCOH (**Figure 6**), this value decreases as more biomethane is used in production but stabilizes between 2€/kWh to 1.6€/kWh from scenario D onwards, maintaining a constant profitability in the system.

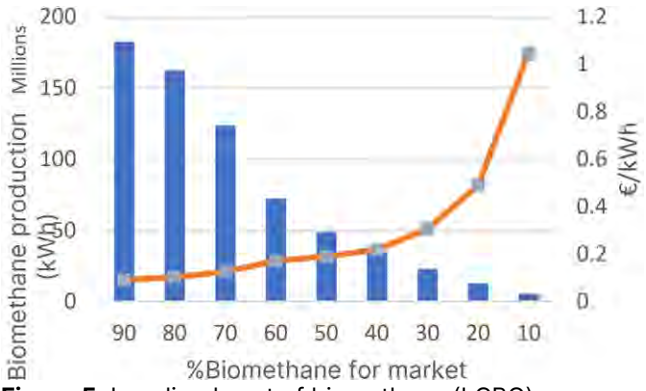

**Figure 5.** Levelized cost of biomethane (LCBG)

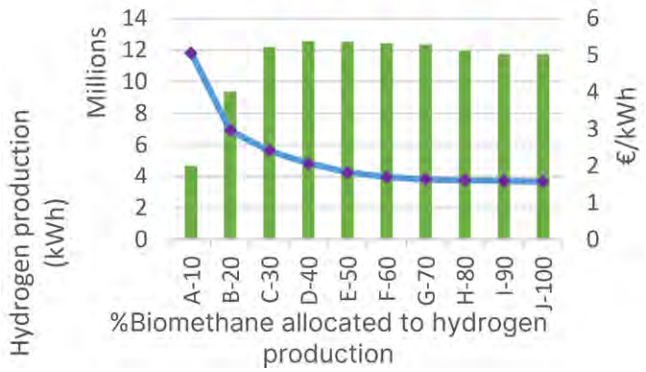

Figure 6. Levelized cost of hydrogen (LCOH)

**Figure 7** provides a schematic representation of the supply chain design resulting from scenario "D", covering six of the most industrialized and energy-driven cities (labelled 1 to 6). The network integrates biogas upgrading, hydrogen production, transport, and refuelling infrastructure to support a sustainable energy transition. In this scenario,1,224,103 tons of biomass are collected at each of the locations, consisting of 3% from organic waste, 11% from cow manure, and 86% from wastewater. To maintain profit margins, biomass is obtained, transformed to biogas and upgraded to biomethane within the same locations where biomethane is distributed. The upgrading technology used to produce biomethane is High-Pressure Water Scrubbing (HPWS), obtaining 8,173,563 $nm^3$ of biomethane to be sold to the demand market, while 4,8249,93 $m^3$ are used to produce hydrogen by SMR, representing a 60-40 ratio. From this configuration 4,187,805 $m^3$ of hydrogen are regasified at the refuelling stations. Hydrogen production plants, storage, and refuelling stations are installed at all locations, and hydrogen distribution prioritizes the demand of the most industrialized cities, locations 1 and 6. The LCBM presents a value of 0.17 €/kWh, while the LCOH is 2.07 €/kWh.

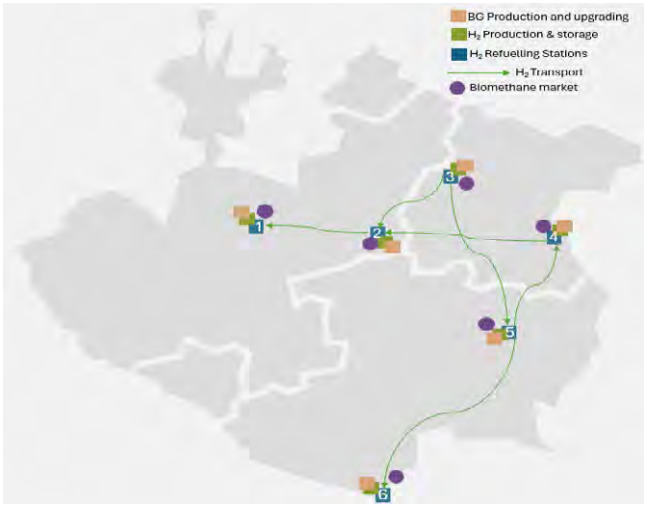

**Figure 7.** Supply chain design for scenario "D".

## 5. Conclusions

The techno-economic optimization for a biomass and hydrogen supply chain is considered for a case study in Mexico. The objective function is profit-maximization of the global supply chain. It is well-established that hydrogen production is an expensive process, compared to biomethane production. Therefore, the optimization problem is formulated as an allocation problem, to distribute the quantity of biomethane that is used for hydrogen production. These results emphasize the importance of balancing resource allocation in shared supply chains. A production scenario with 60% biomethane and 40% hydrogen offers a balanced cost-effectiveness for both products with a LCOH of 2.07 €/kWh and an LCBM of 0.17 €/MWh, with total hydrogen and biomethane production of 12,563 GWh/year and 72,374GWh/year, respectively. While the LCBM is slightly higher than average LCOE for biomethane (0.1 €/MWh [17]), the hydrogen costs are quite further from average LCOH costs in literature. This can be explained by the relatively low demand for hydrogen considered for this case study. However, costs can be reduced through government subsidies, carbon taxes to incentivize the use of cleaner energy sources, as well as considering the optimization of energy-intensive processes. Furthermore, there is a need to conduct an environmental evaluation of the supply chain to assess the impacts of these products on various environmental indicators. One key indicator is water use throughout the supply chain, as water is required at multiple stages, including biogas production in digesters, upgrading biogas to biomethane, and hydrogen production. The comparison between producing hydrogen from biomethane

through SMR, and producing green hydrogen through electrolysers, which relies on fresh water, is a critical consideration, particularly in water-stressed regions. The use of life cycle assessment to evaluate this (and other) environmental indicators will further allow the evaluation of the supply chain from a multi-objective perspective and enrich the discussion of the integration of these technologies, while ensuring compliance with energy policies and sustainability goals.

## ABSTRACT

The climate crisis continues to grow as an existential threat. Establishing reliable energy resources that are renewable and zero-carbon emitting is a critical endeavour. Hydrogen has emerged as one such critical resource due to its high gravimetric energy density and near-abundant availability. However, it suffers from low volumetric energy density and is incredibly challenging to store and transport. The metal hydride, a solid-state storage method, provides a viable solution to the current limitations. Storage is achieved through the chemical absorption of hydrogen into a porous metal alloy's sublattice. But its challenging thermodynamic functionality leaves a gap between the ideal storage capacity that current industry requires and the limited capacity that reusable metal hydrides currently provide. This work used mathematical modelling to determine optimal operating conditions for a metal hydride in order to maximise hydrogen storage capacity. Computational fluid dynamics is used to simulate the coupled heat and mass transfer that occurs during the absorption process into the metal alloy. The finite volume method is used to discretise governing equations, and the alternating direction implicit method is used for numerical solutions as it proved the most stable platform to conduct analyses. An initial investigation into numerical grid sizing is conducted to determine the optimal node allocation. The impact of the hydride bed thickness and supply pressure are varied and optimised. The alloy $MmNi_{4.6}Al_{0.4}$ is used in the investigation.

**Keywords**: Metal Hydride, Optimisation, Computational Fluid Dynamics

## INTRODUCTION

The climate crisis is an anthropological concern that has had an ever-increasing level of importance in the 21st century. The 2015 Paris Agreement, signed by 196 nations, sought to ideally limit the global temperature increase at 1.5 °C [1]. However, in 2022, the Intergovernmental Panel on Climate Change (IPCC) stated that efforts implemented between its 2022 sitting and the 2015 agreement significantly undershot the targets to reach a 1.5 °C limit [2]. The South African government announced strategies to introduce more renewable power production into its energy sector. However, South Africa is not yet meeting its nationally determined contribution to reach the goal of limiting global warming by 1.5 °C [3].

South Africa has sufficient renewable resources to power a transition to zero-emissions power production, but clean energy integration remains a critical issue. 70% of local project developers working in the renewable energy sector found that the limited physical and institutional capacity to integrate the growing number of renewables into the resource mix are a significant hinderance to the country's transition away from fossil fuels [4].

With its natural abundance and high gravimetric energy density, hydrogen has been positioned as a critical player for 21st century decarbonisation ambitions [5]. Despite its growing attention, there remain some key practical hurdles for the mass adoption of hydrogen. This is due to its low volumetric energy density and difficulty when it comes to storage. An area of growing attention is solid-state storage and that is because it provides a solution to the volumetric energy density shortfall that hydrogen suffers from [6]. The metal hydride is among these solid-state storage solutions.

### Background and motivation

Metal hydrides are a very attractive storage pathway for the emerging hydrogen market for several

reasons. The primary is their potential for high storage density. In addition to that, metal hydrides are often recyclable and their formation occurs at safe operational pressures. Once formed, they are also easy to store and can easily by transported [7].

Figure 1 below provides a representation of how the hydrogen molecule approaches the alloy surface and is eventually absorbed into the bulk lattice. The general reaction formula for the formation of a metal hydride where M is the metal, MH is the hydride, x is the hydrogen concentration and Q is the heat released is as follows [8]:

$$M(s) + \frac{x}{2}H_2(g) \leftrightarrow MH_x(g) + Q \quad (1)$$

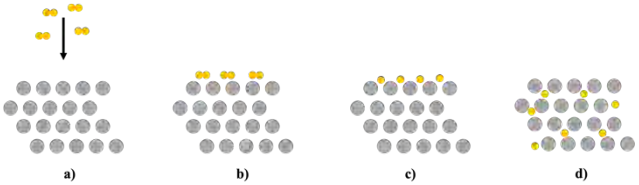

**Figure 1.** Step-by-step visualisation of hydrogen absoprtion process

Extensive work has gone into mathematically modelling the metal hydride. Understanding the interplay between heat generation and storage capacity is key to ensuring this technology can be adopted into industrial use [9]. Equation 1 shows that heat is a critical component to the hydrogen absorption and desorption cycle, the former being an exothermic reaction and the latter endothermic. A good control of the thermodynamic functions of the metal hydride is critical for reaching any attainable goal of maximising its storage potential.

Therefore, this research aims to develop a two-dimensional model that will accurately simulate a metal hydride system with which an optimisation can be performed.

The prescribed objectives are to:

i. Develop a mathematical model for the heat and mass transfer within the metal hydride reactor using given parameters.
ii. Compare the results of the developed model with existing literature and validate model results.
iii. Investigate the effect of varying particular variables.
iv. Conduct an optimisation on the identified variables.

## Literature Review

Metal hydrides can be distinguished into two classifications, interstitial and non-interstitial. The divergence between interstitial and non-interstitial is not drastic but significant enough in that it results in the two classifications having different storage potentials and operating conditions [6]. During the absorption and desorption cycle, very little change occurs to the metal's surface when dealing with an interstitial hydride. The non-interstitial is dependent on the decomposition and recombination of the hydride as a whole. While interstitial hydrides typically have a lower storage density than non-interstitial, they are generally recyclable unlike non-interstitials. It is for this reason that interstitials are perused more commonly in research [6].

Figure 2 shows the general trend across metal hydrides. There is a directly correlative relationship between storage capacity and heat of formation. The lower the storage capacity of a hydride results in a lower the heat of formation and similarly the converse bears true.

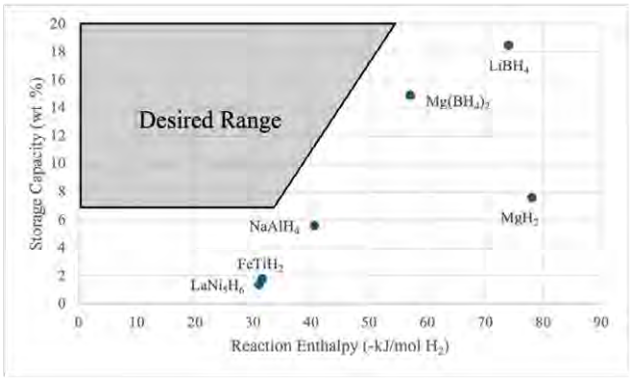

**Figure 2.** Comparison of different metal hydrides' potential storage density and reaction enthalpies [8]

There is a broad range of metal alloys used to make metal hydrides. Among the many metals and alloys used, a classification of three distinct groups can be formed. These three are intermetallics (Eg. $LaNi_5H_6$), magnesium-based hydrides (Eg. $MgH_2$) and complex hydrides (Eg. $LiBH_4$, $NaAlH_4$) [7]. The former group is typically interstitial while the latter two groups are often non-interstitial. Some metrics considered when reviewing the classifications are storage capacity, temperature and recyclability. Some conservative estimations suggest that hydrides need only reach a storage capacity of 2 wt.% for stationary applications [10]. Other investigations peg this minimum to be higher with at least 5 wt.% [8]. The US Department of Energy outlines an ultimate gravimetric density target for any hydrogen fuelled light-duty vehicles to be 6.5 wt. % [11].

Unlike complex hydrides and magnesium hydrides, intermetallics have much more suitable operating conditions. In fact, most academic literature models some kind of intermetallic hydride [9]. This is due to their manageable working temperature and pressure ranges, fast kinetics and reusability. However, their benefits are counteracted by their low storage capacity; often, they do not manage to exceed 2 wt.%. Ultimately, their workability supersedes their storage deficiency. The most common alloy that is investigated is the lanthanum penta-nickel

($LaNi_5$) [12]. $LaNi_5$ is often cited for having a high production cost due to the lanthanum. To circumvent this, some investigations use a cheaper rare-earth mischmetal mixture as a replacement for pure lanthanum [19, 20]. This work conducted its investigation with the alloy $MmNi_{4.6}Al_{0.4}$. It is understood that its ideal storage capacity limit resides somewhere between 1 - 1.4 wt.% [13, 14].

## MATHEMATICAL MODEL

The absorption/desorption cycle of a metal hydride is a process that involves both heat and mass transfer. It is a two-phase system with the gas phase covering the hydrogen and solid phase covering the hydride bed within the storage vessel. This results in the reactor vessel being a discontinuous medium. However, conservation equations that model heat and mass transfer in a porous medium are intended for a continuous medium. To allow the applicability of these equations, the scale of examination is shifted from microscopic to macroscopic. To do this phase averaging is implemented. This allows the average volume, over which heat and mass transfer takes place, to be larger than the individual bed pores [15].

A standard cylindrical vessel with external cooling is considered – see Figure 3. The heat and mass transfer are modeled in two dimensions, the radial and axial flow. Figure 3 shows two reactor geometries. Figure 3A has hydrogen fed through an axial inlet and its hydride bed occupies the full breadth of the vessel. It is modelled asymmetrically for ease. Figure 3B is an expansion on the axisymmetric condition. The geometry potentially offers a much more even distribution of the hydrogen gas and with it an even generation of heat across the hydride bed [14, 16]. This work makes use of Figure 3B geometry.

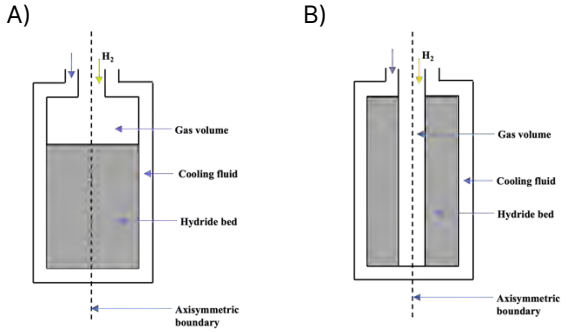

**Figure 3.** A simple diagram of the two most common reactor geometries

An initial starting point for the thermal governing equation, are the following:

$$\varepsilon\rho_g C_{pg}\frac{\partial T_g}{\partial t} = \frac{1}{r}\frac{\partial}{\partial r}\left(\varepsilon\lambda_{ge} r\frac{\partial T_g}{\partial r}\right) + \frac{\partial}{\partial z}\left(\varepsilon\lambda_{ge}\frac{\partial T_g}{\partial z}\right) - \rho_g C_{pg} v_{gr}\frac{\partial T_g}{\partial r} - \rho_g C_{pg} v_{gz}\frac{\partial T_g}{\partial z} + H_{gs}(T_g - T_s)S - mC_{pg}(T_g - T_s) \quad (2)$$

$$(1-\varepsilon)\rho_s C_{ps}\frac{\partial T_s}{\partial t} = \frac{1}{r}\frac{\partial}{\partial r}\left((1-\varepsilon)\lambda_{se} r\frac{\partial T_s}{\partial r}\right) + \frac{\partial}{\partial z}\left((1-\varepsilon)\lambda_{se}\frac{\partial T_s}{\partial z}\right) + H_{gs}(T_g - T_s)S + m(\Delta H^o + C_{pg}T_g - C_{ps}T_s) \quad (3)$$

Equations 2 and 3 are the thermal balance of the gas and solid phase, respectively [15, 17].

The mathematical formation of the governing equations is established with the following assumptions taken into consideration:

i. The gas phase within the vessel and hydride bed exhibits ideal gas behaviour
ii. The local thermal equilibrium hypothesis is taken to be true
iii. Radiative heat transfer is negligible
iv. Viscous dissipation and compression work are considered negligible
v. Hydride porosity, permeability and heat conductivity remain unchanged during absorption cycle

Of the assumptions, one that provides an immediate simplification to the heat transfer model is the local thermal equilibrium assumption. This allows for the temperature within the gas and solid phase along any radial and axial length at any given time to be the same. This, therefore, eliminates the need for two thermal balances and reduces it down to a single thermal equation:

$$(\rho C_p)_e\frac{\partial T}{\partial t} = \frac{1}{r}\frac{\partial}{\partial r}\left(\lambda_e r\frac{\partial T}{\partial r}\right) + \frac{\partial}{\partial z}\left(\lambda_e\frac{\partial T}{\partial z}\right) - \rho_g C_{pg} v_{gr}\frac{\partial T}{\partial r} - \rho_g C_{pg} v_{gz}\frac{\partial T}{\partial z} + m(\Delta H + T(C_{pg} - C_{ps}) \quad (4)$$

$$(\rho C_p)_e = \varepsilon\rho_g C_{p_g} + (1-\varepsilon)\rho_s C_{p_s} \quad (5)$$

$$\lambda_e = \varepsilon\lambda_{ge} + (1-\varepsilon)\lambda_{se} \quad (6)$$

Another assumption that is commonly used is that of ignoring pressure effects within the vessel and, by extension, ignoring the effect of convective heat transfer. To determine if this assumption is applicable to this investigation, a dimensionless ratio seen in Equation 7 helps identify if the effect of gaseous flow can be neglected or not [18]. If N is found to be much less than 1, then ignoring pressure effects will have a negligible effect on the results of the simulation.

$$N = \frac{\lambda_e \cdot M \cdot L_{gas}^2 \cdot \mu}{\frac{\partial P_{eq}}{\partial T}\cdot\Delta H\cdot\rho_g\cdot K\cdot L_{heat}^2} \quad (7)$$

The continuity equation and reaction kinetics for this system are given by Equations 8 - 12. Equations 8 and 11 are similar in that the former records mass absorption and the latter hydrogenation. There are instances where the thermal equation's heat generation term makes use of the hydrogenation model – see Equation 14. Equation 12 shows a modified van't Hoff equation which accounts for varying hydrogen concentration and hysteresis [9, 14]. The benefit of the model employed in this work is its generality for porous multiphase systems [15]. Its specificity comes in the form of the thermo-physical properties

shown in Table 1.

$$m_{abs} = C_a \exp\left(-\frac{Ea}{RT}\right) \ln\left(\frac{P}{P_{eq}}\right)(\rho_{ss} - \rho_s) \quad (8)$$

$$(1-\varepsilon)\frac{\partial \rho_s}{\partial t} = m_{abs} \quad (9)$$

$$\frac{dx}{dt} = \sigma \frac{(p-p_{eq})}{p_{eq}} \frac{(x-x_f)}{(x_o-x_f)} \exp\left(\frac{-E_a}{RT}\right) \quad (10)$$

$$\varepsilon \frac{\partial \rho_g}{\partial t} + \nabla \cdot \left(\rho_g \underset{v}{\rightarrow}\right) = (\rho_{ss} - \rho_s)(1-\varepsilon)\frac{dx}{dt} \quad (11)$$

$$lnP_{eq} = \frac{\Delta H}{R_g T} - \frac{\Delta S}{R_g} + (\emptyset \pm \varphi) tan\left[\pi\left(\frac{\left(\frac{H}{M}\right)}{\left(\frac{H}{M}\right)} - \frac{1}{2}\right)\right] \pm \frac{\beta}{2} \quad (12)$$

The following are the boundary conditions used:
Reactor axis

$$\frac{\partial T}{\partial r}(z, 0, t) = 0 \quad (13a)$$

Reactor base

$$-\lambda_e \frac{\partial T}{\partial z}(H, r, t) = h\big(T(H, r, t) - T_f\big) \quad (13b)$$

Reactor lateral area

$$-\lambda_e \frac{\partial T}{\partial r}(z, R, t) = h\big(T(z, R, t) - T_f\big) \quad (13c)$$

**Table 1:** Alloy and hydrogen thermo-physical properties [15, 18]

## NUMERICAL METHOD

A critical component of computational fluid dynamic work is the discretisation technique used to solve the governing equations. Initially, this work sought an exploration of the possibilities between the finite difference method (FDM) and finite volume method (FVM) [19, 20]. In literature, there are diverging paths with many opting for FVM and few opting for FDM [8]. This work settled on using node-centred FVM. MATLAB was the chosen software to conduct the work.

The conductive terms after the FVM treatment can be seen in Equation 14. Note the hydrogenation modified heat generation term.

$$(\rho C_p)_e \frac{\partial T}{\partial t} = \frac{1}{r_P}\left(r_E \lambda_e \frac{T_E - T_P}{r_E - r_p} - r_W \lambda_e \frac{T_P - T_W}{r_P - r_E}\right) + \left(\lambda_e \frac{T_N - T_P}{Z_N - Z_p} - \lambda_e \frac{T_P - T_S}{Z_P - Z_S}\right) + \frac{\Delta\rho \cdot (1-\varepsilon)\Delta H}{M_{H_2}} \frac{dx}{dt} \quad (14)$$

In addition to the discretisation method, there is a need to select a solution technique for solving these governing equations. On this matter, there is typically one of two ways that can be selected – explicit solutions or implicit solutions. This investigation sought to determine the most beneficial option between using explicit and implicit solution methods [19-21]. The solution which provided the best numerical stability was the implicit solution, specifically the alternating-direction implicit (ADI) method. The application of this is shown in Equation 15 and 16. A tridiagonal matrix algorithm is then utilised. The Dirichlet boundary condition is directly applied, and the Robin boundary conditions are treated with a difference approximation [19, 22].

Radial step:

$$(\rho C_p)_e \frac{T_{i,j}^{n+1/2} - T_{i,j}^{n}}{\Delta t/2} = \frac{1}{r_P}\left(r_E \lambda_e \frac{T_E^{n+1/2} - T_P^{n+1/2}}{r_E - r_p} - r_W \lambda_e \frac{T_P^{n+1/2} - T_E^{n+1/2}}{r_P - r_E}\right) + \left(\lambda_e \frac{T_N^{n} - T_P^{n}}{Z_N - Z_p} - \lambda_e \frac{T_P^{n} - T_S^{n}}{Z_P - Z_S}\right) + Q \quad (15)$$

Axial step:

$$(\rho C_p)_e \frac{T_{i,j}^{n+1} - T_{i,j}^{n+1/2}}{\Delta t/2} = \left(\lambda_e \frac{T_N^{n+1} - T_P^{n+1} + 1}{Z_N - Z_p} - \lambda_e \frac{T_P^{n+1} - T_S^{n+1}}{Z_P - Z_S}\right) + \frac{1}{r_P}\left(r_E \lambda_e \frac{T_E^{n+1/2} - T_P^{n+1/2}}{r_E - r_p} - r_W \lambda_e \frac{T_P^{n+1/2} - T_E^{n+1/2}}{r_P - r_E}\right) + Q \quad (16)$$

## RESULTS

Using the criterion of Equation 7, it was determined that it is suitable for this work to neglect the effect of gaseous flow and neglect convective heat transfer.

An appreciable baseline figure to remember for comparison is an estimation on how much hydrogen would be stored in a high-pressure (350 bar) gas vessel without a packed hydride bed. At a volume of 8.41x10$^{-5}$ m$^3$, radius of 7.5x10$^{-3}$ m and length of 4.75x10$^{-1}$ m, and with the aid of the ideal gas equation, an estimated 2.39x10$^{-3}$ kg can be stored in such a vessel. A vessel of steel composition would result in a storage capacity

somewhere in the region of 0.6 wt.%. A lighter composite of aluminium and carbon fibre, as is increasingly used [23], would raise this to a potential capacity of 0.8 wt.%

### Grid sizing

Before testing the effect of operating conditions, an important consideration is the effect of the numerical grid size used for the simulation. A base 20x200 grid is initially selected. An investigation into varying the gride size across a predetermined range of values was conducted. The adjustment of the radial resolution has a more prominent impact than the axial resolution variation. Figure 3 below shows how increasing nodal points in both the axial and radial direction increases storage capacity. This is understandable as coarser numerical grids often lead to higher inaccuracies.

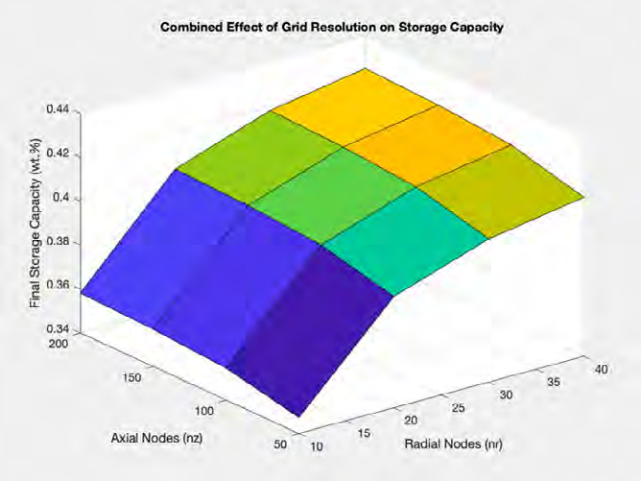

**Figure 3.** 3D plot of the effect of axial and radial nodes numbering on storage capacity

A preliminary optimisation run saw that the Δstorage convergence threshold of 0.5% change was reached at a 270x1295 grid size and yielded 0.448 wt.% capacity.

### Supply pressure and bed thickness

Supply pressure plays a critical role in the attempt to maximise storage. Equation 10 shows how the difference between the P and $P_{eq}$ is a driving force for absorption. Like the grid sizing, pressure was varied across a predetermined range. Table 2 shows that larger supply pressures allow for more hydrogen to be absorbed. The optimisation simulation found convergence at 43.2 bar with a storage of 0.411 wt.%.

In addition to supply pressure, this investigation tested the reactor bed thickness. Something helpful to consider is the surface area/volume ratio. An increased radius increases the required surface area across which the hydrogen must diffuse. Increasing the diffusion area increases the diffusion resistance and ultimately limits the amount absorbed – see Table 3. An optimisation was also run for bed thickness, but the convergence criterion was not met. However, the plotting did indicate that a maximum storage of just over 0.4 wt.% was reached between 0.005m and 0.01m.

**Table 2:** Varied supply pressure and the impact on storage capacity

| Pressure (bar) | Wt.% |
|---|---|
| 5 | 0.016 |
| 10 | 0.096 |
| 15 | 0.186 |
| 20 | 0.270 |
| 25 | 0.337 |
| 30 | 0.390 |

**Table 3:** Varied bed thickness and the impact on storage capacity

| Radius (m) | Wt.% |
|---|---|
| $5x10^{-3}$ | 0.390 |
| $75x10^{-3}$ | 0.169 |
| $10x10^{-2}$ | 0.092 |
| $15x10^{-2}$ | 0.037 |

## CONCLUSIONS

The metal hydride is a promising hydrogen storage pathway. The developed heat and mass transfer modelled for this investigation, simulated on the $MmNi_{4.6}Al_{0.4}$ alloy, yielded stable and comparable results to that seen in literature. The peak storage capacity values achieved in this work, while just under half of what is understood to be the ideal threshold, were appreciable enough for this investigation. It is also lower than the comparably sized high-pressure gas storage vessel.

The intention to store hydrogen at safe and operable pressures which will aid its transportation and storage characteristics remains a significant hurdle to overcome. The metal hydride, at least the intermetallic kind, is still not yet a fully viable route but its promise remains alive. This work produced valuable insight into the effect that numerical grid sizing, supply pressure and bed thickness have on gas absorption for hydride operating.

## ABSTRACT

Climate change, primarily caused by the excessive emission of greenhouse gases, particularly carbon dioxide ($CO_2$), has intensified global efforts toward achieving carbon neutrality. In this context, renewable energy and $CO_2$ utilization technologies have emerged as key strategies for reducing reliance on fossil fuels and mitigating environmental impacts. In this work, a superstructure model is developed to integrate renewable energy network and chemical production processes. The energy network integrates wind, solar, and biomass energy, complemented by storage systems to enhance reliability and reduce reliance on external power sources. The reaction network features various pathways that utilize $CO_2$ as a raw material to produce high value-added chemicals such as polyglycolic acid (PGA), ethylene-vinyl acetate (EVA), and dimethyl carbonate (DMC), allowing for efficient conversion and resource utilization. A mixed-integer linear programming (MILP) model is formulated to minimize production costs while optimizing energy and reaction pathways. This research supports the green transition of the chemical industry by optimizing the integration of renewable energy and $CO_2$-based chemical processes, promoting more sustainable production practices.

**Keywords**: sustainable chemical production, HRES, $CO_2$ utilization, superstructure optimization, MILP

## INTRODUCTION

Global climate change, driven by the excessive emission of greenhouse gases, particularly carbon dioxide ($CO_2$), represents a critical challenge of the 21st century. According to the World Meteorological Organization's (WMO) Greenhouse Gas Bulletin, the global average surface carbon dioxide concentration had reached 420 ppm in 2023, marking an 11.4% increase over the past 20 years [1]. The rapid growth in energy demand, coupled with the finite nature of fossil fuel reserves and their high carbon footprint, underscores the urgent need for a transition to renewable energy sources and implement sustainable development strategies [2]. In the context of China's dual carbon goals, aiming to peaking carbon emissions by 2030 and achieving carbon neutrality by 2060, the emphasis on green chemistry and sustainable production has gained unprecedented importance. These efforts aim to balance economic development with environmental protection, ensuring a sustainable future.

Hybrid renewable energy systems (HRES) have demonstrated significant potential as a solution to enhance the stability and efficiency of renewable energy supply by integrating multiple sources such as solar, wind, and biomass energy. These systems effectively mitigate the intermittency challenges associated with individual renewable sources, contributing to a more reliable and resilient energy network [3]. Meanwhile, the utilization of $CO_2$ as a raw material for high-value chemicals presents a strategic approach to both reduce carbon emissions and foster the circular carbon economy [4]. This approach not only decreases reliance on fossil fuels but also enhances the economic viability of sustainable chemical production by converting $CO_2$ into valuable products like polymers and organic compounds.

However, existing studies often focus either on optimizing renewable energy integration or on specific $CO_2$ conversion technologies, rarely addressing an integrated

approach that combines renewable energy utilization with $CO_2$ conversion in a unified production network. To address this gap, this study develops a novel superstructure model that integrates a hybrid renewable energy system with a chemical production network to optimize the conversion of $CO_2$ into high-value chemicals. In detail, we focus on designing processes driven by renewable energy and optimizing the pathways for $CO_2$ conversion into high-value chemicals including polyglycolic acid (PGA), ethylene-vinyl acetate (EVA), and dimethyl carbonate (DMC). By bridging the gap between renewable energy integration and green chemical production, this research offers valuable insights into achieving carbon neutrality and promoting sustainable production practices.

## MODELING

### Modeling of Hybrid Renewable Energy System (HRES)

The designed HRES in this study consists of two main components: power generation and thermal generation. The superstructure of the HRES is shown in Figure 1. In the power generation section, the system integrates wind power (P1), photovoltaic power (P2), concentrated solar power (P3a,3b), combined cycle gas turbine (P4) technology, and is complemented by battery storage. The thermal generation section includes biomass energy technologies, coal-fired heating (P8) systems, and electric boiler (P9) systems. Biomass undergoes gasification to produce syngas (P5), serving as a dual source for electricity (P6) and heat (P7).

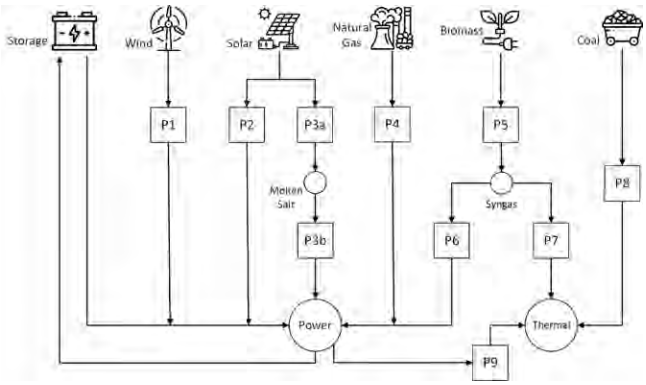

**Figure 1.** Superstructure of the hybrid renewable energy system (HRES).

Wind power and photovoltaic power are among the most widely adopted renewable energy technologies. Wind turbines harness wind energy to produce electricity, while photovoltaic panels directly convert sunlight into electrical power. Despite being environmentally friendly, both of these technologies have significant fluctuations in power generation, often requiring integration with more stable technologies or combined with battery storage. Battery storage facilitates load balancing by storing surplus electricity during off-peak periods and releasing it during peak demand, effectively balancing the energy load and enhancing system reliability. Concentrated solar power (CSP) employs reflective mirrors to concentrate sunlight, generating thermal energy that can be stored via molten salt energy storage (MSES). This thermal storage capability ensures a continuous power supply even during periods without sunlight, improving the dependability of solar energy. The combined cycle gas turbine (CCGT) technology generates electricity by combining gas and steam turbines, using natural gas as the primary fuel. In the context of the HRES, CCGT serves as a reliable supplementary energy source, compensating for any shortfall in renewable energy generation when renewable sources cannot meet demand. Biomass energy offers a dual-purpose solution by generating both electricity and heat through biomass gasification, contributing to a flexible and renewable energy mix. Coal-fired heating generates thermal energy through coal combustion, acting as a transitional technology within the HRES until low-carbon alternatives become more viable. The electric boiler efficiently utilizes surplus electricity during low-demand periods or peak renewable output, enhancing system efficiency and minimizing energy waste.

Each technology in the HRES will be mathematically modeled to evaluate its performance and cost, including both power generation and thermal generation. Technology performance will be assessed considering raw material consumption, installed capacity, and operational efficiency. Energy production costs will be analyzed by integrating raw material, investment, and operational expenses into the cost model. Additionally, the model incorporates dynamic constraints on $CO_2$ emissions, aiming to gradually phase out high-emission technologies and align with global carbon neutrality targets.

### Modeling of Chemical Production Network (CPN)

In the chemical production network (CPN), this study mainly focuses on three products: polyglycolic acid (PGA), ethylene-vinyl acetate copolymer (EVA), and dimethyl carbonate (DMC). PGA is a synthetic polymer with exceptional biodegradability and biocompatibility, widely applied in the pharmaceutical industry and biodegradable plastics [5]. EVA is a versatile polymer known for its flexibility and toughness even at low temperatures, strong adhesion, and stress-cracking resistance, commonly used in applications like footwear materials and packaging molds [6]. DMC is a low-toxicity, environmentally friendly organic compound with applications in polymer synthesis, solvents, and electrolytes [7]. The main raw materials for the production network include $CO_2$, $H_2$, and

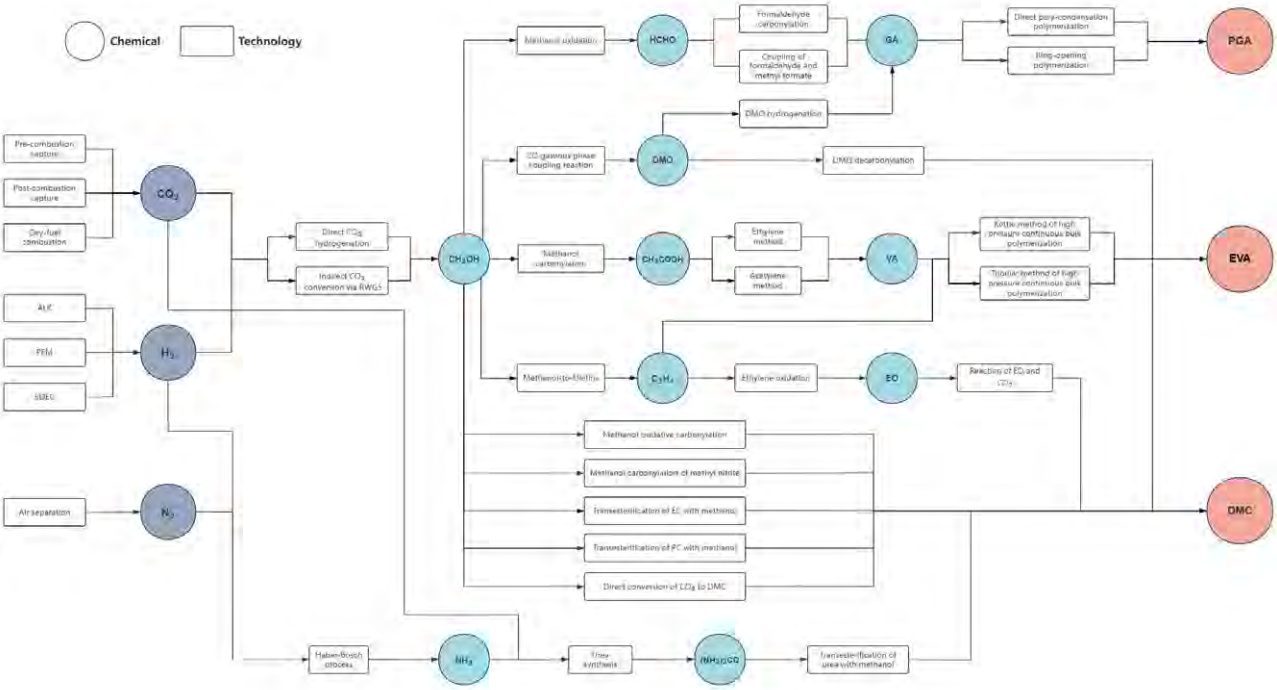

**Figure 2:** Superstructure of the chemical production network (CPN). The figure presents various technological pathways for producing the three main products: PGA, EVA, and DMC. The connections between different chemicals represent the possible pathways from one intermediate chemical to the next.

$N_2$. $CO_2$ can be captured using various methods, while hydrogen is produced through water electrolysis, and nitrogen is typically obtained via air separation technology.

To optimize the conversion of raw materials into final products, a superstructure model encompassing multiple technological options has been developed, as shown in Figure 2. In this model, various technological alternatives may act as substitutes or complements. The selection of a specific technology for each intermediate chemical is mutually exclusive, ensuring only one option is selected for each production step. However, the model allows for multiple technological pathways to produce final products, enhancing the system's design flexibility and operational robustness.

Each technology within the production network is mathematically modeled to represent the chemical conversion and mass balance for both inputs and outputs. Numerous constraints are incorporated to ensure the feasibility and rationality of the model's results, including limitations on feedstock availability, process efficiency, product demand, and network structural constraints. The cost assessments consider investment costs, as well as operational expenses, such as catalyst costs, utility costs, and raw material costs. To estimate these costs, a simplified process simulation approach using Aspen Plus V14 is adopted. This approach focuses on the key stages of chemical production, providing approximations for investment costs and energy demands while avoiding overly complex process details. Investment cost estimation utilizes Aspen Process Economic Analyzer (APEA) V14, while energy consumption, including electricity and thermal demands, is directly assessed through the simulation model. By-products generated during production are treated as additional revenue, which is subtracted from the overall costs. Chemical prices are referenced from market data for cost calculations.

## Integration of HRES and CPN

The integration of HRES and CPN is achieved through the coupling of energy supply and the operational demands of CPN. Electricity generated by the HRES powers key chemical processing equipment, such as pumps, compressors, and mixers, ensuring stable operation and precise process control. Meanwhile, thermal energy is widely employed in heating systems and heat exchange equipment across the production network, meeting the temperature regulation and reaction requirements critical for chemical synthesis.

The energy balance of the integrated system is governed by the energy conservation equations, as represented by Equations (1) and (2).

$$P_{wind,t} + P_{PV,t} + P_{CSP,t} + P_{CCGT,t} + P_{synburn,t} + P^{Out}_{battery,t} = P_{CPN,t} + P^{In}_{battery,t} + P_{cur,t} \quad (1)$$

$$Th_{synburn,t} + Th_{coalburn,t} = Th_{CPN,t} \quad (2)$$

## Optimization Model and Assumptions

### Model Assumptions

1. The relationships between chemical inputs and outputs, as well as the material and energy flows within processes, are simplified and modeled using linear functions.

2. Electricity and heat supplied by the HRES are assumed to be delivered without losses.

3. Transportation and storage costs for raw materials, intermediates, and final products are neglected.

4. A 20-year operational lifecycle is assumed, consistent with the typical lifespan of chemical production facilities.

5. Data sampling is performed at monthly intervals, resulting in 240 discrete time points over the 20-year period.

6. Historical wind and solar energy data for the Qinghai region, China, are used for the HRES analysis, with monthly averages applied to represent each time step.

7. It is assumed that existing CCGT units are already in place and do not require new construction, so the CCGT cost is limited to the operating cost only.

8. Annual chemical production volumes, energy consumption, and thermal demand are assumed to fluctuate randomly within a 10% range.

9. A linear annual reduction in $CO_2$ emissions from CCGT and coal-based heating is enforced, achieving full decarbonization by the ninth operational year.

### Overall Optimization Model

The objective of the optimization model is to minimize the total cost, which includes costs associated with both the HRES and CPN, as shown in Equations (3)-(5). To ensure the accuracy and feasibility of the results, the model incorporates several constraints, as previously discussed. Equation (6) defines the conversion between input and output flow rates for a chemical process technology, which is modeled as a linear relationship. Equation (7) represents the demand constraint for the final products, ensuring that the production quantity of each product meets the specified demand. Equation (8) ensures that only one technological route can be selected for one intermediate chemical to the next.

$$\min obj = C_{HRES} + C_{CPN} \tag{3}$$

$$C_{HRES} = C_{wind} + C_{PV} + C_{CSP} + C_{CCGT} + C_{battery} + C_{bio} + C_{coal} \tag{4}$$

$$C_{CPN} = C_{cap} + C_{operation} + C_{raw} - R_{byprod} \tag{5}$$

$$Output_{P,T} = \alpha_{P,T} \cdot Input_{P,T} \tag{6}$$

$$Flow_P^{final} \geq Demand_P^{final} \tag{7}$$

$$\sum_T x_T^{PP'} = 1 \tag{8}$$

The model was developed using the General Algebraic Modeling System (GAMS) with the CPLEX solver. The model involves 61,555 single equations and 9,037 single variables, including 272 discrete variables.

## RESULTS AND DISCUSSION

### Optimal Route for CPN

The optimization results of the CPN provided insights into the integration of raw material acquisition, intermediate production, and final product synthesis. The optimized network structure, shown in Figure 3, illustrates the production pathways and the selection of related technologies from raw materials to final products. In the optimized network, $CO_2$ is sourced through post-combustion capture, while $H_2$ is generated via alkaline water electrolysis. Methanol emerged as a critical intermediate, enabling the synthesis of various target chemicals through versatile conversion pathways. It is generated through the indirect conversion of $CO_2$ and $H_2$ via the Reverse Water-Gas Shift (RWGS) reaction.

The PGA production pathway begins with methanol participating in a CO gaseous phase coupling reaction to generate dimethyl oxalate (DMO). Subsequently, DMO undergoes hydrogenation to produce glycolic acid (GA), which is polymerized through a ring-opening process to yield the final PGA product. For EVA production, methanol is first converted into formic acid, which is further processed into vinyl acetate (VA) via an acetylene-based reaction. Parallelly, the methanol-to-olefins process produces ethylene. Finally, VA and ethylene react through the tubular method of high-pressure continuous bulk polymerization to produce EVA. In the DMC production route, methanol engages in a transesterification reaction with ethylene carbonate (EC), directly yielding the target product. Notably, the ammonia production route, although included in the network design, was not selected in the optimization. This decision is primarily driven by the high costs associated with using large quantities of green hydrogen, which makes this route economically unfeasible. Overall, the results underscore the significance of methanol as a pivotal intermediate and highlight the economic considerations inherent in the selection of sustainable technologies for chemical production.

### Power and Thermal Generation by HRES

The energy required for the CPN is supplied by the HRES. Figure 4 shows the results of HRES power generation. The system primarily relies on wind energy, which, as expected, exhibits significant fluctuations. To address this variability, a smaller portion of the total energy comes from solar power, which, although still subject to fluctuations, provides more stable generation compared to wind energy. This dual-source approach enhances the

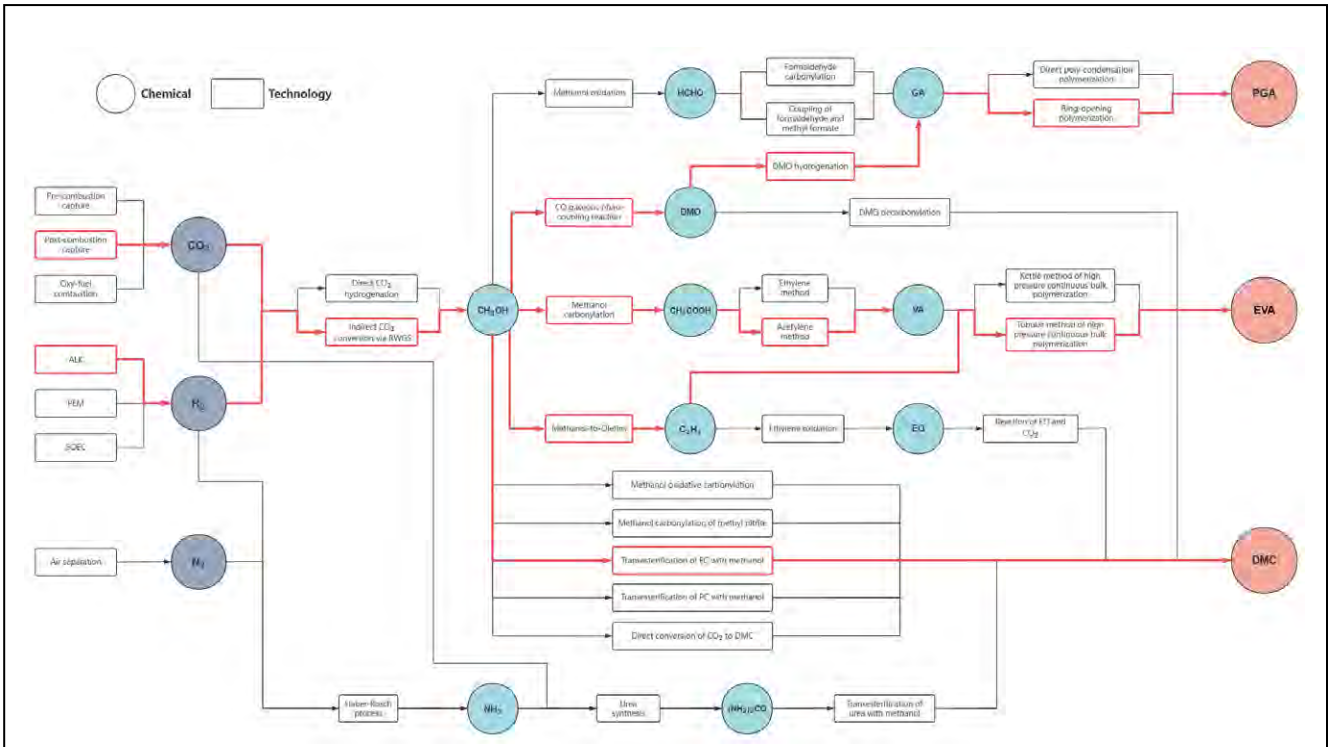

**Figure 3.** Optimized Chemical Production Network Structure.

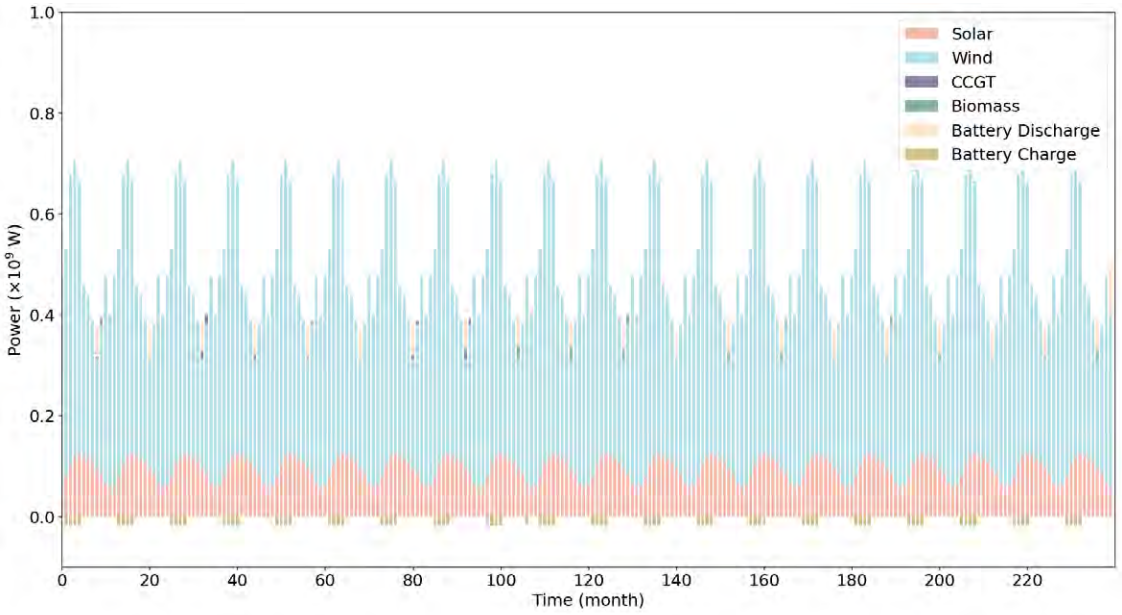

**Figure 4:** Power generation results of HRES. The positive values represent the power generation and discharging portions of the HRES, while the negative values reflect the charging portions.

overall reliability of the power supply. During periods of excess energy, part of the surplus is stored in batteries, while a larger portion is directed to the electric boilers for heat generation, improving the efficiency of electricity utilization. When energy demand exceeds the available renewable generation, the system prioritizes the use of stored energy in batteries to maintain stability. In the initial phase, CCGT technology is used as a supplementary source to bridge the gap. However, as $CO_2$ emission constraints become more stringent, the model gradually reduces reliance on CCGT and transitions towards biomass energy, a more sustainable and low-emission alternative.

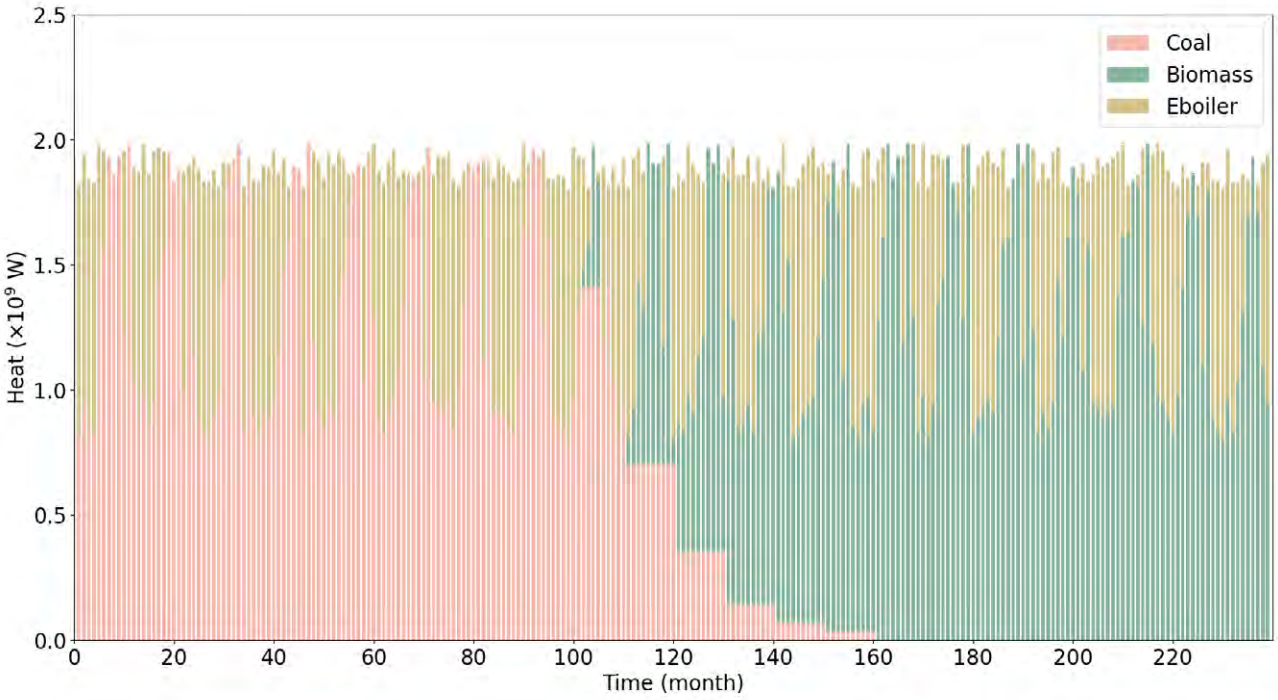

**Figure 5.** Thermal generation results of HRES.

On the other hand, CSP technology was not selected due to its relatively high costs.

The thermal energy generation results, as illustrated in Figure 5, follow a similar trend. In the early stages, the system primarily relies on electric boilers and coal-based heating technology to meet heating demands. Over time, driven by $CO_2$ emission constraints, the model progressively shifts to a combination of electric boilers and biomass energy for heat production. This transition aligns with the goal of reducing carbon emissions and moving towards more sustainable technologies over time.

## Costs of HRES and CPN

The total costs of the HRES and the CPN are crucial in assessing the economic feasibility and efficiency of the integrated system. Table 1 provides an overview of the average power and thermal demands of the CPN, along with the corresponding costs for both the CPN and HRES required to meet these demands. The CPN has production targets of 100,000 tons of PGA, 400,000 tons of EVA, and 400,000 tons of DMC. To meet these production targets, the CPN requires an average power demand of approximately 382.9 MW and a thermal energy demand of 189.6 MW. The total combined cost, represented by the objective function value, amounts to approximately $7.39 billion.

The higher cost of the HRES is largely due to significant initial investments in renewable energy technologies, including wind turbines, solar panels, and energy storage systems. In contrast, the lower cost of the CPN is partly driven by the revenue generated from by-products, which effectively offsets overall production costs. Both the HRES and the CPN are integral components of the overall cost structure, with neither playing a dominant role in the total cost.

**Table 1:** Energy demand of CPN with costs of HRES and CPN.

| Term | Value |
|---|---|
| Average Power demand (W) | $3.829\times10^{8}$ |
| Average Thermal demand (W) | $1.896\times10^{8}$ |
| CPN cost ($) | $3.039\times10^{9}$ |
| HRES cost ($) | $4.349\times10^{9}$ |
| Objective function ($) | $7.388\times10^{9}$ |

## CONCLUSION

In this study, a novel superstructure optimization framework integrating hybrid renewable energy systems (HRES) with chemical production networks (CPN) was developed to address global energy and green chemical production challenges. This approach considers both energy and material flows, enabling a more comprehensive decision-making process for sustainable chemical production. The optimization provides valuable insights into the selection of efficient production technologies for the CPN and the optimal configuration of HRES technologies. The results highlight the ability to create a resilient and

flexible energy supply by combining renewable sources with supplementary technologies such as CCGT and biomass, ensuring a stable and reliable power and heat supply for chemical processes. Additionally, the utilization of $CO_2$ as a feedstock is emphasized as a critical strategy for reducing carbon emissions while contributing to the production of high-value chemicals, further promoting the transition to a sustainable, low-carbon economy.

Despite its contributions, this study has some limitations. The model is based on historical renewable energy data and assumes monthly-averaged values, which may not fully capture real-time fluctuations in energy availability. Additionally, the optimization is conducted within a deterministic framework, meaning that uncertainties in energy supply, raw material prices, and market demand are not explicitly accounted for. Future research will focus on expanding green chemical production pathways, particularly by utilizing $CO_2$ as a feedstock for chemical synthesis. Additionally, incorporating uncertainty factors related to renewable energy availability, raw material supply and product demand will be vital for enhancing the robustness and reliability of the model. By addressing these uncertainties, the aim is to develop more resilient and cost-effective solutions that facilitate the transition toward a carbon-neutral chemical production sector, aligning with global sustainability goals.

## ABSTRACT

Ensuring access to clean water, preserving water reserves, and meeting energy needs are fundamental for sustainability and a priority for global organizations like the UN and EU. The Mediterranean, particularly Greece, faces severe water imbalances due to rising demand, prolonged droughts, and seasonal tourism pressure. This over-exploitation of water resources threatens agriculture, employment, and regional sustainability. Addressing these challenges, this study analyzes the water-energy nexus in high-stress areas and develops an optimization model for sustainable water resource management. The model integrates sectoral demands, energy consumption, and seasonal variability to improve efficiency while balancing economic and environmental constraints. Additionally, it incorporates demand forecasting to align water use with ecosystem sustainability, reducing environmental impacts. By providing a systematic framework for decision-makers, this research supports the development of long-term, resilient water management strategies, ensuring efficient resource allocation in vulnerable regions. The findings will contribute to sustainable water policies and infrastructure planning.

**Keywords**: water resources, water-energy nexus, water sustainability, optimisation, mathematical model

## 1. INTRODUCTION

Water is vital for human survival, socio-economic development, and ecological balance. However, global water scarcity is intensifying due to rising demand and the impacts of climate change. Approximately 844 million people currently lack access to safe drinking water, and nearly 2 billion live in areas of high water stress. By 2050, water demand is expected to rise by 30%, further straining resources and exacerbating challenges in already water-stressed regions [1].

The Mediterranean region, home to over 500 million people, is particularly vulnerable to these challenges. Renewable water resources are estimated at 1,500 km³ annually, but their distribution is highly uneven: 74% is available in the north, 21% in the east, and only 5% in the south. Agriculture, which accounts for over 65% of the region's water withdrawals, is especially at risk from shortages, jeopardizing food security and economic stability [2]. In Greece, seasonal and geographic dynamics compound the issue. The influx of tourists during the summer months significantly increases water stress, particularly in island regions where reserves are already limited. Overexploitation of aquifers has led to the depletion of water reserves, with negative impacts on agriculture, biodiversity, and local economies. Reduced irrigation capacity has contributed to declining agricultural productivity and a shrinking workforce in the sector. These issues are further exacerbated by climate change, which causes prolonged droughts, increased temperatures, and the salinization of freshwater sources, severely diminishing the availability of potable water [2].

Another critical factor is the water-energy nexus, reflecting the interdependence between water and energy systems. Globally, water systems—including supply, treatment, distribution, and wastewater management—consume approximately 7% of total electricity. Drinking water treatment requires energy inputs ranging from 0.4–3 kWh/m³, while seawater desalination, increasingly relied upon in arid regions, demands 3.9–4.3 kWh/m³, making it one of the most energy-intensive processes. This interconnection highlights the need for integrated

strategies that address both water and energy demands efficiently [3].

Sustainable water management is essential for addressing these challenges. Optimization techniques like linear programming, mixed-integer programming, and dynamic simulations enhance resource allocation, reduce losses, and lower energy consumption. Studies show these models can cut leakage rates by up to 30% and achieve 15–20% energy savings in urban water systems [4]. Recognizing the urgency, the EU has prioritized water optimization in its 2030 agenda, promoting smart management technologies like real-time monitoring to reduce inefficiencies and expand clean water access to 70 million citizens [5]. These measures align with sustainability goals and mitigate climate change impacts.

This study explores advanced optimization techniques to balance water resource allocation and energy consumption while adhering to sustainability goals. By integrating innovative tools and approaches, it aims to deliver actionable solutions for sustainable water management, ensuring resilience and alignment with broader climate and development objectives.

## 2. CURRENT SITUATION

### 2.1. Global and economic impact of water scarcity

Despite notable advancements in water management technologies and infrastructure, water scarcity continues to be a pressing global challenge and is recognized as one of the most critical risks for the coming decade. Globally, over 2 billion people are living in regions of high water stress, with projections indicating that this number will increase due to population growth, urbanization, and climate change. Additionally, 1 billion people lack access to clean and safe drinking water, leading to significant health crises, including 3.4 million deaths annually caused by water-related diseases [6].

Agriculture consumes over 80% of global freshwater resources, making it the most vulnerable sector to water shortages, especially in arid and semi-arid regions where irrigation is critical for food production [7]. Urbanization and industrial activities further exacerbate the strain on water availability, highlighting the urgent need for sustainable water resource management. The financial repercussions of droughts, which often exacerbate water scarcity, are substantial. In the United States, annual drought damages are estimated between $2 billion and $6 billion, while in the European Union, these losses amount to approximately $3 billion annually [8]. These costs represent 0.05% to 0.1% of the GDP, though in particularly severe years, the economic burden can rise dramatically, impacting multiple sectors, including agriculture, industry, and domestic water use [9].

### 2.2. Water scarcity in Mediterranean and Greece

The Mediterranean region is home to over 500 million people, with population growth and trends varying across the 24 countries in the area. Between 2008 and 2018, the population increased by **11%**, adding further strain to the region's already limited water resources [1]. The annual water requirement in the Mediterranean, estimated to range between 500 and 1000 $m^3$ per capita, has risen due to the combined pressures of population growth, urbanization, and the expansion of irrigated agriculture [10]. Currently, the region is classified as "water-poor," with less than 1000 $m^3$ of water available per person annually. According to United Nations projections, this water scarcity will intensify, potentially affecting 250 million people by 2040 [1].

Greece possesses a sufficient overall supply of water resources; however, significant challenges remain in ensuring their efficient utilization and management. This is particularly true given the country's distinct geographical features and climatic variability. Greece generates approximately 72 $km^3$ of renewable freshwater annually, while its annual water consumption stands at about 9.5 $km^3$. Water consumption is also heavily influenced by land use patterns, with agriculture being the dominant user. Depending on the district, agricultural water usage ranges from 11% to 92%, with a national average of approximately 74% [11].

## 3. WATER-ENERGY NEXUS

### 3.1. The dynamic interdependence of the water-energy nexus

Water and energy are intricately interconnected, forming a complex relationship that varies at local and regional levels. Communities rely on water for a wide range of purposes, including residential, commercial, industrial, recreational, and agricultural activities. In urban water systems specifically, energy plays a critical role in every stage of the water management cycle, from intake and purification to transmission, distribution, sewage collection, treatment, recycling, and discharge back into natural waterways. This interdependence becomes even more evident as an increase in water demand directly drives a required to manage these resources efficiently [12].

For instance, one study [13] highlighted that groundwater abstraction for drinking water requires significantly higher energy consumption compared to surface water abstraction, demonstrating the energy demands of different water sources. Similarly, research [14] in Germany found that reducing fossil fuel production contributed to alleviating water stress, emphasizing the interconnection between energy policies and water resources. The importance of minimizing energy use in

water and wastewater treatment systems has also been underscored [15], as this can yield substantial environmental and economic benefits. Furthermore, factors such as water use patterns, topography, climate, and operational efficiencies significantly influence energy intensities in water purification processes, highlighting the need for tailored strategies to optimize energy use in specific contexts[16].

### 3.2. Navigating challenges and innovations in the water-energy nexus

The intricate balance between water and energy resources presents significant challenges that are often compounded by trade-offs inherent in their interdependence. For instance, desalination, a vital water source in arid regions, is highly energy-intensive, raising concerns about its environmental and economic sustainability, especially in energy-scarce areas. Similarly, thermoelectric power generation, which relies heavily on water for cooling, is vulnerable to water shortages, particularly in regions experiencing droughts or increased competition for water resources. These examples illustrate how actions to secure one resource can inadvertently strain the other, emphasizing the need for integrated and sustainable approaches to resource management [17].

To address these challenges, technological innovations offer promising solutions. Advances in energy-efficient desalination technologies, such as reverse osmosis membranes with enhanced permeability and durability, are helping to reduce the energy footprint of water production. Similarly, adopting renewable energy sources, such as solar and wind power, for water management processes like pumping, desalination, and wastewater treatment significantly mitigates the reliance on fossil fuels, thereby reducing greenhouse gas emissions. Additionally, smart water systems that incorporate IoT and big data analytics enable real-time monitoring and optimization of water distribution networks, minimizing energy losses and improving overall efficiency [18, 19].

## 4. OPTIMISATION

### 4.1. Optimising water supply systems within the water-energy nexus

Efficient design, management, and planning of water supply systems with a focus on the water-energy nexus can preserve resources and reduce avoidable costs in investments, operations, and management. However, optimization challenges in this nexus have primarily been addressed from either a water or energy perspective, with limited studies focusing on their simultaneous optimization [20, 21].

To bridge these gaps, recent research emphasizes integrative frameworks for dual optimization of water and energy. Multi-objective models have been developed to minimize costs, improve resource efficiency, and mitigate environmental impacts, enabling decision-makers to optimize both systems concurrently and achieve a more sustainable and resilient nexus [22, 23].

One notable strategy is the application of mixed-integer linear programming (MILP) and graphical methods to identify optimal solutions. MILP-based models provide precision and adaptability, accommodating complex interdependencies between water supply systems and energy demands. Similarly, graphical optimization techniques, such as composite curves, visually represent resource flows and help pinpoint the minimum water and energy requirements for a given demand, as demonstrated in case studies like Spain's water-energy nexus [23].

### 4.2. Integrated approaches, challenges and future directions

Integrated approaches are particularly effective in urban areas, where centralized and decentralized systems coexist. Platforms like resilience.io employ agent-based modeling to simulate the spatiotemporal dynamics of resource demand and supply [22]. These simulations facilitate informed planning by considering factors such as demographic changes, urbanization, and renewable energy integration. Moreover, technological innovations play a vital role in optimizing the water-energy nexus. Renewable energy-powered water treatment facilities and decentralized systems have emerged as promising solutions to address resource constraints. For instance, integrating solar-powered desalination systems can significantly reduce energy consumption in water-scarce regions [23]. Despite progress, several challenges remain in advancing nexus optimization. Key issues include the lack of comprehensive datasets, computational limitations in large-scale models, and the need to account for uncertainties such as climate variability and fluctuating resource demands. Future research should prioritize several key areas to advance understanding and practical solutions within the water-energy nexus. First, there is a pressing need to develop adaptive and scalable models that incorporate stochastic variables and scenario-based analyses, allowing for more accurate predictions and better handling of uncertainties. Second, improving data availability and quality is crucial to enhance the accuracy of models and support informed decision-making processes. High-resolution, reliable data can help identify trends, assess resource dependencies, and tailor solutions to specific contexts [24, 25].

## 5. MATHEMATICAL MODEL

### 5.1. Description

Water resource management in Greece faces significant challenges, especially in regions heavily influenced

by tourism. Seasonal peaks during the summer tourist season create high water demand, intensifying the strain on limited water supplies. Furthermore, water extraction and distribution systems are energy-intensive, adding an additional layer of complexity due to environmental and economic considerations. As a result, a strategic approach is required to ensure the efficient and sustainable use of available resources.

To address these challenges, this study presents a linear optimization model designed to optimize water resource allocation while balancing costs, energy consumption, and environmental sustainability. The model integrates sectoral water demands, energy consumption, and seasonal variability to achieve a cost-effective and sustainable solution. Specifically, it is tailored for application in Greece, where water scarcity, tourism-driven seasonal demand, and high energy costs create significant management challenges. Regions such as the Greek islands (e.g., Crete, Cyclades) and mainland agricultural zones (e.g., Thessaly) serve as potential case studies for validating the model's effectiveness in optimizing water allocation and energy use.

The optimization model aims to minimize the total cost of water allocation, taking into account the direct costs of sourcing and distributing water, as well as the energy costs incurred during extraction and distribution. By applying this approach, the model provides a systematic framework for improving water management in high-demand regions, ensuring long-term sustainability while addressing socio-economic and environmental constraints.

The objective function is mathematically expressed as:

$$Z = \sum_{t=1} \sum_{i=1}^{n} \sum_{j=1}^{m} \left( C_{i,j}^{t} * x_{i,j}^{t} + E_i * P_i * x_{i,j}^{t} \right) \quad (1)$$

Where:

- Z: total cost to minimize
- t: index of the time periods (peak, off-season)
- i: index of water sources (i=1,…,n)
- j: index of water demand sectors (j=1,…,m)
- $C_{i,j}^{t}$ : cost per unit of water ($/m³) from source i for sector j in season t
- $x_{i,j}^{t}$: volume of water allocated (m³) from source i to sector j in season t
- $E_i$: energy intensity of water source i (kWh/m³)
- Pi: energy cost for source i ($/kWh)

This function ensures that the water sourcing and energy costs are optimized over all sources, sectors, and seasons. In this model, t represents different time periods, specifically seasonal variations (e.g., peak and off-season demand). Thus, the total cost Z reflects the overall annual expenditure for water allocation and energy use, ensuring cost-effective and sustainable water distribution throughout the year.

## 5.2. Constraints

### 5.2.1. Water availability constraint

The total water extracted from each source i during season t cannot exceed its seasonal availability$W_i^t$, which is influenced by natural recharge rates, legal extraction limits, and infrastructure capacity. In Greece, the touristic season significantly amplifies water demand, especially in island regions and coastal areas. This seasonal surge often coincides with lower rainfall periods, intensifying stress on local water resources. The constraint ensures that extraction levels remain sustainable, balancing the needs of permanent residents and seasonal visitors without compromising long-term water availability. Planning for peak tourist seasons is critical to preventing overexploitation and ensuring sufficient reserves for off-peak periods.

$$\sum_{j=1}^{m} x_{i,j}^{t} \leq W_i^t, \ \forall \ i,t \quad (2)$$

### 5.2.2. Sectoral demand constraint

The total water allocated to each sector j during season t must at least meet its dynamic seasonal demand$D_j^t$. This demand is driven by factors such as peak tourist influx, crop-specific irrigation needs, and domestic water consumption. By ensuring sectoral demands are met, this constraint supports economic activities, such as agriculture and tourism, while safeguarding basic human needs. It also accounts for sector-specific priorities during water shortages; ensuring essential services like healthcare or food production are not compromised.

$$\sum_{i=1}^{n} x_{i,j}^{t} \geq D_j^t \ , \ \forall \ j,t \quad (3)$$

### 5.2.3. Energy sustainability constraint

The total energy required for water extraction and distribution must not exceed the allowable energy threshold $E_{max}$. This includes energy from renewable and non-renewable sources, factoring in energy efficiency and carbon reduction strategies. Energy sustainability is critical to managing the water-energy nexus, reducing operational costs, and achieving climate goals.

$$\sum_{t=1} \sum_{i=1}^{n} \sum_{j=1}^{m} \left( E_i * x_{i,j}^{t} \right) \leq E_{max} \quad (4)$$

### 5.2.4. Environmental sustainability constraint

The environmental impact of water sourcing, expressed as $I_i$, must remain within acceptable ecological limits $I_{max}$. The coefficient $I_i$ represents the environmental impact per cubic meter of water extracted from source i. It can be measured in terms of greenhouse gas emissions

(kg $CO_2/m^3$), water quality degradation (e.g., pollutant levels per $m^3$), or ecosystem disturbance (e.g., groundwater depletion rates). By enforcing this constraint, the model ensures that water sourcing remains within ecologically sustainable limits.. Adherence to this constraint helps minimize the degradation of natural habitats, ensure compliance with environmental regulations, and maintain biodiversity.

$$\sum_{t=1}\sum_{j=1}^{m} x_{i,j}^{t} * I_i \leq I_{max} \ , \ \forall i \quad (5)$$

### 5.2.5. Infrastructure capacity constraint

Each water source has an infrastructure capacity ($F_i$) limiting the maximum water that can be extracted during season t. This constraint considers the physical limits of pumps, pipelines, and storage facilities, as well as maintenance schedules and potential downtime. By enforcing these limits, the constraint prevents overloading of infrastructure and ensures its longevity. It also emphasizes the importance of planned infrastructure upgrades to accommodate future water demands without jeopardizing system reliability.

$$\sum_{j=1}^{m} x_{i,j}^{t} \leq F_i, \ \forall \ i,t \quad (6)$$

### 5.2.6. Non- negativity constraint

The non-negativity constraint ensures that all decision variables in the optimization model take non-negative values. In the context of water resource management, this constraint guarantees that the volume of water allocated from each source to each sector remains physically meaningful and prevents unrealistic negative values in calculations.

$$\sum_{j=1}^{m} x_{i,j}^{t} \leq F_i, \ \forall \ i,t \quad (7)$$

## 6. CONCLUSIONS AND FUTURE STEPS

### 6.1. Conclusions

This study presents an integrated optimization model for sustainable water resource management, addressing water scarcity challenges in regions like Greece and the Mediterranean. Seasonal demand fluctuations, climate change, and rising energy costs for water extraction and distribution intensify these issues. By analyzing the water-energy nexus, this research highlights the interdependencies between water availability, energy use, and economic sustainability, emphasizing the need for multi-objective resource management.

The model enhances water allocation efficiency while balancing economic, energy, and environmental factors. It considers sectoral demand variations, infrastructure constraints, and future consumption trends, ensuring resilient and adaptive distribution. Using multi-objective optimization, it maximizes resource efficiency, reduces losses, and promotes equitable distribution. Integrating renewable energy sources such as solar desalination and wind-assisted distribution can further enhance sustainability and reduce operational costs.

While this study primarily focuses on the model's formulation and theoretical framework, future research will focus on applying the model to real-world case studies. The next steps involve validating its effectiveness using data from Greek regions with high seasonal water demand, such as Aegean Islands. This practical application will allow for a detailed assessment of the model's performance in optimizing water allocation and minimizing environmental impact.

Future research should strengthen the water-energy nexus, embedding energy-efficient technologies like smart grids and wastewater recycling into water systems. Sectoral prioritization must be improved to ensure schools, hospitals, and homes receive priority during scarcity, supported by real-time data analytics. Advances in machine learning and AI-driven forecasting will improve demand predictions, while climate-resilient strategies and early warning systems will enhance preparedness. Expanding hybrid renewable energy solutions will further mitigate reliance on fossil fuels. By integrating these innovations, water-energy optimization can enhance resilience, sustainability, and socio-economic stability in water-stressed regions.

## ACKNOWLEDGEMENTS

This research has been funded under the investment support action "Flagship actions in interdisciplinary scientific areas with a special interest in the connection with the productive tissue" / Emblematic Action of Green Islands in the framework of the circular economy (NHSOS) – TAEDR-0537029. The action is implemented within the framework of the National Recovery and Resilience Plan Greece 2.0 with funding from the European Union - NextGenerationEU.

## ABSTRACT

Hydrogen is increasingly recognized as a key player in future energy systems. However, its production technologies—Steam Methane Reforming (SMR) and electrolysis—present trade-offs. SMR, the dominant method, is cost-effective but has a significant carbon footprint, emitting substantial greenhouse gases (GHGs). In contrast, electrolysis, powered by renewable energy sources, offers a cleaner alternative, albeit at a higher cost. While current hydrogen system optimizations primarily focus on cost reduction and GHG mitigation, they often neglect broader environmental impacts. This paper addresses the challenge of modeling a hydrogen supply chain (HSC) that achieves strong environmental performance at a relatively affordable cost. To this end, a supply chain design optimization is coupled with Life Cycle Assessment (LCA). The novelty of this work lies in the integration of multiple LCA indicators in the supply chain design optimization, rather than focusing solely on costs and Global Warming Potential. The model employs a multi-period (2025–2050) mixed-integer linear programming (MILP) formulation, implemented in the General Algebraic Modeling System (GAMS) environment, using CPLEX as the solver. The Bourgogne-Franche-Comté region is used as a case study to illustrate the framework. Initial optimization results highlight how varying the focus on different parameters can lead to distinct solutions and provide insights into the interactions between indicators. Future research will aim to reduce the dimensionality in multi-objective optimization to improve efficiency while maintaining environmental sustainability in the development of hydrogen networks.

## INTRODUCTION

In the context of energy systems, hydrogen has emerged as a key component of the future energy mix. However, hydrogen production technologies, such as Steam Methane Reforming (SMR) and electrolysis, present significant trade-offs between costs and greenhouse gas (GHG) emissions. SMR currently dominates the market due to its lower production cost, but leads to high GHG emissions. In contrast, electrolysis, when powered by renewable energy, offers a lower-carbon alternative, though at a higher cost. Most existing hydrogen system optimizations focus on reducing costs and minimizing GHG emissions, often overlooking broader environmental considerations.

The central research question addressed by this study is: How can a multi-criteria environmental approach improve the optimal design of hydrogen production systems by including a wider range of environmental factors, and how can the interrelations between these criteria inform more sustainable decision-makers?

To answer this question, this study integrates hydrogen supply chain design with life cycle assessment (LCA). The optimization will be based on Mixed Integer Linear Programming (MILP) and incorporate LCA indicators using the ReCiPe2016 method to calculate environmental indicators. A case study in the French region of Bourgogne-Franche-Comté will illustrate the application of the proposed framework, addressing both industrial and mobility-related hydrogen demand.

## LITERATURE REVIEW

### Hydrogen supply chain

For the production of hydrogen, the most developed technologies include SMR, electrolysis, and gasification, each with significant trade-offs. Today hydrogen is primarily produced via SMR, as the technology is well-established in the market and offers a relatively low production cost (~2 €/kg$H_2$ [1]), despite its substantial greenhouse gas emissions (10-19 kg$CO_2$/kg$H_2$ [1]). Electrolysis is expected to grow and eventually overtake SMR-based technology, as it offers low-carbon alternatives to produce hydrogen, provided that its electricity requirement is met by renewables [2]. Low-temperature electrolyzers, such as alkaline, and proton exchange-membrane (PEM) electrolyzers, are commercially available, while high-temperature solid-oxide electrolyzers remain at the demonstration stage: alkaline and PEM electrolyzers have lower capital costs than solid-oxide electrolyzers; however, electrolysis remains significantly more expensive than fossil fuel-based production (4-9 $/kg$H_2$ [3]). In this study, PEM electrolyzers are considered as the low-carbon option, due to their relatively high efficiency and fast reaction time [4].

Hydrogen can then be transported and/or stored in two forms: liquified hydrogen ($LH_2$) or compressed hydrogen ($CH_2$). A third option, solid interstitial storage, remains at the research and development stage and is not considered in this study. Each of these two options has distinct advantages and disadvantages, depending on transportation infrastructure, distance, and final user requirements. Hydrogen transportation can be carried out via tanks ($CH_2$ or $LH_2$) or gas pipelines, which may be specifically designed for pure $CH_2$ or retrofitted natural gas pipelines, in which methane is enriched with $CH_2$. A promising alternative is the use of ammonia as hydrogen carrier, which is not covered in this study.

All these phases are important when designing and optimizing a supply chain. To understand the environmental impact of each step, LCA is an effective approach for analyzing the entire supply chain. In addition, a Life Cycle Cost approach can complement the analysis.

## Life Cycle Assessment

LCA is crucial when dealing with problems involving extended lifespans and/or the integration of different sectors collaborating towards a shared goal. The literature review highlights that, despite existing studies covering multiple indicators [5-9], current optimization efforts for hydrogen energy systems primarily target cost reduction and greenhouse gas emission minimization, relegating the other parameters to a secondary role. As a result, broader multi-criteria environmental analyses are quite limited [10].

# METHODOLOGICAL FRAMEWORK

The study follows a structured approach to organize the analysis and optimization process. The evaluated supply and distribution chains are summarized in Figure 1. Various energy sources – wind, photovoltaic (PV), hydro, and the national grid – are considered for hydrogen production via electrolysis, in comparison to SMR with and without Carbon Capture and Storage (CCS). Storage options include compression and liquefaction, while transportation is analyzed through pipelines, tanker trucks, and tube trailers. The final users considered in the study are the mobility sector (hydrogen refueling stations, HRS) and industry.

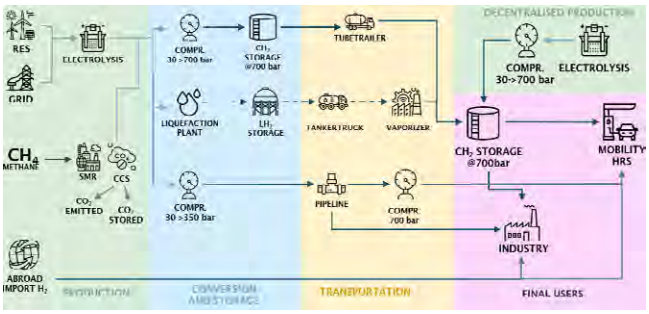

**Figure 1.** Considered actors in the modeling of the supply and distribution chain [11]

A comprehensive LCA was conducted, considering each system component to quantify the environmental impacts associated with each phase.

## Environmental LCA model

Only the main assumptions for the LCA model will be presented. The Functional Unit (FU) , i.e. the service(s) provided, is defined as the amount of hydrogen (1 kg $H_2$) delivered for either mobility or industrial use. The energy requirement for electrolysis, 55 kWh/kg$H_2$ [11,12], was applied to a certain quantity of hydrogen produced to take into account losses during storage and transportation. After considering these losses, the required hydrogen output from the production plant for each kg of hydrogen delivered to the end-user was 1.17 kg. Furthermore, a 4% energy loss was factored into the production process, resulting in a total gross energy demand of approximately 67 kWh/kg$H_2$ for each functional unit of hydrogen delivered. Additionally, the material and resource requirements for the electrolyzer stack and balance of plant (BOP) components, as reported in [13], were incorporated into the LCA study as input data. These values are provided in Table 1 and 2, and refer to a single 1 MW PEM electrolyzer.

To obtain values relevant to the Functional Unit, the total hydrogen production capacity for each production chain (source+electrolysis) over its lifetime was calculated. For each energy plant installation, a lifetime value (in years) and a *Load Factor* (*LF*) [14] were selected based on literature in order to compute the total number of operating hours of the power plant over the chosen

lifetime. Consequently, the total hydrogen production was calculated for each type of plant, as shown in Table 3: this value was then used to allocate the resource quantities per kg of hydrogen produced.

**Table 1.** Material inventory for Balance-of-Plant components for 1 MW PEM Electrolyzer

| Material | Amount [kg] |
|---|---|
| Titanium | 528 |
| Aluminum | 27 |
| Stainless steel | 100 |
| Copper | 4.5 |
| Nafion | 16 |
| Activated Carbon | 9 |
| Iridium | 0.75 |
| Platinum | 0.075 |

**Table 2.** Material inventory for stack of 1 MW PEM Electrolyzer

| Material | Components | Unit | Value |
|---|---|---|---|
| Steel | Container, pump, etc. | kg | 13700 |
| Stainless steel | Air blast chiller | kg | 1100 |
| Copper | Transformer, rectifier, PLC, etc. | kg | 5900 |
| Aluminum | Transformer, rectifier | kg | 1000 |
| Polyethylene | Vessel, pipping, tank | kg | 300 |
| Display panels | 17 inch, Eco Invent 3.3 | - | 1 |
| Concrete | Infrastructure | kg | 5600 |

**Table 3** Resource allocation factors

| Source | Lifetime [years] | LF [%] | Lifetime [hours] | H2 produced during lifetime [t] | Allocation factor/kgH2 |
|---|---|---|---|---|---|
| Wind turbine | 20 | 24% | 42048 | 627.1 | 1.595e-6 |
| Solar PV | 30 | 13% | 34164 | 509.5 | 1.963e-6 |
| Hydro | 100 | 25% | 219000 | 3266.1 | 3.062e-7 |

Using these values, the different hydrogen production pathways were modeled on the LCA software SimaPro (version 9.6.0.1, equipped with EcoInvent 3.10 libraries), along with hydrogen production through SMR with and without CCS, as carbon-rich alternatives.

The same approach was applied to transportation options (pipelines and road truck transport), and conversion technologies including compression to either 350 or 700 bar, and liquefaction.

For Life Cycle Impact Assessment (LCIA), the most commonly used methodology in the relevant literature [15] is ReCiPe midpoint, most often in the hierarchical version. To ensure consistency with the majority of existing studies, ReCiPe 2016 midpoint (H) was selected (version 1.13), for comparison purposes. However, other methodologies, such as Environmental Footprint (EF), will also be used to provide a broader perspective and align with recent impact assessment recommendations.

## LCA results

A total of 15 environmental indicators were considered in the study, but only some of them will be presented for illustration purpose. An initial analysis of the output results from the LCA software SimaPro quantifies the lower climate change impacts associated with renewable energy sources in hydrogen production (Figure 2).

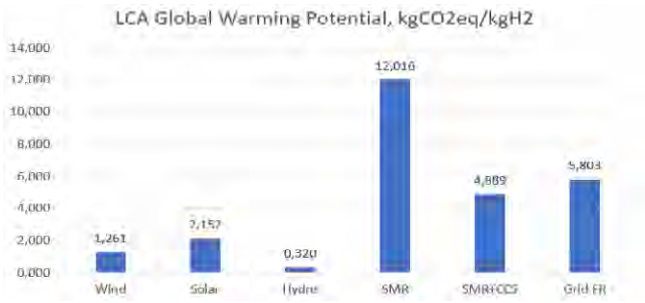

**Figure 2.** $CO_2$-eq emission by producing 1 kg of hydrogen by source (please note that the French electrical grid has low $CO_2$ emissions due to its heavy reliance on nuclear energy, abundant hydroelectric resources, growing integration of renewable energies, and policies promoting low-carbon electricity generation)

A similar pattern was observed for the ozone, water and fossil depletion indicators, with methane-based technologies exhibiting the greatest impacts (Figure 3).

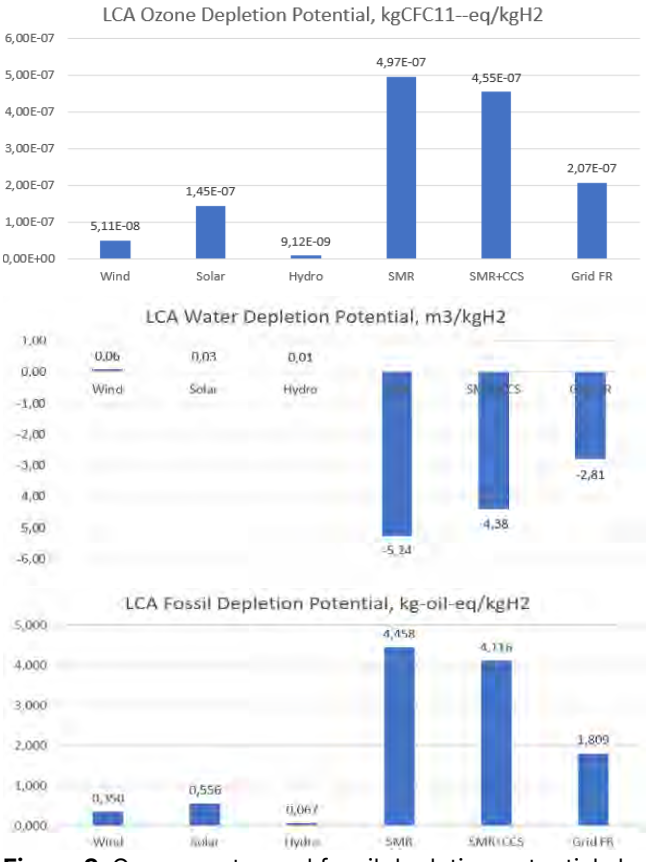

**Figure 3.** Ozone, water and fossil depletion potentials by source, LCA

Indicators such as metal depletion potential, freshwater eutrophication, and particle matter formation potential showed more comparable effects across the different production sources (Figure 4).

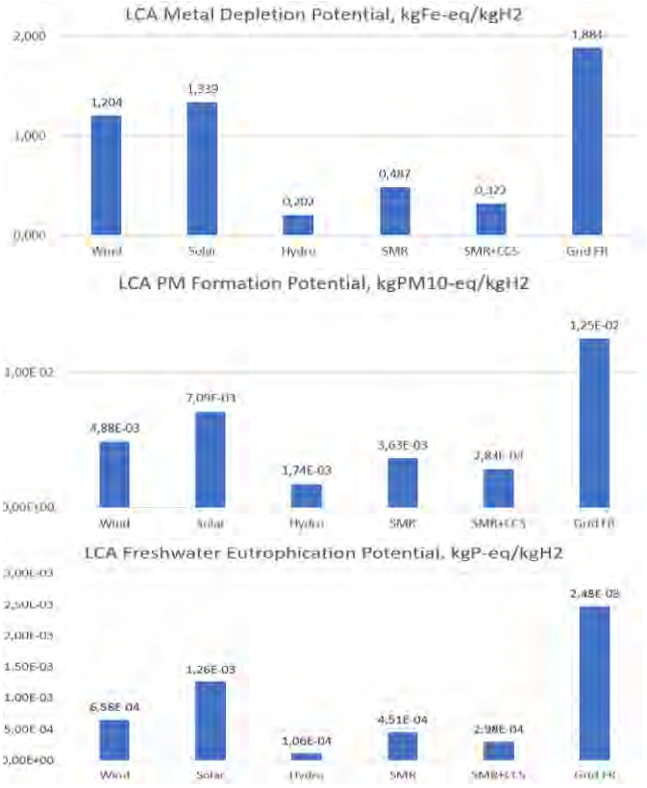

**Figure 4.** LCA values for Metal depletion, PM formation, and Freshwater eutrophication potentials by source

The urban land occupation indicator highlights the significantly larger surface area required for solar-based Hydrogen production (Figure 5).

**Figure 5.** LCA Urban Land Occupation by source, m2/kgH2

For the optimization part these results, specific to each production, transport and conversion method, were integrated in the framework of the supply chain as a whole. It will be the software duty to select the better pathway for the FU, i.e. the kg of hydrogen.

## Supply chain optimization

The model developed in this study extends the work of [11], with the key innovation being the integration of the LCA framework into an existing optimization model for hydrogen deployment in France. The optimization problem is structured as a multi-period, mono-objective model, divided into five-year intervals. The model is implemented in the GAMS® modeling language, using the CPLEX 12 solver. Additional details on the parameters, formulas, and constraints are provided in [11].

## Modeling framework

The first step involved a geographical discretization: the territory of France was divided in its regions, with each region further subdivided into grids corresponding to the 91 French *départements*, to perform single-region studies. In this work, the case of Bourgogne-Franche-Comté is presented as an example (Figure 6). Each grid was equipped with a set of data summarizing, among other factors, the forecasted hydrogen demand from 2025 to 2050, availability of resources, trading route capacity, and renewable energy potential for new installations [11,12].

- Production methods are covered by SMR and green electrolysis. The French electric grid and abroad imports are also considered as energy and hydrogen wells. Three plant sizes are considered: large, small, and on-site, depending on the required quantity.
- Conversion for transport and storage includes compression units (up to 350 or 700 bar) and liquefaction plants.
- For transportation, tanker trucks, tube trailers and pipelines are considered.
- Maximum and minimum capacities for production, transportation and storage are introduced as constraints.
- Data on capital costs and operation and maintenance for production plants are considered, as well as for pipelines. For road transportation, truck fuel economy, driver wages, and load/unload times are taken into account.
- A series of constraints and compatibility checks complete the model structure. For example, no on-site power plants can be coupled with liquified hydrogen production, to avoid missing economies of scale for LH2; there are also controls on the matching between an energy source and a production method (no SMR plant powered by RES, or electrolysis plant powered by $CH_4$).

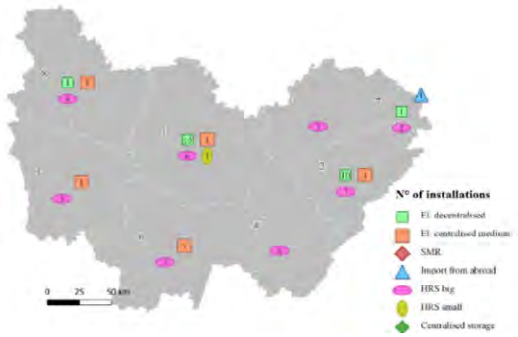

**Figure 6.** Geographical discretization of the region Bourgogne-Franche-Comté. Simulation results in period 2 (2030-2034) from [11]

Each phase of the supply chain corresponds to a separated calculation for each of the parameters evaluated (cost and environmental indicators). Each indicator presents three contributions to its total value: production (P), transportation (T) and conversion (C). Let $Env_x$ be the generic indicator, its calculation is expressed as in Eq. (1):

$$Env_x Total = PEnv_x + CEnv_x + TEnv_x \quad (1)$$

Each one of the $Env_x$ terms was subject of a dedicated optimisation.

The investment cost of the facilities (*FCC*) (Eq. (2)) includes the capital cost for each facility (respectively, *PCC*, *SCC* and *FSCC*) for the installed number of each facility: production (NP), storage (NS), and refueling stations (NFS). These factors are divided by a learning factor (*LearnFt*) to account for cost reductions due to mass production and market penetration of certain technologies (e.g., electrolyzers). They are then discounted to year *n* to reflect their present value (Eq. (3), with *i* as the discount rate.

$$FCC_t = \frac{1}{LearnF_t} \sum_{ig} \left( \sum_{pj} PCC_{pij} NP_{pijgt} + \sum_{sj} SCC_{sij} NS_{sijgt} + \sum_{fj} FSCC_{fkj} NFS_{fkjgt} \right) \quad (2)$$

$$FCC_n = FCC_0 \frac{1}{(1+i)^n} \quad (3)$$

The optimisation criterion is the total cost (TSCTotal), which consists of the sum of investment costs and the sum of the total yearly operating costs (TOC):

$$TSCTotal = \sum_t (FCC_t) + \sum_n TOC_n \quad (4)$$

The total cost then allows for the determination of the Levelized Cost of Hydrogen (LCOH) based on the hydrogen production.

In the first phase, the methodology focused on a single-criteria optimization framework, resulting in 16 scenarios, each illustrating how minimizing a specific criterion impacts the other categories. This phase is essential for understanding the behavior of the criteria, providing a solid foundation for the subsequent development of a multi-objective approach and multi-criteria decision-making, which will be the natural progression of the study.

## Optimization results

The results are organized in a table with a color scale (green-yellow-red) highlighting the performance of each scenario (Figure 7). Each column represents a different scenario, with the objective function to be optimized indicated at the top of the columns. The diagonal shows the minimum values for each parameter. A greener column indicates better overall performance in terms of the indicators.

Validation of the obtained values was performed by comparing them with similar studies analyzing the proposed indicators. Despite minor discrepancies due to differences in the database, LCA method, or update year, the order of magnitude for the various parameters

| Parameter object of the optimisation --> | LCOH | GWP | ODP | AP | FEP | MEP | HTTP | PMFP | ETP | IRP | POFP | ALO | ULO | WDP | MEP | FDP |

**Figure 7:** Optimisation results

showed a high level of consistency [16-19].

The table first reveals a wide variation in the results across the different performance indicators, highlighting the significant potential for optimization.

When comparing the obtained results with the EU's standard for low carbon hydrogen, which allows a maximum of 3.38 kg of $CO_2$-equivalent ($CO_2e$) emissions per kilogram of hydrogen produced and distributed, we see that 10 scenarios remain well below this threshold.

An analysis of results reveals a clear trade-off between cost and GHG minimization. The least expensive solution, while economically favorable, demonstrates a poor overall performance across several environmental indicators.

In contrast, the solution optimized for the minimization of Global Warming Potential (GWP) involves a notable increase in costs, although it yields favorable results for other environmental indicators. Among the various scenarios evaluated, good performances were observed for GWP, Ozone Depletion, and Metal Depletion, primarily driven by a higher proportion of renewable hydrogen production. Conversely, the worst outcomes, particularly for Photochemical Oxidant Formation and Water Depletion, stem from a higher reliance on imported hydrogen and grid electricity, both of which exhibit less favorable life cycle assessment (LCA) parameters compared to green hydrogen.

Finally, the table shows that optimizing solely the "cost-GHG" pair is insufficient, and that other criteria must be considered in the optimization process. It is difficult to go further at this stage without a thorough analysis of the corresponding supply chain structure.

## CONCLUSIONS AND PERSPECTIVES

This study presents a methodological framework for the comprehensive analysis of hydrogen supply chains by integrating Life Cycle Assessment (LCA) with optimization techniques. The proposed approach enables a systematic evaluation of various environmental and economic parameters, offering a more detailed understanding of the trade-offs involved in different hydrogen production pathways. The primary contribution of this work lies in the optimization of individual indicators, highlighting the potential for Multi-Objective Optimization (MOO) to simultaneously improve the performance across various environmental and economic parameters.

The next phase of the research will then focus on MOO to identify optimal trade-offs. Given the computational challenges of MOO (not feasible with the whole group of 16 LCA indicators at once), the study will explore methods to reduce dimensionality without sacrificing the quality of results. This could include analyzing the behavior similarities among different indicators, as revealed by the preliminary results (Figures 2-3-4). This will ensure that the optimization process remains efficient while maintaining its robustness, ultimately offering valuable insights for the design of sustainable and economically viable hydrogen supply chains.

## ABSTRACT

Industrial ecology appears to be a significant means of reducing carbon dioxide emissions from industry. However, beyond flow management, eco-industrial parks can also contribute to a socio-economic transition on a regional scale. Usually, multi-criteria optimization models use economic and environmental criteria in the decision-making process. This article looks at the integration of social criteria in these models, and more broadly at the issues involved in measuring the social impact of an eco-industrial park. The aim of this article is to take a different approach to social indicators, by highlighting the key success factors of an eco-industrial park, such as cooperation within a collective but also between the different scales making up the system. This work is based on bibliographical research and semi-structured interviews with stakeholders in the field. What's more, the process of developing social indicators, particularly participatory ones, seems to be a strong catalyst in the construction of relationships and their dynamics. Finally, the metric of social indicators also has its limitations, which should be considered if we are to be able to address the various issues in a systemic way and potentially envisage other ways of taking into account the social aspect of an eco-industrial park.

**Keywords**: Eco-industrial park, social indicators, relational dimension, co-building

## 1. INTRODUCTION

The technical, economic and environmental benefits of industrial ecology have already been demonstrated through multi-criteria optimization models [1]. Optimization models make possible to implement synergies according to economic and environmental criteria. Numerous studies have proposed several criteria such as: $CO_2$ emissions, Net Present Value or other economic ones, and today the reorganization of industry into eco-industrial parks appears to be a significant way of reducing carbon dioxide emissions into the atmosphere [2]. However, it appears less common to consider eco-industrial parks as an opportunity to modify socio-economic landscapes on a territorial scale.

The aim of this article is therefore to highlight the social impact that a territorial planification of cooperation can have on a territory and conversely. This impact will be assessed in a case study using social indicators such as job creation. This case study is about the development of offshore wind energy expertise in the port of Port-La-Nouvelle in South of France with the port of Sète as a rear base. The aim is to assess the capacity of the port of Sète to host component manufacturing and anchor system storage activities, by evaluating the economic, environmental and social impacts of this approach. We will then highlight the criteria chosen and assess their relevance and limitations, particularly with regard to the social aspect.

To this end, we will define the needs and challenges of an industrial and territorial ecology approach with a relational and human point of view. Semi-directive interviews with players in the field and researchers who have studied this issue will enable us to highlight the complexity of this system and the parameters that determine its success.

In another time, we will examine the real added value of social indicators on this relational dimension, in particular by studying the way in which social indicators are implemented. Indeed, beyond the indicator itself, the

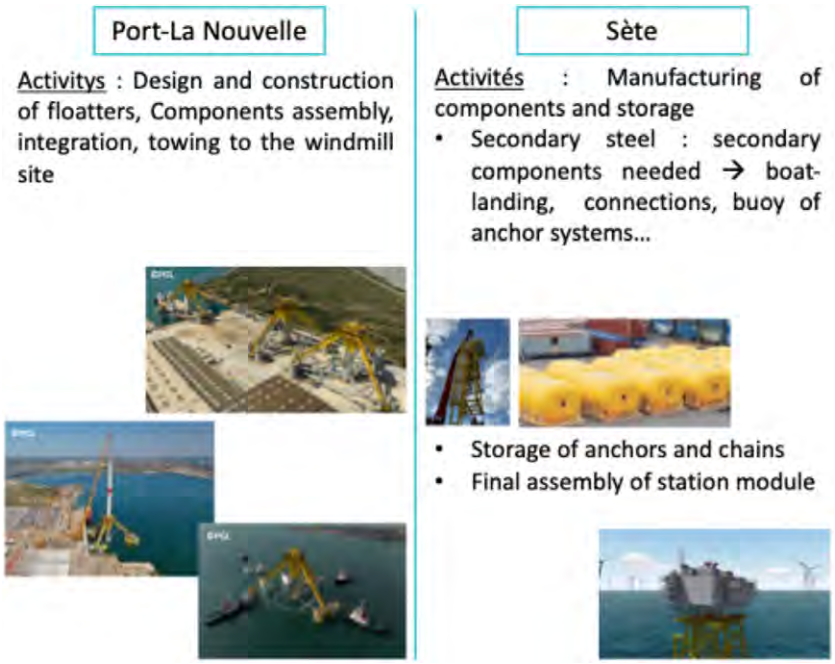

**Figure 1:** Illustration of the different activities to implement in the sites of Port-La-Nouvelle and Sète

process chosen for its elaboration has a real influence on the indicator itself, as well as on the ability of users to appropriate it. We therefore need to consider which process seems most effective in enabling the use of social indicators to provide a new perspective on the context of an industrial and territorial ecology approach.

Finally, we will highlight the limits of metrics based on social indicators, and question their ability to capture a complex, multidimensional social environment [3]. We will also explore the possibility of using other concepts and tools to account for social reality, and assess their relevance to industrial and territorial ecology.

## 2. CASE STUDY

The proposed case study concerns the development of a regional port scheme with the port of Port-La-Nouvelle as a hub for floating offshore wind energy and the port of Sète as a rear base. The aim of the study is to assess the suitability of the port of Sète as a base for manufacturing components and storing anchoring systems (Figure 1). Various scenarios are proposed for evaluation, based on economic, environmental and social criteria.

In this article, we take one of the proposed activities as an example.

Components manufactured in Béziers need to be transported to Sète for finishing stages. Three transport scenarios are proposed:

- Road transport
- Rail transport
- River transport

The criteria presented in Table 1 will enable us to assess the impact of the three scenarios.

**Table 1:** Criteria chosen for the transport scenario

| Economic criterion | Environmental criterion | Social criterion |
|---|---|---|
| C1 Transport costs | C2 Human health | C5 Job creation |
| | C3 Ecosystem quality | |
| | C4 Resources | |

The environmental criteria were selected using the SIMAPRO life-cycle analysis software and the Eco-indicator 99 (E) V2.10 method, which uses end-point indicators. This method has been chosen because it allows for a limited number of criteria and therefore better readability of the results even if the uncertainty increases.

The social criterion was chosen in consultation with the actors of the region, which wanted to measure the contribution of this new activity in terms of employment and dynamization of their territory (attractivity).

The Electre I multicriteria decision aid methodology has been chosen to compare the different scenarios and to propose which one is the best compromise regarding the weights accorded to the criteria by the different actors.

## 3. RESULTS

Tables 2 and 3 show the performance matrix based on criteria reported on Table 1, with different weights affected for each player.

**Table 2:** Manufacturer's performance chart

| Criteria | C1 | C2 | C3 | C4 | C5 |
|---|---|---|---|---|---|
| **Weights** | **3** | **2** | **1** | **2** | **2** |
| Road | 91 | 0,3 | 7,9 | 2,9 | 15 |
| Rail | 68 | 8,5 | 9,7 | 9,5 | 5 |
| Waterway | 62 | 6,3 | 9,7 | 8,2 | 10 |

**Table 3:** Local authorities' performance chart

| Criteria | C1 | C2 | C3 | C4 | C5 |
|---|---|---|---|---|---|
| **Weights** | **1** | **1** | **1** | **1** | **6** |
| Road | 91 | 0,3 | 7,9 | 2,9 | 15 |
| Rail | 68 | 8,5 | 9,7 | 9,5 | 5 |
| Waterway | 62 | 6,3 | 9,7 | 8,2 | 10 |

The results that emerge from this study differ according to the weight attributed by the different stakeholders involved in the project.

According to ELECTRE approach and based on the weights affected using the different interviews, the best option is selected for each actor.

For manufacturers, rail transport is the preferred option, while for the general public, road transport is preferable.

From the point of view of social indicators, this method has its limits.

Firstly, in the context of a multi-criteria optimization model, the loss of qualitative information is very high. The context and its complexity are not taken into account. What's more, the job creation criterion is questionable, as it doesn't highlight the quality of the jobs and doesn't measure the real contribution to the region. We may well wonder what will happen to these jobs once the finishing activity is over.

In conclusion, this type of modeling, incorporating indicators with a social dimension, can be used to guide strategies. It also highlights the divergent viewpoints of stakeholders, thanks to the weights assigned to each criterion. This divergence of interests, objectivized by a mathematical model, can form the basis for discussion between stakeholders, and enable each to understand the stakes of the other. Nevertheless, we can't claim to take the social dimension of the situation into account. To understand social issues, we need to consider the context and its complexity. In order to emphasize and to understand the challenges into the consideration of social aspects in such territorial projects, we propose a new definition of the multi-actor compound of territorial projects.

## 4. KEY FACTORS FOR ECO-INDUSTRIAL PARKS

Given the limitations of the above case study, we turned our attention to the needs and challenges of an eco-industrial park in the context of trying to imagine new synergies to enhance the attractivity of a territory. Figure 2 shows the representation of the structure of an eco-industrial park with this multi stakeholder point of view.

This representation was drawn up on the basis of interviews with two consultancies specializing in industrial and territorial ecology, as well as with 5 industrial and territorial ecology coordinators employed by local authorities.

This representation reveals a complex, multidimensional system with 3 different strata:

- The operational level: made up of manufacturers and their internal ecosystems.
- Tactical level: the park and its key players (local community members, industrialists, park managers and institutions).
- Strategic level: with a more macro-systemic vision (politicians and external stakeholders).

It's interesting to note that some players belong to different scales, both tactical and strategic. For example, a farmer may generate flows that will feed the park. They will therefore be involved in the system, while at the same time having an activity outside the park. The aim of this diagram is to highlight the diversity of players with potentially divergent interests who are brought into contact with each other.

Following this observation, we asked ourselves what ingredients would enable this structure to operate ona good way.

Kalundborg is Europe's benchmark industrial ecology park. The success of this park seems to be linked, among other things, to good communication and the implementation of collaborative relationships between players [4]. What's more, following interviews with one employee of a private company, two park managers and five project managers, it seems obvious that it's socio-economic, human and organizational factors that either block or enable an industrial and territorial ecology approach to develop [5].

Figure 3 summarizes the keys to success identified by the players in the field, according to the park's life stage.

During the reflection phase, it became clear that a detailed analysis of the area was essential. This enables us to determine whether the area is economically and demographically dynamic enough to make such a project viable. The job market and local political will are also key factors.

**Figure 2:** Representation of an eco-industrial park as a multi-stakeholder system

In the start-up phase, the third-party player appeared to be a mainstay.

In the sustainability phase, the trio of communication, trust and cooperation is the key to a healthy collective. In fact, these 3 elements are essential at all stages of the process, and not just during the sustainment phase.

## 5. SOCIAL INDICATORS HELPFUL FOR ECO-INDUSTRIAL PARKS

Having highlighted the key social aspects that enable an eco-park to function, it seems worthwhile to examine the relevance of social indicators as a tool for steering such initiatives.

Social indicators can be approached from different angles. They can be used as external communication tools, evaluation and management tools, decision-making tools or impact measurement tools.

One of the angles chosen in this article concerns the notion of performative social sustainability indicators. These are indicators that raise the ambitious question "what kind of world do we want to create?" [3]. The performative approach allows us to adopt a "real relational orientation towards the causes and conditions that shape outcomes."

This approach aims to question the system, the way it works, as well as highlighting its dysfunctions. For example, this type of indicator can question the potential presence of a space for the expression of divergent points of view.

In addition, the previous chapter highlighted the importance of relationships within a collective, and in particular the need to build a climate of trust and cooperation led by a third-party actor who will be able to animate the industrial and territorial ecology approach throughout the life of the park. It therefore seems essential to pay particular attention to the stakeholders involved in this approach, and to give them the space to express their needs and interests. The method used to construct social indicators plays a decisive role in this process.

Indeed, a constructivist perception of social indicators makes it possible to involve eco-park stakeholders in the process. This involves understanding how individuals have constructed their vision of the world, and enables a more refined approach to the complexity of situations and therefore potential dysfunctions [6].

It turns out that a constructivist vision encourages the implementation of indicators via participatory processes that will enable stakeholders to appropriate these tools and perceive the benefits of using them. However, this approach involves qualitative methods such as interviews and narratives, which can be time-consuming to process.

**Figure 3:** Field analysis of keys to success

## 6. DISCUSSION

It seems that social indicators can bring real added value to the management of industrial and territorial ecology initiatives. They can give an account of a process and its malfunctions, and thus enable the implementation of corrective actions with the aim of developing the trust and cooperation essential to the smooth running of the system. By way of example, we can propose park-wide indicators such as: the composition of governance bodies, the organization and frequency of informal exchanges, the presence of a third-party actor, the existence of collective mediation, and the presence of rules for preserving the confidentiality of strategic data [7]. These indicators are intended to measure the collective dynamic and assess the framework conducive to secure exchanges enabling trust and cooperation.

However, beyond the mere proposal of indicators, their development process seems to be the most impactful contribution. Indeed, the inclusion of stakeholders in their construction generates exchanges that encourage the expression of each party's issues. This space for dialogue is itself a creator of the collective: "The dialogue process must be seen as much more than a selection of indicators. Above all, it creates an opportunity for collective learning and debate between stakeholders, enabling them to perceive the range of issues at stake, and to learn what is important to others, and why." This iterative process of discussion, revision, and validation of indicators not only refines the assessment tools but also strengthens relationships among actors, promoting a culture of transparency, cooperation, and shared governance.

Industrial and territorial ecology can thus be seen as a means of "providing a technical, organizational, or economic response to a challenge felt by the players involved (public and private). Industrial Ecology is therefore no longer an objective in itself (as has often been the case during the many experiments carried out in France), but it constitutes an innovative solution to resolve a problem relating to the management of waste, a resource, energy production, or even the economic development of the territory" [8]. The contextualization of these indicators within the framework of industrial ecology implies that their impact extends beyond operational efficiency and includes socio-economic resilience. By adopting this perspective, stakeholders can integrate social sustainability considerations into their strategies, ensuring that industrial symbiosis initiatives align with broader societal values.

Nevertheless, indicators generate "a simplification of complex social realities into abbreviated symbols for easy communication." This simplification can facilitate the implementation of rather top-down forms of governance, which will focus their attention on the consumer and the market and turn away from questions about the social sustainability of the system such as "worker well-being, industrial equity, and engaged, positive relationships with external communities." The risk of reductionism highlights the need for reflexivity in indicator design. If indicators merely serve to rationalize existing power structures or validate pre-established narratives, they

may obscure deeper systemic issues and reinforce inequitable dynamics.

The political nature of the indicator then needs to be questioned, as claiming that it only describes and analyzes is a mistake. An indicator is a choice, a choice to make certain realities visible and others invisible. It is important to clearly identify the intention behind the choice of indicators and to iteratively question their meaning and objectives. This vigilance is a way of shedding light on manipulative commercial practices, known as Greenwashing. Indeed, isn't taking social issues into account a way for industries to justify themselves and show that they are “repairing,” thereby feeding the myth of sustainable development? If social indicators are merely used as a performative mechanism rather than a genuine tool for progress, they risk being reduced to symbolic gestures rather than catalysts for substantive change.

Furthermore, the integration of social indicators into industrial and territorial ecology can serve as a bridge between quantitative and qualitative assessment frameworks. Traditional environmental and economic models rely heavily on measurable data, but social dimensions require interpretive approaches that capture the nuances of human interactions, trust, and collaboration. Thus, a hybrid methodology that combines quantitative metrics with qualitative insights is necessary to ensure a holistic understanding of industrial ecosystems. This would enable a more inclusive evaluation process that incorporates the lived experiences of various stakeholders.

This study constitutes a key step in our process of developing a generic methodology to design and optimize flows in eco-industrial parks. Indeed, when taking into account several criteria in an optimization model, environmental and economic aspects are the most commonly used and the most easily quantified. The social criterion, however, is more important at a territorial scale and can vary significantly depending on the different actors involved. This study shows which criteria can be chosen and emphasizes the need to conduct preliminary interviews before formulating the problem. Engaging with stakeholders early in the process ensures that the indicators reflect the diversity of perspectives, allowing for a co-built and contextually relevant problem formulation.

Ultimately, the development of social indicators in industrial and territorial ecology is not merely an exercise in measurement but a fundamental practice of participatory governance. As industry and policymakers seek to balance ecological imperatives with economic viability, the social dimension must not be relegated to the background. The success of eco-industrial initiatives depends on the extent to which they integrate social trust, cooperation, and equity into their core frameworks. By fostering inclusive dialogue, continuously refining indicators, and ensuring their alignment with real-world social dynamics, we can create industrial ecosystems that are not only efficient and sustainable but also just and resilient.

## 7. CONCLUSION AND PERSPECTIVES

An eco-industrial park cannot function without particular attention to the links between the various players. Communication, trust and cooperation are the foundations of an effective collective. Social indicators can be used to assess the parameters conducive to this type of climate. We have also found that their participative elaboration has a strong potential to transform the collective.

Ultimately, social indicators in the context of industrial and territorial ecology raise questions about the management of common goods within a territory. The governance of the commons can be approached in ways other than metrics. Elinor Ostrom's work sets out fundamental principles for the management of common goods [9]. Moreover, the notion of principles and values [10] can also be seen as an alternative to social indicators. The idea here is to focus on the collective's values, what it wishes to defend and the principles that will flow from them.

These different avenues of reflection lead the collective, in our case an eco-park, to question the social impact it wishes to have on a micro, meso and macro scale.

In conclusion, this reflection on social indicators highlights a profound question: what impact do we wish to have on the world?

## ACKNOWLEDGEMENTS

This project has been accompanied by Region Occitanie that is fully thanked for the case study. It has been funded by PETRA grant through Defi Clé Circulades and Université de Toulouse.

## ABSTRACT

This study evaluates the environmental impact of carbon capture technology in the context of reducing industrial $CO_2$ emissions within Eco-Industrial Parks (EIP). The primary focus is on the post-combustion absorption process, which uses solvents like monoethanolamine (MOA) to capture $CO_2$ before it is released into the atmosphere. The captured $CO_2$ is either stored or utilized to prevent further contribution to climate change. The study employs a Life Cycle Assessment (LCA) methodology to compare the environmental impacts of two scenarios: one with $CO_2$ capture and the other with the direct release of $CO_2$ into the atmosphere. The LCA considers inputs, outputs, energy requirements, and materials needed for the $CO_2$ absorption process. The functional unit of the assessment is 1000 tons of $CO_2$, to standardize comparisons between both scenarios. Results show that the $CO_2$ absorption process significantly reduces the impact on climate change, capturing over 80% of the $CO_2$ from the stream. In terms of climate change, the absorption process has a much lower environmental impact than releasing $CO_2$ into the atmosphere. However, other ecological impacts, such as resource use and ecotoxicity, are higher in the absorption process due to the materials required and the solvents used. In conclusion, while the $CO_2$ absorption process offers clear climate benefits, it introduces additional environmental challenges. Future studies should explore alternative carbon capture technologies and extend the scope to include $CO_2$ storage impacts and a broader range of LCA tools for more detailed assessments.

**Keywords**: Life Cycle Analysis, Carbon Dioxide Capture, Absorption, Decarbonization

## INTRODUCTION

Human activities are acknowledged to have an impact on the environment ever since the pre-industrial era. This influence on the climate, referred to as climate change, is mainly caused by the burning of fossil fuel [1]. Indeed, large amounts of carbon dioxide ($CO_2$) and other greenhouse gases are released in the atmosphere and act as traps for the sun's heat radiating from the surface of our planet.

Industrial activities are a major factor in climate change, given the amount of greenhouse gases released into the Earth's atmosphere from fossil fuel burning and from the energy required for industrial processes. In an attempt to reduce the environmental impact of the industry on climate change, many technologies are studied and considered.

This study focuses on one of these technologies – carbon capture. Carbon capture refers to the process of trapping $CO_2$ particles before or after the combustion of fossil fuels. Next, the carbon is used or stored in order for it not to reach the atmosphere, where it would be trapped and have a serious impact on climate change, as mentioned previously. This whole process is referred to as Carbon Capture, Utilization and Storage (CCUS). Carbon capture is declined into multiple technologies. This study focuses only on amine absorption, which is described in the next part.

In this study, the process of carbon capture is seen as part of a bigger project aiming at reducing the $CO_2$ emissions of the industry referred as an Eco-Industrial Park (EIP). Indeed, the process is studied in the context of an EIP in order to determine whether setting it up is more or less valuable in terms of ecological impact than the current situation consisting on releasing the greenhouse gases into the atmosphere.

To properly conduct this study, it was necessary to consider various factors of ecological impacts. Indeed, carbon absorption through an amine lowers the amount of $CO_2$ released in the atmosphere but on the other hand, the use of amine as a solvent comes with its share of degradation. For instance, the release of amine in the atmosphere is known to have several impacts such as on human health for instance.

Therefore, it was necessary to involve many different criteria in order to compare the ecological impact of a carbon capture and the ecological impact of the release of industry-produced greenhouse gases. To do so, the Life Cycle Analysis (LCA) method was chosen to assess the environmental impacts of both scenarios. This paper aims at presenting a methodology applicable to any technology in order to determine its environmental impact in the context of an EIP. After explaining the methodology, a case study will be made on post-combustion carbon absorption.

## POST-COMBUSTION ABSORPTION PROCESS DESCRIPTION

$CO_2$ absorption refers to the process in which a liquid solvent absorbs the $CO_2$ contained in a gas stream. In order to capture and separate $CO_2$ from the stream gas, the process of absorption requires solvents with high $CO_2$ binding capacity [2]. A recurrent solvent used for this purpose is a monoethanolamine (MOA) aqueous solution, given its high reactivity with $CO_2$ and its low price for production [3].

In this study, the absorption process was simulated with the Fives ProSim© software. The process is part of the software database and is set to treat 3073 tons of stream gas per hour (Figure 1).

## GOAL AND SCOPE OF THE LIFE CYCLE ASSESSMENT

Having clearly defined the $CO_2$ absorption process in the previous part of this study, this next part is intended to thoroughly define the goal and the scope of the LCA. This exercise is crucial in the LCA methodology as it ensures that the LCA has been performed consistently.

This LCA is conducted in order to quantify the environmental impact of a $CO_2$ absorption process including the design stage of the process. Ultimately, the goal is to define whether this process has an environmental benefit

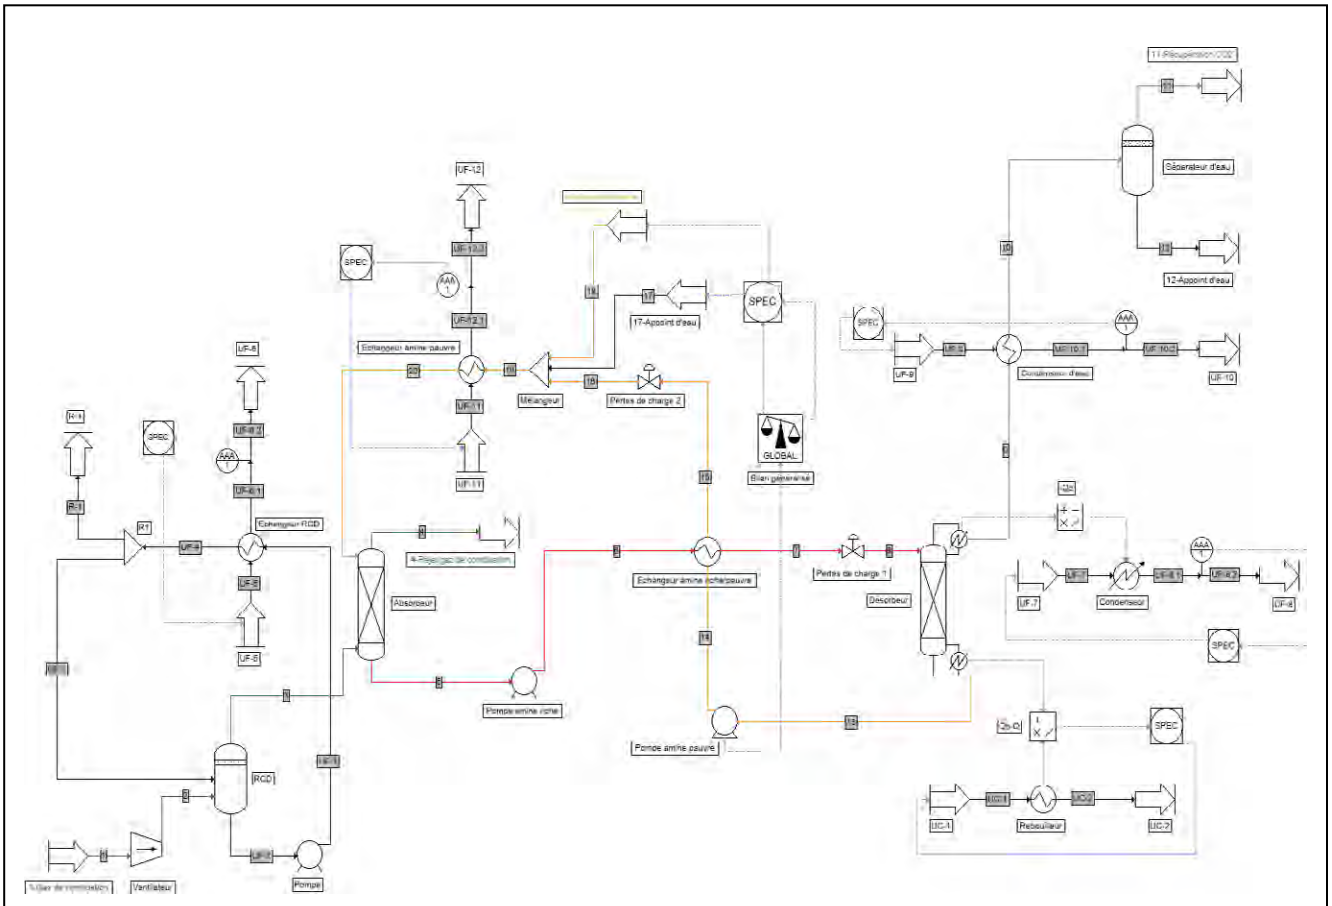

**Figure 1:** Schematic representation of the absorption process

over the gases release in the atmosphere.

In order to compare the impact of the $CO_2$ absorption process to the release of the $CO_2$ in the atmosphere, a functional unit is to be defined. The functional unit refers to any quantifiable unit in which the process' footprint is measured. Choosing a functional unit enables objective comparisons across all the elements considered. The functional unit selected for this study is 1000 tons of $CO_2$ collected at the outlet of the plant and treated or released in the atmosphere. In the context of the absorption process, the functional unit refers to the amount of $CO_2$ contained in the treated stream, whereas in the context of the release in the atmosphere, the functional unit refers to the amount of $CO_2$ contained in the released stream.

The scope defines the stages of the life of the $CO_2$ absorption process considered for the LCA. The usual scope would be cradle-to-grave because it covers every stage of the life of the process. However, this study does not include the last stage of the life of the process – waste disposal. Indeed, the disposal of the outputs of the process are considered, but not the disposal of the raw materials used to build the process in itself. The scope can then be referred to as cradle-to-use [4].

## LIFE CYCLE INVENTORY

The life cycle inventory for the $CO_2$ absorption process consists of the input and output streams, the materials needed to build the process and the energy required to run the process.

### Streams and energy requirements

In order to get an accurate representation of the input required to run the process and the outputs generated, a simulation of the $CO_2$ absorption process was run on Fives ProSim©. The block diagram featured in Figure 2 shows the results of this simulation.

This simulation provided values on the input and output streams as well as the energy requirements of the $CO_2$ absorption process. However, not every stream has to be considered for the LCA. Some hypotheses were made in order to conduct the LCA.

### Assumptions

First, the nitrogen contained in the input stream n°1 and the output stream n°4 are not considered because the amount in both streams is equal, meaning the amount of nitrogen entering the process is equal to the amount exiting the process. Only a trace is exiting the process through R-1 stream, which was considered in the LCA. Moreover, whether stream gas is treated through the $CO_2$ absorption process or released into the atmosphere, the amount of nitrogen released in the atmosphere is *in fine* the same.

Next, the utility streams were not considered either in the LCA because it can be considered as recycled. Indeed, the output and input streams carry the same amount.

Lastly, streams n°1 and n°11 are not considered for the LCA. The input stream n°1 is not considered in the LCA, as the purpose of the $CO_2$ absorption process is to treat said stream by separating the $CO_2$ from the other gases. The output stream n°11 is not considered either because it is the final product of the $CO_2$ absorption process, meaning the stream that contains the $CO_2$

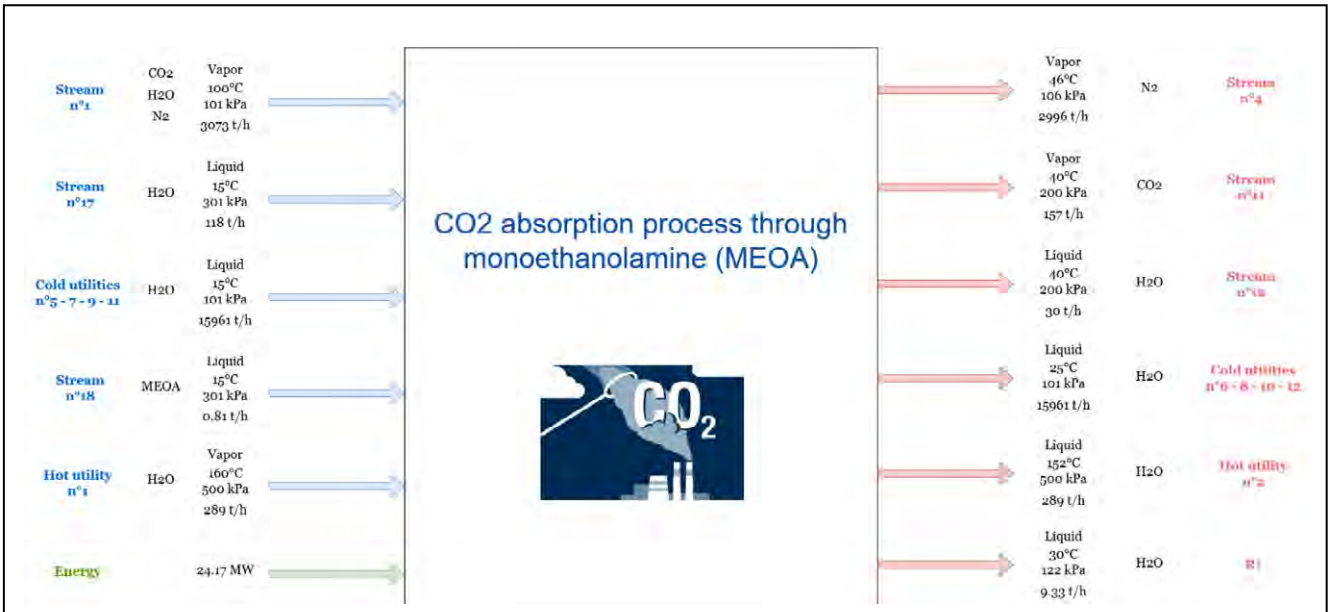

**Figure 2:** Block diagram of the results of the simulation of the $CO_2$ absorption process

separated for the other gases. This stream will then undergo a separate process, which does not fall into the scope of this study.

## Materials for process design

In order to get a rough idea of which materials were required to build the installation of the $CO_2$ absorption process, a Large Language Model was used. This tool provided an estimation of the amount of materials needed for each part of the process, as well as the amount of $CO_2$ treated by the process before the installation requires being replaced. The amount of materials was then brought back to 1000 tons of $CO_2$ to match the functional unit of the LCA. The final results used for the LCA are given in Table 1.

**Table 1:** Materials needed to build the process for 1000T of $CO_2$ treated

| Building materials | Amount needed (Ton) |
|---|---|
| Stainless steel | 0.1683 |
| Nickel-based alloy | 0.0700 |
| Packing materials | 0.0333 |
| Sealing materials | 0.0050 |

# RESULTS AND ANALYSES

The LCA was executed with the SimaPro© software. Figures 3 and 4 show the impacts of respectively the $CO_2$ absorption process and the release of stream gas in the atmosphere. The method Environmental Footprint was used in the software in order to obtain these two diagrams.

Impacts of both strategies to deal with $CO_2$ can be compared when considering the *Climate Change* category. Indeed, the impact of the release of stream gas is around 28kPt when the impact of the $CO_2$ absorption process is around 6.5kPt, meaning more than 4 times lesser than the direct release. 1 Pt is equivalent to the mean annual impact of a European inhabitant for the considered category. This is easily explained by the fact that more than 80% of the $CO_2$ contained in the stream gas is captured when going through the process.

However, the other categories have a greater impact when the stream gas is undergoing the $CO_2$ absorption process than when it is directly released. The analysis of the stream gas by SimaPro© can be discussed, as it appears that the stream gas, composed of 1000 tons of $CO_2$ and 728 tons of water, only impacts the *Climate Change and Water Use categories*.

The LCA was conducted using SimaPro© software. Figures 3 and 4 illustrate the environmental impact of $CO_2$ absorption and direct emissions, respectively, using the Environmental Footprint method.

Additionally, the energy required for the absorption process contributes to its environmental footprint. Future work should explore optimizing energy consumption to further reduce negative impacts. Another aspect to consider is solvent management. Amine-based solvents degrade over time, leading to waste generation. Implementing solvent regeneration techniques could enhance sustainability. Furthermore, alternative solvents with lower environmental impacts should be investigated.

## Integration in an optimization model

This study has been integrated into a previous optimization study (Boix et al., 2024) carried out to model and design the best exchanges of steam in an eco-industrial park. A set of companies operates processes that require vapor, electricity, and water. The objective is to determine the optimal configuration of exchanges between these companies that minimizes both cost and carbon emissions. The decision variables in the mathematical model include all inter-company flows (their existence and physical properties) as well as the sizing of necessary equipment.

A multi-objective optimization approach is applied to an Eco-Industrial Park (EIP) incorporating new facilities to assess their impact on greenhouse gas (GHG) emissions. These facilities include:

- An optimal steam network
- A Hybrid Power System (HPS)
- A $CO_2$ capture unit as modelled in the previous paragraph.

These elements are integrated into the optimization model, which is formulated as a multiperiod Mixed Integer Linear Programming (MILP) approach based on [5, 6]. The study by [7] on Yeosu Industrial Park is used as a case study to demonstrate the applicability of an optimization approach for a steam exchange network in a real industrial complex. The study identifies 15 industries, categorized into two groups: producing companies and consuming companies.

Producing industries generate steam, while consuming industries rely on external steam sources. Each industry has specific steam requirements, varying in type and quantity. The types of steam include:

- Very High-Pressure Steam (THP)
- High-Pressure Steam (HP)
- Medium-Pressure Steam (MP)
- Low-Pressure Steam (BP)

Since demand fluctuates throughout the year, it is divided into four periods based on seasons:

- t1: Spring (April to June)
- t2: Summer (July to September)

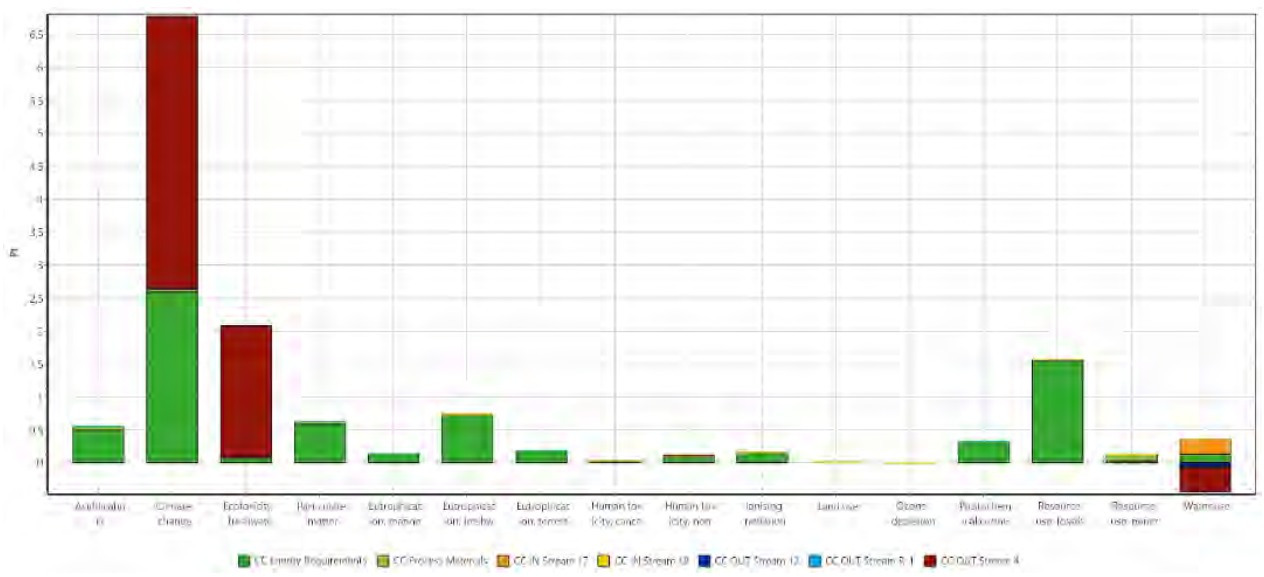

**Figure 3:** Diagram of the impacts of the $CO_2$ absorption process across different categories

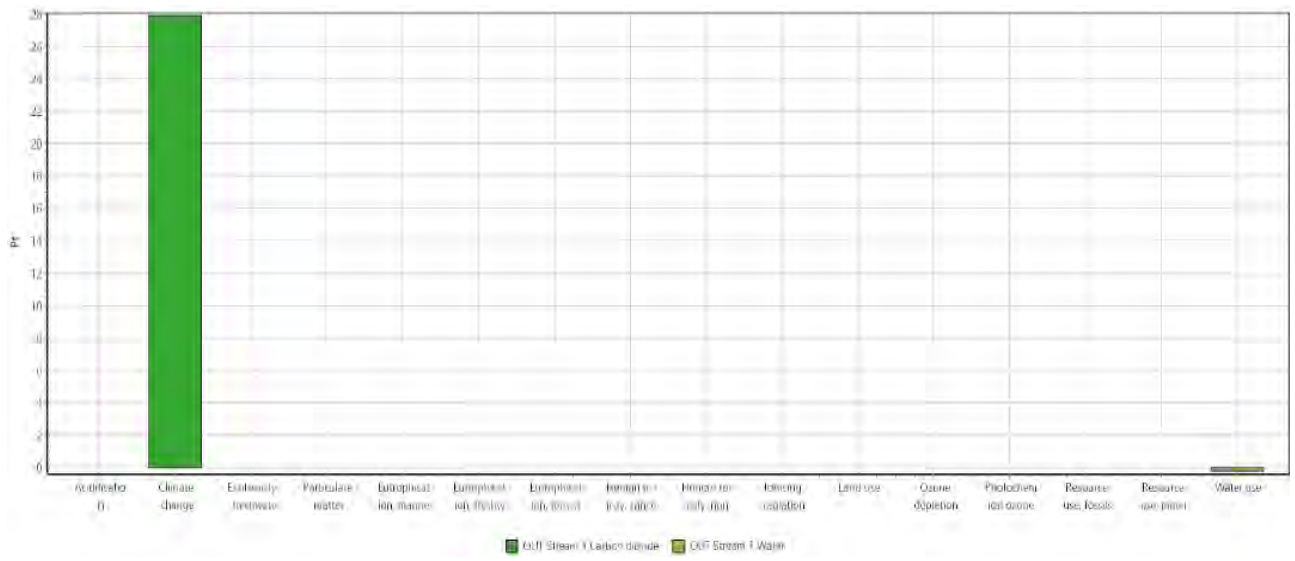

**Figure 4:** Diagram of the impacts of the release of stream gas across different categories

t3: Autumn (October to December)

- t4: Winter (January to March)

The first step in the optimization process involves defining the flue gas to be treated. Several simplifying assumptions are made:

1. The flue gas stream is considered a binary mixture comprising 14% $CO_2$ and 86% $N_2$.
2. The greenhouse gas (GHG) emissions from boilers consist solely of $CO_2$.
3. The flue gas temperature is assumed to be reduced to 25°C.

Using these assumptions, the model calculates the flue gas flow rate to be treated based on the GHG emissions generated by the boilers. This approach provides a structured framework for optimizing industrial symbiosis while integrating cost-efficient and environmentally friendly strategies. According to Table 2, it can be observed that the integration of such a unit in an eco-industrial park can lead to a decrease of GHG emissions of

more than 60% with a little increase of the cost of approximatively 0.4%. The total annual cost refers to the operating cost and also the investment linked to the $CO_2$ capture unit, it includes OPEX and CAPEX.

**Table 2:** Results of the integration of the carbon capture unit in the eco-industrial park

| | **Without $CO_2$ capture** | **With $CO_2$ capture** |
|---|---|---|
| Total annual cost (G$/yr) | 1899 | 1906 |
| Total GHG emissions ($TCO_{2eq.}$/yr) | 10416 | 3304 |

An attention must be paid to the modeling of news processes to be integrated into optimization model and especially with environmental impacts. We suggest that each new technology brick must be carefully modeled in order to quantify environmental impacts before being integrated into an optimization model.

## CONCLUSION AND PERSPECTIVES

Using SimaPro© software, this study demonstrated that $CO_2$ absorption significantly reduces climate change impact compared to direct emissions. Within an EIP, implementing $CO_2$ capture could enhance sustainability efforts. However, increased impacts on ecotoxicity and resource consumption warrant further consideration.

Future research directions include:

- Exploring alternative carbon capture technologies such as adsorption or membrane separation.
- Assessing the environmental impact of $CO_2$ storage.
- Extending the LCA scope to include $CO_2$ sequestration.
- Evaluating different LCA tools for a more comprehensive impact assessment.
- Investigating process improvements to enhance efficiency and sustainability.
- Studying economic feasibility to determine the long-term viability of $CO_2$ capture solutions.
- Investigating policy incentives and industrial cooperation strategies to improve the adoption of carbon capture technologies.

By addressing these considerations, future studies can contribute to the development of more sustainable industrial practices, ultimately mitigating climate change while minimizing adverse environmental effects.

## ABSTRACT

To achieve carbon neutrality, the installation of variable renewable energy (VRE) has been accelerated. However, the inherent variability of VRE can be mitigated through the installation of energy storage. This study aims to evaluate life cycle impacts of energy storage systems utilizing batteries, hydrogen storage, or thermal energy storage. A model of the energy storage systems with VRE was developed, and the annual energy flow simulations were conducted. The energy storage system targeted in this study assumed that all energy derived from VRE was stored in the energy storage and supplied to consumers. The amount of electricity to-be-sold from the energy storage system, based on the capacity of VRE and the installed energy storage, was calculated. A life cycle assessment was performed to evaluate the greenhouse gas (GHG) emissions, abiotic resource depletion (ARD), and intensity of GHG and ARD as life cycle impacts. The smallest life cycle impacts varied depending on the type and scale of energy storage. This quantitative evaluation of the energy supply capacity and the environmental impacts of the energy storage systems could provide valuable insights for designing efficient energy storage systems integrated with VRE, tailored to regional energy supply requirements.

**Keywords**: Batteries, Hydrogen, Thermal energy storage

## INTRODUCTION

The installation of variable renewable energy (VRE) has expanded around the world to promote the transition to a sustainable society, although ensuring a stable electricity supply from VRE remains challenging due to its inherent variability. To accelerate the penetration of VRE, projects are underway to install energy storage technologies, such as batteries, hydrogen ($H_2$) storage, and thermal energy storage (TES).

Selecting the appropriate energy storage technology requires careful consideration of multiple factors. The life cycle greenhouse gas (LC-GHG) of different storage systems is evaluated [1–3]. However, their types and scales should be designed based on regional characteristics because an improperly sized system can lead to increased LC-GHG [4]. There are studies to evaluate the installation of specific energy storage technologies under certain conditions [5], but comparing different storage types remains challenging. To address this, a comprehensive model is needed to assess the performance and environmental impacts of various energy storage options while considering regional conditions, such as VRE installation potential, under a consistent functional unit.

This study developed a model for evaluating environmental impacts of the energy storage systems in a region, based on an existing model by Yamaki et al. [6]. The energy storage systems assumed to include batteries, $H_2$ storage, and TES, which were evaluated using life cycle assessment (LCA). These systems were designed as new energy supply solutions to mitigate the variability of wind energy as a representative VRE source and connect to

the grid. The energy storage systems incorporating batteries, $H_2$ storage, and TES are referred to as a battery system, $H_2$ system, and TES system, respectively.

The model of the energy storage system was constructed to simulate the annual energy flows. We calculated the amount of electricity that could be sold from the energy storage system and analyzed their life cycle impacts. For life cycle impacts, LC-GHG, abiotic resource depletion (ARD), and greenhouse gas (GHG) and ARD intensities were evaluated. We discuss the applicability and implications of these energy storage systems.

## MATERIALS AND METHODS

### Model of the Energy Storage Systems

The model of the energy storage systems is shown in Figure 1. Figure 1(a) shows the energy and material flows of the energy storage systems targeted in this study. In energy storage systems, wind energy is assumed to be stored and supplied as electricity.

