We illustrate our proposed method on a case study that examines 253 snapshots of a distillation column, each described by 27 features, including variables such as temperatures, pressures, and flow rates, with the vapor pressure measured in a laboratory as the target variable [14]. The dataset is normalized between -1 and +1. Three training algorithms were applied to this dataset using a 70% training ratio. The first method, NLP training, employing the Adam optimizer [15] in TensorFlow's Keras [16] framework for 100 epochs. The second, MIP training, introducing binary variables to the problem structure, following previously established formulations in Eq.6. The third, SOSX training, using a convex branch-and-bound approach to train the neural network, recording CPU times. All methods used a single-hidden-layer FNN architecture with neurons ranging from 5 to 30, and for SOSX and MIP, piecewise linear approximation of the tanh activation function with 3 segments were implemented. Figure 1 shows the trend for SOSX training CPU times at different number of neurons. Table 1 summarizes the MSE results for both training and test performances. Figures 2 to 7 depict the corresponding trends for training and test performance across different piecewise approximations at varying number of neurons. In these visualizations, "$n$" denotes the number of neurons, while "$p$" represents the number of pieces used in the approximation. The training and test data are divided by a dashed black vertical line called the "train-test split."

The study initially sought to compare the CPU training times of the SOSX and MIP algorithms. However, under default solver settings, including cuts and optimality gap, MIP training failed to converge. As a result, MIP training was terminated once its CPU time equaled that of SOSX training. Consequently, the training and test results for the MIP algorithm are based on these aborted solutions.

A key finding pertains to CPU time. In MIP formulations, CPU time typically grows exponentially with an increase in the number of binary variables. In contrast, the SOSX algorithm, which replaces binary variables, demonstrates a non-exponential increase in CPU time, as represented in Figure 1.

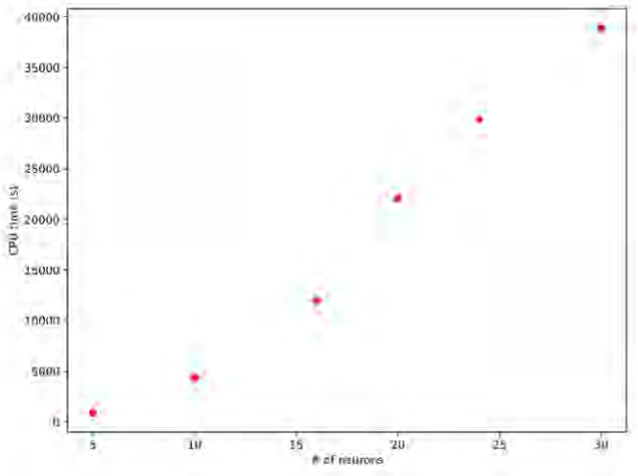

**Figure 1.** CPU times for SOSX training.

Another notable finding from the results is that the SOSX algorithm achieves nearly zero training error without signs of overfitting. The zero-training error is evident in the train split parts of Figures 2-7 as the actual and predicted values overlap. Additionally, in the test splits, SOSX predictions closely follow the actual test value trends, indicating no signs of overfitting. This success is attributed to its specially tailored branching mechanism, which strategically places PWL approximations of the nonlinear activation function. At each iteration, a linear relaxation is solved, and branching progresses based on the location within the PWL function. This approach not only ensures effective network training but also offers a substantial advantage in CPU efficiency.

Figures 2–7 depict the MIP training and test results using green dashed lines. In Figures 2 and 3, which correspond to cases with fewer neurons -specifically, 5-neuron-3-piece (*5n3p*) and 10-neuron-3-piece (*10n3p*)-, MIP training and test results closely follow the actual values compared to cases with a higher number of neurons, although SOSX still outperforms MIP. However, in Figure 4, which represents the 16-neuron-3-piece (*16n3p*) case, no MIP trend is observed, and Table 1 does not contain a corresponding value. This omission occurs because MIP training failed to converge to a feasible solution within the CPU time required by SOSX. In Figure 5, which illustrates the 20-neuron-3-piece (*20n3p*) case, a solution was found, but the MIP training and test results significantly deviate from the actual values. This divergence becomes even more pronounced in Figure 6 for the 24-neuron-3-piece (*24n3p*) case, where MIP training and test results fail to capture the trend altogether. Finally, in Figure 7, representing the 30-neuron-3-piece (*30n3p*) case, no MIP trend is present, mirroring the issue observed in the *16n3p* case. These findings highlight the robustness of the SOSX algorithm, which consistently finds a solution within a timeframe where MIP fails to yield a feasible result. Moreover, SOSX's effectiveness becomes even more evident in cases with a higher number of neurons, indicating its capability to handle more complex scenarios.

An important observation is the difference in test performance between the regular training (NLP) and SOSX algorithms. While SOSX may sometimes underperform due to its reliance on approximations, it still surpasses NLP in 4 out of 6 runs across different number of neurons. The lowest MSE test error was observed in the *24n3p* case, marking a particularly encouraging result. In the test splits of Figures 2–7, this pattern is clearly evident in the trends. Additionally, the actual data exhibit two peaks between data points 200 and 250. For the first peak, NLP predictions overshoot in the *5n3p*, *10n3p*, *16n3p*, and *30n3p* cases, as seen in Figures 2, 3, 4, and 7. Similarly, for the second peak, NLP predictions fall significantly below the actual value in the *24n3p* case, as shown in Figure 6, whereas SOSX predictions closely match the actual values. Overall, SOSX trends remain more aligned with the actual values compared to NLP test performance. These findings indicate that the SOSX algorithm effectively mitigates suboptimal training outcomes by leveraging its convex formulation and robust representation capabilities. Moreover, the benefits of the SOSX algorithm become even more evident in cases with a higher number of neurons.

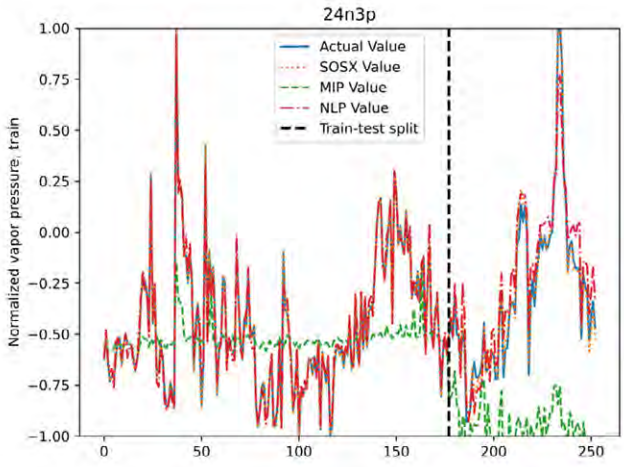

**Figure 6.** Training and test performances for 24 neurons.

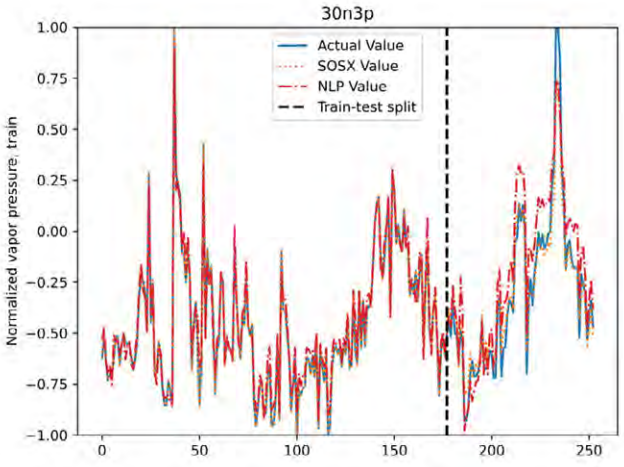

**Figure 7.** Training and test performances for 30 neurons.

The analysis of SOSX CPU times previously focused on how they vary with the number of neurons and piecewise approximations. However, an important question remains: Do these CPU times only apply to the distillation column dataset, or are they statistically significant for datasets with similar dimensionality? To explore this, four datasets are modified to match in dimensionality, ensuring consistency in both dataset size and number of features.

The first dataset is the previously examined distillation column data [14]. The second dataset consists of open simulation data from a wastewater treatment plant, where the target variable represents dissolved oxygen concentration in an activated sludge system [17]. The third dataset comes from a U.S.-based regression study predicting the average annual cancer diagnosis rate based on socioeconomic and demographic factors such as income, population size, age, and race [18]. The fourth dataset is the Boston housing prices dataset, which estimates property values using economic and real estate-related variables [19]. To ensure comparability, all datasets are reduced to eight features using F-value statistics, selecting the variables most strongly correlated with the output. Additionally, the training dataset sizes are standardized to 177 samples across all cases.

Figure 8 presents variations in the logarithm of CPU times across different number of neurons and segmentations in piecewise linear approximations for the four datasets. The plots include 95% confidence intervals, allowing for statistical comparisons between datasets. Since the dataset sizes are adjusted for consistency, their training and test performances should not be directly compared to original benchmarks. Instead, the focus is on determining whether the observed CPU times are statistically significant.

As shown in Figure 8, most data points fall within the 95% confidence interval. Any points outside this range are still close to the boundary and do not qualify as outliers. This suggests that for datasets with the same dimensionality, CPU times remain consistent. Therefore, the CPU times observed in the original analysis are not unique to the distillation column dataset.

## CONCLUSION

This study highlights the efficacy and robustness of the "SOSX" algorithm for convex training of neural networks using PWL approximations. SOSX consistently achieves zero training error while balancing computational efficiency and model accuracy through modifications to the branch-and-bound algorithm. Unlike MIP training, which struggles with convergence for larger problems, SOSX offers superior performance with significantly reduced CPU times.

A comparative analysis reveals key findings. While regular (NLP) training provides reasonable test performance, SOSX outperforms NLP in many cases, such as the *24n3p* configuration, which achieved the lowest MSE test error. Additionally, MIP training struggles with convergence for larger networks, failing to provide feasible solutions within the time frame needed for SOSX.

CPU time analysis shows that SOSX demonstrates greater scalability. Unlike MIP, which exhibits exponential CPU time growth, SOSX displays a more manageable polynomial increase, making it a practical choice for larger-scale problems. In addition, experiments on four different datasets with the same dimensionality show that the CPU times are not dataset specific.

In summary, SOSX offers a robust, efficient framework for training neural networks with piecewise linear approximations. Its ability to achieve zero training error, coupled with its scalability, makes it a promising

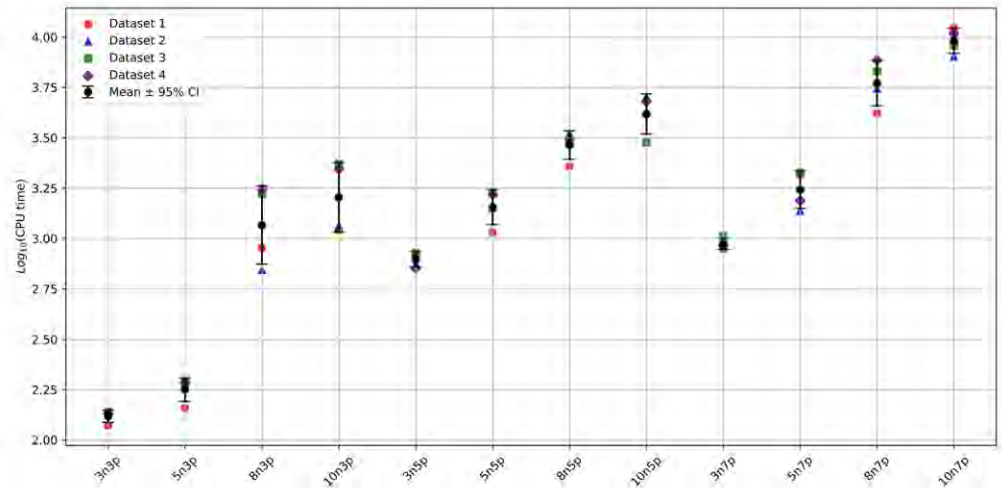

**Figure 8.** CPU times for different datasets.

alternative to methods like NLP and MIP, with strong potential for broader machine learning and optimization applications.

## ABSTRACT

In the chemical industry, soft sensors are deployed to reduce equipment cost or allow for a continuous measurement of process variables. Soft sensors monitor parameters not via physical sensors but infer them from other process variables. On the one hand, the precision of a soft sensors is affected by its architecture, the choice of parametric equations like balances and thermodynamic or kinetic dependencies in the soft sensor model. On the other hand, uncertainty that is inherent to the input variable values propagates through the soft sensor model and impacts the output uncertainty. The latter is affected by the configuration of physical sensors in the chemical process. This paper proposes an approach for the combined optimization of soft sensor architecture and physical sensor configuration. For this purpose, the method combines an automatic extraction of all possible soft sensor architectures from a set of system equations with an uncertainty-based evaluation of sensor configurations. Applied to an in-situ Continuous Stirred Tank Reactor (CSTR), the method is capable of automatically identifying the optimal combination of soft sensor model and physical sensor configuration. It is further discussed, how the explainability of the results can be improved via variance-based uncertainty decomposition, by contributing soft sensor prediction uncertainty to individual inputs or operations along the calculation path.

**Keywords**: Soft Sensor, Sensor Configuration, Uncertainty Analysis, Digraph

## INTRODUCTION

Precise monitoring of variables in chemical processes is essential for ensuring safe and efficient operation, whereby critical process variables can serve as key indicators. Traditionally, these parameters have been measured using physical sensors. However high equipment costs or the inherent difficulty to directly measure certain process variables can necessitate the deployment of soft sensors. These monitor parameters not via physical sensors but model them based on other process variables, often by means of parametric equations like balances and thermodynamic or kinetic dependencies.

A large body of literature is devoted to soft sensor modeling. This includes the preprocessing of available data, selection of suitable features, model choice and training, validation and maintenance of these models. However, available process information provided by a combination of physical sensor configuration and a process model can be insufficient to develop an adequate soft sensor to monitor critical process variables with the required quality. This concern is particularly notable in complex systems such as large-scale brownfield chemical plants, with sparse availability of process information. Suitable process information to create the required soft sensor can be obtained via two approaches: Firstly, adjusting the sensor configuration in a greenfield project or retrofitting additional sensors in a brownfield chemical plant. Secondly, optimizing the process model utilized by the soft sensor. In fact, here the case is made that soft sensor modeling and sensor configuration adjustment should be viewed as one interconnected step, rather than separate tasks.

Altering the sensor configuration of a chemical process requires an estimation of the improvement for the soft sensor prior to the physical sensor deployment. Existing approaches to identify the optimal sensor configuration in a process often convert a determined system of

linearly independent state equations that describe the process in the form of a matrix such as the observability covariance matrix [1], sensitivity matrix [2] measurement error covariance matrix [3] or Fischer information matrix [4]. Based on these matrices, a scalar value is derived, serving as a metric for the useful process information. However, these approaches are mainly concerned with the state of the system rather than individual state variables. Defining an adequate equation system for brownfield chemical plants can be challenging due to information gaps. When focusing on a specific process variable, an equation system describing the state of a process or a sub system of this process is likely unnecessary. Moreover, if enough process knowledge is available to describe relationships between process parameters with equations that result in an overdetermined or locally overdetermined equation system, a determined subset of the equations system must be extracted resulting in process information loss.

Representing process variables as nodes and their relationships as edges in a graph allows to incorporate all available system equations. Sign Directed Graphs (SDG) represent process variables as nodes and their relationships as arcs between these nodes. Arc notations can contain information whether a change in one process variable results in a positive or negative change of another. Mobed et al. [5] utilize SDG to identify the optimal sensor configuration of a CSTR-System. However, due to the qualitative information of the connection between the process variables, the approach is limited to fault diagnosis and does not allow for a continuous modeling of a process variable's values. Bond graphs are a graph representation of the relationships between process variables that include mechanistic knowledge from system equations. In fact, bond graphs can be used for rigorous simulation of a single CSTR [6] or a chemical process [7], but are a less common simulation technique in the field of chemical engineering.

This paper presents an approach that combines an automatic extraction of all possible soft sensor architectures from a set of system equations with an uncertainty-based evaluation of sensor configurations [8]. This allows for the coupled optimization of soft sensor architecture and physical sensor configuration.

## METHOD

A system is given via $m$ state equations $E = \{e_1, \dots, e_m\}$ that describe the relationship between a set of $n$ state variables $v = \{v_1, \dots, v_n\}$. In a determined system, $k = n - m$ state variables are known with $v_{init} = \{v_1, \dots, v_k\}$. For $k > n - m$ the system is overdetermined; for $k < n - m$ the system is undetermined. To infer a target variable $v_t$, multiple calculations paths $M_i$ can be possible relying on different subsets of state variables and state equations. The deviation of state variables from a nominal operation point is given through $d = \{d_1, \dots, d_n\}$, with $d_i$ as a probability density function of $v_i$. Each $v_i$ is observed with uncertainty, which is characterized by a set of probability density functions $f = \{f_1, \dots, f_n\}$. The subset of state variables that are directly measured via physical sensors constitutes the sensor configuration $S_i$, whereby $s = \{s_p, \dots, s_q\}$ with $p, q \in \{1 \dots n\}$.

The goal is to identify the optimal combination of the soft sensor architecture $M_i$ and the physical sensor configuration $S_i$ to monitor $v_t$. Due to the limited number of soft sensor architectures and sensor configurations considered in the use case of this paper, a grid search algorithm is applied scattering $S_i$ against all $M_i$.

### Soft sensor architecture

With a recursive call of the function `comp_tree`, all possible soft sensor architectures $M_i$ to monitor a target variable $v_t$ can be identified:

```
comp_tree(v_r, E, d):
  if eqs is empty or d == 0:
    return branch
  for each e in E:
    if e can be solved for v_r:
      for each variable v_b in solution:
        new_branch=comp_tree(v_b, E\{e},d-1)
        Add new branch to tree
```

The function assesses which equations in a list of equations can be solved for a root variable ($v_r$), constituting a new branch with which the root variable can be inferred. Every branch variable $v_b$ in equations $E$ that can be used to infer $v_r$ becomes a new target variable in the recursive call of the function. To prevent loops, the current equation $e$ must be excluded from the list of potential equations to infer $v_b$. The recursive function call breaks if no usable equations are left or a specified number of recursive functions calls $d$ is reached. Initially, `comp_tree` is called with the target variable as root variable and all $\{e_1, \dots, e_m\}$ as an equation system. The result is stored in the form of a dictionary, as depicted in Figure 1. Whenever a target variable can be inferred via multiple equations, one calculation path is formed for every equation, to convert the calculation paths into executable computational graphs.

### Physical sensor configuration

To evaluate the monitoring capability of a given sensor configuration an uncertainty-based approach for sensor selection is adapted from [8], where an in depths explanation of the deployed algorithm can be found. The precision with which the target variable value can be estimated serves as metric for the monitoring quality.

The uncertainty of leave variables in $M_i$ is dependent on $S_i$. If a leave variable is measured directly via a

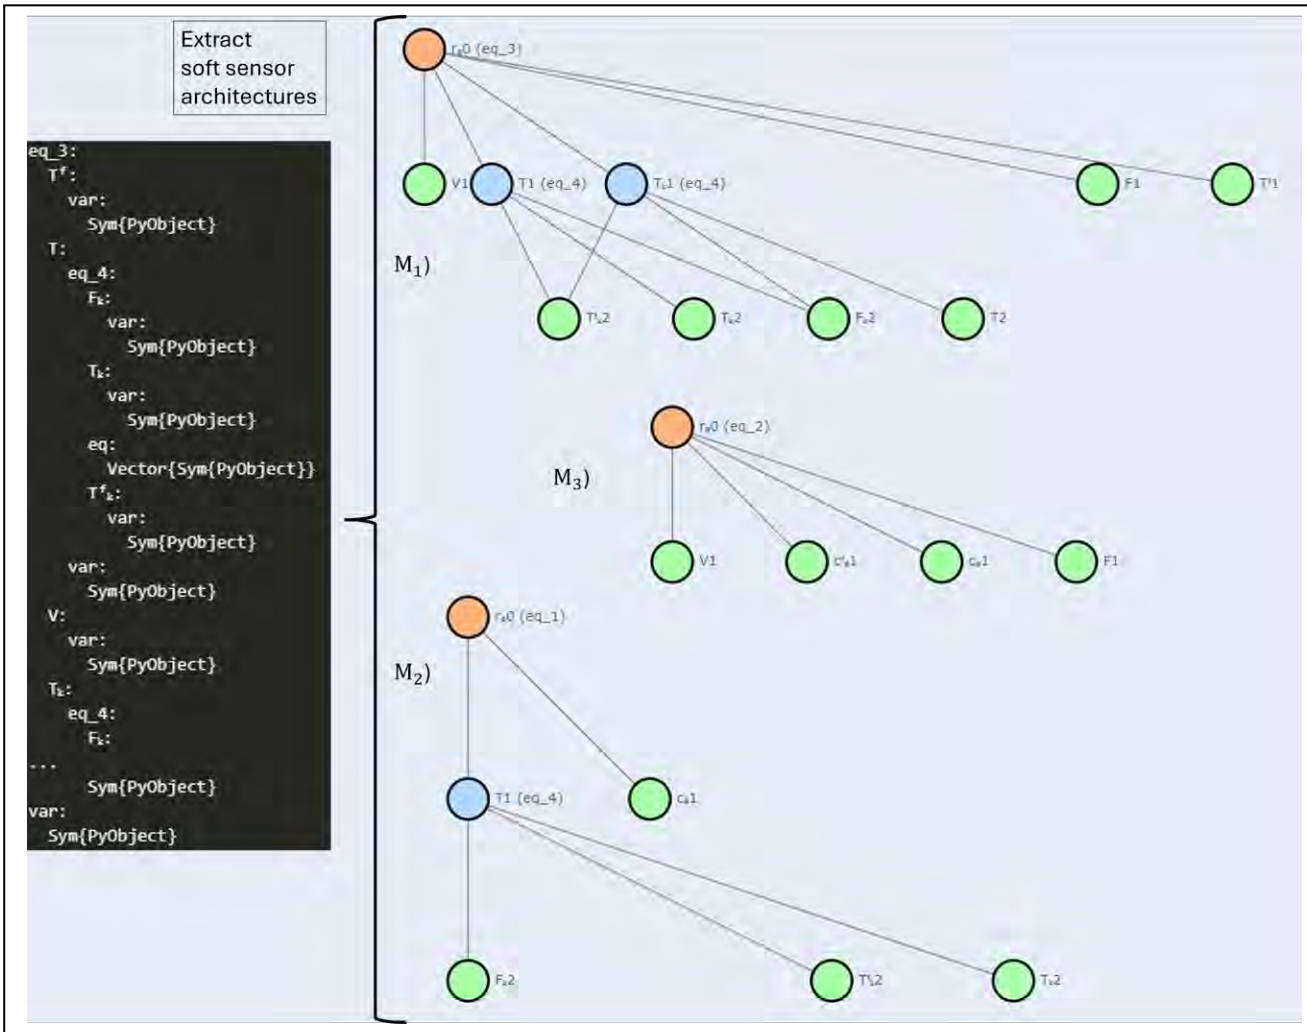

**Figure 1:** Schematic depiction of the automatic extraction of possible soft senor architectures ($M_1$, $M_2$ and $M_3$) given system equations and a targe variable ($r_A$). The recursive call of function `comp_tree` returns a dictionary containing all possible calculation paths that are extracted to form individual models for every soft sensor architecture. The calculation paths are depicted as digraphs. The node colors green, blue and orange indicate a leave, branch or target node, respetively

physical sensor, its uncertainty given through probability density function $f_i$ is expressed via Gaussian sensor error around the nominal operation point. If a leave variable is not measured directly, its uncertainty is expressed via the state variables disturbance $f_i = d_i$ as a best available guess. In a Monte Carlo simulation, all $f_i$ of leave variables are sampled and their uncertainty propagated along the calculation path of $M_i$ yielding an approximation of the ground truth uncertainty of $v_t$.

This sampling-based approach has the advantage of being insusceptible against dependent, non-Gaussian uncertainties. Additionally, the approach promises to incorporate hybrid semi-parametric soft sensors [9], modeling poorly understood effects and dependencies within the process system with data-driven, non-parametric parts.

## USE-CASE STUDY

The proposed algorithm is deployed to an in-situ CSTR, adapted from [3] as can be seen in Figure 2. The reactor feed with substance A has a flow $F$, temperature $T_f$ and concentration $c_A^f$. Within the reactor the concentration $c_A$ of substance A is homogeneous.

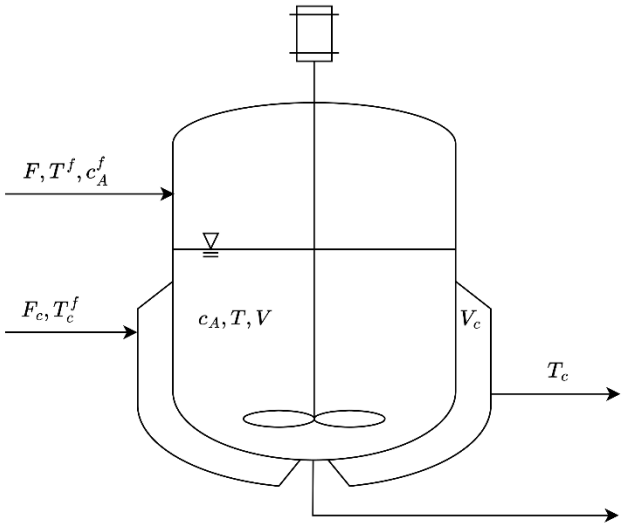

**Figure 2.** Shematic depiction of the in-situ CSTR [8].

The reactor has a volume of $V$ with a homogeneous temperature $T$. The reaction within the CSTR can be described via a first order reaction $A \rightarrow B$ with the reaction enthalpy $\Delta H$, the reaction rate $r_A$, and reaction rate constant $k$. The cooling jacket of the reactor has a volume of $V_c$ containing a coolant flow $F_c$ with coolant inlet temperature $T_c^f$ and coolant outlet temperature $T_c$. For the feed, the fluid density and specific heat capacity are given as $\rho$ and $c_p$ and for the cooling fluid as $\rho_c$ and $c_{p,c}$. Furthermore, the heat transfer area between the reactor and cooling jacket is described by $A$ with a corresponding heat transfer coefficient $h$. The steady-state reactor can be described via the following equations (1)-(4):

$$r_A = k \cdot e^{-\frac{E}{RT}} \cdot c_A \tag{1}$$

$$\dot{c}_A = 0 = \frac{F}{V} \cdot \left(c_A^f - c_A\right) - r_A \tag{2}$$

$$\dot{T} = 0 = \frac{F}{V} \cdot \left(T^f - T\right) + \frac{\Delta H}{\rho \cdot c_p} \cdot r_A - \frac{hA}{\rho \cdot c_p \cdot V} \cdot (T - T_c) \tag{3}$$

$$\dot{T}_c = 0 = \frac{F_C}{V_C} \cdot \left(T_c^f - T_c\right) + \frac{hA}{\rho_c \cdot c_{p,c} \cdot V_c} \cdot (T - T_c) \tag{4}$$

Hereby, the disturbed state variables are $v = \{F, F_c, T^f, T_c^f, V, c_A^f, T, T_c, c_A, r_A\}$ with $v_{init} = \{F, F_c, T^f, T_c^f, V, c_A^f\}$ for the considered sensors. Sensor noise and disturbances are assumed to be independent and normally distributed. The Nominal operation values for the state variables and parameters, the variance of the disturbances, the variance of the sensor noise can be found in [3].

## RESULTS AND DISCUSSION

For the analysis of soft sensor architectures and physical sensor configurations, the reaction rate $r_A$ is considered as target variable. As can be seen in Figure 1, three soft sensor architectures ($M_{1-3}$) can be extracted from the CSTR-equations. Because of the complexity of $M_1$, it is ruled out as soft sensor architecture of choice and $M_2$ and $M_3$ are object of further considerations.

**Table 1:** Sensor configurations $S_{1-3}$.

| **Sensor config** $S_i$ | **Sensor combinations** $s_i$ |
|---|---|
| $S_1$ | $s_1 = \{F, F_c, T^f, T_c^f, V, c_A^f\}$ |
| $S_2$ | $s_2 = \{F, T^f, T_c^f, V\}$ |
| $S_3$ | $s_3 = \{T^f, T_c^f, V\}$ |

The results demonstrate that the choice of sensor configuration significantly influences the monitoring precision of $r_A$. Configuration $S_1$ which deploys all considered sensors $\{F, F_c, T^f, T_c^f, V, c_A^f\}$, provides the lowest uncertainty across both soft sensor models. While being the most expensive, it offers the highest precision in monitoring $r_A$. Configurations $S_2$ and $S_3$ represent reduced sensor setups, with $S_3$ being the most minimalistic, using only $\{T^f, T_c^f, V\}$. The impact of these reduced configurations varies between the two soft sensor models. For $M_2$ , the influence of the sensor configuration is small. On the other hand, $M_3$ shows a significant influence of the sensor configuration changes. Especially reducing the sensor config by the flow sensor for process variable $F$ ($S_2 \rightarrow S_3$) decreases the monitoring precision significantly. As can be seen in Figure 1, the measurement value of $F$ is used as a multiplication factor in the second equation of the equation system which can arguably explain its significance. Nonetheless, the contribution of individual branch nodes or leave node variables to the target variable uncertainty is unknown. The Monte Carlo simulation obtains the uncertainties of all nodes in the calculation path of a soft sensor but yields no information in terms of uncertainty decomposition.

The optimal combination for monitoring $r_A$ is found to be soft sensor architecture $M_3$ with physical sensor configuration $S_1$ under single constraint of target variable value monitoring precision. Additional, constraints like the equipment cost of sensors can be considered [3].

**Table 2:** Soft sensor monitoring precision for $r_A$ in mol/m³/h with combinations of soft sensor architectures $M_{1-2}$ and physical sensor configuration $S_{1-3}$. The optimal combination of soft sensor architecture $M_i$ and physical sensor configuration $S_i$ to monitor $r_A$ is underlined.

| | $M_2$ | $M_3$ |
|---|---|---|
| $S_1$ | 101.1 | <u>26.1</u> |
| $S_2$ | 104.8 | 28.1 |
| $S_3$ | 101.3 | 53.4 |

The choice of soft sensor architecture shows a substantial impact on monitoring precision: $M_3$ consistently outperforms $M_2$ across all sensor configurations. Additionally, the soft sensor architecture has a significant effect on the impact of changes in the sensor configuration. For example, while the change from $S_2 \rightarrow S_3$ results in an insignificant change for $M_2$, the standard deviation of the monitoring precision for $M_3$ almost doubles. This demonstrates the need for a combined examination of changes to the soft sensor architecture $M_i$ and physical sensor configuration $S_i$ in the presented use case.

## CONCLUSION

This paper proposes a combined optimization of changes to the soft sensor architecture and physical sensor configuration. For this purpose, an approach is introduced to automatically extract all possible soft sensors for a critical process variable. It is combined with an uncertainty analysis based approach to sensor configuration adjustments [8]. In an application example, the optimal combination of soft sensor architecture and physical sensor configuration is identified. However, the explainability of the results suffers from the fact that the resulting uncertainty of the critical variable cannot be contributed to individual leave node uncertainties and their interactions. Further work should aim to decompose the uncertainty of target and branch variables within the computational path. Potentially, variance-based uncertainty decomposition can be adapted for this purpose. A key challenge is the likely dependent variable uncertainties along a calculation path which may be accounted for using Shapely effects [10].

## ABSTRACT

Process design deals with the problem of finding the best process set-up, subject to a set of constraints defining the design space (DSp). This selection is guided primarily by economic considerations. Flexibility may also play an important factor in process design, since it embodies "how far" from the design space's bounds are the candidate optimal designs, which in some cases may lead to off-spec products. This work proposes a novel approach for flexibility assessment. In design problems where the design space is constrained by a set of affine bounds, flexibility may be expressed either as the minimum or the maximum distance with respect to the feasible (design) space bounds. For any point in the DSp, the minimum distance provides a good indicator on the minimum flexibility, as the direction that represents the highest risk of violating the constraints. An analogous conclusion can be drawn between the maximum distance and maximum flexibility. These distances can be computed exactly via geometrical approaches, enabling the calculation of a minimum-based and maximum-based flexibility metrics for all points in the DSp. This class of problems are in fact multiparametric programming problems as the goal is to obtain comprehensive flexibility maps, rather than investigating unique points in the DSp. In the case of minimum flexibility, their solutions comprise: (i) a set of critical regions defining a convex hull within the DSp (each associated with a unique nearest bound of the feasible space), (ii) the corresponding optimizer functions (projection at nearest bound), and (iii) objective functions (minimum distance). A novel framework is under development for this class of problems. It enables a new paradigm for flexibility assessment, which can be applied to design problems of any dimension. Complexity is significantly reduced in comparison with the classic multiparametric programming approaches, since only a limited number of active sets need to be considered during solution calculation.

**Keywords**: Process Design, Flexibility, Multiparametric Programming

## INTRODUCTION

Process design is inherently complex, often requiring the need for balancing conflicting objectives across different operational levels. Engineers must navigate physical constraints and specifications which delineate the feasible space within which design decisions can be made [1]. Within this context, process feasibility can be defined as the adherence to a set of predefined constraints during operation. To ensure processes designed are capable of adhering to the constraints, a quantitative measure for process flexibility is required. Swaney and Grossmann (1985) [2] initially addressed this by defining the flexibility index problem, which quantifies the ability of a process to operate within the feasible region under uncertainty. The flexibility index problem aims to identify the size of the largest hyperrectangle that can be inscribed within the feasible space. This concept serves as a crucial metric for determining how robust a process design is against variability in operational parameters and external conditions.

Numerous works have built upon the flexibility index problem to solve complex design and operational challenges. For example, Pistikopoulos and Mazzuchi (1990) [3] introduced a stochastic framework for the flexibility index to quantify the impact of multivariate uncertainty distribution on process flexibility. Kabatek and Swaney (1992) [4] proposed an improved branch-and-bound

algorithm to identify how control actions can compensate for the worst-case scenario problems. In recent years, more work has focused on identifying the full feasible space directly – known as design space identification (DSI). Banerjee and Ierapetritou (2005) [5] proposed to use geometrical envelopes (alpha shapes) for DSI based on the feasibility function. Sachio et al (2023) [6] developed three strategies for constructing alpha shapes, integrating process knowledge and data-driven interpolation to reduce computational effort.

To reduce the computational demand from model simulation, several works have proposed to use data-driven approaches to directly approximate the feasibility function. In this way, the design space is represented by the binary classifier function which indicates the feasibility of an input combination. For this, kriging-based surrogate modelling [7], adaptive sampling techniques [8], and artificial neural networks [9] have been proposed to approximate the classifier function. Such approaches are applicable to high dimensions; however, they do not provide a quantitative measure of process flexibility.

This work builds upon existing foundations in design space identification and feasibility analysis. Specifically, we highlight two key aspects: the process-specific nature of flexibility boundaries, which may not align with box-like assumptions, and the need for flexibility metrics that quantify not just the distance to boundaries but also the variation of process flexibility with this distance. To address these challenges, we propose a novel methodology that leverages multiparametric programming (mp) to integrate design space identification with flexibility analysis. To our knowledge, this is the first application of a mp formulation for this combined problem. Additionally, we introduce two types of flexibility metrics to assess constraint sensitivity and the dependency of average process flexibility on boundary proximity.

## METHODOLOGY

In this work, we consider design spaces defined via a set of affine inequality constraints:

$$Ax \leq b \tag{1}$$

where x is the vector of design variables of size n, and where A and b are a constant matrix and vector, respectively, defining the m bounds of the feasible space. It is assumed that Equation 1 defines a closed convex hull. We denote any design x satisfying Equation 1 as θ, and the full set of θ as the design space Θ.

The goal of this work consists of computing the minimum and maximum distances between all θ in Θ and the corresponding points at the bounds of Θ. Each of these distances are directly related to the minimum and maximum flexibilities: the former/latter concerns the nearest/furthest point at the bounds of the design space with respect to a given θ, and represents, in principle, the highest/lowest risk of violating its bounds.

For design spaces formulated as a set of linear bounds as in Equation 1, the nearest point to a given θ is found when a single bound is active; conversely, the furthest point is found at a corner of the design space. A geometrical motivation is depicted in Figure 1.

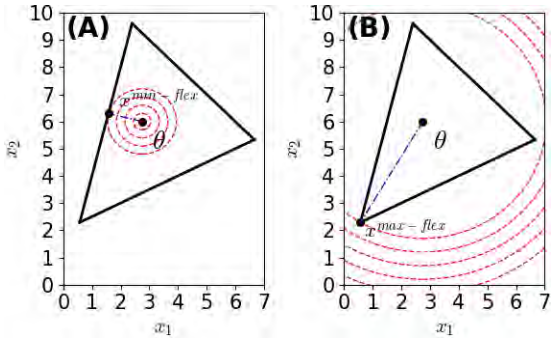

**Figure 1:** 2D illustration of minimum (A) and maximum (B) distances between a given design θ and the bounds of the feasible space as flexibility indicators.

The nearest point to θ (Figure 1A) is obtained by defining the smallest hypersphere centered on θ, such that it includes a unique point - $x^{min-flex}$ – at a single bound of the design space. At $x^{min-flex}$, the hypersphere is tangent to the single active bound, or, in other words, the normal vector connecting θ to $x^{min-flex}$ captures the minimum distance to the bounds. Any combination of the single active bound with one or more bounds of Θ defines a more constrained subspace and cannot contain any point nearer to θ. As a result, the nearest point to any θ at the design space's bounds must conform to this scenario.

The furthest point is obtained by defining the largest hypersphere with center in θ, such that n bounds of Θ are simultaneously active at $x^{max-flex}$ (Figure 1B). By relaxing this condition to include a smaller number of bounds, a less constrained subspace is obtained which necessarily includes points nearer to θ. As a result, the furthest point to any θ must conform to this scenario.

These two extreme scenarios concerning flexibility and a mathematical framework for their calculation are discussed in sequence.

## MINIMUM FLEXIBILITY

Minimum flexibility is defined in this work as the minimum distance between a given θ and the bounds of Θ. The route for its calculation relies on the calculation of all minimum distance functions to each of the m bounds of the feasible space individually. These are defined as the partial minimum flexibilities.

### Partial minimum flexibilities

For design spaces bounded consistently with

Equation 1, the partial minimum flexibilities are computed using simple geometric arguments. Given a design θ and the $j^{th}$ bound of the design space – denoted as $A_j x \leq b_j$ – the nearest point to θ at the $j^{th}$ bound is found via projection:

$$x^{proj,j} - A_j' l^j = \theta \tag{2}$$

$$A_j x^{proj,j} = b_j \tag{3}$$

where $A_j$ is the $j^{th}$ row vector of A and $A_j'$ is the transpose of $A_j$ (column vector), $x^{proj,j}$ is the point at the $j^{th}$ bound of Θ projected from θ along a normal vector to this bound. $l^j$ is a multiplicative factor in Equation 2 defining the depth of the projection. Equation 3, enforces that $x^{proj,j}$ is at the $j^{th}$ bound to obtain the unique nearest point.

Equations 2 and 3 may be written equivalently in a matrix form (Equation 4), and an explicit solution for $x^{proj,j}$ and $l^j$ (Equation 5) is obtained as follows:

$$\begin{bmatrix} I & -A_j' \\ A_j & 0 \end{bmatrix} \begin{bmatrix} x^{proj,j} \\ l^j \end{bmatrix} = \begin{bmatrix} \theta \\ b_j \end{bmatrix} \tag{4}$$

$$\begin{bmatrix} x^{proj,j} \\ l^j \end{bmatrix} = \begin{bmatrix} I & -A_j' \\ -A_j & 0 \end{bmatrix}^{-1} \begin{bmatrix} \theta \\ -b_j \end{bmatrix} \tag{5}$$

The inverse of the symmetric matrix in Equation 5 may be computed numerically or analytically. In this work we focus on the calculation of $l^j$ since it enables a path for minimum distance calculation. For brevity, only the last row of this inverse matrix (at row n+1) is shown:

$$\left[ \begin{matrix} I & -A_j' \\ -A_j & 0 \end{matrix} \right]^{-1} \Bigg|_{n+1} = \frac{[-A_{j,1} \quad \dots \quad -A_{j,n} \quad -1]}{\|A_j\|^2} \tag{6}$$

Since $l^j$ is defined as a multiplicative factor along the direction of the normal vector, it follows that the minimum distance between θ and the $j^{th}$ bound of the design space – $d^{min}_j$ - is obtained from the product of $l^j$ and the norm of $A_j$. Combining Equations 5 and 6:

$$d_j^{min}(\theta) = \frac{[-A_{j,1} \quad \dots \quad -A_{j,n} \quad b_j]}{\|A_j\|} \begin{bmatrix} \theta \\ 1 \end{bmatrix}, j = 1, \dots, m \tag{7}$$

## Computation of minimum flexibility

For any given θ, and consistently with the analysis above, the minimum flexibility - $d^{min}$ - is in fact the minimum of all partial minimum flexibilities. Mathematically:

$$d^{min}(\theta) = \min\{d_1^{min}(\theta), \dots, d_m^{min}(\theta)\} \tag{8}$$

In this work, a solution of this problem for all θ in Θ is required. This is achieved by enforcing the space of parameters via Equation 9 on Equation 8 to deliver a new problem statement. Together, they define a mp problem.

$$A\theta \leq b \tag{9}$$

This formulation is non-conventional in the context of mp, since m candidate optimal objective functions (per each of the m bounds of Θ) are enumerated a priori in Equation 8, instead of a single objective function. This formulation is enabled by the analysis presented earlier, which narrows the optimal candidate active sets for minimum distance calculation to the m single constraint active sets and the corresponding distance functions via Equation 7. The authors are not aware of any algorithm for this class of problems, and the development of a more formal framework will be the subject of future work.

Yet, this problem formulation implicitly suggests a solution strategy as described in sequence. Firstly, we note that explicit expressions for the optimizer functions per optimal active set are not strictly required, though they can be obtained directly from Equation 5. All candidate optimal objective functions of the mp problem are calculated explicitly via Equation 7. To deliver the full solution of this problem it suffices to obtain the critical regions for all m single-constraint active sets. This is achieved via a set of optimality conditions and a set of feasibility conditions. The first kind of conditions results directly from Equation 7: by comparing all partial minimum flexibilities this can be achieved as follows:

$$d_{j1}^{min}(\theta) \leq d_{j2}^{min}(\theta), j_2 = 1, \dots, m, j_2 \neq j_1 \tag{10}$$

where $d^{min}_{j1}$ corresponds to the minimum distance to the $j1^{th}$ bound, which must be lower than or equal to the minimum distances to the remaining bounds. This ensures that the subset of all θ in Θ via Equation 10 yield the minimum distance to this bound. Feasibility conditions must also be defined for critical region construction, which in this case match the bounds of Θ.

# MAXIMUM FLEXIBILITY

Maximum flexibility is defined in this work as the maximum distance to the bounds of the design space for any given θ. The individual distances to all corners of Θ are the relevant candidates for the maximum flexibility, which are defined as the partial maximum flexibilities.

## Partial maximum flexibilities

Given a design θ and the $k^{th}$ corner of the design space – denoted as $\theta^{c,k}$ – the distance between them is computed trivially using the Euclidean norm:

$$d_k^{max}(\theta) = \|\theta - \theta^{c,k}\|, k = 1, \dots, t \tag{11}$$

where t denotes the total number of corners of Θ, which must be computed beforehand. For convenience the square of the partial maximum flexibilities is also presented below, where θ′ denotes the transpose of θ:

$$\left(d_k^{max}(\theta)\right)^2 = \theta'\theta - 2\theta'\theta^{c,k} + (\theta^{c,k})'\theta^{c,k}, \quad k = 1, \dots, t \tag{12}$$

## Computation of maximum flexibility

For any θ, the maximum flexibility - $d^{max}$ - is the

maximum of all partial maximum flexibilities:

$$d^{max}(\theta) = \max\{d_1^{max}(\theta), \dots, d_t^{max}(\theta)\} \quad (13)$$

By combining Equations 9 and 13 a mp problem is defined: it must deliver the maximum distance to the bounds of Θ for all θ in Θ. Similarly to the case of minimum flexibility, the candidate optimal objective functions for each of the t corners are enumerated explicitly in Equation 13. To solve this problem, it suffices to compute the corresponding critical regions. The feasibility constraints are the bounds of Θ (Equation 9), and the optimality constraints are defined conceptually as follows:

$$d_{k1}^{max}(\theta) \geq d_{k2}^{min}(\theta), k_2 = 1, \dots, t, k_2 \neq k_1 \quad (14)$$

where $d^{min}_{k1}$ corresponds to the maximum distance between θ and the $k1^{th}$ corner, which must be greater than the distance to all remaining corners of Θ. This would define a non-linear analytical statement for critical regions construction consistently with Equation 11; to restore linear dependence on the definition of critical regions, it suffices to use the square of the distance functions, enabling a fully equivalent, and more convenient condition (square terms θ'θ cancel each other):

$$\theta'\theta - 2\theta'\theta^{c,k1} + (\theta^{c,k1})'\theta^{c,k1} \geq \theta'\theta - 2\theta'\theta^{c,k2} + (\theta^{c,k2})'\theta^{c,k2},$$
$$k_2 = 1, \dots, t, k_2 \neq k_1 \quad (15)$$

# RESULTS

To illustrate the calculation of the minimum and maximum flexibility maps, two 2D design spaces are presented next. Some notes on high-dimensional problems are presented at the end of this Section.

## Square

We consider the following square design space:

$$\begin{bmatrix} -1 & 0 \\ 1 & 0 \\ 0 & -1 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} \leq \begin{bmatrix} 0 \\ 1 \\ 0 \\ 1 \end{bmatrix} \quad (16)$$

### Minimum flexibility map

Firstly, the partly minimum flexibilities are calculated for each of the four bounds of the design space:

$$\begin{bmatrix} d_1^{min} \\ d_2^{min} \\ d_3^{min} \\ d_4^{min} \end{bmatrix} = \begin{bmatrix} 1.000 & 0.000 & 0.000 \\ -1.000 & 0.000 & 1.000 \\ 0.000 & 1.000 & 0.000 \\ 0.000 & -1.000 & 1.000 \end{bmatrix} \begin{bmatrix} \theta_1 \\ \theta_2 \\ 1 \end{bmatrix} \quad (17)$$

Secondly, by comparing each of these distance functions (optimality conditions) and incorporating the bounds of the design space (feasibility conditions), the maps of critical regions for this problem are obtained.

**Table 1:** Critical regions for minimum flexibility in first example ($CR^A\theta \leq CR^b$).

| Critical region | Active bound | $[CR^A \mid -CR^b]$ |
|---|---|---|
| 1 | $\theta_1 = 0$ | $\left[\begin{array}{cc\|c} -1.000 & 0.000 & 0.000 \\ 1.000 & -1.000 & 0.000 \\ 1.000 & 1.000 & -1.000 \end{array}\right]$ |
| 2 | $\theta_1 = 1$ | $\left[\begin{array}{cc\|c} 1.000 & 1.000 & -1.000 \\ -1.000 & -1.000 & 1.000 \\ -1.000 & 1.000 & 0.000 \end{array}\right]$ |
| 3 | $\theta_2 = 0$ | $\left[\begin{array}{cc\|c} -1.000 & 1.000 & 0.000 \\ 1.000 & 1.000 & -1.000 \\ 0.000 & -1.000 & 0.000 \end{array}\right]$ |
| 4 | $\theta_2 = 1$ | $\left[\begin{array}{cc\|c} -1.000 & -1.000 & 1.000 \\ 1.000 & -1.000 & 0.000 \\ 0.000 & 1.000 & -1.000 \end{array}\right]$ |

The map of critical regions is shown in Figure 2 (A). The flexibility in the full design space is also plotted as a heatmap (B). For this purpose, a grid of points within the design space were selected and the minimum distances calculated from the solution of the mp problem.

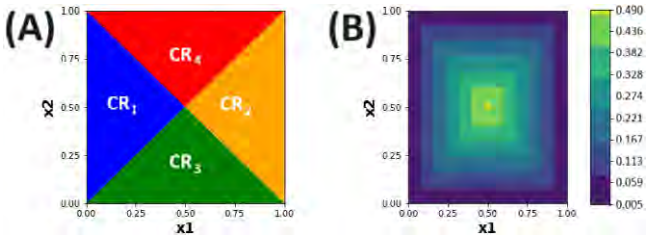

**Figure 2:** Map of critical regions (A) and flexibility design map (B) for minimum design flexibility - first example.

Note that, as expected, all critical regions are in the vicinity of the corresponding nearest bound. This map is useful to identify the nearest bound to any design; yet, by combining this information with the partial minimum distances in Equation 17, the resulting flexibility map (Figure 2B) provides very valuable insight into flexibility. For those points near the bound, the minimum distance is very low; conversely, for those points at the center of the design space, the minimum flexibility becomes increasingly higher. The largest value of the minimum flexibility is found at the center of the box (θ = [0.500, 0.500]), where $d^{min}$ = 0.5 for all active sets.

### Maximum flexibility map

All corners of the feasible space are calculated from the interception of pairs of bounds. These are found at:

$$\begin{bmatrix} \theta^{c,1} \\ \theta^{c,2} \\ \theta^{c,3} \\ \theta^{c,4} \end{bmatrix} = \begin{bmatrix} 0.000 & 0.000 \\ 0.000 & 1.000 \\ 1.000 & 1.000 \\ 1.000 & 0.000 \end{bmatrix} \quad (18)$$

Then, the distance between θ and each of these corners is computed using Equation 11:

$$\begin{bmatrix} d_1^{max} \\ d_2^{max} \\ d_3^{max} \\ d_4^{max} \end{bmatrix} = \theta'\theta \begin{bmatrix} 1 \\ 1 \\ 1 \\ 1 \end{bmatrix} + \begin{bmatrix} 0.000 & 0.000 & 0.000 \\ 0.000 & -2.000 & 1.000 \\ -2.000 & -2.000 & 2.000 \\ -2.000 & 0.000 & 1.000 \end{bmatrix} \begin{bmatrix} \theta_1 \\ \theta_2 \\ 1 \end{bmatrix} \quad (19)$$

At last, the critical regions for all corners are computed via Equations 14 and 15, as listed in Table 2.

**Table 2:** Critical regions for maximum flexibility in first example ($CR^A\theta \leq CR^b$).

| Critical region | Corner | $[CR^A \mid -CR^b]$ |
|---|---|---|
| 1 | $\theta = [0, 0]$ | $\begin{bmatrix} 0.000 & -2.000 & 1.000 \\ -2.000 & 0.000 & 1.000 \\ 1.000 & 0.000 & -1.000 \\ 0.000 & 1.000 & -1.000 \end{bmatrix}$ |
| 2 | $\theta = [0, 1]$ | $\begin{bmatrix} 0.000 & -2.000 & -1.000 \\ -2.000 & 0.000 & 1.000 \\ 1.000 & 0.000 & -1.000 \\ -1.000 & 0.000 & 0.000 \end{bmatrix}$ |
| 3 | $\theta = [1, 1]$ | $\begin{bmatrix} 2.000 & 0.000 & -1.000 \\ 0.000 & 2.000 & -1.000 \\ -1.000 & 0.000 & 0.000 \\ 0.000 & -1.000 & 0.000 \end{bmatrix}$ |
| 4 | $\theta = [1, 0]$ | $\begin{bmatrix} 2.000 & 0.000 & -1.000 \\ 0.000 & -2.000 & 1.000 \\ -1.000 & 0.000 & 0.000 \\ 0.000 & 1.000 & -1.000 \end{bmatrix}$ |

The maps of critical regions and maximum design flexibility are illustrated in Figure 3.

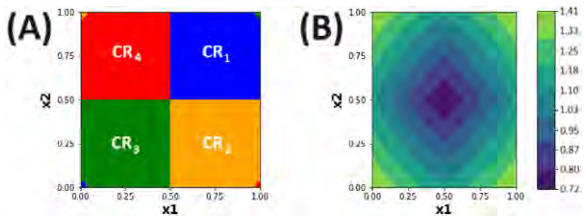

**Figure 3:** Map of critical regions (A) and flexibility design map (B) for maximum design flexibility - first example.

For each corner, the corresponding critical region is in the vicinity of the opposite corner as expected (all corners are highlighted in the same color as the matching critical region in Figure 3A). By combining this information with the partial maximum flexibilities in Equation 18, the maximum flexibility map is delivered as a heatmap in Figure 3B. This is continuous quadratic function of θ. Note that the contours in all critical regions are centered in the opposite, most distant corners. The highest maximum flexibilities are found at the corners, where the maximum distance to the bounds of the feasible space correspond to the opposite corners, as expected ($d^{max} = \sqrt{2}$).

## Hexadecagon

We consider a second 2D example defined via a total of 16 bounds. Its shape will become clear from the analysis of Figures 4 and/or 5.

## Minimum flexibility map

The partial minimum flexibilities were computed for all 16 bounds and the matching critical regions obtained by comparing them. For brevity, these are not listed, and only the maps of critical regions and minimum flexibility are shown in Figure 4.

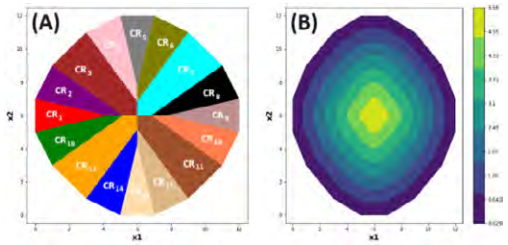

**Figure 4:** Map of critical regions (A) and flexibility design map (B) for maximum design flexibility - second example.

All critical regions extend from the corresponding nearest bound to the boundaries where the partial minimum distances equate those of a neighboring critical region. The minimum design flexibility is null at the bounds of the design space, and as expected increases towards the center of the convex hull. Closer to the center of the convex hull the contours progressively resemble more like a square which is consistent with critical regions 3, 7, 11 and 15 delivering the minimum distance in the vicinity of x = [6.000, 6.000].

## Maximum flexibility map

The partial maximum flexibilities and the corresponding critical regions for all corners were then calculated. For brevity, only the critical region and maximum flexibility maps are shown in Figure 5.

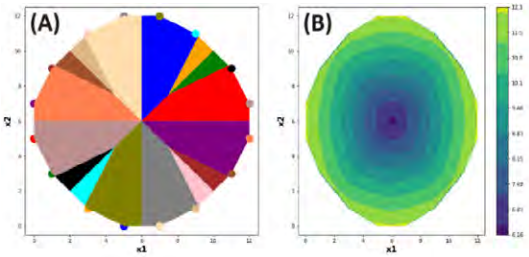

**Figure 5:** Map of critical regions (A) and flexibility design map (B) for maximum design flexibility - second example.

For convenience all corners are highlighted with the same color as the corresponding critical regions. A quick analysis confirms all regions are effectively the most distant to the matching corners. The flexibility map shows that the maximum flexibility increases from the center towards the bounds of the convex hull. Since there are a total of 16 corners, the contours are made of the individual quadratic contours, yielding a more complex, yet fully continuous, map.

## Hypercubes (1D to 10D)

This methodology is particularly attractive for 2D design problems, for which heatmaps can be obtained to provide useful insights on design flexibility. However, it is not constrained by the size of x or even the number of constraints defining the feasible space. The same principles are directly applicable for any design space defined consistently with Equation 1, for which solutions in the format of Equations 17-19 and Tables 1 and 2 are obtained. In this case, for any given θ, the matching critical region must be identified and the minimum or maximum flexibilities determined to provide insights for design.

A total of 10 examples defining boxes between 1D and 10D were defined. These have been defined with the same structure as presented in the first example (Equation 16): restraining the design space between 0 and 1 in the relevant axes. All were successfully solved and validated by the methodology developed.

## CONCLUSIONS AND FUTURE WORK

A new methodology for flexibility assessment in design spaces defined via a set of affine bounds is proposed in this work. The minimum and maximum design flexibilities have been defined as the minimum and maximum distances between a given design and the bounds of the feasible space. This information is useful for design purposes since it quantifies the risk of a given design not complying with the defined design space.

Minimum flexibility is closely related to the distances of individual bounds, while maximum flexibility is associated with the distances to the corners of these convex hulls. Based on this analysis a mathematical framework has been developed to solve problems of this class. Since flexibilities must be computed for all points in the design space, this kind of optimization problem is in fact a multiparametric programming problem. To solve it, the explicit functions for the partial minimum and maximum flexibilities must be calculated, from which the critical regions can be obtained from their comparison. Collectively, these partial flexibilities and the matching critical regions define the flexibility maps, which provide useful information for design. In 2D problems this is particularly relevant since these maps can be shown as heatmaps for effective assessment of flexibility in the full design space.

While the key principles of this methodology have been illustrated in practice, a formal theoretical framework including also the development of algorithms is required. Furthermore, we note that starting with the partial minimum and maximum flexibilities, it is possible not only to calculate the minimum and maximum flexibilities but more broadly, the minimum, average and maximum of these flexibilities, which correspond to a total of 6 potentially flexibility metrics complementing each other. A more detailed examination of the merits and usefulness of these cases will be addressed in our future work.

## ACKNOWLEDGEMENTS

## ABSTRACT

Sustainability is increasingly recognized as a critical global issue. Multi-objective optimization is an important approach for sustainable decision-making, but problems with four or more objectives are hard to interpret due to its high dimensions. In our group's previous work, an algorithm capable of systematically reducing objective dimensionality for (mixed integer) linear Problem has been developed. In this work, we will extend the algorithm to tackle nonlinear many-objective problems. An outer approximation-like method is employed to systematically replace nonlinear objectives and constraints. After converting the original nonlinear problem to linear one, previous linear algorithm can be applied to reduce the dimensionality. The benchmark DTLZ5($I, M$) problem set is used to evaluate the effectiveness of this approach. Our algorithm demonstrates the ability to identify appropriate objective groupings on benchmark problems of up to 20 objectives when algorithm hyperparameters are appropriately chosen. We also conduct extensive testing on the hyperparameters to determine their optimal settings. Additionally, we analyze the computation time required for different components of the algorithm, ensuring efficiency and practical applicability.

**Keywords**: Multi-Objective Optimization, Nonlinear Optimization, Outer Approximation.

## INTRODUCTION

Optimization is an essential mathematical tool for decision making in the chemical industry, enabling solutions of problems in the design, operation, and control of chemical, pharmaceutical and energy processes. Process system optimization is challenging because models of real chemical systems are often complicated, nonlinear and large scale in terms of variables and equations, incorporating both continuous and discrete decisions. The process systems community has been among the leaders in developing powerful theoretical and algorithmic advances in solving the types of challenging optimization problems encountered in decision making for chemical systems [1, 2]. However, most of this effort has been focused on problems containing a single (usually economic) objective [3]. More recently, the chemical industry has come to the forefront as a sector where adopting sustainable practices is essential. To do so requires considering more than just economic drivers for decision making but also include environmental and social objectives during the optimization of chemical engineering process systems.

When considering problems with multiple objectives, there is in almost all cases competition, or tradeoffs, between the different objectives, which can be visualized in a Pareto frontier which presents a set of solutions corresponding to the best one can do in one objective without degrading the others. Multi-objective optimization is an essential tool to generate Pareto frontiers, particularly for problems of two or three objectives [4]. Scalarization approaches, such as the weighted sum or epsilon constraint approach, can be used to generate a set of single-objective optimization problems which rigorously generate Pareto-optimal solutions. This approach enables chemical engineers to simultaneously consider multiple competing objectives and understand their tradeoffs, enabling informed decision-making. However, many disjoint objectives can be thought of as within the purview of "sustainability", and when dealing with more than four objectives (many-objective problems, or MaOPs), a curse of dimensionality emerges. As the number of objectives increases, the computational effort required to solve these problems using rigorous approaches also grows exponentially.

Moreover, visualizing Pareto frontiers in a four or higher dimension space in order to understand tradeoffs and generate a final decision is challenging. Thus, to our knowledge very few works in the process systems literature today formulate and solve high-dimensional MaOP's for sustainable decision making.

To overcome the challenges of objective dimensionality, systematic objective dimensionality reduction for (mixed-integer) linear MaOPs has been previously proposed by our group [5]. For linear problems, optimal solutions always lie on the boundary of the feasible region when the solution is finite. Thus, it is logical to focus the analysis of objective interactions on constraint surfaces. Gradient vectors of the objective functions are projected onto the constraint surfaces. Inner product of the projected vectors and a weighted sum of the constraint interaction strengths are used to determine the total objective correlation strength. Correlation strength is used as edge weight in an objective correlation graph, which consists of nodes corresponding to the different objectives. Finally, a community detection algorithm is applied to identify groups of objectives. For more details about the objective reduction algorithm, please reference our previous works. It has already been successfully used to analyze the correlating and competing nature of a scheduling MaOPs [6]. However, many real-world optimization challenges, particularly in chemical engineering disciplines like process control and system design, are inherently nonlinear. Nonlinear problems introduce additional complexities due to their behavior and interactions, with solutions often not confined to the edges of the feasible region, as well as the potential for locally optimal solutions when the problem is nonconvex, necessitating a more comprehensive approach. Several methods exist for solving mixed-integer nonlinear problems, such as outer approximation [7], generalized benders decomposition [8], and branch and bound [9]. Inspired by these powerful approaches, in this work we extend the dimensionality reduction algorithm to nonlinear MaOPs using an outer approximation-like strategy. The remainder of this paper discusses this approach and is structured as follows. Next, the algorithm for systematically reducing dimensionality of nonlinear MaOPs is described in detail. We then introduce the DZLT5 suite of benchmark MaOP's and discuss why it is an ideal testbed for our algorithm. Then, we present the results of applying our algorithm, making note of the effects of key hyperparameters used in the algorithm. Finally, we provide some concluding remarks and open questions for future work.

# METHODOLOGY

## Nonlinear Dimensionality Reduction Approach

Consider a nonlinear MaOP (Multi-objective Optimization Problem) of the following general form:

$$\min_{x} \{f_1(x), \dots, f_r(x)\}$$
$$s.t. \quad g(x) \leq 0$$

In our previous work [5], we identified that projecting objective cost vectors onto constraint surfaces provided the necessary information for determining groups of correlated objectives. We take a similar approach here, systematically generating approximate linearized constraint surfaces using a first-order Taylor expansion around a feasible fixed point $x^n$ ,as depicted in the equation (1). As additional fixed points are incorporated into the process, the resulting linear constraints progressively provide a closer approximation of the original nonlinear problem when the problem is convex.

$$g(x) \approx g(x^n) + \nabla g(x^n)(x - x^n) \quad (1)$$

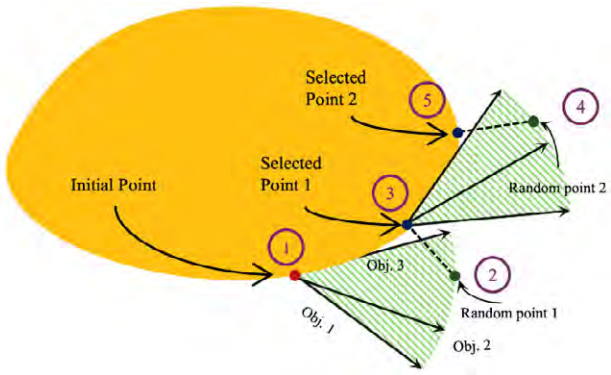

**Figure 1:** How the algorithm choose points. Numbers in the circle shows the sequences of the process.

However, one primary challenge must be addressed to effectively develop this nonlinear method. The challenge involves determining the optimal method for selecting the set of fixed points from which the relaxed linear constraints are derived. We propose a systematic approach that identifies fixed points along the projected gradient descent paths of the objectives. Figure 1 shows how we select the fixed points and the numbers in the purple circle indicated the sequence of the process. It starts from a (set of) initial point $x^n$ on the boundary of $g$. Directions inside the cone of objective gradient vectors indicate directions from the fixed points where the tradeoffs are most likely to occur within this optimization problem, as moving in these directions will improve some objective values. Thus, by strategically selecting new fixed points within the cone of projected objective gradients, new linearized constraints are generated which tend to be concentrated in regions where objective conflicts are most pronounced, that is, along nonlinear

constraints which are active in determining the Pareto frontier.

Unlike linear optimization problems, nonlinear MaOPs can feature single-objective optimal solutions situated within the interior of the feasible region. Therefore, unlike in the linear case, it is crucial to consider the interactions of objectives along constraints where both objective gradients point into the feasible region, which were neglected previouslyWe define a new gradient operator $\nabla f_i(\cdot)_k^*$ , which is equal to the projection of the gradient of objective i onto constraint k if the gradient vector points out of the feasible region, and simply equals the gradient of objective i if the gradient points into the feasible region. Then, for each pair of objectives i and j, the correlation strength along constraint k linearized at fixed point n, $S_{ijkn}$, is:

$$S_{ijkn} = \nabla f_i(x^n)_k^* \cdot \nabla f_j(x^n)_k^* \quad (2)$$

To fully detemine objective correlations, a systematic approach is required for generating new fixed points to use in the generation of linearized constraints. The process for doing so is as follows: first, a random step direction $\Delta$ is chosen that is a conic combination of all projected linearized objectives, such that:

$$\Delta = \frac{\sum_{i=1}^{I} \omega_i \nabla f_i(x^n)_k^p}{\sum_{i=1}^{I} \omega_i} \quad (3)$$

where $\omega_i$ are random values between 0 and 1. A user defined step size parameter $\alpha$ in equation (4) is used to make the fixed point selection more flexible. With this $\Delta$ , a new point (i.e. random point 1 in Figure 1) is obtained: $x^n + \alpha\Delta$. This point may not be feasible to the original problem, so a new feasible point is generated by projecting this point back to the feasible set denoted *X*.

$$x^{n+1} = \text{argmin}_{x \in X} |x - (x^n + \alpha\Delta)|_2^2 \quad (4)$$

In Figure 1, this generates selected fixed point 1 which is the nearest feasible point to the random point 1. This process is repeated applied to the selected fixed points to generate next ones as shown in step 4 and 5 in Figure 1. At each selected fixed point, constraints are linearized and objective correlation strengths are determined using eqn. (2).

Once a sufficient number of fixed points have been generated, we can compile all of the objective correlation strengths into a single value using the same approach as in the linear algorithm:

$$S_{ij}^A = 0.5\left(1 + \frac{\sum_{k=1}^{K}\sum_{n=1}^{N} W_{ijkn} S_{ijkn}}{\sum_{k=1}^{K}\sum_{n=1}^{N} W_{ijkn}}\right) \quad (5)$$

Here, $W_{ijkn}$ is weight that is calculated based on the value of $S_{ijkn}$, taking into account that a competition along a single constraint can cause competition between objectives. We assume that the linearly relaxed constraint space sufficiently approximates the important parts true constraint space for determining objective correlation, enabling the generation of reasonable correlation strengthsThese strengths become the edge weights in an objective correlation graph, which is a fully connected graph where nodes correspond to objectives in the MaOP. Finally, community detection is used on this graph to identify objective groupings for dimensionality reduction.

The nonlinear objective reduction algorithm has two key hyperparameters: the first, as previously described, is the step size to use when generating new fixed points, while the second is the number of fixed points used to determine objective correlation. Determination of the appropriate values to use for each will be assessed using computational experiments that look at, for example, how much new information is added from one additional linearized constraint, and discussed in the results and discussion section.

## DTLZ5($I$, $M$) Problem Set

DTLZ5($I$, $M$) provides MaOPs with a well-defined structure and known objective correlations. Problems from this test set can be of arbitrarily large objective dimensionality It has been widely used to test multi-objective evolutionary algorithms [10], the current state of the art for solving large scale MaOPs. In this problem set, *M* denotes the number of objectives and *I<M* denotes the true dimensionality of the Pareto frontier. All objectives are to be minimized.

$$\min_x \{f_1(x), \ldots, f_M(x)\}$$

$$f_1 = (1+g)\,0.5 \prod_{i=1}^{M-1} cos(\theta_i)$$

$$f_{m=2:M-1} = (1+g)\,0.5 \prod_{i=1}^{M-m} cos(\theta_i) sin(\theta_{M-m+1})$$

$$f_M = (1+g)\,0.5\, sin(\theta_1)$$

$$g = \sum_{i=M}^{M+k-1} (x_i - 0.5)^2$$

$$\theta_{i=1:I-1} = \frac{\pi}{2} x_i$$

$$\theta_{i=I:M-1} = \frac{\pi}{4(1+g)}(1+2gx_i)$$

$$0 \le x_i \le 1, for \ \ldots = 1,2,\ldots,n$$

$$n = M + k - 1$$

All objectives within {f1, . . . , fM−I+1} are positively correlated, while each objective in {fM−I+2, . . . , fM} is conflicting with every other objective in the problem.This

implies that the correct grouping of objectives is to group objectives {f1, . . . , fM−I+1} into a single group, while keeping all remaining I-1 objectives in their own groups. In this work, we choose k = 10, as is consistent with other works using this benchmark problem set. Additionally, the optimal points from the optimization results of individual obejctives of DTLZ5 are used as initial points.

## RESULTS AND DISCUSSION

Our nonlinear dimensionality reduction method has been applied to the DTLZ5 problem set, beginning with DTLZ5(2,3) to assess the feasibility of our algorithm. Our algorithm effectively identified correlated objectives and correctly segmented the multi-objective optimization problem into [f1, f2] and [f3]. This categorization indicates that f1 and f2 are correlated, and both are in competition with f3. This outcome precisely aligns with the specifications defined in the DTLZ5(2,3) problem, confirming the accuracy of our approach.

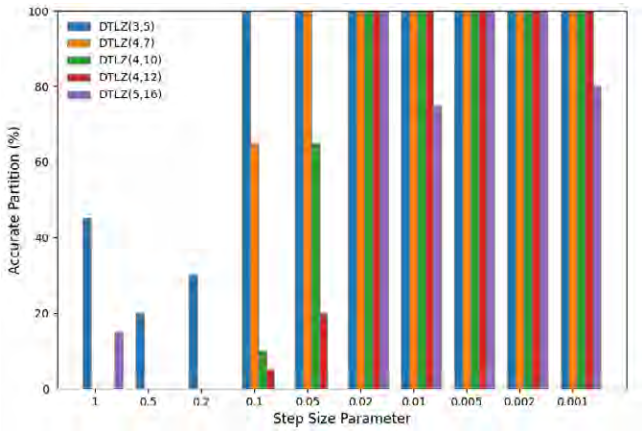

**Figure 2**: Accurate Partition vs Step Size Parameters in different DTLZ5 problems.

However, when testing larger problems such as DTLZ5(3,5) and DTLZ5(4,7), the results are sometimes accurate, but the overall accuracy seemingly decreases as the complexity of the problem increases. This issue may be influenced by the magnitude of the step size hyperparameter used to generate the next selected point. If the step size is too large, it can cause the selected point to fall outside of the region of the feasible space that is active in determining the Pareto frontier, reducing the utility of the linear constraints generated. This effect is consistently observed when selecting fixed points.

To address this, we conducted tests on step size parameters across different DTLZ5 problem sets, as shown in Figure 2. We varied step size parameters from 1 to 0.001 across DTLZ5(3, 5), DTLZ5(4, 7), DTLZ5(4, 10), DTLZ5(4, 12), and DTLZ5(5, 16), using 40 selected fixed points for each objective. Objective groupings for each problem were computed 20 times to mitigate the effects of randomness in step directions. The results show that our algorithm can achieve about 25% or higher accuracy in the DTLZ5(3, 5) tests, even with a large step size parameter. Interestingly, with a step size parameter of 1 in DTLZ5(2, 3), the algorithm still produced high accuracy results, suggesting a high probability of achieving correct results by chance without accurately capturing the conflict zone. When the step size parameter is reduced to 0.1 or lower, the algorithm consistently achieves 100% accuracy, indicating that a smaller step size enhances performance. This trend is also observed in DTLZ5(4, 7), DTLZ5(4, 10), and DTLZ5(4, 12), although the required step size for 100% accuracy decreases as the problem set complexity increases.

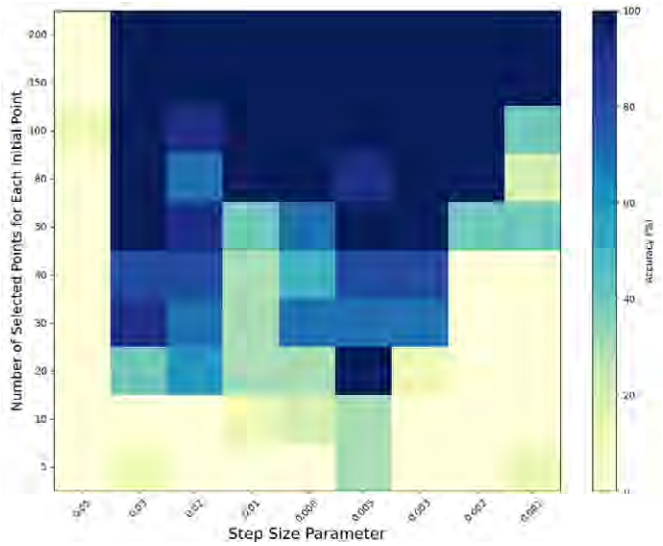

**Figure 3**: Heat map for accuracy of DTLZ(5,20) test results. Each grid in the graph is calculated 10 times with corresponding step size parameters and number of selected points for each starting points.

However, the tests for DTLZ5(5, 16) show relatively lower accuracy when the step size is very small. This suggests that the algorithm's performance can degrade with too small a step size. As the dimension increases, more fixed points are required to move to potential conflict areas. The average random step size direction $\Delta$ also increases with dimensionality. For instance, the average Euclidean distance of random step size direction is about 0.0166 in DTLZ5(3,5), increasing to about 0.0259 in DTLZ5(5,20) with the same step size parameter of 0.03. Therefore, for complex datasets like DTLZ5(5,20), a smaller step size and more selected fixed points are needed to ensure comprehensive mapping of the space and effective location of conflict areas.

To further illustrate the computational performance effected by step size parameter and the number of selected points, a heat map combined with different

selected points and step size parameters are shown in Figure 3. Step size parameter larger than 0.05 would never give a high accuracy results even when 200 selected points are chosen for computation. This matches the conclusion from Figure 2. In this problem set, each variable can feasibly vary between 0 and 1, while from Figure 3, accurate results begin to generate at 0.03. Thus, for this problem it seems a step size of about 3% of the range of the most flexible dimension of the feasible region should be sufficient for most cases in the DTLZ set; however, this finding may be problem-dependent. Moreover, increasing the number of selected points such that the product of the number of steps and step size exceeds the half of longest distances between all the initial points seems to yield good results. A tradeoff clearly emerges similar to that observed in gradient-based optimization: a smaller step size normally will generate higher quality results more reliably, but may require a larger number of iterations, and computational effort, to do so.

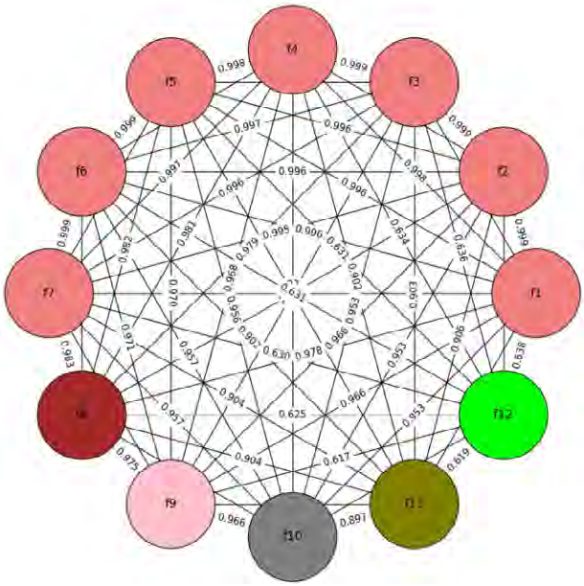

**Figure 4**: Graph results of DTLZ5(6,12). Nodes with the same color indicate that they are in the same group.

After tuning the step size parameter and the number of selected fixed points, the correlating and competing nature of objectives in DTLZ5(5,20) was successfully detected by our nonlinear algorithm. Due to visualization challenges, the graph results of DTLZ5(5,20) are not shown; instead, results from DTLZ5(6,12) are displayed in Figure 4. The lines between different nodes represent the edges indicating the correlation strength between different objectives. Clearly, the largest edge weights, corresponding to pairs of objectives most strongly correlated, occur connecting objectives 1-7, as would be expected for this problem instance.

The time cost of the algorithm for instances of different size was evaluated on a MacBook Air with an M1 CPU and 16GB RAM to assess the algorithm's scalability. In Figure 5, the blue segment illustrates the time spent generating selected points for different optimization problems, while the orange segment indicates the time taken to generate the graph and apply community detection. In this test, each problem includes a total of 240 selected fixed points. Fixed points are generated starting from the optimal solution for each individual objective, which accounts for the slight increase in fixed point generation time as a function of number of objectives. However, the majority of the increase in time as a function of objectives is attibuted to the time required to generate and detect structure in the objective correlation graph. This is consistent with the fact that the number of edge weights calculated is quadratic with the number of objectives, and the community detection algorithm also providing polynomial scaling with number of objectives (graph nodes).

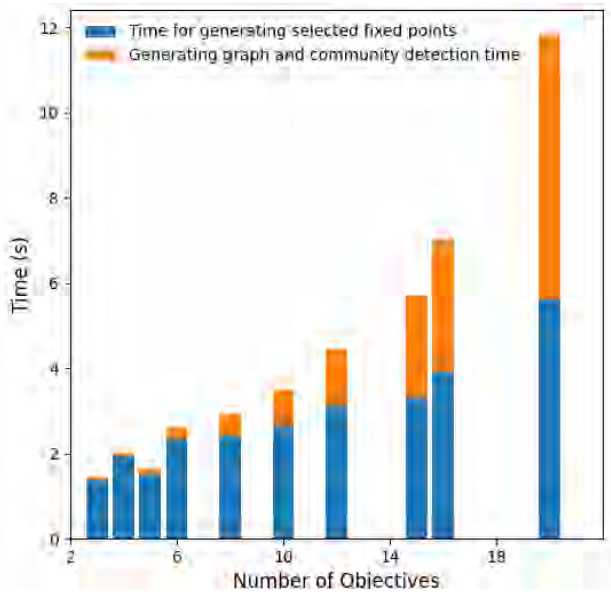

**Figure 5:** Bar graph for time usage of the algorithm with different number of objectives. Total selected points for each of the test is 240.

The relationship between calculation time and the number of selected points is illustrated in Figure 6. To mitigate fluctuations caused by randomness, each data point was calculated 20 times to ensure robustness. As evident, the calculation time increases linearly with the number of selected points, although the slopes vary across different datasets. This trend of increasing slopes corresponds with the observations in Figure 5. Furthermore, the consistent overlap of red and green dots indicates that variations in the step size do not significantly affect the calculation time.

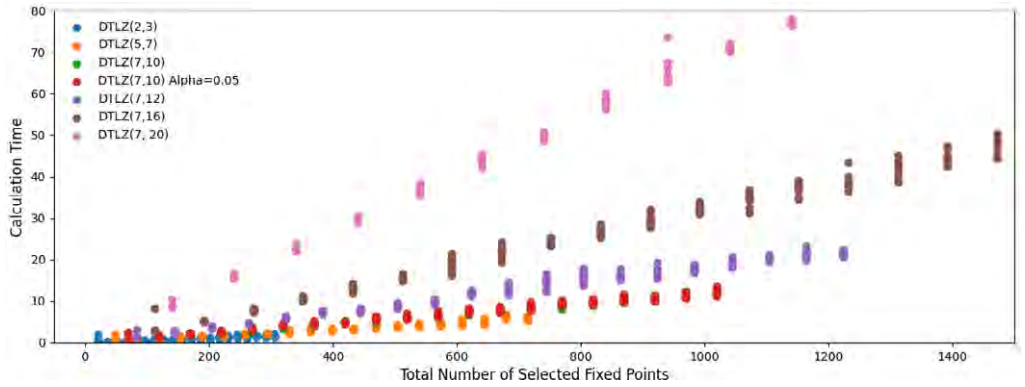

**Figure 6:** Calculation time versus number of selected fixed points in different DTLZ(I,M) problems. Step Size parameter is 0.03 without special annotation.

## CONCLUSION

In this study, we build upon the many-objective dimensionality reduction algorithm developed by our group for linear problems, by introducing a novel algorithm that extends this approach to a nonlinear framework. Utilizing an outer approximation-like method, nonlinear objectives and constraints are converted into linear forms, which are then processed using our existing linear algorithm with minor modifications.

We tested our enhanced algorithm using the DTLZ5(I, M) problem set, a benchmark in many-objective optimization. By carefully adjusting hyperparameters, including the step size and the number of selected fixed points, our algorithm successfully identified the correlating and competing nature of the DTLZ5(I, 20) problem. Additionally, the performance and scalability of the algorithm in terms of computational time is also demonstrated, aligning well with our expectations based on the algorithm's structural design. In the future, we aim to apply this algorithm to problems of practical interest for sustainable decision making in the chemical process industry.

## ABSTRACT

A new method for efficient process development is the direct scale-up from laboratory scale to production scale using mechanistic models [1]. The integration of the Quality by Design approach into this scale-up concept may prove beneficial for a variety of product- and process-related aspects. This paper presents a workflow for the digital twin-supported direct scale-up of processes and process plants, which integrates elements of the Quality by Design methodology. To illustrate the concept, the workflow is implemented for the example of an esterification reaction in a stirred tank reactor. Finally, benefits of the implementation of Quality by Design in the direct scale-up using digital twins regarding the product quality and the process development are discussed as well as its limitations.

**Keywords**: scale-up, digital twin, quality by design.

## INTRODUCTION

The trend towards greater product specialization and shorter product life cycles requires the process industry to shorten the time it takes to establish a process (time–to-process) [2]. The direct scale-up from laboratory scale to production scale allows process development to be accelerated, as there is no time-consuming construction of pilot plants and experiments [1]. Especially if high requirements are set for product quality, ensuring product quality should be considered during the process design phase. For this reason, the application of Quality by Design methodology which is common practice in the pharmaceutical industry could be useful in the development of chemical processes. It promises not only to ensure product quality, but also to deepen process understanding and guarantee process safety [3]. Key elements are the definition of the target product quality and the determination of the design space in which the required product quality is assured [3]. Behavioral models of a digital twin support the implementation of the direct scale-up and enables the incorporation of Quality by Design methods. In this paper a concept for a scale-up workflow is demonstrated by the example of the methyl acetate synthesis in a stirred tank reactor.

## BACKGROUND

### Direct Scale-Up

In direct scale-up, process models are used to transfer the process from the laboratory scale to the production scale without intermediate stages. To ensure the scalability, the laboratory plant should be sufficiently similar to the production plant, for example regarding geometry, mass and heat transfer behavior and hydrodynamics. Data from experiments with the lab scale equipment are used to fit the model for both scales. Later, the process model is adapted further to the operational data of the production plant [1], [4].

### Quality-by-Design

Quality by Design is based on the fundamental idea that uniform and consistent product quality is guaranteed by the design of the process [4]. The methodology follows the ICH guidelines Q8 to Q11. It creates an empirical, data-based product and process understanding. First, the Quality Target Product Profile is defined using Critical Quality Attributes (CQAs). These are physical, chemical or biological properties of a product which need to have an appropriate value to ensure the desired product quality [3]. Second, process parameters and material

attributes of the feed substances that significantly affect the product quality are identified. For these Critical Material Attributes (CMAs) and Critical Process Parameters (CPPs), a permissible range is defined to ensure compliance with the CQAs. Thus, the design space is localized within the knowledge space. According to the found design space, the process is monitored, regulated and adapted [3].

## Digital Twin for Scale-Up

ISO 23247-1 [5] defines a digital twin as a digital representation of an observable manufacturing element, i.e. the process plant and the realized processes. Data transfer between the physical and digital object happens automatically in both directions [6]. According to Mädler et al. [7] the operation models of the digital twin may be divided into two sub-models: The transformation model, whose knowledge lies with the plant operator, and the capability model, which is the knowledge of the plant manufacturer [7]. The transformation model comprises the product and the process model. The product model contains information on the properties of the processed and produced substances. The process model describes the processes empirically or mechanistically. The capability model results from the combination of the process and the resource model, which contains the properties of the equipment.