In the battery system, electricity is assumed to be generated by wind turbines (WTs), stored in batteries, and supplied to meet demand. In the $H_2$ system, $H_2$ is assumed to be produced by electrolyzers using electricity generated in WT. The $H_2$ is then stored as liquefied $H_2$ in tanks and converted into electricity in fuel cells. In the TES system, wind energy is directly converted into thermal energy through wind-thermal energy converters ($WEC_{th}$s), stored in molten salts, and later used to generate steam in a heat exchanger, which drives a steam turbine for electricity production. A $WEC_{th}$ directly converts wind-derived rotational energy into thermal energy [4].

Figure 1(b) expresses the wind speed profile assumed for the energy flow simulations in this study. The meteorological data referred to Cape Erimo in Hokkaido prefecture, which has the highest average wind speed in Japan [7]. Figure 1(c) shows the electricity demand curve for Hokkaido prefecture [8].

LCA was performed on a cradle-to-grave basis, covering energy storage and related facilities, under the assumption of installing a new energy storage system. The LCA covered the batteries and WTs in the battery

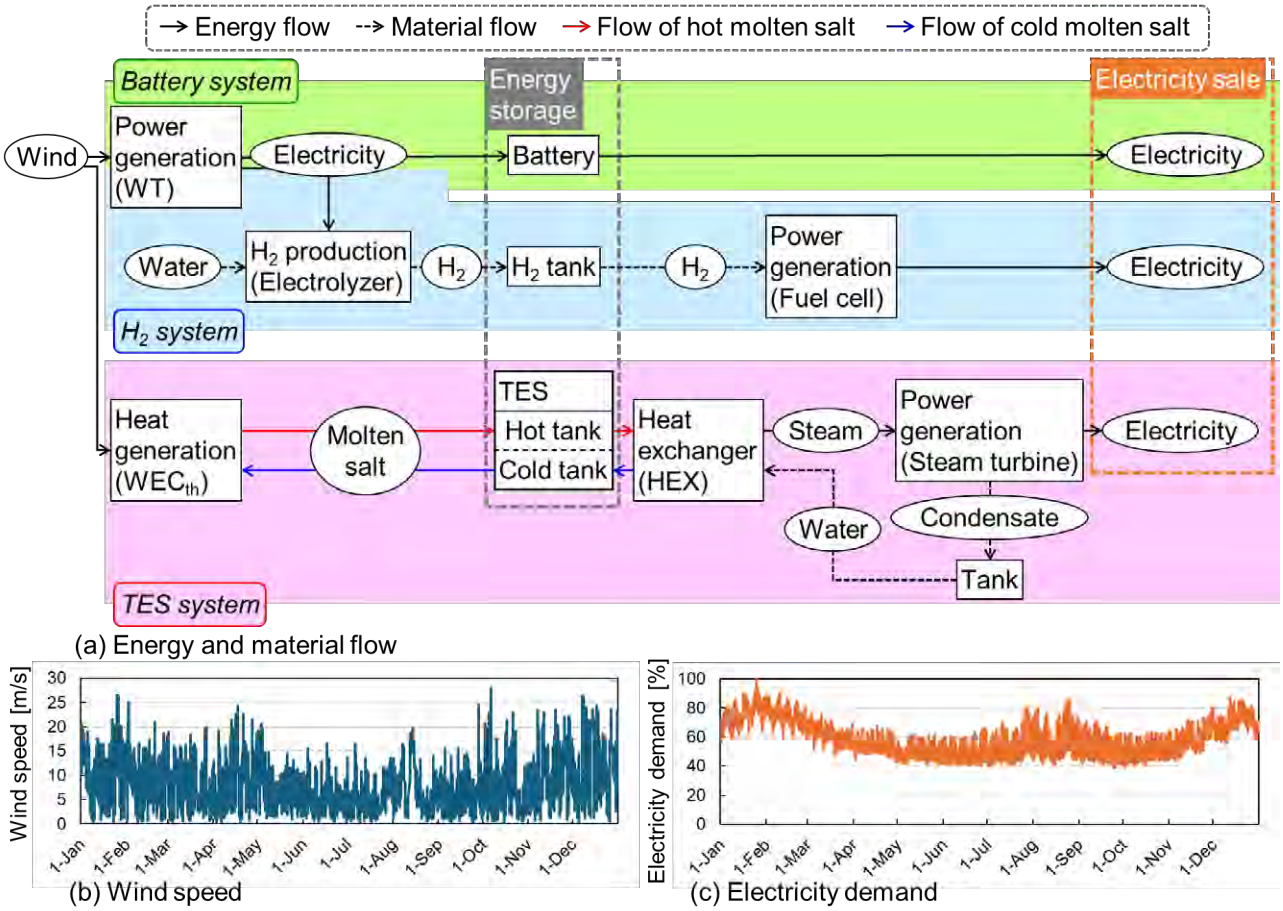

**Figure 1:** Model of energy storage systems. (a) Energy and material flows of the energy storage systems. (b) Wind speed at Erimo cape in Hokkaido prefecture. (c) Electricity demand in Hokkaido prefecture.

system; the $H_2$ tank, electrolyzer, fuel cell, and WTs in the $H_2$ system; and the molten salt, its tanks, heat exchanger, steam turbine, and $WEC_{th}$ in the TES system.

## Energy Flow Simulations

The model developed in this study assumed that all power and heat derived from wind energy were stored in energy storage and supplied as electricity to consumers. The simulations were conducted using Microsoft Excel with energy flows calculated on an hourly basis from 00:00 on January 1 to 24:00 on December 31.

$$Q_{\mathrm{storage}}(t) = Q_{\mathrm{storage}}(t-\Delta t) + Q_{\mathrm{in}}(t) - Q_{\mathrm{out}}(t) - Q_{\mathrm{leakage}}(t) \quad (1)$$

In equation (1), $Q_{\mathrm{storage}}(t)$ represents the energy stored in the targeted energy storage at time *t*, while $Q_{\mathrm{in}}(t)$ is the input energy supplied from wind energy. If electricity or heat generation from wind energy exceeded the energy storage capacity, the excess energy was assumed to be curtailed. $Q_{\mathrm{out}}(t)$ is the output energy from the energy storage, which is calculated based on the electricity sold. The electricity demand curve used in this study is shown in Figure 1(c). $Q_{\mathrm{leakage}}(t)$ represents energy leakage from energy storage, which includes battery self-discharge, $H_2$ leakage, and heat loss. The parameters for the energy flow simulations are extracted from the references [1–4,6,9,10].

The amount of electricity sold is adjusted to occur in periods of zero $Q_{\mathrm{storage}}(t)$, and the electricity sales value represents the maximum electricity that the targeted energy storage system could supply. The simulation also imposed the constraint that energy for selling electricity at time *t* was assumed to be stored at time *t*–Δ*t* in this simulation, as indicated in equation (2).

$$Q_{\mathrm{out}}(t) \leqq Q_{\mathrm{storage}}(t-\Delta t) \quad (2)$$

This study presents the value of electricity sales as a result of total electricity sold over the year. To ensure the energy storage system could supply electricity continuously over multiple years, it was assumed that the stored energy levels at 0:00 on January 1st and at 24:00 on December 31st were the same. This applied to the amounts of charged electricity in the battery, the $H_2$ in the $H_2$ tank, and the temperature and quantity of molten salt in the TES tank.

## Analysis Settings

An LCA was conducted to evaluate the cradle-to-grave impacts of energy storage and related facilities, assuming the installation of a new energy storage system. The LCA covered power and heat generation facilities powered by wind energy, as well as components specific to each energy storage system. For the battery system, lithium-ion batteries were assessed. The $H_2$ system included components such as a $H_2$ tank, an alkaline electrolyzer, and solid oxide fuel cells (SOFC). The scale of the electrolyzer was adjusted according to the capacity of WT and $H_2$ tank. The TES system encompassed the molten salt, its tanks, heat exchanger, and steam turbine.

The functional unit was the annual wind speed shown in Figure 1(b). Foreground data for the LCA was derived from energy flow simulations, while background data, such as materials for the energy systems, were extracted from the Japanese LCA database, the inventory database for environmental analysis version 3.4.1 (IDEA) [11]. The quantities of materials used for production and operation were extracted from the references [1–3,6,10,12–15]. LC-GHG and ARD were calculated by adding the GHG emission and ARD across all stages of the life cycle from production to disposal of the facilities.

The GHG and ARD intensities were expressed as LC-GHG and ARD per electricity sold. Although GHG emissions are reduced by VRE installation, ARD would increase due to the use of rare metals required for energy storage systems. Therefore, it is essential to evaluate both GHG emissions and ARD.

# RESULTS AND DISCUSSIONS

## Annual Energy Flow and Electricity Sold from the Energy Storage Systems

Energy flow simulations for the energy storage systems were conducted to calculate annual electricity sales under varying capacities of WT/$WEC_{th}$ and energy storage. The maximum potential electricity sales were determined for each combination of energy storage capacity and WT/$WEC_{th}$ installations.

Figure 2(a) shows the hourly variation in stored energy and electricity sales, whose demand curve was assumed as shown in Figure 1(c), for a system with 15 GWh-energy storage and 100 MW-wind energy. To maximize electricity sales, the stored energy was depleted to near-zero levels, adhering to the constraints defined in equation (2). Wind-derived energy was curtailed when the energy storage system reached full capacity.

As shown in Figure 2(b), electricity sales increased with larger WT/$WEC_{th}$ and energy storage installations but plateaued or declined with excessive storage capacity. With smaller storage systems, the electricity sales rose as the storable energy, $Q_{\mathrm{in}}(t)$, increased. However, due to the finite availability of wind energy, $Q_{\mathrm{in}}(t)$ cannot grow indefinitely, even with larger storage facilities. The output energy, $Q_{\mathrm{out}}(t)$, is constrained by operational limitations, including the depth of discharge (DoD) in batteries, $H_2$ gasification in a $H_2$ tank, and heat release in the TES system. Excessive energy storage installations led to inefficiencies, as stored energy could not be fully utilized. In TES systems, for example, molten salt stored in the cold tank at 290°C continuously released heat.

These findings suggest that to maximize the effective utilization of stored energy, energy storage

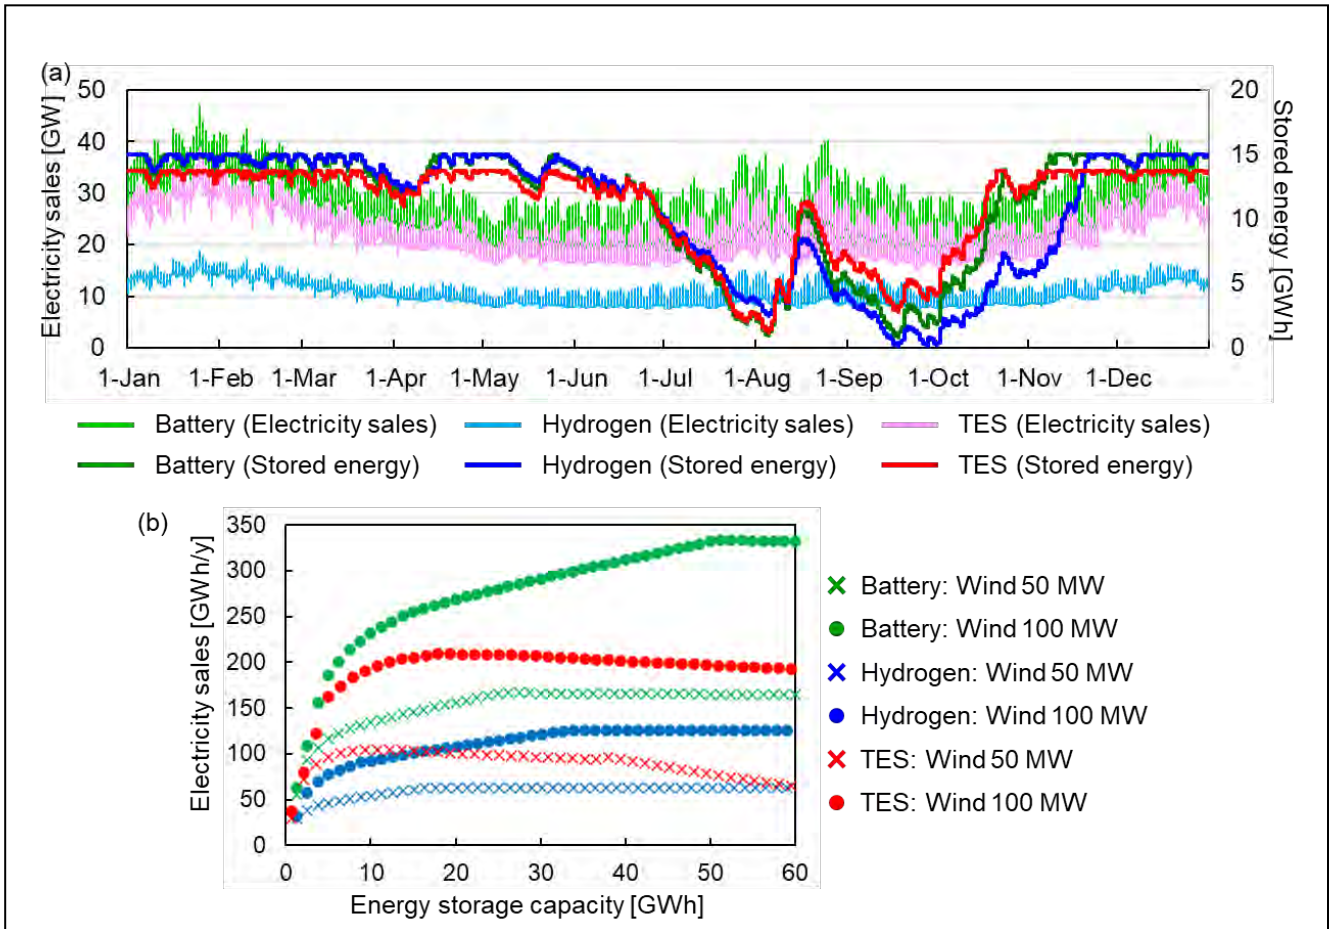

**Figure 2:** Results of energy flow simulations. (a) Hourly variation of the energy storage systems with 15 GWh energy storage and 100 MW class wind energy. (b) Electricity sold from the energy storage system.

capacities must be carefully balanced with the scale of WT/WEC$_{th}$ installations. Over-provisioning energy storage can lead to diminished returns due to storage inefficiencies and energy losses.

## Life Cycle Impacts of the Energy Storage Systems

Life cycle impacts of the energy storage systems were evaluated for various capacities of WT/WEC$_{th}$ and energy storage. LC-GHG and ARD were calculated considering the full life cycle—from production to disposal—of WT/WEC$_{th}$, energy storage, and other related utilities. The related utilities included an electrolyzer and fuel cell in the $H_2$ system, as well as a steam turbine and heat exchanger in the TES system. The GHG and ARD intensities, which were expressed LC-GHG and ARD per unit electricity sold respectively, are shown in Figure 3.

GHG intensities were compared in Figure 3 (a). In all systems, GHG intensities were high with small energy storages due to the large impact of WT/WEC$_{th}$ production. With a moderate number of large energy storage facilities, GHG intensities decreased as electricity sales increased. Conversely, excessive energy storage installations (except in the $H_2$ system) led to increased GHG intensities due to the high GHG emissions from the producing energy storage facilities. In the battery and TES systems, large wind energy installations reduced GHG intensities as electricity sales increased without a corresponding rise in LC-GHG. In the $H_2$ system, GHG intensities remained nearly constant regardless of the scale of WT and $H_2$ tanks. As the scale of WT and $H_2$ tanks increased, electricity sales grew; however, GHG emissions from production of electrolyzers and fuel cells also increased due to the need for large equipment.

The ARD intensities of the energy storage systems are shown in Figure 3 (b). Similar to GHG intensities, ARD intensities were high with very small or excessively large energy storage capacities. Appropriate energy storage capacities resulted in the lowest ARD intensities. Among the systems with 100 MW-wind energy, the TES system demonstrated the lowest ARD intensity.

## Applicability of the Energy Storage Systems

For large-scale WT/WEC$_{th}$ and energy storage

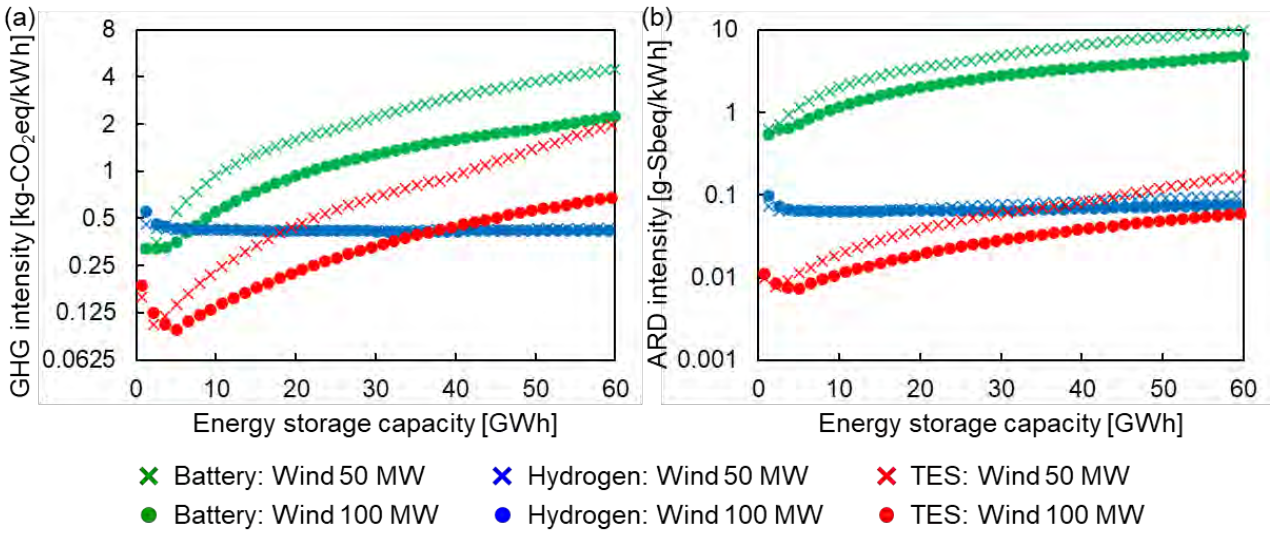

**Figure 3:** Life cycle impacts of the energy storage systems. (a) GHG intensity. (b) ARD intensity.

installations, $H_2$ or TES systems were more suitable due to their lower life cycle impacts compared to battery systems. Selecting the optimal energy storage system requires considering regional energy demands, including H2 for fuel and industry and heat for residential and industrial use. This study facilitates a quantitative assessment of the environmental performance of energy storage systems, encompassing their operation and offering insights into detailed energy storage installation planning.

Each scenario in this study analyzed only one type of energy storage. If a significant amount of VRE-derived electricity is supplied directly without an energy storage system, electricity from the energy storage system must be shut down frequently to meet the electricity demand. Long startup times may fail to supply electricity promptly during demand spikes. This highlights the need for a hybrid energy storage technology to ensure a stable and responsible electricity supply. System designs must account for both load-following capabilities and environmental impacts. While batteries offer fast response times, their LC-GHG and ARD are higher compared to $H_2$ storage and TES. Designing hybrid systems can achieve a balance between stable energy supply, operational flexibility, and minimizing environmental impacts. Enhancing the model developed in this study could support designing such integrated systems.

In this analysis, all facilities were assumed to be disposed of without recycling. Recycling energy storage components offers significant opportunities for improvement [16]. Additionally, operational adjustments could further optimize energy storage system performance [6]. Although the optimizations in this study are not comprehensive, the simulations conducted here demonstrate the potential for designing energy storage systems with low environmental impacts and high efficiency.

The installation of energy storage systems can also deliver broader societal and economic benefits. In regions where these systems are installed, life cycle impacts can be reduced, and the risk of blackouts from natural disasters minimized. Moreover, establishing new facilities such as energy storage systems could create jobs for operation and maintenance. Local socio-economic effects of adopting new technologies can be assessed using Input-Output (IO) models [17]. The energy storage system installation is expected to stimulate the local economy and drive regional revitalization. This study can provide quantitative parameters for analyzing these local socio-economic effects. Thus, energy storage systems may offer diverse applicability, contributing not only to carbon neutrality but also to regional development and resilience.

## CONCLUSIONS

In this study, we developed a model for energy storage systems integrated with VRE and conducted annual energy flow simulations alongside an LCA. The study provided a quantitative comparison of various energy storage technologies, evaluating electricity sales and life cycle impacts based on regional energy demands and storage system characteristics.

Designing energy storage systems in a given region should consider the electricity supply capacity, as this determines the energy demand that the system can meet. The minimum GHG and ARD intensities also depend on the type and scale of the storage system, underscoring the importance of designing systems considering

regional requirements.

Advancements in energy storage technology and operational strategies can enhance efficiency and adaptability to VRE variability. These systems have broad applications, from supporting carbon neutrality to regional revitalization. This study provided a framework for LCA of energy storage systems including operational considerations and would support to design of energy storage systems that are both environmentally sustainable and operationally effective.

# Optimisation of Carbon Capture Utilisation and Storage Supply Chains Under Carbon Trading and Taxation

**Hourissa Soleymani Babadi[a] and Lazaros G. Papageorgiou[a]***

[a] The Sargent Centre for Process Systems Engineering, Department of Chemical Engineering, University College London (UCL), Torrington Place, London WC1E 7JE, UK
* Corresponding Author: l.papageorgiou@ucl.ac.uk

## ABSTRACT

In recent years, several strategies have been developed to reduce the carbon dioxide ($CO_2$) released into the atmosphere. Carbon Capture, Storage and Utilisation (CCUS) is one of the proposed solutions. However, CCUS systems are expensive to install and operate. Furthermore, most studies in the literature have focused on $CO_2$ utilisation and storage separately, without accounting for the effects of other $CO_2$ emission management strategies. To address this gap, a Mixed Integer Linear Programming (MILP) framework for a supply chain network is developed in this work, incorporating $CO_2$ storage, utilisation, permit trading, and carbon emission taxation. Multi-criteria decision analysis (MCDA) techniques are implemented to select $CO_2$-based products for $CO_2$ utilisation. The MILP framework is set to achieve the maximum environmental and economic performance using a Multi-Objective Optimisation (MOO) approach. This involves using the ε-constraint method as a solution procedure to minimise the total cost of the supply chain network while maximising $CO_2$ reduction. A case study of supply chains in Germany is conducted to demonstrate the applicability of the model. The game theoretical Nash approach is successfully applied to determine the fair trade-off between the two objectives.

**Keywords**: CCUS Supply Chains, Multi Objective Optimisation, CO2 Trading and Taxation, Game theoretical Nash Approach.

## INTRODUCTION

The UN's International Panel on Climate Change states that the rise in $CO_2$, which constitutes the majority of greenhouse gas emissions, contributes to global warming and climate change. As a result, scientific research and governmental policies have been working towards the reduction of $CO_2$ emissions in processes across the board. Carbon Capture Utilisation and Storage (CCUS) is considered to be one of the solutions to lower greenhouse gas emissions. New CCUS routes, such as utilising $CO_2$ in the production of fuels, chemicals, and building materials, have the potential to use 5 Gt/year of $CO_2$ [1]. However, this is a challenging task due to the economic costs of developing CCUS products and technologies. Many products can be produced from $CO_2$ conversion, but not all these $CO_2$ utilisation reactions have the potential to be implemented profitably at scale. Therefore, implementing cost-effective CCUS supply chain networks at scale will be beneficial in overcoming the high cost of $CO_2$ combating development.

## LITERATURE REVIEW

Multi-Criteria Decision Analysis (MCDA) is a decision-making methodology that evaluates and ranks a set of $CO_2$-based products by considering multiple criteria, including environmental, social, and economic aspects. Pacheco et al. [2] conducted a comprehensive assessment of the techno-economic, environmental, and social aspects of 122 $CO_2$-based chemical compounds. Implementing six different MCDA methods, methanol, dimethyl ether, methane and a couple of other candidates were identified as the best products.

Hasan et al. [3] developed a CCUS network aimed at reducing $CO_2$ emissions in the United States by 50-80% while minimising the overall cost, incorporating the revenue generated from utilising $CO_2$ in enhanced oil recovery. The approach involved optimising the selection of the emission sources, capture processes and

materials, pipelines, as well as the $CO_2$ utilisation/storage amount. Zhang et al. [4] proposed a superstructure in Northeastern China that includes underground storage and the utilisation of $CO_2$ through several possible conversion paths. Although $CO_2$ conversion may generate a carbon-neutral cycle, the result emphasised the increased costs with more $CO_2$ utilisation. A multi-objective optimisation framework was proposed by Leonzio et al. [5] for CCUS deployment, considering cost as the economic performance measure and $CO_2$ reduction as the environmental performance measure.

In addition to CCUS, various methods exist for carbon emission management, such as introducing carbon pricing. Carbon pricing can take different forms, including carbon taxes or carbon emissions permit trading. The European Union Emissions Trading System (EU ETS), established in 2005, is the oldest cap-and-trade system. This system works by imposing a cap (limit) on the $CO_2$ that can be emitted from each emission source. Within this cap-and-trade framework, emission sources can buy or sell carbon emission permits to achieve their emission reduction targets in the most cost-effective way [6,7]. Considering the $CO_2$ market within the scope of carbon management, Zhang et al. [8] developed a mathematical model integrating CCS and carbon trading. Various price levels for excess emissions exceeding the allocated allowances across several power plants in Qatar were considered. To ensure fair competition among these plants, the game theoretic Nash approach was applied to optimise the cost of CCS infrastructure.

In this work, MCDA methods were employed to identify suitable $CO_2$ utilisation products. Drawing inspiration from the models proposed by Zhang et al. [4] and Zhang et al. [8], a framework was developed for CCUS supply chains incorporating carbon trading and taxation aspects. The ε-constraint method was used to achieve both $CO_2$ reduction maximisation and cost minimisation of the supply chain network. Furthermore, to determine the fair trade-off between the two objectives, the game theoretical Nash approach was applied. A case study focusing on supply chains in Germany was carried out to evaluate the performance of the model.

## PROBLEM STATEMENT

Each emission source has a maximum allowable $CO_2$ emission limit. As shown in the **Figure 1**, the remaining emissions must be managed through CCUS or non-physical carbon management platforms. The first platform involves the physical $CO_2$ supply chain network, where emissions are captured and sent to utilisation or storage sites. The second platform is the non-physical $CO_2$ management system, which allows trading $CO_2$ permits between emission sources or paying a tax to release an excessive amount of $CO_2$ into the atmosphere.

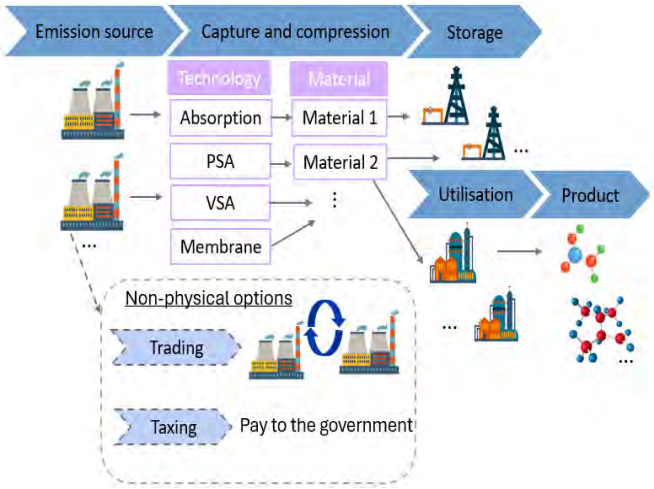

**Figure 1.** Superstructure of CCUS supply chains under carbon trading and taxation.

The overall supply chain can be stated as follows:

**Given:** (a) emission sources with their location, annual $CO_2$ emission and flue gas compositions; (b) combinations of technologies for $CO_2$ capture and compression with the corresponding materials and cost parameters; (c) cost parameters for the $CO_2$ transportation via pipelines; (d) locations of $CO_2$ storage and utilisation sites, their capacities, and the products produced at each utilisation site; (e) for all $CO_2$ utilisation pathways: unit production costs, selling prices, reactions and conversion rates of products; (f) $CO_2$ permit price; (g) carbon tax rate.

**Determine:** (a) $CO_2$ flow rate to be captured from each selected source; (b) $CO_2$ capture technology and material for each selected source; (c) storage and utilisation sources to be used and the amount of $CO_2$ to be utilised/stored; (d) production quantity of each product; (e) pipeline network connecting source and storage/utilisation sites; (f) the quantity of $CO_2$ permit traded between the emission sources; (g) the amount of $CO_2$ released into the atmosphere, with the corresponding tax payment made to cover this release; (h) cap percentage for each emission source; (i) the cost of: flue gas dehydration, $CO_2$ capture and compression, transportation, $CO_2$ storage, $CO_2$ permit trading, and the tax payment; (j) Pareto optimal solutions; (k) game-theoretical Nash approach solution.

**So as to** (a) minimise the total cost; (b) maximise the total $CO_2$ reduction.

**Assumptions:** (a) capture plants and $CO_2$ sources are located in the same place; (b) only one technology-material combination can be selected for $CO_2$ capture at each source; (c) $CO_2$ transportation is possible just through pipelines; (d) the production and selling price of the $CO_2$-based products are fixed; (e) carbon trading occurs within the domestic platform of a country, with no credits being bought or sold internationally; (f) the carbon

tax rate is fixed and uniform across emission sources; (g) a flexible cap is considered for each emission source; (h) carbon permits are traded at a single price.

## METHODOLOGY AND MATHEMATICAL FORMULATION

### Methodology

Using the combination of four common MCDA methods in the CCUS field (TOPSIS, MARCOS, EDAS, VIKOR) returns a ranked list of all alternative $CO_2$-based products based on their scores [9]. Each MCDA method determines the rankings using a mathematical scoring system that calculates the distance of each data point from the ideal and negative ideal solutions.

Regarding the supply chain aspect of this paper, the overall problem was formulated as a Mixed Integer Linear Programming (MILP) model which integrates process, tax and trading constraints in addition to accounting for cost calculations. A brief outline of some of the model equations is next given. To facilitate the mathematical formulation, the indices and sets are used as follows: $i \in I$ represents the emission sources, $j \in J$ the $CO_2$ capture technologies-materials, $k \in K$ the storage and utilisation sites and $p \in P$ represents the $CO_2$-based products. Furthermore, subset $S \subset K$ is especially for the storage site.

### Mathematical Formulation

**Objective functions:** The supply chain problem is formulated as an MOO model with two objective functions. The first objective, total cost ($Cost$), is minimised and includes the cost of each emission source, $CostI_i$ , the production cost of the $CO_2$-based products, $PRC_p$, and the revenue from selling the products, $Re_p$ (see equation (2)). The second objective considers the maximisation of the total amount of $CO_2$ reduction ($CR$), calculated as the sum of the $CO_2$ captured and sent to the storage and utilisation sites, $CK_{ik}$ (see equation (4)).

$$min \quad Cost \tag{1}$$

$$Cost = (\sum_{i\in I} CostI_i) + \left(\sum_{p\in P} PRC_p - Re_p\right) \tag{2}$$

$$\max \quad CR \tag{3}$$

$$CR = \sum_{i\in I, k\in K} CK_{i,k} \tag{4}$$

**Cost calculation:** The supply chain cost for each emission source is calculated using equation (5) which consists of several components: the cost of flue gas dehydration, $FDC_{i,j}$; the investment and operational cost of $CO_2$ capture and compression, $CIC_{i,j}$ and $COC_{i,j}$; the investment and operation cost of transportation, $TIC_{i,k}$ and $TOC_{i,k}$; the cost of $CO_2$ storage, $SC_{i,k}$; the cost of $CO_2$ permit trading, $CTC_i$; and the tax payment. Ravi et al. [10] provided detailed mathematical formulations for calculating the costs of flue gas dehydration, $CO_2$ capture and compression, transportation, and $CO_2$ storage. All these cost components depend on the amount of $CO_2$ captured and sent to storage and utilisation sites ($CK_{ik}$). The tax payment is calculated by multiplying the tax rate per tonne of $CO_2$ emissions (denoted as the parameter $Tax$), by the amount of excess $CO_2$ emissions subject to taxations, $TaxC_i$.

$$CostI_i = \left(\sum_{j\in J} FDC_{i,j} + CIC_{i,j} + COC_{i,j}\right) + \left(\sum_{k\in K} TIC_{i,k} + TOC_{i,k}\right) + \left(\sum_{k\in S} SC_{i,k}\right) + CTC_i + (TaxC_i \cdot Tax) \quad \forall i \in I \tag{5}$$

**$CO_2$ Mass balance:** Equation (6) represents the $CO_2$ mass balance for each emission source. Considering variable emission cap for each source, only (1-$\varphi_i$ ) percent of the total emissions, $E_i$, from each emission site, can be released into the atmosphere without any consideration. According to the cap, $\varphi_i E_i$ is the amount of $CO_2$ emission that each emission source should manage using the available options: capturing and sending $CO_2$ to the storage and utilisation sites, $CK_{ik}$; trading $CO_2$ by selling $CO_2$ permits to other domestic emission sources, $Tr_{ii'}$, or buying the $CO_2$ permits from the domestic sources, $Tr_{i'i}$. Another option exists that allows the emission source to pay tax for excess $CO_2$ emissions ($TaxC_i$).

$$\varphi_i E_i = \sum_k CK_{ik} + \sum_{i'} (Tr_{i'i} - Tr_{ii'}) + TaxC_i \quad \forall i \in I \tag{6}$$

**Trading and taxing constraints:** Each emission source is not allowed to sell carbon permits to other plants while it is paying taxes and/or buying $CO_2$ permits from the domestic market. This is facilitated through constraints (7) and (8), in which $B$ is a big number, and the binary variable $H_i$ equals one when an emission source pays a tax and/or purchases permits for excess $CO_2$ emissions. Furthermore, more than 50% of the $CO_2$ emissions are constrained to be managed through physical CCUS (see equation (9)).

$$TaxC_i + \sum_{i'\in I} Tr_{i'i} \le B\, H_i \qquad \forall i \in I \tag{7}$$

$$\sum_{i'\in I} Tr_{ii'} \le B\,(1 - H_i) \qquad \forall i \in I \tag{8}$$

$$0.5 \sum_{i\in I} \varphi_i\, E_i \le CR \tag{9}$$

**Process constraints:** Equations (10) to (13) represent some of the process constraints in the model. For each emission source, at most one capture technology and material can be selected, as shown in constraint (10). To ensure $CO_2$ will be captured only if at least one storage and/or utilisation site is chosen, equation (11) is used in which $B$ is a big number. The binary variables, $X_{ij}$ and $Y_{ik}$, are equal to one when $CO_2$ is captured from the emission source $i$ with the capture technology material $j$ and sent to the storage and/or utilisation site $k$. The quantity

of the captured $CO_2$ is calculated in (12). The symbol $FR_{ij}$ represents the fraction of $CO_2$ captured from each emission source, which is constrained by an upper-bound $f_j^u$ specific to each capture technology and material, as can be seen in constraint (13).

$$\sum_{j\in J} X_{ij} \leq 1 \quad \forall i \in I \tag{10}$$

$$CK_{ik} \leq B\, Y_{ik} \quad \forall i \in I, k \in K \tag{11}$$

$$\sum_{k\in K} CK_{ik} = \sum_{j\in J} E_i \cdot FR_{ij} \quad \forall i \in I \tag{12}$$

$$FR_{ij} \leq f_j^u\, X_{ij} \quad \forall i \in I, j \in J \tag{13}$$

## SOLUTION APPROACH

### ε-Constraint method

An ε-constraint method [11] is applied to solve the multi-objective optimisation problem. By keeping one objective as the objective function and the other as a constraint (see formulation (14)), along with equations (2) and (4) to (13), the obtained solutions produce Pareto optimal points, any of which can be selected for the CCUS supply chain.

$$min \quad Cost \tag{14}$$
$$s.t. \quad CR \geq \varepsilon\,;$$

### Nash game-theoretic approach

The Nash bargaining approach represents a fair solution for the economic and environmental aspects of the supply chain, given the status quo point. Using this approach, the objective is to maximise the product of the deviations of the optimisation variable cost from the maximum cost ($cost^{quo}$) and the deviation of the optimisation variable $CR$ from the minimum $CO_2$ reduction ($CR^{quo}$) shown in equation (15).

$$Max \quad \mu = (cost^{quo} - cost)\,(CR - CR^{quo}) \tag{15}$$

The nonlinearity of the above equation causes challenges. To address this, logarithmic operation and separable programming approach are applied by defining piecewise linear functions of $n$ prespecifies grid points, converting the objective function into equation (16). By defining SOS2 variables ( $z1_n$ and $z2_n$) and the corresponding values for the cost and $CO_2$ reduction at each grid point ( $\widetilde{cost}_n$ and $\widetilde{CR}_n$ respectively) the nonlinearity is handled. Gjerdrum et al. [12] provides a comprehensive description of game-theoretic Nash approach formulation and linearisation of the Nash objective function. Maximising the Nash variable, $\mu'$, subject to equations (2), (4) to (13), and (16) results in a fair solution for both objectives.

$$Max \quad \mu' = \sum_n z1_n\, ln(cost^{quo} - \widetilde{cost}_n) + \sum_n z2_n\, ln(\widetilde{CR}_n - CR^{quo}) \tag{16}$$

## CASE STUDY

To demonstrate the applicability of the proposed MOO model, a case study of a supply chain network in Germany is conducted. This supply chain network considers 70 power plants with three power generation sources, including coal, oil and gas, as well as 19 storage sites and five utilisation sites. Each utilisation site can either directly convert $CO_2$ to specific products or use the $CO_2$ in the production process of that product.

The required data for the emission sources regarding the estimated power generation and latitude and longitude of the power plants are collected from the Global Power Plant Database [13]. Afterwards, $CO_2$ emission data are obtained for these emission sources using plant efficiency and emission factors. The total $CO_2$ emission from these 70 sources is 77562 kt/year. An emission management range of 60–80% is considered. Twelve combinations of absorption, membrane, PSA, and VSA-based technologies with different materials are considered for $CO_2$ capture and compression. Each material-technology combination has upper and lower bounds on the input $CO_2$ composition it can handle. In this study, the upper bound on the fraction of $CO_2$ that can be captured, $f_j^u$, assumed to be 90%.

By applying the MCDA methods, 70 $CO_2$ utilisation products and pathways are compared across ten criteria, such as product demand, market value, technology readiness level, and others. Methane, cement, and ethylene ranked among the top choices and are selected as the $CO_2$-based products for the supply chain network of this paper. $CO_2$ curing in the cement industry especially improves the mechanical properties of cement-based products and transforms $CO_2$ into thermochemically stable carbonates. In Germany, where cement production is one of the main sources of $CO_2$ emissions, capturing and reusing $CO_2$ within cement plants is particularly beneficial. Among the five considered utilisation sites, two of them can produce ethylene, two of them methane and only one of them can be used for cement.

## RESULTS AND DISCUSSION

The multi-objective optimisation of the developed MILP model is implemented using Gurobi 11.0.0 in GAMS 46.1.0 with an optimality gap set to 0.1%, using a Dell workstation with Intel® Core™ i9-10980XE CPU @ 3.0 GHz and 128 GB RAM. First, the MOO problem is solved using the ε-Constraint method by fixing $\varepsilon$ to 13 values between $CR_{eps}^{min}$ and $CR_{eps}^{max}$. The value for $CR_{eps}^{min}$ is obtained through a single optimisation with the objective of

cost minimisation, and the value for $CR_{eps}^{max}$ is obtained with the objective of maximising the $CO_2$ reduction. The MOO model consists of 21,011 equations and 24,902 variables, of which 2,660 are discrete variables. The entire process to find Pareto optimal solutions (see **Figure 2**) with different values of ε takes 90.8 s CPU time with an average of 6.9 s for each iteration. The total cost of the supply chains gradually increases as the amount of $CO_2$ reduction increases.

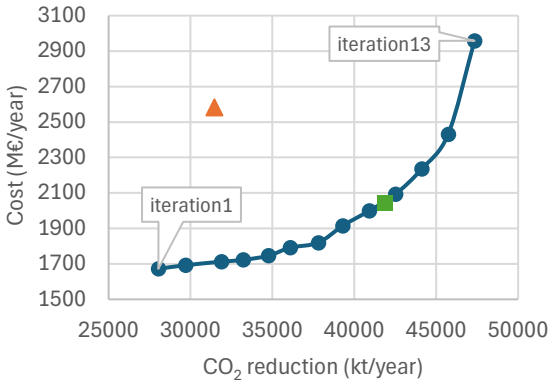

**Figure 2.** Pareto front and the Nash approach solution: • Pareto optimal; ▲ ($CR^{quo}$ , $cost^{quo}$ ); ■ Nash result.

**Figure 3** illustrates the contribution of each component of the supply chain network to the total cost for some iterations on the Pareto curve. It is important to note that since trading is restricted to the domestic market, the cost of $CO_2$ permit trading incurred by buyers will be offset by the benefit for the emission sources who sell the permits. Therefore, the net contribution of carbon trading to the total cost of the supply chain network is zero. On another note, the cost of flue gas dehydration, along with the cost of carbon capture and compression, is high, and this creates a trade between cost minimisation and $CO_2$ reduction because $CO_2$ capture is one of the bottlenecks of the process. The production cost of $CO_2$-based products is another economic concern for CCUS. However, the revenue obtained from selling these products can offset the economic challenges of the utilisation processes. The cost of $CO_2$ storage has a negligible effect on the total costs.

**Table 1** represents the amount of $CO_2$ being covered across different supply chain sections in some iterations that have been chosen to demonstrate the progress of the solver. As $CO_2$ reduction increases, the contribution of $CO_2$ utilisation and storage grows, while $CO_2$ emissions managed through tax payments decrease. By the final iteration on the Pareto front, the amount of $CO_2$ emissions covered by tax payments reaches zero. However, due to capacity limits for the storage and utilisation sites, $CO_2$ trading is an important component of $CO_2$ management to provide the $CO_2$ mass balance.

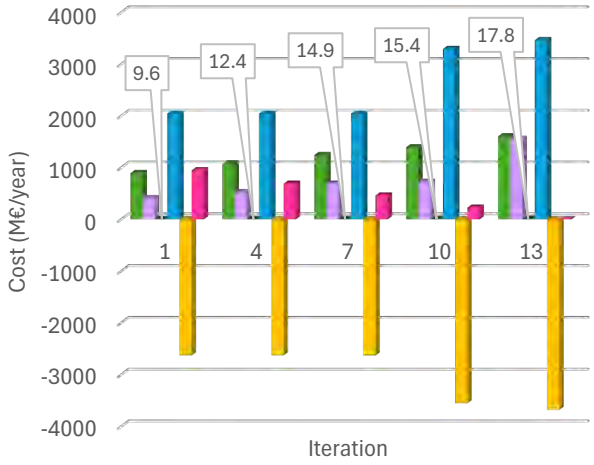

**Figure 3.** Cost breakdown for selected iterations of the ε-Constraint method: total cost of ■ flue gas dehydration and carbon capture and compression; ■ transportation; ■ storage; ■ production of $CO_2$-based products; ■ revenue from selling the products; ■ taxes.

**Table 1.** Management paths for $CO_2$ emissions (Mt/year) in selected iterations and Nash equilibrium.

| | Utilisation | Storage | Permit trading | Tax payment |
|---|---|---|---|---|
| **1** | 10.4 | 17.6 | 8.6 | 18.9 |
| **4** | 10.4 | 22.8 | 10.3 | 13.8 |
| **7** | 10.4 | 27.4 | 11.8 | 9.2 |
| **10** | 14.1 | 28.4 | 13.3 | 4.5 |
| **13** | 14.7 | 32.7 | 13.6 | 0.0 |
| **Nash** | 14.6 | 27.2 | 13.5 | 5.1 |

In order to find the point where cost and $CO_2$ reduction are at equilibrium, the game theoretic Nash approach is implemented in the GAMS using the Gurobi solver. The model consists of 21,015 equations and 24,933 variables, of which 2,660 are discrete variables. The number of grid points for the linearisation in equation (16) is 15, the CPU time required to obtain the solution is 6.3 s, and the relative gap obtained was 0.1%. The quo stat point is obtained with a single objective optimisation in a scenario where trading is not allowed, and all emission sources must manage 80% of their total $CO_2$ emissions. **Table 1** represents the amount of $CO_2$ being covered through different supply chain sections when the Nash equilibrium strategy is considered. The Nash solution is presented in **Figure 2** with a total cost of 2046.6 M€/year (see **Table 2** for the cost breakdown values) and a $CO_2$ reduction value of 41859.8 kt/year, of which 35% is achieved through $CO_2$ utilisation and 65% through storage. Among the 70 emission sources, 10 participate in the CCUS,

using 7 storage sites and 3 utilisation sites to produce 1,660 kt/year of $CO_2$-based ethylene and cure 1,1791.9 kt/year of cement. s

**Table 2.** Total cost breakdown of the Nash result.

| Cost breakdown | (M€/year) |
|---|---|
| Dehydration, capture and compression | 1357.9 |
| Transportation | 634.5 |
| Storage | 14.8 |
| Production of $CO_2$-based products | 3461.5 |
| Tax payment | 256.3 |
| Revenue from selling the products | 3678.3 |

## CONCLUSIONS AND FUTURE WORK

A multi-objective MILP modelling framework is presented for the optimisation of carbon capture utilisation and storage supply chains, which is applied to a case study in Germany. The MOO model demonstrates that the total cost of the proposed supply chain network increases nonlinearly with increasing $CO_2$ reduction quantities. As a guide to decision-makers, the Pareto front of these trade-offs is found. The fair trade-off between these two objectives is determined using the game theoretical Nash approach, and the resulting solution is selected as the optimal strategy in this study. This strategy achieves a $CO_2$ emissions reduction of approximately 54% from the examined sources, corresponding to ca. 7% of $CO_2$ of current German emissions. The estimated cost of €2 billion corresponds to ca. 0.05% of German GDP. This is achieved by sending two-thirds of mitigated $CO_2$ emissions into storage and utilising another third for the production of cement and ethylene. These results rely on assumptions about production, capture, compression, storage and transportation costs, which could affect the profitability of the chosen $CO_2$ management framework. More investigations and technical progress in these areas will enhance the cost efficiency of the optimal $CO_2$ management framework.

## ABSTRACT

Industries with low-temperature heat demand, such as laundry and syrup sectors, heavily rely on natural gas-fired boilers, posing challenges to achieving net-zero emissions by 2050. Like hard-to-abate sectors, they must explore energy transition strategies, including heat recovery, fuel substitution, or carbon capture, to reduce $CO_2$ emissions. This paper evaluates the potential of energy transition in these sectors through case studies, using a mixed integer linear programming (MILP) approach. The analysis focuses on three key performance indicators (KPIs): specific energy consumption, $CO_2$ reduction, and variable costs. By 2050, the adoption of heat pumps and waste valorization emerge as the most promising solutions for the syrup and laundry sectors. Specifically, the use of heat pumps reduces energy demand by at least 50%, while on-site biofuel production can fully replace natural gas consumption, thus eliminating dependency on external energy sources. The analysis highlights the importance of sector-specific strategies to meet climate targets, offering a pathway for low-temperature heat industries to reduce emissions while addressing economic and technological constraints.

## 1. INTRODUCTION

The goal of achieving net zero emissions by 2050 has driven European industries to intensify their efforts toward implementing $CO_2$ reduction strategies. While hard-to-abate sectors like steel, cement, glass, and lime production, etc., characterized by high-temperature energy demands, are the focus of much attention, other sectors characterized by lower emissions and typically low to moderate temperature heat demands are often overlooked. However, these sectors collectively contribute a substantial share of the total industrial emissions of a country [8]. The potential of energy transition to low-emission pathways in these sectors needs to be detailed.

In this study, two low-temperature (low-T) industries, syrup manufacturing, and laundry, are selected as case studies to demonstrate a methodological approach for addressing the energy transition in low-T industries. Key strategies leading to reduced emissions in such industries include heat recovery (via Heat Pumps), fuel substitution (e.g., hydrogen, biofuels), electrification (electric boilers), and $CO_2$ capture (CC). Previously, other research also explored energy transitions in low-T industries [2][5]. Lastly, Best Available Techniques (BAT) documents also provide valuable insights into how such industries can reduce energy consumption (European Commission. Joint Research Centre, 2019). Although previous research tried to explore the potential of these pathways for low-T industries, a comprehensive techno-economic comparison, ranking these technologies from a future energy scenario point of view, is still lacking.

This study examines the potential energy savings and required investments associated with various energy transition strategies in low-T industries through a

detailed techno-economic comparison. Multiple energy transition pathways, including fuel switching, CC, electrification, and heat recovery, are evaluated using key performance indicators (KPIs) such as relative energy consumption, total emissions, and total cost. Furthermore, a superstructure-based optimization is conducted to rank these pathways under different future energy scenarios, which dictate the prices of energy commodities and emissions. This comprehensive approach provides a robust analysis, supporting informed decision-making to identify the pathways that will play a crucial role in reducing emissions in low-T sectors under future scenarios.

# 2. METHODOLOGY

## 2.1 Process Description

This study analyzes two key sectors: laundry and syrup production, selected from industries located in the Liège Province, Belgium. By focusing on one food industry and one sanitation-related industry, the analysis highlights sector-specific opportunities for transitioning to more sustainable energy solutions.

The **laundry sector** cleans textiles using water, air, and energy. A standard cleaning cycle includes pre-washing (30-45°C), washing (45-60°C), rinsing (20°C), spinning, and drying (70-120°C). For healthcare textiles, an additional disinfection step (60-90°C) may be incorporated, achieved through thermal treatment or chemical agents. When chemical disinfection is used, a neutralization stage is required to restore fabric pH, followed by rinsing to remove residual chemicals before spinning and drying. Washing typically employs hot water, heated directly by natural gas (NG) boilers or indirectly via steam through heat exchangers, while cold water is used during rinsing to remove detergent residues. Drying occurs in two phases: mechanical dewatering (spinning or compression) followed by thermal drying, where hot air, often heated by steam, removes the remaining moisture from the textiles [1].

The **syrup production** sector, which can be linked to the sugar industry, is more complex regarding its processes. Two types of syrup can be considered: one made directly from fruit and the other from cereals. The primary distinction between these two lies in the intermediate process. The fruit-based syrup requires cooking, while the cereal-based syrup involves hydrolysis. In both cases, it begins with the cultivation and harvesting of crops. In the plant, the initial step involves preparing the raw materials—either washing, cutting, or milling—requiring electricity consumption [10]. Then, both hydrolysis and cooking demand an energy source to achieve a medium temperature of approximately 100°C. Following these steps, the product undergoes filtration, typically involving mechanical technologies like decantation. The filtrate is then concentrated (80-120°C), transforming the fruit juice or cereal mixture into syrup. The common method for juice concentration is evaporation, particularly quadruple-effect evaporation [9]. This technology reduces energy demand for evaporation by approximately four times, as it recycles the energy from the produced steam. This step is nevertheless energy intensive. Finally, refining (105°C), cooling (65°C), and packaging (65°C to 15°C) can occur.

## 2.2 Superstructure Development

To conduct the optimization analysis, a general superstructure is developed for both industries, incorporating many possible energy transition options. Blueprints (BPs) are first created as equation-based models that include detailed mass and energy balances, as well as cost parameters for each process. These BPs are derived from BAT documents and relevant literature. BPs for all processes in both industries, along with available energy transition options, are integrated into the superstructure.

The superstructure contains the following options for energy transition in both sectors; 1) Heat recovery (via utilization of heat pumps, recovering heat from external and internal sources), 2) Fuel-switching (bio-fuels and $H_2$) 3) Electrification and cogeneration 4) Solid and Liquid waste valorization and 5) CC.

The energy demand in the syrup and laundry sectors is primarily met using NG boilers and electricity. Therefore, the base case configuration for each sector involves a NG-fired boiler with an assumed efficiency of 80% for steam generation. Both can implement fuel substitution, electrification, heat recovery, and CC.

There is considerable flexibility in the choice of fuel for boilers, with options including hydrogen, biomass, biogas, and other alternatives to reduce $CO_2$ emissions associated with NG combustion. Additionally, these boilers can be electrified to achieve similar outcomes. Liquid waste can be treated in water treatment units, where biogas is recovered through anaerobic digestion. Given that water treatment plants are already required in both sectors, biogas is readily accessible. For the syrup sector, solid waste, such as peels, rooted feedstocks, and cereal residues, can be composted to produce biomass. This biomass can either be used as a solid fuel for boilers or as an input for biomethanation. Through biomethanation, organic matter is converted into a combustible biogas, which can be further refined into biomethane. However, solid waste is often prioritized for reuse in crop cultivation, which may limit its availability for energy production. Bio-sourced fuels, regardless of their origin, can thus supply boilers, reducing the reliance on fossil fuels. Additionally, the produced gases can be used to power cogeneration units, thereby improving overall energy efficiency.

Heat recovery is another important option for these sectors. It can be achieved through heat pumps (HP),

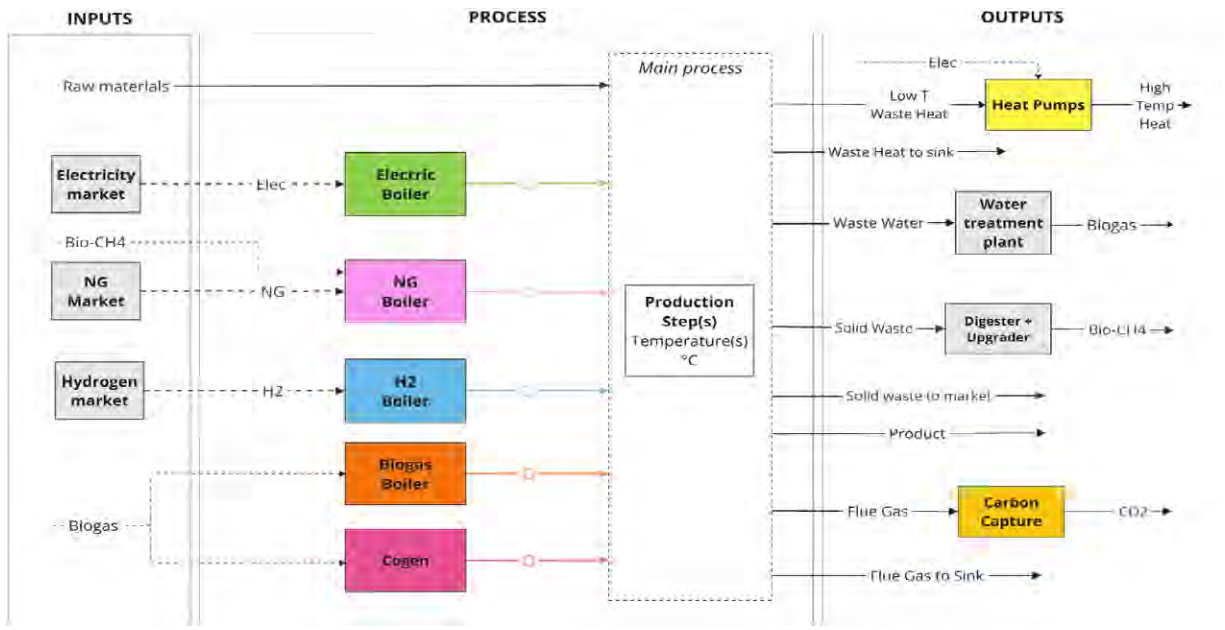

**Figure 1.** A general superstructure for the energy transition

which capture and reuse waste heat, further optimizing energy performance. Depending on the availability of a heat source inside or outside of the process, these are described as internal or external HP.

Lastly, the potential role of CC should be considered: if NG boilers are retained, CC may be necessary to achieve net-zero emissions by 2050. In this context, CC refers to a post-combustion capture process based on chemical absorption using amine solvents.

Figure 1 illustrates a general superstructure for the energy transition in these sectors incorporating all the options discussed above.

Assumptions are made regarding the efficiency and performance of key technologies. For fuel substitution, it is assumed that green electricity operates with an energy efficiency of 90–100%, while green hydrogen is characterized by an energy density of 34 MWh/t with an energy efficiency close to 90%. Biofuels such as biomass and biogas, are considered less efficient, with a thermal efficiency of 70% [3]. In the context of heat recovery, HP functioning within a temperature range of 100°C to 200°C are expected to achieve a coefficient of performance (COP) ranging between 2 and 3 [12]. For CC, post-combustion technologies are assumed to capture at least 90% of $CO_2$ emissions, with energy requirements estimated between 0.9 and 1.4 MWh/t of $CO_2$ captured [6].

## 2.3 Optimization Problem and KPIs

Once the superstructure is developed, the next step is to solve the optimization problem. For this, the Osmose Lua optimization framework [11]. a tool to optimize process and energy systems, is utilized to solve mixed-integer linear programming (MILP)-based formulation containing objective functions of total specific cost and emissions. It optimizes the superstructure of the BPs models, serving as a decision-support tool to identify the most effective $CO_2$ reduction strategy tailored to each sector's specific needs.

The evaluation of various strategies for each sector is based on three KPIs: specific $CO_2$ emissions, specific energy consumption, and specific variable costs.

The two objective functions employed for the evaluation are specific variable cost (€/t of materials) and specific emissions ($tCO_2$//t of materials) and the MILP problem to be solved is outlined in equations (1-4).

$$Annual\ CAPEX_{n,i} = \sum_u \left( CAPEX(u_{ref}) \cdot \left(\frac{s}{s_{ref}}\right)^{0.6} \cdot \frac{CEPCI_{2023}}{CEPCI_{ref}} \cdot i \cdot \frac{(i+1)^n}{(i+1)^{n-1}} \right) \quad (1)$$

$$Annual\ OPEX = \sum_u \left( \sum_e \left( C_{e_u} \cdot \dot{Q}_{e_u} \right) + \left( C_{em_u} \cdot \dot{m}_{em_u} \right) \right) \cdot hr \quad (2)$$

$$\min Cost \left( \frac{€}{ton\ of\ material} \right) = \frac{Annual\ OPEX + Annual\ CAPEX}{ton\ of\ product\ per\ year} \quad (3)$$

$$\min Emissions \left( \frac{ton\ of\ CO_2}{ton\ of\ material} \right) = \frac{\sum_u (\dot{m}_{em_u}) \cdot hr/1000}{ton\ of\ material\ per\ year} \quad (4)$$

CAPEX is annualized over 25 years ($n$) with a 3% discount rate ($i$), $u$ is the unit, $s$ the unit size, $ref$ the reference unit for CAPEX calculations. For OPEX calculation, $C$ represents cost, $e$ the energy source, $\dot{Q}$ energy, $\dot{m}$ mass flow rate, $em$ emissions, and $hr$ total operating hours (8000). CAPEX excludes constant equipment costs across configurations, and OPEX omits raw material costs, as they remain unchanged.

Equation (2) treats energy and emission costs as

input variables, based on future energy projections. The electrification scenario from EnergyVille's Paths2050 study (TIMES-BE) has been selected to provide marginal production costs for electricity, hydrogen, and natural gas, along with $CO_2$ emission costs [7]. This choice favors renewable energy and more particularly electricity use. Table 1 gives a detailed view of the cost. Carbon taxes are evaluated at 350 €/t$CO_2$ for 2050.

**Table 1:** Marginal production costs of energy commodities, based on the Paths2050 study electrification scenario for 2050 [7]

| Price (€/MWh) | Electricity | $H_2$ | Natural Gas |
|---|---|---|---|
| | 56 | 78 | 35 |

## 3. RESULTS AND DISCUSSIONS

### 3.1 Blueprint Validation

Table 2 compares the specific energy consumption derived from the BPs and the data available in the literature. The calculated values fall within the range reported in the literature, confirming the validity of the mass and energy balances for the syrup and laundry sectors.

**Table 2:** Specific energy demand comparison for BPs model and literature [1] [4]

| Sector | Unit | BP model | Literature |
|---|---|---|---|
| Syrup | MWh/t fruits-cereals | 0.23-0.26 | [0.05; 0.6] |
| Laundry | MWh/t laundry | 2.21 | [1.3; 4.6] |

### 3.2 KPI evaluation

First, the specific energy demand and Scope 1 emissions for the laundry and syrup sectors are analyzed for each pathway toward achieving net-zero emissions. The results are presented in Figure 2.

In the laundry sector, the base case scenario consumes 2.21 MWh/t of laundry and generates 0.4 t$CO_2$/t of laundry. Transitioning to hydrogen or electrification results in similar energy demands, with less than 10% variation, due to comparable efficiencies with NG. Nevertheless, electricity and hydrogen offer the advantage of eliminating Scope 1 emissions. Biogas has the same advantage (as it gives biogenic emissions that are not accounted for) but leads to a 20% increase in energy demand compared to NG boilers. In contrast, the laundry sector can adopt CC without going for fuel substitution. This approach results in the highest energy demand but still emits approximately 10% of the $CO_2$ produced from NG, due to capture efficiency. Lastly, external HP use reduces the base case energy consumption by more than half, achieving 0.87 MWh per ton of product, while maintaining zero Scope 1 emissions. Alternatively, a simple electrification with no HP also decreases energy demand (but to a lower extent) and reaches zero scope 1 emissions. In conclusion, for the laundry sector, heat recovery offers the greatest benefits: HP strongly reduce energy demand, also decreasing Scope 2 emissions associated with electricity consumption.

For the syrup sector, the base scenario depicts an energy consumption of 0.26 MWh/t of cereals and 0.05 t$CO_2$/t of cereals. Among the transition pathways, the highest energy demand is associated with CC, then NG substitution by biogas, primarily due to the relatively low efficiency of biogas considered in this study. These paths increase energy consumption by at least 20% while achieving $CO_2$ emission reductions of 50% to 90% compared to the base case. Conversely, the lowest energy demand is linked to internal HP utilization with NG, resulting in a 65% reduction in energy demand. To combine energy consumption reduction while minimizing reliance on NG, HP can also be coupled with cleaner energy sources such as electricity, hydrogen, or biogas. The valorization of biogas from biodigesters, when combined with HP, already achieves a 15% reduction in energy consumption and eliminate Scope 1 $CO_2$ emissions. In the food industry, internal HP enable heat recovery from the cooling process to warm water for cooking purposes. More particularly, quadruple effect evaporation exhibits advantages for HP use. The use of electricity and hydrogen eliminates Scope 1 emissions while maintaining energy consumption levels close to the base case, with only a 5% to 10% variation.

Next, the economic results are discussed. Figure 3 provides the installation and operational costs associated with deploying new units in the laundry and syrup sectors for each pathway. The variable costs linked to the operation of NG boilers in the base case scenario are calculated at 230 €/t for laundry processing and 29 €/t for cereal production. The laundry sector demonstrates the lowest operational costs when utilizing biogas (93% reduction). Biogas is assumed to be produced and used onsite, incurring mainly capital costs for the digester and minimal operating expenses. The laundry sector is expected to integrate biogas production within its existing wastewater treatment plants, which should generate sufficient biogas to meet energy demands. A sensitivity study should be done to assess plant capacity, validate biogas availability, and refine energy requirements for anaerobic digestion, where additional costs are primarily limited to electricity for mixing and pumping. Following biogas, electricity use also demonstrates greater cost-effectiveness compared to the base case scenario, resulting in a cost reduction of nearly 50% with electrification and up to 70% with the integration of HP, despite their higher capital investment compared to conventional boilers. This observation aligns with the 2050 "EnergyVille" scenario proposed by VITO, which prioritizes

electrification as a key pathway for defossilisation. In contrast, CC is the least economically favorable option. The laundry sector's has a relatively low $CO_2$ emissions capacity, resulting in an increase in the specific capital expenditure per ton of $CO_2$ captured. In comparison with considering the cost of $CO_2$ allowances, the investment required for CC remains too high to be economically viable for this sector.

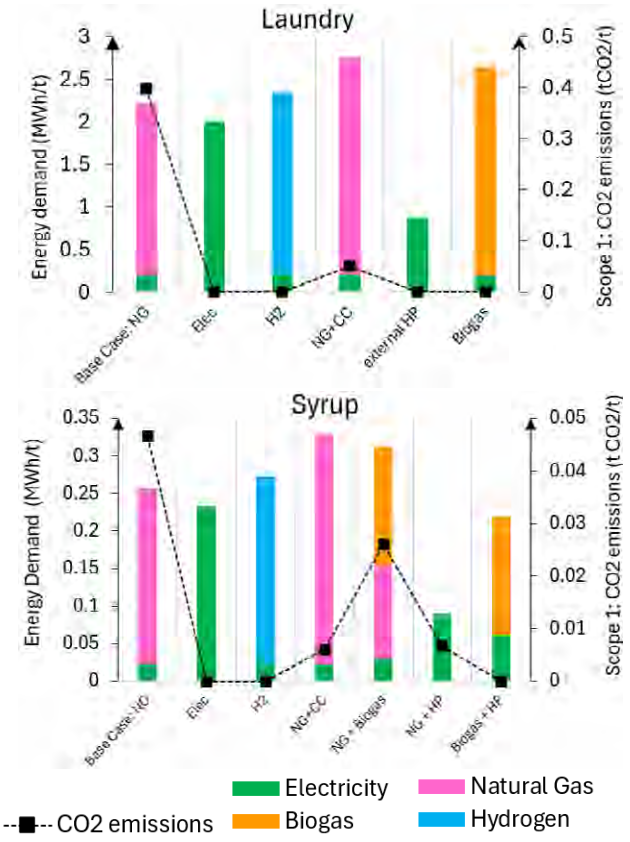

**Figure 2.** Specific energy consumption and $CO_2$ emissions in the laundry and syrup sectors based on energy choices

The analysis of the syrup production sector reveals conclusions analogous to those observed in the laundry sector. Biogas and electricity exhibit the lowest production costs among the evaluated energy sources. Biogas is still considered to be derived from solid waste, leading to low additional cost, while electricity remains more economical than both hydrogen and NG. CC is slightly more economically viable in the syrup sector compared to the laundry sector. This is primarily attributed to the production scale, which generates approximately 86,000 tons of $CO_2$ per year for syrup production, in contrast to 4,000 tons of $CO_2$ per year for the laundry sector. Given this higher volume of emissions, CC is more cost-effective than purchasing CO2 quotas, with a 34% cost reduction compared to the base case.

Overall, based on the KPI analysis, the transition strategies for the sectors under study are highlighted.

The analysis identifies bio-based resources and electrification as the most viable pathways, given their low to moderate process temperature requirements.

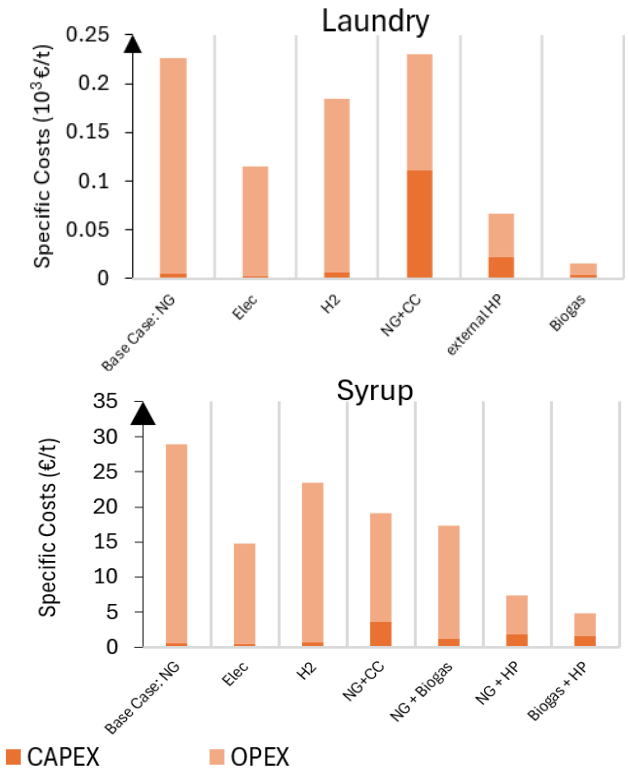

**Figure 3.** Specific costs in the laundry and syrup sectors based on energy choices

Fuel substitution emerges as a viable alternative for the transition. Each form of fuel substitution eliminates Scope 1 $CO_2$ emissions, with the most economically advantageous option being the valorization of solid or liquid waste to produce biogas, even if it requires more energy. In addition, electrification and HP integration present major opportunities for energy transition. Electrification provides higher energy efficiency compared to NG or hydrogen-based systems while eliminating direct $CO_2$ emissions. HP further enhance this advantage by enabling efficient waste heat recovery, reducing overall energy consumption.

Sector-specific differences can still be addressed. In the syrup sector, internal HP are used to recover on-site waste heat, and their efficiency is modeled using Carnot assumptions. Conversely, the laundry sector employs external HP, for which a COP of 3 is assumed, reflecting typical temperature lifts from an ambient temperature source of 20°C to a process requirement below 120°C. As COP values vary according to process conditions, their fluctuation directly impacts the electricity consumption of HP. While unfavorable COPs

can increase electricity use, ongoing technological advancements are expected to improve COP, enhancing the efficiency and cost-effectiveness of this approach.

## 4. CONCLUSIONS & PERSPECTIVES

This study explores the transition pathways for the laundry and syrup sectors toward net-zero emission objectives using the Osmose Lua optimization framework based on MILP. Energy transition strategies analyzed hydrogen utilization, bio-based resources, electrification, CC and HP integration.

Bio-based fuel substitution is particularly relevant for sectors with low-T demand when on-site resources, such as wastewater or solid waste, can produce biofuels, enabling direct reductions in Scope 1 $CO_2$ emissions. Electrification and HP integration offer efficient, cheap, and clean alternatives to fossil fuel use, with facilitating waste heat recovery in the case of HP. Technological improvements in HP, especially in COP, could further enhance its competitiveness. Hydrogen, while efficient and $CO_2$-reducing, faces barriers like infrastructure needs (facility retrofitting, revaluation of transport, storage logistics) and high costs, making it less viable for low-temperature sectors. $H_2$ and CC are deemed less favorable options for the future of the low-T sector. The substantial capital expenditures required for CC are disproportionate relative to the moderate emissions levels of the industries.

As a result, to achieve net-zero Scope 1 emissions in low-temperature industrial sectors by 2050 will likely require a multi-pronged approach combining bio-based fuel substitution, HP integration, and/or electrification. Looking ahead, Effective strategies will depend on sector constraints and energy price trends, with continuous reassessment and scenario-based planning crucial for identifying viable pathways.

## ABSTRACT

In 2022, Uruguay launched its green hydrogen roadmap, due to its renewable energy potential, water availability, and favorable logistics to position itself as an exporter of green hydrogen and derivatives. The energy source for water electrolysis is a key factor in both the final cost and the environmental impact of hydrogen production. In this context, this study evaluates the environmental impact of hydrogen production via water electrolysis, powered by 150 MW of new power sources (solar, wind, and hybrid farms) in Uruguay, all connected to the national grid. A life cycle assessment (LCA) was conducted using OpenLCA software and the Ecoinvent database, with 1 kg of hydrogen as the functional unit and the system boundaries included power generation and the electrolysis system. The analysis focused on global warming potential (GWP), considering different scenarios for the grid energy mix and the inclusion or exclusion of surplus energy as carbon credits. The wind plant is the option that generates the highest energy output and surplus while requiring the least energy purchase from the Uruguayan grid, due to its higher capacity factor. Regarding GWP, it is also the alternative with the lowest environmental impact, with annual average emissions ranging from 0.84 to 1.02 kg $CO_2$/kg $H_2$ not considering carbon credits (CC) and between 0.2 and -1.87 kg $CO_2$/kg $H_2$ when CC are considered. These values represent emissions based on grid connection during the years with the highest proportion of renewable and fossil sources, respectively.

**Keywords**: Hydrogen, Life Cycle Analysis, Renewable and Sustainable Energy

## INTRODUCTION

Several countries have recently developed strategies to advance green hydrogen as a feedstock or energy carrier. Hydrogen has the potential to play a fundamental role in the energy transition, contributing to the decarbonization of sectors like transport and industry.

In 2022, Uruguay launched its green hydrogen roadmap, outlining its plan to promote this emerging market [1]. The country has the capacity to become a producer of green hydrogen derivatives for export due to the potential and complementarity of its renewable energy sources (solar and wind), an electricity matrix with a high share of renewable sources, its availability of water, and favorable logistics [1].

Low-carbon hydrogen currently represents less than 0.1% of global demand, but its use is projected to grow by 6% annually by 2030, according to the International Energy Agency. This underscores the need for low-emission hydrogen production pathways to meet increasing demand while reducing environmental impact [2].

In this context, life cycle assessment (LCA) plays a crucial role in evaluating and comparing the environmental performance of different production methods. A key LCA metric is Global Warming Potential (GWP). GWP index converts greenhouse gas emissions into $CO_2$ equivalents, offering a standardized and widely used measure in environmental studies [3].

Electrolysis-based hydrogen is expected to offer significant environmental benefits, particularly when powered by low-carbon electricity [4]. On average, renewable hydrogen cases exhibited a 68–92% reduction in GWP compared to conventional systems such as coal

gasification and natural gas steam methane reforming [3]. However, the high energy requirements for water electrolysis makes the source of electricity a crucial factor. Emissions associated with electric energy consumption are thus the primary contributors to the environmental impact of hydrogen production [5].

Latin America and the Caribbean (LAC) are developing a hydrogen certification system to establish environmental and social sustainability criteria for clean and low-carbon hydrogen. This framework aims to set greenhouse gas (GHG) emissions thresholds and transparently report energy sources, production technologies, and certified attributes. Methodologies for measuring GHG emissions should align with international ISO standards [6]. For example, China categorizes hydrogen emissions into low-carbon (up to 14.51 kg $CO_2$eq/kg $H_2$), clean (4.9 kg $CO_2$eq/kg $H_2$), and green (below 4.9 kg $CO_2$eq/kg $H_2$) [7]. Similarly, the European Union's CertifHy Green Hydrogen standard requires at least a 60% reduction in GHG emissions compared to natural gas-based steam methane reforming, roughly 4.37 kg $CO_2$eq/kg $H_2$ [8].

The literature reports significant variations in the environmental impact of hydrogen production depending on the energy source, scope of analysis, and methodologies used [2, 3, 9] . For example, studies report that hydrogen produced from wind systems shows GWP values ranging from 0.03 to 5.10 kg $CO_2$eq/kg $H_2$, while photovoltaic systems range from 0.37 to 7.50 kg $CO_2$eq/kg $H_2$ [3]. In the case of hydrogen production using grid electricity in countries with low renewable penetration, the carbon footprint could reach values between 17.2 and 41.4 kg $CO_2$eq/kg $H_2$ [2].

Comparing hydrogen production methods, it was found that biomass gasification ranks highest technically and financially due to high energy and exergy efficiency and low production costs, but it performs poorly environmentally and socially due to high GWP. Wind electrolysis ranks second, offering the best environmental and social performance with the lowest emissions. Solar electrolysis has the weakest technical and financial performance but shows results closer to the wind in environmental and social metrics [10].

Solar and wind energy, when used independently, are limited by their intermittent generation. When combined, they provide benefits such as smoothing output fluctuations, resulting in a more stable energy supply. Additionally, the combined production of wind and solar can be optimized to align with specific demand profiles, effectively addressing variations in energy requirements. To identify the optimal combination of both energy sources for achieving more stable energy generation, many authors use the standard deviation as a metric. This method quantifies how closely the output data cluster around the mean value [11].

This study aims to assess the impact of different energy sources on GWP of hydrogen production in Uruguay. Specifically, it compares solar, wind, and hybrid solar-wind systems connected to the grid, evaluating different grid energy mix scenarios. It also analyses the effect of including or excluding surplus energy from renewable energy plants as carbon credits.

The production of wind and solar energy in Uruguay is quite stable when comparing annual values, but the electric grid relies in high shares of hydropower. The annual rain in this part of South America is strongly dependent on the climate phenomenon El Niño–Southern Oscillation (ENSO), directly impacting energy generation.

## METHODOLOGY

The system evaluated includes a 50 MW PEM electrolyzer, operating at its nominal capacity continuously, 365 days a year, and the installation of 150 MW of new power sources. Three configurations for power production were analyzed: (1) photovoltaic, (2) wind, and (3) hybrid (solar + wind) farms. In all cases, connection to the national power grid was assumed to ensure a reliable and uninterrupted energy supply for plant operation. Energy storage technologies (such as batteries or similar) are not considered.

Different yearly electricity mix scenarios (EMS) were analyzed to assess the environmental impact of hydrogen. The EMS data (Table 1) is based on the average generation of the Uruguayan energy mix over the past five years [12]. The selected data represents different years in Uruguay, influenced by periods of high availability of water and drought, which are key factors directly affecting the composition of the country's electricity matrix.

For the solar and wind generation, hourly data of real plants close to Paysandú region was employed in all the analysis and simulations [13].

The reason to consider the production of new plants hourly, whereas the electric grid composition is considered as an yearly average, is that the first depends on hour to hour availability of resources and the second one depend on seasonal effects. The focus is not on evaluating these specific years, but rather on assessing how different electricity mix compositions may impact GWP.

**Table 1:** Uruguayan Electricity shares for each year

| | Thermal Fossil (%) | Thermal Biomass (%) | Hydropower (%) | Wind (%) | Solar (%) |
|---|---|---|---|---|---|
| EMS_2019 | 2 | 15 | 50 | 30 | 3 |
| EMS_2020 | 6 | 20 | 30 | 40 | 4 |
| EMS_2021 | 15 | 17 | 33 | 31 | 4 |
| EMS_2022 | 9 | 17 | 39 | 32 | 3 |
| EMS_2023 | 8 | 24 | 27 | 37 | 4 |

To determine the shares of renewable energy sources in the hybrid generation scenario, the minimum standard deviation was the metric used to search for the most stable generation. Details of this methodology can be found in the literature [14].

The environmental impact of the different case studies was assessed through a LCA using OpenLCA 2.3.1 software and the Ecoinvent 3.10 database. The analysis was conducted following the IPCC 2013 methodology.

Among the impact categories that can be analyzed by LCA (human health, environmental, resource depletion, etc.), this work focused on the 100-year GWP, using the carbon dioxide as emissions metric. This metric converts greenhouse gas emissions into $CO_2$ equivalents, providing a clear understanding of a system's overall emissions. Additionally, most studies in the literature on this topic utilize this impact category, making future comparisons more straightforward.

Regarding system boundaries, a "cradle-to-gate" approach was considered, including power generation and the electrolysis system used for hydrogen production. As the Ecoinvent database does not include a PEM electrolyzer, the life cycle inventory for the primary materials and energy required to construct a 1 MW PEM electrolyzer (including balance of plant (BOP) components) was taken from the literature [15, 16]. The construction of the electrolyzer was assumed to scale linearly. The electrolyzer's efficiency (70%) and production rate were considered constant over its entire lifetime. The lifetimes of the stack and BOP were assumed to be 7 and 20 years, respectively. For this analysis, 1 kg of produced hydrogen was considered the functional unit.

The main goal of this analysis was to compute the GWP of hydrogen production by electrolysis for each scenario (photovoltaic, wind, and hybrid) including and excluding carbon credits when selling any surplus energy to the national grid.

For the case of carbon credits, it is assumed that all the available energy can be taken by the grid, getting a limit value of change in the GWP by this strategy. If the grid could not take all the energy due to operational restrictions, an intermediate value of GWP between the scenarios with and without carbon credits should be expected.

## RESULTS

Figure 1 compares the energy generation, purchase, and surplus of three power plant configurations (solar, wind, and hybrid), all with a new generation power capacity of 150 MW at the same location in Uruguay. The energy generated by these systems is used for hydrogen production through the electrolysis process.

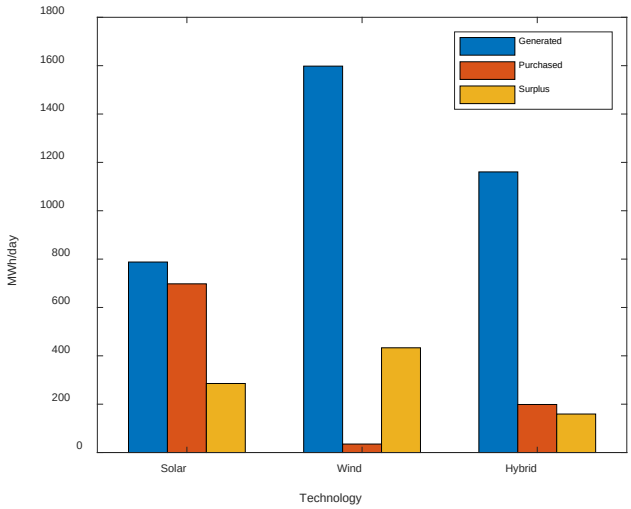

**Figure 1:** Generation, purchase, and surplus energy for a solar, wind, and hybrid park

It can be observed from Figure 1 that the wind farm is the most efficient in terms of energy generation due to its higher capacity factor (0.44) when compared to solar (0.22) and hybrid (0.32) farms. This is attributed to favorable wind conditions in Uruguay most of the year. This installed capacity almost fully meets the energy demand of the electrolysis system (50 MW) for hydrogen production, significantly reducing the need to purchase energy from the National Interconnected System (NIS). Additionally, the generation of surplus energy is considerable and exceeds that of the other systems, highlighting its potential for integration with the power grid, energy storage, or other uses for the plant.

According to the results obtained through the standard deviation method, to achieve a more balanced energy generation at the studied location, a hybrid park with a composition of 54% photovoltaic energy and 46% wind energy is required. This system has a lower capacity factor than the wind plant. However, it provides more stable energy generation throughout the day by combining both complementary technologies. The surpluses generated are moderate, reflecting better synchronization with the demand of the electrolysis system.

The solar plant shows the most significant hourly variability in energy generation due to its direct dependence on solar irradiation. In this regard, this system is limited in consistently meeting the hydrogen plant's energy demand. Additionally, the solar plant produces significant surplus energy during peak solar irradiation hours. This is an opportunity for integration with other systems, including energy storage solutions.

Figure 2 shows the GWP associated with hydrogen production through water electrolysis, evaluating different energy sources: the Uruguayan power grid, a solar plant, a wind plant, and a solar-wind hybrid plant. The

analysis considers five scenarios (EMS_2019, EMS_2020, EMS_2021, EMS_2022, EMS_2023) reflecting the variability in the composition of Uruguay's energy matrix between 2019 and 2023. Additionally, two approaches are examined: with carbon credits derived from the surplus energy generated by the plants and without carbon credits.

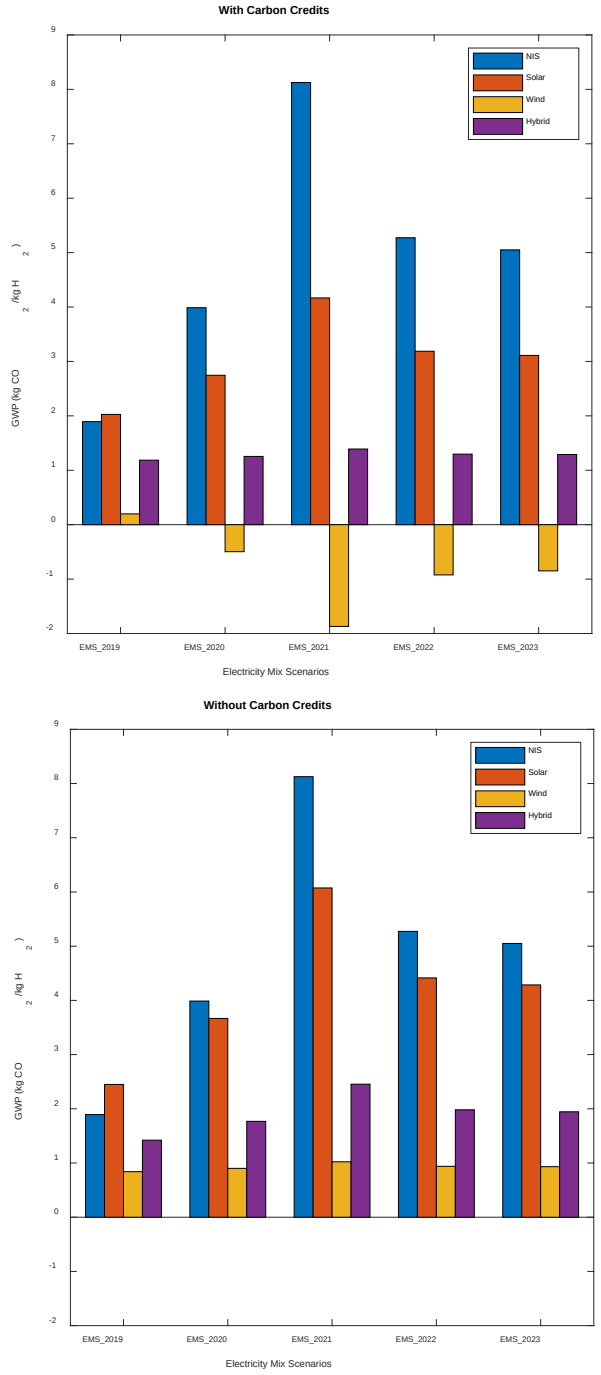

**Figure 2:** GWP for hydrogen production considering different energy souces (NIS, solar, wind and hybrid parks) and electricity mix scenarios.

The NIS showed its lowest environmental impact in 2019 due to a highly renewable energy matrix. However, starting in 2020, the share of fossil fuels and biomass increased in the energy mix significantly raising the GWP. All renewable plants evaluated are connected to the NIS, which means that the GWP is also directly influenced by the composition of the national electricity matrix.

In the case of the solar plant, its GWP in EMS_2019 was higher than that of the NIS, even when considering carbon credits. This is due to the low proportion of fossil fuels in the energy mix that year. It was predominantly composed of hydro and wind power, energy sources with a lower environmental impact than solar energy.

However, as the share of fossil fuels in the NIS mix increased, the GWP of the solar plant became more competitive, achieving lower values than those of the NIS. This is confirmed when comparing the contribution of different energy sources to total emissions. For instance, the solar plant generates an average of 787.8 MWh/day and purchases 697 MWh/day from the NIS.

In the EMS_2019, the solar system contributed 53% of total emissions, while the NIS accounted for 42%. In the EMS_2021, the NIS share rose to 76.7%, while the photovoltaic system's contribution decreased to 21.4%.

Among all evaluated scenarios, the wind plant consistently exhibits the lowest environmental impact. It generates an average of 1598 MWh/day, purchasing only 35.11 MWh/day from the NIS. In the EMS_2019, the wind plant accounted for 80% of total emissions, while the NIS contributed 6.2%. In the EMS_2021, these proportions shifted to 66.7% and 22.9%, respectively. Incorporating carbon credits, the wind plant achieves negative GWP values in the scenarios with a higher share of fossil fuels and biomass in the energy mix (2021–2023), due to the wind system's ability to offset emissions through the carbon credits generated by its energy surpluses.

The hybrid system combines the characteristics of solar and wind systems, resulting in an intermediate environmental impact. Although its GWP is slightly higher than that of the wind plant, it remains significantly lower than that of the NIS and the solar plant, especially when carbon credits are considered.

When carbon credits are not considered, the year with the highest share of renewable energy in the electricity matrix coincides with the lowest GWP for all the analyzed plants. However, this dynamic changes when carbon credits are incorporated. In the case of the wind plant, the lowest GWP is observed in the year with the highest share of fossil fuels in the energy mix, as this plant requires minimal energy from the NIS, and the surpluses generated fully offset the impact of fossil energy consumption associated with hydrogen production and even more, throughout the year. A similar behavior is observed in the hybrid plant, although this effect is limited to five months of the year, when energy surpluses reach

high levels. During these months, the GWPs for EMS_2020 – EMS_2023 are lower than those of EMS_2019. In contrast, this effect is not present in the solar plant due to its greater dependence on energy purchased from the NIS and its higher environmental impact.

**Table 2:** Annual average, maximum and minimum monthly generation (G), and its respectively energy purchased from the NIS (P); and energy surpluses (S) for renewable parks connected to the grid.

| | **G** | **P** | **S** | **Month** |
|---|---|---|---|---|
| **Minimum** (MWh/day)* | | | | |
| Solar | 368.1 | 834.8 | 2.9 | Jun |
| Wind | 1330.9 | 119.3 | 250.8 | Feb |
| Hybrid | 955.6 | 258.2 | 13.8 | Jun |
| **Maximum** (MWh/day)* | | | | |
| Solar | 1171.2 | 593.2 | 564.5 | Dec |
| Wind | 1755.0 | 0 | 555.0 | Oct |
| Hybrid | 1433.4 | 98.0 | 331.5 | Dec |
| **Annual Average** (MWh/day ) | | | | |
| Solar | 787.8 | 697.6 | 285.5 | |
| Wind | 1598.0 | 35.1 | 433.1 | |

| 1 | 2.45 | 2.03 | 0.85 | 0.20 | 1.42 | 1.18 |
| 2 | 6.07 | 4.16 | 1.02 | -1.87 | 2.45 | 1.39 |

Table 2 presents the annual average, monthly maximum and minimum values for energy generation (G) and its respectively energy purchased from the NIS (P); and energy surpluses (S) to solar, wind, and hybrid parks.

Table 3 shows the GWP associated with the cases presented in Table 1, evaluated under the extreme scenarios of the electricity grid composition: (1) EMS_2019 and (2) EMS_2021, characterized by a maximum share of renewable and fossil fuels sources, respectively. Additionally, it includes cases without (w/o CC) and with (w CC) carbon credits.

When comparing the months of minimum and maximum wind energy generation w/o CC in Table 3, the GWP showed an almost negligible increase in EMS_2019. This is attributed to the high percentage of renewable sources in the energy mix that year, and the fact that no energy purchases from the NIS were required during the month of maximum generation. In EMS_2021, the GWP decreased approximately 42% since no energy purchases from the NIS were needed during the month of maximum generation. When incorporating the surpluses generated in both years as carbon credits, the GWP is reduced by 94% in EMS_2019 and by 1330% in EMS_2021. The substantial reduction in EMS_2021 is due to the high share of fossil fuels in the NIS, whose impact is offset by the carbon credits generated by the wind system.

For the solar plant, when comparing the months of minimum and maximum generation w/o CC, the GWP shows a 49% increase in EMS_2019 and a 4.6% reduction in EMS_2021. This is attributed to the higher environmental impact of the photovoltaic system compared to the NIS in EMS_2019 and the lower relative impact of the photovoltaic system compared to the NIS in EMS_2021. When including the energy surpluses generated, the GWP increases by 6.6% in EMS_2019 and decreases significantly by 64% in EMS_2021, reflecting the variation in impact between the photovoltaic system and the NIS across the years. On the other hand, the hybrid plant exhibits an intermediate behavior between the solar and wind systems.

When comparing scenarios w CC and w/o CC for the solar and hybrid systems in the same year, it is observed that the reduction in GWP is almost negligible during months of minimum energy generation. This is due to the low surpluses generated during these periods and the higher environmental impact associated with the photovoltaic system. However, during months of maximum generation, a significant reduction is recorded in both cases, with a more pronounced effect for the hybrid system, especially in EMS_2021. In the case of the wind plant, a considerable reduction in environmental impact is observed during both minimum and maximum generation months. This can be attributed to the higher energy surpluses generated and the inherently lower environmental impact of this system. Additionally, negative GWP values were obtained for the wind system when carbon credits were considered.

In all the evaluated cases, electricity generation was the main contributor to the environmental impact of hydrogen production, varying depending on the production technology used. In 2019, this contribution was lowest in the wind system (86%), followed by the hybrid system (92%) and the solar system (95%). In the year with the

highest share of fossil fuels in the NIS energy mix, there was a slight increase of approximately 3% in this contribution across all cases.

The impact of water treatment is lower than 1% for all cases. For the electrolysis system, the impact varies between approximately 10 and 2.5% when using the wind and photovoltaic systems, respectively. This impact is primarily associated with the materials used in the production of the stack, such as platinum and titanium, as well as the electricity required for its production. These factors were also identified as the main contributors to environmental impact by other authors. Additionally, they reported electricity generation contribution rates ranging from 78–97% for electrolysis using wind energy and 88–99% for electrolysis using photovoltaic energy [3].

The results obtained in this study for the GWP are within the range reported in the literature [3] for the different evaluated case studies. The differences can be attributed to various factors: the system boundaries, the connection of renewable energy generation plants to the NIS (which exhibits different energy mixes depending on the country), and the inclusion or exclusion of carbon credits for the generated energy surpluses. Variations in GWP across different studies have also been reported by several authors in previous research [3, 9].

Moreover, the values found in this study align with the ranges established by European and Chinese organizations [7, 8] for green hydrogen in wind and hybrid systems. In the case of solar energy, the results depend on the composition of the electricity matrix. Hydrogen production by solar energy complemented with energy form the NIS demonstrates greater vulnerability to the effects of climate change, since it affects directly the availability of water to produce hydropower.

## CONCLUSION

The results obtained in this study indicate that the wind plant is the most efficient alternative in terms of energy generation due to its higher capacity factor compared to the other systems. This plant requires the least energy purchase from the NIS and generates the most significant amount of energy surpluses. When carbon credits are considered, these surpluses significantly reduce the environmental impact, even achieving negative GWP values.

In contrast, the solar system exhibited a higher GWP than the electrical grid in scenarios where the grid had a high proportion of low-emission sources, such as hydropower and wind. However, in contexts where the share of non-renewable sources in the grid increased, the relative impact of the solar system decreased, though it did not reach the competitiveness levels observed in the hybrid and wind systems.

The hybrid system demonstrated greater stability in energy generation compared to exclusively solar or wind plants. However, its lower capacity factor relative to the wind system limited its energy production and surplus generation, which in turn increased the energy purchase from the NIS. As a result, it presented an intermediate GWP between the solar and wind systems.

The environmental impact associated with energy generation for the electrolysis process is a critical aspect to evaluate, as it plays the most significant role in the overall impact of hydrogen production, contributing between 78% and 99%, depending on the energy source used. On the other hand, energy surpluses generated by renewable plants offer a crucial opportunity to reduce environmental impact by creating carbon credits, considering that the electrical grid can be integrated and utilize these surpluses effectively.

An important aspect to be evaluated in future studies is the GWP associated with energy storage, either in batteries or as hydrogen, to enable the plant to operate independently from the grid.

## ABSTRACT

Rare earth elements (REE) and many other critical minerals are necessary for the manufacturing of modern everyday technologies, including microchips, batteries and electric motors. Recovery of these materials typically involves aqueous systems which can be modeled as chemical equilibrium problems. One common method for solving these problems is the law of mass action approach (LMA), where a system of non-linear equations involving the equilibrium constants is solved. However, despite being theoretically simple, these problems are in practice very difficult to solve. Currently, the use of iterative heuristics based on saturation indices to decide on which species and reactions to include in the calculations is the state of the art to arrive at a solution. Here, we present an optimization-based alternative to solve chemical equilibria problems involving precipitation/dissolution reactions without the need for such heuristics. Our approach is first validated against the LMA software MINTEQ and PHREEQC for a number of case studies, and then applied to a novel REE recovery process reported in the literature. Overall, our approach was found to have close agreement with MINTEQ and PHREEQC, and we were able to successfully replicate the reported yield and purity for the published REE process.

**Keywords**: Critical Minerals, Precipitation/Dissolution Models, Optimization.

## INTRODUCTION

Rare earth elements and critical minerals are among the most challenging materials to acquire for many modern technologies, often requiring complex processing and extraction methods. Recovery of these minerals, either from ores or unconventional feedstocks such as end-of-life products, involves processes where chemical equilibrium calculations are essential. Chemical equilibria problems are typically solved in one of two ways [1]: either by minimizing the Gibbs free energy of the system (the GEM approach) or by solving a system of non-linear equations involving the equilibrium constants (the law of mass action approach, LMA). GEM methods rely on thermodynamic data that is not always available [1], thus making the older LMA approach the more widely used. However, despite the widespread use and popularity of the LMA approach, it tends to fail when many precipitating species are involved [1].

To address these issues, many LMA software applications use heuristics based on saturation indices to decide on the addition/removal of species and reactions from calculations [1]. For instance, the state-of-the-art software PHREEQC and MINTEQ employ an iterative heuristic approach involving saturation indices ($SI$) [2-4]. The $SI$ represents the saturation of the solution with respect to a particular solid and can be used to determine if precipitation will occur at equilibrium. It is defined as follows [2-4]:

$$SI = Q_{r,sp} - K_{r,sp} \quad (1)$$

In this approach, the equilibrium concentration of the aqueous species in solution is first calculated by ignoring all possible precipitates. Next, the saturation index for each possible precipitate is calculated. The precipitate with the most positive $SI$ is then forced into equilibrium (i.e. $SI = 0$). Next, the equilibrium concentrations of all the aqueous species are re-calculated, followed by the calculation of all saturation indices for all remaining possible precipitates. If they are all undersaturated (i.e. $SI < 0$),

the process is complete. Otherwise, the precipitation procedure is repeated.

In this work, we present an optimization-based approach for solving chemical equilibria problems involving precipitation/dissolution reactions. Our approach models the precipitation reactions as inequality constraints which allows for the prediction of the precipitated species and the final solution state without the need for saturation indices heuristics [2-4]. This approach offers an initial implementation of an alternative formulation that could in the future be used in conjunction with GEM approaches.

## OPTIMIZATION PROBLEM FORMULATION

The objective function of our precipitation model formulation is to minimize the square difference between the ion product $Q_{r,sp}$, defined over the actual concentration in solution, and the solubility constant $K_{r,sp}$, defined over the equilibrium concentrations in the solution,

$$z = \sum_{r \in N_{rxn,sp}} \left(\log(K_{r,sp}) - \log(Q_{r,sp})\right)^2 \quad (2)$$

where $N_{rxn,sp}$ is the set of precipitation/dissolution reactions. By adding in the following constraints, this objective function allows the identification of the species that should precipitate (i.e. $Q_{r,sp} = K_{r,sp}$) and those that should not (i.e. $Q_{r,sp} \leq K_{r,sp}$):

$$\log(Q_{r,sp}) = \sum_{i \in I_{r,products}} \alpha_{i,r} \log\left(C_i^f\right) \ \forall r \in N_{rxn,sp} \quad (3)$$

$$\log(Q_{r,sp}) \leq \log(K_{r,sp}) \ \forall r \in N_{rxn,sp} \quad (4)$$

where $I_{r,products}$ is the set of products formed in reaction $r$. Eq. (3) computes the ionic product based on the actual concentration in the solution; its upper bound is defined by the solubility product (Eq. 4).

Equilibrium conditions are imposed in all reactions that do not involve solids as shown in Eq. (5):

$$\log(K_{r,aq}) = \sum_{i \epsilon I_{r,products}} \alpha_{i,r} \log\left(C_i^f\right) - \sum_{i \epsilon I_{r,reactants}} \alpha_{i,r} \log\left(C_i^f\right) \ \forall r \in N_{rxn,aq} \quad (5)$$

where $\alpha_{i,r}$ is the stoichiometric coefficient of species $i$ in reaction $r$, $C_i^f$ is the equilibrium concentration of species $i$, and $N_{rxn,aq}$ is the set of all aqueous reactions. We use the logarithmic form(s) in Eq. (3) to (5) to minimize numerical issues.

The set of restrictions is completed with the inclusion of mass and concentration balances to calculate the final concentration/ mass of species:

$$C_i^f = C_i^0 + \sum_{r \in N_{rxn,i}} \alpha_{i,r} X_r \ \forall i \in I_{aq} \quad (6)$$

$$m_i^f = m_i^0 + \sum_r^{N_{rxn,i}} \alpha_{i,r} X_r V \ \forall i \in I_{sp} \quad (7)$$

where $C_i^0$ is the initial concentration of species $i$, $N_{rxn,i}$ is the set of all reactions involving species $i$, $X_r$ is the extent of reaction $r$, $I_{aq}$ is the set of all aqueous species, $m_i^0$ is the initial amount of solid species $i$, $V$ is the volume of solvent, and $I_{sp}$ is the set of all precipitates.

The problem was implemented in Python and solved with IPOPT utilizing the linear solver MA57. The model was scaled with custom scaling parameters and the tolerance was set to 1E-12.

## MODEL VALIDATION

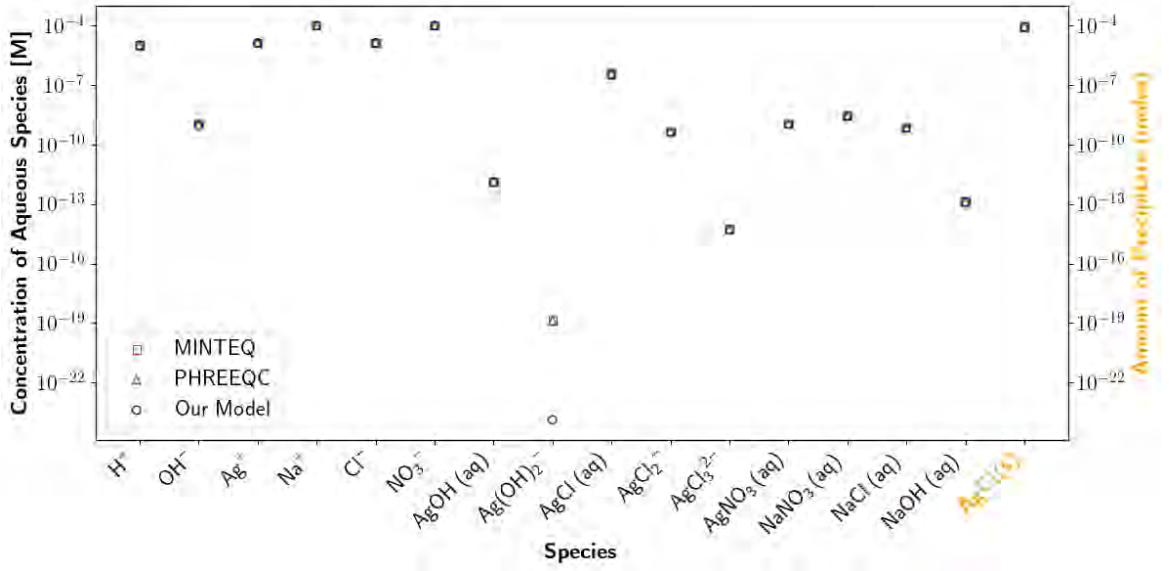

**Figure 1.** Comparison of predicted final concentrations for aqueous species, and predicted final amounts of precipitate formed between MINTEQ, PHREEQC, and our model for Case 1.

To validate our model, we compared the results of several case studies against those from MINTEQ [2,3] and PHREEQC [4], two LMA-based software applications that predict equilibrium calculations based on saturation indices heuristics.

## Case 1: Ag-Cl-$NO_3$ ionic system

For the first case study, we consider a system containing $Ag^+$, $Cl^-$ and $NO_3^-$, with initial concentrations for each species of $1 \times 10^{-4} M$ and a pH of 5. For this system, MINTEQ predicts the formation of 15 aqueous species and one precipitate. The predicted final concentrations and precipitate formed for our model, MINTEQ, and PHREEQC are all shown in Figure 1. All three models show close agreement for the amount of precipitate formed and the final concentrations of all aqueous species with the exception of $Ag(OH)_2^-$.The largest relative difference between our model and PHREEQC, and our model and MINTEQ (excluding $Ag(OH)_2^-$) is 4.9% (for $AgCl_2^-$) and the average one is 1.14%. For $Ag(OH)_2^-$, it was found that both PHREEQC and MINTEQ predicted very similar final concentrations. While our model predicted a lower final concentration, all three models predicted an essentially zero final concentration.

## Case 2: Na-K-Ca-Mg-Cl-$SO_4$ ionic system

For our second validation case, we considered a system based on a subset of the primary ions typically found in water treatment. We intentionally leave carbonate ions out. For the initial concentration in Table 1, MINTEQ predicted 21 aqueous species and one possible precipitate.

**Table 1.** Initial concentration of ions in Case 2.

| Species | Initial Concentration [M] |
|---|---|
| Na+ | $3.35 \times 10^{-4}$ |
| K+ | $4.09 \times 10^{-4}$ |
| Ca2+ | $3.24 \times 10^{-2}$ |
| Mg2+ | $1.23 \times 10^{-4}$ |
| Cl- | $3.33 \times 10^{-4}$ |
| SO42- | $2.50 \times 10^{-2}$ |

The comparisons of the final predicted concentrations of the aqueous species and amount of precipitate formed for all three models are shown in Figure 2. As can be seen in the figure, there is excellent agreement between our model and PHREEQC for all species. However, for species containing $OH^-$, MINTEQ consistently predicted a lower final concentration, and for species containing $H^+$, MINTEQ consistently predicted a higher final concentration than both PHREEQC and our model.

The relative differences between our model and PHREEQC, and our model and MINTEQ are larger than for case 1. However, similar differences are found if the predictions from PREEQC and MINTEQ are compared with each other.

Additional simulations adding carbonate to the ions pool to more accurately represent water treatment processes were performed. The results, not presented here, also show excellent agreement and will be discussed at the conference.

## Case 3: Na-K-Ca-Mg-Cl-$SO_4$-Fe ionic system

Finally, we validated our model in a setting where multiple precipitates are possible. For this, $1 \times 10^{-6} M$ of

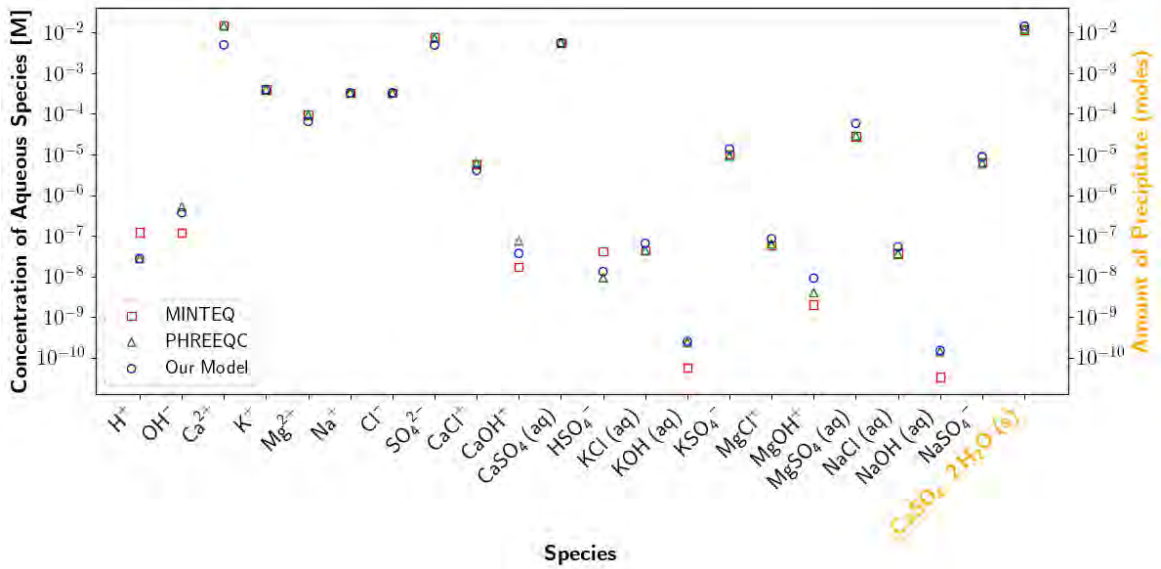

**Figure 2.** Comparison of predicted final concentrations for aqueous species, and predicted final amounts of precipitate formed between MINTEQ, PHREEQC, and our model for Case 2.

$Fe^{3+}$ was added to the initial system of ions shown in Table 1. With this change, MINTEQ predicts 31 different aqueous species and seven potential precipitates: $CaSO_4 \bullet 2H_2O$(s) (gypsum), $Fe(OH)_{2.7}Cl_{0.3}$(s), $Fe(OH)_3$(s) (ferrihydrite), FeO(OH)(s) (goethite), $Fe_2O_3$(s) (hematite), $KFe(SO_4)_2(OH)_6$(s) (k-jarosite), and $Mg(Fe)_2O_4$(s) (magnesioferrite). Comparisons of the final predicted concentrations of the aqueous species and the predicted amount of precipitate formed with the three models are shown in Figure 3. As can be seen, there is good agreement between our model and MINTEQ on the final species concentrations, while PHREEQC slightly underpredicted the final concentrations for many of the aqueous species. For the precipitates, it was found that while all three models predicted the formation of the same amount of gypsum at equilibrium, PHREEQC and MINTEQ also predicted the formation of hematite, while our model predicted the formation of magnesioferrite. None of the models predicted any $Fe(OH)_{2.7}Cl_{0.3}$(s), ferrihydrite, goethite, or k-jarosite to form at equilibrium.

The difference in the predicted final concentration of the precipitates can be attributed to MINTEQ and PHREEQC's reliance on the iterative saturation indices heuristic to determine which species precipitate. This heuristic also implicitly assigns an order in which the species precipitate, which can lead to the exclusion of species that might form under simultaneous equilibrium. In contrast, our model does not rely on such heuristics, as the equilibrium conditions of all possible precipitates are incorporated within the optimization problem. However, to further establish the reliability of our approach, future work needs to involve experimental validation.

## CMI PROCESS CASE STUDY

### Process Description

As a proof of concept on how our model can be used for modeling and future optimization of critical mineral processing, we applied it to a novel REE recovery process developed by the Critical Materials Innovation Hub (CMI) [5,6].

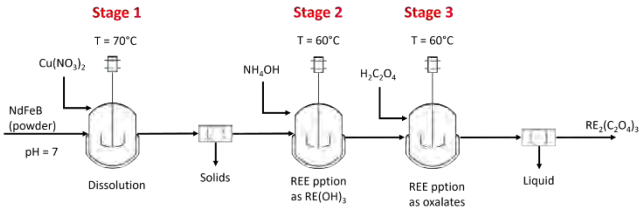

**Figure 4.** Depiction of the CMI process [5,6].

The CMI process is depicted in Figure 4. The process uses a series of dissolution and precipitation reactions to recover rare earth elements as rare earth oxalates from end-of-life (EOL) rare earth permanent magnets (REPM) [5,6]. In the first stage, the NdFeB feed in powder form is dissolved in a solution of copper nitrate salts. This leads to the formation of precipitates containing the iron and boron contaminants ($Cu_3(BO_3)_2$, $Fe(OH)_3$), which are subsequently filtered from the solution. In the next stage, ammonium hydroxide is added to the solution to increase the pH. This leads to the formation of rare earth hydroxides and the conversion of some of the remaining iron in solution into iron hydroxides. Next, in stage 3, oxalic acid is added to the solution. This leads to the formation of soluble iron-ammonium

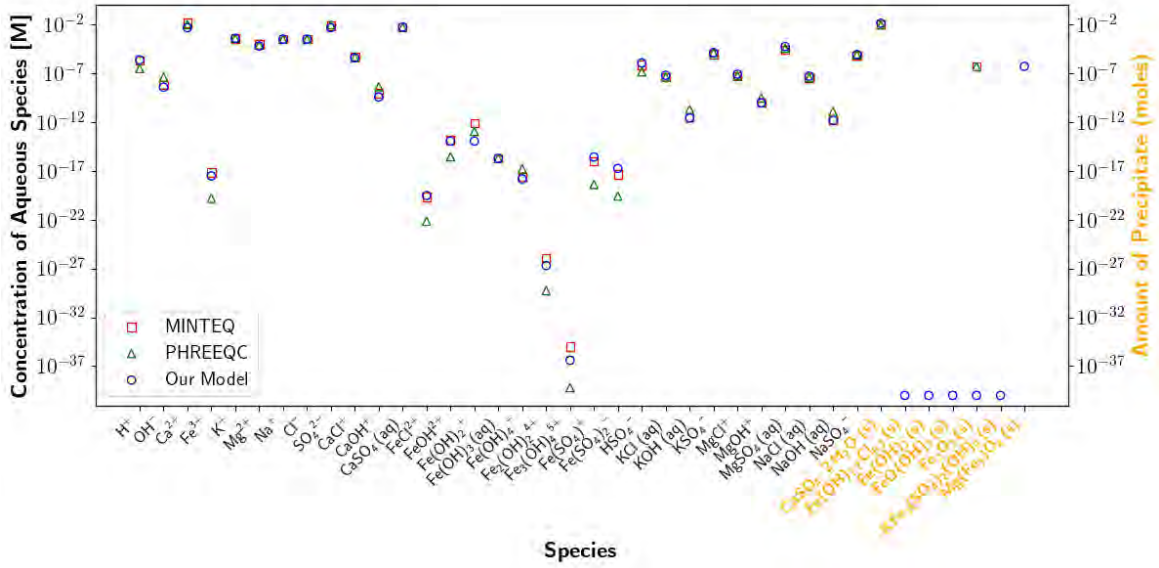

**Figure 3.** Comparison of predicted final concentrations for aqueous species, and predicted final amounts of precipitate formed between MINTEQ, PHREEQC, and our model for Case 3.

oxalate and insoluble rare earth oxalate. The rare earth oxalate precipitate is subsequently separated from the solution.

## Simulation Results

In the paper, a yield of >98% of REEs recovered as rare earth oxalates, and a final purity >99%, was reported for a feedstock consisting of REPM swarf [6]. While the paper also reported REE recoveries from other feedstocks,

REPM swarf was specifically selected for this case study because it consists exclusively of pure REPM material. This eliminates the need to account for mass transfer limitations caused by casing materials, which are a concern in feedstocks like shredded HDDs.

Although the overall yield was reported, some important parameters were not. These include: the final pH of stage 2 and the amount of oxalic acid added to the solution in stage 3. Thus, a sensitivity analysis was conducted on these important parameters to determine if the reported yield and purity could be recreated. To simulate the process, our precipitation model was utilized for stages 1, 2, and 3. Ideal separation between solids and liquids was assumed for all separation steps.

The results of the sensitivity analyses are shown in Figures 5 and 6. It was found that the reported yield and purity could be successfully replicated with our model. Furthermore, the reported yield was found to occur over a range of pH values, and for four out of five of the initial concentrations of oxalic acid that were simulated (0.045M, 0.09M, 0.135M, and 0.18M). The reported purity was also found to occur over a range of pH values and for three out of 5 of the initial concentrations of oxalic acid that were simulated (0.09M, 0.135M, and 0.18M).

As can be seen in Figure 5, increasing the amount of oxalic acid added to the solution in stage 3 was found to increase the amount of neodymium recovered. Additionally, it was also found that increasing the final pH of stage 2 (by adding more ammonium hydroxide) increased the recovery of neodymium, but only up to a point. Increasing the pH past 7 was found to lead to a decrease in the amount of neodymium recovered for all initial concentrations of oxalic acid except for 0.015M.

Figure 6 depicts the effects of the amount of oxalic

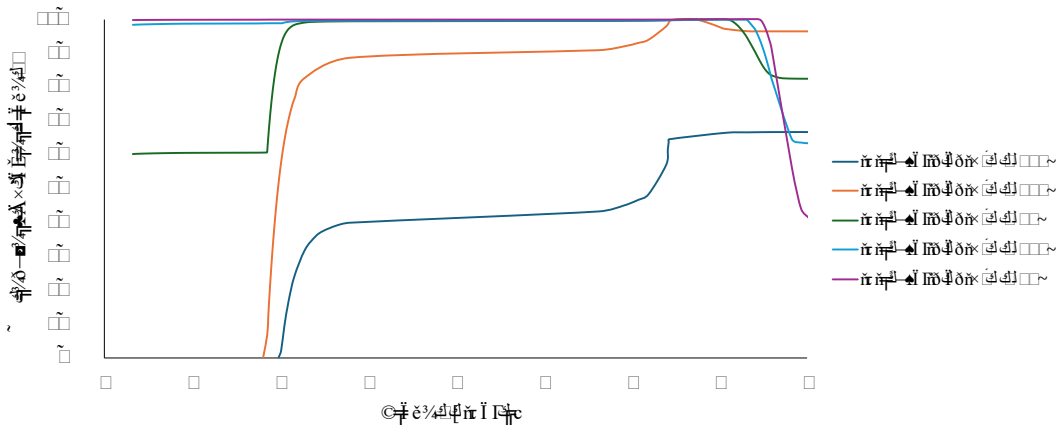

**Figure 5.** Simulation results for the CMI process. Increasing the pH of stage 2 led to an increased recovery of Nd-oxalate up to a point.

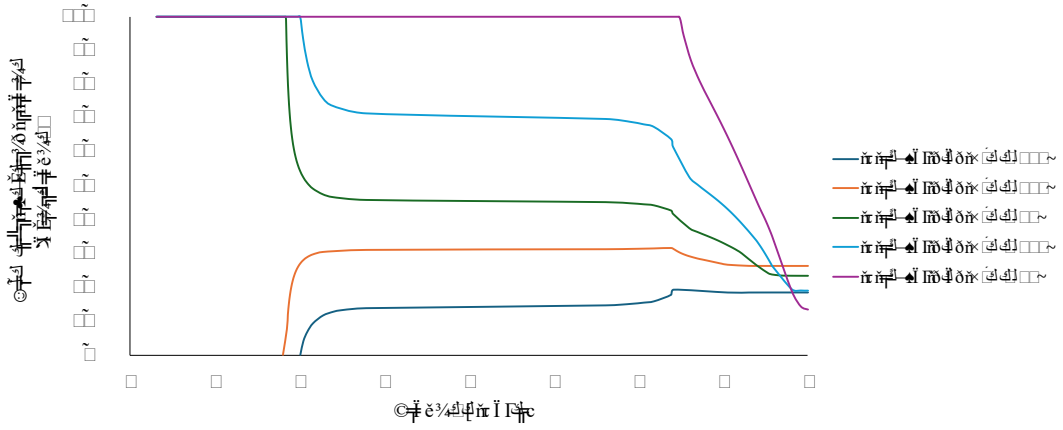

**Figure 6.** Simulation results for the CMI process. Increasing the pH of stage 2 led to a decrease in the purity of the precipitate.

acid added in stage 3, and the pH of stage 2 on the purity of the recovered precipitate. It was found that while increasing the pH of stage 2 led to an increase in the amount of precipitate formed (up to a pH of 7), it also led to a decrease in the purity of the precipitate. This can be attributed to more iron hydroxide being precipitated out of solution as the pH was increased.

Overall, our results suggest that there is room for optimization of the reaction conditions, for example, to find those that minimize acid consumption while keeping the desired purity and yields.

## CONCLUSION

In this work, an initial implementation of an optimization-based approach for solving precipitation/dissolution reactions utilizing equilibrium relations is presented. We first present three case studies to show that the predictions from this model are in good agreement with LMA-based software: MINTEQ and PHREEQC. Then we present a proof of concept where our model is applied to the CMI process [5,6]. By conducting sensitivity analyses on the uncertain parameters of the model, we were able to replicate the paper's reported yield and purity, suggesting that our model is capable of modeling aqueous equilibrium systems accurately.

## ABSTRACT

Sustainable aviation fuels (SAFs) can be pivotal, gradually replacing fossil kerosene and lowering carbon emissions without changing the existing infrastructure. One of the pathways to produce SAFs is through the Fischer-Tropsch synthesis (FTS) process. The present work proposes an integrated process of sustainable aviation fuel production from biogas through a reforming process, Fischer-Tropsch (FT), and a solid oxide electrolysis (SOEC) process. Aspen Plus v14 is used to build an integrated kinetic process model for biogas reforming, FTS and hydrocracking. The technical evaluation is assessed with several key performance indicators, such as carbon efficiency and process efficiency. In addition, two scenarios are investigated in this study for $H_2$ supply from SOEC before and after reforming. The output products consist of kerosene and diesel since the tail gas and naphtha are recycled to the reformer to maximize SAF production. The simulation results show that the carbon efficiency of the integrated process is between 96.3% and 96.5%. Meanwhile, the process efficiency is between 40.1% and 40.9%. The process efficiency can be further improved by investigating the options for heat integration, with subsequent economic and environmental analysis to determine the production cost of SAFs and the $CO_2$ reduction potential compared to conventional aviation fuel. In addition, projection cost analysis is needed to determine the decline in the cost of fuel production in the future.

**Keywords**: sustainable aviation fuels, biogas reforming, Fischer-Tropsch process, solid oxide electrolysis

## 1. INTRODUCTION

The aviation industry is essential for the fast and efficient transportation of people and goods, making it crucial for international business and tourism. However, this sector contributes greenhouse gas (GHG) emissions significantly, releasing around one billion tons of $CO_2$ annually—about 2.5% of global energy-related $CO_2$ emissions. One of the strategies to achieve carbon neutrality in the aviation sector is the adoption of Sustainable Aviation Fuel (SAFs) [1].

A viable method for producing SAFs is the Fischer-Tropsch (FT) process. This method converts syngas into liquid fuels whose composition depends on pressure, temperature, syngas composition, and catalyst type. The FT synthesis can occur at low temperatures (LTFT) and high temperatures (HTFT). The LTFT process is operated at 210–260 °C with a cobalt catalyst, which produces long-chain hydrocarbon. Meanwhile, the HTFT process is operated at 310–340 °C with an iron catalyst, which generates short-chain hydrocarbons [2].

The syngas, which is a mixture of CO, $H_2$, $CO_2$, and $H_2O$, can be produced from a thermochemical conversion process at a high temperature of 900 °C with several routes: reverse water gas shift, steam reforming, and autothermal reforming, with the primary feedstock is natural gas or biogas along with steam or hydrogen. Biogas is an attractive resource because it has carbon sources from methane and $CO_2$, which can be transformed into syngas through steam reforming process [3]. In addition, due to the awareness of Power-to-X (PtX) technologies, this can expand to green hydrogen production from the electrolysis process (e.g., solid oxide electrolysis), which can fulfill the syngas requirement for the FT process [4].

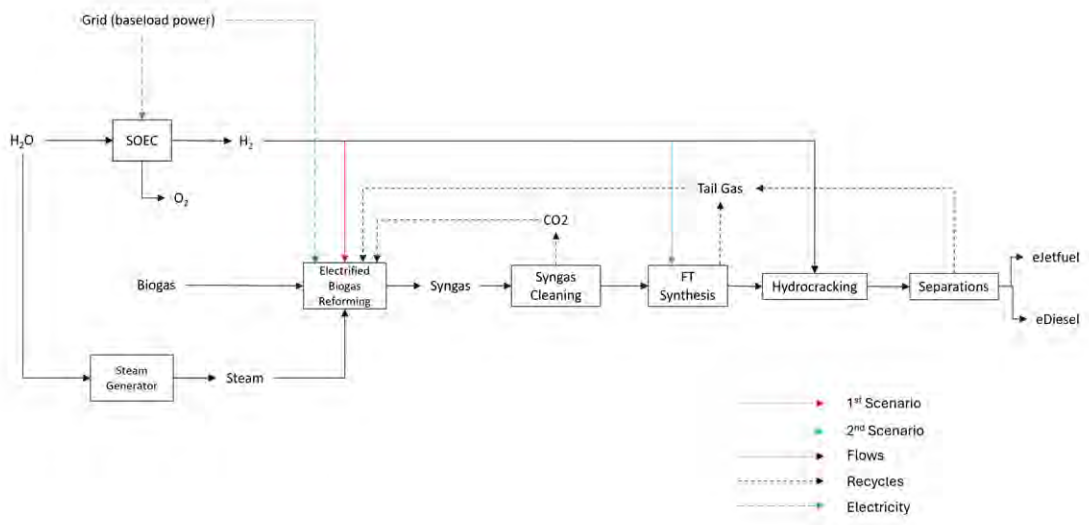

**Figure 1.** Schematic of the system.

Existing studies in process modeling of sustainable aviation fuel through the Fischer-Tropsch process typically focus on a $CO_2$ source from flue gas and ambient air. For instance, Paulsen et al. performed techno-economic assessments of jet fuel production integrated, reverse water gas shift (RWGS), Fischer-Tropsch, and electrolysis process with $CO_2$ source from ambient air through high-temperature direct air capture (HTDAC). It demonstrated that the energy efficiency is up to 39% with specific energy consumption of up to 156 $MJ/kg_{Jet\ fuel}$ [4]. In another $CO_2$ source, Marchese et al. conducted the process modeling of integrated RWGS and co-electrolysis process with the Fischer-Tropsch process to produce the liquid fuels with $CO_2$ source from biogas through MEA absorption. The results show that plant efficiency is 75.8% for co-electrolysis and 70.1% for RWGS [5]. However, these studies do not utilize the methane from biogas as the input to maximize the yield of liquid fuels.

This work aims to develop a rigorous process model of SAF production through the FT process with solid oxide electrolyzer and electrified biogas reforming, which utilize the $CH_4$ and $CO_2$ from biogas as the primary feedstock and the output products consisting of kerosene and diesel. Hydrocracking is employed to crack the wax, and the resulting tail gas and naphtha are recycled to the reformer to maximize the fuel yield. Kinetic models are developed for all reactors (reformer, FT, and hydrocracking) and validated with experimental data.

# 2. METHODOLOGY

## 2.1. Process description

The integrated process model is developed for SAF production via the Fischer-Tropsch process with syngas sources generated from electrified biogas reforming. Two scenarios are investigated in this study. In the first scenario, biogas, steam, and hydrogen from SOEC are input to the steam reforming reactor. Biogas and steam are fed into the reforming reactor, with the additional required hydrogen being input before the FT reactor in the second scenario. The first and second scenarios are presented in Fig. 1.

## 2.2. Process Simulation

The process simulation is developed using Aspen PLUS v14 with Peng-Robinson (biogas reforming and electrolysis), Soave-Redlich-Kwong (Fischer-Tropsch and hydrocracking), and E-NTRL (syngas cleaning) EOS's, as the thermodynamic models. The Aspen simulation workbook (ASW) is employed to solve the complex kinetic model of FT and solid oxide electrolyzer cell (SOEC). The process models developed in this study are illustrated in Fig. 2 (biogas reforming) and Fig. 3 (FT process with hydrocracking and separation).

### 2.2.1 Electrified Biogas Reforming

The electrified biogas reforming along with steam input to produce the syngas was simulated in multi-tubular plug flow reactor (PFR) at P = 20 bar and T = 950 °C. Electrified reformer employs resistance heating to replaces the fired heater, with heating elements powered by an external electricity source to heat the reactor. In terms of energy efficiency, the electrified reformer demonstrated better efficiency compared to conventional fired reformers [3]. A commercial Ni-$CeO_2$/$MgAl_2O_4$ catalyst is selected with LHHW kinetic model that combine steam methane reforming, $CO_2$ reforming, and water gas shift (WGS) reactions developed by Park et al. [6].

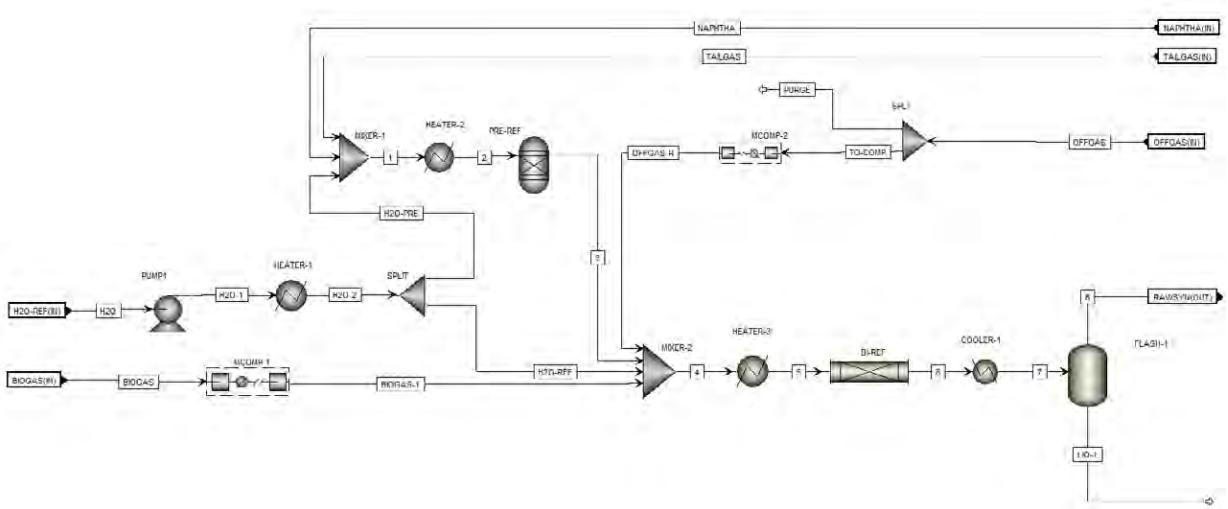

**Figure 2.** Process Simulation of Biogas Reforming

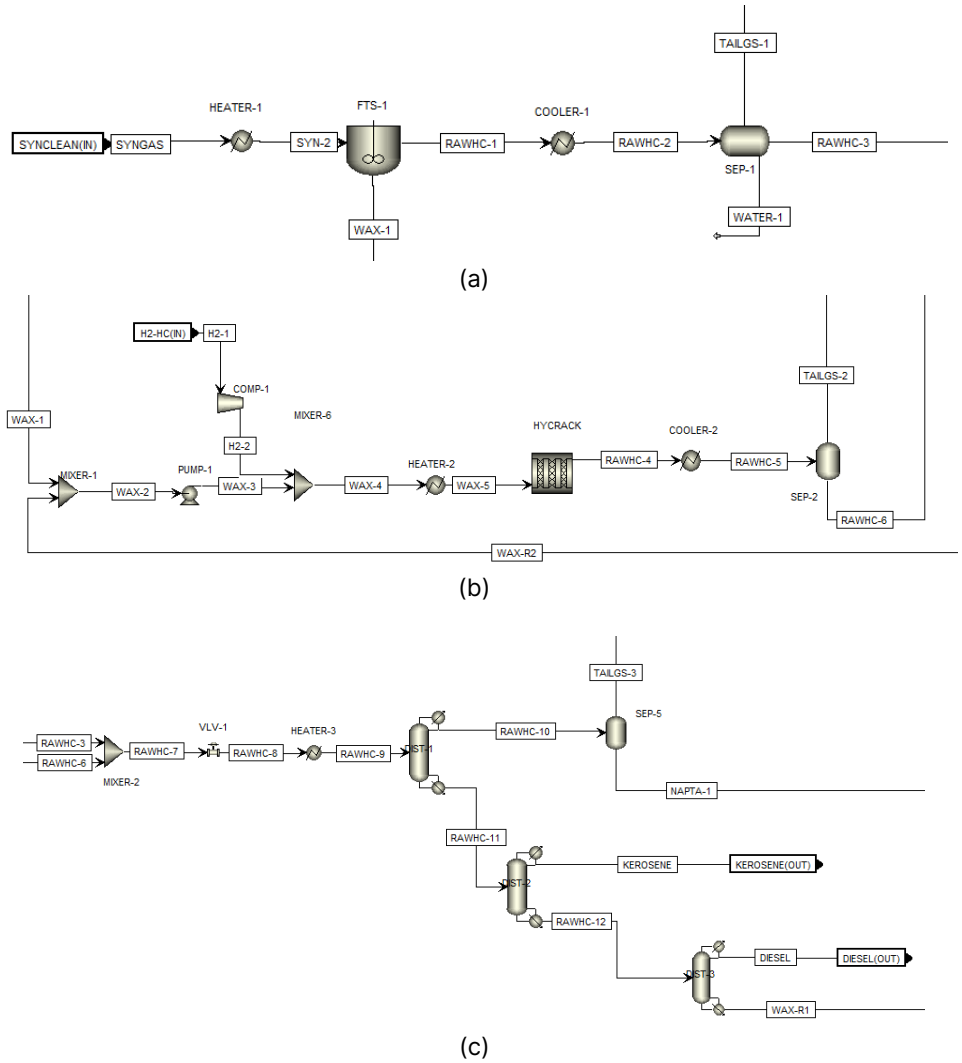

**Figure 3.** Process Simulation of (a) Fischer-Tropsch with (b) Hydrocracking and (c) Separation

### 2.2.2 Solid Oxide Electrolyzer

The solid oxide electrolyzer cell (SOEC) unit is modeled as the stoichiometric reactor at 750 °C and P = 1.15 bar with an $H_2O$ conversion of 60%. The fraction of hydrogen produced from the electrolyzer is recycled back to the stack, and it is adjusted by design specifications so the steam concentration in the feed of the stack is at 90%. The modeling of the electrolytic cell, which is applied in the Aspen Plus stoichiometric reactor, is assisted by the Aspen simulation workbook (ASW). The detailed mathematical model of electrolytic cells is presented by AlZahrani and Dincer [7].

### 2.2.3 Fischer-Tropsch and Hydrocracking

A low-temperature Fischer Tropsch (LTFT) with a cobalt-based catalyst is employed in the process model from the syngas with an H2/CO ratio of around 2.1. The process is modeled in a slurry-bubble column reactor (SBCR) with an operating pressure of 20 bar and a temperature of 230 °C [8]. The SBCR can be modeled as the continuous stirred tank reactor (CSTR) in Aspen Plus, assisted by the Aspen simulation workbook. In general, the reaction follows this highly exothermic reaction:

$$CO + 2H_2 \rightarrow -(CH_2) - + H_2O \quad \Delta H = -150 \frac{kJ}{mol} \quad (1)$$

The term of $-(CH_2)-$ is described as the monomer product through the polymerization process, and the water is a side product of the process. The FTS process is modeled based on chain growth probability and the olefin/paraffin ratio which is presented by Todic et al. with CO conversion per pass = 52.5% [8].

A heavier hydrocarbon in wax produced from the FT reactor is sent to a hydrocracking process to maximize the jet fuel yield. The hydrocracking model with silica-alumina catalyst was simulated in the plug-flow reactor at P = 30 bar and T = 367 °C, assisted by the Aspen simulation workbook. The hydrocracking kinetic model is based on the study by Bhutani et al., 2006 [9].

### 2.2.4 Additional processes

There are additional processes besides reforming, SOEC, and the FT process, e.g., $CO_2$ capture, pre-reforming, and distillation columns, which are needed for a comprehensive evaluation of the biogas-to-jet fuel process.

Syngas cleaning is employed to remove $CO_2$ from the syngas, which is recycled back into the reforming reactor. The MEA absorption process, a well-established industrial process, is used, with a $CO_2$ recovery of 90% and specific heat consumption of 3.5 MJ per kg-$CO_2$ [10].

The raw synfuel from FT and hydrocracking are sent to three stages of distillation columns to separate the tail gas, naphtha, kerosene, diesel, and wax at atmospheric conditions. The tail gas and naphtha are recycled back to the pre-reforming reactor which is operated at P = 20 bar and T = 400 °C and simulated in Gibbs reactor at adiabatic conditions to produce additional CO and $H_2$ from $C_{2+}$. The wax is sent to the hydrocracking reactor along with wax from the FT process.

## 2.3. Performance Indicators

The performance indicators from the proposed process are calculated based on the mass and energy balance, as presented below:

- Carbon conversion ratio, also known as carbon efficiency ($\eta_C$), is defined as the ratio of the carbon atoms in the hydrocarbon after reforming and the Fischer-Tropsch process relative to carbon atoms in the biogas feedstock, as presented in Eq. (2):

$$\eta_C = \frac{\dot{n}_{C,hydrocarbons}}{\dot{n}_{C,feedstock}} \quad (2)$$

- Hydrogen efficiency ($\eta_H$) is defined as the ratio of the hydrogen atoms in the hydrocarbon products relative to the hydrogen atoms in the water for SOEC process, as presented in Eq. (3):

$$\eta_H = \frac{\dot{n}_{H,hydrocarbons}}{\dot{n}_{H,feedstock}} \quad (3)$$

- Process efficiency ($\eta_P$) represents the ratio of the energetic content of hydrocarbon products relative to the energetic content of biogas and the total energy input of the system, including the electrified reforming power, SOEC power, and process power consumption, as shown in Eq. (4):

$$\eta_P = \frac{\dot{m}_{hydrocarbon} \times LHV_{hydrocarbon}}{\dot{m}_{biogas} \times LHV_{biogas} + P_{SOEC} + P_{reforming} + P_{process}} \quad (4)$$

# 3. RESULTS

The integrated modeling of the FT process with electrified biogas reforming considers biogas feedstock volume flow of 45 million $m^3$/year, and the mole fraction is 60% $CH_4$ and 40% $CO_2$. This flow corresponds to 5,544 kg/hr. The validation of the FT process was carried out using mole fraction against the carbon number, as shown in Fig. 4, along with experimental data from Todic et al.[8]. As it can be appreciated there is a good correlation between the model predictions and experimental data for hydrocarbons with up to 15 carbons. Unfortunately, there were no experimental data for long chain hydrocarbons.

Table 1 highlights mass and energy balance of FT fuel process in two scenarios. After recovering and recirculating unreacted $CO_2$ from the syngas cleaning process via MEA absorption, tail gas, and naphtha from FT and separation process, the hydrocarbon output is 2,132 kg/hr of kerosene and 648 kg/hr of diesel meanwhile in the second scenario, the hydrocarbon output is 2,137 kg/hr of kerosene and 648 kg/hr of diesel. In addition, the total electricity consumption for electrified reforming, SOEC, and other processes in the first and second scenarios are 38.9 MW and 37.9 MW, respectively.

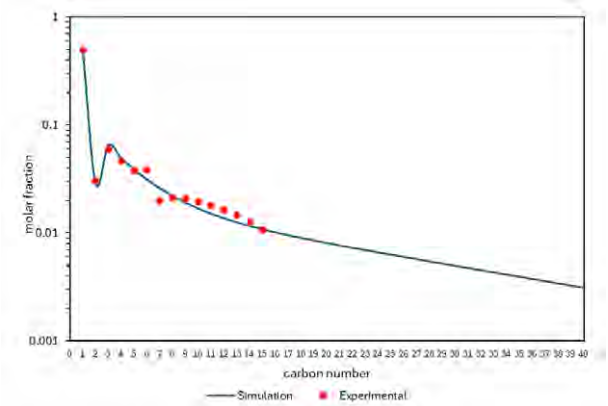

**Figure 4.** The Molar fraction of FT products with Experimental validation

Regarding energy input, the first scenario requires larger electricity consumption (27.9 MW) compared to the second scenario (27.1 MW) due to the electrified reforming consuming more electricity with hydrogen input sent to reforming. It differs from the second scenario, where hydrogen input is sent directly to the FT reactor to fulfill syngas requirements ($H_2/CO \approx 2.1$) for the FT process. However, in the SOEC, electricity consumption is slightly elevated due to the reaction of hydrogen with $CO_2$ in the reformer within the first scenario, which consequently reduces hydrogen output. The electricity requirement for electrified biogas reforming is two times higher than that of the SOEC process because the SOEC process is only employed to supply the lack of hydrogen produced from reforming. In addition, the hydrogen requirement for hydrocracking, supplied by the SOEC, is significantly lower than hydrogen requirement for the reforming process.

**Table 1:** Key Performance Indicators of the FT fuel

| Parameter | 1st Scenario | 2nd Scenario |
|---|---|---|
| Material input (kg/hr) | | |
| Biogas flow rate | 5,544 | 5,544 |
| Process Water | 9,674 | 9,609 |
| Material output (kg/hr) | | |
| Kerosene | 2,132 | 2,137 |
| Diesel | 648 | 648 |
| Energy input (MW) | | |
| Biogas heat flow | 27.2 | 27.2 |
| Electricity input | 38.9 | 37.9 |
| Energy output | | |
| Kerosene | 22.2 | 22.3 |
| Diesel | 4.4 | 4.4 |
| Electricity input (MW) | | |
| Electrified reforming | 27.9 | 27.1 |
| SOEC | 8.9 | 8.7 |
| Compressor | 2.01 | 2.01 |
| Pump | 0.07 | 0.07 |

The performance indicators assessed in this study, include carbon conversion, hydrogen and process efficiencies. As presented in Fig. 5, the overall (kerosene and diesel) carbon conversion efficiency between the two scenarios is relatively the same, around 96%. The carbon loss is in the purge, associated with $CO_2$ recirculation from the syngas cleaning process and tail gas recirculation from the FT process. The total hydrogen efficiency is approximately 27%, significantly lower than carbon conversion efficiency, due to the abundance of water lost after water separation from syngas in reforming and syncrude in the FT process.

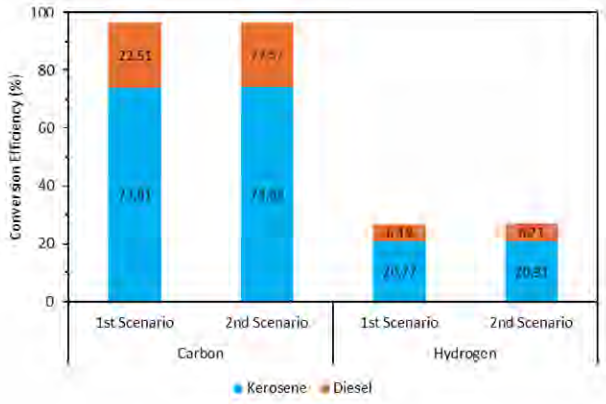

**Figure 5.** Carbon and Hydrogen Conversion Efficiency from Two Scenarios

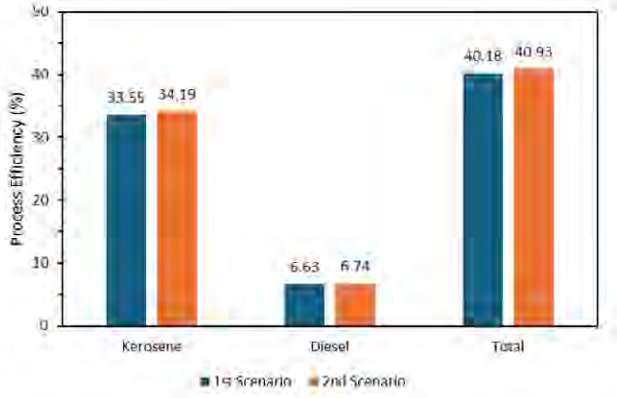

**Figure 6.** Process Efficiency from Two Scenarios

Overall, the process efficiency as shown in Fig. 6 is calculated at approximately 40% due to the large electricity consumption in electrified reforming and SOEC processes. The comparison between the two scenarios reveals insights into mass and energy balances, particularly focusing on process efficiency of two scenarios. The results show that the second scenario exhibits slightly better overall process efficiency, with stable hydrocarbon production, while slightly reducing total electricity consumption. For further analysis, the developed model featuring the two scenarios needs to incorporate heat integration, which will change the electricity consumption and process efficiency. In addition, economic and

environmental assessments are conducted to determine the production cost and carbon reduction potential compared to conventional aviation fuel.

## 4. CONCLUSION

The study evaluated two scenarios of sustainable aviation fuels (SAFs) production from biogas upgrading and the Fischer-Tropsch process, with focus on carbon utilization, process efficiency, and electricity consumption. Rigorous kinetic process models for all involved processes were developed to enhance the accuracy and flexibility of the evaluation. Based on the developed models, the two scenarios achieve stable production of kerosene and diesel. However, providing hydrogen at the inlet of the FT unit (after the reformer) resulted in lower electricity consumption compared to the scenario where the additional hydrogen required for FT is supplied directly at the reformer. In addition, the carbon conversion efficiency remains high (96%), indicating high carbon utilization for hydrocarbon production.

In future work, the study will expand on economic implications to assess the cost of SAF production compared to conventional aviation fuels. In addition, the environmental impact will be assessed via life-cycle assessment to determine the potential of carbon reduction from the whole process.

## ABSTRACT

Sugarcane bioenergy is a reality in Brazil, comprising the production of ethanol and bioelectricity. Sugarcane bioenergy can reduce greenhouse gas (GHG) emissions as compared to fossil fuels. However, there are concerns about the possible implications caused by the expansion of sugarcane production, the displacement of mainly pastureland, but also other croplands, and the potential for indirect land use changes. A promising strategy to enlarge sugarcane bioenergy in Brazil without compromising the cattle industry is to integrate both activities, converting extensive livestock production systems into more intensive ones. The objective of this study is to model and evaluate the socioeconomic impacts and land use change considering the expansion of ethanol production in two scenarios. The first scenario, referred to Business as Usual (BAU), comprises of sugarcane bioenergy and extensive livestock production, without any integration between the two. The second scenario, Integrated Sugarcane-Bioenergy and Livestock (ISBL) in Brazilian agriculture, considers the integration between these activities. To achieve this goal, a computable general equilibrium (CGE) model for the Brazilian economy was implemented. The Brazilian input-output matrix (main data for the model) was estimated for 2021. The closure and the shocks were set to 2031, with an estimated increase of 75% in ethanol production. Additionally, a technological efficiency gain of 5% was considered for the livestock sector within the ISBL system. Our modeling results show that the ISBL scenario is economically more efficient, as a higher gross domestic product and output level were obtained. The aggregate employment level of the economy also increased. Even considering that the integration of sugarcane bioenergy and livestock production took place only in these activities, positive socioeconomic impacts were noticed across other sectors of the economy.

**Keywords**: Ethanol, Biomass, Modelling and Simulations, Renewable and Sustainable Energy, Energy Policy

## 1 INTRODUCTION

The increasing global pressure to reduce greenhouse gas (GHG) emissions and increase sectors' efficiency have driven significant transformations in energy consumption patterns and production models. In this context, biofuels emerge as a strategic solution, particularly ethanol, whose use can reduce up to 90% of $CO_2$ equivalent emissions compared to gasoline [1]. However, the expansion of biofuel production in Brazil faces complex challenges, ranging from direct environmental impacts, such as those related to the intensive use of

agrochemicals and biomass burning, to indirect ("leakage") impacts, such as the displacement of traditional agricultural activities with potential pressures on native ecosystems and to food security [2].

The fulfillment of international emission control agreements is directly linked to reducing deforestation in Brazil, as the agricultural and land-use sectors are the main contributors to GHG emissions in the country, accounting for ca. 75% of Brazil's emissions in 2021 [3]. Indirect land use changes (ILUC), for example driven by ethanol expansion, are a point of consideration, as they might pose pressures to expand deforestation in the Cerrado and Amazon biomes, compromising the achieved levels of GHG emission reductions in addition to the impacts to biodiversity and the environment. Also, displaced livestock and agricultural activities may face output constraints, jeopardizing economic output, employment levels, and food security. In this context, public and private initiatives targeting sustainable intensification approaches have gained relevance and are creating opportunities to transform the externalities of agricultural production into economic, social, and environmental advantages.

Thus, expanding biofuel production, combining the environmental benefits of being a cleaner fuel with the possibility of reducing environmental impacts, becomes a key strategy for Brazil. The integration of sugarcane production with livestock and bioenergy can enhance the efficient use of existing pasture areas and potentially recover degraded pastures, without compromising the level of production.

The integration of biofuel production with livestock farming offers several advantages to the Brazilian economy. Among them, it allows for the use of existing infrastructure and the production of co-products from biorefinery, contributing to the reduction of feeding costs for confined livestock and, at the same time, reducing the need for new areas for raising animals. This allows producers to diversify their activities and maximize the use of their land, creating a more sustainable and efficient economic cycle. Also, backward and forward spillover effects are expected in this process, benefiting other sectors in the economy.

Therefore, the main research question to be addressed in this work is expressed as follows: what are the socioeconomic and land use impacts of the expansion of ethanol production in Brazil, and how does this transformation potentially influence the production levels of the main agricultural sectors, the gross domestic product (GDP), and employment in the country?

## 2 METHODS

The method adopted in this study is based on the development and application of a Computable General Equilibrium (CGE) model for the Brazilian economy, implemented using the GEMPACK v.12 interface with the MINIMAL version [4]. The following key assumptions establish the fundamental framework for the analysis, providing a clear foundation for projecting the effects of ethanol production expansion:

- *Period under analysis:* The study considered a 10-year period, given the fact that the effects of the integration between sugarcane production for bioenergy and livestock farming, as well as changes in land use and agricultural practices, involve costs and require more complex planning, which demands a longer time horizon. Thus, it was focused on the projections and impacts of ethanol production expansion from 2021 (admitted as the first recovered economic year after the Covid-19 crisis in 2020) until 2031. Ethanol expansion followed RenovaBio's target as a policy scenario [5].
- *Input-Output Matrix:* The study utilized the Input-Output Matrix (IOM) for 141 sectors of the Brazilian economy, providing a detailed analysis of the economic impacts of ethanol production expansion across various productive sectors and supply chains. The IOM was estimated for the year 2021, ensuring an up-to-date representation of sectoral interactions.
- *Ethanol Production:* The study considered a 75% increase in hydrated ethanol production, according to the projections established by RenovaBio [5]. This increase was modeled within the IOM, evaluating the effects on other sectors of the economy.
- *Gasohol Usage:* For analytical purposes, it was assumed that there would no substantial changes in the use of gasohol, allowing the isolation of the impacts of expanding hydrated ethanol production, without external interference related to changes in gasohol usage policies.
- *Total Land in Brazil:* Given the government's commitment to achieving zero deforestation by 2030, it is assumed, as a limiting condition, that no additional land beyond the total available in 2021 will be accessible to any economic sector. Consequently, the expansion of ethanol production will not lead to new deforestation or conversion of native vegetation areas. On the contrary, its expansion should be based only on displacing other agricultural activities, as degraded pastureland [6].

### 2.1 Description of scenarios

To analyze the impacts of expanding ethanol production in Brazil, two distinct scenarios were defined: the

BAU (Business as Usual) Scenario and the ISBL (Integrated Sugarcane-Bioenergy and Livestock) Scenario. Each of these scenarios reflects different development trajectories, considering the growth assumptions of the ethanol sector, land use, and interactions with other economic activities, such as livestock farming.

### 2.1.1 The BAU Scenario

This scenario assumes continuity of the current model, with bioenergy production from sugarcane and extensive livestock farming without integration between the activities, representing the most likely production pattern in Brazil.

### 2.1.2 The ISBL Scenario

This scenario proposes the integration of sugarcane production for bioenergy with livestock farming, aiming at more efficient land use and intensification of production. It is assumed that all the released pasturelands will be used for sugarcane production.

## 2.2 Technological efficiency change

To estimate the change in technological efficiency between a representative cattle management system in Brazil and an integrated system, we analyzed the variation in total production cost per carcass between the two models. It was assumed that the unit total cost serves as a good technological indicator, as it reflects the use of primary factors (land, labor, and capital), input consumption, and productivity.

Brazilian cattle farming in 2021 is characterized by the following data: pastureland covers 161.7 million hectares [7]; the total cattle herd consists of 224.6 million heads, with 27.7 million slaughtered annually [8]; among these, 6.5 million are finished in feedlots [9]. Annual beef production reaches 7.456 million tons of carcass equivalent. Based on these figures, the estimated average stocking rate in Brazil is 1.3 heads per hectare. Additionally, it was assumed that conventional management in Brazil involves pasture renewal every five years.

The ISBL system, on the other hand, consists of a first-generation ethanol plant with vinasse biodigestion for electricity generation [10-12]. The selected plant capacity was 4 million tons of sugarcane per year (4MTC/year), which is considered close to the optimal capacity for the biorefinery [13]. This corresponds to a sugarcane plantation area of 64.5 thousand hectares and an annual ethanol production of 345 million liters. Furthermore, it was assumed that soybeans are grown during sugarcane reform and processed at the plant, with by-products such as soybean meal used in animal feed. It was also assumed that all cattle are finished in feedlots, leading to an annual beef production of 60 thousand tons of carcass equivalent [13].

Based on these data and assumptions, production costs were estimated using a techno-economic model developed by Embrapa Digital Agriculture. The estimated cost for the conventional Brazilian system, considering an exchange rate of 1 USD = 6 BRL and a historical average of key input prices in the model, was 3.2 USD/kg of carcass equivalent. In the integrated system, this cost was lower, reaching 2.8 USD/kg of carcass equivalent. When accounting for the total carcass production in each system, this cost variation translates into a -5% difference, indicating an improvement in technological efficiency in the integrated system compared to the conventional one.

## 2.3 Closure of the General Equilibrium Model

For both scenarios, exogenous variables were defined for the general equilibrium model closure, as presented by Horridge (2001) [4]:

- Exchange rate (local currency/foreign currency);
- Wage rate, adjusted by the Consumer Price Index (CPI);
- Gross rate of return;
- Total land area available;
- Ordinary change in the import tax rate;
- Ordinary change in the domestic tax rate, except for the hydrated ethanol sector;
- Use of composite goods by the investment sector;
- Use of composite goods by the government;
- World prices, measured in foreign currency;
- Quantity shift in foreign demand;
- All primary factors augmenting technical change;
- Industrial production of hydrated ethanol and gasohol.

As established, a 75% shock in hydrated ethanol production was applied to both scenarios. In addition to this initial shock, a sensitivity analysis considering variations relative to the original shock of ±50% (e.g. 37.5% and 112.5% range) was modeled. Based on these results, the mean and standard deviation were calculated. Using Chebyshev's theorem, a confidence interval of 88.9% was determined, considering three standard deviations [14].

In the ISBL scenario, in addition to the hydrated ethanol shock, an additional -5% shock was applied to all primary factors augmenting technical change in the livestock sector, as previously estimated. Furthermore, in ISBL, land allocated to agricultural crop sectors was defined as exogenous, replacing the ordinary change in the domestic tax rate for these sectors, which became endogenous.

# 3 RESULTS

In the analysis of the results, the percentage variations in primary factors, total output, household consumption, exports, and domestic taxes and macoeconomics were assessed for key sectors of the Brazilian economy directly related to the study. The analysis was conducted for the BAU and ISBL scenarios, with the difference between them (ISBL – BAU) referred to as Delta.

## 3.1 Primary factors (land, capital, and labor)

The projected increase in ethanol production directly impacts Brazilian agriculture. To assess the effects of this growth on primary factors in the sector, we analyzed changes in sugarcane, corn, soybean, and livestock production, which account for the largest land area usage in the country (Figure 1).

In the BAU scenario, the expansion of sugarcane cultivation required a reduction in land used by other agricultural sectors, even though in different proportions (Figure 1A). This shift highlights the ongoing trade-off between biofuel production and food supply. Although the percentage variations appear small, particularly for corn and soybeans, their absolute impacts are significant.

In the ISBL scenario, there was a more pronounced reduction in land allocated to livestock, a direct consequence of increased efficiency through the adoption of cattle confinement in integrated systems. The freed-up land was almost entirely redirected to sugarcane production without affecting the areas allocated to other crops, which remained constant in the model closure. Additionally, the ISBL system required less land for sugarcane cultivation compared to BAU, likely due to improved efficiency in other primary factors within the sector (Figures 1B and 1C).

The increase in ethanol production also led to a higher demand for labor and capital in the sugarcane sector in both scenarios, with a slightly greater increase in ISBL compared to BAU (Figures 1B and 1C). A similar trend was observed for the corn and soybean sectors, although the rise in primary factors was more pronounced in the ISBL scenario. For the livestock sector, variations in these factors were minimal in both scenarios. However, in ISBL, the variation was even smaller, with a negative impact on capital stock, reflecting improvements in the sector's technological efficiency.

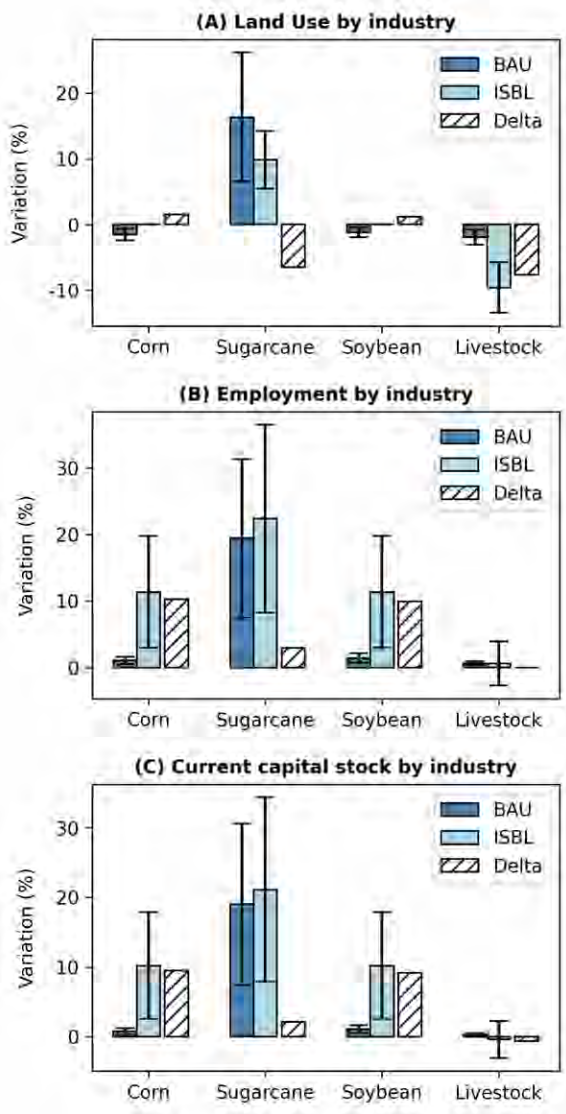

**Figure 1.** Variation in the primary factors of some sectors of the economy. For BAU and ISLB, the 89% confidence interval is indicated.

## 3.2 Total output

Another important aspect of the general equilibrium analysis is the total output across sectors (Figure 2). In addition to sugarcane, corn, soybean, and livestock sectors, the analysis also included beef production and certain fuels, such as gasoline A and anhydrous ethanol. The production of these sectors, along with many others, increased in the scenario projecting a 75% expansion of hydrated ethanol. While the difference between ISBL and BAU scenarios is small for sugarcane production, it becomes more pronounced in other sectors, particularly for corn, soybeans, and beef.

Furthermore, an increase in the production of other fuels is observed, likely as a consequence of the higher productive use in other economic sectors that require these fuels in their pure form.

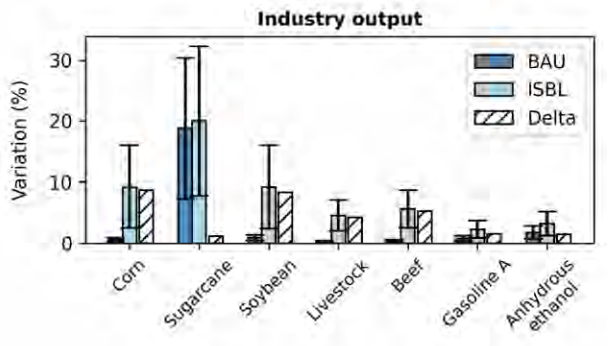

**Figure 2.** Variation in total production in some sectors of the economy.

## 3.3 Household consumption and exports

Household consumption in the beef sector showed a significant increase in the ISBL scenario, while it remained practically unchanged in BAU (Figure 3A). On the other hand, the consumption of gasoline A and anhydrous ethanol decreased in both scenarios, with a more pronounced reduction in ISBL. This decline is likely explained by the increase in exports of these fuels (Figure 3B).

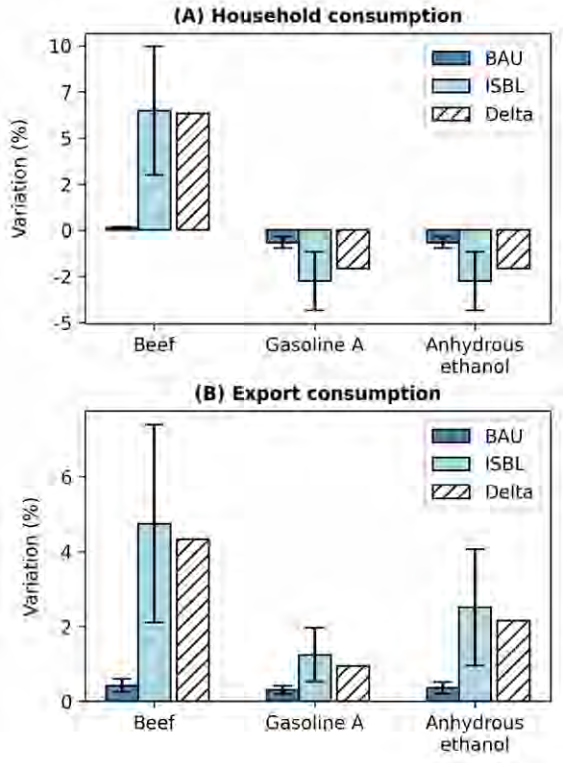

**Figure 3.** Variation in household (A) and export consumption (B) in some sectors of the economy.

## 3.4 Domestic rate taxes

To facilitate the increase in hydrated ethanol production, domestic tax rates on this product were treated as endogenous variables in the ISBL scenario. Consequently, a reduction in the ordinary tax rate of -0.47 would be required for hydrated ethanol in both the BAU and ISBL scenarios. In the ISBL scenario, to validate the premise that sugarcane expansion would occur exclusively over pastureland, it would also be necessary to reduce taxes on agricultural products (Table 1).

**Table 1.** Variation of ordinary change in the domestic tax rate in some sectors of the economy.

| Industry sector | Mean | Confidence interval |
|---|---|---|
| Hydrated ethanol | -0.47 | [-0.62, -0.32] |
| Corn | -0.16 | [-0.28, -0.04] |
| Soybean | -0.17 | [-0.29, -0.05] |

## 3.5 Macroeconomic results

Figure 4 presents the macroeconomic results of the BAU and ISBL systems after the shocks were applied, considering the proposed closure. In both scenarios, there was an increase in aggregate employment, real GDP, real household consumption, export volume index, and import volume index (Figure 4). However, when comparing the scenarios, ISBL exhibited a more significant increase than BAU.

These results suggest that a policy of expanding ethanol production over time could be beneficial to the Brazilian economy under the tested conditions and assumed premises. Additionally, it is noteworthy that land prices increased more in the ISBL scenario (18%) compared to BAU (4%).

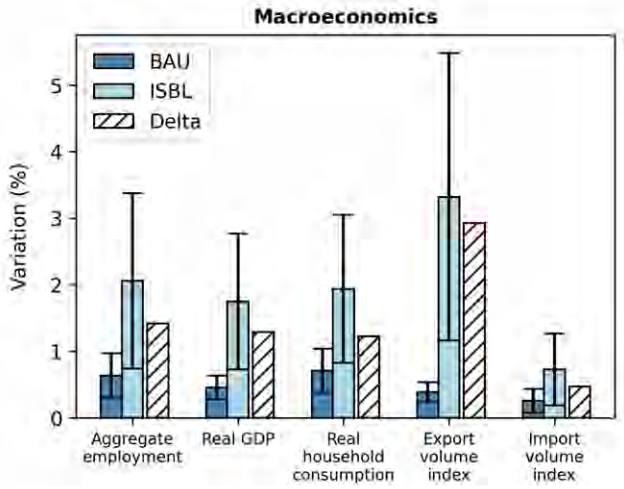

**Figure 4.** Variation in macroeconomic parameters.

# 4 CONCLUSIONS

In comparison to the business-as-usual (BAU) scenario, the ISBL scenario, under the evaluated conditions

and assumptions, demonstrates higher economic efficiency and overall positive effects to other sectors.The integrated scenario makes more rational use of production factors, leading to an increase in productivity driven by technical efficiency gains. Additionally, the ISBL scenario stands out for presenting more substantial real economic growth, reflected in the increase in GDP. This scenario illustrates the potential of an initiative that can contribute to mitigating the impacts on native vegetation areas, showcasing significant potential for the recovery of degraded pastures in Brazil.

Future research is expected to disaggregate the cattle farming sectors in order to distinguish between confinement and pasture systems relative to the broader livestock sector. Furthermore, incorporating greenhouse gas emission levels from each of the economic sectors included in the model will be crucial for constructing a more complete and detailed emissions balance. This approach will allow for a more precise and comprehensive assessment of the environmental impacts associated with each production system, contributing to the understanding of their ecological and economic implications.

Finally, this study demonstrated that the expansion of ethanol production in Brazil, while representing a significant opportunity to strengthen the energy and agricultural sectors, also presents complex challenges to socioeconomic and environmental aspects. The analysis of indirect land use change (ILUC) impacts reveals that the growing demand for ethanol may lead to the intensification of agricultural production, altering the balance between different sectors of the economy and affecting land use in ways that generate both benefits and environmental costs. Additionally, the positive effects on GDP and employment emphasize the opportunities of pursuing and promoting sustainability approaches, balancing bioenergy production with environmental preservation and social well-being. In summary, for Brazil to solidify its position as a leader in ethanol production, it will be essential to adopt strategies that integrate productive efficiency, environmental protection, and social inclusion to ensure a trajectory of sustainable development in the long term.

## ACKNOWLEDGEMENTS

The authors gratefully acknowledge the financial support received from FAPESP (2017/11523-5), CNPq (140029/2022-2), and CAPES (88887.829970/2023-00). Additionally, we extend our appreciation to the team of Embrapa Digital Agriculture for their contribution and support in successfully executing this research project.

## ABSTRACT

A one-dimensional homogeneous reactor model for a cocurrent flow nonadiabatic catalytic membrane reactor operating water gas shift reaction (WGSR) is developed. The model is used to predict the performance of the reactor and estimate the optimal hydrogen flux profiles required to maximize the CO conversion, and control the temperature rise due to the exothermicity. Under the optimized condition, the secured optimal hydrogen flux is found to be a bang-bang type suggesting constructing reactors of different hydrogen permeabilities. To control the reactor temperature, the activity of the reaction side is diluted by distributing axially certain fractions of inert solid, i.e. 0.35, 0.45 and 0.50. The total volume fraction of the inert solid required to maintain the temperature at 320°C (593.15 K) is 0.50 and the profile is obtained to be a singular-arc type with an observed maximum activity at the reactor inlet.

## INTRODUCTION

Hydrogen is considered to be a potential future replacement for fossil fuel [1]. It is produced industrially by steam reforming of hydrocarbons or water gas shift reaction. Both processes are thermodynamically-limited whose conversion is favored by operating the reactions in nonconventional catalytic reactors such as membrane reactors. In membrane reactors, the $H_2$ production can be boosted via in-situ separation which takes place when hydrogen permeative membranes are installed. Two main types of catalysts have been developed over the years for the water gas shift reaction. The first one, which has been used for many years, is an iron–based catalyst on which CO is oxidized in the presence of steam to hydrogen and $CO_2$ at a temperature range of 350–500°C [2]. This catalyst is known to be a high-temperature water gas shift reaction catalyst. The second one is a copper-based catalyst on which the reaction is operated at a temperature range of 150-250°C, and the catalyst is referred to as a low-temperature water gas shift reaction catalyst [3]. For these two types of catalysts, various mathematical reaction rate expressions were developed based on power-law kinetic models, Eley–Rideal, and Langmuir–Hinshelwood kinetic models [4]. An excellent review with a summary of different kinetic models is given by Saeidi et al [5] and Shahid et al [1].

As far as the reactor modelling is concerned, numerous mathematical models were proposed for the water gas shift reactor accounting for the changes in molar flowrates of species, reactor temperature and pressure with different degrees of sophistication [6-8]. Those models were used to conduct parameter sensitivity analysis, predictions, and optimization of reactor performance.

In this work, the theory of optimal control is applied to a cocurrent flow nonadiabatic catalytic membrane WGSR to optimally design for suitable hydrogen fluxes required to maximize the CO conversion and controlling the temperature inside this reactor. This problem has not been yet addressed in the literature for membrane reactors and the results presented in this study can greatly assist in providing rigorous decisions about the proper set-up of the reactor configurations required to achieve the set goals.

## KINETICS AND REACTION RATE LAW

Water gas shift reaction is described by the following stoichiometric equation:

$$CO + H_2O \Leftrightarrow H_2 + CO_2 \; \Delta H^0_{298} = -41.1 \frac{kJ}{mol} \quad [1]$$

The reaction is moderately exothermic, reversible, and its conversion can be favored by operating at low temperatures in conversional fixed bed reactors. The kinetic expression of the water gas shift reaction expressed in mol/ (kg cat ×s) on a commercial Cu/ZnO/$AlO_3$ catalyst is given in terms of the component partial pressure as follows [9,10]:

$$r = 82.4 \times 10^3 \, exp\left(-\frac{47400}{RT}\right)\left[p_{CO}p_{H_2O} - \frac{p_{H_2}p_{CO_2}}{K_{eq}}\right] \quad [2]$$

The equilibrium constant can be estimated using:

$$K_{eq} = exp\left(\frac{4577.8}{T} - 4.33\right) \quad [3]$$

## REACTOR CONFIGURATION

The co-current configuration of the catalytic membrane water gas shift reactor utilized in this study is depicted in Figure 1. The reactor is composed of two main concentric tubes separated by a highly selective hydrogen permeative membrane wall extending along the axial distance of the reactor.

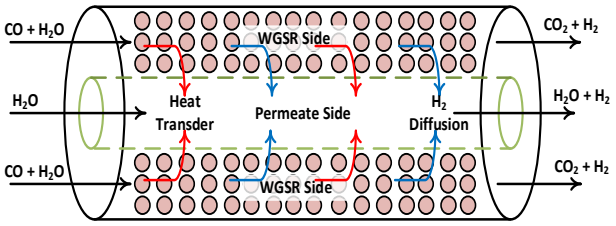

**Figure 1:** Co-current configuration of the catalytic membrane water gas shift reactor.

On the outer side, a copper-based catalyst is used to pack the bed allowing low-temperature water gas shift reaction to take place. The feed to this side is mainly composed of carbon monoxide, steam and inert gases introduced at a temperature of 200°C and a pressure of 1.5 atm. While the reaction takes place in the outer tube, both hydrogen and heat are produced, and exchanged with the permeate side.

On the inner side, pure steam at a temperature of 120°C is introduced. It is used to create an appreciable driving force along the membrane reactor and purge the diffused hydrogen out of the reactor.

## REACTOR MATHEMATICAL MODELLING

The reactor model equations are derived considering the assumptions of steady-state operation of both sides of the reactor, ideal gas behavior, plug-flow reactor model, negligible effect of the catalyst deactivation, adiabatic reactor external wall, negligible diffusional resistances, highly selective hydrogen permeative membranes are installed, the pressure drop on the reaction side is estimated using Ergun's equation, and negligible pressure drop on the permeate side. The governing equations of the reactor are given as:

Mole balance:

$$\frac{dn_i}{dz} = \sigma_i r \rho_s (1-\varepsilon)(1-u_1)A_c - 2\pi R_3 \psi_i u_2 \quad [4]$$

Energy balance:

$$\frac{dT}{dz} = \frac{[-\Delta H(T)]r\rho_s(1-\varepsilon)(1-u_1)A_c - 2\pi R_3 U(T-T') - \sum_{i=1}^{n} 2\pi R_3 \psi_i u_2 \int_{T'}^{T} C_{pi} dT}{\sum_{i=1}^{n} n_i C_{pi}} \quad [5]$$

Pressure drop:

$$\frac{dP}{dz} = -\frac{G}{\rho D_p g_c}\left(\frac{1-\varepsilon}{\varepsilon^3}\right)\left[\frac{150\mu(1-\varepsilon)}{D_p} + 1.75G\right] \quad [6]$$

On the permeate side, the equations are given by:

$$\frac{dn_i'}{dz} = 2\pi R_3 u_2 \quad [7]$$

$$\frac{dT'}{dz} = \frac{2\pi R_3 U(T-T') + \sum_{i=1}^{n} 2\pi R_3 \psi_i u_2 \int_{T'}^{T} C_{pi} dT}{\sum_{i=1}^{n} n_i' C_{pi}'} \quad [8]$$

The boundary conditions are defined at the reactor inlet for the cocurrent configuration as follows:

At $z = 0$:

$$n_i = n_{i0} \qquad T = T_0 \qquad P = P_0 \quad [9]$$

$$n_i' = n_{i0}' \qquad T' = T_0' \quad [10]$$

In the above reactor model equations, two control variables are included, namely the inert solid volume fraction $u_1$ and hydrogen flux $u_2$. The volume inert solid fraction is a dimensionless variable defined as the ratio of the volume of the inert solid to the total solid fraction present on the reaction side, while the hydrogen flux is defined as moles of hydrogen exchanged per unit time per unit surface area. Both variables are determined numerically based on prescribed performance measures. Additionally, the phi parameter $\psi_i$ introduced in the model equations owns a value of one for hydrogen and zero otherwise. The overall heat transfer coefficient $U$ between the reaction side and permeate side is estimated using a composite wall correlation.

## MATHEMATICAL FORMULATION OF THE OPTIMIZATION PROBLEMS

The optimization problems can be stated as follows:

Let $U_1$and $U_2$ be the set of all admissible profiles of solid volume fraction and hydrogen flux, respectively.

The optimization problems encountered in this study is to compute $u_1(z) \in U_1$ and/or $u_2(z) \in U_2$ such that a performance measure is minimized without violating the governing model equations of the catalytic membrane WGSR and/or any other specified equality or inequality constraints.

Three objective functions are considered in this study for the membrane catalytic reactor and defined as conversion of carbon monoxide achieved in the reaction side, temperature cost at the reactor exit, and variation cost of the temperature inside the reactor with respect to a set temperature, i.e. 320°C. The mathematical representation is given as:

$$J_1(x,u_1,u_2) = \frac{n_{CO}^f - n_{CO}}{n_{CO}^f} \quad [11]$$

$$J_2(x,u_1,u_2) = [T(L) - T_R]^2$$

$$[12] J_3(x,u_1,u_2) = [T(L) - T_R]^2 + \int_0^L (T - T_R)^2 dz \quad [13]$$

The mathematical formulation of the optimization problem can be stated as follows:

$$\underset{x,u_1,u_2}{Min}\ J_i(x,u_1,u_2) \qquad i \in \{1,2,3\} \quad [14]$$

Subject to:

$$F(x,u_1,u_2) = 0 \quad [15]$$

The conversion of carbon monoxide is multiplied by "-1" to convert the maximization problem to minimization in Eq [11]. Eq [15] is a vector representing the conservation nonlinear algebraic equations of the reactor model equations obtained by discretizing the ordinary differential equations using Hermite-Simpson collocation technique.

The hydrogen flux along the WGSR expressed in mol/(m$^2$×s) is the main optimal profile to be determined. The bound is set to be:

$$0.5 \le u_2 \le 8.0 \quad [16]$$

The hydrogen recovery defined as cumulative molar flowrate of hydrogen diffused to the permeate side with respect to CO fed to the reactor is controlled by setting a hard constraint given by the following nonlinear algebraic equation:

$$n'_{H_2}(L) - n^R_{H_2} = 0 \quad [17]$$

The hydrogen recovery is varied in this study between two limits, i.e. 1.25 and 1.75 mol/s.

The inert solid volume fraction is introduced to the optimization problems in order to control the temperature inside the reactor. The total volume fraction of the inert solid is defined along the dimensionless axial distance as:

$$\bar{u}_1 = \int_0^{1.0} u_1(\zeta) d\zeta \quad [18]$$

The total volume fraction of the inert solid is varied assuming the values of 0.35, 0.45 and 0.50 and the bound on the solid volume fraction is given by:

$$0.0 \le u_1 \le 1.0 \quad [19]$$

A summary of the optimization problem addressed in this work and the reactor design and operational parameters are given in Tables 1 and 2, respectively. The optimization problems are solved numerically using SNOPT.

**Table 1:** Optimization problem set-up

| Problem | Case No. | Objective function | Control variables | $H_2$ recovery constraints |
|---|---|---|---|---|
| 1 | 1 | $J = J_1$ | $H_2$ flux | NA |
| | 2 | $J = 0.01J_1 + 0.99J_2$ | $H_2$ flux | NA |
| | 3 | $J = J_2 + J_3$ | $H_2$flux | NA |
| 2 | 1 | $J = J_1$ | $H_2$ flux | 1.25 mol/s |
| | 2 | $J = J_1$ | $H_2$ flux | 1.75 mol/s |
| 3 | 1 | $J = J_2 + J_3$ | $H_2$ flux & inert volume fraction | NA |

**Table 2:** Reactor design and operating parameters

| Parameter | Numerical value | Unit |
|---|---|---|
| Reactor length | 3.0 | m |
| Reactor inner radius | 0.05 | m |
| Stainless steel thickness | $2.0\times10^{-3}$ | m |
| Membrane thickness | $1.0\times10^{-6}$ | m |
| Reactor outer radius | 0.08 | m |
| Diameter of catalyst particles | $6.0\times10^{-3}$ | m |
| Catalyst density | 2500 | Kg/m$^3$ |
| Bed porosity | 0.55 | -- |
| *Reaction Side* | | |
| Feed molar flowrate | 5.0 | mol/s |
| *Feed composition* | | |
| CO | 0.2749 | -- |
| $H_2O$ | 0.3165 | -- |
| $CO_2$ | 0.1198 | -- |

| Steam molar flowrate | 25.0 | mol/s |
| Steam feed temperature | 393.15 | K |
| Steam feed pressure | 1.0 | atm |

## Without catalyst dilution

For the first optimization problem, the objective functions considered were the conversion of CO in the reactor, a linear combination of the conversion of CO and

the exit temperature cost with a weight of 0.99 and 0.01, and a temperature cost combining the temperature inside the reactor and at the exit point. The optimization problems were solved for the optimal $H_2$ flux profiles with no constraints on the $H_2$ recovery.

In Figure 2, the conversion of carbon monoxide and the equilibrium conversion are plotted against the dimensionless axial distance for all scenarios. It is observed that the CO conversion inside the membrane reactor is higher than those of the equilibrium due to the hydrogen permeation. The maximum conversion observed is when the objective function is the conversion of CO, while the second highest is observed when the temperature of the reactor is controlled inside the reactor and at the exit. The reduction in CO conversion in the reactor when the temperature is controlled, is due to the low $H_2$ recovery, i.e. less $H_2$ diffused from the reaction side to the permeate side. In all three optimization scenarios, the estimated reactor conversions are >~ 95%.

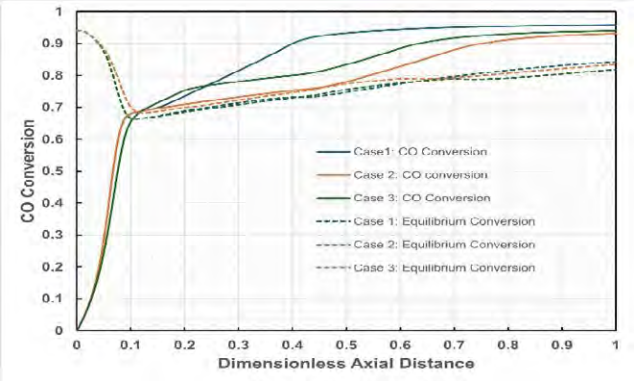

**Figure 2:** CO conversion and equilibrium conversion profiles for the cases of maximizing CO conversion, minimizing exit and reactor temperature.

The optimal hydrogen flux profiles expressed in mole/($m^2$×s) are plotted vs. the dimensionless reactor distance in Figure 3 for all optimization problems.

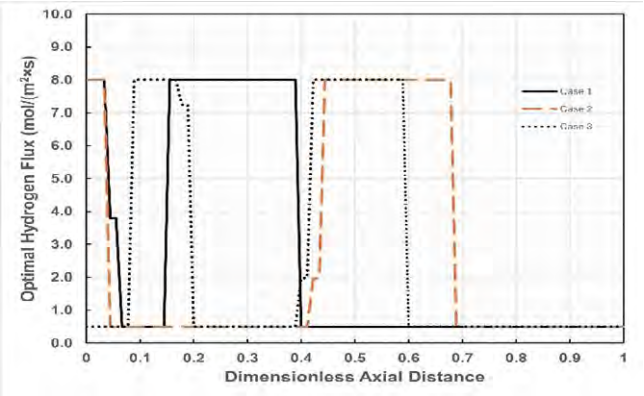

**Figure 3:** Optimal $H_2$ flux profiles based on maximizing CO conversion, minimizing exit and reactor temperature.

All the three control profiles computed are **bang-bang** type with no singular intervals due to the fact that the Hamiltonian for the reactor depends affinely on the hydrogen flux. The hydrogen flux alternates between 8.0 mole/ ($m^2$×s) and 0.5 mole/ ($m^2$×s) representing two types of membrane reactors with high and low $H_2$ permeation rates achieved by the installation of $H_2$ membranes with different fluxes. To maximize the conversion of CO, it is observed that maximum hydrogen flux is required at the reactor inlet, while minimum hydrogen flux is required when the reactor temperature is to be controlled. At the reactor outlet, a low hydrogen flux is required as the conversion of CO approaches completion.

In Figure 4, the temperature profiles on the reaction side are plotted along the dimensionless axial distance. The reactor temperature increases due to the reaction, then decreases due to heat exchange with the permeate side. For a set temperature of 320°C (593.15K), It is observed that the maximum deviation is depicted when the CO conversion is maximized. However, this deviation decreases as the objective function is redefined to include the temperature deviation terms in cases 2 and 3.

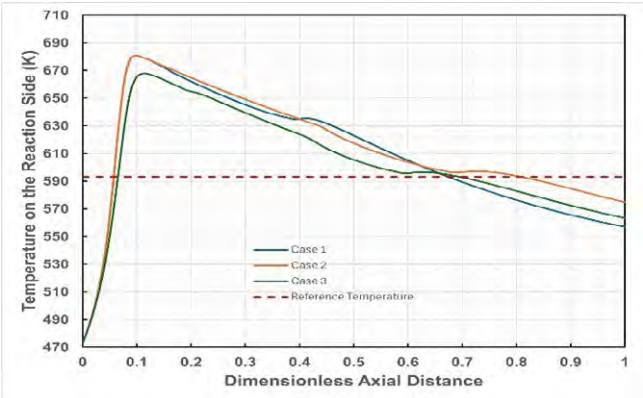

**Figure 4:** Temperature profiles based on maximizing the CO conversion, minimizing exit and reactor temperature.

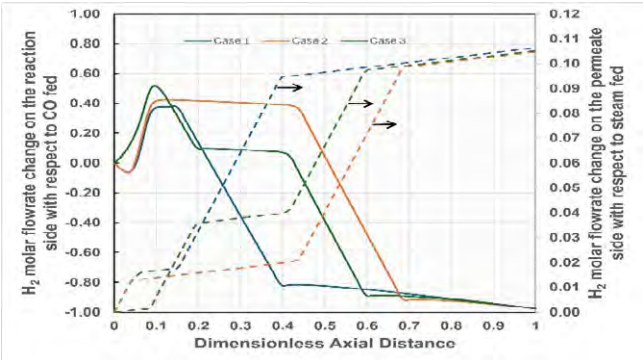

**Figure 5:** Change in $H_2$ molar flowrate profiles on the reaction side and permeate.

The fractional change of the molar flowrates of hydrogen on the reaction side and the permeate side are plotted against the dimensionless distance in Figure 5.

On the reaction side, the molar flowrate of hydrogen decreases within the fractional length of ~0.05 due to the maximum hydrogen flux of 8.0 mol/($m^2$×s) for the case of maximizing the CO conversion, increases due to production by the reaction, then decreases due to the diffusion. When reactor temperature is controlled, hydrogen is maintained inside the reaction side as much as possible as this suppresses the progress of the reaction. On the permeate side of the reactor, it is observed that the sharpest and fastest change is obtained when the CO is maximized where most of hydrogen is recovered within 0.40 fractional length.

In Figure 6, the conversion of CO is plotted along the dimensionless axial distance for unlimited hydrrogen recovrery, 1.25 mol/s, and 1.75 mol/ s. In all cases, the conversion of the carbon monoxide increases along the reactor with a significant difference for the case where the $H_2$ recovery is maximum, i.e. no constraint is set on $H_2$ recovery.

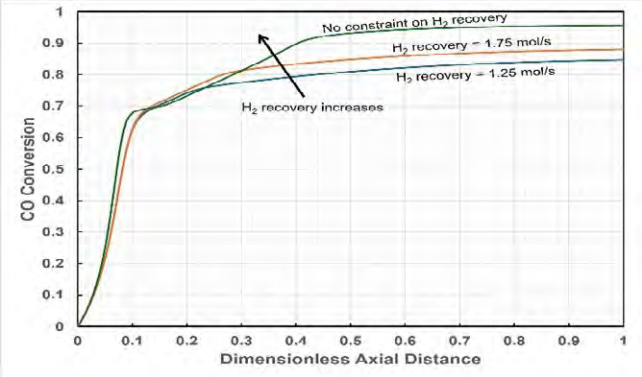

**Figure 6:** Influence of $H_2$ recovery on the CO conversion.

In Figure 7, the molar flowrate of diffused $H_2$ on the permeate side is plotted against the dimensionless axial distance.

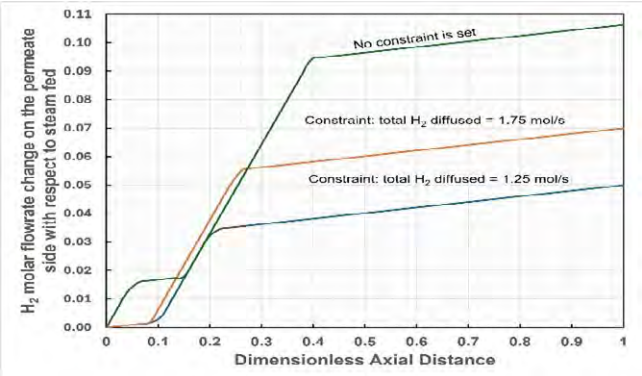

**Figure 7:** Influence of hydrogen recovery on hydrogen flowrate on the permeate side.

All curves show that $H_2$ molar flowrate increases inside the permeate side due to the flux through the membrane but the one with no $H_2$ flux limitation gives the highest $H_2$ recovery in the membrane reactor.

## With catalyst dilution

To control the temperature inside the reactor so that it does not exceed 320°C (593.15K), an inert solid is axially distributed. The distribution profiles of the inert solid for total average amounts of 0.35, 0.45 and 0.50, and the corresponding CO conversion profiles are shown in Figure 8.

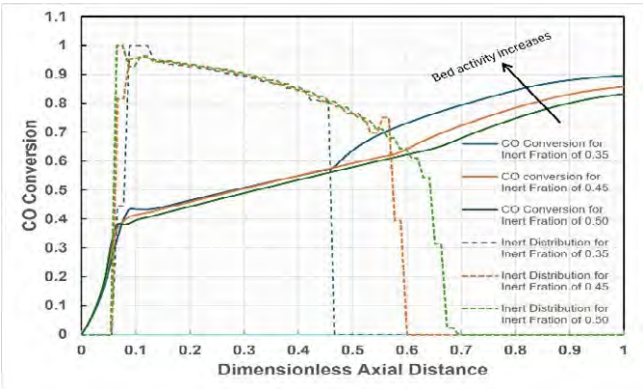

**Figure 8:** Optimal solid inert distribution and the corresponding CO conversion profiles.

At the reactor entrance, it is required to have the catalytic bed fully active indicated by zero inert solid volume fraction. This causes a ramp in the reactor temperature from the feed temperature to the required set temperature as shown in Figure 9.

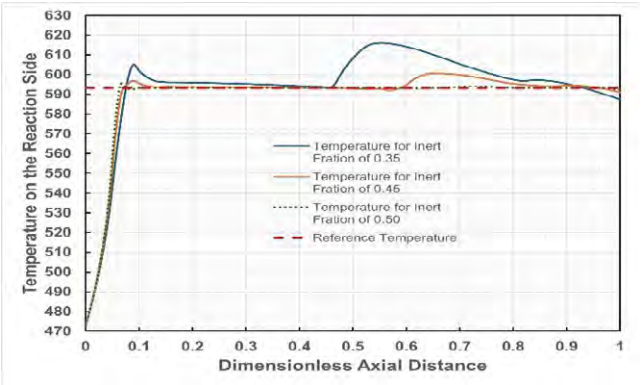

**Figure 9:** Temperature profiles for total inert solid fraction of 0.35, 0.45 and 0.50.

A peak is then formed at which the bed is made to be inactive by setting the volume fraction of the inert solid to unity. This causes the generated reaction heat rate to be zero and only heat exchange between the reaction side and the permeate side takes place. After that, a decreasing inert solid fraction profile is utilized to adjust the temperature to get close to 320°C. The average solid volume fraction of 0.35 gives the highest temperature

deviation compared to the other two scenarios of 0.45 and 0.50 as most of the inert solid is used to reduce the temperature in the reaction side and none is left to maintain the temperature close to 320°C. The optimal inert solid distribution profiles on the reaction side are a **min-max-singular-min** types recommending the utilization of a catalytic membrane reactor with four activity zones, i.e. fully active bed followed by an inactive bed followed by a mixed catalyst bed and finally an active bed.

## CONCLUSION

A 1D homogeneous steady-state reactor model for a membrane catalytic water gas shift reactor was developed. The model was used to secure the optimal $H_2$ flux required to maximize the yield conversion and controlling the temperature along the reactor axial distance. In addition, the reactor model was used to optimize the distribution of the inert solid required to maintain the temperature of the reactor not exceeding 320°C (593.15K) and eliminating the hot spot formed due to the reaction exothermicity. The maximization of CO conversion requires hydrogen flux to be maximum at the reactor entrance as this shift the thermodynamic equilibrium and achieving higher conversion. The scenario was the opposite when the temperature is to be controlled where minimum hydrogen flux is needed at the reactor entrance so that the reaction progress is suppressed and amount of heat released is minimized, too. The hydrogen optimal flux profile is a bang-bang controller type with five switching points indicating that membrane reactors with different permeability must be used. The inert solid distribution used to control the temperature inside the reactor shows that a singular arc must be implemented where a fully active bed has to be used at the entrance to favor the temperature rise to the set temperature.

## ABSTRACT

The production of hydrogen from solar energy has surged in popularity in recent years, driven by global initiatives to combat climate change. The Greater Middle East (GME) region, with its favorable geographical position, offers considerable potential for solar-based hydrogen generation. This study combines Geographic Information System (GIS) spatial analysis and the Analytical Hierarchy Process (AHP) with data-driven optimization models to assess land suitability and hydrogen production potential within the region under various scenarios. Findings highlight that water availability is the primary limiting factor, followed closely by road accessibility in determining land suitability for hydrogen production. According to the AHP analysis, only 3.8% of the GME region is highly suitable for such initiatives. Projections suggest that by 2050, the region could achieve a total hydrogen production capacity of up to 1590 Mt/y, potentially avoiding around 4586 Mt of $CO_2$ emissions if all highly suitable land is utilized effectively. Furthermore, the levelized cost of hydrogen (LCOH) is expected to decrease to a range of $2.56-4.17/kg, while green ammonia and methanol costs are anticipated to fall between $0.56-0.79/kg and $0.67-0.93/kg, respectively. This study offers valuable insights that contribute significantly to the global hydrogen discourse and provides essential guidance for policymakers aiming to develop comprehensive strategies for advancing the hydrogen economy in the GME region.

**Keywords**: Optimization, GAMS, Modelling and Simulation, Energy Management, Hydrogen, GIS-MCDM

## INTRODUCTION

The Greater Middle East (GME) region, encompassing the Middle East, Türkiye, Iran, Iraq, North Africa, Central Asia, and the Caucasus, is strategically located within the global sunbelt and possesses significant potential for solar-driven hydrogen production. For these nations, hydrogen presents an opportunity to decrease dependence on fossil fuels while positioning themselves as major exporters to burgeoning hydrogen markets in the EU, Japan, and South Korea, all of which are actively investing in this sector. Saudi Arabia aims to capture 10% of the global hydrogen market by 2030 [1], while Egypt targets a market share of 4-8%. Additionally, various countries in the region have set ambitious hydrogen production goals and initiated several large-scale projects [2]. Despite these advancements, the green hydrogen industry in the GME remains nascent, with uncertainties surrounding the future dynamics of energy trade in this evolving economy. This raises critical questions about which countries will emerge as dominant players and their capacity to meet both local and global hydrogen demands. To address this, it is essential to first estimate the hydrogen production potential of the region by evaluating the

suitable land area, accompanied by a technical, economic, and environmental evaluation for a broader perspective.

Several studies have examined the hydrogen potential of countries in this region, most of which utilize GIS analysis to identify suitable land areas [3,4]. However, accurately estimating hydrogen production potential requires precise data acquisition, such as hourly solar profiles, which are crucial for making informed decisions regarding solar and electrolyzer operations. The complexity of handling such extensive data often limits these analyses to single locations or a few major cities within a country. Furthermore, only a handful of studies address economic factors, and even fewer incorporate an environmental perspective. In this study, GIS-AHP analysis is employed to estimate the amount of suitable land available for hydrogen production. Additionally, data-driven optimization models are utilized to facilitate hydrogen production estimates on a larger scale. This research considers thirty countries in the GME region, evaluating their hydrogen potential alongside key metrics such as the levelized cost of hydrogen (LCOH), levelized cost of ammonia (LCOA), and levelized cost of methanol (LCOM). The potential for $CO_2$ emissions reduction is also assessed through Life Cycle Assessment (LCA) analysis.

## METHODOLOGY

The study area comprises thirty countries with a total area of 29,544,619 km$^2$. A spatial resolution of 1km x 1km was selected, yielding 29.5 million alternatives (locations) as candidates for suitable sites in the GME region. To determine the most appropriate sites, six key criteria were examined: solar resource availability, proximity to water bodies and waterways, topographical slope, land use, and land cover, accessibility to roads, and proximity to protected or restricted areas. An AHP analysis was then performed which compares all these factors pairwise and assigns weights to them based on their relative importance. The AHP extension tool within ArcMap software was employed to guarantee the accuracy of calculations. The consistency matrix and the scores assigned to each criterion are detailed in the supplementary material.

A data-driven optimization model was employed to estimate the annual hydrogen production potential (AHPP) and the LCOH using a two-stage approach. In the initial stage, 100 locations within the GME region were randomly selected, and their hourly solar profiles were sourced from the Global Solar Atlas. The optimization model was then executed for these locations, yielding optimized data such as electrolyzer operating hours, solar-to-electrolyzer ratios, and power loss. Based on the specific power output of these locations, they were categorized into ten distinct intervals. Average feature values for each interval were calculated, leading to the development of a predictive model. In this model, each location is first assigned to an interval based on its PVOUT and subsequently assigned the average feature values corresponding to that interval. All analyses were conducted for the years 2024 and 2050 under two distinct scenarios. In Case 1 (conservative scenario), it was assumed that each location would be utilized only partially, at a rate of 5% for hydrogen projects. This scenario considered a 2 MW solar plant paired with a 1 MW electrolyzer. In Case 2, an optimistic scenario was evaluated, assuming full utilization of the available area (100% coverage). For this scenario, a 38 MW solar plant with a 19 MW electrolyzer was proposed.

The power ($P_{t,m}$) produced by the solar plant at time *t* in month *m* is estimated as follows:

$$P_{t,m} = \emptyset_{t,m} \times C, \quad \forall\, t \in T, \forall\, m \in M, \tag{1}$$

where $\emptyset_{t,m}$ is temporal photovoltaic power output (kWh/kWp) data for the time *t* in the month *m*. $C$ is the capacity of the solar plant and the primary decision variable in the model.

The power supplied to the electrolyzer can neither exceed its capacity ($\delta$) nor fall below its minimum threshold power ($\alpha$). This is modeled as:

$$P_{t,m} \leq \delta, \quad \forall\, t \in T, \forall\, m \in M, \tag{2}$$

$$P_{t,m} \leq B_{t,m}, \quad \forall\, t \in T, \forall\, m \in M, \tag{3}$$

$$P_{t,m} \geq \alpha \times \delta - \varepsilon \times (1 - B_{t,m}), \forall\, t \in T, \forall\, m \in M, \tag{4}$$

where $B_{t,m}$ represent binary variables to allow power to the electrolyzer and $\varepsilon$ represents the upper bound for power to the electrolyzer according to the Big-M formulation method.

The amount of hydrogen ($H_{t,m}$) produced by the electrolyzer at time *t* in month *m* is estimated as:

$$H_{t,m} = \eta \times P_{t,m}, \quad \forall\, t \in T, \forall\, m \in M, \tag{5}$$

where $\eta$ is the electrolyzer efficiency. The total annual hydrogen (*TH*) produced is calculated as follows:

$$TH = \sum_{t,m} H_{t,m} \times d_m, \tag{6}$$

where $dm$ is days in month *m*.

A discounted cash flow model is formulated for the economic analysis. The LCOH in $/kg is defined as:

$$LCOH = \frac{NPV\ of\ total\ costs}{NPV\ of\ hydrogen\ production}, \tag{7}$$

where *NPV* is the net present value. The *NPV* of total costs and hydrogen production is estimated as follows:

$$NPV\ of\ total\ costs = \sum_{n=0}^{20} \frac{CAPEX+OPEX}{(1+r)^n}, \tag{8}$$

where CAPEX and OPEX are the capital and operating expenditure, respectively.

$$NPV\ of\ hydrogen\ production = \sum_{n=1}^{20} \frac{TH}{(1+r)^n}, \tag{9}$$

where *r* is the internal rate of return and *n* is the project life. Notably, *CAPEX* incurs at $n = 0$ (construction period) and *OPEX* and hydrogen production occur at $1 \leq n \leq 20$.

An estimation of the levelized cost of energy (LCOE) was used to estimate the LCOA and LCOM. The total lifecycle costs (TLCC) and annual power (AP) output are estimated using:

$$TLCC = \sum_{n=0}^{20} \frac{CAPEX + OPEX}{(1+r)^n}, \quad (10)$$

$$AP = \sum_{n=0}^{20} \frac{PVOut \times C \times 365}{(1+r)^n}. \quad (11)$$

The LCOE is then calculated using (10) and (11) as:

$$LCOE = \frac{TLCC}{AP}. \quad (12)$$

The raw material and utility demand for each derivative is estimated using process simulations as described in our previous studies [5]. The final cost of the derivatives was estimated using equations (7-9).

All assumed parameters are given in the supplementary material.

To evaluate the environmental impact of hydrogen in comparison to gasoline, a cradle-to-grave life cycle assessment (LCA) was conducted. This study quantified the potential reduction in carbon emissions achievable by transitioning to solar-driven hydrogen as an alternative to gasoline, referring to this reduction as "avoided $CO_2$ potential" for both conservative and optimistic scenarios. For inventory scaling, 1 kg of hydrogen was utilized as the functional unit. The energy produced from hydrogen, estimated at approximately 120–142 MJ/kg, was converted into its gasoline equivalent of 44–46 MJ/kg, based on usage in a typical fuel-efficient vehicle that consumes 70 grams of fuel per kilometer. The LCA was carried out using SimaPro V8.2.3, employing the CML-IA baseline V3.03 characterization method.

## RESULTS & DISCUSSION

GIS analysis indicates that water availability is the primary factor influencing land suitability for hydrogen production in the GME region, particularly in the Middle Eastern and North African countries. Overall, about 57% of land is considered unsuitable for the deployment of solar-driven hydrogen production facilities. Locations within a 10 km radius of water bodies are deemed suitable, while those further away are not. Among the thirty countries studied, fourteen have less than 50% of their land with accessible water resources. Another constraint is the land slope which should be below 5° to facilitate the large-scale deployment of solar panels. Among the thirty countries analyzed, five—Tajikistan, Kyrgyzstan, Lebanon, Armenia, and Türkiye—have less than 50% of their land suitable due to slope constraints. Approximately 86% of the total land in these regions is suitable for solar panel installation.

When selecting optimal sites, the proximity to roads is a crucial constraint to consider since hydrogen needs to be transported to the end user. Any location that is within 500m of roads or more than 10 km away from them was considered unsuitable for this analysis. Overall, approximately 40% of the total land in the GME region is considered unsuitable for hydrogen production when factoring in proximity to roads. Analysis of the land cover and land use data revealed that approximately 88% of the GME region consists of barren or open land, characterized by minimal man-made infrastructure or restricted/protected areas. This type of land is particularly well-suited for hydrogen facilities. As a result, this constraint has not significantly affected the overall suitability of the land for such projects.

The AHP analysis results, illustrated in **Figure 1**, categorized the GME region into four suitability levels" highly suitable, moderately suitable, low suitable, and not suitable. The results revealed that only 3.8% (about 1.2 million $km^2$) of the land is highly suitable, satisfying all the constraints. It is important to highlight that Saudi Arabia distinguishes itself in the region by having the highest number of optimal sites for hydrogen production. In contrast, the Central Asian states face challenges due to their rugged terrain and slope, resulting in a lower availability of suitable land. North African countries, on the other hand, encounter limitations related to water availability, which restricts their land suitability for solar-driven hydrogen production. An exception is Morocco with a high proportion of suitable land.

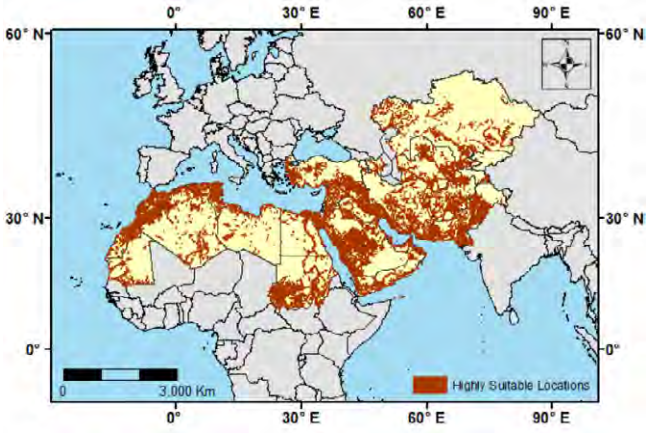

**Figure 1** Highly suitable locations identified through the AHP analysis.

### Hydrogen Production Potential

To estimate the hydrogen production potential of the GME region, the land area identified as highly suitable through the AHP analysis is utilized. Figure 2 illustrates the annual hydrogen production potential for each country in 2024, along with projections for 2025. For smaller nations such as Armenia, Bahrain, Lebanon, and Qatar, the potential remains below 1 Mt/y even under the 100% coverage scenario. In scenario one, all countries

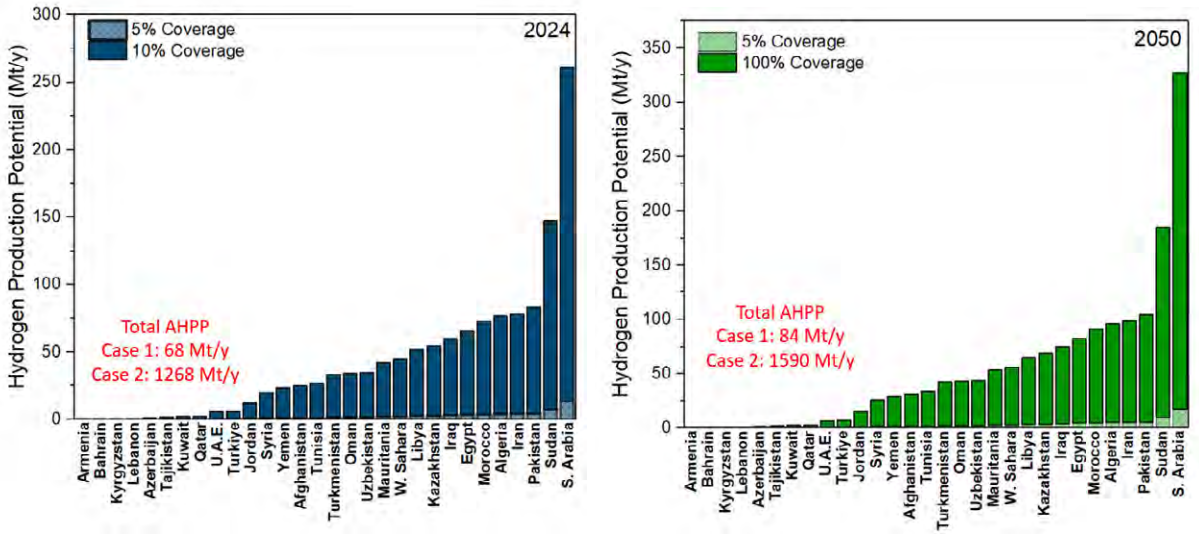

**Figure 2:** Annual Hydrogen Production Potential (AHPP) of thirty countries in the GME region for Case 1 (5% Coverage) and Case 2 (100% Coverage) for 2024 and 2050.

remain below 15-17 Mt/y, indicating that even with minimal land use, these nations can be self-sufficient in meeting their hydrogen needs. The cumulative potential for this scenario totals 68 Mt/y in 2024 and increases to 84 Mt/y by 2050. In a more optimistic scenario (case 2), the region's hydrogen production potential rises significantly to 1268 Mt/y in 2024 and reaches 1590 Mt/y by 2050. Among the countries analyzed, Saudi Arabia stands out with the highest production potential, projected to reach approximately 327 Mt/y by 2050. Meanwhile, Pakistan, Morocco, and Egypt are expected to achieve production potentials of 104 Mt/y, 91 Mt/y, and 82 Mt/y respectively in this optimistic scenario. According to IRENA, global hydrogen demand is projected to reach 450 Mt/y by 2050 [6], with about one-third of this demand expected to be met through international trade. Given these figures, it is evident that the GME region is poised to play a crucial role in capturing a significant share of the global hydrogen market.

## Levelized Cost of Products

A location that is deemed highly suitable based on the aforementioned constraints does not necessarily imply that it is also economically viable. The LCOH serves as the economic indicator for assessing the feasibility of a location by examining the total expenses in the production of hydrogen. Figure 3 illustrates the current and projected ranges of LCOH in the GME region.

The LCOH in the region ranges from 4.6 $/kg to 16.4 $/kg. However, if we consider only the highly suitable locations in the region, Egypt, Saudi Arabia, and Libya have the lowest LCOH of about 4.70, 4.73, and 4.75 $/kg, respectively. On the other hand, Kazakhstan shows the highest LCOH of 7.84 $/kg in 2024. Projections for 2050 indicate that the LCOH range will decrease to 2.5 to 9.1 $/kg with Egypt showing the lowest LCOH while Kazakhstan has one of the highest. Despite the potential for hydrogen production in the region, the LCOH remains higher than that of grey hydrogen produced from fossil fuels, which are still more readily available and affordable in this region. The extent to which a country can lower the CAPEX for solar panels and electrolyzers—through measures such as reducing import taxes—will play a crucial role in facilitating the region's transition to a green hydrogen economy. North African and Middle Eastern countries benefit from abundant solar resources, resulting in relatively lower LCOH in these areas. However, water scarcity may hinder them from fully utilizing this potential. In contrast, Central Asian states have access to good water supplies but face significant challenges due to limited solar resources and challenging topography, which could restrict development. Countries situated between these two extremes—such as Iran, Iraq, Pakistan, Afghanistan, and Turkey—enjoy a favorable balance of both solar and water resources, positioning them well for potential growth in green hydrogen production.

Hydrogen derivatives like Ammonia and Methanol have a significant global market and utilizing green hydrogen to produce these can save up a lot of $CO_2$ emissions. In addition to being valuable products themselves, these chemicals can easily be transported internationally and can serve as cost-effective hydrogen carriers. Figure 3 illustrates the LCOA and LCOM for 2024 and 2050. For highly suitable locations, green ammonia is expected to cost between 0.96-1.38$/kg in 2024 and 0.56-0.79$/kg by 2050 while green LCOM ranges from 1.12-1.59 $/kg in

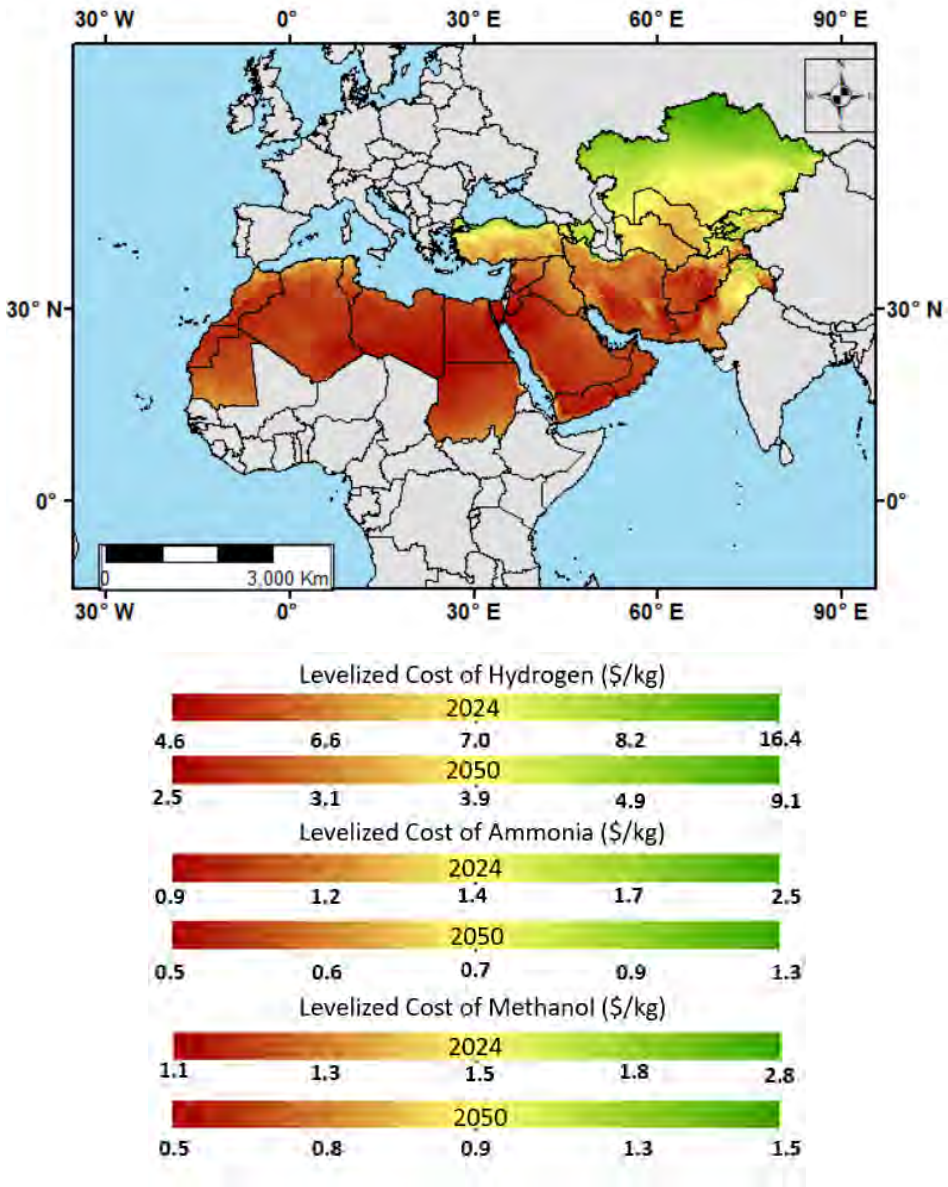

**Figure 3**: Levelized cost of hydrogen, ammonia, and methanol in the GME region for 2024 and 2050.

2024 and is expected to decrease to 0.67-0.93 $/kg by 2050.

**Table 1** $CO_2$ avoided potential for Case 1: 5% coverage and Case 2: 100% coverage for 2024 and 2050.

| Year | Case | $CO_2$ avoided potential (Mt/y) |
|---|---|---|
| 2024 | 1 | 481 |
| | 2 | 3655 |
| 2050 | 1 | 603 |
| | 2 | 4586 |

## $CO_2$ Avoided Potential

The LCA analysis was conducted to quantify the $CO_2$ emissions that could be avoided by substituting gasoline with green hydrogen. The total potential for $CO_2$ emissions reduction in the two scenarios is presented in **Table 1**. For the year 2024, the region has the potential to avoid between 481 and 3655 Mt/y of $CO_2$, depending on whether highly suitable locations are utilized partially (5%) or fully (100%) for hydrogen projects, respectively. By 2050, these values could increase to between 603 and 4586 Mt/y, assuming improved production efficiency of electrolyzers and solar panels. These findings highlight the significant opportunity for the region to achieve its net-zero targets through the adoption of green hydrogen across various sectors. Notably, most countries in the region are self-sufficient and will not need to rely on imported hydrogen to realize this potential.

## CONCLUSION

An integrated approach combining GIS-MCDM analysis, along with data-driven optimization models, was employed to assess the hydrogen potential of the GME region through technical, economic, and environmental evaluations. The GIS analysis identified proximity to water resources as the primary constraint affecting land suitability, particularly in North African and Middle Eastern countries. In contrast, Central Asian states face challenges due to rugged topography that renders much of their land unsuitable. Additionally, proximity to roads emerged as another significant factor impacting land suitability. After conducting the AHP analysis, it was determined that only 3.8% of the GME region is classified as highly suitable for solar-driven hydrogen projects, with Saudi Arabia, Sudan, and Pakistan identified as the top three countries with the most favorable land conditions. However, not all suitable locations are economically viable. The LCOH results indicate that Egypt and Libya have very low LCOH due to their excellent solar resources. The region also possesses the potential to produce green ammonia and methanol, which are valuable chemicals with a strong global market demand. Overall, the hydrogen potential suggests that the GME region could capture a significant share of the global hydrogen market, particularly serving European Union countries and Asia-Pacific nations like Japan and Korea that are actively investing in hydrogen economies. Furthermore, it can meet its net-zero targets by integrating green hydrogen across various sectors. However, establishing a robust hydrogen economy will require significant government efforts and investments. This transition may only be feasible if green hydrogen projects become profitable, which hinges on achieving economies of scale in electrolyzer production and reducing costs in the coming years.

## DIGITAL SUPPLEMENTARY MATERIAL

Details of the AHP analysis as well as all the assumed parameter values in the optimization code are given in the digital supplementary material.

# Food for thought: Delicious problems for Process System Engineering (PSE) courses

**Daniel R. Lewin***

Department of Chemical Engineering, Technion I. I. T., Haifa 32000, Israel
* Corresponding Author: dlewin@technion.ac.il.

## ABSTRACT

Active learning is widely recognized as an effective teaching approach that can improve classroom outcomes. This is enabled by providing the time for students to apply new knowledge, make mistakes, correct them, and repeat the process until mastery is achieved. One way to implement active learning is through the flipped classroom paradigm. However, to be effective, active learning depends on providing students with a variety of open-ended problems, ranging in difficulty from introductory to advanced levels. This paper presents four food-themed problems for use in numerical methods and process control courses:

1. *Formulating Willy Wonka's new chocolate bar*: An introductory linear programming problem focused on translating verbal descriptions into mathematical models.

2. *Optimal production for the Matrix Pizza company*: A more advanced mixed-integer linear programming problem involving multiple scheduling scenarios.

3. *Optimal frying time for fried ice cream production*: A transient heat transfer problem modelled by an initial-value partial differential equation.

4. *Control system design for Uncle Kane's pancake batter machine*: A control design problem involving uncertain process models and the selection of an appropriate operating mode and PI controller design.

These problems aim to engage students in practical, problem-solving activities central to the active learning process.

**Keywords**: Chemical engineering education, flipped classroom, active learning.

## 1. INTRODUCTION

Active learning is widely accepted as a collection of teaching paradigms that have the best potential to yield improved learning outcomes in classroom settings [1-3]. Traditional lecture-centred teaching often struggles to engage students effectively in a discipline characterized by complex processes and systems [4]. By incorporating active learning techniques such as peer instruction [2], problem-based learning [5], and gamification [6-7], educators can enhance student engagement, critical thinking, and real-world application of concepts [8-9].

Adopting the flipped classroom paradigm [10-11], which moves traditional lecture-based transfer of information to online lessons completed by students in advance of class activities, frees class time for the aforementioned student-centred activities. To adopt active learning, some class time needs to be allocated for students to experiment with the application of the newly acquired knowledge, giving them time to make mistakes, correct their errors, try again, and repeat this process as necessary. This cyclic activity is a variant of Kolb's [12] ideas about the cognitive processes involved in learning. One way to allocate time for effective learning would be to adopt the flipped classroom.

To be effective, this form of learning relies on the availability of sufficient open-ended problem sets to provide students with a rich source of practice materials. These should encompass a range of difficulty: from introductory level to "final exam level" and beyond. To that

end, this paper presents a set of problems with an arbitrary common theme close to the author's heart ("the best way to a man's heart is through his stomach"), mostly intended to be utilized in a course on numerical methods, with one extra problem designed for a course on "good old" process control.

## 2. EXAMPLE FOOD-RELATED PROBLEMS FOR PSE COURSES

With "food, glorious food" as a theme, the four example problems presented in this paper are:

1. *Optimal formulation of Willy Wonka's new chocolate bar*. This is an introductory linear programming (LP) problem, which gives students practice in translation of a verbal description into a mathematical formulation, and its solution.
2. *Optimal production for the "Matrix Pizza" company*, a bakery providing quality pizzas to a college campus in mid-West USA. This is a more advanced mixed integer linear programming (MILP) problem including alternative scenarios that need to be accounted for in the optimal scheduling solution.
3. *Optimal frying time for "fried ice cream."* This is a transient heat transfer problem that is defined as an initial value partial differential equation (IVPDE) that needs to be solved numerically.
4. *Control system design for Uncle Kane's continuous pancake batter machine*. This is a single input – single output (SISO) control problem presented as a set of alternative operating modes, each with its own uncertain model description. The student needs to select the operating mode and design a suitable PI controller that meets required specifications.

Each of the above four example problems will be discussed next, focusing on the problem definition, the degree of difficulty, and the learning objectives. Because of space limitations, only sketches of the solutions will be presented here. Full solution outlines to all four problems will appear in the full version of this paper.

### 2.1 Optimal formulation of Willy Wonka's new chocolate bar

**Problem definition:** Willy Wonka has hired you to formulate a new chocolate bar called "Super-Choc," weighing 100 grams. The bar consists of sugar, and two types of chocolate: African and Belgian. The optimal mass of each component needs to be specified to minimize costs, while meeting the following five requirements:

1. Each bar should contain no more than 60 grams of chocolate
2. The amount of African chocolate should not exceed the amount of Belgian chocolate by more than 10 grams.
3. The bar's Sweetness (S) should not exceed 30 units per bar, where each gram of African chocolate reduces S by 0.3 unit (relative to sugar), while each gram of Belgian chocolate raises S by one unit.
4. The bar's Mouth Feel (M) should be at least 40 units. Each gram of African chocolate increases M by 2.2 units, while each gram of Belgian chocolate raises M by one unit.
5. The bar's Luster (L) should be at least 70 units. Each gram of African chocolate increases L by one unit, while each gram of Belgian chocolate raises L by 3.9 units.

If the cost of Belgian chocolate is three times the cost of African chocolate, and the cost of sugar can be neglected, compute the optimal composition of a bar of "Super-Choc."

**Degree of difficulty**: A practice problem to train basic application of LP methodology.
**Learning objectives**: The student will demonstrate the ability to develop an LP based on a written problem description, and to graphically solve the LP to obtain the optimal solution.
**Sketch of solution**: Defining $x_1$ and $x_2$ as the mass in grams, of African and Belgian chocolate, respectively, the problem as defined can be translated to the following LP:

$$\begin{aligned}
&\min_{x_1,x_2} J = x_1 + 3x_2 \quad \text{(B costs 3 times more than A)} \\
&\text{Subject to:} \\
&x_1 + x_2 \le 60 \quad \text{(chocolate content of at most 60 g)} \\
&x_1 - x_2 \le 10 \quad \text{(A content must be up to 10 g more than B)} \\
&-0.3x_1 + x_2 \le 30 \quad \text{(S must be at most 30)} \\
&2.2x_1 + x_2 \ge 40 \quad \text{(M must be at least 40)} \\
&x_1 + 3.9x_2 \ge 70 \quad \text{(L must be at least 70)} \\
&x_1, x_2 \ge 0
\end{aligned} \tag{1}$$

The graphical solution is shown in Figure 1, indicating that the active constraints are those on M and L, and that 56% of the optimal bar is sugar!

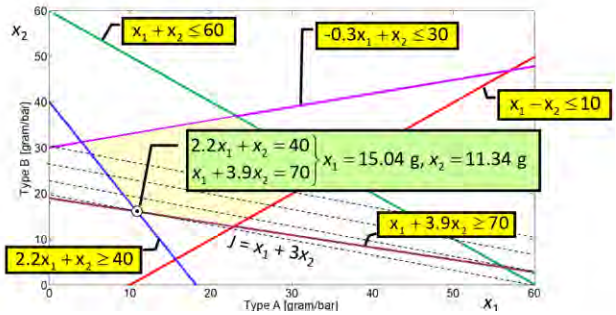

**Figure 1.** Graphical solution for Willy Wonka's chocolate

bar formulation.

## 2.2 Optimal production for the "Matrix Pizza" company

**Problem definition**: "Matrix Pizza" is a pizza bakery that provides quality pizza pies to the college campus in mid-West USA. The bakery produces three types of pizza pies: **Matrix Special**, sold for \$10/pie, **Matrix Pro**, sold for \$7/pie, and **Matrix College**, sold for \$5/pie. The three types of pizza differ only in the toppings, as listed in Table 1.

**Table 1:** Recipes for the Pizzas (quantities of each topping, in grams, on each pizza).

| | Special | Pro | College | Cost (\$/kg) |
|---|---|---|---|---|
| Price (\$/pie) | 10 | 7 | 5 | |
| Tomatoes (g) | 200 | 250 | 350 | 2 |
| Mozzarella (g) | 200 | 250 | 350 | 2 |
| Parmesan (g) | 100 | 100 | 0 | 15 |
| Olives (g) | 100 | 100 | 0 | 20 |
| Tuna (g) | 100 | 0 | 0 | 10 |

In addition to the cost of the toppings, the production costs of the pizza pies also need to account for staff costs estimated at \$1 per pizza pie, as well as operating and maintenance costs of the pizza oven, estimated at \$1,000 per oven per week. For each oven installed, the production capacity is 1,000 pizzas per week. There is no limit on the number of pizza pies that can be produced in the bakery per day, so long as the daily demands, listed in Table 2, are not exceeded on a weekly basis. Your tasks are:

(a) Formulate a MILP whose solution is the optimal quantities of each type of pizza that should be produced each week, including the number of ovens that should be installed in the bakery to maximize profits.
(b) Solve the MILP formulated in step (a).
(c) The college's football team is planning to hold home games each Saturday night. How will this affect the optimal solution if the home games change the pizza demand on Saturdays according to Table 3.

**Table 2:** Typical Demand (pizzas/day for each type).

| Day | Special | Pro | College |
|---|---|---|---|
| Monday | 20 | 60 | 60 |
| Tuesday | 0 | 80 | 80 |
| Wednesday | 0 | 60 | 140 |
| Thursday | 20 | 80 | 160 |
| Friday | 40 | 40 | 120 |
| Saturday | 140 | 60 | 20 |
| Sunday | 100 | 100 | 20 |
| Weekly Total | 320 | 480 | 600 |

**Table 3:** Revised Demand on Saturdays (pizzas/day for each type).

| Day | Special | Pro | College |
|---|---|---|---|
| Saturday | 340 | 160 | 120 |

**Degree of difficulty**: A more advanced MILP problem.
**Learning objectives**: The student will demonstrate the ability to develop a MILP based on a written problem description, and to either solve the problem graphically or using the Simplex method.
**Sketch of solution**: (a) Formulation of the problems as set as a MILP; (b) Solution using a MILP solution method such as Branch-and-bound or by using the Simplex method on separate scenarios.

## 2.3 Optimal frying time for "fried ice cream."

**Problem definition**: "Fried ice cream" is the house specialty of the "Sea Waves" restaurant, overlooking Haifa bay. A portion of ice cream is wrapped in pastry dough and deep-frozen. Just before serving, it is deep fried for a short time in high-temperature oil. A typical portion of "fried ice cream" is shown in Figure 2. You have been hired by the chef to provide an estimate of the time needed to fry the pastry-wrapped ice cream such that the pastry is crispy, and the ice-cream stays frozen.

**Figure 2.** Fried ice cream

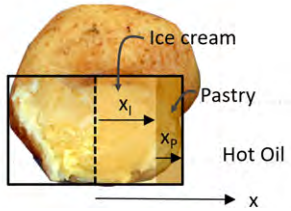

**Figure 3.** Coordinate system

A mathematical model is set up to compute the temperature of the pastry and ice cream as functions of time and position. For simplicity, a one-dimensional model is constructed making use of symmetry, as shown in Figure 3:

$$\text{For ice cream: } \frac{\partial T_I}{\partial t} = \alpha_I \frac{\partial^2 T_I}{\partial x^2},\ T_I(x,0) = T^0,\ 0 \le x \le x_I \qquad (2)$$

$$\text{For pastry: } \frac{\partial T_P}{\partial t} = \alpha_P \frac{\partial^2 T_P}{\partial x^2},\ T_P(x,0) = T^0,\ x_I < x \le x_P \qquad (3)$$

The following boundary conditions apply:

$$@\ x = 0:\ \frac{\partial T_I}{\partial x} = 0 \qquad @\ x = x_I:\ \alpha_I \frac{\partial T_I}{\partial x} = \alpha_P \frac{\partial T_P}{\partial x}$$

$$@\ x = x_I:\ T_I(x_I,t) = T_P(x_I,t) \qquad @\ x = x_P:\ \frac{\partial T_P}{\partial x} = \beta\left(T_{oil} - T_P(x_P,t)\right)$$

**Degree of difficulty**: This problem tests the ability to apply numerical methods for the solution of initial value partial differential equations (IVPDEs).
**Learning objectives**: The student will demonstrate the ability to discretize an IVPDE and its boundary conditions and solve it to ensure a stable numerical solution.
**Sketch of solution**: Development of discretized approximation of the original PDE using a backward difference approximation for the time-differential term to impart unconditional stability on the numerical solution (Crank-Nicolson's method).

### 2.4. Control system design for Uncle Kane's continuous pancake batter machine.

**Problem definition**: Uncle Kane, the famous chemical engineer and expert chef, has developed a continuous process for the production of pancake batter. A controlled stream of liquid, consisting of milk, eggs, and vanilla, $F_1$, is fed to a mixing vessel together with a continuous stream of solid feed consisting mostly of flour and sugar, $F_2$. Uncle Kane has noticed that the frequency of the sound made by the mixer head is related almost linearly to the viscosity of the mixture, which also affects its quality. He has developed an automatic control system that uses a microphone to measure the sound in the mixing vessel, which sends a feedback signal to a controller that manipulates the control valve installed on stream $F_1$. The control system is illustrated schematically in Figure 4.

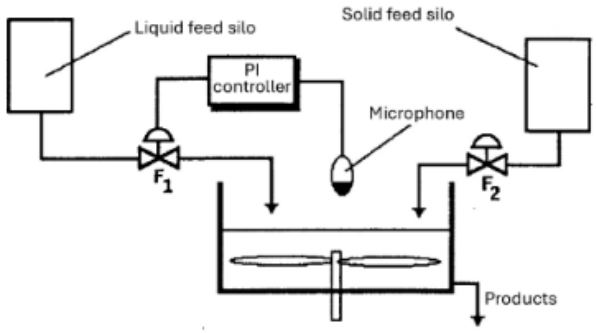

**Figure 4.** Uncle Kane's continuous pancake batter production unit.

After much soul-destroying research, Uncle Kane has succeeded in developing a model relating the flowrate of $F_1$ to the frequency of sound picked up by the microphone, $\phi$:

$$\frac{\phi}{F_1}(s) = p(s) = \frac{K_p(-\alpha s + 1)}{(\tau s + 1)^2} e^{-\theta s} \qquad (4)$$

**Table 4:** Parameters for the model in Eq.(4) as a function of the flow rate $F_2$.

| $F_2$ (kg/h) | $K_p$ | α(s) | τ(s) | θ(s) |
|---|---|---|---|---|
| 750 | $0.9 \le K_p \le 1.1$ | 5 | 5 | 1 |
| 1,000 | $2 \le K_p \le 4$ | 1 | 1 | 0.2 |
| 1,250 | $0.8 \le K_p \le 7.2$ | 5 | 5 | 1 |

His experimental work has also discovered three possible operating points for the production unit, each around a given flow rate of the solid feed, F2. Table 4 presents values of the model parameters in Eq.(4) at each operating point. Design a PI controller to control $\phi$ by manipulating $F_1$ so that the following specifications are satisfied: (a) Robust stability; (b) Bandwidth of the Internal Model Controller (IMC) filter of at least 0.3 rad/sec; (c) Maximizing production.

**Degree of difficulty**: A typical problem in robust control design.

**Learning objectives**: The student will demonstrate the ability to adequately represent the model uncertainty for design purposes and use it to compute PI controller parameters, designed via the IMC parametrization, that meet all the specifications.

**Sketch of solution**: (a) Development of multiplicative approximation accounting both for parametric uncertainty and the consequence of 1st order model implied by the requirement of PI control; (b) Computing stability limit in terms of the time constant of the IMC filter; (c) Usage of these tools to determine the most suitable operating mode and corresponding PI controller tuning.

## 3. INTEGRATION WITH THE FLIPPED CLASS PARADIGM

It would be appropriate to discuss how the problems presented here could be incorporated into the flipped classroom paradigm. While organizational, evaluation and student feedback are addressed in our published papers [10,11], a full version of the paper would provide space to cover these issues in more details.

## 4. DISCUSSION

The use of active learning in engineering education, particularly in courses involving numerical methods and process control, offers numerous benefits over traditional lecture-based teaching [10,11]. Active learning strategies, such as problem-based learning (PBL), peer instruction, and gamification, have been shown to improve student engagement, critical thinking, and long-term retention of knowledge [1-3]. The example problems introduced in this paper, which leverage the flipped classroom paradigm, not only align with these findings but also offer a practical framework for implementing active learning in technically demanding fields such as PSE. They offer a diverse and engaging way to introduce students to fundamental concepts in optimization, heat transfer, and control system design. By utilizing scenarios that range from the formulation of a new chocolate bar to the design of a control system for a pancake batter machine, students are exposed to real-world problems that require both analytical rigor and creative problem-solving skills. This thematic approach—framed around the relatable and engaging concept of food production—appeals to students' interests and can foster a deeper connection to the material, leading to improved motivation and learning outcomes.

### 4.1 Active learning and student engagement

A central goal of active learning is to increase student participation and engagement in the learning

process, which can be particularly challenging in disciplines like PSE where abstract concepts and complex systems are common. Traditional teaching methods often rely on passive learning, where students listen to lectures and absorb information, usually without the opportunity to immediately apply their knowledge for themselves. In contrast, implementing the flipped classroom paradigm, transfers the responsibility of covering the lecture materials to the students as pre-class preparation, and reallocates in-class time for active, hands-on problem-solving.

The problems outlined in this paper facilitate this active learning model by encouraging students to work through open-ended, real-world challenges. This type of problem solving not only reinforces technical knowledge but also helps develop critical thinking, adaptability, and decision-making skills. As students work through problems such as optimizing pizza production or controlling the frying time of ice cream, they learn to balance conflicting objectives, and select appropriate methods for solving complex, dynamic problems. By solving problems iteratively and experimenting, students can internalize the underlying concepts more deeply, improving their ability to transfer this knowledge to new and unfamiliar contexts.

## 4.2 Problem complexity and cognitive development

The problems presented span a broad spectrum of difficulty, catering to students at different levels of expertise. The introductory LP problem on chocolate bar formulation, for example, provides a relatively simple application where students practice translating verbal descriptions into mathematical models. This offers an excellent opportunity for students to gain foundational skills in optimization. On the other hand, more advanced problems—such as the MILP problem for pizza production and the control system design for the pancake batter machine—challenge students to apply more sophisticated mathematical techniques and consider the implications of uncertainty, robustness, and system dynamics.

This range of problem complexity is essential for promoting cognitive development and ensuring that students progress from basic to advanced levels of understanding. By providing a series of problems that increase in complexity, students are able to gradually build their knowledge and skills while reinforcing their learning through multiple iterations. This approach mirrors Kolb's [12] experiential learning cycle, where concrete experience is followed by reflective observation, abstract conceptualization, and active experimentation. Furthermore, the inclusion of open-ended problems allows students to explore different solution paths, promoting deeper cognitive engagement with the material. In the case of the MILP problem for the Matrix Pizza company, for instance, students must navigate the intricacies of balancing resource constraints, demand forecasts, and cost optimization, while considering alternative production schedules. This requires not only mathematical proficiency but also the ability to model and solve real-world optimization problems with multiple variables and constraints.

## 4.3 Interdisciplinary learning and real-world applications

One strength of the food-themed problems is their ability to connect mathematical and engineering concepts to real-world applications. Using familiar scenarios like chocolate bar formulation or fried ice cream production helps students understand the practical implications of the methods they are learning. This connection is vital in engineering education, where students may struggle to relate abstract concepts to real-world problems.

The interdisciplinary nature of the problems also helps students link different areas of study. For example, the optimal frying time problem applies numerical methods to heat transfer, while the control system design for the pancake batter machine highlights the importance of robustness in engineering design. These problems demonstrate that real-world challenges often require skills from multiple fields, enriching students' chemical engineering education.

By framing problems around food production, the paper shows that complex engineering concepts can be communicated in an engaging and accessible way. This approach encourages students to think beyond traditional boundaries and explore diverse applications of chemical engineering.

## 4.4 Limitations and future directions

While the approach described in this paper has considerable promise, there are several limitations that should be considered. One challenge is ensuring that students have the necessary background knowledge to tackle more advanced problems. For example, while the introductory problems on linear programming and optimization may be accessible to students with a basic understanding of mathematics, the more complex problems involving MILP and robust control system design may require additional support in terms of prerequisite knowledge or instructional resources.

Another limitation is the time required for students to engage with these open-ended problems. The flipped classroom paradigm depends on students completing preparatory work outside of class, which may not always be feasible for all students, particularly those who struggle with self-directed learning. To mitigate this, instructors can provide additional support, such as pre-class tutorials, practice exercises, or discussion forums, to ensure students feel confident in their ability to solve the problems [10,11]. Additionally, incorporating peer

collaboration into the learning process—such as through group problem-solving sessions—could help foster a more supportive and dynamic learning environment [2].

Future research could explore the specific impacts of these types of problems on student outcomes, such as academic performance, engagement, and retention of knowledge. It would also be valuable to assess how students respond to the food-themed problems, or other themes, in terms of motivation and interest, and whether these themes contribute to a greater sense of relevance and enjoyment in the learning process.

Finally, one could expand the problem sets presented here to include even more interdisciplinary scenarios, incorporating areas such as environmental sustainability and even space exploration applications [13]. This would not only broaden the applicability of the problems but also encourage students to think about engineering challenges in a more holistic and interconnected way.

## CONCLUSIONS

The use of active learning strategies, particularly within the context of the flipped classroom paradigm, offers significant potential for improving student engagement and learning outcomes in process systems engineering courses. By presenting food-themed problems that span a range of difficulty levels and disciplines, this approach allows students to develop critical thinking, problem-solving, and technical skills in a more interactive and experiential way. Although there are challenges to implementing this approach, the potential benefits for both student learning and motivation are considerable, and future research should explore the broader impacts of such active learning strategies in engineering education. The author has used all of the exercises presented here over decades of teaching with great success. Each of them was used just once in exams and repeatedly since then in the classroom as open-ended practice problems. In the last 10 years, the incorporation of the flipped classroom paradigm in his teaching has released additional contact time to utilize for open-ended problem solving using exercise problems like the ones showcased in this paper.

## ABSTRACT

Three different implementations of the flipped class paradigm were used to teach Chemical Engineering students at Imperial College London (ICL) in the 2023-24 academic year: (1) The 3rd year elective course *Introduction to Numerical Methods (INM)* taught in its entirety in flipped format (the "good"); (2) The 2nd year core course on *Process Dynamics and Control (PDC)*, with the first half of the course on process dynamics taught in traditional lecture format, and the second half on process control taught in flipped format (the "bad"); and (3) a one-week workshop on heat integration, taught as part of a 3rd year core course on *Process Design (PD)*, taught in flipped format (the "surprising"). This paper describes these three implementations in detail and presents and analyzes the responses from student surveys intended to ascertain students' perceptions about the level of their satisfaction with the flipped class approach and the degree to which they achieved mastery of the taught materials. The actual learning outcomes are also analysed, that is, the exam results in the case of the first two courses, and the performance of the students on their design project, for the last course. The paper ends with conclusions and recommendations concerning how the flipped class paradigm should be implemented, depending on the classroom situation for which it is intended.

**Keywords**: Chemical engineering education, flipped classroom, active learning.

## 1. INTRODUCTION

In the 2023-24 academic year, the lead author of this paper was on sabbatical at London's Imperial College Department of Chemical Engineering, where he taught or co-taught three undergraduate courses, using variations of the flipped class paradigm, where lecture materials are viewed as preparation by students, and the class time is largely used for cooperative problem solving and exercises to build mastery:

(a) The 3rd year elective course *Introduction to Numerical Methods, INM* (the "good"), which used "flipping" in each week of the course. This implementation most closely followed the flipped class paradigm implemented at the Technion [1, 2].
(b) The 2nd year core course *Process Dynamics and Control, PDC* (the "bad") consisting of six weeks covering process dynamics, taught by conventional lecturing, followed by five weeks covering process control, taught with a flipped approach.
(c) The workshop on heat integration, taught as part of the 3rd year core course *Process Design, PD* (the "surprising"), which was an integral part of the process design course. It involved three online lessons completed by the students in advance of class activity, with each online lesson associated with a hands-on problem-solving class meeting, to a total of seven contact hours held during a single week of the course.

The reader is probably curious why we have used the epithets "good," "bad," and "surprising" for the three courses, and we promise that all will be clear by the end of the paper. The flipping paradigm proposed by Lewin and Barzilai [1,2] involves three phases, repeated in each week: Phase 1 – *Online Lesson*, Phase 2 – *Class Meeting*, and Phase 3 – *Active Tutorial*. Because sufficient contact time was unavailable at ICL, the implementations there combined the second and third phase into one class

meeting which focused mainly on active tutorial work by the students.

David Kolb [3] famously postulated a continuous cycle of cognitive processes employed by learners to perceive and process information: from concrete experience to reflective observation, to abstract conceptualization, and finally to active experimentation, although he accepted that most learners favor one cognitive learning process over the others. Benjamin Bloom [4] observed that moving from passive, lecturer-centered teaching to active, student-centered learning can improve learning outcomes by one standard deviation.

The flipping paradigm has been adopted with documented success by the lead author in all the courses he has taught at the Technion. With this rich and successful experience behind him, it is not surprising that he requested that all three of his courses taught at Imperial College would be delivered in flipped format, even though the department had experienced disappointing results when flipping had been tried there previously. To their credit, the management supported the principle of allowing the author to teach with his approach.

## 2. COURSE DESCRIPTIONS

Curricula, learning outcomes, and investment expected from both teachers and students for the three courses that were taught in "flipped" format at ICL will be detailed in the full paper. These closely resemble similar courses taught at the Technion as described in Lewin and Barzilai [1,2]. In the space available here, we shall focus on distinguishing between the degree to which the flipping paradigm was implemented in the three courses.

### 2.1 Introduction to Numerical Methods

The first part of the course provides instruction on the basic building blocks of numerical methods, with the second part focusing on the application of those tools for the solution of numerical problems associated with engineering applications (Riggs [5], Carnahan et al. [6]). The course taught at ICL was a version of the hybrid flipped course developed and taught at the Technion in 2022 that was described by Lewin and Barzilai [2].

### 2.2 Process Dynamics and Control

The first part of the course provides the tools to develop first principles and empirical process models. In the second part of the course, the derived models are used to design simple control systems to meet desired closed-loop performance specifications (Seborg et al. [7]). The first part of the course was taught in regular lecture format, which included demonstration of applications of the taught materials, as well as assigned problem sets for the students to try on their own. However, this lecturer-centered teaching did not provide time for students to work problems for themselves in scheduled class time. The second part of the course was taught in flipped format, in which each week, students prepared for the class meeting by watching online lessons in advance. In the class meetings, time was provided for students to solve hands-on exercises for themselves. Unless such active tutorials are offered to students, there is no way to assess their degree of mastery in the formative stage (during the studies). We are left only in testing their mastery in the summative stage (i.e., by exams).

### 2.3 Workshop on Heat Integration

The workshop provides students with instruction in the principles and rules governing the "pinch" design of heat exchanger networks (HENs) and their practical application (Seider et al. [8]). On the completion of the workshop, students are expected to be able to apply all the methodologies taught to perform efficient heat integration in the framework of their design projects. The materials were divided into three lessons taught in flipped format, covering (a) Introduction to HEN synthesis: Targeting and basic HEN design; (b) Advanced HEN design: Heat loops, stream splitting and threshold problems; (c) Heat and power integration: Extracting flowsheet data for HEN synthesis, the usage of the Grand Composite Curve for utility management, and efficient integration of process units within a HEN.

## 3. METHODS

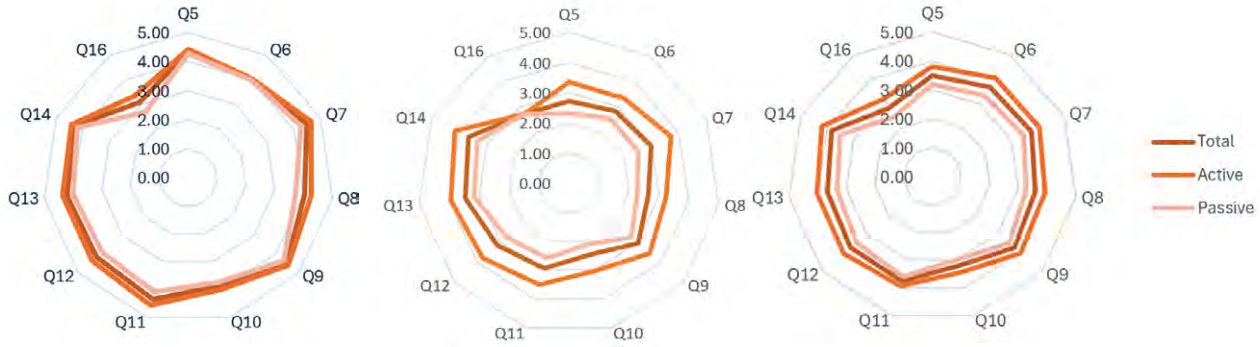
### 3.1 Research Questions

**RQ1.** What was the level of students' approval for the usage of flipping? Was this perception different for those students who engaged more with the course resources and activities, compared to those who engaged less?

**RQ2.** Did the students who engaged most with the course resources and activities achieve better learning outcomes than those who engaged less?

**RQ3.** Which of the three versions of flipping achieved the best results, and why?

### 3.2 Research Methods



Two measures were used to assess effectiveness of the flipping approach as implemented at ICL: (a) The three course cohorts were asked to respond to surveys in which students provided self-assessment of the degree of their engagement with the course components, the degree of satisfaction with the flipped class approach, as well as their estimated degree of learning and mastery. (b) Learning outcomes of the three courses were analyzed, and where relevant, compared with the results of previous years.

**Table 1:** Categorization as "active" students according to response.

| | *INM*, the "good" | *PDC*, the "bad" | *PD*, the "surprising" |
|---|---|---|---|
| No. of registered students | 29 | 140 | 138 |
| No. of responders | 25 (86%) | 105 (75%) | 108 (78%) |
| What was your degree of participation in the following activities? | | | |
| **Q1.** Online lessons (OL) completed | Completed all OLs | Completed all OLs | Completed all OLs |
| **Q2.** Class meetings (CMs) attended | Attended at least 5 out of 10 CMs | Attended at least half of 5 CMs | Attended at least 1 out of 3 CMs |
| What was your degree of active participation in the following activities? | | | |
| **Q3.** Engagement while watching online lessons | Watched some clips repeatedly | Not asked | Watched all clips at least once |
| **Q4.** Degree of active participation in CMs | Tried to solve some or all the class problems | Tried to solve problems in at least half of the CMs | Tried to solve most or all of the class problems |
| No. of "Active" students | 14 (56%) | 41(39%) | 52 (48%) |

**Table 2:** Listing of survey questions regarding students' perceptions of flipped classroom.

| | | |
|---|---|---|
| **Q5.** | Flipped classroom (FC) is more appropriate than traditional teaching | ❶ |
| **Q6.** | FC improved my ability to learn | |
| **Q7.** | FC motivated me to take an active role in my learning | |
| **Q8.** | FC encouraged me to learn more effectively | |
| **Q9.** | FC was a valuable learning experience | |
| **Q10.** | I want to expand my learning opportunities with more courses using FC | |
| **Q11.** | The online lessons (OLs) were helpful in clarifying the course material | ❷ |
| **Q12.** | The OLs prepared me adequately for class meetings | |
| **Q13.** | The in-class activities in the class meetings (CMs) were engaging and interactive | |
| **Q14.** | The CMs helped me to apply concepts I learned from OLs | |
| **Q15.** | List the resons why the CM was effective to your learning (or not) | |
| **Q16.** | What was the level of confidence in your mastery after CMs? | ❸ |

(a) *INM*, the "good" (b) *PDC*, the "bad" (c) *PD*, the "surprising"

**Figure 1:** Summary of responses to the surveys in the three courses, differentiating between the total class and the "active" and "passive" groups.

## 4. SURVEYS RESPONSES: RESULTS AND DISCUSSION

The first four survey questions are intended to gauge the degree of responder engagement in the components of the flipped courses. The first two ascertain the extent of the responder's passive engagement, that is, what percentage of the Online Lessons (OLs) were completed, and class meetings attended. The third and fourth establish the responder's degree of active engagement, that is, for the OLs, were the video clips viewed partially, just once, or often several times to improve understanding, and in the class meeting problem-solving exercises, did the responder just listen to the presented solution, or try to solve a few, most, or all the problems. As shown in Table 1, the responses to these questions distinguish between two approximately equal groups: the so-called "active" students, i.e., those that meet given levels of engagement with the online resources and class meeting exercises, and those that do not, who are termed "passive" students.

The remaining survey questions, listed in Table 2, were intended to ascertain, from each responder: Group ❶ (Q5-Q10), the degree of agreement with several statements concerning the flipped class paradigm as implemented, Group ❷, the degree of agreement with statements concerning the effectiveness of the online lessons and class meetings (Q11-Q14), and Group ❸, their perception of the level of confidence in their understanding of the course material (Q16). Except for Q15 and Q16, the responses were on a Likert scale of 1-5, with 1 = strongly disagree, 2 = disagree, 3 = neither agree nor disagree, 4 = agree, and 5 = strongly agree. Q15 asks the responders to indicate the reasons why the class meeting was effective for their learning or not. For Q16, the scale was: 1 = not at all confident, 2 = somewhat confident, 3 = confident, 4 = very confident, and 5 = extremely confident.

The students' responses to all three surveys are summarized in the radar plots of Figure 1, which shows the average scores returned for three categories of students: The scores for the "active" and "passive" students, on either side of the scores for the entire class. The polar plots provide a visual comparison of the degree of approval for the flipped class paradigm for the three courses; the degree of approval in each course is in proportion to the area encircled by the plots:

(a) The largest area indicating relatively high approval was expressed in the "good" course, where the responses to most questions indicate "agreement" (the "active" students returned an average score of 4.3), with statistically indistinguishable responses for the "active" and "passive" students, with the exception of their degree of confidence in mastery, where "active" students are significantly more confident than "passive" students.

(b) The smallest area indicating relatively low approval was expressed in the "bad" course, with the largest differences between the responses of the "active" and "passive" students out of the three courses: The average responses of the "active" students indicated "agreement" with positive opinions (average score of 3.5), while for the "passive" students, the average indicated disagreement. The average student opinion that their level of confidence was only "somewhat confident."

(c) The survey results indicate that the "surprising" course was perceived somewhere between the other two courses, where again, one can observe that the "active" students were statistically more positive in their opinions than the "passive" ones.

## 5. LEARNING OUTCOMES

For the "good" and "bad" courses, both of which included an examination as the main grade component, this is straight forward, and these are presented and discussed. For the "surprising" course, in which there was no final exam, but rather, a group project, we bring the group project grade distribution of the project component that involved heat integration, with a comparison with its distribution from the previous year, when heat integration was taught by regular lecturing alone. A passing grade at ICL is 40%, with grades of 70% and above being considered 1st Class Honors (the highest grade).

### 5.1 Learning outcomes for the "good" course (INM)

Going by the responses from the first four questions of the corresponding survey (See Table 1) and the lecturer's own observations, most students were actively engaged during the entire semester. Figure 2 presents the exam grade distribution for this course, showing that given this level of motivation in the class, it is not surprising that all the students passed the exam, with an average grade of 71%. The grade distribution is multimodal, indicating that the class is roughly divided into three equally sized groups, one which excelled, one which did well by ICL standards, and one last group who passed the exam with basic capabilities. This pleasing outcome is indicative of a well-prepared exam, which accomplished a clear separation of the course participants by abilities.

### 5.2 Learning outcomes for the "bad" course (PDC)

In this case, most of the students (61%) were not actively engaged during the entire semester. Figure 3 shows the exam grade distribution for this course, indicating that given the relatively low level of engagement

in the class, it is not surprising that the overall class performance was poor, with an average of 50%; 41 out of 149 students failed the exam (28%), with 21 scoring above 70%. Indeed, the primary lecturer reports that this is the worst performance in the course in all the years that she has taught it. As shown in Figure 3, the distribution can be decomposed into a bimodal distribution using the method of Lewin [9], which computes the parameters of two weighted normal distributions that best fit the overall grade distribution: for the better-performing students with an average of 63%, and for the underperformers with an average of 35%. The better-performing students constitute 64% of the class, with the remaining 36% being the underperformers, which can explain the high failure rate. Students cannot realistically expect to achieve mastery in a course if they do not engage, whichever method is used to teach it.

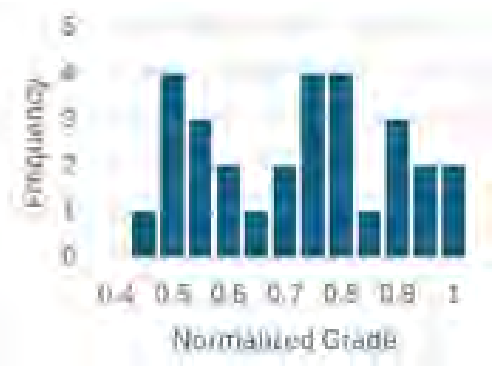


**Figure 2.** Exam grade distribution for *Introduction to Numerical Methods* (the "good" course).

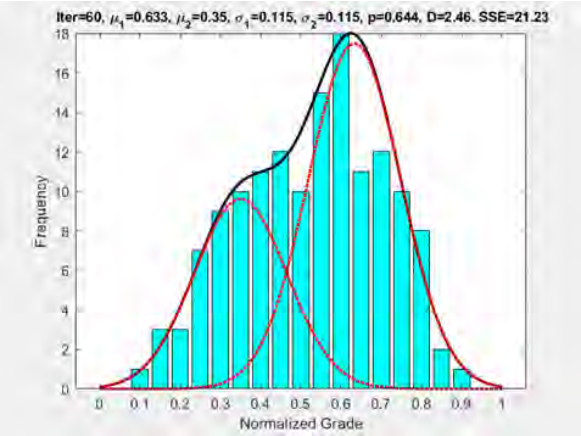

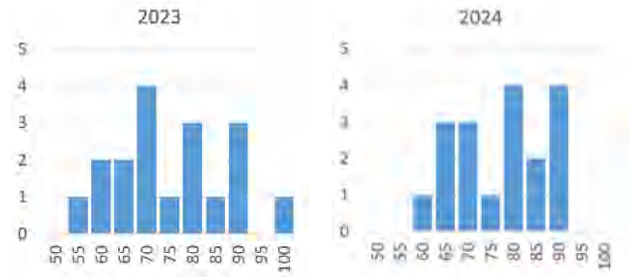

**Figure 3.** Exam grade distribution for *Process Dynamics and Control* (the "bad" course).

## 5.3 Learning outcomes for the "surprising" course (Workshop on Heat Integration)

About half of the students (48%) were actively engaged during the workshop. It is of interest to compare the team grade distribution for the design project's heat integration component awarded last year, when the subject was taught using face-to-face lectures, with this year's grade, in which the subject was instructed by the one-week flipped workshop. As shown in Figure 4, this year's distribution is slightly narrower (the standard deviation has dropped from 12.4% to 10.0%), with a slightly higher average grade (the average has increased from 75.3% to 77.2%). However, this small improvement is not statistically significant.

(a) (b)

**Figure 4.** Grades for the L5 component (heat integration) of the design project: (a) for 2023 (last year), (b) This year's (2024) grades following flipped workshop participation.

## 6. ADDRESSING THE RESEARCH QUESTIONS

The three research questions can now be addressed:

**RQ1.** *For all three courses, what was the level of approval for the usage of flipping? Was this perception different for those students who engaged more with the course resources and activities, compared to those who engaged less?*

We can state that most students perceive the flipped class teaching method positively, with the "active" students perceiving this to a greater extent than the "passive" ones. The least positive perceptions were for PDC, which was not flipped in its entirety.

**RQ2.** *Did the students who engaged most with the course resources and activities achieve better learning achievements than those who engaged less?*

Students that are more engaged with their studies usually achieve better outcomes than those who engage less. The most striking example was seen in the results of the final exam for PDC (see Figure 3), where the class can be divided into high- and low-performing subsets according to the degree of their engagement.

**RQ3.** *Which of the three versions of flipping achieved the best results, and why?*

Based on the survey and outcomes data, the best results were achieved in the elective course INM. This was the only course out of the three that adopted flipping in its entirety and was taught to a relatively small group of committed students. This experience indicates that if the student body come fully onboard, the approach has the capacity to be extraordinarily successful. Again, based both on survey and outcomes data, the lowest level of approval for the flipping method and the poorest outcomes were received by PDC, principally because many of the students opted not to engage with the course. Going by the survey results, the one-week flipped workshop on heat integration was well received by the students, who implemented the materials taught in the workshop successfully into their projects at least as well as with previous experience with the course and certainly more uniformly across the entire class.

## 7. CONCLUSIONS

We have reported the outcomes from a year of flipped teaching at ICL. The three undergraduate courses taught were different variations of the flipped paradigm that has been run successfully at the Technion in Israel: (1) a 3rd year elective course on numerical methods taught in its entirety in flipped format (the "good"); (2) the 2nd year core course on process dynamics and control, with the first half of the course on process dynamics taught in traditional lecture format, and the second half on process control taught in flipped format (the "bad"); and (3) a one-week workshop on heat integration, taught as part of a 3rd year core course on process design, taught in flipped format (the "surprising"). The four main takeaways from this study are as follows:

- If a decision to "flip" a course has been made, the decision should be concerning the entire course. The least successful implementation of flipping reported in this study was the one in which the first half of the course was delivered as lecture-based, with no significant effort being made to ensure students are mastering the topics being taught, and the second half was given by "flipped class." The switch between the two modes caused about half of the students to simply give up on the entire course and rely on cramming a few days before the exam, leading to an abnormally high failure rate.
- In contrast, the elective course on numerical methods, taught as a "flipped" course in its entirety was a clear success – the small class of 29 students were actively engaged to the point that an attempt to differentiate between the perceptions of the most and least engaged students did not produce results of statistical significance.
- The flipped workshop on heat integration was another success, where even the least engaged students perceived that the flipped approach improved their learning. Indeed, the students' approval of the flipped class paradigm was generally good, despite the unusually intensive way it was applied, ergo the epithet "the surprising".
- To obtain reliable results in student perception surveys, it is imperative to separate the responders into those who significantly engage with the course resources and activities, and those who engage less or not at all. High- and low-engagers often become high- and low-performers, respectively, and the perceptions of these two groups can be significantly different.

We have presented these results and our conclusions to assist any lecturer who is considering applying flipping in his or her classroom with useful tips and information.

# Digital Shadow of a Pilot Scale Packed Batch Distillation Column for Real-Time Operator Training- and Support

**Mads Stevnsborg[a], Krist V. Gernaey[a], and Jakob K. Huusom[a]***

[a] Technical University of Denmark, Department of Chemical and Biochemical Engineering, Kgs. Lyngby, Denmark

## ABSTRACT

Digital twins and digital shadows are frequently used terms by industry and academia to describe data-centric models that accurately depict a physical system intended for process monitoring and control. Processes restricted by a low degree of automation rely greatly on operator competencies in key decision-making; a digital shadow can here assist as a guidance tool [1-4]. This work presents a practical implementation of a digital shadow to support operators running a pilot scale-packed batch distillation column at the Technical University of Denmark (DTU) primarily used in education and teaching activities [5]. This operation is selected due to inherent unsteady process dynamics that are controlled by a set of manual valves, which the student operator must continuously balance to meet purity constraints without disrupting the operation. This realisation employ a modular software architecture, separated into four distinct modules compiled into Docker images and independently deployed. These facilitate real-time connection with the equipment via OPC-UA endpoints, process model analysis via HTTP/HTTPS requests, and a dashboard UI presenting the data accessible through any web browser. The final module is realised as a Python package that stores thermodynamic models and is published on the internal GitLab registry for more straightforward utilisation across multiple projects. The advantages of this implementation strategy are flexibility and speed, allowing for continuously updating process models and directly employing them in various projects.

## INTRODUCTION

Today, digitalisation and Industry 4.0 are terms used prolifically in chemical- and biochemical engineering research. It describes various activities that ultimately focus on expanding automation and optimisation in different aspects of manufacturing and research processes. Enhancing data contextualisation and application of data-driven methods in process development and regular operation are both activities associated with digitalisation [1]. Today, the most common and significant barriers to implementation of digitalisation concepts relates to an immature digital infrastructure, data security concerns and complex systems integration. This makes data consolidation and utilisation across various sources challenging and restrict the compliance with the Internet of Things (IoT) and Big Data architectures [2]. Since the digital twin and digital shadow concepts rely heavily on these enabling technologies in practice, most chemical and biochemical manufacturers are generally committed to improving or expanding their respective digital infrastructure [1]. However, there is still an overall challenge in correctly scoping and quantifying the cost/benefit of these digitalisation projects which limit widespread adoption [1-4]. For systems of a lower automation level that rely heavily on employing operators in crucial operation steps, there is an increased focus on developing methods and tools that assist the operator in decision-making during operation [5]. In this work such example is developed for a digital shadow that is intended as support for student operators in an education setting for a pilot scale batch distillation process. Batch distillation is an old and proven volatility-based separation technology that is most frequently employed today in alcoholic beverage production and in the recovery of aromatic compounds and solvents [6]. These processes exhibit a

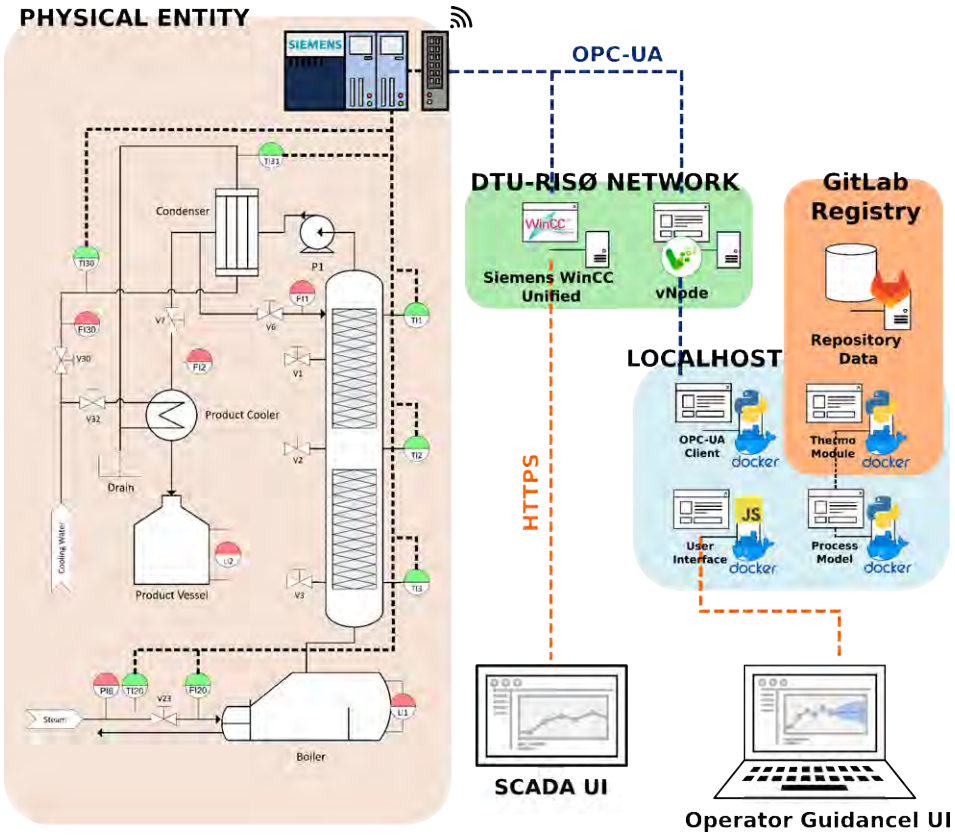

**Figure 1:** The P&ID of the packed batch distillation column at DTU-KT. The connection to the central digital infrastructure is also displayed, and all digital signals are denoted with dashed lines. The digital shadow modular architecture is also depicted with the installable module dependency connected to the central GitLab registry.

continuous transient behaviour as the product is extracted from the otherwise closed system. While most processes have automated flow control and duty utilisation, the central operation is dictated by the operators who specify desired reflux ratios. The Department of Chemical Engineering at the Technical University of Denmark (DTU-KT) manages a manually operated pilot scale packed batch distillation column primarily employed for education purposes and solvent recovery. The unit is included in the digital retrofitting activities described by Jones et al. in 2022 [7].

## MATERIAL AND METHODS

The pilot scale packed batch distillation column at DTU-KT separates a well-documented water-ethanol binary system that forms a high-boiling azeotrope at approximately 92 mol% ethanol. The exercise aims to teach engineers about managing flow rates, reflux ratios, and heating/cooling duty to collect an ethanol product of sufficient purity. The pilot scale equipment consists of a 100L steam-heated boiler (T1) connected to a glass column with an inner diameter of 10 cm. The column is fitted with Mellapak™250Y for a total height of 1.68 m. Atop the column sits a total condenser connected to a pump (P1) that returns the condensate to the column as reflux or to a product tank (T2). The unit is augmented with a total of 13 sensors, of which 6 x temperature (TI) sensors and 1 x flow meter (FI) are logged online with an additional 3 x flowmeters, 2 x level indicators (LI) and 1 x pressure sensor (PI) are read by operators offline. The simplified PI&D for the setup is presented in Figure 1. The initial boiler contains a mixture of approximately 80L 30w% Ethanol. The operator is responsible for manipulating the reflux ratio and the steam- and cooling duty to maximise the recovery and purity of ethanol over an operation period of approximately 2 hours at atmospheric pressure. The digital infrastructure is addressed in a later section.

## MATHEMATICAL MODELS

Even though the unit operation is operated frequently at DTU-KT, the collected data is of limited usability for unit characterisation and model development. This is primarily due to vital analogue information pertaining to flow rates, liquid levels and liquid composition being omitted from the digitally stored data. Therefore, reconstructing mass- and energy balances is challenging

and requires several simplifying assumptions regarding the process operation characteristics. As a result, this caveat limits the applicability of data-driven and hybrid methods due to a lack of data volume. Furthermore, since the operators are instructed to select a specific reflux ratio and keep this constant, it produces a dynamic profile that becomes very similar across experimental runs. The lack of variability in the dataset ultimately limits the effectiveness of using supervised learning methods such as neural networks to derive the operational characteristics, even if a sufficient data volume is available. This work puts emphasises on delivering mathematical models for the given process. Therefore, simple equilibrium-based models have been employed and deemed sufficiently accurate for the application. The future prospect of employing data-centric models is discussed later.

Separation of the water-ethanol binary at atmospheric pressure can confidently be modelled as an ideal vapour phase and non-ideal liquid phase using the modified Raoult's law. The mixture's vapour-liquid phase equilibrium (VLE), Antoine parameters and binary interaction coefficients are presented by Kamihama et al. [8]. The component heat capacities, densities, and latent heat of vaporisation are modelled using fitted 3rd-order polynomial functions with respect to a reduced temperature. The polynomial function is depicted in equation 1. Coefficients are fitted using saturated temperature data from CRC 101st ed.

$$f(T_r) = A + BT_r + CT_r^2 + DT_r^3 \quad (1)$$

The separation efficiency of structured packaging material Mellapak™ 250Y [9] depends on a flow number (*F*) calculated based on the vapour flow rate in an empty column and the vapour density shown in equation 2.

$$F = \omega \cdot \left(\frac{g}{A_c}\right) \sqrt{\frac{T}{P \cdot M_{w,g}}} \quad (2)$$

$$\mathrm{HETP} = a \cdot \log\,[1+F] \cdot \left[\frac{F}{s}\right]^p + x_0 \quad (3)$$

This is a function on the vapour flow rate in an empty column, $\omega \cdot (g/A_c)$ , and the vapour's molar weight, $M_{w,g}$. The flow number takes a value in the interval 0.5 – 3.5, corresponding to packaging material attaining an equilibrium tray equivalent height (HETP) of 0.32/m – 0.45/m. This results in an expected number of equilibrium trays (NETP) between 3.73 and 5.25 for a packed column height of 1.68m. A surrogate model is fitted to the HETP curve provided by Sulzer in Figure 2. to readily determine the packaging material's separation efficiency from estimating the boil-up ratio and vapour composition. Here, the F values refer to a flow number, while the coefficients $a$, $p$, $s$, and $x_0$ are coefficients that are determined by fitting equation 3. to the data presented in the Sulzer data sheet for Mellapak 250Y packing at 960 mbar [9]. The fitted expression is presented in equation 4.

$$\mathrm{HETP} = 0.0634 \cdot \log\,[1+F] \cdot \left[\frac{F}{313}\right]^{30.3} + 0.315 \quad (4)$$

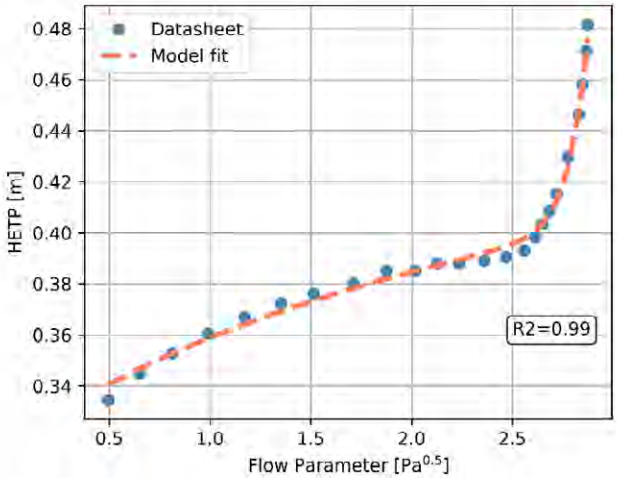

**Figure 2.** Reported Mellapak 250Y separation as a function of the characteristic flow number.

Currently, the operator is guessing the condensate's total volumetric flow rate and perform incremental adjustments from a visual inspection of the condenser hold-up to balance the flows. Approximating the volumetric condensate flow rate can alleviate this task while simultaneously predicting changes from boiler duty or reflux ratio modifications. This can give rise to more accurate control adjustments that allow for possibly operating at variable reflux ratios, improving the process's energy efficiency. If the steam condensation supplies only heat to evaporate the boiler mixture, the estimated vapour flow rate leaving the boiler can be readily estimated from online sensors with equation 5.

$$V_{est.} = \frac{\Delta H_{vap}^{steam} \cdot FI_{20}}{\Delta H_{vap}^{boiler}} \quad (5$$

From the vapour flow rate and estimated vapour composition, the flow number and NETP can be readily determined from the online sensor readings. In combination with user inputs regarding the reflux ratio and estimation of the condensate composition, it is possible to construct a McCabe-Thiele diagram for the operation, as depicted in Figure 4. In addition, the cooling duty in the condenser is employed to estimate energy efficiency $\eta$. It is also employed to estimate the product's composition and thereby track an estimate of the recovered liquid's purity and the remaining amount of ethanol to purify.

## RESULTS AND IMPLEMENTATION

Digital shadows and digital twins are frequently attributed as flexible model realisations that satisfy multiple stakeholders across research and manufacturing and

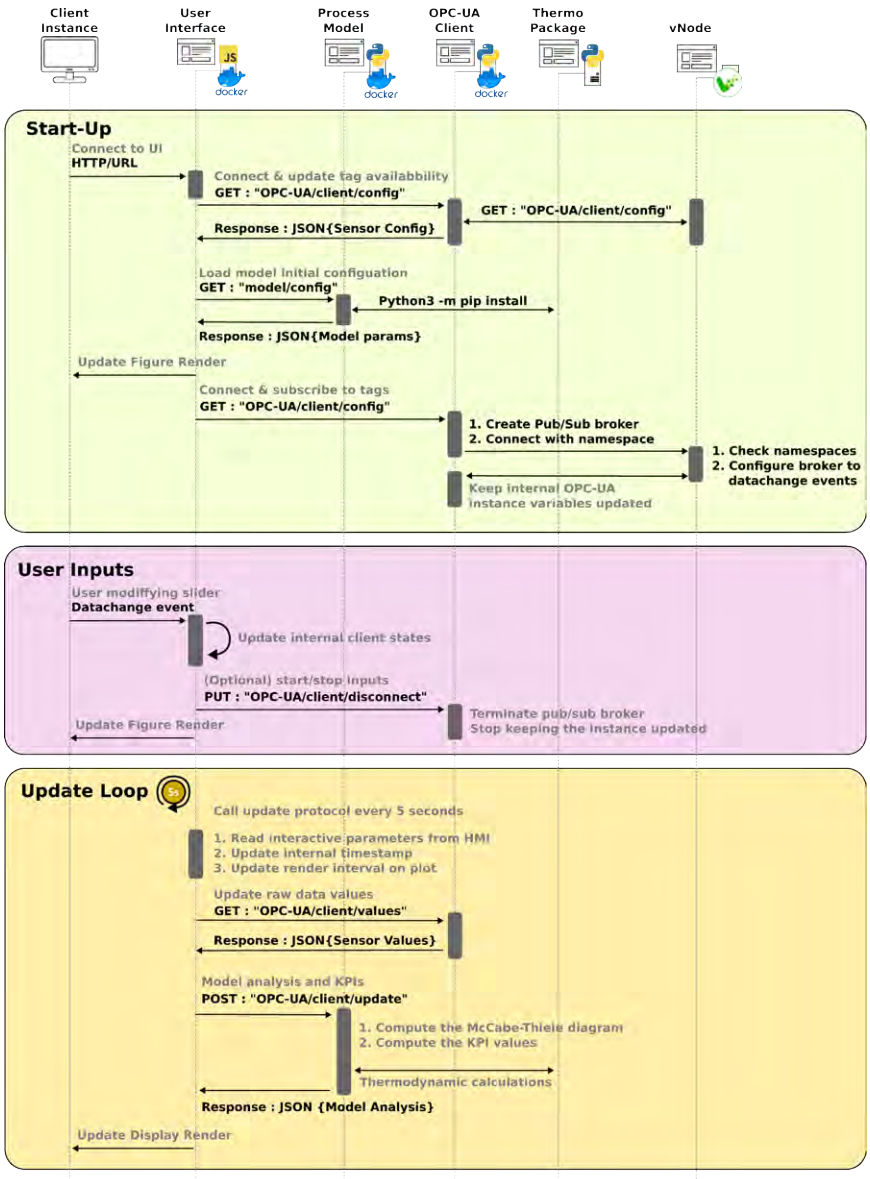

**Figure 3:** A summarised sequence diagram for the packed batch distillation column core functionality. Here, the various resources are depicted in a column format, with the interactions depicted as prompted connections.

interface easily with physical equipment [2,4]. Consensus is that the best approach is to follow a standardised implementation paradigm that link multiple smaller model realisations and software resources together in a central environment. This work adopts a microservice-oriented approach to realising the software implementation. In addition, the workflow adopts the DevOps development paradigm often utilised in conventional software development [10]. The various modules/services developed in this project are version-controlled using git (v2.36.1) and distributed through GitLab with continuous integration and continuous delivery (CI/CD) pipeline compiling Docker images and package installables. The software is structured into four modules, as depicted in Figure 1. Each module functionality is compartmentalised individually using Docker (v24.0.6) except the thermodynamic module, which is configured as a Python installable dependency. The Docker images are configured as a collection using Docker Compose (v2.22.0). This results in a software collection where each module can deploy independently but allows communication between modules in the collection, as depicted in Figure 3. The UI is developed using Next.js (v13.5.0) with Redux (v4.2.1) state management, Materials-UI library components and D3.js (v7.8.5) visual rendering. The connection, storage and model backend is developed in Python (v3.10.15) and deployed using the FastAPI (v0.103.2) and Uvicorn (v0.18.3) libraries. The connection manager is a general-purpose

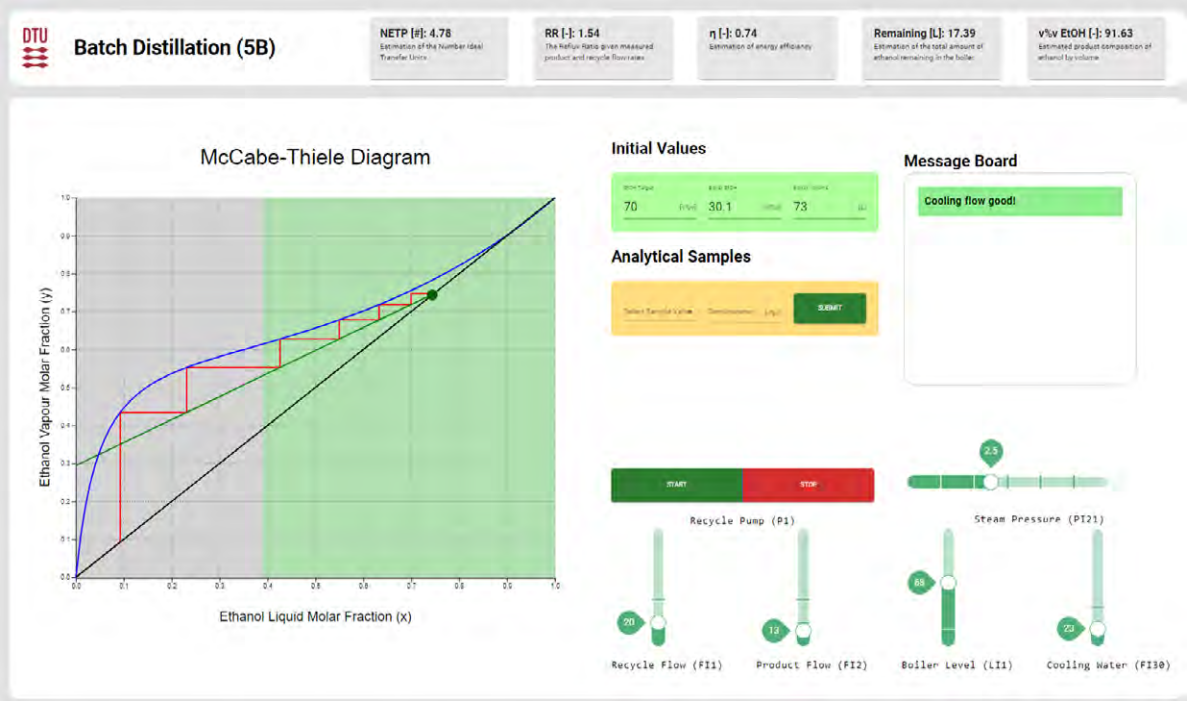

**Figure 4:** Screen capture of the UI for the pilot scale packed batch distillation column. This cas depicts an operation with an initial boiler content of 73 L and approximately 30 vol% ethanol.

OPC-UA client developed in Python and designed to integrate specifically with DTU-KT pilot equipment connected to the vNode intermediary [7]. The operator accesses the UI dashboard through a web browser on a device connected to the secure network. The UI then manages calls to the various API that establish connection and process model functionalities based on the operator interactions through the UI. All logic concerning model prediction and estimation is compartmentalised with Docker, and all functionality is exposed to the software architecture by a REST API construction. The UI updates the relevant elements based on user interaction and automated update loops. The operator interacts with the logic through the UI abstraction. This interface includes a graphical rendering of the current operational state with a summary of key performance indicators as a McCabe-Thiele diagram, depicted in Figure 4. A series of sliders and buttons are also presented to the operator, which she can use to update the offline sensor values quickly. The UI detects the change in slider position and sends the information to the database, where it is stored next to raw sensor inputs and model analysis. The updated user inputs are used in the succeeding API calls to provide updated trajectories on the McCabe-Thiele diagram. From the online temperature sensor measurements, the molar vapour and liquid compositions are determined for the boiler (TI04), middle column (TI02), and top of the column (TI01), assuming phase equilibrium. The online steam flow rate (FI20) and saturated steam temperature (TI20) also provide an online estimate of the applied heat duty. Combined, it is possible to estimate the boil-up rate and flow number readily. Thus, it is possible to provide an estimation of the HETP and NETP from the Sulzer reference sheet [9]. The operator can update the value of the three offline liquid flow meters depicting reflux (FI1), product (FI2) and cooling water (FI30), respectively, with a slider-based input system on the UI. Also, the boiler (LI1) and product tank (LI2) level indicators are updated with a slider input block. Additional performance metrics such as the condenser duty, reflux ratio (RR), and material balance can then be computed and displayed with the online and offline sensor measurements.

## DISCUSSION

This work achieves a practical realisation of a digital shadow for a pilot scale packed batch distillation using a modular implementation approach akin to a microservice architecture which follow a modular architecture suggested in recently published literature [4,7]. In the current configuration, the thermodynamics models are implemented in parallel to the system models and separated into a dedicated thermodynamic installable package. This allows for better utilisation of these models and data across multiple projects for different processes. In this case study, the central objective is not the effectiveness and usability of the final software solution. Instead, focus is placed on the development and delivery process,

evaluating the relative ease of modification and expansion to the presented proof-of-concept. With the modular implementation, updating or substituting the first-principles model, in this case, will be more straightforward if implemented as an API resource accessible with communication protocols such as HTTP/HTTPS. As data is collected throughout multiple runs and analytical data is properly contextualised and stored next to the online measurements in a digital and easy-to-query environment, complete or partial data-driven methods in state estimation will be possible in the future. The OPC-UA connection module is sufficiently generic, which has significantly streamlined integrating connection and delivery of other projects at DTU-KT. The selection of the KPIs employed in this work is based entirely on the authors' perceptions. It is important to include the users in the development loop to effectively continue the development of a digital shadow such as the one presented in this case study. Following the DevOps cycle, the next steps are operations and performance evaluation. Operator support and guidance tools do not have to be overly complicated to be effective. Since this exercise is also leveraged in chemical engineering education, the aim is equally to enhance the learning outcome of the exercise. Ideally, the more complex UI can allow the engineer to experience theoretical material employed on real systems in real-time and observe how the dynamic operation affects the various KPIs. Here, the results are largely qualitative, focusing mostly on delivering a platform that leverages the model-based and domain competencies in a format that generates value. With the infrastructure in place, a succeeding project can more easily implement new metrics or compare against future data for a quantitative assessment of the model accuracy, KPI usefulness, etc. Most of the cases explored in this area are centred on bio-based manufacturing. However, this case illustrates a modular approach to developing digitalisation tools, which can arguably be leveraged for other process types as well.

## CONCLUSION

It is possible to develop and implement a digital shadow for real process equipment using the micro-service software architecture. The case study delivers a proof-of-concept digital shadow that is of an appropriate- and feasible scope given the process description. The application employs a rudimentary model that could offer some model-based support for operators running the packed batch distillation column at DTU-KT. This guidance system focuses on lowering the barrier for operators to report offline sensor values, providing the operator with enhanced insight into the operation state, and improving offline data collection. Future developments will focus on collaborating with the operators to drive the next development steps in a direction that best suits the use-case of this digitalisation tool.

## ACKNOWLEDGEMENTS

The authors of this work acknowledge the efforts of students and staff at DTU-KT and express our gratitude to the Novo Nordisk Foundation for funding through grant NNF19SA0035474.

## ABSTRACT

In this paper, we present our recent advances and achievements in automatic control course in the engineering study of cybernetics at the Faculty of Chemical and Food Technology STU in Bratislava. We describe the course elements and procedures used to improve teaching, learning, and administration experience. We discuss on-line learning management system, various teaching aids like e-books with/without solutions to practice examples, computer generated questions, video lectures, choice of computation and simulation tools. The course is provided in the presence form of study for about 20 students, but it relies on on-line tools and methods. Starting from this academic year, flipped design of the course was designed. We describe our experience in the preparation of such a change and some initial feedback from the students. The course concentrates on input/output linear approximation of processes in chemical and food technology and discusses poles/zeros, process dynamics, frequency and time methods, closed-loop system, design and tuning of PID controllers, root-locus analysis. Although the majority of laboratory exercises is performed using simulation tools, we also provide easy-to-use laboratory device that can be given to all students to work either at school or at home.

**Keywords**: Education, Process Control, MATLAB, Students' Feedback

## INTRODUCTION

The rapid advancements in information technologies have affected engineering education, particularly in the fields of chemical engineering and automatic control. This trend was even strengthened during and after the Covid-19 pandemic.

The course on automatic control is a core component in master programs in the field of cybernetics. The students usually define it as a difficult one, due to heavy use of mathematics, physics, and chemical engineering principles. In addition, IT skills (programming and simulation languages) are needed as well. Therefore, it is of utmost importance to try to improve the learning experience of the students and, at the same time, to maintain the depth of the studied topics.

One innovative approach to enhance student engagement and learning outcomes is the flipped classroom model [3,4,8]. In this model, traditional lectures are replaced with online video lectures that students can watch at their own pace outside of class. In-class time is then used for active learning activities, such as problem-solving, discussions, and group work. This approach has been shown to be effective in promoting deeper understanding and critical thinking skills.

This paper shares our experience and shows an overview of the structure and methods used to improve teaching, learning, and administrative tasks for the course on automatic control for master students at the Faculty of Chemical and Food Engineering, STU in Bratislava.

## PROGRAM AND COURSE CONTENTS

The course *Theory of Automatic Control I* is taught at the Institute of Information Engineering, Automation, and Mathematics in the first semester of the master study in the program *Automation and Information Engineering in Chemistry and Food Industry* accredited under the field of Cybernetics. The program is thus focused on applications control and IT in process industries. It contains several main branches represented by a series of courses:

- Theory of automatic control: fundamentals, state-space methods, multivariable control, process control, robust control, intelligent control, MPC.

- Modeling: fundamental models, identification, separation processes, data processing, machine learning, process optimization.
- Technical means of automation: sensors, actuators, PLC, DCS, visualization, HMI.
- IT: web programming, databases, object-oriented programming, git, LaTeX.

Students that enroll in the program all come from chemical engineering bachelor programs at the faculty but have different levels of knowledge in cybernetics and automatic control. About 10-20% of them completed the bachelor program Process Control and are advanced, but the rest of them are students mostly with chemistry, biology, food or chemical technology backgrounds and with no previous experience with control. Therefore, the institute organizes mini-courses on MATLAB and Python programming, data treatment, and IT skills at the beginning of the first semester.

The course is planned with 2 hours of lectures and 3 hours of seminars/exercises per week and its contents is as follows:

- Mathematical modeling of continuous-time systems: general principles of modeling, linearization, deviation variables, state-space representation.
- Input-output properties: from states to I/O representation, from transfer function to states.
- Poles, zeros, process dynamics.
- Frequency characteristics: complex numbers, frequency responses.
- Control performance: time, frequency, integral indices, poles and zeros.
- Closed-loop system: structures, components, stability, regulation, tracking problems.
- PID controller: review, types, properties, anti-windup, bumpless transfer.
- Root-locus techniques for analysis and design.
- PID controller tuning.

This is a fairly standard course content for the introductory course in automatic control. As it is taught at the chemical engineering faculty, all students have knowledge and experience with standard engineering mathematics and physics, steady-state material and enthalpy balances, chemical engineering fundamentals.

The processes selected for modelling and control are built on this knowledge and include mainly heat exchangers and water tanks. They are used repeatedly in different course topics. A simple heat exchanger can be represented by a first-order transfer function, and a series of them can be used for linear systems of higher order. Two or more water tanks (without pumps) represent stable nonlinear processes, suitable for linearisation, comparison of linear and nonlinear behaviour. If a pump is included, it results in unstable integrating process that needs to be stabilised using feedback control. We note that specific control of more complicated processes is studied in the third semester in the course Theory of Automatic Control III (advanced process control).

## STUDY SYSTEM AND SUPPORT

The course frontend is provided using LMS Moodle that has been in use at the faculty since 2005. Therefore, teachers have a good knowledge of the system. The most used activities/sources are files, links to videos, assignments, and quizzes. Institute courses provide full read access to all teachers - the aim is to know about material and ways how it is provided to students - to increase compatibility level between courses. In addition, limited read access is provided for anonymous course guests (https://elearn.uiam.sk/course/view.php?id=95).