The foundation for the utilization of digital twins for the direct scale-up is presented by Koch et al. [8]: The product-specific transformation model is shared between the laboratory scale plant and the production scale plant. In combination with the corresponding capability model, this results in the operating model. If suitable models are available, the design space can be determined based on experimental data on laboratory scale and then transferred to production scale to avoid expensive experiments on production scale [9].

# CONCEPT

## Workflow for the Integration of Quality-by-Design in the direct Scale-Up

Figure 1 shows the proposed workflow for a direct scale-up using mechanistic behavioral models of a digital twin, incorporating elements of Quality by Design. First, one or multiple mechanistic models are set up for the equipment on both scales. After defining the Quality Target Product Profile, a Global System Analysis (GSA) is performed to identify which model parameters significantly impact the predictions and contribute substantially to their uncertainty. In addition to this, impactful operating variables are identified to support the later determination of CMAs and CPPs. This is followed by an iteration of model-based design of experiments (mbDoE), execution of laboratory-scale experiments and model adaptation. Optionally, one of several competing models is selected (model discrimination). After the validation of the laboratory scale model, parameters of the transformation model including their uncertainty are transferred from the laboratory scale to the production scale. Similarity considerations result in specific values for further model parameters and operating variables. Afterwards, the model for the production plant must also be validated. CPPs and CMAs are determined with the help of a second GSA. The location of the design space within the knowledge space can be located on the laboratory scale and transferred to the production scale. Finally, the operating model of the production plant is used to optimize the process. The Normal Operating Range is set as a subregion of the design space around the optimal operating point

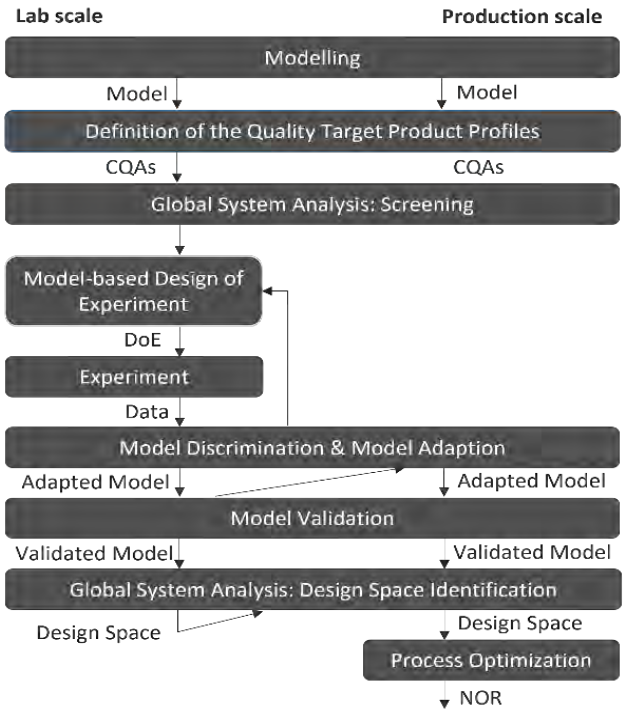

**Figure 1.** Workflow to integrate Quality by Design into a digital twin-supported direct scale-up [10].

# IMPLEMENTATION OF THE CONCEPT

## Introduction of the Use Case

The scale-up concept according to the workflow illustrated in Figure 1 is demonstrated using the esterification of methanol with acetic acid in a stirred tank reactor as an example. The product methyl acetate is used as a solvent for paints or adhesives [12].

$$CH_3OH + CH_3COOH \rightleftharpoons CH_3COOCH_3 + H_2O \quad (1)$$

In the 2 L lab reactor batch experiments are carried out (Figure 2, middle). In contrast, the production reactor

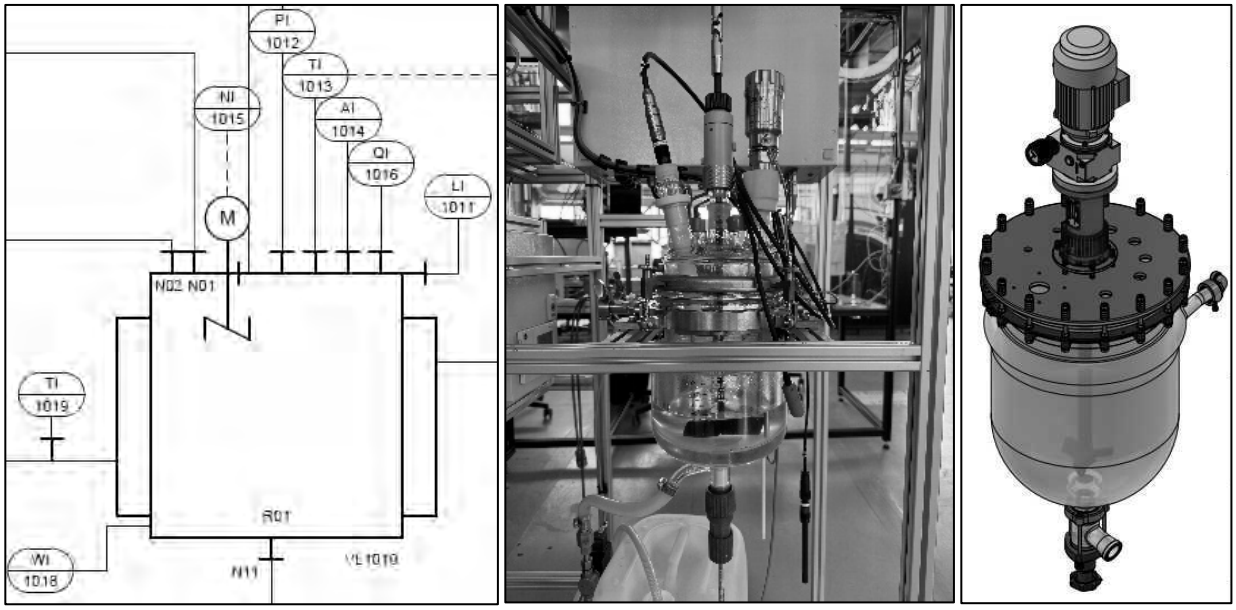

**Figure 2:** P&ID of the stirred tank reactor (left), photo of the laboratory scale reactor (middle) and 3D-model of the production scale reactor (right)

(approx. 50 L) operates stationarily (Figure 2, right).

## Modeling

The reactor is modelled as a cylindrical stirred tank on both scales using the simulation software gPROMS® The mass and energy balance as well as constitutional relationships are set up for this purpose. The kinetic approach for methyl acetate synthesis with the heterogeneous catalyst Amberlyst 15 according to [12] is used (see equation 2). Experimental data from [11] and [12] was also used to validate the simulated behavior in the developed models. Dimensionless numbers such as the Reynolds and Newton number ($Re_{mix}$ and $Ne$) describe the stirring state. To ensure the similarity between the reactors of both scales, common (dimensionless) numbers are used, for instance the volume specific heat transfer area ($A_{spec}$), the specific stirrer performance ($P_{spec}$) or the relation of the height to the diameter of the reactor ($H_{spec}$).

$$r = m_{cat}\,(1.648 \cdot 10^{4}\,\frac{mol}{s\,g}\,e^{\frac{-47.98\frac{kJ}{mol}}{R\,T}}\,x_A x_B - 1.161 \cdot 10^{5}\,\frac{mol}{s\,g}\,e^{\frac{-58.6\frac{kJ}{mol}}{R\,T}}\,x_C x_D) \quad (2)$$

## Definition of the Quality Target Product Profile and GSA for Screening

CQAs are defined in consideration of requirements on the target product quality. The product should contain a minimum molar fraction of methyl acetate ($x_C$) of 1 %. Aiming for an ideal mixture, the Reynolds number $Re_{mix}$ should be higher than $10^4$. As a secondary task, safety requirements are also considered in the CQAs, e.g. the temperature and volume of the reaction mixture ($T$ and $V$) as well as the temperature of the heating fluid ($T_{HM}$). By evaluating scatter plots and variance-based indices resulting from a Monte Carlo simulation, the first GSA shows possible CPPs and CMAs (see Table 1). It also reveals which model parameters are influential on the CQAs and have a high contribution to their uncertainty. For the use case, the activation energies ($E_{A,1}$ and $E_{A,2}$) and the heat transfer coefficient ($k_D$) are found as relevant model parameters as their respective variance-based indices regarding the CQAs exceeded 10 %.

## Experiments, Model Adaptation and Parameter Transfer

By iterating between model-based design of experiments, experiment execution and model adaptation with the maximum likelihood method, the model uncertainty is reduced stepwise as the precision of the model parameters increases. To derive optimal experiments from the model, the D-criterion is used to minimize the variance-covariance matrix of the model parameters. These experiments are simulated with another gPROMS® model with modified parameter values. Afterwards, a normal distributed noise is added on the time series data to represent measurement uncertainties. The reactor model is adapted to fit the resulting experimental data. Model discrimination is not applied in this use case. After that, the model parameters of the transformation model are transferred from the laboratory to the production scale. Further parameters and variables are set for the production

scale model considering similarity between the processes on both scales making sure that the dimensionless numbers equal each other.

## GSA for Design Space Identification and process optimization

A second global system analysis is used to identify CPPs and CMAs for both scales analyzing scatter plots and variance-based indices. A variance-based index of 0 means that the input variable does not affect the output at all while the input variable controls the outcome solely for an index of 1 [13]. If the 1st order variance-based index exceeds 0.1 or there is a clear trend visible in the scatter plot, it is assumed to be a CPP or a CMA. If the total effect is greater than 0.1, it is assumed that the variable contributes significantly to the uncertainty of the investigated CQA. This threshold for the critical value of the variance-based index is set arbitrarily, but the insights resulting out of the analysis of the variance-based indices is reflected in trends visible in the scatter plots.

As Table 1 shows, all CPPs and CMAs that are determined in the second GSA, were already observed as influential operating variables in the screening step. The permissible ranges of the CPPs and CMAs are defined in which the constraints for the QCAs are reached. This reveals the location of the design space within the knowledge space (marked green in Figure 3). A high molar fraction of the educts $x_{A,1}$ and $x_{B,2}$ (CMAs) is needed to reach the target product purity. To guarantee ideal mixing, the stirrer speed $n_{mix}$ (CPP) should be higher than 1 Hz.

Finally, the production process is optimized. In this use case, the yield of methyl acetate relative to methanol should be maximized. Knowing the optimum operating point (marked orange), the Normal Operating Range can be localized (marked light green).

## DISCUSSION, CONCLUSION & OUTLOOK

The proposed workflow was applied successfully to the scale-up of a methyl acetate synthesis in a stirred tank reactor. Although the model presented in the use case has not been validated with real experiments, its predictions show plausible process behaviour.

The integration of the Quality by Design approach into the scale-up of process plants is advantageous in many respects for an effective process scaling. By defining the design space, consistent product quality can be ensured. Furthermore, process safety and robustness are guaranteed. In addition, the Quality by Design methodology deepens process understanding by generating knowledge systematically. This enables a data-based decision about the operating point. Based on this knowledge, the process can be optimized to maximize efficiency and minimize costs [14]. All the advantages are confirmed by results of the use case. The disadvantage of integrating Quality by Design in the direct scale-up is the additional time that is necessary to implement the Quality by Design methods. However, the additional effort can be reduced if digital twins support the process

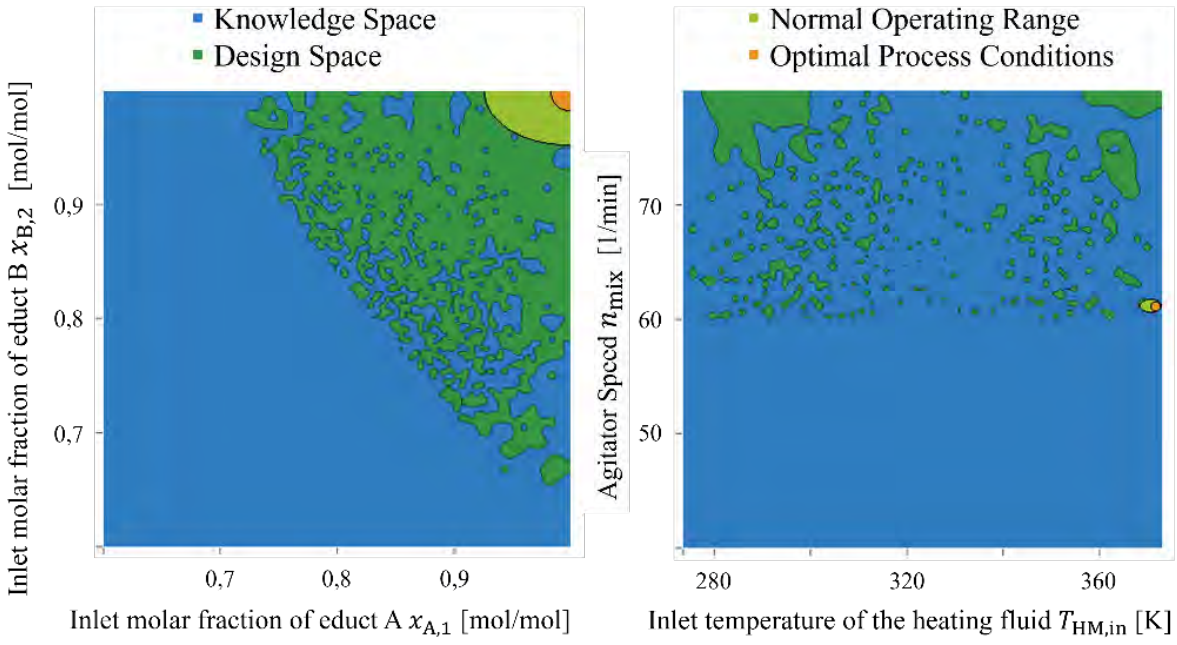

**Figure 3:** Location of the design space and normal operating range within the knowledge space for the production scale reactor (diagram generated with gPROMS®)

development.

To achieve a valid operation model of the digital twin, a large quantity of process data must be generated. The operation model that is build up with the help of the experimental data of the laboratory scale process, needs to be adapted continuously incorporating real time data of the production scale process.

If the data that is used for model adaption and discrimination is incomplete or inaccurate or underlies measurement mistakes, the operational model may not represent the process sufficiently. Thus, not only a high data quantity but also an adequate data quality is required. Another challenge of using digital twins as a tool for process scale-up may be the initial implementation since sensors must be installed at the process plant, a simulation software needs to be set up and a adequate data storage must be made available. As large amounts of data are processed, data security issues must be taken into consideration. Long term use of a digital twin requires maintenance like adding and replacing sensors or updating the simulation software.

In future research projects, the results found for the use case should be validated with measured data, which was not possible as the modular reactors M21 and M22 of the Process-to-Order-Lab-Learning Factory were not operational at the time of this work. The successful application of the workflow should be taken as an opportunity to apply the workflow to other use cases. Furthermore, the workflow could be extended to integrate more Quality by Design methods such as the quality risk analysis and the derivation of a process control strategy

## ACKNOWLEDGEMENTS

The authors would like to thank our partners Merck Electronics KGaA and Siemens AG in the industrial research project Lab2Plant for the fruitful discussions as well as the Process-to-Order Lab Learning Factory at TU Dresden for the information about planned reactor modules M21 and M22.

## ABSTRACT

Heuristic decomposition schemes like moving horizon schemes are a common approach to approximately solve large-scale mixed-integer programs. The authors propose Bayesian optimization as a methodological approach to systematically tune parameters of decomposition schemes for mixed-integer programs. This paper discusses detailed results of three studies of the Bayesian optimization-based approach using hoist scheduling as a case study: Firstly, two objectives of the tuning problem are examined considering sequences of incumbent solutions found by the Bayesian optimization. Secondly, the Bayesian optimization is applied to a set of test instances of the hoist scheduling problem using four types of acquisition functions; they are compared with respect to the convergence of the tuning problem solutions. Thirdly, the scaling behaviour of the Bayesian optimization is studied with respect to the dimension of the space of tuning parameters. The results of the three studies show that the solutions found by the Bayesian optimization converge quickly in smaller and larger tuning parameter spaces using different types of acquisition functions.

**Keywords**: Derivative Free Optimization, Machine Learning, Mixed-Integer Programming

## MOTIVATION

### Decomposition Schemes for MIPs

Heuristic decomposition schemes are a common approach to approximately solve large-scale mixed-integer programs (MIPs) as a sequence of partial MIPs. A typical example are moving horizon schemes applied to scheduling problems. Decomposition schemes usually exhibit parameters which can be used to tune their performance. Examples for parameters of moving horizon schemes are the horizon length and the step size of its movement.

### Existing Tuning Methods

30 publications on decompositions schemes for mixed-integer programs (both linear and non-linear) were analysed with respect to systematic tuning methods. The publication dates range from 2002 to 2025; 26 of the publications are journal papers, 3 are conference papers and 1 is a book section. The mixed-integer programs cover batch scheduling, maintenance scheduling, project scheduling, supply network planning, production routing, bin packing, locomotive assignment, healthcare planning, flowsheet optimization, lot sizing and other optimization problems. The decomposition schemes cover temporal, area, activity, scenario and geographic decomposition as well as rolling horizon and other schemes.

Tuning parameters were clearly identified in 25 publications; in the other 5 publications the existence of tuning parameters could not be decided. Only in 12 publications the tuning parameters were tuned, in 9 of them by grid search [e.g. 1,2,3], in 2 by heuristics and in 1 they were chosen randomly. No publication with an optimization-driven tuning method was found.

### Bayesian Optimization Based Tuning

In a previous paper [4], Bayesian optimization was proposed as a methodological approach to tune decomposition schemes for mixed-integer programs. This approach is reasonable since the tuning problem is a black-box optimization problem with an expensive to evaluate objective function: Each evaluation of the objective function of the Bayesian optimization requires the (approximate) solution of the MIP applying the parametrized decomposition scheme. The mentioned paper demon-

strated by a case study that the proposed approach is feasible and effective in principle. The case study was a mixed-integer hoist scheduling model along with a moving horizon decomposition scheme (see below).

### Scope of this Paper

This paper discusses results of three studies of the Bayesian optimization-based approach using the same case study: Firstly, two objective functions of the tuning problem are examined considering sequences of incumbent solutions found by the Bayesian optimization. (An incumbent solution is the best solution found up to a certain iteration.) Secondly, the Bayesian optimization is applied to a set of test instances of the hoist scheduling problem using four types of acquisition functions; they are compared with respect to the convergence of the tuning problem solutions. Thirdly, the scaling behaviour of the Bayesian optimization is studied with respect to the dimension of the space of tuning-parameters.

## CASE STUDY

### Hoist Scheduling Model

Hoist scheduling is the task of assigning several steps of several jobs to several stations over time. Figure 1 shows an exemplary layout of a batch plant with a hoist (left) and exemplary recipes defining the sequence and duration of steps for two jobs. In addition to the usual job shop scheduling constraints, the hoists must be considered. Hoists transport product carriers between the stations and constrain the solution space due to their finite transportation times. A typical objective of hoist scheduling is makespan minimization. Hoist scheduling problems can be formulated as MIPs.

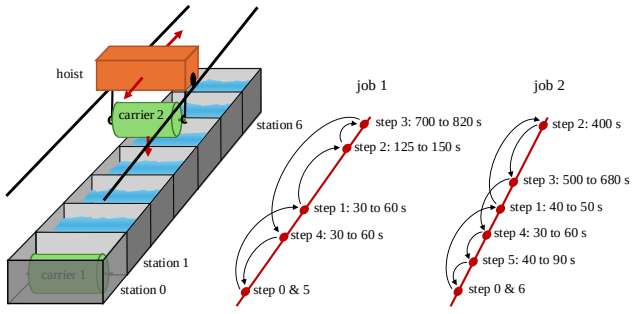

**Figure 1.** Hoist scheduling. Left: Exemplary layout of a batch plant with hoist. Right: Exemplary recipies.

In this paper, the MIP-model by Aguirre at al. [1] is used as a case study. This model considers one hoist, stations with a capacity of one carrier and non-circulating carriers. In the context of this work, it serves as an example for an NP-complete problem, that calls for decomposition schemes for large-scale instances.

### Heuristic Decomposition Scheme

The heuristic decomposition scheme used in this paper is an extension of the moving horizon scheme described by Aguirre et al. [1]. It comprises two sequential phases to schedule jobs from a given list of jobs: a construction phase and an improvement phase.

In the construction phase, jobs 1 to NSJ (number of selected jobs) are scheduled by solving a partial MIP, then jobs 1 to NFJ (number of fixed jobs) are fixed and jobs NFJ+1 to NSJ+NFJ+1 are (re)scheduled, and so on. The number of partial MIPs to be solved is given by the number of jobs divided by NFJ. The construction phase generates a first feasible schedule, which may be improved in the improvement phase.

In the improvement phase, jobs 1 to NRJ (number of released jobs) from the schedule are rescheduled by solving a partial MIP. If the schedule is not improved, jobs 2 to NRJ+1 are rescheduled, and so on. If the schedule is improved, the improvement phase re-starts from the first job in the schedule. The improvement phase terminates if no further improvement is observed. In contrast to the construction phase, the number of partial MIPs to be solved during the improvement phase cannot be predicted.

The tuning parameters NSJ, NFJ and NRJ are integer in nature and have a lower bound of 1. The upper bounds of NSJ and NRJ are the total number of jobs; the upper bound of NFJ is NSJ: NFJ≤NSJ. In addition to the integer parameters, the accepted optimality gap (AOG) of the partial MIPs (termination criterion of the MIP solver) is considered as a continuous tuning parameter within the bounds of 0 % to 100%. Aguirre et al. considered only NSJ and NRJ as tuning parameters; this paper extends the tuning parameter space by NFJ and AOG.

### Architecture of the Tuning Method

Figure 2 illustrates the algorithmic components for the tuning of decomposition schemes for large-scale MIPs and the information exchanged between them.

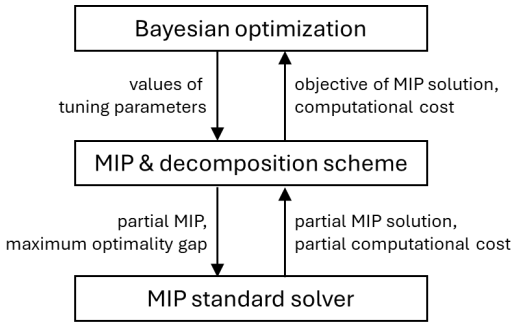

**Figure 2.** Algorithmic architecture for MIP decomposition scheme tuning.

The Bayesian optimization generates the next values of tuning parameters for the decomposition scheme;

the next values are based on previous values of the objective of the MIP solution or the computational cost to apply the decomposition scheme. For the studies in this paper, the implementation SMAC3[1] is used.

Based on the values of the tuning parameters, the decomposition scheme generates a sequence of partial MIPs from the MIP. The MIP and the decomposition scheme are implemented using Pyomo[2].

The MIP standard solver solves the partial MIPs with at least the AOG provided by the Bayesian optimization. It returns the partial MIP solution along with its partial computational cost. For the studies in this paper, CPLEX[3] is used as the MIP standard solver.

## TUNING PROBLEM OBJECTIVES

In the first study two objective functions of the tuning problem are examined considering sequences of incumbent solutions found by the Bayesian optimization.

### Motivation for Different Objectives

Applying heuristic decomposition schemes to large-scale MIPs has two natural and competing objectives: The computational cost shall be minimized while the objective of the MIP shall still be optimized. For the case study at hand, the computational cost is measured by the CPU-time needed to apply the decomposition scheme to the MIP. The MIP objective is to minimize the makespan of the hoist schedule, measured in time units TU.

### Setup of Computational Studies

Heuristic decomposition schemes are useful for large-scale MIPs with computational cost that prohibit their solution. However, the studies in this paper are limited to small-scale MIP-instances that can (exactly) be solved at reasonable computational cost to ensure that all partial MIPs can be solved to proven optimality.

Four instances of the hoist scheduling model comprising six jobs each are considered; the instances differ in the number of steps and stations and in the speed of the hoist.

The number of jobs is kept constant to keep the size of the tuning parameter space constant. In this first study the tuning parameters NSJ und NRJ vary between 1 und 6, while NFJ is set to 1 and AOG is set to 0. This leads to a tuning parameter space with only 36 feasible (integer) solutions, such that a grid search with complete enumeration of all solutions is possible. Only one objective of the tuning problem (computational cost or makespan) is optimized at a time (without limiting the other).

### Computational Results

A grid search in the NSJ-NRJ-space of the tuning problem leads to similar shapes of each of the objective functions for the four instances. Therefore, only the results for instance 1 are discussed in the sequel.

Figure 3 shows the results of the grid search for the computational cost objective combined with the incumbent solutions found by the Bayesian optimization (red line). Note, that only the integer-valued points are feasible while the values of the objective function are interpolated between them to improve the clarity of the figure.

The computational cost objective exhibits multiple minima located at the corners of the tuning parameter space: (1;1), (6;1), (1;6) and (6,6). The Bayesian optimization is initialized at the worst solution (4;4); after finding two local optima it terminates at the global one (1;1). This solution is intuitively reasonable for the computational cost objective, since the partial MIPs in the construction phase and the improvement phase are of minimal size and cheap to solve.

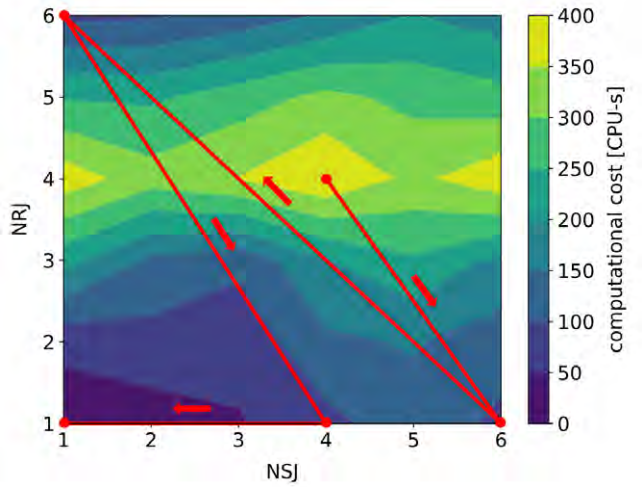

**Figure 3.** Computational cost objective of instance 1 and incumbent solutions found by the Bayesian optimization.

Analogue to Figure 3, Figure 4 shows the results for the makespan objective. The maximum of the makespan objective (1;1) is at the same point as the minimum of the computational cost objective. This exemplifies the competing character of the two objectives and demonstrates the need to balance them appropriately.

Analogue to above, the Bayesian optimization is initialized at the worst solution (1,1). It terminates after the first incumbent solution (6;1). The early termination is obviously favoured by the weakness of the objective function: Since 27 out of 36 solutions are optimal, an optimum is easy to find.

Note, that NSJ=6 or NRJ=6 means that the MIP is neither decomposed in the construction phase nor in the

[1] https://automl.github.io/SMAC3/main/index.html#
[2] https://www.pyomo.org/
[3] https://www.ibm.com/products/ilog-cplex-optimization-studio

improvement phase. The optimality of solutions (6;1), (6,2), … (6,6), (5,6) … (1;6) is intuitively reasonable: Decomposing the MIP bears the risk of losing its optimum, such that by not decomposing it the optimum is secured.

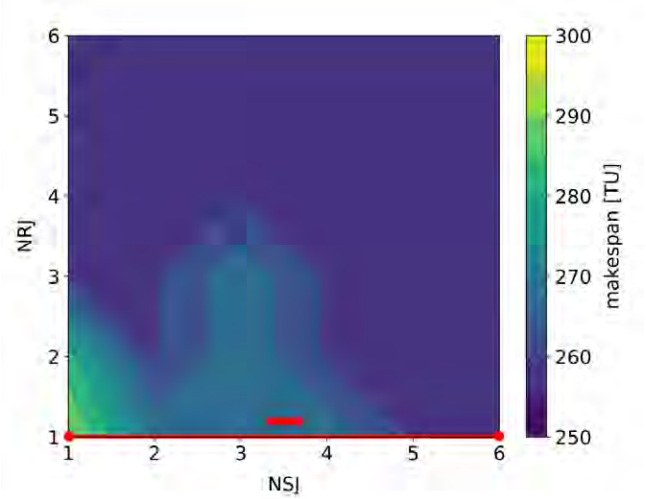

**Figure 4.** Makespan objective of instance 1 and incumbent solutions found by the Bayesian optimization.

## ACQUISITION FUNCTIONS

In the second study the Bayesian optimization is applied to a set of test instances of the hoist scheduling problem using four types of acquisition functions; they are compared with respect to the convergence of the tuning problem solutions.

### Impact of the Acquisition Function

Acquisition functions steer the selection of the next point in the solution space of the Bayesian optimization. Different types of acquisition functions balance the exploitation and the exploration of the search space in different ways. Therefore, the type of acquisition function is assumed to be a design parameter of the Bayesian optimization with a major impact on its performance.

The following four common acquisition functions are applied to the four small-scale instances and the two objective functions from the first study: “expected improvement” (also applied in the first study), “probability of improvement”,” upper confidence bound” and “Thompson sampling”.

### Setup of Computational Studies

For each acquisition function and each objective function, the objective values of the incumbent solutions of the four instances are plotted over the iterations of the Bayesian optimization. To make them comparable, the objective functions are normalized such that the starting point equals 100% and the optimum equals 0%. Note that the optimum in the tuning parameter space is known from the first study. For each iteration, the minimum, the maximum and the mean value of the normalized objective are displayed.

### Computational Results

The results for the acquisitions functions “expected improvement”; “upper confidence bound” and “Thompson Sampling” are similar, while the convergence using the “probability of improvement” function is slower. For the makespan objective the Bayesian optimization converges after 2-3 iterations to an optimum, while for the computational cost objective the number of iterations is higher. (This observation is consistent with study 1.) Therefore, only the results for the computational cost objective and the acquisition functions “probability of improvement” and “expected improvement” are discussed (see Figures 5 und 6).

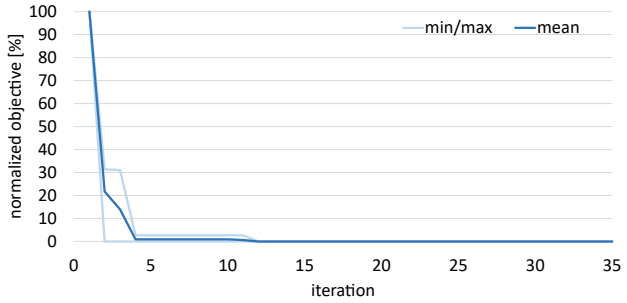

**Figure 5.** Convergence of computational cost objective with acquisition function “expected improvement”.

The acquisition function “expected improvement” considers both, the likelihood of improvement of the next solution and the magnitude of its potential improvement [5]. It balances exploration and exploitation of the tuning parameter space and is therefore well suited for objective functions with multiple local optima.

As Figure 5 shows, the instances converge after 2 to 12 iterations to the global optimum (with a normalized objective of 0%). After 4 iterations the maximum normalized objective over all instances is around 3%. The instances terminate after 14 to 35 iterations. The relevant termination criterion is the maximum number of 16 retries i.e. after 16 iterations no new solution in the tuning parameter space is found.

In contrast to the acquisition function “expected improvement”, the acquisition function “probability of improvement” selects the next solution such that the objective value is most likely to improve [6]. It typically selects the next solution close to the last solutions, such that it behaves more exploitative than explorative.

Applying the acquisition function “probability of improvement” to the case study leads to slower convergence to inferior solutions compared to the other acquisition functions. As Figure 6 shows, the instances terminate after 11 or 13 iterations before the final solution with

normalized objectives between 1% and 13% is reached.

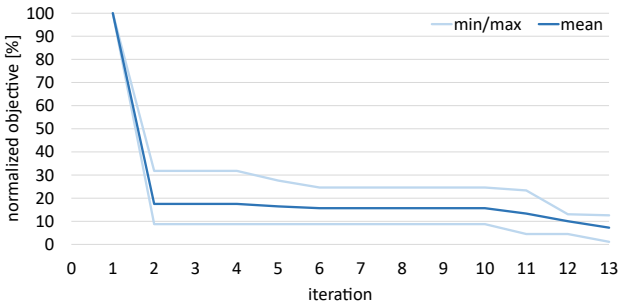

**Figure 6.** Convergence of computational cost objective with acquisition function "probability of improvement".

## TUNING PARAMETER SPACE DIMENSION

The third study analyses the scaling behaviour of the Bayesian optimization with respect to the dimension of the space of tuning parameters.

### Extension of the Tuning Parameter Space

The proposed Bayesian optimization-based approach is particularly useful for tuning parameters spaces of a size that prohibit full grid search. Therefore, the two-dimensional tuning parameter space considered in studies 1 and 2 is extended by two additional dimensions: the integer-valued NFJ and the continuous AOG. (Both were introduced in section "Heuristic Decomposition Scheme" but bound to fixed values in studies 1 and 2.) The same settings as in study 1 were applied.

### Comparative Analysis of the Convergence

To comparatively analyse the convergence speed, the same type of plots with the same normalization is used as in Figures 5 and 6. Figures 7 and 8 show the convergence of both objective functions in the larger tuning parameter space.

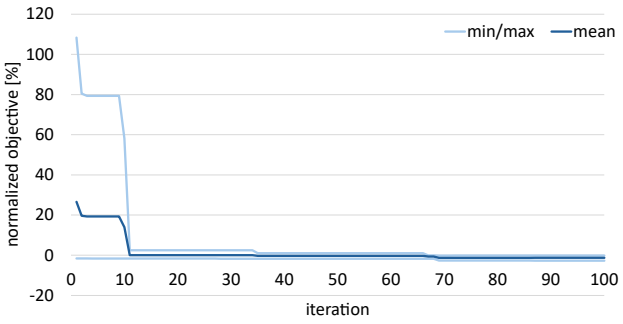

**Figure 7.** Convergence of computational cost objective with four-dimensional tuning parameter space.

As the full grid-search is prohibited, the worst solutions in the tuning parameter space are not know such that they cannot be used to initialize the Bayesian optimization (as in Figures 5 and 6). Instead, arbitrary initialization points were chosen for Figures 7 and 8.

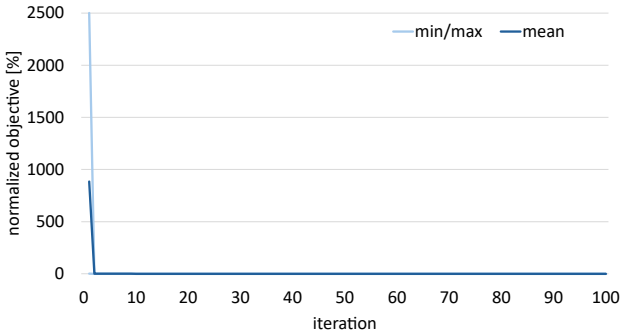

**Figure 8.** Convergence of makespan objective with four-dimensional tuning parameter space.

The worst normalized objective value in Figure 7 is 108% at iteration 1. This shows that the larger search space of this study 3 contains worse solutions than the smaller search space of studies 1 and 2. On the other hand, the Bayesian optimization terminates after 100 iterations at a solution with a normalized objective vale of -3%. This shows that the additional dimensions of the tuning space (NFJ and AOG) provide additional optimization potential that was exploited by the Bayesian optimization.

The convergence speeds in Figures 5 (smaller tuning parameter space) and 7 (large tuning parameter space) are comparable. Figure 7 shows that the maximum normalized objective over all instances is around 3% after 11 iterations (compared to 4 iterations in Figure 5).

Figure 8 shows similar results for the makespan objective than Figure 7 for the computational cost objective: The worst normalized objective in Figure 8 is 2500% (compared to 100% in Figure 6), and the maximum normalized objective over all instances is around 1% already after 2 iterations.

### Comparative Analysis of the Optimized Tuning Parameters

The optimized tuning parameters for the two objectives are shown in Tables 1 and 2.

**Table 1:** Optimized tuning parameters for computational cost objective.

| Instance | NSJ | NRJ | NFJ | AOG |
|---|---|---|---|---|
| 1 | 1 | 1 | 1 | 78% |
| 2 | 4 | 6 | 3 | 86% |
| 3 | 1 | 1 | 1 | 100% |
| 4 | 6 | 6 | 1 | 91% |

**Table 2:** Optimized tuning parameters for makespan objective.

| Instance | NSJ | NRJ | NFJ | AOG |
|---|---|---|---|---|
| 1 | 6 | 2 | 2 | 0% |
| 2 | 3 | 3 | 1 | 2% |
| 3 | 3 | 3 | 1 | 2% |
| 4 | 5 | 5 | 5 | 9% |

For the computational cost objective (see Table 1), most of the values of the integer-valued tuning parameters NSJ, NRJ and NFJ are at their boundaries. This result is reasonable since solving many small or one medium-sized MIP is computationally cheap (compare Figure 3).

The AOG is close to or at 100%, which is also reasonable since the partial MIPs terminate the earlier the larger the AOG is.

For the makespan objective (see Table 2), most of the values of the integer-valued tuning parameters NSJ, NRJ and NFJ are away from their boundaries (contrasting Table 1). This observation can reasonably be explained by the weak optimum of this objective (compare Figure 4).

The AOG is close to or at 0% (also contrasting Table 1). This result is also reasonable since smaller optimality gaps push the MIP solver to better solutions of the partial MIPs.

## CONCLUSIONS AND FUTURE WORK

In this work, a Bayesian optimization-based approach to tune decomposition schemes for MIPs was studied in detail using hoist scheduling as a case study. The results support the following two main conclusions:

Firstly, decomposition schemes comprise tuning parameters which are sensitive to the two natural objectives of decomposing, namely minimizing the computational cost while still optimizing the MIP objective; these two objectives are competing.

Secondly, a reasonable method to tune the parameters of a decomposition scheme is Bayesian optimization due to its following properties:

- The performance of the Bayesian optimization is insensitive against changes of its acquisition function. If exploration and exploitation are not unbalanced, good solutions are found after a few iterations.
- The performance of the Bayesian optimization is insensitive against changes of the parameters of the MIP. The convergence behaviour of different instances of the MIP is similar.
- Multiple local optima and the global optimum in the space of tuning parameters can be found by the Bayesian optimization.
- The Bayesian optimization is efficient in smaller and larger mixed-integer tuning parameter spaces. Its performance in two- and four-dimensional spaces is comparable.

In its present state, Bayesian optimization-based approach exhibits limitations. Future work deals with the approaches to relax them: Multi-objective optimization will be studied; large-scale MIP which cannot be solved to proven optimality will be examined; and methods to deal with multiple MIP-instances will be developed.

## ABSTRACT

One of the most successful continuous high-performance liquid chromatography (HPLC) processes for drug manufacturing is the Simulated Moving Bed (SMB). SMB is a multi-column, continuous, chromatographic process that can handle much higher throughputs than regular batch chromatographic processes. The process is initially transient, but eventually arrives at a cyclic steady state, which makes optimization very challenging, even more so when superstructure optimization is involved. To simplify the optimization problem, many researchers fixed the SMB structure, optimizing only the continuous variables, so they cannot be considered superstructure optimization. In this work, an SMB superstructure that can simultaneously optimize column structure and operation is proposed. The results showed that the superstructure proposed is reliable, and it is more efficient compared to current optimization approaches if the optimal column structure has to be identified.

## INTRODUCTION

Chromatography is one of the most important separation processes in the pharmaceutical industry, used to purify valuable active pharmaceutical ingredients (APIs). The ability to efficiently extract pure (e.g., 99.9 wt%) APIs is crucial to ensure the health and safety of patients ingesting the medicine, but also to reduce waste and maximise profit. The most commonly used chromatographic process, high-performance liquid chromatography (HPLC), features a tightly packed stationary phase within a column, through which a mobile phase containing the feed mixture is passed. There are two operating modes for HPLC – batch or continuous. Although the continuous process is more complex in terms of design and operation, the pharmaceutical industry is slowly transitioning to adopting continuous processes as this mode can improve both efficiency and productivity.

The most successful continuous HPLC process for drug manufacturing is the Simulated Moving Bed (SMB). SMB is a multi-column, continuous, chromatographic process that can handle much higher throughputs than regular batch chromatographic processes. SMB usually has four sections, the desorbent (D), extract (E), feed (F) and raffinate (R) sections, and simulates a counter-current flow between the stationary and mobile phases through periodical and synchronous switching of the inlet and outlet ports in the direction of fluid flow. Figure 1 illustrates the operating principle for an eight-column SMB (two columns per section, *aka* a 2222 SMB), where the ports move forward (in the direction of fluid flow) by one column after a switch time $t_s$, and finally return to the initial state after eight switches (i.e., after a complete cycle). The process is initially transient but eventually arrives at a cyclic steady state (CSS). Each SMB section can have a different number of columns, which must be determined carefully due to physical limitations (e.g., pressure drop) which may have a significant effect on the separation performance. These limitations pose challenges for the modelling and optimization of an SMB process, as will be briefly discussed below.

Firstly, consider the modelling of an SMB process. To capture both the transient startup stage and the CSS, the most straightforward method is to perform a dynamic simulation, where each cycle in the SMB process is simulated until the CSS is identified [1–3]. This approach is,

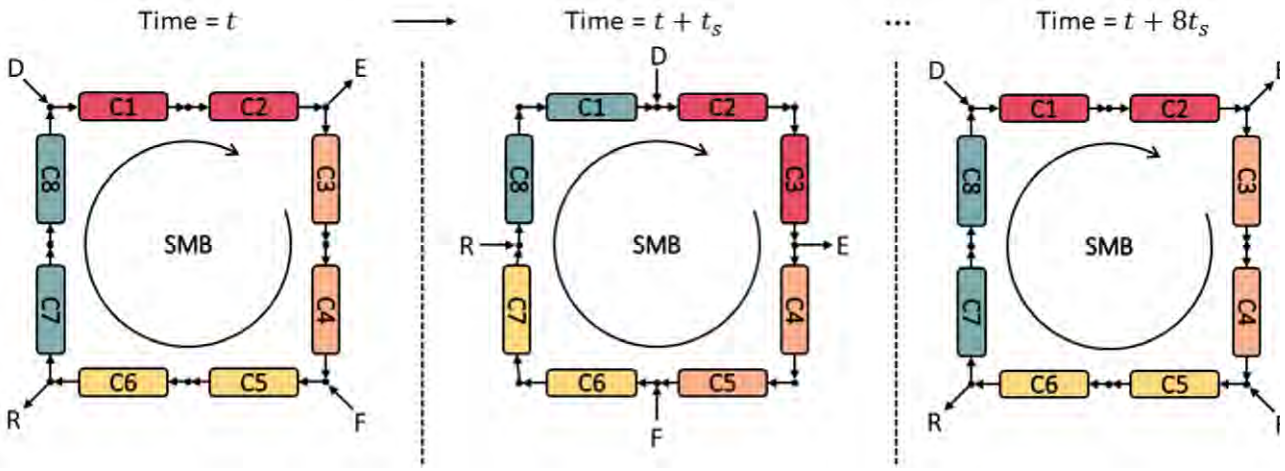

**Figure 1.** Operating procedure of an eight-column SMB (two columns per section), where $t_s$ is the switch time, $C_i$ is column $i$, and D, E, F, R are the desorbent, extract, feed, and raffinate flow rates, respectively. A complete cycle for this structure requires $8t_s$. The circular arrow represents the direction of fluid flow.

however, very time-consuming as CSS is often achieved only after a number of cycles. Information about the transient startup stage is usually redundant when considering optimization; as only the final CSS is of interest for SMB operation. By incorporating the CSS conditions as part of the optimization boundary conditions, the conditions at CSS can be simulated directly, making it faster than dynamic simulation for transient startup. There are two popular ways to include CSS conditions in the boundary conditions: (1) the method by Nilchan and Pantelides [4], where it is assumed that the conditions at the start and end of a cycle are identical, and (2) the method by Kloppenburg and Gilles [5], where the state variables at the outlet of a column are the same as that at the inlet of the next column. However, to incorporate CSS conditions as part of the boundary conditions, a fully discretized model (spatial and temporal domains discretized) is needed, which involves more equations and variables than the partially discretized model (only spatial domain discretized) used for dynamic simulation. It should be noted that the simulation time of both dynamic and direct CSS approaches are highly dependent on the grid discretization; finer grid provides more accurate separation behavior but greatly increases the simulation time, and vice versa. Therefore, whether the dynamic or direct CSS approach is more time-efficient will depend on the discretization grid and method used.

For optimization of SMB, most researchers have conveniently fixed the column structure and optimized only the continuous optimization variables (e.g., [3,6,7]). Only a few studies have considered SMB superstructure optimization, which allows identification also of the column design and arrangement. Kawajiri and Biegler [8–10] explored an SMB superstructure which took into account the standard continuous variables as well as some structural configuration decisions (e.g., the number of columns in each section), but their superstructure was limited to a fixed total number of columns.

This work therefore aims to: (1) discuss and provide solutions for challenges related to handling the number of columns and switch actions in SMB superstructure modelling and optimization, and (2) propose a superstructure approach that allows for simultaneous optimization of the number of columns in each section, as well as the column dimensions (length and diameter) and the switching times and the flow rates. This superstructure optimization problem, which is a mixed integer non-linear programming (MINLP) problem, will determine not only the optimal configuration, but also simultaneously the column design as well as the operating procedure of the SMB process.

## METHODOLOGY

This section will outline the key steps required to construct a superstructure model of an SMB process. Firstly, the superstructure flowsheet must be constructed. In most cases, models are solved with a numerical solver, meaning that the degrees of freedom must be carefully considered when constructing the model (e.g., the number of equations in *if* and *else* branches must be the same). This introduces challenges when handling optimization of the number of columns and port changes, and the solutions to these problems will be discussed. As previously mentioned, the model can be partially or fully discretized depending on the purpose of the study. This work will also discuss the conversion of a partially discretized model into a fully discretized model.

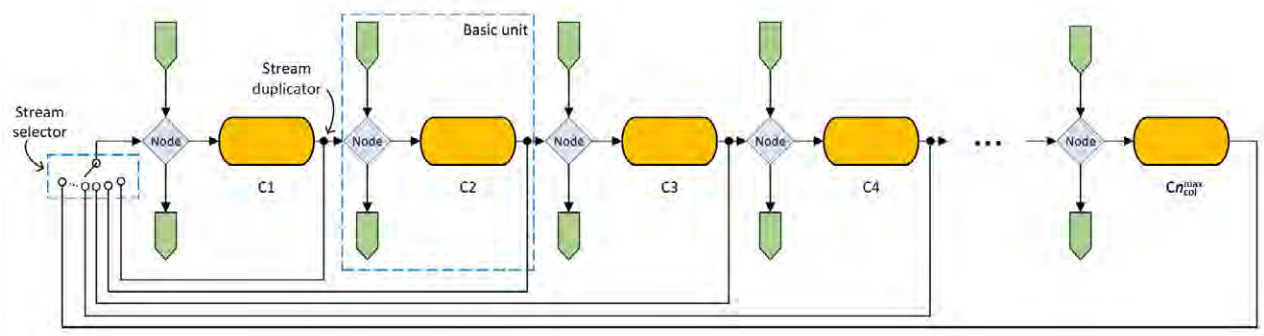

**Figure 2.** Flowsheet of the proposed SMB superstructure made up of $n_{\mathrm{col}}^{\max}$ basic units (node + column).

## Superstructure Flowsheet

The flowsheet of our SMB superstructure is shown in Figure 2. The basic unit is made up of two parts: (1) a node model, where it is modelled as an instantaneous mixer as proposed by Chan et al. [11], followed by (2) a chromatography column model consisting of a transport model (e.g., general rate model or equilibrium dispersive model) and an isotherm model (e.g., linear or Langmuir). The basic unit of node and column is then repeated $n_{\mathrm{col}}^{\max}$ times, where $n_{\mathrm{col}}^{\max}$ is the maximum total number of columns (not number of columns per section) considered in the optimization. This maximum number must be decided *a priori*. The outlet stream of each basic unit (i.e., outlet stream of the column), except for the last basic unit for which the outlet stream is a recycle stream, is connected to a stream duplicator. The stream duplicator does not physically exist, and its existence is solely to duplicate the outlet stream information: for the stream that is sent to the next basic unit (i.e., becomes the inlet stream to the node model) and for a stream selector used to identify the recycle stream location and therefore the optimal number of columns required. Only one stream selector is present in the flowsheet, and it is located prior to the first basic unit. The stream selector connects the recycle stream from the final column (i.e., the recycle stream from column $n_{\mathrm{col}}^{\mathrm{tot}}$) to the inlet of the first basic unit. The other recycle streams that are not selected are treated as redundant streams in the optimization.

## Handle Number of Columns

As previously described, the SMB superstructure flowsheet consists of $n_{\mathrm{col}}^{\max}$ basic units, and this is represented as an array of basic units in the model. When solving the model using numerical solvers, the number of equations cannot change during the simulation/optimization. Therefore, the size of the basic unit array must be fixed *a priori*. Since the number of columns in a section $j$, $n_{col,j}$, is an optimization variable, there are three possible cases: (1) $\sum_{j=1}^{4} n_{col,j} > n_{\mathrm{col}}^{\max}$ which will be treated as an infeasible simulation and discarded, (2) $\sum_{j=1}^{4} n_{col,j} = n_{\mathrm{col}}^{\max}$ where no additional action is required, and (3) $\sum_{j=1}^{4} n_{col,j} < n_{\mathrm{col}}^{\max}$ where there are "redundant" columns that need to be considered. Chia and Sorensen [12] discussed the handling of redundant membrane stages in a membrane superstructure, which is similar in principle to that of an SMB superstructure. Therefore, their strategy where all columns are simulated but the optimal result is collected from the optimal column $n_{\mathrm{col}}^{\mathrm{tot}}$ will be used.

## Handle Port Changes

Referring to Figure 1, a port is the black circle located before each column. For example, the desorbent stream is at port 1 at time $t$, at port 2 at time $t + t_s$, and at port 1 again at time $t + 8t_s$. There are four sections in a typical SMB, and each section has a port number allocated to it at any time. Therefore, a variable $\beta_j$ (where $j$ represents the four sections) is introduced to hold the information about the port number of each section at a given time. During SMB operation, a port moves forward by one column after a switch time $t_s$; hence, the port number should increase by 1 after $t_s$. This change can be captured with an intermediate variable $\beta_j^{\mathrm{raw}}$:

$$\frac{d\beta_j^{\mathrm{raw}}}{dt} = \frac{1}{t_s} \qquad \forall j \in \{1,2,3,4\} \text{ or } \{\mathrm{D},\mathrm{E},\mathrm{F},\mathrm{R}\} \qquad (1)$$

However, Equation 1 will increase the port number beyond the actual total number of columns $n_{\mathrm{col}}^{\mathrm{tot}}$. So, to limit the port number in the range $\left[1, n_{\mathrm{col}}^{\mathrm{tot}}\right]$, a modulo operator where $a \bmod b \equiv a - b \times \left\lfloor \frac{a}{b} \right\rfloor$ is applied:

$$\beta_j = \left\lfloor \left(\beta_j^{\mathrm{raw}} - 1\right) \bmod n_{\mathrm{col}}^{\mathrm{tot}} \right\rfloor \quad \forall j \in \{1,2,3,4\} \text{ or } \{\mathrm{D},\mathrm{E},\mathrm{F},\mathrm{R}\} \qquad (2)$$

With Equation 2, the port number of each section at a given time can be identified, and further actions, such as determining the inlet flow rate of a node at a given time, can be performed using *if-else* statements.

## Discretization of the Superstructure Model

The partially discretized superstructure model,

discretized in the axial direction of the column, has now been constructed. To transform this partially discretized model into a fully discretized model, firstly, all time-variant variables in the partially discretized model must have an additional temporal domain. Then, the initial conditions of the partially discretized model become the boundary conditions for the temporal domain in the fully discretized model. As discussed in the introduction, when formulating the boundary conditions, the CSS condition can be considered as repeating within a cycle [4] or matching inlet-outlet states between columns in a switch [5]. Both options are possible, but the latter allows faster simulation time as it involves fewer equations, hence is applied in this work. To complete the transformation into a fully discretized model, the time-derivative equations must also be transformed into partial derivative equations (e.g., $d\beta_j^{\mathrm{raw}}/dt$ becomes $\partial\beta_j^{\mathrm{raw}}/\partial t$).

Completing the steps above will yield a fully discretized model. The switch time $t_s$ now becomes the upper bound of the temporal domain (i.e., becomes a parameter) and therefore cannot be optimized. To solve this issue, the temporal domain must be normalized. This can be done by introducing a new variable $\tau$, so that $\tau = t/t_s$. This will also transform the range of the temporal domain from $t \in [0, t_s]$ to $\tau \in [0, 1]$. Finally, the partial derivatives need to be transformed with the following equation:

$$\frac{\partial}{\partial t} = \frac{\partial}{\partial(\tau\, t_s)} = \frac{1}{t_s}\frac{\partial}{\partial \tau} \tag{3}$$

After the transformation, the partial derivatives are expressed in terms of $\tau$ and not $t$. Therefore, $t_s$ is freed from the boundary, and returns to becoming a variable that can be optimized (i.e., no longer a parameter).

## MODEL COMPARISON

To demonstrate the performance of the proposed SMB superstructure model, the SMB equations and case study used by Dünnebier et al. [1] is considered. Since this work introduces both partially and fully discretized superstructure models, both models will be considered and compared.

Dünnebier et al. [1] developed a four-zone SMB with two columns in each zone, resulting in a 2222 SMB configuration. The detailed information, including equations of the distributed plug flow and the node, linear isotherm, node equations, and other necessary equations and parameter values, can be found in the literature [1,11], and will therefore not be presented in this work. The maximum allowed number of columns in the superstructure model is set as 12, however, in the optimization only 8 columns will be considered, i.e., 4 columns are "bypassed". This is done to test the methodology and to demonstrate that the redundant 4 columns are not considered in the optimal solution.

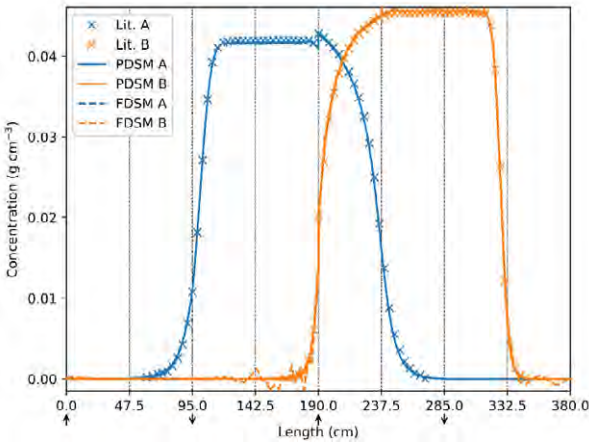

**Figure 3.** Comparison between the steady-state concentration profiles for components A (blue) and B (orange) obtained from literature (Lit.) [1], partially discretized superstructure model (PDSM), and fully discretized superstructure model (FDSM) at the end of a switching time.

The superstructure model in this work is developed in gPROMS. The partially discretized model contains only the spatial domain (i.e., discretization only along the column). A fourth-order orthogonal collocation finite element method (OCFEM) is chosen with ten collocation points. The fully discretized model involves an additional temporal domain. Both spatial and temporal domains in the fully discretized model are described using the fourth-order OCFEM as it can provide a sufficient accuracy with a reasonable computational time (trade-off not shown). All simulations and optimizations are performed on a workstation with a dual Intel Xeon Gold 6226R CPU (64 processors).

The steady-state concentration profiles along a single column for both components A (fructose) and B (glucose) are plotted in Figure 3. Overall, the simulation results from the proposed partially discretized and fully discretized superstructure models are very similar to those from literature. Figure 3 showed only the results for the first eight columns although the superstructure model is set to have 12 columns; the last four columns are bypassed so their results are ignored. The superimposing chromatograms also indicated that the bypassed columns do not affect the optimal results, so the methodology for handling number of columns can be used in optimization. It is noted that some oscillations due to numerical integration appears with the fully discretized model. This could be improved and minimized by using a finer discretization or choosing a more suitable discretization method. In terms of the purity of the products, the difference between the two proposed models is in the order of magnitude of $10^{-4}$ g $g^{-1}$, which is reasonable and more than sufficient for most optimizations. In terms of CPU

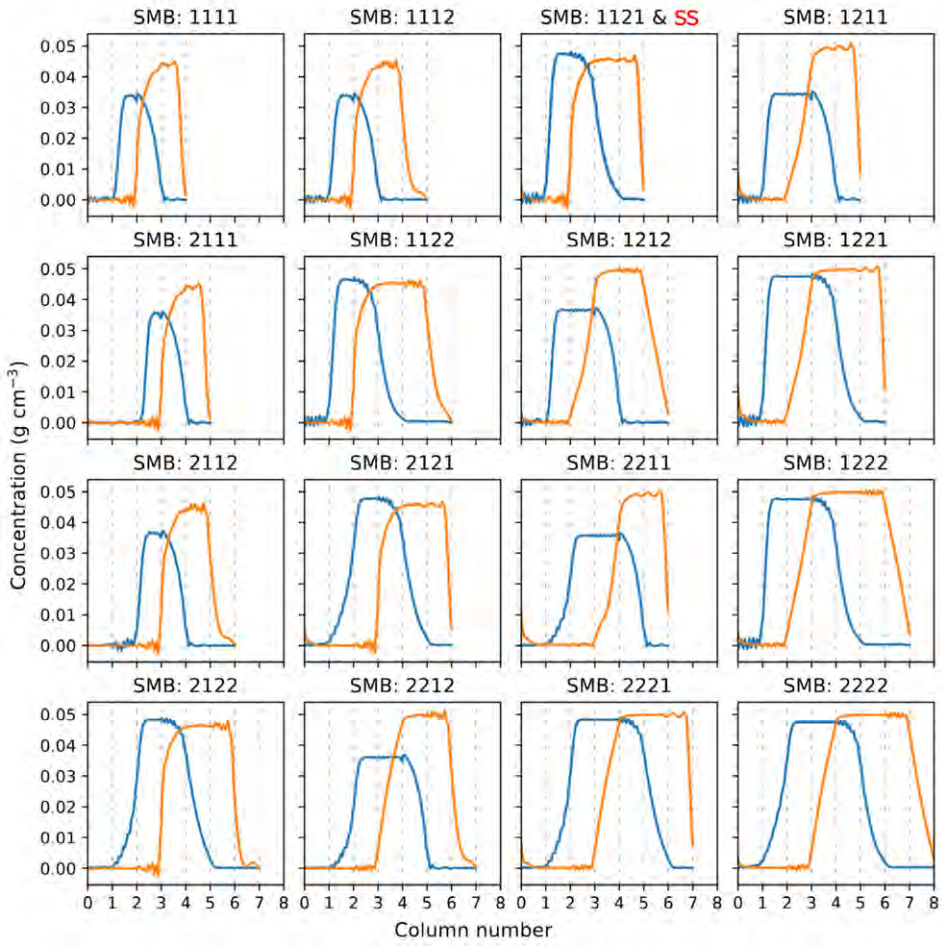

**Figure 4.** Concentration profiles along the columns for the simulated moving bed (SMB) structures investigated, including the optimal design obtained from individual optimization with fixed configuration and superstructure optimization (SS). The numbers in the title indicate the number of columns in the desorbent, extract, feed, and raffinate sections, respectively.

time, the fully discretized model is much faster, with about 8 s per simulation, while the partially discretized model requires 131 s per simulation. This significant difference makes the fully discretized model superior for optimization and cases requiring many simulations (e.g., for global sensitivity analysis).

## SMB OPTIMIZATION

In the following, we will consider superstructure optimization where we simultaneously optimized the number of columns per SMB section, the design of the column (length and diameter) as well as the switch time and flow rates. The model, mixture, and other key parameter values are the same as previously.

In the following, the SMB configurations considered will have one or two columns in each section, which are considered as optimization variables, leading to 16 unique configurations as the maximum number of columns is assumed to be 8 columns (e.g. 1111, 1112, 1122, *etc*). In addition, switch time (500 s to 900 s) and four volumetric flow rates (0.01 $cm^3\ s^{-1}$ to 0.15 $cm^3\ s^{-1}$) are also optimized, leading to nine optimization variables in total (the number of columns for each of the four sections, the switch time and the four flow rates). The objective function considered is to maximize process efficiency defined by the following expression:

$$\text{efficiency} = \frac{\text{throughput}}{\text{rate of solvent consumption} \times \text{total col. volume}}$$

Two constraints are also taken into account: (1) outlet streams should be at least 99 wt% pure, and (2) the pressure drop within each column must be between 13 bar and 100 bar [11]. In terms of the optimizer, particle swarm optimization (PSO) is used due to its robustness and ability to jump out of a local optimum. Fifty particles are used in each iteration, and two stopping criteria are applied: (1) 200 maximum iterations, or (2) the best

objective values remain constant for 20 consecutive iterations, whichever satisfied first.

All concentration profiles for components A and B are plotted in Figure 4, for both individual configurations (i.e., optimization for a fixed column configuration) and for superstructure optimization (SS). Due to the limited space, the optimal designs and objective values for all configurations are not provided. The individual optimization results show that the best configuration is 1121 (i.e., only the feed section has two columns), with an efficiency of 1.086 mg $cm^{-3}$. There is a slight deviation between the individual optimal design for the 1121 configuration and the solution obtained via the superstructure methodology (1.086 vs 1.069 mg $cm^{-3}$) and this is due to local optimality. Note that the concentrations profiles are nevertheless identical in the figure.

## CONCLUSION

This work proposed a novel SMB superstructure, which allows for simultaneous optimization of the number of columns in each SMB section together with other key design variables including column design and operating variables. The modification of the superstructure from a partially discretized model to a fully discretized model was demonstrated and tested, indicating good robustness. The superstructure model was considered to compare superstructure optimization with individual optimization of a fixed column configuration. Both approaches yielded the same optimal result, indicating good efficiency and reliability of the proposed superstructure. The superstructure allows for the direct determination of the optimal process, thus avoiding optimization for each possible column configuration. The proposed superstructure is versatile and can be applied to any type of mass transport model or isotherm used to describe the chromatographic system.

# Development of anomaly detection models independent of noise and missing values using graph Laplacian regularization

**Yuna Tahashi[a], and Koichi Fujiwara[a]**

## ABSTRACT

Anomaly detection is a key technique for maintaining process suitability and safety; however, the quality of process data often deteriorates due to missing or noisy values caused by sensor malfunctions. Such data imperfections may obscure real faults. If anomaly detection models are too sensitive to such abnormal data, they may cause false positives resulting in unnecessary alarms, which may obstruct detection of true process faults. Thus, deterioration of the quality of process data may affect process performance and safety. We propose a new anomaly detection method that utilizes graph Laplacian regularization as a loss function considering data-specific temporal relationships. Graph Laplacian regularization is a mathematical tool used in image processing and denoising to smooth data. We assume that successive process data temporally close to each other have similar values and maintain temporal dependencies among variables. In this study, Laplacian regularization imposes significant penalties when the outputs of neighboring samples lose smoothness, under the assumption that neighboring samples keep similar relationships. Such temporal dependencies can be expressed as a graph structure and extracted with the Nearest Correlation (NC) method. To demonstrate the usefulness of the proposed anomaly detection method, we applied it to an anomaly detection problem in a vinyl acetate monomer (VAM) process. The results show that the model with graph Laplacian regularization achieved higher performance than without graph Laplacian regularization in some fault scenarios. It was confirmed that the proposed method is effective for anomaly detection.

**Keywords**: Anomaly detection, Graph Laplacian regularization, Autoencoder, vinyl acetate monomer process

## INTRODUCTION

Process data frequently suffer from imperfections such as missing values or measurement noise due to sensor malfunction. Such data imperfections pose a significant challenge to detection of process anomalies and can lead to false positives or missed rare fault events. Anomaly detection models with high sensitivity may over-detect these faults, leading to interference in detection of true failure events.

Various anomaly detection methods have been developed to detect such faults, such as One-Class Support Vector Machine (OCSVM) and Multivariate Statistical Process Control (MSPC). Although these methods are common and widely used, they are not always applicable for handling complicated fault events due to incompatibility with time-series data or linear models [1,2].

An autoencoder (AE) is a nonlinear expansion of principal component analysis (PCA) and is a type of neural network trained so that the output becomes close to the input. Since MSPC is based on PCA, AE can also be used for anomaly detection [3]. If an AE is trained only on normal process data, a fault event can be detected when reconstruction error (RE) between the input and the output of AE becomes large.

It is, however, difficult for AE, as well as other conventional anomaly detection methods, to appropriately cope with sudden changes in process data, which may cause false alarms and obstruct detection of true fault events in processes. Thus, deterioration of the quality of

process data may affect process performance and safety.

In order to suppress such false alarms and missed fault events caused by sudden changes in data and to improve process suitability and safety, a regularization term in addition to a loss function can be introduced to a training process of an AE model [4].

A graph-based regularization term expresses the relationship between process variables and imposes a penalty when the relationship changes between input and output, which is expected to emphasize abnormal changes in the process data. Graph Laplacian regularization (GLR) has attracted attention for its ability to smooth data, particularly for denoising image data [5], as a simple and useful method that can make the input data according to a graph expressing definitions of smoothness [6-8]. For example, the distance between pixels of image data can be defined as data smoothness. GLR can be applied not only to image data but to any other type of data as long as the data can be expressed as a graph.

In this study, we utilize GLR for anomaly detection to suppress false alarms and missed fault events caused by sudden changes in process data. We propose a new anomaly detection method based on AE with GLR. In the proposed method, a graph-based regularization term is introduced when training an AE model. In addition, the graph-based regularization term can take the smoothness of data expressed as a graph structure.

In order to use GLR, an appropriate graph needs to be constructed. The proposed method adopts, as a graph construction method, the Nearest Correlation (NC) method, which is a structural learning algorithm that considers correlations between variables [9]. Using GLR based on the NC method, it is expected that missed measurements and noise contained in the process data are automatically corrected in terms of correlations between variables, and only significant changes in process characteristics such as fault events are detected.

The use of GLR with the NC method would realize a reliable anomaly detection model that can improve the efficiency and reliability of process monitoring and control in various industrial applications.

In this study, the usefulness of the proposed anomaly detection method is demonstrated through its application to simulation data of a vinyl acetate monomer (VAM) production process, generated by a process simulator provided by Omega Simulation Co., Ltd [10,11].

# METHODS

## Graph Laplacian regularization

The Laplacian is a mathematical operator that measures the degree of curvature or change in a function, quantifying how different the value of a function is from its surroundings.

The Laplacian operator can be extended to graphs, in which case it is called the graph Laplacian, which is used to describe relationships between the nodes of a graph, and in particular to measure the smoothness of features between neighboring nodes. The graph Laplacian $\boldsymbol{L}$ can be defined as

$$\boldsymbol{L} = \Delta - \boldsymbol{A} \tag{1}$$

where $\boldsymbol{A}$ is the adjacency matrix and $\Delta = \sum_j \boldsymbol{A}_{ij}$ is the order matrix.

GLR is a technique that uses the graph Laplacian to impose smoothness constraints on a model. Particularly, it allows the model to take the graph structure into account by adding a penalty so that the differences in output values between neighboring nodes become small. Although GLR has been mainly used in image processing, it can be used for any type of data if the relationship among variables can be expressed as a graph, such as similarity among variables, rules that variables must follow, or temporary relationships among variables in time-series data.

It is assumed that the numbers of data samples and variables are $N$ and $M$, respectively, $\boldsymbol{x}_i, \boldsymbol{x}_j \in \mathbb{R}^N$ are the $i$th and the $j$th variables of the data matrix $\boldsymbol{X} \in \mathbb{R}^{N\times M}$, and $A_{ij}$ is the similarity or the strength of connection between $x_i$ and $x_j$. Here, $A_{ij}$ is the $(i,j)$ element of the adjacency matrix $\boldsymbol{A} \in \mathbb{R}^{M\times M}$ of the graph. For the predictions $\boldsymbol{y}_i, \boldsymbol{y}_j \in \mathbb{R}^N$ from $\boldsymbol{x}_i, \boldsymbol{x}_j$ and the matrix $\boldsymbol{Y} \in \mathbb{R}^{N\times M}$ containing them, the regularization term $R$ based on GLR is defined by the following equation:

$$\begin{aligned} R = \frac{1}{2}\sum_{i,j=1}^{M} A_{ij}\left\|\boldsymbol{y}_i - \boldsymbol{y}_j\right\|^2 &= \sum_{i=1}^{M} \boldsymbol{y}_i \boldsymbol{y}_i \Delta_{i,i} - \sum_{i=1}^{M} \boldsymbol{y}_i \boldsymbol{y}_j A_{ij} \\ &= \mathrm{Tr}(\boldsymbol{Y}\Delta\boldsymbol{Y}^T) - \mathrm{Tr}(\boldsymbol{Y}\boldsymbol{A}\boldsymbol{Y}^T) \\ &= \mathrm{Tr}(\boldsymbol{Y}\boldsymbol{L}\boldsymbol{Y}^T) \end{aligned} \tag{2}$$

By adding this regularization term to the loss function when training the AE model, the similarity among the data can be considered to be within the model.

## Nearest Correlation method (NC method)

To use GLR, a suitable graph needs to be constructed from the data. In this study, we utilize the NC method.

The NC method was originally proposed as a way to detect multiple samples that have similar correlations with the target sample. An illustrated example of the NC method is shown in Figure 1.

$N$ samples are given and a zero matrix $\boldsymbol{S} \in \mathbb{R}^{N\times N}$ is set up. Here, a target sample is $\boldsymbol{x}_1 \in \mathbb{R}^M$. First, $\boldsymbol{x}_1$ is translated to the origin of the space, that is, $\boldsymbol{x}_i' = \boldsymbol{x}_i - \boldsymbol{x}_1$ and $\boldsymbol{x}_1' = 0$. Then, correlation coefficients are calculated for all possible pairs of samples except $\boldsymbol{x}_1'$, such as $\boldsymbol{x}_2 - \boldsymbol{x}_3$, $\boldsymbol{x}_2 - \boldsymbol{x}_4, \cdots$. A weight of 1 is assigned to the pair when

its correlation coefficient exceeds a predefined threshold of $\gamma$. For example, in Fig. 1, samples $\boldsymbol{x_2}$ and $\boldsymbol{x_6}$, $\boldsymbol{x_3}$ and $\boldsymbol{x_4}$ correspond to pairs with high correlation coefficients. That is, 1 is added to $\boldsymbol{S_{2,6}}$, $\boldsymbol{S_{6,2}}$, $\boldsymbol{S_{3,4}}$ and $\boldsymbol{S_{4,3}}$. This process is repeated until all samples have become the target sample. Finally, the matrix $\boldsymbol{S}$ represents the similarity among samples from the viewpoint of correlation. In this study, the obtained matrix $\boldsymbol{S}$ has integer values greater than or equal to 0, which is then transformed into an unweighted matrix consisting only of elements 0 and 1, with all positive values being 1. The resulting matrix is used as the adjacency matrix $\boldsymbol{A}$ of the graph for GLR.

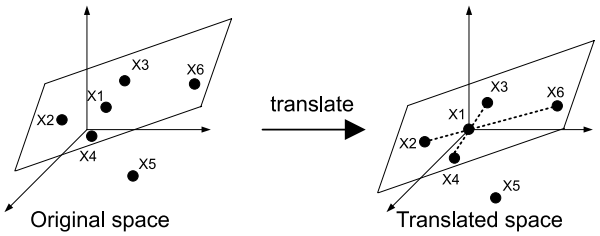

**Figure 1.** Image of NC method

## Proposed method (NCGLR-AE)

In this study, we propose a new anomaly detection method, referred to as NCGLR-AE, which uses GLR and

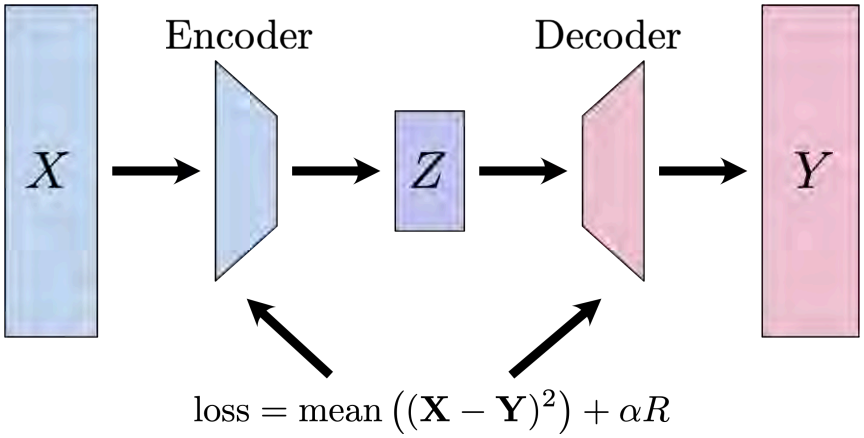

**Figure 2:** Schematic diagram of the proposed anomaly detection method

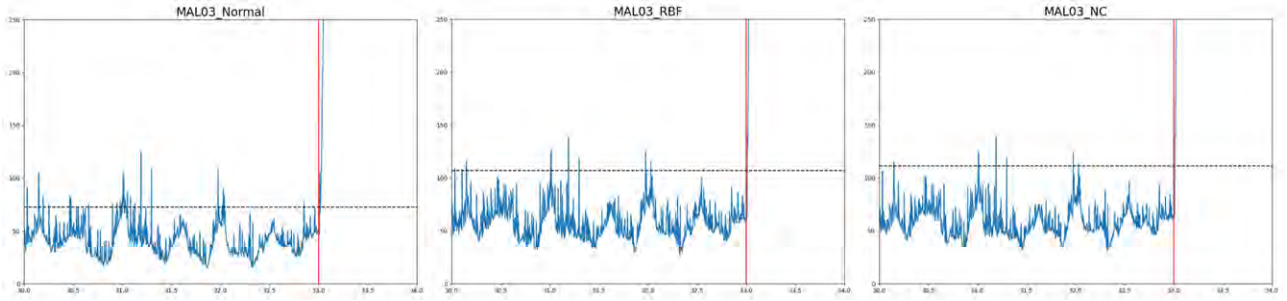

**Figure 3:** RE in VAM process with MAL3

(left: Normal, center: RBF, right: NC)

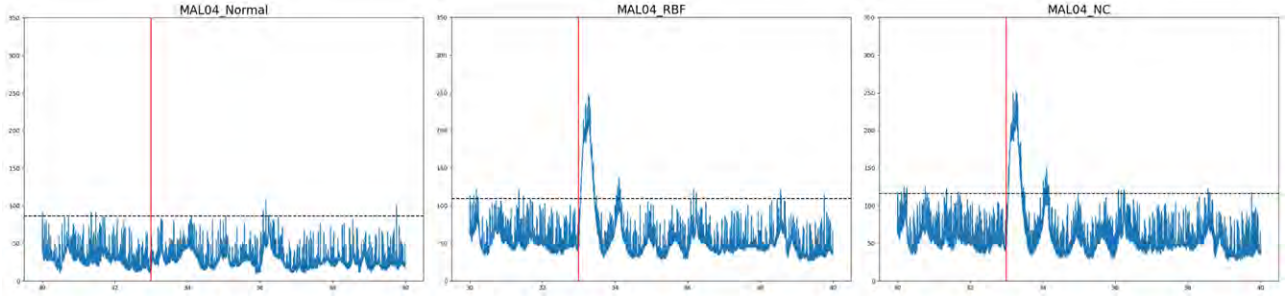

**Figure 4:** RE in VAM process with MAL4
(left: Normal, center: RBF, right: NC)

NC methods during AE training. A schematic diagram of the proposed method is shown in Figure 2. In AE, the input $\boldsymbol{X}$ compress the information into latent variables $\boldsymbol{Z}$ via an encoder. $\boldsymbol{Z}$ is then restored to output $\boldsymbol{Y}$ via a decoder. A graph is created by the NC method with the data variables as nodes from the data matrix $\boldsymbol{X}$. It can be transformed into the GLR $R$ and the AE training is performed with the loss function, defined as

$$\text{loss} = \text{mean}((\boldsymbol{X} - \boldsymbol{Y})^2) + \alpha R \quad (3)$$

where $\alpha$ is a regularization weight.

RE between the input and the output of the trained AE is defined as the anomaly score. A control limit is set as the value at which $\beta$ % is normal with respect to the abnormality score of the training data consisting of normal data only, and the abnormality score calculated from process data. The data are regarded as abnormal only when the abnormality score exceeds the control limit.

The model training procedure of the proposed method is described as follows:

1. Divide the training data $\boldsymbol{X} \in \mathbb{R}^{N \times M}$ into training and validation data so that the order of the time-series does not change.
2. Extract data $\boldsymbol{X}_t \in \mathbb{R}^{B \times M}$ for a batch size $B$.
3. Calculate adjacency matrix $\boldsymbol{A}_t \in \mathbb{R}^{M \times M}$ using the NC method for the variable direction of $\boldsymbol{X}_t$.
4. Input $\boldsymbol{X}_t$ into AE and obtain output $\boldsymbol{Y}_t \in \mathbb{R}^{B \times M}$.
5. Calculate $\boldsymbol{L}_t \in \mathbb{R}^{M \times M}$ from $\boldsymbol{A}_t$ and GLR $R_t$ from $\boldsymbol{L}_t, \boldsymbol{Y}_t$.
6. Calculate the loss function of AE from $\boldsymbol{X}_t$.
7. Extract next data for the next batch size.
8. Repeat steps 3-7 until the validation loss converges.
9. Define the value at which $\beta$ % of the abnormality scores for the training data are normal as the control limit.

# CASE STUDY

## Dataset

Simulated process data generated from the vinyl acetate monomer (VAM) process model was used to assess the performance of the anomaly detection model trained by the proposed method. Forty hours of the VAM process operation data were generated, which included situations where sudden malfunctions occurred 33 hours after the start of measurement. The first 30 hours of data were used for training and the remaining 10 hours for testing. To validate the performance of the model for different types of faults, test data were prepared, including six different faults: faults MAL01 and MAL02, which reduced the feed composition of feedstock ethylene and acetic acid, respectively; MAL03 and MAL04 are malfunctions that reduced the feed pressure of the feedstock ethylene and oxygen, respectively; MAL09 and MAL10 are faults that changed the temperature and pressure of the cooling water, respectively. Sixty-two process variables in the VAM process, measured every 10 seconds, include pressure and flow rate values.

## How to train models and determine thresholds

We employed an autoencoder (AE) as the model for anomaly detection, with a one-layer encoder and a one-layer decoder, and the number of units in the middle layer (30) and the batch size (100) were kept constant for all comparison models.

Taking advantage of the characteristics of time-series data, the graph was constructed under the assumption that data close in time have close values. To calculate the correlations between variables of temporally close data, a graph was constructed using the NC method with the variables as nodes. The GLR was calculated from the adjacency matrix of the graph and added to the loss function during batch training of AE. When validation loss did not decrease for five consecutive times, loss was considered to have converged and AE training was terminated.

In this study, we used "reconstruction error (RE)" as the anomaly score. RE is the square of the error between the input and output values.

In order to compare the performance differences between the graph construction methods, a Gaussian (Radial Basis Function; RBF) kernel, which calculates similarity based on the distance between two points, was employed in addition to the NC method. The Gaussian kernel is calculated by the following equation:

$$A_{ij} = \begin{cases} 1, & \exp\left(-\frac{\|x_i - x_j\|^2}{2\sigma^2}\right) > 0.99 \\ 0, & \exp\left(-\frac{\|x_i - x_j\|^2}{2\sigma^2}\right) \leq 0.99 \end{cases} \quad (4)$$

where $\sigma$ is a hyperparameter that adjusts how far away data can be and still be considered similar; if $\sigma$ is large, a wide range of data points are considered similar. In this case, $\sigma$ was set to 10.

## Results

In this study, we used "False Alarm Rate (FAR)", "Missing Alarm Rate (MAR)" and "Detection Latency (DL)" as evaluation indicators. The definitions of FAR and MAR are given in the following equations:

$$FAR = \frac{False\ Positive}{Number\ of\ Normal\ Samples} \times 100 \quad (5)$$

$$MAR = \frac{False\ Negative}{Number\ of\ Anomalous\ Samples} \times 100 \quad (6)$$

FAR indicates the percentage of samples judged to be abnormal in the normal data before a fault event

**Table 1:** Anomaly detection results for each anomaly scenario. The best value for each test data is shown in bold.

| Malfunction | Model | FAR [%] | MAR [%] | DL [s] |
|---|---|---|---|---|
| MAL01 | - | **0.278** | 0.198 | 52 |
| | RBF | 0.648 | **0.159** | **42** |
| | NC method | 0.648 | **0.159** | **42** |
| MAL02 | - | 0.926 | 0.397 | 103 |
| | RBF | 0.463 | **0.357** | **83** |
| | NC method | **0.370** | 0.397 | 103 |
| MAL03 | - | 3.70 | 0.198 | 44 |
| | RBF | 0.926 | **0.159** | 44 |
| | NC method | **0.741** | **0.159** | 44 |
| MAL04 | - | **0.278** | 99.8 | 11122 |
| | RBF | 0.648 | 94.1 | **212** |
| | NC method | 0.648 | **93.8** | **212** |
| MAL09 | - | 0.0926 | 0.476 | 123 |
| | RBF | 0.0926 | 0.397 | 102 |
| | NC method | 0.0926 | **0.357** | **93** |
| MAL10 | - | 0.185 | **1.67** | **412** |
| | RBF | 0.0926 | 1.74 | 421 |
| | NC method | **0.0** | 1.79 | 452 |

occurred. The lower this indicator, the fewer false detections of abnormalities. MAR indicates the percentage of anomaly data that are incorrectly determined as normal after a fault event occurred. A lower MAR means that anomaly is correctly detected. DL is the time required from the occurrence of a fault event to its detection. DL should be small from the viewpoint of early detection of faults.

Anomaly detection results for each anomaly scenario are shown in Table 1. The best value for each set of test data is shown in bold.

The models with GLR demonstrate significant performance improvements in many anomaly patterns, particularly when graphs were constructed using the NC method. For MAL02, MAL03, and MAL10, the number of false positives was reduced by applying GLR. This indicates that unnecessary alarms were appropriately suppressed, which is expected to reduce operator burden and improve work efficiency.

Figure 3 shows an enlarged view of the MAL03 abnormal score around the normal data. There are several points where the threshold value is exceeded only when GLR is not applied. One possible reason is that the anomaly score fluctuates significantly due to noise when GLR is not applied. This suggests that GLR was effective in removing noise from process data, and that noise removal may enable stable calculation of abnormality scores.

For MAL04 and MAL09, the smallest MAR was achieved with the NC method. Figure 4 shows the MAL04 anomaly score, indicating that the fault event was incorrectly detected without GLR. On the other hand, GLR accurately detected the occurrence of the faults. It is concluded that consideration for the correlation between variables during the training process enabled the accurate detection of fault events. In addition, these results also showed that GLR is useful for time-series data processing.

MAL01 and MAL10, however, had performances that were the same regardless of GLRs, or even better when GLRs were not used. As such, there may be room for improvement in the proposed model.

## CONCLUSION

In this study, an anomaly detection model incorporating graph Laplacian regularization created by the NC method is proposed. Based on the process that data points close in time have close values, it was possible to construct an anomaly detection model that utilizes the properties of time-series data.

The addition of the regularization term successfully improved the anomaly detection rate for many sets of anomaly simulation data compared to cases without the regularization term, and the correlation-aware NC method was effective in detecting anomalies with higher accuracy.

In the future, validation against real data and verification of accuracy will be carried out in order to enable more accurate anomaly detection. In addition, although this study was only validated on AE, future validation will be done on other deep-learning models.