The backend to the course is maintained in Gitlab repository of the institute. This covers LaTeX sources to all study materials, MATLAB and Python sources to scripts. This helps to follow the evolution of the course and facilitates transitions between instructors.

Starting from this school year, flipped design has been used. Since Covid19 times, lectures have been recorded. The most recent 2 hours lecture recordings (approx. 20 hours total) were cut into smaller logical pieces (5-10 minutes each) and uploaded to YouTube. One or two Moodle Lesson activities were then prepared from every lecture and there are one or more questions after each video. Each Lesson begins with definition of its objectives and aims for students. This activity must be completed prior to the actual week. The experience from the first year shows that the average duration of this individual activity takes about 3 hours. Students can repeat the lesson questions, and the best result is used for grading. Knowledge of the material shown in lecture recordings is required in the final oral exam.

As the flipped-design classroom requires students to dedicate significant time to preparing in advance individually, it makes the flipped design a good candidate for putting all students with different backgrounds on the same level. This way, the students get familiar with novel topics at their own pace, and they apply the acquired knowledge in practice at school during active tutorials and seminars.

Instead of the traditional lecture, students come to Active tutorial, supervised by the lecturer. The first part of the Active tutorial reviews the Lesson, student results and their errors in question answers. Then, the lecturer states problems that students try to solve. Students are

encouraged to work in groups, discuss together. There are two types of PDF documents available: unsolved problems with blank space to be filled and the same information with complete solutions. Therefore, students can review again the solutions provided by the lecturer. The level of complexity is chosen in such a way that no computer solutions/simulations are needed, a mobile phone or pocket calculator suffices.

The seminars are held in groups of approximately 10 students in computer laboratories, where every student works with their computer. The teaching assistant follows up on the topic from Active tutorial and gives tasks to the students. Some of the tasks are focused on manual derivations and mathematical analysis to improve students' critical and technical thinking. The teaching assistant strongly leads this part. Most of the tasks are focused on programming and simulations performed in MATLAB. During this part, the students are actively engaged, and the teaching assistant provides technical support.

Regarding the grading of the seminar, students obtain 2 assignments during the semester, and they have approximately 2 weeks to work on them at home and to submit a protocol. At the end of the semester, the students take the final test using MATLAB and MATLAB Simulink. The grade from seminars is calculated as the arithmetic mean from the two assignments and the final test.

Study materials of the course consist of selected parts from the monograph [6]. Of course, the material is standard, and any appropriate feedback control book can be used. In addition, an electronic textbook specially tailored to this course is also provided. Each chapter corresponds to one course topic, and it is divided into:

1. Topic goals, overview and summarization of the theory - this is related to the lecture recordings.
2. Examples - this corresponds to problems treated in Active tutorials.
3. Practice examples - this is the topic for the seminars with the teaching assistant.
4. Problems, MATLAB and Python snippets - supplementary information for interested students.

The individual chapters are used during the seminars. In that case, practice examples in the respective Moodle topic do not contain solutions. However, documents available for download within Moodle course also provide the full version with solutions. This helps both students (if they want to review) and if there is a replacement for a teaching assistant.

The overall course grade consists of completion of Lessons (15%), seminars (25%), and oral exam (60%).

## ELECTRONIC QUIZZES AND QUESTIONS

Assessment of student knowledge can be realized in Moodle using questions. A collection of questions can form Moodle activity Quiz, or it can be part of the Lesson activity. The Quiz question bank supports various plugins - the standard ones are for example true/false, multichoice, short answer, matching, numerical, calculated, drag-and-drop, matching. The Lesson module can use only a few of them, and, unfortunately, for the time being, it is not possible to have only a single question bank for both Quiz and Lesson.

Among other contributed plugins for the Quiz activity, STACK questions have proven to be very beneficial for our engineering the course. STACK [7] is a powerful open-source assessment system for mathematics and related disciplines, designed to enable students to answer questions with mathematical expressions. STACK uses the Computer Algebra System (CAS) Maxima [5] to evaluate the answers. It can accept equivalent expressions (random order of terms, factorization, etc.), it provides controlled randomization and inspection of deployed variants, multipart questions, customized feedback and response trees.

Figure 1 shows an example of a STACK question on inverse Laplace transform. The student specifies the answer which is immediately evaluated to show how it will be interpreted by the system. Therefore, the student can check the answer for correctness before the actual evaluation. Such questions can greatly improve the learning experience.

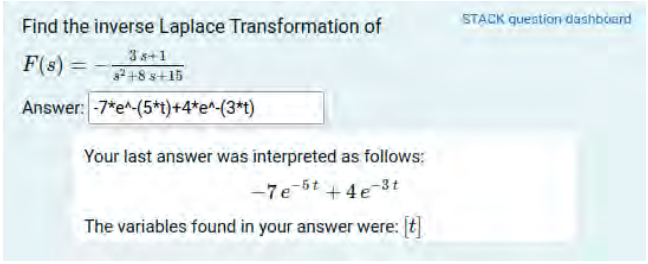

**Figure 1.** Inverse Laplace transform question using STACK.

Due to current shortcomings of the Lesson module, we generate multiple variants of numerical multichoice or short answer questions outside of Moodle using our solution based on MATLAB and XML [1]. MATLAB (or any other language) can be used as a scripting and templating engine to generate automatically many identical questions with different numerical values. Every question then consists of two input files: template XML file with placeholder for numerical values at appropriate places and computational part that generates suitable random sets and prepares the numerical values. MATLAB scripts then generate a desired type and number of questions

and produce an output neutral XML file. Then, XSLT processor is employed to generate a desired output format - this can be for example PDF to be printed (paper quiz with versions for students and for teachers) as well as import XML format suitable for Moodle -- for both Quiz and Lesson activities. One of such random questions is provided to a student using the Cluster and Random question within the page features of the Lesson activity (Figure 2).

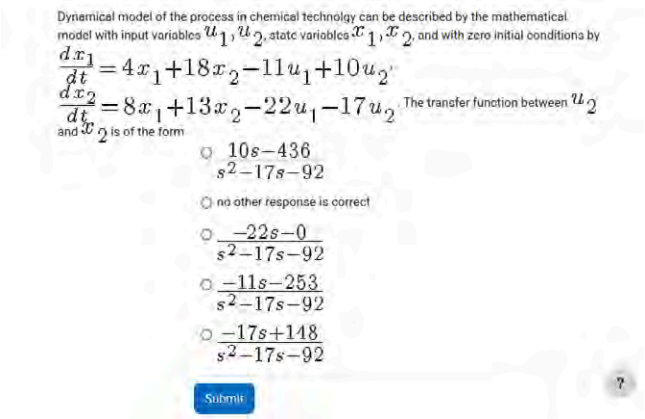

**Figure 2.** A randomly generated question in Lesson module using MATLAB, XML and XSLT.

## REAL-TIME EXPERIMENTS

**Figure 3.** Flexy2 device.

Although most of the semester work is based on simulations, we also devote some time for real-time experiments. Flexy2 device [2], shown in Figure 3, is used to demonstrate practically some steps in process control: selection of signals, observation of dynamical behavior, model estimation, PID controller design.

Flexy2 is a simple dynamical system with one input and one output. The manipulated variable is air flow from a computer fan that propels an air column in an upward vertical direction. The effect of air flow is measured by a flexible sensor that is deployed in the air column. The output variable is electrical resistance of the flexible sensor based on a degree of bend that is caused by hydrodynamic push of air. Figure 4 shows normalized step responses for steps of different magnitude and direction.

The device has a nonlinear behavior, with some minor oscillations at higher air speed. Its small dimensions make it suitable as a portable device and students can borrow it to work at home. Its API is provided both in MATLAB and Python. Both manual and automatic operations are available, the two tuning knobs at the device are programmable, they can be used for manual control or for tuning of controller parameters.

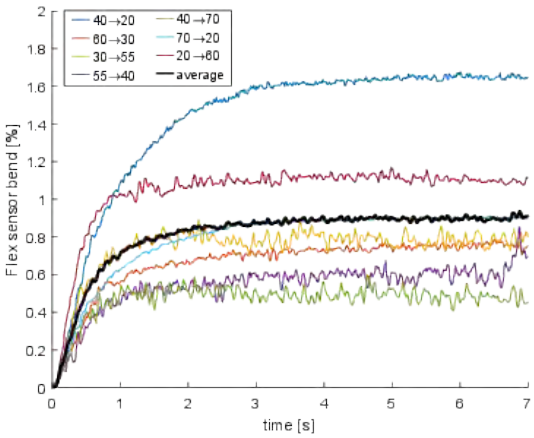

**Figure 4.** Normalized step responses of Flexy2 device.

Students are expected to measure the step responses of the process, estimate its model, design PID controllers using Ziegler-Nichols and SIMC methods, and observe/quantify control performance. Therefore, these experiments usually take place at the end of the semester when they have covered all these topics theoretically.

## FEEDBACK BY STUDENTS

This section provides an overview of the students' feedback collected weekly during the semester, as well as one final survey at the end of the semester.

The main aim of the weekly survey is to examine the students' satisfaction with the subject and teaching process. Feedback is nonmandatory, anonymous, and is collected at the end of every lecture/Active tutorial and seminar. Besides other questions, we ask students to rate the clarity and appropriateness of the presented topic on a scale from 1 (worst) to 5 points (best). In 2023, when the lectures had the standard format, we collected 62 answers during the semester with an average score of 4.76 and a minimum value of 3. One year later, after introducing the Active tutorials, we collected 77 feedbacks with an improved average score of 4.95 and a minimum value of 4.

Students can provide verbal feedback as well, but they usually do not dedicate much time to a deeper

evaluation at the end of every lecture or seminar. Therefore, we created one final survey at the end of the semester, focused on the novel form of the automatic control theory course. The feedback was provided from 10 students. The questions are as follows:

1. How do you evaluate the difficulty of the course?
2. How do you evaluate the coverage of the course by study literature?
3. How do you evaluate the novel format of lectures – Active tutorial?
4. How do you evaluate the format of seminars?
5. To what extent do you think it is possible to work on seminars independently without the guidance of a teacher?

First, we asked students about their opinion on the difficulty of the course on a scale from 1 (very easy) to 5 points (very difficult), see Figure 5. 70% of students rated the difficulty with 4 points, and the remaining 30% rated the difficulty with 3 points, which supports our experience that students usually see this course as a difficult one.

We were also curious about students' opinion about the coverage of the course by study literature on a scale from 1 (worst) to 5 points (best), see Figure 6. 50% of students were satisfied with the study materials and rated them with 5 points, and 40% of students rated them with 4 points.

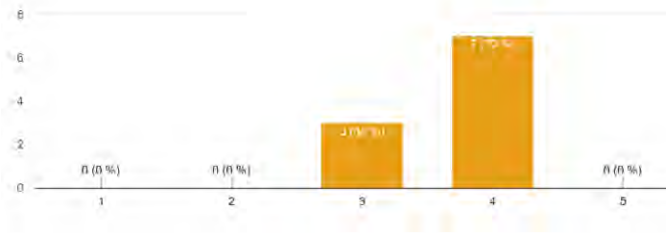

**Figure 5.** Evaluation of the course difficulty (1 – very easy, 5 - very difficult).

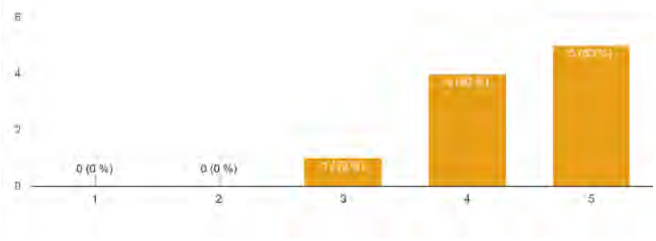

**Figure 6.** Evaluation of the study literature (1 - worst, 5 - best).

In the third question, we asked students to evaluate the format of the Active tutorial on a scale from 1 (worst) to 5 points (best). Although in this feedback, the evaluation is more distributed, majority, i.e., 70% of students rated the Active tutorial format with 4 points, see Figure 7. There was also the ability to write a comment about the novel format of the lectures. Most of the students were satisfied, but they complained about the increased time they needed to dedicate to the course:

*"It was more time-consuming, but I personally liked it because I could take good notes right away. I would probably watch the lectures again before the exam anyway."*

*"It's very time-consuming, it practically doubles the lecture time, and I only fully understand it in class. The recordings are great - you can always return to the topic, and they complement the lectures in class nicely."*

*"I prefer it over a regular lecture."*

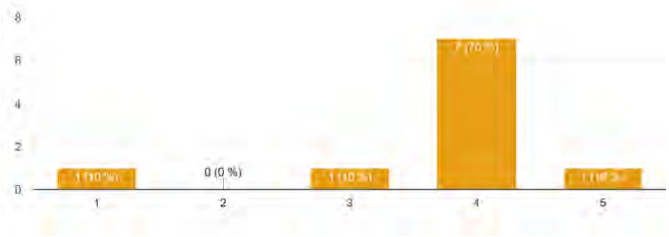

**Figure 7.** Evaluation of the Active tutorial (1 - worst, 5 - best).

In the last two questions we asked about the seminars. First, students evaluated the format of the seminars on a scale from 1 (worst) to 5 points (best), see Figure 8. Here, students expressed their satisfaction, i.e., 90% of students rated the seminars with 5 points and the rest rated them with 4 points.

Finally, we asked students about their opinion on the ability to work independently during seminars, because our aim was to decrease the necessity to lead the students and to support them mostly in work with MATLAB. The students could evaluate the independence during seminars on a scale from 1 (need for lots of support) to 5 points (totally independent), see Figure 9. The evaluation in this question is distributed, but most of the students, i.e., 60%, evaluated the independency with 3 points. The reason behind this is probably that many students studied bachelor's degrees with mostly chemical backgrounds and with no previous experience with automatic control. Students were able to leave a comment to this question, and support our reasoning of the lack of independence during seminars:

*"Many things were new to me and some I barely remembered, so I didn't even know how to start with*

*some tasks. Some questions were perhaps a little complicated and asked about things I hadn't encountered much before."*

*"The exercises were great and over time they became easier to understand. At first, everyone is of course a little lost, but over time, people get into it and start to understand the context and connections."*

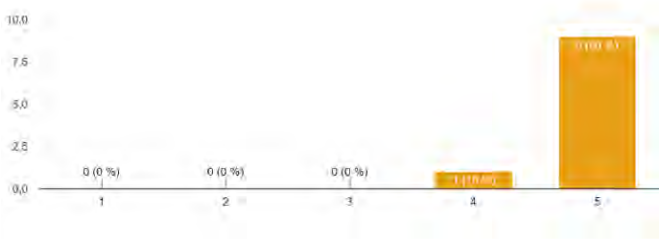

**Figure 8.** Evaluation of the seminars (1 - worst, 5 - best).

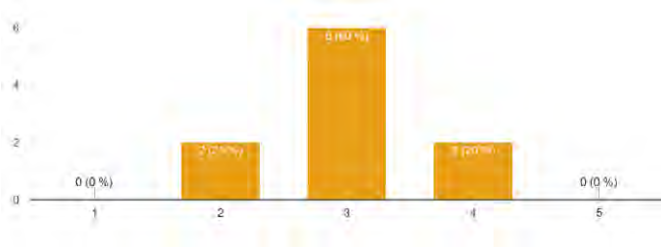

**Figure 9.** Opinion on independence during seminars (1 - need for lots of support, 5 - totally independent).

To summarize, the students see the course as quite a difficult one. Despite this fact, they rate its quality and study materials highly. The novel format of Active tutorials is more time-demanding, but students prefer it over a standard lecture.

## CONCLUSION

This paper presents our experiences and provides an overview of the structure and methods employed to enhance teaching and learning in a master's-level course on automatic control. By leveraging innovative teaching strategies, such as flipped classrooms, active tutorials, real-time experiments, and digital tools like Moodle, we successfully improved the quality of education and student engagement. The course structure integrates mainly theoretical background together with practical applications, supported by comprehensive study materials and hands-on learning through simulations and portable laboratory devices.

The students' feedback indicates a positive response to the novel teaching methods despite the recognized difficulty of the course. Students appreciate the new format, even though it demands significant time and effort. Moreover, introducing the Active tutorials led to improvement in the results of the course weekly survey when comparing this academic year with the previous one.

## ABSTRACT

UCL Chemical Engineering ensures graduates are digitally literate by integrating computational tools like gPROMS, Aspen Plus, and GAMS into the undergraduate curriculum. Students in the first year of undergraduate program use GAMS to solve simple simulation and optimization problems and gPROMS for solving ordinary differential equations (ODEs) in reactor design problems. In the second year, students start using Aspen Plus to simulate more complex chemical process units, interpret and discuss results obtained and justify any differences observed between experimental data and computational results. They use GAMS to simulate and optimize a process flowsheet with considerations of the implications of proper initialization procedures and strategies for obtaining optimal parameters and gPROMS for advanced reactor and separator problems. The computational knowledge acquired in the first two years prepares students for the third-year capstone design project where they use the various tools in designing and simulating their processes during the preliminary, conceptual and detail designs. The computational resources available to students and the additional supports provided by educators help the students succeed on the design project in the third year. This work outlines strategies for delivering the computational tools required for modules in the first two years of the undergraduate program and the application of the knowledge in the third-year design project. It demonstrates how complex process systems engineering (PSE) problems are taught, student support and resources available, and feedback for continuous improvement. It presents some challenges faced due to the use of generative AI tools and how this can be addressed.

**Keywords**: Education, Aspen Plus, GAMS, gPROMS, Process Design, GenAI

## INTRODUCTION

Computational tools are present in most, if not all, Chemical Engineering programmes according to Molaei Chalchooghi and Sorensen [2]. In the digital era we live in, universities prioritise that their graduates are digitally literate, able to use a variety of digital tools. These computational tools could range from process simulators, programming languages, computer packages etc., and are widely used both in academia and industry for solving several problems, from the solution of very simple algebraic equations to the optimisation of complex (i.e. highly non-linear and non-convex) processes and flowsheets [3]These tools include, but are not limited to, Aspen Plus [4], GAMS [5], gPROMS [6], ChemCAD [7], MATLAB [8], Python [9] etc. Some of these tools, among others, are widely used in Chemical Engineering programmes, due to their ease of use, accessibility, availability of teaching and learning materials and resources [10], however, the choice of tools to be used depends on the application, the level of the students etc.

Computational tools in chemical engineering are essential for process design, simulation and optimization and for solving complex problems [11]. Tools like Aspen Plus can be used to model chemical processes, simulate plant operations, and optimize process conditions. These simulators allow engineers to design and test process configurations before physical implementation, reducing cost and risk. While gPROMS ModelBuilder can be used for dynamic simulation and optimization, parameter estimation, experimental design etc, General Algebraic Modelling System (GAMS) is designed to solve large scale

optimization problems. Within the Chemical engineering program, it can be used for process optimization, production planning and scheduling, heat integration and energy management through heat exchanger networks optimization, process synthesis and economic evaluation of processes.

This work explores the approach to teaching computational tools in the first two years of undergraduate chemical engineering program at UCL. It discusses the design of teaching methods, assessment strategies and feedback, along with the development of learning resources and the challenges encountered. Additionally, it highlights the collaborative efforts between students and staff in enhancing computational education and addressing learning difficulties, ensuring students are well-prepared for the third-year capstone design project and beyond.

## COMPUTATIONAL TOOLS TEACHING, ASSESSMENT AND FEEDBACK APPROACHES

### Teaching Approaches and resources

In the department, students are taught how to select the most suitable software for a given problem; and how to use this software effectively in their work before proceeding to solve more challenging problems in their future careers. In addition, teaching staff regularly evaluate the material delivered, to ensure that the concepts and topics discussed align with current research directions and the constantly evolving industrial needs.

The teaching approach includes a combination of lectures, video tutorials, and guided problem-solving sessions, ensuring students have multiple avenues for learning and understanding these tools. Supporting resources such as tutorial videos and lecture slides have been developed to cater to diverse learning needs and allow for self-paced learning.

In the first year of the undergraduate program, students are introduced to GAMS (General Algebraic Modeling System) and gPROMS Model Builder as part of the Computational Modelling and Analysis module. These tools are fundamental in developing computational problem-solving skills relevant for the chemical engineering degree program early in the curriculum. For GAMS, they learn how to solve various problems, starting from basic systems of equations to more applied cases such as simple flash calculations and refinery blending problems. The problems are carefully designed to expose students to different solvers, including constrained non-linear systems (CNS), linear programming (LP), and non-linear programming (NLP) solvers. By working through these exercises, students gain a good foundation in optimization and numerical methods, while developing a good understanding of how different mathematical formulations are applied to practical engineering problems.

For gPROMS, students are taught how to solve basic ordinary differential equations (ODEs) before progressing to more complex problems involving batch and continuous stirred tank reactors (CSTRs). This provides them with an understanding of dynamic systems and the ability to simulate basic reactor problems.

In the second year, students build on their foundational knowledge by tackling more advanced problems using GAMS. They are tasked with solving process design challenges involving complex flowsheets that typically include a flash column, a reactor, heat exchangers, and separation units. The entire process flowsheet is implemented in GAMS, requiring students to integrate multiple unit operations into a cohesive optimization framework. This includes defining an objective function, such as maximizing product yield as well as economic potential or minimizing energy consumption with the use of relevant optimization solvers. Through these activities, students further develop their programming and modeling skills and become more aware of process design and optimization concepts that are relevant to real-world engineering practice.

Additionally, Year 2 introduces students to Aspen Plus in the Separation Processes module in three lectures, integrated within the module curriculum. During these lectures the students are introduced to the Aspen plus as a simulation tool and its application in chemical engineering. They begin by learning to model basic processes, such as heaters, coolers, short cut distillation models (DSTWU), and liquid-liquid extraction. These foundational exercises build their confidence to tackle more complex operations, including rigorous distillation with RadFrac. As the course progresses, students explore advanced tools within Aspen Plus, such as sensitivity analysis for optimization and economic feasibility studies to assess the viability of process designs.

The teaching approach and computational topics covered during the year 1 ,2 and 3 are summarised in Figure 1. This approach ensures that students are equipped with the skills needed to select the most suitable computational tools for specific problems and reflect on their results before their third year capstone design project.

During their studies, students have continuous access to online learning material for all the computational tools used across the entire curriculum (i.e. AspenPlus, gPROMS, GAMS and MATLAB). The material for each of the tools includes how-to videos and step-by-step presentations that explain various concepts and processes, and how these can be implemented and solved using the respective tool. The material is updated regularly to make sure it aligns with the theory taught, or any new elements added, as well as updated versions of the software. For instance, material on how to consider

distributed models in gPROMS, and relevant examples thereof, is available for students to download, study and apply in their own time. Relevant material is available online also for aspects that are not formally considered or assessed as part of any of the taught modules, such as solids processing, so that students can refer to this if they need to consider these aspects as part of an open-ended project. Postgraduate students also make use of these resources as needed in their research and taught modules.

**Figure 1.** Distribution of PSE related tasks and available support over the curriculum.

This supporting material provides additional resources that are useful to the students especially for their projects in 3rd year, when they need to consider processes not previously covered in individual taught modules [1].

## ASSESSMENT APPROACHES

### Assessments Approaches

In all modules discussed in the previous section, assessed projects and team reports evaluate whether the learning outcomes are met, whilst tutorials for the relevant computational tools take place before the release of the material for which the software is required (e.g. project, coursework etc.). In addition, computational help desk sessions are scheduled before the respective assessment deadline so that support by staff is provided to students who may be facing difficulties with the specific software used.

In Year 1, in Process Modelling and Analysis module, students apply their computational knowledge through assessments that account for 50% of the overall module grade. These assessments include both coursework and project designed to evaluate their knowledge of using GAMS and gPROMS for programming and modelling. The problems presented to students cover a wide range of applications, including but not limited to application of some numerical methods, process flowsheeting with recycles, sensitivity analysis, convergence analysis, and simulation of steady-state and dynamic operations by solving relevant ordinary differential equations (ODEs).

In Year 2, as part of the Process Design Principles module, students undertake a project that constitutes 60% of the overall module grade. In this project, students use GAMS and Aspen Plus to design a complete process plant. The project involves solving a complex problem with multiple design variables, where the primary objective is typically to maximize the economic potential of the process and obtain a stream table for the process. Students are required to compare results obtained in GAMS with that of ASPEN and comment on the discrepancy observed. Within this assessment, students perform sensitivity analyses to identify the optimal set of operating parameters that achieve the best economic potential. This task requires the application of advanced features in GAMS, such as the use of flow-control structures (e.g., while loops), enabling them to handle iterative calculations effectively. The project provides students with hands-on experience in tackling design problems and reinforces their understanding of process design, optimization, and modelling using computational tools. Refer to **Table 1** for Computational tool used in year 1 and year 2 as part of different modules' assessments. These assessments are designed to not only test students' technical understanding of the computational tools but also to develop their problem-solving skills and confidence in applying these tools to real-world chemical engineering challenges.

### Artificial Intelligence (AI) Tools and Assessment

Technological advancement has introduced unique challenges in assessment involving the use of computational tools, particularly with the increasing accessibility of AI tools that can generate code in common programming languages such as Python and MATLAB with high accuracy. One of the primary challenges is the potential misuse of these AI tools by students to generate code required as part of their assessment. While these tools could be valuable aids, their misuse can diminish students' critical thinking and proficiency in using the tools. For instance, rather than developing a good understanding of model implementation in these software, students might rely solely on AI-generated solutions.

The situation is further aggravated by the flexibility offered to students in some assessments, where they are free to choose the software or tools they prefer. In these instances, the use of AI assistance could undermine the intended learning outcomes if assessments are not carefully designed.

**Table 1:** Computational tools used in different modules in Year 1 and 2.

| Year of study | Module name | Computational tools used |
|---|---|---|
| Year 1 | Process Modelling and Analysis, | GAMS and gPROMS Model Builder |
| | Design and Professional skills I | GAMS |
| Year 2 | Separation Processes | ASPEN PLUS and gPROMS Model Builder |
| | Process Design Principles | ASPEN PLUS and GAMS |
| | Design and Professional Skills II | ASPEN PLUS and GAMS |

To address this, educators need to adopt strategies that ensure assessments meet their educational goals even when students have access to AI tools. Assignments should be structured in a manner that integrates critical analysis, interpretation of results, and the ability to explain the rationale behind specific computational approaches. For example, tasks that require students to debug, modify, or evaluate AI-generated code can shift the focus back to understanding the implementation rather than just copying the generated codes. Similarly, incorporating reflective components, where students justify their approach to solving a problem, can help educators gauge their understanding.

UCL has also provided a guideline on how generative AI (GenAI) can be used ethically in assessments. Students must acknowledge where and how they have used GenAI in any piece of work they are submitting, and where GenAI is used inappropriately, this is considered academic misconduct that will be referred to the appropriate panels.

## FEED BACK APPROACHES

The application of computational tools is integrated within the curriculum of different modules as presented in **Table 1**. Students' feedback is collected formally three times per modules as part of CMD (continuous module dialogue). UCL's approach to gathering and responding to student feedback prioritizes anonymity and open communication, ensuring students felt comfortable sharing their experiences and suggestions.

To collect feedback effectively, Mentimeter slides are used, which allow students to present their feedback anonymously. This method was chosen to encourage honest communication, ensuring that students could express their views without hesitation [12]. By using this approach, a wide range of perspectives on the students' learning experiences are gathered, along with the challenges they faced, and their suggestions for improvement. After collecting feedback on learning experiences and challenges, the module coordinator analyses the responses and the proposed actions for developing the delivery of computational tools were collaboratively discussed with the teaching team. To maintain transparency, response slides are uploaded to Moodle, ensuring all students have access to the comprehensive overview of the improvements made based on their feedback.

Student feedback over four years for the *Computational Modelling and Analysis* module (Year 1) showed positive responses, with low response rates of 29%, 26%, 27%, and 41%. 75% found the materials useful, and 66% said tutorials met expectations. Feedback led to improvements, enhancing student confidence. Future efforts will address challenges to improve learning outcomes further.

## APPLYING COMPUTIONAL TOOLS IN THE CAPSTONE DESIGN PROJECT

During the Capstone Design Project, students apply the knowledge of computational tools they have developed over their first two years of study to design and optimize a chemical plant. The project is structured into four main stages: Appraise, Select, Unit Design I, and Unit Design II. Computational tools are used in the first three stages the details of which are provided in this section.

In the Appraise stage, students begin by developing a mathematical model of the process plant. Using GAMS, they solve the mass and energy balances for the entire process. This enables them to produce a comprehensive stream table for the flowsheet and estimate the energy requirements for the plant.

In the Select stage, students create a detailed Process Flow Diagram (PFD) and simulate the entire process in Aspen Plus. This simulation helps them assess the initial feasibility of the process and apply heat integration principles to optimize energy recovery for the overall plant, improving efficiency and sustainability.

Finally, during the Unit Design I (UDI) stage, students focus on the detailed design of a major process unit, such as a reactor or a separator. For separation columns, they use Aspen Plus, leveraging its robust capabilities in simulating and designing such systems. For reactor design, students are given the flexibility to choose from various computational tools as they wish. Commonly chosen tools include gPROMS, Python, MATLAB, and Polymath, each offering distinct capabilities for modelling and optimization of chemical processes. For more information on the design project stages, refer to Nayak-Luke et al. [13]

## TEACHING APPROACHES OF COMPUTATIONAL TOOLS IN THE DESIGN PROJECT

In the context of the Capstone Design Project, our teaching approach includes providing structured technical support sessions to assist students in overcoming computational challenges. These sessions are designed to address the diverse technical difficulties faced by students, ensuring that they can effectively simulate and analyze their chemical engineering processes using computational tools.

To facilitate effective learning, the technical support sessions are conducted in small groups of 10-15 students. This group size allows for personalized attention, fostering student engagement and encouraging active participation. Each session is repeated four times depending on the size of the cohort to accommodate different groups of students, ensuring consistent delivery of content across all sessions. The structure of these sessions is informed by educational frameworks [14] and aligned with the key aspects of teaching.

In preparation for each session, we create a forum where students could submit their questions in advance. This approach enabled the teaching team to identify the key issues to be addressed during the session, optimizing the use of time and ensuring that the most pressing concerns were covered. Additionally, this forum allows students who might be hesitant to ask questions during the session to voice their concerns anonymously, fostering a more inclusive learning environment.

The main challenges encountered during these sessions included maintaining consistent content delivery across different groups and addressing all student questions within the limited time available. Moreover, managing the varying levels of simulation skills among students required careful formulation of responses to ensure that all students could understand and apply the information, regardless of their progress.

While the primary focus of the sessions is to provide computational support, an equally important objective is to bridge the gap between theoretical knowledge and practical application. By interpreting the results generated by the computational tools, students are encouraged to critically evaluate whether the outcomes were reasonable in the context of the theoretical concepts they had learned in previous years. This integration of theory and practice is crucial for developing a deep understanding of chemical engineering principles.

Following each session, a comprehensive Frequently Asked Questions (FAQs) document addressing the main points discussed is uploaded. This resource is made available to all students, including those who are unable to attend the sessions or those that had fewer questions asked during their session. The FAQs document serves as a reference, allowing students to revisit key concepts and solutions as they progress through their design projects

## STUDENT-STAFF COLLABORATIONS IN DEVELOPING THE RESOURCES FOR COMPUTATIONAL TOOLS

UCL is committed to fostering staff-student collaboration through projects aimed at enhancing the quality of teaching and learning across departments. The need for student-staff partnership in teaching and learning and its benefit has been documented in literature [15]. In summer 2024, the Faculty of Engineering Sciences funded a project in the Department of Chemical Engineering at UCL to address specific areas where students expressed a need for additional support in computational tools. One such project involved a student developing computational resources over two months, focusing on topics that posed challenges for their peers. These resources included: step-by-step guides (in PowerPoint and Word format) on retrieving experimental data from Aspen, instructions on implementation of column internals for distillation columns, detailed troubleshooting workflows for resolving issues in AspenPlus for increasingly complex chemical processes, and guidelines for configuring more advanced process intensifications in AspenPlus, specifically reactive distillation columns. These materials were made available students on the department's online learning system (Moodle) to provide accessible and structured support for students across all cohorts. They are designed to assist students with coursework and project and to enhance understanding of advanced process simulation topics. Additionally, a similar summer project was undertaken by another student to develop resources aimed at simplifying basic modeling concepts and learning videos and slides on GAMS and gPROMS. The developed materials from this project included: sample GAMS and gPROMS codes for fundamental modeling tasks, troubleshooting tips for common errors in GAMS, and a collection of exercise problems tailored to engineering applications. These materials have also been made available to students on the online learning platform.

The active involvement of students in developing these resources not only addresses immediate learning gaps but also promotes continuous improvement in the teaching of computational tools. This collaboration highlights the value of leveraging student perspectives to improve learning resources and accessibility, while simultaneously equipping them with practical skills in computational problem-solving that could be developed further in the future.

## CONCLUSION

This paper outlined the integration of computational tools within the undergraduate chemical engineering curriculum at UCL, specifically in preparation for the third-year Capstone Design Project. It presents the approach to teaching these tools, the assessments, the feedback received from students and how it is responded to, and the various support mechanism provided to facilitate their learning.

Students are introduced to computational tools in their first year, where they apply them to solving fundamental chemical engineering problems in process modeling and simulation which they further develop in their second year by tackling more complex problems involving process design and optimization. This prepares them for them for the capstone design project in the third year.

The rapid advancement of artificial intelligence presents new challenges in higher education, particularly regarding academic integrity and the potential over-reliance of students on AI-generated solutions. Addressing these concerns requires the careful design of assessments that emphasize critical thinking and problem-solving, ensuring that students develop the deep understanding necessary for professional practice.

By continuously refining the integration of computational tools and adapting teaching strategies to evolving technological trends, chemical engineering education can better equip students with the skills needed for both research and industrial applications.

## ABSTRACT

Current progress in digitalization has led to a wide interest in learning more from available data. Advanced data analytics can be achieved through commercially available software; however, learning to program allows for more flexibility and, ultimately, more freedom in the potentially tailor-suited investigation. Among other programming languages, Python is one of the most requested, in industry and research alike. To intensify the earlier efforts and create both a pedagogical framework to teach programming to (bio)chemical engineers, and provide students with the opportunity to ask questions, we explore the integration of sPyCE and FermentAI into BioVL, a virtual laboratory for teaching (bio)processes, previously implemented by the authors. sPyCE is an open-source series of Python courses tailored to (bio)chemical engineers, FermentAI is a chatbot trained to answer questions about fermentation processes. The main goal of this work is to enable students to (i) learn (bio)processes and how to model them, and (ii) ask questions to a chatbot to clarify their doubts. We believe that the Python tutorials will enable students with different backgrounds and programming skills to learn how to model (bio)processes. Moreover, the chatbot will enable students to ask for clarification right away, without having to search for an answer or wait for a teacher to reply.

**Keywords**: Education, Industry 4.0, Virtual Laboratories, Programming, Chatbots.

## INTRODUCTION

Education 4.0 uses cutting-edge technology and automation to transform learning and work. It encourages creativity and non-traditional thinking. It prepares students for Industry 4.0 by focusing on a broad range of skills and harnessing technological and pedagogical innovation [1-2]. It also aims to empower learners to tackle many new challenges. Among the skills taught under this paradigm, programming and the use of artificial intelligence (AI) are the most requested.

Along with the constant development of new and advancing technologies, comes the need for a qualified workforce [3]. One of the increasingly mandatory requirements is to suitably educate future engineers for Industry 4.0 and its demands. Therefore, it is necessary to improve the quality of education in (bio)chemical engineering processes and increase students' engagement [4].

By fostering a culture of continuous learning and leveraging digital tools and resources, learners can improve their expertise, strive towards excellence, and contribute to the advancement of the field.

One of the ways educators can contribute to this is by teaching students how to code. Integrating coding in the (bio)chemical engineering curriculum is paramount [5], especially with regards to the four following aspects:

- Data analytics: (bio)chemical engineers frequently handle large amounts of data, and coding can automate the data analysis process, making it more efficient.
- Process modelling and simulation: coding skills are increasingly necessary for creating and working with process simulations. (Bio)chemical engineers frequently create models of (bio)chemical processes using coding to simulate different

(a) (b)

**Figure 1:** BioVL platform. Figure (a) Shows the BioVL interface; Figure (b) illustrates the development of the interface based on Bloom's taxonomy (Bloom, 1956).

process design scenarios.

- Optimization: (bio)chemical processes involve complex systems that need to be optimized; we can optimize complex (bio)chemical systems using even pre-existing coding algorithms.
- Sensors and automation: it is currently becoming mandatory for (bio)chemical engineers to possess coding skills to effectively design, modify, and troubleshoot automated systems.

Research suggests that personal tutoring is the most effective mode of learning [6]. However, while it is generally unsustainable in higher education [7], it can be implemented on digital platforms through intelligent tutoring systems, such as generative AI chatbots. This is possible thanks to the recent advancements in AI, which have led researchers to investigate its feasibility, reliability, and validity in many fields, including education.

To train engineers willing to take on the challenge, we previously implemented sPyCE [5], an open-source series of Python courses tailored to (bio)chemical engineers, covering topics such as design of chemical reactors, stoichiometry, data pre-processing, data analysis, and various machine learning methods, from supervised to unsupervised learning and including both classification and regression examples.

We also implemented FermentAI [8], an intelligent tutoring system provided as a chatbot trained to answer questions about fermentation processes.

In order to intensify the previously carried out efforts and provide both a pedagogical framework to teach programming to (bio)chemical engineers and give students the opportunity to ask questions and clarify any doubts regarding their learning material, we explore the integration of sPyCE and FermentAI into BioVL [9], a virtual laboratory for teaching (bio)processes, previously implemented by the authors.

FermentAI was previously used by leveraging a dataset composed of exam questions (and answers) from a master's degree course offered by the Technical University of Denmark (DTU). However, the dataset was enriched with broader fermentation and modelling information for this work. This enables the model to answer questions that students might have when learning how to work with the fermentation models available on the BioVL platform.

The main goal of the work presented in this article is to enable students to (i) learn (bio)processes and how to model them, and (ii) ask questions to a chatbot regarding their doubts. We believe that the Python tutorials, given the stimulant material used along with gamification, is an engaging and insightful way to learn to model (bio)processes. Moreover, this will also enable students with different backgrounds - within the (bio)chemical engineering field - and programming skills to better understand the models available in BioVL, without having to search for additional material. The chatbot will allow students to ask for clarification right away, without any time delay. Therefore, this work aims to provide one centralized platform where all learning aids are available to students.

## MATERIALS AND METHODS

### BioVL: A platform for teaching fermentation processes

BioVL [9], available at http://www.biovl.eu, is an e-learning platform designed to teach (bio)processes. It aims to teach students how to build both simple and more

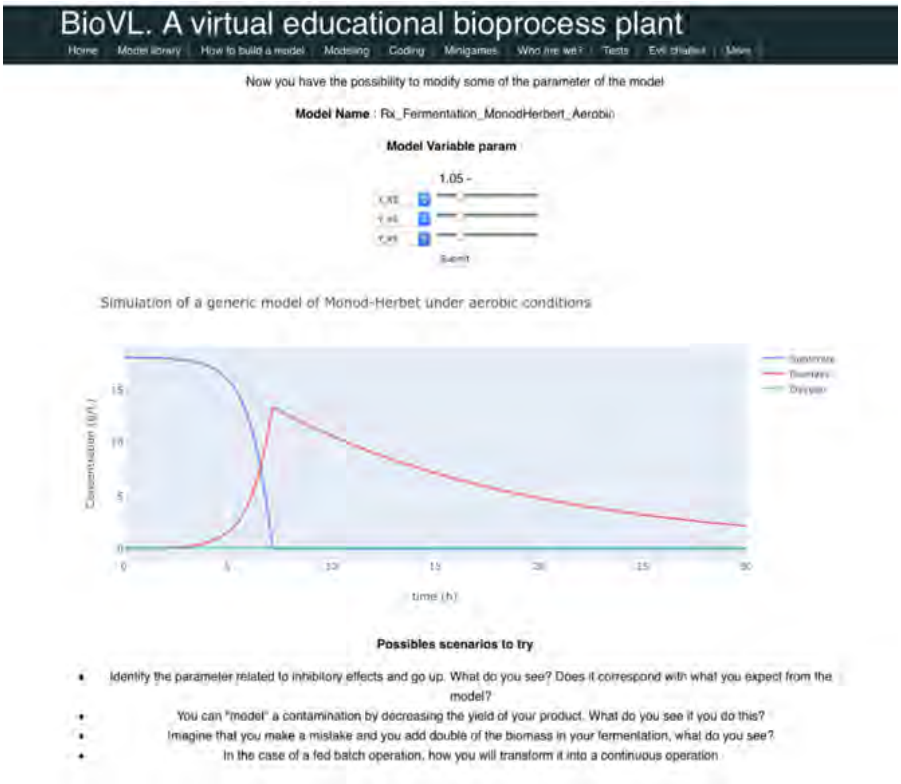

**Figure 2:** BioVL platform that shows how to interactively modify the parameters of a model in the platform (figure adapted from [9]).

complex models.

Figure 1 (a) presents the BioVL home page, while Figure 1 (b) introduces how the interface was developed according to Bloom's taxonomy [10]. The model library contains well-known and used models, such as Monod kinetics (aerobic and anaerobic), *E. coli* (aerobic, batch and fedbatch) and *S. cerevisiae* (aerobic, batch and fedbatch). The experience provided to the students is interactive; in fact, they can learn how different parameters affect the models by tuning the parameters directly on the platform. An example of this is presented in Figure 2.

Of note is that, although BioVL was originally developed aiming to teach (bio)processes (see more details in [9]), the authors have envisioned it to be a suitable centralized and customizable platform to support and e-teach a broader range of content taught in the (bio)chemical engineering curriculum· This provides the motivation behind the work performed for this manuscript: to build on the available platform and expand the capacities enabled. In fact, although the platform already contained a page on which students could train in coding (http://www.biovl.eu/coding), no tailored programming introduction was provided. Therefore, the platform assumed the user to have already an intermediate level of programming skills.

## Educational tools for (bio)chemical engineers: sPyCE and FermentAI

The work presented in this manuscript aims to reduce the expected prerequisites and introduce a tab on the website (www.biovl.eu/spyce) that links to sPyCE [5], an already implemented and abundantly tested series of Python courses tailored for (bio)chemical engineers. This series currently includes two Python courses, "Chemical Reaction Engineering in Python" and "AI for Chemical Engineers". Both courses are open-source and can be downloaded freely by everybody. The first course has been successfully embedded in the curriculum of a B.Eng. course at DTU since the fall semester of 2022. The second course has been tested in various special courses with students at DTU.

In an effort to support students willing to learn about fermentation models independently, the platform also includes FermentAI [8], a chatbot trained to answer questions about fermentation processes. The purpose of introducing the chatbot to the platform is to provide instant 1:1 tutoring support to students, enabling them to quickly ask FermentAI. Students can use the chatbot to answer any question they have about fermentation, or regarding the models provided on the platform. Possible questions

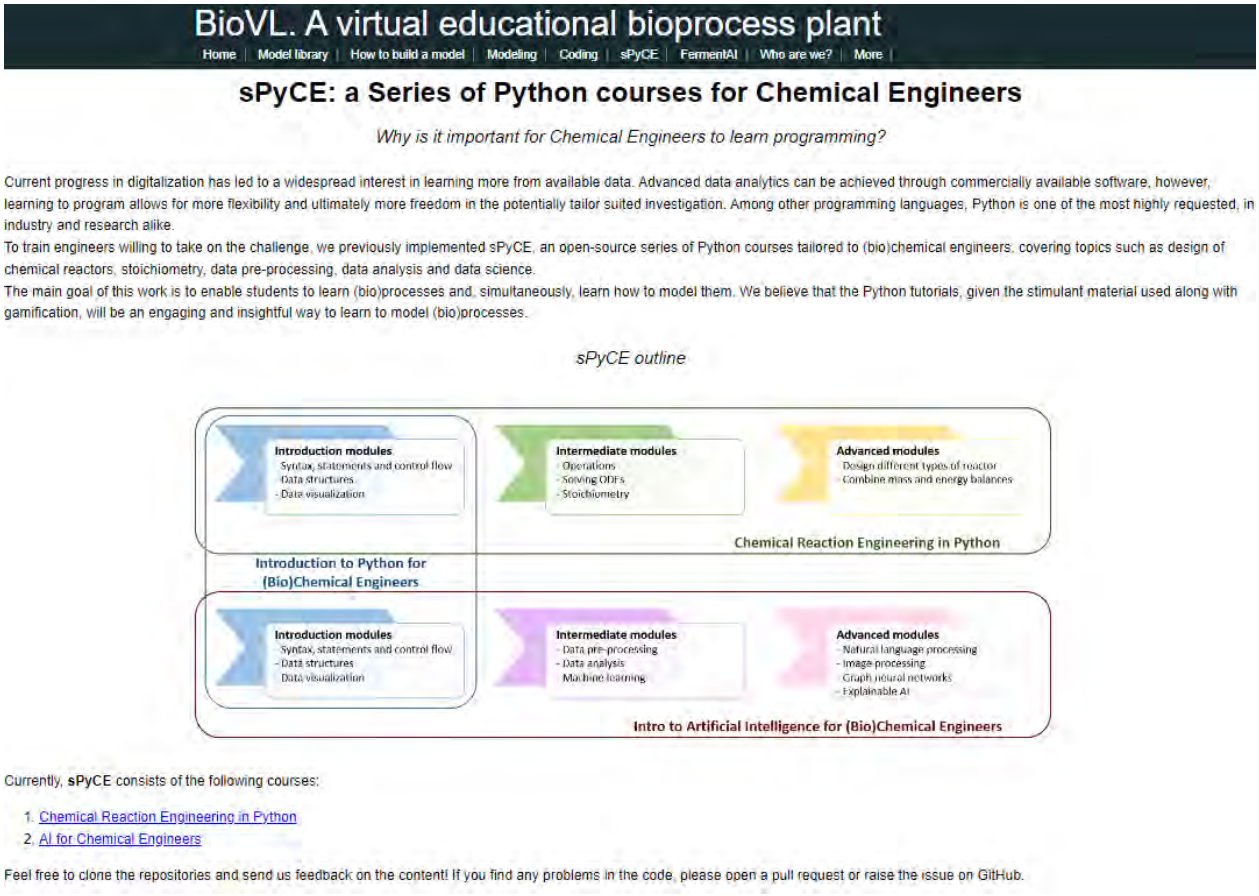

**Figure 3:** Developed tools embedded into BioVL. The Figure presents how sPyCE is integrated into the platform.

could be, for example, about parameter ranges or clarifying why changing an initial substrate amount results in changes in the final yield.

## RESULTS AND DISCUSSION

Figure 3 shows how sPyCE is embedded into BioVL. It is introduced on the website as a new tab, to facilitate students in finding it. First, a description of sPyCE is provided, as well as a contextualization of the motivation behind creating Python courses for (bio)chemical engineers. Afterward, the series outline is introduced, showing the two courses that belong to it.

The first two modules, which introduce the basics of Python, are shared between the courses, enabling students to freely choose the course they want to take to learn this programming language. The GitHub repositories that host the code are then linked at the bottom of the page.

FermentAI is also embedded in the platform as a separate tab, following sPyCE. The chatbot's interface is shown in Figure 4. In the example provided, the user asked about the most well-known fermentation process. The chatbot can be also used to ask further information about the models provided in BioVL. Figure 2 showed a simulation of a generic model of Monod-Herbert. In this case, FermentAI could be used to ask further questions about this fermentation, such as how does it work under aerobic compared to anaerobic conditions. Alternatively, FermentAI could be asked about the effect of a change in the initial parameters on the final concentration.

Although students' feedback has not been yet collected to evaluate this initiative, embedding these tools in a virtual laboratory aims to boost students' understanding by providing further support throughout each stage of their learning.

## CONCLUSION

Digitalization is revolutionizing the field of engineering, empowering it with enhanced efficiency, quality, and scalability. Implementing digital technologies such as AI, robotics, and big data analytics optimizes production processes and enables real-time (or near real-time) decision-making. The examples pursued in our work

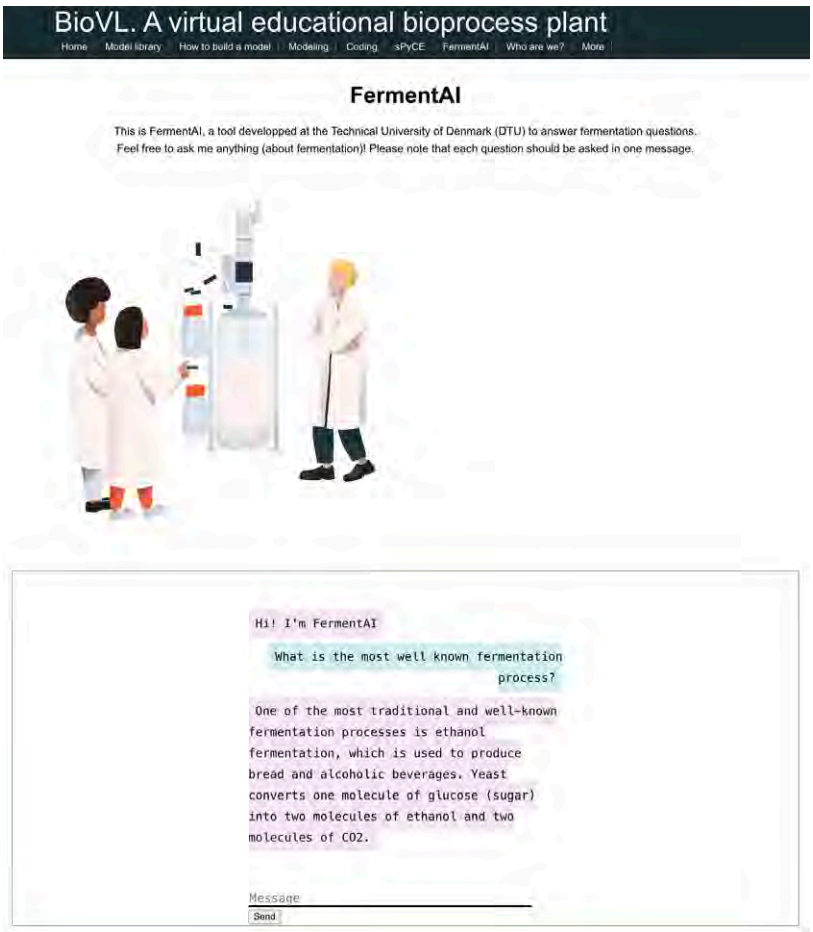

**Figure 4:** Developed tools embedded into BioVL. The Figure shows the chatbot available, FermentAI.

demonstrate the endless possibilities that lie in embracing and implementing the new tech avenues. However, there are some issues and challenges that still need to be addressed, such as how digitalization and its enabling technologies can not only prepare engineers for the biomanufacturing industry but also empower future engineers for Industry 4.0. This work strives to push the boundaries towards this goal, by leveraging technologies such as programming and AI, to facilitate knowledge transfer and improve the platforms that enable it.

More specifically, a previously developed platform, BioVL, is enriched with further capabilities. In fact, sPyCE, a series of Python courses tailored to chemical engineers has been added to the platform, facilitating students who want to learn to program. Furthermore, to provide instant 1:1 tutoring to students, we deploy FermentAI, a chatbot trained to answer fermentation questions, on the platform. The aim of this initiative is to leverage new technologies to facilitate the learning process and provide support to students throughout each stage of their learning.

## LIMITATIONS

The current version of FermentAI is based on questions from a course at DTU. Although the dataset is enriched with broader fermentation and modelling information for this work, further expansion of the database used by FermentAI to retrieve the relevant information would be highly beneficial, and it is therefore planned for the near future. For this reason, we are continuously collecting more questions which will then be answered by experts to enrich the database. We created a survey where both experts and readers can suggest questions to be added to the model. The survey is available here: https://forms.gle/R8NvhgwXouEpem7a7; we welcome any suggestion or further comment related to this work.

The tools added to BioVL have not been evaluated by students yet. This is planned to be performed in connection with the Dig4Bio project, as further explained in the next Section.

## FUTURE PERSPECTIVES

This work is meant to represent a stepping stone to

bring digital tools to other universities and audiences. In fact, the models and tools added to BioVL will be used and extensively evaluated by students and other researchers in three European Universities: DTU, TU Berlin and the Instituto Superior Técnico in Lisbon as part of the European project, Dig4Bio. This thorough evaluation will ensure that the tools are useful, and the users are able to leverage sPyCE and FermentAI to learn (bio)processes in a more efficient manner. This also aims to limit the possible impediments, such as the lack of programming skills or getting stuck with one specific doubt, in achieving this goal.

## DIGITAL SUPPLEMENTARY MATERIAL

BioVL is available at http://www.biovl.eu. sPyCE currently includes two open-source Python courses available at: www.github.com/FiammettaC/Chemical-Reaction-Engineering-in-Python and https://github.com/FiammettaC/AI-for-Chemical-Engineers. The code and interface used to build and deploy FermentAI is available at https://github.com/FiammettaC/FermentAI.

## ACKNOWLEDGEMENTS

Funding was provided by (i) the Novo Nordisk Foundation, grant number NNF22OC0080136 - Real-time sustainability analysis for Industry 4.0 (Sustain4.0); (ii) Technical University of Denmark (DTU) and Novonesis (formerly Novozymes), Denmark; and, (iii) Dig4Bio, European Union under the Horizon Europe research and innovation programme with the grant agreement 101159993, within the HORIZON-WIDERA-2023-ACCESS-02-0 call.

## ABSTRACT

Prompt engineering – improving the command given to a large language model (LLM) – is becoming increasingly useful in order to maximize the performance of the model and therefore the quality of the output. However, in certain instances, the user is not able to enrich the prompt with additional and personalized details, such as the preferred tone and length of generated response. Therefore, it is useful to create models that learn these preferences and implement them directly in the prompt. Current state-of-the-art inductive logic programming (ILP) systems can play an important role in the development and advancement of digitalization strategies. For example, they can be used to learn personal preferences of users without sacrificing human interpretability of the learned outcomes. These systems have recently witnessed the development of data efficient, robust, and human interpretable algorithms and systems for learning predictive models from data and background knowledge. In this paper, one of these systems, ILASP (inductive learning of answer set programs), is used to develop a proof of concept of how personal preferences of groups of students participating in an interview exercise can be learned to tailor and improve the generated response of a LLM used in an educational context.

**Keywords**: Intelligent Systems, Machine Learning, Artificial Intelligence, Education, Industry 4.0.

## INTRODUCTION

One of the primary issues concerning the application of artificial intelligence (AI) in education is the reliability and transparency of the information it generates. In particular, widely accessible generative AI models such as large language models (LLM) are designed to deliver responses even when the correctness of those responses might be questionable. A known phenomenon currently occurring with available chatbots is hallucination, meaning that the model provides incorrect or misleading information. To mitigate this issue, a possible solution could be to reduce the generative abilities of these models by opting for more conservative hyperparameter settings. Among these there is temperature, which controls the randomness of the output. Higher values produce more creative results, while low temperature produces more deterministic and conservative outputs. Other hyperparameters that control the randomness and length of the generated answer are top p, token length and max tokens. Top p computes the cumulative probability distribution, setting a cut off when the distribution exceeds the value. For example, a top p value of 0.3 means that only the tokens comprising the top 30% probability mass are considered. Researchers can use all these hyperparameters to tune how creative or long a response should be, having more control over the generative process. Another strategy for increasing the control over the generation of the LLM is prompt engineering. In this case, the AI model could be combined with more interpretable techniques to enhance the prompts given to the LLM.

The Department of Chemical and Biochemical Engineering at the Technical University of Denmark (DTU) offers a course in Good Manufacturing Practices (GMP). As part of the course, students are required to participate in an audit exercise, in which they take on the role of an auditor investigating a company about its good manufacturing practices. In the audit exercise, the company is fictional and is represented by the teachers. After a few

years of participating in this exercise, teachers have agreed to test the replacement of the physical teacher with ChatGMP [1], an AI-powered digital audit tool to represent the fictional company. The chatbot, tested at DTU in the spring of 2024, proved to be considered a viable alternative by both teachers and students. To be noted is that part of the role of a teacher in educating students is also to understand the personal differences of each student and leverage them to help students achieve the best learning outcome. For example, in the audit exercises the teachers normally deduce whether students prefer to have an elaborate or straight-to-the-point answer and try to act accordingly. Moreover, they would perhaps try to help students in case they realized that they do not understand the answer provided, for example, by repeating it but in a simplified manner. Additionally, teachers would also detect whether students missed asking very important questions for the positive outcome of the exercise. In fact, not asking some important questions could result, in this exercise, in the students not obtaining the correct documents that they need to write an audit report. However, most commonly available chatbots would reply to each user and each question in the standard format, without taking these differences and learned knowledge about the students into account.

An approach that can automatically extract knowledge from given examples and therefore could be used to address both the interpretability and the lack of personalization challenges expressed above is inductive logic programming (ILP). The field of ILP has been subjected to substantial advancements over the course of the past ten years. These systems are capable of automatically extracting knowledge (expressed as logic program) from given examples and domain-specific prior knowledge. The aim of ILP systems is to learn models that together with existing background knowledge, explain labeled data [2-4]. An advantage of these models is that they are easily expressed in plain English and are inherently interpretable. This means that they can be explained to a human user, which in turn can facilitate a closer interaction between humans and machine.

This work aims to investigate the use of ILP to learn user preferences and provide a proof of concept on how these can be injected into the prompt given to ChatGMP. To achieve this, we investigate three main use cases: (1) detect whether students have missed some important question in their audit preparation work, (2) analyze if there are some repetitive questions that the students are asking, and (3) extract user preferences to personalize the response generated by the LLM. Overall, the aim of these investigations is to extract insights and improve the question-answering process. This will be done by (i) providing valuable feedback to the students, (ii) further improving the model's responses, and (iii) learning user preferences to tailor the audit exercise to each individual group of students.

## BACKGROUND

Current state-of-the-art ILP systems such as ILASP (inductive learning of answer set programs) [2] and FastLAS [5] can learn a broad range of interpretable models using answer set programming (ASP) [6]. ASP is a purely declarative language for representing and reasoning about knowledge. Typically, real-world problems are addressed by manually encoding them into ASP programs, followed by computing answer sets, which serve as solutions to the original issues. Due to its expressiveness and ability to efficiently find solutions, ASP is gaining increasing interest in the industry [7].

Cutting-edge ILP systems, to automatically derive models from labeled data, utilize input answer sets that represent positive or negative solution examples of a real-world problem and, alongside existing knowledge, learn ASP programs that encode the original problem. ILP has been effectively utilized in numerous real-world applications, including bioinformatics and chemoinformatics [8-10], natural language processing [11], and web mining [12]. Specific cases within chemistry and engineering include interactive exploration of chemical fragments [13], uncovering hydrogen-bonding patterns in crystals [9], drug design [14] and mining pump control systems. These methodologies highlight the capabilities of ILP in different fields and applications, including education.

## MATERIALS AND METHODS

This work aims to take the experiment performed with the creation of ChatGMP a step further. In fact, it aims to present a proof of concept on how the responses generated by ChatGMP could be improved through the use of ILP.

### Data

To leverage a pre-trained LLM on a specific task, domain specific data needs to be collected and curated.

The data used in this work is mainly collected from the audit exercises performed during the GMP course; the audits were performed and video recorded in the spring semesters of 2022 and 2023, summing up to 35 audits of approximately 45 minutes length each. The audios were then extracted from the videos in Python. To detect the different speakers and therefore being able to identify the questions (asked by the students) and the answers (formulated by the teacher), diarization, a process of automatically partitioning an audio recording into segments that correspond to different speakers, was performed. The speaker segmentation was then used to extract the text through a speech-to-text model. Then all

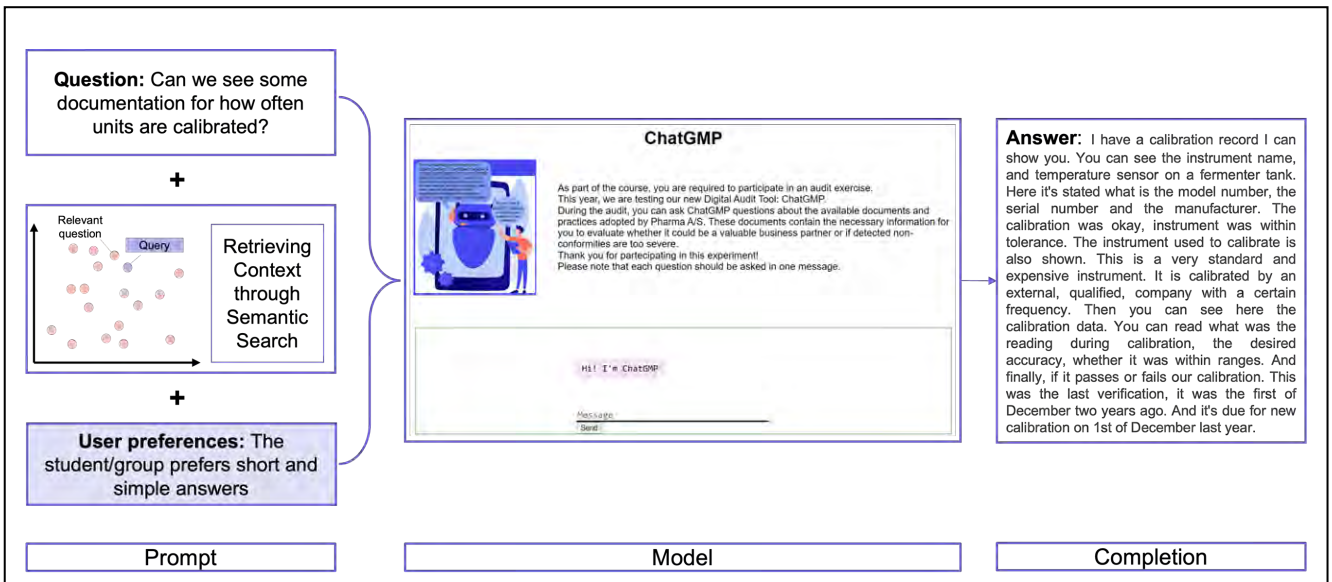

**Figure 1:** Schematics of the prompt given to ChatGMP. ChatGMP is prompted to open the "Calibration record" document, and summarizes it to the students. Here, the prompt is enriched with user preferences, which are weak constraints learned in ILASP. Figure is adapted from [1].

the students' questions were merged, therefore resulting in a document with the question-answer pairs. To ensure the highest quality of data to be used as model input, the resulting text documents (one for each audit performed), were manually checked and edited when necessary. Finally, the curated documents containing the question-answer pairs were concatenated and saved in a JSON file, for easiness of use. Further details can be found in [1].

## ChatGMP Model

ChatGMP is a question-answering (QA) LLM based on a pre-trained model and delivered to the students through an interactive user interface. The LLM component is based on a pre-trained model, FLAN-T5 base [15].

The prompt includes the question asked by the student group performing the audit and is enriched with some context, which contains the response to the question. The context is retrieved through semantic search by calculating the cosine similarity between the query question and the most similar question in the corpus. The LLM then generates an answer to the question asked based on the context provided. Further details are discussed in [1].

## ILP tasks and objectives

For the logic-based part, ILASP is used to learn rules concerning the cases investigated (missing and repetitive questions) and weak constraints to understand the preferences of each group of students. These preferences might concern, for example, the length or level of detail of the questions that they ask, the topic that they focus on more, whether they repeat questions or they are missing fundamental questions to achieve a high grade. The objective of this project is to automatically feed this information and therefore enrich the prompt given to ChatGMP with the weak constraints and user preferences learned. In this manner, ChatGMP could personalize the response based on the user. This process is shown in Figure 4.

The three different cases investigated are:

- *Missing questions*: To achieve a good performance in the audit report, there are two very specific questions (i.e. reference questions) that should be asked. We vectorize both the reference questions and the asked questions and we calculate the cosine similarity between them. Then, based on the similarity between the reference questions and the asked questions, we learn rules to establish whether the group of students asked all questions ("correct" label), if they asked one of them ("semi-correct" label) or if they did not ask any of the reference questions ("wrong" label). The aim of this use case is to directly assess the quality of the questions prepared by the students by checking whether some important questions have not been asked by the group of students, inevitably resulting in a lower grade. Students will then receive feedback on their list of questions, spurring them to further reflection.
- *Repetitive questions*: In the audit exercise, students might not understand a concept and ask for further details or repeat the same question more than once. We assume that question

repetition means that the answer given by the teacher/ChatGMP was inadequate, being either incomplete or not understood by the students. Therefore, we want to predict if students will ask questions with high similarity (repeating one question) to evaluate the understanding of the students. The aim of this use case is to gain deeper insight into the understanding of the students and adjust the agent's answer accordingly, by providing additional details or improving on the quality of the future generated answers.

- *User preferences*: In this case, we want to learn both general rules to achieve a good performance (e.g. questions about a specific topic are to be preferred to another one to maximize performance), as well as personal preferences of the groups, such as length and complexity of the questions, order of the topics, in order to better engineer the prompt given to the LLM for the answer generation. The aim of this use case is to learn user preferences to personalize the responses provided by ChatGMP according to each groups' individual traits and favorable factors.

The examples provided to ILASP were automatically generated using Python and extracted from historical audits recorded in the spring of 2022 and 2023. Explaining the formalism behind ASP is out of the scope of this work. However, from the provided code and learned rules it is possible to extract and discuss some general patterns and insights on the audits.

## RESULTS AND DISCUSSION

The goal of this study is to improve the prompt given to ChatGMP with user preferences learned in ILASP. These rules are easily translatable to natural language and therefore can be appended to the prompt.

Regarding the first case investigated, whether the students are missing important questions, ILASP founds the following rule:

```
relevant(V1) :- similarity(V1,V2); V2 > 62.
```

Provided the given examples and the label for the three classes ("correct", "semi-correct" and "wrong"), ILASP was able to automatically calculate the threshold for differentiating the classes. V1 indicates the reference question (either D1 or D2, since we have two relevant questions that the students should ask). V2 is the cosine similarity between V1 and the asked question. This means that if the cosine similarity between the asked question and the reference question is less than 62, the reference question was not asked. When the example is "correct", it means that the group managed to ask both the reference questions needed. "Semi-correct" means that one of the two questions was asked, while "wrong" indicates that the students did not ask any of the reference questions.

For detecting repetitive questions, the following rule was learned:

```
repeat :- success(V1,V2); repetition(V1,V2,V3); V3 > 60.
```

In this example, V1 and V2 indicate the question sequence (e.g., question 1 and question 2), and V3 is the cosine similarity between the two. Therefore, if two questions in have high cosine similarity, it means that the question is repeated. Here, the threshold learned is 60, so if the cosine similarity of two consequent questions is higher than 60, it indicated that students might be asking the same questions again, maybe because they did not understand the first answer provided by the chatbot.

This rule is useful to extract because, by calculating this similarity of the questions asked by the students, we can learn whether students did not understand an answer given by ChatGMP, so asked a similar question, and inject this information in the prompt of the LLM.

In this case, a possible prompt could be:

- "Please answer the <QUESTION> based on the given <CONTEXT> in a more elaborate manner, since students seem not to have understood the previous response".

This would ensure a more elaborate, complete and perhaps simplified answer from ChatGMP. On the other hand, it is also possible that the chatbot did not understand the question in the first place and therefore prompting it to re-elaborate the answer might lead to a better response. This approach would hopefully lead the students to understand the response and get the answer they were inquiring.

These two use cases are particularly important because the knowledge extracted by ILASP can be helpful when building a chatbot. In fact, detecting whether some questions are missing or if the students did not understand something would enable us to provide feedback back to the students and help them. This would thus ensure that the students have understood and learned the necessary material. This is of the utmost importance, since students' learning should be the ultimate goal. Thus, AI should not be blindly used to replace tasks to save time and resources but rather to help the educator with the automation of repetitive tasks while still ensuring that students reach the learning objectives.

In the last case, concerning user preferences, these are the rules learned:

```
:~ question_type(V1, review), number_questions(V1,
V2).[-V2@3, V1, V2]
 :~ question_type(V1, logistics), number_ques-
tions(V1, V2).[V2@1, V1, V2]
```

This investigation aims to learn the personal preferences of students, for example by learning the preferred number of questions (if many or few) and the length of the outcome. It does it by learning weak constraints. In the learned rule, V1 is the topic of the question, which is defined among 7 topics related to GMP, which are: management, training, quality assurance, quality control, maintenance, production, review and logistics. ILASP learned that the topic is the most important indicator for performance, followed by the number of questions that were asked about the topic. Additionally, how complex the questions are, and the level of details are also relevant considerations.

According to the learned preferences of each user, a possible prompt could be engineered by adding the following request:

- "Please answer the <QUESTION> based on the given <CONTEXT> *in a short and precise manner*".
- "Please answer the <QUESTION> based on the given <CONTEXT> *to include more information*".
- "Please answer the <QUESTION> based on the given <CONTEXT> *and recommend the students to ask more about maintenance*".

Using the weak constraints learned, every prompt could be tailored for the individual student or group of students interacting with the chatbot. This approach also enables to extract which topics, historically, lead to the best results (e.g., grades in the report). This means that, for example, if students ask more questions about logistics, they will get higher grades in the audit report. So, ChatGMP could also use this information to provide feedback to students on some topics they are missing or did not gather enough information about.

Although this study only provides a proof of concept and the ILP approach was not yet integrated into ChatGMP, it aims to give an example of how the prompt of an LLM could be improved through interpretable and reliable insights, incorporating use preferences and tailoring the prompt to the individual user.

## CONCLUSION

AI chatbots are increasingly being used in various contexts, including in education. It is necessary to ensure ethical applications of these models in order to safeguard students, as well as provide the correct and relevant information. Additionally, every student is different, and therefore the responses provided by an LLM should be tailored accordingly, to enhance the learning experience and leverage this individuality. This study provides a proof of concept on how ILASP can be used to learn rules and weak constraints in an audit exercise scenario. This results in the ability to enrich the prompt given to the LLM by including feedback, such as missing questions and lack of understanding, and user preferences. This enables the prompt to be tailored according to the individual user interaction, personalizing the responses and providing instant feedback to students.

## FUTURE PERSPECTIVES

In the near future the second (repetitive questions) and third (user preferences) use case will be combined and further developed to enrich the prompt of ChatGMP. This will ensure that the LLM will receive further information on how to answer the questions. Moreover, by learning the user preferences, the length, complexity and level of details contained in the generated answer can be calibrated based on individual preferences. Once the investigated cases will be integrated into the pipeline of ChatGMP, the role of the chatbot will therefore be to understand how the interaction is evolving, so that it can adapt its answers to improve the learning and aid students further. This is a dynamic approach, since the interaction will be observed in real time rather than a posteriori.

## DIGITAL SUPPLEMENTARY MATERIAL

The ILASP code used is open-source and can be found on GitHub at github.com/FiammettaC/ILP-user-preferences. ChatGMP is published and its code and data are available at github.com/FiammettaC/ChatGMP.

## ABSTRACT

Process control can be one of the most exciting and engaging chemical engineering undergraduate courses! This paper describes our experience transforming *Chemical Process Control* into *Data Analytics, Optimization, and Control* at the University of Notre Dame (second semester required course in the junior year). Our modern course is built around six hands-on experiments in which students practice data-centric modeling and analysis using the Arduino-based Temperature Control Lab (TCLab) hardware. We argue that state-space dynamic modeling and optimization are more critical for educating modern chemical engineers than topics such as frequency domain analysis and controller synthesis emphasized in many classical undergraduate control courses. All the course material is available online at https://ndcbe.github.io/controls.

**Keywords**: Process Control, Education, Dynamic Modelling, System Identification, Model Predictive Control, Pyomo, Process Monitoring, Process Operations, Industry 4.0

## INTRODUCTION

This paper describes several innovations in the undergraduate chemical engineering required process controls course at the University of Notre Dame, including:

- Hands-on experiential learning,
- State-space modeling,
- Advanced data analytics,
- Optimization for decision-making, and
- Model predictive control (MPC) and state estimation.

Through this perspective, we frame key concepts from process control – modeling, feedback, and optimization – through the lens of digital twins, which a recent U.S. National Academies report [1] defines as follows (emphasis ours):

*"A **digital twin** is a set of **virtual information constructs** that mimics the structure, context, and behavior of a **natural**, **engineered**, or **social system** (or **system-of-systems**), is **dynamically updated** with data from its physical twin, has a **predictive capability**, and **informs decisions that realize value**. The **bidirectional interaction** between the virtual and the physical is central to the digital twin."*

**Figure 1** shows the overarching themes for the course. The interplay between the physical and information realms in feedback control closely echoes key themes in the digital twin paradigm.

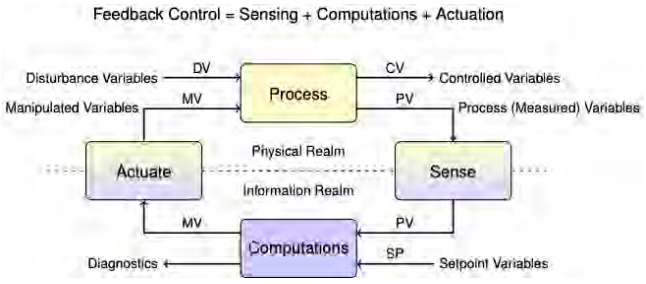

**Figure 1.** Feedback control, realized through integrating the physical and information realms, is the central organizing concept in the course.

### Temperature Control Lab

The course is organized around the Temperature Control Lab (TCLab) [2-5], an inexpensive Arduino device (shown in **Figure 2**) that enables experiential learning. Each student purchases a TCLab device instead of a textbook, as all course material is available online at

https://ndcbe.github.io/controls. Using the TCLab, students:

- Perform step and sine wave tests;
- Identify state-space models via nonlinear regression (with uncertainty quantification);
- Use simulation to tune various classical control algorithms, e.g., on/off control, PI(D) control;
- Implement open-loop and closed-loop model predictive control;
- Learn about state estimation from an optimization perspective; and
- Compare the above-described control algorithms for following the temperature profile for tempering dark chocolate using the TCLab as the physical system

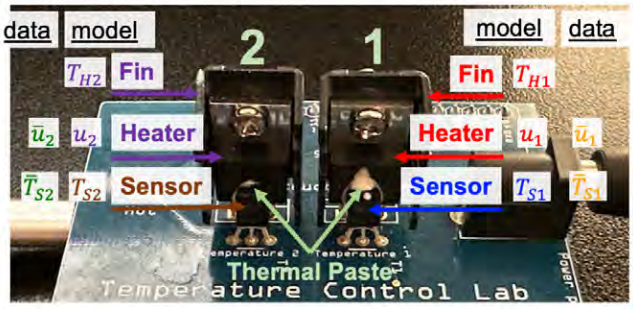

**Figure 2.** Photo of the TCLab hardware with two channels, each consisting of a heater, fin, and sensor. There is visible manufacturing variability in the thermal paste for each channel (and device). As such, each student has a hardware system that exhibits slightly different dynamics.

## Broader Curriculum Context

At Notre Dame, chemical engineering undergraduates enroll in process controls (3 credits) in the second semester of their junior year. As prerequisites, students complete a four-semester calculus sequence, a dedicated linear algebra course, and a department-taught required course on numerical methods and applied statistics. Students concurrently take *Transport II (Heat and Mass)* with process controls. Students enroll in *Chemical Reaction Engineering* in their first semester senior year and capstone *Chemical Process Design* in their final semester. Currently, our students learn MATLAB and Python during their first year through a college-wide required course. Python programming is further taught in the sophomore-required course *Numerical and Statistical Analysis*.

## State-Space Modeling and Data Analytics

Most process control courses focus on frequency domain analysis [6]. While the frequency domain perspective provides beautiful insights into certain aspects of controls (e.g., time delays and responses to periodic inputs), it requires significant time to (re)teach Laplace transformations. Moreover, students often struggle with the abstract nature of frequency domain analysis and have difficulty connecting these concepts with modeling in other core chemical engineering courses.

Compared to this classical treatment, we emphasize mathematical modeling, numerical methods, and applied statistics. The course emphasizes building state-space dynamic models from experimental data, as described below, which naturally complements the (partial) differential (algebraic) equation models taught in transport, kinetics, and thermodynamics. We (anecdotally) find that students conceptually understand state-space modeling, as it is grounded in core chemical engineering concepts, such as mass and energy balances. Moreover, we use advanced data analytics techniques such as nonlinear regression to train these physics-based state-space models from data and characterize the prediction uncertainty.

## Learning Objectives and Organization

The semester learning goals are:

1. Develop mathematical models for dynamical systems from data and first principles using modern statistical methods (in Python);
2. Predict dynamical system performance using numerical methods (in Python);
3. Analyze, implement, tune, and debug feedback controllers using the hands-on laboratory (in Python);
4. Formulate and solve optimization problems for decision-making (in Python); and
5. Demonstrate mastery of at least two of the above skills in an open-ended group project.

The course content and assessments are organized into three parts, as described in the following sections. Students individually complete two homework assignments and six hands-on laboratory assignments, each with significant data analysis and interpretation components. Students take one in-class exam during the semester to assess individual mastery. In place of a final exam, students complete an open-ended group project.

# PART 1: DATA-CENTRIC MODELING OF DYNAMICAL SYSTEMS (4 WEEKS)

Our assessments emphasize data analysis, computer-aided problem-solving, and open-ended discussion questions to connect theoretical concepts from lectures (75 minutes, twice each week) with hands-on activities using the TCLab. Students attend a dedicated 50-

minute laboratory session in a computer classroom once a week to start the new laboratory assignments with easy access to the teaching team when questions arise. Lectures in this part of the course emphasize simulation to understand the performance of (non)linear systems of ordinary differential equations (ODEs).

## Homework 1

Homework 1 reviews key concepts from this later course, especially mathematical modeling, numerical solutions to initial value problems, nonlinear regression, uncertainty quantification (e.g., covariance and correlation matrices), uncertainty propagation, and numerical solutions to systems of nonlinear equations. See our previous work on innovations in modernizing this pre-requisite course. [7-8] Course material is available at https://ndcbe.github.io/data-and-computing.

## Lab 1: Step Test

In the Lab 1 assignment, students perform a step test (**Figure 3**) using their TCLab hardware. Students then practice three methods – graphical analysis, simulation trial-and-error, and nonlinear regression – to build a first-order dynamic model for a single channel of their TCLab hardware:

$$C_p \frac{\mathrm{d}T_1}{\mathrm{dt}} = U_a(T_{amb} - T_1) + \alpha P_1 u_1 \quad (1)$$

where $T_1$ is the average temperature of heater/sensor one, $T_{amb}$ is the ambient temperature, $C_p$ is the heat capacity, $U_a$ is the heat transfer coefficient between the sensor/heat body and the environment, $\alpha$ is a system calibration constant, $P_1$ is the maximum power setting for heater one, and $u_1$ is the percentage of available power for heater one. We reformulate this as a first-order linear model without a time delay using the deviation variable $T'_1 = T_1 - T_{amb}$:

$$\frac{C_p}{U_a}\frac{\mathrm{d}T'_1}{\mathrm{dt}} = -T'_1 + \frac{\alpha P_1}{U_a}u_1 \quad (2)$$

Here $\tau = C_p\, U_a^{-1}$ is the time constant and $K = \alpha P_1 U_a^{-1}$ is the gain. Through discussion questions, students reflect on the pros and cons of each model-building approach and brainstorm ways to handle noisy data.

## Lab 2: Model Identification

In the Lab 2 assignment, students perform a sine wave test with their TCLab hardware. Using their step test (Lab 1) and sine test (Lab 2) data, students build a second-order dynamic model:

$$C_p^H \frac{\mathrm{d}T_{H,1}}{\mathrm{dt}} = U_a\left(T_{amb} - T_{H,1}\right) + U_b\left(T_{S,1} - T_{H,1}\right) + P_1 u_1 \quad (3)$$

$$C_p^S \frac{\mathrm{d}T_{S,1}}{\mathrm{dt}} = U_b\left(T_{H,1} - T_{S,1}\right) \quad (4)$$

where the superscripts (and subscripts) $H$ and $S$ denote the heater and sensor, respectively, and $U_b$ is the heat transfer coefficient between the heater and sensor.

Throughout the Lab 2 assignment, students explore the pros and cons of step tests (**Figure 3**) and sine tests (**Figure 4**) and the two model choices (first- and second-order dynamic models). Specifically, students find that the single-state model is reasonable for the step test data, whereas the two-state model is superior for the sine test data. The two-state model incorporates natural delays in the system due to thermal inertia by considering two different temperatures (sensor and heater/fin). The sine test, which is inherently more dynamic, emphasizes the importance of (approximating) delays. Moreover, the students concurrently take *Heat and Mass Transfer*, which empowers them to connect our state-space modeling course with the broader chemical engineering curriculum and appreciate the physical differences between these two models. On a more applied note, Lab 2 shows the importance of multi-start initialization for nonlinear regression and how simultaneously regressing data from two types of experiments (sine and step tests) results in a model with lower parameter and prediction uncertainty.

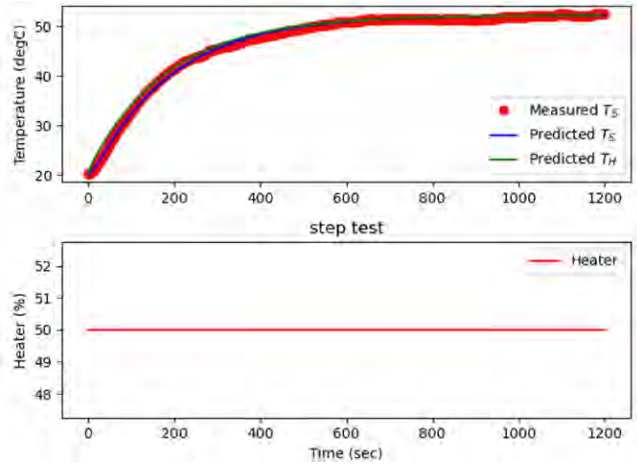

**Figure 3.** Parameter estimation results for the step test in Lab 1.

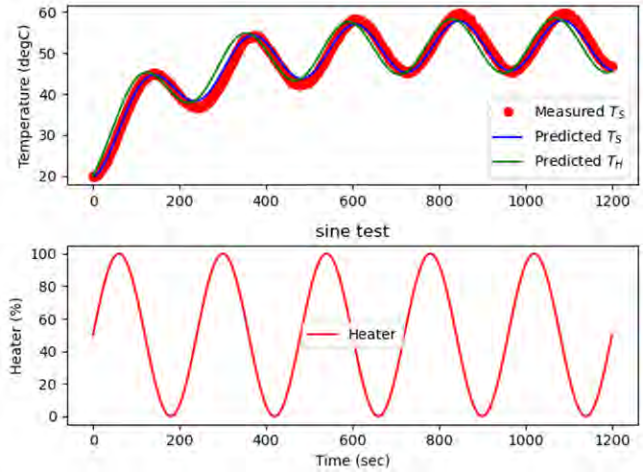

**Figure 4.** Parameter estimation results for the sine test in Lab 2.

## PART 2: FEEDBACK CONTROL (4 WEEKS)

As a motivating example throughout the semester, students compare different control strategies to follow a piecewise linear temperature profile that mimics the process of tempering dark chocolate. This example is well-suited to the temperature range of the TCLab (from ambient to approximately 65 °C). Moreover, students can easily relate to this example and appreciate how other forms of temperature control, e.g., polymerase chain reaction (PCR) or (bio)manufacturing, are relevant to their career interests.

### Lab 3: Relay (On/Off) Control

In Lab 3, students implement a simple relay (on/off) controller with a deadband (**Figure 5**). As a pre-lab exercise, students use their mathematical model from Lab 2 to tune the deadband parameter via simulation. The lab assignment focuses on implementing the controller, quantifying the controller performance, and comparing the performance to the simulation. As a final exercise in Lab 3, students use two relay controllers. One controller tracks the chocolate tempering temperature profile in channel 1. In contrast, the other controller tracks a constant temperature setpoint (30 °C) in channel 2. Through discussion questions, students contemplate potential challenges with independently controlling both channels, which interact due to their proximity.

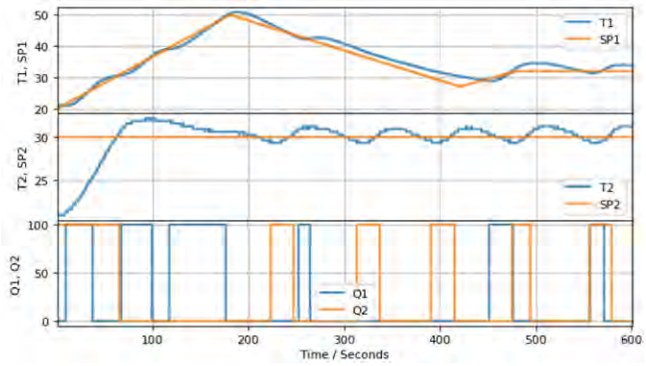

**Figure 5.** TCLab hardware results using relay (on/off) control in Lab 3. Top/Middle: channel 1/2 temperature data and setpoints. Bottom: controller actions.

### Lab 4: PI Control

In Lab 4, students explore two proportional-integral (PI) control implementations: a "textbook" position-form PI controller and a more practical velocity-form PI controller with anti-windup reset and bumpless transfer. As a pre-lab exercise, students use their mathematical model from Lab 2 to tune the gains in both PI controllers by analyzing the eigenvalues of the closed-loop dynamical system. Students then test both controllers and quantify their performance. Thus, this lab introduces students to arguably the most ubiquitous low-level controller in (bio)molecular/chemical processes, emphasizing the power of model-based controller design and analysis. Moreover, in the complementary lectures, students learn how to use linearization to analyze the local dynamics of nonlinear systems.

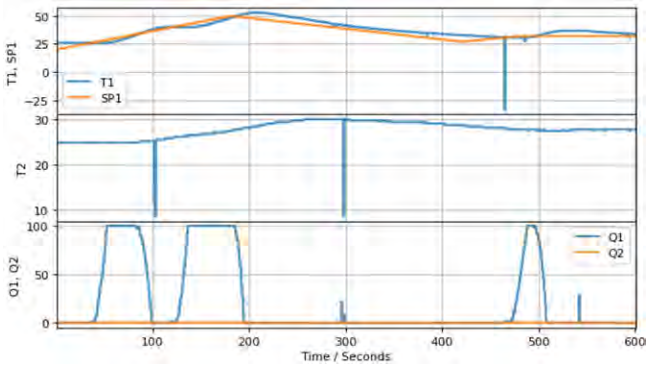

**Figure 6**. TCLab hardware results using PI control in Lab 4. The TCLabs occasionally drop data, which provides a good "real world" lesson: data are messy, and hardware is imperfect!

## PART 3: OPTIMIZATION (4 WEEKS)

Few of our undergraduate alumni are practicing control engineers, but many (anecdotally) regularly use data analytics for decision-making in their professional careers. Thus, we emphasize optimization as a framework for data-driven decision-making. In some of our favorite lectures, we introduce students to linear programming using production planning examples, e.g., blending in a refinery. Students are amazed to see how optimization easily applies to business-relevant analyses, such as pricing the marginal value of overtime labor or additional supplies or determining the best way to change blending operations to accommodate a new product (e.g., mid-grade fuel) or environmental regulations.

### Homework 2: Introduction to Pyomo

In Homework 2, students practice optimization modeling and problem-solving using Pyomo [9], an open-source algebraic modeling environment. Specifically, we focus on two examples – product blending and portfolio management under uncertainty – to appeal to diverse career interests. In the portfolio optimization example, students analyze time-series closing day prices for five funds to compute the covariance of their daily return rate. Students then use quadratic programming to calculate the Pareto optimal trade-off between expected return and volatility (risk). These examples help students appreciate the importance of modeling, data analytics, and optimization for business decisions.

### Lab 5: Open-Loop Optimal Control

Equipped with an operational understanding of Pyomo, in Lab 5, students compute the open-loop, optimal time-varying heating profile $u(t)$ to track the dark chocolate tempering temperature set point. Specifically, students use Pyomo.DAE [10] to formulate and solve the dynamic optimization problem using their model from Lab 2:

$$\min_{u} \int_{t_0}^{t_f} \left( \left\| T_S^{SP}(t) - T_S(t) \right\|^2 + w \left\| T_S^{SP}(t) - T_H(t) \right\|^2 \right) dt \quad (5)$$

$$\text{s.t. } C_p^H \frac{\mathrm{d}T_H}{\mathrm{dt}} = U_a(T_{amb} - T_H) + U_b(T_S - T_H) + Pu(t) + d(t) \quad (6)$$

$$C_p^S \frac{\mathrm{d}T_S}{\mathrm{dt}} = U_b(T_H - T_S) \quad (7)$$

$$T_H(t_0) = T_{amb} \quad (8)$$

$$T_S(t_0) = T_{amb} \quad (9)$$

$$\frac{du}{dt} \leq \dot{u}_{max} \quad (10)$$

$$\frac{du}{dt} \geq \dot{u}_{min} \quad (11)$$

where the superscript $SP$ denotes the setpoint, $d(t)$ is the disturbance (often set to zero), and $\dot{u}_{max}$ and $\dot{u}_{min}$ are the maximum and minimum rate of change of the control action, respectively.

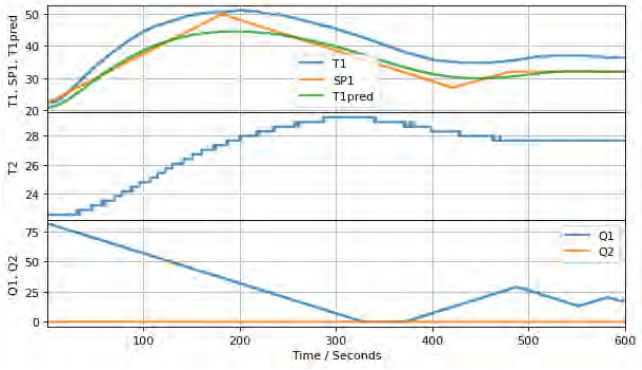

**Figure 7**. TCLab hardware results using open-loop optimal control in Lab 5.

In Lab 5, students execute the open-loop optimal solution with their TCLab hardware and compare their results to the model prediction (**Figure 7**). While much of the code is provided, students add a ramping constraint on the control input $u(t)$ and analyze the impact of this limitation (Equations 10-11). Through discussion questions, students explain why their open-loop optimal solutions make sense from a physical perspective.

Through examples in lectures, students learn how to use Pyomo.DAE to numerically solve boundary value problems with (partial) (differential) algebraic equations. This provides students with modeling tools for other classes, such as *Heat and Mass Transfer*, *Chemical Reaction Engineering*, and *Chemical Process Design*, in addition to our semester final project.

## Lab 6: Model Predictive Control

In Lab 5, students learn that while open-loop optimization can provide a physically sensible plan, without feedback, model mismatch can cause subpar hardware performance compared to other control strategies (e.g., Lab 3, Lab 4). This motivates Lab 6, which focuses on model predictive control (MPC). We describe this to students as essentially putting the optimization formulation from Lab 5 inside of a for loop and repeating the optimization as new measurements become available.

But there is a catch! The preferred TCLab model has one measured state, $T_{S,1}(t)$, and one unmeasured state, $T_{H,1}(t)$. To initialize the optimal planning problem, we need to estimate the unmeasured state. Thus, the TCLab example motivates state estimation, which we pose as an optimization problem:

$$\min_{d(t)} \int_{t_0}^{t_f} (\|\bar{T}_s(t) - T_S(t)\|^2 + w\|d(t)\|^2) dt \quad (12)$$

$$\text{s.t. } C_p^H \frac{\mathrm{d}T_H}{\mathrm{dt}} = U_a(T_{amb} - T_H) + U_b(T_S - T_H) + Pu(t) + d(t) \quad (13)$$

$$C_p^S \frac{\mathrm{d}T_S}{\mathrm{dt}} = U_b(T_H - T_S) \quad (14)$$

$$T_H(t_0) = T_{amb} \quad (15)$$

$$T_S(t_0) = T_{amb} \quad (16)$$

Specifically, we infer the unmeasured disturbance and heater temperature $T_{H,1}(t)$ by minimizing the deviation between the measured sensor temperature $\bar{T}_s$ and the model prediction $T_S$.

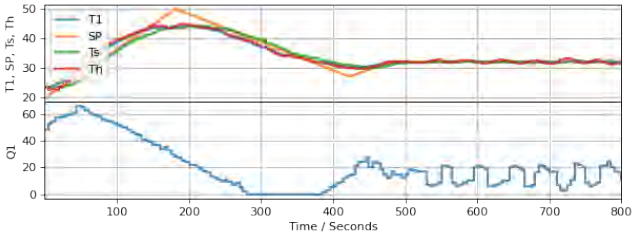

**Figure 8**. TCLab hardware results using MPC in Lab 6.

Lab 6 builds up these concepts by individually solving the optimal planning and state estimation problems separately. Finally, we integrate these to form a complete MPC demonstration (**Figure 8**). The data integration between the state estimation and control optimization problems is nuanced and benefits from advanced

programming concepts, e.g., Object Oriented Programming. As such, the students are provided with most of the code for Lab 6.

Thus, the Lab 6 assignment focuses on running the MPC scheme with their TCLab hardware and critically analyzing the results. Specifically, students are asked to quantitatively compare the performance of the four control strategies studied throughout the semester (Labs 3, 4, 5, and 6) on the same dark chocolate tempering problem. Students then discuss the pros and cons of each approach. Finally, the students describe a real-world application of receding horizon optimal control, state estimation, or both. Many of our students use this to share their creativity or interests. Popular answers include self-driving cars, supply chain management, and financial trading.

## SEMESTER PROJECT (3 WEEKS)

In place of a final exam, teams of three or four students work on a final project incorporating at least two of the class learning objectives. Many groups are very creative, with past project topics including analysis of university sustainability projects (e.g., solar or geothermal energy), glucose modeling for diabetes management, and trajectory planning for a submarine. We use the final three class periods for short presentations. During the two preceding weeks, we hold 6- to 7-minute project consultation meetings with each team during lectures. This has the bonus of introducing students to open-ended projects, meeting preparation, time management, and note-taking skills, which are especially helpful for their capstone projects the following year.

## CONCLUSIONS AND OUTLOOK

In summary, we have reorganized Process Control around six hands-on laboratory experiments, transforming the course from classical frequency domain analysis to emphasize dynamic state-space modeling, data analytics, and optimization for decision-making. The TCLab experiments enable us to distill the course into two key concepts:

1. The importance of feedback (**Figure 1**), both in classical control applications (e.g., temperature regulation) as well as many systems from daily life (e.g., cruise control).
2. The utility of predictive mathematical models for engineering [12].

We argue this modern take on process controls is better suited for today's chemical engineers, especially as the profession diversifies into new application areas and technologies. Moreover, these two key concepts capture the ethos of digital twins, which we believe will play a significant role in the future of engineering. Furthermore, we encourage students who find specific topics especially exciting, such as dynamic modeling, optimization, or statistical analysis, to pursue a technical elective in this area in their final year at Notre Dame.

We conclude by describing several opportunities for future refinement and customization. In parallel to exploring these refinements, we are exploring ways to measure student outcomes to assess the efficacy of the new course organization.

### What about time delays?

One of the great strengths of frequency domain analysis is the ability to model and design control systems to mitigate time delays. Moreover, time delays are especially important in traditional chemical engineering applications (e.g., fluid flowing in a pipe) and newer frontiers (e.g., systems biology). One option is to augment the state-space model with additional states to approximate the time delay. In essence, the two-state TCLab model does this by considering the lag in heat transfer from the heater/fin to the sensor. Another option is to introduce delay differential equations.

### Lost Insights from the Frequency Domain?

While we argue that the state-space perspective is more intuitive for most chemical engineering students, we also acknowledge that frequency domain analysis provides an important modeling perspective. The sine test experiment (Lab 2) starts to introduce these ideas. One opportunity is to expand this course section further to introduce Fourier analysis as a tool for analyzing periodic data. We hypothesize this data analysis perspective would be more engaging for students.

### Advanced Data Science Topics

The TCLab experiments can also be extended to introduce advanced data science topics. For example, time series analysis techniques could be introduced to go beyond standard independent and identically distributed Gaussian error assumptions for systems identification and instead consider auto-correlated measurement errors. This semester, we introduced maximum likelihood estimation to provide students with a more foundational understanding of nonlinear regression and introduce a core concept in many machine learning workflows. Similarly, the course content can be extended to consider more sophisticated uncertainty quantification methods, e.g., Bayesian inference or nonlinear confidence regions. Moreover, we use the TCLab example in our hands-on workshops to introduce Pyomo.DoE, an open-source tool for model-based design of experiments [11]. We have also begun exploring the TCLab as a motivating system for hybrid models to quantify model misspecification [13].

### Advanced Process Control Topics

In a Lab 3 extra credit exercise, students use their Lab 1 to 3 data to build and estimate a four-state model

that captures the interacting dynamics of the two channels in the TCLab (see **Figure 2**). This more sophisticated model motivates advanced topics such as estimability analysis and model-based design of experiments. We encourage students to presume this or other advanced process control topics as final projects. For example, students are encouraged to develop two PI controllers for one channel to follow the dark chocolate tempering profile while the other maintains a constant, elevated temperature (similar to Lab 2 with relay control). This reenforces ideas of interacting control systems. Another project idea includes model-free (e.g., Ziegler-Nichols) PID controller tuning. Some ambitious groups may even try to extend the state estimation formulation in Lab 6 for fault detection, such as determining when a hair dryer starts to blow on the TCLab.

## ACKNOWLEDGEMENTS

Many course design ideas this paper presents originated with Prof. Jeffery Kantor. Jeff spent over five years conceptualizing, testing, and refining this course and creating much of the content in our online textbook. Jeff passed away in 2023. This paper is dedicated to him.

## ABSTRACT

The integration of mixed reality (MR) and virtual reality (VR) into Chemical, Biochemical, and Biomolecular Engineering (CBB) education presents an opportunity to address one of today's most pressing pedagogical challenges: sustaining student attention and engagement. Traditional "magistral" approaches often tend to limit the adoption of interactive methodologies. By contrast, MR/VR technologies can heighten immersion and practical intuition, capturing learner focus more effectively than conventional lectures. Yet, if deployed as superficial, isolated demonstrations, these tools may fail to support deep conceptual understanding and risk supplanting core course content. This work proposes a flipped-classroom model that deliberately embeds MR/VR exercises throughout the typical CBB curriculum. The methodology emphasizes a human-in-the-loop concept, whereby the educator strategically orchestrates virtual simulations and real-world problem-solving, reinforcing theoretical concepts through hands-on digital experiences. We address challenges related to scaling this approach, highlighting the importance of aligning content across multiple years and conducting cost-benefit assessments. Preliminary efforts indicate high student acceptance and potential for enhanced learning outcomes. By blending MR/VR with proven instructional strategies, CBB educators can better equip graduates with the skills and engagement needed for success in an evolving industrial landscape.

**Keywords**: Education, Mixed Reality, Virtual Reality, Flipped Classroom, Human-in-the-loop

## 1. BACKGROUND AND CONTEXT

Teaching Chemical, Biochemical and Biomolecular Engineering (CBB), as well as other engineering degrees has a "quantum-like behaviour" as a system. At the same time, there are two different super positioned teaching states: a) the teaching resources, both in terms of hardware and software are extremely different from those available in 1800s and not even a few decades ago b) the teaching methodology, in which magistral lessons still represents a large share of the teaching methods in our time. As it can be understood, current teaching resembles a superposition state because "the old & the new" live simultaneously, this is, the classical magistral methodology from centuries ago, and the modern resources (internet resources, LLMs, TV displays, etc.).

As reimagined in figure 1, it is clear that "much has changed or nothing at all" as this classical magistral teaching means the "minimum energy state", at which all systems tend to be. The integration of mixed reality (MR) and virtual reality (VR) technologies into CBB engineering education offers potentially promising avenues for enhancing student engagement, intuition and comprehension of practical concepts. Very recently, it came to our knowledge the next idea: "Attention is the new oil" [1]. We cannot agree more with this idea. The current generation of permanent staff at European universities were probably motivated by the fact of better professional prospects. However, even if this idea remains at any percentage of the today's enrolled students, the lack of attention is more evident than ever. The use of tablets and laptops do allow the student to connect to Internet resources, download documents, use CBB related software

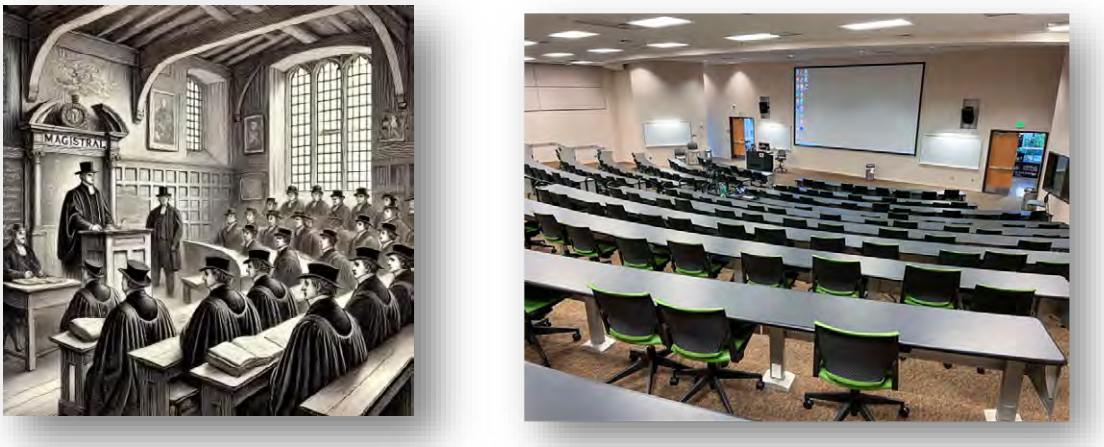

**Figure 1:** On the left, an AI reimagination of magistral course back in the early days of the university, which clearly resembles the picture on the right, which belongs to modern universities in the XXI century.

including spreadsheets, create presentations, chat with AI-based LLMs, etc. But this use of computers is indeed such a temptation to the less motivated students. It is nearly impossible to grab the attention more than the time typically predefined in conferences such as TED Talks, which are basically in the range of 18 min, being favored those of 5 minutes [2]. This means that the long presentations from magistral lessons must adapt and evolve to short-high impact ones.

MR and VR have emerged in universities as hardware-based teaching alternatives to improve the way undergraduate students reach competences in several science domains ranging from medicine to engineering. Literature is full of references about the prospects of the benefits of using MR and VR in university teaching. However, there is an existing risk that MR and VR can supplant the real content of CBB engineering courses. Their use by the teaching staff is expected to regain the attention momentum and serve as augmentative tool that enhance, rather than replace, current existing teaching methodologies. That is, they need to be adapted with a human-in-the-loop concept and social learning theory principles.

Current implementations of MR and VR are often isolated within single topic and lack interoperability with the broader curriculum, resulting in partial educational experiences with ill-defined learning designs that fail to exploit the interconnected nature of CBB engineering disciplines. Their use is essentially limited to individual sessions within courses in which it is an activity with probably low-added value. This siloed approach impedes the development of a cohesive understanding of wide topics ranging from chemical reactor design to heat transfer and limits the potential for integrated learning.

The effective incorporation of MR/VR necessitates the seamless integration of existing teaching materials, including presentations, lecture videos, and textual resources with current modern methodologies. By embedding and blending MR/VR experiences within the current variety of existing methodologies, chemical engineering educators can create enriched learning environments that cater to diverse cognitive preferences without discarding proven instructional methodologies.

Table 1 shows an overview of different current modern methodologies plenty used as well as their pros and cons in relation with the attention. In general, it is possible to combine or blend different methodologies with MR/VR. However, each integrated approach has their own advantages and problems. In this work, we do propose the unique features that can be derived from the combination of MR/VR with the flipped classroom approach. Next is discussed a formal definition of the mentioned integration.

The advent of bringing digital tools such MR/VR into the university classroom to provide a more accessible education to a growing interest in process industries has led to a few fundamental questions around CBB engineering education. However, as previously discussed there has been research indicating that MR/VR tools alone are not completely fulfilling students' learning needs and learning outcomes across bloom taxonomy [3]. One major challenge is to regain students' attention to pursue better learning outcomes by using the MR/VR learning environment and primarily using these tools to create a real-world intuition.

**Figure 2**: A selection of picture of individual Chem Eng students in the process of desassembling a heat exchanger (HX) unit, created to fit the front of the classroom. The size of the HX unit was sized in a previous exercise.

To address this situation, we do propose the integration of the flipped-classroom with MR/VR to devise a learning design that combines MR/VR technologies into flipped classroom models within CBB Engineering education. This framework emphasizes pre-class exposure to traditional content, enabling students to acquire foundational knowledge through established resources. The flipped classroom approach proposes quite a series of advantages that fits very well the integration of MR/VR tools in CBB Engineering. First, the available content can be approached by the students at any time. This gives the flexibility to learn on the way or at more convenient times during the day. Being recorded, student can fit their own pace, which is typically avoided during magistral lessons. Indeed, this is connected to higher grades of self-learning and autonomous learning. Once the students have acquired the knowledge, they are ready to test, experience and feel the application of these concepts on their own under a AR/MR experience. Second, the use of MR/VR in the classroom requires intrinsically the interaction between the students and the teaching staff. The students are clearly guided during the MR/VR activity with a process that demands interaction with the students and the mixed or virtual environments. Third, under proper developments, students can be engaged in a collaborative environment in which they may need to help each other to solve the challenges of the MR/VR activity in which they are involve, in a similar way in which they do in real CBB teaching labs.

Therefore, the set of pre, post and in-class sessions leverage MR/VR to provide immersive, interactive experiences that reinforce, contextualize and deepen in the practical application of the learned theoretical concepts.

The prospect of extending the approach throughout the degree or master facilitates a consolidated practice, which in turn favors the current expectation of students. For instance, students might engage in virtual simulations of chemical reactors to explore reaction kinetics, thermodynamics, and mass transfer phenomena in a controlled and manipulable environment. This holistic educational strategy may align better with industry expectations, preparing students to navigate the multifaceted demands of the professional market and developing the expected digital competences highly demanded by industrial partners. Indeed, in many CBB Engineering degree programs, the foundational sequence begins with Material and Energy Balances, followed by core courses such as Thermodynamics, Fluid Mechanics, Heat Transfer, and Reaction Engineering. More advanced or specialized topics like Biochemical Processes, Process Control, and Plant Design typically appear later in the curriculum. **We do propose in this work that an integrated MR/VR and a flipped-classroom strategy can be used to strengthen student engagement and conceptual understanding** through a holistic hands-on experience integrated along the whole curriculum.

## 2. HOW TO SOLVE CURRENT LIMITATIONS: METHODOLOGY

In our view, a significant challenge lies in bridging the gap between an efficient integration of application of MR/VR technologies with well-established teaching practices. Often, these MR/VR technologies are introduced as engaging but superficial, low-added value demonstrations, lacking alignment with specific learning outcomes and unbalanced cost-benefit implications for educational

institutions. To transcend this limitation, MR/VR must be deliberately deployed to facilitate deep conceptual understanding and practical skill development, rather than serving as mere visual spectacles. Figure 4 shows an example of a heat exchanger unit modelled in Unity. The role of the educator plays a more-than-ever important role, a human-in-the-loop, as they can bridge the gap in a way that learning outcomes can be effectively reached.

The proposed methodology to solve current limitations uses the principles of flipped classroom as the basis to integrate MR/VR as explicit exercises to mimic real-world situations. However, connecting the MR/VR exercises to the curriculum must be done in such way that iteratively, learn, implement and practice principles are adhered. So, our view in this work is that MR/VR tools are valuable tools in a human-in-the-loop context.

First, it is quite difficult to tackle this integration without a proper team. Considering the starting point based on the experience of the teaching team must be properly addressed. Second, the team must discuss the scale-up process. We have identified that a drastic transition from full-magistral lessons to flipped classroom may emerge into a plethora of problems. Mainly, because the classical contents should be prepared to be ready to be adopted to flipped classrooms and MR/VR activities in which the contents prepared in advanced are considered in the blending process rather than be stacked. In this sense, it means that the flipped content cannot be understood without the MR/VR content and vice versa. Otherwise, MR/VR integration would be simply an incremental part of the contents. Third, it is important that contents are used as uniform as possible along individual courses and years. This is quite relevant because of potential crossed unmatched signals. Using the integrated flipped classroom and MR/VR during the first year and then radically extirpated from the remaining years can surely provide a negative experience in the students, as they may feel more attracted by these methodologies, which the main element for its implementation.

As a result, the transition towards the integration of MR/VR into flipped classroom means that actions must be taken at different tiers, which are discussed next:

- Tier 1: integration at program level: we do believe that the effectiveness of this approach is rooted in the possibility to extend it proportionally alongside a full program, for example the 4 years of a CBB degree. This way, the students can understand that using MR/VR is not a mere set of "fireworks" but an effective tool to integrate CBB concepts in a more efficient way.
- Tier 2: integration at module level: using a heat exchanger unit in a typical 101 course of Chemical Engineering using this approach and later on (1 yr. later) using "just slides" to describe the behaviour of the unit within a 100% classical magistral lessons methodology can lead to unwanted situations. Students may feel this point really discouraging, loosing the human-in-the-loop factor.
- Tier 3: integration at course level: similarly, to the tier 2 integration, it can be also discouraging the fact that a heat exchange course faces two different methodologies. This situation may arise when the coordination level of the course is not adequate.

All said, we do not propose that a full program (bachelor degree, master degree or PhD program) must transit to a full the integration of MR/VR in flipped classroom in a single year. What we are really proposing here is that partially fulfilling cherry-picked courses with MR/VR content without a well-thought strategy may entail negative effects. This is especially true as long-term strategy. As firstly discussed, the key element here is to regain the student's attention by more appealing ways of active learning. The main negative effect is perceiving the new tools as another distraction instead of an attraction. Consequently, we consider that the main risk of this approach is the lack of momentum to implement the aforementioned integration. Everything said, there must be a reasonable period of time to transit to the steady state of the integration.

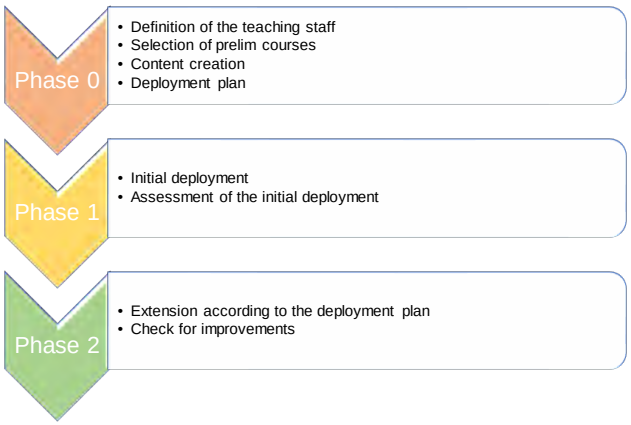

**Figure 3**: A deployment plan of the proposed methodology

We do propose that a reasonable strategy as depicted in figure 3, divided into 3 phases. During phase 0, it is critical to define the teaching staff involved in the plan, being convenient that they can have some degree of responsibility regarding the contents of the courses preliminary selected. Also, it is important the contents can be created with certain anticipation. As a results of this, the team can propose a deployment plant, which should be the deliverable from phase 0. In a later stage corresponding to phase 1, according to the deployment

**Figure 4***:* A simplified example of a heat exchanger in Unity and the final experience in XR.

plan, the teaching staff must initiate the integration of MR/VR with the flipped classroom in the selected courses. It is critical here that the intensity of the learning outcomes can be evaluated as a prior move to phase 2. It is far way more important to complete a proper assessment of the phase 1 than move to phase 2. Finally, once the appropriateness of phase 1 has been achieved, it is possible to move to phase 2, in which a relevant fraction of the courses integrates this approach. The penetration of the methodology into a program must be chosen carefully to promote acceptability among the teaching staff involved in the whole program.

From a methodological point of view, it is also important to provide a skeleton to design in a robust way the integration of MR/VR in the flipped classroom approach according to the deployment plan of phase 0. Next, we discuss the way in which this can be done and the main tips to avoid pitfalls:

- Strong bound between the pre-class material, the in-class material and the post-class material. Students find extremely confusing using different references to the same concepts. This is strongly avoided in magistral lessons as it is usually the same individual the one using all those concepts. However, in our approach, the individual responsible for creating the MR/VR contents must be the teaching staff or at least must be in close contact to the ones creating them. This disconnection may lead to a common pitfall: the MR/VR activity can be about the different elements that belongs to the assembling of a heat exchanger, but the pre-class concept did not mention the very basic elements that form the unit (shell, tubes, headers, etc.). In this sense, this should reinforce the pre-class content rather than being an extension. So, when applied to the aforementioned example, the MR/VR activity must be used to visualize the elements such as the tubes and the shells, which can be difficult using just videos and/or pictures. But the MR/VR activity should not be used to explain what and why the tubes and shell are needed.
- Define and identify clear learning outcomes from every MR/VR activity. While assembling/disassembling a heat exchange unit can be a fun activity for the students (as it would be for any interested individual in CBB), a clear set of learning outcomes must be defined and identified by the teaching staff. This is certainly a relevant issue: learning outcomes clearly identified such as "*understanding the role of shell & tubes in a heat exchanger*" is critical. This means that they can see clearly the dimensions, the numbers of passes, the deflectors, etc. their relative proportions, the challenging related to choosing the shell or tube side, etc. The wrong outcome would be that they found the activity fun because of the possibility of grabbing and throwing the elements of the heat exchanger.
- Evaluation. It is high debatable if the MR/VR activities should deserve a separate piece of evaluation. In our view, to guarantee the coherence of the proposal, it is not advisable to include specific evaluation for the MR/VR activities themselves. The basis for this claim lays on the fact that MR/VR activities are envisaged as an element to improve the intensity of the learning outcomes and the way to reach them. This means that they should be helpful at answering questions such as those practised in the MR/VR activity "is the sizing of this heat exchanger reasonable?". It would be pitfall to try to recreate the MR/VR

activity and assess that one as a separate piece

**Table 1:** A comparison among methodologies with a brief description, pros and cons.

| Methodology | Description | Pros | Cons |
|---|---|---|---|
| Learning-by-Doing | Students learn through direct experience, such as experiments, simulations, or projects, reflecting on their actions and outcomes | The level of attention of high as the students must be focused on the direct experience | The lack of external drivers apart from deadlines may be an issue |
| Problem-based Learning | Students tackle real-world problems in groups, fostering critical thinking, research, and collaboration | The need to work in groups promotes attention | Difficulties for more introvert students |
| Project-based Learning | Students work on extended projects that require applying knowledge to produce a concrete deliverable, often integrating multiple disciplines | The need to work in groups promotes attention | Difficulties for more introvert students, enhanced by a longest contact time due to the project duration |
| Flipped Classroom | Students study theoretical content at home / library (videos, readings) and use classroom time for active problem-solving, discussions, or hands-on activities | Effective discussion time that requests full attention | Low quality or engagement contents disrupt the use of time at home /library |
| Gamification | The use of game-like elements (points, badges, challenges) in learning to boost engagement and motivation | High engagement factor | The game over the content |

Another aspect to the implementation of VR/MR tools is the cost of implementing as opposed to stand alone benefits. An economic assessment of implanting VR/MR tools must be carried out in the context of CBB engineering education [4]. An important issue is the adaption of these without a thoughtful learning design and their integration with other teaching methodologies involving a human teacher may bear substantial economic and adverse learning outcomes.

## 3. FUTURE PROSPECTS AND ON-GOING WORK

The integration of MR/VR technologies within a flipped classroom paradigm can enhance learning outcomes by providing experiential learning opportunities that complement traditional content delivery without any partial withdrawal. The educator's role is even more relevant than ever due to the need of integrating and blending new tools in the CBB engineering course mix with a clear learning design that objectives fulfill learning outcomes. By focusing on the alignment of these technologies with curricular objectives, we can cultivate chemical engineering professionals equipped with both the theoretical acumen and practical skills necessary to excel in a technologically advancing field such as CBB engineering.

On-going efforts suggests preliminary that a proper combination as shown in Figure 2 can be appropriate and the student's acceptance of the tools is high or very high. Furthermore, a use case demonstration is planned at University of Cantabria as a launchpad of this approach. This will enable to evaluate the effectiveness of the approach in conjunction with learning outcomes.

## 4. ACKNOWLEDGEMENTS

Marcos Fallanza and Antonio Dominguez-Ramos acknowledge the financial support of the University of Cantabria for the project PR_35 "Innovación en la formación de ingenieros: Ingeniería inmersiva con herramientas de simulación CFD".

## ABSTRACT

This work gives a detailed description of the models, methods, and equipment used in a bachelor's degree lab course. The connections between simulation results and real-world data are highlighted and tools for making the models useful for process design tasks are portrayed. The models cover the production chain for fuel-grade bioethanol, starting from the fermentation of sugar with yeast. In only one semester (14 weeks with 180 minutes per week) the students achieve to produce high-purity ethanol. Some exemplary results of the process designs and their comparison to the realized intermediate and final products are given together with production cost data.

**Keywords**: Batch Process, Ethanol, Education, Batch Distillation, Biofuels, Data Reconciliation

## INTRODUCTION

The Green Processes Lab module, part of the Green Engineering study program at Berlin University of Applied Science (BHT), trains students to simulate, optimize, and implement an industrially relevant sustainable process within a single semester. The selected process is a fuel-grade bioethanol production, with a minimum purity of 99.8 wt.%, using readily available supermarket feedstocks: sugar and yeast.

In earlier modules of the program, students engage with fundamental unit operations, including vessel reactor (fermentation), batch distillation, batch rectification, filtration, centrifugation, dryer, and adsorber. These operations are extensively covered in theoretical lectures, mathematical modeling, and predefined experiments, ensuring a solid understanding of their behavior. Working in teams, students design their processes in five steps with minimal restrictions, aside from safety regulations and two key constraints: They must use only existing equipment, and each process step is limited to a duration of 180 minutes, including the 30-minute set-up, shutdown and cleaning phase. The groups compete to develop the most cost-effective process maximizing bioethanol yield while minimizing resource consumption—specifically sugar, yeast, and electricity. The time constraint adds complexity, demanding meticulous simulation and process planning.

To tackle this challenge, students utilize the commercial flowsheet simulator CHEMCAD. This software offers fundamental unit operation models and a robust thermodynamic engine for calculating physical properties of pure substances and mixtures. However, the models require parametrization based on the available equipment. Students achieve this through reaction rate regression and data reconciliation, leveraging data from previous experiments and a limited number of newly designed trials.

The parametrized models serve as the foundation for optimizing the economic objective function. Given the stepwise nature of the process, optimizing all process parameters simultaneously is extremely difficult. Instead, teams integrate different optimization strategies refining individual steps while maintaining overall process coherence. This encourages strong intra-group communication, as each member is responsible for a specific process stage. The course can be carried out with four groups, five participants each. Thus, one student is responsible for one process step.

By the end of the semester, each group successfully produced a measurable quantity of bioethanol while tracking the resource consumption. Utility consumption was recorded at each step enabling a precise calculation of specific product costs, facilitating comparisons among

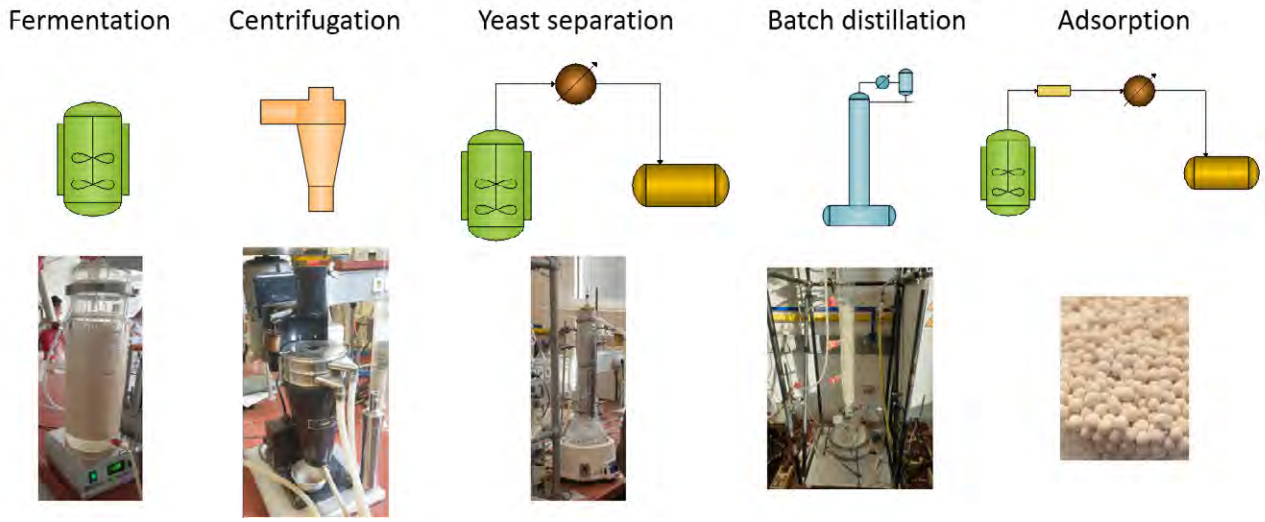

**Figure 1:** Sequence of the process steps with the corresponding CHEMCAD icon and available lab equipment.

groups and against commercially available bioethanol.

## PROCESS EQUIPMENT

Figure 1 illustrates the sequence of process steps alongside the corresponding CHEMCAD icons, which represent the utilized model and the available laboratory equipment. This section provides a summary of the key equipment parameters.

### Vessel reactor with temperature control

The fermentation takes place in a cylindrical glass vessel with a usable volume of six liters. Temperature control is achieved through a double-jacketed system, where water circulates via a thermostat. The water temperature is maintained at 30°C, closely matching fermenter temperature. A magnetic stirrer ensures thorough mixing. The vessel remains sealed, besides a tube that directs the produced gas through a gas meter to the atmosphere.

Liquid samples can be collected from the bottom of the vessel for analysis. Glucose and dry matter are measured using optical measurement methods, while the ethanol content is later determined by gas chromatography. However, an estimate for the current ethanol concentration can be approximated from the gas production rate.

At the end of the fermentation step the reactor contents are harvested and frozen to prevent further glucose conversion. The energy required for freezing and unfreezing is not accounted for in the analysis.

### Tubular centrifuge

The bulk amount of yeast is separated in a tubular centrifuge. The tube has an inlet diameter $d_i$ of 14.5 mm, an inner diameter $d_0$ of 43.5 mm, a length $L$ of 188 mm, and can rotate at speeds up to $n = 25{,}000$ revolutions per minute (RPM). The dry matter content of the feed and the products can be analysed with a high accuracy evaporation scale. At this point the ethanol in the separated centrifugate is replaced by taxed ethanol in compliance with German customs regulations.

### Heated glass bulb with condenser

The intermediate product is purified from yeast and glucose in a single stage distillation conducted in a heated glass bulb with a condenser. Two glass bulbs, each with a volume of three liters and a 500 W heating device are available for the process. To prevent foam from entering the water-cooled condenser, an empty glass column is placed on top of the bulb.

The ethanol content of the distillate is measured by analyzing the refractive index of the liquid. At the end of this step, a sample of the distillate is analyzed in a gas chromatograph to detect and quantify any contamination with methanol or other alcohols.

### Packed batch column

The plant used to increase the ethanol content consists of a four-liter pot, a column with an internal diameter of 50 mm and a height of 1,200 mm, a condenser with integrated reflux control by a magnetic valve, a guard condenser, a product cooler, and three receiver tanks, which can be connected by a magnetic valve. The column was packed with Raschig rings up to a height of 1,000 mm. The pot can be heated with a maximum duty of 1,800 W, although flooding in the condenser occurs earlier, at around 600 W.

Labview™ is used to control the plant and to visualize the measured temperature profiles, the volume rate and the temperature increase of the cooling water, and the added heat duty. The Labview™ screen and a sketch of the column are depicted in Figure 2.

**Figure 2.** Automated batch distillation plant.

## Adsorption plant

The remaining water is adsorbed on the molecular sieve KÖSTROLITH ® 3AK. 120g of this zeolite are allocated in the heated glass column of the adsorption plant.

The ethanol-water mixture is transported by a gear pump to a bulb, where it is evaporated using heat from a thermal oil which is maintained at 180°C by a thermostat. The temperature profile in the column is monitored to detect the breakthrough of water. The vapor from the top of the column is condensed and the liquid product is collected in another bulb. The purity of the product is quantified by a high accuracy density measurement.

The zeolite is regenerated in a drying cabinet, where it is completely regenerated over around six hours at 230°C until no more water is adsorbed on it.

# PROCESS MODELS

Rigorous process models are used to design the process steps and to assess their performance after execution. The models are based on mass and energy balances and on phase equilibrium calculation when applicable.

## Fermentation

The fermenter is modelled as a perfectly mixed reactor. The species carbon dioxide $CO_2$, ethanol $C_2H_5OH$, water $H_2O$, alpha-D-glucose $C_6H_{12}O_6$, and biomass $X$ are considered in the material balances. Only one reaction is taken into account, the growth of biomass with the simultaneous production of ethanol. The mass-based stoichiometry is given in equation (1) using the yield coefficients for ethanol production $Y_{P/S}$ and for biomass production $Y_{X/S}$.

$$C_6H_{12}O_6 \rightarrow Y_{P/S}\, C_2H_5OH + Y_{X/S}\, X + \left(1 - Y_{\frac{P}{S}} - Y_{X/S}\right) CO_2 \qquad (1)$$

The structure of the reaction rate, given in equation (2), is taken from Fogler [1]. The rate uses the mass-based concentrations $c_i$.

$$\dot{r}_1 = \mu_{max} \left(1 - \frac{c_{C_2H_5OH}}{c_{C_2H_5OH}^{tox}}\right)^{0.52} \frac{c_X\, c_{C_6H_{12}O_6}}{K_S + c_{C_6H_{12}O_6}} \qquad (2)$$

The reaction rate is implemented in the vessel reactor model in CHEMCAD.

## Centrifugation

The separation efficiency of the centrifuge is estimated by balancing centrifugal force, lifting force and drag force. This leads to equation (3) for the separation grain diameter $d_T$.

$$d_T = \frac{1}{2\,\pi\, n} \cdot \sqrt{\frac{18\,\eta}{\Delta\rho} \cdot \frac{4\dot{V}}{\pi d_0^2 L} \cdot \frac{d_0}{d_i}} \qquad (3)$$

## Evaporation

The MESH equations (material balances M, equilibrium conditions E, sum equations S and heat balance H) are used to model the evaporation of ethanol and water in the heated glass bulb. The five components mentioned in the Fermenter section are balanced. The caloric properties of the biomass are estimated with the properties of water. The phase equilibrium (K-values / $K_i$) is calculated with the non-random two liquid model (NRTL) from Renon and Prausnitz [2]. In the equations 4 – 10 $x_i$ refers to the molar liquid fraction, $y_i$ to the molar vapor fraction, $M$ to the molar hold-up, $\dot{Q}$ to the heat duty added or removed, $U$ to the inner energy $h$ to the enthalpy, and $V$ to the vapor flow. The indices L and V refer to liquid and vapor.

$$\text{M:}\quad \frac{d(x_i M_L)}{dt} = -y_i V \qquad (4)$$

$$\text{E:}\quad y_i = K_i x_i \qquad (5)$$

$$T_V = T_L \qquad (6)$$

$$P_V = P_L \qquad (7)$$

$$\text{S:}\quad 1 = \sum_{i=1}^{NC} x_i \qquad (8)$$

$$1 = \sum_{i=1}^{NC} y_i \qquad (9)$$

$$\text{H:}\quad \frac{dU_L}{dt} = \dot{Q} - h_V V \qquad (10)$$

The MESH equations are solved in CHEMCAD using the vessel reactor unit operation.

## Packed batch column

The batch column is modelled by solving a set of the MESH equations, with a number of MESH sets equal to the number of theoretical plates. Therefore, the equations 4 and 10 are modified by adding a vapor flow from the lower plate, a liquid flow from the upper plate and by subtracting the liquid flow to the lower plate. The resulting differential-algebraic equation system is solved in the CHEMCAD unit operation batch column. To include non-integer values for the number of theoretical plates Murphree tray efficiencies are used. Heat losses over the column are estimated for each stage with equation (11), where $k$ is the heat transfer coefficient. At the last stage the reboiler duty is added, at the first stage the

condenser duty is removed.

$$\dot{Q}_{\mathrm{HeatLoss}} = k \cdot A_{Stage} \cdot \left(T_{Ambient} - T_{Stage}\right) \quad (11)$$

### Adsorption

The adsorption of water on the zeolite is modelled by assuming a water free adsorbent as initial condition, spherical particles of equal size, and a linear adsorption isotherm. The approximated solution to the partial differential equation system proposed by Rosen is used to calculate the dynamic behaviour of the gas phase concentrations. For further details, see Sattler`s textbook [3].

## PROCESS STEPS

Each process step can only be performed once, making detailed planning of the entire process essential. Process models are developed, fitted to data from preliminary experiments, and used to design the individual process steps.

### Feedstock and product requirements

The sugar alpha-D-glucose monohydrate is used as feedstock, because its concentration in an aqueous mixture with ethanol is easier to measure compared to other sugars. Besides water, the only other feedstock is fresh yeast with a dry matter content of around 30% by weight.

The ethanol concentration in the fuel-grade bioethanol product must exceed 98.7% by weight [4].

### Preliminary experiments

Preliminary experiments are performed to determine missing model parameters. Most of these parameters are obtained by reconciliation of measured data. However, for the design of the fermentation process, the solubility of the sugar, the yeast, and their mixture in water are critical. These parameters are determined through trials which are not directly related to the later process steps.

### Data reconciliation

Data reconciliation is a powerful tool for estimating missing model parameters. It involves using measured data and correcting it by applying conservation equations. This is required because the mathematical models, where these parameters are used follow these fundamental laws, whereas measure data commonly is subject to errors and may not. The models that are used during the data reconciliation are described in the section on process models.

### Reaction kinetics and yield coefficients

A fermentation trial is carried out in the previously described vessel reactor. The concentrations of glucose, yeast, and ethanol are monitored over time. Additionally, the $CO_2$ production rate is measured. A comparison of the initially added glucose with the produced ethanol and the increased amount of yeast at the end of the experiment produces the yield coefficients. The reaction kinetic parameters in equation (2) are determined using the reaction rate regression tool implemented in CHEMCAD.

### Mechanical yeast separation

Although the separation grain diameter can be calculated using equation (3), where all parameters are known, the mechanical yeast separation can not be calculated a priori. The unknown property in this case is the particle size distribution of the yeast in the mixture, which cannot be measured directly. Instead, the remaining amount of yeast in the intermediate product is analyzed.

### Column start-up and total reflux profiles

Several important simulation parameters can be retrieved from the temperature profiles of the column start up. The curves from a preliminary experiment are shown in Figure 3. The next sections will refer to these profiles.

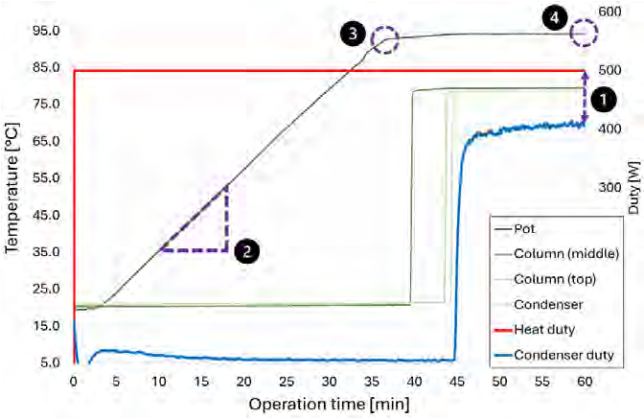

**Figure 3.** Temperature profiles during start-up.

### Heat losses

Heat losses occur in all process steps, but they are particularly significant in the packed distillation column, where they lead to an increased reflux stream and impact the separation efficiency. These losses can be estimated by comparing the heat added to the pot with the heat removed by the cooling water in the condenser. At total reflux the difference of these values gives the overall heat loss (arrows at Point 1 in Figure 3). The heat loss from the pot can be estimated separately by analyzing the heat-up curve (Point 2 in Figure 3).

### Column hold-up

The liquid hold-up in the packing and in the condenser directly influence the dynamic behavior of the batch distillation. These factors must be included in the model to make reasonable predictions of the product concentration in the distillate and receiver tanks.

Fortunately, they can be estimated from the total reflux experiment. Initially, all the column content is allocated in the pot, and its composition is known or can be derived from the temperature profiles during the heat-up

phase (Point 3 in Figure 3). Temperature and composition in the pot change over time and reach a steady state once the total reflux profile is fully established (Point 4 in Figure 3). This change in composition is a result of the transfer of mass from the pot into the column.

The correlation between the hold-up and the temperatures at Points 3 and 4 in Figure 3 is not trivial but can be determined through data reconciliation. However, no direct differentiation between the hold-up in the packing and the hold-up in the condenser is possible. Therefore, one of these parameters should be fixed to a reasonable value during the data reconciliation.

## Separation efficiency

The number of equilibrium stages in the packed column, defined by the modified equation system 4-10, can be estimated using the McCabe-Thiele method, i.e. drawing steps into the x-y equilibrium diagram (Figure 4). This graphical method is not very accurate, often resulting in a non-integer value for the last stage, which is hard to read precisely from the diagram. Additionally, the energy balance is neglected, which is not a valid assumption for columns with considerable heat losses. Consequently, the separation efficiency is estimated by rigorous simulation using Murphree tray efficiencies.

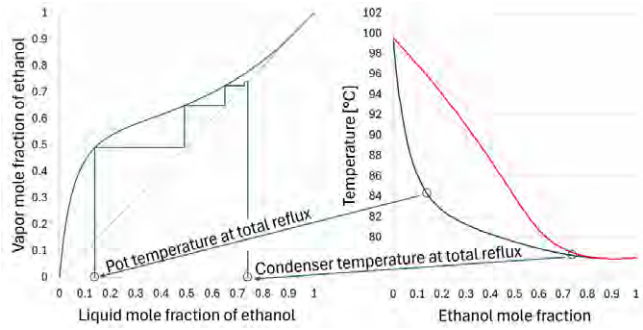

**Figure 4.** McCabe Thiele method for estimating the number of equilibrium stages in the packed column.

Graphically these efficiencies mean, that the step of an equilibrium tray is not drawn until the equilibrium line but ends at a certain percentage (the Murphree efficiency of the tray) of the full distance. The estimation from the McCabe Thiele method still gives a good initial guess for the data reconciliation.

Heat loss, hold-up, and separation efficiency are coupled in a highly non-linear manner, so they must be regressed together. This simultaneous regression is performed using the data reconciliation tool implemented in CHEMCAD. The measured values to be matched include the pot and condenser temperatures, as well as the heat loss over the packed column. Samples can be drawn from the pot and condenser to determine their composition, but these values correlate with the respective temperatures in the case of a binary mixture. The measurements are still used to verify the accuracy of the method.

## Adsorber capacity

The particle diameter and the adsorption isotherms for the zeolite are commonly provided by the vendor, but the packing porosity and the effective diffusivity must be estimated to apply Rosen`s equation. While the packing porosity can be read from volume measurements, the effective diffusivity requires a trial run. The final missing parameter in the adsorber model can be estimated from the breakthrough curves of water.

## Fermentation

The validated model for the conversion of glucose to ethanol, yeast, and carbon dioxide in the given fermenter can be used to maximize the amount of ethanol produced at minimum costs in a 150-minute run. The decision variables include the initial amounts of yeast and glucose, as well as additional glucose fed to the fermenter at any time later in the run. The feedstock content in the fermenter is limited by its solubility. While the operational costs, such as electricity consumption for stirring and cooling remain fixed, feedstock costs directly impact the profitability of the process.

## Yeast removal

The two steps of yeast removal offer little room for optimization but impose constraints to the amount of fermenter broth that can be produced during the fermentation step. Additionally, the liquid volume of the batch distillation plant`s pot is limited, which restricts the amount of condensate generated in the evaporation step. This step also determines the initial ethanol concentration for the distillation and, consequently the maximum product purity achievable with the existing column.

## Distillation

The distillation column has only one degree of freedom during operation: the reflux ratio. In theory, the heat duty added to the pot could be adjusted, but due to the risk of flooding, it is fixed at a safe value.
Nevertheless, designing the distillation step is challenging because the reflux ratio can be adjusted dynamically. Instead of optimizing a single value, the goal is to determine an optimal trajectory over the 150-minute runtime or, alternatively, a sequence of operational steps.
The objective function is also complex. While the operation costs don't vary much (600 W over 150 minutes plus heat-up time), a key decision involves determining how much product should be collected and at what concentration. Product batches of varying volumes and concentrations can be collected in the receiver tanks, adding another layer of optimization.

## Adsorption

Finally, the water content in the product batches

must be removed in the adsorption step, which is the bottleneck of the overall production process. While this step does not feature any decision variables, detailed planning is essential to ensure that all the product from the distillation column is processed efficiently. Due to heat-up and cool-down times, only two adsorption runs can be performed in the 180-minute timeframe.

## RESULTS

All groups successfully produced bioethanol with the required purity. The utilized electrical energy was similar for all groups, but the final product mass varied significantly, ranging from 50g to 200g depending on the process design. Figure 5 presents an example of the fermentation step, comparing the planned concentration trajectories (model) with the measured values. In this specific case the students have decided for a fed-batch strategy. A similar comparison for the distillation step is shown in Figure 6. The primary cost driver in the process is the glucose feedstock, with overall operational expenditures ranging from €20 to €50 per group. The overall student feedback on the project was very positive.

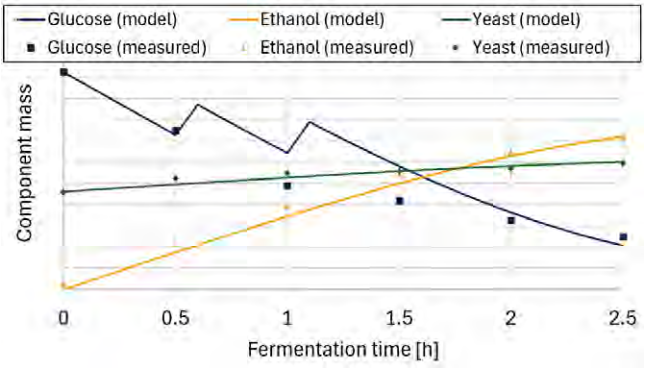

**Figure 5.** Exemplary results of the fermentation step.

## SUMMARY

This work provides a detailed overview of the materials and methods used for a university course during which students produce bioethanol in a demanding competition. It shares key insights from the course, highlighting both challenges and successes. The study emphasizes the importance of mathematical modelling and the challenges in aligning modeled data with measured data. A key takeaway is that while the models may not perfectly capture reality, they are essential for a successful process design, particularly for inexperienced engineers transitioning from academia to industry.

Each student has an individual project, but this project is connected to those from the other group members. Providing reasonable guesses for data that is required in the other projects is very challenging, but also a great learning experience, especially if the guess was good.

This case study shows how combining modelling tasks and experimental tasks and merging them to a project that follows a red thread leads to an extraordinary learning experience for the students. It is intended to motivate the design of similar courses.

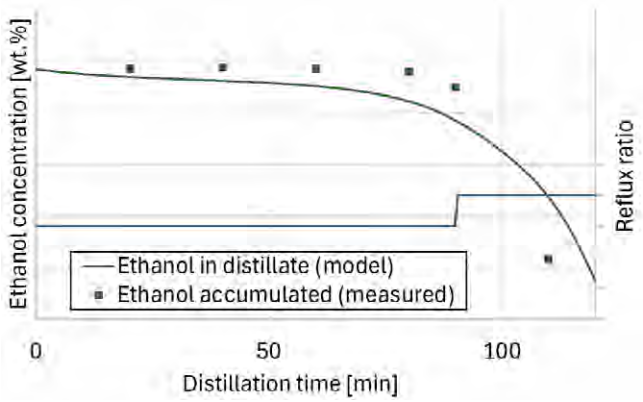

**Figure 6.** Exemplary results of the distillation step.

## DIGITAL SUPPLEMENTARY MATERIAL

The CHEMCAD simulation files for the modelling of the fermentation step, the open distillation step and the batch distillation step are available as digital supplementary material:

# Exergy Examples for the Chemical Engineering Classroom

**Thomas A. Adams II**[a]*

[a] Norwegian University of Science and Technology, Department of Energy and Process Engineering, Trondheim, Norway
* Corresponding Author: thomas.a.adams@ntnu.no

## ABSTRACT

This work explores several examples of how the thermodynamic concept of exergy can be used in the chemical engineering classroom. Examples include using exergy to determine thermodynamic and monetary value of utilities, to identify better heat exchanger network designs, to aid in work-heat integration applications such as heat pumps and organic Rankine cycles, to scope out realistic energy integration cases, and to assess how well chemical potential is being used and managed. The examples are presented in one connected context that makes it easy to see how exergy analyses can be useful across many aspects of chemical and energy industry supply chains.

**Keywords**: Exergy, Education, Energy Efficiency, Process Design

## INTRODUCTION

Exergy is an interesting thermodynamic property that is especially useful for the design, analysis, and optimization of energy systems. Although there are competing definitions of exergy, I believe the definition of Moran et al. [1] is the most general and the easiest for process systems engineers to understand (emphasis mine):

### Definition of Exergy

> Exergy is the **maximum** theoretical work obtainable from an overall system consisting of a system and the environment as the system comes into equilibrium with the environment (passes to the dead state).

The text definition can be written mathematically in a form understandable to process systems engineers:

$$e = \max_{\mathcal{P}} w \tag{1}$$

where $e$ is the exergy, $\mathcal{P}$ is a process that brings the system into equilibrium with the environment, and $\mathbb{P}$ is the set of all possible processes such that $\mathcal{P} \in \mathbb{P}$. [2]. Note that "the system" can include a process, device, unit operation, heat, or a substance.