## ABSTRACT

In the domain of process systems engineering, developing software embedded with advanced computational methods is in great demand to enhance the kinetic comprehension and facilitate industrial applications. Polymer production, characterized by complex reaction mechanisms, represents a particularly intricate process industry. In this work, a scientific software is developed for polymerization modelling and simulation with insight on microscopic resolution. From a software architecture perspective, the software is built on a self-developed process modelling platform that allows flexible user customization. A specific design for polymer species with microscopic chain structure information is conducted. From an algorithm perspective, the software offers high-performance solution strategies for polymerization process modelling by utilizing advanced computation approaches. A Ziegler-Natta copolymerization is presented to demonstrate the software's capability in capturing the microscopic structural information of polymers.

**Keywords**: Polymerization Process, Modular Modelling, Software Development.

## INTRODUCTION

In the domain of process systems engineering, developing process modeling software embedded with advanced computational methods is in great demand to enhance the industrial process simulation, synthesis and optimization.

Industrial systems are often characterized by complex process flowsheets and significant uncertainties, leading to the difficulty in establishing a precise mechanism model. Moreover, the application of these models can be diverse, which may involve the calculation of microscope or macroscope quality indicators, the synthesis of process flowsheets, and the optimization of operating conditions. Due to the complexity of modeling and the diverse applications of the models, some customized modeling software for specific processes has been developed and put into practical industrial applications. In some specific industrial scenarios, these specifically designed software can better meet the diversified and flexible requirements of users.

Polymer production is a particularly intricate process industry. There are many difficulties in developing customized modeling software for the polymerization process. First, a qualified software should model basic reactions involving initiation, propagation, chain transfer and termination, etc., each of which contributes to the overall complexity. Distinct polymerization mechanisms, such as free radical and Ziegler-Natta, add further intricacy. Second, accurate quantification of reaction rate constants, and other kinetic parameters also remains a significant challenge. They are hard to measure experimentally. Estimation of these parameters requires extensive engineering experience and industrial data. Moreover, polymers exhibit a wide variety of molecular structures, such as linear, branched, along with complex molecular weight distributions (MWDs). These microscopic indexes, which significantly influence the product properties, are highly sensitive to reaction conditions, monomer types, and catalysts. Therefore, accurate characterization and prediction of them is crucial and require specialized modeling techniques. Last but not least, polymerization models are inherently nonlinear large-scale equations system[1]. The computational cost of

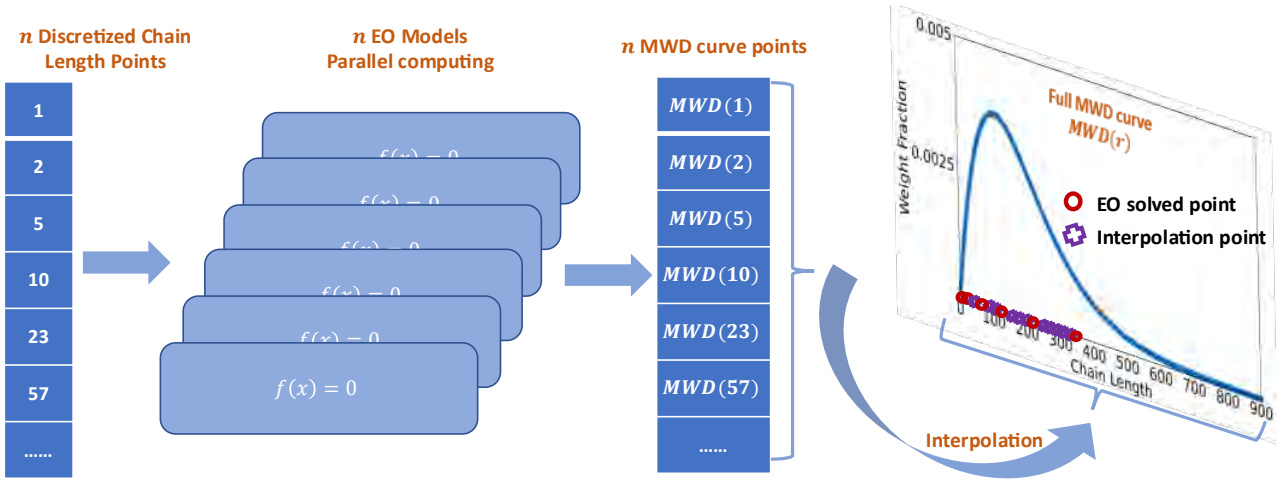

**Figure 1:** A graphic illustration of the solution process for the cumulative MWD is provided. The computation of the full MWD curve is decomposed into *n* sparse systems of linear equations, each with identical topology. These systems are solved to obtain the values of *n* discretized points along the MWD. Using these discretized points, interpolation is applied to reconstruct the full MWD curve. The final MWD curve is constructed from both the discretized points obtained through the solution process and the interpolated points.

solving such models is high. The numerical stability and convergence are also challenging. In light of this, a scientific software is developed for polymerization modelling and simulation with insight on microscopic resolution.

## SOFTWARE ARCHITECTURE

The software is built on a self-developed process modelling platform that allows flexible user customization. It is modularly designed, and each module supports external libraries and secondary development. Pivotal modules, including reaction components, reaction kinetics, process units, process streams and solution strategies, are meticulously constructed and seamlessly integrated.

### Components

The software enables users to define various types of components, including conventional, site-based and polymers. Due to their distinct macroscopic and microscopic representation methods, the corresponding data structures of components in the software are also designed differently. Taking polymer components as an example, their macroscopic properties, such as moments of chain length distribution (CLD) and average molecular weight, as well as microscopic properties, including CLD, molecular weight distribution (MWD), branch structure and monomer composition, are modelled.

Meanwhile, each type of component introduces unique variables that must be solved in the model. Specifically, for all streams, the model needs to solve the flowrate of conventional components, the flowrates of potential, vacant and dead sites of site-based components and moments of polymer distribution.

### Streams

Streams serve as intermediaries between different process units, facilitating the transfer of data structures and solution results of all components. They can also conveniently store various local information that users may wish to retain.

### Units

The software designed a standard unit module for process modelling, which are interconnected through streams. Various unit types and their corresponding functions can be customized, such as continuous stirred tank reactors (CSTR), mixers, and others.

### Kinetics

The designed kinetics module allows for the definition of individual reactions, including the specification of reactants, products, and parameters associated with reaction rates. The defined reaction kinetics can be assigned to reactors and utilized to solve the model. The Arrhenius equation, as shown in Equation 1, is used to calculate the reaction rate $K$, requiring values of the pre-exponential factor $A$, activation energy $E_a$, and reference temperature $T_0$. $R$ is the universal gas constant and $T$ is the temperature.

$$K = A\mathrm{e}^{-\frac{E_a}{R}(\frac{1}{T}-\frac{1}{T_0})} \quad (1)$$

A standard Ziegler Natta reactions library has been developed in this module. The provided polymerization reactions templates, including different kinds of activation, initiation, propagation, chain transfer and deactivation, can be easily called by users. Besides these

reactions, users can also customize various reaction templates.

### Macroscopic process solution strategies

At the flowsheet level, the software provides both an equation-oriented and a sequential-module approach to solve for macroscopic information. The Method of Moment (MoM) is employed to characterize the polymer components throughout the process [2]. As a result, the equation-oriented model will incorporate the balance equations derived from the moment model.

### Microscopic quality indexes solution strategies

The software provides users with both deterministic and stochastic algorithms to predict microscopic quality indexes, particularly the molecular weight distribution. To evaluate cumulative polymer on the stream level, the equation-oriented method is utilized to enable the calculation of cumulative MWD for each stream. For example, in a CSTR with one feed stream and one output stream, the cumulative MWD of the polymer in the output stream is modelled as a weighted sum of the cumulative MWD in the feed stream and the MWD of the newly produced polymer within the CSTR. When solving for the cumulative polymer's MWD of every stream, such equality relationships are systematically established and solved across the entire flowsheet. As shown in Figure 1, efficient solution strategies are adopted during this process. First, the whole MWD curve is discretized into $n$ discrete points. Next, for each discrete point the balance equations model of the whole process is solved. Thus, the dimension of the equations is reduced by a factor of n and we solve $n$ equation models with the exact same topology.

## ALGORITHMS

The software provides users with both deterministic and stochastic algorithms to complete the simulation and computation.

### Stochastic Methods

The SSMC algorithm proposed by our group is used for the modelling and simulation of steady-state polymerization process with complex mechanisms [3]. As illustrated in Figure 2, by utilizing "buffer pool", it decomposed the complex polymerization process into several steps for modelling.

This SSMC algorithm enables the prediction of detailed microscopic structure of polymer. Customized data structures are designed for elaborate polymer chain modeling. Through tracking the formation of every simulated chain, it not only provides MWD information but also offers more detailed insights, such as the number and position of branching in each polymer chain when there involves chain transfer to polymer reaction.

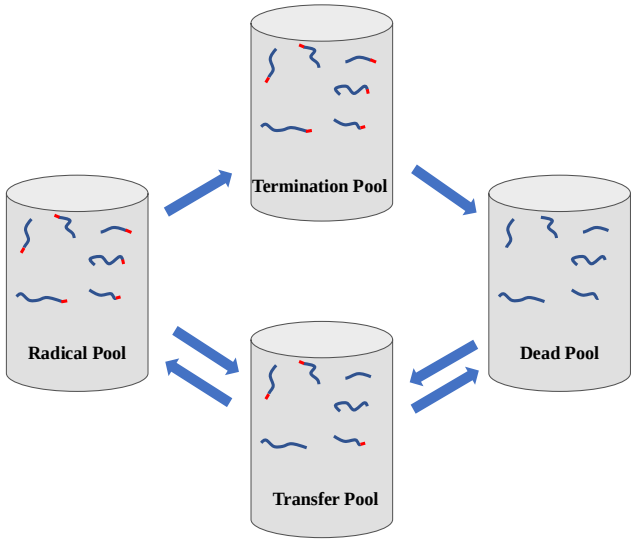

**Figure 2.** Buffer pools and the multistep polymerization model in the SSMC algorithm.

The scheme of this method is shown in Figure 3. It is a general method as long as the moment model can be established and solved by the software. When this algorithm is called in the software, the results from the moment model and the reaction rates from the mechanisms are required, and the microscopic structural information of the polymer is returned as output.

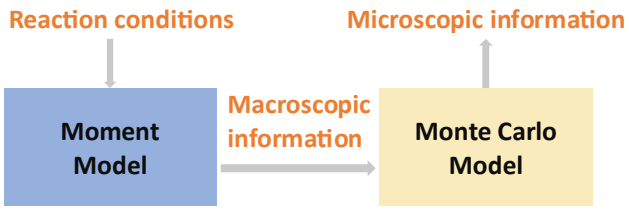

**Figure 3.** Scheme of applying the SSMC algorithm.

Moreover, this SSMC algorithm have an advantage in efficiency compared with traditional Monte Carlo simulation methods which inherently suffer from significant time and computational resource consumption. When the algorithm is implemented in this software as Python code, a modern high-performance code compiler Numba is employed to accelerate Monte Carlo simulations [4]. Numba generates optimized machine code directly from Python code, ensuring improved computational efficiency without compromising the accuracy of the results.

### Deterministic Methods

An orthogonal collocation method with model reformulation strategies for mathematical operations caused by various reactions is involved in the solution algorithms of the software [1]. Theoretically, the number of equilibrium equations of polymer can be infinite if the MWD curve is also inserted in them. This algorithm allows for

the discretization of CLD curve in time and chain length dimensions, thus it significantly decreases the number of equations. It is also applicable for the steady-state considering only chain length dimension.

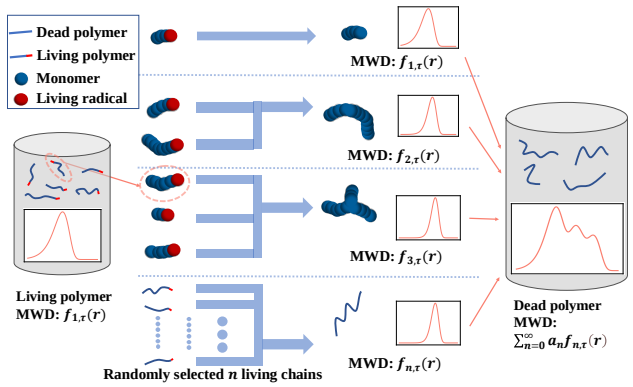

**Figure 4.** Scheme of applying analytical expressions for MWD derivation in the software.

Besides the equation-oriented methods, analytical expressions are derived for the MWDs associated with specific mechanisms. Represented by the Flory distribution, these expressions provide a straightforward way to calculate the MWD. In this method, the classical Flory distribution is extended to a more general form to handle more complex mechanisms, including bi-molecular termination, chain transfer to polymer and reversible reactions. As shown in figure 4, this method defines a general form of probability density functions (PDFs) and basically analyses all the reactions that producing dead polymer and derives the corresponding MWDs. The PDFs is shown in Equation 2, where $n$ and $\tau$ are parameters associated with reaction mechanisms and $r$ is the variable.

$$f_{n,\tau}(r) = \frac{\tau^{n+1} r^n}{n!} e^{-\tau r} \quad (2)$$

The total MWD of all dead polymer is determined as a weighted combination of these MWDs. When this algorithm is called within the software, it requires the mechanisms and results from the moment model as input, and returns the polymer's MWD as output.

## INDUSTRIAL APPLICATION

The software has designed standard functions for defining and solving polymerization models. The core modeling functions are designed for specifying individual modules of the model, including components, streams, units, and kinetics. These functions make the modelling process of each module convenient and efficient. The modelling and simulation steps of this software are illustrated in Figure 5.

An industrial application is next demonstrated by using the software. It is a Ziegler-Natta copolymerization produced by two CSTRs as shown in Figure 6. This case focuses on polymerization kinetics and the microscopic structure of the polymer.

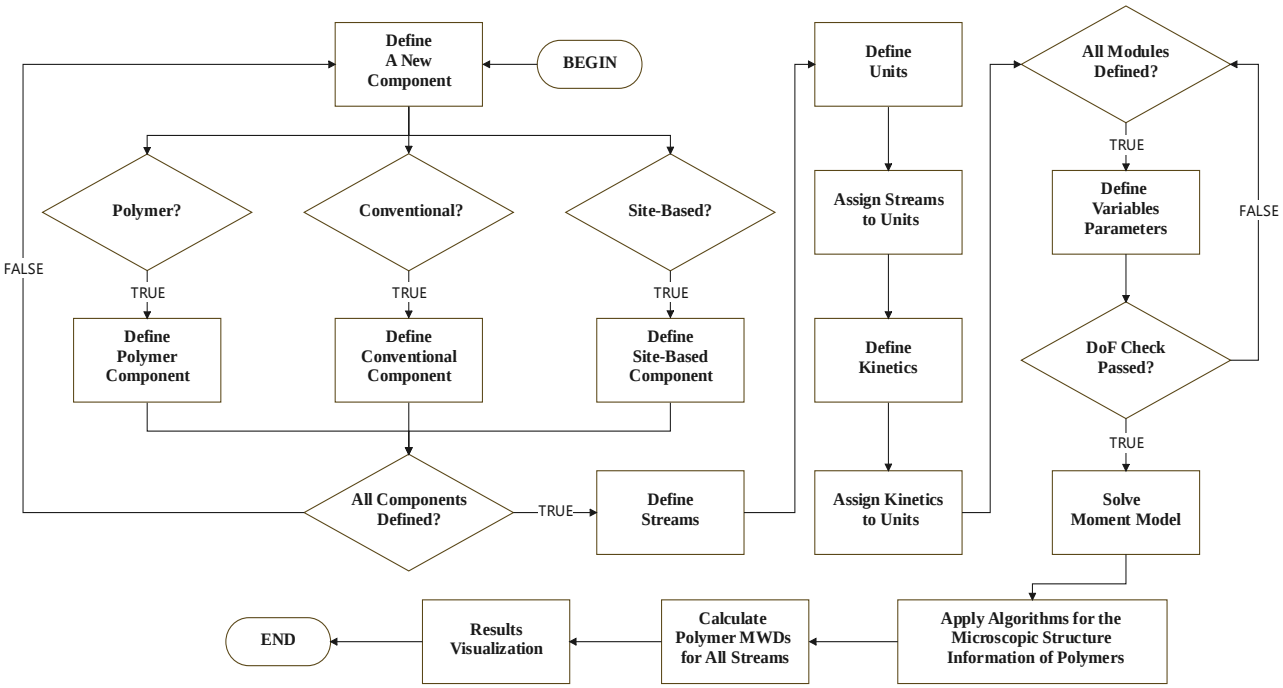

**Figure 5:** The flowchart for the modeling and simulation steps of the software, outlining the sequential process from model definition to simulation execution.

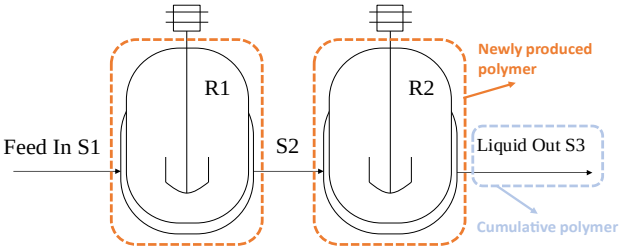

**Figure 6.** The simplified flowsheet of the Ziegler-Natta copolymerization case.

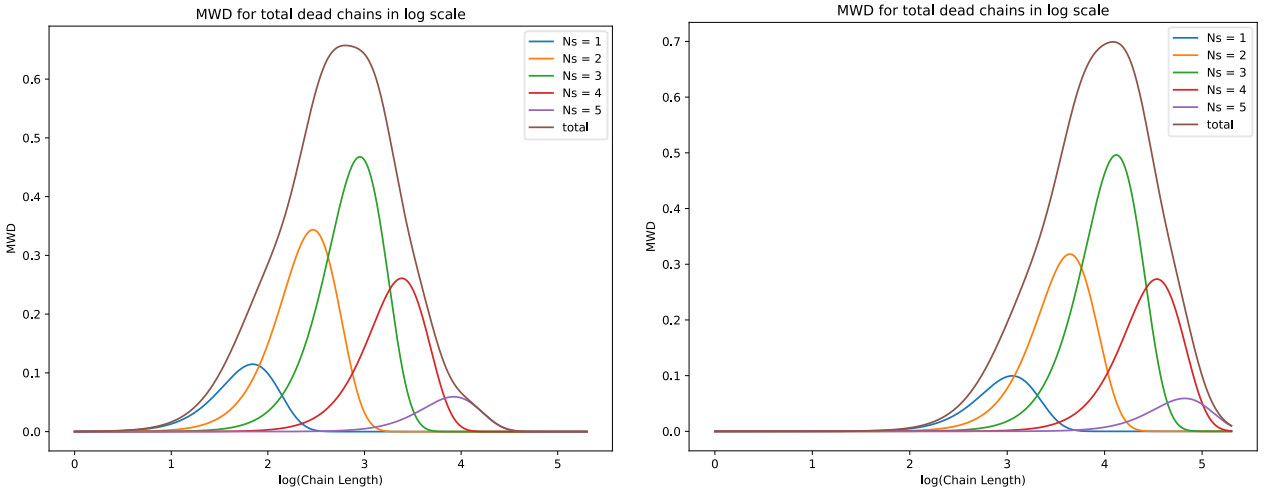
First, we define the components involved in this application. Ethylene and 1-butene are defined as monomers, triethyl aluminum as the cocatalyst, n-hexane as the solvent, and hydrogen as a controlling agent. The site-based component, titanium tetrachloride, is defined as the catalyst, with the potential, vacant, and dead sites being tracked. The number of active sites is set to five. For the olefin polymer, the moments, MWD, and other structure properties are studied.



The CSTRs operate under fixed conditions with a constant liquid phase volume. Next, we define the Ziegler-Natta kinetics with reactions occurring on five active sites. The reactions involved in this kinetic model are listed in Table 1. $P_r^*[M]$ denotes living polymer with chain length $r$ and the end monomer $M$. $D_r$ denotes dead polymer with chain length $r$. Values of the pre-exponential factor $A$, activation energy $E_a$, and reference temperature $T_0$ are specified to calculate the corresponding reaction rates. The defined kinetics are then assigned to the two CSTRs.

Eventually, the moment model is established and solved. The results obtained include the concentrations of conventional components, the concentrations of potential, vacant, and dead sites, as well as the moments of the polymer CLD within the two CSTRs. The self-developed algorithms are applied to derive the MWD of newly produced polymer in R1 and R2. The results are plotted in Figure 7, the MWD curves of five activate sites are derived, respectively.

**Table 1:** Reactions involved in the Ziegler-Natta kinetic.

## CONCLUSION

A modelling and simulation software for polymerization with microscopic resolution is proposed in this study. The module architecture and self-developed efficient algorithms of this software are introduced in detail. To demonstrate the software's capability in capturing the microscopic structural information of polymers, a Ziegler-Natta polymerization is applied. The insights gained from this work open up opportunities for process analysis and optimization of polymerizations.

## ABSTRACT

Second-order optimization algorithms that leverage the exact Hessian or its approximation have been proven to achieve a faster convergence rate than first-order methods. However, their applications on training deep neural networks models, partial differential equations-based optimization problems, and large-scale non-convex problems, are hindered due to high computational cost associated with the Hessian evaluation, Hessian inversion to find the search direction, and ensuring its positive-definiteness. Accordingly, we propose a new search direction based on an interval Hessian and incorporate it into a line-search framework. We apply our algorithm to a set of 210 problems and show that it converges to a local minimum for 70% of the problems. We also compare our algorithm with other approaches. We illustrate that our algorithm is competitive to other methods in finding a local minimum using a smaller number of $O(n^3)$ operations.

**Keywords**: Second-order optimization, Interval Hessian, Line-search framework, Non-Convex optimization.

## 1. INTRODUCTION

We consider the unconstrained optimization problem:

$$\min_{x\in\mathbb{R}^n} f(x)$$

where $f: \mathbb{R}^n \to \mathbb{R}$ is a twice continuously differentiable function, and $n$ is the number of variables. Several first- and second-order methods have been developed to solve the above problem. These algorithms are used in areas like process optimization, communications, machine learning, and signal processing. First-order algorithms, such as steepest descent, stochastic gradient descent, and various adaptive gradient methods, are particularly popular for large-scale problems due to their relatively low computational demands per iteration. Despite their prevalence, first-order methods are limited in that they only guarantee convergence to a first-order stationary point. Thus, these methods can converge to a saddle point rather than a local minimum.

In contrast, second-order optimization algorithms, which utilize the curvature information via the Hessian matrix, provide faster convergence and avoid saddle points. Newton's method, a classic second-order approach, adjusts the gradient direction with a preconditioning matrix derived from the Hessian, achieving convergence to points that meet second-order optimality conditions.

Although Newton's method exhibits impressive convergence characteristics compared to first-order approaches, their broad application to large-scale optimization problems poses significant challenges. First, the memory requirement increases with the square of the number of variables. Second, the Hessian calculation can be expensive. Third, at each iteration, the search direction requires computing the inverse of the Hessian, which requires $O(n^3)$ operations and can be computationally expensive for large $n$. Fourth, Newton's direction for non-convex problems may not be descent at each iteration. However, nonconvexity is ubiquitous in several applications, including, training neural network models, reactor and separation network synthesis, process design, and computational chemistry.

To address these limitations, quasi-Newton methods have been developed as computationally feasible alternatives. Quasi-Newton methods, such as the BFGS algorithm [2], approximate the Hessian using gradients of the previous iteration and thus reduce computational

demands. Sub-sampled Newton methods [5] decrease costs by approximating the Hessian using a subset of data points. Despite these advances, balancing Hessian approximation accuracy with computational tractability remains a fundamental challenge.

Accordingly, we propose a new search direction based on an interval Hessian and incorporate it into a line-search framework. Our approach is inspired by αBB method proposed by Floudas and co-workers [1] to construct a convex underestimator of a twice-differentiable function over an interval $[x^L, x^U]$. Our approach involves using the Hessian of the αBB underestimator. There are three advantages of this approach. First, since the underestimator is convex, its Hessian will always be positive definite. Thus, the search direction is guaranteed to be descent. Second, the same Hessian matrix can be used if the iterates lie in the interval for which the interval Hessian is valid. This results in (1) avoiding computing Hessian at each iteration and (2) the search direction is computed by taking matrix-vector product instead of $O(n^3)$ operations that are typically needed in Newton and Quasi-Newton methods.

## 2. METHODOLOGY

### 2.1. Search Direction

In this article, we propose a variant of the Newton direction to ensure descent at each iteration for non-convex problems. We incorporate the search direction into a line-search framework:

$$x_{k+1} = x_k + \theta_k p_k$$

where $x_k$ is the current iterate, $x_{k+1}$ is the next iterate, $\theta_k$ is the step length, and $p_k$ is the search direction. Our search direction is inspired by the $\alpha BB$ method developed for global optimization of non-convex problems. This method constructs a convex underestimator of a twice continuously differentiable function with the following form:

$$\mathcal{L}(x) = f(x) + \sum_{i=1}^{n} \alpha_i \left(x_i^L - x_i\right)\left(x_i^U - x_i\right)$$

where $\alpha_i \geq 0$. This underestimator is constructed by subtracting a positive term from $f(x)$, making $\mathcal{L}(x)$ a valid underestimator of $f(x)$ within $[x^L, x^U]$. The parameter $\alpha_i$ is calculated to ensure that $\mathcal{L}(x)$ is convex over this interval, which implies that the Hessian of $\mathcal{L}(x)$ is positive semi-definite. Thus, we choose $p_k$ as follows:

$$p_k = -(B_k)^{-1} \nabla f_k \tag{1}$$

where $\nabla f_k = \nabla f(x_k)$ and $B_k = B_{k-1}$ if $x_k$ lies in the interval for which the convex underestimator is valid; otherwise, new variable bounds are constructed and $B_k = \nabla^2 \mathcal{L}_k$. The Hessian of the $\alpha$BB underestimator provides a localized approximation of the objective function's curvature. The relationship between the Hessians of $\mathcal{L}(x)$ and $f(x)$ at $x = x_k$ is:

$$\nabla^2 \mathcal{L}_k = \nabla^2 f_k + 2\Delta$$

where Δ is a diagonal matrix with elements $\alpha_i$. The matrix Δ is referred to as the diagonal shift matrix. For simplicity, we assume a uniform diagonal shift matrix, such that $\alpha_1 = \alpha_2 = \alpha_3 = \cdots = \alpha_n = \alpha$, leading to:

$$\nabla^2 \mathcal{L}_k = \nabla^2 f_k + 2\alpha I$$

where $I$ denotes the identity matrix. Based on the above equation, we conclude that the difference between the Hessian of the function and the $\alpha$BB underestimator depends on $\alpha$. Consequently, the accuracy of computing $\alpha$ determines the search direction quality, which in turn affects the performance of our algorithm.

Maranas and Floudas demonstrated [1] that the underestimator, $\mathcal{L}(x)$, is convex if and only if:

$$\alpha \geq \max\left\{0, -\frac{1}{2} \min_{i, x^L \leq x \leq x^U} \lambda_i \left(\nabla^2 f(x)\right)\right\}$$

where $\lambda_i$ are the eigenvalues of $\nabla^2 f(x)$. Finding $\alpha$ by using the above equation is equivalent to solving a non-convex optimization problem to global optimality, which can require significant computational effort.

To overcome this difficulty, a lower bound on the minimum eigenvalue of the interval matrix, $[\nabla^2 f(x)] \supseteq \nabla^2 f(x), \forall x \in [x^L, x^U]$, is computed. This interval Hessian is then used in further $\alpha$ calculations. In subsequent sections, we explore various approaches to compute $\alpha$ by employing methods with $O(n^2)$ and $O(n^3)$ complexities.

### 2.2. $\alpha$ Calculation Methods

We use three methods to compute the value of lower bound on eigenvalues ($\lambda_{min}$) for a real interval matrix $[A] = \left(\left[\underline{a_{ij}}, \overline{a_{ij}}\right]\right)$. We define following notations useful in computation of $\lambda_{min}$.

$$\underline{A} = \left(\underline{a_{ij}}\right) \text{ and } \overline{A} = \left(\overline{a_{ij}}\right), \Delta a_{ij} = \left(\overline{a_{ij}} - \underline{a_{ij}}\right)/2$$

$$\widetilde{\Delta A} = \left(\widetilde{\Delta a_{ij}}\right), \widetilde{\Delta a_{ij}} = \begin{cases} 0 & \text{if } i = j, \\ \Delta a_{ij} & \text{otherwise} \end{cases}$$

$$A_M = (a_{M,i,j}), a_{M,ij} = \left(\overline{a_{ij}} + \underline{a_{ij}}\right)/2$$

$$\widetilde{A_M} = \left(\widetilde{a_{M,ij}}\right),$$

$$\widetilde{a_{M,ij}} = \begin{cases} \underline{a_{ij}} & \text{if } i = j, \\ a_{M,ij} & \text{otherwise} \end{cases}$$

where, $\Delta A$ is the radius matrix, $\widetilde{\Delta A}$ is the modified radius matrix, $A_M$ is the midpoint matrix, $\widetilde{A_M}$ is the modified midpoint matrix, $\underline{A}$ is the lower vertex matrix and $\overline{A}$ is the upper vertex matrix. The various methods of $O(n^2)$ and $O(n^3)$ complexities to calculate the minimum eigenvalue are given below.

### 2.2.1 Approximate Gerschgorin: Complexity $O(n^2)$

$$\lambda_{min}([A]) \geq \min_i \left[ \underline{a_{ii}} - \sum_{j \neq i} \max\left( \left| \underline{a_{ij}} \right|, \left| \overline{a_{ij}} \right| \right) \right]$$

### 2.2.2. E-Matrix Method: Complexity $O(n^3)$

$$\lambda_{min}([A]) \geq \lambda_{min}\left(\widetilde{A_M} + E\right) - \rho\left(\widetilde{\Delta A} + |E|\right)$$

where E be an arbitrary symmetric matrix, whose value is chosen to be $diag(\Delta A)$ here, $\rho(M)$ denotes the spectral radius of a matrix M, i.e., the maximal absolute eigenvalue and $|E|$ denotes the absolute value taken elementwise.

### 2.2.3. Mori-Kokame Method: Complexity $O(n^3)$

$$\lambda_{min}([A]) \geq \lambda_{min}\left(\underline{A}\right) - \rho\left(\overline{A} - \underline{A}\right)$$

## 2.3. Algorithm

Our algorithm employs a line search technique with the search direction details given in the Section 2.1. The overall framework is outlined in Algorithm 1. We choose two iteration counters, $t$ and $k$. The former serves as the outer iteration counter, and the latter as the inner iteration counter.

We begin by randomly choosing an initial point $x_0$ such that it lies within the interval $[x_0^L, x_0^U]$. The search direction $p_k$ (Eq. (1)) satisfies $\nabla f_k^T p_k < 0$, guaranteeing that it leads to a decrease in the function value. Thus, at each iteration, $f(x_{k+1}) < f(x_k)$.

Once the search direction is determined, we need to decide how far to move in the given direction by choosing an appropriate value of $\theta_k$. We select $\theta_k$ that satisfies the Armijo condition:

$$f(x_k + \theta_k p_k) \leq f(x_k) + c_1 \theta_k \nabla f(x_k)^T p_k$$

where $c_1 \in (0, 1)$. This condition ensures that a sufficiently large decrease in the objective function is achieved. We apply a backtracking line search procedure to find $\theta_k$ that satisfies the Armijo condition.

Our approach leverages interval-based calculations to reduce the need to compute Hessian and its inverse at every iteration. At iteration $k$, if the iterate $x_k$ lies outside the current interval $[x_t^L, x_t^U]$, we update the iteration counter $t$ to $t+1$ and construct an interval of size $\Delta$ around the iterate $x_k$ by setting $x_{t+1}^L = x_k - \frac{\Delta}{2}$ and $x_{t+1}^U = x_k + \frac{\Delta}{2}$. After updating the interval, the interval Hessian is computed using interval arithmetic, the minimum eigenvalue of the interval Hessian is estimated using one of the methods mentioned in section 2.2, and $\nabla^2 L_t$ and its inverse are computed. Thus, at any iteration $t$, depending on the method used to estimate the minimum eigenvalue of the interval Hessian, either one or two $O(n^3)$ operations are performed. On the other hand, at iteration $k$, if the iterate $x_k$ lies inside the current interval $[x_t^L, x_t^U]$, the search direction is updated by taking the product of $(\nabla^2 L_t)^{-1}$ and $\nabla f_k$. Conversely, in Newton's method, Hessian evaluation and its inverse is computed at every iteration. Note that $\nabla^2 L_t$ is a positive-definite matrix, and thus, the search direction is always guaranteed to be descent.

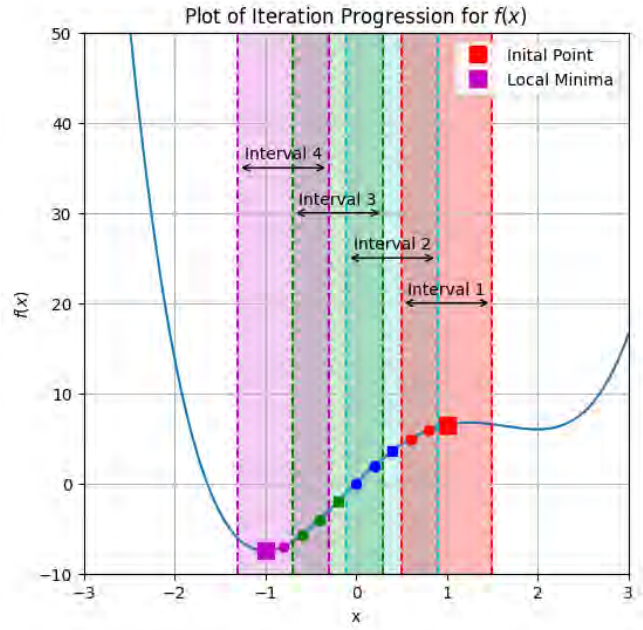

**Figure 1.** Graphical illustration of our proposed algorithm.

Figure 1 demonstrates the iterative mechanics of our approach using a one-dimensional example. The figure illustrates that if the iterates remain within an interval (denoted by a circle marker), the Hessian remains the same, and the search direction is obtained by the matrix-vector product. When an iterate exits the current interval, a new interval is formed around this iterate (denoted by a small square marker), and all the relatively more expensive computations occur.

The algorithm is implemented in C++. We use IBEX for interval Hessian and gradient evaluations and Eigen to compute the matrix inverse.

# 3. COMPETING ALGORITHMS

We compare the performance of our algorithm with the steepest descent, quasi-Newton and the Newton method. The steepest descent amd quasi-Netwon are popular optimization algorithms; their details can be found in a standard optimization textbook [2]. In Newton's method, the search direction, denoted by $p_k^N$, is given by:

$$p_k^N = -(\nabla^2 f_k)^{-1} \nabla f_k$$

At every iteration $k$, finding the search direction requires $O(n^3)$ operations. If the Hessian matrix is positive-definite at the current iterate, $x_k$, then the search

**Algorithm 1** Interval Hessian based line-search method

Set $B_k = \nabla^2 L_t + \lambda_{min} I_n$

$t \leftarrow t + 1$

**else**

**if** $x_k \in [x_t^L, x_t^U]$ **then**

Use the pre-computed Hessian $B_k = B_{k-1}$

**else**

**Hessian Modification** (Compute $B_t$, $x_t^L$, $x_t^U$)

$t \leftarrow t + 1$

**end if**

**end if**

Find the search direction by solving $p_k = -B_t^{-1} g_k$

Compute step length $\theta_k$ satisfying Armijo condition and set $x_{k+1} = x_k + \theta_k p_k$

**end for**

direction is guaranteed to be descent. On the other hand, if the Hessian is indefinite, then it needs to be modified, requiring additional computations. A simple idea to modify the Hessian is to find a parameter $\tau > 0$ such that $\nabla^2 f_k + \tau I$ is positive definite. Algorithm 2 describes a method to iteratively increase the value of $\tau$ until the matrix becomes positive definite, verified by performing Cholesky decomposition.

**Algorithm 2** Brute-force Diagonal Shift

**else** $\tau_{i+1} \leftarrow \tau_i + 1$

**end if**

**end for**

# 4. RESULTS

We illustrate the performance of our algorithm on two illustrative examples and conduct extensive numerical experiments over a comprehensive set of 210 problems [3]. Specifically, we compare the performance based on the number of Hessian evaluations and $O(n^3)$ operations. Since we estimate the interval Hessian at an iteration $t$, we count equivalent to two Hessian evaluations are performed.

## 4.1. Illustrative Examples

### 4.1.1. Example 1

The objective function is of the following form:

$$f(x_1, x_2) = \sum_{j=1}^{17} \sum_{k=1}^{m_j} \left(t_{j,k} - [\exp(-2jx_2)(0.49 - x_1) + x_1]\right)^2$$

where $m_j$ denotes the number of groups at index $j$ and $t_{j,k}$ is a constant. Figure 2(a) shows the paths taken by

the iterates generated by the steepest descent, quasi-newton BFGS and three variants of our algorithm to calculate $\alpha$ based on the methods described in Section 2.2. For this problem, we used $\Delta = 0.1$. It can be observed that the steepest descent can get stuck at regions with small gradients and is unable to reach a local minimum in 10000 iterations. The BFGS method followed a path similar to the steepest descent but failed to find a descent direction after 9 iterations. This occurs because the quasi-Newton method can fail to find a descent direction for non-convex problems if the Armijo condition is used to find the step size $\theta$ (refer chapter 6 of [2]). On the other hand, all our algorithm variants take almost the same path and converge to the same solution. The Gerschgorin-based method requires 8 Hessian evaluations, 8 $O(n^3)$ operations, and 466 iterations. E-matrix based method requires 317, and the Mori-Kokame method converges in 1125 iterations, requiring 7 and 9 Hessian evaluations and 14 and 18 $O(n^3)$ operations respectively.

### 4.1.2. Example 2

We minimize the function of the form:

$$f(x_1, x_2) = C_A x_1 + C_B x_2 + C_C - \left\{ \sum_{(i,j)\in S} C_{ij} x_1^i x_2^j + \frac{C_D}{1 + x_2} + C_E e^{C_F x_1 x_2} \right\}$$

where $C_A, \ldots, C_F$ and $C_{ij}$ are constants. Figure 2(b) shows the paths taken by the iterates generated by brute force method and three variants of our algorithm corresponding to $\alpha$ calculation methods described in Section 2.2. To illustrate the effect of Hessian evaluations, we use the sleep function with 2 seconds when the Hessian is evaluated. Figure 2(c) shows that all the algorithm variants converge to a better solution in less time than the brute force method.

## 4.2. Benchmarking with Data Profiles

We construct data profiles [4] to systematically benchmark the algorithms. A data profile assesses the absolute performance of an algorithm. It determines the ability of an algorithm to solve an optimization problem within some desirable performance metric. For each problem-algorithm pair $(l, a)$, the data profile $d_a(\delta)$ indicates the proportion of problems solved within $\delta$ metric:

$$d_a(\delta) = \frac{1}{|L|} \text{size}\{l \in L : m_{l,a} \leq \delta\}$$

where $|L|$ represents the total number of problems and $m_{l,a}$ is the performance measure. We evaluate the performance of our algorithm based on Hessian evaluations and the number of $O(n^3)$ operations, as these are the most computationally expensive steps in a second-order optimization method.

A key trade-off in the proposed approach lies in the choice of interval size ($\Delta$). Larger intervals reduce the computations associated with Hessian evaluations and inversion but potentially sacrifice accuracy in $\alpha$ estimates. Conversely, smaller intervals enhance precision and robustness in capturing curvature information but at the cost of increased computational overhead. Additionally, the accuracy of $\alpha$ depends on the method employed. We observed that the Mori-Kokame and E-matrix methods provide more accurate $\alpha$ estimates than the Gerschgorin method. While the former two approaches require $O(n^3)$ operations, the latter requires $O(n^2)$ operations.

Accordingly, to study these trade-offs, we consider six variants of our algorithm by choosing three $\Delta$ values (0.1, 0.5, 1) and three methods to estimate the minimum eigenvalue (section 2.2). We apply the algorithms to a set of 210 problems. The results of the computational experiments are shown in Figure 2 (d), which shows that our algorithm could solve 70% of the problems in less than 300 Hessian evaluations. For 13% of the instances terminated, the algorithm reached the maximum number of iterations (10000), 1.9% stopped due to the time limit (3600 seconds), 9% stopped due to small step size, and 0.9% of cases converged to an iterate where the norm of the gradient was below the threshold but failed to satisfy the minimum eigenvalue condition of the Hessian. The remaining 4.8% of cases involved scenarios where a local minimum did not exist or the algorithm started from points with excessively large function values exceeding the range of data type double.We observe that the E-matrix and Mori-Kokame methods with $\Delta = 0.1$ outperform the Gerschgorin method and converge in a smaller number of iterations.

Next, we compare the performance of our algorithm with Newton's method, employing Algorithm 2 to ensure a positive-definite Hessian matrix. To illustrate the effectiveness of the interval-based approach, we also implement the Gerschgorin method of finding $\alpha$ with $\Delta = 0$. For this computational study, we selected the problems requiring Hessian modifications. Figures 2(e) and 2(f) show the data profiles based on the number of Hessian evaluations and $O(n^3)$ operations, respectively.

We make three key observations. First, the interval-based method for finite values of $\Delta$ performs similarly to the Gerschgorin method with $\Delta = 0$ in terms of Hessian evaluations; however, the former method requires a smaller number of $O(n^3)$ operations. Second, when the computational budget is more than 40 $O(n^3)$ operations, the Gerschgorin-based interval method outperforms the other methods, illustrating the effectiveness of the search direction in navigating the non-convex landscape. Finally, Newton's method with brute force method of modifying the Hessian solves the most problems in least number of Hessian evaluations. Still, it requires a higher number of $O(n^3)$ operations. This can be explained by the fact that the brute-force method adds $\tau$ just enough to make the Hessian positive definite, resulting in a better

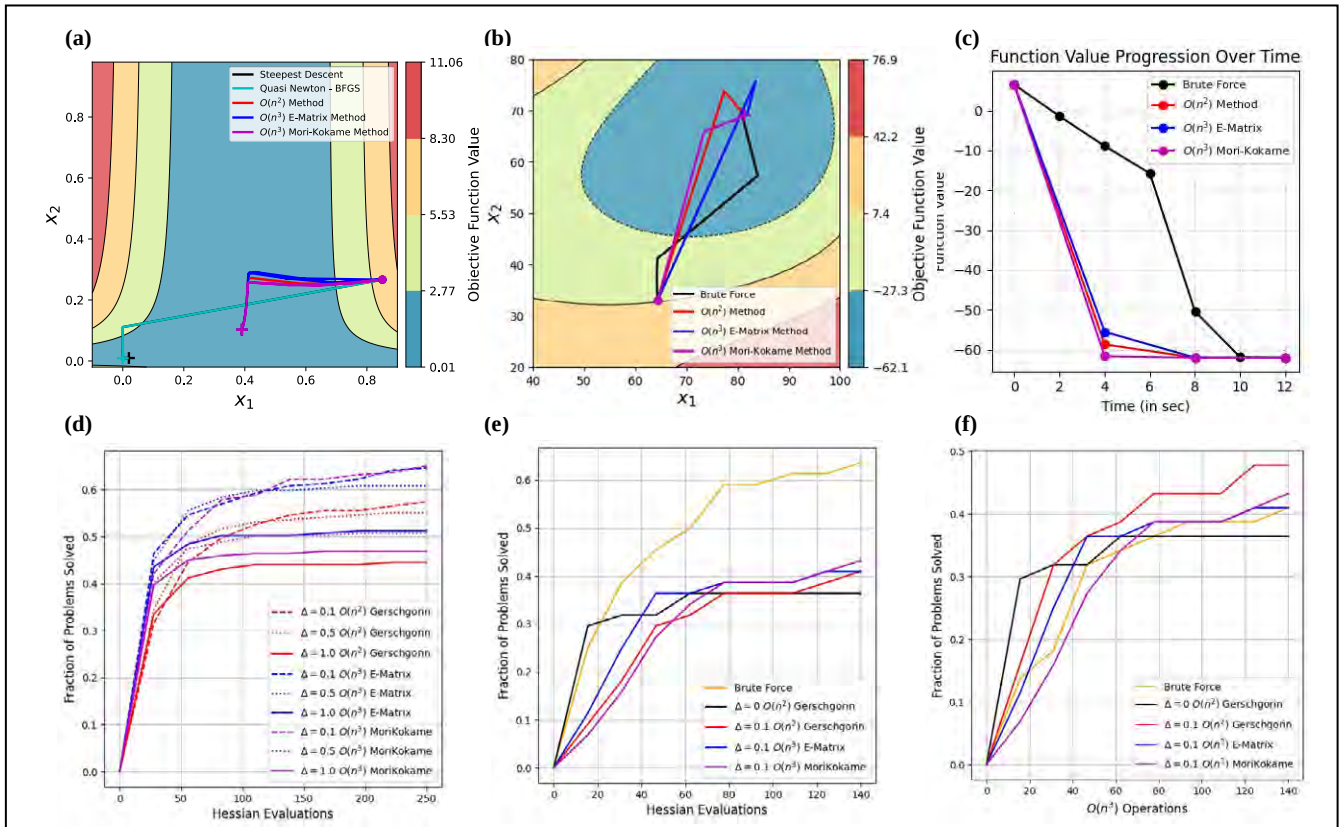

**Figure 2. (a)** and **(b)** compare the paths taken by the iterates generated by various algorithms. **(c)** Function value progression comparison of various algorithms. **(d)** Data profile based on Hessian evaluations for different Δ values and $\alpha$ calculations methods. **(e)** and **(f)** Comparision of our algorithm with other competing algorithms.

search direction. However, this increases $O(n^3)$ operations due to the Cholesky decomposition performed for positive-definiteness verification.

## 5. CONCLUSIONS

In this study, we introduced an interval-based optimization algorithm to find a search direction guaranteed to be descent to find a local minimum of non-convex problems. We show through numerical experiments that our algorithm finds a local minimum for a greater number of problems using less $O(n^3)$ operations compared to Newton's method. The results highlight the potential of our approach to improve the scalability of second-order optimization for complex, real-world applications.

## ABSTRACT

This study introduces a novel methodology that combines Gaussian process regression (GPR) with alpha shape design space reconstruction to visualize multi-dimensional design spaces. The proposed GPR surrogate approach incorporates a kernel optimization step, employing a greedy tree search strategy to identify the optimal combinatorial kernel from a selection of base kernels. This approach efficiently evaluates design spaces around specific points of interest, enabling alpha shape reconstruction. The methodology's adaptability is demonstrated through its application to both lower-dimensional (2D and 3D) cases and more complex, higher-dimensional systems (up to 7D), showcasing its scalability and versatility. Its effectiveness is further validated by its ability to generate accurate surrogate models from limited data. Overall, this study presents a robust framework that leverages GPR surrogate modeling and alpha shape reconstruction to facilitate design space evaluation in complex, multidimensional engineering problems.

**Keywords**: Design Space Identification, Surrogate Modelling, Gaussian Process Regression, Alpha Shapes, Kernel Optimisation.

## INTRODUCTION

The development of advanced computational tools and techniques has significantly enhanced the ability to solve challenging high-dimensional chemical engineering problems affected by uncertainty and complexities of chemical processes. Traditional computational tools are often restricted to simpler, lower-dimensional problems mainly due to numerical complexity. In the task of design space (DSp) identification, a major limitation is the substantial computational resources needed to extract the required knowledge from complex mechanistic models. Given that chemical processes are often characterized by intricate systems of equations, surrogate-based methodologies hold significant potential for enabling design space identification of complex and practical industrial scenarios by reducing the need for extensive modeling. Models like High Dimensional Model Representation (HDMR) [1] and Partial Least Squares (PLS) [2] have been directly utilized in DSp evaluation. More recently, Geremia *et al.* [3] analyzed a range of surrogate modeling techniques for DSp and found that the Gaussian Process (GP) is among the best-performing ones.

Despite surrogate models' potential to aid process design and control, producing highly accurate surrogates remains computationally demanding. This is particularly relevant when analyzing problems of increased dimensionality, where computational requirements can scale exponentially with process complexity. Moreover, meaningful analysis and visualization of the design space are crucial in high-dimensional problems to effectively evaluate quality criteria. The presented study aims to investigate the effectiveness of Gaussian process regression as a surrogate modeling technique within the context of multi-dimensional design space identification for enabling visual representation through alpha shape reconstruction.

## BACKGROUND

### Feasibility and Design Space Identification

Design space identification is a form of feasibility

analysis that aims to determine the feasible region of a design space, defined by the set of input variables that ensure the system output meets all specified constraints. The concept of design space identification is particularly relevant in the framework of Quality by Design (QbD), extensively applied in pharma and biopharma [4], which aims to design robust and efficient processes where quality criteria, or Key Performance Indicators (KPIs), are met in product output at varying input conditions. Design space identification is applied in this context to provide a fundamental understanding of the process operative range and is a key tool for enabling more advanced computational techniques for process enhancement, such as flexibility analysis.

The design space problem is formulated as shown in Eq. (1).

$$\begin{aligned} y &= f(\boldsymbol{\theta}) \\ \boldsymbol{\theta}_L \leq \boldsymbol{\theta} &\leq \boldsymbol{\theta}_U \\ g(\boldsymbol{y}) &\leq 0 \end{aligned} \tag{1}$$

where $\boldsymbol{y}$ is the vector of selected KPIs, $f$ is the system model, $\boldsymbol{\theta}$ is the vector of input variables, and $\boldsymbol{\theta_L}$ and $\boldsymbol{\theta_U}$ are the vectors of the lower and upper bounds of such variables, respectively. Finally, $g$ represents the target KPI constraints that must be satisfied.

## Alpha shapes DSp Reconstruction

Various methodologies exist for identifying and visualizing design spaces. Among them, the alpha shape method has demonstrated high accuracy in capturing both convex and non-convex feasibility regions in two- and three-dimensions [5]. Unlike convex hull methods, alpha shapes provide a flexible geometric representation that adapts to the underlying dataset structure. An alpha shape defines a boundary that encapsulates a set of points based on a shape-controlling parameter, the alpha radius $\alpha_r \in [0, +\infty]$. This parameter determines the level of detail in the reconstructed shape, allowing for fine or coarse representations of the feasibility region depending on the dataset $S$ and application requirements [6].

## Gaussian Process Regression

In this study, Gaussian Process Regression (GPR) is employed as a surrogate model to approximate the system function ($f$ in Eq. (1)). GPR is a non-parametric probabilistic approach that assumes the underlying function follows a multivariate Gaussian distribution, characterized by a mean function, $m(x)$, and a covariance function, called kernel, $k(x, x')$. Common kernel functions include the Radial Basis Function (RBF, also known as the Squared Exponential, SE), Rational Quadratic (RQ), Periodic (Per), and Linear (Lin) kernels. This approach enables flexible modeling of complex, non-linear relationships without requiring an explicit parametric form, instead relying on kernel functions to capture dependencies [7]. The kernel function plays a critical role in capturing relationships between data points, allowing GPR to make interpolative predictions. To model complex dependencies, composite kernels, formed by combining base kernels through addition or multiplication, can be employed, generating effective covariance functions while enhancing model expressiveness, as depicted in **Figure 1**.

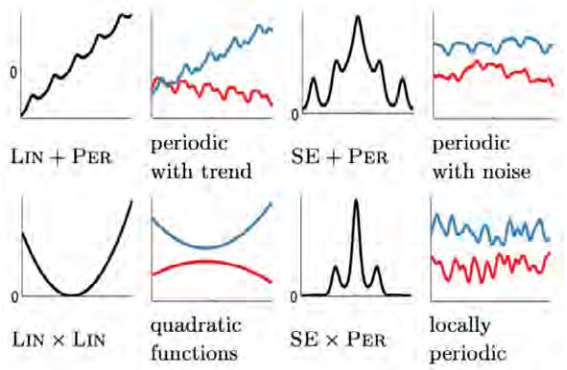

**Figure 1:** Examples of addition and multiplication of base kernels, in black, and the functions they are able to capture, colored, adapted from [8].

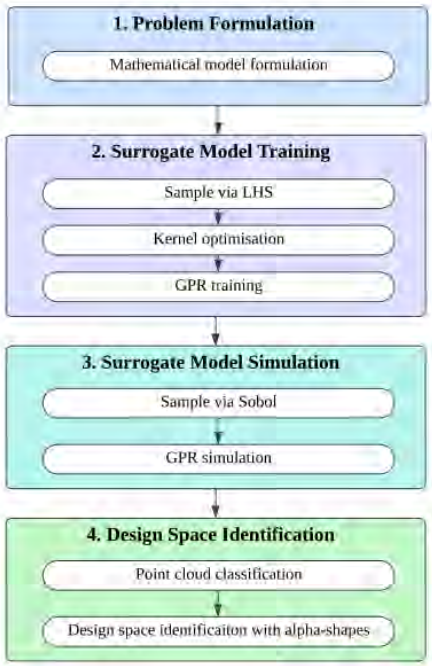

**Figure 2:** Design Space Identification Framework Schematic.

# METHODOLOGY

The methodology proposed in this work, shown in **Figure 2**, is aimed at the identification of the design space of high-dimensional constrained mathematical problems through Gaussian process regression surrogate modeling. In the context of chemical engineering,

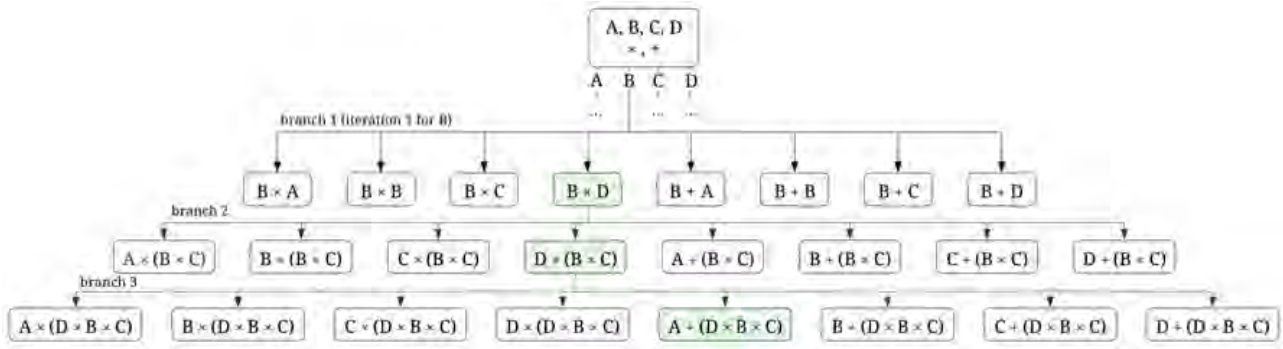

**Figure 3:** Schematic of the kernel optimisation algorithm.

the investigated variables represent design decisions, with the objective function being the process design and/or product specification. This methodology can be integrated as part of the QbD framework by facilitating the exploration of design space and understanding of how process disturbances, process variables, and design variables influence the chemical process and its KPIs.

The computations for this study are conducted in Python and performed using an Intel® Core™ i7–13,700 CPU @ 2.10 GHz. Nevertheless, the proposed framework can be easily implemented and adapted to different programming platforms with minimal changes to the procedure.

## Stage 1: Problem Formulation

The first step of the methodology is defining the objective function, $f(\boldsymbol{x})$, and its constraints, $g(\boldsymbol{x})$, for the analysis. In chemical engineering applications, the objective function may represent the chemical process under investigation or an optimization function that evaluates relevant KPIs. An example of a mathematical problem formulation is presented in **Table 1**.

**Table 1:** Example of a mathematical problem analyzed.

| **The Modified Gomez Function (D=3)** | |
|---|---|
| **Objective function and constraints** | **Search space** |
| $\min f(\boldsymbol{x}) = -\sin(4\pi x_1) + 2sin^2(2\pi x_2) + 4sin^3(\pi x_3)$ <br> $s.t. \quad g_1(\boldsymbol{x}) = f \leq 0$ | $[-1, 1]^3$ |

## Stage 2: Surrogate Model Training and Kernel Optimisation

The problem specifications define the search space within which the knowledge space is sampled using Latin Hypercube Sampling (LHS) for the vector of investigated variables $\boldsymbol{x} = [x_1, x_2, \ldots, x_{n_x}]$ of size $n_x$. The sampled data and computed corresponding outputs constitute the training data on which the surrogate model learns about the system. This training data is thus fed to a kernel optimization algorithm for selecting the best-fit GPR kernel.

The kernel optimization algorithm utilizes a combinatorial method for new kernel construction with a greedy tree search algorithm, as presented by Galeazzi *et al.* [8]. The greedy tree search selects optimal solutions at each step, ensuring the strategy remains computable within reasonable time and computational constraints. New kernels are constructed using four basic kernels (RBF, RQ, Periodic, Linear) and operators (multiplication, addition) to capture intricate model behaviors, as described above. This process is illustrated in the first branch for kernel B in **Figure 3**. Once a branch is composed of all potential kernels, they are evaluated based on the mean absolute error (MAE) parameter, and the kernel with the minimum MAE from the iteration is recorded and used as the basis for generating options in the next branch. This search continues until the user-specified tree depth is achieved, limited to five iterations for this study. All best kernels from each branch are stored, and the final best kernel is selected from this list, thus balancing the model's complexity and performance while mitigating the risk of overfitting that could arise with additional iterations without yielding significant improvements.

## Stage 3: Surrogate Model Testing

To gauge and test the surrogate model performance, after its training, a dense sample set is generated from the benchmark case studies function and MAE and Mean Absolute Percentage Error (MAPE) are re-evaluated for accuracy. Several reference graphs of the true function are generated to provide a visual benchmark, further aiding in the validation of the surrogate's performance. In a practical scenario where a computationally expensive high-fidelity model is implied this step would be skipped. However, in this study, this step is key to understanding the methodology potential.

## Stage 4: Design Space Identification

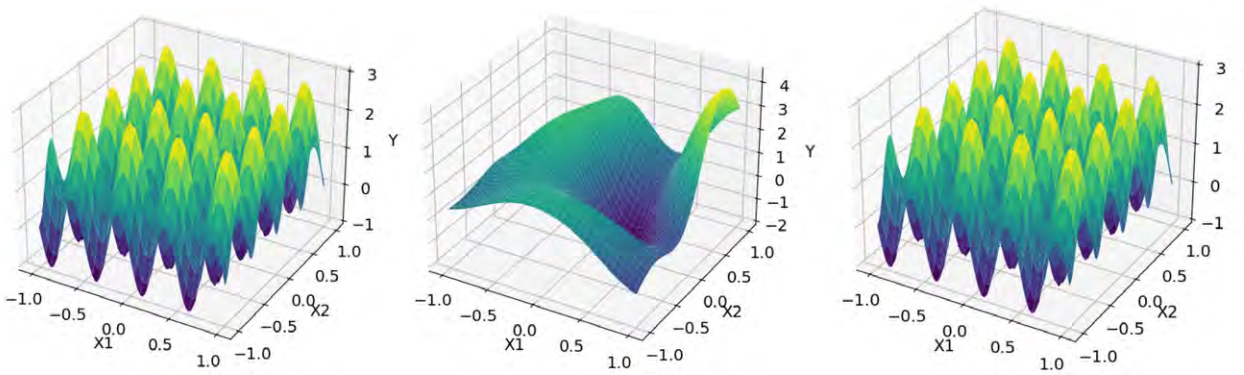

**Figure 4:** (a) Original function, (b) GPR surrogate prediction without kernel optimization, and (c) GPR surrogate prediction with kernel optimization.

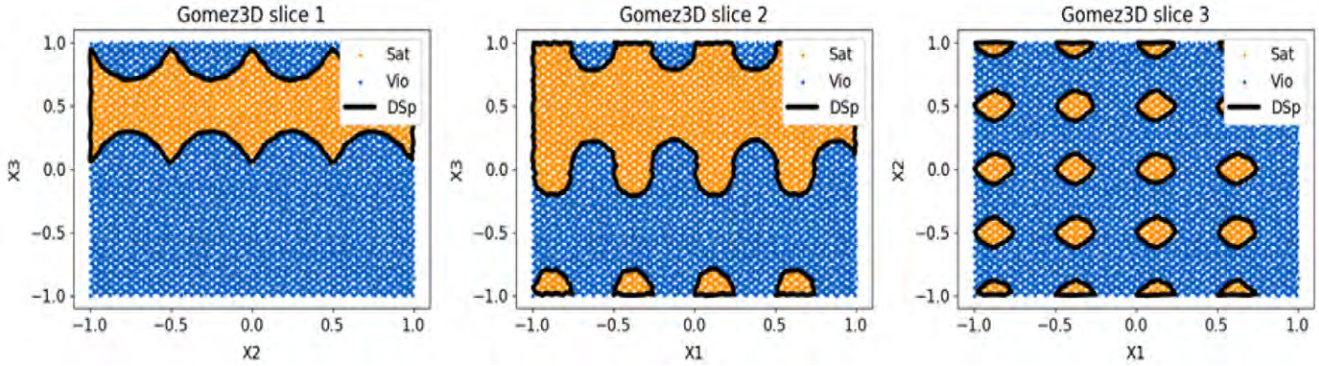

**Figure 5:** Design space (DSp) of the 3D modified Gomez function reconstructed with alpha shapes on 2D slices.

In this stage, the feasibility problem under investigation is developed. In the context of chemical engineering, it involves the selection of design decision variables and KPIs for analysis requirements for which the acceptable region of operation will be defined. In this study, where mathematical functions are employed, the feasibility function is equivalent to the objective function defined in Stage 1, $f(\boldsymbol{x})$, constrained to a user-defined value for DSp evaluation.

The design space is first defined by declaring a nominal point, which is user-selected and can represent any point of interest, such as an optimum. To enable the application of alpha shape reconstruction on higher-dimensional problems, a slicing technique is applied to create lower-dimensional planar slices around the point of interest. As the first stage of DSp identification, the surrogate model is densely resampled around the selected nominal point of interest within the boundaries applied. The slicing function is applied at this stage to create planes for DSp reconstruction. The number of orthogonal slices generated is determined only by the dimensionality of the problem and whether 2D or 3D plots are desired for visualization. Finally, the *dside* package is utilized on each slice for design space identification with alpha shape reconstruction. For a more detailed explanation of the package working principles, the reader is referred to Sachio *et al.* [9].

# RESULTS

## Kernel Optimization in GPR

The quality of design space evaluation is directly linked to the accuracy of predictions made by the surrogate model. Therefore, the initial step in the methodology is to ensure that the GPR can effectively capture even the most intricate relationships within the data. Typically, a basic kernel such as the RBF or Matern 5/2 is employed in GPR analysis. However, this is often insufficient for capturing the complexities of intricate data trends. In chemical engineering, experimentally or computationally collected data often exhibit behaviors that are not characterized a priori, necessitating further analysis to confirm whether the selected kernel is appropriate for the given data type. To avoid this laborious analysis and to create a versatile framework capable of handling any data complexity, kernel optimization was incorporated into the methodology. This optimization allows the construction of a composite kernel, enabling the capture of intricate data trends.

The effectiveness of the developed kernel optimization function was demonstrated using the modified Gomez function, proposed by Geremia *et al.* [3] and shown in **Table 1**. Both the optimized and non-optimized cases

were trained using the same LHS training set of size 38, ensuring that the training set and its size did not influence the accuracy of the surrogate predictions. The original function (**Figure 4.a**), generated using true values, serves as the benchmark for evaluating the GPR surrogate models, illustrating a significant improvement in prediction quality with and without kernel optimization, **Figures 4.c** and **4.b** respectively. This improvement is reflected in the performance metrics reported in **Table 2**, where near-perfect predictions were generated with kernel optimization. GPR training grows cubically as the number of samples increases and this optimization succeeds in reducing the number of training points needed. However, the time required for model training grows linearly with the number of kernels investigated, presenting a trade-off question between computational efficiency and predictive performance.

**Table 2:** Kernel optimization function performance.

| | MAE | $R^2$ | Accuracy | F1 score |
|---|---|---|---|---|
| **Without kernel optimisation** | 1.43 | 0.47 | 73.89% | 73.97 % |
| **With kernel optimisation** | 0.01 | 1.00 | 99.87% | 99.87 % |

## Application to 2D and 3D problems

The application to 2D and 3D case studies is useful in understanding the performance of the proposed methodology and developing heuristics for sample size selection. The latter is of particular importance as with increasing dimensionality the need for balancing computational demand and prediction accuracy arises. Results on the 2D study adapted from Sasena *et al.* [10] showed that a small number of training samples, n = 10D, was sufficient to achieve a 100% F1 score resulting in the DSp being captured fully. However, as expected, with increased dimensionality, and, therefore, problem complexity, the training set requirement increased.

The methodology's efficiency was further validated in the more complex 3D case study using the Modified Gomez function adapted from Geremia *et al.* [3]. As the dimensionality and complexity of the problem increased, a larger number of training samples was required, with an acceptable MAPE achieved only after the fourth incremental increase, where $n = 2(10D) = 60$. As shown in **Table 3**, the model struggled to achieve a good fit with smaller sample sizes, with MAPE ranging from nearly 550% to approximately 140%. This difficulty was primarily due to the surrogate's challenge in capturing the rapid fluctuations in the function's output. A significant improvement in the accuracy of the GPR predictions occurred between the third ($n$ = 53) and fourth ($n$ = 60) iterations. This change is likely due to the search space becoming sufficiently well-sampled, enabling the model to capture the nonlinearities of the original function more effectively, thereby reducing the model's uncertainty. The low standard deviations observed across 10 runs for the $n$ = 60 for MAE (0.00163) and MAPE (0.00521) confirm that the methodology consistently produces reliable and accurate results.

While the metrics generally improved with an increase in the training samples, an exception was noted in the second incremental increase ($n$ = 45), where MAPE increased despite improvements in MAE and $R^2$. This anomaly might be attributed to the overestimation of very small actual values, which disproportionately impacts MAPE due to its sensitivity to such values.

**Table 3:** Methodology results for the 3D case study across different training set sizes, n. Increments refer to the percentile increase of the initial 10D training set.

| Increment | n | MAE | MAPE | $R^2$ |
|---|---|---|---|---|
| Starting | 30 | 1.09952 | 549.45% | 0.67 |
| +25% | 38 | 1.03456 | 441.92% | 0.72 |
| +50% | 45 | 1.01836 | 514.45% | 0.73 |
| +75% | 53 | 0.26165 | 143.90% | 0.98 |
| +100% | 60 | 0.00451 | 1.74% | 1.00 |
| Benchmark | 300 | 0.00002 | 0.01% | 1.00 |

It is important to note that while the methodology is capable of analyzing the system as a 3D problem, as demonstrated by the results for $n$ = 60, 2D planar slicing offers a more understandable visualization of the problem and provides further insights into the method's performance. Such DSp slices are presented in **Figure 5**.

## Application to high-dimensional problems

The results from both 2D and 3D case studies convincingly demonstrate that the proposed methodology utilizing GPR for surrogate modeling and alpha shapes for DSp reconstruction is effective. Based on the analysis of the training size required to encapsulate complex functions, training sample sizes for high dimensional problems were selected following the $2(10D)$ rule.

For higher-dimensional analysis common engineering problems for optimization, listed in **Table 4,** were adapted from Bouhlel *et al.* [11], namely the Gas Transmission Compressor Design (GTCD), Pressure Vessel Design (PVD), and Speed Reducer 7 (RS7) case studies. These cases were chosen because the parameters span different scales, potentially complicating analysis during kernel optimization. Larger-magnitude parameters may disproportionately influence the kernel, causing numerical deviations and reducing model accuracy. However,

the proposed methodology mitigated these issues, achieving high accuracy (**Table 4**) and demonstrating robustness despite parameter variability.

**Table 4:** Methodology results for the high-dimensional case studies.

| Name | D | n | MAE | MAPE | $R^2$ | F1 Score |
|---|---|---|---|---|---|---|
| GTCD | 4 | 80 | 2.79E+01 | 3.86% | 1 | 99.91% |
| PVD | 4 | 80 | 1.20E-02 | 9.09% | 1 | 100.00% |
| RS7 | 7 | 140 | 9.26E-01 | 0.02% | 1 | 92.59% |

The application of the $2(10D)$ rule was effective for 4D cases but proved less efficient in the 7D study, as expected. Higher-dimensional problems typically require exponentially larger training sets, a trend consistent with findings from the 2D and 3D studies. The 7D results exhibited significant deviations across slices, with a tendency for false negatives in half of them, though no false positives were observed. This suggests that the surrogate model struggled to converge optimally in certain slices, indicating that a denser sample set might be needed for accurate design space evaluation. However, this would make alpha shape reconstruction computationally prohibitive. By reducing the 7D problem to 3D through slicing, the methodology enabled DSp evaluation with alpha shapes, demonstrating its efficiency in handling complex design spaces, as shown in **Figure 6**.

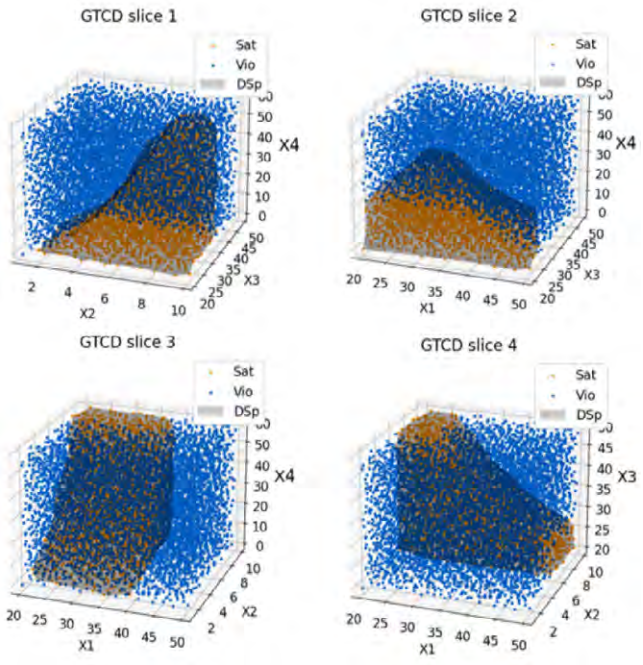

**Figure 6:** DSp of the 4D GTCD Function Reconstructed with Alpha Shapes on 3D Slices.

## CONCLUSIONS

This study presents a methodology that integrates surrogate modeling with alpha shape design space identification to reconstruct complex, high-dimensional design spaces. The framework employs Gaussian Process Regression (GPR) with an optimized kernel selection strategy to capture intricate relationships in complex mathematical systems. GPR enables accurate modeling and representation of feasibility regions, while alpha shape design space identification facilitates the slicing of multidimensional design spaces into two- or three-dimensional projections around a point of interest, allowing for multi-perspective visualization. Its adaptability to different design criteria makes it a powerful tool for evaluating process variations and optimizing design decisions.

The methodology's effectiveness is validated across mathematical problems ranging from two to seven dimensions, demonstrating its scalability and applicability to both low- and high-dimensional challenges.

Ongoing research is focusing on transferring this methodology to real-world problem cases. Future research should tackle refining sample size selection to develop a universal heuristic that balances surrogate model accuracy with GPR computational costs.

## ABSTRACT

Recent advancements in material design have made adsorption a more energy-efficient alternative to traditional thermally driven separation processes. Accurate modelling of adsorption thermodynamics is crucial for designing and operating equilibrium-limited adsorption systems. High-quality open-source packages like PyIAST, PyGAPsare available for processing adsorption data in Python. They provide a robust set of features for processing and analysing isotherms. However, they have no support for automatic differentiation and are not targeted for performance. Langmuir.jl addresses these limitations by leveraging Julia's composable and differentiable programming ecosystem. Langmuir.jl includes tools for processing adsorption thermodynamics data—loading data, fitting isotherms with most often used models, predictive multicomponent adsorption through Ideal Adsorption Solution Theory (IAST) — and, importantly, enabling accurate derivative calculations through Julia's automatic differentiation libraries, without requiring extensive code adjustments. Furthermore, Langmuir.jl achieves two orders of magnitude faster IAST calculations compared to its Python counterpart, PyIAST.

## INTRODUCTION

The separation of fluid mixtures is subject of great attention to chemists and chemical engineers. Traditional methods such as distillation rely on the use of heat to partially vaporize and separate mixtures. Recent advancements in material design have made adsorption a more energy-efficient alternative to traditional thermally driven separation processes [1].

Adsorption is a surface phenomenon that involves the transfer of a substance from a bulk phase of a fluid to the surface of a solid whilst desorption consists of the opposite process. To separate mixtures with this principle, the different affinity of substances (adsorbates) to a solid's surface (adsorbent) is used as driving force. Affinity is linked to the equilibrium concentrations between an adsorbent and adsorbate at a specific temperature. This link is achieved with the well-known adsorption isotherms that seeks to describe the equilibrium relation between bulk concentration, adsorbent concentration and temperature of a fluid or mixture.

Isotherms are fundamental in adsorption as they can be used to describe equilibrium concentrations and to estimate derived quantities such as the Henry coefficient and isosteric heat of adsorption [2]. Classic adsorption isotherms include the Langmuir isotherm, initially developed for gas-phase adsorption on activated carbon, and the simple linear Henry's isotherm. The International Union of Pure and Applied Chemistry (IUPAC) categorizes isotherms into six types based on their shape [3]. With advancements in adsorbents and the discovery of new materials, new isotherms continue to be proposed easily surpassing 20 types today.

When designing adsorption-based separation processes, the typical workflow starts with material characterization and single-component adsorption experiments, as multicomponent adsorption data is challenging to obtain. Single-component data is then fitted to isotherms at different temperatures, enabling the estimation of quantities such as isosteric heat, multicomponent adsorption, and Henry's coefficients, for example. Finally, the predictive capacities of the isotherm and derived

quantities are validated through breakthrough experiments [4].

As the number of isotherms and available data grow with advancements in research and automation, manually performing this workflow becomes increasingly complex, error-prone, and time-consuming. Automating the process with software provides a practical and efficient solution. In the past years, efforts have been made to develop tools that assist users in automating the workflow, enabling the exploration of a broader range of models and potentially enhancing predictive accuracy and process design quality.

While software design has been limited to experts in the past, the advent of high-level dynamically typed programming languages such as Python, Julia and more have made software development possible to a broader range of professionals. In this trend, software for adsorption thermodynamics evolved from statically compiled languages to dynamically typed languages.

IAST++ [5], for example, is an open-source C++ GUI-based software that can fit isotherm data to several models and use the Ideal Adsorbed Solution Theory (IAST) to estimate multicomponent isotherm. Ruptura [4] is also a free and open-source C++ software package for the simulation of gas adsorption breakthrough curves, mixture prediction using IAST-like methods, and fitting of isotherm models' adsorption isotherm data. While C++ is known for its speed and efficient memory management, code syntax is less attractive when compared to high-level languages, which limits cross-collaboration, development, and wider adoption.

Recent advancements in high-level programming languages have led to the development of tools like pyIAST [5] and pyGAPS [6] in Python. PyIAST focuses primarily on providing code interface for initializing and fitting single-component isotherms that can be used for multicomponent prediction through IAST.

In contrast, pyGAPS serves as a "General Adsorption Processing Suite" with a wider range of functionalities. It supports manipulating, storing, visualizing, and processing adsorption isotherms. Its extended feature set includes specific surface area calculations, t- and s-plots, model fitting, IAST calculations, and the estimation of isosteric heat of adsorption from isotherm data.

While Python offers a straightforward and user-friendly environment for software development, particularly with its object-oriented syntax, it often falls short when performance and composability are critical. For instance, the calculation of isosteric heat of adsorption can be performed automatically with exact derivatives, avoiding error approximations and tedious, error-prone derivatives, if automatic differentiation is utilized. However, integrating such functionality directly into tools like pyGAPs could require a significant development effort despite its modular nature. The effort could involve a potential port to a different backend such as JAX or manually writing chain rules for complex operations not supported by numpy-compatible AD frameworks such as autograd – derivatives of root-finding solvers and derivatives of numerical integration routines, for example.

Such a lack of composability in Python often restricts many packages to a specific backend, hindering the adoption and composition of emerging methods from different libraries. The Julia programming language is a language mainly targeted to scientific computing that is known for its composability. It is a fully featured language that can achieve C-like performance native code and, therefore, does not rely heavily on external libraries for numerical computations. Furthermore, it has first-class automatic differentiation support [7]. However, time-to-first execution is a known drawback of JIT compilation in the Julia language. Furthermore, it is a much less popular language than Python, with less mature libraries and a smaller community.

Taking full advantage of Julia's capabilities and its vibrant numerical ecosystem, we present Langmuir.jl: An efficient and composable Julia package for adsorption thermodynamics. Langmuir.jl is part of the Clapeyron-Thermo project that includes the Clapeyron.jl - An Open-Source Fluid Thermodynamics Toolkit in Julia [8] and GCIdentifier.jl – a package for automated group contribution (GC) identification [9].

The remainder of this article is organized as follows: in Section 2, the architecture of Langmuir.jl is explained, as are the isotherm model objects, supported models, core isotherm functions, derived properties, and the use of automatic differentiation. In Section 3, we present case studies of the library and a full workflow for working with adsorption isotherms.

## Adsorption Thermodynamics

To clarify the code structure, it is helpful to briefly introduce the physical meaning and mathematical description of adsorption thermodynamics. This begins with the concept of single-component isotherms and extends to properties derived from their definition. These properties include the isosteric heat, Henry's coefficient, and multicomponent adsorption modeled using the Ideal Adsorbed Solution Theory (IAST).

### Isotherms

Mathematically, the single component adsorption is a smooth, continuous function that defines the loading/solid phase concentration $q_i$ of the component $i$ as a function of bulk concentration $c_i$ or pressure $p_i$ and temperature [4]:

$$q_i = f(c_i, T) \tag{1}$$

To compute the loading, both temperature and bulk concentration must be specified. While other combinations of independent variables are theoretically valid -

such as using solid-phase concentration and temperature as inputs - such cases are less common and involve additional complexity. This approach requires inverting the function $f$, either analytically or by solving a root-finding problem.

The temperature dependence in the isotherm must account for the fact that adsorption is an exothermic process. As temperature increases, the loading $q_i$ decreases. This dependency is typically modeled using parameters that explicitly incorporate the effect of temperature in the affinity parameter, such as in Van't Hoff-like expressions or other temperature-dependent terms in the isotherm equation. The single-site Langmuir isotherm temperature dependency can be written as, for example:

$$q_i = \frac{MKp_i}{1+Kp_i} \tag{2}$$

$$K = K_0\, exp\left(-\frac{E}{RT}\right) \tag{3}$$

## Henry's Coefficient

The Henry coefficient is the slope of the isotherm as the partial pressure tends to zero. Under this condition, adsorbate-adsorbate interactions are negligible, and adsorption is linearly related to the affinity of the adsorbate at a given temperature. Mathematically, it is defined as:

$$H_i = \frac{\partial q_i}{\partial p_i}|p_{i\to 0} \tag{4}$$

Numerically, the Henry coefficient can be determined in one of three ways. The first method involves manually deriving the isotherm and applying the limit $p_i \to 0$, which, while tedious and prone to human and numerical error, would result in an analytical expression. The second approach is automatic differentiation, which provides an accurate result without introducing numerical errors. Lastly, numerical differentiation offers a simpler alternative but can also introduce numerical errors.

## Isosteric Heat of Adsorption

The isosteric heat of adsorption is defined as the differential change in energy when an infinitesimal number of molecules are transferred from the bulk to the adsorbent surface at a fixed temperature, pressure and adsorbent surface area. However, a common way of estimating this quantity is through the Clausius-Clapeyron equation which relates the isosteric heat to the temperature dependence of the adsorption isotherm [2] as follows:

$$q_{st,i} = T\left(V_g - V_a\right)\frac{dp_i}{dT}|_{q_i,A} \tag{5}$$

where $V_g$ is the molar volume of the bulk phase, $V_a$ is the molar volume of the adsorbed phase and $q_{st,i}$ is the isosteric heat. If isotherm is explicit in the loading, one can write:

$$q_{st,i} = -T\left(V_g - V_a\right)\frac{\partial q_i/\partial T|_{p_i}}{\partial q_i/\partial p_i|_T} \tag{2}$$

Similarly to the Henry coefficient, derivatives play an important role in correctly estimating the isosteric heat. This is where the Julia language automatic differentiation support is essential.

## Reduced Grand Potential

Similarly to vapor-liquid equilibrium and the definition of fugacity, adsorption equilibrium has an important quantity used in IAST calculations: the Reduced Grand Potential. It can be defined as:

$$\psi_i = \int_0^{P_{i,0}} \frac{q_i(T,p_i)}{p_i}\, dp_i \tag{3}$$

where $p_i$ is the partial pressure, $T$ is the temperature, $q_i$ is the loading, $\psi_i$ is the grand potential.

This can be obtained analytically for certain types of isotherms. When analytical expressions are not possible, it must be approximated numerically.

# Langmuir.jl Design and Interface

Julia programming adopts a distinct paradigm compared to the object-oriented approach in Python, relying on composite types and multiple dispatch [7]. While a detailed explanation is beyond the scope of this work, in simple terms, multiple dispatch selects the appropriate method or function to execute based on the input types.

The source code of Langmuir.jl follows best practices in Julia programming and is divided into two main components, as illustrated in **Figure 1**.

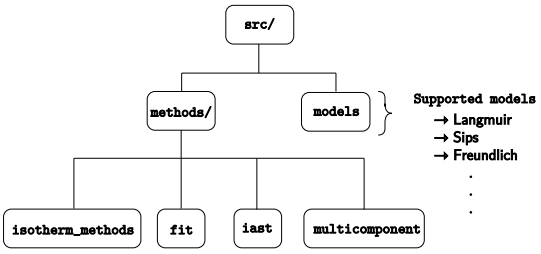

**Figure 1.** Langmuir.jl source-code structure

The *model* component/folder holds all the files that define supported isotherm models' composite types. Those types have all the parameters needed to define the isotherm completely through their fields. Below is an example of the definition of the Langmuir single-site model:

```
@with_metadata struct LangmuirS1{T} <: Iso-
thermModel{T}
    (M::T, (0.0, Inf), "saturation loading")
    (K₀::T, (0.0, Inf), "affinity parameter")
    (E::T, (-Inf, 0.0), "energy parameter")
End
```

The @with_metadata macro in Julia enhances existing code structures by enabling the addition of extra

inputs that generate additional code. In the example provided, `M` represents the saturation loading, `$K_0$` is the affinity parameter, and `E` is the energy parameter. The annotations, such as parentheses and additional characters beside each field, are processed by the macro to define bounds and provide explanatory information for each parameter. This allows the macro to display these details to the user, improving clarity and usability.

The *method* component is subdivided into 4 subcomponents and files: *fit.jl, iast.jl, isotherm_methods.jl and multicomponent.jl*. *isotherm_methods.jl* holds functions dispatched on isotherms to derive properties of interest, such as the Henry coefficient or the spreading pressure. *fit.jl* holds the functions for fitting isotherms using a global optimization approach. *iast.jl* holds the routines for performing the nested-loop IAST and the FastIAS algorithms [10]. Finally, *multicomponent.jl* has the API for unifying multicomponent adsorption prediction given the single component isotherms and bulk conditions of temperature and partial pressures.

## CASE STUDY AND WORKFLOW

This section presents a typical workflow for processing and analyzing isotherm data. The data was obtained from the work of Santana et al. (2024) [11] for an ethane-selective material in an ethane-ethylene mixture, and the results were also compared to what the authors obtained. All the codes for reproducing the results can be found in Langmuir.jl documentation at https://clapeyronthermo.github.io/Langmuir.jl/dev/tutorials/tutorial/.

First, the data is loaded, and then the experimental data is plotted to assess potential isotherms that can fit the data. Then, a model or a set of models is fitted to the data, and the fitting quality is evaluated through a metric and plotted on top of the experimental data. Once the isotherm is obtained, analysis can be performed, such as the isosteric heat of adsorption, Henry coefficient, and multicomponent adsorption estimation with IAST.