Exergy arises from the ways in which the system differs from the environment, such that some process $\mathcal{P}$ can be made to exploit those differences. For example, if a fluid has a higher pressure than the environment, a turbine can be used to produce work by passing the fluid through the turbine into the environment (the reverse direction is also possible [2]). If a substance is hotter than the surrounding environment, a Carnot engine can convert the higher temperature heat from the substance into work and use the environment as the sink for the lower-temperature waste heat (or its reverse [3]). Chemical potential, phase differences, concentration differences, gravity, and other forms of energy can all be exploited for some kind of work production [4], and the exergy is the maximum work theoretically possible using a perfect, reversible, frictionless, lossless process. In this form, exergy is both a measure of quantity and quality of energy simultaneously. For example, 1 kJ of heat at 100°C has less exergy than 1 kJ of heat at 200°C, even though they have the same energy.

To the process systems engineer, and especially to the process designer, this property makes exergy useful for process design, optimization, and analysis. Exergy is a good proxy for value. For example, the exergies of utilities are directly correlated with their market prices [4], exergy losses in flowing systems correlate very well system complexity [5], and exergy can also be used as a proxy for capital cost, making it particularly suitable as an objective in optimal process design problems [6]. It is excellent for debottlenecking, benchmarking, and identifying value and thermodynamic limits. It also works in reverse: exergy is also the thermodynamic minimum work

required to take material and energy from the environment and create high value products. This is particularly useful for modern relevant chemical engineering applications such as direct air capture of $CO_2$, desalination, cryogenic air separation, resource extraction, green hydrogen production from water ("un-combustion of hydrogen"), $CO_2$ conversion into fuels like synthetic methane ( "un-combustion of natural gas"), and environmental remediation.

Despite all these potential uses to the system engineer, exergy is not traditionally taught much in chemical engineering education. It has little to no mention in most major chemical process design textbooks including those by Smith [7], Towler and Sinnot [8], and Peters, Timmerhaus, and West [9]. The 3rd edition of Seider et al. [10] uses the terms "availability" and "2nd law analysis" to express some of the same fundamental concepts, but is relegated to the supplementary material rather than the actual print.

Exergy is a difficult concept for both students and educators. Students need to understand enthalpy and entropy, and many of its benefits to engineering decision making can only be exploited at the senior level or higher. Nevertheless, it can be used at lower levels for analysis purposes, especially when students simply look-up / are given exergy values and skip the difficult computation portion (the book Exergy Tables [4] is simply a compendium of look-up values for students to use, shortcutting the more difficult computational portion). To make this easier, this work provides several examples of how it can be used in the classroom in a variety of contexts.

## CLASSROOM EXERGY EXAMPLES

### Example 1: Exergy as Proxy for Value

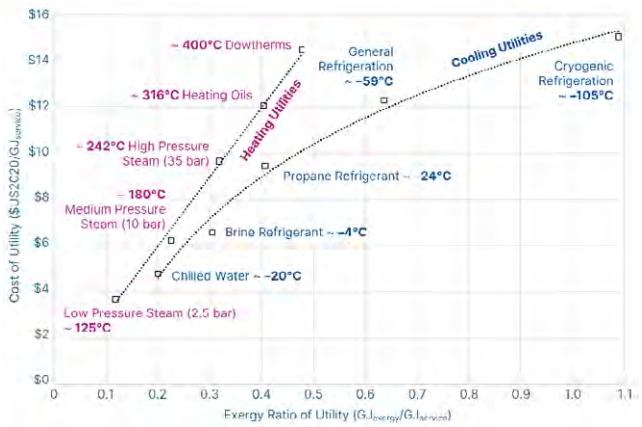

**Figure 1:** The cost of a utility as a function of its exergy ratio using 78°C as $T_{\text{ref}}$ and the assumed average operating temperatures shown. Adapted from [4].

Exergy is an excellent proxy for value and can be used to estimate the market value of cold or hot utilities at any temperature. This is especially convenient when the designer has enough degrees of freedom to choose the temperature of the desired utility. For example, Deng et al. [4] suggested the existence of a so-called "plant ambient" temperature of 78°C that arises from the statistical cost of utilities presented in Seider et al. [10]. The statistical value/cost of heating and cooling services is effectively zero at 78°C and increases as temperature moves away (up or down) from it. Essentially, 78°C statistically arises as the temperature at which something has zero thermal value on average in chemical plants, and all other deviations from there cost money to achieve. As far as utilities are concerned, 78°C is a better definition of "environmental temperature" for a chemical plant than 25°C. Consequently, Deng et al. [4] showed that the cost of utilities is strongly correlated with exergy using 78°C as the reference temperature ($T_{\text{ref}}$), as shown in Figure 1:

The correlation for the cost of hot utilities $C_{\text{heat}}$ is [4]:

$$C_{\text{heat}} = 29.9\ \text{USD}_{2020} R_{\text{ex}} \tag{1}$$

where $R_{\text{ex}}$ is the exergy ratio of the utility at temperature $T$ in °C (sometimes called the exergy quality) which is the amount of exergy of that utility using 78°C as the environmental reference temperature expressed per unit of thermal energy received or delivered by the utility. $\text{USD}_{2020}$ means US dollars in the year 2020. For heat at $T \geq T_{\text{ref}}$ this is:

$$R_{\text{ex}} = 1 - \frac{273.15+T_{\text{ref}}}{273.15+T} \tag{2}$$

For example, heating services at 200°C would have an exergy ratio of 0.258 $\text{GJ}_{\text{exergy}}$ per $\text{GJ}_{\text{heat}}$ and cost 7.71 $\text{USD}_{2020}$ per $\text{GJ}_{\text{heat}}$ purchased. For cold, the exergy ratio is the exergy the heat sink (the cooling sink / utility) at temperature $T$ per unit of thermal energy moved from the hot source to the cold utility. The definition of $R_{\text{ex}}$ switches for $T \leq T_{ref}$:

$$R_{\text{ex}} = \frac{273.15+T_{\text{ref}}}{273.15+T} - 1 \tag{3}$$

and is expressed in $\text{GJ}_{\text{exergy}}$ per $\text{GJ}_{\text{cooling}}$. The corresponding cost of cooling utilities again applies when $R_{\text{ex}}$ is calculated using 78°C for $T_{\text{ref}}$:

$$C_{\text{cool}} = 14.75\ \text{USD}_{2020} + 6.31\ \text{USD}_{2020} \ln R_{\text{ex}} \tag{4}$$

For example, a cooling sink at –40°C (e.g. refrigeration) has an exergy ratio of 0.506 $\text{GJ}_{\text{exergy}}$ per $\text{GJ}_{\text{cooling}}$ and cost 10.5 $\text{USD}_{2020}$ per $\text{GJ}_{\text{cooling}}$ provided. It is very straightforward for students to quickly connect exergy, temperature, and value with these equations for all sorts of uses.

### Example 2: Pinch Analysis & Heat Integration

Consider the balanced composite curves shown for a proposed heat exchanger network (HEN) that meets the minimum energy targets in Figure 2 (left). The red lines indicate the profile of the hot streams of the HEN and the blue lines indicate the cold streams. The heating

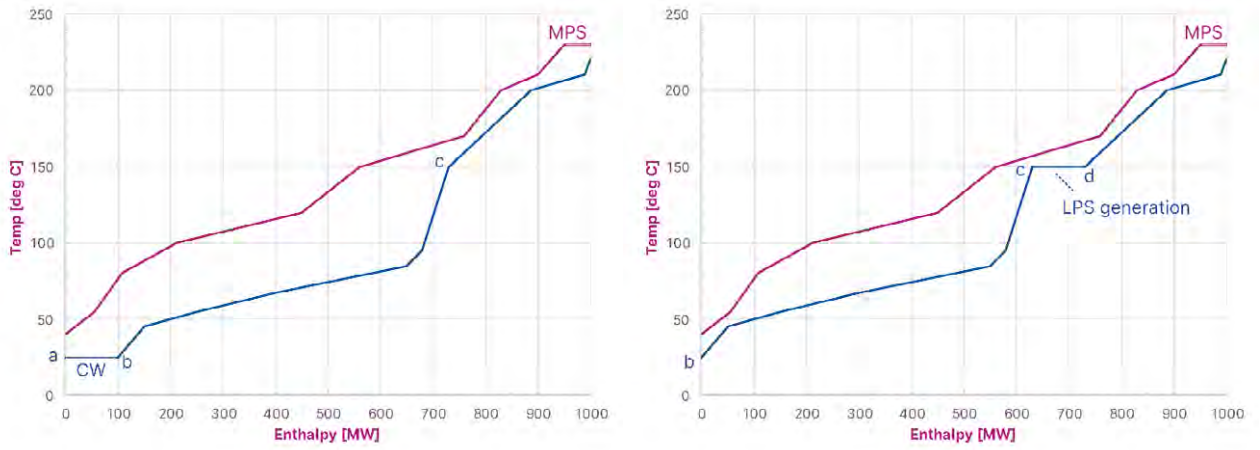

**Figure 2:** (left) Balanced composite curves of a proposed heat exchanger network resulting from classic methods. (right) A suggested improvement by a student.

utility is medium pressure stream (MPS) as shown, and the cooling utility is cooling water (CW), line segment **ab**. This balanced composite curve is typical of one that would be developed with classic minimum energy targeting methods as described in various popular textbooks [7, 10, 11] and taught in many undergraduate courses.

The student can take another step further and evaluate the exergy value or cost of the utilities. Whether selecting the plant ambient or environmental ambient as the reference case, the exergy of the required utilities can be computed, and their market value approximated from equations (1)-(4). Here, the cost of cooling is about 3.85 $USD_{2020}$/GJ and at 100 MW (the width of line **ab**) would cost about 12 million $USD_{2020}$/year. Then the student can identify an improvement to the system which still meets the minimum energy requirements, but has better exergy or monetary value, which are directly correlated.

The general idea is to identify low hanging fruit on the composite curve such that utility loads can shift to places in the HEN with lower cost. For example, a student could suggest that a new HEN could be made with the balanced composite curve shown in Figure 2 (right) by shifting line segment **bc** to the left until a minimum approach temperature other constraint has been reached. In this case, all 100 MW of cooling can be removed, and **bc** shifted all the way to the left. The student can replace the 100 MW of cooling with 100 MW of low-pressure steam (LPS) **generation** at 150°C (segment **cd**). The curves are tighter now for hot-side temperatures around 50°C and 160°C, meaning that the HEN might be more complex and require more heat exchanger area (due to smaller temperature driving forces). But it might be worth it because the utility value improvement is enormous. Instead of spending money on cooling, we can **generate** value up to 16 million USD/year instead of spending 12 million USD/year.

This is simple way to connect many topics relating to energy quantity, quality, economics, thermodynamics, HEN design, and optimization all at once in the classroom. You can immediately see how this can be integrated into the objective functions of optimal heat exchanger network design for more complex class material [6].

## Example 3: Work-Heat Integration

Continuing that example, perhaps we do not want to make LPS because we have no need for it or way to sell it, but we could instead use that steam to produce work. A student can immediately estimate the upper bound work production potential of recovering 100 MW at 150°C against our actual environmental temperature (let us choose the common $T_{\mathrm{ref}}$ of 25°C). From equation (2), the exergy ratio of that recovered heat is about 0.295, meaning that one could produce a theoretical maximum of 0.295 GJ of work per GJ of heat recovered. For 100 MW of waste heat recovered, this is 29.5 MW of work. That is certainly a large enough potential to considering the idea further.

A student can then use exergy to set a few more benchmarks about how the system could work in practice. First, LPS is generally too weak to produce much work in a steam cycle, so at 150°C we might consider an organic Rankine cycle (ORC). Figure 3 shows an example of how a simple ORC might work using R113 as a working fluid on a Temperature-Enthalpy-Exergy diagram. Thermo-mechanical exergy ($e^{\mathrm{tm}}$, blue lines) is computed using $T_{\mathrm{ref}}$ of 25°C and the following equations for thermo-mechanical exergy of a substance [2]:

$$e_1^{\mathrm{tm}} = \begin{cases} (h - h_{\mathrm{ref}}) - T_{\mathrm{ref}}(s - s_{\mathrm{ref}}) & p \geq p_{ref} \\ (2h_* - h - h_{\mathrm{ref}}) - T_{\mathrm{ref}}(s - s_{\mathrm{ref}}) & p \leq p_{ref} \end{cases} \quad (5)$$

where $h$, $s$, and $p$ are the intensive enthalpy, entropy, and pressure of the point of interest; $h_{\mathrm{ref}}$, $s_{\mathrm{ref}}$, and $p_{\mathrm{ref}}$ are the

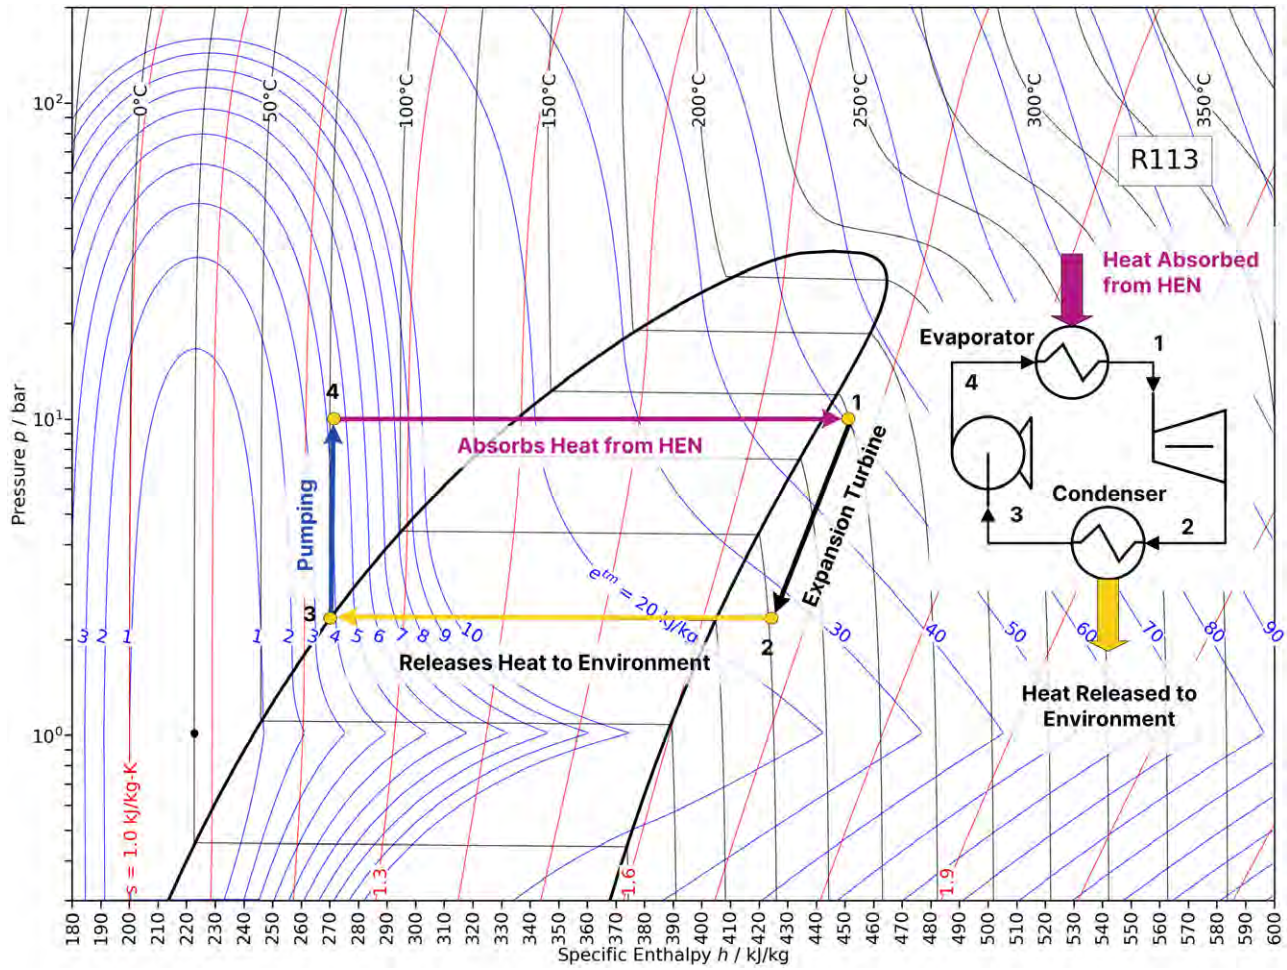

**Figure 3:** The pressure-enthalpy-entropy diagram for R113 (adapted from [2]), with the working fluid state changes overlaid with coloured arrows. The inset shows the corresponding ORC design with corresponding streams.

intensive enthalpy, entropy, and pressure at the reference conditions (the reference pressure chosen is $p_{\text{ref}}$= 1 atm); and $h_* = h(p_{\text{ref}}, s)$.

Using Figure 3 or equation (5), the student can quickly select some good starting points for an ORC design. The student has chosen point **1** to be the highest pressure that R113 can get while being slightly superheated and at the maximum possible 150°C (about 10 bar, see Table 1 for approximate stream conditions), since this is the temperature of our sink. This student selected the pressure of Point **2** to be the lowest pressure R113 can get along a path of isentropic expansion such that the temperature is still high enough to dump heat to the environment via the condenser. For example, we could decide we want to use cooling towers and so maybe we would pick a temperature of, say, 40°C. The lower the temperature, the more work produced, but then the higher the cost for cooling in the condenser.

**Table 1.** Approximate stream conditions for the ORC shown in Figure 3.

| **Stream** | **1** | **2** | **3** | **4** |
|---|---|---|---|---|
| $T$ °C | 150 | 101 | 78 | 78 |
| $P$ bar | 10 | 2.1 | 2.1 | 10 |
| $h$ kJ/kg | 450 | 425 | 272 | 272 |
| $e^{\text{tm}}$ kJ/kg | 51 | 26 | 4 | 4 |
| $E$ MW | 28.7 | 14.6 | | |

However, remembering example 2, the point of this was to avoid cooling towers, so the student chose a point at 2.1 bar such that phase change occurs close to the plant ambient temperature so that heat removal in the condenser is basically free. Point **3** is chosen as simply the point at which the R113 is fully condensed. Point **4** is point where the pressure returns to 10 bar isentropically. This line of thinking is simple and quick enough such that points can be chosen by hand and sketched with a pencil on an exam.

The student can quickly determine key several metrics by reading off the diagram or using more rigorous formulas (see Table 1). For example, the flow rate of the working fluid is quickly determined by the enthalpy difference between points 4 and 1 ($h_4 - h_1$ = 178 kJ of heat adsorbed per kg of R113, which at 100 MW absorbed is 562 kg/s of R113).

The exergy at point **1** is about 51 kJ/kg, which at the system flow rate is about 29 MW. This is a good check because it cannot be higher than the theoretical maximum exergy of the 100 MW heat of 29.5 MW exergy we computed earlier. Given the limited precision of Figure 3, it means our choice for point **1** is very good and there is little room for improvement by changing the conditions. Note that for this sketch, the work required by the pump ($h_4 - h_3$) is too small to be considered within the precision of this analysis.

The work produced by the turbine is simply the enthalpy difference between points **1** and **2** ($h_1 - h_2$ = 25 kJ/kg, which for 562 kg/s of R113 is 14 MW). That's a sizeable amount of work and perhaps worth pursuing. Note however, that the work produced by the turbine is also the thermo-mechanical exergy difference between point **1** and point **2** ($e_1^{\text{tm}} - e_2^{\text{tm}}$ = 25 kJ/kg also). We can see immediately since point **2** has a thermo-mechanical exergy of $e_2^{\text{tm}}$ = 26 kJ/kg that we are not using, we are leaving about half of our potential value on the table with this ORC.

It is instructive for the student to compute some useful metrics such as the energy efficiency ($\eta_{\text{en}}$) and the exergy efficiency ($\eta_{\text{ex}}$), noting that work is pure exergy:

$$\eta_{\text{en}} = \frac{\text{Power Produced}}{\text{Heat Supplied}} = \frac{14\ \text{MW}}{100\ \text{MW}} = 14\% \qquad (6)$$

$$\eta_{\text{ex}} = \frac{\text{Exergy Produced}}{\text{Exergy Supplied}} = \frac{14\ \text{MW}}{29.5\ \text{MW}} = 47\% \qquad (7)$$

The metrics show that although percentage of the waste we convert to power is relatively small (14%), we recover 47% of the **value**, which is quite good for low quality waste heat! Considering all the metrics together, the student can conclude that (1) the 150°C waste heat is sufficiently large to be meaningful, (2) the ORC design captures about half the value of that heat, which is also meaningful, and (3) there is still much room to improve the design with changes like a lower turbine outlet pressure or an economizer. The process of sketching out design concepts, linking them to thermodynamic states, and then computing and analyzing important metrics relating to energy and exergy is an important take-away skill set for any student approaching any kind of energy engineering problem.

## Example 4: MPS Generation by Combustion

Let's continue that example but focus on the MPS utility requirement. Utility steam generation usually requires natural gas or some other fossil fuel combustion to produce. A student can quickly estimate the cost and exergy value of this steam (50 MW at 230°C) using equations (1) – (4) to be about 14 million USD/yr with an exergy value relative to 25°C of 18.6 MW. Suppose the student should design a boiler process to create this steam from natural gas, and proposes a design shown in Figure 4, with stream conditions in Table 2 determined by Aspen Plus V14 simulation (see end of paper for downloadable link). To deliver heating services by condensing at about 230°C we need steam at 29 bar, and we should make it superheated to 235°C as a safety margin. The steam flow can be determined via the latent heat of vaporization of steam at 29 bar knowing that we need 50 MW of heating service. The rest of the stream rates are determined by other design requirements such as complete combustion of the natural gas, maximum combustion zone temperature, a minimum driving force temperature in the boiler heat exchanger, and assumed conditions about the condensed steam that returns to the boiler in a closed loop.

**Table 2.** Approximate mass and exergy flows for the boiler process shown in Figure 4.

| **Stream** | F (kg/s) | $e^{\text{ch}}$ (MJ/kg) | $e^{\text{tm}}$ (MJ/kg) | $E$ (MW) |
|---|---|---|---|---|
| **1** | 2.68 | 48.3 | - | 129 |
| **2** | 2.68 | 48.3 | 0.013 | 129 |
| **3** | 225 | - | - | - |
| **4** | 225 | - | 0.007 | 1.6 |
| **5** | 227 | 0.009 | 0.063 | 16.4 |
| **6** | 27.7 | 0.049 | 0.207 | 7.1 |
| **7** | 27.7 | 0.049 | 0.209 | 7.2 |
| **8** | 27.7 | 0.526 | 0.964 | 41.3 |
| Blow. 1 | 44 kW | | | 0.04 |
| Blow. 2 | 2.2 MW | | | 2.23 |
| Pump | 10 kW | | | 0.01 |

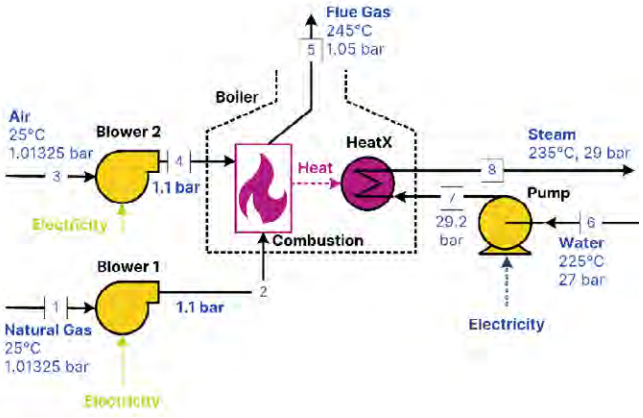

**Figure 4.** A proposed boiler for generating MPS (29 bar steam slightly superheated to 235°C) which can be used to deliver heat at about 230°C as it condenses.

The thermo-mechanical exergy of the relevant streams can be quickly determined through equation (5) or found in tables such as in the book Exergy Tables [4]. Similarly, the chemical exergy ($e^{\text{ch}}$) of the streams (the

work potential associated with chemical bonds, phase, and its chemical composition difference against the environment), can also be found in Exergy Tables to be 831.7 MJ/kmol (or 48.27 MJ/kg) of US Average Pipeline Natural Gas. From this information, the total exergy flows ($E$, the sum of thermo-mechanical and chemical exergy) can be computed and shown in a Sankey diagram (Figure 5). Exergy efficiency also can be computed with equation 7 ($\eta_{\text{ex}} = 31\%$).

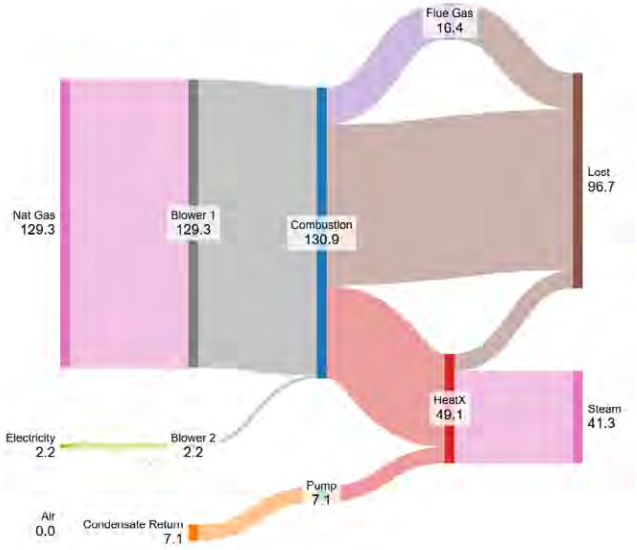

**Figure 5.** Exergy flows in MW of the boiler process of Figure 4. Generated at Sankeymatic.com.

The Sankey diagram is an excellent teaching tool to visualize the exergy flow (the energetic **value**) through the system. The student can immediately see the relatively small importance of the electricity compared to the chemical exergy of the natural gas. The condensate return (stream 6) matters too. The losses though are the most telling. For example, a sizeable amount of heat is lost in the flue gas, identifying this as a possible place to capture that heat for some purpose and recover a decent amount of value of up to 16.4 MW. Again, the exact values do not matter so much; using different reference conditions or different approximations for exergy will still result in a diagram that looks very much the same with the same analytic usefulness to the engineer.

However, most of the exergy lost is through exergy destruction in the combustion step. In other words, combustion as a process inherently destroys much of the chemical exergy value in the fuel. This has bigger picture concerns in the world of power production in which most transportation mechanical power and municipal electric power is produced from fossil fuels via combustion. Now the student can see the connection between combustion and how well the natural gas is used. This is an opportunity to start larger discussions into sustainability and modern technologies like fuel cells that are not limited by combustion and therefore can theoretically better use our fossil-fuel resources via non-combustion approaches to heating and power.

## Example 5: Heat Pumps

With that note, we can continue the example further by considering whether we can avoid combustion entirely. Looking at the balanced composite curves in Figure 2 (right), we might be able to use a heat pump to take the waste heat from our new 100 MW heat sink at 150°C (with 29.5 MW of exergy) and upgrade it to a heat source at 230°C, potentially replacing the need for some or all of the 50 MW of MPS generation from natural gas.

The student can immediately scope this out with exergy because the 29.5 MW waste heat exergy is higher than the 20.4 MW of exergy needed to provide 50 MW of 230°C heat to our HEN cold streams. In theory, there is more than enough exergy available from the waste heat to convert it to a high temperature heating utility by using **theoretically perfect and fully reversible machines**. In fact, we would only need to recover about 20.4 / 29.5 = 69% of the exergy of our waste heat to replace all MPS needs. Of course, the practical reality can be quite different. Nevertheless, this proposed match is potentially suitable from an exergy perspective and deserving of a closer look.

One option is a chemical heat pump, which uses chemical loop where an endothermic reaction absorbs the low temperature waste heat, and then later the reaction is run in reverse exothermically to release heat at a higher temperature. This process requires relatively little work and is mostly powered by the waste heat [12], so it is a good option when electricity is expensive or has a high carbon footprint. A recent study considered several candidate chemical systems and recommended an optimal design using an isopropanol-acetone-hydrogen chemical heat pump that could take waste heat at 150°C and produce heat at 225°C (very close to this example) with an exergy efficiency (relative to 25°C) of about 33% and a coefficient of performance of about 18% [13]. This is a meaningful amount of exergy recovery for something that is powered almost entirely by waste heat. In other words, instead of using cooling water for this HEN, or instead of building an ORC, this chemical heat pump would convert the 100 MW waste heat at 150°C to about 18 MW at 230°C, reducing the MPS production load by 36% and its associated greenhouse gas emissions from natural gas combustion. The student can then estimate if this concept is worth it by considering the exergy flows and cost as predicted by exergy discussed earlier.

Mechanical heat pumps could be another option, in which a meaningful (but not huge) amount of work is used to upgrade waste heat to higher temperatures. If we had access to low cost and/or low carbon-footprint electricity, this might be a good way to avoid natural gas

combustion for MPS production. However, most so-called "high temperature" mechanical heat pumps operate at ranges well below our targeted application [14] with the next frontier going up to the 200°C range [15]. Unfortunately we need to go to 230°C with an 80°C temperature lift, something that has not been well-proven yet but is under active study.

However, based on some of the highest temperature mechanical heat pumps that have been studied, we can make some estimates using exergy. An ammonia-water absorption-compression heat pump can reach temperatures of 230°C, although perhaps not with this high of a temperature lift. Regardless, based on studies at similar temperatures [16], at best we could expect a coefficient of performance of about 3 in a future system. For a mechanical heat pump, this is:

$$COP = \frac{high\ temperature\ heat\ produed}{work\ consumed} \quad (8)$$

So, for A COP of 3 we would need 16.7 $MW_{el}$ of electric work (which is 16.7 MW of pure exergy) to produce 50 MW of 230°C heat, and by energy balance we would consume 33 MW, or 33% of the 150°C waste heat (so there is amply supply). The student can quickly compute the exergy efficiency of the mechanical heat pump to be:

$$\eta_{ex,mhp} = \frac{20.4\ \mathrm{MW}_{230\mathrm{C,heat}}}{(0.33)29.5\ \mathrm{MW}_{150\mathrm{C,heat}}+16.7\ \mathrm{MW}_{\mathrm{el}}} = 77\% \quad (9)$$

This is a high number and is a good use of high-exergy electricity—much higher than the 31% exergy efficiency from natural gas combustion, and higher than the chemical heat pump to boot. In fact, this is even better than if we used a resistance-type electric heating system (which has 100% energy efficiency!), because the exergy efficiency of that would be only 20.4 MW / 50 MW = 41%. Thus, although the technology has not been well studied yet for this application, there is a real potential value in it.

## Other Energy and Sustainability Examples

Some other interesting classroom examples include:

- **Direct Air Capture of $CO_2$.** Exergy Tables lists the chemical exergy of $CO_2$ at about 19.8 kJ/mol [4], which is the **maximum** amount of work that could be produced by taking pure $CO_2$ at 25°C and 1 atm and exploiting the concentration difference with the environment (at hundreds of ppm levels). However, it is also the reverse; it is the thermodynamic **minimum** work required to extract pure $CO_2$ from the atmosphere at 25°C and 1 atm. Good classroom discussions can follow which compare existing DAC technologies to this bound, or cross-compare against other kinds of $CO_2$ mitigation or capture technologies.
- **$CO_2$ Compression for Transport.** $CO_2$ captured from power plant exhaust or other process streams is generally high-purity $CO_2$ near environmental temperature and pressure. The next step usually is compression to supercritical conditions for pipeline transport (often for sequestration). The $e^{\mathrm{tm}}_{\mathrm{CO2}}$ at common pipeline conditions (120 bar, 30°C) is about 220 kJ/kg [4], meaning that $e^{\mathrm{tm}}_{\mathrm{CO2}}$ is a great lower bound on the work required to do the compression. Students can use this benchmark to compare quality of compression train designs or for broad-level analyses that place it in a larger picture of $CO_2$ mitigation technology options for many different supply chains.
- **Liquefied natural gas (LNG) and liquid hydrogen ($LH_2$).** Exergy Tables [4] lists chemical and thermo-mechanical exergy for many transport fuels. For example, $e^{\mathrm{tm}}_{\mathrm{LNG}}$ is roughly 1.1 MJ/kg, which is about 2% of its chemical exergy. $e^{\mathrm{tm}}_{\mathrm{LH2}}$ is about 12 MJ/kg, a whopping 10% of its chemical exergy. These are the thermo-dynamic minimum work requirements to liquify each fuel in preparation for transport, highlighting the substantial energy penalty required. It illustrates one major problem with switching from LNG supply chains to $LH_2$ supply chains since 10% of the chemical value of the $H_2$ must be spent just to prepare it for transport. This is an interesting, big-picture way of seeing the global problem. It also is a great launch point for discussing cold exergy, since some of that work can be recaptured during regasification.

## FINAL NOTES

There is a longstanding debate as to how much importance should be placed on the concept of exergy. Some perhaps place it on too-high of a pedestal with other thermodynamic concepts such as Gibbs or Helmholtz free energies. Thermo-mechanical exergy appears very similar in structure to those fundamental properties, but in the final analysis, exergy lacks the deeper thermo-chemical nuance owing to its dependence on non-arbitrary reference conditions which are very difficult to define and ultimately are always changing [4]. Thus, some argue passionately over the "correct" reference conditions and use cases. Others reject exergy entirely in favour of similar approaches like lost-work analysis (entropy generation), citing the various ambiguities in exergy analysis and the reliance on a subjective determination of what **precisely** constitutes "the environment" [17]. The reader is referred to work by Gößling-Reisemann for a historical overview of this ongoing debate [18].

In my view, the value of exergy is in its usefulness to us process systems engineers. For the examples we have given, it does not truly matter if one person choses slightly different environmental reference conditions than

another, thus arriving at different actual values of exergy, because differences in the precise values of exergy ultimately do not hinder its usefulness. If I use exergy as a proxy for cost in a design optimization problem, I can get very good optimal design results that will end up being a very good design, regardless of those precise choices. If I use exergy for a thermodynamic bound on my performance, my real performance will never get very close to the perfect theoretical limit anyway, but it remains very helpful in my continual strive to improve my process and approach this bound. It is still very useful for identifying bottlenecks and energy integration opportunities even if the measured size of that opportunity changes a little bit depending on who is doing the asking. The point is in the identification, in the doing, and in the outcomes, not the final metric. My suggestion to the educator is to continually present the material in the context of how it helps the designer make good decisions and focus less on the exact values of the numbers themselves.

# Teaching of Process Design Courses – The CMU experience, trends and challenges

**Ana I. Torres and Ignacio E. Grossmann***

Department of Chemical Engineering, Carnegie Mellon University, Pittsburgh, PA, USA
* Corresponding Author: grossmann@cmu.edu

## ABSTRACT

Carnegie Mellon University (CMU) has a strong tradition and expertise in Chemical Process Systems Engineering. This short article comments on the CMU PSE-related courses and describes in more detail our approach to teaching Chemical Process Design. We discuss (i) our emphasis on proposing processes related to energy and sustainability and (ii) some of the challenges that are currently faced when teaching this course.

**Keywords**: Process Design, Education

## INTRODUCTION

Process design has been the traditional capstone course for chemical engineering. It is generally the course where the material learned in previous semesters is integrated and applied to a major design project. A major component of this course is decision-making since students have to select the process technology, the flowsheet configuration, and its operating parameters. Modern educational trends emphasize process invention [1] (i.e., synthesis of flowsheets) and the teaching of systematic techniques for design. These include synthesis strategies (e.g., hierarchical decomposition, separation synthesis, heat exchanger networks, energy integration, and water networks), process simulation tools to perform the mass and energy balances, detailed modeling tools for chemical reactors and separators, and economic evaluation.

Process design projects are also ideal for introducing emerging topics such as energy, decarbonization, and sustainability and environmental justice which are becoming highly relevant in the professional education of chemical engineering students. In our experience, students have been highly motivated by design projects that focus on these areas, which in turn can help increase enrollments in chemical engineering.

In this paper, we provide an overview of the Process Systems Engineering related courses offered at CMU and describe, in detail, our approach to teaching Process Design.

## PROCESS SYSTEMS ENGINEERING COURSES TAUGHT AT CMU

Dating back to the pioneering vision by Professor Arthur Westerberg in the late 70s, Process Systems Engineering (PSE) is a major research and education strength of the Chemical Engineering Program at Carnegie Mellon University. Currently, five tenure track faculty members (Biegler, Gounaris, Grossmann, Laird, Torres) focus their research on PSE. They maintain an active research environment, seminar series, the CAPD industrial consortium [2], and a cohort of graduate students at the master's and doctorate levels. The CAPD faculty have written several textbooks in the area [3-7] .

While many chemical engineering programs struggle to cover design courses with tenure-track faculty [8] within a curriculum, our strength in this area of Chemical Engineering allows us to cover design-related courses with specialists. This tenure-track faculty is complemented by adjunct faculty with extensive industrial experience who actively participate in teaching design courses covering practical topics such as process safety.

At CMU, the Chemical Process Systems Design course is the major engineering design experience required by ABET [9]. This course represents 12 units, where one unit expects one hour per week of work and is taught during the fall semester of the senior year (fourth year). Then, students take Chemical Product Design (9

units) in the spring semester of their senior year. These courses build on previous courses that include two design-related courses: Unit Operations (9 units) in the junior year and Unit Operations Laboratory (9 units) in the senior year, and two PSE-related mini-courses (6 units each): Numerical Methods and Machine Learning for Chemical Engineering and Optimization Modeling and Algorithms taken during the fall semester of the junior year. The PSE sequence is completed by Chemical Engineering Process Control (9 units) taken in the senior spring semester.

At the graduate level, we regularly offer three PSE-related courses: Advanced Process Systems Engineering (A-PSE), Process Systems Modeling/Design and Optimization of Sustainable Processes (PSM), and Computational Methods for Large Scale Process Design & Analysis (CMPMO).

A-PSE covers the fundamentals and algorithms of optimization techniques for linear and nonlinear programming, mixed-integer linear and nonlinear programming, generalized disjunctive programming, flexibility analysis, and stochastic programming. It also covers the application of these techniques to the synthesis of heat exchanger networks, distillation sequences, water networks, and process flowsheets as well as the planning and scheduling of batch and continuous processes.

PSM is a long-standing course targeted at masters-level students that covers the simulation and optimization of complex flowsheets using Process Simulation Software. Starting in 2025, this course has been reformulated to (i) introduce these topics in the context of sustainable process design and (ii) improve the process de-sign, simulation, and evaluation skills for those graduate students who come to the PhD program without a strong Process Design background. PSM currently covers modeling simulation evaluation and optimization of state-of-the-art technologies for the conversion of biomass and waste to fuels and chemicals, electrification of chemical processes, the use and storage of energy from intermit-tent non-programmable sources (including batteries, hydrogen, and chemicals), and carbon capture, among others. The course is also offered as an elective for under-graduate senior and PhD students. Currently, all students have the same assignments regardless of whether they did the full PSE sequence at CMU or not.

CMPMO deals with the underlying computer-aided design techniques for steady-state and dynamic simulation, numerical solution and decomposition strategies for large systems of sparse nonlinear algebraic equations, stiff ordinary differential equations, strategies

for mixed algebraic/differential systems and computer architectures for process systems.

In addition, more specialized courses are offered in an intermittent fashion as Special Topics courses: Nonlinear Optimization in Process Systems Engineering is aimed at graduate-level students and is based on the textbook in [4]. It covers methods for solution and optimization for engineering systems described by nonlinear algebraic and/or differential equations. Production and Supply Chain Optimization also targets graduate students and aims to familiarize them with popular decision-making contexts related to production and supply chain optimization and with the numerical optimization methods (both model-based and metaheuristics-based) employed in such settings.

## OUR APPROACH TO TEACH CHEMICAL PROCESS SYSTEMS DESIGN

As with many capstone design courses, Chemical Process Systems Design covers screening process alternatives and computational strategies for preliminary material and heat balances in large chemical processes, including preliminary sizing of process equipment. A key part of the course is evaluating the economics of alternative flowsheet configurations and technologies. Currently, the teaching team comprises two tenure-track faculty, one adjunct faculty, and four teaching assistants (TAs), who are usually PhD students. Class size has oscillated over time and is currently at 50-60 students per cohort.

The course involves lectures and a major project. The main topics in the lectures include techniques for the conceptual design of chemical processes, preliminary process calculations, systematic methods for pro-cess synthesis and energy recovery, economic evaluations of competing processes, fundamentals of flowsheet simulation, and design and scheduling for batch pro-cessing. These topics are covered in the textbook that is used in this course, “Systematic Methods of Chemical Process Design” [3]. Students are also given as references the textbooks by Seider at al [11], Towler and Sinnot [12] and Turton et.al [13]. Students are given two tests that are graded: the first on preliminary mass and energy balances and equipment sizing to prepare them for memo 2; the second on economic evaluation and pro-cess synthesis to prepare them for their final report, project memo 3.

The project itself, for more than a decade, has been defined with input from Dr. Jeff Siirola an expert in process design, former Technology Fellow at Eastman Chemical Company, and current Professor of Engineering Practice at Purdue and Adjunct Faculty at Carnegie Mellon University. The project is organized around the design of a process for a hypothetical “Andrew Corporation” that requests their team of engineers within the Special Projects Group to study a novel processing approach. For example, the 2022 course dealt with the design of a blue hydrogen plant, the 2023 course with chemical depolymerization of PET plastics, and the 2024 course with polyolefin depolymerization.

Students are required to work in a self-selected team of four people. All teams are given the same memo with a brief description of the project, design specifications, and constraints such as production rate, product purity, available feedstocks, location, and economic data. It is important to note that the project is a new unsolved problem, so each team must conduct a literature review and gather data on relevant technologies and chemistries, process conditions, etc., to come up with their own solution. After the preliminary literature review, each team is expected to postulate a superstructure with the major alternatives they have found and, from it, extract a process flowsheet with all the major pieces of equipment and approximate operating conditions.

Students are asked to solve the mass and energy balances for that flowsheet by considering simplified (linear) models for the unit operations prior to using commercial process simulators. Formulating these equations and solving them using simple spreadsheets serves the purpose of teaching the students approximation techniques to allow them to quickly screen design alternatives by generating reasonable first guesses. These first guesses help in building intuition and greatly simplify subsequent rigorous modeling in commercial simulators. We use Aspen Plus as the process simulation software. At CMU, Aspen Plus is also taught as part of the Design Course; this is, students do not generally have prior expo-sure to the software.

In addition, students must perform heat integration using pinch analysis and perform an economic evaluation to determine the net present value or breakeven point of their proposed design. We use and teach commercial software (Synheat, Aspen Energy Analyzer, As-pen Process Economic Analyzer) to facilitate calculations. Safety analysis is covered via a Failure Modes and Effects Analysis (FMEA). Starting in 2024, students are also required to perform a gate-to-gate emission evaluation. To this end, we use EPA's GREENSCOPE tool [10], whose use and logics is also introduced during lectures.

To mock a real engineering position, each team is assigned a TA or faculty member who acts as the project manager to whom the students report progress on a weekly basis. The TA/ faculty member also provides guidance to the students on establishing appropriate goals and planning doable tasks to meet the project objectives. It is worth noting that teams create their flowsheets/designs throughout the course and do not share them with other groups. Hence, their proposed flowsheets differ despite addressing the same design project.

We evaluate the designs by requesting students to submit three reports in the form of memos. The literature search and flowsheet development are reported in Memo 1, preliminary mass and energy balances in Memo 2, and full economic evaluation, gate-to-gate environ-mental assessment, and FMEA analysis in Memo 3. Finally, students give a final oral presentation to summarize their major findings in the design project, which is judged by the TAs, faculty members, and people from industry. We invite industrial colleagues (usually members of the CAPD center) to attend these final presentations. Students are given 5 minutes for the presentation with 5 minutes for questions. The short 5-min presentations force the students to highlight their major results, findings, and recommendations to an industrial audience. The fact that real engineers judge their designs and presentations greatly motivates the students and adds reality to the design experience. The evaluation of the course itself is completed by weekly short homework exercises that assess what was covered in the week and two midterm exams that assess the students' performance at the individual level.

## THE GOOD, THE BAD AND THE CHALLENGES

From the activities described above, the CMU Process Systems Design experience is clearly a challenging one. Feedback from the students indicates that they tend to spend more than the 12-hour expectation, typically 17 hours on average. A number of factors may influence this perception, some of which are discussed below. Despite the time commitment, students find this course to be one of the most valuable ones. As examples, the following sentences are copied verbatim from the 2023 and 2024 faculty and course evaluations (FCEs):

> "I personally thought that while Memo was a ton of work and involved an overwhelming time commitment, it was definitely one of the most useful assignments Ive done in the ChemE curriculum so far in actually preparing us for the future. "

> "While this class was a ton of work I really learned a lot (...) The material is important to a career in chemical engineering, and the skills feel transferable."

> "This course was a lot of work, but I am happy with what I learned from it. It was clear to see the importance and relevance of the coursework with content even from intro tied in. Thank you."

Personal interaction with the students indicates that focusing the project on current topics of relevance, such as clean energy, decarbonization, and sustainability, is, in general, very well received. The positive reception seems to be linked to two facts. One is that these topics are becoming highly relevant in the Chemical Engineering job postings, and being knowledgeable of the newer technologies differentiates them from other applicants. The

second one is that designing novel processes adds the innovation edge that is common in the final projects of other engineering disciplines; this innovation edge is missed if we pick known designs of commodity chemicals as the case study. The downside of selecting novel processes is that some of the operations required to model and simulate them are not well covered in Chemical Engineering curricula, not only at CMU, but to the best of our knowledge across the USA. In addition, commercial simulators do not really have advanced models for non-traditional components such as different types of biomasses. As an example, the polymer recycling processes considered in the last two years required solid processing operations which students were not familiar with; verbatim comments from the FCEs are as follows:

> "Handling of Solids for the project is really problematic when important solid separators are not taught in class."

> "... solids modeling is so difficult in ASPEN and very little was done analytically. "

As faculty, we may argue or expect senior students to be able to learn about novel operations from literature independently. However, for reasons that are not clear to us, self-learning is a barrier for our students.

Another major challenge we face when teaching the process design course is the increasing reduction of fundamental chemical engineering courses (e.g. thermodynamics, fluid mechanics, heat and mass transfer, unit operations) at the expense of the introduction of new courses. Some of these courses are related to new chemical engineering areas (e.g. biological engineering and nanomaterials) and some to general education requirements. These new courses certainly enrich students' education; however, this decrease in fundamentals impacts the design course teaching as one must cover additional basic topics that would have been taken for granted 10-15 years ago. At this point, we as instructors phase the dilemma of cutting process design material, thus lowering the educational value of the course, or phase increasingly lower FCEs as our course is perceived as being too demanding. The latter not only lowers the morale of faculty but also affects faculty's careers as in most American universities, FCEs are one of the main metrics taken into account for faculty reappointment and promotion. In our view, this trend of decrease in fundamentals could be reversed by assigning more hours per week to the design course, e.g., in our case at CMU, for example from 12 to 15 hours. This has been our de facto approach.

From our perspective, the trend in lower process design skills seems to be happening across many ChemE programs. This comment is supported by the authors' observation of our graduate student cohort, including those who come to CMU to pursue MS and PhDs in the PSE at the graduate level. Most of these students have excellent analytical skills and are very well-trained in programming. Many of them are also familiar with the use of commercial process simulators. However, a worrisome problem is that, more commonly than not, students are unable to distinguish between conceptual design and plant design or have the intuition to critically assess whether the result of a simulation makes sense or not. In terms of process evaluation, most students have been exposed to cost correlations to estimate equipment purchase costs. Still, not too many know how to go from equipment purchase cost to installed equipment cost or which terms should be included in operating expenses. We hypothesize that this might be the result of the shift from tenure to non-tenure track faculty reported in [8]. It is only those departments that have faculty in process systems engineering that a regular faculty member teaches the design course. We believe this is a worrying trend because it means that the faculty will increasingly become unable to teach this core course in undergraduate chemical engineering. We very much hope that this trend will be reversed in the future.

## ABSTRACT

The Integrated Project in the Master of Chemical Engineering and Materials Science at the University of Liège (ULiège) aims to consolidate technical knowledge and promote the acquisition of soft skills by integrating various chemical engineering disciplines. The project focus on the design of an industrial process and is divided into five parts: individual work on mass balances and literature reviews, detailed modeling of thermodynamics and key unit operations, sensitivity studies, process integration, and report to a general audience. Key learning outcomes include developing critical thinking, addressing complex multidisciplinary topics, and understanding the role of science and technology in society. Students enhance their soft skills in project management, teamwork, and effective communication in English. Regular interactions with industry and academic experts, along with support from the ULiège Soft Skills Team, ensure comprehensive development. Evaluation includes both technical and soft skills assessments, with individual and group performance contributing to final grades. This project, running for several years, is highly regarded by students for its rigorous and instructive nature, preparing them well for their future careers.

**Keywords**: Education, Process Design, Modelling and Simulations, Interdisciplinary

## INTRODUCTION

In many universities, courses are given independently of each other and it can be observed that students tend to focus on each course and each exam separately, missing the overarching links between disciplines. However, integration into applied projects of different but related disciplines (such as catalysis, reaction engineering, chemical thermodynamics, separation processes or process system engineering among others...) is key for the training of future chemical and process engineers. Indeed, most chemical processes include reaction, separation and/or purification steps, pumps and/or compressors, heat exchangers... However, modeling these is only possible with the choice of an appropriate thermodynamic method and adequate kinetics. It is thus important that students are taught these disciplines and are able to integrate them for designing a relevant and efficient process, while justifying each choice and simplification. This approach is called for by industry, international education evaluators, and often by university authorities as well [1].

The project described in the present paper forces students to consider different disciplines as part of a coherent whole necessary to solve a given process design problem inspired by an industrial case study. Previous work has shown that process design is being taught in most Chemical Engineering curricula, and that it often includes teamwork activities in addition of individual mastery of the disciplines [2]. A recent work has surveyed the practices and the usual teaching methods regarding process design, evidencing the central importance of this topic in the chemical engineering education. It also highlighted common lines but also differences in approaches among universities [3]. In this paper, we present the Integrated Project offered to chemical engineering students at the University of Liège. We first describe the general context of the project and its objectives. Then, the teaching methods for technical skills are presented following the yearly progression of the work, and a specific focus set on soft skills development is highlighted.

## PROJECT'S CONTEXT AND OBJECTIVES

This project is offered to senior students in

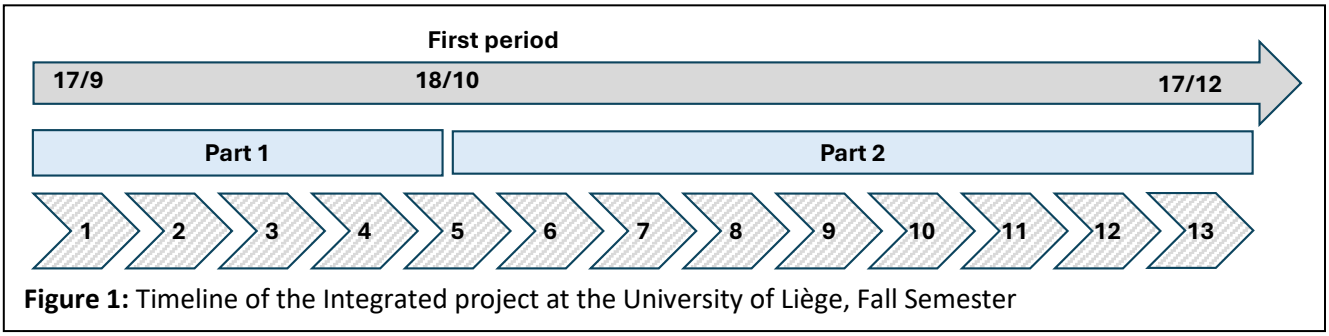

**Figure 1:** Timeline of the Integrated project at the University of Liège, Fall Semester

Chemical Engineering and Material Science at the University of Liège, i.e. a number of students usually ranging between 10 and 20. It was designed about 10 years ago and has evolved with the objective of confronting students with a less academic situation, more akin to what they will encounter in the industrial world. Groups are defined randomly, although the teaching team may intervene to make sure that the final student distribution respects some equity principles with respect to the student's background, e.g. Erasmus students are reasonably split among the groups. A new theme is proposed each year by a different industrial expert identified among the Department's network and who is accepting to provide some follow-up during the year. The initial definition is extremely broad: "propose a process to produce XX tons per year of YY product with ZZ purity." The technical key learning outcomes for the project are listed as follows [4]:

- Consolidate technical knowledge by integrating and linking the different disciplines of chemical engineering and integrate these disciplines within one unique project.
- Acquire critical thinking and ability to challenge and validate assumptions made. This includes the acquisition of a gut feeling for orders of magnitude typical of engineers.
- Address complex and multi-disciplinary topics centered on chemical industry.
- Develop knowledge about current hot topics in chemical engineering and increase the awareness about the role of science & technology in society.
- Use powers of judgment as engineers in order to work with complex and possibly incomplete information, to recognize discrepancies and to deal with them
- Recognize the need for information, find and provide information

Beyond the process design and the integration of technical skills, the development of soft skills is another major goal of this project. There, the key learning outcomes are also presented to the students, as follows [4]:

- Ability to work in large groups (between 7-12 students, random selection of members).
- Management of project and deadlines.
- Writing of technical reports in English, with written feed-back from teachers after each report.
- Communication to scientific and non-scientific audience: technical presentations to teachers, and final presentation to a larger audience with general engineering background.
- Communication in English, written and oral (all group members must talk).

The Integrated Project spans the entire academic year, from the first week of classes in September to the last week in May, with a break during the exam session from the end of December to early February. Each project is handled by a group of 6 to 12 students and accounts for 10 credits in an academic year that contains 60 credits. In this paper, we illustrate the Integrated Project of the 2024-2025 academic year, which is dedicated to the synthesis of Vinyl Chloride Monomer (VCM), a topic proposed by INOVYN.

## TEACHING METHODS

The Integrated Project is supervised by a whole teaching team gathering 7 Professors of the Chemical Engineering and Material Science + Energy Engineering curricula. A teaching assistant is present to support the project logistics (planification of teaching sessions, communication with the students…) but is not involved in the technical supervision. Additionally, a support is provided by the University of Liège's soft skills team, composed of two psychologists with experience in social psychology of groups and organizations.

Teaching methods include a few hours (about 20 hours spread over the year) of theoretical courses with Professors or external experts, but mostly group work by students and face-to-face interactions between a Professor and a sub-group of students. Plenary meetings gathering all student groups and the whole teaching team take place every month to ensure consistency and follow-up on the groups' progress. The respective share of these teaching activities depends on the moment of the

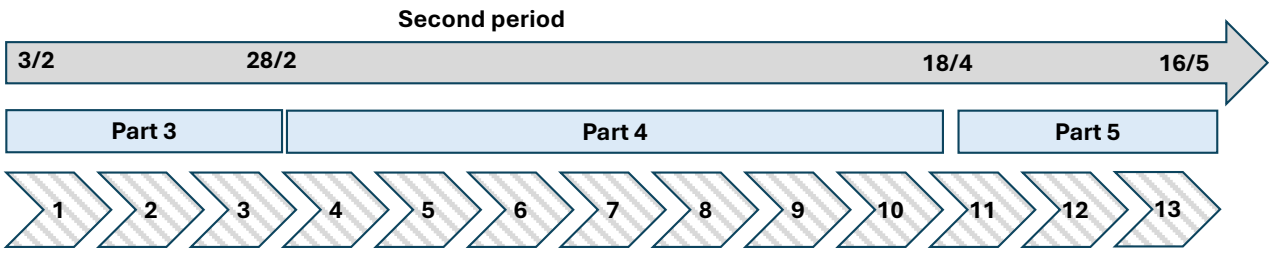

**Figure 2:** Timeline of the Integrated project at the University of Liège, Spring Semester

year and on the discipline covered at that time. The project is indeed divided into 5 parts, each concluding with a final report and presentation. At the University of Liège, an academic year consists of two semesters (two periods) of 13 weeks of classes, each followed by an exam session. The first semester starts on September 15th, and the second on February 3rd. The distribution of the different parts is presented in Figures 1 & 2.

## Part 1: Individual Work

### Individual Work on Mass Balances and Literature Reviews

In the first phase of the Integrated Project, students engage in individual work focusing successively on mass balances and literature review. This phase aims to establish a solid foundation for the subsequent stages of the project and individual deliverables (reports) are expected so that each student has to commit from the very beginning. Each student is indeed responsible for conducting a comprehensive mass balance for the synthesis of Vinyl Chloride Monomer (VCM), ensuring a thorough understanding of the material inputs and outputs involved in the process. Additionally, each student performs a detailed literature review to gather relevant information on the chemical and process engineering aspects of VCM production. This includes reviewing existing technologies, process conditions, and recent advancements in the field. The mass balance analysis as well as the literature review last respectively about 1 and 2 weeks.

### Consolidation of results and project planning

Following the individual efforts, students consolidate their findings in group sessions. These collaborative meetings are designed to integrate individual results, allowing for the identification of common themes and discrepancies. The groups then plan the next steps of the project, setting clear objectives and timelines. This phase lasts about 1 week and culminates in a presentation where students showcase their mass balance results, literature review insights, and initial process design concepts. This structured approach ensures that all participants have a robust understanding of the project's foundational elements before progressing to more complex modeling and integration tasks.

## Part 2: Detailed Models for Thermodynamics, Process Techno-Economics, Kinetics, Reactors, Separation, and Unit Operations

In the second phase of the Integrated Project, students focus on developing detailed models for key unit operations, including thermodynamics, reaction kinetics, and separation processes. This phase is crucial for understanding the fundamental aspects of the process and preparing for the integration phase.

From this second part onwards, students will freely divide into 3 different sub-groups, each of them being followed-up by a Professor:

- Thermodynamics, energy balances and process costing,
- Kinetics and Reaction Engineering
- Separation and Unit Operations

Each sub-group is responsible for a part of the project but of course, close interactions between the subgroups are necessary for the successful completion of the tasks. Regular progress reports presentations (about every 2-3 weeks) are made to share the results with the teaching team.

**Thermodynamics, energy balances and process costing:** Students begin by selecting appropriate thermodynamic models to describe the behavior of pure components and mixtures within the process operating ranges. They evaluate properties such as density, heat capacity, enthalpy, and vapor pressure. The selection of thermodynamic methods for real systems involves comparing real solution properties to ideal solutions and discussing the differences. Validation of these models is essential, requiring consistency checks based on thermodynamic relations and comparison with at least one other data source. Relevant phase equilibria for pure components and mixtures are characterized, and appropriate thermodynamic models are selected and validated with experimental data. Students also perform initial energy balances and evaluate the rough profitability of the process, creating a proper Process Flow Diagram (PFD).

**Kinetics and Reaction Engineering:** This section involves determining kinetic laws and mechanisms,

selecting catalysts, and designing reactors. Students explore kinetic laws and parameters available in the literature. They propose reaction mechanisms that align with suggested reaction rate laws and demonstrate these laws, explaining any simplifications made. The design and modeling of reactors are performed using Matlab or Python, where students establish mass and energy balances, compute concentration and temperature profiles, and evaluate yield and selectivity. Heat exchange is also considered, usually initiated by a comparison between isothermal and adiabatic approaches and followed by making the link with the types of reactors identified in the literature or from discussion with the industry.

**Separation and Unit Operations:** Students design and model separation equipment and heat exchangers. They define the separation tasks, including flow rates, compositions, and conditions like pressure and temperature limits. Using first short cut equations, then McCabe-Thiele diagrams, students determine the required number of theoretical stages and design the height and diameter of columns. They also model and size heat exchangers, considering constraints such as volume, length, pressure drop, and velocity. Preliminary designs are rated using methods like Kern and Bell-Delaware, and the results are compared to ensure accuracy.

## Part 3: Sensitivity Studies and Model Validation

In the third phase, students focus on performing sensitivity studies and validating the models developed in Part 2. This phase aims to refine the process models and ensure their robustness by evaluating the impact of key process parameters. Moreover, from a soft skills point of view, it is noted that the sub-groups are modified between phase 2 and phase 3 in line with what was announced to students at the beginning of the project. Each student is required to change topics and work with different team members, ensuring a comprehensive understanding of the entire process. This change of subgroups has several objectives. First, it is intended to foster the acquisition of new technical skills (it is not wished to form specialists in one single discipline in this course). Second, this enhances knowledge transfer as students know from Part 2 that the model they develop will be then used by others in Part 3, and it forces them to keep all other students continuously informed about their choices and difficulties. Finally, it helps developing critical thinking as students in Part 3 have to validate the assumptions and results reached by their peers in Part 2.

**Thermodynamics, energy balances and process costing:** if needed, students refine their thermodynamic models by validating the models against additional data sources and ensuring consistency with thermodynamic principles. Moreover, they gather the inputs from all subgroups into the process flow diagram that they then use to refine energy balance and profitability estimates performed in Part 2. This task also comes with the first steps towards process design optimization.

**Kinetics and Reaction Engineering:** In this phase, sensitivity analyses are conducted to optimize reactor performance, considering factors such as feed composition and operating conditions. This involves software tools like Matlab or Python to simulate scenarios and optimize the reactor design. Students also validate their kinetic models and have to identify potential mass and heat transfer limitations related to their choice of catalyst. This step is crucial for ensuring that the kinetic models are reliable and can later be used for process optimization.

**Separation and Unit Operations:** Students conduct sensitivity studies on the separation processes and unit operations designed in Part 2. They evaluate the impact of variations in flow rates, compositions, and operating conditions on the performance of separation equipment and heat exchangers. This involves using tools like Aspen Plus or Aspen Exchanger Design and Rating (EDR) to simulate different scenarios and optimize the design. Students validate their models by comparing the results with experimental data from the literature and ensuring that the assumptions made in the design are reasonable. This step helps to identify the most critical parameters and optimize the separation processes for better performance and cost efficiency. For the rating of the heat exchanger design, the work is supported by a professor from the energy engineering program, which is very instructive as it forces chemical engineering students to interact with non-chemical engineers.

## Part 4: Process Integration

In the fourth phase, students focus on integrating the various components of the process into a cohesive and optimized global flowsheet in Aspen Plus. This phase is critical for ensuring that all elements of the process work together efficiently and effectively.

**Global Process Flowsheet:** Students begin by combining the sub-models developed in previous parts into a comprehensive global process flowsheet in Aspen Plus. This involves refining the models and identifying key variables that impact the overall process performance. The goal is to create a detailed and accurate representation of the entire VCM production process.

**Optimization of Process Operating Conditions:** Students work towards optimizing the process operating conditions to enhance efficiency and reduce costs. This includes topological optimization, where the layout of the process is adjusted for optimal performance, and parameter optimization, where specific operating conditions are fine-tuned. Techniques such as pinch analysis are applied for heat integration, ensuring that energy usage is minimized, and heat recovery is maximized.

**Cost Evaluation:** A detailed cost evaluation of the

process is conducted, building on the initial assessments made in previous parts. Students analyze both capital expenditures (CAPEX) and operating expenses (OPEX) to determine the overall economic feasibility of the VCM production process. They also need to come up with a first cash flow diagram of the process that will be used to evaluate the impact of CAPEX, utilities, raw material and product price, process performances... on profitability.

**Environmental Impact and Life Cycle Assessment (LCA):** Students develop a life cycle thinking approach to assess the environmental impact of the VCM production process. This includes evaluating the process from a cradle-to-grave perspective, considering factors such as raw material extraction, production, usage, and disposal. The goal is not to perform a full LCA, but to identify opportunities for reducing the environmental footprint and improving the sustainability of the process.

**Literature Review:** An extended literature review is initiated again, now to compare the results obtained from the process models with existing data in the literature. This helps validate the efficiency and effectiveness of their VCM production process. Key Process Indicators (KPIs) such as $t_{CO2}/t_{VCM}$, $kWh/t_{VCM}$, and $t_{Cl2}/t_{VCM}$ are used for ease of comparison. Students also identify technological alternatives and potential improvements to the process, considering factors such as raw material efficiency, energy consumption, and environmental impact.

### Part 5: Report to a General Audience

In the fifth and final phase of the Integrated Project, students focus on summarizing their work and presenting it to a broader audience. This phase involves updating and validating the project's results, concluding the extended literature review, and considering the broader societal implications of the VCM production process. Regarding this last point, students consider a broader societal overview, assessing the environmental footprint, costs, raw materials use, safety, market conditions, recyclability, toxicity and alternative manufacturing pathways and product replacement solutions. This holistic approach ensures that the VCM production process is evaluated not only from a technical perspective but also in terms of its societal and environmental impact.

The final report is concise, limited to 15 pages and written in the form of a journal article for online publication (see results of the five previous years, [5]). It describes the context of the project and the technical challenge, presents a summary of the main technical results, and validates these results by comparing them to the literature. The report also includes the results of the cost evaluation and the LCA approach. It is designed to be understandable for external readers with a background in chemical engineering. A few days after report submission, students then present their findings in front of the Chemical Engineering Department of ULiège and external experts. The presentation needs to be professional yet engaging, with a maximum duration of 30 minutes per group. The presentation slides are reviewed in advance by the industrial partner to ensure that no confidential information is divulged. An industrial agreement is also required before publishing the project's final article.

Students are encouraged to present results clearly, with enough details, and discuss their impacts critically. They are reminded to follow communication guidelines for both the report and presentation, ensuring that their work is well-documented and easily understandable.

## SOFT SKILLS DEVELOPMENT

### Additional Lectures

Several "theoretical" lectures are given to students throughout the year. These lectures are either technical and aim to transfer the knowledge needed to solve the technical tasks of the project or dedicated to learning soft skills or reflection. All courses are given by a lecturer specialized in the field. Some courses are also attended by energy engineering students, enriching discussions by bringing together students from different backgrounds.

The first type of course includes process design theory (hierarchical approach), economic evaluation, heat exchanger design and introduction to LCA. These technical skills are not yet mastered by students in their first year of the master's program, but they are necessary to successfully complete the integrated project.

Other courses are also given, linked to the development of non-technical skills such as literature research or scientific writing and presentation. At the start of the project, a lecture is also given on Fermi's questions, where students learn how to solve problems by focusing on orders of magnitude as a first approach. During the fourth part of the project, when the students already have an overview of the process and are integrating all parts into a single flowsheet, an experienced chemical engineer gives a presentation on industrial project management. This session is particularly appreciated by the students, as it enables them to have a very fruitful exchange with a professional about industrial work. The final sessions organized as part of the project are two discussions on ethics and sustainability, led by ULiège's SPIRAL group. The aim of these two sessions is to raise questions and encourage dialogue and reflection on less technical subjects that are also essential for the future chemical engineers taking part in the project.

A visit to the industrial partner's production plant is also planned, usually in Spring. This visit enables students to see the equipment they have designed over the course of the year in real-life conditions, and to observe how the chemical plant operates. The visit is also an opportunity to talk to industrial partners, and to get a better idea of the day-to-day operation of the process, which

the students did not necessarily consider during process design. The visit usually lasts a day, enabling the process to be studied in detail and showing students what working in industrial companies is really looking like.

### Group Sessions with ULiège Soft Skills Team

During the year, students are supervised by the ULiège Soft Skills team. As said, this team is made up of two psychologists specialized in group management. At least five sessions are organized over the course of the year, where these specialists present the important concepts of group management, and where students can reflect and discuss about their own group dynamics. Discussion is always encouraged at these sessions, as it helps first to highlight and then to solve any problems that may arise during the year.

At the end of Part 1, the Soft Skills team helps students to build up their sub-groups based on the characteristics of each student. A session is then organized a month later to discuss how the group is functioning and to help students communicate better if necessary. At the end of Part 2, a session is organized during which the students watch the recording of their own presentation, then discuss it with the "soft skills" team and possibly a few teachers. Two further sessions are organized in the second semester, on group communication and problem-solving. At the end of the year, a final debriefing of the project is carried out with the Soft Skills team and the two teachers coordinating the teaching team. On the one hand, this debriefing enables the professors to see what the problems and positive points were, so to improve for the next year, and on the other, it helps students to summarize everything they have learned over the year and realize what their abilities and problems were. This forms a good basis for future group work, which they will most probably have in their careers. The Soft Skills team is also always available during the year to help students with any problems they may have, either as a group or individually.

These sessions are also used to discuss the student's peer-evaluation. Part of the final grade for the project is indeed awarded to this assessment done in groups (for details of the evaluation methods, see [4]). This evaluation is based on a discussion between the students, supervised by the Soft Skills team. A grade is assigned to each student, which is then approved by the whole group. This assessment is new from 2024-2025, and replaces the usual peer assessment that was done by each student individually. The aim here again is to open a discussion on each student's work and contribution to the life of the group, and to discuss each student's contributions and shortcomings to give constructive feedback on his or her contribution to the group's work.

## CONCLUSION

The Integrated Project in the Master of Chemical Engineering and Materials Science at the University of Liège offers a unique opportunity for students to develop both technical and soft skills essential for their future careers. By working on industrial case studies, such as the synthesis of Vinyl Chloride Monomer (VCM) this year, students face real-world challenges that prepare them for complex industrial situations. The project emphasizes the integration of chemical engineering disciplines, detailed process modeling and optimization of operating conditions, while considering economic and environmental impacts. Regular interactions with industry and academic experts, along with support from the ULiège Soft Skills Team, ensure comprehensive student development. In conclusion, this rigorous and instructive project is highly valued by students and provides solid preparation for their professional future.

## ABSTRACT

This paper examines the current state of green and digital integration in traditional chemical engineering education, focusing on how artificial intelligence (AI) can enhance learning. A review of curricula shows that sustainability principles, such as green chemistry, circular economy, and resource efficiency, are often confined to electives rather than core courses. Likewise, digital skills are introduced at a basic level, with limited exposure to AI, especially machine learning, and advanced process optimization. The paper emphasizes the need for a structured approach to integrating sustainability and digitalization into core subjects, supported by interdisciplinary learning. It also explores AI's role in transforming education, particularly in predictive modeling, process optimization, and adaptive learning. The study provides recommendations for redesigning the traditional chemical engineering curriculum to strengthen green and digital transformation.

**Keywords**: Education, Artificial Intelligence, Optimization, Green Transition, Digitalization

## INTRODUCTION

The mission of chemical engineering higher education, particularly computer-aided chemical engineering, is to equip students with the knowledge and skills they need to drive the green and digital transformation. The EFCE Bologna recommendations emphasize data management and digitalization tools as fundamental components of informatics in the first cycle and place a general focus on digitalization at the second cycle [1].

While chemical engineering programs certainly include elements of green and digital engineering, their systematic integration into core subjects is often implicit, making them less visible to students and industry [2]. In fact, the definition of what 'green content' entails is not precisely established. It can encompass the formal 12 principles of green chemistry [3], the 12 principles of green engineering [4], and the 17 sustainable development goals (SDG) [5], as well as more specific topics such as the circular economy, industrial symbiosis, environmental protection, production technologies with reduced environmental impact, sustainable materials and catalysts and related areas.

The curriculum analysis at our institution shows that only a few green engineering principles, such as maximizing efficiency and integrating energy flows, are explicitly covered. Others appear indirectly through case studies but lack systematic integration. Digital skills are mostly limited to spreadsheet-based data processing, basic programming, and process simulation and optimization. Green and digital topics are explored more deeply in project work, advanced studies, electives, and final theses.

Artificial Intelligence (AI), a key driver of digitalization, presents an opportunity to enhance both digital and green engineering education. It is already significantly impacting education by transforming teaching methods and driving advancements in chemical engineering curricula, especially in PSE/CAPE related courses. However, the interdisciplinary complexity of AI poses challenges, as students need a solid foundation in programming, data science, and statistics, and more importantly, they should acquire skills for the right comprehension and interpretation of solutions they obtained using AI tools. For effective integration, AI should be introduced gradually [6], balancing technical skills with critical thinking, creativity, and ethical awareness while maintaining core engineering fundamentals.

This article examines the readiness of higher education institutions to equip chemical engineering

students for the digital and green transition, along with the challenges they face and the strategies they employ to address them.

## CHALLENGES AND CONCEPTS FOR GREEN AND DIGITAL TRANSFORMATION

The main challenge of our society is how to efficiently and effectively address severe global issues—population growth, depletion of non-renewable resources, and environmental and societal degradation. The community strives for sustainable development in general, with a particular focus on sustainable chemical and biochemical industries. To reverse the negative climate trends, the European Commission launched the European Green Deal in 2020 [7] and initiated the foundation of the European Climate Pact [8], with the main goal of making the EU climate-neutral by 2050. Probably the two main related topics are green and digital transformations, which are happening in the EU at an increasing pace, demanding faster and faster economic, social, and personal adaptation. This brings a need for the continuous refinement of the education system, focused on more efficient teaching methods and the introduction of relevant topics and outcomes that students should acquire to be able to face current and future professional challenges.

At the level of the European Federation of Chemical Engineering (EFCE), this transformation is managed through 20 working parties (WPs). The Education WP is primarily focused on teaching methods, topics, and outcomes, while the CAPE WP concentrates on the development and application of process systems engineering (PSE) concepts, algorithms, modelling, and tools. Additionally, there are seven sections, with the Energy and Sustainability section predominantly focused on green transformation.

To cope with current challenges and needs, EFCE recently issued a renewed recommendations for chemical engineering study programs, the EFCE Bologna Recommendations 2020 [1], which can serve as a guide for developing new or adapting current study programs. It can also be used by professionals to assess their missing knowledge and skills, helping them identify areas for their supplementary lifelong learning.

The programming outcomes follow an arrangement introduced by the EUR-ACE® Framework Standards [9], from knowledge to understanding, engineering analysis, engineering design, investigations, engineering practice, making judgements, communication and team-working, and lifelong learning, structured hierarchically over the first and second cycles by applying Bloom's taxonomies. As the first cycle typically provides students with basic knowledge and skills, the first four taxonomy levels are predominantly in place—knowledge, comprehension, application, and analysis. The second cycle aims to deepen knowledge and skills by incorporating synthesis and evaluation. At the doctoral (third) cycle, it is evident that the highest levels should be applied, enabling students to develop new knowledge and innovative skills for novel engineering applications or enhancing existing ones.

The traditional basic structure of higher education chemical engineering core curriculum [10] is sketch on Figure 1 in black colour. It starts with fundamentals of science and natural sciences like mathematics, physics and chemistry, continuous with engineering fundamentals based on mass and energy balances, transport phenomena as well as separation and reaction engineering and process control. At the second cycle, a process systems approach is introduced, with the primary learning outcome being the synthesis of knowledge in subjects such as process design, dynamics and optimization, culminating in the student project course. The doctoral level is dedicated to generating new knowledge through the application and advancement of cutting-edge methods, as well as the development of novel approaches based on computer-based chemical engineering.

Green, sustainability, and circularity, also regenerative principles related to chemical engineering study programs, are listed together with the four basic components and five branches of AI in Table 1. The reader can find a more detailed description and explanation in the given references. The challenge is how to integrate the principles and AI components into chemical engineering study programs and to what extent. Some principles are simple, others complex, and all interrelated, with varying complexity across AI components. For teaching and study, they should be hierarchically classified using Bloom's taxonomies.

## INTEGRATING GREEN AND DIGITAL TRANSFORMATION IN CHEMICAL ENGINEERING EDUCATION

Transforming the traditional chemical engineering curriculum to equip graduates for the demands of a green, digital, and resilient economy is a critical challenge. Larger universities with substantial student populations have addressed this by establishing specialized programs or modules such as Data Science in Chemical Engineering (Purdue), Machine Learning in Process Engineering (Imperial College), Chemical and Biochemical Engineering (DTU) to mention just a few. They pilot AI-driven projects, including digital twins for process control, machine learning for experiment optimization, neural networks for predicting thermodynamic properties, among others. Smaller institutions, meanwhile, must integrate these topics into existing courses.

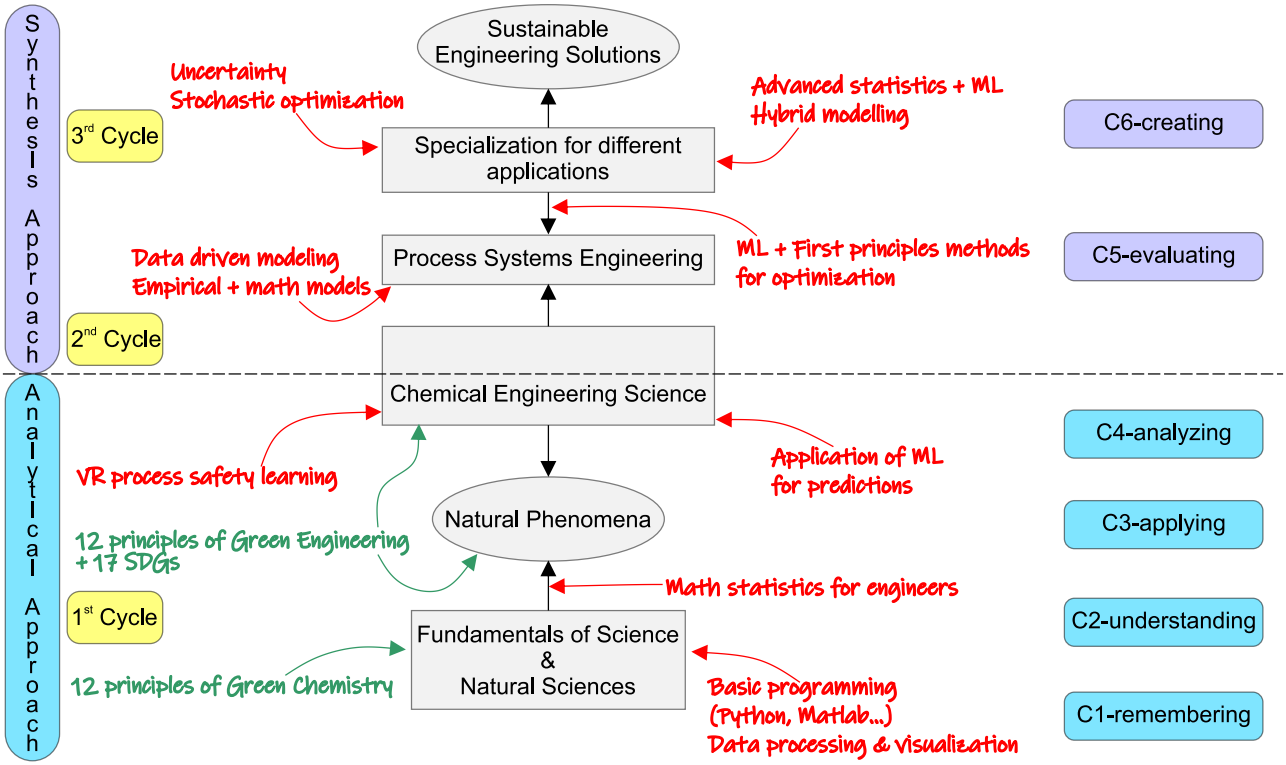

**Figure 1:** Traditional chemical engineering core curriculum (black), upgraded for green (green) and digital transformation (red). Bloom's taxonomy: Analytical Approach (C1-C4), Synthesis Approach (C5-C6)

**Table 1**: Green, sustainability and circularity principles, and basic components and branches of AI

| | |
|---|---|
| Principles of green chemistry [3] | i) Prevention, ii) atom economy, iii) less hazardous chemical syntheses, iv) designing safer chemicals, v) safer solvents and auxiliaries, vi) design for energy efficiency, vii) use of renewable feedstocks, viii) reduce derivatives, ix) catalysis, x) design for degradation, xi) real-time analysis for pollution prevention, xii) inherently safer chemistry for accident prevention |
| Principles of green engineering [4] | i) Inherent rather than circumstantial, ii) prevention instead of treatment, iii) design for separation, iv) maximize efficiency, v) output-pulled versus input-pushed, vi) conserve complexity, vii) durability rather than immortality, viii) meet need, minimize excess, ix) minimize material diversity, x) integrate material and energy flows, xi )design for commercial "afterlife", xii) renewable rather than depleting |
| Engineering sustainability principles [11,12] | i) Contribute to building a sustainable society, present and future, ii) apply professional and responsible judgement and take a leadership role, iii) do more than just comply with legislation and codes, iv) use resources efficiently and effectively, v) seek multiple views to solve sustainability challenges, and vi) manage risk to minimise adverse impact to people or the environment. |
| Core circularity principles [13] | i) Eliminate waste and pollution, ii) circulate products and materials, and iii) regenerate nature |
| Basic AI components and branches [14] | *Components*: i) learning, ii) reasoning and decision making, iii) problem solving and iv) perception<br>*Branches*: i) machine learning, ii) deep learning, iii) natural language processing, iv) robotics and v) fuzzy logic |

Several decades ago, bioengineering and other life science related courses, such as biochemistry, biotechnology, bioreaction engineering, biocatalysis, microbiology, genetic engineering etc., were thoroughly integrated into traditional chemical engineering curricula. However, green content remains largely absent in core courses like transport phenomena, materials, process design, control, and optimization. Illustrative examples in these areas continue to focus predominantly on base industries, which are largely fossil-based.

Digitalization in curricula has been limited to basic tools, such as spreadsheets, introductory programming, process simulation or optimization based on first-principles models using software like Aspen or GAMS. Basic

statistical concepts, including hypothesis testing, receive little attention. Topics like artificial intelligence and its subsets (e.g., machine learning, digital twins) are almost entirely absent at the first and second levels. The same applies to other emerging technologies, such as the Internet of Things (IoT) and blockchain, except for the occasional use of generative AI for text writing. Topics like environmental protection, sustainable development, and the circular economy are primarily confined to elective courses, student projects, and final theses.

The foundational textbooks for chemical and process systems engineering, primarily written in the 1970s and 1980s, remain staples in chemical engineering education, while those on the green transition and digitalization are scarce. This lack of resources has slowed the integration of these emerging topics into curricula. Meanwhile, the shift from traditional textbooks to digital learning platforms for self-paced learning of digital content is becoming increasingly evident.

Group of experts identified key areas for integrating machine learning into research and industry, including materials and catalyst design, industrial analysis, process dynamics and control, and optimization [15]. The challenge lies in selecting suitable courses and defining graduates' roles, whether as users or developers of machine learning tools. Given the field's interdisciplinary nature, they must master both traditional engineering principles and essential digital skills for the future [16].

To tackle these challenges, we present examples of how green chemical engineering and digitalization can be integrated both vertically and horizontally into selected traditional courses (green and red in Figure 1), aligning with key topics from the EFCE Bologna Recommendations [1]. This list is not exhaustive; the examples serve as initial suggestions, and we encourage readers to contribute ideas to enrich the discussion. We advocate integrating the proposed topics into existing subjects instead of adding numerous new courses, as shown in the following examples. A modular approach with pilot projects, electives, and project-based learning allows a gradual transition without overwhelming faculty and students.

## Fundamentals of science and natural sciences

Chemistry, physics, and bio-courses should explicitly incorporate all 12 principles of green chemistry into the curriculum, ensuring their clear visibility and practical applications.

Computer programming should include an introduction to a general-purpose programming language, e.g. Python, computing platform, e.g. MATLAB, and preferably also modelling environment, e.g. GAMS along with fundamental libraries for data visualization. It should also cover basic machine learning models, such as linear regression and decision trees, with applications in engineering problem-solving.

Mathematical statistics for engineers should cover hypothesis testing, regression analysis, statistical inference, and data analysis for process monitoring and optimization.

## Chemical engineering fundamentals

These courses need to identify ways to explicitly emphasize the 12 principles of green engineering, the 17 SDGs, as well as more advanced principles of circular, restorative and regenerative economics.

Process balances should incorporate the visualization of mass and material flows using modern tools like Sankey diagrams. It should also include the formulation of mass balances for recycling and material reuse processes, emphasizing closed-loop systems and minimizing material losses.

Heat and mass transfer should focus on developing predictive models to evaluate efficiency, integrating experimental data with machine learning algorithms. It should include, for example, the use of recycled insulation materials, supported by case studies on energy efficiency improvements. Additionally, it should explore waste heat recovery technologies in industrial settings.

Thermodynamics should incorporate the application of machine learning for predicting thermodynamic properties of fluids, phase equilibria, and chemical reaction equilibria. It should also integrate data-driven models with classical thermodynamic equations of state to enhance prediction accuracy.

Separation processes should incorporate the use of digital twins to simulate and optimize distillation, absorption, and extraction processes. It should also include case studies on energy-efficient separation techniques.

Reaction engineering should include the prediction of reaction kinetics based on experimental data using data-driven models. It could also integrate advanced algorithms to optimize reactor design and operational conditions, with a focus on sustainable reaction pathways.

## Core chemical engineering applications

Chemical process safety could integrate operator training in virtual reality (VR), root-cause analysis to enhance emergency response planning and risk mitigation, and blockchain for secure data management, compliance tracking, and supply chain transparency.

Process optimization for chemical engineering at first cycle should include not only single-objective linear and nonlinear optimization but also statistical analysis, multivariate analysis, multi-objective optimization, and data-driven modeling of complex phenomena and units. It could introduce the integration of such empirical models with mathematical models to improve process efficiency.

## Process systems engineering

Process dynamics should encompass mechanistic,

data-driven, and hybrid models, considering both continuous and discrete data due to digitalization. Analysis can be performed using dynamic simulators, computing platforms (e.g., MATLAB, Mathematica), or general-purpose languages like Python. From a control perspective, classical linear controllers, model-based approaches, and AI-driven strategies for nonlinear control should be explored. Additionally, machine learning can enhance adaptive control, real-time fault detection, predictive maintenance, and forecasting.

Process design could incorporate machine learning for selecting optimal process flowsheets, including tools for generating alternative solutions that minimize waste and energy consumption. It should also emphasize life cycle assessment (LCA) to evaluate the environmental impact of different design options.

Advanced process optimization should encompass mixed-integer linear and nonlinear programming, integrating first-principle models with machine learning models to enhance predictive capabilities. It should incorporate multi-objective optimization techniques linking statistical techniques with process optimization for sustainable and efficient system design. The PhD level could explore stochastic optimization methods that incorporate uncertainty quantification and probabilistic modeling.

## PERSPECTIVES AND CHALLENGES OF ARTIFICIAL INTELLIGENCE IN CHEMICAL ENGINEERING EDUCATION

Artificial intelligence (AI) is transforming industry and academia, making its integration into chemical engineering education essential. Tailored approaches for undergraduate and graduate programs maximize the potential of AI while addressing the specific challenges.

At the undergraduate level, the introduction of AI tools can enhance fundamental chemical engineering subjects such as thermodynamics, reaction engineering and process control. The benefits of integrating AI at this stage are many. Students are exposed to cutting-edge technologies early on, which improves their problem-solving skills and prepares them for the demands of industry. In addition, AI can personalize learning through adaptive educational platforms and allow students to address their weaknesses in core subjects. However, challenges include the steep learning curve of AI tools and the risk of students relying too much on algorithms without grasping the underlying principles of chemical engineering. A recent study on implementation of generative artificial intelligence in chemical engineering education [17] clearly indicates that a balance between traditional engineering principles and AI applications is crucial to avoid such pitfalls. For lecturers, the inclusion of AI requires curriculum redesign and professional development to ensure effective teaching. Lecturers need to be able to handle AI tools themselves and contextualize their applications in chemical engineering. This increases their workload but also provides opportunities for collaborative research with students on AI-driven projects, which encourages academic innovation.

At the graduate level, AI can drive specialized research and innovation. Advanced topics such as data-driven modeling, optimization, and predictive maintenance can be integrated into courses. The benefits of AI at the graduate level go beyond skill development and also foster interdisciplinary collaboration. Graduate students can work at the intersection of AI, chemistry and engineering, exploring novel solutions to industry challenges. However, there are still pitfalls, such as the possibility of over-fitting models or misinterpreting AI-generated results due to an insufficient understanding of the principles of data science. This requires a solid foundation in statistics and programming, which may require additional courses or self-directed learning. For educators, integrating AI at the graduate level provides an opportunity to advance their research agendas and obtain funding in emerging fields. However, it also requires significant effort to keep pace with rapidly evolving AI technologies and their applications. Collaboration between faculty in chemical engineering, computer science and data science departments can alleviate some of these challenges and promote a holistic approach to AI education.

Looking to the future, the role of AI in chemical engineering education is poised to grow. Advances in generative AI, real-time data analytics, and digital twins will continue to transform the curriculum. Students will be able to interact with AI tutors, design processes in virtual environments and contribute to AI-powered research projects. While these developments are very promising, ethical considerations, such as data privacy and algorithmic bias, must be carefully considered. It is clear that integrating AI into the chemical engineering curriculum represents both a challenge and an opportunity. By thoughtfully incorporating AI tools into the undergraduate and graduate curriculum, educational institutions can prepare their students to lead and shape the future of chemical engineering and raise a generation of engineers who are not only technically proficient, but also adaptable and innovative.

It is not difficult to imagine all the benefits that digitalization and artificial intelligence will bring to the learning processes in chemical engineering. From the students' perspective, these will certainly include personalized learning with an increasing presence of virtual reality. This ranges from digital twins of the phenomena and processes studied to digital twins of entire courses and eventually even the lecturers — why not? From the lecturers' perspective, before we are replaced by digital twins, AI will enable data-driven curriculum

improvements, advanced teaching materials with virtual and augmented reality demonstrations, early warning systems to detect student learning difficulties, and curriculum progress tracking, among other things.

However, it is important to emphasize that due to digitalization and/or artificial intelligence, it will be crucial for chemical engineering students to acquire sound skills in data processing (e.g. data mining, data crunching and pre-processing, understanding data bias and variability, feature engineering, ethical and legal considerations, etc.) as well as in processing, analysis and, most importantly, in assessing the validity and significance of the results obtained.

## CONCLUSION

This study highlights the lag in integrating green and digital competencies into the core chemical engineering courses. Systematic teaching materials, both traditional and digital, are essential for educators and students. As a novel approach, we propose the incorporation of green and digital content across the entire vertical structure of chemical engineering education, aligned with EFCE Bologna recommendations—spanning from fundamental sciences through chemical engineering principles to process systems engineering. To support this transition, we encourage the development of common guidelines, e.g. by EFCE, EURECHA or other professional associations, enriched with clear instructions for embedding green and digital competencies into chemical engineering curricula, equipping future engineers with the necessary skills to drive sustainable and digital transformation.

## ABSTRACT

The field of Process Systems Engineering (PSE) is undergoing a renaissance through the integration of artificial intelligence (AI) and machine learning (ML). This transformation is driven by the vast availability of industrial data and advanced computing power, enabling the practical application of sophisticated ML models. These models enhance PSE capabilities in design, control, optimization, and safety. The progress of ML and ever-present data collection address previously intractable problems, particularly in system integration and life-cycle modeling. ML-powered predictive algorithms are augmenting traditional control systems, showing potential in supply chain optimization and increasing operational resilience. Additionally, ML-driven fault prediction and diagnostics are enhancing process safety systems, allowing for predictive maintenance and minimizing risks of accidents. A case study of the collaboration between the University of West Attica and Helleniq Energy through the MSc program in Oil and Gas Process Systems Engineering showcases the practical application of advanced technologies and knowledge transfer, emphasizing the importance of blending AI with traditional PSE education.

**Keywords**: Artificial Intelligence, Machine Learning, Education, Knowledge Transfer, Oil and Gas.

## INTRODUCTION

The field of process systems engineering (PSE) has long been characterized by a deep theoretical foundation. Pioneers like George Stephanopoulos [1] and David Himmelblau [2] laid the initiative. A lot of other researchers have laid the groundwork, exploring the potential of early artificial intelligence (AI) concepts to model and optimize complex industrial processes. However, these ambitious ideas often outstripped the available computing power and the quantity and quality of data. The models were constrained, not by theory, but by practical limitations. Today, the situation is dramatically different. The confluence of vast industrial data repositories and highly accessible cloud computing has created a fertile ground for the practical application of sophisticated machine learning (ML) models augmenting PSE modelling capabilities. This is driving a renaissance in PSE, transforming how we approach design, control, optimization and safety within the process industry.

### The Dawn of Data-Driven Process Systems Engineering

The maturation of ML, combined with ubiquitous data collection, allows for previously intractable problems to be addressed. The most intractable problem in PSE is the integration of systems in a life-cycle model of the process.

In PSE, the focus is shifting to two key areas:

1. Advanced Control and Optimization
2. Fault Detection and Diagnosis or Enhanced Process Safety and Reliability

A description of this trend as expressed by academia can be found in [12], [13].

### Advanced Control and Optimization

Traditional control systems, typically implemented on Distributed Control Systems (DCS) and Advanced

Control Systems (APC) using real-time operating systems, are being augmented by ML-powered predictive algorithms. These algorithms, often implemented as neural networks and deep learning architectures, can handle the complexities of large-scale systems more effectively than classical methods. While full plant-wide optimization remains a challenge, progress is being made in areas such as supply chain optimization. This is supported by research and industrial adoption, showing a clear potential to boost efficiency, reduce costs and increase operational resilience. Academic institutions (see for example [5]) are actively researching supply chain optimization using ML, seeking to understand how algorithms can predict demand, optimize production scheduling and manage inventory effectively. This area showcases a clear transition towards more intelligent manufacturing and is currently being implemented on pilot scales within various industries.

Reluctance of market participants has resulted in applications which have different origins towards autonomy (mostly arbitrary and team driven).

In the area of Reinforcement learning controls there are examples of:

1. Off-line reinforcement learning optimization (AIO) by IMUBIT (www.imubit.com)
2. Other similar to IMUBIT partial efforts toward real time AI augmented optimization (YOKOGAWA- KBC, ASPENTECH, C3.AI etc.) depending on the application.
3. Online gain adapting controllers by Honeywell, ExxonMobil and Yokogawa.

Information currently can be obtained mainly by their patents and traced back to theory as the descriptions are usually very detailed and can be easily compared with Google Reinforcement Learning (RL) models or among them all [8], [9], [10], [11].

It is very much of a coincidence indicating the difficulty of the problem that Anderson controller described in [2] is also tested today by some companies like Honeywell and Yokogawa in laboratory environments.

Of course, this list is by no means exhaustive but gives the dynamics of the problem, i.e very few companies are involved because of the difficulty of the subject but the development thrives in this area (there are patents and products). Note that development is mostly associated with academia for all the above companies.

## Fault Detection and Diagnosis or Enhanced Process Safety and Reliability

Process safety systems, implemented on Programmable Logic Controllers (PLCs) and also known as Interlock or Emergency Shutdown Systems, are now being enhanced with ML-driven fault detection and diagnosis. Most of industrial applications are given as ad-hoc cases for special equipment e.g. furnaces, compressors, mixers or individual unit emergency s/d. Details can be found in [6] on the internet. While still ad-hoc, a systematic Abnormal situation management system is of paramount importance as described for example in [7]. Comparison in [7] of 7 methods with 10 criteria concludes that no one can serve more that 70% of the criteria and no criterion can be served by more than half of the methods. This adds to theoretical complexity as much as safety requirements add to the implementation of the methods. For example, explainability criterion clearly can be fulfilled by expert systems but not by neural networks. Alternatives to these criteria are still evolving.

Fault Detection and Diagnostics (FDD) in reliability is especially impactful in asset performance management, where ML is used to predict failures in rotating machinery and other critical assets. Predictive maintenance allows companies to take proactive measures, minimizing the risks of accidents and avoiding production losses by maintenance planning. ML algorithms learn from sensor data (vibration, temperature, pressure) to identify patterns indicating potential failures, enabling preventive maintenance interventions. This is vital for preventing catastrophic events and ensuring a smooth production process.

Currently there are vast alternatives for predictive maintenance applications and large machinery equipment provide ML software as a standard part of their machines (for monitoring by both client and manufacturer). Still reinforcement learning equipment switching is not provided yet to the clients.

Most market participants employ ML for advice to operations with statistical ML methods, providing ML libraries (in edge i.e. field computers) with particular case studies.

An important field for continuous plants is the ML augmented procedural automation standards (ISO 106) and implementations which automate the step-wise procedures required in starting-up and shutting-down.

## The Challenges of Interdisciplinary Integration

While the potential benefits of ML in PSE are clear, several significant challenges hinder its widespread adoption. These challenges mainly concern education at any level (undergraduate, postgraduate, continuing). This problem has been already pinpointed e.g. in [4] by defining a partial role of a “process data scientist”. Also, in [3] where it is noted that there is a tendency to rush off and teach courses that are cookbook-style offerings, where students learn to mechanically apply different software packages without a deeper understanding of the fundamentals knowing not only how to apply but also why to apply.

Currently with a relatively narrow industrial application environment a bonus starting point is also “where to

apply" with industrial applications guiding theoretical analysis efforts with a dynamic curriculum.

The integration of PSE with ML and data engineering presents a triple challenge:

1. Understanding Process Systems Engineering Fundamentals: The first challenge resides in the complexity of PSE itself, requiring a deep understanding of chemical, physical, and thermodynamic principles. This alone is a demanding discipline. Students need a robust foundation in process modeling, simulation and control theory to grasp the notion of industrial processes.

2. Mastering Machine Learning Techniques: ML, while powerful, is also a complex discipline that requires familiarity with statistical modeling, algorithm design and optimization. This understanding is paramount for applying ML correctly and understanding its limitations, ensuring that ML is being used in a suitable way and not only as a black box.

3. Developing Data Engineering Skills: The sheer volume of data generated by modern industrial processes demands a proficiency in data engineering. This involves skills in database management, cloud computing, data preprocessing, data architecture and data governance. Without the ability to effectively handle and structure data, advanced ML algorithms cannot reach their full potential.

These are three distinct disciplines, each with its own language, frameworks and modes of thinking. To fully leverage the power of ML in PSE, there needs to be a convergence of these disciplines, and reframing of classical engineering principles to incorporate the new methodologies. This requires a shift in education methodologies, moving past siloed subjects and into an integrated approach.

A similar shift is expected from an industry point of view because of low inventory of both experience and head count. Both represent hurdles which can be surpassed by educational means only and beyond classical business measures per se.

## The Need for Rapid Adaptation

The pace of technological change demands that the PSE field adapts quickly. While new generations, are adept at hands-on learning and readily embracing new technologies, seasoned engineers may find this transition overwhelming. The ability of companies and academia to adapt to the changes of incorporating the new technologies and the development of novel talent will be the main factors for the survival of businesses in the coming years.

Evolution of similar systems like APC may predict that AI will mature in the next decade (50 years as other PSE systems).

Having noticed that, it is also clear that the arguments expressed for AI in [1] in 1986 are still valid:

1. Limited by complexity 1986 – Still a problem in 2025
2. Limited by computing power 1986 – Still a problem for combinatorial or factorial size processes in PSE.
3. Limited by data (Industry is not mature) 1986 – still a problem but Digital transformation is underway, and data quality is an issue followed by data marketing problems.
4. Not existing market pull (conceptually successful, implementation and workflow limited) 1986 – Still a problem if AI hype is removed but cloud facilitates development. ML for PSE might help but General AI for PSE is rather not yet. AutoML slowly evolves to be an option for ad-hoc model building.
5. High hanging fruits for the period 1986– Multivariable Predictive Control took over the low hanging fruits 1995-2005 – Still a problem in 2025 to maintain MPC apps and a new high hanging challenge is integration of MPC with Scheduling and Supply chain Optimization on a theoretical and practical ground.

The rapid adaptation of AI by the companies and academia is required because of the momentum of Digital transform. As an example of such efforts, currently, a change management project supports the digital transformation of the Helleniq Energy Group, introducing an extensive training program for engineers and technical personnel. More than 12k manhours training in 2023 and approximately 30k manhours training for 2025, are spent for several digital transformation tools applications (Asset Management, Digital OPS/HSE, HC Supply Chain, Energy Management Cyber Security etc.). This momentum was not present in the distant 1986 or even 2016 and presents a large factor of evolution.

Still, the development of theory is not yet complete and Autonomous plants are a distant vision.

## Future Trajectory: Plant-Wide Intelligence

The future of AI in PSE lies in the development of intelligent plant-wide optimization and fault detection and diagnosis models.

A partial example is discussed in [5] where academic and industrial experience have put reinforcement learning methods in chemical plant scheduling. Operations continue with these models for years already.

These systems will leverage ML to optimize every aspect of the production process, from resource allocation to energy management and maintenance, and provide real-time diagnostics, enabling highly reliable operations.

# A CASE STUDY IN COLLABORATION: ACADEMIA AND INDUSTRY PARTNERSHIP

The Master of Science Postgraduate Program (MSc)

"MSc in Oil and Gas Process Systems Engineering" began its first cycle in April 2019. The MSc is implemented by a scientific team from the Department of Mechanical Engineering at the University of West Attica (UNIWA), who have significant and long-standing experience in reputable postgraduate programs in the energy field, with the support of Hellenic Petroleum and, until recently, the Aspropyrgos Municipality.

The Program, which awards a Master of Science - MSc in Oil and Gas Process Systems Engineering, focuses on:

- Industrial systems and hydrocarbon processing (H/C),
- Production, storage, supply chain of liquid and gaseous hydrocarbons, and
- Optimization of processes and production planning/control of hydrocarboNIns.

The MSc is a full-time program, lasting four (4) academic semesters, equivalent to 120 ECTS, and includes:

- Attendance of ten courses (out of 13 offered in total),
- Completion of a research master's thesis, and
- Completion of a two-month internship in an industry or organization.

Currently, one hundred students are being trained, while many of the MSc instructors come from Helleniq Energy Group: over twenty subject matter experts - production and process engineers with PhD teaching courses such as Basics of Refinery Operations, Process Safety, Natural Gas Processing - Transportation and Distribution, Supply Chain Management in Oil and Gas Industries, Optimization and Decision Making in Oil and Gas Process Industry, etc. This is a unique competitive feature as it transfers genuine knowledge and valuable real-world experience to the MSc students. This is especially pronounced during their thesis preparation, where the collaboration becomes even closer with the allocation of industrial research subjects to be investigated by the students.

From the highly successful course of the Postgraduate Program so far, it is concluded that there are excellent prospects for further development. In the next steps, the Postgraduate Program will design fully English-taught courses to meet the educational needs of company executives and hydrocarbon organizations abroad. Today the Course is bilingual, with teaching to be carried out in Greek but the Assignments, Dissertation and most of the educational material to be in English. Additionally, already implemented activities that will be further strengthened in the Program include scheduled lectures by field experts, as well as selected high-specialization and know-how seminars. The program runs exclusively with the physical presence of students and instructors/professors. However, recent COVID experience had inspired the preparation of e-learning material. Therefore, some of the highly specialised or wide interest courses may also be carried out in distant mode, allowing wider participation from executives of hydrocarbon companies and local municipalities.

With the expansion of Helleniq Energy Group's activities into other energy fields (RES, green hydrogen production) and its pioneering role in energy issues beyond Greece, joint actions with the laboratories of UNIWA, which also have a long history and specialization in modern energy issues, can be expanded.

This article highlights the ongoing collaboration between the Helleniq Energy, the largest energy company in Greece and a leading university UNIWA. This partnership is facilitating the transfer of knowledge in the practical implementation of advanced technologies through postgraduate and potential doctoral programs. These programs will enhance the understanding of novel AI implementation within the process industry.

The collaboration provides real-world industrial data for testing and implementation, promoting the education of students by offering a unique insight to the real application of the academic taught principles and enabling faster adaptation for the industrial partners.

This type of collaboration acts as a catalyst, accelerating the implementation of innovative AI solutions within industry, while also enabling a deeper theoretical understanding for all sides involved.

## Practical aspects of the case study

The artificial intelligence has been introduced in both UNIWA and Helleniq Energy with a pace corresponding to Helleniq Energy Digital Transformation so that firm steps are presented to the students as a supplement in particular courses. A faster pace would be possible but was deemed overwhelmingly evolving and difficult to bottle in a comprehensive course. A significant feature of the process is that AI is a bridge between fossil fuels technology and green fuels technologies enabling the persistence of the latter reducing costs and improving efficiency which enables energy transformation. So, digital and energy transformation go hand in hand and AI is augmenting capability down this path.

Furthermore, and in addition to initial efforts, a course in AI is planned with considerations from all involved subjects. The MSc program evolves and targets AI-augmented contemporary industrial needs.

## AI lectures in MSc program: already in place

Methods for exploiting and utilizing the readily available data are presented in various modules of the MSc course. The most extensive and systematic amalgamation of conventional engineering approaches with novel data-driven techniques, is found in the “Advanced Process Control and Digital Transformation” module, that contains lectures, tutorials, as well as a reverse MATLAB PC-lab, which is split between control systems synthesis and analysis, and ML methodologies. Namely, although the module focuses on real-world control systems, both

classical and advanced, it also entails lectures on measurements and real-world data-cleaning, ML (supervised, unsupervised, reinforcement learning), ensemble methods and actual case studies. A couple of reverse labs are on supervised learning and reinforcement learning. The agile methodology is introduced, to break the project into phases and emphasize on the continuous collaboration and improvement, by following a cycle of planning, executing, and evaluating. The goal of this approach to teach Process Control through a modern prism, is to provide students with practical skills and foster real-life intuitions.

Current efforts focus involve a number of seminars on the subject at hand:

1. A Seminar on the application of statistical modeling in maintenance. A predictive maintenance (and asset management in general) related subject outline, the theory and ML methods used as well as the target and scope of Industrial applications. The predictive maintenance applications of Helleniq Energy are discussed as examples of applications.

2. One Seminar on the application of reinforcement learning in Control and Scheduling applications with an outline of the methods used. These two areas of PSE have distinct scientists in both academia and industry and completely different understanding depending on the origin, be it control or scheduling. Again, examples of blending and unit operations (FCC unit) of Helleniq Energy are used from the control point of view with examples in MATLAB. In the future the Scheduling point of view will be incorporated.

3. A Seminar after supply chain and process design courses for supply chain integration. The focus is on historical evolution of machine learning especially in PSE but also recent advances, Process monitoring examples, emphasis on better quality inference with ML, reinforcement learning theory and current use in the industry, fault detection and diagnosis not only in predictive maintenance but in all process, equipment rotating or static and finally operating procedures (start-up, shutdown)

4. A seminar focused on non-technical aspects of AI as it is applied in Refinery unit optimization. For non-technical people reading the press, there is a lot of simplifications and analogies for AI and ML which are misleading. Also, General AI in PSE or even AI is rather just an intention yet (2025). A grounded fact is ML for PSE. So, there is a need of specifying where and how existing systems are augmented and how the augmentation would produce benefits without the need for programming or Machine learning fundamentals.

### AI in MSc program evolution: Enrichment with AI courses

A plan for a course in “ML applications in PSE in Oil and Gas” which will not replace references inside particular courses but rather setup a basic understanding of breadth and depth of ML applications. Several other courses are known in the academia including that of V. Venkatasubramanian [3]

The plan involves the following considerations:

1. Preparatory course: Two courses are proposed by V. Venkatasubramanian [3] namely undergraduate and postgraduate. To cover for the scenario of continuing education students, a two-month preparatory course with basic elements (ML methods, PSE subjects and uses) in the postgraduate (MSc) will replace and enhance the current seminar covered subjects. A special focus on all three elements (PSE, ML Programming, Data Engineering) will be characterizing this effort.

2. An elective course will cover applications of AI in PSE expanding all the subjects of preparatory course and focusing in current (growing) applications in Industry as well machine learning (see for example Kumar and Cerrillo [4]) as outlined in the following:

a. Machine Learning subjects for Process Monitoring, Advice and Predictions

i. Classification techniques
ii. Regression techniques
iii. Ensemble Learning, Boosting, Random Forests
iv. Deep Neural Networks
v. Deep Belief Networks and Classifiers

b. Reinforcement Learning, theory, applications and offline/online RL agents for control and scheduling integration.

c. Applications in PSE

i. Optimization of Unit operations and Blending
ii. Fault Detection and Diagnosis in rotating equipment
iii. Fault Detection and Diagnosis in process equipment
iv. Procedural automation augmented with AI
v. Scheduling and Control integrated and augmented with AI
vi. Quality and Quantity Inferentials augmented with AI.
vii. Large Language models as operator/engineering and predictive maintenance advisors

These courses are under review for the next year starting with the preparatory course but current status of AI in the industry and academia forces their introduction as soon as possible. It is well understood that as applications are evolving, a dynamic curriculum should be anticipated and a process in the curriculum for its improvement should be built in.

## CONCLUSIONS

### Paradigm of Continuous Improvement Culture: Continuous process performance improvement and optimization

The "MSc in Oil and Gas Process Systems Engineering", is a Paradigm of Academia and Industry Partnership in Greece and EU, providing sustainable and continuous

improvement culture in both industry and university [14].

The MSc Program is well designed to enhance the academic program of West Attika University, but also to support the sustainable development and operation of the Helleniq Energy Group business areas, covering continuously and in an advanced way the educational needs of its Technical Personnel.

The long-lasting expertise acquired in the Oil & Gas sector, is transferred to the academia through the pool of knowledge of its experts and their valuable contribution.

Technical experts of almost all the business units of Helleniq Energy Refineries, actively support the program with lectures, industrial case studies and thesis work supervision.

It is of paramount importance in this point to emphasize that the inspiration of AI and ML introduction in the Aspropyrgos Refinery of Helleniq Energy SA has been provided by the detailed, enthusiastic and thorough investigation of the state of the art in these issues that has been carried out for the successful implementation of an intensive highly specialised course in the above MSc Course, delivered by one of the authors of the present paper and embraced from the whole team and the management of the company.

Furthermore, one more invaluable reciprocal benefits of the MSc Course should be recalled, namely the high quality of the education that is provided to the technical personnel of the company, as well as the development – through the Course of excellent quality instructors that will in their own turn educate the rest of the company's technical personnel.

During its six years of operation the PG Course has been educating 120 professionals, mostly working in the hydrocarbons field. Almost 40 of them have already graduated and have advanced their career in petroleum and natural gas industries. On the other hand, the knowledge acquired form the graduates has been implemented through the implementation of advanced methods and tools for the design, operation and optimization of the processes and supply chains.

To conclude, the convergence of ML, cloud computing, and vast datasets is revolutionizing process systems engineering. The challenge lies in integrating these new tools and skills into the core of the PSE discipline, thus creating a new kind of engineer. This will require cross-disciplinary education, industry-academia partnerships, and a commitment to embracing the potential of AI to unlock unprecedented levels of efficiency, safety, and sustainability in industrial operations. The ability to adapt is going to be paramount for the industry and academia..

# Sociotechnical Transition: An Exploratory Study on the Social Appropriability of Users of Smart Meters in Wallonia.

**Boissézon Elisa**[a*]

[a] University of Mons, Department of Social Pedagogy and Andragogy, Mons, Belgium
* elisa.boissezon@umons.ac.be.

## ABSTRACT

Optimal and autonomous daily use of new technologies isn't a reality for everyone. In a societal context driven by sociotechnical transitions [1] many people lack access to digital equipment and skills, preventing their participation in digital social life, including energy services. Our exploratory and phenomenological research, guided by European Union directives [2], explores the social appropriation [3] of new technologies during the deployment of smart meters in Wallonia. The study investigates social behaviour of audiences with support during smart meter installation and identifies barriers to technology appropriation. In an exclusively qualitative approach, the field surveys aim to determine to what extent individual participatory forms [4][5] and collective forms [8][9] of support, through active pedagogies like experiential learning [6][7], can include digitally vulnerable users. The central role of field professionals as interfaces [10] is also highlighted within the service relationship [11] that connects, on one hand, the end consumers and, on the other hand, the organization responsible for deploying the smart meters. While our study does not directly utilize CAPE methods and tools, it investigates the current social implications of digitalization.

**Keywords**: Sociotechnical Transition, Social Appropriability, Smart Meters.

## A SOCIOTECHNICAL CONTEXT

### The sociotechnical transition

The innovations developed to deal with the climate challenges of our century raise several questions regarding the adoption of new transition technologies by households with very diverse socio-economic realities and digital skills. In this context, energy transition is carried out alongside the digital transition, making them complementary [12]. Therefore, Socio-technical transitions differ from technological transitions in that they include changes in user practices and institutional (e.g., regulatory and cultural) structures, in addition to the technological dimension [1]. For instance, the need for innovation in managing complex energy systems [12] is reflected, among other things, in EU directives mandating 80% smart grid deployment by 2020 across its territories [13]. Despite practical challenges, this deployment is crucial for achieving the EU's energy transition goals: renewable energy investment, energy efficiency, and energy sobriety [2].

### The deployment of smart meters in Wallonia

In Wallonia, the deployment of smart meters follows the European directives on energy transition. According to the decree of July 19, 2018, the smart meter is defined as an electronic system that can measure the energy taken or injected by adding information that a conventional meter does not provide, that can transmit and receive data in the form of electronic communication, and that can be operated remotely (...) (art. 2, 29°bis). However, the numerous investments in technology for ecological sustainability and energy efficiency raise questions about end-user technological adoption. Literature suggests that with increasing household innovations, service provisions will become more self-organized by individuals (or communities), limiting professional intervention to key moments [14]. Therefore, users, including the most vulnerable, will need to be able to familiarize themselves with these devices for autonomous use post-service provision.

### Smart meters and their users

Besides concerns about electromagnetic waves and privacy, users doubt the intelligent nature of the technology [15]. While technology outcomes depend on users, their digital skills often do not evolve at the same pace as the technological advancements, leading to dependence rather than empowerment [3][16]. Thus, studies highlight user difficulties in understanding device data and using complementary tools like websites or platforms. Users also struggle with complex data presentations via multiple graphs, units in kWh, etc. [17]. In the wake of these results, the issue of digital inequalities emerges, encompassing aspects related to access, use, and digital participation in the social life of users.

### Digital divide in Wallonia

The digital divide is multifaceted and occurs at three levels: access to ICT, use of ICT and digital skills, and active participation in social life via ICT, such as e-services. In Wallonia, the digital divide is significant. According to the Digital Maturity Barometer of Walloon Citizen, in 2023, 6% of individuals lacked access to digital devices [18]. Beyond the material dimension, it has been observed that having access to the internet (...) does not guarantee full and complete practice, that is, autonomous and effective (...) and is therefore not synonymous with greater equality. However, digital practices are not self-evident and require 'digital skills' [19]. Digital exclusion is an important factor to consider in the deployment of smart meters, especially for vulnerable populations. Not all their users have internet access or digital devices to manage their consumption data or use online tools.

### Using smart meters through digital divide

According to the Walloon legislator [20] the deployment of smart meters in Wallonia primarily targets households in payment default, one of the objective indicators of energy poverty [21]. Digital inequalities, linked to poverty, exacerbate this issue, as those experiencing energy poverty are often most affected by the digital divide [22]. When resources are limited, digital inclusion is not a priority and may lead to debt for acquiring equipment, training, etc. [23]. Furthermore, digital skills vary widely based on income, age, socioeconomic status, sociodemographic characteristics, education, employment status, illiteracy or disability [24][25]. In 2021, 32,2% of households faced energy poverty [21]. Considering those elements, it seems more than appropriate for energy professionals, as well as users, to consider diverse public profiles to ensure effective smart meter deployment (profiles, needs, expectations, etc.) while supporting the population.

## THE SOCIAL APPROPRIATION OF TECHNOLOGIES

### The interface situation and the service relationship

In the context of the deployment of smart meters, the support relationship involves an interface situation with devices for the public, managed by professionals [10]. The interface situation forms a triangular relationship between the public (client-experimenter, client of a service relationship, user, local partner, manager, decision-maker, etc.), devices (technical objects, management devices, and organizational structures), and professionals (actors positioned at the boundaries of different dimensions and responsible for managing the uncertainties arising from them). This interface situation links various social worlds (users, professionals, organizations, etc.) and their respective issues through which energy exists [10].

The backdrop of this interface relationship between the client and the professional in the context of the deployment of smart meters can be framed by the service relationship which is defined as a triangular relationship bringing together a professional (holder of a skill requested for the accomplishment of a 'repair'), an object to be repaired, and its owner (requesting the skill of this professional for the purpose of repair). The realization of the service here requires the involvement and cooperation of both parties. In this sense, the service participates in a social relationship through the confrontation and mutual adjustment it demands from each of its parties [11][26]. Therefore, field professionals act as intermediaries between the device, the public, and themselves. However, despite theoretical preparations for user support, real-world challenges arise due to the unique characteristics of users, such as socioeconomic status, sociodemographic characteristics, social inequalities, etc.

### From acceptability to appropriability

The introduction of technologies in the energy market faces several challenges since their logic are not necessarily compatible with social logics [27]. Moreover, these technologies are based on standardized conceptions of social practices [27] and their use assumes that their users possess skills they do not necessarily have [19]. Engineering sciences use the concept of social acceptability of the technological devices [27], which allows for the analysis of the mechanisms governing the anchoring of a project or decision within a social dynamic without reducing them to the formal institutional framework [28]. However, this concept is questioned in the scientific literature since to reason in terms of social acceptability is to shift the responsibility to the target public to adopt or not the concerned technologies. It is to consider that only the social dimension plays a role in realizing the potentials invested in the technologies [29]. Nevertheless, given that the reluctance to engage with

technologies is more complex than just a socioeconomic barrier, the technical dimension must also be considered. Thus, it is more appropriate to speak of social appropriability which encompasses a set of complex processes: the technical culture of users, their social representations, the origin of the innovation and the means by which it was presented to its users, the practices and uses of the innovation, the type of communication that accompanies it, the users' lifestyle and their relationship to comfort, their previous technical experiences, the collective dynamics in which they are involved, etc. [30].

## SOCIAL APPROPRIATION THROUGH PARTICIPATION

### User participation in the service relationship

In response to the challenges related to the process of social appropriability of technologies, the service literature highlights positive aspects of user participation in the service relationship [4][5][14]. In this context, consumer participation, in the broad sense, characterizes an involvement (physical and/or mental) in the process of producing the company's product or service [4]. In Wallonia, smart meter deployment involves a standardized support protocol, inviting the client to participate in system demonstrations or satisfaction online surveys. However, user participation is not guaranteed. To engage users, the system must be able to interest them, engage them, or also socialize clients who have different perceptions of participation: the idea is thus to develop a flexible and evolving system, integrating options, services, and communication supports to remove potential barriers to participation [4]. Moreover, when the public adheres to the support system, positive effects of client participation include increased productivity, leveraging consumer know-how for innovation, strengthened company attachment, a sense of freedom of choice, power transfer to users, alignment with client preferences, and improved service quality [4][5][14].

### User participation against social inequalities

Active public involvement presents numerous advantages in addressing digital inequalities, especially when user participation is viewed through the lens of active pedagogies. Firstly, experiential learning, through a meaningful practice, is essential in the context of training adult learners in the use of ICT: the 'learning-by-doing' and 'do-it-yourself' approaches appear even more important as the primary goal of adult learners in training is not to assimilate theoretical and technical concepts, but rather to concretely learn to use certain aspects of ICT for activities carefully selected based on daily concerns [7]. Secondly, social proximity also plays a crucial role in individuals' digital usage [7]. Indeed, group learning in mastering ICT represents a significant advantage [8] considering that bringing people together around the same table and involving them in a common project promotes meeting and socialization, as well as collaboration and informal learning among learners, which are essential dimensions for the successful completion of ICT training [6]. These advantages are important to consider for vulnerable and/or precarious populations, who are often isolated and lack support assistance. Similarly, the group effect represents a significant asset when support is aimed at non-voluntary or hard-to-reach individuals [9], which are populations also affected by the deployment of smart meters in Wallonia.

### The sociotechnical transition through user participation

Through participation, the consumer, who was previously passive towards services, becomes a 'prosumer' or, in other words, a consumer who participates and engages alongside companies [31]. Additionally, participation seems to restore a central role to clients by considering the human factor in support processes, regarding real-life experiences from the field. Thus, this approach redefines individuals as 'users' rather than just 'consumers' or 'clients'. However, considering user support in smart meter deployment solely through the lens of participation is not sufficient. User engagement depends on numerous factors, with the central question ultimately being the meaningfulness of using the technologies in question. In fact, user engagement depends on the meaningfulness of technology use. Considering that, the Reflexive Practice theory [32] emphasizes that autonomy and systematic thinking lead to relevant practice changes [33]. This principle also applies to the deployment of smart meters and their sustainable use in the daily management of household energy.

## METHODOLOGY

The present research focuses on the support provided to the public in the context of deployment of smart meters in Wallonia in an exploratory and phenomenological perspective. Considering all the elements reviewed and presented in the conceptual framework, our research question is as follows: do the current support mechanisms for the public (individual or collective) enable the social appropriability of smart meters in Wallonia?

To achieve this, data collection was conducted using semi-structured interviews with four samples: non-requesting users (N=10), requesting users (N=17), field professionals (N=5) and mixed profiles users (N=10). The investigation of individual public support was conducted with reference to the following indicators, derived from scientific literature on engagement, including the use of ICTs: digital inequalities, perception, attitude, motivation, voluntarism, sense of social justice, trust, user postures,

and relationship to energy. On the other hand, collective support was observed through the conduct of focus groups workshops.

Data analysis and processing were conducted using a hybrid method that combines general inductive analysis [34] with analysis using conceptual categories [35], with the aim of identifying potential links between (sub-)categories through updating coherences [35]. In addition, the data collected from field professionals were analyzed using thematic analysis [35].

# RESULTS

## Individual support

The linking of conceptual entities for individual support highlighted differences in the social appropriability of smart meters and associated online tools between sample 1 (non-requesting users) and sample 2 (requesting users). First, digital inclusion was linked to educational attainment, with half of sample 1, who were experiencing digital inequalities or disconnection, having no higher education degrees. The level of digital inclusion among participants also appeared to impact their proactivity in engaging with the technology. Thus, the results show that in sample 2, all of whom were digitally included, 15 individuals were proactive in using the smart meter and associated online tools, compared to only one person in sample 1. User voluntarism also appears as a determining variable in the process of social appropriability of technologies. Three relationships were identified between voluntarism and amotivation, the level of proactivity, as well as trust. Indeed, the results showed that among the non-voluntary participants regarding the deployment of smart meters, 5 individuals exhibited signs of amotivation to use the technology, compared to only one amotivated person in sample 2, which consisted of voluntary users. Additionally, among the 10 individuals in the non-voluntary sample, only one person showed signs of proactivity, compared to 12 proactive individuals in the voluntary sample. Furthermore, within the non-voluntary sample, 7 out of 10 individuals exhibited signs of distrust towards both the technology (the smart meter and associated online tools) and the organization overseeing the deployment of these technologies. Additionally, in this group, 8 out of 10 individuals showed signs of prescribed (default) trust, partly due to digital inequalities that hinder their access to relevant information. Conversely, 14 out of 17 individuals in the voluntary sample felt confident about the smart metering system at all levels (technical, organizational, and the expertise of field professionals), with 7 individuals exhibiting prescribed (default) trust. Finally, two relationships were observed between users' usage stance towards the smart meter, including the associated online tools, and on the one hand, their relationship with energy, and, on the other hand, their attitude towards technological change. First, all 5 individuals in sample 1 who were experiencing digital inequalities or disconnection adopted a disinterested usage stance towards the smart meter and associated online tools. Additionally, out of the 10 individuals in sample 1, 2 showed some interest in the technological change but considered its use not a priority in their daily lives. In contrast, within sample 2, which consists of individuals digitally included, 10 out 17 adopted a non-priority usage stance, while 7 were disinterested. Second, regarding the attitude towards technological change, 5 out of 10 individuals in the sample 1 who adopted a potential contributor usage stance (volunteers for involvement in the support management process), 4 of them had a positive view of the deployment of smart meters. Within sample 2, among the 9 out the 17 individuals who adopted the same potential contributor stance, 4 also had a positive view of the change.

## The perspective of field professionals

In addition to field surveys with users, interviews were conducted with field professionals to explore their experiences of individual support within the deployment of smart meters. The thematic analysis of the data highlighted several themes related to their role in the service relationship. First, training: generally, technicians receive standardized technical training for the smart meter installation, but not for using associated online tools. While their technical training is well-received, technicians often didn't feel fully prepared for field contingencies. Second: fieldwork. Technicians must adopt multiple roles beyond technical tasks, including communication and social interaction, and adapt to the unique profiles of individuals they encounter (vulnerabilities, inequalities, delicate situations, etc.). This necessitates continuous hands-on-training, often self-directed or peer-supported. Third, application of training: despite having a standardized support protocol, the level of support provided varies widely, from 'fully applied, with additional personal contributions' to 'not applied at all'.

## Collective support

The data analysis collected from sample 4 (mixed profiles users) highlighted four relationships between conceptual entities for collective support. The first relationship is situated at the level of experiential learning, between pedagogical demonstration and the active participation of users supported in collective workshops. The results showed that among the 5 out of 10 individuals experiencing digital inequalities, all left with a higher sense of digital competence thanks to their active participation during the pedagogical demonstration (handling of a real smart meter, moments of exchanges and sharing, exploration of guides and brochures, discovery of online tools, etc.). Additionally, for the 2 more digitally

experienced individuals of the group, the workshop served as a constructive reminder. The second relationship is situated between pedagogical demonstration and the collective participation of users during the workshops. For all group members, collective participation in the pedagogical demonstration facilitated new theorical and technical learning. As well, 8 out of 10 individuals reported a positive customer experience. The third relationship is situated between pedagogical demonstration and the collective participation of users during the workshops. The third identified relationship relates to group effect, between the interactions and social support experienced by users during the workshops. Indeed, thanks to the interactions and sharing of experiences, 7 out of 10 individuals felt social support during their active participation in the workshop. The fourth and final relationship for collective support is between collective participation and the evolution of users' energy management. At the end of the workshops, among the 8 out of 10 individuals who had a positive customer experience, 5 left with the intention to improve their home energy system through new practices or by utilizing digital tools. Moreover, the 2 digitally vulnerable individuals in the group left the workshops with a renewed interest in using the smart meter and associated online tools, which they had previously given up.

## DISCUSSION AND CONCLUSION

Overall, our research findings align with the scientific literature and support the issues highlighted by the scientific community in the field of social appropriability of technologies. Therefore, we answer our research question both affirmatively and negatively. Yes, the current support systems (individual or collective) in Wallonia enable the social appropriability of smart meters for digitally proficient individuals and/or those interested in digital matters. However, the standardized support systems do not facilitate the social appropriability of technologies for less digitally proficient and/or digitally vulnerable individuals. Nevertheless, our results highlight the importance of local and collective support, which seems to be effective in this context. In conclusion, our research has highlighted the importance of supporting the public from a holistic perspective that considers the unique profiles of individuals. It also underscores the significance of technician training, particularly through practical cases, to ensure quality support. Furthermore, it is essential to promote the development of local and participatory support protocols, paying special attention to vulnerable populations, who are often overlooked by statistics or sociotechnical transition scenarios.

## ACKNOWLEDGEMENTS

We would like to express our sincere thanks to Prof. Willy Lahaye for his guidance and promotion throughout the course of this research. We also acknowledge the financial support provided by the University of Mons and the Walloon distribution network operator ORES. Special thanks to our colleagues from the Department of Social Andragogy and Pedagogy for their constructive discussions and suggestions. Additionally, we offer our heartfelt gratitude to all the participants of this research (ORES collaborators, users, technicians, etc.). Finally, we also extend our sincere thanks to the anonymous reviewers fort their thorough review and helpful comments, which significantly improved the quality of this paper.

## ABSTRACT

The paradigm shift into an era of Industry 4.0, also referred to as the fourth Industrial Revolution, has emphasized the need for intelligent networking between process equipment and industrial processes themselves. This has brought on an age of research and framework development for smart manufacturing in the name of Industry 4.0 [1]. While the physical and digital advancements towards smart manufacturing integration are substantial the inclusion of engineers themselves amongst this shift is often less considered [2]. There are educational efforts in Europe to create and implement smart manufacturing curriculum for non-traditional or adult learners already integrated in the workforce, but attention is also needed on a next generation smart manufacturing curriculum for pre-career students [3]. We, the teaching team of CHE 554: Smart Manufacturing at Purdue University, developed and implemented a curriculum geared towards the training of undergraduate, graduate, and non-traditional students in methods of smart manufacturing as they apply directly to industrial scenarios. Through this elective course, taught primarily through the context of chemical engineering but enrolling students from other disciplines, we introduce concepts not covered in its entirety by the core engineering curriculum. Our course includes but is not limited to material on data reconciliation, machine learning, chemometrics, data-driven fault detection, digital twin development, and process optimization. Further, these concepts are executed through the context of open-source Python packages, enabling the accessible and practical application of smart manufacturing in the form of assignments and in the context of professional application in the future [4,5]. The integration of modern tools and Python libraries connects academic solutions to industrial challenges with industrial practice becoming evident for students who would otherwise be unaware of these resources. With the creation and implementation of the Purdue University Smart Manufacturing elective course, we help develop a uniquely prepared and technologically educated generation of engineering students capable of bringing Smart Manufacturing capabilities to industry. This helps catalyze smart manufacturing knowledge transfer where all enrolled students are given the tools to apply their knowledge mastery to their specific engineering discipline and industrial application.

## INTRODUCTION

Industrial revolutions have consistently marked transformative eras of technological advancement, shaping the modern world. Industry 4.0, also known as the Fourth Industrial Revolution, is no exception [1]. This era has witnessed an unprecedented integration of novel technologies into manufacturing, aimed at making processes more sustainable, robust, customizable, and profitable. However, despite the transformative potential of these technologies, their adoption is not always met with universal success. Even in companies that

enthusiastically embrace Industry 4.0, a critical gap often arises. Students entering the workforce frequently lack exposure to the technologies and concepts foundational to Industry 4.0. This unawareness highlights the opportunity for academic institutions to prepare graduates with concepts that allow them to immediately contribute to industrial engineering and manufacturing.

Purdue University has long been recognized as a leader in fostering experiential learning through co-ops, internships, and other opportunities for industrial engagement. However, sending graduates into the chemical manufacturing workforce during an era defined by Industry 4.0 necessitates equipping them with relevant skills for evolving industrial landscapes. To equip students properly, universities must critically evaluate their core curricula and integrate data-centric and digitally focused material alongside traditional engineering education, transitioning academic programs into the realm of Education 4.0 [7]. Recognizing this need, Purdue's Davidson School of Chemical Engineering leveraged its strong process systems engineering community to develop an innovative elective course: Smart Manufacturing. This course is designed with several features that enhance accessibility across physical, generational, computational, and disciplinary boundaries. By welcoming a diverse range of learners—from different ages, backgrounds, and disciplines—this elective provides an inclusive platform to engage with Industry 4.0 concepts. The course has successfully run for six semesters at Purdue University and continues to evolve, reflecting technological advancements to ensure students remain at the forefront of smart manufacturing education.

The following sections of this article will explore the course's key features, assignments, and guiding philosophies that contribute to its success, making it a valuable and adaptable model for other institutions aiming to bridge the gap between academia and the demands of Industry 4.0.

## COURSE DESCRIPTION

### Course Philosophy

This course surveys the tools and techniques which are relevant to support the multiple levels of technical decisions that arise in modern integrated operation of manufacturing resources in the chemical, petrochemical and pharmaceutical industries. The real time generation and sharing of associated data and knowledge via relevant IT methodology and the effective use of this information in the various levels of the process operations management hierarchy are currently termed Industry 4.0 (Europe) and Smart Manufacturing (US). The topics covered in the course span all the technical components and decision levels in the operations decision hierarchy. Topics include the role of on-line and at-line process measurements, elements of sensor network design, information systems to support process operations, plant data reconciliation, detection and diagnosis of process faults, condition-based monitoring of plant assets, plant wide control, real time process optimization, production planning and scheduling, and supply chain management. Each topic is addressed by first summarizing the basic role and scope of that component, then discussing the elements of the decision problem, and outlining some representative tools available to address that decision problem. Each major topic includes a lecture given by an industrial practitioner who offers a perspective on the state of industrial practice.

### Learning Outcomes

The Smart Manufacturing elective communicates a short list of learning outcomes to each student to serve as a target for the minimum goals that should be achieved over the course of the semester. They are as follows:

- Explain the key decisions that are made at each level of the operational hierarchy of an integrated process system.
- Define what the various types of manufacturing and enterprise data are, how they are generated and managed and what their functions are in supporting these decisions.
- Explain the role of models in supporting the decisions made at each level of the operational hierarchy.
- Evaluate and improve a plant wide control system for a given manufacturing system.
- Identify condition-based monitoring of a manufacturing system, how it is performed and what its outcomes should be.
- Explain the nature and role of planning and scheduling models and tools as applied at the plant and supply chain levels.

### Critical Features

The success of the Smart Manufacturing elective can be attributed to several strategic course and curriculum design decisions. A few key elements that distinguish this course and contribute to its ongoing success are particularly noteworthy.

Firstly, offering this course exclusively online as an asynchronous learning opportunity enables access for engineers who are already in the field or industry, often with several years of professional experience. This format allows them to explore Industry 4.0 tools and gain insights relevant to their roles without the need to enroll in a traditional, in-person degree program. Such flexibility

is particularly valuable for experienced professionals, including older generations of engineers, who might otherwise find it challenging to engage in further education.

Another unique aspect of the course is the deliberate emphasis on open-source software packages, particularly those based in Python. These packages are integrated into various assignments and projects, ensuring that students gain proficiency in tools that remain accessible after their time at Purdue. This approach significantly enhances the transferability and adaptability of the skills learned, enabling integration into the industrial workflows of their (future) employers.

Finally, a critical factor in the course's success is the commitment to frequent and thorough updates to the curriculum. As the field of smart manufacturing evolves, new tools emerge, existing software packages improve, and industry standards shift. Staying current with these advancements is essential for a course centered on cutting-edge technologies. Regular updates ensure that students are equipped with the most relevant and advanced knowledge, keeping pace with the rapidly changing landscape of smart manufacturing. These foundational principles—broad accessibility, the use of open-source tools, and a commitment to staying at the forefront of technological advancements—are integral to the continued success and impact of the Smart Manufacturing elective.

## Course Audience

The Smart Manufacturing elective is a 500-level elective course (for both undergraduate- and graduate-level students) offered through the School of Chemical Engineering although students across departments and education levels are encouraged to enroll. As a result, our student body actively enrolled in the course spans undergraduate, graduate (Master's and Ph.D.), and adult learners across multiple departments ranging from Industrial Pharmacy to Mechanical Engineering to Industry.

# PROJECT DESCRIPTIONS

## Data Reconciliation

The efficiency, safety, and overall success of chemical manufacturing operations rely on several critical factors, including robust process controls, effective monitoring, and sound process design. When sensors or process controls fail, undetected deviations can result in costly operational disruptions and potentially catastrophic safety incidents. As a result, one critical function of an operator and/or engineer is the ability to reconcile data and detect deviations. This concept appears in three of the course projects, however in this homework assignment, students are asked to approach data reconciliation through the lens of statistics, emphasizing confidence interval calculations and error minimization. The chosen application for communicating this technique was methanol synthesis reconciliation of flowrate data, represented as the network shown in Figure 1.

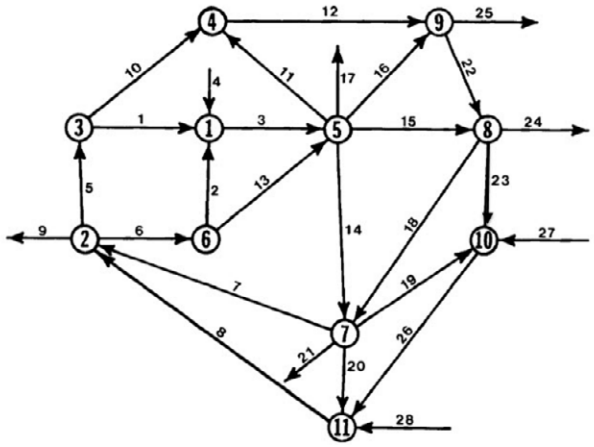

**Figure 1.** Network representation of process steam system for a methanol synthesis unit [Seth and Heenan, 1986].

After designing a simple optimization problem from the stream networks material balances, students reconcile the data by minimizing the error between the actual and desired stream flowrates. After this error function validation, students are asked to calculate the upper and lower bounds of specific stream flowrates that would have to be reached to trigger a fault. The magnitude of this range being determined by the established confidence interval.

## Chemometrics and Fault Detection

Process monitoring can allow for deviation detection when coupled with various data handling tools. However, variable correlation that enables the association of cause with effect cannot be effectively determined with all the same tools. In a homework assignment, students are asked to apply Principal Component Analysis (PCA) and Partial Least Squares (PLS) to a sensor-based dataset which contains a known fault. Students are asked to leverage the chemometric tools to identify the onset time of the fault, the associated variables, and suggest a sound engineering reason for the fault. The process schema and associated points of data collection are represented in Figure 2.

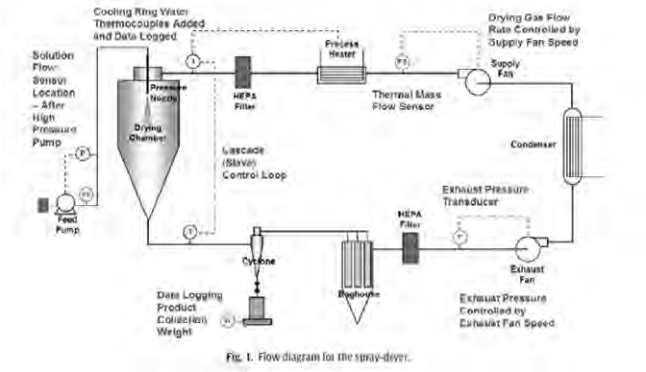

**Figure 2.** Spray-dryer flow diagram, [Garcia-Munoz S & Settell D, 2009].

This project serves as one of the most unifying projects because regardless of engineering discipline, the core descriptor of an engineer is the ability to think critically, and problem solve. Unlike other assignments where accuracy is determined by exact numerical values, this assignment is more open in terms of what is given full credit and not. One example would be after identifying that the greatest contributions to fault data were the variables "Outlet Temperature" and "Cyclone Differential Pressure" a potential engineering explanation could be but not limited to:

- Temperature sensor failure leading to fault in the cascade control loop around the spray dryer
- Clogging in the cyclone filter leading to a pressure build up and subsequent process temperature increase upstream
- Temperature sensor failure leading to unregulated temperature control, altering process conditions enough to change particle size, impacting cyclone performance

## Digital Twin Development and Process Optimization

In the age of Industry 4.0, engineers have seen a boom in the leveraging of process modeling capabilities for applications such as design space analysis, sensitivity analysis, and process optimization. However, no catch all parameters exist that can make these process models universal for all systems. As a result, the development of digital twins is required for the robust consideration of these application spaces. In pharmaceutical manufacturing specifically such analyses aid in time to submission, reduced process uncertainty in a highly regulated market and other market specific benefits. As a result, this assignment asks students to consider the critical drug substance unit operation, crystallization. One key advancement in process modeling, particularly in the context of accessible education, was the development of the open-source, python-based software package, PharmaPy. Laid out in full detail, as a component of a complimentary course, by Laky D, et al. (2023) this crystallization assignment asks students to leverage the model libraries available in PharmaPy to progress through:

- Model Discrimination
- Parameter Estimation

Students then finalize the development of a system/species specific digitial twin which is then applied to single and multiple objective process optimization. Since students have previously been introduced to confidence interval calculations and error minimization in the first assignment, the learning curve for parameter estimation is reduced and allows for students to more fully engage with the process of model discrimination, and digital twin development without being a barrier to entry. Additionally, conducting this assignment through the usage of Jupyter notebooks reduces the computational learning curve for students that are beginners and novices in Python based coding [8]. An example of one of the process optimization prompts is illustrated in Figure 3, where students are asked to optimize a cooling temperature profile (linear and quadratic) to either minimize or maximize a predetermined set of critical quality attributes for drug substance manufacturing.

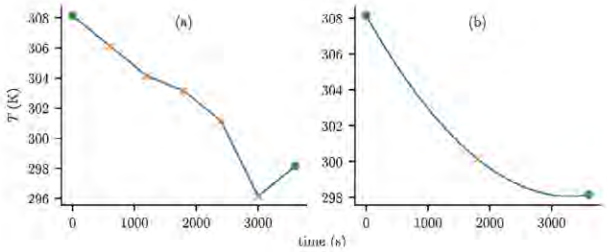

**Figure 3.** Examples of piecewise linear (a) and quadratic (b) temperature profiles. Internal points are equidistant decision variables marked orange 'x' symbols.

## Machine Learning

The influence of artificial intelligence (AI) and machine learning (ML) are widespread, impacting many aspects of modern life, particularly in manufacturing. These technologies offer significant potential for growth, enabling advancements in decision-making processes and accelerating the pace at which those decisions are made. At the early stage of launching the Smart Manufacturing elective, AI and ML were still emerging, especially in terms of their representation in academic literature. Consequently, our machine learning-based assignment was intentionally designed to be straightforward. Students were tasked with exploring two distinct datasets: one related to regression (solubility

data) and another focused on classification (drug product quality data). Using these datasets, students developed machine learning models tailored to each scenario, providing a practical introduction to AI/ML applications in manufacturing.

Future iterations of this assignment will incorporate more advanced and challenging evaluations of AI and ML applications in the context of manufacturing. For example, a potential assignment could involve analyzing *in-situ* concentration trends as determined from raw analytical data using a machine learning model, and comparing the results to a chemometric based model such as PLS regression. A critical aspect of this evaluation is the ability to determine trade-off points, resource intensity, and overall payoffs when comparing the two choices.

This approach explores the ongoing trend of using Industry 4.0 tools to address persistent manufacturing challenges while fostering an understanding that no single tool is universally applicable. Such assignments aim to enhance students' ability to make informed, scientifically grounded decisions, a critical skill for all engineers working in manufacturing and industry-based roles.

### Planning and Scheduling

Engineering process planning and scheduling is a long-established and critical aspect of process design and operation, essential for effective resource allocation and timing. While this skill is a common component of undergraduate engineering curricula (typically addressed in design courses), it is often taught with unbounded or flexible constraints. In contrast, industrial planning and scheduling problems are often highly constrained, requiring optimization procedures that can identify and explore this smaller feasible space. To bridge this gap, the penultimate assignment in this course involves a self-guided development of a knapsack problem [6]. Students are provided with specific constraints to follow, but the application and subject matter of their knapsack problem are entirely self-determined. This approach encourages students to critically evaluate real-world situations where a knapsack formulation would be valuable, such as equipment budgeting or resource allocation. As part of the assignment, students are required to construct a branch-and-bound tree for their problem, offering a visual representation of their solution process. Additionally, students are introduced to the concept of NP-completeness and other advanced algorithmic concepts, which are often absent from traditional undergraduate education but are increasingly relevant in modern industrial manufacturing.

### Final Project

The planning and scheduling assignment serves as a capstone for the course prior to the final project. It emphasizes how every decision an engineer makes in manufacturing has upstream and downstream impacts. While engineers are often responsible for individual operations, decisions ranging from sensor placement to data handling, model building, and final planning and scheduling are interconnected. The final project is designed to reinforce these ideas by challenging students to think holistically about how Industry 4.0 advancements can positively influence the manufacturing environment. Students are asked to propose an engineering problem or application and develop a solution using at least two of the concepts introduced during the course. This open-ended approach fosters creativity, critical thinking, and a deeper understanding of how these tools can interact to address complex engineering challenges effectively.

Past project examples have included:

- PCA evaluation for identifying UV wavelength unique to a specific molecule coupled with PLSR for in-situ concentration modeling
- Machine learning evaluation of fitted kinetic parameters for pattern detection of parameter coupling
- Plantwide control schema coupled with sensor prioritization via scheduling decision making
- Batch versus continuous manufacturing evaluations following the development of a reaction with isolation process digital twin
- Fault detection from historic wind farm data and proposed process control schemas for switching between energy systems in the case of successful fault detection

Through these strategically designed assignments, students are equipped to think beyond isolated tasks, understanding how their decisions contribute to the broader manufacturing process and how moving forward they can leverage modern tools to improve industrial operations. In unique cases, this project gives non-traditional students the opportunity to apply smart manufacturing techniques to their real-life plant data and current vocational challenges to test the appropriate digital tools and innovate new workflows for their given industrial discipline.

## ADJACENT COURSE DEVELOPMENT

Integration of the software tool PharmaPy into the Smart Manufacturing elective catalyzed student inquiries about process modeling outside of software encountered in undergraduate education like flowsheet packages. Encouraged by this and developed alongside an additional course offered at Purdue University through the school

of chemical engineering is CHE 553 - Pharmaceutical Process, Development and Design. This course focuses on similar process systems engineering challenges but dives deeper into pharmaceutical processes only and covers multiple unit operations, all using PharmaPy within Jupyter notebooks [8].

## CONCLUSIONS

As digitalization increases in industry, the preparation of students for the new challenges of manufacturing in the Industry 4.0 era is paramount. We present six modules that address industrially relevant problems which can be solved with the implementation of smart manufacturing techniques. Such approaches do not exist within the inherited and established core curriculum across engineering, and in particular chemical engineering. The introduction of such modules in parallel with the curriculum and teaching philosophy presented in this manuscript have proven to successfully advance the industrial preparedness of undergraduate, graduate, and non-traditional students at Purdue University.

The Smart Manufacturing elective described in this manuscript can be readily developed by other universities. Manufacturing-based alumni can offer guest lectures to connect course concepts to practice. A Smart Manufacturing course is valuable for advanced undergraduate, graduate, and practitioner learning. Given the rapid pace of technology change, instructors should be prepared to evolve the course and assignments. Purdue University offers the Smart Manufacturing course as an elective every semester to 20-40 students.

## ABSTRACT

The growing concern over the environmental impacts of the wine industry has driven the search for sustainable technologies to manage its waste, particularly the residual sludge generated during effluent treatment. This sludge, rich in organic matter, represents a significant source of pollution if not properly treated. However, their energy content allows them to turn this environmental liability into an asset through innovative valorization. Hydrothermal liquefaction (HTL) emerges as a promising technology in this context. This process allows the direct conversion of residual sludge into high-energy-value liquid biofuels. Unlike other treatment methods, HTL can process wet biomass without needing prior drying, making it particularly suitable for managing sludge from wine effluents. Thus, this research aims to evaluate the conversion of residual sludge derived from wine effluent treatment into biofuels through a hydrothermal liquefaction simulation, integrating this process into a sustainable biorefinery for levulinic acid and bioethanol production. The methodology considers the determination of the composition and treatment of the wine effluent to define a case study. The biorefinery processes, as well as the HTL, are designed and simulated in Aspen Plus V.14, and also they are evaluated technically and economically. As a result, levulinic acid, sustainable aviation fuel, bioethanol, propylene glycol, and electrical energy are produced. In addition, the biorefinery reduces the effluent's Chemical Oxygen Demand (COD) by 99%. In conclusion, valorizing suspended solids from wine effluents through HTL is technically and economically feasible.

**Keywords**: Hydrothermal liquefaction, Biorefinery, Wine effluents, Sludge valorization, Aspen Plus V.14.

## INTRODUCTION

The winemaking industry releases large quantities of waste, being wine effluents between them. According to Buitron et al. (2019) [1], the ratio of wastewater per liter of wine produced is 2-4. Due to its features, the effluent is treated by using biological processes, such as anaerobic fermentation [1]; unfortunately, the organic material remotion in wastewater generates considerable quantities of sludge, which represents a significant source of pollution if it is not adequately treated [2]. Sludge derived from effluent treatment can be valorized to generate new products. In the literature, several alternative processes for treating sludge are reported. These processes are feasible from a technical point of view, but they fail to reach economic viability. In this context, the concept of biorefinery arises. A biorefinery is an implemented process involving unit operations aiming to transform raw materials, mainly biological ones, into a wide range of value-added products, biofuels, energy, or renewable materials [3].

Among the value-added products, levulinic acid is highlighted. The National Renewable Energy Laboratory identifies 12 essential chemical compounds, which are value-added products that can be produced from sugars through biological or chemical conversions; among these

compounds is levulinic acid. This component presents enormous economic potential because it is a raw material of various industrially important chemicals, such as methyl-tetrahydrofuran [4]. Besides, levulinic acid is a value-added product used in producing nylon, synthetic rubbers, plastics, and pharmaceuticals.

On the other hand, biofuels and chemicals, bioethanol, sustainable aviation fuel, and propylene glycol are of interest due to their wide applications in the industrial sectors. Bioethanol is a liquid biofuel from renewable biomass sources such as agricultural waste, winery effluent, and lignocellulosic residues. Its increasing use in the energy matrix addresses the need to reduce dependence on fossil fuels and lower greenhouse gas emissions, thereby contributing to climate change mitigation and energy sustainability [5]. Moreover, propylene glycol and dipropylene glycol are used as an antifreeze liquid in airplane engines. Employing ethylene oxide hydration and propylene oxide hydration can produce a mixture of glycols that have an industrial value [5]. Finally, sustainable aviation fuel is the best alternative for decarbonizing the aviation sector.

Therefore, this work proposes using sludge derived from wine effluent treatment to produce levulinic acid, bioethanol, propylene glycol, and sustainable aviation fuel. To the authors' knowledge, this approach has not been reported in the literature. For this, a biorefinery is modeled and simulated, considering hydrothermal liquefaction; this last technology is a promising solution to transform wet biomass, such as sludge, into valuable bio-oil, offering advantages like waste volume reduction, energy recovery, and decrement of greenhouse gas emission [6].

## METHODOLOGY

The research is divided into six stages:

1. Definition of a case study. It consists of considering a calculous base that represents an actual situation; according to that, the process feed stream is chemically characterized using literature searching.
2. Development of a conceptual design for biorefinery. It proposes the products obtained from the raw material stream and the unit operations needed to reach them.
3. Compilation of thermodynamic and chemical kinetic data. Through a literature search, chemical kinetic parameters and equations are joined to describe reactors' behavior. In addition, thermodynamic parameters are taken to guarantee a close approach to actual process performance. Carlson algorithm has been employed to define thermodynamic models in each unit operation [7].
4. Aspen Plus V.14 simulation. Using rigorous models, the conceptual design of biorefinery is simulated in Aspen Plus V.14.
5. Parametric analysis. Sensitivity analyses are carried out for each unit operation to define the final values of manipulated variables.
6. Technical and economic evaluation. Technic and economic parameters are calculated to evaluate the biorefinery performance. These are described by equations (1 - 12). Equipment costs are estimated by using the Guthrie method [8]. In addition, chemical oxygen demand (COD) is calculated using Aspen Plus V. 14 as a technical and environmental indicator.

$$rec = \frac{oms}{fms} \quad (1)$$

$$cv = \frac{r_{in} - r_{out}}{r_{in}} \quad (2)$$

$$Yd = \frac{pmf}{tpm} \quad (3)$$

$$pmr = \frac{mp}{rmm} \quad (4)$$

$$PFT = (Ah)(psale - rmc - UC_T) - (\mathrm{k})(\mathrm{EC}) \quad (5)$$

$$psale = \sum_1^j \left((mp_j)(pp_j)\right) \quad (6)$$

$$Log_{10} C_P^{\circ} = K_1 + K_2 Log_{10}(\mathrm{A}) + K_3 (Log_{10}(\mathrm{A}))^2 \quad (12)$$

Where: rec = component recuperation, oms = output mass flow (kg/h), fms = feed mass flow (kg/h), cv =conversion, $r_{in}$ = reactant input to process (mol/h), $r_{out}$ = reactant output to process (mol/h), Yd = Yield, pmf = moles of desired product formed (mol), tpm = theoretical product moles (mol), pmr = product mass ratio, mp = product mass flow (kg/h), rmm = raw material mass flow (kg/h), PFT= Annual profit (USD/y), Ah = hours per year (8,766 h/y), PSALE = product sale (USD/h), RMC = raw material cost (USD/h), UCT = Utilities total cost (USD/h), k = annualization factor, EC = Equipment cost (USD), pp = product price (USD/kg), prmm = raw material price (USD/kg), UC = Utility cost, i = interest rate (10 %), n = project life period (20 years), $C^{\circ}_p$ = Equipment base cost (USD), A = capacity or measurement parameter for the equipment, ($K_1$, $K_2$, $K_3$, $B_1$, $B_2$,) = Guthrie's constants, $F_M$ = material factor, $F_P$ = pressure factor, $C_{BM}$ = module cost (USD), $C_1$ = Equipment cost at reference time (USD), $C_2$ =

Cost of equipment in the desired time (USD), $I_1$ = Reference time cost index, $I_2$ = Desired Time Cost Index. Subscripts: j = product stream, g = raw material stream, i = utility. It is important to mention that utility costs are calculated by using Aspen Plus V.14 software.

Table 1 shows the wine effluent composition. The solids, which are considered the sludge's main components, are represented by cellulose ($C_6H_{10}O_5$), hemicellulose ($C_5H_8O_4$), lignin ($C_{7.3}H_{13.9}O_{1.3}$), and lees (dead yeast, $CH_{1.83}O_{0.56}N_{0.17}$) [9].

**Table 1:** Comparison between wine effluent and treated water.

| Parameter | Wine effluent | Treated water |
|---|---|---|
| Mass Flow (kg/h) | 10,000 | 4,333.16 |
| Water (% mass) | 71.76 | 99.99 |
| Ethanol (% mass) | 7.39 | 0 |
| Glucose(% mass) | 5.26 | 0 |
| Solid (% mass) | 15.59 | 0 |
| COD (PPM) | 210,052 | 32.19 |

Figure 1 represents the conceptual biorefinery. Wine effluent is fed to process through a decanter tank (DCT-01), where some solids are separated from the liquid matrix. NRTL is employed as a thermodynamic model for this unit operation. The remaining solids in the liquid phase are sent to the centrifuge (CN-01). This equipment uses NRTL as thermodynamic model. Liquid flow coming from CN-01 goes to reactive distillation column # 1 (RD-01); on the other side, the solids from CN-01 are mixed with those coming from DCT-01 to be pumped and heated for reaching the operational conditions in hydrothermal liquefaction reactor (R-01).

The liquid phase of water, ethanol, and glucose feeds RD-01. Inside the reactive column reactions (1) and (2), are carried out, Table 2. The kinetic parameters are taken from the literature [4]. Glucose is transformed to 5-Hydroximetilfurfural, then converted to levulinic acid and formic acid. For RD-01 modeling, the Rad Frac block and NRTL thermodynamic model are employed. The RD-01 top releases ethanol and water to a conventional distillation column (DC-03). Moreover, the stream coming from the RD-01 bottom is constituted by levulinic, formic, and sulphuric acids; this stream is fed to DC-01, a conventional distillation column that separates formic acid from the acid mixture.

DC-01 is modeled by Rad Frac block and uses NRTL as a thermodynamic model. DC-01 bottoms are directed to DC-02, where levulinic acid is separated from the mixture that contains the catalyst, $H_2SO_4$. DC-02 is simulated with the same rigorous models as DC-01. The catalyst is recirculated to RD-01.

DC-03 purifies the water by releasing all the organic compounds, mainly ethanol and traces of formic acid, from its top. From the DC-03 bottom, treated water is obtained. The thermodynamic model employed is Wilson, and Rad Frac block is used.

RD-02 receives the diluted ethanol, 53.94 % mass from DC-03, and propylene oxide as raw material. Inside this reactive column, reactions (3) and (4) are carried out [5], Table 2. The water reacts with propylene oxide to get propylene glycol. In addition, propylene oxide reacts with propylene glycol to produce dipropylene glycol. Rad frac block and NRTL thermodynamic model are used. Kinetic parameters are obtained from the literature [5]. On the RD-02 top, bioethanol production is reached, while glycols are released on the RD-02 bottom. It is important to mention that the glycol stream is coupled to the organic Rankine cycle, which uses R235FA as a working fluid to get electrical power; this aims to reduce electrical utility consumption.

**Table 2:** Reactions carried out in reactive distillation columns.

| Reaction | # |
|---|---|
| $C_6H_{12}O_6 \xrightarrow{H_2SO_4} C_6H_6O_3 + 3H_2O$ | (1) |
| $C_6H_6O_3 + 2H_2O \rightarrow C_3H_8O_3 + CH_2O_2$ | (2) |
| $C_3H_6O + H_2O \rightarrow C_3H_8O_2$ | (3) |
| $C_3H_6O + C_3H_8O_2 \rightarrow C_6H_{14}O_3$ | (4) |

R-01 is represented by the RBatch block and Peng-Robinson thermodynamic model. The solid compounds are transformed into biogas, bio-oil, and aqueous phase [10-11]. Operational conditions reached by R-01 are 400 °C and 220 bar. Reactions are described in Table 3. The kinetic parameters are taken from the literature [12].

Once products are obtained from R-01, they are separated using Flash Tank #1 (FL-01). FL-01 is modeled through a Sep block and NRTL thermodynamic model. Operational conditions are 20 °C and 1 bar.

The biogas and aqueous phases are considered by-products. The bio-oil is sent to the up-grading process in reactor #2 (R-02), the hydrotreatment. R-02 is a batch reactor, represented by RBatch block and Peng-Robinson thermodynamic model. It operates at 450 °C and 20 MPa. The reactions involved are those shown in Table 4. Kinetic parameters are taken from the literature [13]. At the end of this unit operation, residual gas (mainly $H_2$), biofuel, and aqueous phase are obtained. The mixture goes to Flash Tank #2 (FL-02).

A Sep block represents FL-02 and uses the NRTL thermodynamic model. Operation conditions are 30 °C and 1.52 bar. The biofuel stream is fed to conventional distillation column #4 (DC-04). DC-04 separates naphtha from the top and sustainable aviation fuel (biojet fuel) by the column bottoms. This column uses a Rad frac block and BK-10 as thermodynamic models.

## RESULTS

As the study case, the wine effluent generated in a year by the Baja, California, Mexico wine industry is considered because this Mexican State generates 80% of national production [14,15]. Table 1 shows the study case's effluent characterization and the mass flow rates. Moreover, Table 5 shows the obtained products through the biorefinery scheme.

According to Table 5, water, glycols, bioethanol, biogas, and levulinic acid represent 58.12%, 23.9%, 6.5%, 3.89%, and 2.94% of the total production, respectively. These results are consistent with the inputs; the most abundant compound in wine effluents is water, which justifies that water has the highest value. The percentage of glycols comes from the reaction between the attached water in the diluted ethanol stream at the DC-03 dome outlet and the supplied propylene oxide. Although the solid presence is higher than ethanol and glucose in wine effluent, bioethanol and levulinic acid production are more significant than the biofuels (naphtha and sustainable aviation fuel) from sludge hydrothermal liquefaction. The cause is that not all solids produce bio-oil to upgrade to biofuels because they have both aqueous phase and biogas production; thus, bioethanol and levulinic acid production are more significant than liquid biofuels.

**Table 4:** Reactions carried out in bio-oil hydrotreatment reactor.

| Reaction | # |
|---|---|
| $C_{12}H_{10}O + 9H_2 \rightarrow C_{12}H_{28} + H_2O$ | (37) |
| $C_{12}H_{10}O + 8H_2 \rightarrow C_{12}H_{24} + H_2O$ | (38) |
| $C_{14}H_{12} + 9H_2 \rightarrow C_{14}H_{30}$ | (39) |
| $C_{14}H_{12} + 10H_2 \rightarrow 2C_7H_{16}$ | (40) |
| $C_6H_6 + 4H_2 \rightarrow C_6H_{14}$ | (41) |
| $C_6H_6 + 3H_2 \rightarrow C_6H_{12}$ | (42) |
| $C_8H_8O + 6H_2 \rightarrow C_8H_{18} + H_2O$ | (43) |
| $C_8H_8O + 5H_2 \rightarrow C_8H_{16} + H_2O$ | (44) |
| $C_{15}H_{14}O + 10H_2 \rightarrow C_{15}H_{32} + H_2O$ | (45) |
| $C_{15}H_{14}O + 9H_2 \rightarrow C_{15}H_{30} + H_2O$ | (46) |
| $C_4H_5N + 4H_2 \rightarrow C_4H_{10} + NH_3$ | (47) |
| $C_4H_5N + 3H_2 \rightarrow C_4H_8 + NH_3$ | (48) |
| $C_4H_4N_2 + 6H_2 \rightarrow C_4H_{10} + 2NH_3$ | (49) |
| $C_4H_4N_2 + 5H_2 \rightarrow C_4H_8 + 2NH_3$ | (50) |
| $C_4H_9N + 2H_2 \rightarrow C_4H_{10} + NH_3$ | (51) |
| $C_4H_9N + H_2 \rightarrow C_4H_8 + NH_3$ | (52) |
| $C_5H_4O_2 + 6H_2 \rightarrow C_5H_{12} + 2H_2O$ | (53) |
| $C_5H_4O_2 + 5H_2 \rightarrow C_5H_{10} + 2H_2O$ | (54) |
| $C_5H_8O_3 + 5H_2 \rightarrow C_5H_{12} + 3H_2O$ | (55) |
| $C_5H_8O_3 + 4H_2 \rightarrow C_5H_{10} + 3H_2O$ | (56) |

**Table 5:** Product mass flow

| Product | Mass flow (kg/h) |
|---|---|
| Biogas | 290.32 |
| Naphtha | 90.14 |
| Sustainable aviation fuel | 158.22 |
| Levulinic acid | 219.05 |
| Bioethanol | 485 |
| Water | 4,333.16 |
| Glycols | 1,781.68 |
| Formic acid | 93.5 |
| Residual gas | 5.03 |

Table 6 shows the technical indicators obtained. It is essential to highlight the conversion of solids and glucose that reach 100%. This means finding a sustainable solution for managing all residual sludge in treating wine effluents is possible. Water recuperation seems to have a low value; however, a water mass flow is consumed in glycol production, and another part goes to the aqueous phase, with the mass balance of ethanol, in the sludge hydrothermal liquefaction. The glycol yield is attractive because it is greater than 95 %. The levulinic acid yield may not seem good enough. However, it has to be highlighted that the reaction to obtain levulinic acid involved the production of formic acid, so it represents an attractive yield for reaching a value higher than 50%.

The ratios obtained in Table 6 give the impression that they are too small, though as shown in Table 1, the mass flow of wine effluent is several times greater than the obtained products. In addition, water is the main component of wine effluent, and it does not directly contribute to almost all products except glycol production; it

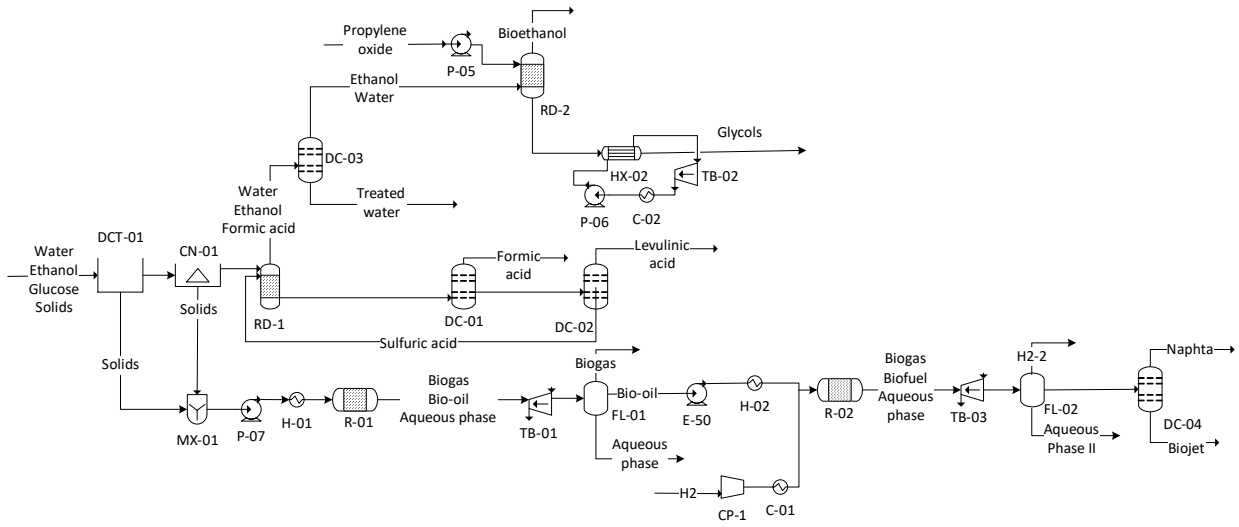

**Figure 1:** Biorefinery scheme. Where DCT=Decanter tank, CN= Centrifuge, RD= Reactive distillation column, DC= Distillation column, R= reactor, FT= Flash tank, MX= Mixer, TB=Turbine, C= condenser, P= Pump, CP= Compressor, HX= Heat exchanger, MX= Mixer.

provokes ratios that seem too insignificant. It does not happen with glycol production, where water is a reactant.

**Table 6:** Technical indicators

| Parameter | Value |
|---|---|
| $rec_{Water}$ | 60.38 % |
| $rec_{Ethanol}$ | 65.63 % |
| $cv_{Glucose}$ | 100 % |
| $cv_{Solids}$ | 100 % |
| $Yd_{Levulinic\ acid}$ | 64.63 % |
| $Yd_{Glycol}$ | 97.21 % |
| $pmr_{Biogas}$ | 0.029 |
| $pmr_{Naphtha}$ | 0.009 |
| $pmr_{Biojet}$ | 0.0158 |
| $pmr_{Levulinic\ acid}$ | 0.0219 |
| $pmr_{Bioethanol}$ | 0.0485 |
| $pmr_{Water}$ | 0.4333 |
| $pmr_{Glycols}$ | 0.1782 |
| $pmr_{Formic\ acid}$ | 0.0093 |
| $pmr_{Residual\ gas}$ | 0.0005 |
| COD removed | 99.99% |

For finishing the technical parameters, the COD reduction in treated water is so attractive because it is under the Official Mexican Standards (NOM-001-SEMARNAT-2021 and NOM-127-SSA1- 2021) that stipulate a COD level lower than 75 ppm is adequate to human use.

On the other hand, Table 7 shows the economic indicators. Regarding raw material cost, $H_2$ constitutes 50.2 % of the total, and the propylene oxide cost completes the balance. In product sales, levulinic acid gives the 86.89 % of the total, glycols the 8.86%, and bioethanol the 1.89%. Considering utility cost, the reboiler in RD-01 spent 91.52 % of the total; it is due to there being a large quantity of water and ethanol mass that has to be evaporated to separate it from the matrix with glucose, sulphuric acid, and formic acid; besides, it presents a higher reflux ratio, 20. these features consume too much energy, 136,043.28 kW.

**Table 7:** Economic indicators

| Parameter | Value |
|---|---|
| Raw material cost (USD/h) | $129.75 |
| Product sale (USD/h) | $31,010.08 |
| Levulinic acid (USD/kg) | $123 |
| Glycols (USD/kg) | $1.76 |
| Bioethanol (USD/Kg) | $1.21 |
| SAF (USD/kg) | $2.44 |
| Naphtha (USD/kg) | $1.56 |
| Biogas (USD/kg) | $1.39 |
| Utilities cost (USD/h) | $1,507.88 |
| Equipment cost (USD) | $51,335,863.95 |
| Annual equipment cost (USD/y) | $6,029,891.32 |
| Total annual cost (USD/y) | $20,385,357.23 |
| Profit (USD/y) | $251,449,023.39 |

Regarding equipment cost, RD-01 represents the most expensive by using 41.45 % of the total, followed by R-01, the hydrothermal liquefaction reactor, with 23.51%, and R-02, the bio-oil hydrotreatment reactor. RD-01 has the highest cost due to its size and operational pressure, contributing to a more considerable equipment thickness.

## CONCLUSIONS

This research presents the technical and economic feasibility of obtaining biofuels and value-added molecules through a biorefinery scheme. Different products, such as levulinic acid, bioethanol, biogas, glycols, naphtha, sustainable aviation fuel, and formic acid, are obtained from this biorefinery. This shows that the valuation of wine effluents and their sludge is possible using a biorefinery scheme.

Regarding the economic analysis, it is clear that levulinic acid production is essential in reaching the economic feasibility of wine effluent and its sludge valorization. However, expanding the range of generated products enhances the economic condition of the process, particularly when including biofuels, whose market price is lower than other higher-value-added products.

The presented strategy provides an efficient solution for waste management in the wine industry. However, a similar approach can be implemented for other sludge types. Moreover, this strategy contributes to the transition toward a circular economy by turning waste into energy-rich and value-added products.

## ABSTRACT

The 2,3-, 1,4- and 1,3-butanediols (BDOs) are valuable platform chemicals traditionally produced through petrochemical routes. Alternatively, there is growing interest in synthesizing these chemicals through fermentation processes. However, several drawbacks of the fermentation process (e.g. low product concentration, formation of by-products and high-boiling temperatures of BDOs) hinder the downstream process and increase overall production costs. This original research proposes an advanced large-scale (processing capacity of 160 ktonne/y) process design for the purification of different BDOs after fermentation. The initial preconcentration step removes most water and light impurities in heat pump-assisted distillation column. The heart of the developed process is an integrated dividing-wall column that effectively separates high-purity BDO (>99.4 wt% in all cases) from the remaining impurities. Each BDO isomer was purified cost-effectively (0.208 – 0.243 $/kg$_{BDO}$) and energy-efficiently (1.854 – 2.176 kW$_{th}$h/kg$_{BDO}$) using a single process design, offering flexibility in the development of sustainable bioprocesses for BDO production.

**Keywords**: butanediols, dividing-wall column, downstream processing

## INTRODUCTION

Uncertainties related to fossil fuel-based production pathways are driving interest in developing sustainable alternatives. Fermentation emerges as a promising substitute for the petrochemical production of many chemicals. Among these potential bioproducts, butanediols (BDOs) are very important platform chemicals with a wide variety of applications (e.g. pharmaceuticals, cosmetics, softening agents, solvents, plasticizers, fertilizers, printing inks, polymers, etc.). Significant research effort has been put into developing genetically engineered microorganisms that can produce BDOs from different renewable carbon sources. So far, fermentative production of 2,3-, 1,4- and 1,3-butanediol resulted in significant product titers and may have potential for industrial-scale production. Contrarily, titers of 1,2-BDO achieved so far are very low and additional improvements in the fermentation are needed before considering scale-up. Despite the significant research on developing the upstream process, the recovery of BDOs from fermentation broth has not been nearly as promptly addressed. Given the drawbacks of the fermentation process (low product concentrations, formation of by-products, high boiling temperatures of BDOs, etc.), the costs of the separation process may significantly contribute to the total production costs.

## PROBLEM STATEMENT

Published studies on BDO recovery after fermentation mainly focus on 2,3-BDO, with comparatively less research dedicated to the recovery of other BDOs. Due to the complex composition of the fermentation broth and high boiling point of BDO products, several steps are required in downstream processing. Consequently, costs of the purification process may significantly contribute to the total production costs [1]. Different techniques have been considered for the separation of BDO from fermentation broth (e.g. solvent extraction, salting-out extraction, sugaring-out extraction, reactive extraction, pervaporation, etc.) [1–5]. Nonetheless, these methods have some drawbacks that hinder effective large-scale

implementation (low product recovery, large amounts of required solvent, subsequent solvent recovery, large amounts of salting-out agents, potential solvent toxicity, significant waste production, membrane fouling, etc.). Moreover, these techniques require additional steps to obtain high-purity BDO product. Alternatively, conventional filtration and ion exchange steps can be used to remove most of the microorganisms, large organic molecules and salts (see Figure 1, preconcentration and final purification (green boxes) are the focus of this research). After these initial downstream processing steps, additional purification is needed to remove the remaining water and obtain a high-purity BDO product. Due to the significant temperature differences and absence of azeotropes, distillation may be used for both preconcentration and final purification. Nonetheless, distillation implies evaporating large amounts of water and advanced energy-saving techniques are required to make the process efficient. Several distillation-based configurations have been proposed (consecutive distillation, extractive distillation, multi-effect distillation, dividing-wall column distillation) [6–9] with energy requirements of 3.1 – 6.5 $kW_{th}h/kg_{BDO}$ (~6.2 to recover 90% of 2,3-BDO using dividing-wall column [10]).

The main goal of our research is to significantly decrease the energy requirements of the preconcentration and final purification parts of the recovery process. Recently, we have achieved this goal by developing a state-of-the-art large-scale downstream processing design (broth processing capacity of 160 ktonne/y with a production capacity of 11 – 15 ktonne/y) that may be easily adapted to purify 2,3- (case 2-3), 1,4- (case 1-4) or 1,3-BDO (case 1-3) after fermentation, and conventional filtration and ion-exchange steps [11]. These initial filtration and ion exchange steps are commonly used in industrial-scale purification processes and were not designed in this study.

## METHODS

Aspen Plus was employed as a computer-aided process engineering (CAPE) tool to design BDO purification processes, whereby rigorous simulations were performed for all process operations. The compositions of the fermentation broths from published literature [7, 12, 13] were used to obtain feed streams for the recovery process (see Figure 3). Generally, concentrations of BDO and water are about 7 – 9 wt% and 87 – 91 wt%, while some light impurities (ethanol, formic acid, acetic acid, etc.) and heavy impurities (lactic acid, succinic acid, glucose, etc.) are present in all cases. Thermodynamic interactions between different components in the broth were described using the Non-Random Two Liquid (NRTL) property model. Hayden-O'Connell (HOC) extension was used to describe vapor phase interactions if polar components (e.g. carboxylic acids) are present (cases 2-3 and 1-3)[14].

## RESULTS AND DISCUSSION

This section contains the main results related to the design of large-scale processes for the recovery of BDOs after fermentation. Flowsheets for these cases, with the main elements of mass and energy balances, are presented in Figure 3.

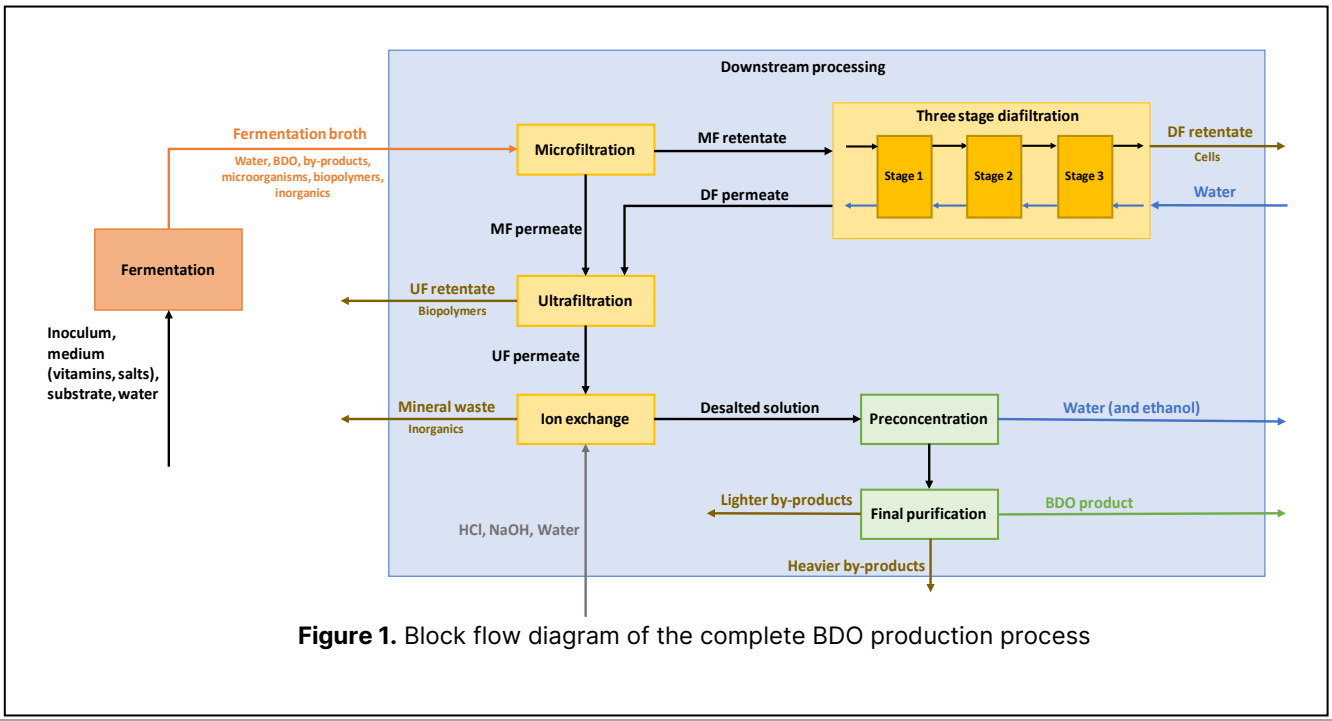

**Figure 1.** Block flow diagram of the complete BDO production process

## Preconcentration step

Following the initial filtration and ion exchange steps necessary to remove microorganisms, large organic molecules and inorganics, the fermentation broth is still very dilute. Hence, a preconcentration step is performed in distillation column C1 to separate most of the water with some light impurities (distillate), from BDO with heavy and remaining light impurities (bottom product). Reduced pressure operation (top pressure of 0.130 bar) was chosen to avoid high temperatures, facilitate separation and decrease energy requirements. Due to the applied vacuum, structured packing was assumed for this column's internals. Given the high concentration of water in broth, the preconcentration step is very energy intensive (> 12 $MW_{th}$). Thus, the implementation of advanced energy-saving techniques is crucial for the energy efficiency of the whole recovery process. Theoretically, all components lighter than BDO can be separated as the top product of column C1. However, this would limit the application of heat pump systems as the temperature difference between the top and the bottom of column C1 would be very large. On the contrary, the proper choice of operating parameters (distillate-to-feed ratio) allows the implementation of a mechanical vapor recompression system (MVR) [15]. This heat pump system implies compressing vapor from the top of a column and using it as a heating utility in a reboiler. The measure of obtained energy savings by implementing this system is the coefficient of performance (COP) – the ratio of exchanged thermal energy and required compressor power. COP values of the MVR systems implemented to column C1 are > 14 in all cases. Given that a COP of over 2.5 testifies to the energy efficiency of heat pump systems, it may be concluded these MVR systems result in significant energy savings. Valorisation of by-products from the top aqueous stream of column C1 was not considered due to their low concentration. Instead, as the worst-case scenario, it was assumed that this stream would be sent to wastewater treatment and appropriate costs were accounted for.

The benefits of the proposed multi-stage preconcentration step in the heat pump-assisted distillation column are manifold. Firstly, removing most of the water drastically reduces equipment size and reboiler duty for the final purification step. Secondly, multi-stage preconcentration in the distillation column allows the separation of water and light impurities without losing BDO product. Thirdly, the applied MVR system significantly decreases energy requirements for the overall recovery process and enables complete (green)electrification of this step. To our knowledge, a multi-stage preconcentration step that removes most of the water and light impurities without losing BDO product and that can be powered completely by electricity has not been proposed so far.

## Further purification

Following the preconcentration step, additional processing is needed to obtain a high-purity final BDO product. This may be performed in a sequence of two distillation columns, whereby the first one removes the remaining water and light impurities, while the second one separates BDO from heavy impurities. Alternatively, these two columns may be integrated into one dividing-wall column (DWC) with a divided overhead section and common bottom section [16]. This highly integrated system combines two columns into one shell with two condensers and only one reboiler. In addition to reducing capital costs (through the number of columns, heat exchangers, and required area for installation), DWC may significantly reduce energy requirements for separation. Although DWC technology has certain limitations, such as a potentially more complex control strategy, its implementation has been successfully proven in multiple large-scale applications [17, 18]. As no DWC unit is available off-the-shelf in Aspen Plus, it was simulated as a thermodynamical equivalent sequence of distillation columns (see Figure 2). The bottom liquid from the left part of the DWC ($DWC_L$) is sent to the right part ($DWC_R$). Simultaneously, part of vapor rising in $DWC_R$ is redirected to $DWC_L$ to ensure sufficient vapor flow in this part of the column. The DWC has 20 stages in total, with the first and the last stages being condenser and reboiler by the convention of Aspen Plus. The wall is placed in the top 14 stages (13 excluding the condenser). Due to the large temperature difference between the BDO and light impurities (top products), thermal insulation will be needed to ensure the energy efficiency of the DWC Reduced pressure operation (top pressure of 0.1 bar) was implemented to avoid high temperatures that may lead to decomposition. Due to the vacuum operation, structured packing was assumed for the DWC's internals. Finally, high purity (>99.4 wt% in all cases) BDO product was recovered as the top product from $DWC_R$. The remaining light and heavy impurities are separated as the top product from $DWC_L$ and the bottom product from $DWC_R$. As a worst-case scenario, and due to the low concentrations, it was assumed that water and light impurities would be sent to wastewater treatment, while heavy impurities would be burnt for energy. Appropriate economic and environmental metrics are included in the evaluation of the developed process.

**Table 1.** Key performance indicators

| | Case 2-3 | Case 1-4 | Case 1-3 |
|---|---|---|---|
| **Economic indicators** | | | |
| CAPEX (k$) | 9,402 | 8,419 | 9,111 |
| OPEX ($/$kg_{BDO}$) | 0.159 | 0.132 | 0.164 |
| Total annual costs ($/$kg_{BDO}$), 10 years payback period | 0.222 | 0.208 | 0.243 |
| **Sustainability metrics** | | | |
| Thermal energy requirements ($kW_{th}h/kg_{BDO}$) | 0.506 | 0.662 | 0.615 |
| Electrical energy requirements ($kW_eh/kg_{BDO}$) | 0.539 | 0.502 | 0.624 |
| Primary energy requirements ($kW_{th}h/kg_{BDO}$) | 1.854 | 1.917 | 2.176 |
| $CO_2$ emissions, grey / green electricity ($kg_{CO2}/kg_{BDO}$) | 0.319 / 0.073 | 0.324 / 0.096 | 0.373 / 0.089 |

| Material intensity ($kg_{waste}/kg_{BDO}$) | 0.037 | 0.004 | 0.024 |

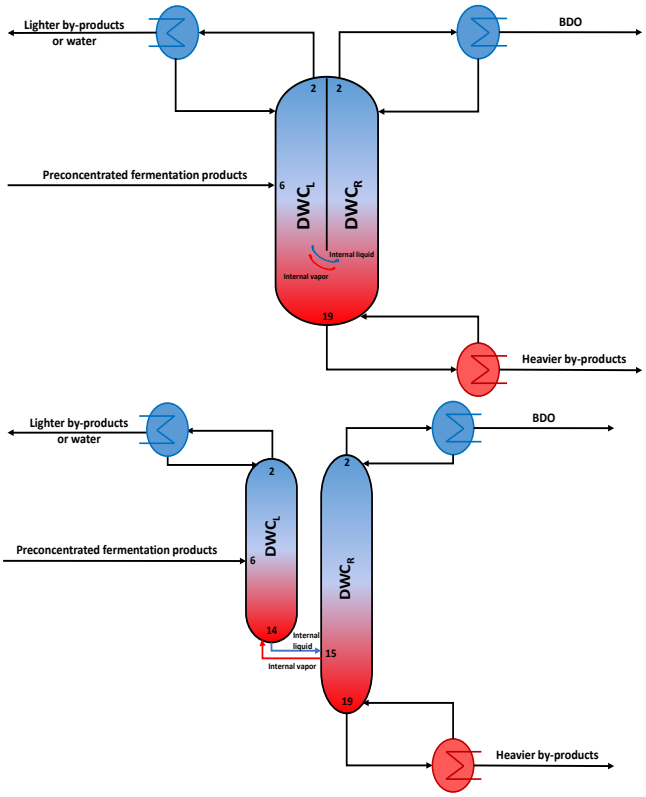

**Figure 2.** DWC (top) and equivalent sequence of distillation columns (bottom)

## Analysis of economic and environmental impact

The performance of the developed recovery processes was evaluated by analyzing economic indicators and sustainability metrics following the published recommendations [19, 20]. A comparison between the three processes is presented in Table 1.

Slightly lower capital costs in case 1-4 are due to marginally lower costs of distillation columns and compressor in the MVR system. Similarly, lower operating costs (OPEX) in case 1–4 are mainly because of lower wastewater treatment and electricity expenses (due to lower amount of light impurities and lower required compressor power in the MVR system). Total annual costs that include both CAPEX and OPEX with a payback period of 10 years are 0.222, 0.208 and 0.243 $/kgBDO in cases 2-3, 1-4 and 1-3, respectively. Thus, despite a somewhat lower initial concentration of 1,4-BDO (6.97 wt%) compared to 2,3-BDO (9.30 wt%) and 1,3-BDO (7.25 wt%), process performance is slightly better due to lower amounts of light impurities. Nonetheless, given that the minimum selling price for 2,3-BDO produced from sucrose, molasses or glycerol has been estimated to be 3.7 – 5.7 $/$kg_{BDO}$ [5], the proposed cost-effective recovery process may present a major advancement toward competitive fermentative production of BDO. Furthermore, there is significant margin compared to the price of petrochemically produced BDOs (about 1.8 $/kg [21]). However, fermentation costs still need to be accounted for to obtain a real picture.

Furthermore, thermal energy requirements are the lowest in case 2-3 (0.506 $kW_{th}h/kg_{BDO}$) due to the largest product flowrate. On the contrary, electrical energy requirements are the lowest in case 1-4 because of the lowest compressor power in the MVR system. The total primary energy requirements were calculated considering a conservative electrical-to-thermal conversion factor of 2.5. This metric ranges from 1.85 $kW_{th}h/kg_{BDO}$ for case 2-3 to 2.18 $kW_{th}h/kg_{BDO}$ for case 1-3, which is much lower than the 3.1 – 6.5 $kW_{th}h/kg_{BDO}$, reported in the literature. Related to energy use are $CO_2$ emissions, which are again the lowest in case 2-3. Water consumption (including 7 % loss of cooling water and 70 % recovery of condensate in the steam cycle) is also the lowest in case 2-3 due to the lowest thermal energy requirements. Material intensity is the lowest in case 1-4 because of the lowest amounts of light impurities.

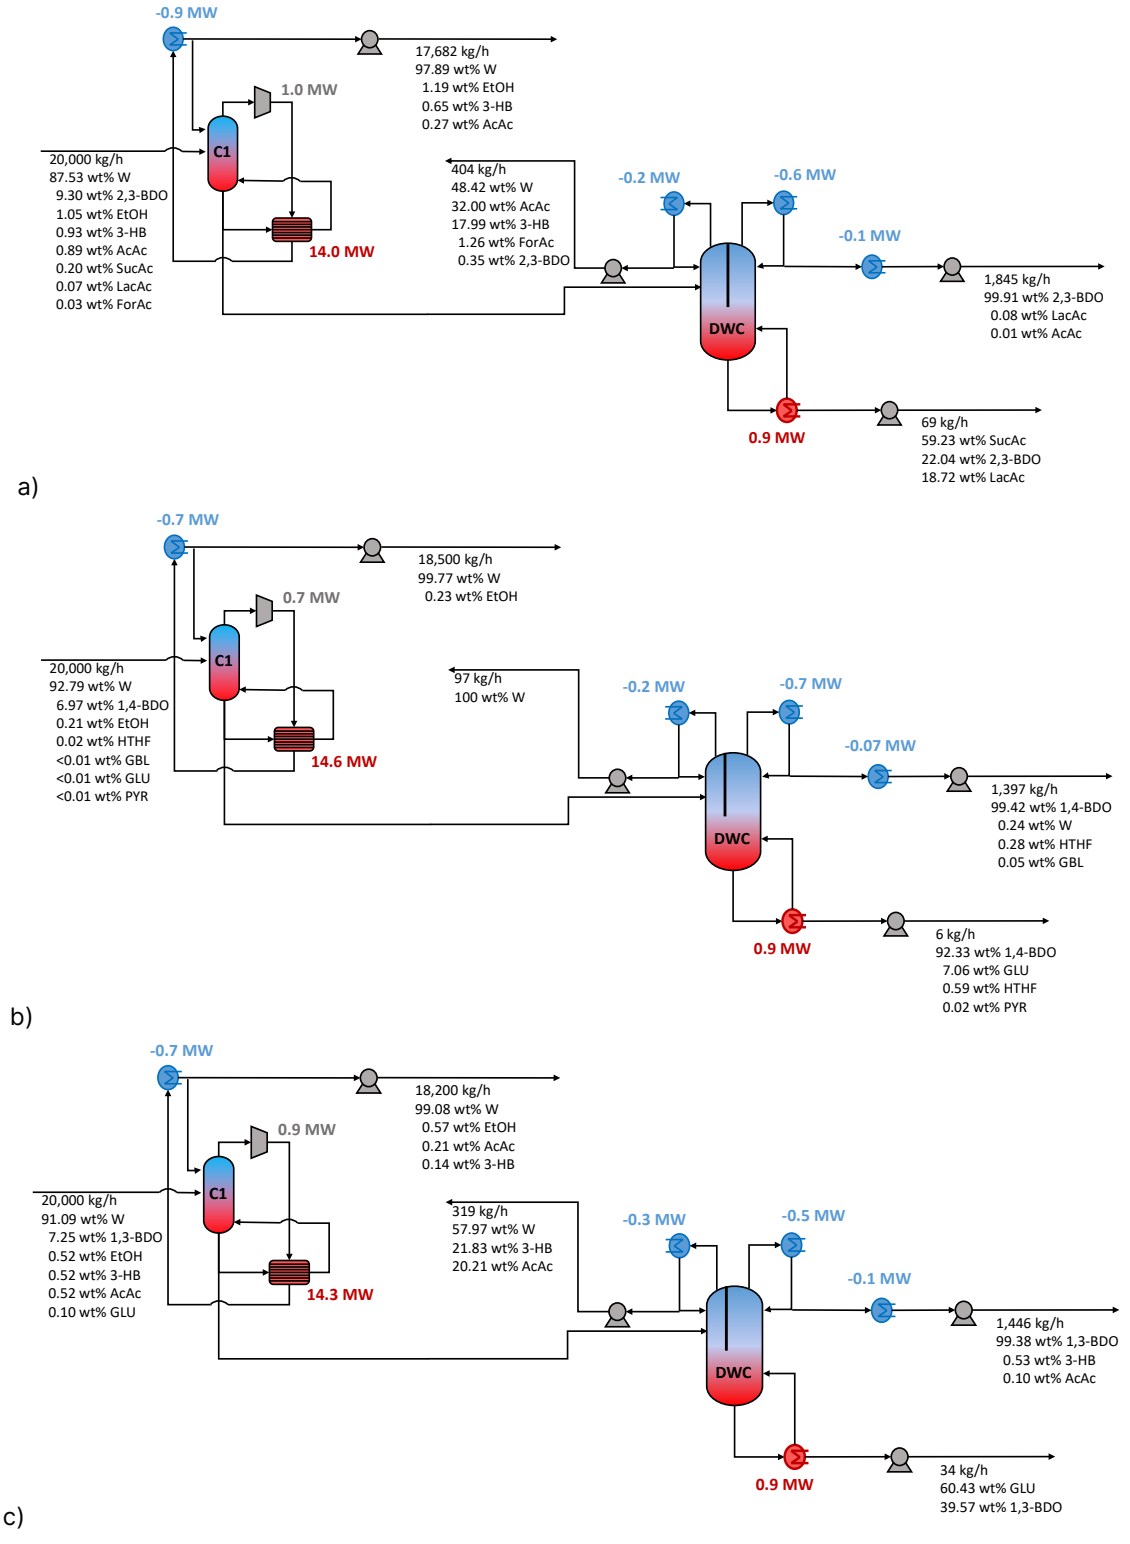

**Figure 3.** Flowsheet of BDOs' recovery process: a) 2,3-BDO, b) 1,4-BDO and c) 1,3-BDO

## CONCLUSION

This original paper proposes an eco-efficient large-scale downstream processing design for the preconcentration and final purification steps in the purification of

different BDOs (2,3-, 1,4- and 1,4-) after fermentation. Due to similar fermentation broth compositions and thermodynamic properties, a single process design was proven to cost-effectively (0.208 – 0.243 $/kg$_{BDO}$) and energy-efficiently (1.85 – 2.18 kW$_{th}$h/kg$_{BDO}$) recover over 99% of BDO from different fermentation processes. Implementation of the advanced process intensification and heat integration techniques reduced energy requirements by over 33% compared to the existing literature. Furthermore, the adaptable purification process offers flexibility in developing sustainable business models. Lastly, the results of this novel work highlight the importance of using CAPE tools in developing competitive bioprocesses by demonstrating that computer-aided simulations may play a crucial role in advancing sustainable industrial fermentation.

## OUTLOOK

While this study provides valuable insights into the techno-economic and environmental feasibility of the proposed processes for the recovery of BDOs after fermentation, there is room for further research to enhance its applicability and robustness. Although the developed process simulations rely on well-established thermodynamic models and rigorously validated unit operation models in Aspen Plus, experimental validation remains essential to ensure successful industrial implementation. Computational simulations should serve as a guiding framework for experiments, ensuring a more efficient and reliable approach to process development. Additionally, while the feasibility of DWC has been demonstrated in real-world applications, further research is needed to optimize equipment design and control strategies for maximizing operational efficiency.

Expanding the process design to include the fermentation reaction would provide a more comprehensive evaluation of economic competitiveness and enable a fair comparison with existing BDO production methods. Moreover, conducting a sensitivity analysis to assess the impact of variations in key factors—such as feedstock costs, utility prices, wastewater treatment costs, and BDO market prices—would offer deeper economic insights. A full life cycle assessment (LCA) would also be valuable in obtaining a more comprehensive understanding of the sustainability of the entire process.

Furthermore, an interesting avenue for future research is the development of a flexible process capable of producing multiple BDO isomers based on market demand. Given the fluctuating market dynamics of bio-based chemicals, designing a process that can adapt to varying production needs could enhance economic viability and commercial competitiveness.

## ABSTRACT

Maintaining consistent product quality and yield in bioprocess operations is challenging due to uncertainties inherent in biological systems. Thus, robust strategies are essential to ensure key performance indicators (KPIs), such as product concentration and yield, are consistently met despite the uncertainties. Real-time feedback co Interntrol, though widely used, is often impractical due to its reliance on expensive sensors, rapid data processing, and high-speed control actions. This paper proposes a novel approach to address these challenges by identifying the operational space for control variables, ensuring KPI reliability without requiring real-time control. This operational space serves as a guideline such that, if we operate within this space, the KPIs can be reliably achieved, regardless of the considered uncertainties. Specifically, we reformulate the problem as an optimization task to maximize the operational space, subject to constraints imposed by process dynamics and performance criteria. Using CasADi for symbolic computation and IPOPT for optimization, a stage-wise procedure is implemented to enhance computational efficiency. Unlike surrogate-based methods, this approach directly preserves model fidelity and accommodates path constraints effectively. The method is validated in a case study of fermentation process, involving a time-varying control variable and seven uncertain model parameters. Results demonstrate the ability to define a reliable operational space that enables KPI adherence across parameter variations, proving the method's efficiency and practical applicability.

**Keywords**: Design Under Uncertainty, Process Control, Biosystems, Operational Space

## INTRODUCTION

Bioprocess industries, including pharmaceuticals, biotechnology, and food production, rely heavily on biological systems to produce products of consistent quality and yield. However, biological processes are inherently variable due to the complex and often poorly understood interactions within living organisms [1,2].

Traditionally, system identification techniques are employed to develop mathematical models that describe the dynamic behavior of bioprocesses [3,4]. These models are then used to design control strategies to maintain process variables within desired ranges. However, when models rely solely on nominal parameter values, they may not adequately account for the uncertainties inherent in biological systems, leading to deviations in process performance [5]. Real-time feedback control is commonly employed to manage such uncertainties by continuously adjusting control variables based on real-time measurements [6]. While effective, this approach can be costly and impractical due to the need for high-speed data processing, robust sensors, and rapid control actions [7]. Moreover, in bioprocessing environments where measurements may be infrequent or delayed, real-time control becomes even more challenging [8].

To address these challenges, there is a need for control strategies that ensure key performance indicators (KPIs), such as final product concentration and yield, are consistently met despite uncertainties, without relying heavily on real-time feedback mechanisms. Here, uncertainties can arise from biological variability, measurement inaccuracies, and model simplifications. In this paper, we focus on the uncertainties introduced by model parameters involved in system identification.

Various methods have been developed to manage model uncertainties in control problems, aiming to ensure KPIs are met despite parameter variability. Semi-Infinite Programming (SIP) addresses uncertainties by including infinitely many constraints to guarantee performance for all parameter values within specified bounds [9]. While comprehensive, SIP is computationally intensive and difficult to solve [10]. Scenario Optimization reduces this complexity by approximating the uncertainty space with a finite set of scenarios generated through sampling techniques like Monte Carlo or Latin Hypercube Sampling [11]. Though more tractable, this method may require numerous scenarios to achieve robustness, increasing computational demands. Robust Optimization ensures feasibility across the entire uncertainty set without explicit enumeration, but it can lead to conservative solutions and is constrained by the structure of the uncertainty and problem type [12,13]. Similarly. worst-Case Identification via Optimization formulates a bilevel optimization problem, where the outer optimization seeks optimal controls, and the inner problem identifies the most adverse parameter values. While precise for handling extreme uncertainties, this approach is computationally demanding [14]. Surrogate-Based Methods leverage simplified models like Kriging, polynomial chaos expansions, or neural networks to approximate high-fidelity systems, enabling efficient exploration under uncertainty. However, these methods depend on high-quality training data and face challenges in high-dimensional spaces, where accurately constructing surrogates becomes increasingly complex and resource-intensive [15].

Despite the advances in these methods, challenges remain in efficiently handling parameter uncertainties in control problems, especially when the worst-case scenarios do not occur at the parameter extremes. Computational complexity and the need for approximations or surrogate models can limit their practical applicability in bioprocess operations.

### Contribution

In this paper, we propose an alternative scenario optimization approach that effectively addresses the computational challenges while maintaining accuracy and fidelity to the original process dynamics. We reformulate the problem as an optimization task aimed at maximizing the operational space of relevant control variables, subject to path and terminal constraints imposed by process dynamics and performance specifications.

Our approach integrates symbolic frameworks using CasADi [16], a software tool for numerical optimization that facilitates the formulation and efficient evaluation of gradients and Hessians. We solve the formulated optimization problem using IPOPT [17], an interior-point optimizer well-suited for large-scale nonlinear programming. Different from conventional scenario optimization methods, a novel stage-wise optimization procedure is implemented to reduce computational burden.

The paper is organized as follows. The target problem is first described, followed by the proposed solution methods. Then, a case study of fermentation process is discussed. Lastly, future works are noted.

## PROBLEM DESCRIPTION

Consider a bioprocess described by a mechanistic model consisting ordinary differential equations (ODEs): $\dot{\boldsymbol{x}}(t) = \boldsymbol{F}(t, \boldsymbol{x}(t), \boldsymbol{u}(t), \boldsymbol{p}, \boldsymbol{\theta})$, where, $\boldsymbol{x}$ and $\boldsymbol{u}$ are the vector of state variables (e.g., biomass concentration, substrate concentration, etc.) and control inputs (e.g., feed rate, temperature, etc.), respectively, with $\boldsymbol{\theta}$ and $\boldsymbol{p}$ being the fixed parameters and the parameters subject to bounded uncertainties (i.e., $\boldsymbol{p} \in [\boldsymbol{p}_{\min}, \boldsymbol{p}_{\max}]$), respectively.

The following assumptions are made in this study: $(i)$ the range of the uncertain parameters is known or can be estimated during system identification; $(ii)$ the initial state of the system is known and it is the same across different batches; $(iii)$ the desired output and its relevant acceptable bounds have been defined; $(iv)$ the control input can be time-varying, and a reference trajectory is provided or can be calculated; $(v)$ the operational space we aim to identify for the control input can be time-varying, and the system operates on a fixed time horizon; and $(vi)$ the system dynamics can be identified.

The goal is to identify a practical and flexible operational space for $\boldsymbol{u}$ such that, if we operate within this space, the KPIs are likely to be consistently met independent of the uncertain parameters $\boldsymbol{p}$.

## PROPOSED METHOD

### Optimization problem formulation

We discretize the time horizon $[0, T]$ into $N$ intervals with piecewise constant controls $\boldsymbol{u}_k$ for $k = 0, \ldots, N-1$. Our objective is to find the largest operational space for the control inputs subject to process constraints. Specifically, we consider maximizing the difference between the upper ($\overline{\boldsymbol{u}}_k$) and lower ($\underline{\boldsymbol{u}}_k$) bounds of the control inputs over the time horizon:

$$\max_{\underline{\boldsymbol{u}}_k, \overline{\boldsymbol{u}}_k} \quad \text{dist}\{\overline{\boldsymbol{u}}_k - \underline{\boldsymbol{u}}_k\} \text{ for } k = 0, \ldots, N-1. \tag{1}$$

The optimization problem (1) is subject to different constraints. For example, the dynamics of the process will follow the system model, some path constraints can be involved, and process KPIs need to be respected.

### Solution approach

For conventional scenario optimization methods, samples of uncertain parameters are drawn from their ranges and incorporated as constraints into the

optimization problem (1) as constraints, which is then solved in a single step. However, achieving robustness typically requires a large number of samples to adequately represent the uncertainty. This makes solving (1) computationally expensive and increases the risk of getting trapped in local optima. To address the challenges, we propose a new scenario optimization method that integrates a stage-wise optimization procedure to enhance computational efficiency. Additionally, a looped verification step is integrated within the framework to enhance the robustness of the approach.

The proposed method aims to iteratively update the lower and upper bounds of control inputs to accommodate parameter uncertainties while respecting system constraints. The process involves sampling parameters, grouping them based on computational capacity, and solving optimization problems to adjust the bounds accordingly. The steps are summarized in Algorithm 1.

**Algorithm 1:** Stage-wise optimization for operational space design.

**Input:** Parameter uncertainty bounds $\boldsymbol{p}_{\min}, \boldsymbol{p}_{\max}$; number of discretization steps $N$; initial control input $\tilde{\boldsymbol{u}}_k$, weights $w_{jk}$, for $k = 0, \dots, N-1$ and $j = 1, \dots, m$; number of parameter samples $N_{\text{sp}}$; number of computational groups $N_{\text{gp}}$
**Output:** Updated control input bounds $\underline{\boldsymbol{u}}_k$, $\overline{\boldsymbol{u}}_k$

**Initialization:** $\underline{\boldsymbol{u}}_k \leftarrow \tilde{\boldsymbol{u}}_k$, $\overline{\boldsymbol{u}}_k \leftarrow \tilde{\boldsymbol{u}}_k$, for $k = 0, \dots, N-1$
**Sampling Parameters:** Sample $N_{\text{sp}}$ parameters: $\{\boldsymbol{p}^i\}_{i=1}^{N_{\text{sp}}} \sim \mathcal{U}(\boldsymbol{p}_{\min}, \boldsymbol{p}_{\max})$
**Dividing Samples into Groups:** divide $N_{\text{sp}}$ samples into $N_{\text{gp}}$ groups
**For** $z = 1$ **to** $N_{\text{gp}}$ **do**
  **If** $findLowerbound$ **then**
    $\underline{\boldsymbol{u}}_{k,\text{old}} \leftarrow \underline{\boldsymbol{u}}_k$
    **If** $z == 1$ **then**
      Solve the following optimization problem to get $\underline{\boldsymbol{u}}_k$:

$$\max_{\underline{\boldsymbol{u}}_k} \ \min_{j=1}^{m} \min_{k=0}^{N-1} \underline{w}_{jk} \left(\underline{u}_{jk,\text{old}} - \underline{u}_{jk}\right) \quad (2)$$

      s.t. path & terminal constraints

$$\underline{u}_{jk,\text{old}} \geq \underline{u}_{jk}, \ \forall j, k$$

    **Else**
      Solve the following optimization problem to get $\underline{\boldsymbol{u}}_k$:

$$\min_{\underline{\boldsymbol{u}}_k} \ \sum_{j=1}^{m} \sum_{k=0}^{N-1} \underline{w}_{jk} \left(\underline{u}_{jk} - \underline{u}_{jk,\text{old}}\right) \quad (3)$$

      s.t. path & terminal constraints

$$\underline{u}_{jk,\text{old}} \leq \underline{u}_{jk} \leq \tilde{u}_{jk}, \ \forall j, k$$

  **If** $findUpperbound$ **then**
    $\overline{\boldsymbol{u}}_{k,\text{old}} \leftarrow \overline{\boldsymbol{u}}_k$
    **If** $z == 1$ **then**
      Solve the following optimization problem to get $\overline{\boldsymbol{u}}_k$:

$$\max_{\overline{\boldsymbol{u}}_k} \ \min_{j=1}^{m} \min_{k=0}^{N-1} \overline{w}_{jk} \left(\overline{u}_{jk} - \overline{u}_{jk,\text{old}}\right) \quad (4)$$

      s.t. path & terminal constraints

$$\overline{u}_{jk,\text{old}} \leq \overline{u}_{jk}, \ \forall j, k$$

    **Else**
      Solve the following optimization problem to get $\overline{\boldsymbol{u}}_k$:

$$\min_{\overline{\boldsymbol{u}}_k} \ \sum_{j=1}^{m} \sum_{k=0}^{N-1} \overline{w}_{jk} \left(\overline{u}_{jk,\text{old}} - \overline{u}_{jk}\right) \quad (5)$$

      s.t. path & terminal constraints

$$\overline{u}_{jk,\text{old}} \geq \overline{u}_{jk} \geq \tilde{u}_{jk}, \ \forall j, k$$

In the following, we elaborate each step of Algorithm 1. We first initialize the lower and upper control input bounds to the nominal control input $\tilde{\boldsymbol{u}}_k$, which we assumed to be known or can be identified via optimal control strategies with uncertain parameters set to their nominal values (e.g., the middle points of the uncertain ranges). Then we sample $N_{\text{sp}}$ sets of parameters from the uncertainty bounds using a uniform distribution, with each $\boldsymbol{p}^i$ represents a possible set of parameter realization within the specified bounds $\boldsymbol{p}_{\min}$ and $\boldsymbol{p}_{\max}$. We then divide $N_{\text{sp}}$ samples into $N_{\text{gp}}$ groups, with each group, except the last group, containing $\left\lceil \frac{N_{\text{sp}}}{N_{\text{gp}}} \right\rceil$ samples, and the last group containing the remaining samples. Note that the last group will contain $\left\lceil \frac{N_{\text{sp}}}{N_{\text{gp}}} \right\rceil$ samples, if $N_{\text{sp}}$ is exactly divisible by $N_{\text{gp}}$, i.e., $\left\lceil \frac{N_{\text{sp}}}{N_{\text{gp}}} \right\rceil = \frac{N_{\text{sp}}}{N_{\text{gp}}}$. For each group $z = 1,2, \dots, N_{\text{gp}}$, we perform iterative optimization to adjust the control input bounds. Depending on whether the lower bounds, upper bounds, or both need to be updated (as indicated by the flags $findLowerbound$ and $findUpperbound$ in Algorithm 1), the following procedures are executed: ($i$) if $findLowerbound$ is true, the algorithm first stores the current lower bounds by setting $\underline{\boldsymbol{u}}_{k,\text{old}} = \underline{\boldsymbol{u}}_k$ for every time segment $k$. This serves as a reference point and initial guess for the optimization. For the first group ($z = 1$), the updated bounds need to satisfy the system constraints only for the initial set of sampled uncertain parameters. Therefore, the algorithm aims to maximize the minimum weighted difference between the old and new lower bounds, effectively pushing the lower bounds downward as much as possible while satisfying all constraints. This is formulated as the optimization problem in (2). The constraints ensure that the system dynamics, safety requirements and process KPIs are met, and that the new lower bounds do not exceed the old ones. For the subsequent groups ($z > 1$), the updated bounds must satisfy the constraints for all parameter realizations sampled thus far, including those in the current group. This cumulative requirement incorporates more constraints, leading to a more restricted operational space. As a result, the algorithm focuses on minimizing the total weighted increase from the previous lower bounds to the new lower bounds, making only the necessary adjustments to accommodate the new constraints. This conservative adjustment is formulated in (3). ($ii$) similarly, if $findUpperbound$ is true, the algorithm updates the upper bounds by solving the optimization problem (4) for the first group ($z = 1$), and optimization problem (5) for subsequent groups ($z > 1$). Different from the lower bound identification, for upper bound identification, we first try to expand the operational space by *increasing* the upper bounds as much as possible within the constraints during the first group. In subsequent groups, we minimize the total weighted

decrease from the previous upper bounds to the new upper bounds, making only necessary *reductions* to satisfy the accumulated constraints introduced by the new parameter samples.

We remark that this stage-wise procedure divides sampled uncertain parameters into small subset, making it easier for the optimization solver to find optimal solutions for each sub-problem. Since the initially identified bounds serve as constraints for later iterations, it is important to have good starting profiles. Therefore, for the first group ($z = 1$), we select the optimization problem (2) and (4) as maximizing the minimal weighted difference between the nominal/previous control inputs and the updated bounds. This *max-min* formulation is preferred over maximizing the sum (*max-sum*) of differences (as used for the subsequent groups' optimization problems (3) and (5)) to prevent scenarios where only a few control inputs have large deviations from the nominal/previous values while the majority deviations remain close to zero. Such uneven adjustments can result in less useful bounds, as they may introduce impractical control actions. To illustrate this difference, consider an example illustrated in Figure 1, where the *max-sum* approach leads to a larger total deviation from the nominal control inputs than the *max-min* approach, but the deviations are concentrated in only two segments. Specifically, most of the control actions identified by the *max-sum* approach overlap with the nominal ones, with deviations only occurs between Index 2 and 3, and between Index 3 and 4). In contrast, the max-min approach distributes the deviations across all segments. As for the subsequent groups, since the general shape of the control bounds is already defined after the first group, we can use the max-sum approach to limit the adjustments and maintain as much of the operational space as possible.

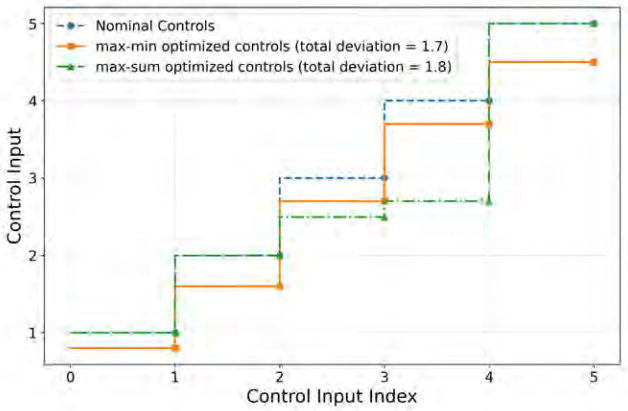

**Figure 1.** Comparison of *max-min* and *max-sum* optimization results.

We also note that bioprocesses often involve path constraints to ensure safety and synthesis requirements are met throughout the operation. To ensure feasibility, a symbolic framework is incorporated into the optimization procedure. We use CasADi [16], a powerful tool tailored for handling complex optimal control problems. This framework allows for efficient modeling of system dynamics and constraints. The resulting optimization problem is then solved using IPOPT [17], which is well-integrated with CasADi [16]. Also, by processing the parameter samples in groups, the algorithm balances computational efficiency with the need for robustness against uncertainties. The distinction between the first and subsequent groups allows for an initial broad adjustment of the bounds, followed by finer tuning in later iterations.

Finally, we validate the identified control bounds on a larger set of testing samples by running additional MC simulations, ensuring that the KPIs are consistently met despite parameter uncertainties, as long as the control input remains within the identified bounds. To further improve robustness, if any samples result in KPI violations, they are incorporated into optimization problems (3) and (5) to further adjust the lower and upper bounds, respectively. A new batch of test samples is then sampled and used to verify the adjusted bounds. This process is repeated until the percentage of KPI violations is lower than a user-defined acceptable threshold in the test sets. The accumulative nature of these formulations allows new samples to be added without re-running previous ones, improving computational efficiency.

## CASE STUDY

We demonstrate the proposed method using a fermentation case study of astaxanthin production in a fed-batch bioprocess under parameter uncertainty [6]. The kinetic model of the bioprocess is taken from [6] and is converted to the fed-batch model by including the feed flow rate $F_{\text{in}}(t)$ as the control input:

$$\frac{dV(t)}{dt} = F_{\text{in}}(t) \tag{6a}$$

$$\frac{dX(t)}{dt} = \mu_m(t)X(t) - \mu_d X(t) - \frac{X(t)}{V(t)}F_{\text{in}}(t) \tag{6b}$$

$$\frac{dS(t)}{dt} = \frac{F_{\text{in}}(t)}{V(t)}S_{\text{in}} - Y_S\mu_m(t)X(t) - \frac{S(t)}{V}F_{\text{in}}(t) \tag{6c}$$

$$\frac{dP(t)}{dt} = \alpha\mu_m(t)X(t) + \beta X(t) - k_d X^2(t) - \frac{P(t)}{V(t)}F_{\text{in}}(t) \tag{6d}$$

where $\mu_m(t) = \mu_m \frac{S(t)}{S(t)+K_c X(t)}$. Here, $X(t)$ is the biomass concentration (g/L); $S(t)$ is the substrate concentration (g/L) with $S_{\text{in}}$ being the substrate concentration in the input flow; $F_{\text{in}}(t)$ is the input flowrate; $P(t)$ is the product concentration (mg/L), and t is time (h). The remaining parameters are noted in Table 1. For the case study, the state values $\boldsymbol{x}(t) = [V(t), X(t), S(t), P(t)]^{\top}$, the control input $\boldsymbol{u}(t) = F_{\text{in}}(t)$, and the uncertain parameters $\boldsymbol{p} = [\mu_m, K_c, \mu_d, Y_S, \alpha, \beta, k_d]^{\top}$, with the fixed parameter $\theta = S_{\text{in}}$.

## Operation conditions

We consider uncertainties in the parameters with a $\pm 2\%$ variations around their nominal values (Table 1). The process begins with an initial volume $\mathrm{V}(0)$ of 0.4 L, an initial biomass concentration $X(0)$ of 0.1 g/L, an initial substrate concentration $S(0)$ of 6 g/L, and an initial product concentration $P(0)$ of 0 mg/L. The substrate concentration in the feed $\mathrm{S_{in}}$ is set to 12 g/L, and the reactor's volume is 2 L ($\mathrm{V_{reactor}}$). The process is run for 168 hours ($T$), The feed flow rate $\mathrm{F_{in}(t)}$ is adjusted every 12 hours, leading to 14 discretized time segments (N).

**Table 1:** Model parameters for astaxanthin production.

| Parameter | Description | Nominal Value |
|---|---|---|
| $\mu_m$ | Maximum specific growth rate | 0.43 $h^{-1}$ |
| $K_c$ | Substrate saturation constant | 63.7 (-) |
| $\mu_d$ | Specific decay rate | 0.0021 $h^{-1}$ |
| $Y_S$ | Substrate yield coefficient | 2.58 g/g |
| $\alpha$ | Growth-dependent yield coefficient | 7.88 mg/g |
| $\beta$ | Growth-independent yield coefficient | 0.236 mg/(g·h) |
| $k_d$ | Specific consumption rate | 0.0648 mg·L/($g^{-2}h^{-1}$) |

The nominal control trajectory $\tilde{\boldsymbol{u}}_k$ is identified based on an optimal control strategy with nominal parameter values. The KPI in this case is to ensure that the mass production of astaxanthin (the product) at the end of the time horizon is higher than 58 mg, i.e., $\mathrm{V(N)P(N)} \geq 58$ mg. Several path constraints are involved: $(i)$ all the state variables are nonnegative, i.e., $\boldsymbol{x}(\mathrm{t}) \geq 0$, for $\mathrm{t} \in [0, \mathrm{T}]$; $(ii)$ maximum working volume should not exceed 95% of the reactor's volume, i.e., $\mathrm{V(t)} \leq 0.95\mathrm{V_{reactor}}$; $(iii)$ no feed in the first and last days (24 hours), i.e., $\mathrm{u_k} = 0$, for $\mathrm{k} \in \{0, 1, \mathrm{N}-3, \mathrm{N}-2\}$; $(iv)$ the substrate concentration should not change dramatically, i.e., $\frac{\mathrm{dS(t)}}{\mathrm{dt}} \leq 3$ g/L; and $(v)$ the mass of the product astaxanthin should increase throughout the process, i.e., $\frac{\mathrm{dP(t)}}{\mathrm{dt}} \geq 0$.

Since the operational space is not unique, additional constraints can be introduced to shape its profile. For example, if it is known in advance that control is critical at a certain time step and limited variation is preferred, constraints can be added to enforce this. In our case, we introduce constraints that increase control variability in the middle time segments over the time horizon, specifically, $\overline{u}_{k+1} - \tilde{u}_{k+1} \geq \overline{u}_k - \tilde{u}_k$ and $\tilde{u}_{k+1} - \underline{u}_{k+1} \geq \tilde{u}_k - \underline{u}_k$ for $k \in \{3, \ldots, N-5\}$. The rationale is that by closely following the desired operation in the early stages, we allow for greater flexibility in the later stages of the process.

To identify the operational space, 1,000 sets of uncertain parameters ($N_{\mathrm{sp}}$) are drawn, which are divided into 100 groups ($N_{\mathrm{gp}}$). For a comparison study, the same problem is solved with a conventional scenario optimization method—we solve optimization problem (2) and (4) with the entire set of sampled uncertain parameters in a single step. Computations are performed on an Intel i7-13700H 2.40-GHz CPU laptop with 32GB of RAM.

## Results and discussions

The proposed method effectively identifies the operational space for the feed flow rate $F_{\mathrm{in}}(t)$ under parameter uncertainties, optimizing both the lower and upper control bounds. This approach ensures that the process constraints are satisfied across all sampled uncertainties while maximizing the operational space. Compared to the conventional scenario optimization method, which solves the problem in a single step using the full set of uncertain parameters, the proposed method significantly reduces computational time. Specifically, the CPU time for the proposed approach was 279.86 seconds, compared to 10,995.06 seconds for the conventional method.

Additionally, the identified operational space by the proposed method (shaded regions in Figure 2) offers greater flexibility in control inputs compared to the one identified by the conventional scenario optimization method (shaded regions in Figure 3). The MC simulations, which sampled controls from their operational space and parameters from their uncertainty bounds (10,000 samples each), further verified that the process consistently meets performance criteria when the control input remains within the identified bounds. Additionally, no violations of the constraints were observed, confirming the reliability of the identified control strategy.

# CONCLUSION AND FUTURE WORK

We have presented a novel scenario optimization approach to identify the operational space for control variables in bioprocess operations with known parameter uncertainties. By integrating symbolic frameworks, the method efficiently handles complex nonlinear dynamics and constraints.

The implementation of a new stage-wise optimization procedure significantly reduces computational burden, making the approach practical for industrial applications. The method ensures that key performance indicators are consistently met without the need for costly real-time feedback control systems, offering a cost-effective and reliable means of maintaining product quality and yield in the bioprocess industry.

Future work may explore the application of the method to more complex systems with higher-dimensional uncertainty spaces and investigate the integration of real-time data to update the operational space as new

information becomes available.

## ABSTRACT

Hybrid modelling utilizes advantageous aspects of both mechanistic (white box) and data-driven (black box) modelling. Combining the physical interpretability of kinetic modelling with the power of a data-driven Artificial Neural Network (ANN) yields a hybrid (grey box) model with superior accuracy when compared to a traditional mechanistic model, while requiring less data than a purely data-driven model. This study demonstrates the construction a hybrid model with transfer learning for the predictive modelling and optimization of a high-cell-density microalgal fermentation process for lutein production. Dynamic optimization was conducted to identify a feeding strategy that maximized final lutein production. The results were then experimentally validated. Overall, this work presents a novel digital twin application that can be easily adapted to general bioprocesses for model predictive control and process optimization.

**Keywords**: Machine Learning, Dynamic Modelling, Biosystems, Hybrid Modelling, Dynamic Optimization

## 1 INTRODUCTION

### 1.1 Motivation

Bioprocesses connect an abundance of global research interests, including the production of renewable plastics, fuels, and other valuable bioproducts. Economically speaking, the UK bioeconomy alone was worth around £220 billion in 2018, and is set to double by 2030 [1], making the field lucrative for research. Supporting bioprocess development requires overcoming several challenges, including batch-to-batch variation, deficient metabolic and secretory phenotypes for protein production, by-product accumulation, and reduced yields in the upscaling of bioreactors. Tackling these challenges involves identifying suitable microbial strains and their optimal operating conditions, as well as the development of optimal operation and control strategies. Conducting such process optimization exhaustively can be extremely time-consuming and resource-depleting; employing modelling can reduce the time and resources spent by using predictions to rule out less useful experiments.

With the ever-progressing fourth industrial revolution underway, digitalization is seeing increased application; utilizing digital twins has significant potential in the application of process optimization and control, as well as design of experiments. The concept of machine learning is being continuously applied in novel ways to unveil more economical, ethical, safer, efficient, and sustainable approaches to chemical processing. With the current growth of interest within the fields of both bioprocess engineering and artificial intelligence, there has not been a better time to harness and combine the advantages of each. However, accounting for uncertainty is an equally important step in the development of a model as it provides information surrounding the achievability of a found control strategy or optimum.

An example of where the combining of different modelling methodologies may be required is high-cell-density cultures (HCDCs). HCDCs can be capable of producing larger quantities of desired products, an example of which is lutein, a carotenoid pigment commonly used in the food industry. However, HCDCs can demonstrate self-inhibitory effects, where growth and/or substrate uptake is inhibited by the high cell density or high accumulation of products [2]. Gaining a better understanding

of these inhibitory effects is pertinent for optimizing processes utilizing HCDCs.

### 1.2 Aims

Ultimately, this model aspires to require minimal data and computational expense, while maximizing simulation accuracy for process optimization and control applications. The model should also have good generalisability, allowing for easy incorporation of new data to retrain the model. Fulfilling these goals will make the modelling methodology described in this work applicable to other bioprocesses involving HCDCs, such as Akkermansia muciniphila which has received recent attention for its probiotic capabilities in the intestinal tract [3]. With HCDCs being well suited to fed-batch and perfusion operation, they play a key role in moving towards the continuous operation of bioprocesses; such progression can be accelerated by the modelling and optimization strategy discussed in the recent study [4].

In this work, the term *hybrid modelling* relates to the combination of a physically derivable (white-box) model, with a data-driven (black-box) model to yield an overall hybrid (grey-box) model.

### 1.3 Case Study

The case study at hand looks at the production of lutein from Chlorella sorokiniana under fed-batch conditions using urea as the source of nitrogen and glucose as the carbon source. The dataset available also includes a preliminary batch using sodium nitrate (an alternative to urea) as the nitrogen source. Experiments were run for 168 hours with measurements of biomass density and lutein content taken art least every 12 hours. The fed-batch saw continuous feeding of high concentrations of glucose and urea (750 g $L^{-1}$ and 46.5 g $L^{-1}$, respectively).

## 2 METHODOLOGY

### 2.1 Experimental setup

Initially, a single batch process in a 250 mL flask (with 100 mL of working volume) was conducted using $NaNO_3$ as the nitrogen source, to which a preliminary kinetic model was fitted. Fed-batch operation was then conducted in a 5 L bioreactor with urea (which behaves similarly to $NaNO_3$) as the nitrogen source and continuous feeding over 168 h.

### 2.2 Macro-scale kinetic modelling

For the initial batch experiment, Monod-inspired kinetics were utilized. The concentrations of the substrates glucose ($G$) and urea ($N$), as well as cell density ($X$) and lutein content ($L_C$), are described by the system of 4 Ordinary Differential Equations (ODEs) as in

$$\frac{dX}{dt} = \mu \cdot X - d_X \cdot X \tag{1}$$

$$\frac{dG}{dt} = -v_{\max_G} \cdot \frac{G}{K_G+G} \cdot X \tag{2}$$

$$\frac{dN}{dt} = -v_{\max_N} \cdot \frac{N}{K_N+N} \cdot X \tag{3}$$

$$\frac{dL_C}{dt} = Y_{LX} - d_L \cdot L_C - \mu \cdot L_C \tag{4}$$

$$\mu = \mu_{\max} \cdot \frac{G}{K_G+G} \tag{5}$$

where $\mu_{\max}$ refers to the maximum specific growth rate of biomass, with $v_{\max_i}$ being the maximum specific uptake rate for a given substrate $i$, $K_i$ being the affinity constant for a given substrate $i$, $Y_{LX}$ being the specific production rate of lutein from biomass, and $d_i$ representing a decay term for a given product $i$. It should be noted that $L_C$ represents an intracellular concentration measured in mg (g biomass)$^{-1}$. To consider the overall lutein concentration in the reactor ($L$), product rule can be used with equations (1) and (4) to give the result as in

$$\frac{dL}{dt} = Y_{LX} \cdot X - d_L \cdot L \tag{6}$$

It is essential for parameters in the Monod model to remain positive in value to retain physical feasibility, as in

$$\boldsymbol{\beta} \geq \mathbf{0} \tag{7}$$

where $\boldsymbol{\beta}$ is the vector of Monod model parameters. Parameters were identified by minimizing the mean squared error objective function, as in

$$\min \frac{1}{n} \cdot \sum_{t,\text{meas}} \sum_i \left( \frac{C_{i_t} - C_{i_{\text{meas}_t}}}{\sigma_i} \right)^2 \tag{8}$$

where $n$ is the number of datapoints. The objective function minimizes the difference between the simulated extracellular concentration profiles and the measured averages at each timepoint; each term $i$ is weighted by its experimental measurement standard deviation; $\sigma_i$.

### 2.3 Hybrid modelling and transfer learning

Despite good fitting of the initial batch process, the parameters identified could not capture the entire fed-batch process, highlighting the difference between the $NaNO_3$-fed and urea-fed systems. The most noticeable process-model mismatches can be seen later in the process during high cell densities, particularly once the culture reaches a cell density over 5 times that seen in the preliminary batch experiment (seen around 30 h into the fed-operation). This indicates that substrate uptake and/or growth are being inhibited by high cell density, which can be due to poorer mass transfer of substrates to the cells due to their close proximity; a phenomenon observed in literature [5]. Therefore, three time-varying parameters were introduced: two capture the respective substrate uptake inhibition of glucose and nitrate ($\theta_G(\cdot)$ and $\theta_N(\cdot)$, respectively); and the other captures biomass growth inhibition ($\theta_X(\cdot)$). These time-varying parameters

are functions of state variables in the form of an ANN. Equations (1), (2), and (3) are therefore rewritten as in

$$\frac{dX}{dt} = \theta_X(\mathbf{S}) \cdot \mu \cdot X - d_X \cdot X - \frac{F}{V} \cdot X \quad (9)$$

$$\frac{dG}{dt} = \left(G_f - G\right) \cdot \frac{F}{V} - \theta_G(\mathbf{S}) \cdot v_{\max_G} \cdot \frac{G}{K_G + G} \cdot X \quad (10)$$

$$\frac{dN}{dt} = \left(N_f - N\right) \cdot \frac{F}{V} - \theta_N(\mathbf{S}) \cdot v_{\max_N} \cdot \frac{N}{K_N + N} \cdot X \quad (11)$$

$$\mathbf{S} = [X, N, G] \quad (12)$$

where $G_f$ and $N_f$ are the feed concentrations of glucose and urea, respectively, $F$ and $V$ are the feed rate and reactor volume, respectively, $\mathbf{S}$ is the vector of state variables, and the remaining parameters in Equations (4)-(5) and (9)-(11) take the same value as those previously identified. Constant volume is assumed. During the identification of time-varying parameters, their deviations are penalised to try and follow the kinetic model dynamics as closely as possible, thus maximizing knowledge transfer, Penalization is done using a penalty term, that is added to the objective function shown in Equation (8), as in

$$\min \frac{1}{n} \cdot \sum_{t,\text{meas}} \sum_i \left(\frac{C_{i_t} - C_{i_{\text{meas}_t}}}{\sigma_i}\right)^2 + \rho \cdot \sum_{t,\text{TVP}} \sum_i \left(\theta_i(t) - \theta_i(t-1)\right)^2 \quad (13)$$

where $\rho$ is a hyperparameter to be tuned. The time-varying parameters are then reformulated as a function of state variables using an ANN. The ANN is embedded within the system of ODEs as illustrated in Figure 1, where state variables update the ANN which updates the time-varying parameters, which can be used in the system of ODEs to update the state variables, thus generating state variable profiles.

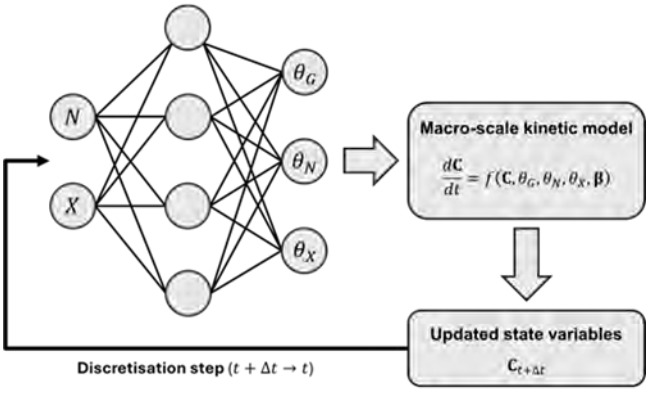

**Figure 1.** Hybrid model structure: Simulation of time-varying parameters based on system components using an ANN.

Comparing the performance of several ANN architectures allowed the identification of the most appropriate ANN structure. The Akaike Information Criterion with correction for small sample sizes (AICc) was employed to quantify the performance of each ANN structure, as in

$$AICc = n \ln Z + 2\,k + \frac{2\,k^2 + 2\,k}{n - k - 1} \quad (14)$$

where $k$ is the number of parameters with a correction for the small sample size $n$. The ANN architecture with the lowest AICc score was chosen as the best trade-off between minimal overfitting and accuracy.

## 2.4 Uncertainty analysis

Uncertainty analysis was conducted using bootstrapping which involved taking samples of the training dataset and training the model on each sample separately, generating a distribution of model outputs, as illustrated in Figure 2. A 95% confidence interval ($z_{CI}$) of each component $z$ was generated by sampling from the resulting output distribution, as in

$$z_{CI} = \bar{z} \pm c \cdot \frac{\sigma_z}{\sqrt{\frac{n_z - 1}{n_z}}} \quad (15)$$

where $\bar{z}$ is the mean of the component $z$, $c$ is the confidence level, $n_z$ is the number of samples of the component $z$, and $\sigma_z$ is the standard deviation of the component $z$. In this study, bootstrapping was conducted by removing 48-hour segments of data, a third of the fed-batch time horizon.

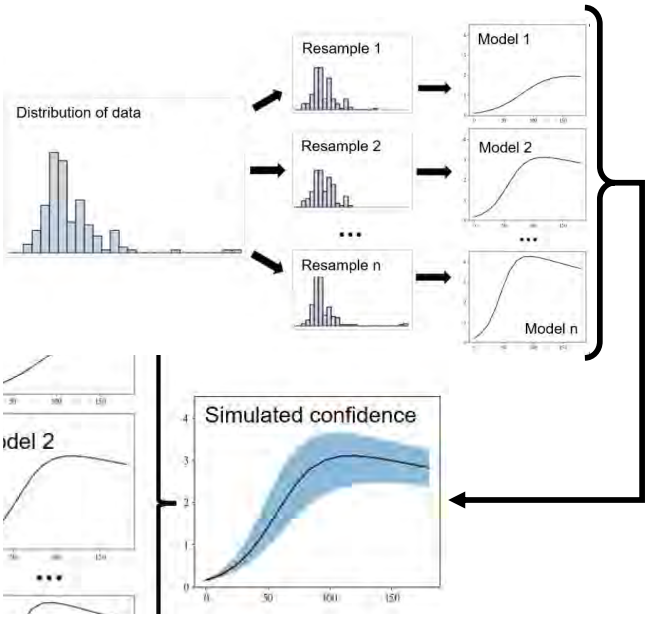

**Figure 2.** Bootstrapping: Schematic.

## 2.5 Feed optimization

The dynamic optimization problem follows the general NLP problem described by

$$\min_{\mathbf{F},\mathbf{N_f}} -L(t_f) \quad (15)$$

s. t. $$0 \leq F(t) \leq 50 \text{ mL h}^{-1} \quad (16)$$

$$0 \leq N_f(t) \leq 60 \text{ g L}^{-1} \quad (17)$$

where $\mathbf{F}$ and $\mathbf{N_f}$ are the vectors of discretized dynamic feed rate and urea feed concentration, respectively, and $t_f$ is the predetermined final time of the batch. Both feed rate and urea feed concentration were allowed to vary every 12 hours, giving the optimization problem 28 degrees of freedom. The dynamic optimization problem was solved using a gradient descent method in the Python optimization package Pyomo. Glucose concentration was also constrained between 3 and 7.5 g $L^{-1}$ beyond a time of 30 h to ensure stable fed-batch operation.

## 2.6 Methodology summary

The overall modelling methodology was conducted in a manner that requires minimal data collection for model construction and is illustrated in Figure 3.

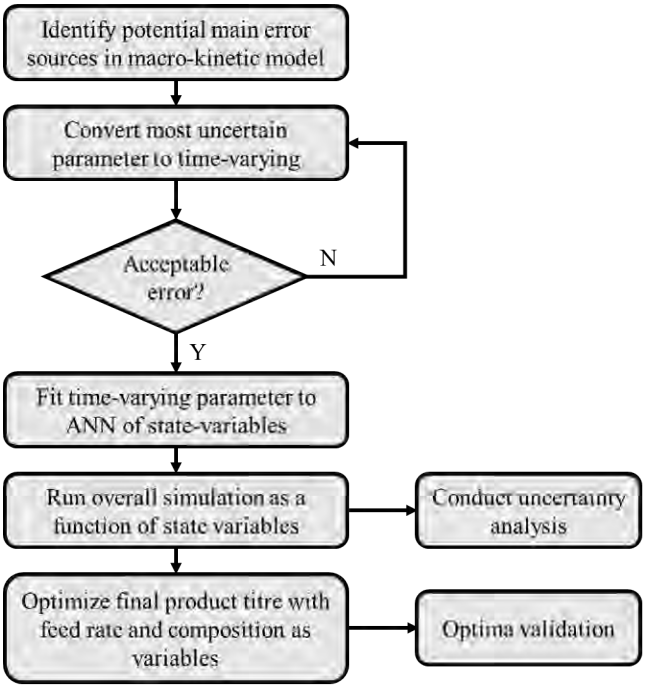

**Figure 3.** Methodology: Summary of dynamic optimization from hybrid model construction for fed-batch lutein production under uncertainty.

# 3 RESULTS AND DISCUSISON

## 3.1 Results of hybrid modelling

The purely mechanistic macro-scale kinetic model was first fit with Equations (1)-(5) with no time-varying parameters. The fitting of the preliminary kinetic model has a mean $R^2$ value of 0.995 and is shown in Figure 4. Parameter estimation converged after 50 iterations using a derivative-free Particle Swarm Optimization (PSO) algorithm. The selected algorithm has strong exploratory capabilities for parameter estimation in the stiff fed-batch system simulated in this study. The problem was run 5 times, each with 100 particles, to confirm the same optima was being found, increasing the confidence in it being a global optimal solution.

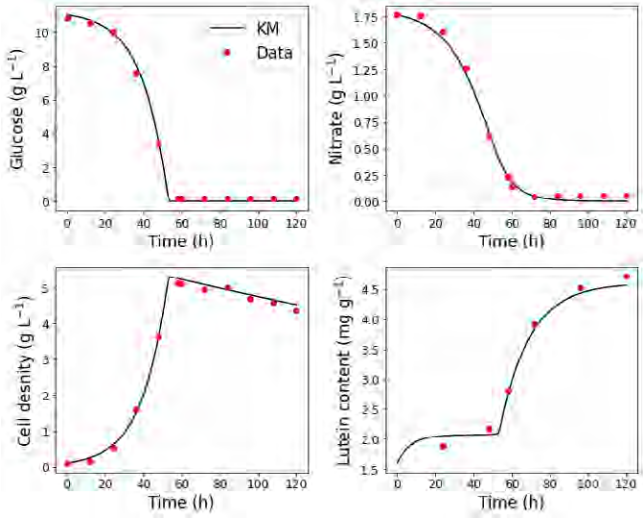

**Figure 4.** Kinetic model (KM): Plots of substrates glucose and nitrate, biomass and lutein content fitted to the original batch using $NaNO_3$ as a nitrogen source.

The application of this kinetic model to a 5 L fed-batch process, where the cell density reaches levels in excess of 10 times higher than the batch process, illustrated significant process-model mismatch, particularly in the latter stages at the highest cell densities, which is evident in the resulting mean $R^2$ value of -0.026 for the overall system. This motivated the introduction of time-varying parameters to better fit the more challenging dynamics seen in the latter stages of the fed-batch process. Time-varying parameters were first introduced to a fed-batch operation that reinstated the same initial substrate concentrations as the preliminary batch process after each injection of concentrated medium. Time-varying parameters were initially simulated as a discretized function of time. Parameter estimation converged within 100 iterations of the IPOPT algorithm in the Python package SciPy.

The resulting time-varying parameter profiles were then used to train the ANN. The most appropriate ANN architecture had seven hidden nodes and sigmoid activation functions. The ANN was trained over 1700 epochs using data augmentation, following the method described in a previous study [6]. The fitting of the hybrid model is shown in Figure 5, with the profiles of the corresponding time-varying parameters shown in Figure 6. The introduction of time-varying parameters increased the mean $R^2$ value for cell density and lutein content from

-0.026 to 0.855. The decreasing trend of the time-varying parameters simulated by the ANN for glucose and biomass highlights the inhibitory effects that the high-cell-density has on substrate uptake and growth. It is observable that all parameters saw an overall decrease in value from start to finish, further emphasizing the inhibitory effects of a HCDC system.

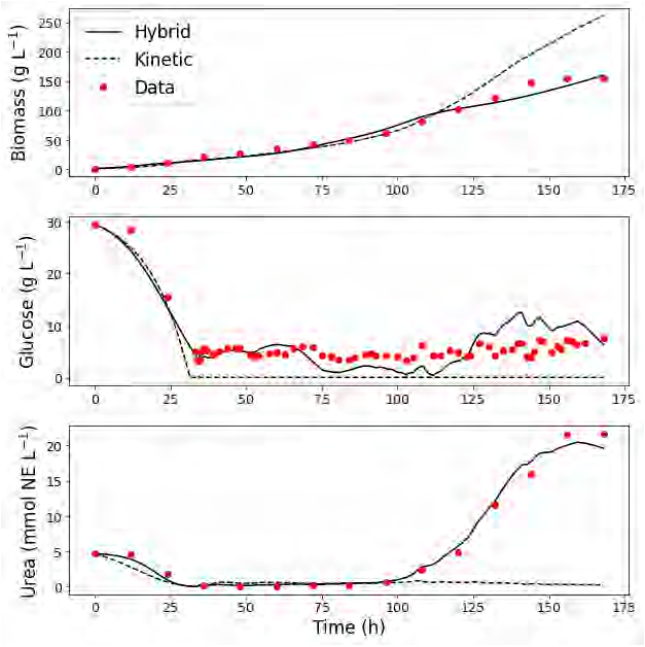

**Figure 5.** Hybrid model (HM): Plots of substrates glucose and nitrate, and biomass for fed-batch simulation with comparison to the original Kinetic Model (KM). Note that Nitrate Equivalent (NE) refers to the equivalent concentration of nitrogen in a solution of $NaNO_3$.

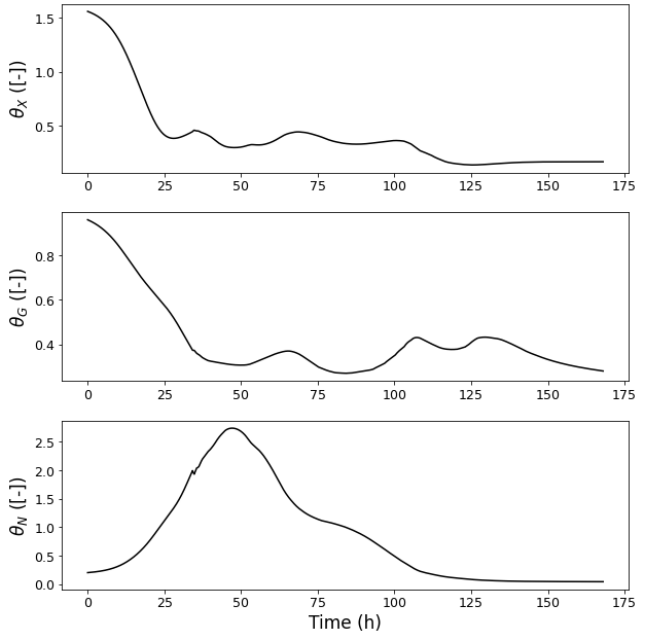

**Figure 6.** Hybrid model: Time-varying parameters.

## 3.2 Results of feed optimization

The optimization of feed rate and composition was successfully conducted, converging within 500 iterations of the IPOPT algorithm on the Python package Pyomo. Figure 7 shows the optimized trajectories in comparison to the original experimental conditions. All constraints were successfully satisfied.

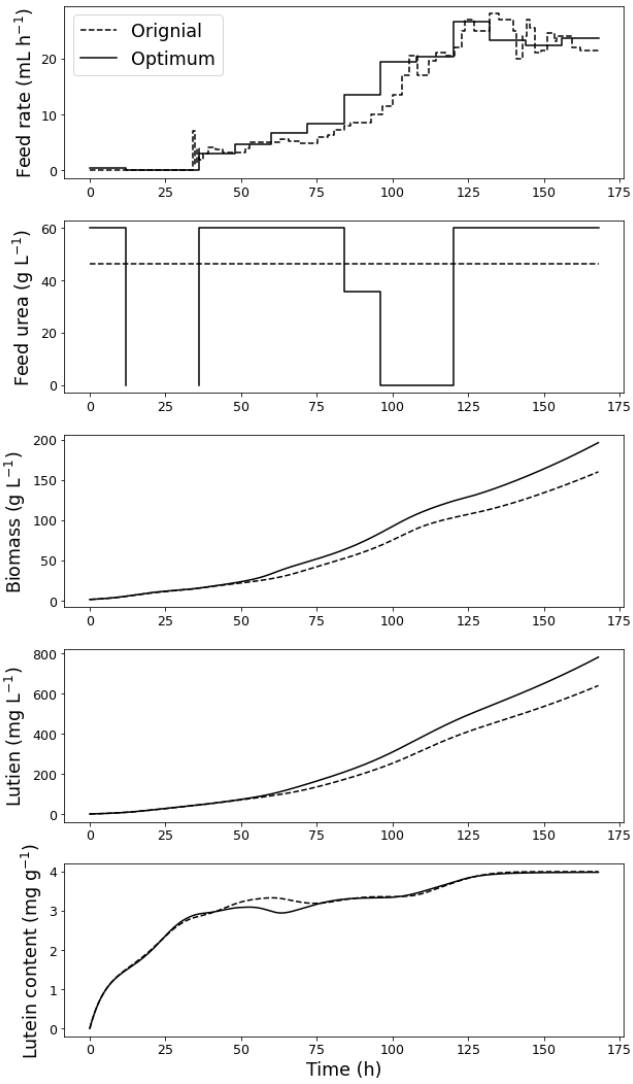

**Figure 7.** Optimized feeding: Plots of feeding rate and feed urea concentration changing every 12 hours, as well as plots of biomass and lutein concentration and content for both the original and optimized cases. It should be noted that there is no urea feed concentraiton between times 12 h and 36 h since there is no feeding during this period.

Figure 7 shows an increase in lutein production from the original experiment of over 25%. Since the lutein content is almost unchanged, the increased production is coming exclusively from increased biomass growth, which is most noticeable beyond a time of 50 h. This

implies that for optimizing the lutein content of the cell, strain modification would be a more attractive option as external control variables have less impact on the internal lutein content than the biomass growth.

A significant difference between the substrate trajectories can be seen for urea, for which the optimized case demonstrates the maintenance of a low urea concentration within the vessel, while still feeding enough to sustain the biomass. This implies that nitrate may be inhibitory towards optimal product formation, despite being required for biomass growth.

In terms of the feed trajectories, the most noticeable difference between the original and the optimized case for feed rate is between 60-110 h, where the optimized trajectory shows higher flowrate. This causes an increase in growth during this period without causing a spike in glucose concentration within the reactor, thus allowing more lutein to be produced. Urea feed concentration generally lies at the upper bound of 60 g $L^{-1}$, with the exception of 12-36 h where there is no flow, and 84-120 h where the spike in urea concentration occurred in the original experiment, suggesting that such an increase in urea concentration may be inhibitory to the system.

Although increasing the number of discretization steps for the feed profile could further improve the optima, it would need to be coupled with uncertainty to assess the attainability of a more specific solution.

## 4 CONCLUSIONS

In this study, a hybrid model was constructed with transfer learning to simulate a fed-batch HCDC system for lutein production. The introduction of time-varying parameters facilitated the capture of increasingly inhibited system dynamics during the latter stages of fed-batch operation. The varying system dynamics were accurately captured, thus maximizing the model's applicability to simulate fed-batch processes under alternate operating conditions. Time-varying parameter values were also penalized, which maximized knowledge transfer and assisted in reducing model overfitting by avoiding dramatic changes between subsequent time-varying parameter values. The kinetic backbone used for the hybrid model construction incorporated as much physical information as possible, meaning minimal additional data was required to train the ANN for both the original hybrid model and the transfer learning updated hybrid model. The ANN allowed the hybrid model to remain a function of observable state variables while being able to capture nonlinear dynamics that cannot be considered by the kinetic backbone. The successful implementation of dynamic optimization facilitated the prediction of optimal feeding trajectories under plausible operating conditions for experimental validation.

Overall, the optimization shows plausible predictions for experimental validation. The success of this modelling strategy and application to fed-batch optimization paves the way towards the development of an effective digital twin for the modelling of fed-batch systems for maximizing lutein production and yield for future fed-batch HCDC operation. The ability of this framework to incorporate a data-driven model with minimal data gives it substantial potential in applications to novel bioprocesses, where both experimental data and mechanistic understanding are limited.

# Plant-wide Modelling of a Biorefinery: Microalgae for the Valorization of Digestate in Biomethane plants

**Davide Carecci[a], Elena Ficara[b], Ignazio Geraci[c], Alberto Leva[a] and Gianni Ferretti[a*]**

## ABSTRACT

Microalgae cultivation on liquid digestate from the anaerobic co-digestion of agricultural feedstocks is an interesting option for digestate nutrient removal and resource recovery coupled to value-added biomass production. In this paper, a first-principle plant-wide modelling of the process is described. Two well-established models for anaerobic digestion (IWA – ADM1) and algae-based bioremediation processes (ALBA) were considered and modified with necessary equations and extensions to develop a coherent interface between the state variables of the two models. The resulting system is composed by highly non-linear and non-smooth DAEs. Open-loop scenario analysis for different upstream co-digester design and operating conditions was carried out to assess the impacts on the downstream microalgae outputs. It highlighted the importance of a proper biorefinery design and yet a noteworthy robustness of the system performance. The exploitation of the model can facilitate: a more realistic assessment of the process's technical-economic feasibility and the design/validation of classical and advanced feedback control strategies.

**Keywords**: Plant-wide modelling, Anaerobic co-digestion, Microalgae bioremediation, Digestate valorisation.

## I. INTRODUCTION

The production of bio-methane in Europe, currently supported by regulatory and economic tools, is increasing. Growing phototrophic microalgal biomass on the liquid fraction of bio-methane plant's digestate is an interesting possibility for the low-energy request, high potential for nutrients recycling, and simultaneous valorisation of $CO_2$ from biogas upgrading. Some microalgae strains have interesting plant's bio-stimulating properties, making them particularly suitable for the integration of algal nutrient recovery in a highly growing market. To assess the techno-economic feasibility of this biorefinery approach, a plant-wide model was developed integrating previously validated mathematical models and developing the required interfaces [1]. The plant-wide modelling framework includes two main mechanistic grey-box (uncertain parameters) physico-chemical and biological three-phase (liquid, solid, gas) models. The bio-methane plant model (agri-AcoDM) is based on the IWA ADM1 model [2], that was validated over a wide range of operational and feeding conditions [3]. The latter has been extended to account for phosphorous (P) transformations and for the non-ideality of the equations in the pH sub-model [4]. For the case studies of interest, it was proved that was reasonable to neglect ion-pairing equations, considering only major calcium and magnesium salt precipitates. For the modeling of the hydrolysis of multiple and complex feedstocks, some original state variables have been de-lumped [5]. The ALBA model [6] was used to predict the growth of algae-bacteria consortia in outdoor raceway ponds (RWP): the original model, validated on synthetic wastewater and liquid fraction of digestate, was integrated to consider organic acids in the influent. The precipitation of major P salts was also integrated, in continuity with the agri-AcoDM `block`. The evolution of temperature in the RWP system (either open or covered with single- or double-covered greenhouses) is a key factor for optimal algal growth and was modelled with a validated greenhouse pond system's (GPS) mechanistic model [7], integrating also temperature's feedback control to maintain the culture within strain-specific optimal ranges. Two solid-liquid (S/L) separation units were considered (a screw press followed by cationic

polyelectrolyte-assisted flocculation and centrifugation) to reduce digestate turbidity and guarantee light penetration in the algae pond. A "Copp-like interface" was implemented to properly relate the agri-AcoDM to the ALBA state variables, by lumping and redistributing the chemical oxygen demand (COD), carbon (C), nitrogen (N) and P contents; mass conservation was guaranteed by inorganic dissolved nutrients as sources or sinks [4].

The paper is organized as follows: Section II illustrates the model structure; Section III recalls the case study; in Section IV the simulation results are discussed; finally, in Section V a conclusion is drawn.

## II. MODEL STRUCTURE AND IMPLEMENTATION

The model was implemented using Modelica, an open-source, high-level, declarative and object-oriented modelling language employing the free OpenModelica interpreter (Fig. 1) [8]. The overall differential algebraic equation (DAE) system is defined as Eq.1, where $\boldsymbol{x}$ and $\boldsymbol{z}$ are dynamic and algebraic variables respectively, $\boldsymbol{u}$, $\boldsymbol{\theta}$ and $\boldsymbol{y}$ are inputs, fixed parameters and measurable outputs respectively. Functions $\boldsymbol{f}$ and $\boldsymbol{g}$ are highly non-linear (in some cases $\in C^0$).

$$\begin{cases} \dot{\boldsymbol{x}} = \boldsymbol{f}(\boldsymbol{x}, \boldsymbol{z}, \boldsymbol{u}, \boldsymbol{\theta}) \\ \boldsymbol{0} = \boldsymbol{g}(\boldsymbol{x}, \boldsymbol{z}, \boldsymbol{u}, \boldsymbol{\theta}) \\ \boldsymbol{y} = \boldsymbol{h}(\boldsymbol{x}, \boldsymbol{z}, \boldsymbol{u}, \boldsymbol{\theta}) \end{cases} \quad (1)$$

Parameters $\boldsymbol{\theta}$ are partitioned to the concentration (kg m$^{-3}$) of variables in the $i^{th}$ co-feedstock input flux ($\boldsymbol{\theta_{u,i}}$) and stoichiometric, physico-chemical and kinetic parameters ($\boldsymbol{\theta_p}$). Within a new Modelica library, each unit `block` of the **`biorefinery`** class has been defined by a dedicated model equipped with the necessary input/output information ports and physical connectors. In particular, two different types of connectors have been created to allow for the exchange of gas media (biogas, as perfect gas mixture) and of non-ideal heterogenous solid/liquid mixtures (feedstocks, digestate, algae suspension): the latter is agri-AcoDM- and ALBA-specific, due to the different state variables of the two models. For this reason, a dedicated model (the "Copp-like interface") to convert the two model's state variables have also been considered in the library. Of particular interest, is the exploitation of the **`stream`** connectors in the declaration of the interface components, to allow for immediate and flexible mixing of the different co-feedstocks. In the following, the sub-models in Fig. 1 are briefly described.

### (a) Model inputs

The inputs to the **`biorefinery`** model are process design fixed parameters, weather data for the GPS and influent feedstock's nutrient compositions for agri-AcoDM. The latter can be set both as $\boldsymbol{\theta_{u,i}}$ or from `CombiTimeTables` to consider feedstock variability. Dedicated conversions' equations between composition's data and model's state variables are performed for both pumpable and stock-piled feedstocks [3, 9].

### (b) Anaerobic co-digester (agri-AcoDM)

From the hydraulic standpoint, the reactor is a closed and completely stirred tank reactor (CSTR) with constant volume. The ordinary differential equation (ODE) system state variables are 38 concentrations (kg m$^{-3}$) in the specific media of either bacterial populations or organic/inorganic chemical total components, dissolved and gaseous. The state variables interact with each other via biological (hydrolysis, uptake, decay) and physico-chemical (precipitation/dissolution and gas-liquid mass transfer (two-film theory)) process rates $r$ (kg m$^{-3}$ s$^{-1}$). The generic ODE equation for the liquid-solid mixture mass balances is:

$$\begin{cases} \dot{\boldsymbol{x}} = \frac{\sum_{i=1}^{n} u_i}{V}(\boldsymbol{x_{in}} - \boldsymbol{x}) + \mathbf{K_G}\mathbf{r}(\boldsymbol{x}, \boldsymbol{\theta_p}, \boldsymbol{z}) \\ \boldsymbol{x_{in}} = \frac{\sum_{i=1}^{n} u_i \boldsymbol{\theta_{u,i}}}{\sum_{i=1}^{n} u_i} \end{cases} \quad (2)$$

where $\boldsymbol{x}$ are the state variables, $V$ (m$^3$) is the reactor volume, $u_i$ (m$^3$ d$^{-1}$) is the volume flowrate of the $i^{th}$ input co-feedstock and $\mathbf{K_G}$ is the transposed stoichiometric Gujer matrix, that guarantees COD and atomic mass conservation, extended and modified according to the new variables and processes introduced. Note that $\boldsymbol{r}$ depends on $\boldsymbol{z}$ too, as the latter refers to physico-chemical quantities characterized by very fast dynamics and later described. For gaseous states, Eq.2 still holds and has a null influent contribution, $V$ is the reactor headspace volume and $u_i$ is the biogas outflow, regulated by a SISO PI controller that keeps the reactor headspace slightly over atmospheric pressure. An example of the model non-linearities is shown in Eq.3, defining the general structure of a bioprocess kinetic rate $r$ representing the gross growth of a bacteria population with concentration $X_{ac}$ (aceto-clastic methanogens), i.e.:

$$r = \mu_{max} f_{pH} \frac{K_{i,nh3}}{K_{i,nh3} + S_{nh3}} \min_j \left( \frac{S_j}{S_j + K_{s,j}} \right) X_{ac} \quad (3)$$

where $\mu_{max}$ (d$^{-1}$) is the maximum specific growth rate and $f_{pH}$ is an empirical sigmoidal function that describes pH inhibition. Free ammonia ($S_{nh3}$ (M)) inhibition is represented by the non-competitive function which shape is defined by $K_{i,nh3}$ (M). Growth limitation by nutrient uptake is described by secondary Monod functions subject to the Liebig's minimum law, where $K_{s,j}$ (M) is the half-saturation constant for the nutrient $S_j$ ($j$ = {inorganic C, N, P and acetic acid}) [2]. A multiplicative term that depends on the sign of the saturation index $SI$ is used to discriminate precipitation ($r_{p,+}$) from dissolution ($r_{p,-}$) kinetics for

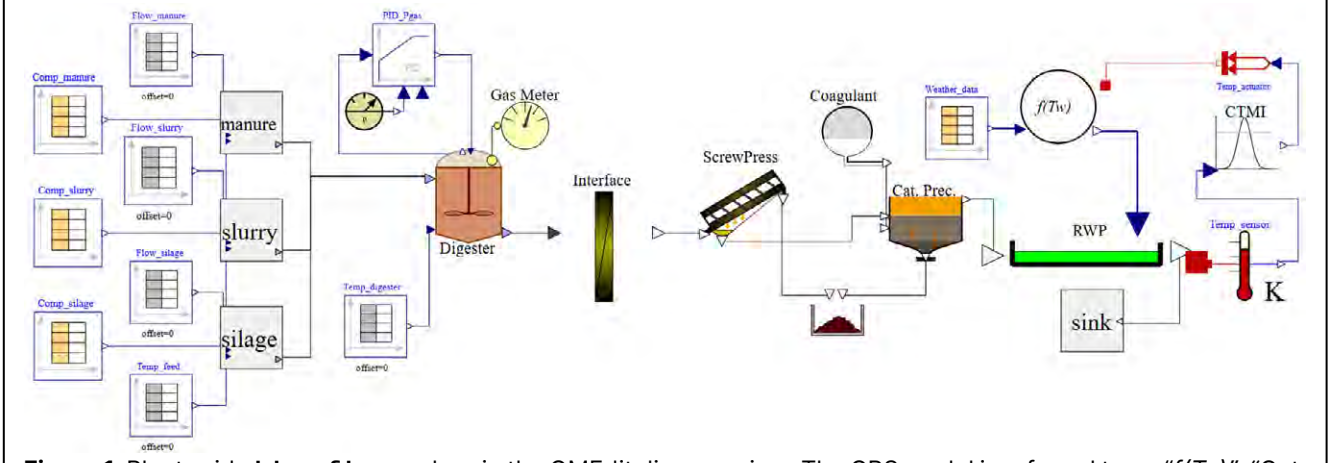

**Figure 1:** Plant-wide **`biorefinery`** class in the OMEdit diagram view. The GPS model is referred to as *"$f(T_w)$"*. "Cat. Prec." (cationic precipitation) refers to be flocculation unit. The Copp-like interface was called "Interface".

each salt with concentration $X_{salt}$, as in Eq.4:

$$r_{p,\pm} = \frac{1\pm sign(SI)}{2} k_{cryst} X_{salt} \left[ \left( \frac{\prod_{i=1}^{n_r} a_{i,j}}{K_{sp}} \right)^{\frac{1}{n_r}} - 1 \right]^2 \quad (4)$$

where $a_{i,j}$ (M) are the activities of the chemical ionic species involved in the process, $j$ is their stoichiometric coefficient, $n_r$ is the number of moles of reactants, $K_{sp}$ (M) the solubility product constant and $k_{cryst}$ the kinetic constant ($s^{-1}$) [10]. To avoid excessive stiffness for the ODE solver, the acid-base physico-chemical reaction equations have been modeled as an algebraic equation (AE) system ($\boldsymbol{z} \in \mathbb{R}^{30}$), within a **`partial model`** extended to the reactor model (the $\boldsymbol{g}$ function of Eq.1). The latter has a subset of state chemical total components $x_j, j = 1 \dots N_c$ as input and outputs the chemical ionic speciation $S_i, i = 1 \dots N_s$, the pH and the ionic strength $I$ ($mol_{eq}$ $L^{-1}$) of the liquid mixture, exploiting $N_c$ molar balances (Eq.5), $N_s - N_c$ chemical equilibrium equations, the charge balance over mixture neutrality hypothesis (Eq.6) and the definition of $I$ (Eq.7) [10]; activity corrections $\gamma$ are computed from the Davies equation (Eq.8):

$$0 = x_j - \sum_{i=1}^{N_s} \upsilon_{i,j} S_i \quad (5)$$

$$0 = \sum_{i=1}^{N_s} z_i^2 S_i^{z_i} - S_{OH^-} + S_{H^+} \quad (6)$$

$$I = \frac{1}{2} \sum_{i=1}^{N_s} z_i^2 S_i^{z_i} \quad (7)$$

$$\log_{10} \gamma = -A z_i^2 \left( \frac{\sqrt{I}}{1+\sqrt{I}} - BI \right) \quad (8)$$

where $S_i$ is a molar concentration (M) of the $i^{th}$ chemical ionic species and $z_i$ its charge, $\upsilon_{i,j}$ are stoichiometric parameters, A and B are solution-specific parameters, $S_{OH^-}$ and $S_{H^+}$ (M) are the molar concentrations of water hydroxide and hydrogen ions. The resulting non-linear algebraic loop was simplified by neglecting ion-pairing reactions, so that the number of residual equations after *tearing* is reduced from $N_c + 1$ down to 2 ($I$, pH), reducing the dependency of the Newton-Raphson solver on proper start guesses. The consistency of the physico-chemical sub-model extensions and hypothesis was verified by comparison with both results from literature [4] and Visual MINTEQ 3.1.

### (c) Copp-like interface

The interface contains algebraic equations intended to redistribute or lump the nutrient contents in the inlet stream to the components of the outlet connector. This is primarily because the two bio-process models are characterized by a different lumping degree of the chemical components that describe the liquid mixture. Consequently, some of them are also characterized by different elemental contents. For example, the biodegradable particulate organic matter concentration $X_s$ ($g_{COD}$ $m^{-3}$) in ALBA is intended to lump the biodegradable particulate carbohydrates $X_{ch}$ ($kg_{COD}$ $m^{-3}$), proteins $X_{pr}$) ($kg_{COD}$ $m^{-3}$) and lipids $X_{li}$ ($kg_{COD}$ $m^{-3}$) of agri-AcoDM, as well the biodegradable fraction of the bacterial biomass that does not survive in the RWP:

$$X_s = 10^3 \left[ \left(1 - f_{xh,xb} - f_{xnit,xb}\right)\left(1 - f_{xi,xb}\right) \sum_{i=1}^{5} X_{bm_i} + \right.$$
$$\left. + \left(1 - f_{xi,xb}\right) \sum_{i=1}^{2} X_{bm_j} + X_{pr} + X_{ch} + X_{li} \right] \quad (9)$$

where $f_{..}$ are portioning parameters, $X_{bm_i}$ and $X_{bm_j}$ ($kg_{COD}$ $m^{-3}$) are agri-AcoDM facultative aerobic and strictly anaerobic bacterial populations respectively. Any difference in the elemental contents is added/removed from the correspondent dissolved inorganic concentration $S_j$ of element $j$ (C, N, P) to guarantee atomic mass conservation, i.e.:

$$S_j = \sum_{i=1}^{n} x_i \nu_{j,i} - \sum_{k=1}^{m} x_k \nu_{j,k} \quad (10)$$

where $n$ and $m$ are the number of agri-AcoDM and ALBA states restricted to the liquid-solid mixture respectively, and $\nu_{j,i}$ ($g_j$ $g_i^{-1}$) are the stoichiometric fixed parameters that represent the content of element $j$ in the state $i$

(same holds for $k$).

### (d) Solid-liquid separation units

The screw-press model contains mass balance algebraic equations. Additional equations are used to specify the portioning of each state variable to the two output mass ports, via fixed average removal efficiencies. The flocculation unit contains similar equations, while accounting for the dilution factor introduced by the coagulant dosage.

### (e) Thermal sub-models (GPS)

The state variables are the 3 temperatures of the interacting heat capacities and the water vapour content $e_{int,air}$ (kg $m_{air}^{-3}$) of the greenhouse internal air. The state variables interact with each other via conductive, convective, latent-convective and radiative heat fluxes $\mathbf{\Phi}$ (W). The ODE ($\boldsymbol{x} \in \mathbb{R}^4$) are the energy balances of each uniform layer, i.e.:

$$CV\dot{\boldsymbol{T}} = Q(\boldsymbol{T_{in}} - \boldsymbol{T}) + \mathbf{\Phi}(\mathbf{T}, \boldsymbol{\theta}, \boldsymbol{d}) + \boldsymbol{u} \quad (11)$$

where $C$ (J $m^{-3}$ $°C^{-1}$) is the volume-specific heat capacity, $V$ ($m^3$) is the volume, $\boldsymbol{\theta}$ are fixed parameters, $\boldsymbol{d}$ are the external disturbances (i.e. external global irradiance at ground $I_0$ (W)) and $\boldsymbol{u}$ are the control inputs. The first additive forcing term is related to the enthalpic contributions of inlet/outlet flows of matter $Q$ ($m^3$ $s^{-1}$), which are present only for the internal air and RWP water layers. Water mass balance over the greenhouse internal air is used to calculate $e_{int,air}$, which is involved in the latent-convective heat exchange. The cover temperatures are algebraic variables (negligible heat capacity). A MISO conditional PID control is in place on RWP water temperature via both direct heat/cool flux and indirect mechanical ventilation air exchanges as control variables.

### (f) Raceway pond (ALBA)

From the hydraulic standpoints, the reactor is an open and completely stirred tank reactor (CSTR) with constant volume. The same acid-base reactions algebraic system described in (b) was extended to this model. The state variables $\boldsymbol{x}$ are 31 concentrations in the specific media of either bacterial aerobic populations, microalgae or organic/inorganic matter total components. Some of the latter are not present in agri-AcoDM and viceversa (e.g. dissolved oxygen $S_{O_2}$). The state variables interact with each other via biological (hydrolysis, growth, respiration, decay) and the same physico-chemical process rates described in (b). The ODE for the liquid-solid mixture are mass balances similar to the one described in (b), i.e.:

$$\dot{\boldsymbol{x}} = \frac{Q}{V}(\boldsymbol{x_{in}} - \boldsymbol{x}) + \mathbf{K_P}\,\mathbf{r}\left(\boldsymbol{x}, \boldsymbol{\theta_p}, \boldsymbol{z}, \boldsymbol{d}\right) \quad (12)$$

where $Q$ ($m^3$ $d^{-1}$) is the volumetric flowrate of influent diluted and separated liquid digestate and $\boldsymbol{d}$ are disturbances, mainly external air temperature T (°C) and total solar irradiance at ground (converted to photo-synthetically active radiation (PAR) $I_{PAR}$ (µmol $s^{-1}$)). Matrix $\mathbf{K_P}$ is the transposed stoichiometric Peterson matrix [6] that guarantees COD and atomic mass conservation, extended and modified according to the new variables and processes introduced. The general expression of bio-process kinetics is similar to the one reported in (b), but additional multiplicative terms related to temperature and PAR dependency are present for microalgae rates. A SISO conditional (upper-bound) P control is performed on raceway pH via $CO_2$ injection as control variable.

## III. MODEL APPLICATION

The following design assumptions and data were used for the biorefinery under study:

- *Location and weather data*. The plant is located in the Northern Italy (Cremona) and local weather data were used to run simulations.
- *Anaerobic co-digester*. A 1-MW plant was considered with two parallel fermenters and a post-fermenter (hydraulic retention time (HRT) = 33 d, 42°C). The plant is fed with cattle slurry (72%$_{ww}$), solid cattle manure (8 %$_{ww}$) and, according to the season, maize silage (October-June) or tomato peels (July-September) (20%$_{ww}$). An average biogas flowrate of approximately 11'000 $Nm^3$ $d^{-1}$ ($CH_4$: 51.5%, $CO_2$: 48.5% v/v) is generated, along with 180 $m^3$ $d^{-1}$ of raw digestate (6–7 %TS).
- *Digestate S/L separation and pre-treatments*. The liquid fraction of digestate is further separated through screw press and flocculant-assisted centrifugation.
- *Algal cultivation ponds*. A large-scale system (surface 7'560 $m^2$, liquid height 20 cm, HRT = 5 d) was designed to grow a *Chlorella-Scenedesmus* consortium. In the latter, pH is controlled to remain below 7.5, whereas temperature is not.

The flexibility and applicability of the model was tested in an open loop scenario analysis (Table 1) to verify the process feasibility in terms of microalgae biomass harvesting rates, when forcing the system with different agri-AcoD influent diet (e.g. slurry/maize ratio) and design (e.g. HRT) and thermal boundary conditions (e.g. number of greenhouse's covers). The DASSL solver [11], an implicit, gradient-based, integration algorithm with variable step size (suitable for stiff systems) was selected for the numerical resolution of the DAE system.

## IV. RESULTS AND DISCUSSIONS

The verification of the consistency of the physico-chemical sub-model hypothesis returned relative mean

**Table 1:** Open-loop scenarios studied for the case-study of interest.

| Scenario ID | Scope | HRT (d) | Silage-tomato load (ton $d^{-1}$) | Cow slurry load (ton $d^{-1}$) | Greenhouse cover |
|---|---|---|---|---|---|
| S.1.1.1-O | Baseline | 33 | 37 | 130 | Open |
| S.2.1.1-O | Effect of AcoD operative conditions | 66 | 37 | 130 | Open |
| S.1.2.2-O | | 33 | 67 | 100 | Open |
| S.2.2.2-O | | 66 | 67 | 100 | Open |
| S.1.1.1-1C | Effect of microalgae cultivation configuration | 33 | 37 | 130 | One-cover |
| S.1.1.1-2C | | 33 | 37 | 130 | Two-covers |

errors (RMEs) of 0.04% and 0.4% for the prediction of the digester pH (7.5) and $I$ (0.25 $mol_{eq}$ $L^{-1}$) respectively. It is worth noticing that the low RMEs obtained in this case-study were likely due to the low contribution of water hardness components (dissolved calcium $S_{ca}$ and magnesium $S_{mg}$) to the overall $I$, that was mainly composed by the other dissolved inorganics (P ($S_{ip}$), N ($S_{in}$), C $S_{ic}$)), and cations (dissolved potassium ($S_K$)).
This holds specifically for agro-zootechnical co-feedstocks, whereas this simplified approach that neglects ion-pairing reactions may lead to higher RMEs with other type of AcoD influent compositions.

The simulation of the biorefinery allowed to evaluate the quality of the liquid digestate produced and its suitability to be fed to the algal cultivation unit. Precipitation was quite severe in the agri-AcoD unit (66% of outflow inorganic P is precipitated) due to the high presence of free carbonate ($CO_3^{2-}$) and ammonia ($NH_3$) ions, and the main precipitated salts were struvite ($X_{stru}$ 9.2 mol $m^{-3}$) and calcite ($X_{ccm}$, 5 mol $m^{-3}$). Amorphous calcium phosphate ($X_{acp}$) precipitation was hindered by the high average N/P ratio ($5.7_{w/w}$) of this type of digestate. Indeed, a relevant portion of the total inorganic P is removed ($\approx 80\%$) during flocculation along with coagulated solids, so that the nutrient load reaching the RWP cannot be fully exploited. Nonetheless, the incoming salt seeding material tends to redissolve in the RWP thanks to microalgae inorganic dissolved C and N uptake, guaranteeing a 'stock' of nutrients that becomes available to microorganism under proper pH and $I$ conditions. Figure 2a depicts the trend of algal concentration for the four different agri-AcoD scenarios. The best performance in terms of algal biomass production was observed during spring for the scenario with an increased co-digester HRT and unchanged feeding strategy (S.2.1.1-O). This can be primarily accountable to the higher $S_{ip}$ concentration in the liquid digestate that leads to a lower microalgal P limitation, thanks to (i) the higher content of influent $S_{ip}$ in cow slurry and (ii) a longer residence time in the co-digester that allows a higher extent of lipids' hydrolysis. During summer, the feeding of tomato peels to the agri-AcoD unit features a lower volatile solid and a higher lipid content with respect to maize silage, so that it leads to (i) a 6% higher biogas methane content, (ii) a 12% lower biogas flowrate and (iii) an increase in the effluent $S_{ip}$ up to a peak 70% and 35% on average. Due to the slow dynamics of this state variable, sufficient nutrient availability was provided in autumn, resulting in a narrower difference between scenarios. The concentration of aerobic bacteria was higher for the scenarios S.1.2.2-O and S.2.2.2-O, mostly due to the increased undegraded organic matter load coming from the co-digester. This, in turn, would determine lower $CO_2$ injection rates to perform pH control, but lower 'pureness' of the outflow biomass product. The yearly productivity was estimated to be 54 $ton_{DM}$ $y^{-1}$ (19 $g_{DM}$ $m^{-2}$ $d^{-1}$, 78% of microalgae over total microorganism concentration, which are values in line with experimental literature) for the baseline scenario (S.1.1.1-O).

The effect of greenhouse covering in the RWP configuration is shown in Figure 3. Although a greenhouse ensures higher productivity during winter compared to open ponds, excessive covering (S.1.1.1-2C) can lead to strong overheat during summer and resulting in culture breakdown (-60% yearly average productivity). This outcome depends on the plant's latitude (weather data) and on the algal thermal response's $\boldsymbol{\theta_p}$. The summer productivity was more sensitive to temperature variations, while the productivity in winter was mainly limited by low $I_{PAR}$.

## V. CONCLUSIONS AND FUTURE WORK

The scenario analysis improved process understanding through a preliminary assessment of the impact of co-digester design and feeding strategy on digestate properties and microalgae production, with particular focus on the risk of algal P limitations due to precipitation. Results highlighted the importance of properly designing the whole biorefinery, and yet a noteworthy robustness of the microalgae cultivation's performance: however, it can be strongly affected by the presence of greenhouse covers on the RWP. It is remarked that the overall **`biorefinery`** model has not been validated yet, due to the lack of data, but that each major sub-model was extensively validated in previous works, proving its reliability. Nevertheless, the fine-tuning of the uncertain biological kinetic parameters and an overall validation over real

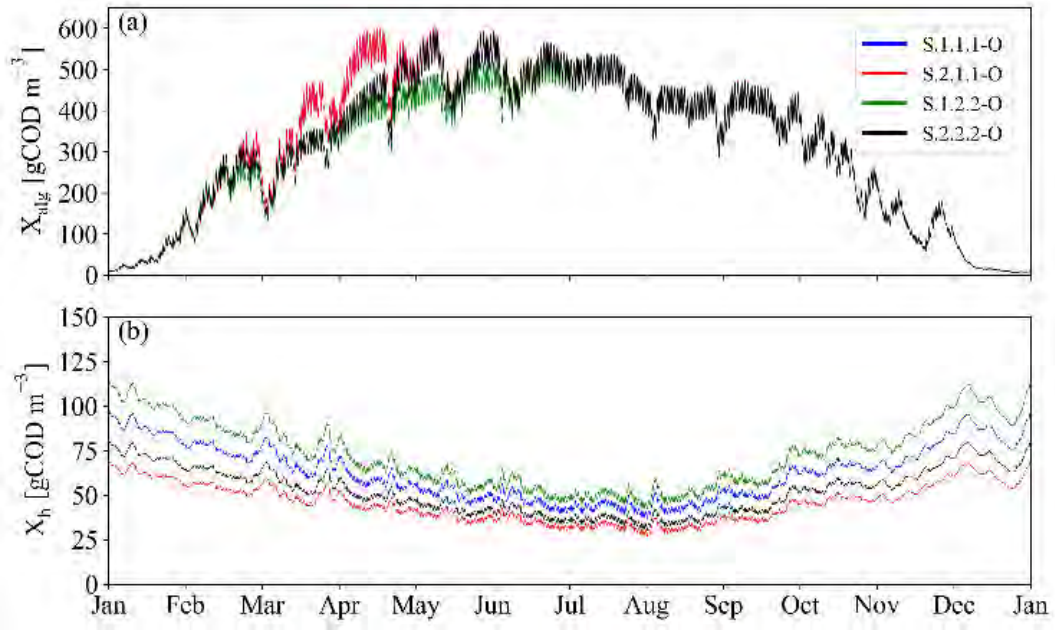

**Figure 2:** Simulation results: (a) yearly microalgae ($X_{alg}$) and (b) aerobic bacteria ($X_h$) concentrations for different scenario (AcoD operative conditions).

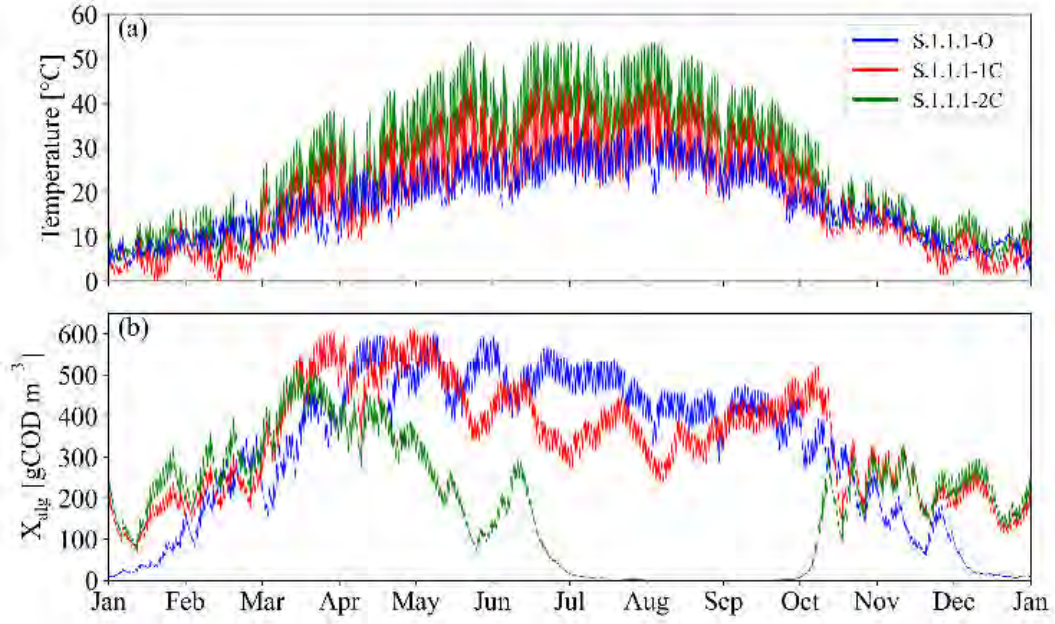

**Figure 3:** Simulation results: (a) RWP's water temperature and (b) yearly microalgae ($X_{alg}$) concentration for the different scenario (GPS-RWP thermal configurations).

data for the specific case of study will be required. Afterwards, the model could be exploited for the optimal techno-economic design of the process and as a high-fidelity '*real plant*' to validate classical/advanced control schemes, in support of the technology's scale-up. It is remarked that feedback control loops over the whole plant would require the frequent (e.g. 1 d$^{-1}$)/automatic measurement of the inorganic nutrients (mainly P, N), that is far from being cost-effectively applicable, especially for anaerobic digesters. Further insights on the modeling of S/L separation units will be required too. Yet, the model could serve, for example, (i) to assess the cost-effectiveness of heating/cooling inputs to boost microalgae productivity, and (ii) the validation of control schemes with bioreactors' HRTs/BRTs as $\boldsymbol{u}$ and revenues from biomethane and microalgae production as $\boldsymbol{y}$. Eventually, the aim of this work was to open novel discussions for the implementation of biorefineries' plant-wide models.

## ABSTRACT

To match the growing demand for biomethane production, anaerobic digestors need an optimal and time-varying adaptation of the input diet. Dynamic co-digestion constitutes a hard challenge for the limited instrumentation and control equipment typically installed aboard full-scale plants. The development of prediction models is foreseen to support process (optimal) design and control. In this work, a rigorous framework was applied to take full-scale applicability into account while dealing with the design and training of both high-fidelity and control-oriented first-principle/grey-box models, to be used for real-time optimization and process control respectively.

**Keywords**: Control-oriented modeling, Anaerobic co-digestion, Parameter estimation, Identifiability analysis.

## I. INTRODUCTION

To achieve energy independence and environmental sustainability, European bio-methane production is expected to increase over the incoming decades. Anaerobic digestion (AD) processes convert the biodegradable components of organic biomass into bio-methane and biogenic carbon dioxide (biogas), contributing to reduce the greenhouse gas emissions in the agricultural and waste sectors. AD entails a complex sequence of bio-chemical processes (hydrolysis, acidogenesis, acetogenesis, methanogenesis) which requires strict control of the operating conditions to avoid reductions in biogas production, or even complete process failure. Today, the techno-economic performance of bio-methane production via AD is increasingly tied to the plants' capability to embrace co-digestion (AcoD) of multiple co-feedstocks and adapting its input diet to the dynamic supply-chain market (e.g. seasonality). As typical of bio-chemical processes, there are two mains 'time-scales' of optimization tools: (i) high-level scheduling and (ii) low-level process control, to support plant managers and operators respectively. The ability of process models to predict the effect of diet change in advance is of primary importance to pursue those goals. However, the implementation of model-based control is hindered by (i) poor measurement instrumentation (typically gas flowrate and composition being the sole data frequently and automatically (i.e. *online*) measured); (ii) highly non-linear and slow kinetics (time of response from some hours to days); (iii) high parameter uncertainty; (iv) input variability/disturbances; (v) under-actuation. Indeed, literature has primarily focused on developing comprehensive first-principle, grey-box models rather than data-driven ones. The IWA ADM1 model [2] remains the state-of-the-art of AD modeling for process understanding, *offline* optimization and scenario analysis, but it is not suitable to be directly applied to model-based control due to its poor observability/identifiability. The AM2 [3], a simpler two-stage reaction model, was specifically designed with structural local observability and identifiability, to control the AD of simple and soluble feedstocks. After model definition, uncertain parameters shall be estimated: literature is flourish in ADM1 and AM2 tuning for different case studies [9], but their application to dynamic agro-zootechnical AcoD remains scarce [1], as well as the use of general/reliable guidelines for parameter estimation [7].

The aim of this work is to derive a reliable model for control purposes. The approach was to rely as much as possible on a trustworthy 'high-fidelity' model, following the steps: (i) a high-fidelity ADM1-like and a control-oriented (i.e. reduced-order) AM2-like models were extended/adapted for agro-zootechnical AcoD; (ii) with the constraints of industrial practice in mind, data from a

pilot-scale reactor were collected and an identifiable subset of the uncertain high-fidelity model's parameters was selected for estimation, exploiting also batch activity tests for improved practical identifiability; (iii) the reduced-order models' parameters were firstly trained in a 'physically-informed' way with highly informative synthetic data generated by the high-fidelity model, and, later, only a practically identifiable subset of parameters was 'refined' on real data. A model adaptation routine was tested to update the parameters estimated *offline* when model performance is poor. Considerations for the future application of the reduced-order models in control schemes are reported too.

## II. PROCESS MODEL

### A. High-fidelity: from ADM1 to agri-AcoDM

The high-fidelity model (named agri-AcoDM) is an extension of the ADM1, and resulted in a strongly non-linear differential algebraic equation (DAE) system with 43 state variables. Most of the extensions are described in detail elsewhere [5] and are summarized in the Digital Supplementary Material (DSM). In particular, (i) hydrolysis was extended to consider macromolecules with different times of response (e.g. readily/slowly biodegradable); (ii) salt precipitation and the non-ideality of acid-base equilibrium were considered for a better prediction of pH and inorganic nutrient (nitrogen N, phosphorous P) availability; (iii) the Monod functions used to describe acetate and propionate uptakes were substituted with Haldane ones, since high volatile fatty acids (VFA) concentration was proved to be inhibiting by itself, regardless the pH value [6]. The uncertainty in the model may lay both in the input parameters (characterization of the co-feedstocks in state variables' terms) and in stoichiometric, physico-chemical and kinetic parameters $\boldsymbol{\theta_p}$, but it is common to consider kinetics as the most relevant source of uncertainty. Further details on the system of equation are reported in the DSM.

### B. Reduced-order: from AM2 to AM2HN/tan

The reduced-order model extends the AM2HN [8] - itself an extension of the AM2 - with additional state variables and processes for the hydrolysis of the biodegradable particulate fraction of each of the *n* co-feedstocks (i.e. $\boldsymbol{X_h}$ $(g_{VS}\ L^{-1}) \in \mathbb{R}^n$). The resulting ordinary differential equation (ODE) system is reported in the DSM. Since inhibition from free ammonia ($S_{nh3}$) released by N-rich co-feedstocks (e.g. animal slurries) can be relevant [9], two model versions with ('AM2HNtan') and without ('AM2HN') $S_{nh3}$ inhibition were studied: a state variable (*N*) for the total ammoniacal nitrogen (TAN) was added in the AM2HNtan, along with a multiplicative non-competitive inhibition function in the $\mu_2$ expression, compared to the sole original Haldane function present in the AM2HN.

## III. PARAMETER ESTIMATION

Due to the high number of uncertain model's parameters and their collinearity, parameter estimation is all but a trivial task. The availability of data with sufficiently high frequency is of primary importance to stimulate parameter sensitivity, resulting in narrower estimation's confidence intervals. However, this is available in practice only for gas measurements at full-scale and continuous operation data are often poorly informative. Sporadic bio-methane potential tests (BMP) and activity tests are relatively cheap and yet very informative experiments, but the collinearity between $\boldsymbol{\theta_p}$ and unknown state's initial conditions hinders their exploitation. From these realistic considerations it came the intuition of combining data from continuous and batch tests: deriving the inoculum composition from the continuous operation, a mapping from $\boldsymbol{\theta_p}$ to the batch initial conditions is implicitly obtained and the degrees of freedom of unknowns are thus reduced [6]. Batch test's data were used only in the agri-AcoDM $\boldsymbol{\theta_p}$'s estimation, and the knowledge was then 'transferred' to the AM2HN/tan models exploiting synthetic data generated from agri-AcoDM.

A parameter subset selection (PSS) scheme based on both sensitivity and collinearity analysis was run to select a subset $\boldsymbol{\theta}_{PSS} \subseteq \boldsymbol{\theta_p}$ for estimation. For agri-AcoDM, 24 highly uncertain kinetic $\boldsymbol{\theta_p}$ [9] were selected to conduct and compare both linear/local (L.) and global (G.) dynamic sensitivity analysis (see DSM). The relative-relative sensitivity ($\boldsymbol{SI_{rr}}$) matrixes and the practical identifiability of each subset of parameters were computed as in [4]. The average over the data time points of the squared sensitivity values ($\boldsymbol{\delta}^{msqr}$) was selected as metric to rank the parameters, obtaining their ranking indexes $\boldsymbol{\rho}$.