### Data loading

The data is assumed to be in a standard file format with comma-separated values and loaded into a Julia-native type - an array. The array is then used to construct an isotherm data instance, an abstraction of the Langmuir.jl isotherm. Below is a code snippet. The data can be found at https://github.com/ClapeyronThermo/Langmuir.jl/tree/main/docs/src/tutorials/sample_data.

```
    using Plots, DelimitedFiles, Langmuir
    ethane_data_path = joinpath(@__DIR__,
"sample_data/ethane_tpl_data.csv")
    ethylene_data_path = joinpath(@__DIR__,
"sample_data/ethylene_tpl_data.csv")
    ethane_data = readdlm(ethane_data_path,
',')
    P_ethane = ethane_data[:, 2]*1e5
    T_ethane = ethane_data[:, 1]
    l_ethane = ethane_data[:, 3]
    d_ethane = isotherm_data(P_ethane,
l_ethane, T_ethane)
    Ts_ethane, lp_ethane = split_data_by_tem-
perature(d_ethane)
```

The function split_data_by_temperature function uses the isotherm_data object and returns all the temperatures in an vector and a 3D array holding the loading and pressure for each temperature. By plotting the loading pressure pairs for two of the temperatures for both ethane and ethylene, we can visualize the isotherm in **Figure 2**.

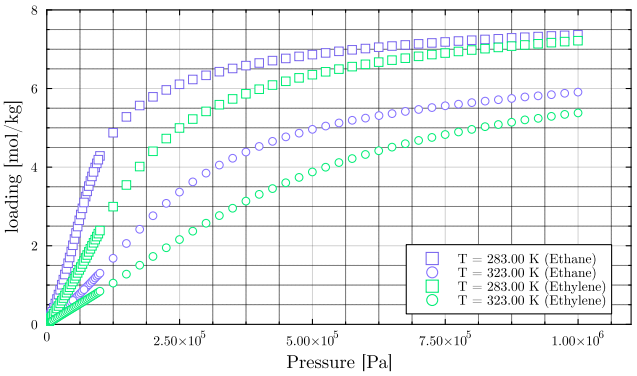

**Figure 2.** Experimental isotherm data for ethane and ethylene at 283.0 K and 323.0 K.

It can be observed that the isotherms are s-shaped, i.e., the derivative of the loading with respect to the pressure has a maximum. For example, in ethane at 283.00 K, the maximum derivative seems to take place for pressures less than $1.25 \times 10^5$ Pa. This behavior is not captured by a single-site Langmuir isotherm. Therefore, a Quadratic isotherm was proposed in the reference manuscript and used in this workflow demonstration.

### Isotherm fitting

To fit the quadratic or any other Isotherm in Langmuir.jl, one can first formulate the isotherm fitting problem by providing the isotherm type, the isotherm data wrapped into the isotherm_data object, a fitting criterion, an initial guess and lower and upper bounds for the parameters by using the IsothermFittingProblem abstraction syntax. If initial guesses and lower or upper bouds are not provided, they are defaulted according to each isotherm – more details found in the package's documentation. The code snippet below shows how to formulate the fitting problem for ethane using the mean squared error as the fitting criterion for loading-pressure data, for example.

```
prob_ethane = IsothermFittingProblem(Quadratic{eltype(d_ethane)}, d_ethane, nothing, abs2, x0_ethane, lb_ethane, ub_ethane)
```

Once the fitting problem is set, an optimizer must be selected for minimizing the objective function. In Langmuir.jl differential evolution, which is a global optimization algorithm, is used through the library BlackBoxOptim.jl. Below is a code snippet showing how to set up the optimizer and perform the fitting for ethane isotherm.

```
alg = DEIsothermFittingSolver(max_steps = 5000, population_size = 50,
logspace = true, verbose = true)
loss_fit_ethane, ethane_isotherm = fit(prob_ethane, alg)
```

After running the fitting for both ethane and ethylene and plotting the corresponding models's loadings with experimental values, we obtained the results shown in **Figure 3**.

The loadings for any model can be obtained by calling the function loading as follows:

```
loading(isotherm, p, T)
```

where p is the pressure, T is the temperature and isotherm is an instance of the supported isotherm models.

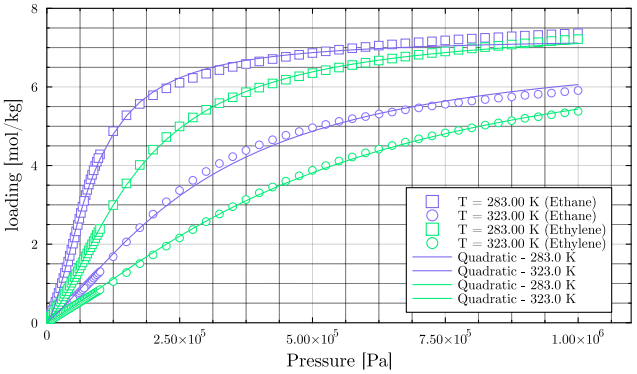

**Figure 3.** Quadratic isotherm fitting vs experimental data at 283.0 K and 323.0 K.

From the fitting results, the isotherm parameters closely match those reported in the reference manuscript. For example, the saturation loading parameter was estimated at 3.68 in the manuscript, while it is 3.64 in this analysis. However, the energy parameters exhibit a more significant discrepancy as it can be seen from **Table 1** and **Table 2**. This discrepancy is due to a different framing of the optimization problem and different optimization strategies. The reference manuscript imposes the same maximum loading capacity for both components and uses a local optimization method. In our case, no such constraint is set, and we use a global optimizer. Finally, without calorimetric data, resolving the accuracy of these values is challenging, as parameter identifiability is limited and suffers from degeneracy when relying solely on loading data for fitting.

**Table 1.** Estimated parameters using Langmuir.jl compared to the ones obtained in Santana et al. (2024) [11] for ethane.

| | $K_A$ | $K_B$ | $E_A$ (kJ/mol) | $E_B$ (k/mol) | $M$ |
|---|---|---|---|---|---|
| Langmuir.jl | $2.51 \times 10^{-7}$ | $2.138 \times 10^{-19}$ | $-6.898$ | $-47.789$ | 3.64 |
| Reference | $3.214 \times 10^{-8}$ | $1.4237 \times 10^{-14}$ | $-12.19$ | $-48.63$ | 3.68 |

**Table 2.** Estimated parameters using Langmuir.jl compared to the ones obtained in Santana et al. (2024) [11] for ethylene.

| | $K_A$ | $K_B$ | $E_A$ (kJ/mol) | $E_B$ (k/mol) | $M$ |
|---|---|---|---|---|---|
| Langmuir.jl | $2.6 \times 10^{-8}$ | $7.13 \times 10^{-19}$ | $-11.79$ | $-41.702$ | 3.83 |
| Reference | $6.282 \times 10^{-8}$ | $8.275 \times 10^{-14}$ | $-9.40$ | $-41.70$ | 3.68 |

## Single component isosteric heat of adsorption using automatic differentiation

The isosteric heat can be derived from the isotherm by using Equation 6. In Langmuir.jl, we leverage forward mode automatic differentiation and dual numbers algebra to obtain the derivatives using ForwardDiff.jl. The molar volume of the gas phase is defaulted to the ideal gas molar volume. For the quadratic isotherms, the isosteric heat varies with the amount adsorbed as it can be seen in **Figure 4**. Changes in temperature also affect the isosteric heat but is not depicted in the Figure.

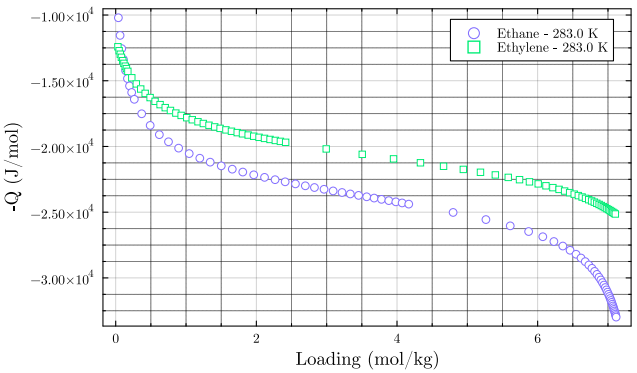

**Figure 4.** Estimated isosteric heat from isotherm vs loading for ethane and ethylene and 283.0 K.

## Multicomponent adsorption with IAST

After obtaining the individual isotherms' parameters for both components, a next step is to use these two isotherms combined to predict the loading in the adsorbent given a mixture of the two components at a certain temperature, pressure and composition. One of the possibles ways to perform such calculations is through the IAST method. To perform IAST calculations in Langmuir, the

two isotherms can first be wrapped into an abstraction named IASTModels where information about the two or more isotherms can be stored and accessed easily:

```
Isotherms = IASTModels(ethane_isotherm, ethylene_isotherm)
```

The loading can be estimated using a similar syntax to the one used for single component isotherm:

```
loading(isotherms, p, T, y)
```

The only difference is that an extra argument (y) must correspond to each component's mole fraction.

### Benchmarking IAST – PyIAST and Langmuir.jl

To compare the efficiency of our proposed solution in Julia with existing Python solutions, a benchmarking test was run to solve an IAST problem in PyIAST and Langmuir.jl, considering the isotherms for ethane and ethylene described above. The IAST problem consists of estimating the solid phase composition of ethane and ethylene given a pressure of 101325.0 Pa, temperature of 323K, and equimolar bulk concentration. The isotherms are quadratic parametrized according to **Table 1** and **Table 2** in Langmuir.jl. Since PyIAST does not support temperature dependency in the parameters, isotherms were fitted to both components at 323.0K and used for running IAST. Therefore, the parameters obtained are not the same as those obtained in Langmuir.jl, but they are close.

PyIAST version 1.4.3 using Python 3.11.5 and Langmuir.jl 0.1.1 with Julia 1.10.7 were used. The calculations were run on a laptop with an Intel i5-1250P 1.7 GHz processor and 16 GB of RAM. PyIAST utilizes scipy.root root-finding solver Levenberg-Marquardt (LM) with default tolerances not shown in the documentation. Langmuir.jl has a built-in implementation of nested loop and FastIAS, as described above. Tolerances (relative and absolute) in Langmuir.jl were set to $1x10^{-7}$. To benchmark PyIAST, the Python library time was used, and the same code ran 10000 times. To benchmark Langmuir.jl, the @benchmark macro in BenchmarkTools.jl library was also used with 10000 samples. The mean and standard deviation of run times are displayed on **Table 3**. The Table shows that Langmuir.jl achieves two orders of magnitude faster calculations for this benchmarking problem.

**Table 3.** Benchmarking of Langmuir.jl and PyIAST (the lower, the better).

| Tool / Solver | Mean run time (μs) | Standard Deviation (μs) |
|---|---|---|
| PyIAST/LM | 206.34 | 164.35 |
| Langmuir.jl /Nested loop | 0.80098 | 1.5670 |
| Langmuir.jl /FastIAS | 0.74962 | 1.1040 |

## CONCLUSIONS AND FUTURE WORK

This work introduces Langmuir.jl, an open-source Julia library for adsorption thermodynamics. To the best of the author's knowledge, it is the first package in Julia to offer such tools. Langmuir.jl benefits from Julia's modern scientific computing environment, known for its user-friendly syntax, efficiency and robust support for differentiable programming. Automatic differentiation, a core feature of Julia, is particularly advantageous for thermodynamics, where derivatives play a critical role, ensuring maintainability and extensibility. Compared with PyIAST, Langmuir.jl presents two orders of magnitude faster calculations in the IAST problem. However, it is placed in a less popular programming language and has fewer features than PyGAPs, for example. Future developments aim to integrate property calculations, such as loading and isosteric heat, into breakthrough curve simulations, similar to the functionality provided by Ruptura software.

## DIGITAL SUPPLEMENTARY MATERIAL

The source code and documentation for Langmuir.jl can be found at https://github.com/Clapeyron-Thermo/Langmuir.jl/tree/main.

## ABSTRACT

Solvent selection is a critical decision-making process that balances economic, environmental, and societal factors. The vast chemical space makes evaluating all potential solvents impractical, necessitating pre-selection strategies to identify promising candidates. Predictive thermodynamic models, such as the UNIFAC model, are commonly used for this purpose. Recent advancements in deep learning have led to models like the Gibbs-Helmholtz Graph Neural Network (GH-GNN), which overall offers higher accuracy in predicting infinite dilution activity coefficients over a broader chemical space than UNIFAC. This study presents a systematic comparison of solvent pre-selection using GH-GNN and UNIFAC-IL in the context of liquid-liquid extraction. The original GH-GNN model is extended to simultaneously predict organic and ionic systems. This extended GH-GNN model predicts more than 92 % of the logarithmic IDACs with an absolute error of less than 0.3. By comparison, UNIFAC-based models only achieve such accuracy for less than 65 %. A case study is used involving the ionic liquid ethyl-3-methylimidazolium tetrafluoroborate ([EMIM][BF4]) and caprolactam, relevant for the solvolytic depolymerization of polyamide 6. Results indicate a significant correlation in solvent rankings across both methods, with a Spearman's coefficient of 0.62, suggesting that deep learning-based models like GH-GNN are viable alternatives for solvent pre-selection. Additionally, chemical similarity metrics, such as Tanimoto similarity, can assess confidence in solvent rankings, allowing users to determine acceptable risk levels in predictions across a vast chemical space.

## INTRODUCTION

Solvents are used in various areas of chemical processes, including reaction and separation units. Selecting appropriate solvents is a complex task that involves decision-making from multiple perspectives. On one hand, the actual thermodynamic performance of the solvents must be considered. On the other hand, the implications of using such solvents must also be considered from environmental and societal perspectives.

From this perspective, the task of predicting solvent properties becomes central to assessing the overall performance of solvents within a specific process system. While important molecular properties can be measured in the laboratory, the vast extension of chemical space makes it inefficient to explore all promising solvent alternatives solely through experimental means. Therefore, predictive thermodynamic models are of key interest during the early stages of process design, especially for those involving solvents.

Pre-selection strategies aim to reduce the time and resources needed during the design of chemical processes by exploring the chemical space and allowing to focus on the most promising solvent candidates. These candidates can then be evaluated using more precise methods and eventually, the top-performer(s), could be investigated experimentally. Typically, the assessment of solvent performance in extraction applications relies on

the prediction of activity coefficients at infinite dilution (IDACs) [1]. Under these conditions, the solvent effect is at its maximum, which is why it is commonly used as a starting point for evaluating and ranking solvent candidates.

In this context, a popular choice is to use the UNIFAC model. However, with the rise of deep learning, novel alternative models have recently been proposed for predicting IDACs, showing overall more accurate predictions [2,3]. One of these alternatives is the so-called Gibbs-Helmholtz Graph Neural Network (GH-GNN), which was originally trained to predict IDACs of organic systems [4], and has also been extended to handle polymer solutions [5].

While the GH-GNN model has been previously used for solvent pre-selection [1], a systematic comparison of the resulting pre-selection to traditional methods is still lacking. Furthermore, given that the GH-GNN model was previously limited to predicting organic systems, we present here a series of extension strategies for expanding the GH-GNN model to simultaneously predict organic systems and mixtures containing ionic liquids (ILs).

This extension is particularly relevant in the context of chemical recycling of polyamide 6, also known as nylon 6, where ionic liquids have been identified as promising candidates due to their non-volatility and catalytic properties, though a complete assessment and process simulation were previously hindered by missing thermodynamic data [8]. The advantage of this approach is elucidated regarding the separation of the monomer caprolactam from the ionic liquid ethyl-3-methylimidazolium tetrafluoroborate ([EMIM][BF4]).

This work is structured as follows. First, the GH-GNN model is briefly described. Then, the extension strategies for systems containing ionic-liquids are presented. Subsequently, using the aforementioned case study, a systematic comparison of solvent pre-selection is conducted by comparing the extended GH-GNN model to UNIFAC-IL. Finally, conclusions and future directions are discussed.

# METHODS

## UNIFAC-IL

The UNIFAC model is a method used to estimate the excess Gibbs energy of a system, which in turn is used to determine the activity coefficients of its components. It operates on the principle of a "solution of groups," where molecules are decomposed into functional groups. This approach simplifies the model by reducing the parameter space from one that requires individual parameters for each unique molecule to one that only needs parameters for each type of group. This reduction in complexity enhances the model's predictive capabilities, allowing it to explore a wider range of chemical systems more efficiently.

Originally, the UNIFAC model was parameterized for predicting organic mixtures. However, extensions of the UNIFAC model to systems that include ionic liquids have also been developed in the past. In this work, we use the UNIFAC-IL extension from [6]. In this extension, a neural recommender system was first trained on experimentally determined IDACs of mixtures containing ionic liquids. Then, this recommender system was used to fill in the missing entries in a previously reported solute-solvent interaction matrix. Finally, the completed matrix was used to regress the binary interaction parameters of the UNIFAC model extended to ionic liquids.

This version of UNIFAC-IL [6] employs the original form of the UNIFAC model, and contains all necessary binary interaction parameters for 22 conventional main groups, 11 cationic main groups and 38 anionic main groups, with overall 102 subgroups. For further details on the model, readers are referred to the original publications mentioned earlier.

## Gibbs-Helmholtz Graph Neural Network

The GH-GNN model was first introduced in [4]. Unlike the UNIFAC model, the GH-GNN model uses a graph representation of molecules, where non-hydrogen atoms are represented as nodes and covalent chemical bonds as edges. Each node and edge in the molecular graph is assigned a vector of binary values containing relevant attributes of the atom or bond, respectively. Information about hydrogen atoms is implicitly included as part of the node features in the graph.

The GH-GNN model consists of two graph neural networks (GNNs) operating at different levels. The first GNN processes molecular graphs to obtain learned representations tailored for the prediction of IDACs. The second GNN operates at the mixture level, using a graph where the learned molecular representations of distinct chemical species in the mixture define the nodes and hydrogen-bonding interactions are represented as edges. These two GNNs are sequentially arranged to predict parameters $K_{1,ij}$ and $K_{2,ij}$ of the following equation derived from the Gibbs-Helmholtz relationship:

$$\ln \gamma_{ij}^{\infty} = K_{1,ij} + \frac{K_{2,ij}}{T} \quad (1)$$

Parameters $K_{1,ij}$ and $K_{2,ij}$ are temperature-independent and specific to the precise solvent-solute combination. As shown in Eq. 1, predicting these two parameters is sufficient to estimate the temperature-dependent IDACs. For further details on the model, readers are referred to the original publication [4].

### Tanimoto similarity for risk level assessment

As demonstrated in the original publication [4], the accuracy of the GH-GNN predictions is correlated with the distance within the chemical space between the

systems observed during training and the systems being predicted. If the distance is relatively short, the predictions tend to be more accurate. Conversely, as the distance increases, the accuracy of the predictions begins to decrease.

The distance between distinct solute-solvent systems can be approximated using the Tanimoto similarity metric, as mentioned in [4]. This metric is designed to estimate the "level of extrapolation" that the GH-GNN must undertake when predicting a system containing a chemical species that was not observed during training (extrapolated species).

The Tanimoto similarity metric is computed by taking the Jaccard distance between the molecular fingerprints of the "extrapolated species" and the set of the $n$ most similar molecules observed during training. This allows the model user to estimate the level of accuracy of the GH-GNN predictions and can inform decisions regarding the level of risk the user is willing to take during the exploration of the chemical space. This feature is not available for models like UNIFAC.

## Solvent pre-selection for liquid-liquid extraction

Measuring the thermodynamic performance of solvents participating in liquid-liquid extraction processes is typically carried out by computing the separation factor [9] defined by Eq. 2

$$K_s = \frac{\gamma_i^R \gamma_j^E}{\gamma_i^E \gamma_j^R} \quad (2)$$

In Eq. 2, the effects of the solvent in the raffinate phase $R$ and the extract phase $E$ are considered. In the case study analyzed here, species $i$ corresponds to the monomer caprolactam, and species $j$ corresponds to the ionic liquid [EMIM][BF4]. Therefore, the ratio $\gamma_i^R/\gamma_i^E$ measures the performance of the solvent within the extraction step, where it is desirable for caprolactam in the extract phase to be as enriched as much as possible while its content in the raffinate phase to be as low as possible. Similarly, the ratio $\gamma_j^E/\gamma_j^R$ measures the performance at the recovery step, where [EMIM][BF4] should be easily separable from the extract phase and preferably move to the raffinate phase.

As a pre-selection metric, the following separation factor at infinite dilution was used, which similarly to Eq. 2 considers the solvent performance at both the extraction and recovery stages:

$$K_s^\infty = \frac{\gamma_{sj}^\infty}{\gamma_{is}^\infty} \quad (3)$$

Eq. 3 results in larger separation factor values for solvents that are easily separable from the raffinate phase (mostly composed by [EMIM][BF4]), while entraining caprolactam as much as possible from the original mixture. This separation factor at infinite dilution was computed for every solvent considering the ambient temperature of 298.15 K, on which the extraction process is assumed to be operated.

# RESULTS

## GH-GNN extension strategies to ionic liquids

Three different strategies were studied to extend the original GH-GNN model from organic systems to ionic liquids. For this purpose, experimental IDAC data reported in the literature for ionic systems was included alongside the data for organic systems originally used to develop the GH-GNN [4]. The ionic liquids dataset corresponds to the compendium of ILThermo (v2.0), originally retrieved by [6] and further processed by [3].

The first extension strategy (S1) involved a complete re-training of the GH-GNN framework using only ionic liquid data. The second strategy (S2) consisted of a pre-training phase of the model using only organic systems, followed by a fine-tuning phase with the ionic liquid data. The third strategy (S3) involved a concurrent re-training of the GH-GNN model using the combined datasets for both organic and ionic liquid systems. In all cases, the same training and test split was used as in the original referenced publications [3,4].

Table 1 compares the three strategies based on the percentage of systems in the test set that are predicted with an absolute error of less than or equal to 0.3.

**Table 1:** Comparison of the percentage of systems predicted with an absolute error less than or equal to 0.3.

| Model | Organic | Ionic liquid |
|---|---|---|
| (Original) GH-GNN | 91.7 % | 16.8 % |
| S1: (IL) GH-GNN | 10.2 % | 94.3 % |
| S2: (pre-trained) GH-GNN | 10.9 % | 94.1 % |
| S3: (concurrent) GH-GNN | 92.4 % | 94.0 % |
| GNN [3] | | 93.8 % |
| Matrix Completion [3] | | 94.1 % |
| UNIFAC (Dortmund) | 64.3 % | |
| UNIFAC-IL [6] | | 50.5 % |

It can be observed that while the original GH-GNN model excels in predicting IDACs for organic systems, its performance when extrapolating to systems with ionic liquids is poor, and is considerably worse than UNIFAC-IL. In contrast, the model developed using the first strategy S1 (i.e., (IL) GH-GNN) achieves high accuracy for ionic liquid systems, even surpassing the GNN model previously reported by [3]. However, when tested for predicting organic systems, the model performs poorly. Analyzing the GH-GNN model extended with the second strategy S2 (i.e., (pre-trained) GH-GNN), the accuracy for predicting organic systems slightly increases, but at the expense of slightly decreasing the accuracy for ionic

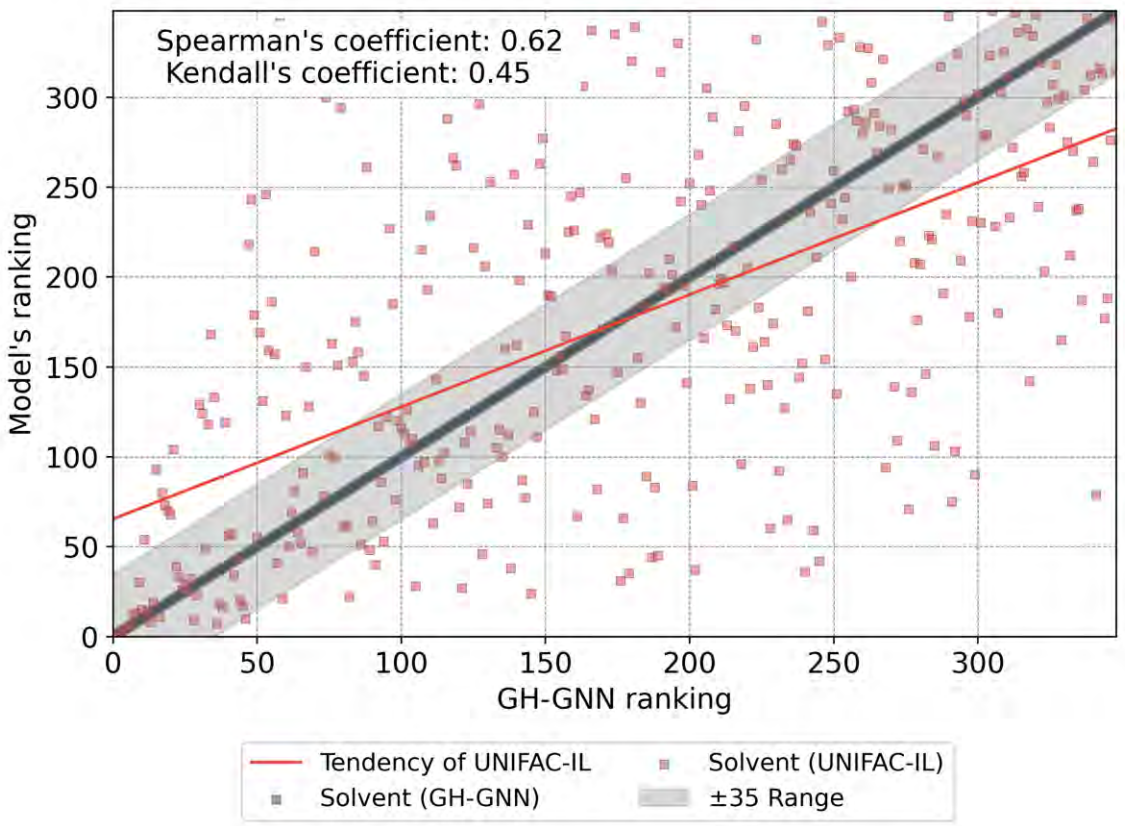

**Figure 1:** Comparison of relative solvent rankings obtained by the GH-GNN model and the UNIFAC-IL model. The linear tendency of the ranking of UNIFAC-IL with respect to the one of GH-GNN is also shown. The gray shaded area indicates ± 35 (10 %) places in the ranking of the GH-GNN.

liquid systems. This mutually exclusive behaviour in accurately predicting either organic or ionic systems highlights the difficulty of exploring vast chemical spaces while extrapolating beyond the types of systems used during training.

Remarkably, the GH-GNN model extended using the third strategy S3 (i.e., (concurrent) GH-GNN) achieves the highest accuracy for predicting organic systems among all compared models, while also performing remarkably well in predicting systems with ionic liquids. Interestingly, as a result of including ionic liquid data, the model's performance in predicting organic systems even surpasses that of the original GH-GNN model. This suggests that the model is able to extract relevant information from systems of organic molecules infinitely diluted in ionic liquids, which is beneficial for capturing effects in organic systems alone. The comparison of the extended (concurrent) GH-GNN model with the UNIFAC models demonstrates the potential of this alternative methods to predict IDACs with significantly higher overall accuracy.

## Comparison of solvent pre-selection between GH-GNN and UNIFAC-IL

The GH-GNN model extended to ionic liquids using the concurrent strategy was employed here to compare solvent pre-selection against UNIFAC-IL. The selection of solvents is aimed at separating caprolactam from ([EMIM][BF4]), a mixture arising in the context of the chemical recycling of polyamide 6. In total, 700 solvents were considered as potential candidates, based on the selection of molecules collected by [7]. Only organic molecules are included among the candidate solvents.

The chemical space that UNIFAC-IL can predict is more restricted compared to that of the GH-GNN model. As a result, the first difference between the methods is encountered: while the necessary IDACs involving all 700 solvents can be predicted by GH-GNN, only the IDACs for 359 solvents are feasible to predict with UNIFAC-IL due to limitations in the "set of functional groups" representation of the molecules and/or the lack of required group binary interaction parameters.

Fig. 1 presents the comparison of the obtained solvent rankings according to GH-GNN and UNIFAC-IL. A Spearman's rank correlation coefficient of 0.62 is obtained between the two rankings, indicating a moderate positive monotonic correlation. When computing Kendall's correlation coefficient for the rankings, a value of 0.45 is obtained, also suggesting a moderate positive correlation. This implies that while the two methods do not rank the solvents identically, there is a substantial level of agreement in their rankings, indicating that they may be capturing similar underlying patterns or properties of the solvents.

However, the exact solvent rankings obtained using GH-GNN and UNIFAC-IL also show significant discrepancies that might influence which solvents are preferred over others. Given that the accuracy of GH-GNN for computing IDACs is significantly higher than that of UNIFAC-IL, it is reasonable to assume that the solvent ranking provided by GH-GNN offers a more reliable description of the physical behaviour.

In total, 42.4 % of the solvents lie within the 10 % (i.e., 35 ranking places) deviation from each method (shaded area in Figure 2). Interestingly, both methods agree on the set of top 7 solvents, which are shown in Table 2. Note that the ranking of these solvents is solely based on their performance according to Eq. 3. Other practical aspects relevant to the application should also be considered in the selection process (e.g., normal boiling points for solvent recovery and environmental properties).

As discussed earlier, the Tanimoto similarity index within the GH-GNN model framework can provide additional insights into the risk or confidence associated with its predictions. For all 7 solvents shown in Tab. 2, the Tanimoto index is relatively high and exceeds the recommended value given in [4] (i.e., 0.35). This suggests a high level of confidence in these predictions. Out of the 349 solvents compared here, only 4 have a Tanimoto metric smaller than 0.35.

## CONCLUSIONS

The procedure of solvent pre-selection is central to the efficient exploration of the vast chemical space, enabling efficient use of resources during the early stages of process design. Predictive thermodynamic methods, such as UNIFAC-based models, are typically employed for this purpose. However, their use is limited by the extent to which the involved molecules can be successfully fragmented into functional groups and the availability of the necessary interaction parameters. The accuracy of such methods is also limited when compared to recent alternatives developed by use of deep learning approaches.

A hybrid graph neural network model, the GH-GNN [4], was here extended to accommodate the simultaneous prediction of organic and ionic systems. Three different extension strategies were compared, and a highly accurate GH-GNN model that can simultaneously predict organic and ionic systems was developed. We demonstrate that while the selection of solvents between UNIFAC-IL and GH-GNN overlaps to a great extent, there are also significant differences that might influence the outcomes of the early stages of process design. The higher accuracy of GH-GNN and larger applicability across the chemical space when compared to UNIFAC-IL, makes the GH-GNN model a potentially more reliable alternative for solvent pre-selection.

In the context of sustainable chemistry, we have chosen a relevant case study for the extraction of the monomer caprolactam from the ionic liquid [EMIM][BF4].

**Table 2:** Top 7 solvents selected by the GH-GNN and UNIFAC-IL. The ranking of the respective solvent for both GH-GNN and UNIFAC-IL is shown. Tanimoto similarity index of the GH-GNN model is also presented.

| Solvent | Rank GH-GNN | Rank UNIFAC-IL | Tanimoto index |
|---|---|---|---|
| Diisononyl adipate | 1 | 3 | 0.88 |
| Eicosane | 2 | 1 | 1 |
| Hexadecane | 3 | 2 | 1 |
| Stearic acid | 4 | 4 | 0.96 |
| Dodecane | 5 | 5 | 1 |
| Tridecyl alcohol | 6 | 6 | 1 |
| Dibutyl sebacate | 7 | 7 | 0.98 |

The top 7 solvents by both GH-GNN and UNIFAC-IL predictions were given for this case study and the Tanimoto index was close to 1 for most of these, showing a high confidence level. The need for such an extraction process arises in the context of chemical recycling of polyamide 6, highlighting the enormous potential of models like GH-GNN to support chemical engineers in developing more powerful and sustainable separation processes.

## ABSTRACT

Rubber mixing (RM) is a vital batch process producing high-quality composites, which serve as input material for manufacturing different types of final products, such as tires. Due to its complexity, this process faces two main challenges regarding the final quality: i) lack of online measurement and ii) limited comprehension of the influence of the different factors involved in the process. While data-driven and machine learning (ML) based soft-sensing methods have been widely applied to address the first challenge, the second challenge, to the best of the author's knowledge, has not yet been addressed in the rubber industry. This work presents a data-driven method for extracting knowledge and providing explainability in the quality prediction in RM processes. The method centers on an XGBoost model while leveraging high-dimensional data collected over extended time periods from one of Michelin's complex mixing processes. First, a recursive feature elimination-based procedure is used for selecting relevant features, which reduces the number of input features used for building the ML model by 82% while improving its predictive performance by 17%. Secondly, SHapley Additive exPlanations (SHAP) techniques are employed to explain the ML model's predictions through global and local analyses of feature interactions. The selected quality-related variables can be leveraged to improve process control and supervision. Finally, an uncertainty quantification (UQ) module, based on Split Conformal Prediction (SCP), is combined with the ML model, providing confidence intervals with 90% coverage and empirically verified theoretical guarantees. This module ensures prediction reliability and robustness in real applications.

**Keywords**: quality monitoring, explainable machine learning, uncertainty quantification, rubber mixing

## I. INTRODUCTION

In the rubber industry, mixing is a key process where raw rubber is blended with several components, such as additives and accelerators, to generate a composite with enhanced properties ideal for the subsequent production of tires. Real-time tracking of the mixing process's quality indicators, such as Mooney viscosity, is currently challenging. The only available methods to obtain their ground truth values are offline sampling and laboratory analyses, which take hours after the batch has been discharged, even though a batch is completed in just 30 minutes. This significant disadvantage hinders efficient process monitoring and control.

Predicting RM quality through physics-based models is also highly challenging. This is due to (i) the nonlinear and heterogeneous nature of the process since it involves several physical, thermal, and chemical transformations, (ii) the varying properties of the feeding raw materials, and (iii) the evolution and degradation of the production machinery status **[1]**. Instead, ML-based softening methods have been widely adopted to achieve this objective: ML models are trained using the process history data to capture the complex relationships between the mixing process variables and the final quality. The trained ML model can be used online as a soft sensor for cheap, real-time quality estimation. In this direction, global modeling techniques have been proposed,

commonly using Partial Least Square **[2]**, Extreme Learning Machine **[3]**, and Artificial Neural Networks models **[4]**. However, they struggle with nonlinearities and local characteristics of the process behavior. To tackle this issue, local modeling techniques have been proposed and can be categorized into three main types:

(1) **Just-in-time Learning (JITL):** each time the online prediction is required, a new ML model is trained. The training uses a few patterns carefully selected from the entire process history data, based on their similarities to the current prediction point. This technique is particularly effective for processes characterized by strong nonlinearities and localities **[3,5]**.

(2) **Ensemble-based method (ENS):** several ML models are trained using different subsets of the process history data. The training subsets can be randomly selected or based on local sub-regions within the input space where the process exhibits distinct local behaviors. The final prediction is then obtained by aggregating the predictions from the individual models. This technique enhances the prediction and its robustness, leveraging the diversity of the ensemble **[4]**.

(3) **Moving Window-based method (MW):** This approach involves training a ML model using past observations up to a certain time window. Unlike JITL, this method effectively handles progressive drifts of the process **[5]**.

Many other approaches have also been developed based on different combinations of the aforementioned types: JITL, ENS, and MW.

Despite their success, all these ML-based softening approaches applied in the rubber industry suffer from remarkable limitations. First, they offer little insight into the underlying physical processes or the influence of conditions on the final quality — an understanding that is crucial for control. Second, they consider basic process variables (e.g., power) as the sole input for the ML model, neglecting critical factors like material characteristics and weather conditions **[1,3,4]**, which can be vital, especially when ultra-quality grades with minimal variation must be achieved. Third, these approaches lack UQ capabilities, which reduces their reliability.

This work addresses these challenges by proposing an explainable and robust ML-based method with UQ to analyze the hidden relationships between final batch quality and influencing factors in RM processes.

## II. CASE STUDY

This study focuses on one of Michelin's RM lines and utilizes a dataset collected over nearly two years of production and comprising 35125 mixing batches. The dataset comprises 316 features, including direct measurements of process variables and engineered features derived from expert knowledge. These features can be categorized into 5 groups (**Table 1**):

(i) Context, such as campaign and batch information
(ii) Process States (PS), such as the mixer's internal temperature and rotor rotation speed.
(iii) Raw material quality (RMQ), such as properties of input materials.
(iv) Weather conditions (WC), such as the ambient temperature and humidity.
(v) Production recipe settings (PRS), such as machines' settings.

**Table 1:** Detailed characteristics of the dataset

| Group | Context | PS | RMQ | WC | PRS |
|---|---|---|---|---|---|
| Number of features | 4 | 99 | 37 | 22 | 154 |
| Range feature identifier: "data_" | 001 - 004 | 005 - 103 | 104 - 140 | 141 – 162 | 183 – 609 |

Moreover, the dataset includes sub-quality targets, represented by rheological parameters like the maximum torque derived from rapid and low-cost tests **[6]**.

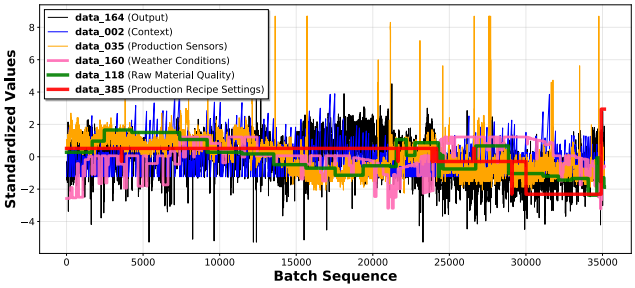

**Figure 1.** Evolution of some features and the sub-quality target over the 35125 batches.

## III. METHODOLOGY

The proposed methodology is built around the XGBoost model, an implementation of gradient-boosting decision trees, and involves four main steps described in the following subsections. For more details about the XGBoost model, we refer to **[7]**. Note that before performing any of these four steps, the available dataset $D = \{(X, y \mid X \in R^{n \times d}, y \in R^{n \times 1})\}$ with $n = 35125$ and $d = 316$, is randomly divided into three subsets for training $(D^T)$, calibration $(D^C)$, and testing $(D^t)$, using a ratio of 70%, 15%, and 15%, respectively where $n^T = |D^T|, n^C = |D^C|$, and $n^t = |D^t|$. This division is done prior to standardization. Importantly, the indices of the patterns included in each of the three subsets strictly remain the same throughout all steps of this study to ensure reproducibility and consistency.

## A. Initial feature selection

Given the high dimensionality of the features measured during the mixing process, selecting informative features relevant to mixing quality is crucial. This step eliminates redundancy, reduces the dimensionality of the input space for the ML model, and ultimately enhances its performance by improving computational efficiency, predictive accuracy, and interpretability.

This work develops a Frequency-based Feature Selection (FFS) method, which relies on a Recursive Feature Elimination (RFE) technique **[8]**. The RFE is a wrapper technique that iteratively excludes features contributing the least to the ML model predictions while minimizing multicollinearity among the features.

The proposed FFS method applies the RFE algorithm $Q$ times. In the $q^{th}$application, a different dataset $D_q^{T\prime}$ is randomly sampled from the original training subset $D^T$, such that $D_q^{T\prime} \subset D^T$, and is used for training a ML model $f_{\theta_q}$, where $\theta_q$ is the model parameters. Then, the RFE iterates, where in each iteration, it calculates an importance score for each feature based on different criteria derived from the ML model's predictions to discard a predefined number $s$ of features with the lowest scores. Although the scores are calculated in a univariate manner, the recursive mechanism of the algorithm effectively induces a multivariate selection process **[8]**. The algorithm terminates once a predefined minimum number of features $d$ is reached, where $d \ll d$.

The $Q$ applications of the RFE techniques yield $Q$ groups of best-selected features which are further analyzed based on frequency: a feature is eventually considered relevant if it appears in at least 80% of the $Q$ selections. In this way, the FFS provides the most informative features $X_* \in R^{n\times\mathcal{K}}$ where $\mathcal{K} \ll d$, and at the same time, guarantees their robustness. The total dataset is then reduced to $D_* = \{(X_*, y \mid X_* \in R^{n\times\mathcal{K}}, y \in R^{n\times 1})\}$, which will be the basis for the next step keeping the same splits for training, calibration and testing.

## B. Refinement of the initially selected features

In the second step, the initially selected set of best features, $D_*$, is refined to reduce its size further. It relies on a SHAP-based Feature Selection (SFS) method. SHAP is a model-agnostic approach that provides local and global interpretability of a ML model $f_\theta$ **[9]**.

For a given query point $x$, SHAP calculates a contribution score $\phi_j$ for each feature $j$, representing its relative impact on the model's prediction. The Shapley value is defined as follows:

$$\phi_j(x) = \sum_{S\subseteq\{1,\dots,\mathcal{K}\}\setminus\{j\}} \frac{|S|!(\mathcal{K}-|S|-1)!}{\mathcal{K}!}\left[v\left(x_{S\cup\{j\}}\right) - v(x_S)\right] \quad (1)$$

where $j \in \{1,\dots,\mathcal{K}\}$ is the index of a feature, $S$ is any subset of features that does not include $j$, and $v(x_S)$ represents the value function of the features in the subset $S$, typically corresponding to the ML model's output when only the features in $S$ are considered. This formulation ensures an equitable allocation of contributions based on all possible combinatorial subsets of features $S$.

For assessing the global importance of features, a global importance index $I_j$ can be calculated for each feature $j$ by averaging the absolute Shapley values obtained over the training set $D_*^T$, as shown in equation (2).

$$I_j = \frac{1}{|D_*^T|}\sum_{i=1}^{|D_*^T|} |\phi_j(x_i)| \quad (2)$$

Next, the $\mathcal{K}$ features are ranked in descending order based on their importance index, where a higher importance index corresponds to a higher rank. In other words, feature $j$ is considered more important than feature $j'$ if $I_j > I_{j'}$. Finally, the ranked feature set denoted as $\boldsymbol{X}^{*\boldsymbol{rnk}} = \{x^1, x^2, \dots, x^l, \dots, x^{\mathcal{K}}\}$ is obtained, where $x^r$ represents the $r-th$ most important feature with respect to the output quality, $y$, among all $\mathcal{K}$ features.

The validation step involves an iterative procedure for training ML models with different feature subsets. Specifically, at the generic $r-th$ iteration, a ML model $f^l$ is trained using the $l$ top-ranked features, where $l \in \{1,2,\dots,\mathcal{K}\}$:

$$\hat{y} = f_\theta^l(\boldsymbol{X}_l^{*rnk})$$

$$\boldsymbol{X}_l^{*rnk} = \{x^1, \dots, x^l\}$$

where $\boldsymbol{X}_l^{*rnk}$ represents the subset of the first $l$ most important features from the ranked set $\boldsymbol{X}^{*rnk}$. The model's performance is then evaluated to assess the effectiveness of these feature subsets in predicting the output $y$.

Finally, the selected subset of top-ranked features corresponds to the smallest subset after which adding more features to the ML model's input does not significantly improve its predictive performance. Consequently, the final dataset can be denoted as $D_+ = \{(X_+, y \mid X_+ \in R^{n\times\ell}, y \in R^{n\times 1})\}$, where $\ell < \mathcal{K}$. Note that, $D_+$ is the final dataset, which will be used to develop and analyze ML models.

Additionally, the same pattern splits initially performed in the first paragraph of **Section III** are strictly maintained to divide the dataset into three subsets: training ($D_+^T$), calibration ($D_+^C$), and testing ($D_+^t$).

## C. Explainability

The explainability of ML models ensures transparency and provides deep insights into their behavior by revealing how predictions are made. This explainability offers valuable information to industry experts, thereby supporting decision-making, particularly in process monitoring and supervision tasks.

While SHAP is used for feature ranking and selection in **Section III-B**, it is also applied to explain the final ML

model $f_\theta^+$ developed using the best features subset $D_+$.

SHAP, a widely used game theory-based tool, provides explainability by coupling an explainer with a trained ML model. It supports (i) global analyses on the entire testing dataset to reveal overall trends and (ii) local analyses for specific instances to detect drifts. Additionally, SHAP visualizes feature interactions using Dependence Plots (DPs).

## D. Uncertainty Quantification

The final step of the proposed approach focuses on the prediction uncertainty of the trained ML model $f_\theta^+$ to enhance its reliability for in-field quality prediction. To achieve this, SCP is employed for UQ due to its advantageous properties, including i) its model-agnostic nature, enabling applicability to any ML model, ii) its distribution-free framework, and iii) its ability to provide mathematical guarantees on the estimated uncertainties.

Relying only on the exchangeability assumption, SCP approximates the true probability, denoted as $P$ in equation (4), ensuring that the estimated prediction intervals achieve the desired coverage level $\delta$ **[10]**. This results in an uncertainty envelope defined by the average quantile value of the non-conformity scores.

$$\delta \leq P\left(y_+^t \in \Gamma_{D_+^C}^{\delta}(X_+^t)\right) \leq \delta + \frac{1}{n^C+1} \qquad (4)$$

where $\Gamma_{D_+^C}^{\delta}$ stands for the prediction set constructed on $D_+^C$.

**Algorithm 1:** SCP Algorithm

**Input:** Calibration set $D_+^C = \{(X_+^C, y^C) \mid X_+^C \in R^{n^C \times l}, y^C \in R^{n^C \times 1}\}$, Coverage level $\delta$, number of splits $\mathcal{S}$, trained ML model $f_\theta^+$.
**Output:** Avg empirical coverage $C^\delta$, avg quantile value $Q^\delta$.

**for** split $s \in \{1, \dots, \mathcal{S}\}$ in **do**
- Shuffle $D_+^C$.
- Split $D_+^C$ into a sub-calibration set $D_{+,s}^{SC} = (X_+^{SC}, y^{SC})_s$ and a validation set $D_{+,s}^V = (X_+^V, y^V)_s$.
- Predict sub-calibration outputs $\hat{y}_s^{SC} = f_\theta^+(X_{+,s}^{SC})$.
- Compute non-conformity scores $A_s = |\hat{y}_s^{SC} - y_s^{SC}|$.
- Calculate the quantile value $Q_s^\delta = quantile(A_s, \delta)$.
- Calculate prediction intervals for each validation point $i \in \{1, \dots, n^V\}$ with $n^V = |D^V|$:
$$\Gamma_{D_{+,s}^{SC}}^{\delta,s}(x_{+,i,s}^V) = \{\hat{y}_{i,s}^V \pm Q_s^\delta\}\ \forall i.$$
- Compute the empirical coverage:
$$C_{\Gamma_{D_{+,s}^{SC}}^{\delta,s}}(X_{+,s}^V) = \frac{1}{n^V}\sum_{i=1}^{n^V} 1_{[y_{i,s}^V \in \Gamma_{D_{+,s}^{SC}}^{\delta,s}(x_{+,i,s}^V)]}$$
- Compute the average empirical coverage:
$$C_s^\delta = \frac{1}{\mathcal{S}}\sum_{k=1}^{\mathcal{S}} C_{\Gamma_{D_{+,s}^{SC}}^{\delta,k}}$$

**end**

Compute the full average empirical coverage: $C^\delta = \frac{1}{\mathcal{S}}\sum_{s=1}^{\mathcal{S}} C_s^\delta$.

Compute the full average quantile value: $Q^\delta = \frac{1}{\mathcal{S}}\sum_{s=1}^{\mathcal{S}} Q_s^\delta$.

The SCP algorithm detailed **above** requires, as inputs, a trained ML model $f_\theta^+$ a calibration dataset ($D_+^C$), and a user-defined value representing a desired coverage level $\delta$ for future predictions. SCP performs its computations over $\mathcal{S}$ iterations, where in each iteration $s \in \{1, \dots, \mathcal{S}\}$ it shuffles the whole calibration dataset then splits it into two subsets: a calibration subset ($D_+^{SC}$) and a validation subset ($D_+^V$). The shuffling and splitting mechanisms enhance robustness and efficiency compared to full CP. This leads to the creation of narrower prediction intervals while mitigating biases that may arise from a single split in full CP.

All in all, SCP is a robust method that offers key statistical properties, including finite-sample coverage, validity, and efficiency. Finite-sample coverage ensures that the constructed prediction intervals maintain their statistical guarantees even with limited data. Validity corresponds to the lower bound $\delta$ and ensures that at least $\delta\%$ of future test observations fall within the prediction sets. Efficiency, defined by the upper bound $\delta + \frac{1}{n^C+1}$, ensures that the intervals remain as tight as possible without being overly conservative.

# IV. RESULTS

As a baseline, the XGBoost model is first constructed using the original dataset $D$. Our model uses 784 estimators as hyperparameters, with a maximum depth of 22 and a learning rate of 0.076. To assess its performance, the Mean Square Error (MSE) and the Coefficient of determination ($R^2$) are used, as defined in equations (5) and (6). In these equations, $y^t \in R^{n^t \times 1}$ represents the ground truth output values in the testing subset, $\bar{y}^t \in R^{1\times 1}$ denotes their mean, and $\hat{y}^t \in R^{n^t \times 1}$ corresponds to their predicted values.

$$MSE = \frac{1}{n^t}\sum_{i=1}^{n^t} (y_i^t - \hat{y}_i^t)^2 \qquad (5)$$

$$R^2 = 1 - \frac{\sum_{i=1}^{n^t} (y_i^t - \hat{y}_i^t)^2}{\sum_{i=1}^{n^t} (y_i^t - \bar{y}^t)^2} \qquad (6)$$

Firstly, the FFS method proposed in **Section III-A** is applied to the original dataset $D$, where the RFE algorithm is executed $Q = 10$ times. This step discards 244 irrelevant or correlated features, resulting in a condensed dataset $D_*$ that includes $\mathcal{K} = 72$ potential features.

Secondly, the SFS method for feature refinement defined in **Section III-B** is applied to the condensed dataset $D_*$ to rank the 72 features. The best subset is then selected according to the impact of the sequential addition of top-ranked features to the ML model's input.

**Figure 2** displays the 72 features ranked in descending order according to their importance, with *data_474* being the most relevant and *data_159* the least relevant to mixing sub-quality. It also illustrates the evolution of the ML model's performance as one of the top-ranked features is sequentially added to its input.

The selection of the optimal subset of top-ranked features $\ell$ is largely influenced by the modeler's trade-off between the desired level of accuracy and model simplicity. In our case, we observe that after the 58th top-

ranked feature, adding more features to the ML model's input does not improve the performance. Finally, the refined dataset $D_+$ comprising the top $\ell = 58$ features is obtained. The corresponding ML model $f_\theta^+$, is then trained and tested using this dataset. Both will be utilized in the subsequent steps for explainability and UQ.

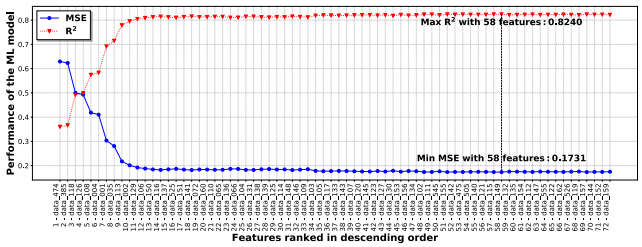

**Figure 2.** Evolution of ML model's performance as a function of the number of top-ranked features included in its input (SFS method).

**Table 2** compares the performance of the ML models developed using step 1 FFS with $D_*$ and step 2 FFS-SFS with $D_+$ of the proposed method to the baseline case, where the original dataset $D$ is used for model development. Compared to the baseline, the FFS step achieves a significant improvement in all three metrics (MSE, $R^2$, and number of features). In comparison to the FFS step, the FFS-SFS step shows a slight improvement in MSE while further reducing the number of features.

**Table 2:** Comparison of ML model performance at each step of the method. **Bold** indicates the best results.

| Dataset used for model development | ML model performance | | Improvement relative to baseline (%) | | |
|---|---|---|---|---|---|
| | MSE | $R^2$ | MSE | $R^2$ | No. of features |
| $D$ ($d$ = 316) | 0.209 | 0.788 | / | / | / |
| $D_*$ ($\mathcal{K}$= 72) | 0.174 | 0.824 | 17% | 4.6% | -77% |
| $D_+$ ($\ell$ = 58) | **0.173** | **0.824** | **17%** | **4.6%** | **-82%** |

A breakdown of the top 58 ranked features identified through Shapley analyses, categorized by the five feature groups, reveals the following distribution: 3 features belong to the Context group, 6 to PS, 31 to RMQ, 12 to WC, and 6 to PRS.

The identification of PRS features as highly important is logical and aligns with most findings in the literature. This is because PRS variables represent control parameters and manipulated machinery settings that can be adjusted to define specific operational regimes or modes, ultimately exerting a strong influence on quality.

Contrary to findings in the literature, numerous and diverse variables are found to significantly influence quality estimation, such as RMQ and WC. Particularly, RMQ features play a crucial role in both quantity and impact, a conclusion further validated by domain experts.

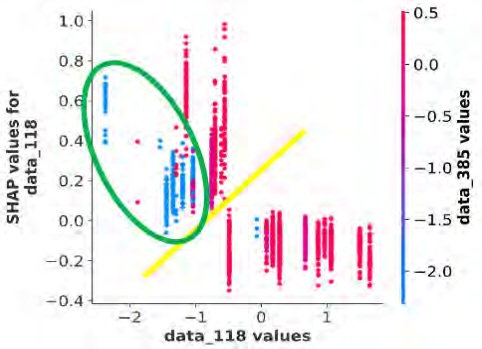

**Figure 3.** SHAP DP of *data_118* against the distribution of feature *data_385*.

Conversely, local analyses using SHAP DPs provide deeper insights into how specific feature ranges contribute to model predictions. As an example, **Figure 3** shows the DP of the second top-ranked feature *data_118* with point colors representing the distribution of the third top-ranked feature *data_385*. It reveals a bimodal behavior in *data_118*, separated by the yellow line. The first one indicates a positive contribution when the feature value is below $-0.75$. In contrast, the second mode exhibits a slightly negative contribution when *data_118* exceeds this threshold. In addition to this bimodal effect, the color distribution based on *data_385* highlights an interaction between both features. Specifically, the green ellipse shows that *data_385* reaches its lowest values almost exclusively when *data_118* is less than $-1$, suggesting a potential relationship between these two features.

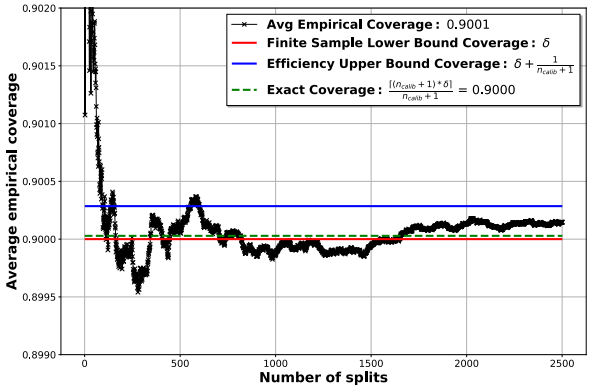

**Figure 4.** SCP convergence and theoretical guarantees with an expected coverage of $\delta = 90\%$.

Finally, regarding the UQ of the model predictions, the SCP method is applied, targeting a coverage level $\delta = 0.9$ while considering multiple splits $\mathcal{S} = 2500$.

The convergence graph in **Figure 4** demonstrates the theoretical guarantees' validation based on the calibration set $D_+^{\mathcal{C}}$. Initially, the average empirical coverage $C^\delta$ lies outside the estimated bounds $[\delta, \delta + \frac{1}{1+n^{\mathcal{C}}}]$ represented by the red and blue lines. However, as the

number of splits increases, $C^{\delta}$ converges within these bounds, aligning with the target coverage level $C^{*} = \frac{\lceil (n^{C}+1)\times\delta \rceil}{n^{C}+1}$.

Statistical properties are upheld during inference as the marginal coverage aligns with the desired level $\delta = 0.9$. Specifically, the testing coverage $C^{t} = 90.09\%$ is achieved with tight confidence intervals, ensuring reliable UQ, as shown in **Figure 5**.

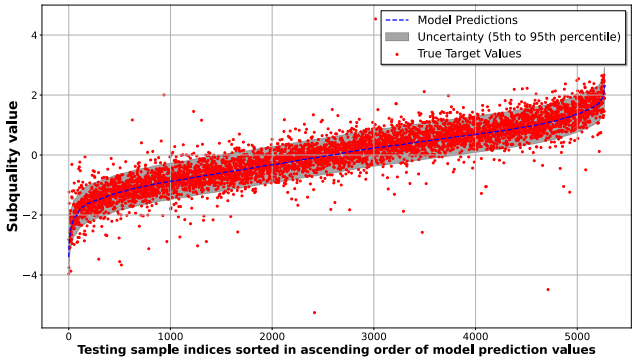

**Figure 5.** SCP uncertainty estimates with a testing coverage of $C^{t} = 90.09\%$

## V. CONCLUSION

This work proposes a data-driven framework for knowledge discovery and the reliable prediction of products' final quality in batch processes, with real application to RM. The proposed FFS and SFS methods for feature selection and refinement effectively address the challenge of high process dimensionality by discarding irrelevant and correlated features. These methods enable identifying the most informative and key features related to batch quality, leading to an 82% reduction in the number of input features while simultaneously enhancing the predictive performance of the ML model by 17% compared to the baseline.

Concerning knowledge discovery, SHAP techniques are harnessed to provide insights into the relationships between the best group of input features, previously identified, and to quantify their global and local impacts on the batch quality. These analyses also revealed the importance of previously overlooked factors in the literature, such as initial material properties and weather conditions, in predicting rubber composite quality.

Finally, the developed SCP-based UQ module can generate reliable confidence intervals with strong mathematical guarantees. This module achieves 90% coverage of the ML model's predictions, ensuring robustness and reliability in real-world industrial applications.

## ABSTRACT

Processes increasingly need to consider electricity markets, which shifts the traditional demand side management scope towards a more dynamic nature. Instead of only focusing on day-ahead energy trading, demand-side management scope should be broadened towards being able to support the power grid stability during frequency events. This paper studies an artificial example process, similar to the melt-shop process from the steel industry, highlighting the challenges and opportunities of an energy intensive process. We show the potential benefits of having a battery energy storage system on-site, as well as opportunities in lowering the electricity cost by participating in the bidding process of various ancillary products.

**Keywords**: Stochastic Optimization, Renewable and Sustainable Energy, Planning & Scheduling, Energy markets, Battery Energy Storage Systems, Price Uncertainties

## INTRODUCTION

The ongoing and planned electrification of many industries and processes will increase the interdependencies with the power infrastructure due to the increasing electricity demands. This also results in that all disturbances or changes in production processes will directly require countermeasures at the power grid level to maintain stability. As the electricity infrastructure is already facing increasing volatility on the supply side due to the growing number of renewable energy source (RES) generation units, it is also important to tap the potential of the electrification and the flexibility it can enable. Processes will have a strong impact and can also help compensate for the RES-fluctuations, ensuring that the electricity demand and supply are balanced at all times. This opportunity has already been recognized [1] and in this paper we further elaborate on the concept by adding a battery energy storage system (BESS) to support the balancing between the production targets and grid stability.

Apart from the traditional demand-side management [2], which is often based on a day-ahead production scheduling, acknowledging the next day electricity prices – either based on forecasts or actual market clearing prices – electricity bidding offers more opportunities than only forecasting the electricity price and adapting the load accordingly. Large consumers must actively participate in the electricity markets ahead of time and their energy bids will affect the market clearing. Such consumers are called price makers. This mechanism allows to schedule the power plants to ensure sufficient supply, but with increasing RES participation it becomes a challenge to deliver to promise and here industrial loads could potentially participate, also in helping to maintain the grid stability. The main vehicle to deal with large unplanned supply variations is ancillary services [3], which from the consumer point of view means committing to potentially increase or lowering the energy consumption if called upon. This raises the practical question how much the process industries can plan for such volatility as they primarily need to focus on delivering to customers.

A common option – also seen by many RES unit owners – is to invest in BESS to act as a buffer between the consuming load and the power grid. This can also shield the process owner from unwanted and infeasible power volatilities, which can have an immense effect on critical electricity-dependent processes. With such an energy storage system in place, there is an option to use the BESS for offering ancillary services, as well as participating in energy arbitrage trading [4], i.e. benefiting from buying electricity during low prices and selling it back during high prices. This could also help justifying the investment costs. However, the key question is how to

operate such a combined system in a profitable manner, also taking into account the uncertainty over electricity prices. In this paper, we extend the approach in [5], where several energy and ancillary service products are co-optimized taking into account the uncertainty about price developments. The previous approach was targeted at RES/BESS owners, where the forecasted load was relatively stable and mainly consisted of the control system focused on keeping the system running. Here, we change the load behavior to be not a forecasted parameter but a variable and link this to a process schedule, which is co-optimized with the bidding decisions. Much following the concepts in [6], we compare the cases with different combination of products (energy and ancillary products) and different sizes of BESS systems using a simplified stochastic approach, which reduces to a deterministic optimization approach if there is only one price scenario available, which is the case in this paper. The example process is modeled using the resource task network (RTN) [7] approach.

## THE EXAMPLE PROCESS

We introduce a steel-plant like energy-intensive process equipped with electric arc furnaces (EAF) and having four processing stages and two parallel units in the first EAF-stage. The process is shown in Figure 1.

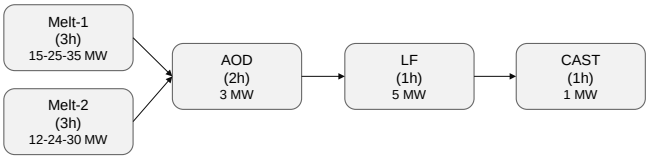

**Figure 1**. Example four-stage energy-intensive process, inspired by the steel-making process

The process durations and electricity consumptions are shown in the figure. Note that the melting process electricity demand increases along the processing time (e.g. 15 MW for hour 1, 25 MW for hour 2 and 35 MW for hour 3 in Melt-1). We can also see that the two EAFs are not equal. The batch size across the processing stage is 25 tons and constant. This example represents a strongly simplified small steel production process and we e.g. ignore the cooling effect caused by waiting times between process stages. We model the process using the discrete-time RTN approach presented in Castro et al. [8], which considered demand-response aspects of a cement plant. The corresponding RTN graph is shown in Figure 2, where we see all resources represented by circles and tasks by rectangles. The resources are: EAFs, argon-oxygen decarburization unit (AOD), ladle furnace (LF) and continuous caster (CAST) and electricity (ELEC). Intermediate product resources are molten metal (MET), the same after AOD (AODMET) and after LF (LFMET). After the casting, we get the final product (SLAB). We refer the interested reader to further process details described in [9] and [10].

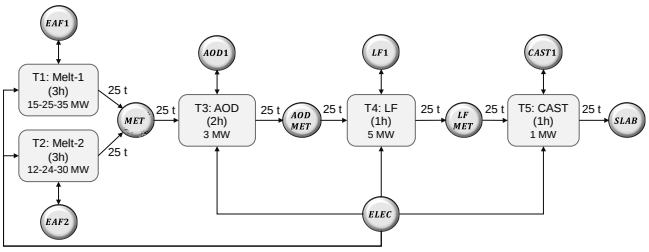

**Figure 2**. RTN graph of the example process

The RTN diagram can be easily converted into an RTN model, which basically has the following structure. We have a number of processing tasks $i$, a set of discrete-time points $t$ and the binary variable, $N_{i,t}$, indicating whether a task $i$ starts at time point $t$. This variable is used in the resource balance equation (1), in which we have ignored the batch size term, as all batches weigh 25 tons. The equation considers the initial resource $r$ amount at time point 1 ($R_r^0$) and else refers to the previous time point $R_{r,t-1}$.

$$R_{r,t} = R_r^0|_{t=1} + R_{r,t-1} + \sum_{i \in I} \sum_{\theta=0}^{\tau_i} \mu_{i,r,\theta} N_{i,t-\theta} + \Pi_{r,t} \; \forall r, t \quad (1)$$

As we use a time discretization of one hour, the actual processing time is represented by the number of time points ($\tau_i$) needed for processing the tasks. The parameter $\mu_{i,r,\theta}$ tracks how much resource $r$ is consumed or produced at each time point $\theta$. The final variable, $\Pi_{r,t}$, indicates interactions with the environment, e.g. electricity purchase in this case. Each resource must stay within given bounds as shown in Eq. (2).

$$R_{r,t}^{min} \leq R_{r,t} \leq R_{r,t}^{max} \quad \forall r \in R, t \in T \quad (2)$$

For electricity the bound is typically zero, unless we have energy storage units available, since all electricity must be purchased at the time of use. Finally, variable definitions are shown in Eq. (3).

$$\pi_t \in \mathbb{R}, R_{r,t} \geq \mathbb{R}^+, N_{i,t} \in \{0,1\} \quad (3)$$

## OPTIMIZING THE PROCESS

In this paper, we focus on a two-day production horizon (48 hours) and assume that the demand of slabs is 500 tons, i.e. 20 batches and that the price per ton ($c_{slab}$) is 2500 EUR. In this case we assume that material, equipment and labor cost is about 70% of the steel price – before electricity costs (considered by a profit factor, $p_{fact} = 0.3$). This also means that there is not so much flexibility to adapt the production according to electricity price deviations. To make the case, we selected a week where the electricity was relatively expensive (DK-2 spot

market on June 28-29th,2023) and assume in this study that the example steel plant is a price-taker and must pay the standard day-ahead market price (normally this is not the case, as will be discussed later). The considered electricity prices are shown in Figure 3 – here we assume "perfect knowledge" and do not involve stochastic elements for the sake of the length of this paper. Note that this corresponds to a maximum of 167 EUR/MWh (about 2-3 times the price of normal industrial energy cost).

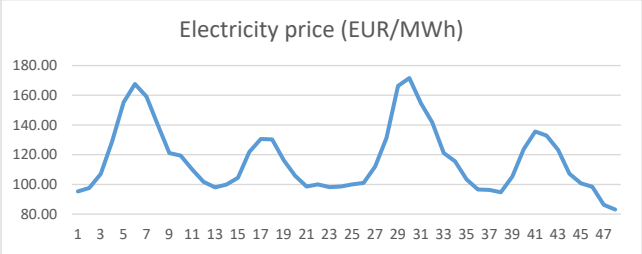

**Figure 3.** Electricity prices for the studied 48-hour period

Let us first optimize the production without considering the electricity price at all – as well as without any energy storage option (worst case). Specifically, we minimize only the makespan ($MS$) which is defined as shown in Eq. (4).

$$MS \geq N_{i,t} \cdot (t + \tau_i - 1) \quad \forall i, t \tag{4}$$

This, as expected, results in a schedule that completely ignores the electricity price.

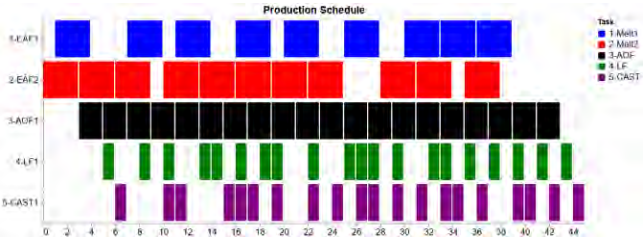

**Figure 4.** Schedule minimizing the makespan

The corresponding Gantt chart is shown in Figure 4 and while the makespan is 45 hours (3 hours of unused production time), this results in a profit of about 182 kEUR after deducting the electricity costs. Note that we enforce the production of minimum 500 tons. If, however, we include the electricity cost into the scheduling objective (Eq. 5),

$$\max \sum_t p_{fact} \cdot c_{slab} \cdot R_{slab,t} - c_{elec,t} \cdot \pi_{elec,t} \tag{5}$$

the results change significantly. The profit increases by 11% to 202 kEUR and the resulting production plan in Figure 5 shows that the full 48 hours are used and the less electricity intensive EAF2 is preferred. Also, one extra batch is produced to increase the profit (total production 525 tons), while simultaneously lowering the electricity costs by 0.6%. This example illustrates that considering the electricity pricing, i.e. doing demand-response has a significant effect on the profitability.

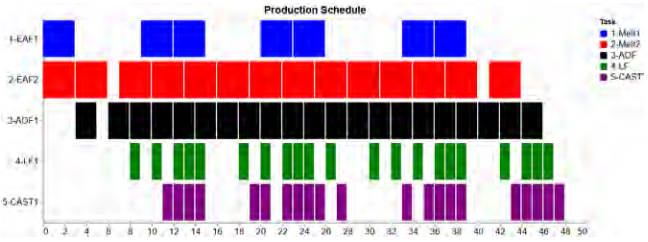

**Figure 5.** Schedule considering electricity cost

If we allow electricity to be stored i.e. by adapting the parameter $R_{r,t}^{max}$ this changes the situation. Having e.g. a 50 MWh battery energy storage system (BESS) unit, which is initially empty, increases the profit by an additional 4.3% to 210 kEUR with minor changes to the production schedule shown in Figure 6. The main change is the time of purchasing as the previous schedule already operates during the cheapest times.

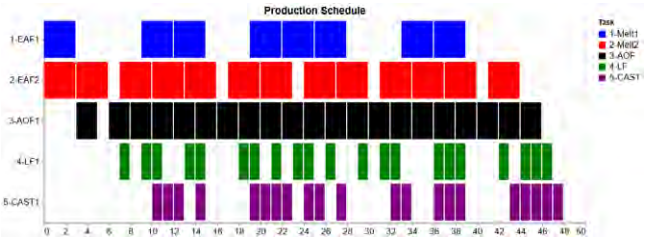

**Figure 6.** Schedule with a BESS of 50 MWh

The use of the BESS capacity correlates well with the electricity price development, as seen in Figure 7, where the storage is filled up during cheaper prices and emptied during peak prices. This shows that it is worth considering both demand-side management scenarios, as well as investing in a BESS, which can shift the electricity purchases to a more profitable period.

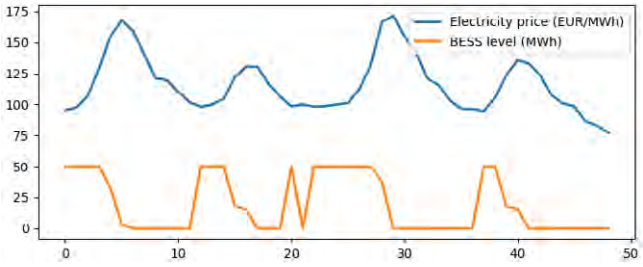

**Figure 7.** Use of BESS capacity w.r.t. electricity price

Optimization results of using three different BESS-sizes is shown in Table 1. As expected, a larger BESS-size increases the profit through the lowered electricity costs. For the two first cases, the production plan did not deviate from the one shown in Figure 5. Here, we cannot analyze the return of investment, but at least provide a

more concrete picture about potential savings (upper bound) of having a BESS installed on site.

**Table 1.** BESS size impact on profit

| BESS size | Profit | Electricity cost |
|---|---|---|
| 0 MWh | 202088.5 | 191661.5 |
| 10 MWh | 203615.2 | 190134.8 |
| 20 MWh | 205621.7 | 188128.3 |
| 50 MWh | 210748.7 | 183001.3 |

## BIDDING TO ELECTRICITY MARKETS

There exists many literature contributions about bidding into various electricity markets [4,5,6] with or without a BESS. The "traditional" market, where industrial consumers have been participating and bidding to, is the electricity market. Typically, large consumers have various electricity contracts, e.g. time-of-use or fixed base tariffs. As mentioned before, here we assume that the example consumer does not impact the final price ("price taker"). Other options that are becoming increasingly important is to bid into ancillary service markets to help stabilizing the power grids during network disturbances, i.e. when the power frequency exits a given threshold (too low or too high). A key requirement here is that ancillary services are always required to be available but mostly not used (in some markets, only 1-2% of the committed capacity is deployed). Therefore, in many markets it is mandatory that the ancillary service capacity be immediately available, i.e. mostly stored within a BESS. Here we build upon the work presented in [5], which discusses a solar power plant combined with a BESS. In this work, we ignore any renewable sources but focus on the process system, discussed in the previous chapter, having an installed BESS capacity (50 MWh), which allows us to participate in the ancillary markets.

We consider two different ancillary markets, where the market M1 requires bidding 36 hours before start of the trading day and market M2 respectively 12 hours before. The products comprise both up and down regulation of the frequency through either injecting (discharging BESS) or extracting (charging BESS) power to/from the grid. We name the products as follows: P1 (up), P2 (down) and P3 (up & down). Product P3 is symmetric and requires exactly same potential capacity (MW) into both directions. The ancillary service capacity cannot be shared by multiple products. For the energy trading, we use only the day-ahead energy market (DAEN).

The modeling is done as follows. We link the RTN model defined above to the model from [5]. The key is the energy balance equation, which basically implies that the amount of energy bought, $x_t^{buy}$, and discharged from BESS, $x_{B,t}^{dc}$, must equal the energy sold, $x_t^{sell}$, charged to BESS, $x_{B,t}^{ch}$, or consumed by a load behind the meter, $X_t^{load}$, as depicted in Eq. (6).

Here, instead of using a fixed load forecast $X_t^{load}$ as was done in [5], we define the load based on the production schedule, i.e. through Eq. (7).

$$x_t^{buy} + \sum_{B \in BESS} x_{B,t}^{dc} \cdot \Delta_t = X_t^{load} \cdot \Delta_t + x_t^{sell} + \sum_{B \in BESS} x_{B,t}^{ch} \cdot \Delta_t \quad \forall t \tag{6}$$

$$\pi_{elec,t} = X_t^{load} \quad \forall t \tag{7}$$

This allows us to directly link a very complex bidding model into the variable load of the generated RTN schedule. We add the first term from the profit function in Eq. (5) into the objective function, which might strongly dominate over bidding profits. Nonetheless, we expect to see some indications of the possible benefits of this co-existence. The electricity cost part (second term in Eq. (5)) is already fully embedded into the bidding scheme. We assume again a BESS configuration with the capacity of 50 MWh, and initial state of charge (SoC) of 50% (25 MWh), which can be fully (dis)charged in 2 hours. Using exactly the same information as in [5], but only considering 48 hours instead of 144, we can now optimize the trading.

The profit increases to 417 kEUR, which is a significant improvement (113%). Figure 8 shows the day-ahead energy market price (DAENprice), which was used earlier, with the ancillary product pricing across the three products and two markets discussed above.

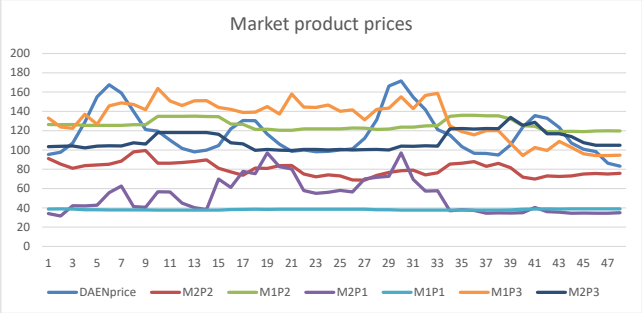

**Figure 8.** Market prices of different products

Using this approach the production schedule remains unchanged and the Gantt chart in Figure 5 is still valid. The trading volumes are shown in Figure 9. Note that energy trading is done in MWh, whereas ancillary products are mainly traded in MW (power).

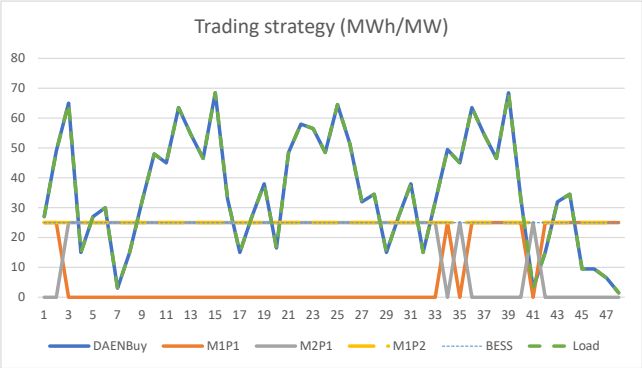

Figure 9. Trading results across multiple markets

Here, we can observe a few facts:

- The energy purchase is 1:1 with the load, i.e. the BESS is not used to shift the electricity demand
- As a consequence, the state of charge (BESS in the figure) is constant and stays exactly in the middle (25 MWh) during the entire planning horizon
- The reason for the above is that the BESS capacity is fully used for trading ancillary services in both directions (25 MW each), which maximizes the trading benefits. Product P3 is not used.

Here we assume the ideal situation that there are no ancillary events, which means that all ancillary trading profits are direct revenues. In this example, the energy purchasing cost is 192 kEUR (as for the 0 MWh case in Table 1) and the earnings from the ancillary service markets 215 kEUR, i.e. the net electricity cost is -23 kEUR. Using the BESS for participating in the ancillary markets would thus completely cover the electricity costs and strongly support the return of investment. However, a more thorough CAPEX estimation would require a more holistic and longer-term studies including seasonal electricity price variations and simulations where ancillary events actually take place, which are out of the scope of this paper.

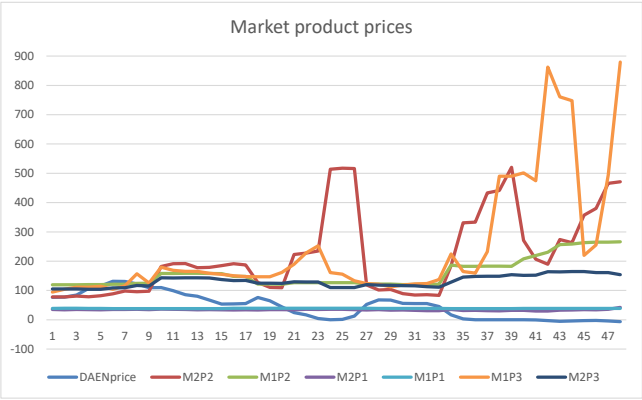

**Figure 10.** Market prices of the second example

## More volatile price profiles

In a second example we study another price profile, which is from the same market but two days later (Figure 10). The volatility of the electricity price (EUR/MWh) is very high (min=-6.62, max=131) and at the end of the time horizon, we can see negative energy prices and very high-prices on the ancillary product P3 (M1P3). Also, compared to the earlier example with an average electricity price of 116 EUR/MWh, in the second example the average price is 45 EUR/MWh, which can be considered more typical.

When running exactly the same problem as earlier, only with the new market prices, the profit increases further by 67% to 696 kEUR. We can also see in Figure 11 that the production schedule is affected and the cheaper or even negative electricity prices at the end of the scheduling horizon are utilized activating the more energy-intensive EAF-1.

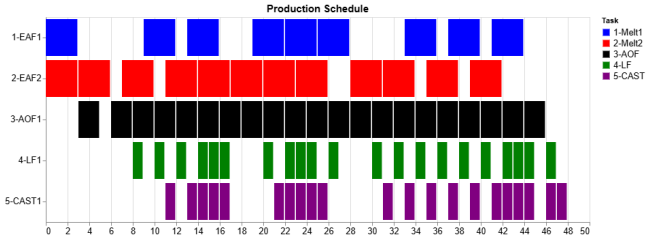

**Figure 11.** Production schedule of the second example

The trading volumes for this volatile example are shown in **Figure 12**, clearly illustrating that now the symmetric product P3 is used as well, especially towards the end of the schedule. We can further observe that the BESS level is slightly adjusted to maximize the trading profit. In general – maybe surprisingly – the ancillary service revenues are so high and do not involve any corrective actions after a true ancillary event that the optimization is keeping the BESS SoC mainly constant in order to leave sufficient headroom for both up/down directions. Thus, in most cases the energy trading is exactly 1:1 with the load at each point of time.

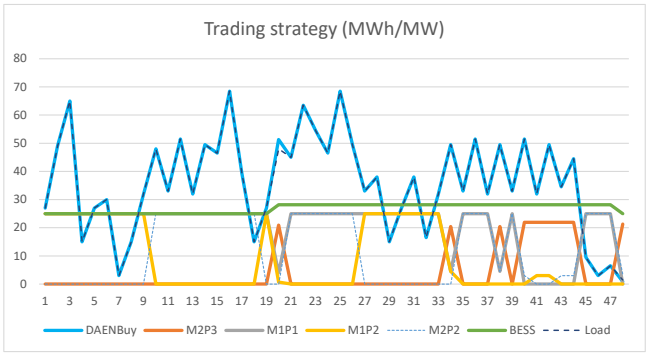

**Figure 12.** Trading volumes for the second example

## CONCLUSIONS

This paper has studied the option of enhancing the traditional demand-side management with BESS utilization and more complex trading schemes, including ancillary services. Both approaches show significant potential. The BESS helps decouple the load and energy purchases, thus reducing trading during the most expensive peak times. If ancillary services are included, the BESS is mainly dedicated to support the enabling of maximum ancillary service trading volumes in both directions. This supports the frequency regulations in various disturbances and ancillary events. The main benefit in the more elaborate trading schemes is that in the two examples ancillary service trading could generate revenues that may fully compensate for the energy costs, making the electricity practically “free”.

However, what we did not address in this short paper were the price uncertainties, which can be easily incorporated into the presented concept. Also, we assumed that all ancillary bids are accepted and did not discuss how an occurring ancillary event would affect the production line and whether e.g. intra-day trading could be used to compensate for these uncertain events. Also, an on-site BESS could also be used to balance possible process disturbances and avoid the resulting demand-peaks. Without having any ancillary events, the production process and energy trading remain practically almost fully decoupled, and one can question the motivation in investing in a BESS. Nevertheless, it is important that future energy-intensive industries also have the capability of, when needed, supporting the grid stability in order to avoid blackouts. As the study shows, this can in ideal situations even be a profitable feature.

## ACKNOWLEDGEMENTS

This paper is dedicated to Prof. Pedro Miguel Castro (1973-2024) acknowledging his remarkable contributions within the areas of planning, scheduling and optimization – some of which are reflected in this paper.

## ABSTRACT

Optimization under uncertainty is inherent to many PSE applications ranging from process design to RTO. Reaching process true optima often involves learning from experimentation, but actual experiments involve a cost (economic, resources, time) and a budget limit usually exists. Finding the best trade-off on cumulative process performance and experimental cost over a finite budget is a Partially Observable Markov Decision Process (POMDP), known to be computationally intractable. This paper follows the nonmyopic Bayesian optimization (BO) approximation to POMDPs developed by the machine-learning community, that naturally enables the use of hybrid plant surrogate models formed by fundamental laws and Gaussian processes (GP). Although nonmyopic BO using GPs may look more tractable, evaluating multi-step decision trees to find the best first-stage candidate action to apply is still expensive with evolutionary or NLP optimizers. Hence, we propose modelling the value function of the first-stage decision also with a GP, whose data will correspond to virtual evaluations of second-stage decision trees build upon myopic rollouts. Thus, the nonmyopic initial decision can be efficiently optimized via BO and the virtually learned value function. Effectiveness of the approach is demonstrated in a wide benchmark with synthetically generated functions as well as to optimize small batch production with a chemical reactor.

**Keywords**: Optimization, Machine Learning, Batch Process, Algorithms, Design Under Uncertainty, POMDP

## INTRODUCTION

Process optimization in actual applications must deal with uncertainty in exogenous factors (such as weather predictions or market prices), partial and noisy measurements, as well as plant-model mismatch (either parametric or structural). There are widely used techniques to deal with each one of these factors in isolation: multi-stage stochastic optimization offers a good performance-robustness compromise in the case of exogenous and measurable parametric uncertainty [1]; Kalman-based filters and data reconciliation deal with partial and noisy measurements [2]; and extremum seeking [3], modifier adaptation [4], policy search [5], or Bayesian optimization (BO) [6], are typical approaches used to drive the operation point of a real process to its true steady-state optimum by acquiring experimental information. Focusing on the existence of plant-model mismatch and partial information available through measurements, the reader will note that none of the cited approaches include the cost of experimentation (either economic, resource consumption, or number of batches to produce) explicitly. In other words, their objective is just to reach the closest possible neighborhood of true optimum at any cost. But a limit on the experimental budget usually exists in practice. Moreover, with limited budgets one may be interested in finding the best trade-off between an accumulated exploration cost and exploitation performance.

The right way to formulate the problem of finding the best cumulative trade-off on process performance and experimental cost under uncertainty over a finite budget is a Partially-Observable Markov Decision Process (POMDP) whose states are uncertain process beliefs [7]. The general way to approach these problems is evaluating belief trees of candidate actions and plausible observations via dynamic programming, as Monte Carlo Tree Search (MCTS) algorithms do [8]. But their computational cost is prohibitive when the state and action

spaces are of continuous nature.

If such a belief is modeled by a Gaussian process (GP), the nonmyopic BO acquisition functions developed by the machine learning community are a more tractable way to approximate POMDPs. The key idea of nonmyopic BO is to look ahead several steps and compute the best candidate decisions based on an estimation on the cumulative expected value or improvement over the budget horizon [9]. Anyway, optimizing multi-step trees with GPs as states in one shot is also challenging, and rollout algorithms with default myopic BO acquisition functions are normally used to complete the value function estimation after the first lookahead step [10], which can lead to conservative results.

Following this path, recently we proposed a variant tailored for process experimental optimization [11], in which the decision in each action node of the tree is provided by a myopic BO acquisition function from a list of the most widely used in the literature. In this way, the algorithm can dynamically select the most promising acquisition function along the sequence of decisions to optimize the expected value over the decision horizon or budget. We also used Gauss-Hermite Quadrature [12] in each observation node as an efficient way to approximate the value function. Although the approach is much more tractable than other nonmyopic BO in the literature (note that no nested optimizations are involved), its expected optimality proven to be slightly lower due to limiting the first-stage decisions on myopic BO acquisition functions.

To remove such conservativeness, hence unlocking the extra performance that nonmyopic BO can provide in theory but at lower computational costs than the existing proposals in the literature, here we propose *learning the value function of the first-stage decision* also with a GP, whose data will correspond to virtual evaluations of our POMDP decision tree in [11] for the subsequent stages, instead of typical rollouts with expected value or improvement BO. In this way, the first-stage decision can be efficiently optimized via BO with the virtually learned value-function GP. In other words, we use *myopic BO to optimize the nonmyopic BO acquisition function*. Note that evaluating a POMDP decision tree via approximate dynamic programming (ADP) is an expensive function from the computational perspective, which fits into the main hypothesis of BO.

In the next section we briefly summarize the key methods involved in our proposal. Then, we present the nonmyopic BO-POMDP strategy and a basic pseudocode. The proposal is then evaluated in a synthetic benchmark of unconstrained optimization functions, where we also provide the results gathered when comparing to some state of the art nonmyopic and myopic BO. The paper closes with an illustrative application to the Otto-Williams reactor and some remarks.

# METHODS AND PROBLEM STATEMENT

## Hybrid models with Gaussian Processes

The hybrid plant models in this work are understood as a basis of fundamental laws that is then customized to a particular process with gathered experimental data. In this case, instead of incorporating deterministic machine learning sub-models obtained, for instance, with sum-of-squares polynomial regression [13], we employ probabilistic Gaussian Process regression to adjust first-principles predictions to the real data, getting confidence intervals around.

GPs are characterized by a mean function $\mu(x)$ and a covariance generator $\kappa(x_a, x_b) \coloneqq \mathrm{cov}\big(f(x_a) - f(x_b)\big)$, being $f(x)$ the true function whose knowledge is partially unknown. A $GP\{X, Y\}$ is built from input-output data

$$X \coloneqq [x_0, x_1, x_2, \dots, x_n]; \quad Y \coloneqq [y(x_0), y(x_1), \dots, y(x_n)];$$

where measurements are assumed to be $y(x) = f(x) + w$, $w \approx \mathcal{N}(0, \lambda^2)$, being $\lambda$ the noise standard deviation. The a priori mean $\mu(x) \coloneqq 0$ if pure experimental optimization is to be pursued [11], or set to a first-principles model.

Every time new data is gathered, the GP mean and covariance kernel are updated by [14]:

$$\mu(x) = \mu(x) + \kappa(x, X)(\kappa(X, X) + \lambda^2 I)^{-1}\big(Y - \mu(X)\big) \tag{1}$$

$$\kappa(x_a, x_b) = \kappa(x_a, x_b) - \kappa(x_a, X) \cdot (\kappa(X, X) + \lambda^2 I)^{-1} \kappa(x_b, X)^T \tag{2}$$

Moreover, GPs can themselves contain parametric components with adjustable parameters $\theta$, such that $\phi(x)\theta$ is the deterministic prediction by these components. In such a case, the GP covariance kernel becomes

$$\bar{\kappa}(x_a, x_b) \coloneqq \kappa(x_a, x_b) + \phi(x_a)\Sigma_\theta \phi(x_b)^T \tag{3}$$

where $\Sigma_\theta$ is the a priori parameter covariance matrix.

## Myopic Bayesian optimization

The goal of BO is to reach the optimum of a static mapping $f(x)$. In particular, BO proposes the next experiment to actually test by means of optimizing an acquisition function $F(\mathrm{GP}, x)$ with a surrogate model (cheaper to evaluate than $f(x)$), usually a GP built from process data.

The acquisition function $F(\mathrm{GP}, x)$ is the cornerstone of the method, because it defines a certain tradeoff between exploitation of the already acquired knowledge and exploration to improve such a knowledge. There are several well-known heuristics in the BO literature that perform really well and are cheap to optimize [15]: Expected Value; Probability of Improvement; Expected Improvement; Lower-Upper Confidence Bound.

Given a GP, the basic BO algorithm is a one-step optimization and subsequent GP update, as follows:

$$x = \arg\min_{x \in \mathbb{X}} F(\mathrm{GP}, x) \text{ or } x = \arg\max_{x \in \mathbb{X}} F(\mathrm{GP}, x) \tag{4}$$

$$GP \leftarrow GP \oplus \{x, y(x)\} = \{X \cup x, Y \cup y(x)\} \quad (5)$$

This process repeats until some criteria is met, for instance, no improvement observed, number of experiments, o time exhausted. Of course, constraints $g(x) < 0$ can be also realized in BO in straightforward ways [11].

However, the exploitation-exploration tradeoff that these standard functions define is just a myopic heuristic that does not account for the potential gains of optimizing at several steps. There are improved heuristics that look two steps ahead, such as Knowledge Gradient or Predictive Entropy Search [16]. These usually show better performance than the classic ones, but at much higher computational cost. Anyway, none of these considers problem-specific cumulative costs and budgets.

## Multi-stage scenario optimization

Multi-stage scenario optimization (MSSO) [1] is often the approach to approximate complex Markov decision processes. It combines decision optimization with simulation steps on potential scenarios that may realize (sampling from a probability distribution) within a planning horizon. Basically, MSSO builds a tree of sample paths of depth $N$ through possible states and observations. This is the forward-in-time propagation step. Then, state-value functions can be estimated by backward propagation, providing the best decision for each stage.

If such a decision tree is iteratively built, *value functions can be learned* through the evaluations, which might allow generalization across states, i.e., the already visited states or evaluated decisions might tell us something about the value of the ones not visited yet [17].

In this paper we recall the Gauss-Hermite quadrature (GHQ) method [18] to approximate integrals as an efficient way to build sample-paths trees and to estimate state-value functions in POMDPs.

## Problem statement

Assume that a statistical belief of the actual $f(x)$ and $g(x)$ given by GPs is available, constructed from a prior inaccurate model and a set of past data $X_0$,$Y_0$ (e.g. the optimum of the first-principles model tested in the actual plant). Then, there is a finite budget of $N$ experiments or production batches to realize, so that the task is deciding which will be the most promising sequence of decisions $x$ to perform such that they are optimal in some sense related to a POMDP. After each decision $x_k$ ($k = 1, \dots, N-1$) is taken, a process observation $y_k$ will be available, so that an immediate reward or cost $r([X_{k-1}, x_k], [Y_{k-1}, y_k])$ is computed. Compact notation $r(X_k, Y_k)$ is used from now on when the order of the samples does not matter. A terminal cost $J_N(X_N, Y_N)$ will be attained as a result of the last decision $x_N$. Then, the goal is to optimize the expected overall cumulative cost (being $\gamma > 0$ a discount factor)

$$J \coloneqq \mathbb{E}\{\gamma^N J_N(X_N, Y_{f,N}) + \sum_{k=1}^{N-1} \gamma^k r(X_k, Y_{f,k})\} \quad (6)$$

over a set of $N$ future observations of $f(x)$ denoted by $Y_{f,N} \coloneqq \{y_f(x_1), \dots, y_f(x_N)\}$, such that the observations of process constraints $Y_{g,N} \coloneqq \{y_g(x_1), \dots, y_g(x_N)\} < 0$ hold with desired probability threshold, e.g., $2\sigma$ confidence.

## NONMYOPIC OPTIMIZATION STRATEGY

Our proposal of nonmyopic acquisition function approximates the value function of the first-stage decision set $x_0$ by ADP, building scenario trees that branch with some easy-to-compute acquisition functions from myopic BO at the decision nodes and with GHQ points at the observation ones [11]. Evaluating this tree backwards for each first-stage candidate $\tilde{x}_i$ provides the corresponding value-function estimate $\hat{V}_i$, data that serves to fit a GP model of the first-stage value function. The proposed exploration strategy is illustrated in Figure 1 on next page, where the root node has a fixed current belief on the process to be optimized after incorporating previous actual observations, and a value-function belief that is learned dynamically with each subsequent tree evaluation.

Hence, the idea is to progressively improve such a value function model $GP_V\{\tilde{x}, \hat{V}\}$ while performing myopic BO on it to propose new candidates $\tilde{x}_i$. When this learning-optimization process converges (e.g. reaching an input-deviation tolerance or maximum iteration number), the best candidate decision found is tested in the real process and everything repeats for the remaining budget horizon. Algorithm 1 summarizes de proposed procedure.

**Algorithm 1:** Nonmyopic BO acquisition function.

**Global:** $X_0, Y_0, N, H_r, V_0$, optol %Initial data
**1: Create** $GP_c\{X_0, Y_0\}$ %Build root cost GP
**2: For** $k \coloneqq 1$ **to** $N$ **do:**
**3:** **If** $k = 1$ **then** $\tilde{x} \leftarrow X_0$**; otherwise** $\tilde{x} \leftarrow \arg\min_{x \in \mathbb{X}} F(GP_V, x)$ %Value-function BO
**4:** $b = \text{NodeV}(GP_c)$ %Create the root node
**5:** $\bar{H} \leftarrow N - k$ %Reduce prediction horizon
**6:** $b.\text{Expand}(\tilde{x})$ %Branch second-stage tree
**7:** $\hat{V} \leftarrow b.\text{ValueFunction}()$ %Estimate V($\tilde{x}$)
**8:** $GP_V \leftarrow GP_V \oplus \{\tilde{x}, \hat{V}\}$ %Update GP of V(x)
**9:** **If** $|V_0 - \hat{V}| >$ optol **then** $V_0 \leftarrow \min_{\hat{\mathbb{V}}} GP_V$**; Goto 3**
**10: Realize** $x \leftarrow \arg\min_{\tilde{\mathbb{x}}} \min_{\hat{\mathbb{V}}} GP_V$ %Actual experiment
**11: Get** $y_f \leftarrow f(x) + w$ %New observation
**12:** $GP_c \leftarrow GP_c \oplus \{x, y_f\}$; %Update GP of r(X,Y)

Where, abusing notation, $\min_{\hat{\mathbb{V}}} GP_V$ finds the lowest value $[V^*, i_d] = \min GP_V.\hat{\mathbb{V}}$ already in the GP dataset, and $\arg\min_{\tilde{\mathbb{x}}} \min_{\hat{\mathbb{V}}} GP_V$ stands for the $x$-coordinate in the GP data corresponding to such a $V^*$, i.e., $x^* = GP_V.\tilde{\mathbb{x}}[i_d]$.

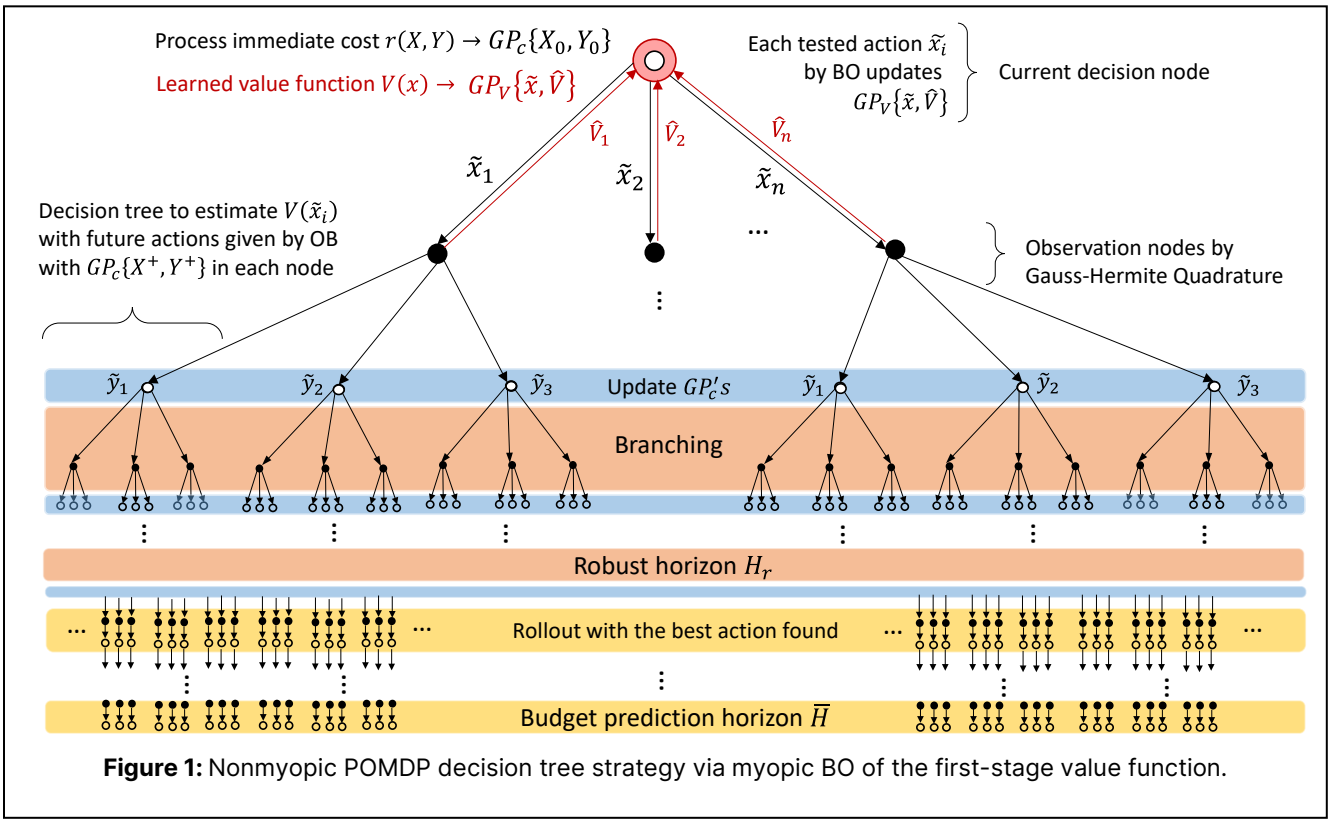

**Figure 1:** Nonmyopic POMDP decision tree strategy via myopic BO of the first-stage value function.

Note that Algorithm 1 here presented is a simple version that does not include process constraints for the sake of clarity, but considering them is straightforward. See our previous work [11] (and references therein) for ideas to deal with constraints in BO-POMDP as well as details and pseudocode on the exploration-decision tree. Moreover, Algorithm 1 assumes a very basic myopic BO in statements 3 and 9, but there is no inconvenience in calling sophisticated software BO packages instead. In fact, Bayesian adaptive direct search (BADS) [19] turned to be a good implementation to realize this higher first-stage BO without worrying on hyperparameter tuning and right covariance-kernel choice for the value-function GP.

## Performance evaluation

To evaluate the proposed nonmyopic optimization strategy, we tested it to optimize the cumulative cost (6) on 100 functions $f(x)$ of two decision variables (normalized to the squared range [-1,1]) and zero mean, synthetically generated from the exponential covariance kernel

$$\kappa(x_a, x_b) = \Sigma \cdot e^{-\frac{\|x_b - x_a\|^2}{2 \cdot \sigma^2}}, \qquad (7)$$

with $\sigma = 0.25$, $\Sigma = 1$, and considering a measurement noise level $\lambda = 0.002$. The problem budget is $N = 10$. Algorithm 1 as well as the proposals of [10] and [11] are both set to branch up to a horizon $H_r = 2$, and the discount factor is set to no discount ($\gamma = 1$).

The average performance got by Algorithm 1, references [10] and [11], as well as myopic BO with typical acquisition functions of negligible computation time (expected improvement, probability of improvement, and expected value) are presented in Table 1 below.

**Table 1:** Average regrets with respect to the best achievable performance (always knowing the true optimum).

| **Method**: | **[10]** | **Alg 1** | **[11]** | **PI** | **EV** | **EI** |
|---|---|---|---|---|---|---|
| **Regret:** | 7.92 | 7.77 | 8.28 | 9.93 | 9.73 | 11.47 |
| **CPU (s):** | 22.3 | 13 | 0.68 | - | - | - |

Algorithm 1 is the one that got lower average regret in the benchmark, followed by our implementation of [10] consisting in a multi-start strategy of a regular grid on the first-stage input space that provides the initial guess to an interior-point NLP optimizer. Furthermore, the average computation load of the proposed Algorithm 1 is about half of the required by [10], as expected because BO is an efficient approach to optimize expensive-to-evaluate functions. Note also that our reduced first-stage exploration strategy [11], although gets a slightly higher regret, it does the work at much lower computation time. Moreover, it outperforms by 15% the best myopic BO tested, and by 30% the usually used expected improvement acquisition function. The evaluation was run in a standard laptop equipped with an Intel Core i7-4510U CPU.

## SMALL-BATCH PRODUCTION EXAMPLE

Next, Algorithm 1 is tested in a simulated chemical batch production process with the Otto-Williams stirred tank reactor. There are two reactants, A and B, whose stream $F_A$ is not controlled but known and $F_B$ is decision variable. The reactor temperature $T_R$ can be set so it is also decision variable. These two define the quality of the product at the reactor outlet once the three chemical reactions are completed. In total, six compounds (or species) exist inside the reactor: 4 products (C, E, G, and P) and the reactants A and B. The equations of the chemical dynamic model and associated parameters are omitted for brevity. See [20] and references therein.

As the mass fraction of the product C is one order of magnitude below the rest of the compounds, a usual gross representation of the process is to consider only the other five species, with the corresponding structural and parametric plant-model mismatch. Then, only two parallel reactions inside the reactor are considered:

$$A + 2B \xrightarrow{r_1} P + E; \quad A + B + P \xrightarrow{r_2} G + E$$

The mass-fraction equations in steady state to act as prior mean $\mu(F_B, T_R)$ for the process belief are:

$$\begin{aligned}
\frac{dX_A}{dt} &\coloneqq \mathrm{F_A} - (\mathrm{F_A} + F_B)\, X_A - (r_1 + r_2)\, \mathrm{V_R} = 0 \\
\frac{dX_B}{dt} &\coloneqq F_B - (\mathrm{F_A} + F_B)\, X_B - (2\, r_1 + r_2)\, \mathrm{V_R} = 0 \\
\frac{dX_E}{dt} &\coloneqq -(\mathrm{F_A} + F_B)\, X_E + 2\, r_1 \mathrm{V_R} = 0 \\
\frac{dX_G}{dt} &\coloneqq -(\mathrm{F_A} + F_B)\, X_G + 3\, r_2 \mathrm{V_R} = 0 \\
\frac{dX_P}{dt} &\coloneqq -(\mathrm{F_A} + F_B)\, X_E + (r_1 - r_2)\, \mathrm{V_R} = 0
\end{aligned} \tag{8}$$

where $\mathrm{F_A} = 1.8275$, $\mathrm{V_R} = 2105$, and the reaction rates:

$$r_1 \coloneqq 1.65 \cdot 10^8\, e^{-\frac{8097}{273+T_R}}\, X_A\, X_B^2$$

$$r_2 \coloneqq 2.61 \cdot 10^{13}\, e^{-\frac{12398}{273+T_R}}\, X_A\, X_B\, X_P$$

The optimization is to sequentially decide the production setpoints $x \coloneqq [F_B, T_R]$ that get the highest cumulative economic benefit at the end of producing $N = 7$ batches of the products P and E with the actual reactor:

$$\max_{F_B, T_R} J \coloneqq \textstyle\sum_{k=1}^{10} \big(X_{P,k}\, \mathrm{P_P} + X_{E,k}\, \mathrm{P_E}\big)\big(\mathrm{F_A} + F_{B,k}\big) - \mathrm{F_A C_A} - F_{B,k} \mathrm{C_B}$$

$$\text{s.t.: } X_{G,k} < 9.5\%; \;\; 3 \le F_{B,k} \le 6\mathrm{kg/s}; \;\; 70 \le T_{R,k} \le 100°\mathrm{C} \tag{9}$$

where $\mathrm{P_p} = 1143.38$ and $\mathrm{P_E} = 25.92$ are product selling prices, $\mathrm{C_A} = 76.23$ and $\mathrm{C_B} = 114.34$ are reactant costs.

The simple non-parametric exponential kernel with $\Sigma_{\kappa_f} = 25$ and $\sigma_f = \sqrt{0.2}$ is chosen to build the GP belief for the immediate economic benefit plant-model mismatch:

$$\kappa_f(x_a, x_b) \coloneqq \Sigma_{\kappa_f}\, e^{-\frac{\|x_b - x_a\|^2}{2 \cdot \sigma_f^2}} \tag{10}$$

Inputs are normalized to $x \in [-1,1]$ to easily interpret the length scale $\sigma_f$. Same kernel class is set up for $\kappa_g(x_a, x_b)$ to model the limit on $X_G$, but with $\sigma_g = \sqrt{0.2}$ and $\Sigma_{\kappa_g} = 0.5$. These values are chosen by mere intuition in accordance with model (8), and no GP-hyperparameter tuning is then performed from run to run with the reactor due to the small batch assumption.

The given measurement noise is $\lambda_f = 0.5$ for the immediate benefit and $\lambda_g = 0.1$ for the constraint on $X_G$.

Algorithm 1 has been set up with $H_r = 3$, optol equal to BADS default tolerance. The first batch is run at $x_0 = [4.62\mathrm{kg\,s^{-1}}, 81.9°\mathrm{C}]$, which is the mean model (8) optimum without violating constraints, whose predicted immediate economic benefit is 157€. However, the actual benefit (noise free) at such a $x_0$ is 176.17€. Note that model (8) is pessimistic so, under non-negligible measurement noise, greedy BO algorithms are not able to see any potential benefit in testing nearby $x_0$ instead of remaining on it.

The actual-reactor optimum batch satisfying constraints provides 188.92€ at $x^* = [4.89\mathrm{kg\,s^{-1}}, 87.64°\mathrm{C}]$, but the goal is not to reach it at any cumulative cost (9).

Table 2 below shows the performance obtained by Algorithm 1 to produce the 7 batches. Myopic BO has been also applied with four widely used acquisition functions: expected improvement, probability of improvement, upper confidence bound, and expected value.

**Table 2:** Regrets with respect to the best achievable performance (computed noise free with the "actual" reactor).

| **Method:** | **Alg 1** | **EI** | **PI** | **UCB** | **EV** |
|---|---|---|---|---|---|
| **Regret (€):** | 44.37 | 56.64 | 74.7 | 48.38 | 76.45 |

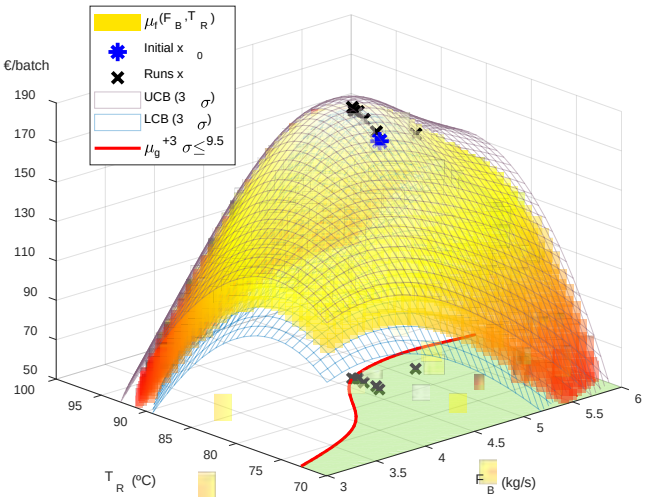

**Figure 2.** Reactor knowledge after producing 7 batches.

For completeness, Figure 2 shows the sequence of batches decided by Algorithm 1 and the final a posteriori belief on the process (mean model (8) plus the GPs fitted to the measured data).

## CONCLUDING REMARKS

This paper proves the advantages of non-myopic BO in process optimization problems of POMDP nature. In contrast to other computationally intensive strategies, we proposed a non-myopic acquisition function that uses efficient myopic BO to evaluate rollout POMDP trees.

In the test with the chemical reactor, our proposal performs better than standard BO, as expected. However, a single run with a particular reactor is not statistically conclusive. Anyway, this "one-chance run" is often the situation in multiproduct industrial plants.

The main performance limitation in practice comes from the ability of the probabilistic belief to represent the actual plant-model mismatch.

## ABSTRACT

The growing demand for sustainable alternatives to petroleum-based products drives the development of biomanufacturing using agriculture-based sugars. However, agricultural sugar production faces significant challenges due to limited production capacity and potential negative environmental impacts. This research examines chemical sugar synthesis as an alternative, assessing its environmental impact with conventional agricultural production methods through life cycle assessment. As formaldehyde serves as a primary substrate in chemical synthesis, four production cases were evaluated—comprising two pathways (conventional methods and $CO_2$ capture and utilization (CCU) technologies), each implemented with either fossil fuels or renewable energy sources. The analysis revealed that semi-batch reactors in chemical synthesis substantially reduce environmental impacts compared to batch reactors. Chemical sugar synthesis demonstrated marked advantages in reducing eutrophication, land use change, and water resources consumption across all formaldehyde production methods evaluated. However, the formaldehyde production process was identified as the determining factor in the overall environmental profile. While chemical synthesis offers environmental advantages in several categories, implementing CCU technologies with renewable energy integration remains necessary to reduce climate change impacts and resource consumption. This work demonstrates the potential of optimized chemical sugar synthesis as an alternative to agricultural sugar production and provides direction for future process development.

## INTRODUCTION

### Sugar supply in biomanufacturing

The transition away from dependence on fossil fuels is a critical challenge faced by the global community, and the shift toward the production of materials and energy using biomass as a raw material is accelerating. Currently, the most commonly used sources of reducing power and carbon for the bio-based production of valuable substances are sugars (agriculture-based sugars) obtained from crops such as sugarcane and corn. Bioproduction processes utilizing these sugars have been shown to reduce greenhouse gas emissions compared to fossil fuel-based processes [1]. However, the production volume of agriculture-based sugars is insufficient to meet the massive demand for fuels and chemicals, and excessive industrial use of such sugars risks competing with food supply demands [2]. Additionally, concerns have been raised regarding potential decreases in crop yields due to climate change and supply instability arising from geopolitical risks.

### Sugar synthesis and its life-cycle assessment

Against this background, research has been

conducted to synthesize these sugars through catalytic processes that do not rely on agriculture [3]. The chemical synthesis of sugars is achieved by integrating the production of formaldehyde via $CO_2$ reduction with sugar synthesis reactions using formaldehyde as a raw material (Figure 1). Compared to photosynthesis processes that agriculture-based sugars depend on, this method is significantly faster, allows for production near consumption sites, and drastically reduces the consumption of resources such as land and water [4]. As a result, it is expected to address the challenges of raw material supply in bio-production. On the other hand, this method requires more energy compared to conventional agricultural processes, posing challenges in terms of electricity procurement and economic feasibility. Nonetheless, bio-production technologies are essential for the transition to a circular economy, and systems capable of supplying raw materials in large quantities and with stability are equally necessary. Therefore, it is crucial to provide quantitative and objective insights into the changes brought about by the introduction of such technologies, including energy requirements and environmental impacts.

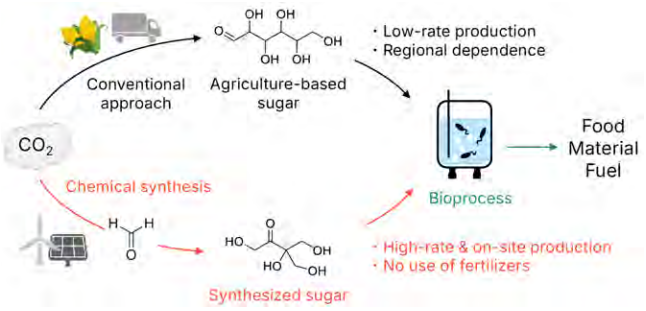

**Figure 1.** A scheme of biomanufacturing using chemically synthesized sugars as the substrates.

In this study, to determine whether the challenges of raw material supply in biomanufacturing can be addressed through the chemical synthesis of sugars, the energy requirements and environmental impacts of each process were evaluated using life-cycle assessment (LCA).

# MATERIALS & METHOD

## Numerical simulation

The time-dependent concentration changes of reactants and products in the chemical reaction were modeled using a set of coupled ordinary differential equations (ODEs). These equations were derived from the reaction rate laws, assuming homogeneous reaction conditions. The system of ODEs was solved numerically using MATLAB (version R2024b, MathWorks, Natick, MA, USA). The ode45 solver, based on an adaptive Runge-Kutta (4,5) method, was employed. The reaction rate constants were taken from the literature [5].

## Life-cycle assessment

### Goal and Scope Definition

The primary goal of this study is to evaluate the environmental impacts associated with the chemical synthesis of sugar using a simulation-based yield of the reaction. The assessment was conducted following the ISO 14040 and ISO 14044 standards. The functional unit was defined as 1 kg of synthesized sugar, and the system boundary encompassed a "cradle-to-gate" approach, including raw material extraction and chemical synthesis.

### System Boundaries

The LCA model encompassed four primary stages: raw material acquisition, chemical reaction (modeled using MATLAB to calculate sugar yield), catalyst removal, and product concentration. For the procurement of formaldehyde as a feedstock for chemical synthesis, two methods of production were considered: conventional production from fossil fuels based on the IDEA database, and production via $CO_2$ capture and utilization (CCU) technologies [6]. As the synthesized sugar product is intended to be used directly as a substrate for bioprocesses following concentration of the product [7], no further purification of the sugar product was considered. Infrastructure development, maintenance, and the transportation of raw materials and final products were excluded from the system boundary, as their contributions were deemed negligible for this study.

### Environmental impact assessment

The life-cycle inventory was calculated using data obtained from the following sources: Material and energy balances were calculated based on stoichiometric equations and simulation results from the material balance and energy consumption for the reaction. Background data such as energy production and chemical manufacturing were sourced from the IDEA ver. 3.4.1 database.

Environmental impacts were assessed using life-cycle impact assessment (LCIA) methods. Global warming potential was evaluated using climate change factors from IPCC 2021 GWP 100a with LULUCF (Land Use, Land-Use Change and Forestry). The other environmental impacts, including eutrophication, land use (transformation), resource consumption, and water resources consumption were assessed using the LIME2 (Life-cycle Impact assessment Method based on Endpoint modeling 2) methodology.

# RESULTS & DISCUSSION

## Kinetic simulation of the formose reaction

The kinetic simulation of the formose reaction were

performed using the mathematical model proposed by Socha et al. (1981) [5], which consists of a system of differential equations describing the concentration changes of formaldehyde and carbohydrates (C2-C7) over time. The model incorporates five key reactions: (1) aldol condensation of formaldehyde with sugars, (2) aldol condensation between sugars, (3) retro-aldol reaction of sugars, (4) Cannizzaro reaction, and (5) saccharinic acid formation.

The simulation was performed using MATLAB to solve the coupled differential equations numerically. The results demonstrated that the total yield of sugars (C2-C7) reached 65.2% under the given reaction conditions (40°C, 200 minutes, initial formaldehyde concentration of 4.5% (w/w)) (Figure 2). This value represents the combined yields of various carbohydrates formed through the complex reaction network. The obtained sugar yield was subsequently used as a basis for mass balance calculations in the sugar synthesis process design.

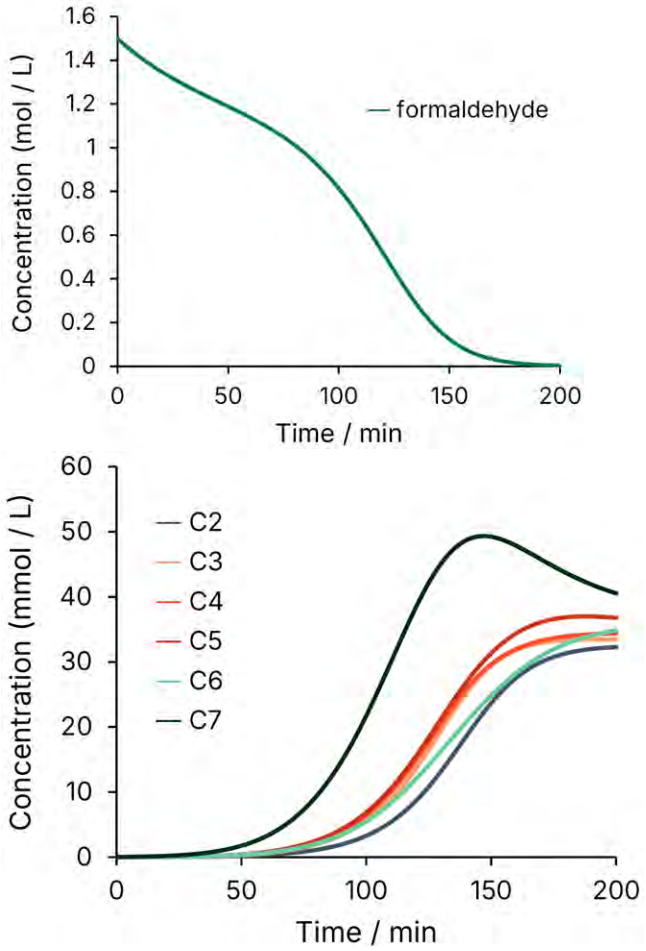

**Figure 2.** Simulation results showing the concentration changes of formaldehyde and each sugar species (C2-C7) during the formose reaction.

## Environmental impact assessment of sugar synthesis

Mass and energy balances were calculated for each process step in the chemical synthesis of sugars, including the thermal reaction, catalyst removal, and the evaporative heating for removal of residual substrate and water solvent. The theoretical energy requirements for heating and evaporation processes were determined using thermodynamic properties. To account for real process conditions, an energy efficiency factor of 70% was applied to calculate the actual energy requirements for each unit operation.

Figure 3 shows the environmental impacts of the sugar synthesis process when using a batch reactor for the formose reaction. The results were categorized into five impact categories: climate change, eutrophication, land use (transformation), resource consumption, and water resources consumption. The impacts were presented as relative contributions (%) of each input: formaldehyde (37% aqueous solution), water, calcium hydroxide, sulfuric acid, and heat energy. As shown in Figure 3, the impact of heat energy was significant in the categories of climate change, land use (transformation), and water resources consumption. The contribution of heat energy was particularly large in these categories, accounting for more than 50% of each impact. In the category of eutrophication, the impact of formaldehyde was dominant, accounting for more than 50% of the total impact. For resource consumption, both formaldehyde and heat energy showed significant contributions.

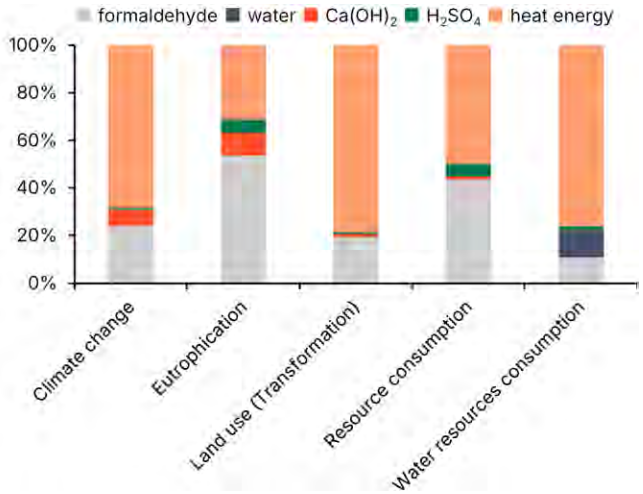

**Figure 3.** Contribution of each input to the environmental impacts (climate change, eutrophication, land use (transformation), resource consumption, and water resources consumption) in the sugar synthesis process using a batch reactor.

Importantly, the formose reaction possesses an autocatalytic reaction cycle [8], allowing for continuous

sugar synthesis by continuously adding formaldehyde during the reaction, that is, by adopting a semi-batch reactor. Therefore, the impact on climate change by adopting a semi-batch reactor was evaluated (Figure 4). The vertical axis shows the GHG emissions per 1 kg sugar produced, and the horizontal axis shows the product concentration. It was revealed that by increasing the product concentration through continuous addition of the substrate, the amount of calcium hydroxide used as a catalyst and the energy required for the concentration process can be significantly reduced. For example, increasing the product concentration to 20% (w/w) can reduce GHG emissions by more than 60% compared to the use of a batch reactor where the product concentration was 4.5%. This reduction is mainly attributed to the decreased energy needed for evaporating water in the concentration process due to the higher sugar concentration, as well as the reduced amount of calcium hydroxide used per unit of sugar produced. These findings demonstrate the effectiveness of the semi-batch reactor in improving energy efficiency and reducing the environmental impact of sugar synthesis.

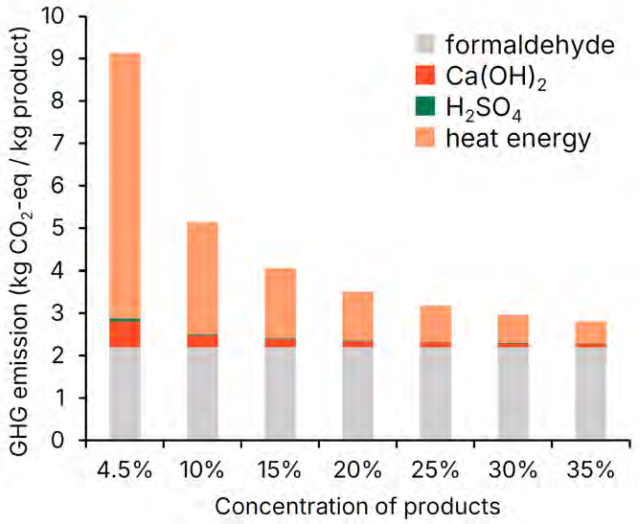

**Figure 4.** Changes in GHG emissions (kg $CO_2$-eq) per input with increasing product concentration when using a semi-batch reactor.

Figure 5 shows the contribution of each impact category when a semi-batch reactor is adopted, and the product concentration is increased to 20% (w/w). As the contribution of heat energy decreased, the contribution of formaldehyde became dominant in each environmental impact. This highlights the significant influence of the formaldehyde production process on the overall environmental performance of sugar synthesis. These findings suggest that improving the manufacturing process of the substrate, formaldehyde, is a crucial factor in reducing the environmental impact of chemical sugar synthesis.

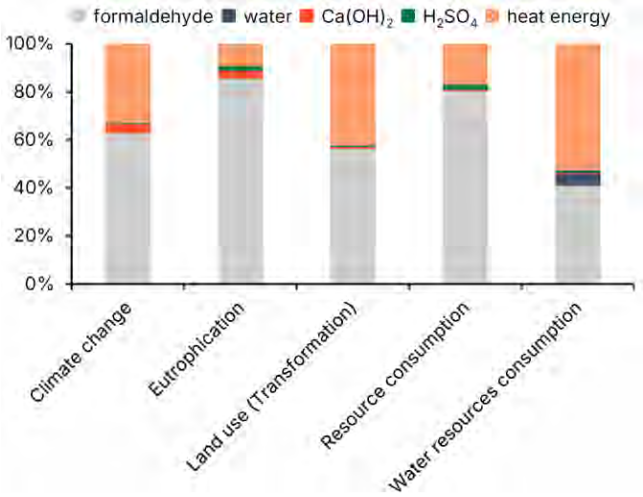

**Figure 5.** Contribution of each input to the environmental impacts (climate change, eutrophication, land use (transformation), resource consumption, and water resources consumption) in the sugar synthesis process using a semi-batch reactor with a product concentration of 20%.

## Changes in environmental impact due to the adoption of $CO_2$ conversion technology

Building upon the previous findings highlighting the significant contribution of formaldehyde to the environmental impact, the environmental impact of formaldehyde production using $CO_2$ as a raw material was evaluated. The assessment employed inventory data from existing literature for the CAMERE process to model $CO_2$ utilization [6]. Figure 6 illustrates a comparison of GHG emissions across different cases. Cases A and B represent conventional formaldehyde production methods. Case A utilized the IDEA database's local heat supply (global) as the emission factor for heat energy, while Case B assumed that heat energy was supplied by renewable energy (geothermal energy). In contrast, Cases C and D represent formaldehyde production via CCU technologies. Case C assumed that the required hydrogen is derived from natural gas, with the heat energy source being the same as in Case A. Case D assumed that the required hydrogen was obtained from water electrolysis powered by geothermal power generation, and also the heat energy was supplied by geothermal. Furthermore, since the carbon source for the sugar produced in Cases C and D was $CO_2$, the calculated emissions took into account the amount of $CO_2$ absorbed.

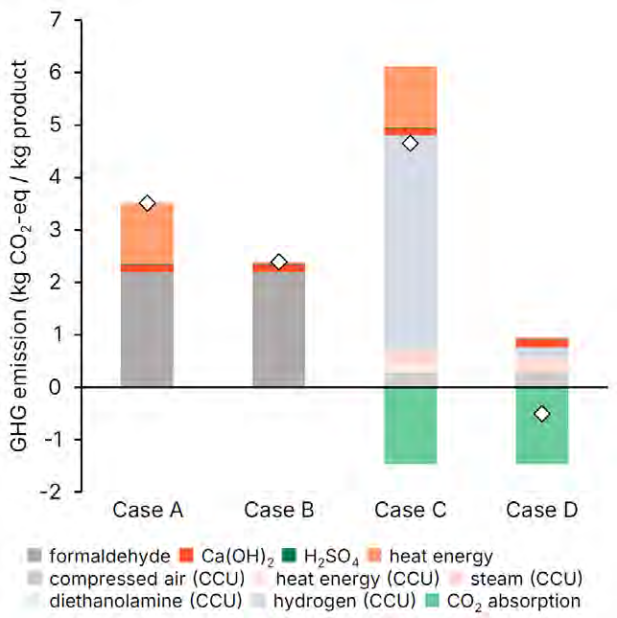

**Figure 6.** Comparison of GHG emissions (kg $CO_2$-eq) per kg of sugar produced under four different cases (Cases A-D). Cases A and B represent conventional formaldehyde production methods, while Cases C and D represent formaldehyde production methods utilizing $CO_2$. Cases A and C assume heat supply mainly from fossil fuels, and Cases B and D assume heat supply from geothermal power generation.

Figure 6 compares the GHG emissions for the four different cases, highlighting the significant impact of the formaldehyde production method. In Case A, which used the current energy supply as energy resources, the GHG emissions were estimated to be approximately 3.5 kg $CO_2$ per 1 kg of sugar. Using renewable geothermal energy for the heat energy in Case B reduced the emissions to around 2.4 kg $CO_2$. However, when $CO_2$ was used as the raw material in Case C, the emissions increased to approximately 4.6 kg $CO_2$, primarily due to the natural gas-derived hydrogen. Despite $CO_2$ uptake, the overall emissions remained high. In stark contrast, Case D, which utilizes hydrogen produced from water electrolysis powered by geothermal energy and uses geothermal energy for heat, achieved a remarkable reduction in emissions, resulting in approximately -0.6 kg $CO_2$. This negative value signifies that the process absorbs more $CO_2$ than it emits (although it is important to note that the synthesized sugar will eventually be emitted as $CO_2$ during its use and disposal, so this does not mean that the emissions are negative over the entire life-cycle). These results clearly demonstrate that while adopting CCU technologies is a promising approach, the introduction of renewable energy is indispensable for maximizing its environmental benefits. Without the integration of renewable energy, the benefits of CCU technologies may be significantly diminished, and could even lead to a higher GHG footprint than conventional methods, as observed in Case C.

## Comparison with agriculture-based sugar

Figure 7 compares the environmental impacts of the four cases (A-D) described in the previous section with those of agriculture-based sugar production across five environmental impact categories. The values are normalized, setting the largest environmental impact among the compared cases to 1 for each impact category. It should be noted that their functional unit differs from that of agriculture-based sugars (glucose in this case) while chemically synthesized sugars are reported to be metabolizable by microorganisms [9] and usable as a raw material for biomanufacturing [7]. The results showed that regardless of the case, the adoption of chemical sugar synthesis technology could significantly reduce environmental impacts in terms of eutrophication, land use (transformation), and water resources consumption. For instance, the impact on eutrophication from chemical synthesis was, at most, approximately 1/10,000th (Case A), and could be as low as approximately 1/24,000th (Case D) of agriculture-based sugar. Similarly, the impact on land use was between approximately 1/70th (Case C) and 1/140th (Case D), and the impact on water resources consumption was between approximately 1/9th (Case A) and 1/30th (Case D) that of agriculture-based sugar. On the other hand, in terms of climate change and resource consumption, the introduction of CCU technologies, premised on the implementation of renewable energy, was essential for reducing environmental impact.

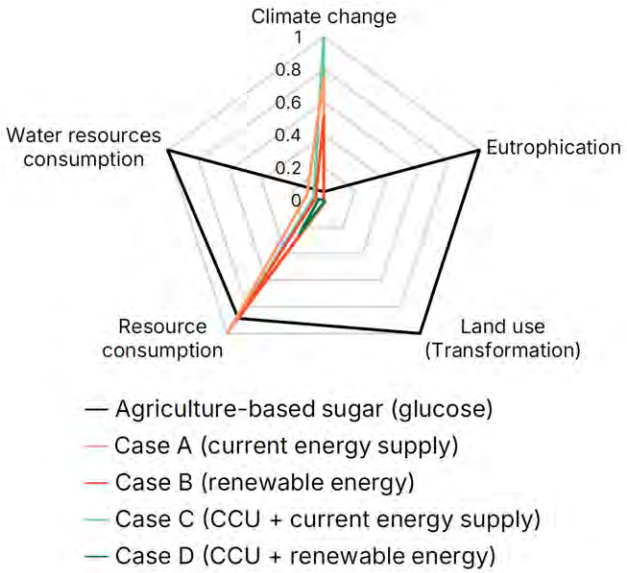

**Figure 7.** A radar chart of indices for all cases of sugar synthesis and agriculture-based sugar, the values of which are normalized as the maximum one in an indicator is set to 1.

## CONCLUSION

This study assessed the environmental impact of chemical sugar synthesis as an alternative to agriculture-based sugar production. The results demonstrated that the chemical synthesis of sugar, particularly when adopting a semi-batch reactor, can significantly reduce environmental impacts in terms of eutrophication, land use, and water resources consumption compared to conventional agriculture-based sugar production. However, the study also highlighted the crucial role of formaldehyde production in the overall environmental footprint. The introduction of CCU technologies for formaldehyde production, premised on the implementation of renewable energy, proved essential for reducing the environmental impact, particularly regarding climate change and resource consumption. Case D, utilizing both CCU and geothermal energy, showed the most promising results among the cases. The findings provide valuable insights for process optimization and future research directions, particularly in the development of more efficient and sustainable formaldehyde production technologies. Further studies should investigate the economic feasibility and scalability of the proposed process, and also focus on a more detailed analysis considering other potential environmental impacts.

The environmental impact of the excessive expansion of agriculture-based sugar utilization has been pointed out in the past. However, as of yet, no replacement methods have been established. In contrast, chemical sugar synthesis is much faster than the agricultural process, and it consumes far fewer resources, such as land and water. This study quantitatively demonstrates the social significance of supplementing sugar production with chemical synthesis processes. Consequently, it is expected to provide new methodologies and perspectives for the field of biomanufacturing, which has been based on the use of agriculture-based sugars, and ultimately for the entire carbon resource recycling system, including food production.

## ABSTRACT

This study presents a simple tool to provide decision-makers data that will facilitate informed decisions in selecting utilization for small- to medium-scale utilization of stranded natural gas resources that would otherwise be flared. The methodology involves the simulation of different natural gas utilization technologies on Aspen Plus simulation software and utilizing the results to develop a tool on python that enables the user to assess recoverable valuable products from different natural gas profiles. Ten utilization technologies were implemented and six different natural gas profiles (rich and lean) were used as case studies to ascertain the capabilities of the tool. The results provide the user with the Net Present Values (NPV) of different technologies and the most profitable or infeasible utilization technology. The results also show the potentials of utilizing the gas over flaring. For very small volumes of gas the results favored the compressed natural gas (CNG) with positive NPV, and next electricity production. Small to medium volumes of lean gas favoured the turquoise methanol. Mini- Liquefied Natural Gas (LNG) were the least profitable especially for small volumes. This tool can facilitate the evaluation of several gas profiles to assess the impact of utilizing natural gas over flaring in the sustainable future paradigm.

**Keywords**: Aspen Plus, Methanol, Energy Storage, Carbon Dioxide Capture, Alternative Fuels.

## INTRODUCTION

The global efforts aimed at mitigating carbon emissions include curbing gas flaring. Several initiatives have been introduced by stakeholders, including the World Bank's zero routine gas flaring by 2030, launched in 2015, to achieve this goal of reducing $CO_2$ emissions due to gas flaring. The initiatives led to the development of a gas flaring tracking tool, the Global Gas Flaring Reduction (GGFR) initiatives that foster the development of technologies for the valorization of small natural gas volumes that are routinely flared for safety, logistical, and economic constraints [1]. However, flaring continues to contribute significantly to global emissions, and the last World Bank report observes a reversal of the significant progress made by the GGFR initiatives with an increase in gas flaring volume by 7% [2]. Therefore, innovative solutions are required to facilitate the efficient and sustainable valorization of these otherwise stranded gas volumes to reduce resource waste and curb emissions [3-4].

### Literature review

Numerous studies from oil- and gas-producing countries have evaluated different routes to valorize stranded natural gas resources and avoid flaring. A study that reviewed the different natural gas utilization technologies that can be applied to mitigate flaring showed that gas-to-liquids producing Syncrude, methanol (MeOH) or dimethyl ether (DME), gas-to-wire, which generates electricity and heat in some cases, and natural gas liquid extraction or dry gas liquefaction are economically favorable for small- to medium-scale gas volumes [3]. A detailed World Bank report demonstrates the different technological innovations in the market with the potential to handle small gas volumes that would widely be flared [4]. In the same way, [5] did an environmental and economic analysis of various types of gas feed to group the utilization technologies. This study proposes the integration of data from existing research with new technologies to develop a tool that quickly checks if a gas profile is available for other uses besides flaring.

# METHODOLOGY

## Tool overview

The decision-making tool proposed in this study consists of two parts, described below: the first one, that calculates technology-specific prices, costs and yields, is implemented a priori in ASPEN Plus. The second one, that calculates Net Present Values and obtains the environmental analyses with user-supplied data, is an application programmed in Python. An overview of the tool is exhibited in Fig 1.

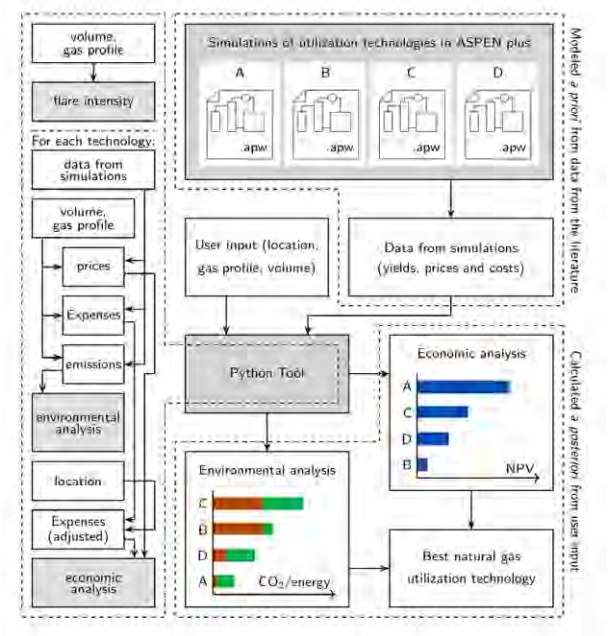

Figure 1. The decision-making tool methodology.

Initially, data from the literature was used to implement simulations of all utilization technologies and pretreatments. These simulations returned capital and operational expenses for a plant with fixed size and yields that could be attainable by each process (and, therefore, the prices of their output streams).

The data obtained through the simulations was then incorporated into the Python tool. This tool reads data supplied by the user (such as gas profile and volume, gas field location, and carbon tax) and calculates, firstly, the emissions if the gas is flared, then, it yields, net present values (NPV) for each utilization technology, considering scale, shipping and installation multipliers (for CAPEX adjustment) and the local discount rate. Besides the NPV, the $CO_2$-equivalent emissions and energy usage are also obtained. For each utilization technology, the cheapest feasible pretreatment was selected, and the economic (NPV) and environmental ($CO_2$ emissions and energy usage) analyses are sorted and presented to the user, who should select the best technology.

## Assumptions

The following assumptions were made in the collection of data and the tool design: Onshore application of technologies, small to medium scale from 0.1 – 20 MMSCFD, Steady state process simulations, HHV values at 15°C and 1 atm, modular units, project implementation of 6-12 months, average gas profile for 10 years, all products are utilized within the vicinity hence transportation costs are not included.

## Data collection

The natural gas field selection was based on the world bank platform for gas flaring monitoring [1]. Gas fields from 5 continents with gas flaring records were selected based on available field data representation as presented in Table 1.

Table 1: Utilization technologies simulation data.

| Process | Conditions | Ref |
|---|---|---|
| Full Fractionation | Dry gas (%):C1-98.9, C2-35, C3-5 | [4,7] |
| NGLs removal | Dry gas (%):C1-98.9, C2-65, C3-5 | [4] |
| Dehydration | Dry gas C3+<5% | [7] |
| LNG | -154°C | [7] |
| CNG | 250bar | [4] |
| G MeOH | S:C=4, 20bar, 850-900°C | [8] |
| T MeOH | 1 bar, 1200°C | [8,9] |
| NGCCT | 7bar, GT: 950°C, ST:480°C, 42 barg | |
| NGCCT+CCS | $CCS_{in}$: 42 bar, $CO2_{in}$ - 0,093, $CO2_{Out}$: 150 bar,98.5% | [10] |
| NGT(CHP)+CCS | 7bar, GT: 950°C, Steam:184°C, 10 barg | [11] |
| NGT(CHP) | Steam:184°C, 10 barg | [12] |
| NGT | 7bar, GT: 950°C | [12,13] |
| NGE | | [4] |

Several reviews on the different valuable products from small scale gas utilization technologies to prevent gas flaring were analysed. This study classified the most common profitable valorization technologies into dry gas liquefaction and compression (mini-LNG, CNG) for storage and transport, gas to liquid/chemicals (methanol was selected) and gas to wire (electricity production) technologies. Ten (10) prospective utilization technologies to obtain valuable products were considered based on available data [2]. These technologies were simulated in Aspen Plus to obtain thermodynamics, mass and energy balance data used for technology assessment. The references used for the different technologies are presented in Table 1.

## Process Simulation

The processes considered were simulated in Aspen plus on a basis of an initial feed gas flowrate of 1 MMSCFD for simplicity. The super structure in Fig 2 represents the different scenarios for simulations carried out using data from the literature as in Table 1.

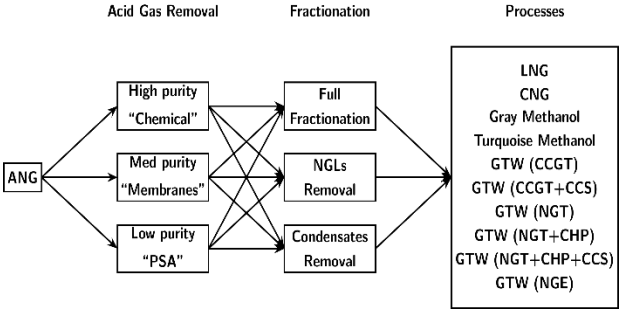

Figure 2. Process case study superstructure.

The Aspen simulation includes the cleaning requirements for different technologies. The acid gas removal and NGLs removal were represented with the SEP component model and the separation parameters obtained from the detailed reporting in the literature [2]. Three acid gas removal purity levels were considered, based on the different purity levels required for different technologies. Similarly, depending on the gas quality, the removal of NGLs may be required for some utilization processes. Thus, different scenarios are simulated for full fractionation into individual products, de-methanization to remove NGLs or basic dehydration (for a clean lean gas) is required for each utilization technology or different valuable products produced.

## Dry gas Storage (Mini-LNG and CNG)

Traditionally, large scale volumes of natural gas are cooled to liquid state at very low temperatures (-145°C to -165°C) for ease and safe transport over long distances where it would be too expensive or infeasible to install. The introduction of the mini-LNG plants facilitates the processing of gas into LNG, the simulation of the LNG plant was carried out based on [2], [3]. CNG can serve as a virtual pipeline, it involves natural gas compression by 250 times (250bar) at ambient temperature. It is used to transport or store gas over short distances for a short period.

## Gas to Wire (Microturbines, Small-scale Engines)

The production of electricity is the most common utilization of natural gas as it accommodates a variety of gas profiles. The use of micro turbines and small gas engines for the combined heat and power process is commonplace in oil and gas production sites. However, this process involves the combustion of the fuel gas which produces $CO_2$. In this study, the application of carbon capture and storage (CCS) was explored. The $CO_2$ mole fraction in the exhaust stream is very low. Hence, for the application of CCS the exhaust gas is recycled to improve the $CO_2$ mole content and less air is required for the combustion as implemented in this work for the NGCCGT with CCS case [4]. Whereas without the application of $CO_2$, the excess gas required is more to maintain the turbine inlet temperature as applied here [5], [6].

## Gas to Liquid/Chemicals (Methanol Synthesis)

The gas to liquid or chemical where natural gas is converted to syngas through steam reforming and subsequently higher hydrocarbons like diesel or the syngas converted to MeOH (Grey methanol), DME or anhydrous ammonia. For small volumes, methanol is usually more profitable and avoids the production of $CO_2$. Equations 2-4 shows the chemical reactions for steam reforming methanol synthesis.

Currently, small-scale $CO_2$ hydrogenation to produces methanol emerges to facilitate renewable (green) methanol. However, green methanol is not cost competitive with conventional methanol. Turquoise methanol (T MeOH) shows the potential to be more competitive. The process involves $CO_2$ hydrogenation using pure hydrogen from methane pyrolysis. Based on Equation 1 methane is split into $H_2$ and solid C. This study applied the technology using a regenerative heat exchanger reactor (RHER) to facilitate heat exchange between reactant, bed and products in a counter-current flow, reducing energy consumption and heat waste as shown in Figure 2.

$$CH_4 \rightarrow 2H_2 + C \quad (1)$$

$$CO + 2H_2 \leftrightarrow CH_3OH \quad (2)$$

$$CO + H_2O \leftrightarrow H_2 + CO_2 \quad (3)$$

$$CO_2 + 3H_2 \leftrightarrow CH_3OH + H_2O \quad (4)$$

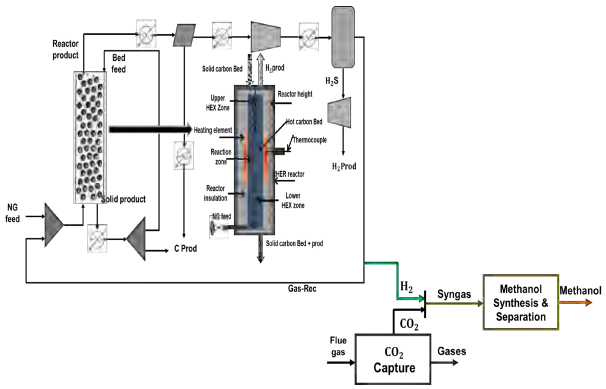

Figure 3. Turquoise Methanol Synthesis.

The RHER uses electricity through ohmic heating. Therefore, when renewable electricity is used the technology does produce $CO_2$ but valuable carbon as a by-product adding to the economic competitiveness of the product. Thus, it is included as an emerging technology in this study based on [7].

## Performance Indices

To evaluate the different technologies, some sustainability (material, energy, economic and environmental) metrics were calculated.

The emission of gas if flared or recoverable products and byproducts if gas is used are calculated based on emission intensity or product yield:

$$CO_{2_{prod}} = \frac{(\%VW_{CO_2})_t}{100\%} + \sum_{y=1}^{Y}\left\{\varepsilon * \frac{(\%C_y)_t}{100\%} * CNM_y\right\} \quad (5)$$

$$E_{CO_2} = \left[(V_{flare})_t * \frac{MW_{CO_2}}{MVC} * K * CO_{2_{prod}}\right] \quad (6)$$

where $CO_{2_{prod}}$ accounts for the $CO_2$ produced from combustion of hydrocarbons in the feed gas and the $CO_2$ components before combustion, $\varepsilon$ is the flare efficiency, y is the index for carbon containing components other than $CO_2$, %VW is the mole concentration of $CO_2$ in the gas stream, t is the time period under consideration CNM is the precursor mole number of carbon. $E_{CO_2}$ is the $CO_2$ emission intensity, $V_{flare}$ is the volume of gas to be flared, MW is the molecular weight, MVC is the molar volume conversion factor and K is the unit conversion factor.

Alternatively, all emissions can be calculated using the heating value and emission factor for each pollutant. This is given by

$$E_i = K * \varepsilon * \sum_{t=1}^{T}\left((V_{flare})_t * HHV * EF_i\right) \quad (7)$$

where $E_i$ is the emission intensity of pollutant, HHV is the higher heating value, $EF_i$ is the emission factor for each pollutant.

The product yield is calculated based on the type of product such as gas, chemical or electricity as follows:

$$Product\ yield(\alpha) = \frac{F_{output}}{F_{input}} = \frac{F_{output} * HHV}{F_{input} * HHV} \quad (8)$$

$$Q_{Prod,mat}(kg/h) = Q_{gas} * \alpha(j) \quad (9)$$

$$Q_{Prod,elect}(kW) = Q_{gas} * \alpha(j) * HHV \quad (10)$$

where $Q$ is the flowrate, $\alpha(j)$ is the product yield for process $j$. The HHV of all NG components was obtained from Aspen Plus and for each gas composition, the summation of the product of each component fraction and its HHV was used.

For this study, the rate of energy consumption, the efficiency, the $CO_2$ equivalent emission or avoided by each technology was also computed:

$$E_{rate} = \frac{E_{input}}{Q_{product}} \quad (11)$$

$$\varepsilon_j = \frac{E_{output}}{E_{input}} * 100\% \quad (12)$$

$$CO_{2_{rate}} = \frac{FCO_{2,product} + FCO_{2,utilities}}{Q_{product}} \quad (13)$$

Likewise, the economics metrics including the capital cost (CAPEX), operating cost (OPEX), rate of returns on investment (ROI), payback period and the production cost were computed:

$$ATCI = CAPEX * \frac{i(1+i)^t}{(1+i)^t - 1} \quad (14)$$

where ATCI is the annualized total capital investment (CAPEX), the annuity factor using the interest $i$ and the time period $t$. The fixed operating cost FOC including the labor cost, general maintenance etc., VOC is the variable operating cost consisting of the energy cost, feed cost, catalyst cost etc. Although in this case, the feed cost is zero being a waste gas.

$$OPEX = FOC + VOC \quad (14)$$

$$Product\ cost = \frac{CAPEX * OPEX}{Q_{product}} = \frac{TAC}{Q_{product}} \quad (15)$$

The total annual cost (TAC) is used to calculate the production cost and the profit, and the profit is used to compute the rate of returns (ROR), and the payback period.

$$Profit = Q_{product} * P_{price} - TAC \quad (16)$$

## Case Studies

To evaluate the capabilities of the model for quick decisions, a few case studies were analyzed, encompassing different sizes (from 0.5 MMSCFD to 20 MMSCFD), geographical locations and gas profiles. The data were selected from the world bank gas flaring tracker [1], six fields were selected. Three of them with a rich gas profile, from Saudi Arabia (SAU), the United States (USA) and the United Kingdom (UK), shown in Table 2, and three of them with a lean gas profile, from Brazil, Australia and Nigeria, shown in Table 3

Besides this analysis, another case study was performed, introducing an increasingly large carbon tax and checking its impact over the models' choices.

# RESULTS

Inline with the user interface presented in Fig S2, the first tab enables the decision maker to initiate the evaluation by providing the profile of the natural gas, the alternatives are provided in the second tab and the user is able to select the preferred result.

The results are presented in the third tab, these results from the evaluation of the model assessing different gas profiles from different locations considered are discussed:

## Rich Gases

Three of the case studies concerned rich gases, that is, gases with a higher concentration of heavier hydrocarbons as shown in Table S1 of the supplementary material.

Despite the physical feasibility of all utilization

technologies with the Saudi gas field, the production of LNG and the usage of Natural Gas Engines are not profitable, with a negative Net Present Value (NPV) of 7.028 million dollars for the former and 4.862 million dollars for the latter. All other utilization technologies can be made profitable through an optimal choice of pretreatment and cleaning processes. The best performing utilization technology was the production of CNG, after chemical Acid Gas removal and simple Natural Gas Liquids removal. This technology yields a positive NPV of 10.377 million dollars.

On the other hand, the gas from the American field can always be profitably explored, regardless of choice of utilization technology, with even the least lucrative choice, LNG production, yielding a modest, but positive, NPV of 7.65 million dollars, after a membrane-based acid gas removal step and after separation of natural gas liquids. Meanwhile, the best choice, turquoise methanol production, exhibits a positive NPV of 72.636 million dollars, using the cheapest acid gas removal technology (PSA) followed by NGL separation.

Finally, the British field shows results very similar to the American ones, when the proportions are taken into account: the least profitable utilization technology is the same (LNG with membrane cleaning and NGL separation), and the most profitable is very similar (also Turquoise Methanol production after NGL separation, but the higher acid gas fraction must be removed through a chemical process, more efficient but also more expensive). The NPVs range from 56.477 million dollars (LNG) to 325.49 million dollars (for the Turquoise Methanol).

## Lean Gases

The other three gas fields analyzed in this work are lean gas fields, that is, with a higher methane content. as shown in Table S1 of the supplementary material.

The Brazilian field can profitably deploy all utilization technologies, with the exception of LNG production. In this situation its NPV is negative and has a value of 2.759 million dollars. On the other hand, the production of CNG is the most profitable choice, with a Net Present Value of 8.292 million dollars. This difference originates from the impurity tolerances of LNG and CNG: while the first must be of higher purity, demanding expensive and complex treatment systems, the second is laxer. Hence, cheaper and simpler technologies can be applied to its purification before usage. Indeed, while the best case for LNG demanded full fractionation and chemical acid gas removal, the most profitable cleaning process for the CNG needed no acid gas removal.

The Australian field also shows the trend of Methanol synthesis being the most profitable choice above a certain gas volume. Despite all choices yielding positive NPVs, the list was headed by Turquoise and Gray Methanol synthesis, with a simple acid gas removal and natural gas liquids separation.

These utilization technologies achieved an NPV of 59.903 million dollars and 57.903 million dollars, respectively. The bottom of the list, as before, is still occupied by the LNG production, with an NPV of 6.584 million dollars.

Lastly, the gas from the Nigerian field is best explored through the synthesis of Methanol: Turquoise and Gray Methanol once again headed the list, with NPVs of 417.56 million dollars and 347.71 million dollars, respectively. The worst, but still profitable, utilization technology for this field is not, however, LNG production as previous examples show, but electricity generation using Natural gas Engines (NGEs).

## Carbon Tax Impact

To assess the economical impacts of a Carbon Capture & Storage technology, 500 new simulations of the United Kingdom gas field described in the previous section were analyzed. Unlike the previous simulations, a Carbon Tax is introduced, spanning from zero to 20 USD/$tCO_2$ emitted. The Net Present Values for different technologies in these circumstances are shown in Figure 3.

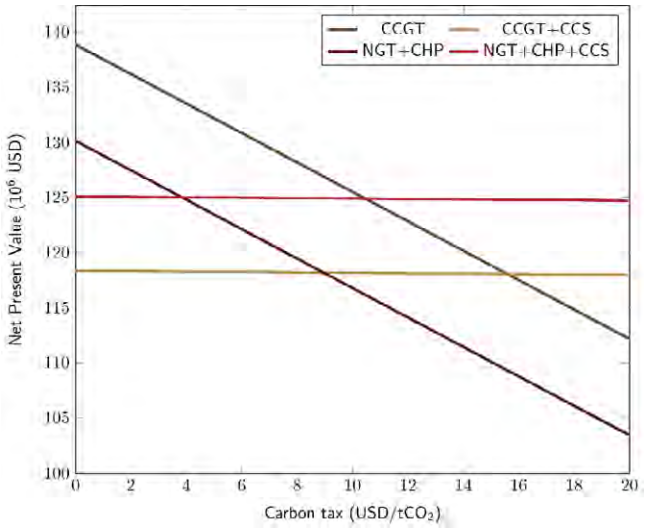

Figure 4. Net Present Values of Gas-To-Wire utilization technologies, with a growing Carbon Tax

It can be observed that, for these Gas-To-Wire technologies, a Carbon Capture system becomes economically superior for a Carbon Tax greater than 10 USD/$tCO_2$.

## CONCLUSION AND FURTHER WORKS

This work presents a tool to provide decision-makers data that will facilitate informed decisions in selecting utilization for small- to medium-scale utilization of stranded natural gas resources that would otherwise be

flared. This would mitigate flaring and reduce waste of valuable resources. The tool also provides data for achieving improved economical performance and sustainability by selecting profitable technology for each gas profile and volume, accounting for the requirements of each one. The application of this tool to a collection of case studies enables quick assessments that impact sustainable future policies, since several scenarios can be assessed before detailed project development. Case study results favored CNG followed by electricity as expected given that they have the least cost. However, CNG can only be applied to short distances within the locality of production. The study also showed the potential for producing clean chemicals, such as emission-free turquoise methanol.

Despite considering location for installation and shipping costs, the uncertain and varying factors (such as product prices and transportation costs) were assumed constant, hence limiting the study. Further works will include the implementation of a stochastic model and the possibility to account for future market movements to greatly improve the tool.

## ABSTRACT

Batch chemical processes face significant challenges due to frequent operational shifts and varying conditions, requiring models to be retrained for each new scenario. This high retraining demand limits the scalability of traditional process monitoring systems, making them unsuitable for dynamic batch operations. To address this, we propose a transfer learning-based framework that enhances adaptability by reusing learned features across different batch conditions, reducing the need for extensive retraining. Proposed method integrates Temporal Convolutional Networks (TCNs) for capturing temporal dependencies in batch data and predicting Quality-Indicative Variables (QIVs) to identify deviations. The core innovation lies in transfer learning, enabling the model to adapt to new process variations with minimal updates. This approach ensures robust, accurate monitoring even under evolving conditions. This framework is validated using the IndPenSim penicillin fermentation dataset, which simulates real-world batch process variability. Results show that the transfer learning-enhanced model effectively predicts QIVs and detects deviations across varying control strategies, demonstrating improved adaptability and reduced retraining requirements. This study highlights the potential of transfer learning to revolutionize batch process monitoring by addressing core challenges in dynamic chemical operations.

**Keywords**: Batch Process, Fermentation, Artificial Intelligence, Machine Learning, Process Monitoring, Fault Detection

## 1 INTRODUCTION

The production of high-value-added products like pharmaceuticals, biochemicals, and specialty chemicals heavily relies on batch processes due to their operational flexibility, enabling seamless transitions between various formulations and operating modes within a single facility. However, this flexibility introduces complexities such as intricate process phases and frequent mode switching, which complicate real-time monitoring and control, particularly for quality indicator variables (QIVs) [1]. Since QIVs are often challenging to measure continuously, soft sensors have become a widely adopted solution in industrial settings.

While first-principles models theoretically offer detailed insights into the underlying physicochemical mechanisms, they frequently encounter challenges in modeling the complex nonlinearities and dynamics typical of industrial processes [2]. As an alternative, data-driven methods leverage extensive historical datasets to extract latent features for QIV estimation [3]. Traditional feature extraction approaches include linear methods (e.g., PCA, PLS, ICA) [4,5] and kernel-based variants (e.g., kernel PCA, kernel PLS, SVR) [6], which have shown some efficacy in handling nonlinearity. However, these conventional techniques are often constrained by moderate computational overhead and reduced generalizability when faced with large-scale data and constantly changing operational conditions [7]. This issue becomes especially critical in batch processes, where multi-stage operations, a three-dimensional data structure (time, variables, batches), and multiple operating modes necessitate frequent model reconfiguration, thus restricting their real-time applicability.

Recent advances in deep learning offer promising

avenues for addressing these challenges. Feedforward neural networks and recurrent neural networks (RNNs) exhibit relative strengths in modeling nonlinear and time-varying processes [8], while LSTM networks excel in capturing long-term dependencies [9]. Despite these advantages, LSTM-based methods may still struggle to capture short-term dynamic features between different batch phases and are susceptible to performance degradation under frequent mode transitions and significant batch-to-batch variability [10]. Consequently, transfer learning has gained traction for batch applications, as it facilitates the adaptation of previously acquired knowledge to new modes or new batches, substantially reducing the need for repeated training .

In this context, the present study proposes a soft sensing framework that integrates transfer learning with Temporal Convolutional Networks (TCNs) to achieve both feature extraction and QIV prediction. By introducing a transfer learning mechanism, the model effectively adapts to diverse operating conditions while minimizing retraining efforts. In addition, a variable selection strategy is employed to discard features with limited relevance to QIVs, thereby enhancing predictive accuracy and computational efficiency. The proposed framework addresses the following key challenges:

1. Multi-mode switching: The model can adapt to different operating modes without extensive retraining, addressing batch-to-batch variability.
2. Complex temporal dynamics: TCNs are employed to capture both short-term and long-term dependencies within batch processes.
3. Variable relevance: A variable selection method is introduced to enhance the model's accuracy by focusing on variables that have a strong influence on QIV prediction.

The proposed framework is validated using the IndPenSim penicillin fermentation dataset, which encompasses a variety of control strategies and considerable batch-to-batch variability, thus closely reflecting industrial batch production scenarios. Experimental results indicate that the proposed approach not only captures both short- and long-term temporal dependencies but also sustains robust prediction performance amid frequent mode switching. Consequently, it presents a scalable and readily adaptable solution for real-time QIV prediction and process monitoring in industrial batch operations.

# 2 PRELMINARIES

## 2.1 Benjamini-Hochborg Test

The Benjamini-Hochberg (BH) test controls the false discovery rate (FDR) in multiple hypothesis testing [11]. For soft sensor variable selection, it identifies variables significantly correlated with Quality Indicator Variables (QIVs) by ranking p-values and comparing them to an FDR-adjusted threshold. Variables below the threshold are retained, reducing dimensionality while preserving key features for accurate QIV prediction. Figure 1 illustrates the flow diagram of BH testing.

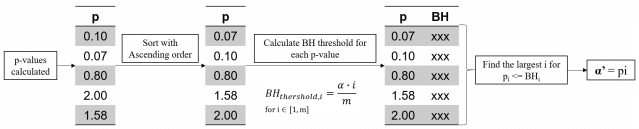

**Figure 1.** Benjamini-Hochberg (BH) program for FDR Control

## 2.2 Temporal Convolutional Network

Temporal Convolutional Networks (TCNs) are deep learning models for sequence modeling that capture both short- and long-term temporal dependencies. Unlike RNNs, which process sequences step by step, TCNs use causal convolutions to ensure predictions depend only on past data. They leverage dilated convolutions to expand their receptive field without requiring deep architectures, and residual connections to stabilize training and mitigate vanishing gradients. TCNs also produce sequence-to-sequence outputs, making them effective for time-series applications in batch processes. Figure 2 shows the TCN framework.

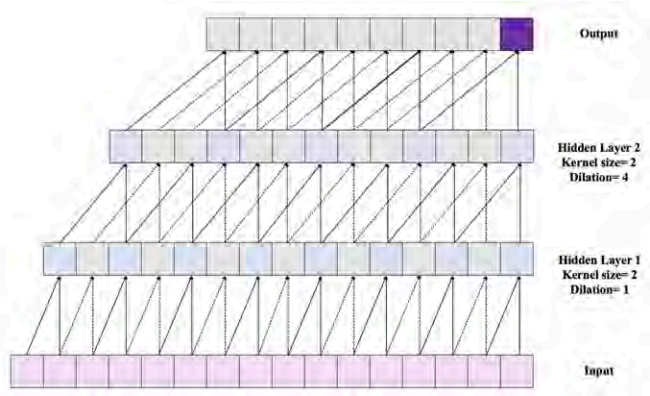

**Figure 2.** Structure of Temporal Convolutional Network

## 2.3 Transfer Learning

Transfer learning reuses knowledge from one task to improve performance on a related but different task [12]. It is particularly useful in batch processes, which often involve variability and multi-mode switching, making it impractical to gather sufficient labeled data for every new condition.

Key components include:

1. Pretrained Feature Extraction: Train a base model on one batch process or condition to capture generalizable patterns.
2. Fine-Tuning: Retrain this model on a smaller dataset from the new condition, reducing data and time

requirements while maintaining accuracy.

Domain Adaptation: Employ methods (e.g., domain-invariant feature extraction) to handle discrepancies between source and target domains. Figure 3 illustrates the transfer learning framework.

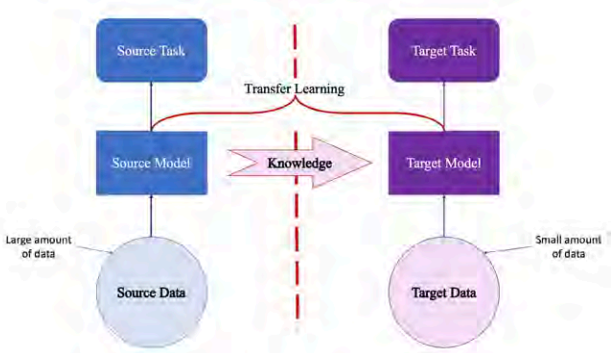

**Figure 3.** Framework of Transfer Learning

# 3 METHODOLOGY

## 3.1 Procedure of Quality Monitoring Framework

The proposed quality monitoring framework follows a two-stage approach, comprising an offline training phase and an online monitoring phase: The proposed quality monitoring framework follows a two-stage approach, comprising an offline training phase and an online monitoring phase:

1. Offline Training Phase

Historical data from past batches under normal conditions are collected, including process variables and Quality Indicator Variables (QIVs). Relevant variables are selected using a mutual information-based method combined with a Benjamini-Hochberg permutation test. A Temporal Convolutional Network (TCN) is trained on the filtered data to capture temporal dynamics, and transfer learning is incorporated for adaptability across different operating modes. Statistical thresholds for fault detection are set using the 3-sigma rule based on model prediction errors.

2. Online Monitoring Phase

Real-time process data are continuously fed into the trained TCN model, which estimates QIVs for comparison with reference profiles or setpoints. Significant deviations outside the 3-sigma thresholds trigger alarms for potential faults. When major process changes occur, transfer learning updates the model with minimal retraining to maintain monitoring accuracy.

A schematic flow chart illustrated the interplay between the offline and online stages in figure 4.

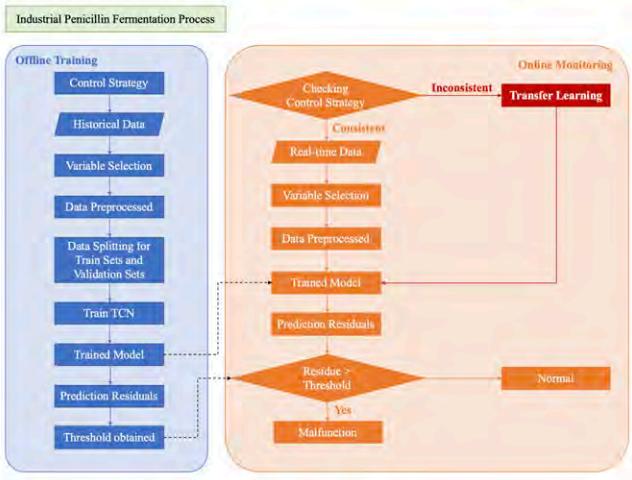

**Figure 4.** The Procedure of Monitoring Framework

## 3.2 Variable Selection by Permutation Test

### 3.2.1 Mutual Information

As an initial step, the mutual information (MI) between each process variable and the QIV is computed. MI measures the shared information between two random variables and captures both linear and nonlinear dependencies. The MI between a candidate variable X and the QIV Y is defined as:

$$I(X;Y) = \iint p(x,y) log \frac{p(x,y)}{p(x)p(y)}\, dx\, dy \quad (1)$$

where $p\,(x, y)$ is the joint probability density of $X$ and $Y$, and $p(x)$, $p(y)$ are their marginal distributions. Variables with high MI values indicate stronger relevance to QIVs, while variables with low MI suggest weaker connections.

### 1.2.2 BH Program-based Permutation Test

Although MI identifies candidate variables, it does not provide a definitive threshold for deciding which variables to keep or discard. To address this, a BH-based permutation test is employed.

The variable selection process begins by removing clearly irrelevant variables (e.g., batch number, condition flag) and computing the mutual information (MI) between each candidate variable $X_k$ and the QIV $Y$. Next, a permutation test is performed by randomly shuffling each $X_k$ multiple times to generate a null distribution of MI values, and a p-value is calculated between $X_k$ and $Y$ based on how often the observed MI exceeds the permuted values. The p-values are then sorted and the Benjamini-Hochberg (BH) procedure is applied to control the false discovery rate (FDR), retaining variables with p-values below the threshold. Finally, the significant variables from the BH test formed the final subset for model development.

Figure 5 illustrates the whole procedure of variable selection proposed by this work.

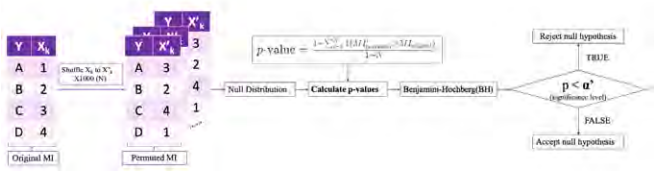

**Figure 5.** Variable Selection through MI Value and BH program -based Permutation Test

## 3.3 Proposed TCN with Transfer Learning Strategy

### 3.3.1 Batch Process Data Preprocessing

Batch processes inherently produce three-dimensional data: batch index, time, and process variables. Traditional data unfolding methods reshape these data into two dimensions, but they may disrupt the inherent structure of batch trajectories, especially when batches vary in length or exhibit phase transitions.

Instead of unfolding all batches onto a single extended axis, this work employed a sliding window approach within each batch. This strategy respects the boundary of each batch by ensuring that a window never overlaps data from different batches. Consequently, it better preserves local temporal correlations and phase-wise characteristics for. Figure 6 shows the strategy of sliding window to cope with the uneven length situation.

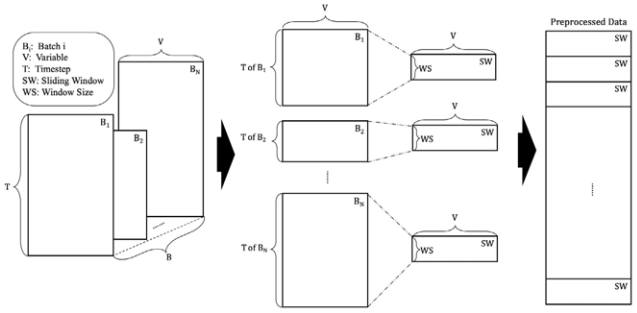

**Figure 6.** Proposed Data Preprocessing Strategy

### 3.3.2 Model Structure and Transfer Learning

The proposed framework involves the following steps after data preprocessing, which ensures synchronization of batch data and standardization of variables. First, a TCN is trained using Normal Operating Condition (NOC) data to capture temporal dependencies and predict Quality Indicator Variables (QIVs).