The scalar cost function (Eq. 1) was the sum of the percentage mean relative squared (simulation) errors ($MRSE_{\%}$) over the different outputs of the dataset (see Section IV):

$$J = \sum_y w_y \frac{1}{N_y} \sum_{i=1}^{N_y} \left(\frac{y_i - \hat{y}_i}{\bar{y}}\right)^2 \quad (1)$$

where the '$y$' nomenclature refers to each data type ('Name' in Table I of the DSM), $N_y$ is the number of time observation points, $\hat{y}_i$ is the '$y$' model output at the $i^{th}$ time instant and $w_y$ is a user-configurable weighting parameter to drive the 'efforts' of the minimization problem toward a specific $y$. The average value $\bar{\boldsymbol{y}}$ normalizes simulation errors for variables of different magnitudes. The cost function was minimized by 30 iterations of the Differential Evolution (DE) algorithm and later 'polished' by the Nelder-Mead algorithm. Parameters' initial guesses (*nominal* $\boldsymbol{\theta}_{PSS}$) were set to literature-suggested values (Table 1-2). The algorithm moved within the feasibility set $\boldsymbol{\Theta} \subset \mathbb{R}_{>0}$ (large yet compact, based on literature values) returned the (*optimal*) minimizer $\boldsymbol{\theta}^*_{PSS}$. Spearman's

coefficient of determination ($R^2$) and Mean Absolute Relative Error (MARE) were used to quantify model's performances. After the estimation of the $\boldsymbol{\theta}^*_{PSS}$ *expected values*, the Fisher Information Matrix (**FIM**) was evaluated as a lower-bound of the covariance matrix to compute the 95% confidence intervals (CI) of the $\boldsymbol{\theta}^*_{PSS}$ estimates, and T-student hypothesis testing was performed [6]. The uncertainty was then linearly propagated to each *optimal* $\hat{\boldsymbol{y}}^*$ trajectory (see DSM for references).

For the AM2HN/tan models, the estimation entailed two stages: (i) a first 'physically-informed' training on agri-AcoDM-generated synthetic data under highly exciting and well-distributed input profile, and (ii) a 'refinement' on real data of the practically identifiable parameters only. The identifiability analysis was conducted on almost all stoichiometric and kinetic $\boldsymbol{\theta_p}$ (18 in total). Stage '(i)' was designed to *activate*/excite the VFA inhibition to provide information on the Haldane curve's parameters. All the available correspondences between ADM1- and AM2-like variables were exploited in this stage (see DSM Table I) [8]: however, $\boldsymbol{k_h}$ was estimated before stage '(i)', considering the simulation error on the sum of $\boldsymbol{X_h}$ only to limit the effect of other mismatches on its estimate.

## IV. THE DATASET

Considering the poor identifiability of agri-AcoDM and the limited budget of companies, the dataset must be minimal yet smartly designed to *activate* the parameters of interest and avoid overfitting. Data from a continuous pilot-scale reactor (12 L working volume, 42°C, initial D = 0.03 $d^{-1}$, organic loading rate (OLR) = 2.84 $g_{COD}$ $d^{-1}L^{-1}$ with 30, 47 and 23% of maize silage, cow slurry and tomato sauce respectively) resembling the operation of a full-scale plant were considered. Coherently to the industrial practice, the methane and carbon dioxide flowrate ($Q_{ch4}, Q_{co2}$) and the biogas composition ratio ($CO_2/CH_4$) only were considered as *online* data. In addition, it is reasonable to assume that some spot *offline* VFA (and TAN) data would be available at full-scale, especially during periods of diet change, so that some measurements of acetate ($S_{ac}$) and propionate ($S_{pro}$) concentrations were included. The peculiarity of the entire dataset (15/12/2023-10/04/2024) is that it entails various operative conditions (e.g. impulse and long free-responses (22/12/2023-08/01/2024)), that is an effective way to prevent overfitting. In particular, the *transient* between two different loads and diet compositions was included in the training dataset (05-23/02/2024).

A comprehensive feedstock characterization is usually available in full-scale plants, yet with low frequency, (e.g. seasonal): for each co-feedstock, characterization was performed as in [5] only once, along with BMP tests to derive information about the biodegradability.

On the 10/04/2024 some batch tests were run using the pilot-scale digestate as inoculum: activity on $S_{ac}$ and $S_{pro}$ were tested, with initial substrate concentrations hypothesised to range from limited to inhibited conditions. Hourly $Q_{ch4}$ of all the batch tests was recorded. Additional practical details on the dataset and its exploitation are present in the DSM-Table II.

## V. RESULTS AND DISCUSSIONS

### A. Agri-AcoDM calibration and performance

A reasonably collinear (collinearity index $\gamma \leq 20$) $\boldsymbol{\theta}_{PSS}$ of 14 sensitive ($\boldsymbol{\delta}^{msqr} \geq 0.1$) parameters was returned by the PSS. The ranking indexes $\boldsymbol{\rho}$, *nominal* and *optimal* values (± 95% CI) of each $\boldsymbol{\theta}^*_{PSS}$ are reported in Table 1. The T-student test rejected the null hypothesis for $k_{m,su}$, $k_{m,h2}$, $K_{i,h2,pro}$ and $K_{s,h2}$ (p-value $\leq 0.05$), in agreement with previous findings [6]. Figure 1 shows model's performances over the most interesting operative period: although not reported for readability reasons, the propagated uncertainty resulted in the definition of $\hat{\boldsymbol{y}}$ CI that included almost all model mismatches for $Q_{ch4}$ and $CO_2/CH_4$ (10%-65% and 5%-25% mean-max deviations from the $\hat{\boldsymbol{y}}$ *expected values,* respectively). However, too large and narrow sets for VFAs (120%-230%) and pH ($\leq$ 2%) were returned, respectively. Table 3 reports the metrics of model's performances over training and test periods. Remarkably, the MARE value for $Q_{ch4}$ and $S_{ac}$ decreased by 32% and 92% respectively, compared to the predictions with the *nominal* $\boldsymbol{\theta}_{PSS}$ values over the training period, and $R^2$ increased substantially. The good performance obtained for $CO_2/CH_4$ over the test period is very encouraging as well. The high MARE on $S_{pro}$ is due to many data points being near the lower analytical detection limit: $k_{m,pro}$ was reduced to improve the fitting of the high-concentration values and of the activity tests, with a consequent worse fit of low-concentration points. pH values were stably within the 7.1-7.5 range due to the system's high buffering capacity: consequently, the MARE value for pH is low ($\leq$ 4%), but the true challenge of capturing the pH dynamics is reflected by the lousy $R^2$ (yet a remarkable 0.7 over the training data, but lower than 0.42 over the test data). The validation period was particularly challenging due to the presence of prolonged free-responses (far from actual operation), so that, overall, the performances are satisfactory. In addition, the main falls of model's performance occur over free-responses and transient periods, whereas it is very satisfactory over the two 'steady-states' before and after the diet change (all $R^2$-MARE higher-lower than 0.6-20% respectively). Indeed, the most interesting experimental finding for control with diet adaptation is the recorded VFA (mainly acetate) increase during the transient period, suggesting unbalanced biological performances which are to be avoided (see Section IV and Figure 1).

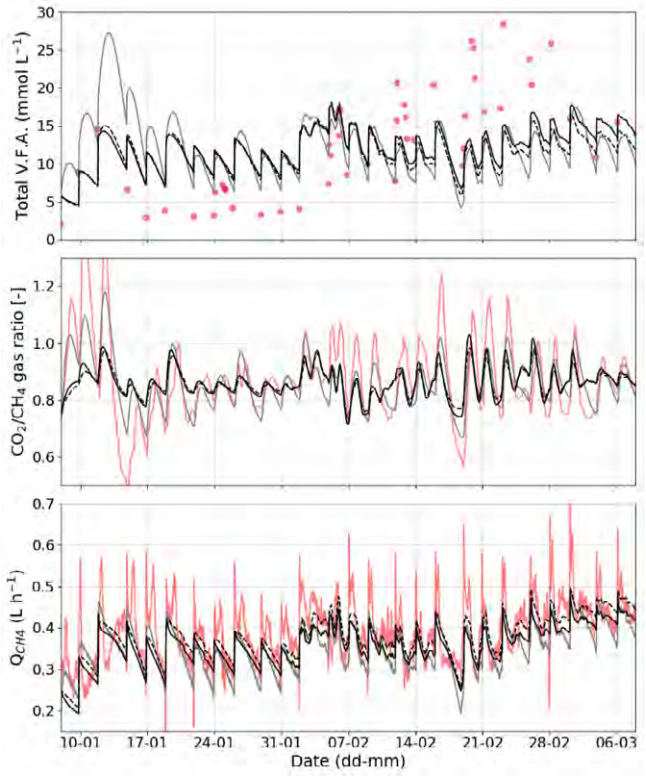

**Figure 1.** Models' performances: agri-AcoDM (grey line), AM2HN (black line) and AM2HNtan (dashed black line) vs data (red).

The low variability of pH suggests that no pH inhibition of the methanogenesis took place, thus remarking the need to introduce the Haldane functions to justify the VFA increase. Anyway, neither pH nor VFA inhibitions appear to be sufficient to explain such accumulation, since the optimal points of the Haldane functions resulted at values that were not reached during the transient (2.81, 0.26 $g_{COD}$ $L^{-1}$ for $S_{ac}$ and $S_{pro}$ respectively).

Figure 2 highlights the relevant improvements in model's predictions over the activity tests: MARE decreased on average by 55%. For the high substrate's initial concentration tests, $R^2$ were 0.92 and 0.64 for $S_{ac}$ and $S_{pro}$ respectively. For the BMP test on cow slurry, mean-max deviations were 28%-35%, and 40%-70% and 100%-200% for low and high initial concentration's activity tests respectively.

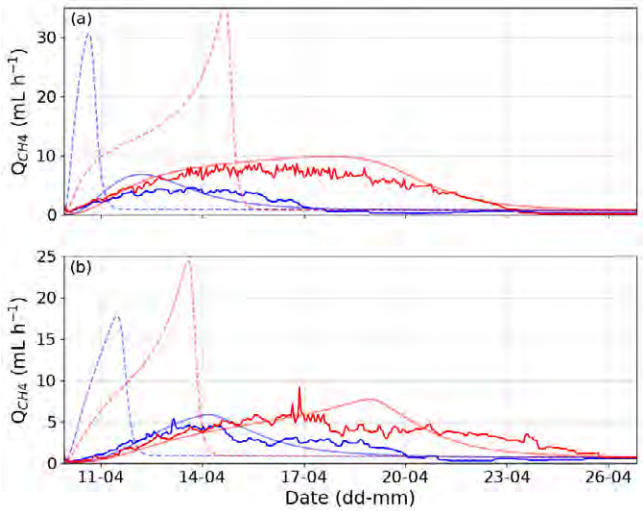

**Figure 2.** Agri-AcoDM model's performance for the batch tests on $S_{ac}$ (blue) and $S_{pro}$ (red): *nominal* (dashed line) and *optimal* (thinner continuous line) $\boldsymbol{\theta}_{PSS}$ vs data (thicker continuous line). Tests with high (a; ≥ 6 g $L^{-1}$) and low substrate's initial concentrations (b; 3 g $L^{-1}$).

## B. AM2HN/tan calibration and performance

Results from the first-stage estimation for the reduced-order models on synthetic data were very satisfactory: $R^2$ was higher than 0.6 for all states and outputs; MARE below 10% for $X_1$ and $X_2$, and below 30% for $S_1$ and $S_2$ (total VFA). A reasonably collinear $\boldsymbol{\theta}_{PSS}$ ($\gamma \leq 10$) of 4 sensitive parameters was returned by the PSS for the second-stage estimation. The *optimal* parameter values are reported in Table 2, along with the $SI_{rr}$ ranking indexes $\boldsymbol{\rho}$ of the AM2HNtan: the $\boldsymbol{\theta}^*_{PSS}$ values are reported within brackets ± 95% CI. Two mid-low $r$ parameters ($k_{La}$, $K_{s,2}$) were selected instead of a more sensitive one (e.g. $\mu_{max,2}$ was not selected due to its collinearity with $k_6$) disclosing the main drawback of this PSS method i.e. its strong dependence on the user choice of a $\gamma$'s upper threshold. Compared to agri-AcoDM, due to the lower dimensionality of $\boldsymbol{\theta}_{PSS}$, the propagated uncertainty resulted in narrower $\hat{\boldsymbol{y}}$ CI (9%-28%, 3%-18%, 14%-55% of mean-max deviation from the $\hat{\boldsymbol{y}}$ *expected values* of $Q_{ch4}$, $CO_2/CH_4$ and $S_2$ respectively). Table 3 and Figure 1 show model performances after both stages of estimation: compared to agri-AcoDM, similar performances for $Q_{ch4}$ and total VFA were obtained, and yet less ability to reproduce the $CO_2/CH_4$ dynamics. Interestingly, for both

reduced models, the Haldane curves have similar total VFA's ($S_2$) optimal value compared to the one on $S_{ac}$ in agri-AcoDM (difference ≤ 30%), whereas the maximum methanogenesis Haldane's rate are different (up to 70% difference), probably due to the higher complexity of agri-AcoDM (see DSM). The introduction of N release improved the fitting of $Q_{co2}$ by 5-10% only, whereas modeling the hydrolysis was of great relevance. AM2HNtan reported a better performance over pH (0.7% vs 1.5% MARE): overall, the higher complexity of AM2HNtan may be justified when (i) the system is poorly buffered and thus a better pH prediction may be more relevant, and/or (ii) the load of N-rich co-feedstocks is used as control action.

**Table 3:** Models' performances over train/test periods.

| | $R^2$; MARE (%) | | |
|---|---|---|---|
| | $Q_{ch4}$ | $CO_2/CH_4$ | $S_2(S_{ac},S_{pro})$ |
| agri-AcoDM train | 0.80; 23 | 0.73; 4 | (0.29,0.81); (45,143) |

| AM2HN train | 0.73; 18 | 0.28; 11 | 0.29; 51 |
| AM2HN test | 0.71; 33 | 0.13; 15 | 0.27; 57 |
| AM2HNtan train | 0.72; 17 | 0.21; 12 | 0.25; 52 |
| AM2HNtan test | 0.71; 32 | 0.10; 18 | 0.21; 55 |

## C. Recursive AM2HN parameter update

To reduce the relevant model mismatch over the diet transient, a modeler could either choose to add physical knowledge to the agri-AcoDM (e.g. lactate metabolism) or to embrace the philosophy for which *'no model is perfect':* in this work, a model adaptation scheme was tested for the AM2HN, via *'online'* recursive estimation of time-varying parameters over 10-days-long time windows (sliding, not overlapping) of the pilot-scale dataset. An *arrival* cost was added to the objective function to penalize 'useless' explorations far from the previously learned parameter values, thus preventing the risk to overfit process drifts and of catastrophic forgetting of the 'reference' parameters learned *offline* (Table 2). A weighting approach ($\boldsymbol{W_\theta}$) based on the $\boldsymbol{\rho}$ of the local $\boldsymbol{SI_{rr,k}}$ computed on the $k^{th}$ window was applied to the *arrival* cost (see DSM): the resulting optimization problem on each $k^{th}$ window returned the minimizer $\boldsymbol{\theta^*_{p,k}}$ expressed by Eq.2, where $J_k$ is Eq.1 evaluated on the $k^{th}$ window and $\boldsymbol{\theta^*_{p,k-1}}$ is the vector of *optimal* parameter values learned on the previous $k^{th-1}$ window.

$$\boldsymbol{\theta^*_{p,k}} = \underset{\boldsymbol{\theta_p}\in\Theta}{argmin}\ J_k + ||\boldsymbol{\theta_{p,k}} - \boldsymbol{\theta^*_{p,k-1}}||_{2,\boldsymbol{W_\theta}}\ \forall_k \qquad (2)$$

The capability of the AM2HN to improve the fitting of $S_2$ data over the transient period is shown in Table 3 and Figure 3: considering the 'posterior' model trajectories (i.e. evaluated with the $\boldsymbol{\theta^*_{p,k}}$ on each window) the $S_2$ MARE reduced on average by 50% compared to the model's performance with the fixed parameters learned *offline*. The average relative standard deviation of the $\boldsymbol{\theta^*_p}$ over the windows was lower than 6%, with the only exception of $\mu_{max,2}$ that varied on average by 26%: it is likely that the latter triggered the most the adaptation to the $S_2$ transient. Although the most sensitive parameters were always $\mu_{max,2}$, $k_5$ and $k_6$, the $K_{I,2}$ jumped forward in the $\boldsymbol{SI_{rr,k}}$ ranking when $S_2$ reached high values thus activating the inhibition function (e.g. $5^{th}$ window). It follows that, in the prospective of a nonlinear model predictive controller (NMPC) design, the update could be beneficial to prevent overloading the system (e.g. on the $4^{th}$ and $5^{th}$ windows, where $S_2$ accumulation is foreseen by the 'prior' model trajectories i.e. evaluated with the parameters estimated on the $3^{th}$ and $4^{th}$ windows ($\boldsymbol{\theta^*_{p,3}}$ and $\boldsymbol{\theta^*_{p,4}}$)). Eventually, this AM2HN structure seems to be suited for *online* control purposes owing to its fair prediction ability and restricted complexity (i.e. optimization's duration etc.).

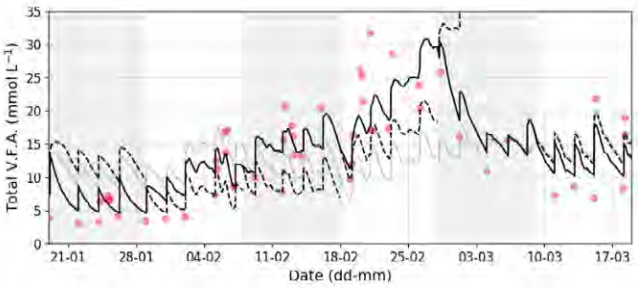

**Figure 3.** AM2HN model's performance with the *optimal offline* (grey line), the 'prior' (dashed black line) and the 'posterior' (black line) time-varying $\boldsymbol{\theta^*_p}$ vs data (red). Time windows are identified by the background color.

## VI. CONCLUSIONS AND FUTURE WORK

Both high-fidelity and reduced-order models were tuned on an informative and challenging agro-zootechnical anaerobic co-digestion dataset. The results encourage the use of the AM2HN/AM2HNtan in model-based control applications. However, the models' current structure appeared to fail in describing the transient dynamics of a diet change: a model adaptation scheme was tested to reduce the model's mismatch, 'following' the transient. It is difficult to say whether the cause of such mismatch was due to a misleading agri-AcoDM's reconstruction of the unmeasured states, then inherited by AM2HN/tan, or to time-varying parameters. To put the record straight and to move toward NMPC design, further efforts will focus on the design of state observers. For such scope, an asynchronous separation between unmeasured states and slowly time-varying $\boldsymbol{\theta_p}$'s estimations can be beneficial, due to the strong collinearity between the two on the outputs (e.g. $\mu_{max,2}$ and $X_2$ on $Q_{ch4}$). The ultimate goal is the design and validation of a robust NMPC scheme over similar diet changes, to serve as a digital twin for a concrete and transparent improved management of full-scale reactors.

## ABSTRACT

Machine learning algorithms have led to the development of numerous vector embeddings for biological entities such as metabolites, proteins, genes, and enzymes. However, these embeddings often lack contextual information due to their specialized focus on individual omics. Disease progression and biosynthesis pathways are increasingly understood through complex, multi-layered networks that integrate diverse omics data and intricate signaling and reaction sequences. Capturing these relationships in a meaningful way requires embeddings that account for both functional and multi-modal dependencies. We propose an embedding approach that unifies these different biological modalities by treating them as directions in a shared space rather than as isolated data types. Similar to how word embeddings in natural language processing reveal meaningful relationships (e.g., Tokyo – Japan + UK = London, indicating a directional representation of capitals), we can model genes and proteins in a way that captures their inherent connections. A gene implies information about the protein it encodes, and vice versa, forming a structured and interpretable representation of biological pathways. Our model, inspired by NLP techniques, breaks down pathway sequences into contextual pairs spanning different omics types. By aligning pathway steps in proximity, the embeddings reflect biologically relevant relationships, enhancing their interpretability and utility. Because these embeddings are generated from pathway sequences, they can be applied to optimize reaction pathways, aiding retrosynthesis in microbiomes, drug development, and even human health interventions.

**Keywords**: Chemical fingerprints, Biological Pathways, multi-omics, Drug Discovery, Biosynthesis

## INTRODUCTION

Machine Learning models can be fitted to predict a diverse set of properties or interactions between proteins, genes, small molecules etc. In every case a digital vector representation is necessary to represent physical/experimental data in a machine learning model. Specialised fingerprints exist for the different modalities (genes, proteins, small molecules) that aim to capture their own intricacies (amino acid sequence for a protein, nucleotide sequence for a gene or SMILES for a small molecule). However, in a bioprocess we use multiple omics together to promote the synthesis of targets through a biological pathway. Consequentially, predicting multi-omics interactions in a bioreactor requires a mapping between multiple spaces – the embedding space of proteins, of genes and small molecules. To increase the interpretability, efficiency and accuracy of predicting relations between multi-omics data we propose a new embedding space that encapsulates multi-omics layers together. Traversing a direction encoding omics-type allows us to find interacting compounds.

### Bioprocesses

Bioprocesses underpin a vast array of engineering or medical challenges such as synthesis trough engineered *E. Coli* strains [12], degradation and valorisation of waste material and disease progression [11]. The rise of high throughput analysis of genomics, proteomics etc. has vastly increased our ability to probe complex

systems. The next step is to optimise processes further using the new insights. An early approach is Flux Balance analysis where multi-omics pathways are modelled to increase the flux along preferred reactions that produce the desired products [7]. A bottleneck to FBA is the fact that detailed pathway knowledge is required. Identifying all pathways first to then eliminated unwanted fluxes involves inference across multi-omics. The proposed work facilitates the processing of multi-omics data by placing them in the same embedding space, where proximity in space codes for interaction strengths.

## Fingerprints in biological Networks

Biological systems whether we mean an organism-scale (e.g. microbiome), an organ or tissue scale, exhibit complex interaction networks [3, 4]. Different modalities like genes, proteins and small molecules interact e.g. to synthesise new proteins or start an inflammation reaction. To accurately model reaction cascades, signalling and metabolic networks we need to respect every modality (omics layer) as it can make or break the system's function [4, 6]. Drug design as well as bioreactors are increasingly relying on more complex networks for synthesis of proteins or the treatment of disease [11, 12]. In many more challenging cases long cascades and networks need to be optimised to improve a condition or achieve a higher yield. The analysis and generation of pathways using Machine Learning requires a digital vector-based representation of the compound. The approaches to obtain a descriptive vector for molecules can be grouped into different categories: 1. Chemical structure based [2] 2. Functional Group based [9] 3. Property based 4. Learned fingerprints [8]. Each of the fingerprints (MACCSKeys, Protein fingeprints etc.) have an applicability domain to a specific biological entity or an application in e.g. specifically drug like molecules. Due to the connected nature of multi-omics in biological networks, we propose a fingerprint that encapsulates multi-omics layers and can thus model an entire biological system within the same space. As the availability of established bioprocesses and pathway networks is still limited we aim to facilitate the discovery and analysis of biological systems.

# METHODS

Creating a descriptive embedding model based on pathway data requires a large pool of pathway diagrams. The pathway data are downloaded from the Pathway database (PDB) MetaCyc [1] and then sampled for the use in the embedding model. The model itself is based on the Word2Vec [5] architecture which has been used to find descriptive embeddings for natural language. Fig.1 exemplifies the complex interaction network found in biological systems.

Traditional structure-based fingerprints such as Morgan's (ECFP) fingerprint [2] use an iterative graph algorithm to derive a local neighborhood embedding which is aggregated and across all neighborhoods to define the final vector embedding. Its hyperparameters can control the influence of distant atoms to the local neighborhood. A fingerprint for functional groups is MACCS Keys [9]. They use a predefined set of substructures which are matched against the given molecule. If a substructure is matched the corresponding bit in the fingerprint vector is assigned a "1". Learned fingerprints [8] can be found e.g. by using an LLM which trains over SMILES string. The internal representation which the model has learned after converging can be extracted and used in Cheminformatics tasks. Our hypothesis is that from the reaction networks themselves (Fig. 1) comprising proteins, genes and small molecules we can extract semantic properties and develop a common embedding space for all involved components.

## Data Preparation

Downloading every pathway diagram contained in MetaCyc [1] yields a CSV file containing substrates, products, enzymes and genes. From this data we can infer which genes are translated into which proteins, which of these proteins are enzymes for a reaction and what substrates and products that reaction consists of. Using these relations, we can find possible subsequent interactions for a starting point i.e. interactions of the same pathway and related to a product of the previous reaction. After compiling the list of every interaction and its possible successors we sample a sequence of interactions in the pathway space. We start by picking a random reaction and then create a chain until no succeeding interaction can be found or the *sequence_length* limit is reached [Fig.1].

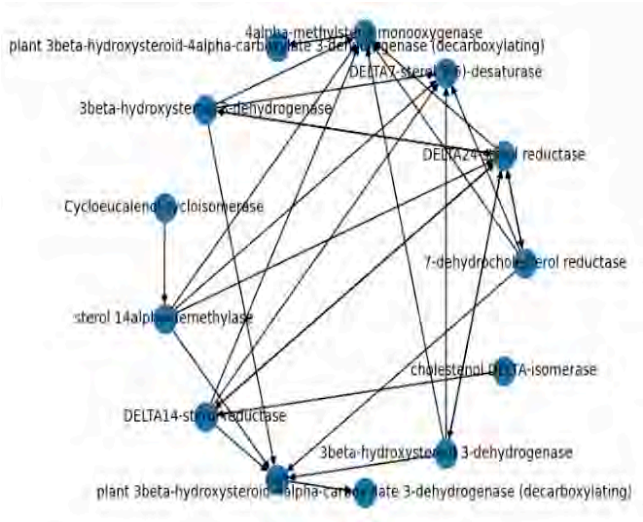

**Figure 1.** Processed reaction interaction network of cholesterol biosynthesis

The sampled trajectory through the space is further divided into context windows using the *context_window_size* parameter. From the sampled sequence of interactions in the pathway space we pick pairs of related nodes within the context window (regardless of which omics layer they represent). Our final training data are comprised of a list of related nodes and is supplement with a list of random unrelated nodes.

## Embedding Model

A shallow autoencoder network is used to compress the initial one-hot encoded nodes into a lower dimensional space. We optimise the network by using an objective that aims to align vectors of related nodes and misalign unrelated embedding vectors. By using both positive and negative examples we maximise the usage of our available training data and add additional information for the model to learn. The model structure is illustrated in Fig.2. Different linear layers are used for the target

**Figure** Embedding Model

```
class BioEmbeddingModel
    function init (vocab_size, embed_dim)
        target_embedding ← Linear(vocab_size, embed_dim)
        context_embedding ← Linear(vocab_size, embed_dim)
        activation function ← tanh
    function Forward (input, context)
        target_embeddings ← target_embedding(input)
        context_embeddings ← context_embedding(context)
        target_embeddings ← tanh(target_embeddings)
        context_embeddings ← tanh(context_embeddings)
        return Dots(target_embeddings, context_embeddings)
    function GetWordEmbedding (word)
        embedding ← target_embedding(word)
        return tanh(embedding)
```

**Figure 2.** Embedding Model

At the start of the training every node is assigned a one-hot encoded vector. At every iteration we create batch of positive and negative context nodes. The target word is given to the target network which compresses the vector of length *num_nodes* to the *embedding dimension* size (128). The context words are fed to the context layer which compresses the one hot encoding in the same way. Finally, we calculate the dot product between the target and context. The loss is calculated between the dot products of the context and target node embedding and the *learning_target*. The target is 1 if the node pair was a positive pair i.e. the nodes were in the same context in a pathway and 0 if the node were negative i.e. unrelated/ not-interacting. Our loss function is the mean squared error between the prediction and target. The objective aims to find embeddings that allow for a direct inference of its context in pathways.

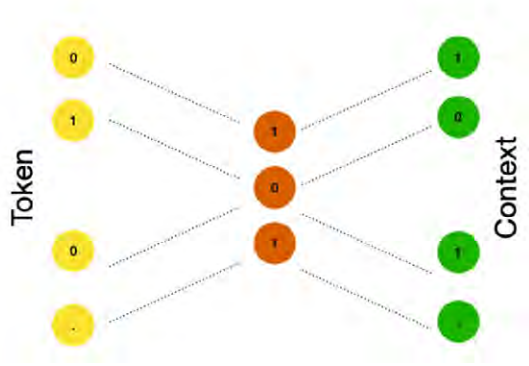

**Figure 3.** Embedding Model Objective Schematic

# RESULTS

Training the model according to the objective listed in yields new 128-dimensional vectors for every node of a MetaCyc [1] pathway. To visualise the newly found space we first run a t-SNE dimensionality reduction algorithm. The dimensionality reduced vectors are plotted in a two-dimensional space (Fig. 4a, b). In the space we find distinct islands which according to our objective we expect to represent interacting/ related pathway nodes across all omics-layers. The validation of our hypothesis is carried out by running a clustering algorithm which then enables us to analyse the properties of our clusters/ islands Fig. 4a. The coloured section in the plot show related nodes (highly aligned embedding vectors). In contrast to Fig. 4a we visualise omics-layers in Fig.4b. by coloring genes, proteins and small molecules.

## Embedding Space

We find that different pathway modalities are well distributed in the space despite genes being more abundant in the left half (Fig.4b). Therefore, in most clusters (Fig. 4a) we can identify closely related genes, proteins, enzymes and small molecules easily by searching in the neighborhood. To find the meaning of the clusters themselves we run 1. look at direct links between the most similar embeddings and 2. run a pathway enrichment analysis.

### Links between aligned nodes

As an example, we take UDP-alpha-D-galactose and its related node in the embedding space which encodes phosphoglucomutase-1 (PGM1). Their proximity in the space is valid because MetaCyc [1] indeed states UDP-alpha-D-galactose as an intermediate in carbohydrate metabolism, and its relation to phosphoglucomutase-1 (PGM1) lies in its role in glucose and galactose metabolism. Their relation is defined by the following characteristics:

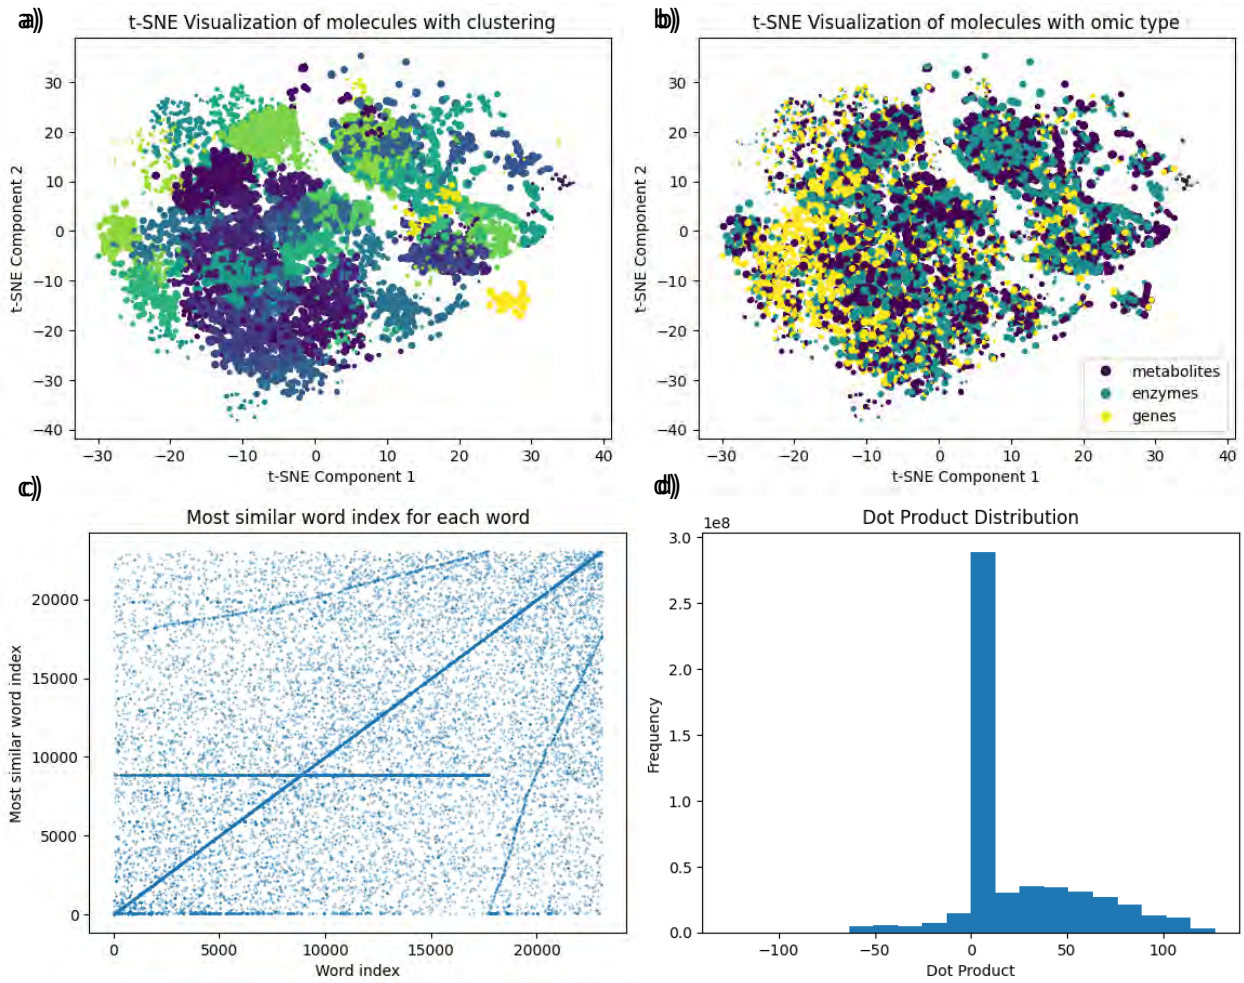

**Figure 4:** Resulting embedding space after running the embedding model

1. **PGM1 function**: Phosphoglucomutase-1 catalyzes the reversible conversion between glucose-1-phosphate (G1P) and glucose-6-phosphate (G6P). This step is crucial for glycogen breakdown, glycolysis, and the generation of nucleotide sugars such as UDP-glucose.
2. **UDP-galactose synthesis**: UDP-alpha-D-galactose is derived from UDP-glucose through the action of UDP-galactose-4-epimerase. UDP-glucose is synthesized from G1P by the enzyme UDP-glucose pyrophosphorylase, and PGM1 provides the necessary G1P by converting G6P.
3. **Interconnection**: PGM1 indirectly supports the biosynthesis of UDP-galactose because it ensures the availability of G1P, a precursor for the production of UDP-glucose, which is required for UDP-galactose formation. Therefore, PGM1 plays a foundational role in the metabolic pathways that produce UDP-galactose.

Similar results are found for other pairs of embeddings and thus verify that the model correctly relates different omics to aligned embeddings based on a functional connection.

In Fig. 4c we visualise the most related pathway node for every node. We achieved achieve a good coverage of the space because we limited the effect of highly common intermediates such as water, oxygen or carbon dioxide by under-sampling them. The model has therefore given an equal weighting to all related nodes. The diagonal has been set to zero. What looks like a diagonal in the picture originates from the fact that the nodes are implicitly ordered because we assign the indices as we process pathways. Hence, a similar index results in a higher likelihood of appearing first in a similar pathway. The overall distribution of dot products between all embeddings (Fig. 4d) follows the shape of a mixture of two distribution. One distribution belonging to related nodes with a smaller but wider peak and the other distribution of unrelated nodes with a sharp narrow peak.

## Pathway Enrichment Analysis

Based on the pathway enrichment analysis for the clusters in Fig. 4 we found that clusters share a set of common characteristics. Cluster 0 in the example contains

biosynthesis pathways focusing on Pyrimidine Nucleotide Biosynthesis, Pyrimidine Deoxyribonucleotide Biosynthesis and related processes. Based on the functional connections revealed by the enriched pathways within clusters we have shown that closely aligned nodes interact and share similar behaviours/ functions. The interactions can be grouped into the following categories:

1. **Shared Enzymes and Genes**: dut (Deoxyuridine 5'-triphosphate nucleotidohydrolase): Present in multiple pyrimidine-related pathways (e.g. pyrimidine biosynthesis and degradation)
2. **Key Reactions:** Conversion of nucleotides or nucleotide precursors like UMP, dUMP, and dTTP. Hydrolysis of diphosphates, ensuring the regulation of nucleotide intermediates.
3. **Cofactors and Byproducts:** Common usage of ADP, diphosphate, and AMP. Generation or utilization of cofactors like NADP+ and CO2 in related biosynthetic processes.
4. **Organisms and Applications:** The pathways include contributions from diverse organisms) highlighting conserved metabolic roles in nucleotide synthesis and homeostasis.
5. **Interconnection with Metabolic Networks:** These processes are interconnected with biosynthetic pathways like baumannoferrin biosynthesis and teichoic acid biosynthesis, emphasizing the role of nucleotides as substrates for broader cellular functions (e.g. synthesis of wall components or coenzymes).

# DISCUSSION

We have shown that clustering/ proximity in the embedding implies an interaction between the nodes (See Embedding Space Analysis). Unlike specific protein sequence, SMILES or gene embeddings we can directly link instances of genes, proteins and small molecules to learn about their relationship by computing the alignment of their embedding vectors/ proximity in the embedding space (Fig. 4b).

The amount of meaningful interactions an embedding vector captures depends on the data availability. Annotated pathways are limited, especially when we move away from model organisms or well understood disease metabolic networks. If we only witness a certain function of a protein in one domain and see no other examples of its behaviour in other contexts then it is unlikely that its embedding can generalise well to other domains. Additionally, Networks from MetaCyc [1] are biased in the sense that they have undergone a step of curation and are not direct results of experiments but rather a product of experimental studies and its subsequent analysis. Through this process we also lose some information. The networks found in MetCyc [1] are binary and no interaction strength or confidence of interactions can be inferred. We lose information on lower confidence interactions that still add nuanced detail to the characterisation of the nodes. Additionally, some interactions that were perhaps not relevant in pathway can be omitted making it more difficult to assess unknown or new pathways.

## High throughput experimental results

By providing additional experimental data from high throughput differential expression, we can reduce bias and increase the amount and diversity of training data. Currently, the focus lies on annotated and curated pathways from PDBs. The interactions contained in these databases are reliable reactions that support the higher order function of a pathway. However, these pathways networks have limited availability especially outside model organisms. Through additional experimental methods we can establish more linkages between metabolites, genes and proteins [10]. The interpretation of differential expression data is different however because correlations between two analytes do not necessitate a linkage by chemical reactions as it is the case in PDBs. In the context of this work the different interpretation is not an issue because we only consider the context of two analytes in a training objective. If two analytes are differentially expressed it means that a specific context change has had an effect on the analytes and there must be a pathway that co-affects them.

## Unknown Nodes

To find fingerprints for nodes not found in MetaCyc [1] we can provide the model with the node context. MetaCyc [1] is a large database of metabolic networks, and it contains many proteins, genes and small molecules. However, given the vast size of the chemical/ biological universe there are still a significant number of nodes which are not present. In the case that related nodes within the training set are known we can still find an embedding for them by feeding in all the related nodes to the encoder network by summing their one-hot encodings. A more generalizable approach to finding embeddings of unknown compounds would be to define a mapping from atom/ sequence space to the embedding space. Especially a bijective mapping can enable the embedding to be extended to generative applications. If we assume a generator model creates molecules in the embedding space with given properties, then these are unlikely to have been part of the training data. Thus, we require a mapping back from the embedding space to SMILES or sequences. To implement the additional mapping, we can create 3 new networks for each omics layer that can learn to map into the embedding space.

## FUTURE WORK

To address the issues of the limited network availability and bias as well as the loss of data due to binary edges we can supplement curated biological pathways with general high throughput experiments of protein-protein interactions, gene-protein interactions and metabolite interactions. Using data directly from experiments removes the need of curation from a Pathway Databases which reduces bias. Additionally, we can reduce our reliance on PDBs to contain data for the domain we are interested in. Certain disease networks might be very well represented in a database but venturing into a lesser-known disease requires data not yet found in Pathway databases. Apart from chemical reactions in metabolic networks gene regulation with transcription factors and cell signalling can be included to widen the applicability domain of the model as well as producing more nuanced embeddings.

### Structural and functional data

An additional structural, functional or compositional component in the embedding vector adds information to the training data that the embedding model can learn. The sequence (nucleotides, amino acids) provides information on the presence of functional groups, can show how related two genes are or give information on the 3D structure. To an extent these datapoint are implicitly present in the pathway network. However, Pathway Databases are never complete. They represent a subset of highly curated reaction networks, and we lose information by only teaching the model to reproduce these relations instead of also identifying new relationships purely on functional properties.

### Application to Pathway Discovery

The proposed fingerprints offer direct relationships between multi-omics data. Using the fingerprints to identify missing edges/ interactions in metabolic networks is a fitting application to test their predictive strength. Going even further we can use the fingerprints as the basis for generative models to create new pathway networks. As the interactions between nodes lie at the core of this fingerprint, we expect generative models to benefit from this single space embedding that capture multiple omics layers at once.

## ABSTRACT

The European Union is transitioning towards a circular and low-carbon economy, emphasizing renewable biological resources. This study explores the production of high-value compounds like chitosan from fungal biomass and presents a potential design for a sustainable biorefinery process, contributing to the diversification and optimisation of biomass feedstock utilisation. The process simulation includes dedicated sub-models for each unit operation, based on laboratory data and integrated into a comprehensive process flow sheet using COCO-COFE. The productivity of the simulated plant results in 2 500 tons of triglyceride oils and 1 800 tons of chitosan that can be produced from 15 000 tons of *Aspergillus niger*. On-site acetic acid production meets 45% of the total plant's demand, significantly reducing the amount of additional acetic acid to be purchased as raw material. Additionally, large-scale enzyme consumption and the substantial heat demand for biomass processing are key economic and environmental factors that need to be central in successful process design.

**Keywords**: waste valorisation, process design, sustainable product development, biomass conversion, data-driven modelling.

## INTRODUCTION

The European Union is shifting towards a circular and low-carbon economy, which focuses on renewable biological resources [1]. A promising alternative to conventional plant biomass is the utilisation of non-plant biomass, such as microbial, fungal, and animal-derived materials. One example is the production of high-value compounds, such as chitosan, from fungal biomass [2]. A significant advantage of valorising non-plant biomass is the reduction in competition with food production. Unlike plant biomass, which often requires arable land and can lead to biodiversity loss and land use changes, non-plant biomass can be sourced from waste streams and by-products, minimising competition with food and environmental impact [3]. Innovative technologies are essential to diversify and optimise the use of available, underutilised, and more sustainable biomass feedstocks. An integrated strategy that can replace multiple conventional products derived from fossil feedstocks or unsustainable agricultural practices, such as palm oil production, is urgently needed.

A promising new conversion process focuses on the upcycling the residue of the fungus *A. niger*, generated in large quantities during citric acid production (over 2 million tonnes produced yearly, globally [4]).This biomass is expected to reach a scale of 3.3 million tons by 2028 [4] and holds potential for higher-value applications beyond its current use as low-value animal feed. This study investigates the design of a biorefinery process, which comprises parallel production of two value-added products, namely yeast oil as a greener alternative to palm oil and non-animal-derived chitosan.

Yeast oil can be obtained from a fermentation process of solubilised *A. niger* biomass (hydrolysate) followed by a hydrolysis process. The resulting oil is based on triglycerides showing relative palmitic, stearic, oleic, and linoleic acid contents similar to the ones observed in conventional plant-based oils, such as palm and coconut oil. The oil can be used directly or hydrolysed by chemicals (acid or base) or enzymes to yield free glycerol and a mix of free fatty acids resembling closely those of rapeseed and sunflower oil. Thus, yeast oil can be valorised as biobased chemical in a variety of applications such as

cosmetics formulations, biofuel production, the food industry, and the pharmaceutical sector. It is noteworthy, that downstream processing of the raw yeast oil obtained from fermentation and hydrolysis can lead to the production of specific additives for cosmetics (stearates), as well as coating applications (alkyd resins). The main expected benefits are the high oil purity (no need for solvent traces removal), reduced specific greenhouse gas emissions with respect to conventional plant-based oils, good recycling potential, biodegradability, and sustainability.

Chitosan, which can be derived from chitin fraction of the fungal biomass, and its higher-value derived products, such as chitosan oligosaccharides (CHOS), are non-toxic and biocompatible. Moreover, a part of these derivatives is characterised by a low molecular weight, which guarantees their water-solubility and enhances the spectrum of possible applications. Remarkably, CHOS have a wide variety of interesting properties for applications in food, agriculture, medicine, pharmaceuticals, and cosmetics [5].

The developed process simulation consists of dedicated sub-models for each unit operation, which are based on laboratory data and implemented as plug-ins and further integrated in a comprehensive process flow using COCO-COFE v3.6, a license-free CAPE-open simulation software developed by AmsterChem. The process is sized based on the fungal waste biomass generated in an industrial-size citric acid production plant located in Germany. The mass and energy balances from the simulation are exploited for a preliminary feasibility study of the new proposed process. In particular, this study shows the energy consumption associated with all the involved unit operations and the Key Performance Indicators (KPIs) of the novel fungal biomass valorisation process.

## MODELLING

### Block Flow Diagram

The process comprises six primary steps, as displayed in Figure 1. Initially, the fungal biomass undergoes enzymatic solubilisation, yielding a sugar-rich aqueous solution. This hydrolysate is first utilised for on-site acetic acid production. In a subsequent main fermentation step, a lipid-rich yeast biomass is cultivated, utilizing residual glucose and acetic acid as carbon sources. All nutrients, such as salts and inerts, are for simplicity not displayed in the model. The lipids produced are then released during the hydrolysis step, resulting in the separation of the product into three distinct phases: solid, aqueous, and oil. Concurrently, the non-solubilised, chitin-rich fraction from the enzymatic solubilisation of the fungal residues is subjected to a combination of enzymatic and chemical treatments to produce chitosan and CHOS.

### Sub-models

Specific sub-models have been developed for the characterisation of each unit operation. A data-driven approach has been adopted where needed. According to this methodology, the conversion and yield of the reactions involved in the process are defined using correlations that contain adjustable parameters, which are fitted directly to the available experimental data. Therefore, the developed sub-models are only valid within the tested ranges of operating conditions and types of feedstocks.

We emphasise, that the process simulation approach and the criteria adopted to define representative molecular formulas for complex species are using well-established and thoroughly calibrated methods based on previous work [6].

### Enzymatic solubilisation

The process can be characterised as a hydrolysis reaction, where glucan polymers are broken down to form simple glucose monomers with the addition of water

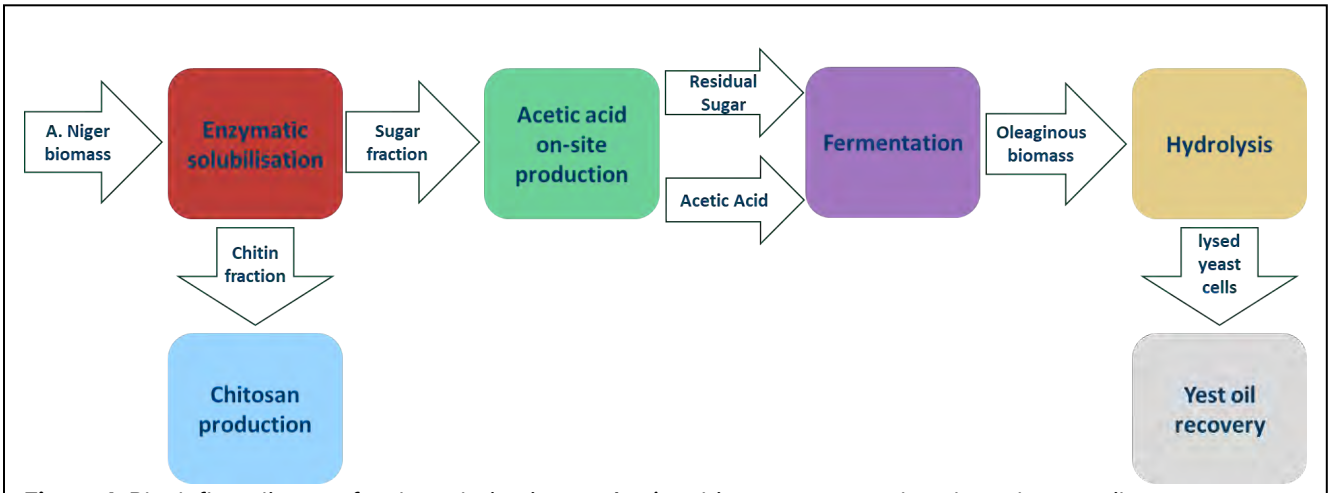

**Figure 1:** Block flow diagram for the valorisation og *A. niger* biomass to non-plant-based yeast oil.

molecules (glucan + water → glucose) and complex proteins into their shorter oligopeptides or their amino acid constituents, here simplified as protein + water → amino acids, as described by reactions (1) and (2), respectively.

$$C_6H_{10}O_5 + H_2O \rightarrow C_6H_{12}O_6 \quad (1)$$

$$C_{5.35}H_{9.8}N_{1.5}O_{2.45} + H_2O \rightarrow C_{5.35}H_{11.8}N_{1.5}O_{3.45} \quad (2)$$

The conversion rates of these reactions characterise the efficiency of the glucan/protein solubilisation. Lab-scale experiments reached an overall percentage of solubilised fungal biomass of 73%(w/w). Moreover, a comparable degree of solubilisation was observed for glucan and protein fractions. Therefore, assuming that no chitin is solubilised, the corresponding solubilisation factor for both glucan and protein is 85.3%(w/w).

## Chitosan production

The chitosan synthesis involves both deacetylation and depolymerisation of chitin. During deacetylation, the chitin polymer reacts with NaOH (chitin polymer + sodium hydroxide → chitosan polymer + sodium acetate) according to expression (3). A chitosan polymer, with a degree of polymerisation equal to the one of the reacting chitin polymer is formed. The conversion (equal to the degree of deacetylation) is 84%.

$$C_{40040}H_{65067}N_{5005}O_{25026} + 5005\ NaOH \rightarrow C_{30030}H_{55057}N_{5005}O_{20021} + 5005\ NaC_2H_3O_2 \quad (3)$$

In the depolymerisation the complex chitosan polymer is broken down into shorter-chain oligomers (chitosan polymer + water → chitosan oligomer). Given that experimental observations only provide the average degree of polymerisation of the product (without details on the chain length distribution), a simplified model based on the literature has been developed (conversion is set to 100%), see equation (4) [7].

$$C_{30030}H_{55057}N_{5005}O_{25026} + 384\ H_2O \rightarrow 385\ C_{78}H_{145}N_{13}O_{53} \quad (4)$$

## Acetic acid on-site production

The sugar-rich hydrolysate fraction is used for on-site production of acetic acid (AA) by fermentation. The AA will further be used as a co-feed carbon source in the main fermentation, where the AA and the residual sugar from the initial hydrolysate is exploited to grow oleaginous biomass. An inoculum flow equal to 4% of the mass of glucose in the hydrolysate is introduced in the medium to carry out the fermentation. Oxygen in the form of air is added as an input with 20% excess [8]. The conversion is defined considering the overall aerobic fermentation reaction of sugar to AA (glucose + oxygen → AA + carbon dioxide + water), described in equation (5). Based on the available literature, the average conversion is set to 85% [8,9]. The remaining 15% is the percentage of hydrolysate left after the acetic acid production step, to be exploited as the sugar source for the main fermenter. As a result, the AA to glucose molar ratio in the output stream is equal to 18:1.

$$C_6H_{12}O_6 + 2\ O_2 \rightarrow 2\ CH_3COOH + 2\ CO_2 + 2\ H_2 \quad (5)$$

## Fermentation

The chemical formula for the main fermentation (initial cell mass + hydrolysate + AA + oxygen → oleaginous biomass + carbon dioxide + water) is implemented as described in reaction (6). All nutrients, such as salts and inert species in the medium, are for simplicity not displayed in the model. The initial cell mass chemical formula represents the overall chemical composition of the medium that takes part in the reaction. Nitrogen is added to close the mass balance.

$$C_{5.35}H_{9.8}O_{2.45}N_{1.5} + 1.5\ C_6H_{12}O_6 + 40.5\ C_2H_4O_2 + 4.85\ O_2 \rightarrow C_{67.95}H_{112.65}O_{8.81}N_{1.04} + 27.39\ CO_2 + 38.58\ H_2O + 0.23\ N_2 \quad (6)$$

An external AA input is added to the system since the AA to glucose ratio available from the on-site production is not sufficient to meet the fermentation reaction stoichiometry, which requires an input ratio of at least 27:1. Based on experimental data created in the project, the conversion rates were set to 98% for glucose and 70% for AA.

## Hydrolysis of the yeast biomass

The hydrolysis is split into the release of triglyceride (oleaginous biomass → Tripalmitin + Tristearin + Triolein + Trilinolein + non-lipid biomass), which is presented in reaction (7), and the hydrolysis (non-lipid biomass + water → amino acid + sugar + lipid biomass), displayed in equation (8). Based on experimental data from project partners the overall conversion rate is set to 68%.

$$C_{67.95}H_{112.65}O_{8.81}N_{1.04} \rightarrow 0.403\ C_{57}H_{104}O_6 + 0.249\ C_{57}H_{110}O_6 + 0.045\ C_{57}H_{98}O_6 + 0.216\ C_{51}H_{98}O_6 + 1.855\ C_{9.3}H_{9.61}O_{1.8}N_{0.56} \quad (7)$$

$$C_{9.3}H_{9.61}O_{1.8}N_{0.56} + 2.5\ H_2O \rightarrow 0.2\ C_{13.42}H_{10.52}O_{0.014}N_{0.8} + 0.8\ C_{5.35}H_{9.8}O_{2.45}N_{0.5} + 0.39\ C_6H_{12}O_6 \quad (8)$$

The hydrolysis process yields a multiphase mixture with three fractions: (1) a solid fraction of dead cell mass and residual oleaginous biomass; (2) an organic liquid phase rich in lipids; (3) an aqueous phase, containing glucose, unreacted AA, and proteins.

## Yeast oil separation

The modelled separation involves three compound splitters (Sep-1 to Sep-3): 83% of the aqueous phase is recycled to the main fermenter, 100% of the produced triglyceride oil is separated, and the residual mixture is split to remove solids, with the aqueous solution being recycled back to the main fermentation.

## Flowsheet development

The sub-models described in section 2.2. have been integrated in the COCO-COFE process simulator. COCO (CAPE-OPEN to CAPE-OPEN) is a free-of-charge CAPE-OPEN compliant steady-state simulation environment. COFE (CAPE-OPEN Flowsheet Environment) is a user-friendly graphical user interface integrated in COCO for chemical flowsheeting provided with sequential solution algorithm using automatic tear streams. COFE displays properties of streams, deals with unit-conversion and provides plotting facilities. The system requirements to run COFE are Windows XP or higher.

A snapshot of the flowsheet is depicted in Figure 2. The Vapor-Liquid equilibrium in the process was simulated using the Raoult equation. Relevant physico-chemical properties, such as the chemical formula, ideal gas heat of formation, ideal gas entropy of formation, ideal gas heat capacity and vapor pressure, have been retrieved to characterise all species in the process simulator. In the absence of data or correlations from the literature, the vapor pressure of high molecular weight molecules such as enzymes, oleaginous yeast, and cell mass has been set to a fixed fictitious constant value of 0.000001. The reasonable implication of this simplifying assumption is that no vaporisation of the mentioned species occurs at the operating temperatures and pressures of interest for the investigated process.

The simulation was carried out assuming that the plant is treating 15 000 ton/year of dry *A. niger* biomass, which corresponds to the total annual amount of fungal waste generated by a citric acid industrial production site located in Germany. The fungal biomass feedstock contains 68%(w/w) glucan, 13%(w/w) chitin, 9%(w/w) amino acids and 10%(w/w) inert components. The latter one is a fraction of fatty acids and other components which do not react in the studied process and therefore are not displayed in the model. The *A. niger* biomass is diluted with water to a dry matter content of 15%(w/w) in the feed stream and preheated with steam to 121°C for 1 hour (autoclave sterilisation). After cooling, a dedicated enzyme cocktail is added to hydrolyse the glucan and protein present in the fungal biomass. Two dedicated fixed-conversion reactors are modelled to describe the protein (R100a deproteinisation) and glucan conversion (R100b glucan solubilisation), respectively. The residence time for the two enzymatic hydrolysis steps is set to 16 h and 40 h, respectively. Both reactors operate at a constant temperature of 50°C. The stream leaving R100b contains the sugar-rich hydrolysate and a residual solid fraction, containing chitin and unreacted glucan. These two fractions are separated in a filter (F-101). In this work, 100% of the filtrate is used for AA production.

The solid fraction (chitin and glucan) is pre-cooled to 25 °C in Cooler_chitin and chilled to 4 °C in another heat exchanger, named Chiller_chitin. The solid mixture is mixed with NaOH, which is also cooled to the same temperature in Chiller_NaOH, and then fed to the deacetylation reactor (R200-Deacetylation) and, subsequently, to the depolymerisation vessel (R200-Depolymerisation). The overall residence time inside the two vessels is 48 h. The mixture leaving R200-Depolymerisation is centrifugated to separate the water-insoluble compounds, including chitin and remaining glucan. For the centrifuge, a separation efficiency of 90% is assumed. The chitin-rich solid fraction can be utilised as animal feed. The chitosan-rich water stream is dried at 130°C using steam as utility. The dryer is designed to achieve 98% moisture removal. The dried CHOS product

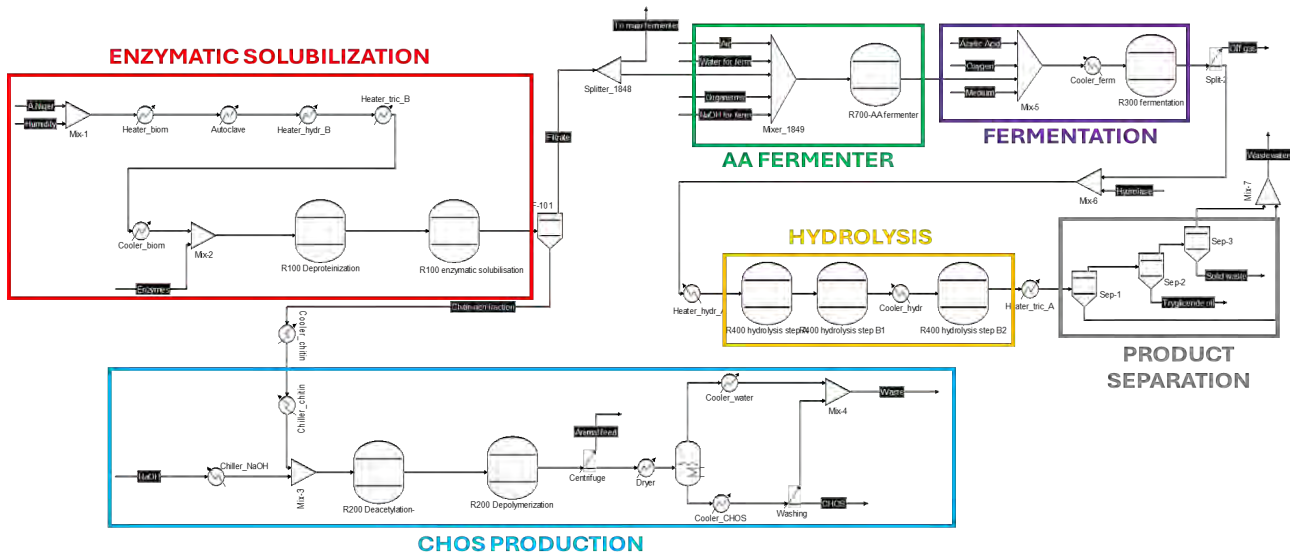

**Figure 2:** Process flowsheet implemented in COCO-COFE.

is cooled down to ambient temperature in Cooler_CHOS and sent to a washing step to remove residual impurities before storage.

The glucose-rich hydrolysate is mixed with all the other inputs required for fermentation in Mix-5: these streams are the fermentation organisms, additional water, NaOH for pH control, and air to provide oxygen. The mixed input enters a vessel where AA is produced (R500-AA fermenter). The residence time inside R500 is set to 50 hours. The output stream contains AA and glucose; thus, it represents the feed for the main fermenter. The additional feedstocks for the main fermentation medium, oxygen, and supplementary AA are mixed in Mix-6 and cooled down to 28 °C in Cooler_ferm. The residence time inside the fermenter is 72 h. Downstream the fermenter, a $CO_2$-rich off-gas is released, and the product is mixed with enzymes for the hydrolysis step. Finally, the mixture is heated up to 45 °C. The preheated stream is conveyed to hydrolysis.

In reactors (R400 hydrolysis step A and R400 hydrolysis step B), the non-lipid portion of the biomass is hydrolysed, producing glucose. Hydrolysis takes place in two vessels in series, operating at a temperature of 45 °C and 37 °C, with a residence time of 20 h and 6 h, respectively. Finally, the product is heated back to 45 °C in a process-process heat exchanger (Heater_tric) and sent to the product separation.

All residence time and operating conditions selected to model each process step represent the optimal conditions resulting from lab-scale tests carried out by our partners in VALUABLE.

## RESULTS

The Key Performance Indicators (KPIs) of the simulated plant include the productivity of triglyceride oil and chitosan (product targets), the on-site productivity of AA as an intermediate for the biomass conversion process, as well as the overall consumption of raw materials (the ones for which a major effect on the plant operating costs is expected), and the total steam demand (main utility for this plant). The KPIs are shown both on an absolute basis (see Table 1) and on a relative basis, assuming 1 kg of dry *A. niger* biomass as a reference (see Table 2).

**Table 1:** List of the Key Performance Indicators of the simulated plant on an absolute basis. AN – *Aspergillus niger*.

| Indicator | Value | Unit |
|---|---|---|
| Triglyceride oil productivity | 2446.5 | ton/year |
| Chitosan productivity | 1813.5 | ton/year |
| On-site AA productivity | 5221.9 | ton/year |
| Extra demand for AA | 6297.4 | ton/year |
| Total heat duty (LP steam) | 8.88 | MW |

The results show that about 2 450 tons of triglyceride oils and 1 800 tons of chitosan can be produced starting from 15 000 tons of *A. niger* biomass. The productivity of yeast oil is rather limited, considering that the glucan content in the biomass feedstock is 76%. However, this result can be justified considering that a significant portion of the glucan from the *A. niger* biomass is consumed to generate the AA needed as a co-carbon source for fermentation. On-site AA productivity turns out to cover 45% of the total AA demand of the plant: this is expected to have a positive effect on the operating costs, leading to a significant reduction of the amount of AA to be purchased.

**Table 2:** List of the Key Performance Indicators of the simulated plant (relative values per unit of feedstock). AN – *Aspergillus niger*

| Indicator | Value | Unit |
|---|---|---|
| Triglyceride oil productivity | 0.16 | kg/kg AN |
| Chitosan productivity | 0.12 | kg/kg AN |
| On-site AA productivity | 0.35 | kg/kg AN |
| Extra demand for AA | 0.42 | kg/kg AN |
| Total heat duty (LP steam) | 18.67 | MJ/kg AN |

The overall enzyme consumption represents a considerable challenge when considering a large-scale operation. Therefore, enzyme purchase cost is expected to be a key driver in the economic assessment of the plant.

Table 3 gathers a breakdown of the energy consumption associated with the single unit operations involved in the process.

**Table 3:** List of the energy requirements (and utility type) associated with each unit operation. C.W. - cooling water

| Unit operation | Duty (kW) | Utility |
|---|---|---|
| Heater_biom | 8337.95 | steam |
| Cooler_biom | 1730.39 | C.W. |
| Cooler_ferm | 4779.41 | C.W. |
| Cooler_hydr | 2421.24 | C.W. |
| Cooler_chitin | 88.58 | C.W. |
| Chiller_chitin | 72.36 | Electricity* |
| Chiller_NaOH | 0.76 | Electricity* |
| Dryer | 2891.88 | steam |
| Cooler_water | 3012.99 | C.W. |
| Cooler_CHOS | 137.55 | C.W. |

*Electricity consumption for the refrigeration cycle

The overall steam and cooling duty demands are 11.23 MW and 12.17 MW, respectively. Electricity consumption for the refrigeration cycle is a minor consumption. It is important to mention that the real electricity demand to run the plant will be higher since circulation pumps to overcome pressure drops must also be considered. However, based on the outcomes of the current

energy balance, the main conclusion is that the main operating cost associated with utilities is undoubtedly the one linked with the steam demand for the initial preheating of the fungal biomass to 121°C upstream of the autoclaving step.

## CONCLUSIONS

In the present work, two key milestones of the preliminary feasibility study of the novel process developed in the VALUBALE project, namely process design and simulation, and estimation of KPIs, have been accomplished.

The proposed process offers a sustainable solution for transforming an industrial waste (i.e., *A. niger* biomass) into multiple high-value products. The main novelties are enhanced sustainability and the promotion of a circular economy by converting waste into valuable resources.

In this study, we established a novel integrated bioconversion of acetic acid and sugar to sustainable yeast oil production. Moreover, by integrating on-site acetic acid production through fermentation, the need for external acetic acid purchase is significantly reduced. As a result, the cost gap compared to plant-based lipids is expected to be considerably reduced.

The results achieved in this work will be exploited as a basic framework to carry out a detailed Techno-Economic Assessment (TEA), Life-Cycle Assessment (LCA) and social acceptance assessment of the novel VALUABLE process. The main target will be to compare its economic and environmental impact with benchmark processes for oil production based on plant biomass and chitosan production based on crustacean waste. More specifically, palm oil production and chitosan production from shrimp cells will be used as reference cases.

## ACKNOWLEDGEMENTS

This publication is part of the VALUABLE project. The project has received funding from the European Union's Horizon 2020 research and innovation program under grant agreement No. 101059786.

## ABSTRACT

In recent years, burgeoning interest in products derived from microbial production across various sectors has significantly propelled the evolution of the field of metabolic engineering. As a Gram-negative bacterium, *Vibrio natriegens* is characterized by its fast growth, robust metabolic capabilities, and a broad substrate spectrum, making it a promising candidate as a standard biological host for the industrial bioproduction of metabolites. Genome-scale metabolic models (GSMMs) are mathematical representations constructed based on genome annotations and gene-protein-reaction (GPR) associations within a cell. These models enable the computational simulation of intracellular reaction flux distributions. In this study, we developed a hybrid method based on metaheuristic algorithms and the GSMM to optimize metabolism for the production of ethanol and 1,3-propanediol (1,3-PDO) as target products in *Vibrio natriegens*. The modified GSMM used in this study contains 1195 reactions, 1094 metabolites, and 880 genes, with the metaheuristic algorithms employed being Genetic Algorithm (GA) and Particle Swarm Optimization (PSO). The optimization results indicate that the method proposed in this study can achieve the production of ethanol and 1,3-PDO by adjusting the expression levels of just 2-4 genes, with the production of 1,3-PDO reaching its theoretical maximum. The strategies developed in this study can effectively increase the production capacity of specific target metabolites in *Vibrio natriegens*, serving as a starting point for metabolic engineering and providing guidance for metabolic engineering targets in practical experiments.

## INTRODUCTION

In recent years, there has been a growing interest across various industries in products synthesized by microorganisms, which has spurred the development of metabolic engineering. The natural pathways of natural product hosts may face issues such as low efficiency, slow production rates, and susceptibility to interference. With the advancement of synthetic biology, scientists have begun to perform local or global metabolic engineering modifications on wild-type host chassis based on specific target products. This leads to the creation of chassis cells with improved traits and competitive advantages. Specifically, metabolic engineering aims to increase the yield of specific target compounds as much as possible by identifying the optimal design of microbial cell factories [1]. Metabolic engineering techniques allow for precise regulation of gene expression levels in engineered bacteria, with flux simulation, computation, and optimization driving strain modification towards greater efficiency and precision. *Escherichia coli*, *Saccharomyces cerevisiae*, and *Corynebacterium glutamicum* stand as the most prevalent biological hosts for constructing these cell factories. *Vibrio natriegens* is a Gram-negative bacterium known for its remarkable growth rate, robust metabolic capabilities, and a broad substrate spectrum, holding promise as a prospective standard biotechnological host for laboratory and industrial bio-production,

specifically tailored to produce target metabolites [2].

The advancement of genome sequencing technology and the gradual completion of biochemical databases have driven the development of GSMMs, establishing them as an important tool for studying cellular metabolic characteristics. GSMMs are mathematical representations of cellular models that originate from the cell's annotated genomic information. They construct a matrix of all the metabolic reactions in the cell based on GPR associations. GSMMs effectively integrate the intracellular metabolites, enzyme-catalyzed metabolic reactions, enzymes, and the genes responsible for enzyme expression, thus constructing complex models of metabolic networks. Currently, GSMMs are extensively utilized in the field of metabolic engineering for the computational tasks, simulations, and analyses of cells. They can predict cellular growth under various gene expression conditions and environmental changes, assessing the global distribution of metabolic fluxes, and determining the production flux of specific metabolites, making them vital tools for gene essentiality analysis and the prediction of cellular viability. GSMMs have been established for various model microorganisms, with continuous improvements being made to the number of genes, reactions, and metabolites included in the models, as well as the constraints applied, all of which enhance the accuracy of the models. In 2023, Coppens et al. [2] developed the first GSMM for *Vibrio natriegens*, which showed good consistency with experimental data. With the increasing convergence of computer science and bioinformatics, and considering the efficiency and effectiveness of metaheuristic algorithms in finding global optima, scientists have begun to apply metaheuristic algorithms to the analysis of GSMMs for hosts such as *Escherichia coli* [3].

In this study, we propose a hybrid method for the metabolic optimization of *Vibrio natriegens*. We first modified the GSMM for *Vibrio natriegens* developed by Coppens et al., and then we combined it with different metaheuristic algorithms, including GA and PSO, to identify the optimal gene expression level optimization strategies encompassing both knockouts and underexpression, as well as overexpression, for maximizing production fluxes of ethanol and 1,3-PDO, our two target products. Integrating machine learning with traditional metabolic engineering can aid in a more efficient discovery of better metabolic optimization strategies and facilitate a more comprehensive understanding of the reasons why different metabolic optimization strategies are conducive to increasing the yield of target metabolites. The optimization results suggest that the hybrid method can effectively enhance the production capabilities of specific targeted metabolites in *Vibrio natriegens*, offering strategic guidance for target selection in metabolic engineering modifications for practical experiments.

## PROBLEM STATEMENT

### The mathematical expression of metabolic engineering strategy optimization

The optimization of metabolic engineering strategies based on GSMM is a bi-level optimization problem. The inner layer consists of a linear programming problem, also known as the simulation of the GSMM, which aims to optimize an objective function defined as the linear combination of the reaction fluxes within the network (for example, the flux of the biomass production reaction). This is achieved by employing equality constraints derived from the quasi-steady-state assumption in the cell, along with inequality constraints that impose direct limits on the maximum and minimum values of the reaction fluxes. The inner layer provides the distribution of reaction fluxes within the metabolic network, as well as the maximum value of the corresponding objective function. Building on the distribution, the outer optimization introduces various gene expression optimization strategies, with objective functions such as Biomass-Product Coupled Yield (BPCY) and Weighted Yield (WYIELD) that are related to the target product production flux. Gene expression strategies encompass gene knockout, underexpression, and overexpression, which impact the inequality constraints of the inner layer optimization. This, in turn, affects the distribution of network fluxes and, as a result, the optimization results as well as the value of the objective function in the outer optimization.

The bi-level optimization problem can be mathematically represented as equations 1-4.

$$F(\boldsymbol{strategy}) = \max\{BPCY(\boldsymbol{v}),\ WYIELD(\boldsymbol{v}),\ etc.\} \quad (1)$$

$$Z = \max\{\boldsymbol{C}^{\mathrm{T}} \cdot \boldsymbol{v}\} \quad (2)$$

$$\boldsymbol{S} \cdot \boldsymbol{v} = 0 \quad (3)$$

$$\boldsymbol{lb}(\boldsymbol{strategy}) \le \boldsymbol{v} \le \boldsymbol{ub}(\boldsymbol{strategy}) \quad (4)$$

Where $\boldsymbol{v}$ is the flux vector composed of the fluxes of all reactions in the metabolic network, with a dimension of $N$, which corresponds to the number of reactions in the model; $\boldsymbol{C}^{\mathrm{T}}$ is the transposed vector of the integer coefficient of each flux in the objective function $Z$; $\boldsymbol{S}$ (M×N) is the stoichiometric matrix ($S_{ij}$ corresponds to the stoichiometric coefficient of metabolite $i$ in reaction $j$); $\boldsymbol{ub}$ and $\boldsymbol{lb}$ record the upper and lower bounds for the flux of each reaction in the model, respectively; $\boldsymbol{strategy}$ indicates the gene expression optimization strategy, where each dimension corresponds to a gene in the model, and each gene corresponds to an enzyme (A $strategy_i$ value of 0 signifies that the gene is knocked out, a value between 0 and 1 signifies underexpression, and a value greater than 1 signifies overexpression); $BPCY$ is the product of biomass and the yield of the target product, whereas $WYIELD$ is the weighted sum of the minimum and

maximum product fluxes under a fixed growth rate, with the weight for the maximum product flux set at 0.3.

## Impact of gene expression optimization strategies on flux constraints

Changes in gene expression levels affect the concentration of enzymes in the system, thereby influencing the flux constraints of reactions. Figure 1 is a schematic diagram illustrating how gene expression optimization strategies affect reaction flux constraints.

In a GSMM, each gene expresses a protein (enzyme) that catalyzes a reaction; however, enzymes and reactions do not correspond on a one-to-one basis. There may be multiple enzymes that work together to catalyze a single reaction (cooperative), or several enzymes that can each independently catalyze a particular reaction (competitive). Before determining the new constraints for each reaction, the following calculations need to be performed: (1) Calculate the reaction fluxes of the initial model (wild type) as a $\boldsymbol{reference}$; (2) Calculate the values of the optimization strategies for each reaction. For cooperative genes (G3 and G4), the corresponding reaction optimization strategy is taken as the minimum of the gene strategies, whereas for competitive genes (G2 and G3), the reaction optimization strategy is the maximum of the gene strategies, as shown in Figure 1. Based on the optimization strategy ($strategy_i$) and reference flux value ($reference_i$) for each reaction, updating the constraint of the reaction flux involves two steps. (1) Determine the direction of the reaction: if $reference_i > 0$ (forward reaction), set the lower bound of the reaction to 0; if $reference_i < 0$ (backward reaction), set the upper bound of the reaction to 0. (2) Update the constraint according to the direction of the reaction and the optimization strategy. For knockouts (strategy equals 0), set both the upper and lower bounds of the reaction to 0; for underexpression (strategy between 0 and 1), underexpressing a forward (backward) reaction is achieved by setting the upper (lower) bound to $strategy_i \times reference_i$; for overexpression, overexpressing a forward (backward) reaction involves setting the lower (upper) bound to $strategy_i \times reference_i$.

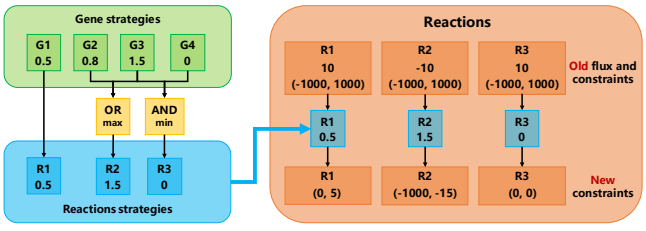

**Figure 1.** The relationship between reaction flux constraints and gene expression optimization strategies.

# MATERIALS AND METHODS

## Dataset and experiment setup

We utilized the only published GSMM of *Vibrio natriegens* in SBML format and made the following modifications to it. We adjusted the upper and lower bounds of the glycerol demand reaction in the model, enabling the model to simulate cell culture processes with glycerol as the sole carbon source. We controlled the oxygen input in the model to be greater than zero (aerobic cultivation). We also removed three reactions that were not directly adjacent to the main reaction network, along with the corresponding six metabolites and three genes. Additionally, since the metabolic network of the wild-type *Vibrio natriegens* does not contain 1,3-PDO, we introduced a two-step heterologous pathway for the conversion of glycerol to 1,3-PDO via 3-hydroxypropionic acid, ensuring that the model could be used for metabolic optimization of 1,3-PDO production. The modified GSMM comprises 1195 reactions, 1094 metabolites, and 880 genes. We employed parsimonious Flux Balance Analysis (pFBA) [4] to simulate each phenotype during the optimization process. The pFBA method can return a flux distribution result where the total flux of all metabolic reactions is minimized while still maximizing the objective function. GA and PSO were used to perform metabolic optimization with ethanol and 1,3-PDO as the target products of cellular production. All simulations and optimizations of the GSMMs were conducted in Python, utilizing the Cobrapy [5] and Mewpy [6]. The hyperparameter settings for the GA and PSO are shown in Table 1. In both algorithms, we limited the maximum number of genes with adjusted expression levels to 6.

**Table 1.** Hyperparameter settings for GA and PSO.

| Algorithm | Hyperparameter | Value |
|---|---|---|
| GA | Number of generations | 100 |
| | Others | Default |
| PSO | Number of particles | 2500 |
| | Number of iterations | 100 |
| | Inertia weight | 1.5 |
| | Personal learning rate | 2.1 |
| | Global learning rate | 1.6 |
| Both | Maximum number of genes with adjusted expression levels | 6 |
| | Fold of expression levels | {0.125,0.25, 0.5,1,2,4,8} |

## Description of the hybrid metabolic optimization method

Simulation methods such as pFBA can determine the global distribution of reaction fluxes under various gene expression strategies, but they do not provide guidance on how to optimize these strategies. Given that the relationship between the production flux of biomass and

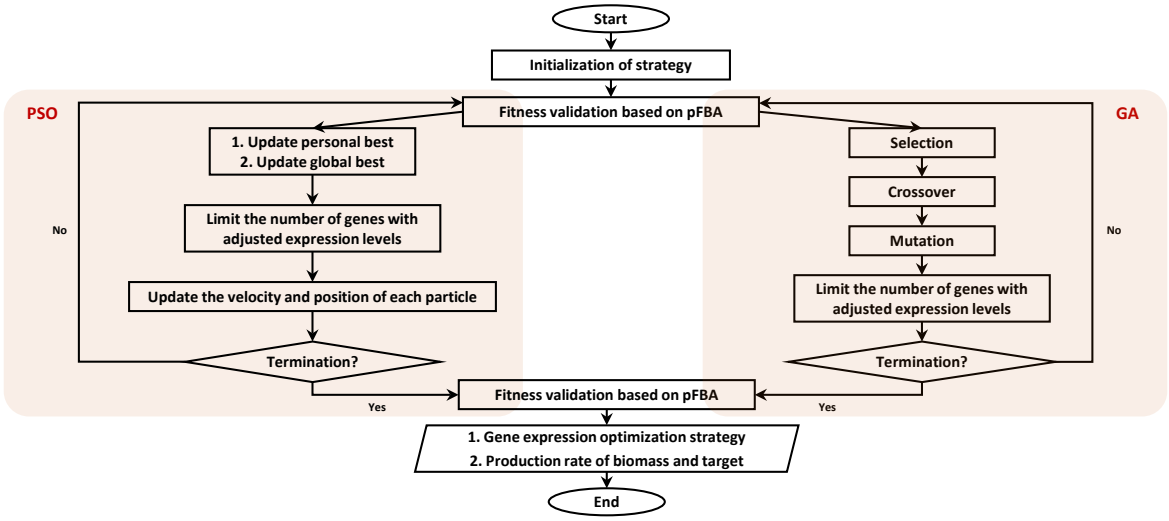

**Figure 2.** Flowchart of the hybrid optimization method.

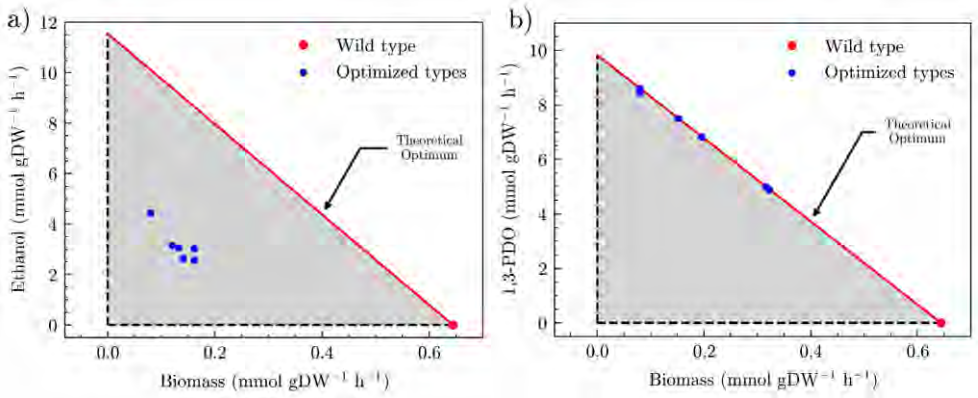

**Figure 3.** Visualization of metabolic optimization for a) ethanol production, and b) 1,3-PDO production.

the target product is not a simple function of the strategy vector, and that calculating the gradient is challenging due to the complexity of the system, coupled with the extensive search space for the strategy vector, it is particularly appropriate to employ metaheuristic algorithms to find more optimal values of the strategy vector. The metabolic optimization method proposed in this paper has explored the use of different metaheuristic algorithms to control the update of the strategy vector. The pFBA method is employed to validate whether this strategy vector can indeed optimize the production rate of the target products while ensuring cell viability. Figure 2 is a flowchart of the hybrid optimization method. The method ultimately outputs both the optimal strategy vector and the corresponding production rate of biomass and target product.

## RESULTS AND DISCUSSION

Metabolic optimization was carried out for ethanol and 1,3-PDO as separate target products, with glycerol being used as the sole carbon source for cell growth and its uptake rate controlled at 10 mmol $gDW^{-1}$ $hr^{-1}$. The experiment found that it was not possible to increase the production rate of the product solely by gene knockout, likely because the competing pathways for intermediates are essential for cell growth. However, through optimization, some feasible sites for gene overexpression and underexpression were identified. These strategies demonstrated effective increases in the production rate of the target product. Table 2 shows the results of the optimized gene expression strategies, where each row corresponds to a strategy, including genes that are knocked out, overexpressed, or underexpressed, along with the associated strategy values. In addition, the heuristic algorithm corresponding to each strategy, the biomass, target production rate, and the values of the objective functions were also calculated and recorded.

Ethanol is one of the typical fermentation products, generally associated with acetyl-CoA in the metabolic network. Figure 3a illustrates the cell biomass and ethanol production corresponding to strategies obtained by metabolic optimization. The gray triangular area in Figure 3 represents the theoretically feasible combinations of biomass and target production, while the red line indicates the theoretical maximum target production for

**Table 2.** Metabolic optimization results.

a: In *Vibrio natriegens*, the prefix for all gene ids is "PN96_". For example, the gene corresponding to id: 14435 would be "PN96_14435".
b: In the table, each grid may contain multiple Ids, indicating that the expression levels of genes corresponding to each Id will be controlled in that strategy.
c: BPCY is the product of biomass and the production rate of the target product. The units for WYIELD, biomass, and production rate are all mmol $gDW^{-1}\,hr^{-1}$.

each biomass level. The red dot represents the wild type corresponding to the original GSMM, and each blue dot corresponds to a strategy listed in Table 2. Figure 3a shows that the optimized GSMM can demonstrate ethanol production, and there is a negative correlation between ethanol production and biomass. However, there is still a certain distance from the theoretical maximum production of ethanol, which may be due to competition from other fermentation products such as acetate.

The maximum production strategy for ethanol from GA involves the overexpression of the gene PN96_14435 (gpmM), which increases the flux from glycerate-3-phosphate to glycerate-2-phosphate, thereby enhancing the production of pyruvate and acetyl-CoA, consequently benefiting the production of ethanol. The strategy also involves the underexpression of the gene PN96_02835 (aroC), which leads to a reduction in the production of branch acids, attenuating the biosynthesis of phenylalanine, tyrosine, and tryptophan, thereby diverting flux into glycolysis, which in turn facilitates the production of ethanol. The strategy provided by PSO involves the overexpression of genes PN96_00270 (lysC) and PN96_14435 (gpmM). The former enhances the phosphorylation of aspartate, which is beneficial for the generation of fermentation products, while the latter is the same as in the GA strategy. The strategy also underexpresses gene PN96_10255 (ppnK) and knocks out gene PN96_01945 (glpD). The former regulates the intracellular redox balance, while the latter ensures that glycerol-3-phosphate is converted into glycerone-phosphate only through interactions with NADP+ or NAD+, also regulating the intracellular redox balance, thus promoting the production of ethanol.

Unlike ethanol, the production of 1,3-PDO has been introduced into the metabolic network as an exogenous pathway, competing with the accumulation of cell biomass directly for the carbon source glycerol. Figure 3b visualizes the biomass and 1,3-PDO production

corresponding to the optimized strategies, demonstrating that all strategies in Table 2 can achieve (or nearly achieve) the theoretical maximum production of 1,3-PDO while sacrificing a certain amount of biomass.

Compared to ethanol, the strategy for targeting 1,3-PDO as the product is simpler, requiring the underexpression of as few as one gene. For example, by reducing the expression of the gene PN96_00900 (pgk), the flux from 1,3-bisphosphoglycerate to 3-phosphoglycerate can be decreased, thereby weakening the glycolytic process and the accumulation of biomass, ultimately favoring the diversion of the carbon source towards 1,3-PDO. Building on this, further overexpression of gene PN96_11695 (mdh) can enhance the conversion of L-glutamate to L-aspartate, increasing the production of 1,3-PDO without reducing biomass.

In fact, due to the complexity of the GSMM and the metabolic network, there are multiple different gene strategies that can exhibit the same optimization effect. When selecting a strategy, one should comprehensively consider its biomass, stability (WYIELD), and cost (number of gene edits), which is also the reason why multiple strategies are listed in Table 2. Although the actual system may not conform to the quasi-steady-state assumption of the current simulation and optimization, with various intermediates possibly accumulating within the cells and affecting viability and target production, the existing strategies are valuable references for actual experiments and require subsequent experimental verification to confirm their practical effects.

To further enhance the precision of GSMM simulations and the reliability of the optimization strategy results of the hybrid method, future research may include: (1) further optimization of the GSMM, including more GPR associations and improved data annotation; (2) adding enzyme kinetics and thermodynamic constraints to the optimized GSMM to refine the feasible flux space and increase the accuracy of the GSMM simulations; (3) trying more algorithms, such as combining GA and PSO, to leverage PSO's strengths in locating and exploring local optima and GA's enhanced capability to search the global space; (4) further incorporating knowledge into the optimization process to avoid completely random searches and improve the interpretability of the strategies.

## CONCLUSIONS

In this study, we combined machine learning with traditional metabolic engineering, and developed a hybrid method for metabolic optimization of *Vibrio natriegens*. We utilized the modified GSMM of the *Vibrio natriegens*, integrated with two heuristic algorithms, GA and PSO, to perform metabolic optimization with the endogenous metabolite ethanol and the exogenous metabolite 1,3-PDO as target products, respectively. The optimization process used glycerol as the sole carbon source, with its uptake flux kept constant, and the gene expression level optimization strategies included knockouts, underexpression, and overexpression. The optimization results indicate that the GSMM, optimized with the hybrid method developed in this study, can exhibit production of either ethanol or 1,3-PDO by adjusting the expression levels of only 2-4 genes, with a negative correlation between the production of the target products and biomass. The production of ethanol has not reached the theoretical optimum due to the competitive fermentation products such as acetate, while the production of 1,3-PDO can reach the theoretical maximum due to its direct competition for the carbon source. The strategies obtained in this study can be served as a starting point for metabolic engineering, providing guidance for metabolic engineering targets in practical experiments.

## ABSTRACT

Pharmacokinetic and pharmacodynamic (PK/PD) models are used to predict drug transport in the body and to assess treatment efficacy and optimal dosage. The kinetic parameters embedded in the models, which define transport across body compartments or drug efficacy, can be linked to patient-specific characteristics; understanding the parameter space-model output relationship is critical towards linking patient population heterogeneity to the therapeutic outcome variability. Global Sensitivity Analysis (GSA) is a well-established tool used to examine parameter-to-parameter interactions, shedding light on underlying interactions towards enhanced system understanding. Despite its potential and usefulness, GSA performance is dependent to the model complexity; large-scale and nonlinear PK/PD models, which often have large sets of parameters, can render GSA challenging to perform, requiring excessive computational effort. Proposed approaches to reduce GSA complexity, such as segmentation in parameter subsets or the introduction of surrogate metamodels, become less effective as the number of kinetic parameters grows. In this work, we investigate the potential of Machine Learning (ML) to reduce the complexity of PK/PD models by exploring how the level of hybridisation can impact the GSA performance and, critically, whether the use of surrogates affects the resulting model sensitivity to parametric uncertainty. We show that ML-based surrogates can reliably identify parameter interactions and sensitivities while requiring only a limited number of simulations of the reference mechanistic model. Further, surrogates models effectively reduce the computational expenditure of GSA of multi-dimensional nonlinear PK/PD models. The accelerated execution of GSA enables performing patient cohort-specific analysis, with potential applications for optimal study design and for precision medicine.

## INTRODUCTION

The efficacy of a pharmacological treatment depends on achieving adequate drug concentration at the designated target site within the body. Once administered, drug molecules undergo absorption, distribution, metabolism, and excretion (ADME) processes that collectively determine the drug's fate within the organism. Pharmacokinetics (PK) is the scientific discipline that studies these processes. Experimental PK traditionally involves administering a drug to a biological system, collecting samples (typically blood) at multiple time points, and measuring the drug concentration. This produces a concentration-time profile. If a relationship between concentration and pharmacological effect can be established, PK can be adopted as a surrogate indicator of the expected efficacy or toxicity. This information is essential for guiding dosing regimens, ensuring patient safety, and informing early-stage clinical drug development.

The field of PK has been substantially advanced by the introduction of mathematical modelling and

simulation approaches, collectively known as pharmacometrics. Classic pharmacometric analyses rely on ordinary differential equations to simulate drug concentration profiles in blood [1,2]. Over time, several PK modelling approaches have emerged: Population PK adopts nonlinear mixed-effects modelling to characterize the variability in PK parameters across patients; Physiologically-Based Pharmacokinetic (PBPK) models focus on an anatomically-based and physiology-driven representation of ADME processes to support inter-species extrapolation; PK/PD (pharmacodynamics) models link drug concentrations to biological effects to predict therapeutic and adverse outcomes.

Quantitative Systems Pharmacology (QSP) is a related modelling discipline that builds upon the pharmacometric approach by incorporating systems biology concepts [3]. QSP models can be used to link molecular, cellular, tissue, and organ-level data into multi-scale, mechanistic frameworks. QSP has a broad application space, models typically capture the dynamics of a biological system undergoing disease progression with or without the modulatory intervention of a therapy and considering the inter-individual differences. This integrative approach enables the bridging of empirical data and mechanistic understanding, thereby informing rational drug design, hypothesis testing, and personalized therapeutic strategies.

For mechanistic approaches like PBPK or QSP, model parameterization is critical. During model design, the parameterization strategy has implications on model identifiability and model fit. During model application, alternative parameterization of the same underlying model structure is used to characterize the diversity across patient population or disease status and therefore project the consequential disease progression/treatment variability. Here, sensitivity analysis is adopted to study the role of the various model parameters on the model endpoint. Collectively, identifiability and sensitivity analyses are fundamental tools employed to determine whether unique parameter values can be inferred from available data, to ascertain whether model structures require simplification, and to quantify how parameter values influence model outputs of interest.

Classical sensitivity analysis involves perturbing individual parameters from a reference set and evaluating changes in model outputs. In contrast, global sensitivity analysis (GSA) considers the entire parameter space, recognizing that biological parameters often exist as distributions rather than fixed values. GSA identifies which parameters most strongly influence model outputs across a wide range of plausible parameter values, thereby providing a more comprehensive understanding of parameter importance under uncertainty. Some concrete examples of applications of GSA in QSP include: (i) identification of disease pathways which significantly influence outcome and should therefore be primary focus of research, (ii) support of patient stratification, by selecting those whose characteristics are more strongly associated to an endpoint of interest, (iii) model complexity reduction, by identifying the most relevant model components related to the endpoint of interest and therefore reducing the structure to include only them, or (iv) provide rationale for the creation of reduced-order surrogate models.

Each individual patient has unique characteristics, such as age, and sex, or the presence of adverse conditions. When performing GSA, these individual characteristics are aggregated into a broader parameter space representing an entire cohort, meaning the sensitivity analysis results reflect the response of the whole ensemble rather than specific individuals. This generalization, while necessary for computational tractability, can lead to suboptimal decisions in experimental design for preclinical trials, particularly when certain subpopulations (such as pediatric patients within a mixed-age population, or critically-ill patients in a mixed-health population) have distinct characteristics that significantly influence the PK/PD response and the resultant sensitivity [4], [5]. The developed therapeutic strategy might under- or over-dosage specific cohorts within the population and result in sub-optimal therapeutic outcomes. The ability to perform cohort-specific GSA would enable more targeted sensitivity analyses, allowing for better understanding of parameter importance within specific subpopulations and potentially leading to more effective experimental designs for these groups and improved parametric identifiability.

GSA of a mechanistic PK model for a single set of parametric bounds requires a high number of simulations and computational time; this approach quickly becomes intractable if cohort-specific GSA with multiple sets of parameters is to be explored. One approach to reduce GSA complexity involves parameter grouping, which does not however universally consider the whole parametric domain [6]. Metamodelling-based GSA methods struggle with high-dimensional problems as they become computationally intractable to train and predict [7].

Machine-learning surrogates have been widely used by the Process Systems community to reduce the computational expenditure of complex mechanistic models [8]. After training on a set of input and output samples generated by the mechanistic model, the surrogate can predict model outputs quicker, albeit at a reduced fidelity if the surrogate structure and training points are not chosen carefully; surrogate accuracy is affected by the number of training samples used, surrogate type and surrogate structure, which is generally problem-specific and therefore must be tailored to the mechanistic model available.

This work explores how machine-learning

**Table 1:** Kinetic parameter descriptions with lower and upper bounds for training and GSA

| Name | Description | Training LB | Training UB | GSA LB | GSA UB |
|---|---|---|---|---|---|
| $j_{\text{PT-P}}$ | Mass transfer coefficient from poorly-perfused tissues to plasma compartments | 0.191 | 0.767 | 0.240 | 0.720 |
| $j_{\text{P-PT}}$ | Mass transfer coefficient from plasma to poorly-perfused tissues compartments | 0.191 | 0.767 | 0.240 | 0.720 |

| $\text{Eff}^{\text{Plasma}}$ | Kidney efficiency of elimination | 0.158 | 0.631 | 0.197 | 0.590 |

surrogates can be used to reduce the computational expenditure involved with generating predictions for GSA and enable cohort-specific GSA of PK models. Importantly, the goal of GSA is to probe the PK model and corresponding parameter space for improved understanding and assessment of parameter identifiability, and not to identify influential parameters to formulate a reduced-order model and train a smaller surrogate. GSA is first carried out with a mechanistic PK model to confirm the high computational expenditure involved with the method, and use the identified sensitivity indices as reference for the surrogate-enabled GSA. Feed-forward Neural Networks and Random Forests surrogates are then trained on a much-smaller number of samples and used to generate GSA samples in a fraction of the time required with a fully-mechanistic methodology. The effort to reach GSA convergence and sensitivity index misidentification are assessed.

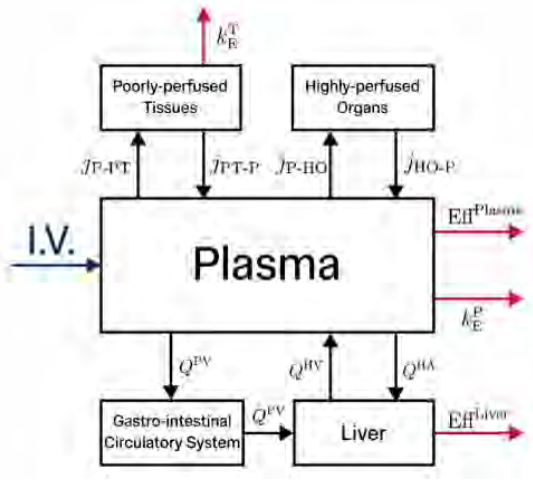

**Figure 1:** Compartmental structure of the mechanistic PK model from Abbiati (2016) [1]

# METHODOLOGY

## Mechanistic PK models

In this work we employ a validated minimal-PBPK model from Abbiati *et al.* (2016) [1], that describes the transport of a small-molecule drug, Remifentanil, through the human body (Figure 1). The model is experimentally validated against measurements from 6 patients and 4 drug dosages, and is therefore suitable to be used as a platform for cohort-specific PK modelling, as well as cohort-specific GSA.

The model assumes the drug is administered intravenously (IV) to the plasma compartment and is distributed via the circulatory system to the liver and the other body organs, here lumped into the Poorly-perfused Tissues (PT) (fat, bones, heart, skin, muscles) and Highly-perfused organs (HP) (brain, kidneys, spleen) compartments. The model considers mass transfer between the plasma and the two compartments (PT and HP), as well as elimination of the drug from the PT, plasma and liver compartments. The model predicts the drug concentration profiles for each of the 5 compartments, using 8 input parameters (Table 1). To reduce the computational expenditure, the scalar Area Under the Curve (AUC) output is considered. The AUC, often used with PK models, is the concentration profile integral over time for each compartment and measures drug exposure in the body [9]. The reader is referred to Abbiati *et al.* (2016) [1] for the complete set of model equations and further model formulation details.

The mechanistic model used in this work comprises 8 ordinary differential equations which were solved in Python with an implicit time-stepping algorithm ($t_{end} = 120$ min, abstol $= 10^{-4}$, relative tol. $= 10^{-2}$). The AUC is calculated with trapezoidal integration of the calculated concentration profiles.

## Surrogate modelling

Here, surrogate models are developed and assessed for their suitability as computationally-efficient substitutes of the mechanistic model. Table 1 summarises the upper and lower bounds used for the training of the models, as well as the GSA later on. To ensure that the surrogate models are not performing extrapolation during GSA, the bounds of the SA are chosen to be tighter than the ones used for the training of the surrogates. Latin Hypercube sampling (LHS) is used to generate 4096 training data points. Input samples are standardized in the $[-1, 1]$ interval before training the surrogate models. The surrogates are trained to predict each output's AUC for a given combination of kinetic parameters.

**Table 2:** Collected hyper-parameters for the neural net and random-forests surrogates

| Surr. | Hyper-parameter | | | |
|---|---|---|---|---|
| RF | *# of estimators* | | *Max depth* | |
| | 100 | | 25 | |
| NN | *# of hidden layers* | *# of neurons* | *Learning rate* | *Training epochs* |
| | 5 | 32 | 0.015 | 450 |

Random Forests (RF) and feed-forward neural nets (NN) single-output surrogates from the `scikit-learn` library are tested in this work. RF hyper-parameters (# of estimators and maximum depth of the ensemble) are optimised by grid-searching possible surrogate structures with 5-fold cross-validation to minimise the test root-mean-squared error (RMSE). NN hyper-parameters (# of hidden layers, # of neurons in each layer, learning rate, training epochs) are similarly optimised using the `Optuna` library and a 'Tree-structured Parzen' algorithm to efficiently search the possible combinations. Although the optimal NN structures differ between each output, they are fixed to a single, common combination before the surrogates are used for GSA. The final hyper-parameters are collected in Table 2.

## Global sensitivity analysis

The GSA method is model-agnostic and proceeds identically regardless of the model type used. Variance-based GSA (Sobol method) is performed using the SALIB library to calculate first-, second- and total-order sensitivity indices [10]. To perform GSA for a given parameter domain, an input matrix with $N(2D + 2)$ parameter combinations is generated by SALIB which follows a quasi-random Sobol sequence ($N$ is a power of 2 and $D$ is the number of input dimensions). Each combination is then simulated to collect predicted AUC values for each output, after which sensitivity indices can be calculated. GSA convergence for each output is assessed by summing all parameter's first- and second- order indices; convergence is indicated by sums which approach 1 and the identified sensitivities remain stable across different sample sizes, as suggested by Sarrazin *et al.* (2016) [11]. First-order Sobol' sensitivity indices quantify the independent effect that a varying parameter $\theta_i$ has on the model output of interest, neglecting cross-parameter interactions. In its' computation, the effect of other parameters is averaged out, such that they can be excluded. Total-order Sobol' sensitivity indices instead group both the independent effect and the cross-parameter interactions of $\theta_i$, calculated by subtracting the effect of all other parameters. The reader is referred to Saltelli (2008) [10] for further details.

# RESULTS AND DISCUSSION

The calculated first-, second- and total-order sensitivity indices for each of the 5 outputs of the mechanistic model are reported in Figure 2 and Table 3. The chosen sensitivity threshold ($S_{\theta,\,\mathrm{Tot.}}$ = 0.05) to segregate parameters into critical and non-critical sets indicates non-critical parameters cause less than 5% variance of the output variable of interest. The same critical set of parameters ($j_{\mathrm{PT\text{-}P}}$, $j_{\mathrm{P\text{-}PT}}$, $k_{\mathrm{E}}^{\mathrm{P}}$) is identified for the first 4 outputs ($C_{\mathrm{Plasma}}$, $C_{\mathrm{PT}}$, $C_{\mathrm{GICS}}$, $C_{\mathrm{Liver}}$) of the model, while a larger set ($j_{\mathrm{PT\text{-}P}}$, $j_{\mathrm{P\text{-}PT}}$, $j_{\mathrm{P\text{-}HO}}$, $j_{\mathrm{HO\text{-}P}}$, $k_{\mathrm{E}}^{\mathrm{P}}$) is identified for $C_{\mathrm{HO}}$. Non-negligible second-order interactions between the critical parameters are also identified, indicating the presence of correlations between parameters which can impede effective parameter estimation and identification of PK models. In the context of PK/PD models parametrised against measurements from human patients, the plasma is the only compartment considered to be easily-measurable as sampling other compartments involves invasive procedures. The sensitivity indices reveal that only 3 out of 8 parameters are identifiable within the parameter domain used for GSA. Three of the non-critical parameters, $j_{\mathrm{P\text{-}HO}}$, $j_{\mathrm{HO\text{-}P}}$ and $\mathrm{Eff}^{\mathrm{Plasma}}$, directly affect the plasma compartment to a lesser extent than the critical parameters and inestimable. The remaining two parameters, $k_{\mathrm{E}}^{\mathrm{T}}$ and $\mathrm{Eff}^{\mathrm{Liver}}$, already classed as non-critical with respect to the $C_{\mathrm{PT}}$ and $C_{\mathrm{Liver}}$ outputs respectively, do not cause significant-enough interactions in the plasma to be estimable by drug concentration measurements in the plasma alone.

Feed-forward neural networks (NNs) and Random Forests (RF) full-order surrogates are trained on 4096 Latin Hypercube samples from the mechanistic model. The surrogates are then used to generate the necessary Sobol-indexed samples for GSA. While other surrogate models (such as Gaussian Process regressors and Radial Basis Function interpolators) were tested, they could not reliably approximate the PK model and were therefore omitted from the presented work.

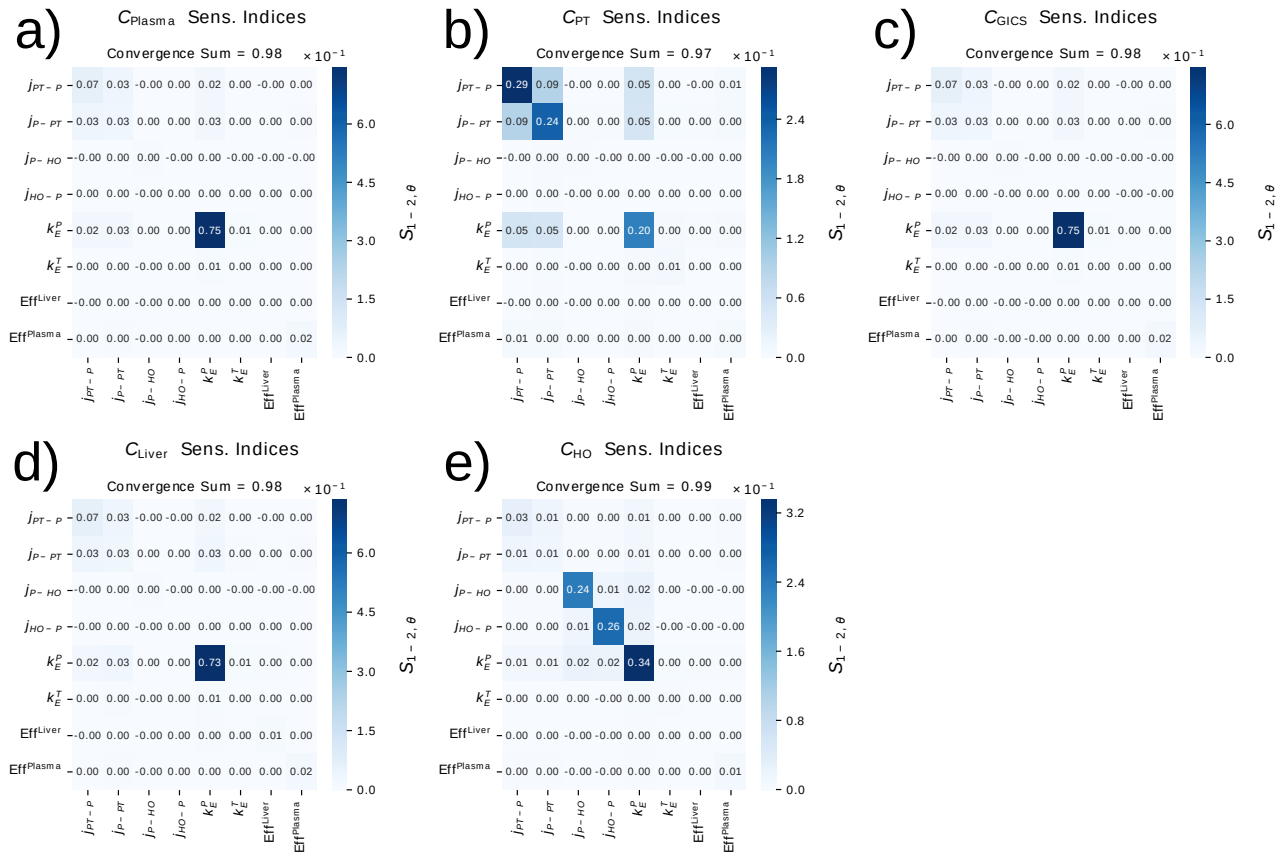

**Figure 2:** 1st, 2nd Order Sensitivity Indices of the mechanistic model for a) $C_{Plasma}$, b) $C_{PT}$, c) $C_{GICS}$, d) $C_{Liver}$, e) $C_{HO}$, calculated with 1179648 simulations

**Table 3:** Total-order sensitivity indices of the mechanistic model calculated with 1179648 simulations

| Parameter | Mechanistic Model Total-Order Sensitivity Indices $S^T_{\theta,\text{Mech.}}$ | | | | |
|---|---|---|---|---|---|
| | $C_{Plasma}$ | $C_{PT}$ | $C_{GICS}$ | $C_{Liver}$ | $C_{HO}$ |
| $j_{PT-P}$ | 0.16 | 0.5 | 0.16 | 0.16 | 0.07 |
| $j_{P-PT}$ | 0.13 | 0.44 | 0.13 | 0.13 | 0.05 |
| $j_{P-HO}$ | 0.02 | 0.01 | 0.02 | 0.02 | 0.29 |
| $j_{HO-P}$ | 0 | 0 | 0 | 0 | 0.30 |
| $k_E^P$ | 0.85 | 0.36 | 0.85 | 0.83 | 0.42 |
| $k_E^T$ | 0.01 | 0.02 | 0.01 | 0.01 | 0 |
| $Eff^{Liver}$ | 0 | 0 | 0 | 0.02 | 0 |
| $Eff^{Plasma}$ | 0.04 | 0.02 | 0.04 | 0.03 | 0.02 |

Importantly, LHS is chosen over a Sobol' sequence for the generation of training data as it led to more accurate surrogates, as Sobol sequences do not capture points at the parametric bounds as effectively. The generation of GSA samples with surrogates introduces minimal computational expenditure compared to the training data generation and GSA decomposition and analysis, making the LHS more effective than a Sobol' sequence for surrogate training. Fewer training samples (1024) were also assessed. The trained surrogates however had low AUC prediction accuracy, which led to different GSA indices compared to the mechanistic model. Each surrogate's AUC prediction error was generally lowest in the middle of the parametric bounds, increasing as the lower or upper bounds were approached.

**Table 4:** GSA convergence sums for an increasing number of samples of the mechanistic model

| Output | 294,912 Simulations | 1,179,648 Simulations |
|---|---|---|
| $C_{Plasma}$ | 0.93 | 0.98 |
| $C_{PT}$ | 0.9 | 0.97 |
| $C_{GICS}$ | 0.93 | 0.98 |
| $C_{Liver}$ | 0.93 | 0.98 |
| $C_{HO}$ | 0.96 | 0.99 |

Convergence sums for increasing numbers of samples are reported in Table 4. The computational difficulty involved in performing GSA of PK models is evident by the results with 295,000 samples; the low sums indicate

that for all outputs except $C_{HO}$ GSA remains un-converged. Over 1 million simulations are needed to observe stable sensitivity indices and achieve GSA convergence of the mechanistic PK model, which in turn leads to high computational expenditure requirements to perform GSA and examine model and parametric sensitivity.

After GSA convergence was confirmed, limited sensitivity indices mispredictions from the two surrogates are identified. The NN-derived simulation results lead to a converged GSA with the same number of samples as the mechanistic PK model. As observed from the negligible deviation in indices reported in Table 5, NN-derived GSA identified the same critical sets of parameters for each output, along with identical sensitivity and identifiability trends of the mechanistic model in a fraction of the time. Sensitivity index errors with respect to each output and parameter are limited to 1-3% at most and can be considered identical to the mechanistic-derived results. RF-derived GSA instead requires an increased number of samples for GSA to fully converge, and on average had greater sensitivity mispredictions than the NN surrogate. While identical critical parameter sets are identified for the first four outputs, only $j_{\text{P-HO}}$,$j_{\text{HO-P}}$ and $k_{\text{E}}^{\text{P}}$ are identified as critical with respect to $C_{HO}$; $S_{j_{\text{PT-P}},\text{T}}$ and $S_{j_{\text{P-PT}},\text{T}}$ are underpredicted to be below the critical threshold. For this reason, RF-enabled GSA leads to different parameter criticality conclusions compared to the mechanistic and NN-enabled GSA.

Assessing the computational expenditure, the mechanistic GSA took 14291 s (14190 s for sample generation) and the NN GSA took 243 s (137 s for net training on CPU) to simulate 1.1 million samples, while the RF GSA took 911 s (13 s for RF training) to simulate 4.7 million samples. Surrogate-enabled GSA leads to a noticeable reduction in runtime. Regardless of the surrogates' training requirement, the mechanistic GSA was slower by at least 1 order of magnitude, highlighting the surrogate's ability to lighten the computational burden involved with GSA while producing GSA results.

**Table 5:** NN-derived total-order sensitivity index deviations from the mechanistic model

| Parameter | Neural Net - $S^T_{\theta,\text{Mech.}} - S^T_{\theta,\text{NN.}}$ | | | | |
|---|---|---|---|---|---|
| | $C_{Plasma}$ | $C_{PT}$ | $C_{GICS}$ | $C_{Liver}$ | $C_{HO}$ |
| $j_{\text{PT-P}}$ | 0.01 | 0.02 | -0.01 | 0.01 | 0 |

## CONCLUSIONS

Global Sensitivity Analysis is a necessary tool for the development and application of PK and QSP models since it informs model structure design and enables parametric analysis. These are crucial to characterize biological variability across the patient population in relation to disease features and response to therapy. However, the large computational requirements of GSA when applied to large-scale and non-linear models limits its adoption and application in the pharma R&D space. In this work, we have shown how GSA computational requirements can be lowered by integrating machine-learning surrogates of the original mechanistic ODE model, trained on a significantly reduced number of mechanistic simulations, into the GSA framework. We tested two surrogate models based on Random Forests and on Feed-forward neural nets. The GSA with Random Forests surrogates identified a slightly-reduced critical set of parameters compared to the GSA conducted with the reference ODE-based model. Feed-forward neural nets were instead able to accurately predict mechanistic model outputs and consequently identify identical sensitivity indices and parameter criticality with minimal error (maximum deviation <3%). We show that surrogates can reliably capture parameter interactions from a limited set of training data derived from the ODE-based PK model and with a fraction of the computational expenditure compared to a fully ODE-based workflow. The ML-enhanced GSA is suitable for PBPK models given their mathematical features (ODE-based, non-linear and multi-parametric). The methodology is expected to be applicable to other modelling approaches, like PK/PD and QSP, that have similar mathematical characteristics. Surrogate-based GSA approach is especially valuable for the pharma R&D modeling community when implementing large differential equation-based model like PBPK or QSP, which typically require thorough identifiability and sensitivity analyses, as well

as intensive computation for generating or simulating virtual patient populations. Future work should explore the rapid generation of individualised GSA profiles to assess optimal cohort-specific measurement strategies for effective parameter estimation of PK/PD and QSP models. Instead of lumping cohorts into a single population, cohort-specific GSA assessments can support clinical trial and PBPK model development. Drug dosage regimens can be more effectively tailored to population subsets, improving the therapeutic outcomes of all patients.

## ABSTRACT

Incorporating process knowledge from various sources often presents challenges in process development, optimization, and control. To utilize available knowledge, linking existing process models is a viable approach. This work introduces a methodology using latent variable models, specifically sequential and orthogonalized partial least squares (SO-PLS), to capture and quantify the contribution of first-principles knowledge in process models. Applied to a continuously stirred tank reactor (CSTR) case study, the methodology demonstrates how available knowledge can be quantified and how structural and parametric errors in first-principles are addressed using measured data. The methodology is discussed in relation to root cause analysis in bioprocesses.

**Keywords**: Process models, Root cause analysis, Latent variable models, Multiblock partial least squares

## INTRODUCTION

Process development, optimization, and control based on process modeling are significantly advancing pharmaceutical manufacturing. These efforts are reducing development times and manufacturing costs, improving productivity and quality control, and enhancing overall process understanding [1]. Using terminology from knowledge management, process models can be seen as representations of accumulated expert knowledge generated over the years. These models enable the simulation of system behavior under various perturbations [2]. In the pharmaceutical industry, process models are typically developed for individual unit operations to capture specific product and technology phenomena. Recently, *integrated process models* have emerged, representing processes with multiple steps or unit operations. These models transform the output of one unit into the input of the next, simulating material flow across operations and capturing interactions between upstream and downstream equipment. Applications include control strategy design, risk analysis, experimental design, and process optimization [3-5], and they range from being first-principles-based [5] to fully data-driven [4].

In first-principles modeling, we rely on a physical understanding of the system, where the model's equations represent the known mechanisms driving the process. Parameters are typically tuned using data from well-designed laboratory experiments, allowing for some extrapolation beyond the calibration range. However, when comparing first-principles models to historical data from a full-scale commercial plant, outputs may not match accurately. This discrepancy can be due to limited knowledge of the process, oversimplification of physical phenomena, or inappropriate parameter values [6].

Due to their simplicity, ease of development, and increasing computational efficiency, data-driven models are an attractive alternative. These models involve selecting a structure and identifying parameters using available data [6], which can be readily sourced from full-scale plants. However, since many observations remain constant during plant operation and rarely change, extrapolation can be challenging for data-driven models.

Therefore, it is of interest to develop schemes that combine both modeling techniques to create more effective and efficient process models. For integrated process models specifically, this involves incorporating connectivity information from the process flowsheet along with first-principles knowledge from each unit operation.

Incorporating connectivity information into process models often relies on data from full-scale commercial manufacturing, where consecutive runs of an integrated

process are logged. Given the vast amount of data and the presence of complex, unknown physical phenomena in a full-scale plant, a data-driven foundation is often chosen for integrated process models. Among various methods, sequential-orthogonalized partial least squares (SO-PLS) has recently emerged as a promising approach [7-9]. SO-PLS sequentially applies regular PLS to different data blocks, each representing a specific unit operation, and uses orthogonalization between steps to eliminate overlapping information. By ordering the blocks with respect to the flowsheet topology and removing redundant information explained by upstream units through orthogonalization, this model naturally incorporates connectivity information. Additionally, being based on PLS, it effectively handles the high-dimensional data matrices common in full-scale plants.

Inspired by the use of SO-PLS to incorporate flowsheet connectivity information, this paper presents a systematic methodology to further augment the model with first-principles knowledge, utilizing elements from hybrid modeling and path modeling [10]. While the concept is initially demonstrated for a single unit operation, it can be readily extended to encompass a multi-unit process. The key questions we aim to address are:

- *How can we incorporate flowsheet connectivity information and unit-specific first-principles knowledge into a unified model?*
- *How can we quantify the variance explained by first-principles knowledge versus measured data?*
- *How can the approach be used to identify root causes of deviations from quality or productivity targets in an integrated bioprocess?*

This paper addresses the first two questions, while the last question will be explored in future work in combination with the framework presented in [9]. The paper is organized as follows: First, we provide background on SO-PLS and explain how this model fits within parallel hybrid architectures. Next, we describe the methodology for incorporating first-principles knowledge into the SO-PLS model. This concept is demonstrated using a toy example based on the van de Vusse reaction scheme [11]. Finally, we discuss this work in the context of integrated process modeling and present future work and challenges.

## MODELING BACKGROUND

This work is based on partial least squares (PLS), also known as projection to latent structures. Consider an input data matrix $\boldsymbol{X} \in \mathbb{R}^{N\times J}$ and an output data matrix $\boldsymbol{Y} \in \mathbb{R}^{N\times K}$. The core principle of PLS is to build a model by relating the latent variables (LVs) associated with $\boldsymbol{X}$ and $\boldsymbol{Y}$. PLS achieves this by linearly transforming both $\boldsymbol{X}$ and $\boldsymbol{Y}$ into their respective LVs and then relating these transformed variables by maximizing their covariance. For more details, see [12]. In process modeling, PLS is particularly useful for batch processes, with specialized algorithms for handling batches of varying lengths. While process knowledge is often incorporated into PLS models through additional calculated variables, the direct integration of first-principles models with PLS has been explored to a limited extent [13].

When combining first-principles and data-driven models, often referred to as hybrid or grey-box models, two main architectures are commonly discussed. The first is the series approach, where a first-principles model is developed initially, followed by a data-driven model, such as neural networks, to determine the parameters. The second is the parallel approach, where a data-driven model is used to capture the error (residuals) between the actual process outputs and the estimated outputs from the first-principles model. In this approach, a neural network can serve as the data-driven model, but any data-driven model can be used [14].

As will be shown, the presented methodology bears resemblance to the parallel hybrid architecture. For reference, this architecture is illustrated in Fig. 1.

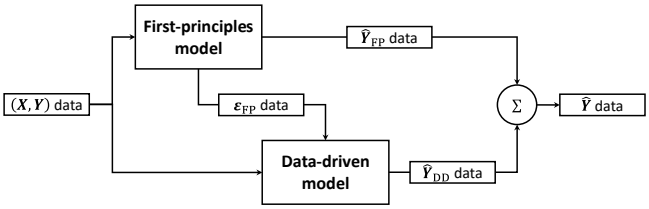

**Figure 1.** The parallel hybrid architecture. $\boldsymbol{\varepsilon}$ refers to the residuals of the estimates made by the first-principles model. $\hat{\boldsymbol{Y}}$ refers to the estimates made by a model.

### Sequential-orthogonalized PLS

To illustrate the SO-PLS method, we will focus on the case with two (autoscaled) input blocks, named $\boldsymbol{X} \in \mathbb{R}^{N\times J}$ and $\boldsymbol{Z} \in \mathbb{R}^{N\times L}$, and an (autoscaled) output block, or response matrix, referred to as $\boldsymbol{Y} \in \mathbb{R}^{N\times K}$. The multiblock linear regression model estimated by SO-PLS can be represented by the following equation

$$\boldsymbol{Y} = \boldsymbol{XB} + \boldsymbol{ZC} + \boldsymbol{F}, \tag{1}$$

where $\boldsymbol{B} \in \mathbb{R}^{J\times K}$ and $\boldsymbol{C} \in \mathbb{R}^{L\times K}$ are the regression coefficients, and $\boldsymbol{F} \in \mathbb{R}^{N\times K}$ is the residual matrix. As explained later in the methodology section, $\boldsymbol{X}$ will serve as the *mechanistic block*, containing output data generated by the first-principles model. In contrast, $\boldsymbol{Z}$ will be the *measured block*, containing various process variables, including some measured process outputs.

The SO-PLS algorithm is given in Tbl. 1 and relies solely on regular PLS [9]. Recall that regular PLS for input block $\boldsymbol{X}$ and output block $\boldsymbol{Y}$ produces a set of $\boldsymbol{X}$-scores ($\boldsymbol{T}$) summarizing the relationships between samples, a set of $\boldsymbol{X}$-loadings ($\boldsymbol{P}$) summarizing the relationships between

variables, and an optimal weight matrix ($\boldsymbol{R}$), transforming $\boldsymbol{X}$ into $\boldsymbol{T}$ through $\boldsymbol{XR} = \boldsymbol{T}$. The five steps of the algorithm are briefly described as follows: *(i)* First, a regular PLS regression is performed between the response matrix $\boldsymbol{Y}$ and mechanistic block $\boldsymbol{X}$, resulting in $\boldsymbol{X}$-scores $\boldsymbol{T}^{(1)}$ and $\boldsymbol{X}$-loadings $\boldsymbol{P}^{(1)}$.*(ii)* The measured block $\boldsymbol{Z}$ is orthogonalized with respect to $\boldsymbol{T}^{(1)}$ using the projection matrix

$$\boldsymbol{H} = \boldsymbol{T}^{(1)} \left( \left(\boldsymbol{T}^{(1)}\right)^{\intercal} \boldsymbol{T}^{(1)} \right)^{-1} \left(\boldsymbol{T}^{(1)}\right)^{\intercal}, \tag{2}$$

which is also commonly referred to as the *hat matrix* in statistics. The orthogonalization involves removing the shared information between $\boldsymbol{X}$ and $\boldsymbol{Z}$ embedded in the projection, resulting in $\boldsymbol{Z}^{\mathrm{ort}} = (\boldsymbol{I} - \boldsymbol{H})\boldsymbol{Z}$. *(iii)* Next, a similar orthogonalization is performed on the response matrix, yielding the residuals $\boldsymbol{Y}^{\mathrm{ort}} = (\boldsymbol{I} - \boldsymbol{H})\boldsymbol{Y}$. *(iv)* After orthogonalization, another regular PLS regression is performed between $\boldsymbol{Y}^{\mathrm{ort}}$ and $\boldsymbol{Z}^{\mathrm{ort}}$, resulting in $\boldsymbol{Z}^{\mathrm{ort}}$-scores $\boldsymbol{T}^{(2)}$ and $\boldsymbol{Z}^{\mathrm{ort}}$-loadings $\boldsymbol{P}^{(2)}$. *(v)* Finally, $\boldsymbol{T}^{(1)}$ and $\boldsymbol{T}^{(2)}$ are used as independent variables in a least squares regression with $\boldsymbol{Y}$. The estimate $\widehat{\boldsymbol{Y}}$ (with coefficients $\boldsymbol{Q}^{(1)}, \boldsymbol{Q}^{(2)}$) is given by

$$\widehat{\boldsymbol{Y}} = \boldsymbol{T}^{(1)}\boldsymbol{Q}^{(1)} + \boldsymbol{T}^{(2)}\boldsymbol{Q}^{(2)}. \tag{3}$$

**Table 1:** Pseudo-code for (two-block) SO-PLS model

| | | |
|---|---|---|
| **Mechanistic block** | | |
| *(i)* | $\mathrm{PLS}(\boldsymbol{X}, \boldsymbol{Y}) \implies \boldsymbol{T}^{(1)}, \boldsymbol{P}^{(1)}$ | PLS regression for $\boldsymbol{X}$ and $\boldsymbol{Y}$ |
| *(ii)* | $\boldsymbol{Z}^{\mathrm{ort}} = (\boldsymbol{I} - \boldsymbol{H})\boldsymbol{Z}$ | Orthogonalization of $\boldsymbol{Z}$ on $\boldsymbol{T}^{(1)}$ |
| *(iii)* | $\boldsymbol{Y}^{\mathrm{ort}} = (\boldsymbol{I} - \boldsymbol{H})\boldsymbol{Y}$ | Orthogonalization of $\boldsymbol{Y}$ on $\boldsymbol{T}^{(1)}$ |
| **Measured block** | | |
| *(iv)* | $\mathrm{PLS}(\boldsymbol{Z}^{\mathrm{ort}}, \boldsymbol{Y}^{\mathrm{ort}}) \implies \boldsymbol{T}^{(2)}, \boldsymbol{P}^{(2)}$ | PLS regression for $\boldsymbol{Z}^{\mathrm{ort}}$ and $\boldsymbol{Y}^{\mathrm{ort}}$ |
| *(v)* | $\boldsymbol{Y} = \boldsymbol{T}^{(1)}\boldsymbol{Q}^{(1)} + \boldsymbol{T}^{(2)}\boldsymbol{Q}^{(2)} + \boldsymbol{F}$ | Least squares for $\boldsymbol{T}^{(1)}, \boldsymbol{T}^{(2)}$ and $\boldsymbol{Y}$ |

**Remark 1:** Letting $\boldsymbol{R}^{(1)}$ and $\boldsymbol{R}^{(2)}$ be the weight matrices used to obtain the scores $\boldsymbol{T}^{(1)}$ and $\boldsymbol{T}^{(2)}$ from $\boldsymbol{X}$ and $\boldsymbol{Z}^{\mathrm{ort}}$, the link between Eq. (1) and (3) follows from

$$\begin{aligned} \widehat{\boldsymbol{Y}} &= \boldsymbol{X}\boldsymbol{R}^{(1)}\boldsymbol{Q}^{(1)} + \boldsymbol{Z}^{\mathrm{ort}}\boldsymbol{R}^{(2)}\boldsymbol{Q}^{(2)} \\ &= \boldsymbol{X}\boldsymbol{R}^{(1)}\boldsymbol{Q}^{(1)} + (\boldsymbol{I} - \boldsymbol{H})\boldsymbol{Z}\boldsymbol{R}^{(2)}\boldsymbol{Q}^{(2)} \\ &= \boldsymbol{X}\boldsymbol{R}^{(1)}\boldsymbol{Q}^{(*)} + \boldsymbol{Z}\boldsymbol{R}^{(2)}\boldsymbol{Q}^{(2)}, \end{aligned} \tag{4}$$

with $\boldsymbol{Q}^{(*)} := \boldsymbol{Q}^{(1)} - \left( \left(\boldsymbol{T}^{(1)}\right)^{\intercal} \boldsymbol{T}^{(1)} \right)^{-1} \left(\boldsymbol{T}^{(1)}\right)^{\intercal} \boldsymbol{Z}\boldsymbol{R}^{(2)}\boldsymbol{Q}^{(2)}$. The selection of $\boldsymbol{B}$ and $\boldsymbol{C}$ follows implicitly.

**Remark 2:** It is worth noting the strong resemblance between SO-PLS and the Frisch–Waugh–Lovell theorem from ordinary least squares. Note also that due to the symmetric and idempotent nature of $\boldsymbol{I} - \boldsymbol{H}$, the model would not change if $\boldsymbol{Y}$ is not orthogonalized. Furthermore, the regression coefficients $\boldsymbol{Q}^{(1)}$ and $\boldsymbol{Q}^{(2)}$ found in step *(v)* coincide with the (transposed) $\boldsymbol{Y}$-loadings that can be extracted from the PLS steps in *(i)* and *(iv)*.

**Remark 3:** Because the orthogonalization step removes redundant information (information in $\boldsymbol{Z}$ already explained by $\boldsymbol{X}$), the additional explained variance gained by adding the new block $\boldsymbol{Z}$ represents information not included in previous blocks. This makes the method useful in path modeling; a discipline of analyzing direct and indirect effects of different sets of variables on an output [9].

To briefly explain how this works for SO-PLS, we can use the notation in (1) to write

$$\widehat{\boldsymbol{Y}} = \boldsymbol{X}\boldsymbol{B} + \boldsymbol{H}\boldsymbol{Z}\boldsymbol{C} + (\boldsymbol{I} - \boldsymbol{H})\boldsymbol{Z}\boldsymbol{C} = \boldsymbol{X}\widetilde{\boldsymbol{B}} + \boldsymbol{Z}^{\mathrm{ort}}\boldsymbol{C}, \tag{5}$$

with $\widetilde{\boldsymbol{B}} := \boldsymbol{B} + \boldsymbol{R}^{(1)}\boldsymbol{Q}^{(1)} \left( \left(\boldsymbol{T}^{(1)}\right)^{\intercal} \boldsymbol{T}^{(1)} \right)^{-1} \left(\boldsymbol{T}^{(1)}\right)^{\intercal}$. Note that by reordering the blocks and orthogonalizing on $\boldsymbol{Z}^{\mathrm{ort}}$ instead, a similar expression, $\widehat{\boldsymbol{Y}} = \boldsymbol{X}^{\mathrm{ort}}\boldsymbol{B} + \boldsymbol{Z}\widetilde{\boldsymbol{C}}$, can be obtained. Recall that the sum of squares of $\widehat{\boldsymbol{Y}}$ can be calculated as $\mathrm{tr}\left(\widehat{\boldsymbol{Y}}^{\intercal}\widehat{\boldsymbol{Y}}\right)$. Due to the orthogonality between blocks, we obtain the decomposition

$$\mathrm{tr}\left(\widehat{\boldsymbol{Y}}^{\intercal}\widehat{\boldsymbol{Y}}\right) = \mathrm{tr}\left(\widetilde{\boldsymbol{B}}^{\intercal}\boldsymbol{X}^{\intercal}\boldsymbol{X}\widetilde{\boldsymbol{B}}\right) + \mathrm{tr}(\boldsymbol{C}^{\intercal}(\boldsymbol{Z}^{\mathrm{ort}})^{\intercal}\boldsymbol{Z}^{\mathrm{ort}}\boldsymbol{C}). \tag{6}$$

Eq. (6) is referred to as the *overall effect*. The first term, $\mathrm{tr}\left(\widetilde{\boldsymbol{B}}^{\intercal}\boldsymbol{X}^{\intercal}\boldsymbol{X}\widetilde{\boldsymbol{B}}\right)$, is known as the *total effect* of $\boldsymbol{X}$, and the second term, $\mathrm{tr}(\boldsymbol{C}^{\intercal}(\boldsymbol{Z}^{\mathrm{ort}})^{\intercal}\boldsymbol{Z}^{\mathrm{ort}}\boldsymbol{C})$, is known as the *additional* effect of $\boldsymbol{Z}$. The total effect can be further decomposed into a *direct effect*, which represents the influence of $\boldsymbol{X}$ that is uncorrelated with $\boldsymbol{Z}$, i.e., $\mathrm{tr}(\boldsymbol{B}^{\intercal}(\boldsymbol{X}^{\mathrm{ort}})^{\intercal}\boldsymbol{X}^{\mathrm{ort}}\boldsymbol{B})$, and an *indirect effect,* which is the difference between the total and the direct effect. This variance decomposition will be useful for measuring how much of the variance is explained by the first-principles model ($\boldsymbol{X}$) and how much is corrected by the data ($\boldsymbol{Z}$). Due to the assumption of unit variance in data, the effects can be interpreted as relative explained variances.

## PROPOSED METHODOLOGY

This section introduces a systematic methodology for incorporating first-principles process knowledge into the SO-PLS model, as depicted in Fig. 2. The framework utilizes first-principles models that describe the unit operations under study, typically consisting of nonlinear ordinary or partial differential and algebraic equations (PDAEs), which are validated through (small-scale) experiments. Furthermore, measurements from multiple (large-scale) historical batches are employed.

***Step 1: Data augmentation by first-principles:*** In this step, the goal is to construct two data blocks using measurement data from the observed system and additional data generated from the first-principles model, initialized with the initial conditions ($\boldsymbol{X}_0$) from the process. Following the structure in [13], the measurement data include manipulated inputs ($\boldsymbol{U}$) and observed system output states ($\boldsymbol{X}_{\mathrm{UO}}$) (e.g., reaction temperatures). The sampled quality variables ($\boldsymbol{Y}$) (e.g., component concentrations) constitute the model output. Note that we only assume access to steady-state data, not full trajectories. However, the method can be extended to trajectory data using techniques like unfolding [13]. The synthetic output

states generated from the first-principles model are denoted $\boldsymbol{X}_{\mathrm{FP}}$. The model may include expressions for states not measured in the full-scale system, thereby augmenting the data matrix with additional information. The initial conditions of the unmeasured states are assumed to be known. Ultimately, we obtain the following data blocks:

- *Mechanistic block:* $\boldsymbol{X} = [\boldsymbol{X}_0, \boldsymbol{U}, \boldsymbol{X}_{\mathrm{FP}}]$.
- *Measured block:* $\boldsymbol{Z} = \boldsymbol{X}_{\mathrm{UO}}$.
- *Output block:* $\boldsymbol{Y}$.

***Step 2: Model fitting by SO-PLS:*** In the next step, an SO-PLS model is fitted, with the number of components for each block selected based on the minimal root mean squared error obtained through K-fold cross-validation (RMSECV). The SO-PLS architecture, shown in Fig. 2, resembles that of Fig. 1.

***Step 3: Variance decomposition by SO-PLS:*** Once the model is fitted, the overall variance in $\widehat{\boldsymbol{Y}}$ is decomposed into total (direct + indirect) and additional effects:

- *Total:* Variance explained by mechanistic block.
- *Direct:* Variance explained by part of mechanistic block uncorrelated with measured block.
- *Indirect:* Variance explained by part of mechanistic block correlated with measured block.
- *Additional:* Variance explained by measured block.

It is worth noting that with this methodology, the first-principles model does not necessarily need to be recalibrated to process data, as the data is projected into a latent space. Consequently, there can be biases between the true and synthetic states. The key point to consider is that the synthetic states, although biased, exhibit correlation structures comparable to the real system. This aspect of the methodology presents an opportunity to incorporate small-scale knowledge with full-scale data.

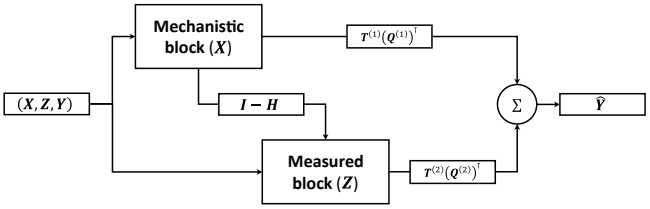

**Figure 2.** SO-PLS architecture. $\boldsymbol{I} - \boldsymbol{H}$ is the *residual-maker matrix*, like in parallel hybrid architectures.

## TOY EXAMPLE

The proposed methodology is tested on a simulated case study involving a temperature-controlled, constant-volume continuous stirred tank reactor (CSTR) [10]. The reaction network consists in conversion of component $A$ into component $B$ and then into component $C$. A side reaction also produces component $D$ which, along with component $C$, is an undesired by-product.

$$A \overset{k_1}{\rightarrow} B \overset{k_2}{\rightarrow} C,$$

$$2A \overset{k_3}{\rightarrow} D.$$

Let $\mathcal{C}$ and $\mathcal{R}$ denote the set of components and reactions respectively. Then $\mathcal{C} = \{A, B, C, D\}$ and $\mathcal{R} = \{1,2,3\}$. Further, let $\boldsymbol{r} \in \mathbb{R}^{|\mathcal{R}|}$ be a vector of rates of reactions. Then

$$r_1 = r_1(C_A, T) = k_1(T)C_A,$$
$$r_2 = r_2(C_B, T) = k_2(T)C_B,$$
$$r_3 = r_3(C_A, T) = k_3(T)C_A^2,$$

where $C_A, C_B$ (and $C_C, C_D$) are component concentrations and $T$ is the temperature. All variables are implicitly time dependent. The specific reaction rates are defined by the Arrhenius expression

$$k_i(T) = k_{i0} \exp\left(-\frac{E_i}{RT}\right), \quad i = 1,2,3.$$

We define the production rate vector $\boldsymbol{R} \in \mathbb{R}^{|\mathcal{C}|}$ using the stoichiometry of the reaction network

$$R_A = R_A(C_A, T) = -r_1(C_A, T) - 2r_3(C_A, T),$$
$$R_B = R_B(C_A, C_B, T) = r_1(C_A, T) - r_2(C_B, T),$$
$$R_C = R_C(C_B, T) = r_2(C_B, T),$$
$$R_D = R_D(C_A, T) = r_3(C_A, T).$$

By using the stoichiometric matrix $\boldsymbol{S} \in \mathbb{R}^{|\mathcal{R}| \times |\mathcal{C}|}$, this can be written compactly as $\boldsymbol{R} = \boldsymbol{S}^{\intercal}\boldsymbol{r}$, with

$$\boldsymbol{S} = \begin{bmatrix} -1 & 1 & 0 & 0 \\ 0 & -1 & 1 & 0 \\ -2 & 0 & 0 & 1 \end{bmatrix}.$$

The reactor can be modelled by six mass and energy balances, yielding the ordinary differential equation system

$$\begin{aligned}
\frac{\mathrm{d}C_A}{\mathrm{d}t} &= \frac{F}{V}\left(C_{A,\mathrm{in}} - C_A\right) + R_A, \\
\frac{\mathrm{d}C_B}{\mathrm{d}t} &= -\frac{F}{V}C_B + R_B, \\
\frac{\mathrm{D}C_C}{\mathrm{d}t} &= -\frac{F}{V}C_C + R_C, \\
\frac{\mathrm{D}C_D}{\mathrm{d}t} &= -\frac{F}{V}C_D + R_D, \\
\frac{\mathrm{d}T}{\mathrm{d}t} &= \frac{F}{V}(T_{\mathrm{in}} - T) + \frac{UA}{\mu V c_p}(T_c - T) \\
&\quad - \frac{1}{\mu c_p}\frac{F}{V}(r_1\Delta H_1 + r_2\Delta H_2 + r_3\Delta H_3), \\
\frac{\mathrm{d}T_c}{\mathrm{d}t} &= \frac{1}{m_c c_{pc}}\left(Q_c + UA(T - T_c)\right),
\end{aligned} \tag{7}$$

where $T_c$ is the temperature inside the cooling jacket. The parameters and measured variables of the system are presented in Tbl. 2. To introduce input uncertainty, the input variables are treated as random

variables.

**Table 2:** Values of the parameters and measured variables used to generate the dataset

| Parameter | Description | Value |
|---|---|---|
| $V$ | Volume | 10 L |
| $A$ | Heat transfer area | 0.215 $m^2$ |
| $U$ | Heat transfer coef. | 4032 kJ/(h $m^2$ K) |
| $c_p$ | Heat capacity (mix.) | 3.01 kJ/(kg K) |
| $c_{pc}$ | Heat capacity (cool.) | 2 kJ/(kg K) |
| $\mu$ | Density of mix. | 0.9342 kg/L |
| $m_c$ | Mass of cool. fluid | 5 kg |
| $\Delta H_1$ | Heat of reaction 1 | 4.2 kJ/mol |
| $\Delta H_2$ | Heat of reaction 2 | −11 kJ/mol |
| $\Delta H_3$ | Heat of reaction 3 | −41.85 kJ/mol |
| $k_{10}$ | Reaction rate const. 1 | $1.287 \cdot 10^{12}$ $h^{-1}$ |
| $k_{20}$ | Reaction rate const. 2 | $1.287 \cdot 10^{12}$ $h^{-1}$ |
| $k_{30}$ | Reaction rate const. 3 | $9.043 \cdot 10^{9}$ L/(h mol) |
| $E_1/R$ | Activation energy 1 | 9758.3 K |
| $E_2/R$ | Activation energy 2 | 9758.3 K |
| $E_3/R$ | Activation energy 3 | 8560 K |
| **Variable** | **Description** | **Distribution** |
| $C_{A,\mathrm{in}}$ | Inflow concentration A | $\mathcal{N}(5.1\ \mathrm{mol/L}, 1^2)$ |
| $T_{\mathrm{in}}$ | Inflow temperature | $\mathcal{N}(378.05\ \mathrm{K}, 5^2)$ |
| $F$ | Flowrate | $\mathcal{N}(141.9\ \mathrm{L/h}, 5^2)$ |
| $Q_c$ | Heat transfer rate | $\mathcal{N}(-1113.5\ \mathrm{kJ/h}, 50^2)$ |
| **Error** | **Description** | **Value** |
| $\boldsymbol{\Sigma}$ | Diffusion term | diag[0.01,0.01,0.01,0.01,0.1,0.1] |
| $\boldsymbol{E}$ | Measurement noise | diag[0.02,0.02,0.02,0.02,0.5,0.5] |

To introduce additional variability across different simulations, the deterministic system in Eq. (7) is augmented by a stochastic term. (7) can be represented as

$$\frac{\mathrm{d}\boldsymbol{x}(t)}{\mathrm{d}t} = f\big(\boldsymbol{x}(t)\big),$$

where $\boldsymbol{x} = [C_A, C_B, C_C, C_D, T, T_c]^\intercal$. We can then write the corresponding system of stochastic differential equations as

$$\mathrm{d}\boldsymbol{x}(t) = f\big(\boldsymbol{x}(t)\big)\mathrm{d}t + \mathrm{d}\boldsymbol{\Sigma}\boldsymbol{W}(t), \tag{8}$$

where $\boldsymbol{W}(t) \sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{I}\mathrm{d}t)$ is a multivariate Wiener process, while the diffusion term $\boldsymbol{\Sigma}$ is given in Tbl. 2.