In this study, Normal Operating Data (NOC data) are used to train the TCN model by minimizing the mean squared error (MSE) between estimated and actual QIV values:

$$min\ MSE = \frac{1}{N}\sum_{i=1}^{N}(\hat{Y}_i - Y_i)^2 \tag{2}$$

where $\hat{Y}_i$ denotes the predicted QIV and $Y_i$ is the true QIV.

To address multi-mode switching and between-batch variability, transfer learning is incorporated into the TCN framework. Once a base TCN model is trained on one operating regime, it can be adapted to new or slightly changed conditions with fewer additional data. The pre-trained TCN is fine-tuned using limited data from a new regime to adapt to changes in operating conditions, such as control strategy variations or raw material differences to validate the transfer learning strategy. Real-time QIV predictions are compared against thresholds derived during training to detect deviations indicative of faults.

### 1.3.4 Process Quality Monitoring

After the TCN model is trained or adapted, it serves as the core of the quality monitoring system:

1. Real-Time QIV Prediction: During operation, the TCN predicts QIV values from incoming sensor data.
2. Threshold Determination: 3-sigma rules (Montgomery, 2012) are applied to the residuals (prediction errors) obtained during the offline training stage. Let the residuals be:

$$e_t = \left|\hat{Y}_t - Y_t\right|^2 \tag{3}$$

Then the control limits can be set as:

$$Threshold = \mu_e \pm 3\sigma_e \tag{4}$$

where $\mu_e$ and $\sigma_e$ are the mean and standard deviation of residuals under normal conditions.

3. Fault Detection: If the residual at time $t$ exceeds these control limits, an alarm is raised to signal a potential fault or deviation from the normal operating condition.
4. Validation with Fault Data: To evaluate fault-detection performance, representative fault scenarios or abnormal batches are introduced, and the detection rate is observed based on the discrepancy of predicted QIVs from normal ranges.

This monitoring approach allows operators to detect process anomalies promptly, maintain product quality, and facilitate proactive adjustments in dynamic batch operations.

# 4 EXPERIMENT

## 4.1 Description of IndPenSim Datasets

The experiments are conducted using the IndPenSim dataset, an industrial-scale penicillin fermentation simulation developed by Goldrick et al. (2019) [13]. Unlike the traditional PenSim benchmark [14], IndPenSim models a 100,000 L bioreactor, bringing it closer to real-world industrial conditions and validated by historical industrial data. Detailed process descriptions and operational specifics can be found at the IndPenSim website and in the original publications [13]. Figure 7 illustrates the summary of IndPenSim.

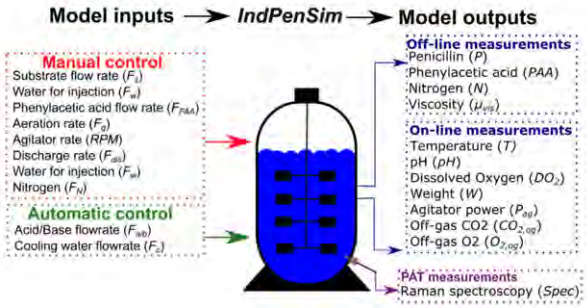

**Figure 7.** Summary of Inputs and Outputs of IndPenSim

This study uses a dataset of 100 simulated batches, with batch lengths ranging from 167 to 290 hours, sampled every 0.2 hours. The first 90 batches represent normal operating conditions and are divided into three groups of 30, each corresponding to a different control strategy. The remaining 10 batches simulate fault conditions to evaluate the fault detection capability. For model training, 20 batches from each control strategy (total of 60 batches) are used, with 30 additional normal batches reserved for evaluation. The 10 fault batches are excluded from training, as the fault conditions and control strategies are unknown. Fault batch data for transfer learning evaluation is generated using a simulator for each control strategy. Detailed batch description and corresponding control strategies are provided in Table 1 and Table 2.

**Table 1:** Batch Description from IndPenSim Datasets.

| Batch No. | Control Strategy | Batch Type |
|---|---|---|
| 1-30 | Recipe Driven Approach | Normal Batch |
| 31-60 | Operators | Normal Batch |
| 61-90 | Advanced Process Control (APC) & Raman Spectroscopy | Normal Batch |
| 91-100 | Unknown | Fault Batch |

**Table 2:** Faulty Batch generated from IndPenSim.

| Fault Batch No. | Control Strategy | Fault Type |
|---|---|---|
| 1 | Recipe Driven Approach | Quality-related |
| 2 | Operators | Quality-related |

## 4.2 Results of Variable Selection

Initially, all 32 process variables are screened based on domain knowledge, removing irrelevant ones not linked to penicillin concentration (QIV) to simplify further analysis. The BH-program-based permutation test is then applied for refined variable selection. Mutual information (MI) values between the retained variables and QIV are computed, and the permutation test evaluates their statistical significance, filtering out weak or insignificant correlations. The final set of highly relevant variables, summarized in Table 3, ensures efficient and effective model development. Figures 8 shows the MI values for the selected variables.

**Table 3:** Screened Variables by Variable Selection.

| Variable No. | Variable description | Unit |
|---|---|---|
| 1 | Aeration rate | L/h |
| 2 | Sugar feed rate | L/h |
| 3 | Acid flow rate | L/h |
| 4 | Base flow rate | L/h |

## 4.3 Results of Process Monitoring with Transfer Learning

The performance of the proposed TCN-based soft sensor model is evaluated through real-time quality prediction and fault detection. By using normal operating data, the TCN model is trained to predict QIV values. The accuracy of these predictions is illustrated in Figure 9,

which compares predicted QIV trajectories against actual values over time. High fidelity between predictions and true values underlines the model's capability in capturing complex process dynamics.

The model's ability to detect deviations is assessed using fault batches. Figure 10 also shows the residual errors (difference between predicted and measured QIV) alongside the statistically determined control limits based on the 3-sigma rule. Instances where residuals exceed these thresholds indicate faults, demonstrating effective anomaly detection in real-time scenarios.

To validate the adaptability of the proposed framework, the model trained under Control Strategy 1 is adapted to Control Strategy 2 using transfer learning techniques. Figure 11 and 12 depicts the monitoring results after applying transfer learning, showing how the model successfully transitions between different operational strategies with minimal additional training. Table 4 illustrates the Fault Detection Rate (FDR) and False Alarm Rate (FAR) of both without transfer learning and with transfer learning strategy.

| Transfer Learning | 97.22 | 2.73 |

## 5 CONCLUSION

This study presents a real-time quality monitoring framework for industrial batch processes, integrating robust variable selection, TCN-based modeling, and transfer learning. It effectively tackles challenges including nonlinear dynamics, multi-phase operations, and batch-to-batch variability. The variable selection method uses mutual information combined with a Benjamini-Hochberg-based permutation test, while TCNs capture complex temporal dependencies and transfer learning enables swift adaptation to different control strategies. A 3-sigma rule–based threshold is employed for real-time fault detection, and experiments on the IndPenSim dataset confirm the framework's enhanced prediction, reliable monitoring, and scalability.

Looking ahead, we plan to incorporate additional sensor types such as images and vibration signals to improve adaptability in complex conditions, explore more sophisticated domain adaptation methods to handle broader operational scenarios, and apply the framework to diverse industrial data to validate its robustness and generality.

## ABSTRACT

Prospective life-cycle design of emerging technologies is important in discussions of decarbonization and resource circulation strategies. This study demonstrates the role of computer-aided process engineering in reflecting technology information with appropriate granularity and accuracy using air conditioning as a case study. Process simulations involving heat exchangers (indoor/outdoor units), compressors, and expansion valves were developed to model air conditioners to quantify changes in performance and heat exchanger size as existing and alternative refrigerants are introduced. The process simulation results were incorporated into a material flow analysis and life cycle assessment to quantify the change in life cycle greenhouse gas (GHG) emissions through 2050 for each refrigerant installed. The results show that operational emissions dominate the life cycle GHG emissions of air conditioners, that decarbonization of electricity can significantly reduce life cycle GHG emissions, with similar results regardless of which refrigerant is used, and that differences in design policies when alternative refrigerants are introduced strongly affect the breakdown of emissions in 2050.

**Keywords**: Life Cycle Analysis, Interdisciplinary, Modelling and Simulations, Process Design.

## INTRODUCTION

The prospective life cycle design of emerging technologies, combined with Life Cycle Assessment (LCA), Material Flow Analysis (MFA) and Input-Output Analysis (IOA), plays an important role in the design of sustainable societies and business strategies[1]. However, prospective life cycle design is usually not seamlessly linked to technological development. In the example of air conditioners, state-of-the-art development takes place for each component, including the development of new refrigerants and mixture of existing refrigerants[2], clarification and improvement of evaporation and condensation heat transfer phenomena in heat exchangers (evaporators and condensers)[3], design of new compressors[4], improvement of connecting pipes[5], etc. However, this development data is too detailed to be used for life cycle design to build a business strategy. On the other hand, useful indicators such as COP (coefficient of performance) do not show any relationship between design parameters, making it difficult to support decision making.

Figure 1 shows a schematic of the prospective life cycle design of emerging technologies[6] based on seamless analysis from nm to km, using air conditioners as an example. The study of emerging technologies is divided into three major levels: the "materials and components" level (nm to mm level), the "process" level (mm to m level), and the "system" level (m to km level). At the "materials and components" level, taking air conditioners as an example, a variety of research is being conducted. On the other hand, at the "system" level, research is conducted that combines LCA, MFA, IOA and several future scenarios to predict the future, identify gaps between the vision and the predicted future, and identify the need for emerging technologies through back-casting. Computer-aided process engineering is the intermediate process-level research that plays the role of reflecting technical information in system-level analyses with appropriate granularity and precision.

In this study, computer-aided process engineering

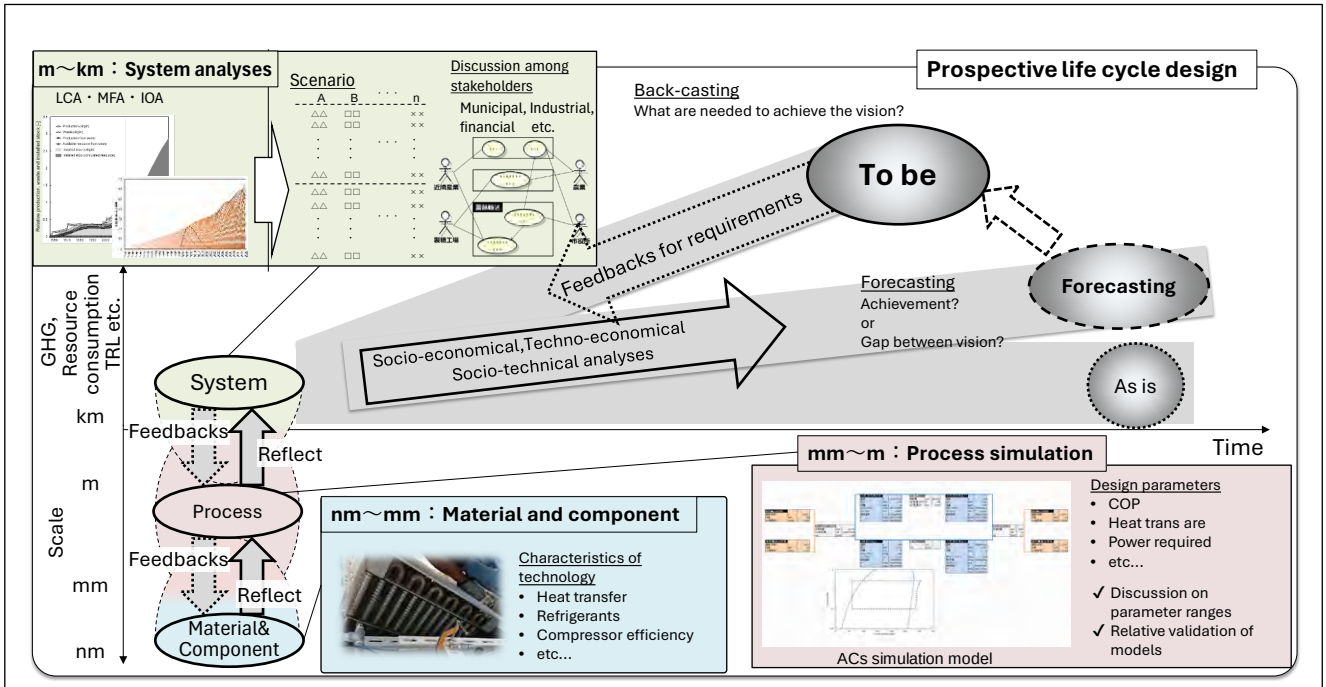

**Figure 1.** Schematic of prospective life cycle assessment for design by seamless analysis from nm~km

is positioned as a function that links technology development and system-level analyses, and a fundamental model combining process simulation of air conditioners, MFA, and LCA was developed to identify the effect of replacing conventional refrigerants with natural refrigerants on life cycle greenhouse gas (GHG) emissions.

## MATERIAL AND METHODOLOGY

Figure 2 shows the linkage diagram among each analysis for prospective life cycle design of air conditioners. Technological data such as like heat transfer coefficient, thermophysical data of refrigerant, design of heat exchangers, efficiency of compressors and fans and the like were aggregated into the process modeling. Figure 3 shows the schematic of process flow diagram of air conditioners. A 2.2 kW air conditioner was simulated as a model machine. In the process modeling, a process flow diagram including heat exchangers for indoor and outdoor, a compressor and an expansion valve was modelled as shown in Figure 3, and for the compressor, the specific enthalpy after compression was calculated assuming an adiabatic efficiency of 90% and for the expansion valve, the refrigerant temperature after expansion was calculated assuming isenthalpy expansion. In the heat exchangers for indoor and outdoor units, the heat exchange process between refrigerants and outdoor air and indoor air was plotted on a temperature-enthalpy diagram, then the UA (overall heat transfer coefficient) values of each heat exchanger were quantified to calculate the relative change in heat exchanger size. The configuration of heat exchangers was based on a typical plate-fin heat exchanger, the number of stages and other sizes have been determined to match the calculated heat transfer area. The refrigerant flow rate was set to give a heat exchange rate of 2.2 kW, which is the performance of the model machine. Based on the determined refrigerant flow rate, the heat exchanger geometry and the pipe length, which was assumed to be 5 m, the pressure losses for the liquid and vapour phases were calculated, respectively. The thermophysical properties of the refrigerant have been calculated using REFPROP10[7]. By using this process modeling, operating power and size of each component for conventional and natural refrigerants could be defined. These results of process simulation were reflected in the MFA and LCA.

In the MFA, statistical data on past and estimated future cooling demand were first incorporated[8,9], then the amount of air conditioners shipped was calculated by balancing the installed stock and the amount of waste estimated by Weibull distribution[10]. Two scenarios were created in which conventional refrigerants continue to be shipped from 2020 to 2050, and a scenario in which $CO_2$ refrigerants are introduced at the same rate as conventional refrigerants from 2030.

In this study, only climate change was considered for the midpoint impact category, since the objective of the LCA in this study is to clarify the impact of refrigerant substitution for the purpose of GWP reduction and changes in electricity emissions intensity on GHG emissions from residential air conditioners in Japan through 2050. The life cycle boundary was set as cradle to gate of conditioned air (manufacturing and operation of air conditioners). The functional unit was defined as cooling

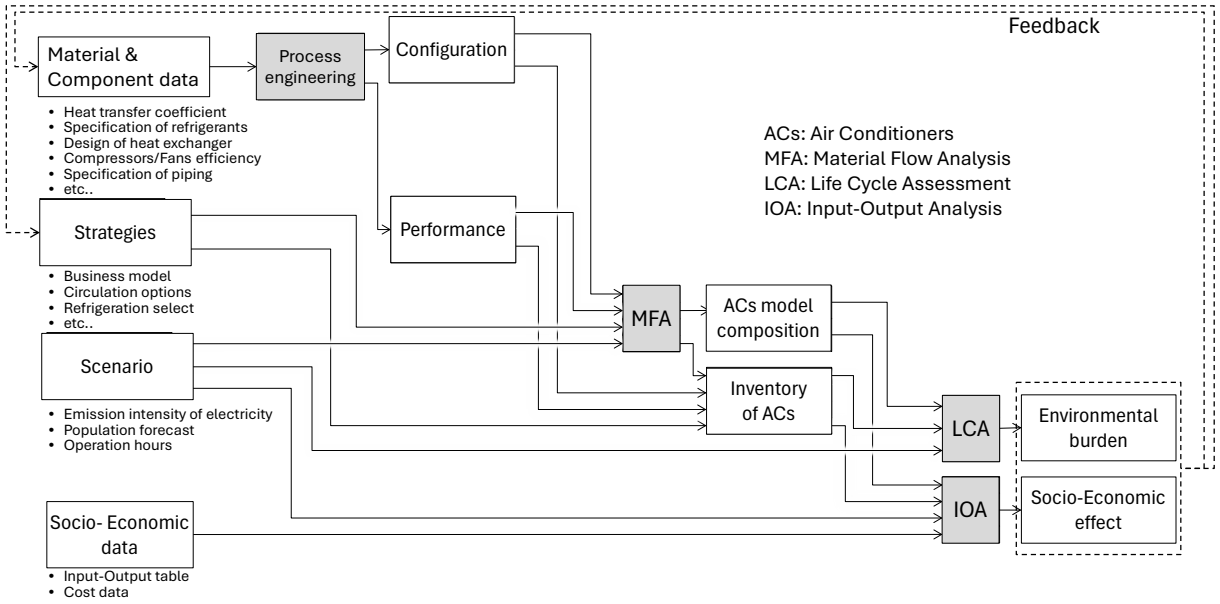

**Figure 2**. Linkage diagram of analyses (Process modeling, Material Flow Analysis, Life Cycle Assessment, and Input Output Analysis) for air conditioners

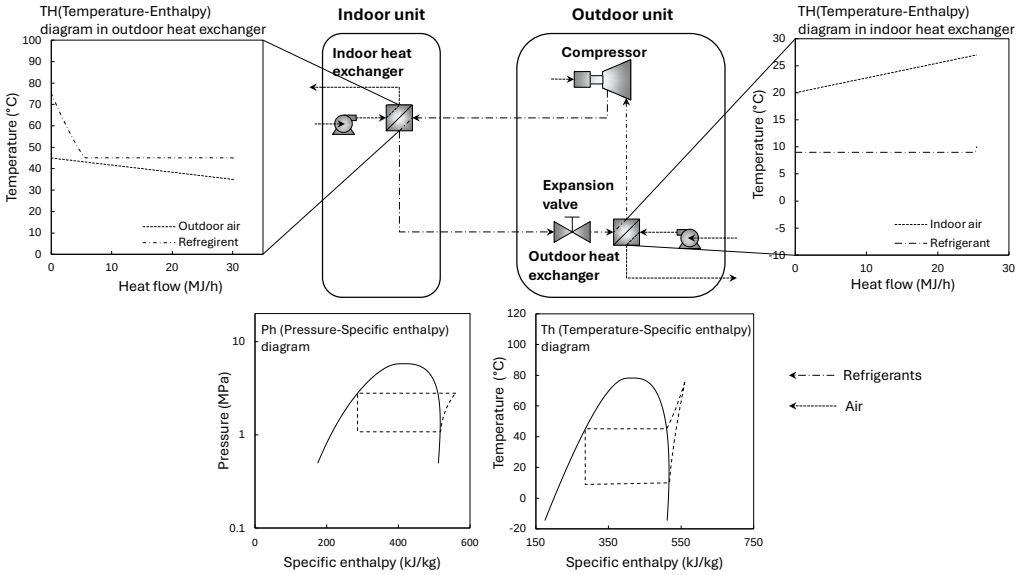

**Figure 3.** Schematic of process flow diagram of air conditioner

and heating by residential air conditioners in Japan through 2050. Inventory data from the manufacture of air conditioners using conventional refrigerant was set[11], and it was assumed that the environmental impact of manufacturing piping and compressors would increase in proportion to the maximum operating pressure ratio with conventional refrigerant when $CO_2$ refrigerant was introduced. Refrigerant leakage was set at 2% per year. Annual power consumption was estimated using performance calculated by the process modeling, annual operation hours, and the results of MFA.

The operating rate was estimated from the energy consumption of air conditioners in the residential sector in the Comprehensive Energy Statistics [12] and the number of units in the market stock calculated by the MFA, and cooling and heating degree days were calculated, then the number of operating days per year was estimated. Annual operating hours were calculated from the operating rate and number of days from 2000 to 2020 and linearly extrapolated to 2050. For electricity emission intensity, two cases were examined: one in which Japan's electricity intensity for the past 10 years is linearly extrapolated to 2050 (almost decarbonized by 2050), and the other in which the intensity in 2020 is maintained.

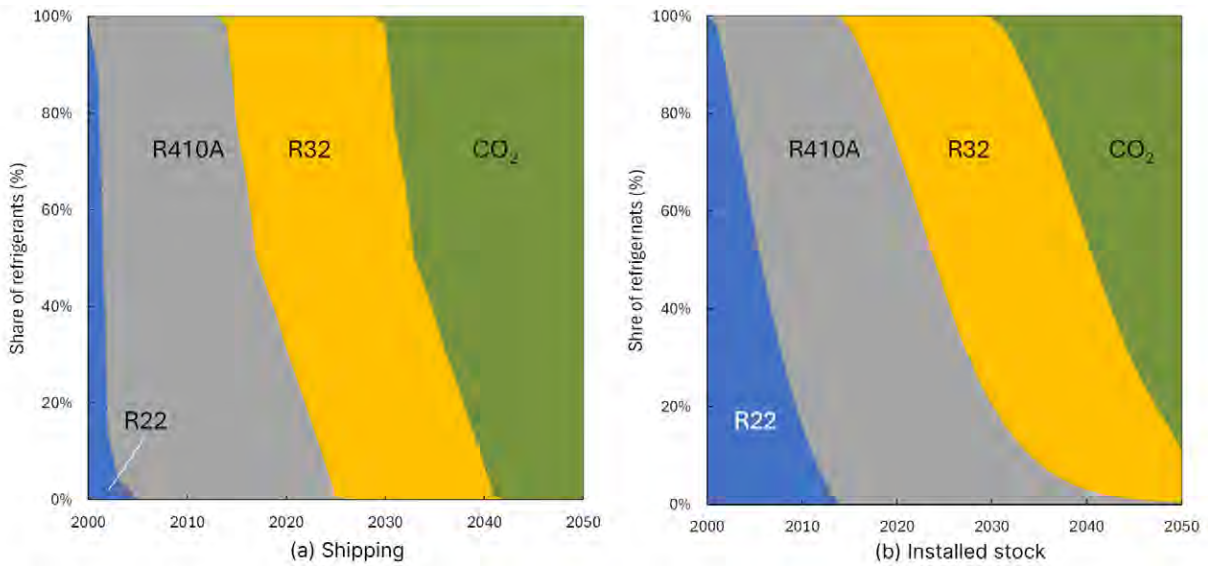

**Figure 4.** Results of material flow analysis of refrigerant when $CO_2$ refrigerant is installed

## RESULTS AND DISCUSSION

Table 1 shows an example of process simulation results for an air conditioner using conventional refrigerant (R32) and $CO_2$ refrigerant. If an air conditioner using $CO_2$ refrigerant is designed to perform the same as an air conditioner using conventional refrigerant, the size of the heat exchanger will be 6 times larger when $CO_2$ is used as the refrigerant. On the other hand, if the heat exchanger of an air conditioner using $CO_2$ refrigerant is designed to be the same size as that of an air conditioner using conventional refrigerant, the COP of an air conditioner using $CO_2$ refrigerant is 30% worse than that of an air conditioner using conventional refrigerant.

Figure 4(b) shows the results of the MFA analysis of the installed stock of refrigerants when $CO_2$ refrigerant is introduced, based on the refrigerant shipment scenario in Figure 4(a). Assuming that $CO_2$ refrigerant shipments begin after 2030 and are introduced at the same rate as conventional refrigerants, $CO_2$ refrigerant will account for 90% of the total in 2050, with the remaining 10% being conventional R32 refrigerant. Using these refrigerant proportions and the results of the process simulation, an LCA up to 2050 was performed.

As illustrated in Figure 5(a), the results of life cycle GHG emissions from 2000 to 2050 are presented for a scenario in which conventional refrigerants continue to be used for air conditioners, and the emission intensity of electricity is equivalent to that of the year 2020. In this scenario, over 90% of the 2050 life cycle GHG emissions are derived from operations. Figure 5(b) presents the results of the life cycle GHG emissions for the electricity decarbonization scenario. A substantial decrease in GHG emissions from operations is estimated, although the emission does not reach zero. This is attributable to the presence of residual electricity emissions intensity at 2050, estimated through linear extrapolation over the past decade, and the persistence of emissions from manufacturing and refrigerant leaks at approximately the same levels.

As illustrated in Figure 5(c), the life cycle GHG emissions from 2000 to 2050 for an air conditioning system designed to utilize a $CO_2$ refrigerant as a substitute for conventional refrigerant, with equivalent performance characteristics, are depicted. The straight lines represent the results for the non-decarbonization scenario, while the area graphs represent the results for the decarbonization scenario. In the non-decarbonization scenario, GHG emissions from operations are the predominant contributor to the total emissions, as estimated in scenarios that utilize conventional refrigerants. In the decarbonization scenario, heat exchangers will increase in size to maintain the same COP as conventional refrigerants. Consequently, GHG emissions derived from the manufacturing phase will account for a greater proportion of total emissions in 2050. In this case, circulation strategies such as heat exchanger recycling play a pivotal role.

**Table 1:** Results of process simulation of air conditioners utilizing conventional refrigerant (R32) and alternative refrigerant ($CO_2$) with two cases

| Refrigerants | Relative COP | Relative size of outdoor unit HEX |
|---|---|---|
| R32 | 100% | 100% |
| $CO_2$ (COP equivalent) | 100% | 574% |
| $CO_2$ (Size equivalent) | 70% | 100% |

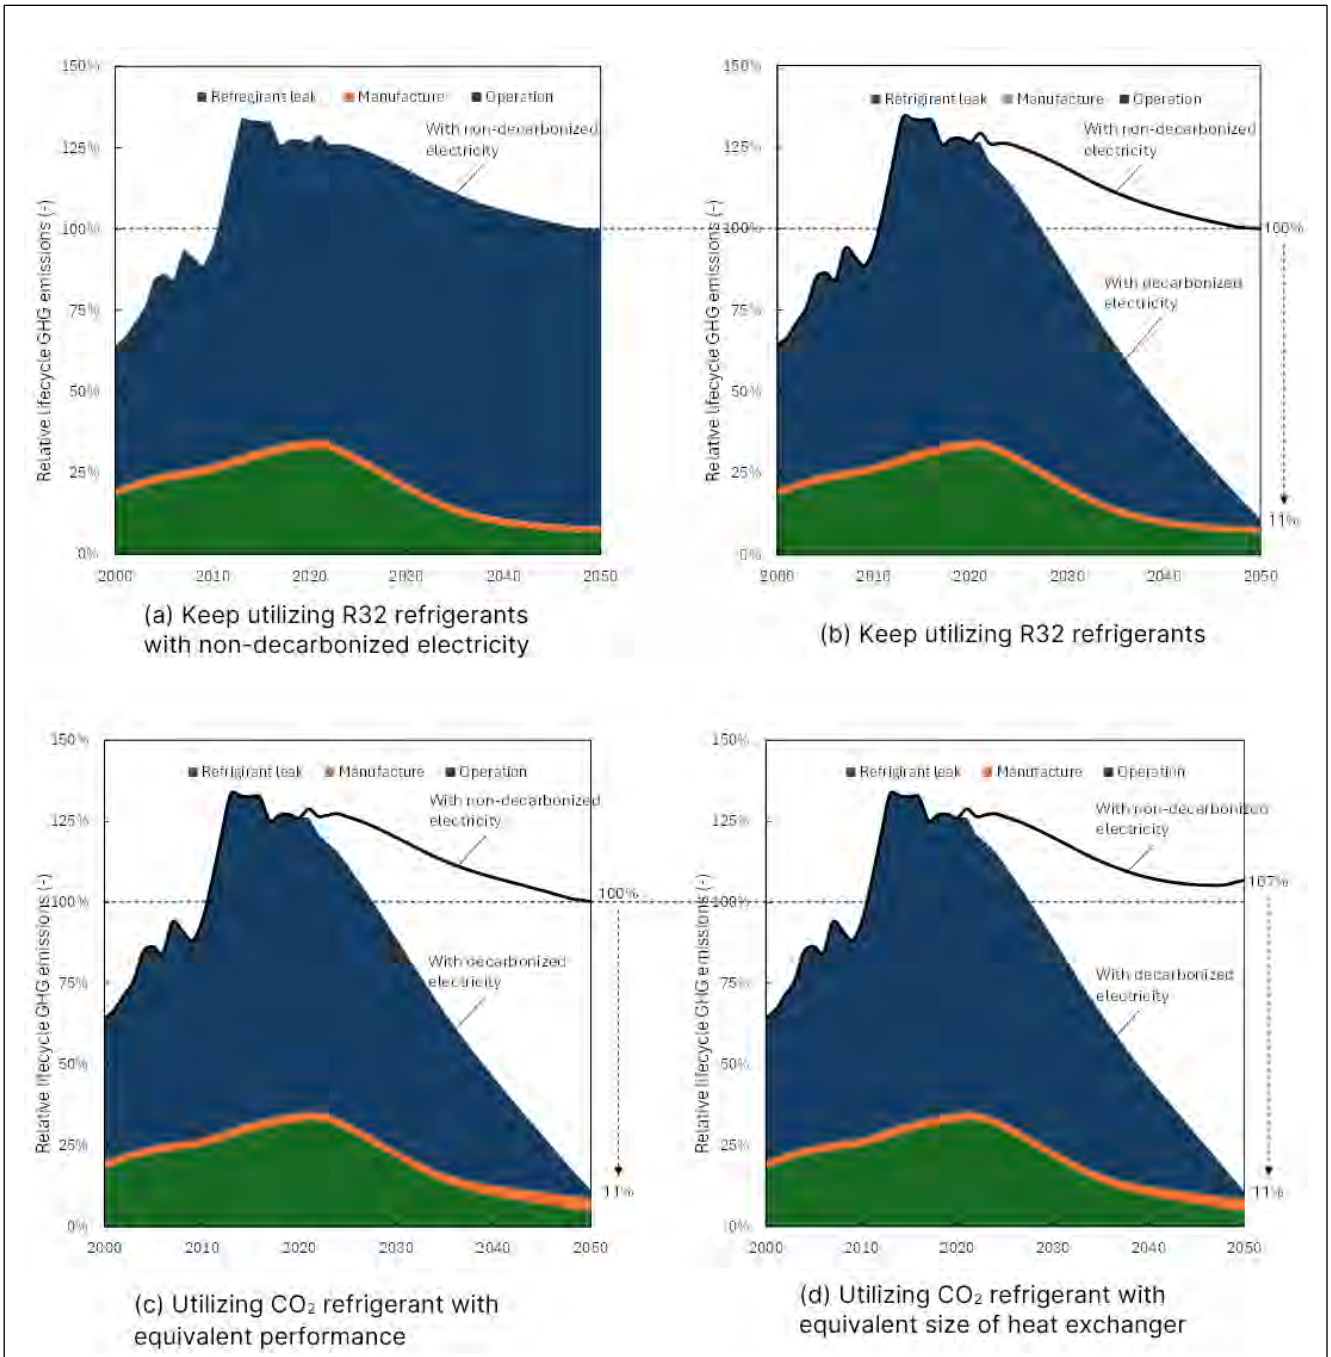

**Figure 5.** Result of life cycle assessment

Figure 5(d) shows the life cycle GHG emissions from 2000 to 2050 for an air conditioning system utilizing $CO_2$ refrigerant with equivalent size of heat exchanger. In this case, the COP of the air conditioner using $CO_2$ refrigerant was worse than that of the air conditioner using conventional refrigerant. In the electricity decarbonization scenario, GHGs derived from electricity consumption are significantly reduced in all cases, so that even if refrigerants are replaced and heat exchangers are enlarged or electricity consumption is increased, total emissions in 2050 would be about the same level as shown in Figure 5(b), (c), and (d), while the non-decarbonization electricity scenario results in increased electricity consumption and accompanying total GHG emissions due to lower performance for the air conditioning system utilizing $CO_2$ refrigerant with equivalent size of heat exchanger as shown in Figure 5(d).

In summary, the dominant factor in the life cycle GHG emissions of air conditioners is derived from electricity consumption, and to move towards carbon neutrality, reducing electricity consumption must be a priority first, and as electricity is decarbonized, the impact of

refrigerants must be considered in the future. As shown in the examples above, computational process simulation can be seamlessly integrated with MFA and LCA to reflect technological information likely to be introduced in the future, while feedback from system analyses can be used to change the strategy of the technology and discuss the feasibility of the technology. Therefore, process engineering plays an important role in prospective life cycle design in resource circulation and decarbonization strategies

## CONCLUSION

In this study, computer-aided process modeling is positioned between technology development and system evaluation to promote feedback from system evaluation by reflecting technical information. The process simulation was developed to visualize the impact of refrigerant substitution by linking MFA and LCA. The results showed that the development of a process simulation that can reflect technological information has the potential to promote discussions on resource circulation and decarbonization strategies.

## ABSTRACT

Currently, state-of-the-art approaches to solving complex optimization problems have focused solely on methods requiring high computational time and unable to find the global optimal solution. In this work, a methodology based on quantum computing is presented to overcome these drawbacks. The novelty of this framework stems from the quantum computer's architecture and taking into consideration the quantum phenomena that take place to solve optimization problems with specific structure. The proposed methodology includes steps for the transformation of the initial optimization problem into an unconstrainted optimization problem with binary variables and its embedding onto a quantum device. Moreover, different resolution levels for the transformation step and different architectures for the embedding process are utilized. To illustrate the procedure, a case study based on Haverly's pooling and blending problem is examined while demonstrating the potential of the proposed approach. The results indicate that the succinct formulation exhibited higher success rate during the embedding procedure for the different examined architectures, and the quantum annealing solver exhibited the best performance among the various solvers investigated. This highlights the potential of the approach for solving this type of problems with the rapid development and improvement of quantum hardware and expanding it to more complex chemical engineering optimization systems.

**Keywords**: Optimization, Scheduling, Algorithms, Quantum Computing, Quantum Annealing

## 1. INTRODUCTION

Combinatorial optimization (CO) is a branch of mathematical optimization that is applied for a broad set of applications in the fields of industrial engineering, transportation or manufacturing. Finding the global solutions for this type of problems is challenging, due to its NP-hard nature [1].

In real-world applications, processes are described by highly nonlinear and nonconvex expressions leading to an exponential growth of the number of local solutions as the number of variables increases [2].

Several strategies, based on classical optimization techniques, heuristics and neural network methods, have been proposed to solve optimization problems [3]. Nonetheless, these state-of-the-art methods exhibit the following limitations:

1. High computational timeframes are required in deterministic optimization algorithms.
2. Solution quality is not guaranteed in heuristic approaches, leading to suboptimal results.
3. The training and the tuning of the neural networks, as well as the use of small instances of problems affects the solution.

Quantum computing (QC) is a rapidly growing research field and promising technology that differentiates itself from classical computers and utilize quantum phenomena such as entanglement and superposition to perform calculations and simulations. QC is capable of providing polynomial-time solutions for problems in the BQP (bounded error, quantum, polynomial time) complexity class [4].

To address these drawbacks, this contribution proposes a solution framework, based on QC, that involves formulating the original optimization problem as a Quadratic Unconstrained Binary Optimization (QUBO) problem and embedding it onto a quantum device.

The remainder of the contribution is structured as

follows: in Section 2 the methodology for reformulating the CO problem into QUBO is presented. The proposed solution framework is applied for a case study in Section 3. The key results and future work required are summarized in Sections 4 and 5, respectively.

## 2. METHODOLOGY

In the first step, the original CO problem is formulated as a QUBO problem, where continuous and integer variables are transformed into binaries and its formulation is given by:

$$\min_x xQx^T, x \in \{0,1\} \quad (1)$$

where $x$ represents the vector of binary decision variables and $Q$ is a square matrix of constants.

To construct the $Q$ matrix, additional steps are required such as: the transformation of inequality constraints into equalities, the removal of bilinear terms and the introduction of quadratic penalty terms, as shown in Figure 1.

The QUBO problem, defined by Eq. (1), is subsequently solved using Quantum Annealing (QA) in a quantum adiabatic environment. QA is a model of quantum computation that utilizes quantum fluctuations to search for ground state solutions of the CO problem that is encoded as a Hamiltonian by applying a transverse field [5]. Furthermore, QA in D-Wave systems utilizes the QUBO formulation for optimization problems, supports over 5,000 physical qubits, and can efficiently explore the solution space by overcoming local minima.

Apart from QA, the D-Wave suite offers different solution approaches that can be utilized to solve QUBO such as the multistart Tabu search (TS) and qboslv (TN) solvers. TS is based on memory-based strategies, and explores regions of the solution space and prevents the recurrence of recent moves. TN partitions the original problem into smaller sub-problems defined by the algorithm which are solved by simulated annealing (SA). Furthermore, the user can define the size of the sub-problem (TSN-x solver), where x represents the maximum number of variables allowed in each subproblem.

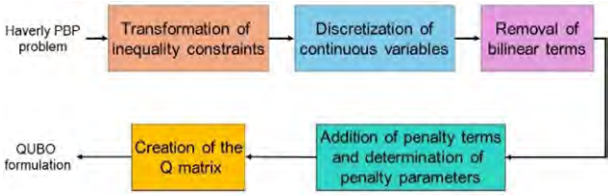

**Figure 1.** Tranformation procedure of the PBP into QUBO

After the QUBO transformation, an embedding procedure onto the QA hardware is required to find the optimal solution, involving mapping the graph described by the QUBO problem as a minor of the graph representing the qubit lattice of the QA system.

To achieve this, Chimera and Pegasus topology unit cells are used to attain connectivity among the qubits which are available in D-Wave systems. These embedding architectures depend on QA hardware design, and parameters such as the largest complete subgraph of an arbitrary problem system (maximal clique size) and the number of nodes in one half of the bipartite cell (shore size).

The benefits of the proposed solution scheme are summarized below:

- The QA framework has the ability to explore the solution space more broadly and not get stuck in a local solution through quantum tunneling.
- Multiple states can be simultaneously explored during the annealing process, reducing the required computational time due to quantum superposition.

## 3. COMPUTATIONAL RESULTS

In this section, a case study based on Haverly's pooling and blending problem (PBP) [6] is examined using the proposed methodology. This problem is selected due to its non-convex nature and the existence of bilinear terms, which can result in multiple local minima. Furthermore, PBPs are easily scalable in terms of complexity, as the problem definition can be readily expanded to include additional streams, products, and pools.

All the simulations are performed in Python, where the NetworkX package is used for creating and analyzing the Chimera and Pegasus graph objects and the D-Wave's Ocean software for embedding and solving the QUBO problem.

The p-formulation of the PBP including three reagent streams, two product streams, and one pool in which two reagents are blended is given by:

$$\min F_A C_A + F_B C_B + F_{Cx} C_C + F_{Cy} C_C + F_X C_X + F_Y C_Y \quad (2a)$$

$$\text{s.t. } F_{px} + F_{py} - F_A - F_B = 0 \quad (2b)$$

$$F_x - F_{Cx} - F_{px} = 0 \quad (2c)$$

$$F_y - F_{Cy} - F_{py} = 0 \quad (2d)$$

$$S_p F_{px} + \mathrm{S_p} F_{py} - \mathrm{S_A F_A} - \mathrm{S_B F_B} = 0 \quad (2e)$$

$$S_p F_{px} + \mathrm{S_C} F_{Cx} - \mathrm{S_x F_x} \leq 0 \quad (2f)$$

$$S_p F_{py} + \mathrm{S_C} F_{Cy} - \mathrm{S_y F_y} \leq 0 \quad (2g)$$

$$F_x - 100 \leq 0 \quad (2h)$$

$$F_y - 200 \leq 0 \quad (2i)$$

where $F_A$, $F_B$, $F_{Cx}$, and $F_{Cy}$ are the feed streams, $F_{px}$ and $F_{py}$ are the pool streams, $F_x$ and $F_y$ denote the product streams, and $S_x$ and $S_y$ represent the product composition. The values of parameters for the examined Haverly

PBP are given in Figure 2.

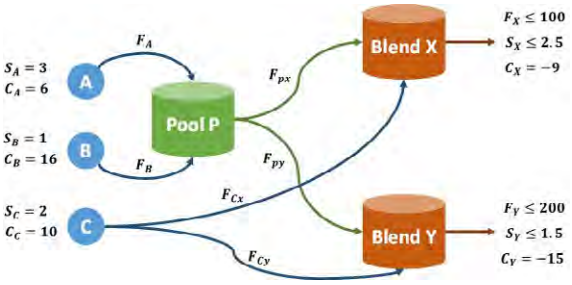

**Figure 2.** Schematic representation of Harvely PBP

Following the steps illustrated in Figure 1, the reformulated PBP can be written as:

$$\min F_A C_A + F_B C_B + F_{Cx} C_C + F_{Cy} C_C + F_x C_x + F_y C_y + P\left\{\left(F_{px} + F_{py} - F_A - F_B\right)^2 + \left(F_x + F_{Cx} - F_{px}\right)^2 + \left(F_y + F_{Cy} - F_{py}\right)^2 + (T_x + \mathrm{S_C F_{Cx}} - \mathrm{S_x F_x} + \Gamma_3)^2 + \left(T_y + \mathrm{S_C F_{Cy}} - \mathrm{S_y F_y} + \Gamma_4\right)^2 + \left(T_x + T_y - S_A F_A - S_B F_B\right)^2 + (F_x - 100 + \Gamma_1)^2 + \left(F_y - 200 + \Gamma_2\right)^2 + \sum_{i=1}^{n_{fpx}} \sum_{j=1}^{n_{sp}} \left(F_{px,i} S_{p,j} - 2T_{x,ij} F_{px,i} - 2T_{x,ij} S_{p,j} + 3T_{x,ij}\right) + \sum_{i=1}^{n_{fpy}} \sum_{j=1}^{n_{sp}} \left(F_{py,i} S_{p,j} - 2T_{y,ij} F_{py,i} - 2T_{y,ij} S_{p,j} + 3T_{y,ij}\right)\right\} \quad (3)$$

where $\Gamma_1 - \Gamma_4$ are the slack variables, $P$ is the penalty parameter, and $T_x$ and $T_y$ are the binary transformation variables for the removal of bilinear terms $S_p F_{px}$ and $S_p F_{py}$, respectively.

In the following, two transformations have been utilized: a verbose transformation, in which the discretized variables are expanded to allow for greater precision, and a succinct transformation, where each variable is constrained to integer values.

In both formulations, the number of binary variables is determined based on the required precision for expressing the continuous variables of the Haverly's PBP. Furthermore, the slack variables introduced to transform the inequality constraints to equalities utilize more qubits compared to the continuous to prevent the imposition of suboptimal values. Based on this protocol, the succinct formulation needed approximately two-thirds fewer binary variables to represent the problem compared to the verbose formulation. This reduction can be attributed to the decrease in the number of transformation variables required to eliminate the bilinear terms present in Eqs. 2e – 2g. Table 1 presents some of the parameters of the resulting succinct and verbose formulations.

Once the QUBO transformation is obtained, the embedding process is employed to insert the reformulated optimization problem into the lattice of qubits that form the quantum processing unit. In this study, the Chimera and Pegasus graphs are used for the embedding. To successfully insert the QUBO to the QA, the value of the maximal clique is required. The maximal cliques for both qubit architectures are obtained using the Bron and Kerboch algorithm [7] and found to be 75 and 30 for the verbose and succinct formulations, respectively, as shown in Table 1.

**Table 1:** Succinct and verbose QUBO characteristics for the Haverly's PBP

| Parameter | Verbose | Succinct |
|---|---|---|
| Binaries for continuous variables | 66 | 63 |
| Binaries for slack variables | 36 | 30 |
| Binaries for transformation variables | 75 | 30 |
| Maximum clique size | 75 | 30 |
| Q matrix size | 177 | 123 |
| Non-zero matrix elements | 7,765 | 3,319 |
| Total binary combinations | $1.9\times10^{53}$ | $1.0\times10^{37}$ |

## 4. RESULTS AND DISCUSSION

All the simulations for the reformulation of the PBP are performed in Python using the D-Wave Ocean toolbox [8], where SA, TS, TN and TSN-x solvers as well as the Pegasus and Chimera topologies are used to solve the succinct and the verbose formulations. As a reference case, the QUBO problem is solved using the Multistart and GlobalSearch solvers available in MATLAB's Global Optimization (GO) toolbox. After the execution of each solver, a sample set is returned and the set with the most occurrences among the collected data is returned as the best solution.

### 4.1 PBP embedding procedure

In this subsection, the performance of the different embedding architectures is examined and compared. Apart form the calculation of the maximum clique value, there are other features that affect the performance of the embedding procedure, such as the number of units, shore size, and the unit's height and width.

In the Chimera graph architecture, two different cases are examined. In the first case, the shore size is fixed to the value of 4 and the height and the width of the graph varied in integer increments from 16 to 26 with the structure remaining symmetric. In the second case, the graph's height and width kept constant to 16 and the shore size varied in integer increments from 4 to 10. In both cases, the probability and the time required to embed the problem system into the Chimera graph are obtained.

It can be observed that the verbose formulation requires a high number of qubits compared to the succinct formulation for a successful embedding, as shown in Figure 3. Furthermore, the verbose architecture failed to embed on any of the Chimera graphs with shore size

equal to 4 and varying graph's height and width.

Figure 4 presents the required wall clock for successful embedding. The succinct architecture exhibits rapid convergence in the range of 20-30 seconds with a standard deviation of 15-30 seconds. On the other hand, the verbose embedding requires higher average embedding times and standard deviations.

It can be concluded that when the embedding is successful, the embedding time will converge, with the rate of convergence being influenced by the system's connectivity.

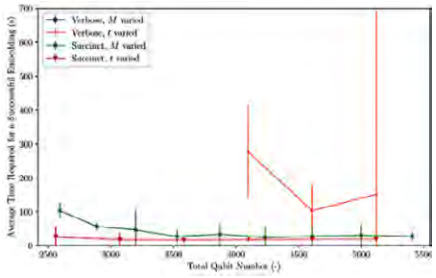

**Figure 3.** Required time for successful embedding in a Chimera graph as a function of qubit number

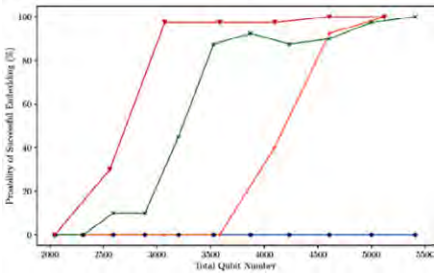

**Figure 4.** Propability for the problem system in a Chimera graph as a funtion of qubit number

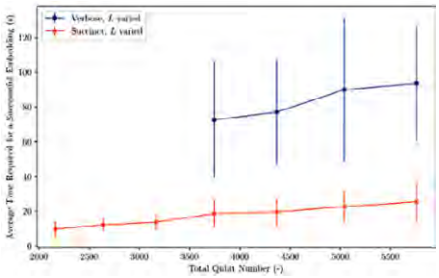

**Figure 5.** Required time for successful embedding in a Pegasus graph as a function of qubit number

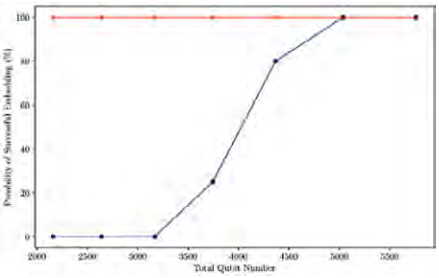

**Figure 6.** Propability for the problem system in a Pegasus graph as a funtion of qubit number

The same procedure is used for the Pegasus configuration where the graph's size parameter is varied in integer increments from 10 to 16. It can be seen that the succinct formulation is successfully embedded for all the sizes, whereas the verbose formulation only when the number of qubits is 3,700 and above, as shown in Figure 5.

Contrary to the behaviour observed for the Chimera embedding, Figure 6 illustrates that the required wall clock time as well as the standard deviation for the embedding step increases with the increase in the number of qubits.

## 4.2 Penalty multiplier value selection

As mentioned in Section 2, a penalty term is introduced during the QUBO transformation procedure to enforce constrained behaviour without the use of constraints. The selection of the appropriate $P$ value is a non-trivial task because there is a trade-off between enforcing constrained behaviour that usually requires large values and retaining the objective function information [9].

For this task, the optimal value of the penalty multiplier was found by solving the verbose and succinct formulations of the problem at different values ranging from 75% to 150% of the optimal objective function value, $\hat{f}^*$ (which is equal to -400), in 5% increments. Each system was solved using 40 calls and the obtained values were processed to yield the unweighted objective function value, given by:

$$\bar{f} = \frac{(\hat{f}-c)}{k} \tag{4}$$

where $c$ is a constant representing the total sum of the constant cross terms from the quadratic penalties and $k$ is a constant ranging from 0.75 to 1.5.

In Figure 7, it can be observed that the succinct formulation of the QUBO problem is solved more easily than the verbose formulation. Furthermore, this effect is most clear in the TN method, while for the TSN-x method is the least evident.

As far as the constraint violation is concerned, the verbose formulation demonstrates lower values compared to the succinct, as shown in Figure 8. Furthermore, SA and TS solvers exhibit the highest and the lowest value for the squared constraint violation, respectively.

It should be noted that none of the solvers returned negative solutions and consequently corresponding all to a setup that would be unprofitable or physically impossible. For each solver, the optimal value of the penalty parameter was obtained by calculating a composite rank that is equally weighted in terms of the objective function value and constraint violations. The obtained results of the ranking method are shown in Table 2.

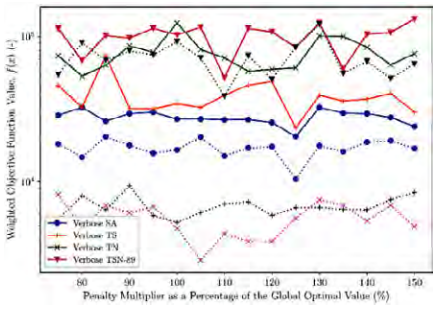

**Figure 7.** Avarage unweighted objective function value

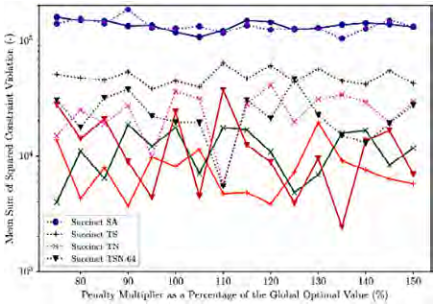

**Figure 8.** Mean sum of squared constraint violation

**Table 2:** Penalty multiplier values $P$ as a % of the objective function values that yielded the lowest composite score

| Formulation | SA | TS | TN | TSN-x |
|---|---|---|---|---|
| Verbose | 125% | 90% | 125% | 135% |
| Succinct | 110% | 95% | 110% | 110% |

## 4.3 QUBO solution

Based on the penalty multiplier values determined in Section 4.2, both the succinct and verbose formulations were created and each problem system is solved using all the aforementioned solvers, using a total of 500 calls and 10,000 initial points. For the GO solvers, the findings indicate that the inclusion of penalty terms enhances the complexity of the resulting system due to the bilinear transformation, thereby making it more challenging to solve.

Tables 3 and 4 present the statistics for the verbose and the succinct of the PBP formulation. It can be seen that the succinct formulation delivers better solutions in terms of the unweighted objective function across all solvers. In particular, this effect is more visible for the TN solver. Furthermore, SA exhibits the best performance for the verbose and the second-best for the succinct formulation among the examined solvers, producing low standard deviations for the unweighted objective function value.

In contrast, the verbose formulation shows better performance in the mean sum of squared violations, except for the case of the TN solver. It can be observed that the succinct formulation exhibits lower performance compared to the verbose at the recovered values of the original objective function.

Based on these findings, the succinct formulation runs into fewer local minima. Therefore, this behaviour can be explained as a result of minimizing toward better underlying solutions but being unable to reduce the error in those solutions.

The TN solver demonstrates better performance in constraint violation and unweighted objective function value compared to the SA solver, as shown in Tables 3

**Table 3:** Summary of results for the verbose formulation of the PBP

| Parameter | SA | TS | TN | TSN-89 | TSN-45 | TSN-23 |
|---|---|---|---|---|---|---|
| Average solving time (ms) | 214 | 596 | 2,087 | 3,039 | 1,875 | 782 |
| Mean of $\bar{f}$ | 6,290 | 14,600 | 24,800 | 30,300 | 23,800 | 36,000 |
| Standard deviation of $\bar{f}$ | 972 | 17,100 | 27,000 | 31,700 | 27,100 | 31,300 |
| Mean of $c$ | 76,240 | 44,990 | 40,961 | 50,174 | 41,436 | 51,999 |
| Standard deviation of $c$ | 81,999 | 74,329 | 73,619 | 79,924 | 73,528 | 73,324 |
| Mean of $f$ | -9.62 | -77.85 | -72.27 | -76.98 | -79.59 | -76.35 |
| Standard deviation of $f$ | 238 | 205 | 254 | 263 | 243 | 271 |

**Table 4:** Summary of results for the succinct formulation of the PBP

| Parameter | SA | TS | TN | TSN-62 | TSN-31 | TSN-16 |
|---|---|---|---|---|---|---|
| Average solving time (ms) | 93 | 587 | 1,514 | 1,480 | 960 | 481 |
| Mean of $\bar{f}$ | 3,340 | 3,900 | 1,620 | 11,400 | 5,560 | 30,700 |
| Standard deviation of $\bar{f}$ | 732 | 1,360 | 625 | 16,700 | 8,690 | 32,900 |
| Mean of $c$ | 81,282 | 76,608 | 28,499 | 64,408 | 52,443 | 59,919 |
| Standard deviation of $c$ | 88,689 | 89,682 | 54,898 | 90,968 | 82,191 | 87,127 |
| Mean of $f$ | -25.02 | 54.75 | -46.43 | -34.15 | -38.06 | -60.16 |
| Standard deviation of $f$ | 241 | 252 | 168 | 158 | 217 | 294 |

and 4. However, the TN solver requires approximately 10 – 15 times more computational time. In the case of the TSN solver, its performance is notably sensitive to the size of the sub-problems, highlighting the pivotal role of subproblem size in achieving optimal solutions.

Overall, the SA solver shows strong performance in terms of the unweighted objective function value and computational time. Therefore, the SA solver is the most promising candidate which is capable of producing good quality results and is suitable for solving QUBO formulation problems successfully.

## 5. CONCLUSIONS

This contribution introduces a quantum approach to formulating and solving CO problems using a QA solution framework. In this work, the procedure for the CO reformulation is showcased as well as embedding and solution of the QUBO reformulation of the Haverly PBP on a quantum machine.

Two QUBO problem formulations, verbose and succinct, are selected and compared. The results revealed that the succinct version of the optimization problem requires smaller value for penalty multipliers and produced better results compared to the verbose formulation.

The numerical experiments have shown that the verbose formulation can be embedded even on very large Chimera graphs. Contrary, the Pegasus architecture is able to successfully handle both succinct and verbose formulations, requiring an average of 25 and 90 seconds, respectively.

The SA solver showed the best performance among the examined solvers in the D-Wave platform and the deterministic GO solvers, although it required high computational time. Furthermore, the results of the TSN-x solver highly depend on the size of subproblem.

This methodology holds the potential for solving efficiently CO problems with the improvement capabilities of the quantum computers in terms of computational power and the availability of the maximum qubits. This approach can be extended to solve chemical engineering applications such as process synthesis and design and production planning and scheduling problems.

As future work, alternative ways for handling bilinear and higher order terms and the transformation of the continuous and integer variables into binaries should be investigated to obtain good quality results in lower computational time.

Additionally, the structure of the optimization problem plays an important role in the solution procedure. Specifically, the embedding algorithm, the sub-problem size and the penalty multiplier values can be optimized, providing the ability of QA systems to offer scaling advantages over traditional heuristics when applied to larger PBPs.

## ABSTRACT

Bayesian classification (BC) is a powerful supervised machine learning method for modelling the relationship between a set of continuous variables and a set of discrete variables that represent classes. BC has been successful in engineering and medical applications, including feasibility analysis and clinical diagnosis. Gaussian process (GP) models are widely used in BC methods to model the probability of assigning a class to an input point, typically through an indirect approach: a GP predicts a continuous function value based on Bayesian inference, which is then transformed into class probabilities using a nonlinear function like a sigmoid. The final class labels are assigned based on these probabilities. In this commonly used workflow, the uncertainty associated with the class prediction is usually evaluated as the uncertainty in the GP function values. A disadvantage of this approach is that it does not consider the uncertainty directly associated with the decision-making. In this work, we propagate the uncertainty from the space of GP function values to the class probability space and use this to quantify the uncertainty directly associated with the decision-making process. Additionally, we employ the propagated uncertainty as the objective function in an active learning (AL) method to generate new informative data points for the GP classifier training. We compare the proposed AL method to existing state-of-the-art methods to evaluate its performance.

**Keywords**: Bayesian classification, Gaussian process, active learning, uncertainty propagation.

## 1. INTRODUCTION

Probabilistic learning is key to developing autonomous systems that adapt and make reliable decisions without human intervention [1]. One of the popular probabilistic learning approaches that has key applications in engineering and medical domains is Bayesian classification (BC) [2].

BC involves a probabilistic approach to the classification problem. A classification problem is a supervised machine learning method used to build a functional relationship between a set of input variables and a set of classes or categories related to the input variables. Usually, the classes are labelled using discrete values such as 0, 1, 2 etc. BC has proven successful in applications such as medical diagnosis [3] and feasibility analysis [4], where the uncertainty of model predictions is critical. A popular choice of BC implementation involves BC with Gaussian processes (GPs) [5].

In problems of BC with GPs, the posterior GP model, i.e. the model obtained after data fitting or learning through Bayesian inference [5], provides probability predictions corresponding to the class labels along with an associated uncertainty value. This uncertainty offers meaningful insights into the model and supports the design of learning strategies that utilize it. This field of informed learning process to facilitate efficient training of a GP model with limited informative data is known as active learning (AL) [6]. Therefore, the GP model's ability to quantify uncertainty is closely linked to the learning approach employed in AL.

Two approaches are commonly used for uncertainty quantification in BC with GPs: 1) aleatoric or intrinsic uncertainty associated with the class prediction and 2) uncertainty in the GP model predictions. In 1), the class conditional probability values predicted by the GP model are

used for uncertainty quantification. For instance, extremely low or extremely high probabilities indicate low uncertainty in the outcome predicted by the model while probabilities near 0.5 indicate a presence of high uncertainty. In 2), uncertainty in BC is quantified as the uncertainty around the point estimates of the GP model predictions. The point estimates of the GP model predictions are further transformed into class probabilities for deciding the class label prediction. Both approaches do not consider the uncertainty around the predicted class probabilities which are used in decision-making regarding the class selection. This could lead to slow convergence of the classifier learning process or could result in a classifier model that is not accurately reliable. In this work, we propagate the uncertainty from the predictions of the posterior GP model to the class probability predictions using a linear error propagation rule. This propagated uncertainty is proposed to quantify the uncertainty associated with the BC problem. Further, we employ the propagated uncertainty in an AL framework to generate informative datasets to train the classifier model. This proposed novel AL strategy is compared with the existing methods (methods based on the approaches 1 and 2 discussed above) to demonstrate its usefulness in the context of AL.

## 2. METHODOLOGY

### 2.1 Bayesian binary classification with Gaussian processes

Binary classification involves the problem of assigning one of the two classes (0 or 1) to an input vector $\mathbf{x}$ by predicting the probability $\phi$ of class 1 given $\mathbf{x}$, $\phi = P(c = 1|\mathbf{x})$. This probability can be modelled as $\phi = g(h(\mathbf{x}))$, where $h(\mathbf{x})$ is a latent function, which is a mapping from the inputs $\mathbf{x}$ to continuous real values (latent function values) $y$, and $g$ is the sigmoid transformation defined as $g(y) = 1/1 + e^{-y}$, which is a mapping from the latent function values $y$ to the unit interval $[0,1]$. In Bayesian classification with Gaussian processes, a Gaussian process prior is placed over the latent function $h(\mathbf{x})$.

$$h(\mathbf{x}) \sim \mathcal{N}\big(m(\mathbf{x}), k(\mathbf{x}, \mathbf{x}')\big) \tag{1}$$

As discussed in [5], here the latent function $h$ plays the role of a nuisance function, in the sense that we are not particularly interested in the values of $h$, but rather in $g(h(\mathbf{x}))$. We observe only the inputs $\mathbf{X}$ and the class labels $\mathbf{c}$. Let $\mathbf{X} = [\mathbf{x}_1, \ldots, \mathbf{x}_n]^\intercal$ are the inputs corresponding to $n$ data points. A GP prior is a collection of random variables $\{\mathbf{Y}(\mathbf{x})|\mathbf{x} \in \mathbf{X}\}$ indexed by the set $\mathbf{X}$, where any finite set of $\mathbf{Y}$ follows a joint multivariate Gaussian distribution. A GP prior is fully specified by its mean function $m(\mathbf{x}) = \mathrm{E}[\mathbf{Y}(\mathbf{x})]$ and its covariance function $k(\mathbf{x}, \mathbf{x}') = \mathrm{E}\big[\big(\mathbf{Y}(\mathbf{x}) - m(\mathbf{x})\big)\big(\mathbf{Y}(\mathbf{x}') - m(\mathbf{x}')\big)\big]$. For simplicity, we set the prior mean to zero, i.e., $m(\mathbf{x}) = 0$. For the covariance function, we employed the popular squared exponential covariance function with automatic relevance determination (ARD) distance measure. For the mathematical expression of the squared exponential kernel function, the readers are referred to [5]. We denote all the learned parameters of the covariance function that include the signal variance and the characteristic length scales by the hyperparameter vector $\boldsymbol{\theta}$. With this specification of prior mean and the covariance function, the prior over the latent function is jointly Gaussian. Let $y_\mathrm{i} = h(\mathbf{x}_\mathrm{i})$ and $\mathbf{y} = [y_1, \ldots, y_\mathrm{n}]^\intercal$ denote the latent function values, then the prior takes the form:

$$p(\mathbf{y}|\mathbf{X}, \boldsymbol{\theta}) = \mathcal{N}(\mathbf{0}, \mathbf{K}) \tag{2}$$

where $\mathbf{K}$ is the $n \times n$ covariance matrix with elements defined by $\mathrm{K}_{ij} = k(\mathbf{x}_i, \mathbf{x}_j), i, j = 1, \ldots, n$. Corresponding to each input data point $\mathbf{x}_i$, the probability of observing the class label 1 can be represented using a Bernoulli distribution. That is, given $\mathbf{x}_i$ and $c_i$, $\hat{c}_i = 1 \sim Bernoulli\left(g\big(h(\mathbf{x}_i)\big)\right)$, where $g\big(h(\mathbf{x}_i)\big) = \phi_i$ is the predicted probability of obtaining a class 1. For $n$ independent data points, the likelihood $p(\mathbf{c}|\mathbf{y})$ can be derived from the probability mass function of the individual Bernoulli distributions as:

$$p(\mathbf{c}|\mathbf{y}) = \prod_{i=1}^{n} \left(g\big(h(\mathbf{x}_i)\big)\right)^{c_i} \left(1 - g\big(h(\mathbf{x}_i)\big)\right)^{1-c_i} \tag{3}$$

The posterior distribution over the latent function values $p(\mathbf{y}|\mathbf{X}, \mathbf{c}, \boldsymbol{\theta})$ can be computed from the prior and the likelihood using the Bayesian rule:

$$p(\mathbf{y}|\mathbf{X}, \mathbf{c}, \boldsymbol{\theta}) = \frac{p(\mathbf{y}|\mathbf{X}, \boldsymbol{\theta})}{p(\mathbf{c}|\mathbf{X}, \boldsymbol{\theta})} p(\mathbf{c}|\mathbf{y}) \tag{4}$$

where $p(\mathbf{c}|\mathbf{X}, \boldsymbol{\theta}) = \int p(\mathbf{c}|\mathbf{y})\, p(\mathbf{y}|\mathbf{X}, \boldsymbol{\theta}) d\mathbf{y}$ is the marginal likelihood. The evaluation of the posterior allows to make predictions $h(\mathbf{x}_*)$ for a new test point $\mathbf{x}_*$. However, the computation of the posterior distribution in Equation (4) is analytically intractable due to the non-Gaussian likelihood in Equation (3), which makes the evaluation of the integral on the right-hand side of the marginal likelihood impossible [5]. Owing to this, the training of the GP model (which involves maximizing the marginal likelihood) as well as the inference problem (making predictions based on the sample data, by using the learned hyperparameters) are evaluated using variational inference methods [7]. We employed evidence lower bound (ELBO) [7] as the variational inference loss function for GP model training.

### 2.2 Uncertainty in the inference

Common practices to quantify the uncertainty in the inference of BC with GP model involve either estimating the uncertainty as the variance over the latent function values or estimating it as the variance of the predicted

classification outcomes. For any new input point $\mathbf{x}_*$, the variance over the latent function values can be computed as:

$$\sigma_y^2(\mathbf{x}_*) = k(\mathbf{x}_*, \mathbf{x}_*) - k_*^{\mathrm{T}}\mathbf{K}^{-1}k_* \quad (5)$$

where $k_* = [k(\mathbf{x}_1, \mathbf{x}_*), \ldots, k(\mathbf{x}_n, \mathbf{x}_*)]^{\mathrm{T}}$. With the assumption that the predicted distribution of class labels is the same as the true distribution, the uncertainty of the classification outcome for any new input data point $\mathbf{x}_*$ can be computed as the random variance of the Bernoulli distribution corresponding to predicting a class 1 with a probability $\phi_*$. This variance can be computed as:

$$\sigma_{\hat{c}}^2(\mathbf{x}_*) = \phi_*(1 - \phi_*) \quad (6)$$

## 2.3 The propagated uncertainty

In this work, we quantify the uncertainty around point estimates of the class probability predictions by propagating the uncertainty over the latent function values to the predicted probability values using the linear error propagation rule. The propagated uncertainty is computed as:

$$\sigma_\phi^2(\mathbf{x}_*) = \left(\left.\frac{d\phi}{dy}\right|_{\mathbf{x}_*} \times \sigma_y(\mathbf{x}_*)\right)^2 = \left(\frac{e^y}{(1+e^y)^2}\right)^2 \times \sigma_y^2\Big|_{\mathbf{x}_*} \quad (7)$$

The uncertainty propagation is visually depicted in Figure 1.

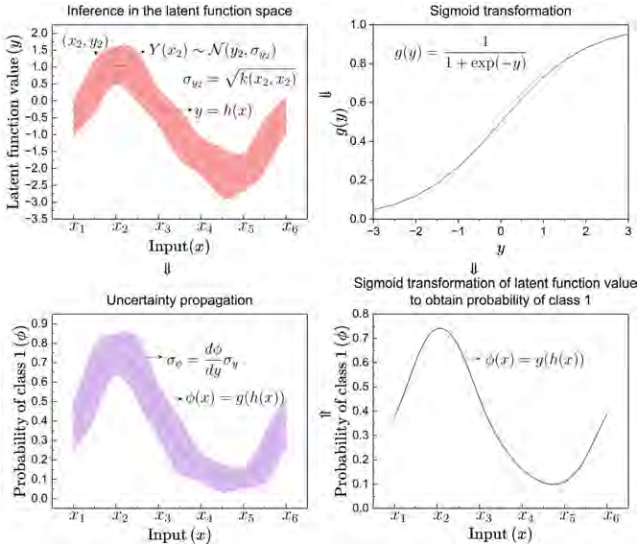

**Figure 1.** Uncertainty propagation to probability space.

## 2.4 Simulation study

A simulation study was designed to compare the performance of the three AL methods: **Method 1** using $\sigma_{\hat{c}}^2(\mathbf{x}_*)$ as the objective function (Equation (6)); **Method 2** using $\sigma_y^2(\mathbf{x}_*)$ as the objective function (Equation (5)) and **Method 3** using the proposed propagated uncertainty, $\sigma_\phi^2(\mathbf{x}_*)$ as the AL objective function (Equation 7). In all the three cases, the design of new experiments using the AL method involved seeking conditions where the corresponding objective function value is a maximum.

The steps involved in the simulation study are summarised in Figure 2. As explained in Figure 2, a classification dataset was first selected as the case study. The second step involved training of a selected classifier model on the full dataset selected in the first step. This trained model was assumed as the "True model" in the simulation study. Next, a limited number of preliminary experiments were designed using design of experiments (DoE) methods and the corresponding class labels were obtained by the simulation of the true model. The preliminary labelled dataset was used to train the GP model which is the test model to compare the AL methods. The GP model was subsequently trained using experiments designed through one of the AL methods.

It is often difficult to evaluate the performance of a classification model based on a single criterion. While accuracy is the simplest criterion, it could be misleading in case of imbalanced class problems. In addition, accuracy is a score based on the final class decision and not based on the statistical quality of model fitting. Therefore, in this work, the performance of the trained GP model was assessed using four different classification metrics: i) accuracy (%), ii) balanced accuracy (%), iii) ROC-AUC score, and iv) cross-entropy loss. The ROC-AUC score provides an aggregate performance measure of the classifier model across all possible threshold values on the predicted probabilities, which are ultimately used to decide class labels. The cross-entropy loss is a score that accounts for the statistical quality of the model fitting, evaluated with the expectation if the predicted class distribution is the same as the true class distribution (which is inferred from the sample data). A brief description of these metrics is provided in Table 1.

In the description of the accuracy and the balanced accuracy metrics, the variables $TP, TN, FP$ and $FN$ respectively indicate the number of true positive, true negative, false positive and false negative datapoints in the binary classification result. True positive are the datapoints that have been labelled as positive by the model (predicted label, $\hat{c} = 1$) and they are actually positive (observed label, $c = 1$), while false positive are the datapoints that have been labelled as positive by the model, but they are actually negative. The same logic applies to the definitions of true negative and false negative datapoints. The values of the metrics accuracy and balanced accuracy range between 0 and 100. The higher the values of these metrics, the better the performance of the classifier model. The ROC-AUC score is defined as the area under the receiver operating characteristic (ROC) curve [8]. The ROC-AUC score ranges from 0 to 1, with a value of 1 indicating perfect classification. The values

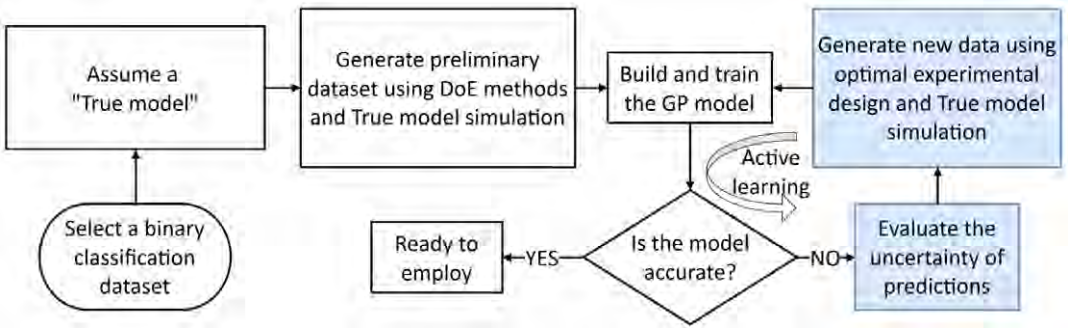

**Figure 2:** Steps involved in the simulation study to compare the different active learning methods.

closer to 1 indicate better classification performance. The cross-entropy loss is defined as the negative log-likelihood of the classifier given the true class labels. A lower cross-entropy loss value indicates better model performance.

**Table 1:** Classification metrics used for performance evaluation.

| Metrics | Description |
|---|---|
| Accuracy (%) | $\frac{TP+TN}{TP+TN+FP+FN}\times 100$ |
| Balanced accuracy (%) | $\frac{1}{2}\left(\frac{TP}{TP+FN}+\frac{TN}{TN+FP}\right)\times 100$ |
| ROC-AUC score | Area under the ROC curve |
| Cross-entropy loss | $-\frac{1}{n}\sum_{i=1}^{n}[c_i \log \phi_i + (1-c_i)\log(1-\phi_i)]$ |

## 3. CASE STUDY

A classification dataset was selected from our recently published work on antisolvent precipitation of ibuprofen particles in a continuous flow precipitator [4]. The classification dataset published in this work consisted of three input variables, which are provided in Table 2. As explained in [4], the dataset was formed from the flow precipitation experiments carried out by varying the inputs provided in Table 2. The experiments resulted in three categories of outcome, which were labelled as: i) class 0 – infeasible experiments, which caused fouling in the flow channels and hindered the particle size measurements, ii) class 1 – partially feasible experiments that caused deposition of fine particles in the flow channels, but produced particle size measurements, and iii) class 2 – fully feasible experiments with no fouling issues. In this work, this multiclass classification dataset was converted to a binary classification problem by treating experiments with class label 1 also as infeasible experiments with label 0. Naturally, the class label 1 was then used to denote all the feasible experiments. The binary classification dataset formed in this way from the original multiclass classification dataset reported in [4] was trained on an SVM model with rbf kernel function. The trained SVM model was assumed as the true model.

**Table 2:** Input variables in classification dataset.

| Input | Bound |
|---|---|
| Antisolvent flow rate (ml/min) | 1 – 4 |
| Antisolvent to solvent flow rate ratio (-) | 1 – 9 |
| Additive concentration (wt.%) | 0 – 3 |

## 4. RESULTS AND DISCUSSION

In the simulation study, eight preliminary experiments were first designed using Sobol sampling method applied to the inputs and their bounds shown in Table 2. Class labels for the preliminary experiments were generated using the true model simulations. The GP model was then trained on the preliminary dataset. Then, twenty-two new experiments were designed one at a time using a specific AL method. To compare the three AL methods, the simulation study included three separate runs, each starting with the same DoE experiments but using different AL methods for the subsequent experiment designs. The results of the simulation study are summarised in Figure 3. In panel (a), the figure provides the scatter plots of marginal histograms of the input condition and the class labels. In each marginal histogram plot, the scatter plot represents the joint distribution of the specific input variable and the class labels. The horizontal histogram represents the class distribution, and the vertical histogram represents the distribution of the specific input variable. In Figure 3 (a), the histograms of Method 2 suggest that the method resulted in an imbalanced classification dataset, with most of the experiments concentrated in the extreme regions (extremely high and extremely low values of the input variables). Upon reviewing the dataset generated in Method 2, a possible explanation is that the

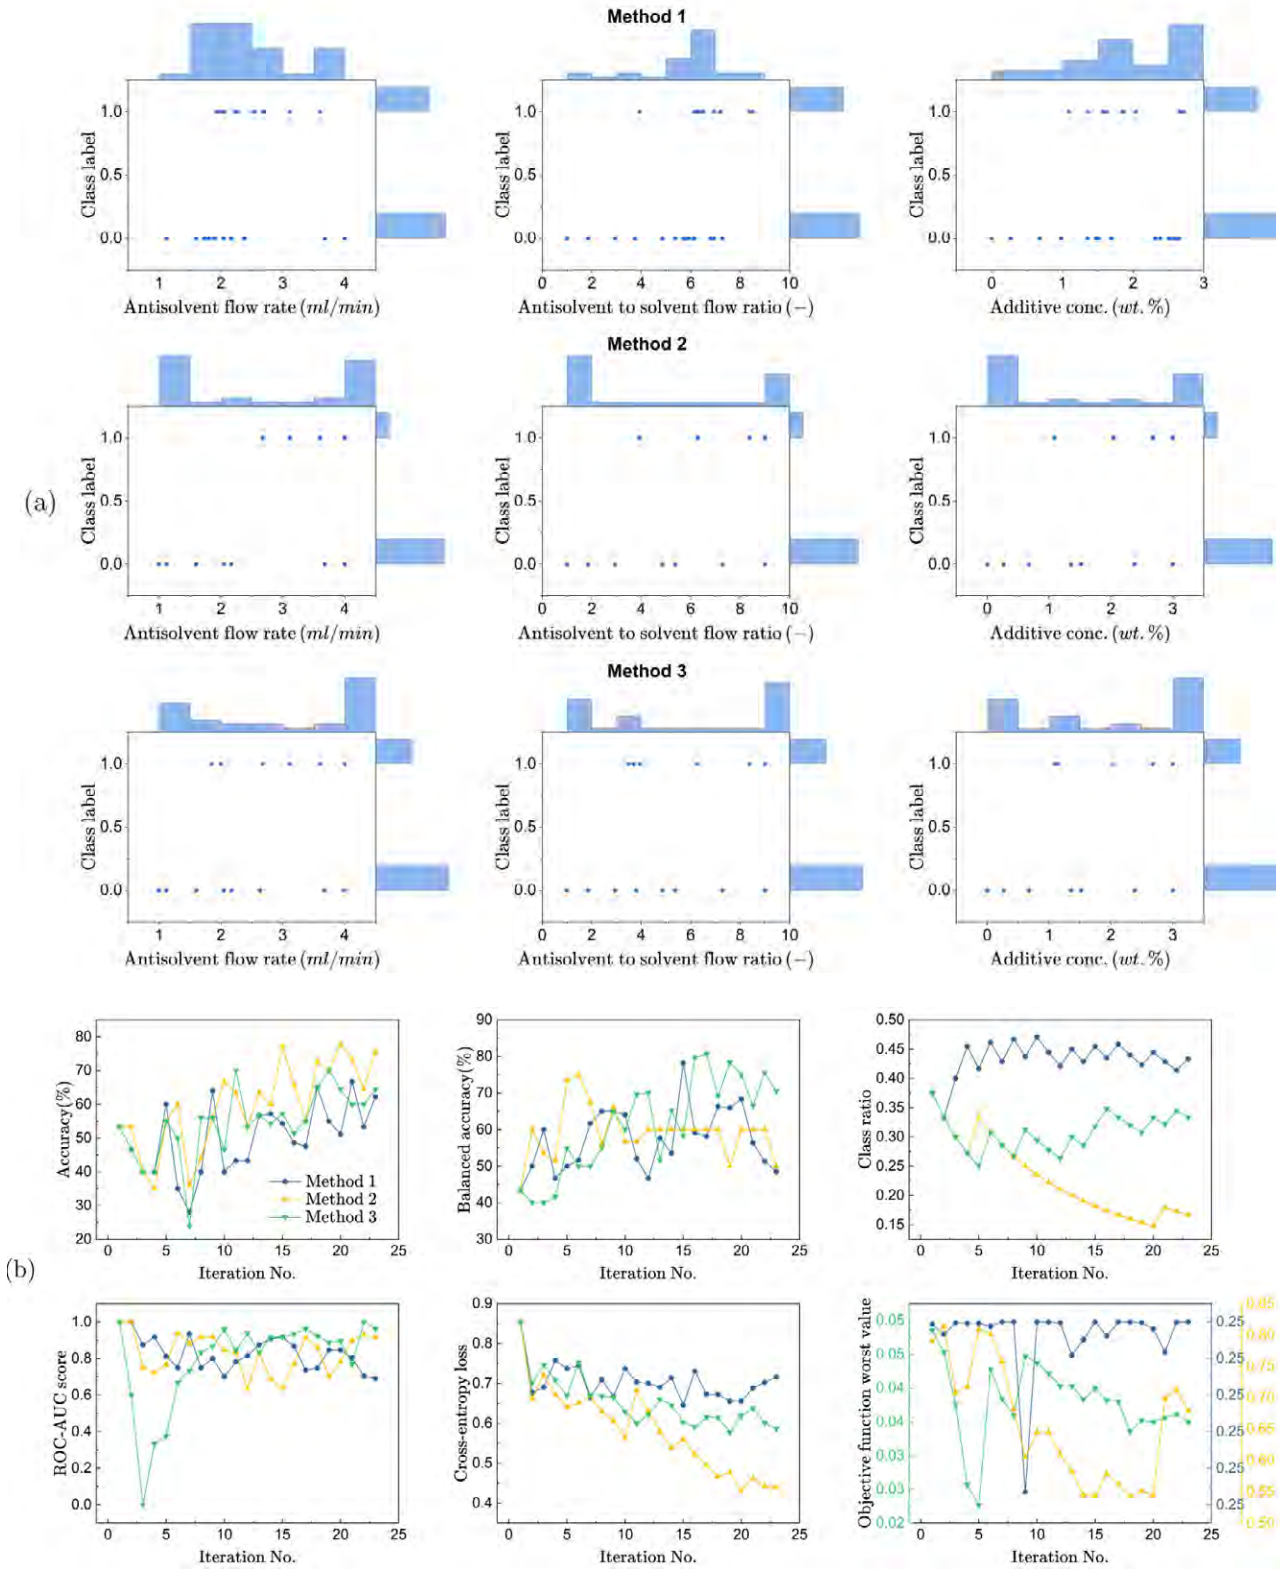

**Figure 3:** Comparison of the AL methods: (a) in terms of experimental design results and (b) in terms of the performance assessed using the classification metrics.

extreme regions were not explored in the initial experiments designed using Sobol sampling. This would have

led to a higher variance at the extreme points, prompting Method 2 to focus on these regions. Figure 3 (a) also indicates that compared to Method 2, the other methods resulted in a more balanced classification, with Method 1 producing the best results. Moreover, we observe that in Methods 1 and 3, the experiments are more evenly distributed, and hence more explorative.

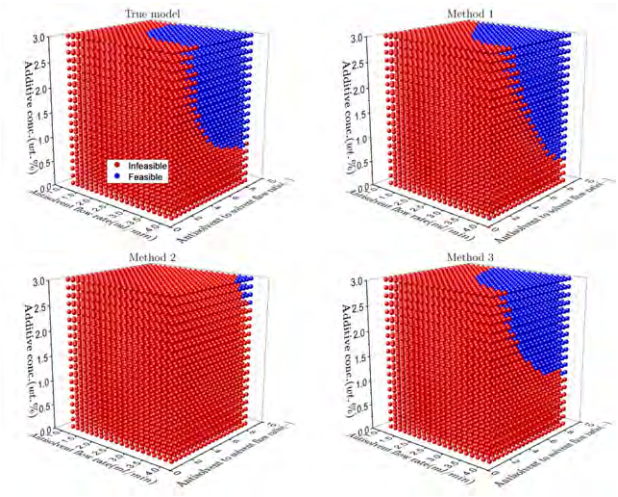

**Figure 4.** Simulations of the classifier models generated using the AL methods vs. the true model behaviour.

In Figure 3(b), the performance of classifier models developed using the three AL methods is evaluated using classification metrics averaged over five-fold cross-validation. While Method 2 shows higher classification accuracy, this is misleading due to the highly imbalanced dataset generated by this method. Balanced accuracy, which accounts for minority class contributions, shows how Method 3 performed best, scoring 70% compared to 48% for Method 1 and 50% for Method 2. Class ratios in Figure 3(b) and marginal distributions in Figure 3(a) reveal that Method 2 sampled many infeasible points, which were correctly classified but added limited learning value. This is evident from the poor decision boundary of Method 2 compared to the true model in Figure 4. Overall, Method 3 outperforms all the others by achieving the highest ROC-AUC score (0.96 compared to 0.91 for Method 2 and 0.69 for Method 1), good class balance (better than Method 2, but worse than Method 1), decreasing cross-entropy loss, and gradual reduction in the propagated uncertainty over the AL iterations. Its final classifier closely aligns with the true model, as shown in the simulation profiles of Figure 4.

## 5. CONCLUSION

We proposed a new method to quantify uncertainty in Bayesian classification. The proposed method focuses on propagating uncertainty from GP model predictions to the space of class probabilities. In a simulation study for binary classification, the method outperformed existing techniques in designing experiments that effectively train classifier models. Further studies will be needed to extend the applicability of the method to multiclass classification problems, and to validate its performance based on actual physical data.

## ABSTRACT

Individual-based modeling (IbM) has emerged as a powerful approach for studying microbial populations, offering a bottom-up framework to simulate cellular behaviors and their interactions. Unlike continuum-based models, IbM explicitly captures the heterogeneity and emergent dynamics of microbial communities, making it invaluable for studying spatially structured phenomena such as nutrient competition, biofilm formation, and colony interactions. However, IbM faces significant computational challenges, particularly in resolving spatial overlaps during simulations of large microbial populations. Traditional approaches, such as pairwise comparisons or kd-trees, are computationally expensive and scale poorly with population size. The Discretized Overlap Resolution Algorithm (DORA) introduces a novel grid-based solution to overcome these limitations. By encoding spatial information into an occupancy matrix, DORA achieves a time complexity of O(N), enabling efficient resolution of overlaps while maintaining spatial fidelity. To validate its capabilities, we applied DORA to a case study of microbial colony merging. Two scenarios were tested: (1) colonies inoculated 40 µm apart merged at the center due to nutrient depletion, and (2) colonies inoculated 120 µm apart remained separate, with a no-growth zone forming between them. In both cases, DORA replicated observed phenomena with high accuracy and demonstrated linear scalability, significantly reducing simulation time compared to traditional methods. DORA's computational efficiency and scalability position it as a robust tool for large-scale IbM simulations, advancing our ability to study complex microbial systems in diverse ecological and industrial contexts.

**Keywords**: Individual-based modeling, Grid-based algorithm, microbial ecology

## INTRODUCTION

Microbial populations are integral to a wide range of biochemical engineering applications, including wastewater treatment, bioreactor optimization, and the formation of biofilms on industrial and medical surfaces. Understanding and predicting the behavior of these populations require robust modeling frameworks capable of capturing individual cellular behaviors and the emergent dynamics of entire populations. Among these frameworks, Individual-based modeling (IbM) has emerged as a powerful computational framework for studying microbial systems. Unlike continuum-based models, which rely on averaged properties, IbM explicitly captures the behavior and interactions of individual cells, enabling a bottom-up analysis of population-level dynamics. By modeling each cell's local interactions, growth, division, and motility, IbM provides insights into how spatial structure influences social behaviors such as nutrient competition, metabolic cooperation, and quorum sensing [1,2]. These capabilities make IbM particularly valuable in industries where microbial interactions critically impact process performance, stability, and safety, such as food preservation, bioreactor optimization, wastewater treatment, and synthetic biology. By bridging microscale cell behavior with macroscale community dynamics, IbM offers practical insights into microbial processes across diverse natural, medical, and industrial applications [3].

Despite its strengths, IbM faces significant computational challenges, particularly when applied to large

microbial populations. A primary bottleneck lies in resolving spatial overlaps between cells, a critical step in maintaining spatial fidelity during simulations. Traditional methods for resolving overlaps often rely on pairwise comparisons between cells, relying on data structures such as kd-trees. These kd-trees recursively partition the simulation space to reduce the complexity of neighbor searches to O(log N), a substantial improvement over earlier array-based methods with $O(N^2)$ complexity. However, while such complexity is efficient in theory, it still poses a significant computational burden when considering the exponential growth of microbial populations in simulations. This rapid growth exacerbates the demands of spatial overlap resolution, particularly in dynamic simulations where cells grow, divide, and move frequently [4][5].

To address these challenges, we developed the Discretized Overlap Resolution Algorithm (DORA), a novel grid-based method designed to optimize the overlap resolution process. By encoding the spatial information of cells into a grid-based occupancy matrix, which then guides cellular movements, DORA circumvents the need for pairwise comparisons entirely, reducing computational complexity to $O(N^2)$. The algorithm operates in three main steps: (i) forward translation, where the spatial information of cells is encoded into an occupancy matrix; (ii) overlap resolution, which employs a diffusion-like process to iteratively redistribute excess occupancy values; and (iii) backward translation, where the resolved grid data are converted back into movement vectors for individual cells. This grid-based framework hence improves computational efficiency and allows the implementation of large-scale simulations [6].

DORA was integrated into MICRODIMS, an in-house IbM platform [7][8] built on the Repast Simphony toolkit [9]. MICRODIMS provides a flexible framework for simulating microbial growth dynamics, nutrient diffusion, and biofilm formation [10]. The integration of DORA significantly enhanced MICRODIMS's performance and enabled it to handle large-scale simulations of microbial colonies and biofilms within computationally feasible timeframes.

To further test DORA's performance and its applicability under biologically relevant conditions, we introduced a stochastic displacement component prior to the overlap resolution step. This component captures inherent biological variability, such as microbial motility and environmental fluctuations, thereby enhancing the realism of the simulations. As a case study, we applied DORA to simulate the merging of two microbial colonies—a process influenced by complex factors such as the distance between colonies, nutrient availability, and medium diffusivity [8]. This scenario presents a challenging test case for spatial fidelity, requiring the algorithm to accurately capture the conditions under which colony merging occurs. Our results demonstrated that DORA effectively modeled the process, providing high-fidelity representations of colony merging dynamics across different environmental conditions.

## MATERIALS AND METHODS

### The Discretized Overlap Resolution Algorithm (DORA)

Resolving spatial overlaps in IbMs traditionally relies on data structures such as arrays or kd-trees. Arrays store cell positions directly but require computationally expensive pairwise comparisons (complexity $O(N^2)$) [4]. Kd-trees improve efficiency by recursively partitioning space, reducing neighbor searches to O(log N) per query. However, dynamic simulations require frequent tree rebalancing due to cell movement and growth, increasing computational and memory overhead, especially at high cell densities [5].

DORA overcomes these limitations by discretizing the simulation space into an occupancy matrix, avoiding pairwise comparisons entirely and achieving an overall complexity of O(N). Additionally, DORA can incorporate a stochastic motion step before overlap resolution to introduce biologically relevant variability, such as microbial motility.

### Stochastic Motion

Before executing the main steps of the DORA algorithm, a stochastic displacement is applied to each cell. A random displacement vector $(\Delta x,\ \Delta y)$ is sampled from a Gaussian distribution:

$$\Delta x,\ \Delta y \sim N\ (0, \sigma^2) \tag{1}$$

where $\sigma$ represents the standard deviation of the displacement. The new cell positions are calculated as:

$$\mathrm{x}' = \mathrm{x} + \Delta \mathrm{x} \tag{2}$$

$$\mathrm{y}' = \mathrm{y} + \Delta \mathrm{y} \tag{3}$$

subject to the constraints of the simulation environment. This stochastic motion introduces biologically relevant noise into the simulation, simulating random fluctuations in cell movements.

### Forward Translation

The next step maps the spatial attributes of cells onto a discretized occupancy matrix, Ω, which divides the simulation environment into grid units of width w and height h. Each unit in the grid stores a value representing the fraction of its area occupied by cells.

For a cell centered at $(x_c, y_c)$ with radius $r$, its boundaries relative to the grid are calculated as:

$$x_{left/right} = x_c \pm \frac{r}{w} \tag{5}$$

$$y_{bottom/top} = y_c \pm \frac{r}{h} \quad (6)$$

The occupancy of a grid unit $(i, j)$ by cell $k$ is determined by the overlap between the cell and the grid unit, calculated as:

$$\Omega^k_{\{i,j\}} = \frac{horizontal\ overlap \times vertical\ overlap}{w \times h} \quad (7)$$

The horizontal overlap is computed as:

$$\max\left(0, \min\left(\mathrm{i}+1, \mathrm{x}_{\mathrm{right}}\right) - \max\left(\mathrm{i}, \mathrm{x}_{\mathrm{left}}\right)\right) \quad (8)$$

and similarly for the vertical overlap:

$$\max\left(0, \min\left(\mathrm{j}+1, \mathrm{j}_{\mathrm{top}}\right) - \max\left(\mathrm{j}, \mathrm{x}_{\mathrm{bottom}}\right)\right) \quad (9)$$

The total occupancy of grid unit $(i, j)$ is the sum of contributions from all cells overlapping the unit:

$$\Omega[\mathrm{i}][\mathrm{j}] = \sum_{\mathrm{k}} \Omega^k_{ij} \quad (10)$$

Values of $\Omega[\mathrm{i}][\mathrm{j}] < 1$ indicate under-occupied units, $\Omega[\mathrm{i}][\mathrm{j}] = 1$ represents fully occupied units, and $\Omega[\mathrm{i}][\mathrm{j}] > 1$ identifies over-occupied units requiring resolution.

## Overlap Resolution

Overlap is identified wherever $\Omega[\mathrm{i}][\mathrm{j}] > 1$. An excess matrix $E$ is defined to quantify the surplus occupancy:

$$E_{ij} = \max\left(0, \Omega_{ij} - 1\right) \quad (11)$$

The algorithm redistributes excess values iteratively across neighboring grid units within the Von Neumann neighborhood $N_{ij}$, which includes the four adjacent units (up, down, left, and right). The redistribution is governed by:

$$\Omega'_{ij} = \Omega_{ij} - \alpha \times \left(E_{ij} - \frac{1}{4} \sum_{(k,l) \in N_{ij}} E_{kl}\right) \quad (12)$$

where $\alpha$ is a diffusivity factor that ensures numerical stability. A motion tensor $M$ is used to track the directional displacements required to resolve overlaps. For a grid unit $(i, j)$ and a neighboring unit $(k, l)$, the displacement in direction $d$ is updated as:

$$M^d_{ij}(\mathrm{t}+1) = M^d_{ij}(\mathrm{t}) + \alpha \times \frac{1}{4}(E_{ij} - E_{kl}) \quad (13)$$

## Backward Translation

In the final step, the computed displacements in the motion tensor M are translated back to movement vectors for individual cells. For a grid unit $(i, j)$ occupied by a cell, the local movement vector is:

$$\left(v_{x_{ij}}, v_{y_{ij}}\right) = \left(M^{right}_{ij} - M^{left}_{ij}, M^{top}_{ij} - M^{bottom}_{ij}\right) \quad (14)$$

For cells spanning multiple grid units, the overall movement vector is determined by summing contributions from all occupied units:

$$V_x = \sum_{(i,j) \in Cell's grid\ units} v_{x_{ij}} \quad (15)$$

$$V_y = \sum_{(i,j) \in Cell's grid\ units} v_{y_{ij}} \quad (16)$$

To optimize computational efficiency, the simulation dynamically determines the active simulation area, restricting calculations to the region where cells are present. Let $x_c$ and $y_c$ denote the coordinates of all cells. To optimize computational efficiency, the simulation restricts calculations to the active region, defined as:

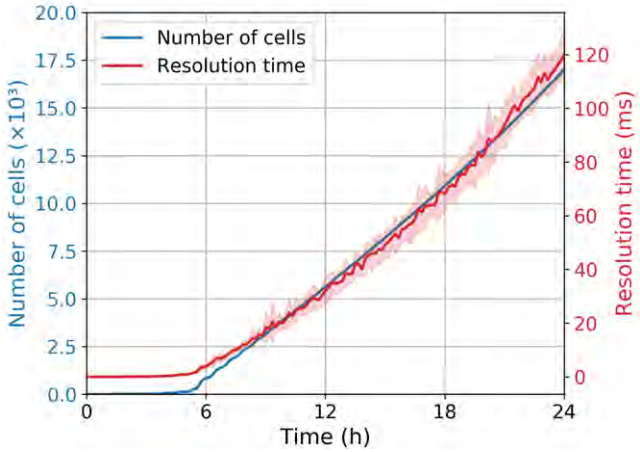
$$Left, Right = \max(0, \min(x_c) - \Delta), \min(W, \max(x_c) + \Delta) \quad (17)$$

where $\Delta$ represents a buffer margin added around the bounding box to prevent edge effects, and $W$ is the total width of the simulation domain. And similarly, for $Bottom, Top$. The algorithm operates only within the box:

$$\mathrm{B} = \{(x, y) \mid Left \le x \le Right, Bottom \le y \le Top\} \quad (18)$$

By dynamically restricting calculations to $\mathrm{B}$, DORA minimizes unnecessary computations, improving efficiency.

DORA is implemented in the MICRODIMS platform, built on the Repast Simphony toolkit. The simulation environment is discretized into a $600 \times 600$ μm grid with periodic boundary conditions. Cell growth follows Monod kinetics, and substrate diffusion is resolved using the Forward-Time Central-Space (FTCS) scheme. Temporal resolution is achieved by updating cell positions and metabolic processes every 0.01 min.



# RESULTS

Modeling cell collisions and resolving spatial overlaps are critical steps in IbM of cells. To test the DORA algorithm's ability to reproduce complex spatial phenomena, we conducted a case study of colony merging, previously explored by Tack et al. [8]. Depending on local conditions, diffusivity, nutrient concentration, inoculation density, and the distance between inocula, colonies close to each other may either merge or remain separate.

## Scenario 1: Merging of Colonies

In the first scenario, we inoculated the medium with two cells positioned 40 μm apart. The results, shown in Figure 1, indicate that the colonies continued to grow until they merged at the center. The DORA algorithm handled spatial resolution effectively during both the growth phase and the merging process, successfully replicating this spatial phenomenon.

In Figure 1(a), we plotted the evolution of the population size and the resolution time required to resolve spatial overlaps at each simulation step over 24 hours. The results represent the mean of 20 simulation runs, with the line thickness indicating the standard deviation. Notably, the growth curve is more linear rather than exponential, which is attributed to the limited diffusivity of the medium. Additionally, the resolution time curve closely follows the population growth, a result of the

(a)

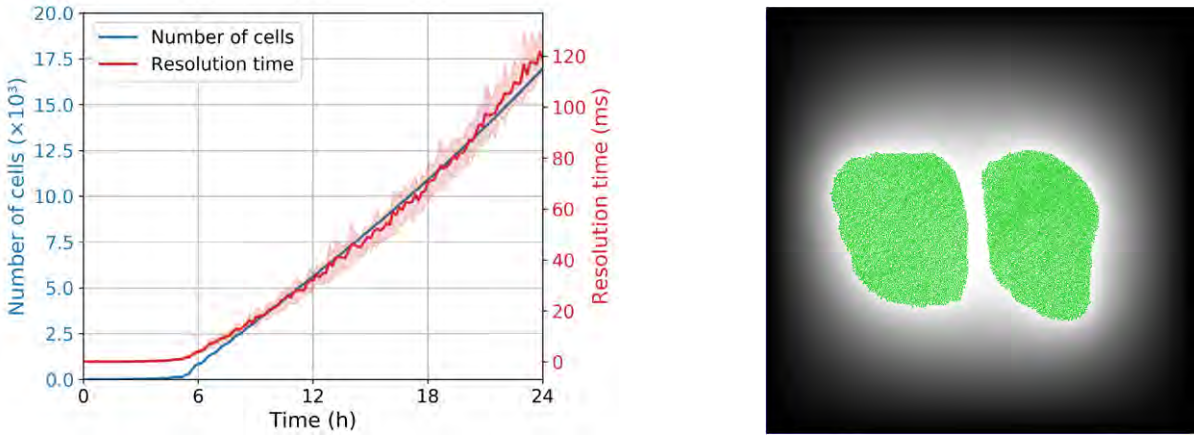
(b)

**Figure 1:** Merging of two colonies: simulation of two colonies inoculated with one cell each, positioned 40 µm apart, and grown for 24 hours. (a) Evolution of the number of cells over time (blue, left y-axis) and the resolution time for resolving overlaps between cells at each time step in milliseconds (red, right y-axis). The lines represent the mean of 20 simulation runs, and the line thickness indicates the standard deviation. (b) Snapshot of the simulation at the end of 24 hours, showing the merging of the two colonies. Microbial cells are shown in green, while black shading represents nutrient concentration. Areas appearing white correspond to depleted nutrient zones.

algorithm's time complexity of O(N). This highlights the efficiency of the DORA algorithm compared to the original array-based overlap resolution method with a time complexity of $O(N^2)$. The reduced computational demands decreased the total simulation time to approximately 10 minutes per run, compared to several hours required in the original simulation.

Another observation is the asymmetry between the two colonies despite the symmetric initial conditions. This can be attributed to the stochastic component incorporated into the DORA algorithm, which introduces variability in spatial dynamics and accounts for the variance observed across the simulation runs.

## Scenario 2: Non-Merging of Colonies



In the second scenario, the two cells were inoculated at 120 µm apart. As shown in Figure 2, the colonies grew by consuming the nutrients in the intercolony region. Due to the larger initial distance, the colonies grew to relatively larger sizes, completely depleting the nutrients between them and creating a no-growth zone in-between that acts as a barrier to merging.

While this scenario is spatially less complex than the merging case, the DORA algorithm successfully replicated the phenomenon. Figure 2(a) presents the mean population size and resolution time for 20 runs, with the standard deviation shown by the line thickness. The growth dynamics and asymmetry between the colonies observed in this scenario were consistent with the first case. The incorporation of stochasticity accounts for the spatial variability and the variance in the results.

The spatial interactions captured by DORA and reproduced in these simulations reflect fundamental microbial behaviors typically observed in structured environments. In such settings, colony growth is shaped by nutrient availability, diffusion constraints, and spatial competition, where interactions occur not only between individual cells but also at the colony level. The observed merging and non-merging results align with previous experimental and modeling studies, which have shown that microbial colonies can either coalesce or remain spatially segregated depending on local resource depletion and diffusivity. For example, studies on Escherichia coli K-12 growing in structured media have demonstrated that higher inoculum densities lead to intensified intercolony competition, often resulting in smaller final colony sizes and the formation of distinct separation zones between neighboring populations.

Beyond computational efficiency, the ability to model colony merging and segregation has implications for understanding microbial coexistence and strain diversity. In natural and engineered microbial ecosystems, spatial structuring plays a crucial role in determining whether different strains or species compete, coexist, or evolve specialized niches. By capturing these interactions, DORA provides a valuable framework for exploring how spatial constraints influence microbial diversity, community stability, and ecological succession.

These results demonstrate that the DORA-based IbM efficiently reproduces both merging and non-merging colony behaviors, maintaining high spatial fidelity while significantly reducing computational overhead. This

(a) (b)

**Figure 2:** Non-merging of two colonies: simulation of two colonies inoculated with one cell each, positioned 120 µm apart, and grown for 24 hours. (a) Evolution of the number of cells over time (blue, left y-axis) and the resolution time for resolving overlaps between cells at each time step in milliseconds (red, right y-axis). The lines represent the mean of 20 simulation runs, and the line thickness indicates the standard deviation. (b) Snapshot of the simulation at the end of 24 hours, showing the two colonies remaining separate and failing to merge. Microbial cells are shown in green, while black shading represents nutrient concentration. A starvation zone emerges between the two colonies, appearing as a white region where nutrients have been fully depleted, preventing further growth and colony merging.

establishes the DORA algorithm as a scalable and reliable tool for modeling complex spatial phenomena in microbial systems.

## CONCLUSION

This study demonstrates the effectiveness of the DORA algorithm in resolving spatial overlaps and replicating complex growth phenomena in microbial simulations. Through the case study of microbial colony merging, DORA was shown to accurately model both merging and non-merging scenarios under varying inoculation distances. By leveraging a grid-based framework with a time complexity of O(N), DORA achieved significant reductions in computational overhead compared to traditional methods, enabling faster simulations without sacrificing spatial fidelity. The incorporation of stochastic components introduced biologically relevant variability, further validating the robustness of the algorithm.

By improving the computational feasibility of large-scale simulations, DORA enhances the applicability of IbMs in biochemical engineering, ecological modeling, and bioprocess optimization.

## ABSTRACT

Pressure swing adsorption (PSA) is an energy-efficient technology for gas separation, while the multi-objective optimization of PSA is a challenging task. To tackle this, we propose a hybrid optimization framework, which integrates three steps. In the first step, we establish surrogate models for the constraints using Gaussian processes (GPs) and employ multi-objective Bayesian optimization to search for feasible points that satisfy the constraints. In the second step, we establish surrogate models for the objective function and constraints using GPs and utilize constrained multi-objective Bayesian optimization to search for an approximate Pareto front. In the third step, we perform a local search based on the approximate Pareto front. By employing the trust region filter method, we construct quadratic models for each constraint and objective function and refine the Pareto front to achieve local optimality. This framework demonstrates the efficiency of Bayesian optimization and the local optimality of the trust region method. A comparison with the popular evolutionary algorithm, Nondominated Sorting Genetic Algorithm II (NSGA-II), showed that this framework had a higher hypervolume of the Pareto front while halving the runtime and reducing the number of simulations by a factor of 20.

**Keywords**: Pressure swing adsorption, data-driven optimization, machine learning, multi-objective optimization

## INTRODUCTION

Optimizing large-scale partial differential algebraic equation (PDAE) systems has always been a challenging task in chemical engineering. In recent years, there has been an increasing demand for multi-objective optimization of PDAE systems with coupled constraints. Therefore, it is necessary to develop an optimization framework that can be used to solve such problems. The main challenges in optimizing PDAE systems with coupled constraints include:

1. The coupled constraints with PDAEs make it difficult to obtain feasible solutions.
2. Solving PDAEs is very expensive, and satisfactory Pareto fronts need to be obtained within a limited number of solution iterations.
3. The gradient is difficult to obtain, which greatly restricts the use of gradient-based algorithms.

Pressure swing adsorption (PSA) for gas separation is a typical PDAE problem and the most common research subject. Researchers preferred to use Artificial Neural Networks to construct surrogate models and use Nondominated Sorting Genetic Algorithm II (NSGA-II) [1] for solving it [2]. While employing this approach can lead to an enhanced Pareto front, it necessitates the utilization of numerous PDAE problem solutions for acquiring training samples. Recently, Hao et al. [3] developed a hybrid optimization framework efficiently solving unconstrained PSA optimization problems using the Thompson sampling efficient multi-objective optimization (TSEMO) algorithm and DyOS, but it cannot handle PSA problems with coupled constraints. Pini et al. [4] used penalty function method to handle coupled constraints, but the selection of penalty function parameters becomes a new issue.

Therefore, we will develop a hybrid optimization framework that combines the advantages of multi-objective Bayesian optimization and local search to handle large PDAE problems with coupled constraints. This

framework can obtain a satisfactory Pareto front within a limited budget and handle challenging coupled constraints.

## PROBLEM STATEMENTS

A PSA process usually operates cyclically with at least three steps: high-pressure adsorption, low-pressure desorption and pressurisation. Additional steps, such as pressure equalisation, rinse, and purge, are often incorporated to improve process performance. Figure 1 presents an example of the four-step PSA cycle for $CO_2/N_2$ separation from Haghpanah et al. [5], which comprises feed pressurisation, adsorption, blowdown and evacuation.

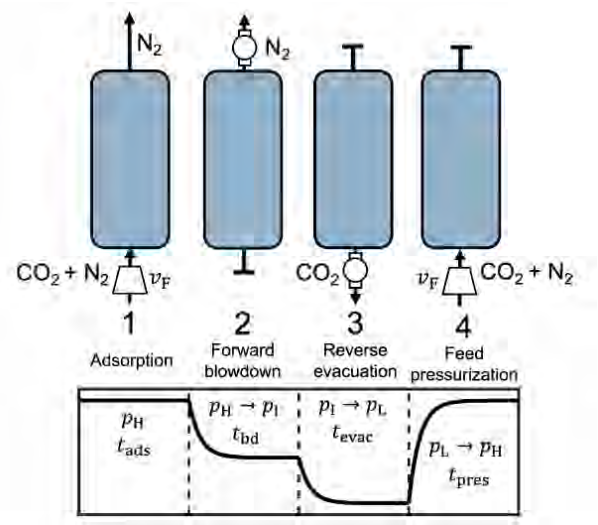

**Figure 1.** Schematic representation of the four-step PSA cycle for $CO_2/N_2$ separation

The problem can be stated as follows,

### Given:

1. The number of adsorption bed, adsorbent layers.
2. Feed conditions such as flow rate, composition, temperature, and pressure.
3. Bed configuration, physical properties of the adsorbent and the corresponding adsorption isotherms.
4. Product purity requirement.

### Determine:

1. The time for each step.
2. Operating conditions, such as operating pressures and flow velocity.

### Assumptions:

- Gas phase follows ideal gas law.
- Non-isothermal adsorption process.
- The bulk flow pattern follows a plug flow model.
- The adsorption equilibrium is described by a dual-site Langmuir model with pure component isotherms dependent on gas phase concentration.
- The mass transfer is described by a linear driving force (LDF) model where the mass transfer resistance is controlled by the molecular diffusion in the macropores.
- The heat of adsorption of each gas component is constant.
- Instantaneous heat transfer between bulk fluid and adsorbent.
- Uniform bed with constant bed void fraction, particle porosity and particle size.
- No radial gradients in concentration, temperature, or pressure.

The objectives are to minimize energy cost and maximize productivity simultaneously while meeting cyclic steady-state (CSS) condition and requirements of product purity and recovery.

The dimensionless form of the PSA rigorous model equations from Liao et al. [6] is used in this work, which is a simplified version from that in Haghpanah et al. [5]. This is because the simplified model effectively captures the full dynamics of the PSA system without loss of accuracy whilst markedly improving simulation efficiency [6]. The PSA model equations are presented in Eqs(1-6). This model consists of PDEs that govern conservation of mass, momentum and bed energy, an ODE for calculating the fractional solid loading, complemented by the dual-site Langmuir adsorption isotherms and the Ergun equation that establishes the correlation between the pressure gradient and the local interstitial velocity. Two additional assumptions are made as follows in the model of Liao et al. [6]:

- The impact of axial dispersion is omitted.
- The column wall temperature is held constant at 298.15K.

$$\frac{\partial y_i}{\partial \tau} = -\frac{\bar{T}}{\bar{P}}\frac{\partial}{\partial Z}\left(\frac{y_i \bar{P}}{\bar{T}}\bar{v}\right) - \Psi\frac{\bar{T}}{\bar{P}}\frac{\partial x_i}{\partial \tau} - \frac{y_i}{\bar{P}}\frac{\partial \bar{P}}{\partial \tau} - \frac{y_i}{\bar{T}}\frac{\partial \bar{T}}{\partial \tau} \quad (1)$$

$$\frac{\partial \bar{P}}{\partial \tau} = -\bar{T}\frac{\partial}{\partial Z}\left(\frac{\bar{P}}{\bar{T}}\bar{v}\right) - \Psi\bar{T}\sum_{i=1}^{n_{comp}}\frac{\partial x_i}{\partial \tau} + \frac{\bar{P}}{\bar{T}}\frac{\partial \bar{T}}{\partial \tau} \quad (2)$$

$$\frac{\partial \bar{T}}{\partial \tau} = -\Omega_1\frac{\partial}{\partial Z}(\bar{v}\bar{P}) - \Omega_2\bar{T}\sum_{i=1}^{n_{comp}}\frac{\partial x_i}{\partial \tau} + \sum_{i=1}^{n_{comp}}(\sigma_i\frac{\partial x_i}{\partial \tau}) + -\Omega_3(\bar{T} - \bar{T}_w) - \Omega_1\frac{\partial \bar{P}}{\partial \tau} \quad (3)$$

$$\frac{\partial x_i}{\partial \tau} = \alpha_i(x_i^* - x_i) \quad (4)$$

$$q_i^* = \frac{q_{sb,i} b_i c_i}{1+\sum_{i=1}^{n_{comp}} b_i c_i} + \frac{q_{sd,i} d_i c_i}{1+\sum_{i=1}^{n_{comp}} d_i c_i} \quad (5)$$

$$\frac{\partial \bar{P}}{\partial Z} = -\frac{150}{4}\frac{1}{r_p^2}\left(\frac{1-\varepsilon}{\varepsilon}\right)^2 \frac{v_0 L}{P_0}\mu\bar{v} + \frac{1.75}{2}\frac{1}{r_p}\frac{1-\varepsilon}{\varepsilon}\frac{v_0^2 L}{P_0}\rho_g|\bar{v}|\bar{v} \quad (6)$$

All decision variables (denoted as x) must satisfy their respective lower and upper bounds (Table 1).

$$x_L \le x \le x_U \quad (7)$$

**Table 1:** Bounds of decision variables.

| Variable | Lower bound | Upper bound |
|---|---|---|
| $t_{ads}$ [s] | 20 | 100 |
| $t_{bd}$ [s] | 30 | 200 |
| $t_{evac}$ [s] | 30 | 200 |
| $P_L$ [bar] | 0.1 | 0.5 |
| $P_I$ [bar] | 0.13 | 3 |
| $P_H$ [bar] | 1 | 10 |
| $v_{feed}$ [m/s] | 0.1 | 2 |

Some logical constraints may be imposed for the operating pressures to avoid unrealistic pressure values.

$$P_I \ge P_L + \Delta P \quad (8)$$

$$P_H \ge P_I + \Delta P \quad (9)$$

where $\Delta P$ is defined as the minimum allowable difference between $P_L$, $P_I$ and $P_H$. In this work, $\Delta P$ =0.01bar. The objectives are to minimize energy cost and maximize productivity simultaneously while meeting CSS condition and requirements of product purity and recovery, which can be calculated below,

$$Purity = \frac{n_{CO_2,out}^{evac}}{n_{CO_2,out}^{evac}+n_{N_2,out}^{evac}} \times 100\% \quad (10)$$

where $n_{CO_2,out}^{evac}$ and $n_{N_2,out}^{evac}$ are the amounts of $CO_2$ and $N_2$ extracted during the evacuation step, respectively.

$$Recovery = \frac{n_{CO_2,out}^{evac}}{n_{CO_2,in}^{pres}+n_{CO_2,in}^{ads}} \times 100\% \quad (11)$$

where $n_{CO_2,in}^{pres}$ and $n_{CO_2,in}^{ads}$ are the amounts of $CO_2$ fed in the pressurization and adsorption steps.

$$CSS\ condition = st(t) - st(t+t_{cycle}) \le \varepsilon \quad (12)$$

where $st(t)$ and $st(t+t_{cycle})$ is defined as the state variables at a given time $t$, and $\varepsilon$ represents the tolerance vector.

$$Productivity = \frac{n_{CO_2,out}^{evac}}{V_{bed} \cdot t_{cycle}} \quad (13)$$

where $V_{bed}$ is the volume of the adsorption bed, and $t_{cycle}$ is the total amount of time required for one complete cycle.

$$Energy\ consumption = \frac{E_{ads}+E_{bd}+E_{evac}+E_{pres}}{m_{CO_2,out}^{evac}} \quad (14)$$

where $E_{ads}$, $E_{bd}$, $E_{evac}$ and $E_{pres}$ are the amounts of energy consumed by the four steps, and $m_{CO_2,out}^{evac}$ represents the mass of $CO_2$ extracted during the evacuation step.

The multi-objective optimization problem (denoted as MOOP) can be stated as follows,

$$\begin{aligned} (\mathbf{MOOP}) \quad & \max \quad Productivity \\ & \min \quad Energy\ consumption \\ \text{s.t.} \quad & \text{Eqs. (1)-(6)} \\ & \text{Eqs. (7)-(14)} \\ & \text{Purity} \geqslant 95\% \\ & \text{Recovery} \geqslant 90\% \\ & \text{Boundary conditions} \end{aligned}$$

The multi-objective optimization (MOOP) is difficult to solve due to the challenge of meeting two coupled constraints and the high cost of simulations. The two constraints, purity and recovery of $CO_2$ product, conflict with each other and are difficult to satisfy simultaneously. Moreover, the expensive PDAE solving process requires the use of efficient surrogate models to reduce optimization time. Therefore, it is necessary to develop a hybrid framework to efficiently optimize the PSA process design.

## HYBRID OPTIMIZATION FRAMEWORK

A hybrid optimization framework is developed to solve the PSA problem. This framework combines multi-objective Bayesian optimization with a trust region algorithm, leveraging the strengths of both to solve expensive constrained multi-objective black-box problems within acceptable computational resources. Multi-objective Bayesian optimization (MOBO) is a global optimization algorithm that constructs surrogate models based on validated data points using a Gaussian process and updates the surrogate model by incorporating new validated points obtained in each iteration. In each iteration, an acquisition function is used as the evaluation criterion to determine the next sampled point for validation. Therefore, multi-objective Bayesian optimization can be used for efficient global search. Conversely, the trust region filter method (TRF) used in this work, constructs a quadratic surrogate model within a region defined by the trust radius to obtain a local optimal solution. The trust radius and center point are then adjusted based on the optimal solution, iteratively, until the hypervolume increment falls below a specified threshold. Therefore, this trust region algorithm is local, deterministic, and derivative-free. The hybrid framework combines these two approaches, executing a "rough to refined" search strategy to efficiently solve expensive black-box problems. Figure 2 shows the overall optimization process.

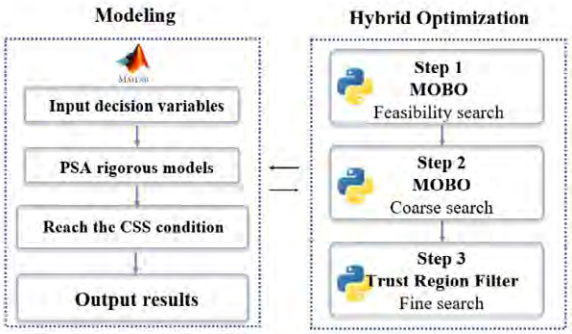

**Figure 2.** The overall PSA process optimization Schematic

The framework consists of three steps:

1. Searching for feasible points under unconstrained conditions using the multi-objective Bayesian optimization algorithm.
2. Searching for a rough Pareto front that satisfies the constraints based on the feasible points.
3. Obtaining an accurate Pareto front based on the rough Pareto front using the trust region method.

In the first step, our objective is to obtain feasible combinations of decision variables (feasible points) that satisfy the constraints. To achieve this, we treat the PSA problem as an unconstrained problem (in this phase, the decision variables remain unchanged, while the objective function becomes the two constraints: purity and recovery). In this way, we can use a multi-objective Bayesian optimization algorithm (e.g., TSEMO [7]) for solving. TSEMO first uses Latin hypercube sampling to randomly sample this black-box problem (in this experiment, 35 initial sampling points are extracted). After obtaining the starting point set, Gaussian surrogate models are constructed for each of the two constraints. After determining the acquisition function, NSGA-II is used for optimization. During the optimization process, we need to add two constraints (purity$\geqslant$95%, recovery$\geqslant$90%) to ensure that the obtained points satisfy the two constraints as much as possible. Then, new data points are validated, and the data set is updated. The new data set is used to construct a new Gaussian surrogate model, and this process repeats iteratively. After multiple iterations, we obtain a set of points that satisfy the constraints of purity and recovery.

In the second step, our objective is to obtain a rough Pareto front concerning energy consumption and productivity. We still use a specialized multi-objective Bayesian optimization (MOBO) to construct a surrogate model for solving this problem. First, we select a reference point $P_{refer}$ (Productivity=0, Energy consumption=600kW·h/ton) and calculate the current hypervolume based on the feasible point set. Then, we use the entire data set to construct Gaussian surrogate models for purity, recovery, energy consumption, and productivity. The hypervolume improvement expectation with constraints is used as the acquisition function. This hypervolume improvement expectation can be expressed as:

$$EHVI_{con} = I_c \cdot EHVI \tag{15}$$

where $I_c$ represents the probability of satisfying the purity and recovery constraints [8], and $EHVI$ represents the hypervolume improvement expectation under unconstrained conditions [9]. We use NSGA-II to optimize the acquisition function and determine the next evaluation point. After simulation, the data set, Gaussian surrogate model, and hypervolume are updated, and this process repeats iteratively. After multiple cycles, we obtain a rough Pareto front.

In the third step, our goal is to optimize the Pareto front. After the two steps of rough search, we have obtained points that satisfy the constraints and a rough Pareto front. However, there great gaps between the points on the Pareto front, and the hypervolume can improve further. Therefore, we need to use local search to further improve the Pareto front. We use the trust region method [10,11] to enhance the Pareto front. First, we select the points on the Pareto front and construct four local quadratic surrogate models (for purity, recovery, energy consumption, and productivity) within a predetermined trust radius. Based on these quadratic surrogate models, we construct a function for hypervolume increment and find the maximum value of hypervolume increment within the trust region. After validation, if the point significantly improves the hypervolume, the trust radius is increased; if the point slightly improves the hypervolume, the trust radius remains unchanged; if the point cannot improve the hypervolume, the trust radius is reduced. The termination conditions are set to an improvement less than $10^{-3}$. After performing this process for each point in the trust region, the algorithm terminates, and we obtain the final Pareto front. Figure 3 shows the workflow of the hybrid optimization framework.

## RESULTS AND DISCUSSION

As a comparison, we use NSGA-II to solve this problem to verify the computational efficiency and accuracy of this framework. In the hybrid optimization framework mentioned above, the first step employs the TSEMO algorithm implemented in MATLAB, while the second and third steps utilize optimization algorithms implemented in Python. The PSA numerical simulation model is solved in MATLAB, and the results are called through MALAB Engine API. All experiments were conducted on an Intel computer with 16 cores and 32GB memory. The Python version used was 3.10.0, and the MATLAB version was 2023a.

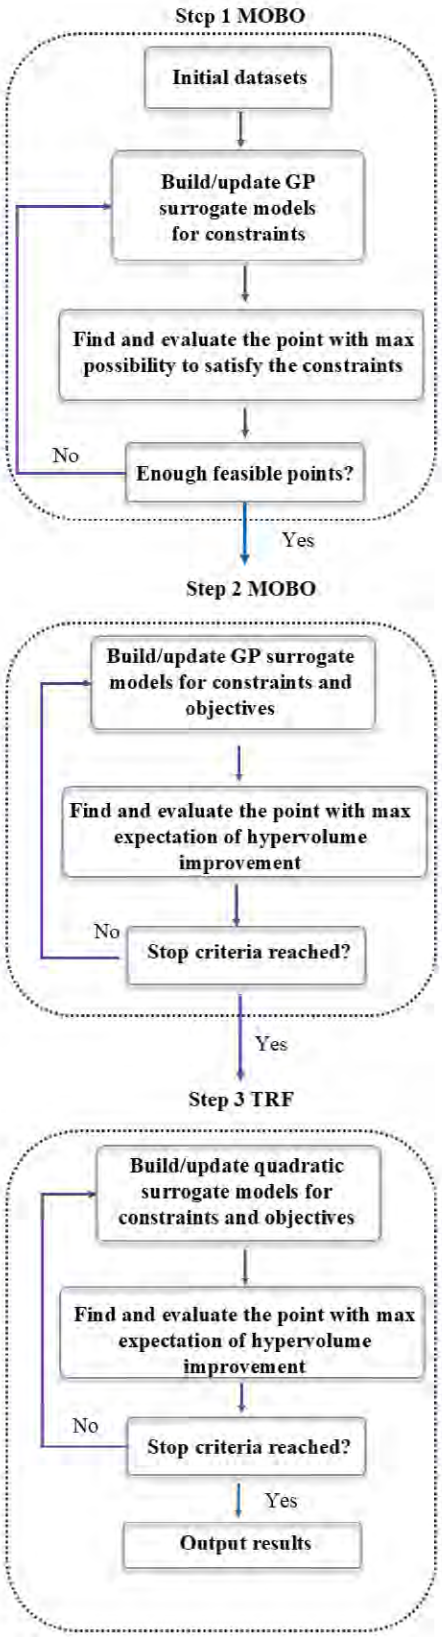

**Figure 3.** Workflow of the hybrid optimization framework

The first step of this hybrid optimization framework is to efficiently search for feasible points using multi-objective Bayesian optimization. In this step, we utilize the TSEMO algorithm as the external optimizer. To initialize the TSEMO algorithm, 35 sets of decision variables were randomly selected using Latin hypercube sampling and numerically simulated to obtain corresponding outputs. These data sets were used to train Gaussian process models. Based on these Gaussian processes, TSEMO evaluates the decision variable combinations that are most likely to satisfy the constraints and performs simulations. Subsequently, the simulation results are added to the entire data set to update the GP model for the next iteration. In this case, we conducted 300 simulations in the first step and recorded the increasing trend in the number of feasible points. When we conducted 300 simulations, we obtained 44 feasible points. However, conducting excessive simulations in the first step would prolong the time for building the Gaussian process model in the second step. Moreover, 44 feasible points are already sufficient to establish the hypervolume reference for productivity and energy consumption. To balance the efficiency of the second step's search, we only use 300 simulations in the first step before proceeding to the second step. In this step, with a wall time of 1.5 hours, an initial Pareto front with a hypervolume of 194.55 was obtained.

In the second step of this hybrid optimization framework, we optimize the original problem based on the feasible points obtained using multi-objective Bayesian optimization (MOBO). Firstly, we calculate the initial hypervolume reference value using the feasible points obtained in the first step. Then, we establish a multi-output Gaussian process model using all the data points. Using the $EHVI_{con}$ acquisition function, we search for the next set of decision variable combinations that are most likely to make progress. After performing simulations, we recalculate the hypervolume and update the data set and Gaussian process for the next iteration. In the second step, we conducted 600 simulations and obtained a rough Pareto front that cannot guarantee local optimality. As the number of simulations increases, the hypervolume also stabilizes and increases. However, after surpassing 500 simulations, the growth trend of the hypervolume noticeably slows down. It can be observed that when the number of simulations reaches 600, the efficiency of improving the hypervolume becomes extremely low. Therefore, we decided to stop the multi-objective Bayesian optimization at 600 simulations and proceed to the third step, where we use a local optimization algorithm to refine the Pareto front. In this step, with a wall time of 5.9 hours, a Pareto front with a hypervolume of 358.13 was obtained.

In the third step, the trust region filter method, a derivative-free local optimization method, will be employed

to enhance the hypervolume. The feasible points on the rough Pareto front obtained in the second step will serve as the starting points for the search. Sampling within the trust region of these points, local quadratic models will be constructed to optimize the hypervolume. After each iteration, the hypervolume will be recalculated, and the process will continue until the convergence condition is met. A total of 5737 simulations were conducted in the local search. In this step, with a wall time of 12.8 hours (8 cores), a Pareto front with a hypervolume of 429.28 was obtained.

To assess the performance of this hybrid optimization framework, we also employed NSGA-II to solve the problem. We utilized NSGA-II to solve the problem three times, selecting the best result from the obtained set. In the process of solving the problem with NSGA-II, a total of 600 iterations were executed. Each iteration consisted of a population of 250, calculated using 8 cores, taking a wall time of 44.3 hours. The resulting hypervolume of the Pareto front obtained was 373.73. Figure 4 shows the Pareto fronts of the hybrid optimization framework and NSGA-II. Table 3 presents a comparative analysis of the optimization performance between the hybrid optimization framework and NSGA-II. The results demonstrate that the hybrid approach yielded a 14% increase in hypervolume and a 62.5% augmentation in the number of Pareto front solutions relative to NSGA-II. The hybrid optimization framework demonstrates the ability to identify feasible points with an energy consumption close to 500 and a productivity of 5, showing superior global search capability compared to NSGA-II under limited wall time. Additionally, the search time of the hybrid optimization framework is only half of the wall time of NSGA-II, indicating significantly higher search efficiency. In summary, the hybrid optimization framework developed in this study effectively addresses the multi-objective optimization problem with coupled constraints.

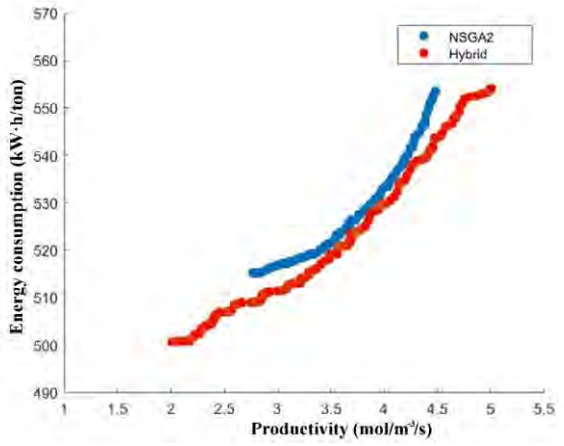

**Figure 4.** Hypervolume comparison between hybrid optimization framework and NSGA-II

**Table 3:** Performance Comparison

| Method | Hybrid optimization framework | NSGA-II |
|---|---|---|
| Wall time (h) | 20.2 | 44.3 |
| CPU time (h) | 109.8 | 364.4 |
| Hypervolume | 429.28 | 376.73 |
| $N_{PF}$ | 143 | 88 |
| $N$ | 6672 | 150000 |

$N_{PF}$ represents the number of points on the Pareto front, and $N$ is the number of rigorous model evaluations conducted.

Compared to the framework developed by Hao et al [3], this hybrid framework has two major advantages. Firstly, this method has improved the coarse search process, making it capable of handling multi-objective optimization problems with coupled constraints. On the other hand, Hao et al's framework [3] can only handle unconstrained multi-objective optimization problems. Secondly, this method uses the trust region method for fine search without using derivative information from dynamic systems, significantly improving computational efficiency. In contrast, Hao et al's framework [3] used the derivative-based DyOS algorithm for deterministic optimization. There are many limitations when using DyOS, including the reduction of decision variables and changes to CSS criteria, which may affect the results.

## CONCLUSIONS

The main challenge in solving the design problems of chemical engineering processes, represented by the PSA process, is the high computational cost. Hence, it is imperative to develop an optimization framework capable of efficiently exploring the Pareto set for design problems. In this work, a hybrid optimization framework was developed, which can efficiently and quickly solve the $CO_2$ capture pressure swing adsorption problem. In the case study of PSA optimization design, this framework has achieved superior Pareto fronts while requiring only half the time compared to NSGA-II. In future research, we will focus on improving the coarse search step of this method to enhance the accuracy and efficiency of the coarse search while increasing compatibility with parallel computing.

## ACKNOWLEDGEMENTS

Siyang Ma would like to thank Yangyanbing Liao and Andrew Wright for their assistance in constructing the PSA model. Jie Li would like to appreciate the financial support from UKRI Impact Acceleration Account (IAA 424).

## ABSTRACT

This work addresses the process design of Power-to-Ammonia plants (*i.e.* ammonia from renewable-powered electrolysis) by a novel methodology based on the multi-objective optimization of the "Three pillars of sustainability": economic, environmental, and social. Specifically, we developed a tool estimating the installed capacities of every main process section typically featured by Power-to-Ammonia facilities (*e.g.*, the renewable power plant, the electrolyzer, energy and hydrogen storage systems, *etc.*) to maximize the plant's "Global Sustainability Score".

**Keywords**: Green ammonia, Decarbonization, Renewable energy, Power-to-X, Three pillars of sustainability

## INTRODUCTION

In 2020, about 185 Mt/y of ammonia were produced worldwide, causing 1% of that year's global greenhouse gas (GHG) emissions [1]. Indeed, more than 96% of today's global hydrogen input for ammonia derives from fossil fuels. Specifically, the most common synthetic pathways for hydrogen feedstocks heading to Haber-Bosch reactors are (i) steam methane reforming, *i.e.* hydrogen from natural gas, accounting for about 70% of global sourcing and emitting from 2.5 to 3 $t_{CO2eq}/t_{NH3}$; (ii) coal gasification, providing 26% of hydrogen feedstocks and emitting ca. 5 $t_{CO2eq}/t_{NH3}$; (iii) partial oxidation of heavy oil, accounting for less than 1%; and (iv) hydrogen from electrolysis, currently representing few isolated cases [2]. The fossil-based routes are classified as "gray" ammonia if no carbon capture and storage (CCS) technologies are implemented or "blue" ammonia if featuring CCS. Conversely, employing hydrogen from electrolysis is defined as "green" ammonia if renewable energy is used to power the electrolyzer, ideally resulting in zero direct carbon emissions. That is why the optimal design of Power-to-Ammonia plants (*i.e.* facilities converting renewable power into green ammonia via water electrolysis) is a topic of significant interest in the recent scientific literature. In particular, the erratic trend of non-dispatchable renewable sources (*e.g.*, solar, wind, *etc.*) leads to several process complications in running (thus designing) such plants: above all, the need for dynamic operations instead of conventional steady-state ones and the demand for buffer mass and energy storage to mitigate the effects of oversupply or shortage occurrences in the renewable inputs. This paper introduces a methodology to optimally design Power-to-Ammonia plants according to the "Three pillars", *i.e.* economic, environmental, and social, "of sustainability". Precisely, the fundamentals of such an approach lie in the works of Scotti *et al.* (2017, 2018) [3,4], as they proposed a solution strategy for the multi-objective optimization (MOO) of sustainability in the conceptual design of conventional (*i.e.* fossil-based, thus operating in stationary conditions) chemical plants. Specifically, this work aims to enhance such an approach by extending it to the much more challenging green process field that calls for an intrinsically dynamic methodology to conceptual design.

## METHODOLOGY

**Figure 1** depicts the investigated Power-to-Ammonia plant's process sections and battery limits (*i.e.* the control volume of the present assessment). Specifically, to achieve an average productivity target of 100 $t_{NH3}$/d, such a facility features (a) a renewable (*i.e.* solar and wind) power plant; (b) an alkaline water electrolyzer; (c) an air separation unit, *i.e.* ASU; (d) a conventional ammonia synthesis loop (*i.e.* Haber-Bosch process); and both

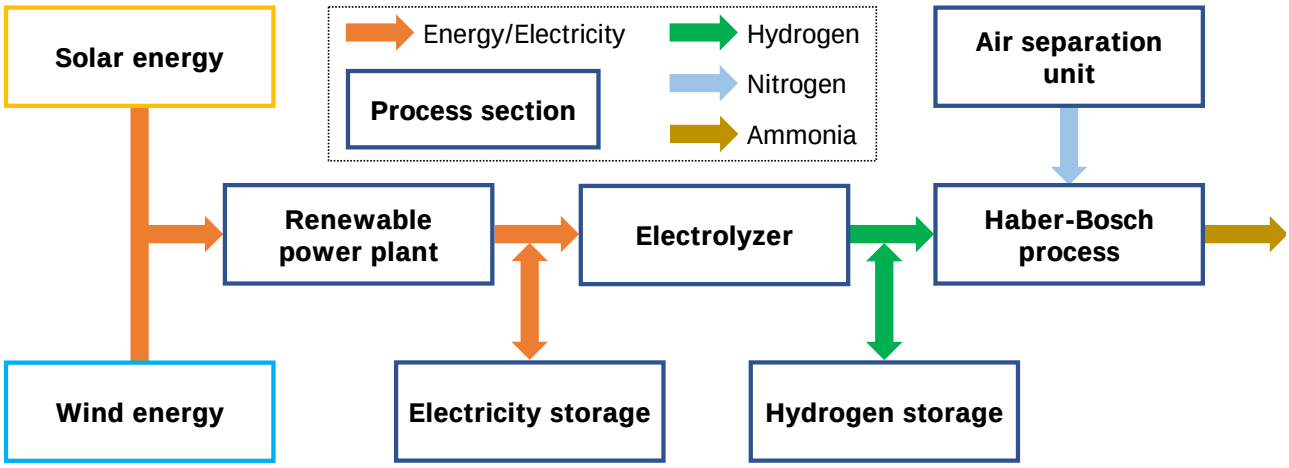

**Figure 1:** Block flow diagram of the assessed Power-to-Ammonia plant.

(e) energy and (f) mass buffer storages (namely, a lithium-ion battery amidst the power plant and the electrolyzer, and hydrogen pressurized tanks amid the electrolyzer and the ammonia plant) to dampen any process discontinuities introduced by solar and wind profiles. Furthermore, an auxiliary electricity supply from the power grid can be provided to meet the electric demand of the ASU, the Haber-Bosch process, and the multistage centrifugal compressors within the hydrogen storage section whenever the renewable electricity inputs exceeding the electrolysis demand are insufficient to power them. Both MATLAB™ R2024 (the power plant, electrolyzer, and storage systems) and UniSim® Design R492 (the ASU and Haber-Bosch process) were used to model the plant according to the renewable inputs, *i.e.* 2023 solar and wind profiles from CAISO (California Independent System Operator) [5], and the optimal policies for flexible mass and electricity storage discussed in Isella and Manca (2025a, 2025b) [6,7]. Accordingly, such process models provide the equation-oriented (in MATLAB™) and black-box (in UniSim®) equality constraints (*e.g.*, mass and energy balances) of the optimization problem. Moreover, the related degrees of freedom are the solar and wind installed capacities (*i.e.* the renewable power plant), determining the energy input to the electrolyzer (and the battery holdup) and thus the hydrogen input to the ammonia synthesis loop (and the hydrogen storage size). Consequently, the resulting capacities for such process sections (conversely, both ASU and Haber-Bosch dimensions are already given according to the high technological maturity of small-scale gray ammonia plants) lead to a "global sustainability score" (GSS) that allows practical comparisons between multiple process configurations. Indeed, the present MOO problem has been approached by the scalarization technique, *i.e.* a solution method aggregating all the different objective functions (namely, the economic, the environmental, and the social ones) into a single one by a suitable scalarization function (in this specific case, their linear combination). Thus, the sustainability metrics formulated for each sustainability pillar are (1) the levelized cost of ammonia, *i.e.* LCOA, for the economic dimension; (2) the global warming potential, *i.e.* GWP, for the environmental dimension (as it counts the cradle-to-grave $CO_2$-equivalent emissions released per mass unit of ammonia product); and (3) the Fire and Explosion Index [8], *i.e.* FEI, for the social dimension. Then, to be scalarized (hence making them comparable with each other), these parameters need to be normalized first through "normalized sustainability indexes":

$$EcoSI_i = \frac{\max(LCOA) - LCOA_i}{\max(LCOA) - \min(LCOA)} \quad (1)$$

$$EnvSI_i = \frac{\max(GWP) - GWP_i}{\max(GWP) - \min(GWP)} \quad (2)$$

$$SocSI_i = \frac{\max(FEI) - FEI_i}{\max(FEI) - \min(FEI)} \quad (3)$$

Where the $i$ subscript denotes the i-th assessed process configuration within the decision space.

As evident from their formulation, all these indexes range from 0 (*i.e.* the least sustainable scenario) to 1 (*i.e.* the most sustainable scenario). Lastly, as mentioned above, the ultimate expression of the GSS (*i.e.* the objective function of the MOO problem, to be maximized) is the linear combination of such indexes, whose coefficients act as user-defined weighting factors for each sustainability pillar:

$$GSS = w_{ECO} \cdot EcoSI + w_{ENV} \cdot EnvSI + w_{SOC} \cdot SocSI \quad (4)$$

Please note that the sum of the weighting factors must always be equal to 1 (*i.e.* 100%) and that, like the normalized sustainability indexes, even the GSS spans in the same sense from 0 to 1.

**Table 1:** Input data for the Power-to-Ammonia model [9].

## RESULTS

The optimization problem, as defined in the previous section, is then applied to a Power-to-Ammonia plant showing the features reported in **Table 1**. Both degrees of freedom (*i.e.* the solar and wind installed capacities) are iteratively varied from 0 to 500 MW (according to a 10 MW step size) by a brute-force grid-search method. Multi-objective optimization always requires some human decision-making: in this particular case, such a

feature lies in the weighting factors that the user must assign *a priori* (*i.e.* before the searching phase) according to the emphasis given to each sustainability pillar.

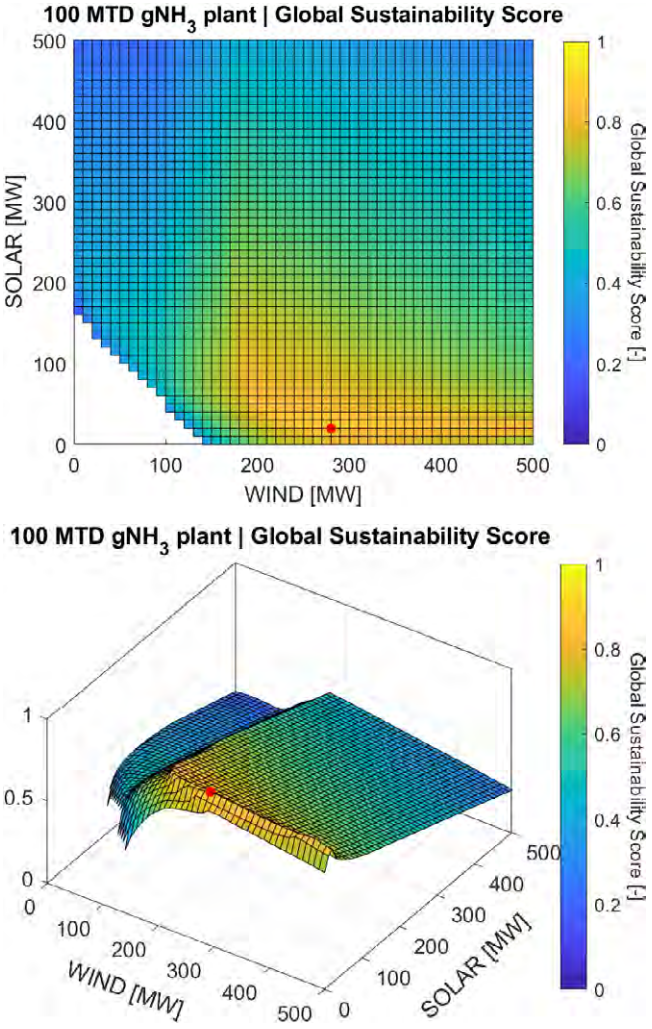

**Figure 2:** 2D (above) and 3D (below) diagrams of the GSS (the red dot corresponds to the maximum, *i.e.* 88.25%).

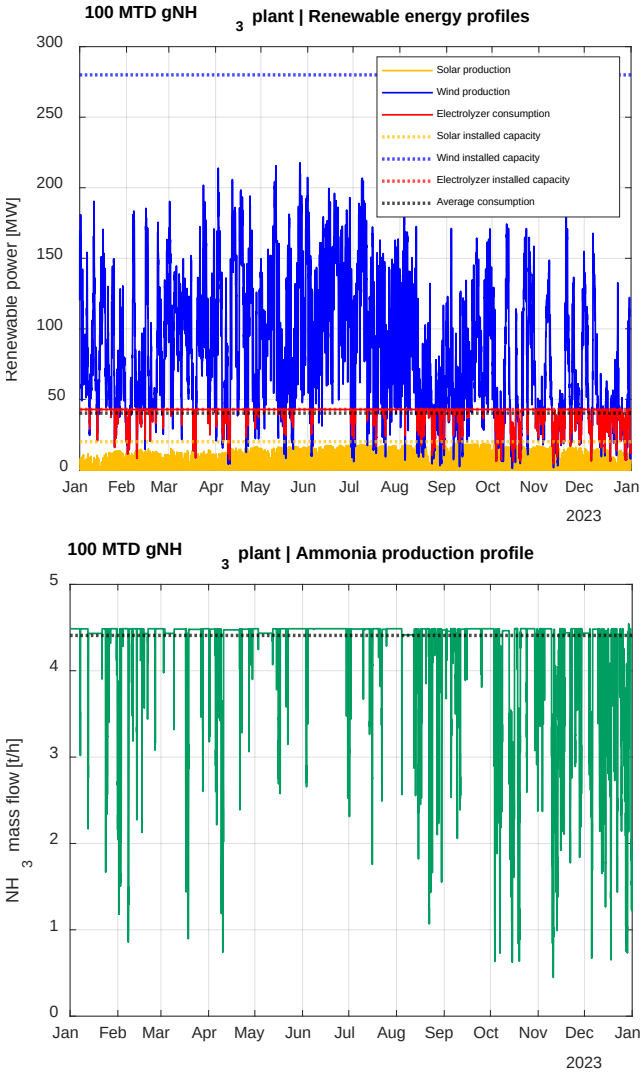
For example, let us assume: 50% economic; 25% environmental; and 25% social. **Figure 2** shows the two- and three-dimensional topologies of the resulting objective function, while the two panels of **Figure 3** return the main operating profiles of the optimal process configuration. Each pillar aims for a different solution: (A) economic sustainability typically results in a compromise solution on the installed capacity of the renewable power plant as lower ones would imply bigger electrolyzers and storage systems (to process, and mitigate, any energy input made available by the small power plant), and *vice versa*. Specifically, wind power is preferred to solar as its higher availability throughout the day reduces the storage systems' need (hence the size and total costs). (B) Environmental sustainability tends to minimize the renewable power plant sizes as they lead to far higher GWP values than the storage systems. However, the GWP associated with the electrolyzer (as, like its size, increases when the power plant size decreases) counterbalances such a trend, making the optimal power plant slightly more significant than the minimum allowable one. (C) Lastly, social sustainability pushes for huge renewable power plants as they minimize the electrolyzer and hydrogen storage sizes (hence the well-known hydrogen-related process hazards). Consequently, the resulting objective function (see **Figure 2**) displays all these features, though the corresponding weighting factors partially mitigate them. The corresponding optimal GSS is 88.25%, meaning the three sustainability pillars agreed fairly (although not entirely).



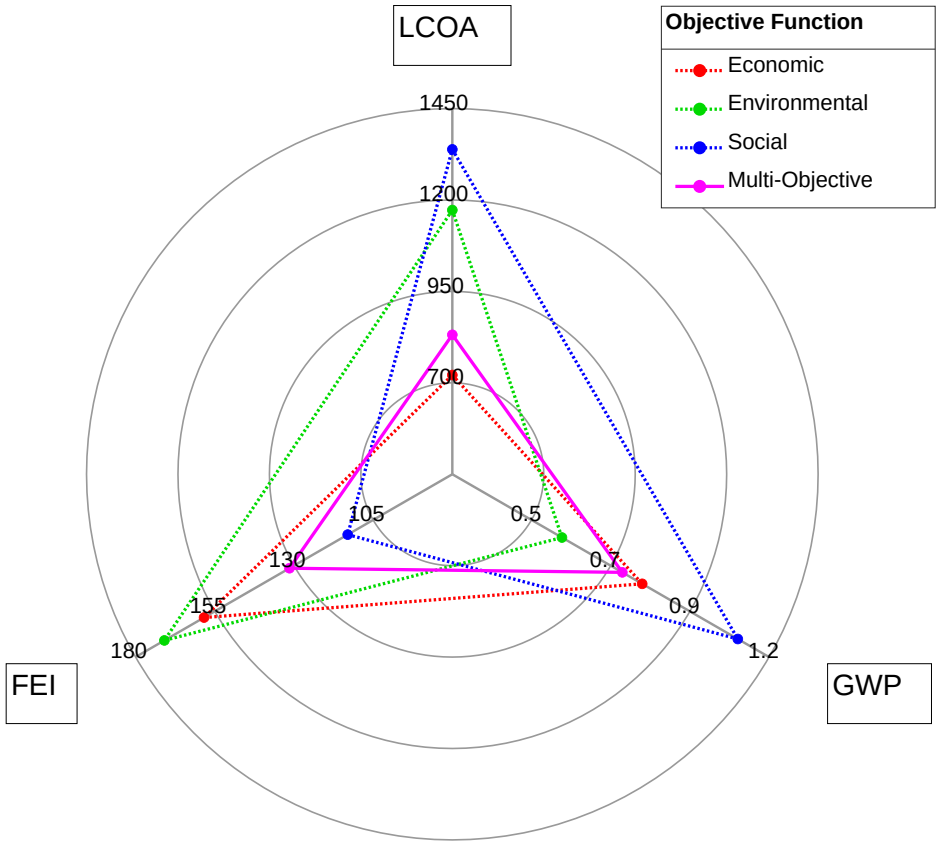


**Figure 3:** Renewable power generation vs. consumption (above) and ammonia production (below) profiles by the optimal Power-to-Ammonia plant process configuration.

Finally, **Table 2** summarizes the installed capacities and sustainability metrics resulting from the optimization

**Table 2:** Main results of the optimal process configuration.

| **Optimal process configuration: 50% economic + 25% environmental + 25% social** | | |
|---|---|---|
| Solar | 20 | [MW] |
| Wind | 280 | [MW] |
| Electrolyzer | 42.87 | [MW] |
| Electricity storage | 2.29 | [MWh] |
| Hydrogen storage | 38.39 | [$kg_{H2}$] |
| LCOA | 871.86 | [USD/$t_{NH3}$] |
| GWP | 0.77 | [$t_{CO2eq}/t_{NH3}$] |
| FEI | 131.40 | [-] |
| GSS | 88.25% | [-] |

problem. Specifically, the optimal process configuration features high wind-power installed capacities and negligible storage sizes (*i.e.* battery and tanks).

As evident from **Table 2**, compared to the economically optimal scenario (*i.e.* the single-objective optimization of the economic dimension only), both environmental and social sustainability improved (−3.5% in GWP and −17% in FEI, respectively) at the expense of the ammonia production cost (+21% in LCOA).

Please also note that solving the three single-objective optimization problems together (economic, environmental, and social) would allow visualizing the Pareto fronts, *i.e.* those points within the decision space whose corresponding objective function values cannot be concurrently improved. This is a traditional "*a posteriori*" technique (meaning that the decision process is postponed after the searching phase; thus, no preference criteria need to be provided "*a priori*"), giving interesting insights on the conciliation among every single objective function. However, the Pareto front approach may be unsatisfactory and confusing for many reasons. Above all, the somewhat chaotic representation of all the solutions explored and the high number of Pareto optimal points (60 out of 2601 process configurations investigated) still leaves too much space for the decision maker's discretion. That is why we opted for the scalarization method:

indeed, as an "*a priori*" technique, it provides the decision criterion (assuming a specific hierarchy of importance in the objective functions according to the weighting factors) before the searching phase, thus allowing for the examination of a unique solution.

## CONCLUSIONS

This work presented a methodology to identify the process design of Power-to-Ammonia plants that best maximizes and harmonizes the three pillars of sustainability: economic, environmental, and social. Resorting to the scalarization method proved to be a successful approach to solving such a multi-objective optimization problem and allowing the users (*e.g.*, academic researchers and industrial stakeholders) to quickly compare the different results arising from the arbitrary choice of the three pillar-related weighting factors. Furthermore, this work stressed the importance of process flexibility in renewable-energy-powered chemical plants to adapt appropriately to the erratic nature of renewable energy sources. Indeed, the higher the process flexibility, the lower the required storage systems' capacities to mitigate the discontinuities in renewable power (hence, the lower the production costs).

## ABSTRACT

Robust optimisation is a powerful approach for addressing uncertainty ensuring constraint satisfaction for all uncertain parameter realisations. While convex robust optimisation problems are effectively tackled using robust reformulations and cutting plane methods, extending these techniques to non-convex problems remains largely unexplored. In this work we propose a method that is based on a parallel robustness and optimality search. We introduce a novel spatial Branch-and-Bound algorithm integrated with robust cutting-planes for solving non-convex robust optimisation problems. The algorithm systematically incorporates global and robust optimisation techniques, leveraging McCormick relaxations. The proposed algorithm is evaluated on benchmark pooling problems with uncertain feed quality, demonstrating algorithm stability and solution robustness. The computational time for the examined case studies is within the same order of magnitude as state-of-the-art. The findings of this work highlight the potential of the proposed algorithm in tackling quadratic non-convex robust optimisation problems, particularly in chemical engineering applications.

**Keywords**: Algorithms, Pyomo, Robust Optimisation, Pooling Problem, Global Optimisation, spatial Branch-and-Bound

## INTRODUCTION

Robust optimisation is widely used to identify worst-case scenarios, ensuring constraint satisfaction under uncertainty or when statistical data is unavailable, as an alternative to scenario-based approaches [1]. The most prevalent solution algorithms for convex problems are robust reformulation and robust cutting planes [2]. Under the assumptions of convex uncertainty set and the problem constraints being concave in the uncertain parameter, both methods can be extended to non-convex problems [3]. Cutting-planes involve sequentially solving an upper-level deterministic problem and lower-level problems to find uncertainty values that cause the maximum constraint violation. For those values, corresponding cuts are added to the upper-level problem. Implementations of cutting-planes can be found in solvers like PyROS [4] and the ROmodel package [5] in Python, which rely on local or global solvers to handle intermediate problems. However, traditional robust cutting-planes are heavily influenced by the performance of the chosen solver, and if the solver fails to converge during a cut-round, the entire algorithm may fail to converge [4]. At the same time, for computationally challenging case studies the cost of solving the problem to global optimality multiple times may be prohibitive.

Nonlinear functions are present in a multitude of chemical engineering problems, especially when data-driven methods are employed, there is a need for systematic techniques that handle non-convex problems under uncertainty [6]. In this study we focus on the class of non-convex quadratic problems, and we leverage spatial Branch-and-Bound (sBB) algorithm. sBB is a deterministic global optimisation algorithm which is suitable for optimisation problems that require branching on the continuous variables. Early application of the sBB in the process systems engineering literature include solving linear fractional and bi-linear problems [7], as well as addressing various NLP and MINLP design problems [8]. sBB algorithms rely on the generation of lower and upper bounds of the objective function over any given variable subdomain. In a minimisation problem, the upper bound value is

selected as a local minimiser in the current subdomain. Depending on the structure of the original problem, different convexification methods can be used to formulate a relaxation of the original problem, corresponding to a lower bounding solution.

Solving non-convex problems to robust optimality requires the connection of the robust algorithms and global optimisation methods. The most prevailing approach to achieve this is by deriving the dual reformulation and using either directly or adaptively a global solver to retrieve a solution [9,10]. Recently, different process case studies have been examined using a local linearisation approach based on an iterative random sampling of the uncertain parameters [11]. The non-convex pooling problem under concave uncertainty is addressed in [3] following two solution paths, reformulation and cutting planes using a global solver. This study proposes a novel spatial Branch-and-Bound algorithm integrated with robust cutting-planes (RsBB) for solving non-convex robust optimisation problems. The proposed algorithm is implemented to solve benchmark pooling problems with uncertain feed quality, using McCormick relaxations [12]. In the RsBB algorithm, robust infeasibility checks are performed at each node of the BB tree. The infeasibility cuts are added both on the original and the relaxed problem. The performance of the proposed RsBB algorithm is compared with and state-of-the-art software in terms of computational efficiency and solution robustness.

## POOLING PROBLEM

The pooling problem is a well-studied benchmark problem in process systems engineering and optimisation communities being non-convex quadratic problem with quadratic constraints. A simple pooling topology is depicted in Fig. 1, where a number of inlet components is mixed into the available pools from which different products are retrieved.

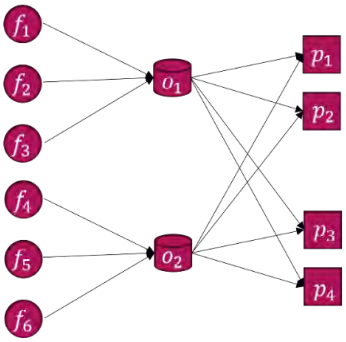

**Figure 1.** Conceptual representation of pooling problem, corresponding to 6 feed components, 2 pools and 4 products.

### Problem definition

Throughout the years several formulations of the pooling problem have been proposed. In this work, we follow the pq-formulation [13] of the standard pooling problem using auxiliary variables. The objective function is to minimise the cost,

$$\min \sum_{ilj} c_i v_{ilj} - \sum_{jl} d_j y_{lj} + \sum_{ji} d_j z_{ij} \tag{1}$$

satisfying constraints on feed availability

$$\text{s.t.} \sum_{lj} v_{ilj} + \sum_{j} z_{ij} \le A_i, \quad \forall i \tag{2}$$

pool capacity

$$\sum_{j} y_{lj} \le S_l, \quad \forall l \tag{3}$$

product demand satisfaction

$$\sum_{l} y_{lj} + \sum_{i} z_{ij} \le D_j, \quad \forall j \tag{4}$$

product quality

$$\sum_{il} C_{ik} v_{ilj} + \sum_{i} C_{ik} z_{ij} \le P_{jk}^{U} f_j, \quad \forall j,k \tag{5}$$

total flow

$$\sum_{l} y_{lj} + \sum_{i} z_{ij} = f_j, \quad \forall j \tag{6}$$

RLT constraints

$$\sum_{i} q_i = y_{lj}, \quad \forall l \tag{7}$$

$$\sum_{i} v_{ilj} = y_{lj}, \quad \forall l \tag{8}$$

and auxiliary constraints.

$$v_{ilj} = q_{il} y_{lj} \; \forall i,l,j \tag{9}$$

**Table 1:** Problem definitions.

| Step | Problem | Notation | Equations |
|---|---|---|---|
| 1st | Original pooling | $\Pi$ | (1)-(9) |
| | Relaxed pooling | $\Pi_R$ | (1)-(8), (10)-(13) |
| 2nd | Quality robustness | $\pi$ | (14), (16)-(18) |

The pq-formulation results in a non-convex problem with quadratic constraints. A convex relaxation is achieved replacing Eq. (9) with the corresponding McCormick envelopes [14] as follows:

$$v_{ilj} \ge \underline{q}_{il} y_{lj} + q_{il} \underline{y}_{lj} - \underline{q}_{il} \underline{y}_{lj}, \quad \forall i,l,j \tag{10}$$

$$v_{ilj} \le \overline{q}_{il} y_{lj} + q_{il} \underline{y}_{lj} - \overline{q}_{il} \underline{y}_{lj}, \quad \forall i,l,j \tag{11}$$

$$v_{ilj} \ge \overline{q}_{il} y_{lj} + q_{il} \overline{y}_{lj} - \overline{q}_{il} \overline{y}_{lj}, \quad \forall i,l,j \tag{12}$$

$$v_{ilj} \le \underline{q}_{il} y_{lj} + q_{il} \overline{y}_{lj} - \underline{q}_{il} \overline{y}_{lj}, \quad \forall i,l,j \tag{13}$$

where $\underline{q}_{il}, \underline{y}_{lj}$ and $\overline{q}_{il}, \overline{y}_{lj}$ correspond to the lower and upper bounds of the complicating variables. The definitions of the problem formulations are displayed in Table 1.

## Uncertainty consideration

In this work uncertainty is introduced in the inlet quality parameters $C_{ik}$ and subsequently in the product quality constraints of Eq. (5). The true value of the uncertain level quality $\tilde{C}_{ik}$ can be formulated as:

$$\tilde{C}_{ik} = C_{ik} + \xi_{ik}\hat{C}_{ik} \tag{14}$$

where $C_{ik}$ represents the nominal value, $\hat{C}_{ik}$ the constant perturbation (which is positive) and $\xi_{ik}$ is a vector of random variables which are subject to uncertainty. The robust counterpart of Eq. (5) for a selected box uncertainty set is derived in Eq. (15).

$$\sum_{il} \tilde{C}_{ik} v_{ilj} + \sum_{i} \tilde{C}_{ik}\, z_{ij} \le P^U_{jk} f_j, \quad \forall \boldsymbol{\xi} \in \mathcal{U}_\infty, \forall j,k \tag{15}$$

Eq.(15) is a semi-infinite constraint which is typically handled either via dual reformulation or robust cutting planes [2]. Following the robust cutting planes, Eq.(15) can be replaced by the quality robustness problem which should be solved $\forall j,k$ quality constraints:

$$\max_{\xi} \phi_{jk} \tag{16}$$

$$s.t. \phi_{jk} = \sum_{il} \tilde{C}_{ik}\, v^*_{ilj} + \sum_{i} \tilde{C}_{ik}\, z^*_{ij} - P^U_{jk} f^*_j \tag{17}$$

$$|\xi_{ik}| \le \Psi, \qquad \forall i,k \tag{18}$$

# METHODOLOGY

## Robust cutting planes

Robust cutting planes approach is an iterative optimisation algorithm. In the first step, the original pooling problem $\Pi$ is solved and the set of solutions $v^*_{ilj}, z^*_{ij}$ and $f^*_j$ is passed in the second-step problems $\pi$. Problems $\pi$ are solved for all $j,k$ maximising the random variable $\xi$ within a selected uncertainty set $\mathcal{U}_\mathrm{p}$. For every $C^*_{ik}$ that $\phi_{jk} > 0$ the equivalent robust cut is added to problem $\Pi$:

$$\sum_{il} C^*_{ik} v_{ilj} + \sum_{i} C^*_{ik} z_{ij} \le P^U_{jk} f_j, \quad \forall j,k \tag{19}$$

The algorithm iterates until no more quality violations are detected, then the algorithm terminates in a robust solution. Depending on the choice of solver for $\Pi$ the solution can be either robust optimal, using a global solver, or robust feasible, using a local solver.

## Robust-spatial-Branch-and-Bound

In the proposed Robust-spatial-Branch-and-Bound algorithm (RsBB), we aim to integrate the robust cutting planes with the spatial Branch-and-Bound (sBB) algorithm. Relying on a local NLP solver, the proposed algorithm is evaluating the robustness of the solutions in a branching tree. The outline of the proposed algorithm is presented in Figure 2. Let the complicating variables $q_{il}$ and $y_{lj}$ be the branching candidates. For the initial variable bounds at the root node, problem $\Pi$ is solved using a local solver. The robustness of the local solution is evaluated solving linear problems $\pi\ \forall j,k$ and the corresponding robust cuts (Eq. (19)) are added both to $\Pi$ and $\Pi_R$if a feasibility violation is detected, i.e. $\phi_{jk} > 0$. The cutting plane algorithm continues at the root node until no more robustness violations are detected. Until this step, the proposed algorithm follows the typical robust cutting plane algorithm.

The following steps of the algorithm correspond the Branch-and-Bound algorithm. Let $q^{R*}_{il}, y^{R*}_{lj}, v^{R*}_{ilj}$ be the solutions of the relaxed linear $\Pi_R$ problem. The branching variable is selected based on the maximum approximation error. Let $x_{br}$ be the branching variable for which:

$$x_{br} = arg\max\{q^{error}_{il}, y^{error}_{lj}\} \tag{20}$$

$$q^{error}_{il} = \sum_{j} v^{R*}_{ilj} - q^{R*}_{il}\, y^{R*}_{lj} \tag{21}$$

$$y^{error}_{lj} = \sum_{i} v^{R*}_{ilj} - q^{R*}_{il}\, y^{R*}_{lj} \tag{22}$$

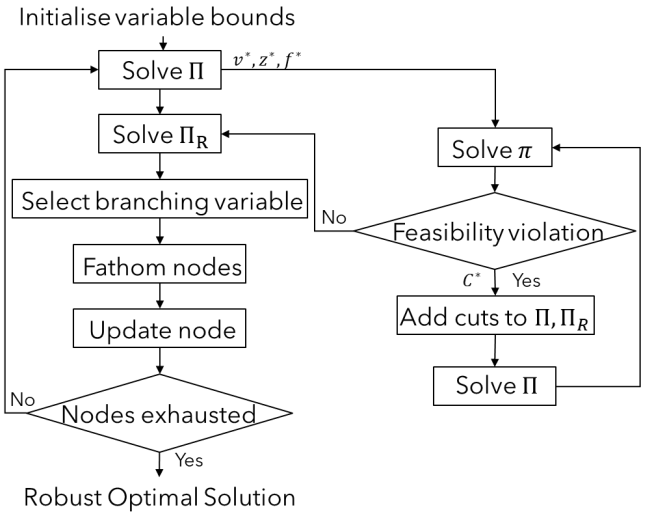

**Figure 2.** The Robust-spatial-Branch-and-Bound algorithm

The branching point is selected as the incumbent solution of the branching variable. Hence the bounds for the first two child nodes the new bounds will be $x_{br} \in X_1 = [\underline{x}_{br}, x^{R*}_{br}]$ and $x_{br} \in X_2 = [x^{R*}_{br}, \overline{x}_{br}]$. Nodes for which the $\Pi_R$ solution is greater than the best-found solution of $\Pi$ are fathomed. The next node is updated as the waiting node with the lowest $\Pi_R$ solution. If the waiting nodes are exhausted, the robust optimal solution of the

problem is obtained.

## COMPUTATIONAL EXPERIMENTS

The RsBB algorithm is evaluated in 10 benchmark pooling instances with varying size, details of the problems can be found in Table 2. For the uncertain inlet quality, we set $\hat{C}_{ik} = C_{ik}$ and examine the results for three different uncertainty sizes, i.e. $\Psi \coloneqq \{0.05, 0.1, 0.15\}$ which correspond to 5%, 10% and 15% allowed perturbation from the nominal inlet quality value. The selected modelling environment is Pyomo v6.7. For the RsBB algorithm HiGHS v.1.5.3 is used as the LP solver and conopt4 as the local NLP solver. The proposed algorithm is compared with PyROS v1.2.8 using Gurobi v11.1 as the LP solver, conopt4 and BARON v23.6.22 as local and global solvers respectively.

**Table 2:** Benchmark pooling problems.

| Problem | #Feeds | #Pools | #Products | #Qualities |
|---|---|---|---|---|
| haverly1-3 | 3 | 1 | 2 | 1 |
| foulds2 | 6 | 2 | 4 | 1 |
| bental4 | 4 | 1 | 2 | 1 |
| bental5 | 13 | 3 | 5 | 2 |
| adhya1 | 5 | 2 | 4 | 4 |
| adhya2 | 5 | 2 | 4 | 6 |
| adhya3 | 8 | 3 | 4 | 6 |
| adhya4 | 8 | 2 | 5 | 4 |

### Results

The proposed algorithm is compared with PyROS solver in Fig.3. PyROS is a built-in solver in Pyomo that is implementing the robust cutting planes algorithm. For each of the 10 benchmark problems, three variants of different uncertainty size were examined resulting to 30 instances in total. The robust optimum is obtained by the RsBB algorithm for all instances. In contrast, using PyROS with local solver conopt4 solves only 10% of the instances to robust optimality and for 40% terminates in a local robust solution. Given that the instances examined are relatively small and represent well-studied benchmarks in the field of global optimisation, PyROS, using the global solver BARON, obtained the robust optimal solution in reduced total computational time compared to RsBB. The instances with the highest CPU time in RsBB correspond to the Adhya problems for $\Psi = 0.05$. Since pooling problems have multiple local optima, introducing uncertainty via robust cutting planes reduces the feasible region and possibly rendering regions with local solutions infeasible.

The impact of the problem size and uncertainty size in the RsBB algorithm is evaluated via Fig.4. Foulds2 problem is double in size of the Haverly2. As expected, in Haverly3 RsBB closes the optimality gap in fewer nodes compared to Foulds2 (Figure 4a, b). Unexpectedly, the optimality gap at root node in Foulds2 is below 15% for all $\Psi$ while above 90% in the Haverly instance. In Foulds2 there is a negative correlation between the uncertainty

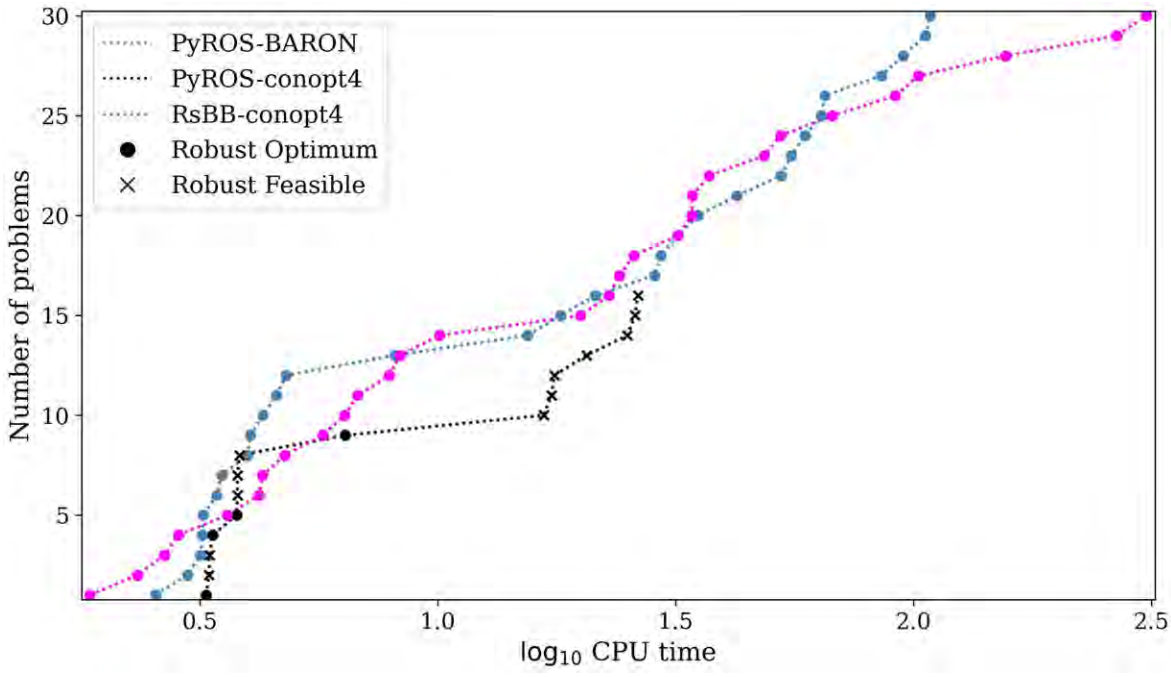

**Figure 3**: Computational time for problems solved by examined algorithms. 30 problems in total, corresponding to 3 different $\Psi$ values for 10 benchmark pooling problems.