The stochastic system in (8) is simulated using the Euler-Maruyama method with a step size of $0.001$ h and initial conditions $\boldsymbol{x}_0 = \big[C_{A,\mathrm{in}}, 0, 0, 0, T_{\mathrm{in}}, 375\big]^\intercal$. A total of $50$ simulations are performed. To create the dataset from these simulations, the system is run until it reaches steady state. The final values of $\boldsymbol{x}(t_s)$ at steady state $t_s$ are then recorded as data points. Additionally, measurement uncertainty is added by assuming that $\boldsymbol{x}(t_s)$ is observed with a noise component, $\boldsymbol{x}(t_s) + \boldsymbol{\varepsilon}$, where $\boldsymbol{\varepsilon} \sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{E})$ with $\boldsymbol{E}$ defined in Tbl. 2. As a result, the final dataset generated from Eq. (8) is an $\mathbb{R}^{50\times 7}$ matrix. The columns correspond to the measured variables and states ($C_{A,\mathrm{in}}$, $T_{\mathrm{in}}$, $F$, $Q_c$, $C_A$, $C_B$, $C_C$, $C_D$, $T$).

## Application of methodology

To illustrate the SO-PLS method, two case studies are considered: ***Case (i)*** with a structural error due to a missing reaction in the first-principles model, and ***Case (ii)*** with a severe parametric error. The goal is to assess how well the measured data corrects these errors.

***Case (i):*** In *Step 1*, we assume access to a calibrated first-principles process model for the CSTR system. However, unlike the real system, we assume no knowledge of the third reaction, $2A \rightarrow D$. I.e., the model is similar to Eq. (7) with $r_3 = 0$. We collect the synthetic system states and process inputs in the mechanistic block $\boldsymbol{X} = \big[\boldsymbol{X}_0, \boldsymbol{U}, \widetilde{\boldsymbol{C}}_A, \widetilde{\boldsymbol{C}}_B, \widetilde{\boldsymbol{C}}_C, \widetilde{\boldsymbol{T}}, \widetilde{\boldsymbol{T}}_c\big] \in \mathbb{R}^{50\times 7}$, where $\big[\widetilde{\boldsymbol{C}}_A, \widetilde{\boldsymbol{C}}_B, \widetilde{\boldsymbol{C}}_C, \widetilde{\boldsymbol{T}}, \widetilde{\boldsymbol{T}}_c\big] \in \mathbb{R}^{50\times 5}$ are generated from the mis-specified first-principles model over 50 batches. For the output block, we assume access only to samples of components $A$ and $B$, so $\boldsymbol{Y} = [\boldsymbol{C}_A, \boldsymbol{C}_B] \in \mathbb{R}^{50\times 2}$. The measured block contains observed system states, $\boldsymbol{Z} = [\boldsymbol{T}, \boldsymbol{T}_c] \in \mathbb{R}^{50\times 2}$.

In *Step 2*, the SO-PLS model is fitted, and the number of latent variables is chosen using $10$-fold cross-validation, giving an optimal choice of $\{6,1\}$ latent variables for the $\boldsymbol{X}$ and $\boldsymbol{Z}$ blocks, respectively. The performance is compared to the first-principles model and the Hybrid PLS model proposed by [13] (where PLS is applied to the augmented matrix $[\boldsymbol{X}, \boldsymbol{Z}]$), shown in the first two rows of Tbl. 3. The Hybrid PLS model is cross-validated, yielding a model of $7$ latent variables. The first-principles model shows low performance ($R^2 = 37.3\%$). The Hybrid PLS fit shows significant information contained in $\boldsymbol{X}$ and $\boldsymbol{Z}$ when projecting the columns into a latent space ($R^2 = 97.2\%$). The SO-PLS model performs similarly ($R^2 = 97.1\%$) and exhibits slightly higher $Q^2$ than Hybrid PLS, indicating less overfitting. This is likely due to the sequential selection of latent variables [7]. Additionally, SO-PLS offers an extra layer of interpretation by measuring the incremental contribution of the $\boldsymbol{Z}$ block.

**Table 3.** Calibration and validation metrics averaged over output states ($\boldsymbol{Y} = [\boldsymbol{C}_A, \boldsymbol{C}_B]$). The parameters of the FP model are assumed to be validated upon receival of the model, hence no new validation is performed.

| | Calibration | | | Validation | | |
|---|---|---|---|---|---|---|
| | FP | Hyb-PLS | SO-PLS | FP | Hyb-PLS | SO-PLS |
| $R^2$, $Q^2$ *(i)* | 37.3% | 97.2% | 97.1% | - | 94.5% | 96.0% |
| RMSE *(i)* | 0.74 | 0.15 | 0.16 | - | 0.23 | 0.21 |
| $R^2$, $Q^2$ *(ii)* | 60.5% | 94.3% | 94.4% | - | 86.3% | 88.9% |
| RMSE *(ii)* | 0.57 | 0.27 | 0.27 | - | 0.37 | 0.35 |

In *Step 3*, the overall variance of $\hat{\boldsymbol{Y}}$ model is decomposed according to $\boldsymbol{X}$ and $\boldsymbol{Z}$. While similar precision could be achieved by concatenating $\boldsymbol{X}$ and $\boldsymbol{Z}$ into one block and fitting them against $\boldsymbol{Y}$ in a regular PLS model, the SO-PLS model allows for block-wise interpretations. As shown in Tbl. 4, the measured data improve the overall fit by $3\%$. The variance directly influenced by the mechanistic block is $44.9\%$, while $48.1\%$ is indirectly influenced through the measured block, mainly due to the shared states $\boldsymbol{T}$ and $\boldsymbol{T}_c$. An additional feature of the SO-PLS model is the residual output block $\boldsymbol{Y}^{\mathrm{ort}}$, which encodes the information

not explained by $\boldsymbol{X}$. Fig. 3(a) shows that the model fails to capture some quadratic behavior, aligning with the structural error introduced in the first-principles model.

**Table 4.** Decomposition of overall explained variance ($Q^2$) with standard errors (based on bootstrapping).

| | Direct | Indirect | Additional | Overall |
|---|---|---|---|---|
| Case *(i)* | 44.9% (0.6%) | 48.1% (0.4%) | 3.0% (0.6%) | 96.0% (0.5%) |
| Case *(ii)* | 44.4% (1.5%) | 37.8% (1.7%) | 6.6% (2.2%) | 88.9% (1.4%) |

***Case (ii):*** In *Step 1*, we use a calibrated first-principles process model structurally equivalent to (7), but with parameters $k_{i0}, E_i/R$, $i = 1,2,3$, perturbed randomly by up to 50%. The construction of $\boldsymbol{X}$, $\boldsymbol{Z}$, and $\boldsymbol{Y}$ remains the same, with the addition of state $\widetilde{\boldsymbol{C}}_D$ to $\boldsymbol{X}$.

In *Step 2*, optimal $\{6,1\}$ latent variables are chosen for $\boldsymbol{X}$ and $\boldsymbol{Z}$, respectively. Performance is compared to the first-principles model and a Hybrid PLS model fitted to $([\boldsymbol{X}, \boldsymbol{Z}], \boldsymbol{Y})$ with optimal 7 latent variables in the two last rows of Tbl. 3. Again, SO-PLS shows less overfitting, evident from the smaller difference between $R^2$ and $Q^2$.

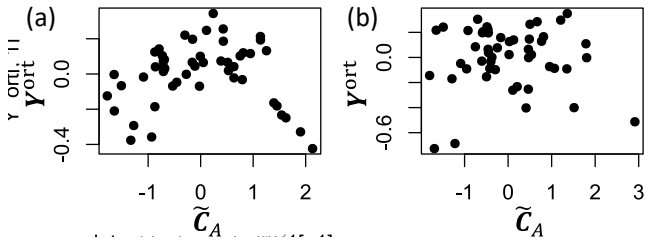

**Figure 3.** $\widetilde{\boldsymbol{C}}_A$ vs $\boldsymbol{Y}^{\text{ort}}$ for *Case (i)* (a) and *(ii)* (b).

In *Step 3*, as shown in Tbl. 4, measured data improve the overall fit by 6.6%. Compared to *Case (i)*, the mechanistic block explains less total variance (82.2%), despite the correct model formulation. The results show that measured data improve the model fit, but also highlight a limit to how much the first-principles model can be miscalibrated (given the lower overall $R^2$ at 88.9%). Furthermore, as expected, no structural errors are observed in the residuals (Fig. 3(b)).

## CONCLUSION

In this work, we present a methodology based on SO-PLS for incorporating process knowledge into latent-variable models. This approach efficiently integrates first-principles models with measured process data without needing to recalibrate the first-principles model to the full-scale system. The methodology is demonstrated using a CSTR case example. The results show that it can decouple the variance explained by first-principles from that explained purely by data and capture mismatches.

Current work aims to apply this procedure in an industrial setting to identify root causes of disturbances in bioprocesses, using variance decomposition to pinpoint sources of abnormalities. Future work seeks to integrate process-wide interactions with first-principles knowledge into a unified SO-PLS model, extending previous research [7]. Increased complexity in the first-principles model can increase computational costs, necessitating the use of a surrogate model for generating synthetic data. Furthermore, the SO-PLS model's repeated deflation steps can be computationally demanding, especially in process-wide models with many blocks, due to the need to explore all latent variable combinations during cross-validation. The response-oriented sequential alternation (ROSA) model offers a viable alternative to address these challenges [15].

# Exploring Design Space and Optimization of nutrient factors for maximizing lipid production in *Metchnikowia pulcherrima* with Design of Experiments

**Nichakorn Fungprasertkul[a]*, James Winterburn[a], and Peter Martin[a]**

[a] School of Chemical Engineering, University of Manchester, Manchester, M13 9PL, UK
* Main Author: nichakorn.fungprasertkul@postgrad.manchester.ac.uk.

## ABSTRACT

Due to the importance of unsaturated fatty acids for human health and the increasing global demand in the food and food crop area, oleaginous yeasts are promising alternative microorganisms for commercial lipid production due to the high volumetric productivity, with *Metchnikowia pulcherrima* being an underexplored oleaginous yeast with potential as a lipid producer. Critical to achieving high productivity lipid production are nutrient factors. A sensitivity test identified carbon and nitrogen sources as important factors in nitrogen limited broth (NLB) for lipid production in *M. pulcherrima* i.e. glucose, yeast extract and Ammonium sulphate. Response Surface Methodology (RSM) involving sets of 15 experimental runs of three-factor three-level Box-Behnken Design (BBD) was implemented for exploring the design of the carbon and nitrogen source in the growth media composition. Quadratic surfaces were least-square fitted and used to identify regions of optimal lipid yield. Multiple sets of runs were conducted with the parameter range progressively adapted and repeated until a clear optimum was identified. The highest total lipid production was in the low carbon concentration range (2.27-21.5 g/L) which suggests the process is more productive with the optimised media compared to NLB media (30.4 g/L of carbon). The optimal carbon concentration was 14.8 g/L whereas the dependence on nitrogen was not found to be significant. The yield of optimal point ($Y_{P/S}$) was 2.39 times higher than NLB media after validation because the depletion of glucose at the end of fermentation (72-104 h) contributes the high increase of lipid accumulation (mg Lipid/ 100 ml culture) of the optimal point (94.5%) which was higher than NLB media (34.5%) for 60%.

## 1. INTRODUCTION

In 2023 the World Health Organization (WHO) suggested that unsaturated fatty acids should be a primary source of fat consumption for humans in its guidance as they can decrease the risk of heart disease by lowering cholesterol levels [1]. The global population is predicted to reach 9 billion people by 2050, resulting in greater demand for food and food crops [2]. In the same way, lipid consumption has increased globally from 83.5 to over 223 million tonnes in past 30 years to serve several purposes including; biofuels, food, supplements, oleochemicals and animal feed. Oleaginous yeasts are considered as viable microorganisms for commercial lipid production because of the high specific growth rate and lipid accumulation. *Metchnikowia pulcherrima* is an under-explored oleaginous yeast with potential as a lipid producer [3]. Critical to achieving high productivity lipid production are nutrient factors [3-4].

This study focuses on understanding the effect of factors toward the growth and lipid production of *M. pulcherrima* and optimizing the important factors to maximize lipid production. A sensitivity test was used to identify the most influential factors on the responses [5]. Plackett-Burman design with a first degree polynomial model was used within this sensitivity test because it focuses

on main effects and properties to minimise the variances in independent estimates with a small number of experimental runs [6]. Box-Behnken design and a quadratic model were used for exploring the design space and optimization. Box-Behnken design can meet a requirement of quadratic system with fewer runs than central composite design [7]. To maximize the lipid production in *M. pulcherrima* by optimizing the important media compositions that have a significant impact on Total Lipid from the sensitivity test.

# 2. METHODOLOGY

## 2.1 Sample preparation

### 2.1.1 Microorganism and Cultivation Techniques

The yeast strain *Metchnikowia Pulcherrima* NCYC2580 (National Collection of Yeast Cultures, Norfolk, UK) was stored in a 23% (v/v) glycerol stock at – 80 °C. For preculture, one cryovial (1.6 ml) of working stock was incubated in 20 ml MEA media (malt extract 30 g/L; mycological peptone 5 g/L) in a 125 ml Erlenmeyer flask at 200 rpm at 20 °C in Infors HT Multitron 2 Incu-bator Shaker with Cooling for 24 h. Fermentation for the control flasks was prepared using nitrogen limited broth (NLB) (NLB: $KH_2PO_4$ 7 g/L; $(NH4)_2SO_4$ 2 g/L; $Na_2HPO_4$ 1 g/L; $MgSO_4{\cdot}7H_2O$ 1.5 g/L; yeast extract 1 g/L; glucose 80 g/L; pH 5). The fermentation was carried out by adding 1 ml of preculture in 100 ml of broth in 500 ml Erlenmeyer flask. The flasks were incubated at 200 rpm at 15 °C for 104 h [4].

### 2.1.2 Residue biomass, Lipid Content and Total Lipid measurement

After the fermentations had reached their end point at 104 h, biomass was measured by centrifuging 1 ml of culture broth, followed by removal of the supernatant and drying of the obtained cell pellets in a vacuum drier at 50 °C until constant weight. Biomass was recorded in units of g/g (dried cell weight/ culture weight). Lipid content was determined as the percentage of lipid weight per dry cell weight after lipid extraction process as the details in supplementary material (Section S1.1). Residual biomass was calculated by subtraction of the amount of the lipid in 1 g of biomass. Total Lipid (mg Lipid/100 ml culture) was recorded as the total amount of lipid obtained from one flask.

### 2.1.3 Additional Chemical Analysis

Total Organic Carbon (TOC) and Total Nitrogen (TN) were measured for understanding carbon and nitrogen source consumption. The liquid samples were diluted for 2 and 10 times for TOC and TN analysis respectively and filtered (0.22 µm, Millipore). The TOC and TN values were measured on Shimadzu TOC-V cpn Dissolved Carbon and TNM-1 Nitrogen Analyser at Manchester Analytical Geochemistry Unit (MAGU), The University of Manchester, UK. The measurement was done in duplicates. Glucose concentration in culture was measured daily to understand carbon source consumption. Glucose concentration was quantified as the details in supplementary material (Section S1.2).

## 2.2 Sensitivity Test

The experimental design for a sensitivity test was constructed to study the influences of seven nutrient factors on *M. pulcherrima* Residual Biomass and Lipid Content. The seven nutrient factors are six factors in NLB and glycerol supplementation. The levels in this experiment were considered from the concentration of the factors in NLB and the possible concentration range that can be developed for optimization as shown in Table 1. The experimental design was constructed on seven-factor Plackett-Burman design as the details in supplementary material (Section S2).

**Table 1:** Levels of factors for Sensitivity Test

| Factors (g/L) | Symbol | Low Level (-) | High Level (+) |
|---|---|---|---|
| Glucose | $x_1$ | 40 | 80* |
| Glycerol | $x_2$ | 0 | 9 |
| Yeast Extract | $x_3$ | 1* | 4 |
| $(NH_4)_2SO_4$ | $x_4$ | 2* | 8 |
| $Na_2HPO_4$ | $x_5$ | 1* | 4 |
| $MgSO_4{\cdot}7H_2O$ | $x_6$ | 1.5* | 6 |
| $KH_2PO_4$ | $x_7$ | 7* | 15.75 |

*Concentration in Nitrogen limited broth (NLB)

Following the running of the Plackett-Burman design experiment (eight runs for three replications per the levels of factor in Table 1), a multiple linear regression model was fitted, equation 1. Where $Y$ is the predicted response, $a_0$ is the intercept of mean and $a_1 \ldots a_7$ are the respective coefficients of factor $x_1$ until $x_7$ respectively [6]. Statistical analysis of the multiple linear regression model and response surface plots were carried out in Python 3.11.3 by Statsmodels and Plotly Library.

$$Y = a_0 + a_1x_1 + \cdots + a_7x_7 \quad (1)$$

## 2.3 Exploring the design space and Optimization

After running the sensitivity test, the important factors for residual biomass and lipid content were identified. The level of the important factor was assigned to the same range with the sensitivity test to visualize the potential range of the optimal point. A three-factor three-level Box-Behnken design was constructed for exploring the design space as the details in supplementary material (Section S3).

Following running the Box-Behnken design experiment (15 runs for two replications as per the levels of

factor in Table S2), a quadratic model was fitted as the equation 2. Where $Y$ is the predicted response, $\beta_o, \beta_i, \beta_{ii}, \beta_{ij}$ are regression coefficients of the model for the intercept, linear, square, interaction effects respectively, and $x_i$, $x_j$ are the factors [8]. RSM Library in R programming was used for fitting the quadratic model and analysing Analysis of variance (ANOVA) of the models [9], and response surface plots were carried out in Python 3.11.3 using the Plotly Library.

$$Y = \beta_0 + \sum \beta_i x_i + \sum \beta_{ii} x_i^2 + \sum \beta_{ij} x_i x_j \quad (2)$$

Subsequent to exploring the design space, the parameter range was progressively adapted and repeated until a clear optimum was identified. It can be identified when the peak of the important factor of a quadratic model is shown on a response surface clearly. The optimal point was identified after running Box-Behnken design as the levels of factor as shown in Table 2 in two replications. A three-factor three-level Box-Behnken design was constructed for optimization as the details in supplementary material (Section S4). The statistical analysis and response surface fitting were done in the same manner as for the previous exploring the design space step.

**Table 2:** Levels of factors for optimization

| Factors (g/L) | Symbol | Level (-1) | Level (0) | Level (+1) |
|---|---|---|---|---|
| Glucose | $x_1$ | 5 | 27.5 | 50 |
| Yeast Extract | $x_2$ | 1 | 4 | 7 |
| $(NH_4)_2SO_4$ | $x_3$ | 2 | 8 | 14 |

After the optimal point was identified, it was validated by running an experiment at the optimal point in triplicate and comparing with the control sample (NLB). The yield of the optimal sample was calculated using equation 3 and compared with the control sample.

$$Y_{P/S} = \frac{mass\ product\ produced\ (g)}{mass\ substrate\ consumed\ (g)} \quad (3)$$

## 2.4 Repeatability of Exploring the design space and Optimization Experiments

The experiments were repeated by using the different preculture for two and five replications for the exploring the design space and optimization respectively to observe the percentage change as per equation 4. Where $x_1$, $x_2$ are the old and new values accordingly.

$$Percentage\ change = \frac{x_2 - x_1}{x_1} \times 100 \quad (4)$$

# 3. RESULTS AND DISCUSSION

## 3.1 Sensitivity Test

Subsequent to running the experiment of the sensitivity test, the multiple linear regressions of Residual Biomass and Lipid Content were fitted. The linear regression coefficient ($R^2$ = 0.912, Adjusted R-squared 0.873, F-statistic: 23.57) of multiple regression linear model of Residual Biomass indicates a goodness of the model to explain total variation among responses. The significant factors for Residual Biomass are yeast extract (1-4 g/L), glucose (40-80 g/L) and $(NH_4)_2SO_4$ (2-8 g/L) which are positive impacts. The response surface in figure 1 shows the increase of the Residual Biomass with the glucose and $(NH_4)_2SO_4$ concentrations. These important factors for Residual Biomass are carbon and nitrogen sources in the media. In the initial phase of fermentation, the carbon and nitrogen sources are important for increasing the cell division and protein synthesis to increase the cell density, resulting in the increase of biomass [10]. In the case of Lipid Content, the linear regression coefficient ($R^2$ = 0.921, Adjusted R-squared 0.887, F-statistic: 26.81) of the model of Lipid Content indicates goodness of the model to explain total variation among responses. Although yeast extract (1-4 g/L), glucose (40-80 g/L) and $(NH_4)_2SO_4$ (2-8 g/L) are significant factors for Lipid Content as well, they have negative effects for lipid content. Figure 1 shows that Lipid Content decreased with the increase of yeast extract and glucose in the response surface from the multiple linear regression model because of the limitation of the nutrient contributes the lipid accumulation inside of an oleaginous cell by activating citrate formation, thus ATP Citrate lyase start to change citrate to a substrate to a triglyceride formation or lipid droplet in the end [10].

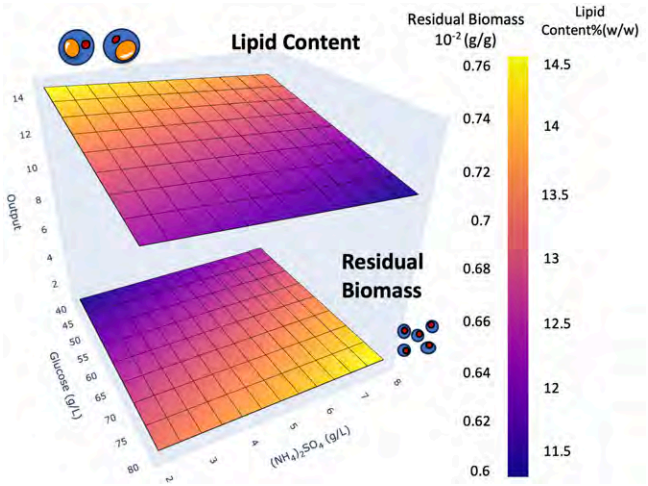

**Figure 1:** Response surface of multiple regression linear model of Lipid Content and Residual Biomass model from plotting Glucose (g/L) and $(NH_4)_2SO_4$ (g/L).

## 3.2 Exploring the design space and Optimization

To maximize the lipid production in the culture volume (100 ml), Total Lipid (mg Lipid/100 ml culture) was defined in order to optimize the important factors to

maximize the lipid production. Since the important factors for Residual Biomass and Lipid Content are yeast extract, glucose and $(NH_4)_2SO_4$ which are carbon and nitrogen sources, the important factors were converted to the concentrations of carbon and nitrogen from TOC and TN analysis. From running the experiments as the Box-Behnken design for exploring the design space, the data were fitted as a quadratic model. From the statistical analysis, the model has a moderate correlation (Multiple R-squared: 0.5948, Adjusted R-squared: 0.3696) with non-significant of Lack of fit (Pr(>F) = 0.12870, exceed 0.05) as shown in Table 3, thus the model is valid for the work. The statistical result in Table 4 shows that carbon is the important factor in both linear ($x_1$) and pure quadratic term ($x_1^2$), and nitrogen was not found to be significant. This could be because of the insignificant nitrogen concentration in this design space, the model has the low adjusted R-squared because the model cannot fully represent the data. The carbon sources in this process are glucose and yeast extract. They can contribute the high cell density of biomass in fermentation [11]. It is the first stage of lipid production. During the excess of the nutrients condition, the cells actively grow, resulting in the cell mass increase [10]

**Table 3:** Analysis of variance (ANOVA) for the quadratic regression model of Total Lipid (TL) after running the exploring the design space experiments (1).

| $x_1x_2$ | -1.46881 | 1.9027 | 0.45993 |
| $x_1^2$ | 0.41444 | 0.1689 | 0.03651[a] |
| $x_2^2$ | -1.26624 | 21.5253 | 0.95438 |

[a] Significant under 95% level of confidence.

The contour plot from the response surface of the model in Figure 2 shows the highest Total Lipid in the low carbon range. For this reason, the parameter range in the experimental design was adapted progressively towards the to lower carbon concentration for optimization. Since nitrogen was found to be insignificant, the range of nitrogen concentration was expanded to include higher concentrations (2-14 g/L) for optimization.

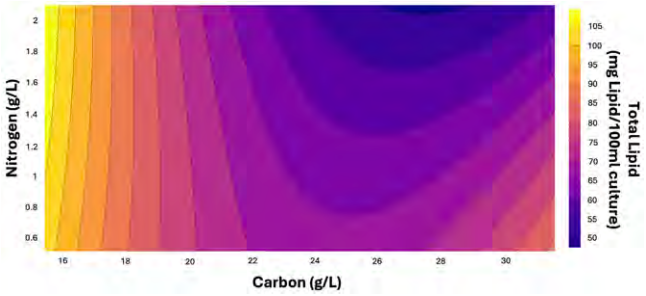

**Figure 2:** Contour plot of the quadratic model of Total Lipid from plotting Carbon (g/L) and Nitrogen (g/L) from Exploring the design space experiment.

After running the low carbon concentration experiments as per Table 2 for optimising the carbon and nitrogen concentration to maximise the Total Lipid, a quadratic model was fitted. From statistical analysis, the quadratic model has the moderate correlation (Multiple $R^2$: 0.5672 and Adjusted $R^2$: 0.3268). Lack of fit of the model is nonsignificant (Pr(>F) = 0.2359, exceed 0.05) as shown in Table 5, so the model is valid for the work. The statistical result in Table 6 shows that carbon (2.27-21.5 g/L) is an important factor for Total Lipid production in both linear ($x_1$) and pure quadratic term ($x_1^2$), and nitrogen was not found to be significant. In the same way with the Total Lipid model in exploring the design space, the irrelevant nitrogen concentration in this optmization design space could cause the low adjusted R-squared because the model cannot fully represent the data.

The optimal carbon concentration was 14.8 g/L, and it can be observed from the response surface as shown Figure 3. The optimal nitrogen concentration was identified from the highest Total Lipid that can be achieved at the optimal carbon concentration within the design space. Thus, the model was experimental validated at 14.8 g/L of carbon and 0.52 g/L of nitrogen which is comprised of glucose 38.5 g/L, yeast extract 1 g/L and $(NH_4)_2SO_4$ 2 g/L. After the model validation, the different percentage between the model and the experimental validation point (54.1 ± 2.78 (mg Lipid/ 100 ml culture)) was 6.93%. Carbon to nitrogen ratio of this optimal point in this process was 28.46 (g/g) which is a parameter for a fermentation process for lipid production by an oleaginous yeast [12]. The yield of the optimal point sample and NLB sample which was considered from the Total Lipid (mg lipid/100 ml culture) and the consumed carbon

concentration (mg consumed carbon/100 ml culture). The yield of optimal point ($Y_{P/S}$) was 2.39 times higher than NLB media after validation. The reasons of the high optimal yield were studied further from the glucose consumption and lipid accumulation daily examination.

**Table 5:** Analysis of variance (ANOVA) for the quadratic regression model of Total Lipid (TL) after running optimization experiments (1).

[a] Significant under 95% level of confidence.

Since glucose is comprised 97.47% (w/w) of the total carbon the change of glucose with Total Lipid of the optimal point was examined every day to understand the metabolism of lipid accumulation and carbon source consumption by *M. pulcherrima* during fermentation. The study found that the optimal sample gave a high yield because of the depletion of glucose at the end of fermentation (72-104 h), contributing to the increase of lipid accumulation (mg Lipid/ 100 ml culture) at the optimal point (94.5%) which was higher than NLB media (34.5%) for 60%. This is because there are two stages of lipid accumulation for the carbon limitation media of the optimal point. In the first stage, the cells grow and accumulate gradually at the same time. However, at the end of the fermentation (72-104 h), the glucose was completely consumed, and the Lipid Content was increased dramatically to 7.67% (1.86 times of NLB samples) [13]. In contrast, the lipid accumulation in the NLB fermentations increased gradually with biomass. At the end of the process, the Lipid Content at 104 h was only 4.14%, and there was residual glucose for 15.17 g/L.

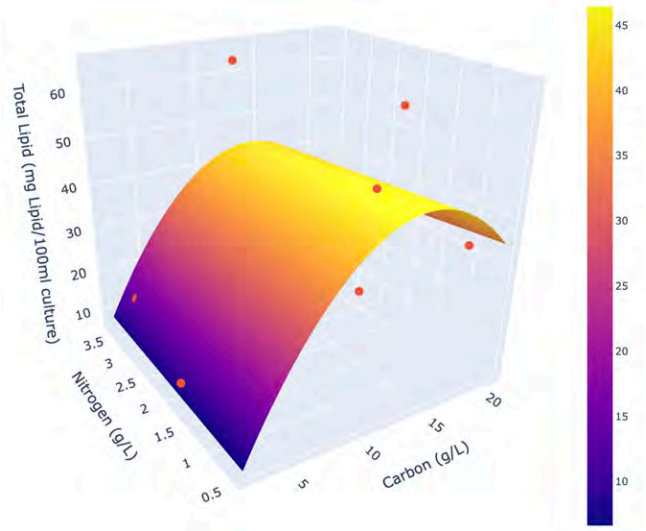

**Figure 3:** Response surface of quadratic model of Total Lipid from plotting Carbon (g/L) and Nitrogen (g/L) from Low Carbon Concentration from Box-Behnken Design.

## 3.3 Repeatability of Exploring the design space and Optimization Experiments

From the study of repeatability of the exploring design space experiment, the highest percentage change, 55.78% of the total lipid. This value indicates the likelihood of repeating the experiment by running the different preculture batch. In the same way, the repeatability of the optimization experiment was studied to observe the different change from running the different preculture batch and error during the experimental run as shown in Figure 4. The higher than expected total lipid of the third replication was observed. This is because of contamination of biomass during lipid separation, thus the weight of lipid in this data set are higher than the other replication. The different percentage the Total Lipid data was decreased for 4.97% from 92.1% to 87.2% by excluding the third replication in the data set. Removing an error data set before plotting a quadratic model was operated because the value of the third replication cannot represent the likelihood of the data set. Thus, the model could be representing the behavior of *M. pulcherrima* precisely by including only the data set that was experimented correctly.

## 4. CONCLUSION

The sensitivity test, the exploring the design space and optimization successfully maximized lipid production in the limited volume (100 ml) from *M. pulcherrima.* The sensitivity test from Plackett-Burman design and multiple linear regression model identified carbon and nitrogen sources as the important factors as expected in nitrogen limited broth (NLB) for lipid production by *M. pulcherrima* which are glucose, yeast extract and Ammonium sulphate. The important factors have a positive impact on

the Residual Biomass but a negative impact on the Lipid Content because they are the nutrients for the cell growth, but the starvation of nutrients contributes the lipid accumulation. Box-Behnken Design with quadratic model fitting suggests the maximal lipid production point on the response surface at the low carbon concentration range (2.27-21.5 g/L) for optimization of the Total Lipid. The optimal carbon concentration was 14.8 g/L, thus the optimal carbon to nitrogen ration was 28.46 (g/g). The yield of optimal point was higher than NLB media at 2.39 times because the depletion of glucose at the end of fermentation (72-104 h) contributes the high increase of lipid accumulation of the optimal point. The repeatability of the exploring the design space and optimization experiments were tested to understand the behavior of *M. pulcherrima*. and potential experimental error during running the experiments.

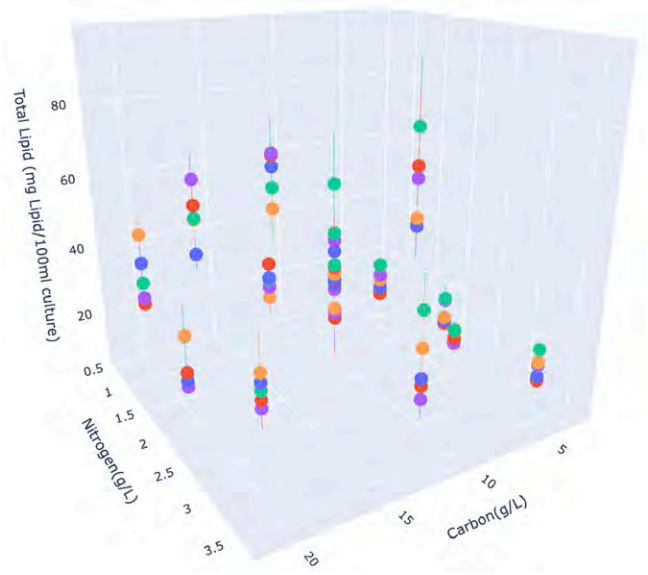

**Figure 4:** Scatter from plotting the experimental data of Total Lipid model on carbon and nitrogen concentrations axes from running the optimization experiment (blue-first replication, red-second replication, green-third replication, fourth-purple replication and orange-fifth replication).

## ABSTRACT

The extraction of lycopene from tomato waste has been largely evaluated at an experimental level, leading to the creation of polynomial models or response surfaces that allow the representation of the extraction behavior. However, these studies are based on laboratory level and an extraction process has not yet been scaled up. This study evaluates the design and optimization of the lycopene extraction process from tomato waste. The proposed model is solved through a link between Python and Aspen Plus, performing the optimization a genetic algorithm (GA) in Pymoo. The minimum value of TAC is 211,692.2 USD/yr, corresponding to a production of 2.29 g/h of lycopene, starting from 1000 kg/h of tomato waste. This work represents a first approach to the design of a commercial-scale lycopene production process.

**Keywords**: tomato waste, lycopene, solvent extraction, stochastic optimization.

## INTRODUCTION

Approximately 13.2% of the world's food is lost before being harvested [1]. Thus, food waste management has high relevance. Particularly in Mexico, the agricultural sector contributes with 3.4% of the national GDP, where the fruits and vegetables sector stand out with 45% of the sector's exportations. Tomatoes contributes to exportation with 8.41%. Mexico is the main supplier of this product worldwide, with a 19% share of the exported volume in the period 2003-2017 [2]. However, not all tomatoes are used due to their short shelf life, causing approximately 30% of the crop to be wasted [3]. In addition, waste from tomato sauce production can also be valorized. Tomato waste can be used to isolate high-value compounds such as carotenoids, polyphenols, vitamins, fibers, flavonoids, among others. Among these, lycopene is considered a well-known carotenoid and the most abundant pigment in tomatoes, responsible for giving them their color. It is used as a raw material in the cosmetic, pharmaceutical and food industries [4]. Lycopene from tomato waste is traditionally recovered by solvent extraction, but research on this topic has only been carried out through laboratory-scale experimentation [5, 6]. An important aspect in lycopene extraction is the type of solvent used in the extraction, as this can have economic, environmental or health drawbacks, depending on the application for which it is used. Some studies work with traditional solvents [6,7], others use enzymes that help with greater extraction [5,8], and others work with supercritical fluids [9]. Various alternatives have been proposed, but all of them have been developed at laboratory level, without scaling up.

This work addresses the systematic design and optimization of an industrial-scale process for obtaining lycopene from tomato waste. A comparison is made between a base case and the optimized design using a conventional solvent mixture: acetone-n-hexane. A stochastic single-objective optimization strategy is employed to minimize to total annual cost (TAC) of the proposed process.

# METHODOLOGY

## Process Design

Tomato waste is used as raw material to produce lycopene. This waste is passed through a tray-type dryer, reducing the water content to 10%. The waste is then subjected to a mill until it reaches an average particle size of 78 mm. Lycopene is then extracted from tomato waste using an acetone-n-hexane solvent mixture in a stirred tank reactor. The lycopene rich stream passes to a flash tank to separate large volumes of solvents and concentrate the lycopene. Finally, the lycopene stream is purified in a distillation column to achieve 95% purity, food grade. The process is summarized in Figure 1.

## Mathematical modeling

The mathematical model of the process consisted of the design equations for the drying, grinding and extraction stages, which have been coded in Python, linked to the simulation in Aspen Plus for the separation and purification stages (flash tank and distillation column).

For the drying stage the main equations are given by eqs. (1), (2) and (3) [10]:

$$\frac{q_T}{\dot{m}_s} = c_{ps}(T_{sb} - T_{sa}) + X_a c_{pL}(T_v - T_{sa}) + (X_a - X_b)\lambda + X_b c_{pL}(T_{sb} - T_v) + (X_a - X_b)c_{pv}(T_{va} - T_v) \quad (1)$$

Where $q_T$ it is the necessary heat (W), $\dot{m}_s$ is the solid biomass flowrate (g/s), $T_{sa}$ is feed temperature (°C), $T_v$ is vaporization temperature (°C), $T_{sb}$ is final temperature of the solids (°C). $T_{va}$ is final stream temperature (°C), $\lambda$ is latent heat of vaporization (J/g°C). $c_{ps}$, $c_{pL}$, $c_{pv}$ are the specific heats of solid, liquid and vapor (J/g°C).

$$q_T = \dot{m}_s c_{sb}(T_{hb} - T_{ha}) \quad (2)$$

In equation (2), $c_{sb}$ is the gas heat capacity for inlet moisture (J/g°C), $T_{hb}$ is hot gas inlet temperature (°C), $T_{hb}$ is hot gas outlet temperature (°C).

$$q_T = UA\overline{\Delta T} \quad (3)$$

In equation (3), $U$ is the overall heat transfer coefficient (W/m²°C), $A$ is the area and $\overline{\Delta T}$ is the average temperature difference (°C).

For the grinding stage the main equations is [10]:

$$\frac{P}{\dot{m}} = 0.3162 W_i \left(\frac{1}{\sqrt{D_{pb}}} - \frac{1}{\sqrt{D_{pa}}}\right) \quad (4)$$

Where P is the power (kW), $\dot{m}$ is the waste stream rate (t/h), $D_{pb}$ is the particle size at outlet (mm),$D_{pa}$ is the particle size at inlet (mm) and $W_i$ is work index (kW/t) [11].

For the extraction stage, equation 5 was used:

$$Y = 0.009621 - 0.0028125A + 0.0010875B - 0.0014875C + 0.00525D + 0.00045AB + 0.00265AC - 0.0022875AD - 0.000775BC + 0.0000375BD - 0.0009625CD \quad (5)$$

Where $Y$ is the amount of lycopene (mg/g) extracted from the biomass. A, B, C and D are the normalized temperature, residence time, acetone/n-hexane ratio, and volume of solvent mixture, respectively. This extraction model was obtained from experimental data [6]. The normalization of the variables is given by:

$$L_{Ni} = (L_i - L_{Lower})/(L_{Upper} - L_{Lower}) \quad (6)$$

Where $L_{Ni}$ is the value of normalized variable $L_i$, $L_{Upper}$ is de upper limit of variable i and $L_{Lower}$ is the lower limit of variable i.

For the solvent separation and lycopene purification stage, the flash tank and the distillation column were modeled in Aspen Plus. These devices were linked to Python to run the process continuously.

## Optimization variables

For this problem, seven variables were considered,

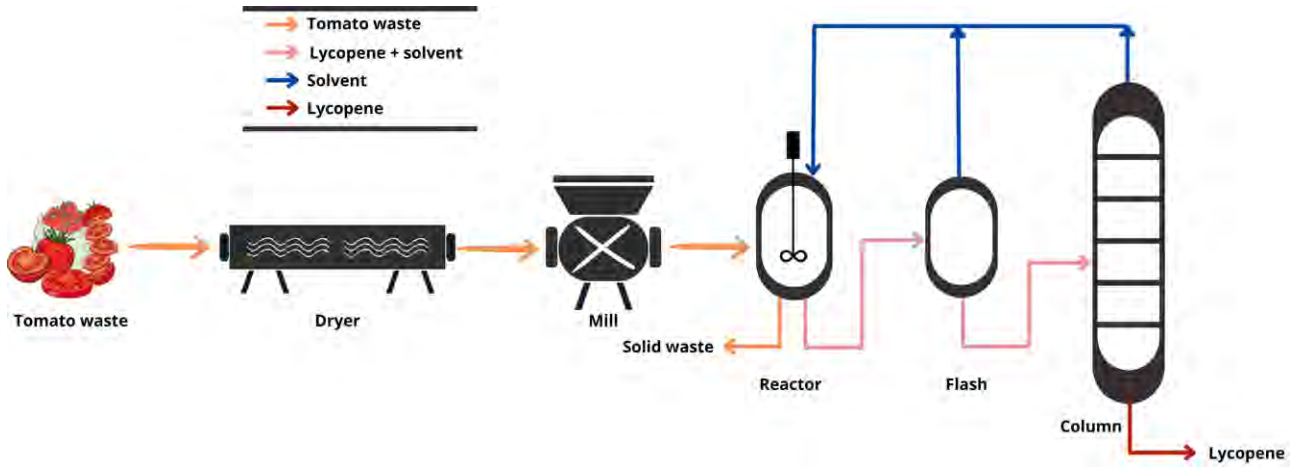

**Figure 1:** Diagram of the lycopene production process.

the first four correspond to the variables of the lycopene extraction model and the other three variables correspond to the distillation column for purification. These variables and their limits are presented in Table 1.

**Table 1:** Optimization variables for lycopene production.

| Variable | Symbols | Units | Limits |
|---|---|---|---|
| Temperature | $T_{ext}$ | °C | [30, 50] |
| Residence time | t | min | [1, 60] |
| Acetone/n-hexane ratio | A:H | % | [25, 75] |
| Volume of solvent mixture | $V_{solv}$ | L | [10, 30] |
| Number of stages | $N_t$ | - | [5, 20] |
| Feed stage | $N_F$ | - | [1, $N_t$] |
| Reflux ratio | | - | [0.1, 2] |

The feed stage has a dynamic upper limit, Herrera-Velázquez et.al. worked with these kinds of limits [12], as it depends on the number of total stages selected. This strategy prevents the feed stage from taking a value greater than the total number of stages in the column.

## Process optimization

The mathematical model implemented in Python and linked with Aspen Plus used the Pymoo environment [13]. Having a model that includes the link with Aspen Plus, where the exact equations to be considered are not explicitly available, made stochastic optimization an adequate approach, where the use of Pymoo can be advantageous [14]. The optimization was performed using the genetic algorithm (GA) method considering a population of 100 individuals with 21 generations, implying a total of 2100 evaluations.

## Objective function

The objective function is the total annual cost (TAC). To calculate the equipment cost the Guthrie method [15] and the equations presented by Turton et al. [16] were used. Equipment cost has been adjusted to 2023 with a CEPCI of 797.9. Additionally, five years of payback time are assumed. Cost calculations are represented by equations (7), (8) and (9).

$$CT_{equip} = \sum_{i=1}^{7} C_{i,equip} \quad (7)$$

$$CT_{oper} = \sum_{i=1}^{n} C_{i,cooling} + \sum_{i=1}^{n} C_{i,steam} + \sum_{i=1}^{n} C_{i,elect} + \sum_{i=1}^{n} C_{i,solvent} \quad (8)$$

$$TAC = CT_{oper} + \left( \frac{CT_{equip}\left(\frac{CEPCI\ 2023}{CEPCI\ 2001}\right)}{payback\ time} \right) \quad (9)$$

Where, $C_{i,equip}$ is the cost of each of equipment (USD), considering in addition to the five main equipment, the condenser and reboiler of the distillation column. $CT_{equip}$ is the total cost of equipment (USD), $C_{i,cooling}$ is the cooling utility cost (USD/yr), $C_{i,stream}$ is the steam utility cost (USD/yr). $C_{i,elect}$ is the cost of electricity (USD/yr), $C_{i,solvent}$ is the cost of solvent used in the process (USD/yr), $CT_{oper}$ is operating cost (USD/yr), and $TAC$ is the total annual cost (USD/yr).

A flowchart of the optimization algorithm is shown in Figure 2.

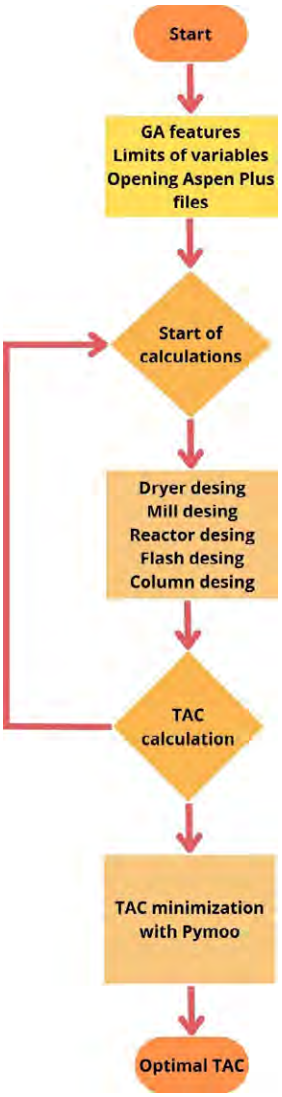

**Figure 2.** Flowchart of the optimization process.

## Base case

The base case contemplates the following values of the optimization variables: a temperature of 40°C, a residence time of 30.5 min, an acetone/n-hexane ratio of 50%, a solvent volume of 50 L, 6 stages in the distillation column with feed in the 3rd stage and a reflux ratio of 0.9, for a lycopene purity of 95%mol. The values of the variables associated to the extraction stage (A, B, C and D)

correspond to the central points for the boundaries shown in Table 1. On the other hand, the values for the design variables of the distillation column have been obtained from short-cut methods. This case is compared with the design obtained from optimization.

## RESULTS

### TAC optimization

The Python code linked to Aspen Plus for TAC minimization was run using Pymoo with GA, a population of 100 individuals and 21 generations. The algorithm took a total of 81.33 minutes to execute the allotted 2100 evaluations. Figure 3 shows how the algorithm progressed in seeking to minimize TAC over the iterations. A greater dispersion in the results is observed in the first iterations, the red line marks the best solution found at that time and continues to be compared, showing that out of 2100 option evaluated, 1957 converged and at that time the change between the solution found stabilizes and finds the optimum.

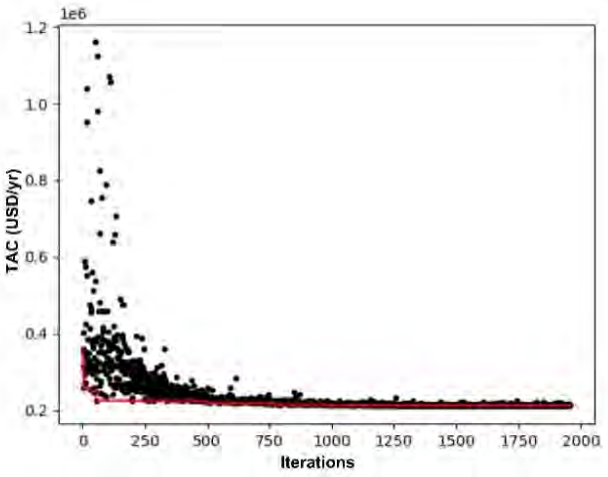

**Figure 3.** Iterations vs TAC.

### Comparison between solutions

Table 2 shows a comparison between the variables and the TAC value between the base case and the optimized solution. The results show that the optimal solution requires a higher temperature as well as a longer residence time and reflux ratio compared to the base case. The favorable solvent ratio is 25% acetone and 75% hexane, and a volume of 10 liters of solvent is sufficient. For the case of distillation column, it requires one less stage than the base case and the feed is kept on the third stage. The optimal solution shows a reduction of the TAC by 147,575.7 USD/yr, equivalent to a reduction of 41.07% of the total annual cost. Table 3 shows more details of the lycopene production process for the optimal solution.

**Table 2:** Comparison of the base case and the optimal solution.

| Variable | Units | Base case | Optimal Solution |
|---|---|---|---|
| Temperature | °C | 40 | 49.89 |
| Residence time | min | 30.5 | 51.39 |
| Acetone/n-hexano ratio | % | 50 | 25 |
| Volume of solvent mixture | L | 50 | 10 |
| Number of stages | - | 6 | 5 |
| Feed stage | - | 3 | 3 |
| Reflux ratio | - | 0.9 | 1.29 |
| **TAC** | **USD/yr** | **359,267.9** | **211,692.2** |

The study allowed obtaining relevant details of the process and the characteristics of the equipment that allow the TAC to be 211,692.2 USD/yr for a production of 2.29 g/h of lycopene, starting from 1000 kg/h of tomato waste. For this desing, the dryer, the mill and the flash tank are equipment that have no optimization variables, so these equipment behave in a similar way during the optimization process. The reactor and the distillation column are the equipment that present the greatest changes in the operating variables and dimensions.

The lycopene/acetone-n-hexane mixture is easy to separate and therefore the thermal loads in the flash tank, the condenser and the reboiler of the distillation column have low values. The solvent/lycopene ratio is something that can affect the maximum purity that can be achieved in the column, since if there is too little lycopene compared to the solvent, more energy is required. Here, it is important to highligh that the reboiler temperature must not be higher than 80°C, since the lycopene can start to degrade. Therefore, it is important to take care of the operating conditions of the distillation column to avoid damaging the product.

## CONCLUSIONS

The results indicate that it is possible to develop and optimize a lycopene production process from tomato waste. The design was obtained using Python linked to Aspen Plus, then optimized with a genetic algorithm to minimize the TAC. The results show that the optimized processs achieved a TAC of 211,692.2 USD/yr, reducing the initial TAC of 359,267.9 USD/yr by 41.07%. This study was carried out for a specific experimental model of lycopene extraction, but there are other mathematical extraction models in the literature that are good to be

able to compare in the future to explore other alternatives, especially in terms of solvents, to be used to improve the lycopene extraction process. Lycopene extraction models have only reached the formulation of an extraction polynomial or response surfaces, but considering the design on a large scale, it allows to visualize which aspects are important to improve for scaling-up such route for the conversion of wastes into a valuable product.

## ABSTRACT

Optimizing greenhouse operations in arid regions is essential for sustainable agriculture due to limited water resources and high energy demands for climate control. This paper proposes a multi-objective optimization framework aimed at minimizing both the operational costs and environmental emissions of a climate-controlled greenhouse. The framework determines optimal allocation of growing area among three crops (tomato, cucumber, and bell pepper) throughout the year. These crops were selected for their varying growth conditions, which induce variability in energy and water inputs, providing a comprehensive assessment of the optimization model. The model integrates factors such as temperature, humidity, light intensity, and irrigation requirements specific to each crop. It is solved using a genetic algorithm combined with Pareto front analysis to address the multi-objective nature effectively. This approach facilitates the identification of optimal trade-offs between cost, emissions, and yield, offering a set of efficient solutions for decision-makers. Applied to a greenhouse in Qatar, the model evaluates two scenarios: a hydroponic system and a conventional soil-based system. Results indicate that the multi-objective optimization effectively reduces operational costs and environmental emissions while fulfilling crop demand.The hydroponic scenario demonstrates higher water-use efficiency, resulting in lower overall emissions despite higher initial setup expenses. The soil-based system shows higher emissions due to increased fertilizer use and water consumption. The optimized allocation balances multiple crops simultaneously throughout the year based on seasonal conditions, enhancing overall sustainability. This study underscores the potential of advanced optimization techniques in enhancing the efficiency and sustainability of greenhouse agriculture in challenging environments.

**Keywords**: Multi-Objective Optimization, Hydroponics, Climate-controlled Agriculture, Greenhouses

## INTRODUCTION

### Background

The growing global demand for food, coupled with the challenges posed by climate change and resource scarcity, has intensified the need for innovative agricultural practices. In arid regions, the situation is particularly critical, as extreme temperatures, limited water availability, and high energy requirements create significant obstacles for sustainable food production. Greenhouse agriculture has emerged as a viable solution to address these challenges by enabling controlled environments for crop cultivation. However, optimizing greenhouse operations to balance resource use, operational costs, and environmental impact remains a complex task.

Greenhouses offer a controlled environment that can mitigate the adverse effects of harsh climatic conditions, making them indispensable in arid regions. By regulating factors such as temperature, humidity, and light intensity, greenhouses facilitate year-round cultivation and higher yields. Nevertheless, maintaining these conditions requires substantial water and energy inputs, particularly for cooling and irrigation systems, which can increase costs and environmental emissions. To ensure the

sustainability of greenhouse agriculture, it is imperative to adopt strategies that optimize resource allocation while minimizing operational expenses and environmental impacts [1].

Research on greenhouse optimization in arid climates covers a broad spectrum of topics, including water management, energy efficiency, and crop scheduling. Early work by [2] demonstrated the advantages of greenhouse cultivation for extending growing seasons and improving crop yields in regions with scarce water resources. In parallel, studies have shown that precise climate control systems significantly reduce water wastage and energy consumption, particularly when combined with automation technologies [3]. Furthermore, recent investigations by [4] have highlighted the potential of integrating renewable energy sources, such as solar power, to reduce the carbon footprint of greenhouse operations.

Hydroponic systems have emerged as one promising avenue for achieving high water-use efficiency [5]. Compared to conventional soil-based approaches, hydroponics can lower water consumption while maintaining or even enhancing crop yield. Additionally, the nutrient solution in hydroponic setups can be carefully regulated and recycled, minimizing both resource use and environmental discharge. Despite these advantages, challenges remain in balancing initial setup costs and the technical expertise needed to maintain such systems, as indicated by [6].

Multi-objective optimization has also been widely explored to identify trade-offs between economic viability and environmental sustainability. By employing advanced computational methods such as genetic algorithms, researchers have been able to analyze various configurations of crop types, resource allocations, and climate control strategies, revealing Pareto-optimal solutions that can guide policymakers and greenhouse operators [7]. However, many existing models focus on one or two objectives (e.g., water or energy), highlighting the need for a holistic framework that simultaneously considers cost, emissions, and other operational constraints.

These studies highlight the importance of a multifaceted approach to greenhouse optimization in arid environments. By building prior work in water management, energy efficiency, and multi-objective optimization, the present study seeks to advance the state of the art through an integrated framework that addresses the complex interplay of cost, emissions, and resource limitations in a comprehensive manner.

### Objectives and Outline

This study aims to create an integrated optimization framework that enhances the sustainability of climate-controlled greenhouse operations, particularly in arid regions. The research focuses on three interconnected objectives. Firstly, it aims to minimize operational costs, specifically targeting water and energy expenses, which are significant contributors to overall costs. Secondly, it seeks to reduce environmental emissions linked to energy consumption and cooling needs. Finally, the study emphasizes the importance of maintaining adequate crop diversity to satisfy market demands and strengthen agricultural resilience against climatic and economic challenges.

Following this introduction, the data and methods describe the methodology, detailing the mathematical formulation, decision variables, objectives, and constraints. Afterward, the case study section focuses on the implementation of the genetic algorithm, emphasizing how multi-objective optimization is employed to handle competing goals. Then, the results are presented and analyzed, offering insights into the trade-offs between cost and emissions under the two cultivation scenarios. Finally, the conclusion concludes by summarizing the key findings, discussing the implications for greenhouse operations in arid regions, and suggesting avenues for further research.

## DATA AND METHODS

### Case study

This study develops an optimization framework to enhance the sustainability of climate-controlled greenhouse operations in arid regions, notably in Qatar. Greenhouses located in these areas face unique challenges, such as extreme temperatures, water scarcity, and high electricity demands for cooling and irrigation purposes. Addressing these challenges requires a holistic approach that accounts for the tradeoffs between economic costs, environmental impacts, and resource constraints. The proposed framework introduces a multi-objective optimization model that determines efficient allocation of growing area to multiple crops simultaneously, aiming to reduce greenhouse emissions and costs while satisfying market demands. A case study was conducted to evaluate the framework's applicability to a medium-scale greenhouse in Qatar. The greenhouse was designed to cultivate three crops: tomato, cucumber, and bell pepper, selected for their economic value, varying resource requirements, and high consumption in the local market. The study considered two cultivation systems: a hydroponic system, which offers higher water-use efficiency and precise nutrient management, and a conventional soil-based system, which is more commonly adopted but generally less efficient in water usage. The optimization model was tailored to reflect the specific environmental conditions of Qatar, taking into consideration the average monthly temperatures, water availability, and electricity prices. The methodology integrates multi-objective optimization and scenario analysis to achieve operational efficiency while minimizing environmental emissions. The

subsequent section describes the mathematical formulation utilized in this model.

**Table 1:** Key data used in the optimisation model.

| Parameter | Value | Unit |
|---|---|---|
| Average Monthly Temp. | 25 – 40 | °C |
| Water Availability | 1000 - 1500 | Liters/day |
| Energy Cost | 0.12 - 0.15 | USD/kWh |
| Water Cost | 0.05 - 0.07 | USD/Liter |
| Greenhouse Area | 500 | m² |
| Heat Transfer Coeff | 5 - 6 | W/(m²·K) |
| Cooling Capacity | 30000 | BTU/h |

## Mathematical Formulation

This model optimizes the operational cost, environmental emissions, and crop yield of a climate-controlled greenhouse. The greenhouse is designed to grow three crops: tomato, cucumber, and bell pepper, over a 12-month period with the ability to allocate different percentages of growing area to each crop monthly. The mathematical formulation of the multi-objective optimization problem is presented below:

*Objective functions:*

Minimize the operational cost (*C*):

$$C = \sum_{j=1}^{12} \sum_{i} \left( W_i \cdot x_{ij} \cdot c_w + E_i \cdot x_{ij} \cdot c_e \right) \quad (1)$$

Where:

$i \in \{Tomato, Cucumber, Bell\ Pepper\}$

$j \in \{1,2,\ldots,12\}$

$W_i$: Water requirement of crop *i* (liters/month).

$c_w$: Cost per unit of water.

$E_i$: Energy requirement of crop *i* (kWh/month).

$E_i$: Cost per unit of energy.

Minimize Environmental Emissions (*E*):

$$E = \sum_{j=1}^{12} \sum_{i} \left( E_i \cdot x_{\{ij\}} \cdot e_e + Q_{\{ij\}} \cdot e_c \right) \quad (2)$$

where:

$i \in \{Tomato, Cucumber, Bell\ Pepper\}$

$e_e$: Emission factor per unit of energy.

$Q_{ij}$: Cooling load for crop *i* in month *j*, calculated as:

$$Q_{ij} = U \cdot A \cdot \Delta T_{ij} \quad (3)$$

*U* : Heat transfer coefficient (W/m²·K).

*A:* Greenhouse surface area (m²).

$\Delta T_{ij}$: Temperature difference between the greenhouse interior and the external environment for crop *i* during month *j.*

$e_c$: Emission factor for cooling load (kg $CO_2$ per unit energy).

*Decision variable:*

$x_{ij} \in \{0,1\}$ is the binary decision variable such that $x_{ij}=1$ if crop *i* is cultivated during month *j*, and $x_{ij}=0$ otherwise.

Subject to the following constraints:

Crop Diversity Constraint: To meet market demands and ensure crop diversity, each crop must be cultivated at least once annually:

$$\sum_{j=1}^{12} x_{ij} \geq 1 \quad (4)$$

Water usage constraint**:** The total water usage across all crops must not exceed the annual water availability, which is equal to 2000 L/day:

$$\sum_{j=1}^{12} \sum_{i} \left( W_i \cdot x_{ij} \right) \leq water\ limit \quad (5)$$

Energy usage constraint: The total energy consumption must not exceed the available energy budget, which is equal to 25000 kWh/day:

$$\sum_{j=1}^{12} \sum_{i} \left( E_i \cdot x_{ij} \right) \leq energy\ limit \quad (6)$$

Cooling capacity constraint: The total cooling load must remain within the greenhouse's cooling capacity, which is equal to 300,000 BTU/h:

$$\sum_{j=1}^{12} \sum_{i} \left( Q_i \cdot x_{ij} \right) \leq Cooling\ capacity \quad (7)$$

Monthly cultivation constraint**:** Only one crop can be cultivated in the greenhouse during each month:

$$\sum_{i} x_{ij} = 1 \quad (8)$$

Non-negativity and binary constraints: The decision variables are binary:

$$x_{ij} \in \{0,1\}, = \forall i,j$$

A genetic algorithm (GA) is employed to solve the multi-objective optimization problem. The GA is chosen due to its robustness in handling complex, non-linear problems with multiple objectives and constraints.

## Scenario Analysis

The optimization framework is applied to two scenarios. The first scenario assumes the greenhouse is equipped with a hydroponic system, which allows for precise control of water and nutrients.Hydroponic systems reduce water usage by up to 30-40% compared to soil-based systems and optimize fertilizer application to match plant growth requirements, minimizing waste. Energy demand in this scenario is primarily for pumping water and maintaining nutrient solutions, with substantial requirements for climate control in Qatar's hot environment.

The second scenario represents a traditional soil-based cultivation approach. Soil systems typically have higher water requirements due to evaporation and less efficient delivery methods. Nutrient delivery is less precise, potentially leading to higher fertilizer use and leaching. The model accounts for these differences by adjusting the water efficiency parameters and nutrient costs appropriately. Each scenario is evaluated for its ability to meet crop demands while minimizing costs and emissions. The model allows for simultaneous cultivation of multiple crops with flexible area allocation, reflecting real-world greenhouse operations. This approach enables more efficient resource utilization as different crops can be allocated optimal space based on their specific requirements and market value during each month.

## Results and discussion

This section presents the outcomes of the multi-objective genetic algorithm applied to optimize greenhouse operations in the two scenarios described previously: hydroponic and soil-based systems. The results focus on (i) cost, emissions, and yield trade-offs, (ii) monthly resource usage, and (iii) crop distribution over the 12-month planning horizon.The genetic algorithm was executed for 50 generations with a population size of 100 individuals. The optimization yielded a set of Pareto-optimal solutions representing different trade-offs between operational cost, environmental emissions, and crop yield. Figure 1 illustrates the 3D Pareto front, showing the relationship between operational cost (USD), environmental emissions (kg $CO_2$-eq), and total yield (kg) for both systems. The results reveal distinct regions in the solution space for each cultivation system. The hydroponic system generally occupies a region with higher costs but lower emissions, while the soil-based system shows lower costs but higher emissions. This pattern aligns with the inherent characteristics of each system: hydroponic systems require higher initial investment and maintenance but offer better resource efficiency. Table 2 summarizes key indicators for the best Pareto-optimal solution identified in each scenario based on the optimization results.Figure 1. Pareto-optimal solution.

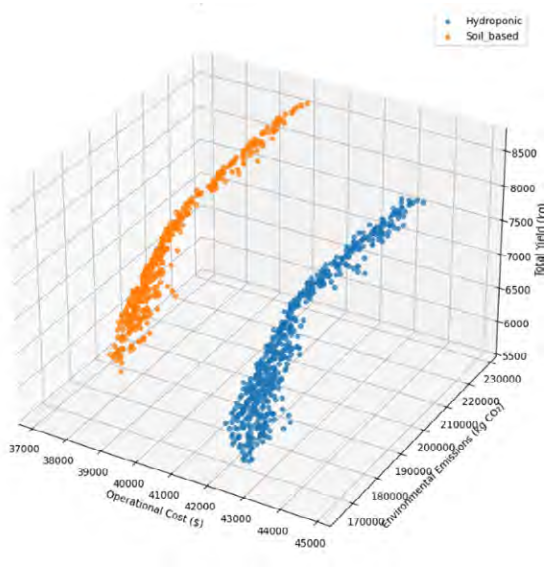

**Table 2.** Comparison of key performance metrics between Cultivation Systems

| Metric | Hydroponic System | Soil-Based System | Difference (%) |
|---|---|---|---|
| Total Operational Cost ($) | 39,682.43 | 35,174.01 | -11.36 |
| Environmental Emissions (kg $CO_2$) | 170,842.96 | 186,321.28 | 9.06 |
| Water Usage (liters) | 218,636.69 | 328,635.76 | 50.31 |
| Energy Usage (kWh) | 290,353.62 | 288,190.91 | -0.74 |
| Total Yield (kg) | 5,910.15 | 5,686.28 | -3.79 |

The optimization results reveal several important insights regarding greenhouse operations in Qatar's arid climate. In terms of operational costs, the soil-based system shows an 11.36% cost advantage over the hydroponic system. This finding might initially seem counterintuitive given hydroponics' reputation for efficiency. However, it reflects the higher installation,

equipment, and maintenance costs associated with hydroponic systems, which offset some of their operational advantages. Despite its cost advantage, the soil-based system produces 9.06% higher environmental emissions than the hydroponic system. This difference primarily stems from the additional fertilizer emissions in soil-based cultivation and the higher water consumption, which has associated emissions from pumping and treatment. The hydroponic system's better nutrient management and recycling capabilities help reduce its overall environmental footprint. The most striking difference between the two systems is in water usage. The soil-based system requires 50.31% more water than the hydroponic system, a significant consideration in Qatar's water-scarce environment where desalination is both expensive and energy-intensive. This substantial difference in water efficiency represents a compelling advantage for hydroponics in arid regions. Interestingly, energy usage remains relatively similar between the two systems (only 0.74% difference). This result suggests that while hydroponic systems have additional energy requirements for pumping and circulation systems, these are largely offset by the soil-based system's potentially higher cooling needs due to heat retention in the soil medium. In terms of crop yields, the soil-based system produces 3.79% less total yield than the hydroponic system. The crop-specific breakdown reveals interesting patterns: soil-based systems perform better for tomatoes (+25.14%) and bell peppers (+3.19%), while hydroponic systems excel at cucumber production (-25.93% in soil compared to hydroponic). These differences reflect the varying suitability of each crop to different growing environments and the optimization algorithm's response to these factors.

The optimized monthly crop allocation reveals a strategic approach to dealing with Qatar's climate variations. During the hottest months (May-September), the model allocates more space to heat-tolerant crops. In both systems, cucumber receives higher allocation during the hottest summer months (July-August in hydroponic; August-October in soil-based) when its water efficiency and heat tolerance provide advantages. Bell pepper, which generally requires less extreme temperatures, receives higher allocation during the milder months. Tomato allocations are strategically distributed throughout the year, with higher percentages in transitional seasons. These allocation patterns demonstrate how the optimization balances multiple factors: crop-specific requirements, seasonal temperature variations, resource constraints, and market demands. The ability to allocate growing area flexibly among multiple crops simultaneously enables more efficient greenhouse utilization compared to single-crop approaches.

In the context of Qatar's specific challenges, these results underscore the importance of considering multiple criteria when selecting greenhouse systems. While hydroponics offers clear advantages in water efficiency, critical in a water-scarce environment, soil-based systems may still be attractive for farms with limited capital or technical expertise. The model provides decision-makers with valuable information on the trade-offs involved, allowing them to select solutions that best align with their specific priorities, constraints, and environmental conditions.

## CONCLUSION

This study presents a multi-objective optimization framework tailored to the challenging climatic and resource conditions of Qatar. By simultaneously minimizing operational costs and environmental emissions while maximizing crop yield, the framework reveals important trade-offs between water-efficient hydroponic systems and more traditional soil-based approaches. The results underscore that hydroponic cultivation can substantially reduce water usage, of particular importance in a country reliant on energy-intensive desalination, while also moderating emissions through more precise nutrient management. Nevertheless, the soil-based scenario retains economic viability through lower operational costs, though it incurs higher resource consumption and resultant environmental impacts over time. A key insight from this study is the value of flexible crop allocation throughout the year. The optimization shows that simultaneously growing multiple crops with varying area allocations based on seasonal conditions can significantly improve overall greenhouse performance compared to single-crop approaches. Strategic alignment of crop allocations with monthly temperature variations can reduce both water consumption and cooling loads, thus lowering operational costs and emissions. The differences between hydroponic and soil-based systems are substantial in some metrics (particularly water usage, with a 50.31% difference) but minimal in others (such as energy usage, with only a 0.74% difference). These nuanced findings highlight the importance of comprehensive analysis that considers multiple factors rather than focusing on single metrics when evaluating greenhouse systems. These insights are particularly valuable for policymakers, agricultural planners, and greenhouse operators seeking to optimize production efficiency under harsh climatic constraints. Future work could expand upon this research by integrating real-time climate data, exploring additional crop varieties, or leveraging renewable energy sources to further mitigate environmental impacts and foster resilient, cost-effective greenhouse systems in Qatar and beyond.

## ABSTRACT

Water lily (*Eichhornia crassipes*) has been identified as an invasive exotic plant with high proliferation in Mexico, affecting aquatic bodies, such as lakes. After extraction, the water hyacinth biomass can be used as raw material for the production of bioproducts and bioenergy, however, the majority of them not covered the region's needs, and their economic profitability decreases significantly. Also, few reports present its use as raw material inside a biorefinery scheme. In this work, we propose a local biorefinery scheme to produce power and bioproducts from water lilies, using Aspen Plus V.10.0, per the needs of the Patzcuaro Lake community in Michoacán, Mexico. The scheme has been designed to process the harvested and sun-dried water lily from 197.6 kg/h of total wet harvested biomass, according to the extraction region schedule. The biomass is separated: root (RT) and stems-leaves (SL). The processing scheme involves the RT combustion to produce electric power, and two processes to SL; the first one, anaerobic digestion to produce fertilizer and biogas, while, pyrolysis and gasification as second one. The biogas is converted to electricity, while, the pyrolysis products are separated in bio-oil and biochar; the last one is inserted to gasification reactor to produce syngas, and then, electric power. According with results, this scheme produces 35.6 % of fertilizer, 1 % of bio-oil, and 3.5 kWh of electric power. The scheme requires energy efficiency tools to improve its energetic performance, however, is a potential solution for the use of water lily in the region.

**Keywords**: Water hyacinth, local-biorefinery scheme, modelling and simulation, Aspen Plus.

## INTRODUCTION

The conservation of aquatic bodies is a priority issue worldwide, due their ecosystems provide essential services such as, biodiversity maintenance, nutritious soils, climatic regulation, carbon sequestration and recreational activities. However, some have been affected by high resource exploitation, changing climatic patterns, or alien plant invasions (API), which contribute to deteriorating their ecological functions and causing the loss of native species. In accordance with [1], in Mexico have been identified 665 invasive exotic plants, among them the Water lily (*Eichhornia crassipes*) stands out due to its rapid proliferation, which enables it to cover several aquatic bodies, mainly lakes, across the country. The invasive plant impacts local ecosystems and human communities, making its management a pressing environmental and economic concern. In this sense, various strategies have been proposed to control and utilize *E. crassipes*, aiming to mitigate its negative effects while exploring its potential applications [2]. After extraction, the water hyacinth biomass has been used as raw material for the production of some bioproducts and bioenergy in the form of individual processes [3-6]; nevertheless, most of these products have not covered the region´s needs or have not been produced into an integral use framework, such as a biorefinery scheme, thus, in the most of cases their technical performance and economic

profitability have not been reached. Few works have reported the use of water hyacinth into a biorefinery scheme [7-10]. In this work, we propose the modelling and simulation of a local biorefinery scheme to produce electric power and bioproducts from water lilies, using Aspen Plus V.10.0, per the needs of the Patzcuaro Lake community in Michoacan, Mexico.

## METHODOLOGY

The methodology followed for carrying out this work is presented next. As first step, the conceptual design of biorefinery scheme was proposed from physical and chemical composition of water lily, and taking account the energetic needs of Patzcuaro community. Then, the proposed biorefinery was modelled from literature information to describe the reactive systems and obtain operational conditions for each processing zone; next, the simulation was carried out using Aspen Plus V.10.0. Finally, in order to analyze the proposed scheme, two performance indicators were constructed and applied.

### Conceptual Design

Patzcuaro, small municipality of Michoacan, Mexico is a fertile region, which include a famous lake called Patzcuaro´s lake. The economy of this region includes agriculture, fishing, crafts and tourism activities around the lake. However, the water lily invasion on the lake has been a recurrent issue since long time ago. In accordance with [11], the lake posses a defined extraction schedule and the appropriate machinery to do it. According with the extraction program an average of 197.6 kg/h of water lily are extracted every year. This biomass is composed by two main compounds: root (RT, 47 wt % of total plant) and steams-leaves (SL, 53 wt % of total plant) with high moisture content, 93 % and 91.8 %, respectively. Usually the wet biomass is sun dried and its final disposal is not regulated. For this reason, in this work is proposed a biorefinery scheme from the extracted and sun-dried water lily, assuming 1 % of water content for both biomass components; its block diagram is presented in Figure 1. The processing scheme starts with RT conversion by a combustion device to obtain electric power. Then, the SL are separated in two streams with 50 wt % each one; the first one enters to an anerobic digestion process, while the second one is inserted to a pyrolysis and gasification zone. Biogas and fertilizer are obtained from anaerobic digestion, then, the biogas is used to produce power; on the other hand, pyrolysis bio-oil and biochar are obtained from pyrolysis, next, the biochar is processed by gasification to obtain syngas, which is converted to electricity.

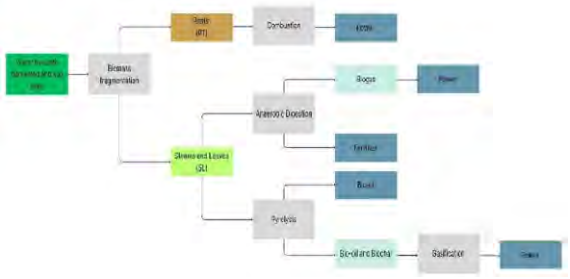

**Figure 1.** Block diagram for conceptual design of biorefinery scheme from water lily.

### Modelling and Simulation

The RT composition involves 24.53 wt % fiber, 12.31 wt % protein, 36.94 wt % carbohydrates, 5.65 wt % lipids and 20.57 wt % ash; while the SL composition is 21.44 wt % fiber, 18.90 wt % protein, 34.69 wt % carbohydrates, 8.16 wt % lipids and 16.9 wt % ash [12-13]. To model the biomass, the majority compounds (3 or 4) of each fraction for RT and SL were selected and normalized to be inserted into the simulation sheet. The flow diagram for the biorefinery scheme from Aspen Plus is presented in Figure 2. The ROOTS stream enters to mixer (MIX-1) along with 30 % excess air to carry out the combustion. The mixed stream is inserted to combustion reactor (R-COMBUS) modelled with R-Stoic module; the operational conditions were 550 °C, 1 bar and a fractional conversion for set combustion reactions of 85 %, in accordance with experimental information provided by [14]. Then, the out-stream from combustion enters to CYCLONE module to separate the solid fraction, next, the condensable compounds traces into the gas fraction (GAS-COMB) were separated by SEP module (SEP-1); the cleaned gas fraction is converted to electric power by a turbine using the COMPRESSOR module (TURB-COM). This process was modelled using the Peng-Robinson model [15].

Regarding to SL, the STE+LEAV with SL composition enters to SPLIT module (SPLIT-1) to get two streams: 50 wt % for anaerobic digestion process (SL-AD) and the other one for pyrolysis and gasification train (SL-PY-G). The SL-AD stream enters to anaerobic digestion reactor (R-AD) modelled by R-STOIC module at 38 °C and 1 bar, adding water as digestion medium (1:10, biomass to water, mass ratio) [16-17]. The out-stream from R-AD is inserted to simple separator (SEP-2, SEP module) to obtain BIOGAS and FERTILIZER. Then, the BIOGAS stream is converted to electricity by a turbine (TURBI-AD, COMPRESSOR module). In accordance with [15], the thermodynamic models used for this process were NRTL and Peng-Robinson. On the other hand, SL-PY-G stream enters to pyrolysis reactor, modelled by R-BATCH module (R-PIRO) at 329.7 °C and 1 bar, using a first order kinetic model provided by [18], specifying as stop criteria 5 h of operation. The out-stream from R-PIRO (PIRO-OUT) is

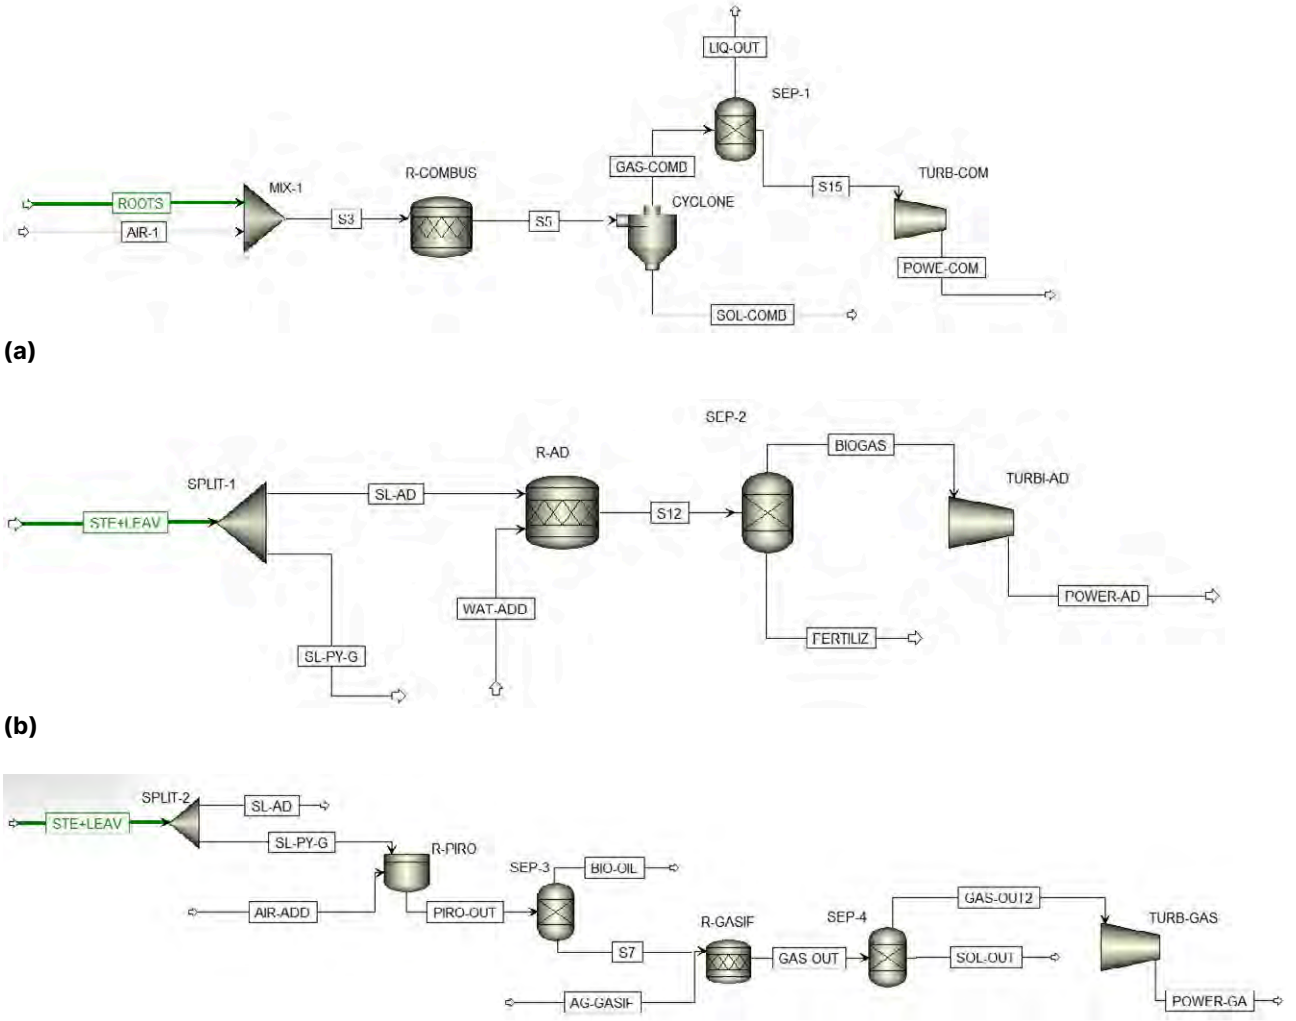

**Figure 2.** Aspen Plus flow diagram of biorefinery scheme from water lily: a) RT processing, b) SL for anaerobic digestion processing, and c) SL for pyrolysis and gasification train.

separated to remove the condensable products (BIO-OIL) using a SEP module (SEP-3); the remaining non-condensable gases and biochar were inserted to gasification reactor, modelled by R-STOIC module (R-GASIF). The operational parameters for R-GASIF were 700 °C and 1 bar, adding steam at 200 °C as gasifying agent (10 wt %, regarding the S7 stream mass) [19]. The out-stream from R-GASIF (GAS-OUT) was inserted to SEP module (SEP-4) to clean the syngas. Then, the syngas stream (GAS-OUT2) is converted to power by a turbine (TURB-GAS) using the COMPRESSOR module. The reactions set for each processing zone is provided at supplementary information section.

## Performance Indicators

To analyze the technical performance of the biorefinery scheme, two indicators are proposed next.

1.- EI-EP defined as the relation between the invested energy for the processing (reactor heating and electrical needs), regarding to the energy provided by the products.

For this case, the products considered by this indicator include the electric power provided by turbines, and pyrolysis bio-oil.

2.- PM-EM defined as the relation between total product mass generated by the scheme, including combustion gases, biogas, fertilizer, pyrolysis bio-oil and syngas, regarding to the water lily mass (RT and SL).

It is worth mentioning that according to the definition of these indicators, both are dimensionless.

## RESULTS

In this section are presented the results and their

analysis from water lily biorefinery scheme. In Table 1, 2 and 3 is presented the product distribution for outstreams after R-COMBUS, R-AD and R-PIRO+R-GASIF, respectively. As it can be observed, the proposed processes have low conversion efficiency, thus the amount of non-converted biomass is high.

**Table 1:** Mass flow at the exit of the combustion process.

| Component | Description | Mass Flow (kg/hr) |
|---|---|---|
| Unreacted biomass[a] | Non-converted biomass in the combustion process | 1.6753 |
| Combustion gases | O2 | 2.8022 |
| | N2 | 13.5634 |
| | CO2 | 1.6454 |
| | CO | 0.3901 |
| | CH4 | 0.2224 |
| | NH3 | 0.0007 |
| | NO2 | 0.0018 |

[a] Crude fiber, proteins, carbohydrates, lipids and ashes contents in the biomass that doesn't react during the process.

**Table 2:** Mass flow at the exit of the anaerobic digestion

| Component | Description | Mass Flow (kg/hr) |
|---|---|---|
| Unreacted biomass[b] | Non-converted biomass in the combustion process | 0.059 |
| Biogas | CO2 | 0.6047 |
| | CH4 | 0.2695 |
| | NH3 | 0.0012 |

[b] Crude fiber, proteins, carbohydrates, lipids and ashes contents in the biomass that doesn't react during the process.

**Table 3:** Mass flow at the exit of pyrolysis process and gasification.

| Component | Description | Mass Flow (kg/hr) |
|---|---|---|
| Unreacted biomass[c] | Non-converted biomass in the combustion process | 0.7010 |
| Bio-oil | C7H8 | 0.0909 |
| | C6H6O | 0.1128 |
| | C10H14O | 0.1483 |
| Biochar | C6H5O2 | 0.1077 |
| Gases | CO | 0.0148 |
| | CO2 | 0.0280 |
| | N2 | 13.0114 |
| | O2 | 4.0261 |
| Syngas | H2 | 0.01394 |
| | CO | 0.07537 |

[c] Crude fiber, proteins, carbohydrates, lipids and ashes contents in the biomass that doesn't react during the process.

Then, in Table 4 are presented the mass flows of each product derived from scheme. It is worth to mention that, the combustion gases, biogas and syngas were cleaned before the turbines, in order to avoid operational troubles and get electric power. In Table 5 are presented the power data derived from scheme. As it can be observed, the combustion process and pyrolysis-gasification train produce the majority of electricity. It is due to conversion aim for both processes are gaseous products with high energetic content. Also, it is noticeable that the combustion gases and fertilizer represent roughly 90 % of total obtained products.

**Table 4**. Mass flow total of products.

| Process | Product | Mass Flow (kg/hr) |
|---|---|---|
| Combustion | Combustion gases | 18.6261 |
| Anaerobic Digestion | Biogas | 0.8755 |
| | Fertilizer | 11.059 |
| Pyrolysis and Gasification | Bio-oil | 0.3520 |
| | Syngas | 0.0893 |

**Table 5**. Power produced by processing scheme.

| Process | Equipment | Power (KW) |
|---|---|---|
| Combustion | TURB-COM, | 1.5194 |
| Anaerobic Digestion | TURB-Dal | 0.035 |
| Pyrolysis and Gasification | TURB-GA | 1.944 |

Finally, in Table 6 are presented the results derived from EI-EP and PM-EM indicators. According with these results, the energy invested to processing is extensively high in comparison with the energy delivered by the products, which means that this scheme must be improved to enhance its energy efficiency. Energy efficiency tools, such as mass and energy integration or process intensification must be implemented. It is worth to mention that the EP was calculated from enthalpy values provided by simulation. On the other hand, regarding to second indicator, the products obtained from the scheme are almost 4-times less than the total mass available for processing; which means low conversion efficiency. This value must be improved by analyzing the operational conditions and using specific kinetic models to represent each processing unit.

**Table 6**. Evaluation Indicators

| Indicator | Factor | Value |
|---|---|---|
| EI - EP | EI (kW) = 2.6783E+16<br>EP (kW) = 5.6979 | 4.7006E+15 |
| PM – EM | PM (kg/h) = 51.0423<br>EM (kg/h) = 196.5502 | 0.2597 |

## CONCLUSIONS

In this work, a biorefinery scheme from water lily has been proposed, modelled and simulated using Aspen Plus V.10.0. This proposal attends to specific needs of Patzcuaro´s lake community located in Michoacan, Mexico, wherein the water lily infestation is a huge problem, affecting the natural ecosystem and local human society. The biorefinery scheme was designed to process the harvested and sun-dried biomass, in accordance with the local extraction program; also, the integrated processes into the scheme were included to generate mainly power, current demand in the region. According with results, this scheme produces 35.6 % of fertilizer, 1 % of bio-oil, and 3.5 kWh of electric power. It is important to mention that, the bio-oil can be integrated as biofuel in the combustion process to get more energy. On the other hand, regarding the indicators results, EI-EP demonstrates the need of implementing energy efficiency tools on the scheme to improve its energetic performance, while the PM-EM is almost 4-times less than the total mass available for processing, which means low conversion efficiency, thus kinetic values for each processing unit must be added to get better performance of the scheme. This proposal represents a first and integrated option to produce local bioenergy at the study region; also, in accordance with the opportunity areas detected from scheme, technical improvements could be implemented, representing a potential solution for the sustainable use of water lily in the region.

## ABSTRACT

Predicting water quality is essential for effective environmental management and pollution control. Dissolved oxygen (DO), one of key water quality parameters, plays a vital role in biological wastewater treatment [1]. This study aims to forecast DO levels in activated sludge tanks of an oil refinery's wastewater treatment plant (WWTP). Proper oxygen concentration is critical for microbial activity, as inadequate levels can disrupt the biological breakdown of pollutants. The objective is to develop predictive models to identify operational risks early, enhancing treatment efficiency and optimizing resources like chemicals, bacterial cultures, and aeration systems. Additionally, the study aims to provide early warnings to operators, minimizing reliance on laboratory tests and ensuring optimal conditions for bacteria, leading to better operational performance, cost reduction, and improved water quality ultimately promoting sustainable wastewater treatment. Various deep learning models, including Recurrent Neural Network (RNN), Gated Recurrent Unit (GRU), and Long-Short Term Memory (LSTM), were applied to a two-year real-time dataset with 24 features and 8-hour intervals. Model performance was assessed using process data for training, validation, and testing. The results reveal that GRU-based models effectively predict DO concentration in sludge tanks, achieving an $R^2$ of 0.7, MSE of 0.01, and MAE of 0.07. These soft sensors demonstrate strong potential for system control.

**Keywords**: Machine learning model, Timeseries future forecasting, Wastewater treatment plant, Deep Learning, Dissolved oxygen

## INTRODUCTION

Since water is essential to life, its quality can be greatly impacted by pollution, which can have a negative impact on the sustainable and effective use of water resources [1]. Reusing water and preventing pollution of water sources are the goals of the wastewater treatment plant (WWTP) process [2].

WWTPs use a combination of physical, chemical and biological processes to treat and recycle wastewater [3]. These systems are critical to sustaining the global water cycle and ensuring a clean and safe environment. The increasing complexity of the wastewater treatment process and external factors like weather conditions and wastewater make accurate modeling challenging [3,4]. Traditional methods are often not sufficient to deal with this level of complexity, forcing a transition to digital solutions. [5,6] Recent advances in predictive modeling and data-driven techniques, particularly prediction of water quality parameters, have shown great promise for enhancing WWTP processes [6,7].

Deep learning is effectively used in assessing water quality and optimizing water treatment and management systems. It also provides solutions for water pollution control, improving water quality, and ensuring watershed ecosystem security. These methods are widely applied across various water environments, including surface water, groundwater, drinking water, sewage, and

seawater [8].

Dissolved oxygen (DO) is an important indicator of aquatic ecosystem health. Low DO levels can stress aquatic organisms and lead to mortality. Changes in DO also affect biochemical cycles and nutrient release from sediments [9]. DO concentration is affected by factors like temperature, pH, and other water quality variables. Thus, creating a predictive DO model is crucial for effective water quality management [1]. Researchers are increasingly using data-driven models to predict DO levels. For example, Dong et al. [1] proposes a combined model, which integrates the Savitzky-Golay filter with a Long Short-Term Memory (LSTM)-based network to predict DO water quality time series, offering more accurate predictions than existing methods. Li et al. [10] compared the Recurrent Neural Network (RNN), LSTM, and Gated Recurrent Units (GRU) models for predicting DO in fishery ponds. Their results indicated that GRU outperformed RNN and was like LSTM, with the added benefits of lower energy consumption, cost, and fewer parameters, making it more suitable for practical applications. In another study, multi-step deep learning models for predicting DO were compared. It was found that GRU performed the best, while LSTM showed the lowest performance [11].

This paper presents a detailed comparison of oxygen prediction using multiple deep learning models to identify the most effective approaches to provide operators with an early warning system. By comparing model performances, it provides actionable insights into the use of advanced predictive algorithms in wastewater treatment. This study stands out for its comprehensive approach, as it examines both standalone and hybrid deep learning models unlike previous research that focused only one method. Additionally, studies on oxygen concentration prediction in activated sludge tanks are limited. This research has the potential to serve as a solution for other refineries.

The manuscript is structured into three sections. Section 1 covers materials and methods, including the WWTP description and methodology, which details data collection, the prediction framework, deep learning models, and performance indicators. Section 2 presents the results and discussion, while Section 3 highlights the impact of the study and future research directions.

# MATERIALS AND METHODS

## Wastewater treatment plant description

Wastewater treatment is a comprehensive process that involves the treatment of wastewater using physical, chemical, and biological methods, as shown in Figure 1. In the first stage, coarse and fine screens are used to remove large solid particles, sand and oil from the wastewater. Then, equalization tanks are used to balance the load of the wastewater and achieve physical treatment. Next, API separators separate water and oil based on their density differences. In the coagulation stage, coagulants are added to the wastewater, causing colloidal and suspended solids to aggregate and become ready for flocculation. In the flocculation stage, the wastewater is mixed at an appropriate speed to allow small particles to combine and form flocs that can easily settle. The DAF (Dissolved Air Flotation) process then separates solid or liquid particles based on density differences, performing the opposite of sedimentation. The activated sludge process is a treatment method that uses the metabolic reactions of microorganisms suspended in activated sludge tanks to remove organic pollutants from wastewater. Important process parameters in the activated sludge system include pH, DO, temperature, and sludge age. Finally, the clarification process separates suspended solids from the wastewater through sedimentation, and the process is completed with the discharge of the water. All of these stages ensure that the effluent is discharged without harm to the environment and are controlled by continuous monitoring systems.

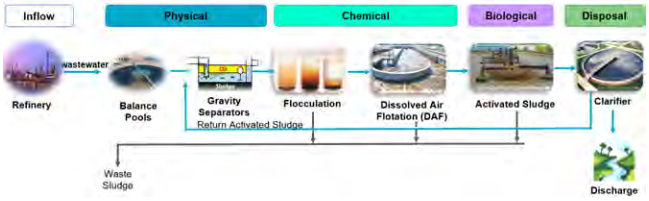

**Figure 1.** Wastewater treatment process.

## Methodology

The methodology employed in this study consists of four main steps in Figure 2 designed to ensure accurate prediction of oxygen concentration in activated sludge tanks. Initially, a two-year time series dataset was collected. Secondly, in the data pre-processing phase, outliers and erroneous values caused by sensor malfunction were removed, and the dataset was normalized. Thirdly, various machine learning and deep learning models were developed and tested to predict oxygen concentration. Finally, the models were evaluated using several metrics to provide a comprehensive understanding of their predictive capabilities.

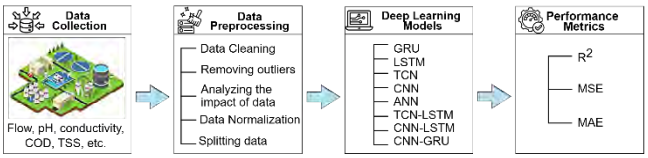

**Figure 2.** Basic structure of the methodological scheme.

## Data Collection and preparation

As mentioned in the process description section, this unit is a complex unit, and many parameters must be

considered simultaneously. As the aim of this study was to estimate the oxygen in the activated sludge tanks, an attempt was made to consider other features that would affect this parameter. The expertise of the process engineers in the plant was used in this process.

The dataset utilized in this study was categorized into two groups: laboratory measurements and flow parameters. The analyzed variables comprised a range of parameters, including temperature, pH, total suspended solids (TSS), sediment, sulfur, $NH_4$-N, nitrogen, Chemical Oxygen Demand (COD), phosphate, conductivity, and unit flow, amounting to a total of 29 variables. These values were collected from various points within the system, including the unit inlet feed, tanks, floater, clarifier, and other interconnected units, ensuring a comprehensive dataset that reflects the contributions and interactions of all relevant processes. The data were collected over a two-year period at 8-hour intervals. The reason behind selecting an 8-hour frequency is that users require foresight into the oxygen levels for the upcoming shift. This enables them to create a proactive action plan based on the predicted values. The actual operational data can't be shared directly for privacy reasons. Principal Component Analysis (PCA) was employed during the preprocessing phase to eliminate irrelevant features. Based on the PCA results and subsequent discussions with process engineers, it was determined that five features should be removed. Thus, five variables were excluded from the dataset, leaving 24 variables for further modeling. Moreover, faulty negative values resulting from sensor errors, were removed from the dataset. Subsequently, data normalization was performed according to Equation 1 to ensure consistency across the features:

$$X_{norm} = \frac{X - X_{min}}{X_{max} - X_{min}}, \quad (1)$$

where X shows the values of each parameter in the data set, $X_{norm}$ is the normalized dataset of X, and $X_{min}$ and $X_{max}$ are the minimum and maximum values in X, respectively. Following the normalization process, the dataset was divided into three subsets: 80% was used for training the models, while 10% was allocated for testing and the remaining 10% for validation.

## Prediction Framework

The prediction framework is based on a time-series forecasting approach, leveraging a 24-hour historical window to predict DO concentration for the following 8 hours, as shown in Figure 3.

As shown in Figure 4, the model architecture is consisted of an input layer that processed normalized data, three hidden layers that captured complex temporal patterns, and an output layer that generated predictions for the next 8 hours.

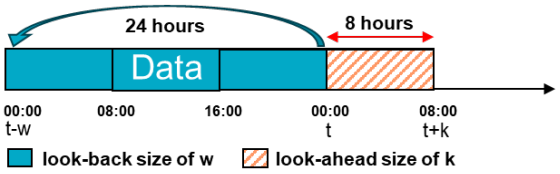

**Figure 3.** Predicting future $k$ time steps by looking back $w$ time steps.

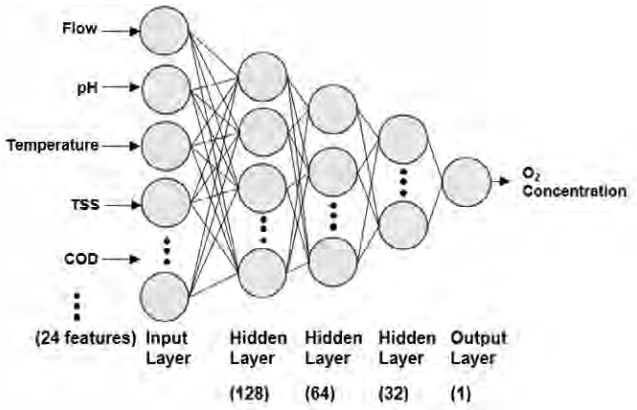

**Figure 4.** The proposed model architecture.

## Deep learning models

In this study, several models and their combinations were applied. These models are GRU, LSTM, Temporal Convolutional Network (TCN), Convolutional Neural Network (CNN), Artificial Neural Network (ANN), TCN-LSTM, CNN-LSTM, CNN-GRU.

GRU and LSTM are the recurrent neural network models, and they have been developed as a solution to the problems in RNN models. Unlike RNNs, there are gates in the models and these gates regulate the flow of information. In LSTM there are an input gate, a forget gate and an output gate. The input gate is selective and decides what information to feed into the model, the forget gate decides what information to forget and the output gate decides what information to feed out. This helps to learn long-term dependencies [12,13]. Unlike LSTM, GRU has only two gates, the reset and update gates. The update gate corresponds to the task of two gates in LSTM, the input and forget gates. The only difference is that the previous gate is reset [13].

Moreover, ANN is known as the equivalent of the human brain. Non-linear relationships between inputs and outputs can be captured with the ANN. The structure of ANN consists of input, hidden and output layers. The architecture of ANN is shown in Figure 5. The input layer consists of the input parameters, nonlinear transformation occurs in the hidden layers and output layer gives a prediction of the desired value [14].

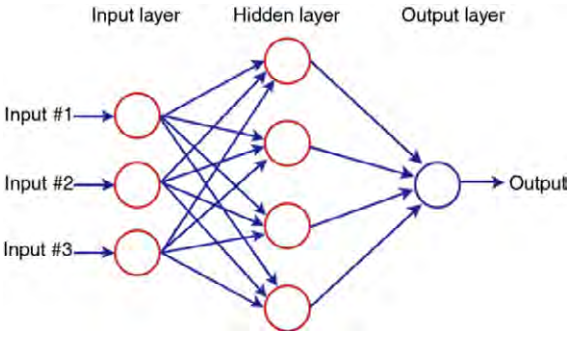

**Figure 5.** ANN architecture.

Other method which is the CNNs are specialized deep learning architectures designed to analyze structured data like images or sequences. They extract patterns and features from input data through convolutional operations, which apply filters to capture local relationships. These networks typically consist of convolutional layers, pooling layers for down sampling, and fully connected layers to produce predictions. By leveraging weight sharing and focusing on localized interactions, CNNs efficiently model complex data while reducing computational overhead [15]. Their capability to automatically learn hierarchical representations has positioned them as a fundamental tool in fields such as computer vision, pattern recognition, and time series analysis. The architecture of this model is shown in Figure 6 [16].

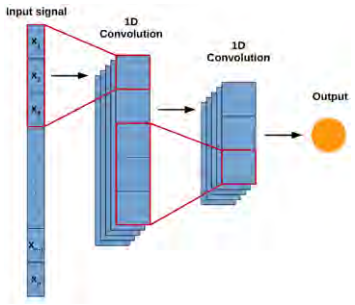

**Figure 6.** Architecture of CNN [16].

The final model is TCN which models sequential dependencies in time series data. The architecture shown in Figure 7 utilizes convolutional layers with dilated convolutions to ensure a large receptive field while preserving causality. Techniques such as activation functions and dropout enhance model performance and prevent overfitting [17].

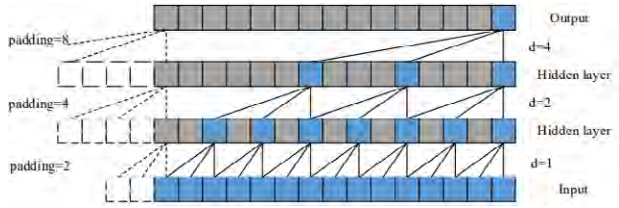

**Figure 7.** Simple TCN representation [17].

In many studies, hybrid models have shown improved performance compared to standalone models. Hybrid deep learning models leverage the advantages of various deep learning algorithms to enhance prediction accuracy [18, 19].

## Model performance indicators

To evaluate the performance of oxygen concentration predictions, three key metrics were employed in the Table 1: The Coefficient of Determination ($R^2$), Mean Squared Error (MSE), and Mean Absolute Error (MAE).

$R^2$, or the Coefficient of Determination, quantifies the proportion of variance in the target variable explained by the model. MSE measures the average squared difference between predicted and actual values. MAE calculates the mean absolute difference between predicted and actual values. As MSE and MAE decrease, and $R^2$ increases, the predictive accuracy of the model improves. These metrics collectively provide a comprehensive evaluation of the model's ability to forecast oxygen concentration accurately.

**Table 1:** Prediction accuracy metrics [19].

| Parameter | Computation |
|---|---|
| $R^2$ | $1-\frac{\sum_{i=1}^{N}(\hat{y}_i-y_i)^2}{\sum_{i=1}^{N}(\bar{y}-y_i)^2}$ |
| MSE | $\frac{1}{N}\sum_{i=1}^{N}(\hat{y}_i-y_i)^2$ |
| MAE | $\frac{1}{N}\sum_{i=1}^{N}\lvert\hat{y}_i-y_i\rvert$ |

where $\bar{y}$ represents the average of y over the N data points, $\hat{y}_i$ denotes the predicted time series of the DO concentration, and $y_i$ refers to the observed time series of the DO concentration.

# RESULTS AND DISCUSSIONS

The primary objective of this study was to evaluate the effectiveness of various deep learning models and their hybrid versions in predicting oxygen concentration in activated sludge tanks. A total of eight models were tested: GRU, LSTM, TCN, CNN, ANN, TCN-LSTM, CNN-LSTM, and CNN-GRU. Based on the performance metrics presented in Table 2, the GRU model demonstrated the best predictive accuracy, achieving an $R^2$ of 0.685, an MSE of 0.01, and an MAE of 0.068.

The results of this study are consistent with those reported in similar studies in the literature. In particular, the GRU model showed superior performance in predicting DO levels. This observation is consistent with the results presented by Li et al. and Qin [10,11], where the GRU model also produced the best results. Both studies highlight the higher accuracy of the GRU model compared to

other DO prediction models. This underscores the robust predictive capability of the GRU model for time series data and its effectiveness as a tool for predicting DO concentrations.

**Table 2:** Statistics of prediction accuracy of the deep learning models for DO concentration.

| Model/Metrics | $R^2$ | MSE | MAE |
|---|---|---|---|
| GRU | 0.685 | 0.010 | 0.068 |
| LSTM | 0.601 | 0.013 | 0.074 |
| TCN | 0.055 | 0.030 | 0.113 |
| CNN | 0.081 | 0.029 | 0.094 |
| ANN | -0.298 | 0.041 | 0.112 |
| TCN-LSTM | 0.403 | 0.019 | 0.086 |
| CNN-LSTM | 0.603 | 0.013 | 0.072 |
| CNN-GRU | 0.001 | 0.032 | 0.109 |

Due to the advantage of hybrid models mentioned in the materials and methods section, hybrid models were also explored in this study. The results indicate that standalone TCN and CNN models showed limited performance in predicting oxygen concentration. However, their hybrid counterparts, CNN-LSTM and TCN-LSTM, delivered notably better results as seen in Table 2. However, based on the results of this study, it can still be concluded that standalone LSTM and GRU models outperform the hybrid configurations in this specific case.

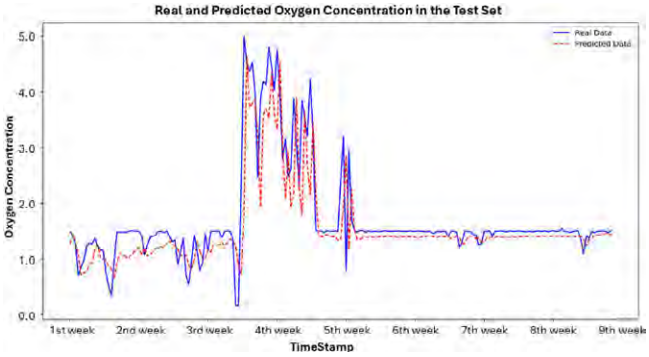

**Figure 8.** Real and predicted DO concentration in the test set.

To further assess model performance, a comparison graph as seen in Figure 8 was included to visualize the GRU model's predictions against actual values in the test dataset. In this graph, the real data is represented by a blue line, while the predicted values are displayed as a red dashed line.

Another noteworthy observation from Figure 9 highlights the model's ability to capture trend shifts in oxygen concentration. Typically, based on the past 24 hours (shown by the orange line), a decrease in oxygen levels would be expected. However, both the real (blue dot) and forecasted (red dot) values show an increasing trend over the next 8 hours. The model's accurate prediction, despite the recent downward trend, highlights its ability to detect changes rather than simply following past patterns. This demonstrates its reliability in real-world applications.

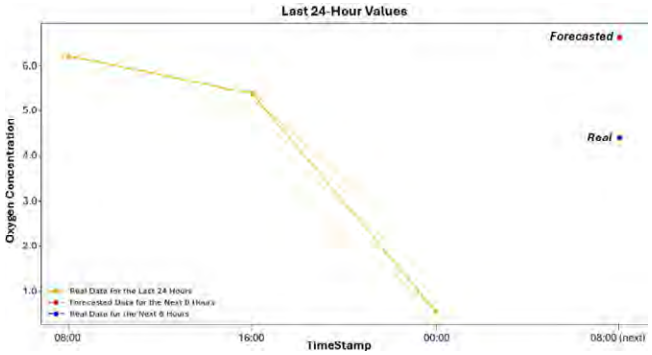

**Figure 9.** Predicted versus real DO concentration for the next 8-Hour forecast.

This study focuses on capturing trends rather than achieving exact predictions. With an $R^2$ of approximately 0.7, the model effectively reflects oxygen concentration patterns, offering valuable insights for decision-making and process adjustments. This level of accuracy is sufficient for practical applications, enabling proactive operational support.

Additionally, random time points were selected to validate the model's predictions for the next 8 hours. These results are summarized in Table 3. The residuals observed during this validation process were low, further confirming the model's reliability.

**Table 3:** Model validation for random time points.

| Time | Residual |
|---|---|
| 16.07.2023 08:00:00 | 0.17 |
| 16.08.2023 08:00:00 | 0.04 |
| 23.08.2023 00:00:00 | 0.18 |

Overall, the results highlight the robustness of the GRU model in forecasting DO concentration. Its strong predictive performance, even under varying scenarios, indicates its potential for practical applications in WWTP systems.

## CONCLUSION

The DO level is of great importance in the WWTP. To ensure microorganisms work effectively, adequate oxygen levels must be maintained. Insufficient oxygen disrupts the biological treatment process and reduces treatment efficiency. Providing sufficient oxygen to microorganisms is vital for biological treatment activities. Therefore, accurately predicting DO levels is critical for optimizing the treatment process and efficiently using resources such as chemicals, bacterial cultures, and

aeration systems. This study offers an innovative solution by delivering accurate and reliable predictions for a complex system based on 24 real-time data points. By utilizing the developed GRU model, which achieves an $R^2$ of 0.7, MSE of 0.01, and MAE of 0.07, it enables operators and process engineers to proactively detect potential operational issues without relying on laboratory results. Future work will focus on continuous monitoring and necessary adjustments, the development of an integrated system to optimize chemical usage, and the adaptation of the model for different types of WWTP in refineries.

## ABSTRACT

Understanding the complexity of human digestion is critical for designing models that serve as valuable research tools for process simulation and prediction. Due to the high cost of medical intervention & recent advancements in *in vitro* digestion protocols, increased demand for inexpensive *in silico* solutions emerges. This study aims to develop a mathematical model that simulates the *in vitro* dynamic Food Digestion SIMulator (FooDSIM) functionalities via a digital twin approach. Ordinary Differential Equations (ODEs) simulate the system as a series of Continuously Stirred Tank Reactors (CSTRs) and describe different regions of human organs (stomach, duodenum, ileum, colon) of the human Gastrointestinal Tract (GIT). Various time horizons were used to investigate the effect of periodic feeding on the dynamic stabilisation of the inherently simulated processes (hydraulics, pH, biochemical interactions between enzymes & substrates, and nutrient absorption). A Polynomial Chaos Expansion (PCE)-based Global Sensitivity Analysis (GSA) was performed to explore causal relationships between input & output variables by performing uncertainty quantification. Results indicate that the system self-stabilizes only after 3-4 feeding cycles. Initially, enzyme concentration increases in the duodenum above the input feed threshold, thus significantly affecting the digestion kinetics in the subsequent reactors. Two cardinal models used for the fitting of enzymatic activity data with pH values indicate satisfactory Mean Squared Error (MSE) scores (<0.0114 for Model 1, <0.0134 for Model 2). Overall, this research highlights the potential of mathematical modeling for simulating digestion and predicting experiment outcomes.

## INTRODUCTION

Human digestion is a complex process that takes place in multiple sites along the human GIT, during which a wide range of digestive fluids and enzymes is secreted. These participate in mechanical and biochemical processes while altering the food matrices to achieve specific goals (e.g. optimal nutrient delivery, local release, and absorption) [1].

However, exploring human digestion is challenging due to the system's complexity. Multiple environmental conditions greatly influence the outcome of human digestion. Inherent variability in samples obtained through *in* vivo studies and limited intervention techniques pose challenging hurdles for exploring human digestion. Therefore, a rise has been given to the development of dynamic *in vitro* digestion systems that offer a simple, fast, and flexible solution to digestion studies.

Besides their advantages, these dynamic *in vitro* systems require laborious and time-consuming experiments. As a response, *in silico* computational approaches are developed to simulate human digestion numerically. That way, predictive information for the *in vitro* systems' inherent digestion processes can be provided. Often, these include highlights not evident during *in vitro* experiments and enable the strategic exploration of research hypotheses [2].

This paper aims to develop a mathematical model for the FooDSIM dynamic *in vitro* simulator by implementing a digital twin approach. The FooDSIM is a laboratory system that consists of four CSTRs connected in series that mimic human digestion. To achieve this, it introduces dynamic processes and reagents to simulate the physiological conditions of digestion. The *in silico* model will simulate the dynamics of these processes by employing a series of ODEs. While both physicochemical and microbial processes aim to be simulated, this paper will primarily focus on describing only physicochemical phenomena.

# MATERIALS AND METHODS

## Dynamic Food Digestion SIMulator – FooDSIM

### General

The exact protocol of development and operation of the FooDSIM laboratory analogue has been previously described by Gaspari et al. (2024) [3]. Thus, within the context of this paper, only some relevant operation features and mathematical formulations that concern the digital twin will be addressed.

The FooDSIM is a computer-controlled, multi-compartmental dynamic *in vitro* simulator that describes major physiological processes within the human GIT. It consists of four Applikon MiniBio bioreactors connected in series that operate as fed-batch or CSTR while representing the stomach, upper/lower small intestine, and colon (Figure 1). Simulated digestive fluids and enzyme solutions are introduced to the respective vessels to simulate the digestion environment. Controlled conditions (37 $^{o}$C, pH, oxygen saturation) and continuous stirring led to homogenous mixing. The feeding process takes place through introducing a Food Model System (FMS), which is fed to the 1$^{st}$ vessel. The FMS dynamically interacts with the digestion environment.

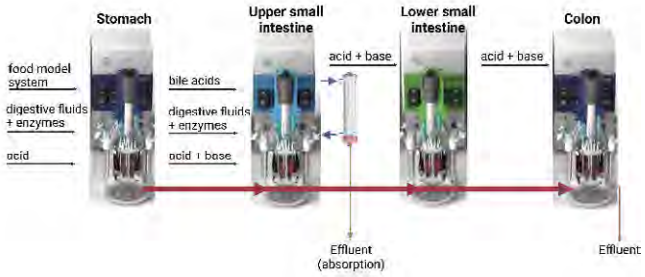

**Figure 1.** Schematic representation of FooDSIM.

### Hydraulics

#### Emptying Rate

The emptying rate of the 1$^{st}$ vessel (stomach) towards the 2$^{nd}$ (duodenum) is described by the Elashoff emptying rate; an exponential equation that describes the stomach emptying process as a function of time.

$$f(t) = 1 - 2^{-\left(\frac{t}{t_{\frac{1}{2}}}\right)^{\beta}}, \quad (1)$$

where $f$ denotes the fraction of content delivered, $t$ signifies the time $(h)$, and $t_{1/2}$ is the half-time of content emptying, equal to 1,16 hours. Moreover, $\beta$ is a shape factor equal to 2 and is retrieved from literature [3].

#### Mass Balance

Every vessel has unique feeding and emptying flow rates. A set of ODEs describes the total mass present in each vessel as a function of time. More specifically:

$$\frac{dM(t)}{dt} = M_{in}(t) - M_{out}(t), \quad (2)$$

where $M\,(g)$ is the mass in every reactor and $M_{in}, M_{out}\,(g/h)$ are the compartment feeding and emptying rates, respectively.

#### pH Values

The $pH$ in each compartment is actively controlled during every subsequent feeding cycle. More specifically, the $pH$ profile of the stomach follows an exponential decrease from its initial value upon the first introduction of FMS. After the end of each feeding cycle, the controller maintains the low $pH$ of the fasted stomach ($pH_{inf}$), until the next feeding occurs. There, the $pH$ of the stomach vessel is increasing only due to the buffering effect of the FMS. Once the maximum $pH$ of the fed stomach ($pH_o$) is reached, the controller is activated again to maintain this $pH$, and acidification occurs during the stomach's emptying process. The $pH$ in the duodenum, ileum, and colon is fixed and constant. In the stomach, Equation 3 describes the acidification process:

$$pH(t) = pH_o + (pH_{inf} - pH_o) * e^{-\lambda * t}, \quad (3)$$

where $\lambda$ is an exponential rate equal to 1.5. Every reset of $pH$ between the acidified and initial state is simulated with a linear increase between the upper and lower $pH$ values and lasts for the same time interval as the feeding process.

### Digestion Kinetics

#### Food Model System - FMS

The FMS used in FooDSIM is an oil-in-water emulsion that consists of carbohydrates, fats, proteins, and salts. Its composition, along with the respective molecular weights, is shown in Table 1. The protocol for its formulation is described by Gaspari et al. (2024) [3].

**Table 1:** Properties of FMS constituents.

| Substrate | Concentration (g/L) | Molecular Weight (g/mol) |
|---|---|---|
| Soluble Potato Starch | 99,00 | 162,14 |
| Sucrose | 37,70 | 342,30 |
| Dietary Fibre | 16,00 | 300.000,00 |
| Corn Oil | 43,00 | 850,00 |
| Whey Protein | 44,40 | 19.328,00 |
| NaCl | 2,50 | 58,44 |

#### Digestion Kinetics

Three enzyme solutions are used to facilitate the enzymatic reactions in FooDSIM, and their main properties are listed in Table 2.

**Table 2:** Properties of enzymes.

| Enzyme | EC Number | Solution Concentration (g/L) | Activity (U/mg) |
|---|---|---|---|
| A-amylase | 3.2.1.1 | 15 | 50 |
| Pepsin | 3.4.23.1 | 100 | 400 |
| Pancreatic A-amylase | 3.2.1.1 | 3.75 | 100 |
| Pancreatic TAG lipase | 3.1.1.3 | 3.75 | 100 |
| Pancreatic trypsin | 3.4.21.4 | 3.75 | 100 |

To simulate the kinetics between available substrates and enzymes in the system, a map of enzyme/substrate specificity is constructed (Table 3).

**Table 3:** Map of enzyme/substrate specificity. The symbol x indicates affinity between the selected enzyme and substrate.

| Substrate | Enzymes | | |
|---|---|---|---|
| | A-amylase | Pepsin | Pancreatin |
| Soluble Potato Starch | x | - | x |
| Sucrose | - | - | - |
| Dietary Fibre | - | - | - |
| Corn Oil | - | - | x |
| Whey Protein | - | x | x |
| NaCl | - | - | - |

Assuming the system is well stirred, all substrates are instantaneously available to all enzymes in each vessel. Thus, the Michaelis Menten kinetics (4) is used to describe interactions between single enzyme/substrate combinations:

$$r(t) = \frac{Vmax * C_s(t)}{Km + C_s(t)}, \quad (4)$$

where, $C_s$ $(g/L)$ is the dynamic substrate concentration, $Km$ $(g/L)$ is the Michaelis-Menten affinity constant, and $Vmax$ $(g/L*h)$ is the maximum reaction velocity for each combination of enzyme and substrate. When different enzymes degrade simultaneously the same substrate, added terms express each one's kinetics.

The parameter $V_{max}$ is defined as the product of enzyme concentration with respective catalytic reaction rate, as shown in equation 5. This relationship directly assumes that all available enzymes in the reactor are characterized by a maximum catalytic reaction rate when saturated with substrate. Thus, the maximum reaction velocity of the enzyme/substrate reaction kinetics can be calculated. The catalytic reaction rate values for each combination of enzyme/substrate are quantified by utilizing the manufacturer's specifications for enzymatic activity and molecular weight of the substrate, as indicated below:

$$V_{max}(t, pH) = k_{cat} * C_{enz}(t) * AI(pH) \quad (5)$$

$$k_{cat} = U_{enz} * c * MW \quad (6)$$

where, $k_{cat}$ $(1/h)$ is the overall catalytic conversion rate of each enzyme, $C_{enz}$ $(g/L)$ is the enzyme concentration in each compartment, $AI$ $(-)$ is the Activity Index for each enzyme as described further below, $U_{enz}$ $(U/mg)$ is the activity of each enzyme and $c$ $(1/h)$ is a unit conversion factor equal to $6*10^{-5}$.

## Enzyme Concentration Balances

Similarly to mass balances, a set of ODEs describes the change of enzyme concentration in every vessel. During the dialysis process, the cut-off limit of the membrane (<5kDa) does not permit the absorption of enzymes. Thus, equation 7 describes the change of enzyme concentration in all reactors except for the 2nd, where dialysis occurs. For that one, a modified ODE (8) accounts for the dynamic accumulation of enzymes, as presented below:

$$\frac{dC_{enz}(t)}{dt} = \frac{M_{in}(t)}{M(t)} * \left(C_{enz,in}(t) - C_{enz}(t)\right) \quad (7)$$

$$\frac{dC_{enz}(t)}{dt} = \frac{M_{in}(t) * \left(C_{enz,in}(t) - C_{enz}(t)\right) + M_{filter}(t) * C_{enz}(t)}{M(t)} \quad (8)$$

where $C_{enz,in}$ $(g/L)$ is the input enzyme concentration in the stomach, and $M_{filter}$ $(g)$ is a term that expresses the mass removed from the compartment due to dialysis.

## Effect of pH on Enzymatic Activity

To express the impact of pH on enzymatic activity within the dynamic framework of FooDSIM, the introduction of an Activity Index $(AI)$ takes place. It is calculated by using 2 modified cardinal models, as described by Baka et al. (2013) [4]. The $AI$ can take values between 0-1 and is defined according to the following relationship:

$$AI = \begin{cases} pH < pH_{min}, & 0 \\ pH_{min} < pH < pH_{max}, & AI_{opt} * \rho_i(pH) \\ pH > pH_{max}, & 0 \end{cases} \quad (9)$$

where $pH_{min}$, $pH_{max}$, $pH_{opt}$ are the lower, upper, and optimal values for measured enzymatic activity, and $AI_{opt}$ $(-)$ is the optimal $AI$ for each enzyme, respectively. The factor $\rho_i$ is expressed by one of two adjusted nonlinear cardinal models, with one having an inflection point.

$$\rho_1(pH) = \frac{(pH - pH_{min}) * (pH - pH_{max})}{(pH - pH_{min}) * (pH - pH_{max}) - (pH - pH_{opt})^2} \quad (10)$$

$$\rho_2(pH) = \frac{(pH - pH_{min})^2 * (pH - pH_{max})}{(pH_{opt} - pH_{min}) * \left((pH_{opt} - pH_{min}) * (pH - pH_{opt}) - (pH_{opt} - pH_{max}) * (pH_{opt} + pH_{min} - 2 * pH)\right)} \quad (11)$$

Parameter estimation for $pH_{min}$, $pH_{max}$, $pH_{opt}$ was performed with least squares regression. Values for pH and residual enzymatic activity were retrieved from the literature for every enzyme. To assess the goodness of fit, the Mean Squared Error (MSE) is used, based on the calculation of the Least Squared Error (LSE):

$$\mathrm{LSE} = \min \sum_{i}^{N} \left(y_{sampled} - y_{(\theta)}\right)^2 \quad (12)$$

$$\mathrm{MSE} = \frac{1}{n_{sampled} - n_{\theta}} * \mathrm{LSE} \quad (13)$$

where $y_{sampled}$ are the measured and $y_{\theta}$ are the predicted values of ρ, based on the predicted parameters θ.Moreover, $n$ signifies the amount of sampled data and parameters.

### Substrate Concentration Balance

The change in concentration of each substrate in every compartment is described using a set of ODEs (14-15). Like equations 7 and 8, equation 14 accounts for substrate concentration in all reactors except for the 2nd one, where equation 15 describes the accumulation of non-absorbable substrates.

$$\frac{dC_s(t)}{dt} = \frac{M_{in}(t)}{M(t)} * \left(C_{s,in}(t) - C_s(t)\right) - r(t) \quad (14)$$

$$\frac{dC_s(t)}{dt} = \frac{M_{in}(t) * \left(C_{s,in}(t) - C_s(t)\right) + M_{filter}(t) * C_s(t)}{M(t)} - r(t) \quad (15)$$

where $C_{s.in}$ $(g/L)$ is the input substrate concentration and $C_s$ $(g/L)$ is the substrate concentration in each reactor.

### Digestion Product Concentration Balance

The concentration of digestion products generated by the degradation of substrates due to enzymatic hydrolysis is described by the following ODE:

$$\frac{dC_p(t)}{dt} = \frac{M_{in}(t)}{M(t)} * \left(C_{p,in}(t) - C_p(t)\right) + r(t), \quad (16)$$

where $C_{p,in}$ $(g/L)$ is the input concentration of digestion products and $C_p$ $(g/L)$ is the concentration of digestion products for each substrate in each compartment.

## Dialysis Absorption

To explicitly simulate the absorption of substrates and digestion products during the dialysis in the duodenum phase, the following set of ODEs (17-19) is used:

$$\frac{dM_{filt}(t)}{dt} = M_{filt}(t) \quad (17)$$

$$\frac{dC_{s,filt}(t)}{dt} = C_{s,filt.in}(t) - C_{s,filt}(t) \quad (18)$$

$$\frac{dC_{p,filt}(t)}{dt} = C_{p,filt,in}(t) - C_{p,filt}(t) \quad (19)$$

where, $C_{s,filt}$, $C_{s,filt,in}$ $(g/L)$ express the current and input value of substrates' concentrations. $C_{p,filt,}$ and $C_{p,filt,in}$ express the current and input concentrations of digestion products in the dialysate.

## Numerical Simulations

### Software and Solver

Numerical simulations for a 7-day operation of FooDSIM were performed with MATLAB R2023a software. The system of ODEs (71 equations) was solved with the ode15s function within 135 s.

### Uncertainty Quantification

#### Global Sensitivity Analysis - GSA

GSA was employed to examine two different scenarios by using the open-source UQLab Sensitivity Analysis Module. Various uniform, independent uncertainty distributions were created for the i) composition of FMS (±10% deviation) and ii) enzyme activity (0-max activity). The proposed uncertainty distribution resembles error during the preparation of the FMS and partial/complete enzyme inactivation, respectively.

Both scenarios quantify the outcome of input uncertainty on the response variables (dialysate digestion product concentration) at an individual level (first order) and by incorporating their interactions (higher order). The sum of them is called total Sobol's sensitivity indices.

#### Polynomial Chaos Expansion - PCE

Due to the high computational cost of the FooDSIM model, the PCE meta-modelling technique is used to approximate the Sobol decomposition. More specifically, PCE estimates the model's response by an infinite sum of orthogonal basis functions, leading to fewer summands in the decomposition for Sobol's indices estimation. A truncated version of this sum of $M$ terms is presented below:

$$f(\theta) = yPCE = \sum_{i=0}^{M} a_i \Phi_i(\theta) \quad (20)$$

$$M + 1 = \frac{(p+d)!}{p!d!} \quad (21)$$

where $\Phi$ is a basis function, a is an unknown coefficient, $p$ is the polynomial order, and $d$ is the number of random inputs [5]. The maximum polynomial degree is defined as 6, and the maximum size of samples is 100 in all cases.

# RESULTS AND DISCUSSION

The results for a 7-day simulation of the FooDSIM Digital Twin are presented in Figure 2. Recurring dilution in all compartments leads to a cyclic steady state of FooDSIM. Among all the processes simulated, the dialysis in duodenum is highlighted for achieving an 80% reduction in mass per feeding cycle. Enzymes are generally not absorbed during this process, and their concentrations spike. This concentration increase irreversibly influences the reaction kinetics in all subsequent vessels.

However, the dynamic change of pH impacts the enzymatic/substrate reaction kinetics, as indicated in

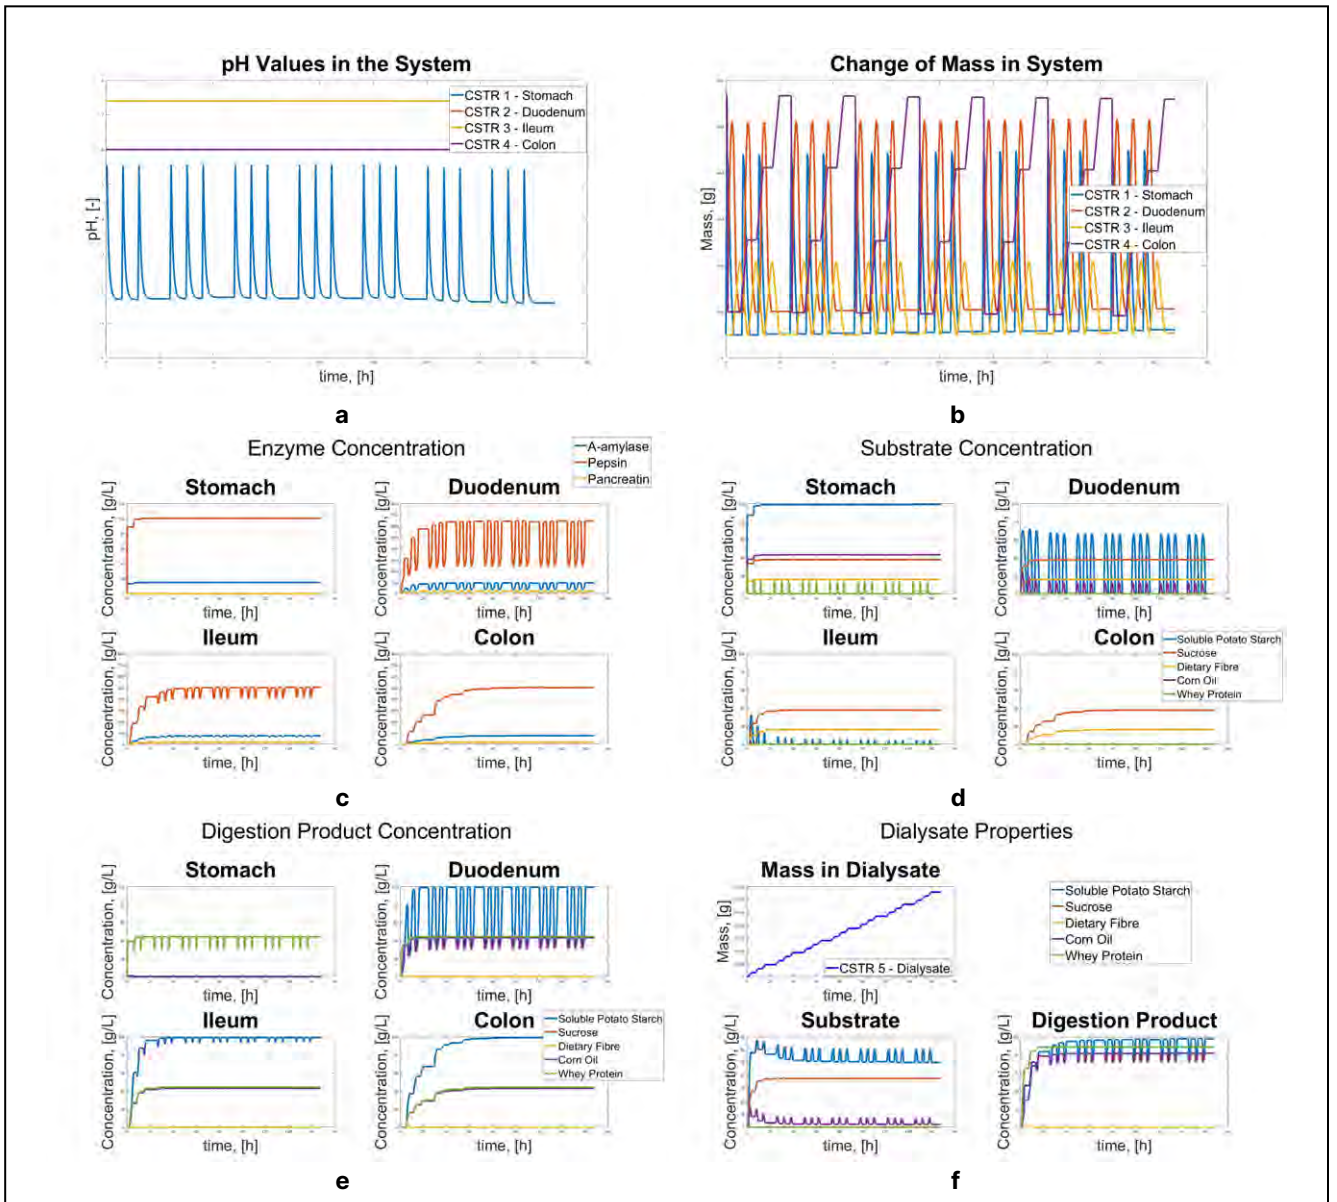

**Figure 2: Quantitative results for 7 days of FooDSIM simulation. a)** Dynamic pH value in FooDSIM, **b)** Dynamic mass change in FooDSIM, **c)** Dynamic change of three enzyme concentrations, **d)** Dynamic change of five substrate concentrations in FooDSIM, **e)** Dynamic change of digestion products in FooDSIM, **f)** Dynamic change of mass, substrate and digestion products concentration in Dialysate**.**

Figure 3. Parameter estimation using the 2 cardinal models on sampled data exhibits satisfactory goodness of fit. Model 1 describes the activity of α-amylase, pepsin, pancreatic α-amylase, and pancreatic lipase (MSE= 0.0091, 0.0114, 0.0091, 0.0027, respectively). Model 2 is suitable for pancreatic trypsin (MSE = 0.0134) due to the inflection point in its formulation. Therefore, substrates susceptible to enzymatic degradation follow a cyclic profile, too.

Due to the inactivation of salivary α-amylase in the acidified stomach compartment, soluble potato starch is partially consumed and broken down by pancreatic α-amylase instead. It should be noted that all substrates are degraded before the colon. The simulation results indicate that it takes at least 3-4 feeding cycles (1-1,5 days) to achieve a steady regime in the system.

Overall, PCE-based GSA results indicate clear connections within the model's input uncertainties with response variable outcomes, as expected. Total Sobol's indices do not indicate interferences between input variables. The connection between FMS composition and digestion products demonstrates that reaction kinetics occur only between specific enzymes and their allocated substrates. Lastly, GSA for enzyme activity highlights the relative contribution of α-amylase/ pancreatin to degrading soluble potato starch.

## CONCLUSIONS

Overall, the FooDSIM Digital Twin provides predictive information that emerges from many parallel physicochemical processes. Its white-box structure permits direct inference and modification of its degrees of freedom. One of the most important outputs is the necessity for at least 3-4 feeding cycles for the system to reach a cyclic steady state regime. This information was hidden and is a critical finding for designing *in vitro* experiments with FooDSIM. Results before the stabilization point could have high inherent variability. The dynamic FooDSIM Digital Twin leads to insights on long-term digestion-related effects. Overall, this model provides a clear view of the physicochemical processes within FooDSIM, and its validation with *in vitro* experiments is a future step.

## ABSTRACT

Effective prediction of nutrient demands is crucial for optimising microalgae growth, maximising productivity and minimising the waste of resources. With the increasing amount of data related to microalgae cultivation systems, data mining and machine learning models to extract additional knowledge have gained popularity. In the development of such models, a data preprocessing stage is necessary due to the poor data quality. At this stage, cleaning and outlier removal techniques are employed to eliminate missing data and outliers, respectively. Afterwards, data splitting and cross-validation strategies are employed to ensure that the models are trained and evaluated with representative subsets of the data. Principal component analysis is also applied to simplify complex environmental datasets by reducing the number of features while retaining as much information as possible. To further improve prediction capabilities, ensemble methods are incorporated, leveraging multiple models to achieve a higher overall performance. Stacking, a popular ensemble technique, is used to combine the outputs of individual models into a single meta-model. The application of these machine learning methods has been demonstrated using a dataset acquired from the cultivation of the microalgae *Dunaliella* in a flat-panel photobioreactor. The results have shown that the data mining workflow, in combination with different machine learning models, was able to describe the nutrients' requirements enforcing good performance of microalgae *Dunaliella* β-carotene production in the carotenogenic phase.

**Keywords**: Machine Learning, Data Mining, Microalgae Cultivation, *Dunaliella* carotenogenesis.

## INTRODUCTION

The use of data mining techniques and machine learning methods is rapidly increasing due to the need of extracting meaningful insights from large datasets. Data mining (DM) focuses on discovering patterns, trends, and valuable knowledge from the data, while machine learning (ML) develops algorithms that enable machines to improve at a task by learning from data without explicit programming [1]. In the DM process, various techniques are typically employed to uncover the underlying structure of data. However, when prediction of new instances is also crucial, ML algorithms are embedded within DM workflows to develop different models. This integration allows for more robust and accurate analysis, enhancing the overall capability of the DM process [2].

Various studies are found in the literature applying DM and ML methods to uncover valuable insights from large datasets on microalgae systems [3–5]. In this work, the application of these methods is demonstrated using a dataset obtained from the cultivation of the microalgae *Dunaliella* in a flat-panel photobioreactor (FP-PBR). This microalga is known for its ability to accumulate large amounts of carotenoids, with β-carotene being the most predominant. The high concentrations of this carotenoid change the colour of microalgae cells from green to orange. For the induction of β-carotene accumulation, *Dunaliella* cells should be exposed to certain growth

conditions, often also referred to as carotenogenic conditions, which are characterized by high salinity and light intensities, and limited nitrogen [6,7].

The main advantages of using FP-PBR systems to cultivate *Dunaliella* microalgae are their high productivity and uniform light distribution, employing narrow panels to achieve high area-to-volume ratios [8]. Therefore, the objective of this study is to develop ML models capable of predicting the nutrient requirements necessary to achieve good performance in the production of *Dunaliella* microalgae during the carotenogenic phase, for β-carotene production, in a FP-PBR system. This paper delves into the methods, where it is described the data preprocessing stage followed by the approach used for model development. The results section presents a comparative analysis of the different ML models, describing their evaluation metrics. Finally, the paper concludes by summarizing the key findings and highlighting their significance for process modeling.

# METHODOLOGY

## Dataset description and data preprocessing

Dataset was acquired from cultivating the microalga *Dunaliella* in a FP-PBR system. Data was selected based on two criteria: increase of the biomass concentration and production of carotenoids. Different features were considered to determine the target variable, i.e., the nutrient requirements of this microalga in carotenogenic phase. These features are described in the next section.

Data preprocessing is a critical step in the DM and ML pipeline, where raw data is transformed into a clean and usable format to improve data quality, ultimately enhancing the performance and accuracy of ML models. Typical preprocessing techniques include data cleaning, outlier detection and removal, feature scaling, feature selection, and dimensionality reduction.

### Data cleaning

Data cleaning involves removing missing data, noise and correcting inconsistencies in the data [9]. In this work, it was decided to remove the observations with the missing values. Although this method is not very effective, its application can avoid the potential biases introduced by imputation methods like mean imputation.

### Outlier detection and removal

Outliers are observations that significantly deviate from the overall distribution, which can skew results and lead to inaccurate model predictions. In datasets with multiple dimensions, one of the methods for detecting outliers is the calculation of the Mahalanobis distance [8], represented by the following equation:

$$D_M = \sqrt{(X-\mu)^T S^{-1} (X-\mu)} \quad (1)$$

In this formulation, $X$ is the observation, $\mu$ is the mean of all observations, and $S$ is the covariance matrix. The Mahalanobis distance follows a chi-squared distribution with degrees of freedom equal to the number of variables in the dataset. By selecting a significance level, a threshold can be determined from the chi-squared distribution. Observations with a squared Mahalanobis distance exceeding this threshold are detected as potential outliers and, therefore, should be removed [10].

### Feature scaling

Feature scaling ensures that all numerical features are on a comparable scale. Without feature scaling, features with larger magnitudes can dominate the learning process, leading to biased or suboptimal model performance [9]. In this work, the z-score normalization was performed, also known as standardization. This approach transforms features to have a mean of 0 and a standard deviation of 1, being represented by the equation:

$$Z = \frac{X-\mu}{\sigma}, \quad (2)$$

where $X$ is the feature value, $\mu$ is the mean, $\sigma$ is the standard deviation.

### Feature selection

Feature selection involves selecting a subset of the most relevant features from a dataset to improve model performance, reduce complexity, and prevent overfitting. One of the feature selection techniques is called minimum redundancy maximum relevance (mRMR). The criterion of maximum relevance ensures that the selected features are highly correlated with the target variable, therefore contributing significantly to the prediction task, while the criterion of minimum redundancy aims to reduce overlap between the selected features, ensuring that each one contributes unique information to the model. By selecting the most relevant features, mRMR helps in the development of models that are more accurate and interpretable [11].

### Dimensionality reduction

When dealing with high-dimensional data, it is essential to perform dimensionality reduction techniques to decrease the number of variables in a dataset while retaining as much information as possible. Among various dimensionality reduction techniques, Principal Component Analysis (PCA) stands out as one of the most widely used and effective methods. PCA transforms the original features into a smaller set of uncorrelated components, called principal components (PC), which capture the maximum variance in the data [10]. The number of PC chosen is an important decision that is often guided by examining the plot of cumulative explained variance ratio versus number of PC, selecting the smallest number of PC that explain most of the data variance [9,12].

## Model development

After data preprocessing stage, this work employed a systematic approach to model development, focusing on the design of different ML models. This approach consists of various stages, including data splitting, cross-validation, hyperparameter tuning, and ensemble learning.

In this work, the DM process and ML methods were programmed in Python 3.12 using the library Scikit-learn 1.4 and constructed using Jupyter Notebook 7.0 from Anaconda Navigator.

### Data splitting

Data splitting consists of dividing the observations into at least training and test sets, where the training set is used for model construction and the test set for model evaluation. In this work, the Kennard-Stone (KS) algorithm was implemented for data splitting with a train-test split ratio of 80:20. The KS algorithm operates by maximizing the Euclidean distance between selected samples, ensuring that the chosen observations are evenly distributed across the feature space [13].

### Cross-validation

Cross-validation (CV) is a method used to evaluate model performance and ensure generalizability to unseen data. One of the most popular techniques is k-fold CV, where the data is divided into k folds, and the model is trained and tested k times, each time using a different fold as the test set. Then, the results from each fold are averaged to produce a more robust estimate of the model performance [9,10]. In this work, it was applied k-fold CV with the training set being divided into 5 folds.

### Hyperparameter tuning

Hyperparameters are settings that control the learning process of a ML model, such as learning rate, number of layers, or regularization strength. Unlike model parameters, which are learned from the data during training, hyperparameters must be predefined and set before the training process. Hyperparameter tuning is the process of selecting the optimal values for a ML model's hyperparameters. One effective method for hyperparameter tuning is GridSearch, which systematically evaluates all possible combinations of predefined hyperparameter values. This method ensures thorough exploration but can be computationally expensive [1,2].

### Ensemble learning

Ensemble learning methods combine multiple models to improve prediction capabilities, robustness and generalization compared to individual models. Stacking, a popular ensemble technique, integrates predictions from several models using a single meta-model, which learns to optimize the final predictions. This approach leverages the strengths of different models, making stacking highly effective for complex problems [1,2].

Other ensemble technique is bagging, also known as bootstrap aggregating. This technique reduces variance by training multiple models on random subsets with replacement. Each model learns independently, and their outputs are aggregated. Bagging enhances stability and reduces overfitting, with random forest being the most common example that applies bagging to decision trees for improved performance [1,9].

## Model evaluation

Evaluation metrics are essential for assessing the performance of ML models. The coefficient of determination ($R^2$) is used to measure the proportion of variance in the dependent variable that is explained by the model [10], being mathematically expressed by the equation below:

$$R^2 = 1 - \frac{\sum_{i=1}^{n}(y_i - \hat{y}_i)^2}{\sum_{i=1}^{n}(y_i - \bar{y}_i)^2} \quad (3)$$

where $n$ is the number of observations, $y$ is the actual output, $\hat{y}$ is the predicted output, and $\bar{y}$ is the mean of the actual output.

Root mean squared error (RMSE) is another evaluation metric, whose value quantifies the average magnitude of errors between predicted and actual values, with lower values indicating higher accuracy [1]. RMSE is calculated according to the equation below:

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2} \quad (4)$$

While $R^2$ provides a relative measure of fit, RMSE gives an absolute measure of prediction errors, making them complementary metrics for model evaluation.

# RESULTS

## Data preprocessing and constructing dataset

In the analysed dataset, the percentage of missing values was around 7 %. After removing such values, the Mahalanobis distance was calculated for each observation to detect possible outliers, as shown in Figure 1.

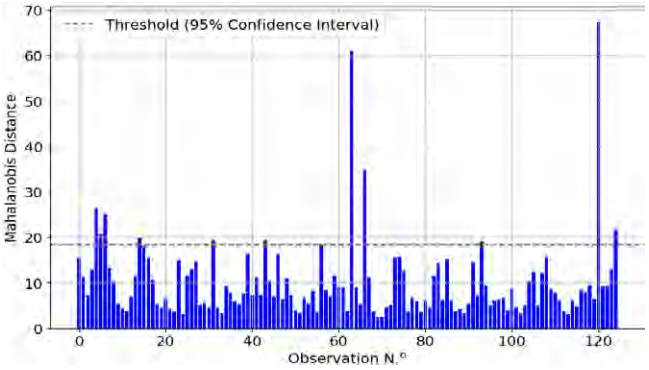

**Figure 1:** Mahalanobis distance for each observation in the analysed dataset.