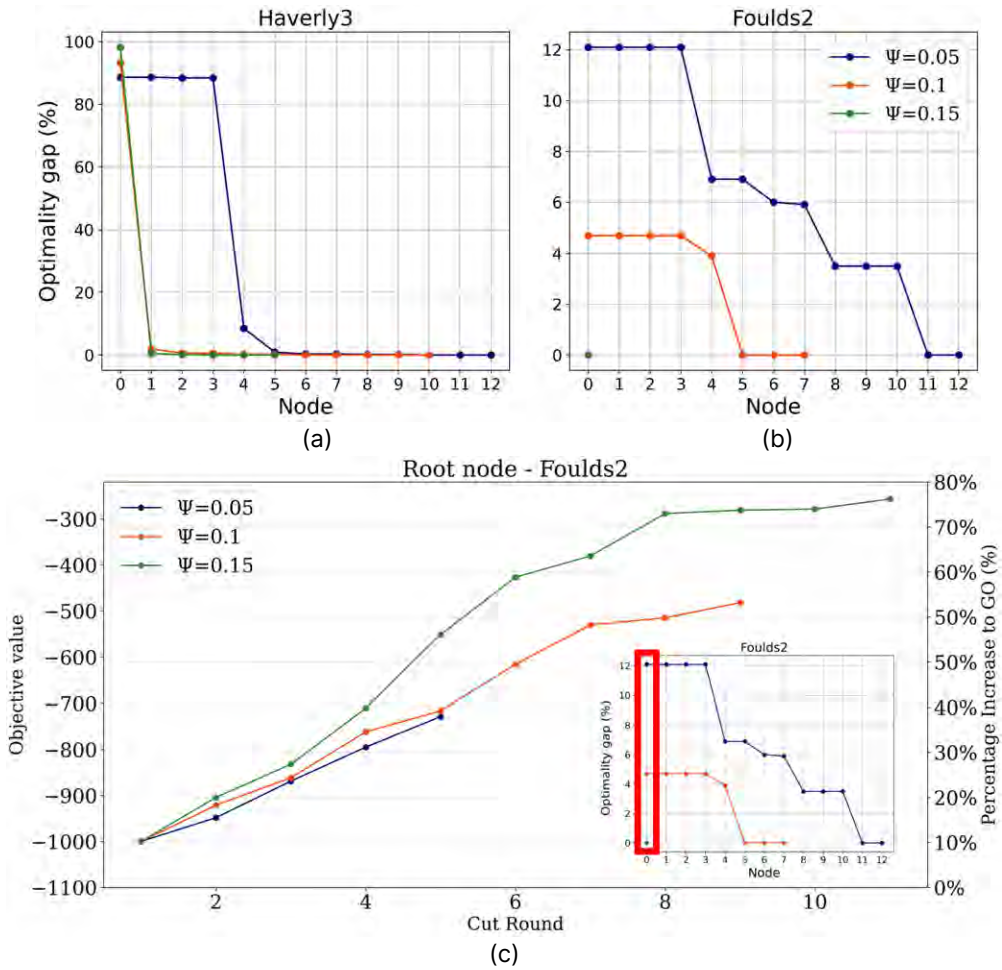

**Figure 4:** a+b) Optimality gap closure at evaluated tree node for Havely3 and Foulds2 problems for varying uncertanty size. c) Objective value decrease at root node of Foulds2 for robust cut iterations.

set size and the optimality gap at the root node, while for $\Psi = 0.15$ the RsBB algorithm terminates at the root node. To elucidate this observation, we focus on the root node of Foulds2 and the iterations of the robust cutting planes in Figure 4c. As the uncertainty size increases, so do the required robust cutting plane iterations to find a robust feasible solution at the root node. At the same time, the increase in robust cut iterations results in a smaller optimality gap. For $\Psi = 0.15$, 12 robust cut iterations are required that result in a robust optimal solution in the root node. Analogously, for $\Psi = 0.1$ 9 robust cut iterations are required for a robust feasible solution in the root node. The added cuts aid the RsBB algorithm to terminate in 7 nodes. To this end, robust cutting planes facilitate the optimality search. For larger uncertainty set size, the corresponding cuts are more restraining the cuts, which allow for an earlier termination of the sBB algorithm. In the same plot the price of robustness can be highlighted. Accounting for 15% increase in the uncertain parameter results in an increase of 75% of the objective value. Even for a 5% increase in the inlet quality increases the cost by almost 40%. Thus, increasing the uncertainty size fortifies the problem against higher uncertainty variations, increases conservativism and at the same time reduces the degeneracy of the problems.

## CONCLUSIONS

In this work, we introduced a novel algorithm by coupling global and robust optimisation methods. The proposed RsBB algorithm integrates the principles of sBB and robust cutting planes to solve non-convex problems with concave uncertain parameters. The performance of the algorithm was evaluated on well-studied benchmark pooling problems with box uncertainty set. The computational results of our study suggest that the proposed method offers stability and guaranteed robust optimality for the examined problems while using a local solver. We observed that using robust cutting planes in the sBB algorithm works as a feasibility bounds tightening method.

Overall, the proposed algorithm is a promising method in tackling non-convex robust optimisation problems. In our future work, we will examine different types of uncertainty sets and extend our method to general non-convex problems.

## NOMENCLATURE

**Sets:**

| | |
|---|---|
| $i$ | Components |
| $l$ | Pools |
| $j$ | Products |
| $k$ | Qualities |

**Parameters:**

| | |
|---|---|
| $\xi_{ik}$ | Random variable of quality |
| $\Psi$ | Adjustable parameter for the uncertainty size |
| $A_i$ | Upper bound for component availability |
| $D_j$ | Upper bound for product demand |
| $S_l$ | Upper bound for pool size |
| $P_{jk}^U$ | Upper bound for product quality |
| $C_{ik}$ | Nominal inlet quality value |
| $\tilde{C}_{ik}$ | True inlet quality value |
| $\hat{C}_{ik}$ | Perturbed inlet quality value |
| $c_i$ | Component unit price |
| $d_j$ | Product unit price |

**Variables:**

| | |
|---|---|
| $q_{il}$ | Flow of component $i$ entering pool $l$ |
| $y_{lj}$ | Flow from pool $l$ to product $j$ |
| $z_{ij}$ | Flow from component $i$ to product $j$ |
| $f_j$ | Total flow to product $j$ |
| $v_{ilj}$ | Flow of component $i$ entering pool $l$ to product $j$ |

## ABSTRACT

Large Language Models have demonstrated potential in accelerating scientific discovery, but they face challenges when making inferences in rapidly evolving and niche domains like Process Systems Engineering (PSE). To address this, we propose a Graph-based Retrieval-Augmented Generation (RAG) pipeline specifically designed for PSE papers. Our pipeline includes custom document parsing, knowledge graph construction, and refinement to enhance retrieval accuracy. We evaluate the effectiveness of our approach using an automatically generated benchmark consisting entirely of PSE-related questions. The results show that our pipeline outperforms both non-RAG and vanilla RAG implementations in terms of relevant document retrieval and overall answer quality. Additionally, our implementation is fully customizable, allowing users to select the papers most relevant to their specific tasks. This framework is openly available, providing a flexible solution for those working in PSE or similar domains.

**Keywords**: Large Language Model, Retrieval-Augmented Generation, Graph-based Retrieval, Process Systems Engineering

## INTRODUCTION

Large Language Models (LLMs) have shown remarkable capabilities, performing well across a wide range of tasks, including accelerating scientific discovery in different fields. More specifically, in the field of Process Systems Engineering (PSE), LLMs have been adapted to various tasks, including flowsheet generation, the prediction of chemical properties, and infeasibility diagnosis in optimization models [1-2]. Still, off-the-shelf LLMs are inherently limited to the information present in their training data, which may become outdated or fail to cover specialized topics comprehensively [3]. This limitation is particularly relevant in both rapidly evolving and highly specialized fields, like PSE [4].

Retrieval-Augmented Generation (RAG) is an advanced framework that enhances the capabilities of LLMs by integrating them with external knowledge retrieval systems. Unlike standard LLMs, which rely solely on pre-trained knowledge, RAG combines parametric memory (the information encoded in the model's weights) with non-parametric memory (external data sources, such as databases or knowledge repositories). A retriever dynamically identifies and retrieves relevant information from these external sources, presenting it to the model alongside user inputs [5]. This approach enables RAG to provide more accurate, factual, and context-specific responses, while allowing the knowledge base to be updated without requiring model retraining. Such dynamic and interpretable knowledge integration makes RAG particularly valuable for addressing complex, knowledge-intensive tasks. Therefore, the PSE community can benefit from a domain-specific RAG to improve standard LLM performance, while ensuring that the responses remain grounded in truthful and updated information.

Graph-based knowledge structures are powerful tools to study complex and interconnected information, such as the one in scientific domains. Graph RAG enhances traditional RAG frameworks by leveraging knowledge graphs to represent and retrieve interconnected information more effectively. Unlike standard indexed databases that overlook relationships across documents, Graph RAG can be used to construct knowledge

graphs from academic papers, linking entities, concepts, and their relationships. This approach captures the interconnected nature of scientific knowledge, enabling more accurate and context-aware retrieval [6-7]. For example, Graph RAGs have successfully been used in medicine to improve retrieval accuracy and response quality by modeling relationships among diseases, treatments, and outcomes [8].

In this work, we propose a Graph RAG specifically designed to incorporate domain-specific knowledge from PSE. To achieve this, we develop a pipeline that parses academic papers and constructs tailored knowledge graphs from PSE literature. Additionally, we create a benchmark dataset of PSE-specific questions and answers derived from the utilized corpus to evaluate the accuracy and quality of the retrieved information. While copyright restrictions prevent us from publishing graph databases from the model, the pipeline developed in this work is freely accessible through a GitHub repository. This pipeline allows users to fully replicate and customize their selection of papers, enabling the construction of a Graph-based Retrieval Agent for Process Systems Engineering (GRAPSE) that is precisely aligned with their desired body of literature.

## Standard Retrieval-Augmented Generation

RAG is a framework that enables LLMs to infer knowledge from documents that were not directly trained on. This approach leverages the strength of LLMs in abstracting information from text when the relevant content is provided as part of the prompt, often referred to as the context. The primary objective of RAG is to retrieve the most relevant document(s) from a given set based on a user query, ensuring that the retrieved information is passed as context. This enriched prompt, containing both the query and the related context, allows the LLM to perform accurate and informed inference, effectively answering the query [5].

They key part of the RAG framework are embeddings, which are are numeric vector representations of text that encode semantic and contextual information. Words or phrases with similar meanings are positioned closer together in this high-dimensional space, where the distance and angle between vectors represent the degree of similarity. Transformer-based models, unlike traditional embedding methods like TF-DF [9], create contextual embeddings, meaning that the vector representation of a word adapts based on its surrounding context, capturing complex relationships in language.

Once documents have been split, chunks of text are passed through a transformer embedding model, which processes the input and produces high-dimensional vectors that reflect the semantic and contextual meaning of the text. These embeddings are then stored in a vector database, which indexes both the original text and its corresponding vectors. This setup allows for efficient storage and fast retrieval, as the database can perform similarity searches by comparing query embeddings to stored vectors. Typically, a cosine similarity metric is used to determine alignment between vectors.

The chunks corresponding to the vectors with the highest similarity to the embedded query vector are retrieved from the database and provided to the LLM as contextual input. A sketch of a standard RAG methodology is presented in Figure 1.

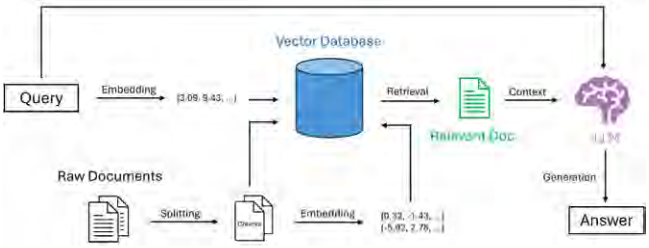

**Figure 1.** Standard Retrieval Augmented Generation pipeline. Raw documents are divided into chunks based on a predefined criterion, often a fixed character length. Each chunk is then converted into a high-dimensional vector using a transformer-based embedding model and indexed within a vector database. Similarly, the query is embedded using the same model to produce its vector representation. A similarity search is performed between the query vector and the vectors stored in the database. The chunks corresponding to the top $k$ most similar vectors are retrieved and incorporated into the prompt as context. This enriched prompt, combining the original query with the retrieved context, is then passed to an LLM for final answer generation.

# METHODOLOGY

The following subsections outline our proposed Graph RAG methodology, detailing the process of transforming raw papers into a refined knowledge graph. For reference, a representation of the entire pipeline is provided in Figure 2.

## Document Parsing

The first step in our approach involves the user selecting the academic papers that will form the knowledge base for the retrieval system. Once the papers are chosen, the pipeline begins by processing each paper, breaking it down into smaller units of information commonly referred to as "chunks". Some traditional RAG methodologies often utilize a fixed character-length chunking strategy, where the chunk size is limited by the maximum input length supported by the embedding model, with overlapping regions between consecutive chunks [5]. While this general approach is applicable to

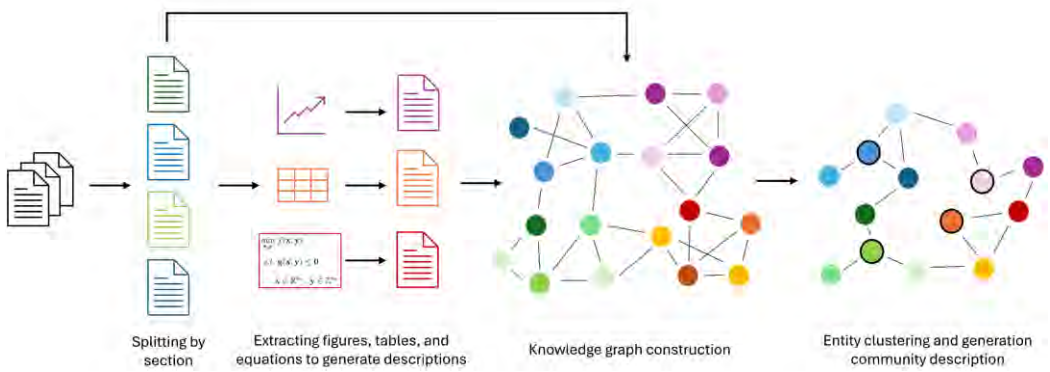

**Figure 2:** Sketch of the proposed Graph RAG pipeline. Raw papers are divided into sections, and each section is analyzed to extract all figures, tables, and equations. A multimodal LLM generates descriptions for these extracted elements, which are then appended to their corresponding sections. From this enriched set of documents, a knowledge graph is constructed, where nodes represent entities identified in the documents, and edges capture their relationships. In the figure, colors denote the topics found in the documents, illustrating the degree of their relation. Similar entities are merged to eliminate duplicates, and a community detection algorithm is applied to group nodes into clusters [7]. Nodes with black borders represent the descriptions generated based on the information within each community. The final knowledge graph is stored in a graph vector database for efficient search and retrieval.

any document, it does not consider the inherent structure of academic papers. Consequently, important ideas may be fragmented across multiple chunks, potentially reducing the retrieval quality.

To address this limitation, our pipeline parses each paper to identify its structural components, such as sections, subsections, and other logical divisions. Instead of relying on arbitrary fixed-size chunking, we allow each section to form its own chunk. This ensures that each chunk represents a self-contained idea or concept, preserving the coherence and contextual integrity of the information.

Academic papers in PSE often include a significant amount of information formatted as equations, tables, and figures. To effectively integrate this knowledge into the retrieval system, we extract these elements and generate detailed text descriptions for each using a multimodal LLM. These descriptions provide contextual information about the purpose, content, and relevance of the equations, tables, and figures, enhancing their interpretability and utility within the knowledge base.

The generated descriptions are not only linked to the specific chunk where the corresponding equation, table, or figure appears but are also associated with all chunks that reference them. For instance, the description of "Figure 1" is attached to both the chunk where the figure resides and all other chunks that mention "Figure 1." This approach ensures that users querying the system can access enriched and cohesive context related to these important elements, regardless of where they are discussed within the academic paper.

## Knowledge Graph Construction

After parsing and processing all the selected papers, the next step of the pipeline is to construct a knowledge graph that integrates and relates the extracted information across the entire body of literature. To achieve this, entities are first identified and extracted from the documents [6]. Tailoring the pipeline to academic literature, entity recognition is constrained to specific categories: papers, solvers, authors, algorithms, institutions, benchmarks, and software. However, this categorization can be customized by users to include additional or alternative categories, allowing greater flexibility and adaptability.

For each identified entity, a detailed description is generated based on the contextual information found in the text. Once these descriptions are established, relationships between entities are inferred and created to form a network [6]. To ensure greater coherence and maintain the integrity of the source information, each chunk from the parsed documents is treated as a separate entity within the graph and linked to the entities extracted from it. The entire knowledge graph construction process is implemented using the Neo4j graph database, enabling efficient storage, querying, and visualization of the interconnected knowledge [10].

## Graph Enhancement

To improve the efficiency of the constructed knowledge graph, the pipeline incorporates a step to group similar entities, reducing redundancy and improving query performance. This step ensures that semantically or contextually identical entities, which may be represented with slight variations (e.g., "Ignacio Grossmann"

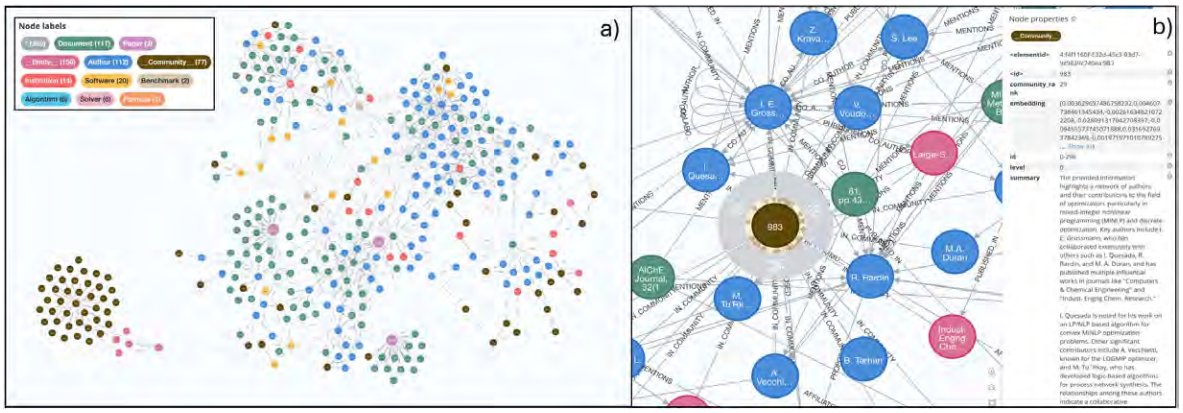

**Figure 3:** Knowledge graph visualization. Figure a) illustrates the complete knowledge graph built from a large collection of PSE papers, with node colors representing various entity types across the network. Figure b) provides a detailed view of a single community within the graph, showing the relationships among entities in the community and the corresponding community description.

vs. "I.E. Grossmann"), are unified into a single node within the graph.

The grouping process begins with a fuzzy search across the recognized entities to identify potential matches based on similarities in names, descriptions, or other attributes. Once potential matches are identified, a clustering algorithm is applied to group these similar entities systematically [7]. The clustering consolidates entities with high similarity scores while preserving entities that are sufficiently different.

Generating communities within a knowledge graph and creating descriptions of these communities play a crucial role in enabling global inference across the graph as seen in Edge et al. [7]. These community summaries provide a foundation for answering high-level, global questions that go above the scope of individual text chunks. By leveraging the Leiden community detection algorithm, the graph is partitioned into clusters of closely related entities, each meaning to represent a distinct theme or area of knowledge within the corpus.

Once communities are identified, generating comprehensive descriptions of each community enhances the ability of the system to perform global query-focused summarization. Analogue to the approach by Edge et al. [7], we separate queries into two distinct vector searches: one local, targeting raw chunks, and one global, focused on community descriptions. By combining the results of the two searches, we create a single retrieved context that simultaneously accounts for both granular details and high-level abstractions. This approach has proven more effective for answering open-ended questions that require various levels of knowledge abstraction [11]. A visualization of the obtained knowledge graphs is provided in Figure 3.

We employed the OpenAI API framework with *ChatGPT-4o-mini* as the generation model, utilized the *text-embedding-ada-002* model for embedding generation, and leveraged Chroma and Neo4j [10] as vector databases. To make sure GRAPSE is easily accessible, all computations were conducted on MacBook Air M1 (16 GB RAM). For all vector searches across the RAG pipelines, we employed similarity search with a threshold of 0.3. The LLMs were used with default settings, except the temperature was set to 0.0, and the same prompts were used uniformly across all pipelines.

## EVALUATION

Evaluating LLM frameworks is a key step in their development, requiring well-defined benchmarks of questions and corresponding metrics. While there are several established benchmarks for LLMs covering topics such as history, reasoning, coding, and math, no such benchmark currently exists for PSE questions. One potential solution is to collect questions from PSE textbooks and tests, but this approach is constrained by copyright issues. Alternatively, manually creating a question set is possible, but it is labor-intensive and would limit users from readily testing their customized pipelines. To address these challenges, we leverage Ragas to automatically generate a benchmark of PSE-specific questions and answers for evaluating retrieval pipeline performance [11]. This method uses the raw documents in the corpus to provide ground truth, enabling reliable assessment of retrieval quality. The metrics employed to evaluate the pipeline are detailed below.

### 1. Context Recall

Context Recall (CR) evaluates how effectively relevant documents or information are retrieved, ensuring no important details are missed. Higher scores, ranging from 0 to 1, indicate better performance by capturing all pertinent material. This metric simplifies evaluation by

breaking the reference answer into individual claims and verifying alignment with the retrieved contexts, eliminating the need for time-intensive direct annotation of reference contexts. CR is calculated using the input, reference answer, and retrieved contexts, emphasizing completeness in retrieval as:

$$CR = \frac{\#\ of\ claims\ in\ reference\ supported\ by\ retrieved\ context}{Total\ \#\ of\ claims\ in\ the\ reference} \quad (1)$$

## 2. Faithfulness

The Faithfulness (F) metric measures the factual alignment of a response with the retrieved context, with scores ranging from 0 to 1, where higher values indicate greater consistency. A response is considered fully faithful when all its claims are supported by the given context. This metric is calculated by identifying individual claims in the response and verifying their support within the retrieved context, ensuring a precise assessment of factual accuracy as:

$$F = \frac{\#\ of\ claims\ in\ response\ supported\ by\ retrieved\ context}{Total\ \#\ of\ claims\ in\ the\ response} \quad (2)$$

## 3. Factual Correctness

Factual Correctness (FC) assesses how accurately a generated response aligns with a given reference, assigning a score between 0 and 1, where higher values indicate better factual consistency. The response and reference are broken into individual claims, and their overlap is evaluated using an LLM. The metric is derived as an F1 score, with true positives representing claims in the response that match the reference, false positives as unmatched claims in the response, and false negatives as reference claims missing from the response. Precision and Recall are combined to compute the final F1 score as:

$$FC = 2\,\frac{Precision \cdot Recall}{Precision + Recall} \quad (3)$$

## 4. Semantic Similarity

Semantic Similarity measures how closely the meaning of a generated response aligns with the ground truth, with scores ranging from 0 to 1, where higher values indicate a stronger semantic match. This metric evaluates response quality by assessing alignment in the semantic embedding space. The ground truth and generated response are transformed into vector representations using the same embedding model, and their similarity is calculated using cosine similarity.

# RESULTS

The entire field of PSE cannot be comprehensively represented through a modest selection of papers due to its wide-ranging diversity in research areas [4]. For the purpose of this work, we based our document selection on the references cited in the *Advanced Optimization for Process Systems Engineering* book by Professor Grossmann [12]. This selection includes 48 papers with the full list available in the GitHub repository. While this is not an exhaustive representation of all research areas within PSE, it serves as an illustrative proof of concept for this study. Importantly, our pipeline is designed to be paper-agnostic, allowing users to customize their selection of documents to suit their specific tasks and apply the methodology accordingly. Our resulting benchmark consists of 577 questions.

## Metric Comparison

We compared four distinct pipelines. The *azure_openai* pipeline represents a straightforward use of the LLM, equivalent to a single, simple API call. The *langchain_basic* pipeline corresponds to a standard RAG implementation, as illustrated in Figure 1. The *graph_db_vector* pipeline performs vector search within the graph database without any additional enhancements. Lastly, the *grapse* pipeline reflects the complete methodology proposed in this work. The results of this comparison are presented in Figure 4.

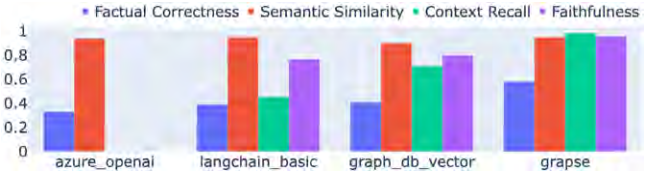

**Figure 4.** Metric comparison for different LLM pipelines performing in a PSE benchmark. Note a score of 1 is the best in all metrics.

Our proposed pipeline consistently achieves the highest scores across all evaluated metrics. The Factual Correctness and Faithfulness metrics are not applicable to the simple LLM call, as it lacks a retrieval mechanism. The Semantic Similarity metric shows minimal variation across pipelines, as it primarily reflects closeness in the embedded space rather than natural language similarity, which explains the uniformly high similarity between responses and queries. The most critical metric, however, is Context Recall, which evaluates the effectiveness of the retrieval mechanism. This metric shows the most significant improvement in our pipeline, demonstrating that the retrieved documents effectively support the generation of accurate answers.

## Q&A

To demonstrate the practical application of our framework, we posed two illustrative questions to our pipeline. The LLM was instructed to provide two distinct types of responses, showcasing the system's flexibility, while maintaining quality and rigor. The questions and corresponding answers are presented in Figure 5.

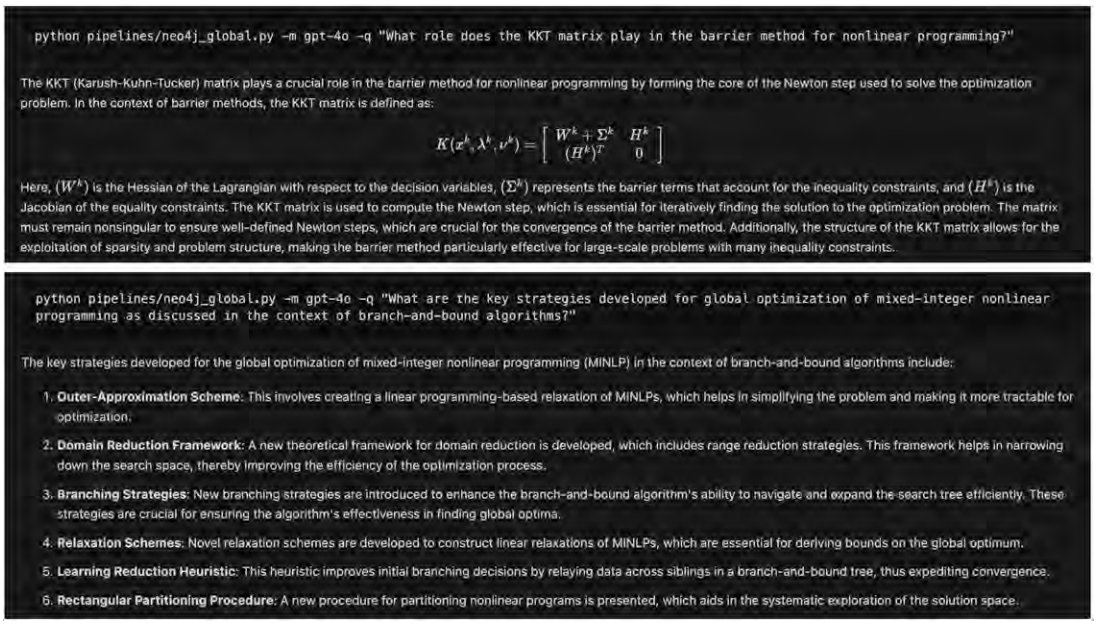

**Figure 5:** Responses generated by our proposed pipeline for two illustrative questions. For the first question the LLM was instructed to provide a concise and mathematically focused answer For the second question, it was prompted to provide a broader and more general explanation.

## CONCLUSIONS

We proposed a graph-based retrieval-augmented generation pipeline specifically designed for PSE papers. The pipeline is fully replicable and customizable to accommodate any papers the user requires. Additionally, we integrated a benchmark generation tool to facilitate the evaluation of the resulting RAGs, potentially paving the way for the creation of PSE question sets. Our pipeline outperforms both non-RAG and vanilla RAG implementations demonstrating its effectiveness. In this paper, we focused on zero-shot prompting to generate and evaluate answers. However, future work will involve integrating this pipeline with reasoning models to further enhance answer quality.

## DIGITAL SUPPLEMENTARY MATERIAL

All the code used in this work can be found in an openly availably GitHub repository: https://github.com/arpanseth/GRAPSE

## ABSTRACT

This paper presents a novel fault detection method based on key variable forecasting models. The approach integrates future forecasts of key variables into a time window, allowing for early fault detection without modifying the offline training phase of the existing fault detection model. By incorporating predicted data into the detection process, the proposed method significantly improves fault detection rates and reduces detection delays. Experiments using the Continuous Stirred Tank Heater (CSTH) system demonstrate the superiority of our method over traditional approaches, showing the advantages of forecasting in enhancing detection performance. However, our results also highlight the dependency of the method's effectiveness on the quality of the forecasting model, suggesting the need for more advanced time-series forecasting techniques. Additionally, the current point forecasting method may not be sufficient in real-world applications, where probabilistic modeling of key variables would provide more reliable detection results. Future research directions will focus on refining forecasting models and exploring probabilistic approaches for more accurate fault detection.

**Keywords**: Fault Detection, Key Variable Forecasting, Artificial Intelligence, Process Monitoring

## INTRODUCTION

With the advancement of industrial production toward digitalization and automation, process monitoring has become an essential technical tool for ensuring the safe and efficient operation of chemical processes [1]. Despite significant advancements in process engineering, the potential for process failures continues to exist. If such faults are not detected and diagnosed at an early stage, they may go beyond control. Over the past decades, various fault detection approaches have been proposed, including model-driven, knowledge-driven, and data-driven methods. Data-driven methods, in particular, have gained prominence, as they rely primarily on large amounts of process data, making them especially relevant with the widespread application of the Internet of Things (IoT). Among these, neural-network-based methods have emerged as a prominent approach. By stacking feature extraction layers and applying nonlinear activation functions between them, deep neural networks exhibit a strong capacity to capture complex, nonlinear patterns. This aligns well with the nature of chemical process variables, which are inherently nonlinear, strongly coupled with control loops, multivariate, and subject to time lags.

In industrial applications, fault detection algorithms rely on the time-series data of key variables. However, statistical methods, such as Principal Component Analysis (PCA) and Partial Least Squares (PLS), face significant limitations. These techniques struggle to capture the temporal dependencies between consecutive data points, are often ill-equipped to handle large-scale datasets, and fail to effectively leverage higher-order information—key shortcomings frequently highlighted in critiques of multivariate process monitoring, such as Multiway Principal Component Analysis (MPCA) [2]. Despite their tremendous success in certain contexts, current statistical analysis technologies still have difficulty utilizing higher-order information for multivariate process monitoring, which limits their ability to model complex, dynamic systems comprehensively [3]. To address this,

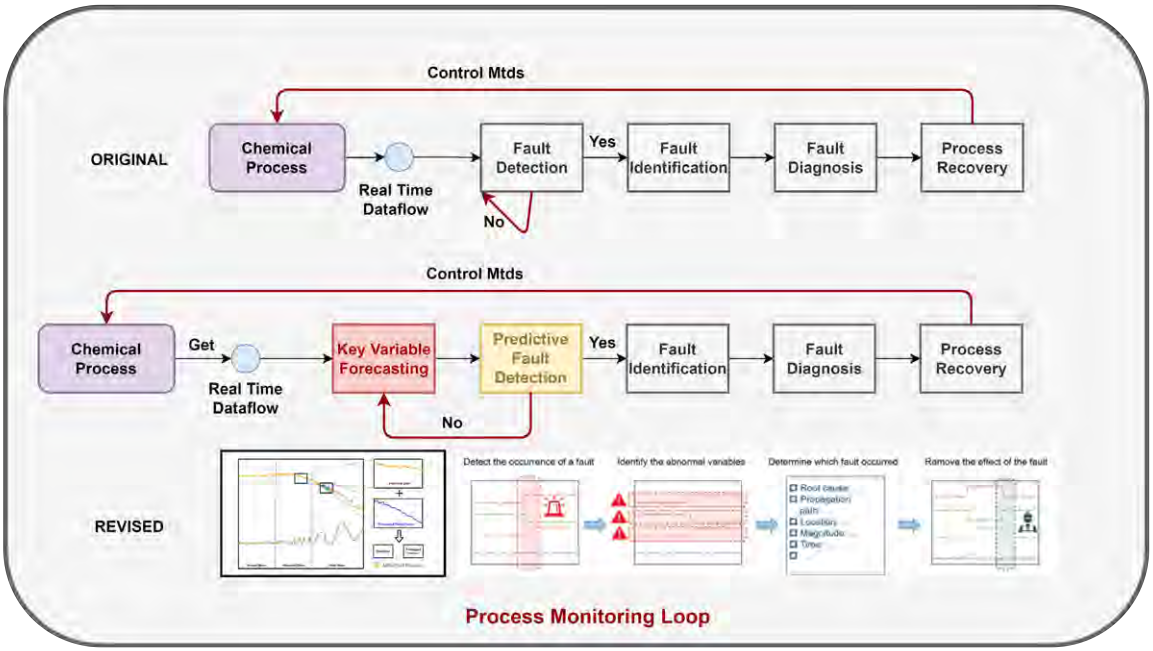

**Figure 1:** Relationship between key variable forecasting and process monitoring.

architectures such as Autoencoders (AE), Convolutional Neural Networks (CNN), and Transformers [4] incorporate the relationships between time points through sliding window sampling. However, this approach can dilute fault signals, leading to delayed fault detection. Most existing methods focus on historical data, but what if we shift the focus from the past to the future? Inspired by the human decision-making process, where adverse future trends are often considered to enable timely responses to unfavorable outcomes, we propose incorporating key variables that have already entered a fault state in future time points into the fault detection model. This proactive inclusion of future fault indicators can significantly improve the timeliness of fault detection.

Building on the aforementioned concept, this work develops and implements a proactive fault detection method based on key variable forecasting. This approach employs predictive models (Transformer and furtherly VCformer) to actively forecast key variables over a future time horizon. The predicted results, combined with historical information, are used as inputs to a variational autoencoder (VAE) to calculate the reconstruction error for fault detection. The detection component of the method is trained using normal operating data, and faults are identified by evaluating the reconstruction error. The forecasting component is trained with mixed data, where the initial part contains normal data, followed by the selective introduction of faults after a certain period, enabling the predictive model to capture both fault evolution trends and normal data characteristics.

The proposed method has been validated on the CSTH dataset, demonstrating that incorporating future information at the current time point significantly enhances early fault detection. However, optimizing the design of the reconstruction loss function and the model architecture is necessary to mitigate false alarms. Introducing future expectations into current assessments shows great potential for advancing early fault detection and diagnosis but also poses challenges, requiring higher performance from key variable forecasting models.

## METHODOLOGY

The proposed methodology consists of two stages: key variable forecasting and subsequent fault detection. A reliable key variable forecasting algorithm is used to extract the trends of key variables from multivariate time-series data, whereas the fault detection algorithm further utilizes the results of predicted key variable in conjunction with the information of existing variables for the over-the-top detection of faults.

The upper loop in Figure 1 illustrates the conventional process monitoring workflow, in which the online detection phase relies on a time window of selected key variables spanning from a previous time point to the current moment. In practical industrial applications, plants often use specific key monitoring variables as the control indicators. If these variables exceed predefined thresholds, an alarm is triggered to notify the operators of the

corrective actions. This suggests that certain key variables play a crucial role in the early detection and control of potential faults. If the evolution of key fault variables can be reliably predicted using an effective forecasting algorithm, future key variable trends can be incorporated into the current decision-making process (i.e., determining whether a fault is occurring). This results in an enhanced revised process-monitoring loop, as depicted in Figure 1. The integration of predicted key variable trends allows for an earlier warning of potential faults, thereby significantly reducing the probability of actual fault occurrences and enhancing overall process safety.

### Key Variable Forecasting Method: VCformer

RNN, Temporal Convolutional Networks (TCN), and Transformer are all neural networks used for modeling time series. Among these, Transformer utilizes the attention mechanism, which allows it to achieve better long-range dependency matching and faster training speeds compared to RNN and CNN. In both chemical process simulations and real industrial processes, key variables often exhibit unidirectional or bidirectional causal relationships owing to the interconnections of physical structures. Several time-series forecasting algorithms have already utilized the attention mechanism to capture these causal relationships, thereby improving the forecast accuracy. Notable examples include Crossformer [5], which employs a two-stage attention mechanism (channel-wise and time-wise), and VCformer [6], which further models the time lag between variables.

### Subsequent Fault Detection

This study uses the traditional method based on Variational Autoencoders (VAE) for fault detection. An Autoencoder (AE) consists of an encoder and a decoder. Given unlabeled data $\mathrm{X} = \{\mathrm{x}^{\mathrm{i}}\}_{\mathrm{i}=1}^{\mathrm{N}}$, the encoder function $\mathrm{f}_\theta$ generates a feature vector $h^i$ in the latent space, and the decoder function $g_\varphi$ reconstructs the latent-space feature vector to obtain the reconstructed vector $\hat{x}^i$ (which contains trainable parameters θ and φ).

$$\hat{x}^i = g_\varphi(h^i) = g_\varphi(\mathrm{f}_\theta(\mathrm{x}^{\mathrm{i}})) \tag{1}$$

The Variational Autoencoder (VAE) employs a directed probabilistic model to characterize the probability distribution of the latent variables. VAE utilizes two separate neural networks to model the mean and variance of the latent variables, which are sampled from a normal distribution. The loss function of the VAE is formulated as follows (n and m are dimensions of x and h respectively):

$$L_{VAE} = \frac{1}{2n} \sum_{i=1}^{n} \left( \|x_i - \hat{x}_i\|_2^2 + \beta \sum_{j=1}^{m} \left( \left(\mu_i^{(j)}\right)^2 + \left(\sigma_i^{(j)}\right)^2 - 1 - \log\left(\left(\sigma_i^{(j)}\right)^2\right) \right) \right) \tag{2}$$

In fault detection, the Negative Variational Score (NVS) is used as the monitoring indicator [7]. Since VAE is a static deep network, it is unable to capture the dynamic correlations and features of time-series variables. Thus, it serves as an ideal baseline method for fault detection afterwards.

## THE PROPOSED METHOD

The proposed Key-Variable-Forecasting-based fault detection algorithm is presented in Table 1.

## APPLICATIONS

In this section, we validate the effectiveness of the proposed fault detection method based on key variable forecasting using the Continuous Stirred Tank Heater (CSTH) as a benchmark, demonstrated in Figure 2. An ablation study is conducted to compare the proposed model with a fault detection algorithm purely based on VAE (No future forecasting information incorporated), highlighting the superiority of our approach. The experiments are implemented on a computing server equipped with an Intel Xeon Gold 5118 CPU and an NVIDIA TITAN RTX GPU.

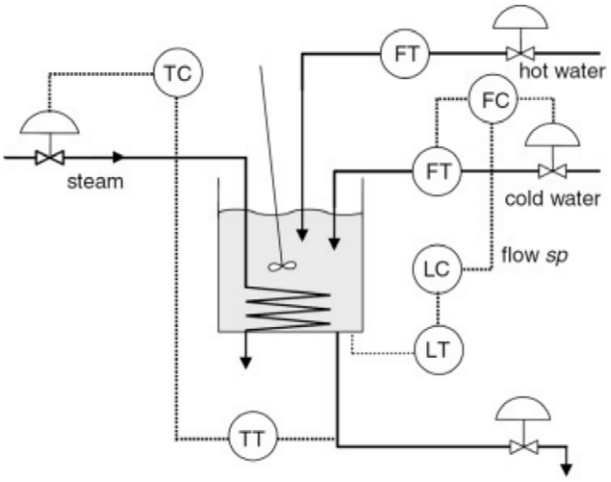

**Figure 2.** Continuous Stirred Tank Heater (CSTH) [8].

CSTH is a typical mixing vessel in chemical processes. The data used in this study originates from the MATLAB Simulink model developed by Thornhill et al. for a CSTH pilot plant. The system operates by supplying a stream of hot water and a stream of cold water into the stirred tank, which is then heated using steam. The water is uniformly mixed, and the outlet water temperature reflects the temperature of the tank.

In this study, five variables are monitored: cold water flow rate (CWflow), cold water valve position (CWValve), tank level (Level), outlet temperature (Temp),

and steam valve position (SteamValve). All measurements are represented as electrical signals in the range of 4–20 mA.

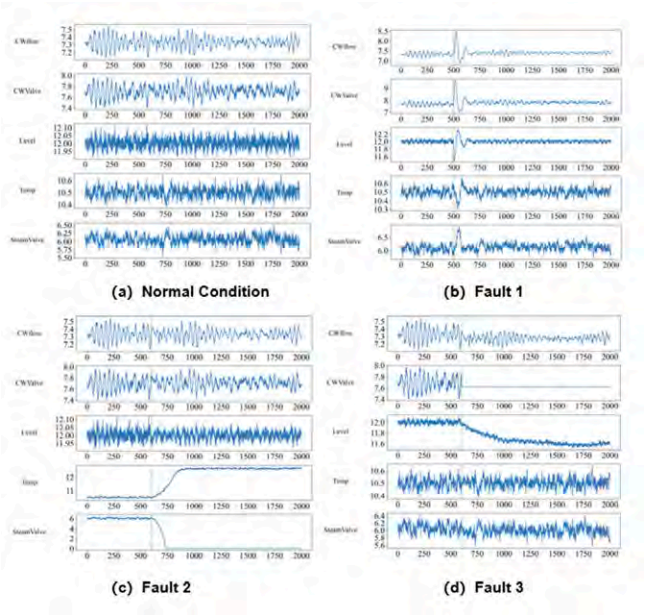

**Figure 3.** Time series data of the five CSTH variables:(a) Under normal operating conditions, (b) Under Fault 1, (c) Under Fault 2, (d) Under Fault 3.

The Simulink program generates data under normal conditions with realistic disturbances, while fault condition data must be generated by manually modifying the program. The CSTH dataset has been widely used as a benchmark in various studies, demonstrating its effectiveness.

In this simulation, due to the limited number of variables, all five variables are extracted as key variables. A total of three types of faults are designed and analyzed, as shown in Table 2. Figure 3 illustrates the temporal variations of each variable under normal operating conditions and the three fault conditions.

## Key Variable Forecasting

To enable the proposed method to learn the dynamic characteristics of the data, Fault 1 data is used as the training dataset when training the key variable forecasting model. This dataset consists of 2400 time points, with the fault introduced at the 2100th time point. Since Fault 1 does not exhibit abrupt changes in variables and does not cause system shutdown, it is well-suited for capturing the dependencies between key variables under both normal and faulty conditions.

The model hyperparameters are set as follows: seq_len = 32, pred_len = 32, encoder_layer = 1, decoder_layer = 1, learning rate = 0.0003, hidden_dim = d_model = 256.

**Table 2:** Fault descriptions in CSTH simulation.

| Fault Num | Description | Type | Usage |
|---|---|---|---|
| 1 | Tank Level | Step Drop | Key Variable Forecasting |
| 2 | Hot water temperature | Slow increase | Fault Detection |
| 3 | Cold water valve | Sticking | Fault Detection |

Figure 4 illustrates the forecasting performance of VCformer for the temperature variable under fault conditions. The model forecasts the values of key variables for the next 32 time points using data from the preceding 32 time points. Mean Squared Error (MSE) and Mean Absolute Error (MAE) are used to quantitatively evaluate the accuracy of the point predictions. Due to its built-in Variable Correlation Attention mechanism, which quantitatively models inter-variable relationships, VCformer achieves the lowest MSE and MAE values compared to methods such as Transformer, DLinear [9], and Crossformer in the forecasting task. It also demonstrates superior capability in capturing short-term dependencies among variables. Detailed quantitative results can be found in Table 3. Through comparative analysis, VCformer exhibits more stable and reliable performance in key variable prediction tasks compared to standard Transformer architectures, RNN-based models, and ARIMA, making it a preferred choice for providing accurate predictions in the subsequent fault detection process.

To further improve the forecasting model's performance, optimizing the regularization term in the loss function to enhance the model's ability to capture short-term variable relationships or designing a new model architecture could be considered.

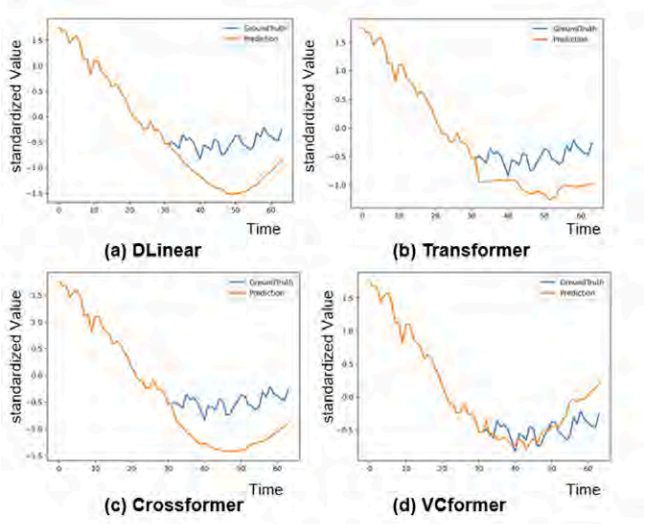

**Figure 4.** Forecasting results of the Steam Valve opening (standardized) at t=100 in the test set.

**Table 3:** Key Variable Forecasting Performance Evaluation (Bold indicates the best model, and the underlined model indicates the second-best model).

| Model | MSE | MAE |
|---|---|---|
| DLinear | 0.3735 | <u>0.3754</u> |
| Transformer | <u>0.2942</u> | 0.4016 |
| Crossformer | 0.3876 | 0.4220 |
| VCformer | **0.2680** | **0.3703** |

## Fault Detection based on Key Variable Forecasting

To demonstrate the improvement in model performance by incorporating future forecasted data, we use the Variational Autoencoder (VAE) as the baseline framework, which lacks the capability to capture the dynamic characteristics of time-series data due to its static latent representation. This limitation stems from VAE's reliance on a fixed encoding-decoding process that does not inherently account for temporal evolution, making it less effective for fault detection in dynamic industrial systems. This study investigates the contribution of the forecasting module to fault detection using the designed Fault 2 and Fault 3 conditions, with detailed fault descriptions provided in Table 1. In both fault conditions, the fault is introduced after 600 samples of normal operation, allowing us to evaluate how well the model transitions from normal to anomalous states under controlled conditions.

During the offline training phase, normal data is split into training and validation sets, with 1500 samples in the training set and 500 samples in the validation set. The test set consists of two groups of data corresponding to the two fault conditions, each containing 1500 sample time points, selected using a sliding window approach. This sliding window technique ensures that the temporal context of the data is preserved, enabling the model to analyze sequential patterns effectively. The model structure is configured as follows: VAE (Encoder: $5 \rightarrow 32 \rightarrow 10$, Reparameterization: $10 \rightarrow 10$, Decoder: $10 \rightarrow 32 \rightarrow 5$). Here, the encoder compresses the 5-dimensional input

**Table 4:** Fault detection performance of all methods for CSTH.

| Model | Fault 2 | | Fault 3 | |
|---|---|---|---|---|
| | Detection Rate | Detection Delay (s) | Detection Rate | Detection Delay (s) |
| PCA | 93.6% | 58 | 90.2% | 88 |
| KPCA | 94.2% | 52 | 91.9% | 73 |
| VAE-base | 94.7% | 49 | 94.1% | 55 |
| VAE-Predictive | **96.0%** | **37** | **95.0%** | **47** |

into a 10-dimensional latent space via an intermediate 32-unit layer, while the decoder reconstructs the data symmetrically, with reparameterization ensuring stable training of the latent variables. The hyperparameters are set as follows: learning rate = 0.0001, beta = 0.001, batch_size = 16, where the low learning rate ensures gradual convergence, beta controls the KL-divergence penalty in the VAE loss, and the small batch size balances computational efficiency with model generalization.

Table 4 compares the results of fault detection without future data incorporation (VAE-base) and fault detection with future forecasted data (VAE-Predictive) in an ablation study. Additionally, the results are compared with classical detection methods such as PCA and Kernel PCA (KPCA). The comparison shows that by incorporating future information ($w$=32, $t$=8), the proposed fault detection method is able to detect faults earlier and achieves a higher fault detection rate (FDR). Specifically, the window size $w$=32 defines the length of the input sequence, while $t$=8 indicates that 8 future time points are forecasted and integrated, enhancing the model's ability to anticipate fault onset compared to purely historical data-driven approaches like PCA and KPCA.

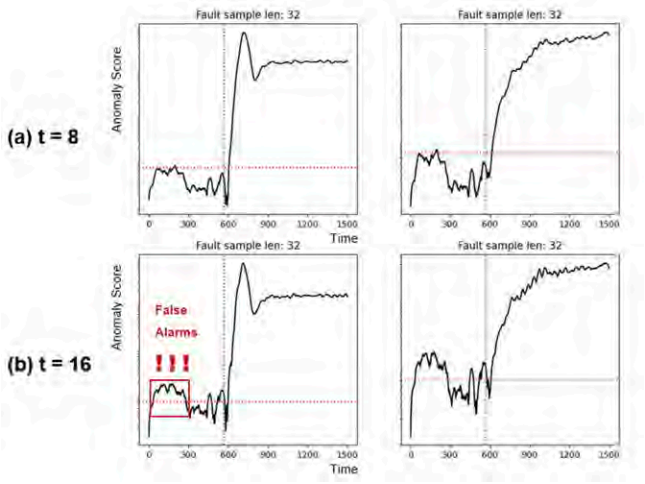

**Figure 5.** The anomaly score over time for the Fault 2 and 3.

Furthermore, we also investigate the impact of the number of future time points $t$ on fault detection. As $t$ increases, the proportion of future information within the new sliding window becomes larger. However, errors in key variable forecasting may also introduce a higher False Positive Rate (FPR) into the detection algorithm. This trade-off arises because forecasting inaccuracies, compounded over longer prediction horizons, can mislead the model into flagging normal variations as faults. By increasing $t$ to 16 (where future data occupies half of the time window length), a significant increase in false alarms is observed, as illustrated in Figure 5. For instance, at $t$=16, the anomaly scores in Figure 5 show more frequent spikes in non-fault regions, reflecting the amplified uncertainty from extended forecasts. This suggests that incorporating future trends may lead to increased fluctuations in diagnostic results, which might necessitate adjustments to the loss function—such as increasing the weight of reconstruction error relative to forecasting error or introducing a penalty term for false positives—to mitigate false positives and stabilize performance.

## CONCLUSIONS

In this paper, we introduce an innovative fault detection framework that leverages key variable forecasting models to enhance diagnostic precision. Our approach begins by employing a forecasting method to predict variable values over an upcoming time window. These predictions are then seamlessly integrated with the current time window data and fed into the detection model. A standout feature of this method is its plug-and-play versatility: it requires no alterations to the original fault detection model during offline training, with future predicted values simply appended to the input time window during online deployment. This elegant design yields superior fault detection rates, reduces detection latency, and can be effortlessly incorporated into existing state-of-the-art (SOTA) models to amplify their effectiveness.

Nevertheless, supplementary experiments reveal that the efficacy of our fault detection model hinges

closely on the accuracy of the forecasting component, underscoring the need for robust time-series forecasting techniques tailored to chemical processes. A further limitation lies in our reliance on point forecasting, which, while effective, falls short of capturing the full complexity of real-world scenarios. In practice, modeling the probability distributions of key variables alongside their point estimates could provide more reliable and confident detection outcomes. This observation paves the way for exciting new directions in our ongoing research.

## ABSTRACT

The electrification of industrial heat is a promising pathway for decarbonization, yet challenges persist in balancing capital costs, operating costs, and emissions reduction. While previous studies have assessed electrification through heat integration and graphical methods, these approaches do not inherently determine the optimal hybrid technology configuration. This study introduces an optimization-based framework that systematically evaluates the cost-optimal allocation of electrified and conventional heating technologies. Formulated as a Mixed-Integer Linear Programming (MILP) model and implemented in Gurobi, the framework minimizes Total Annualized Cost (TAC) while satisfying heat demand, technology constraints, and emissions targets. Applied to an industrial case study, the model compares three scenarios: a fully conventional system relying on steam boilers and fired heaters, a fully electrified system utilizing high-temperature heat pumps, electrode boilers, and electric heaters, and an optimized hybrid system that strategically integrates both conventional and electrified technologies. The results demonstrate that the optimized hybrid system achieves a 75% electrification rate, reducing TAC by 7% compared to previous graphical electrification assessments. The model selects a combination of a high-temperature heat pump and a steam boiler, highlighting the importance of accounting for heat pump cost savings in economic evaluations. Additionally, a comparison with Carbon Capture and Storage (CCS) reveals that partial electrification results in a lower $CO_2$ abatement cost of 131 \$/t$CO_2$, compared to 140 \$/t$CO_2$ for CCS, reinforcing the economic viability of industrial heat electrification. This study provides a systematic optimization framework for guiding industrial electrification decisions and emphasizes the role of carbon taxation, electricity pricing, and renewable energy incentives in shaping cost-effectiveness. The findings underscore the importance of integrating process optimization with techno-economic analysis to accelerate industrial decarbonization.

**Keywords**: Optimization, Renewable and Sustainable Energy, Energy Systems, Technoeconomic Analysis

## INTRODUCTION

The industrial sector is a major contributor to global energy consumption and greenhouse gas (GHG) emissions, with process heat accounting for over half of industrial energy use [1]. Traditionally, industrial heat has been generated using fossil fuel-based technologies, leading to significant $CO_2$ emissions. Decarbonizing industrial heat generation is therefore essential for achieving sustainability targets and reducing reliance on fossil fuels. One of the most promising pathways for industrial decarbonization is electrification, where technologies such as high-temperature heat pumps (HTHPs), electrode boilers (EBs), and electric heaters (EHs) replace conventional systems.

A comprehensive analysis has shown that 78% of industrial energy demand is electrifiable, with potential $CO_2$ reductions of up to 78% as the power sector decarbonizes [3]. Industrial process heating, particularly electrifying industrial boilers, has been identified as a high-impact application, potentially reducing emissions by 19 million metric tons of $CO_2$ equivalent (MMmt$CO_2$e) under a high-renewables energy grid scenario [4]. Gaps remain in developing systematic, cost-effective electrification processes tailored to specific industries, particularly in chemical sectors and high-temperature heat pump

applications [5].

Beyond technological feasibility, policies and economic incentives play a critical role in accelerating industrial electrification [7]. However, transitioning to electrified heat generation presents several key challenges. Matching electrical heating technologies to specific temperature requirements and industrial applications remains complex, as different processes require different heating profiles [6]. Additionally, electrified heating systems often have higher capital and operating costs compared to conventional fossil-fuel-based technologies, making economic feasibility highly dependent on electricity prices and carbon taxation policies [2]. At the same time, there is a pressing need for a systematic framework that optimizes hybrid heat system configurations while leveraging renewable electricity sources to minimize $CO_2$ emissions and enhance sustainability.

## BACKGROUND AND RELATED WORK

Industrial heat electrification has gained significant attention as a key strategy for reducing greenhouse gas emissions and improving energy efficiency in industrial processes. Several studies have explored the techno-economic feasibility of electrification technologies, particularly high-temperature heat pumps (HTHPs), electrode boilers, and electrochemical processes. HTHPs have demonstrated high efficiencies, with coefficient of performance (COP) values ranging from 2.5 to 7 for low-to-medium temperature applications (≤160°C) [8]. However, their adoption remains limited by temperature constraints and high capital costs, restricting their widespread application in high-temperature industrial processes. Recognizing these limitations, Zühlsdorf et al. analyzed the potential for heat pump-based process heat supply at large capacities and temperatures exceeding 150°C, assessing the technical and economic feasibility of integrating heat pumps into industrial systems [9].

Beyond conventional electrification technologies, innovative electrochemical processes are also being explored for cleaner and more energy-efficient industrial applications. Electrochemical synthesis has shown promise in producing ethylene and propylene oxides, providing a cleaner alternative to conventional petrochemical production methods [11]. However, despite their selectivity and efficiency, technical bottlenecks remain, particularly in scaling up these processes for widespread industrial adoption [10]. The integration of electrochemical pathways into industrial heat systems requires further research to address these challenges and enhance their feasibility for large-scale operations.

Several studies have examined the broader implications of industrial electrification on energy systems. Lechtenböhmer et al. found that a fully electrified industry would create significant demand for electricity, which could place major strains on existing power infrastructure [12]. Similarly, Kosmadakis) estimated that high-temperature heat pumps (above 150°C) could meet only 1.5% of industrial heat demand in Europe, underscoring the limitations of single-technology solutions[13]. Bühler et al. investigated the electrification potential in Danish industries, concluding that while up to 80% of heat demand could technically be electrified, economic feasibility remains a major challenge due to high upfront costs and fluctuating electricity prices [14]. These studies highlight the varying degrees of electrification potential across industries but emphasize the need for a more holistic approach that integrates flexibility, cost analysis, and system-level impacts.

Techno-economic analysis (TEA) is commonly employed to evaluate Total Annualized Cost (TAC), Levelized Cost of Heat (LCOH), and $CO_2$ abatement costs, with studies showing that low electricity prices and high carbon taxes are essential for making electrification competitive with fossil-fuel-based systems [16].

Furthermore, individual electrification technologies, optimization-based frameworks have been proposed to evaluate the electrification of industrial heating systems. A multi-period graph-theoretical (P-graph) approach has been applied to assess refinery electrification, optimizing technology selection under different economic and environmental scenarios [18]. Similarly, a deterministic global optimization model has been developed to evaluate solar thermal and photovoltaic (PV) hybridization for industrial process heat, identifying parabolic trough collectors with thermal energy storage as the most cost-effective solution [19]. While these studies provide valuable insights into electrification strategies, they primarily focus on energy sourcing and hybridization, rather than optimizing the allocation of electrified heating technologies within an integrated process heat system.

This study develops an optimized electrification framework for hybrid industrial heat system, integrating heat integration techniques with Mixed-Integer Linear Programming (MILP) optimization. The framework systematically evaluates and allocates heat generation technologies based on TAC, emissions constraints, and technical feasibility. A key contribution is the comparison between previous graphical electrification assessments and an optimization-based approach, demonstrating improvements in hybrid system allocation and cost-effectiveness. The model is applied to an industrial case study, enabling a comparative analysis of full electrification, hybrid heating systems, and conventional fossil-based technologies. By integrating process integration, techno-economic analysis, and carbon taxes, this research provides a comprehensive and practical roadmap for achieving cost-effective and sustainable industrial heat systems.

## OPTIMIZATION FRAMEWORK

Industrial heat electrification presents significant economic and technical challenges, necessitating a systematic approach to determine the most cost-effective integration of electrified and conventional heat generation technologies. While graphical heat integration techniques can provide initial insights, they do not inherently identify the optimal hybrid system allocation that balances cost and emissions reduction. This study introduces an optimization-based framework formulated as a Mixed-Integer Linear Programming (MILP) model, implemented using Gurobi, to achieve a cost-optimal hybrid heat system configuration.

The model is designed to minimize the Total Annualized Cost (TAC) while ensuring compliance with industrial heat demand, technology constraints, and emissions targets. The technologies included are both electrified (High-Temperature Heat Pumps, Electric Boilers, Electric Heaters) and conevtional ones (Steam Boilers and Fired Heaters).

To assess the optimization framework, the model is applied to an industrial case study, generating an optimized hybrid heating system. This system identifies the most cost-effective mix of conventional and electrified technologies for an industrial plant. The optimized system is then compared to scenarios using only conventional technologies (steam boilers and fired heaters) and a fully electrified system (relying solely on HTHPs, EBs, and EHs).

The comparison highlights the trade-offs between capital costs, electricity prices, and carbon taxation policies.

## METHODOLOGY

### Overview

To evaluate the electrification potential of an industrial heating system, a two-stage approach is employed:

- Graphical Analysis Using Heat Integration – Heat recovery is maximized using Pinch Technology, and the Grand Composite Curve (GCC) is generated to determine minimum heating and cooling demands. This step establishes a benchmark for heating utility selection and technology placement.
- Optimization via MILP Model – An MILP-based framework is developed to determine the optimal technology mix that minimizes cost while meeting emissions constraints.

While graphical methods provide valuable initial insights, they do not yield an optimal solution. The MILP optimization model builds upon heat integration findings, ensuring that the electrification strategy is both technically feasible and economically optimal.

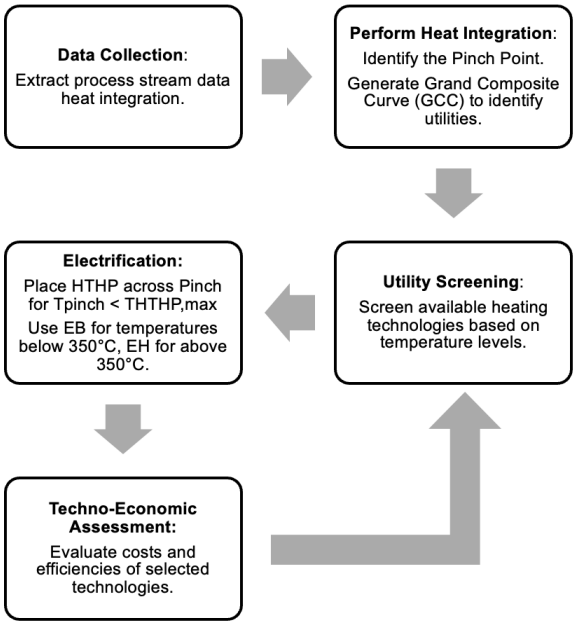

**Figure 1.** Electrification framework.

To evaluate the electrification potential of an industrial heating system, heat integration is first performed to maximize heat recovery and establish a baseline for assessing various heating technologies. Process stream data is extracted, and Pinch Technology is applied to determine minimum heating and cooling demands. The Grand Composite Curve (GCC) is generated, which helps identify utility requirements and guides the selection of suitable utilities based on the required heat load and corresponding temperatures. The GCC also informs the placement of available heat-supplying technologies. By integrating a heat pump and utilizing heat integration, the placement of the heat pump further reduces the minimum utility requirements. Once the technologies are placed and a final system design is achieved, a techno-economic assessment compares the costs and efficiencies of each option, and Technology Readiness Levels (TRL) ensure the feasibility of implementing electrification.

While this approach uses graphical methods to provide insights, it does not yield the optimal solution. Therefore, once the framework is established, it becomes clear that an optimization model, utilizing heat integration as a benchmark, is necessary to achieve the desired optimal outcome.

The MILP optimization model developed in this study determines the optimal allocation of heat generation technologies while ensuring compliance with technical constraints, economic feasibility, and emissions reduction goals.

## Objective Function

The objective function minimizes the Total Annualized Cost (TAC), incorporating:

$$TAC = = \sum(\text{Capital Costs}) + \sum(\text{Operating Costs}) - Cost\ Savings\ from\ Heat\ Recovery \quad (1)$$

where capital costs (CAPEX) account for the investment cost of each technology, and operating costs (OPEX) include electricity and fuel expenditures. $CO_2$ taxes are incorporated to penalize emissions, incentivizing a transition toward low-carbon heat sources.

The decision variables in the model represent the heat supplied by each technology across different temperature levels. Additionally, a binary variable is introduced to govern the usage of HTHPs, ensuring that the heat pump can only operate when its temperature constraints are satisfied.

## Constraints

### Heat Balance Constraint

At each temperature level iii, the total heat supplied by all technologies must satisfy the corresponding heat demand:

$$\sum Qtech, i = Di, \forall \text{i} \quad (2)$$

where $Q_{tech,i}$ is the heat provided by each technology at interval i, and Di represents the industrial process heat demand at the same interval.

### Technology Operating Temperature Constraints

Each heat generation technology is restricted to operate within its maximum allowable temperature range to ensure technical feasibility:

$$Tmax, i \geq Ti, \forall \text{i} \quad (3)$$

where $T_{max,tech}$ is the maximum operating temperature of a given technology, and $T_i$ is the required process temperature at interval i.

### Emissions Constraint

To ensure emissions reduction, the total $CO_2$ emissions fossil fueled technologies must be below a predefined threshold:

$$\sum Econventional \leq \text{Ethreshold} \quad (4)$$

where $E_{conventional}$ represent the $CO_2$ emissions from conventional technologies. And $E_{threshold}$ enforces a cap on total emissions, encouraging greater electrification.

### Piecewise Linearization of Heat Pump COP

The Coefficient of Performance (COP) of heat pumps is a nonlinear function of the heat load and temperature lift, requiring piecewise linearization for integration into the MILP model:

$$COPhthp = f(Qhthp, Tlift) \quad (5)$$

This approximation ensures computational efficiency while capturing nonlinear COP behavior.

The COP curve was approximated using 13 breakpoints, placed at 5 (K) increments across the 0–70 (K) temperature lift range. At the identified optimal solution, the linearization error was 0.6%. A sensitivity analysis was conducted by varying the number of breakpoints (7–13). The results showed that the Total Annualized Cost (TAC) varied by less than 5% across different configurations, while the hybrid technology mix, such as the combination of high-temperature heat pumps (HTHPs) and steam boilers, remained stable. Only minor shifts in heat allocation were observed, with HTHP utilization varying by approximately ±3%. These findings confirm that the model's conclusions are robust to reasonable changes in linearization parameters, reinforcing the validity of the approach.

### Cost Modeling

Conventional equipment cost estimation followed guidelines by Smith (2016) [17]. Cost data is represented through charts showing costs relative to equipment capacity or expressed as a power law of capacity:

$$C_E = C_B(\frac{Q}{Q_B})^M \quad (6)$$

Where $C_E$ is the equipment cost at Q capacity, $C_B$ is the base cost for equipment of $Q_B$ capacity, and M is an equipment type dependent constant.

Capital costs of electrified technologies are estimated using CAPEX factors from the literature.

$$Capital\ Cost = Capacity\ (MW) \times CAPEX\ factor\ (\$/MW) \quad (7)$$

The operating cost includes electricity cost for electric technologies and fuel cost for steam boilers and fired heaters.

The optimization model is solved using Gurobi, and the output includes the optimal technology mix, representing the megawatts of heat supplied by each technology at eachtemperature level, along with the Total Annualized Cost (TAC), total $CO_2$ emissions, and the percentage of electrification achieved.

# CASE STUDY AND RESULTS

This case study builds upon previous work in which heat integration techniques were applied and the assessment of electrification in an industrial plant heating system was performed graphically, following the developed framework shown in Figure 1. The analysis demonstrated a significant reduction in minimum heating and cooling utilities, with the heating utility for the plant after heat integration, Qhmin, at 16.5 MW and the minimum cooling utility, Qcmin, at 26.1 MW. The application of a high-temperature heat pump (HTHP) further lowered the minimum

heating and cooling demands by utilizing waste heat. The study evaluated several scenarios, including partial and full electrification with renewable and conventional electricity, comparing the impacts on operating costs, capital costs, and $CO_2$ emissions.

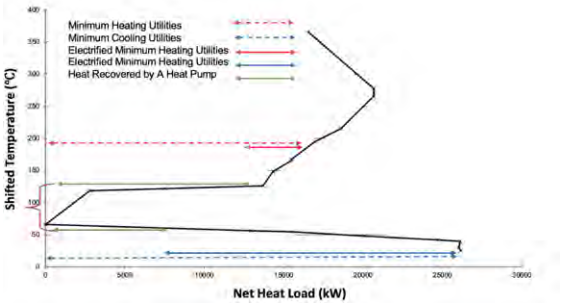

**Figure 2.** GCC of Case Study.

The Partial Electrification with Renewable Electricity scenario is used here as the case study for the optimization model, as it was the best-performing scenario when combining both emissions reduction and economic viability. In this scenario, the integration of an HTHP reduced heating demand by over 83%, resulting in an 80% reduction in emissions and lower annualized costs compared to conventional technologies. This scenario serves as the baseline for the optimization approach in the current study, which aims to evaluate and compare the performance of hybrid heat systems using a multi-criteria optimization model.

**Table 1:** Summary of scenarios results.

| Scenario | $CO_2$ reduction (%) | TAC (MM$/y) |
|---|---|---|
| 100 % electrified | 100 | 7.9 |
| Partial electrification | 83 | 6.1 |
| Partial electrification (Optimized) | 75 | 5.8 |

## DISCUSSION

The The optimization results revealed an optimal hybrid heat system configuration, where 75% of the heating demand was met using electrified technologies. The model selected a combination of a high-temperature heat pump (HTHP) and a steam boiler (SB) as the most cost-effective solution. The preference for a steam boiler over a fired heater was expected, as the steam boiler provides a more economical alternative, particularly when the temperature levels within the case study allowed for full coverage using steam. Similarly, the selection of an HTHP instead of an electrode boiler (EB) was largely influenced by the model's ability to account for heat pump cost savings within the objective function.

Interestingly, previous studies have not explicitly accounted for the cost savings associated with heat pump integration, which may have led to underestimations of electrification's economic feasibility. This omission may explain why electrification has often been perceived as less competitive compared to other decarbonization strategies. In this study, while the reduction in Total Annualized Cost (TAC) was modest (~7%), the computational efficiency and ease of implementation of the optimization model indicate that the trade-off is worthwhile. The limited TAC reduction aligns with expectations, as the capital investment required for electrified technologies remains fixed regardless of optimization. Once a technology falls within a certain capacity range, its investment cost remains relatively unchanged between the optimized and non-optimized cases.

In addition to evaluating full and partial electrification, this study also compared Carbon Capture and Storage (CCS) as an alternative decarbonization strategy. While CCS is a well-established technology, it is capital-intensive and raises concerns regarding the long-term environmental impacts of $CO_2$ sequestration. The results indicate that partial electrification achieved the lowest $CO_2$ abatement cost at 131 \$/t$CO_2$, compared to CCS at 140 \$/t$CO_2$. However, after optimization, the abatement cost increased to 133 \$/t$CO_2$, which can be attributed to the nonlinear relationship between cost and the percentage of electrification. Unlike the trade-off between emissions reduction and electrification percentage, which is relatively linear, the cost vs. electrification percentage relationship is more complex.

Since the optimized scenario resulted in a lower percentage of electrification, it also incurred lower overall costs, but at the expense of higher emissions compared to the non-optimized case. This, in turn, led to a higher abatement cost due to the increased cost per unit of $CO_2$ reduction. Nevertheless, electrification remains a more attractive decarbonization strategy than CCS in this case study, as it offers a lower abatement cost and avoids uncertainties associated with long-term carbon sequestration.

## ABSTRACT

While bilevel optimization is gaining prominence across various domains, the field lacks standardized tools for generating test problems that can effectively evaluate and guide the development of efficient solution algorithms. We define the term "trivial bilevel optimization problem" as a bilevel problem whose high-point relaxation solution is also feasible. These easy-to-solve problems frequently arise in naïve implementations of random bilevel optimization problem generators, significantly impacting the evaluation of bilevel solution algorithms. However, this problem has not been addressed in the literature to our best knowledge. This work introduces a non-trivial mixed-integer bilevel optimization problem generator, NT-BMIPGen, and a problem library, designed to eliminate the generation of trivial bilevel problems. Through analysis of the bilevel problem structure, we identify key factors contributing to problem triviality. Particularly, the upper to lower variable ratios and the number of decoupled lower-level continuous variables increasing two-level competition significantly impact problem triviality. The proposed generator allows users to customize problem structures while ensuring non-triviality by checking the bilevel feasibility of highpoint relaxation. Additionally, we present a library of 105 non-trivial problems to support algorithm development and testing. This work advances the understanding of bilevel problem complexity and provides essential tools for the systematic evaluation of bilevel optimization algorithms.

**Keywords**: Bilevel Optimization, Random Problem Generator, Algorithm Evaluation

## INTRODUCTION

Bilevel optimization, characterized by nested optimization problems, has gained prominence in modeling two-player interactions across various domains, including environmental policy [1], electricity markets [2], hierarchical optimal control [3], supply chain optimization [4], and industrial planning and scheduling [5, 6]. Despite its potential wide applicability, bilevel optimization is not widely utilized as its solution is very challenging, known to be NP-hard [7]. Mixed-integer bilevel optimization problems are even more challenging to solve [8], prompting the development of diverse solution methods, such as Bender's decomposition [9], multiparametric optimization [10, 11], penalty functions [12], and branch-and-bound/cut algorithms [13].

Metaheuristic methods, while not guaranteeing optimality or feasibility in finite time, have gained significant attention for addressing non-linear bilevel problems beyond the reach of deterministic approaches [14]. These problems are often tackled iteratively by alternating between the upper and lower levels, using techniques such as genetic algorithms [15], particle swarm optimization [16], etc. Recently, hybrid approaches have emerged, combining metaheuristics in upper-level with deterministic optimization solvers to handle the lower-level problem within this iterative framework and have guarantees of feasibility [1].

Existing bilevel problem generators and libraries provide valuable resources for testing and evaluating algorithms. For instance, problem generators tailored to specific structures have been developed [17]. A bilevel parametric optimization toolbox (B-POP) is developed with a random problem generator and problem library

[18]. BOBILib [19] offers a comprehensive mixed-integer bilevel problem library containing 2,500 problems. However, due to the diversity in problem types—encompassing different variable types, constraints, and objective functions—the field lacks standardized problem generators or libraries that are adaptable to user-defined problem structures and sizes. While random problem generators are widely used for algorithm evaluation [11], they often result to a significant number of very short solving time bilevel problems [19], limiting their utility for rigorous algorithm testing.

This article presents a non-trivial mixed-integer bilevel optimization problem generator (NT-BMIPGen) and accompanying problem library designed to support the understanding, analysis, and evaluation of bilevel optimization problems. We first outline the problem structure (number of upper/lower variables, binary/continuous, coupled/decoupled variables, and constraints). Next, we examine the concept of problem triviality and its underlying causes. We then present the bilevel problem generator and a bilevel problem library containing 105 problems, highlighting their utility in evaluating diverse non-trivial bilevel problem structures. Finally, we conclude with a discussion of future research opportunities in bilevel optimization.

## GENERAL BILEVEL PROBLEM STRUCTURE

A general Mixed-Integer Bilevel programming problem (B-MIP) can be written in the form of Equation (1). The problem contains two objective functions, an upper-level objective function $F$ and a lower-level objective function $f$. The problem includes both continuous and integer variables, where $\boldsymbol{x}$ is a vector of all continuous variables, $\boldsymbol{y}$ is a vector of all integer variables, subscripts $u$ and $l$ indicate upper- and lower-level variables respectively, and function vectors $\boldsymbol{G}$ and $\boldsymbol{g}$ represent upper- and lower-level constraints respectively.

$$\min_{\boldsymbol{x},\boldsymbol{y}} F(\boldsymbol{x},\boldsymbol{y})$$

$$s.t.\, G(\boldsymbol{x},\boldsymbol{y}) \le 0,$$

$$\boldsymbol{x_l},\boldsymbol{y_l} \in arg\min_{\boldsymbol{x_l},\boldsymbol{y_l}}\{f(\boldsymbol{x},\boldsymbol{y}): g(\boldsymbol{x},\boldsymbol{y}) \le 0\}$$

$$\boldsymbol{x} = \begin{bmatrix}\boldsymbol{x_u}\\ \boldsymbol{x_l}\end{bmatrix}^T, \boldsymbol{y} = \begin{bmatrix}\boldsymbol{y_u}\\ \boldsymbol{y_l}\end{bmatrix}^T,$$

$$\boldsymbol{x} \in R^n, \boldsymbol{y} \in Z^m \qquad (1)$$

Bilevel programming problems couples two distinct optimization problems by embedding the lower-level optimization problem as a constraint of the upper-level optimization problem. A bilevel problem is feasible if both upper- and lower-level constraints ($G$, $g$) are satisfied, and the lower-level problem is solved to global optimality at the selected optimal upper-level variables.

## Coupling bilevel optimization structure

Couplings between the two optimization levels appear linked when upper-level and lower-level variables emerge together in either the constraints and/or objective functions of the problem. Coupled variables, defined as variables that appear in constraint or objective functions that doesn't belongs to their own level, enhance the interaction between the two optimization levels. Coupled variables can manifest as either collaborative or competitive dynamics. In contrast, decoupled variables lack direct interaction with the other level and only exist in their own level but can still increase the overall problem complexity by increasing the complexity of the problem within each level.

To explore the coupling behavior of the bilevel optimization problems, general B-MIPs can be reformulated, without loss of generality, as Equation (2). This form is modified from [16] and can help introduce different B-MIP structures to explore coupling behavior.

$$\min_{\boldsymbol{x},\boldsymbol{y}} F = F_u(\boldsymbol{x_{ud}},\boldsymbol{y_{ud}}) + F_l(\boldsymbol{x_{ld}},\boldsymbol{y_{ld}}) + F_c(\boldsymbol{x_{uc}},\boldsymbol{x_{lc}},\boldsymbol{y_{uc}},\boldsymbol{y_{lc}})$$

$$s.t.\, G_{ud}(\boldsymbol{x_{ud}},\boldsymbol{y_{ud}}) \le 0, G_{uc}(\boldsymbol{x_{ud}},\boldsymbol{x_{uc}},\boldsymbol{y_{ud}},\boldsymbol{y_{uc}}) \le 0$$

$$\boldsymbol{x_{ld}},\boldsymbol{x_{lc}},\boldsymbol{y_{ld}},\boldsymbol{y_{lc}} \in arg\min_{x_{ld},x_{lc},y_{ld},y_{lc}}\{f(\boldsymbol{x},\boldsymbol{y}) = f_l(\boldsymbol{x_{ld}},\boldsymbol{y_{ld}}) + f_c(\boldsymbol{x_{uc}},\boldsymbol{x_{lc}},\boldsymbol{y_{uc}},\boldsymbol{y_{lc}}): g_{ld}(\boldsymbol{x_{ld}},\boldsymbol{y_{ld}}) \le 0, g_{lc}(\boldsymbol{x_l},\boldsymbol{y_l}) \le 0, g_g(\boldsymbol{x_{uc}},\boldsymbol{x_{lc}},\boldsymbol{y_{uc}},\boldsymbol{y_{lc}}) \le 0\}$$

$$\boldsymbol{x} = \begin{bmatrix}\boldsymbol{x_{ud}}\\ \boldsymbol{x_{uc}}\\ \boldsymbol{x_{ld}}\\ \boldsymbol{x_{lc}}\end{bmatrix}^T, y = \begin{bmatrix}\boldsymbol{y_{ud}}\\ \boldsymbol{y_{uc}}\\ \boldsymbol{y_{ld}}\\ \boldsymbol{y_{lc}}\end{bmatrix}^T,$$

$$\boldsymbol{x} \in R^n, \boldsymbol{y} \in Z^m \qquad (2)$$

,where $\boldsymbol{x}$ is a vector of all continuous variables, $\boldsymbol{y}$ is a vector of all integer variables, subscripts $u$ and $l$ indicate upper and lower levels respectively; and subscripts $c$ and $d$ indicates coupled and decoupled respectively as shown in Table 1

**Table 1:** Variable Classification by Type and Coupling.

| | Continuous ($\boldsymbol{x}$) | | | | Binary ($\boldsymbol{y}$) | | | |
|---|---|---|---|---|---|---|---|---|
| | $\boldsymbol{x_{ud}}$ | $\boldsymbol{x_{uc}}$ | $\boldsymbol{x_{ld}}$ | $\boldsymbol{x_{lc}}$ | $\boldsymbol{y_{ud}}$ | $\boldsymbol{y_{uc}}$ | $\boldsymbol{y_{ld}}$ | $\boldsymbol{y_{lc}}$ |
| Upper | ✓ | ✓ | | | ✓ | ✓ | | |
| Lower | | | ✓ | ✓ | | | ✓ | ✓ |
| Coupled | | ✓ | | ✓ | | ✓ | | ✓ |
| Decoupled | ✓ | | ✓ | | ✓ | | ✓ | |

The constraints $G$ and $g$ correspond to the upper and lower constraints respectively, which can be categorized into 5 types based on the type of variables that can appear within them (Table 2). Functions $F$ and $f$ are the

upper and lower-level objective functions, which can also be decomposed into five subtypes based on their structure. A detailed classification of the five types of constraints and objective functions is provided in Table 2.

**Table 2:** Constraints and Objective Function Classification by Type and Coupling.

| | Name | Description |
|---|---|---|
| **Constraints** | | |
| 1 | $G_{ud}(\boldsymbol{x_{ud}}, \boldsymbol{y_{ud}})$ | Upper decoupled |
| 2 | $G_{uc}(\boldsymbol{x_{ud}}, \boldsymbol{x_{uc}}, \boldsymbol{y_{ud}}, \boldsymbol{y_{uc}})$ | Upper coupled |
| 3 | $g_{ld}(\boldsymbol{x_{ld}}, \boldsymbol{y_{ld}})$ | Lower decoupled |
| 4 | $g_{lc}(\boldsymbol{x_{ld}}, \boldsymbol{x_{lc}}, \boldsymbol{y_{ld}}, \boldsymbol{y_{lc}})$ | Lower coupled |
| 5 | $g_g(\boldsymbol{x_{uc}}, \boldsymbol{y_{uc}}, \boldsymbol{x_{lc}}, \boldsymbol{y_{lc}})$ | General |
| **Objective Functions** | | |
| 1 | $F_u(\boldsymbol{x_{ud}}, \boldsymbol{y_{ud}})$ | Upper decoupled upper-level |
| 2 | $F_l(\boldsymbol{x_{ld}}, \boldsymbol{y_{ld}})$ | Lower decoupled upper-level |
| 3 | $F_c(\boldsymbol{x_{uc}}, \boldsymbol{x_{lc}}, \boldsymbol{y_{ud}}, \boldsymbol{y_{lc}})$ | Coupled upper-level |
| $F = F_u + F_l + F_c$ | | Full upper-level |
| 4 | $f_l(\boldsymbol{x_{ld}}, \boldsymbol{y_{ld}})$ | Lower decoupled lower-level |
| 5 | $f_c(\boldsymbol{x_{uc}}, \boldsymbol{x_{lc}}, \boldsymbol{y_{ud}}, \boldsymbol{y_{lc}})$ | Coupled lower-level |
| $f = f_l + f_c$ | | Full lower-level |

## BILEVEL PROBLEM TRIVIALITY

Even though bilevel optimization problems have been proved to be hard to solve, randomly generated bilevel optimization problems are not always hard to solve. As shown in [19], randomly generated problems of the same size and structure have a large range of solving time, some of them can be solved within seconds while some need hours to be solved. Some of the quickly and easily solvable problems are likely trivial and should not be used for algorithm development or evaluation, as they fail to represent the true complexity of bilevel optimization problems. To determine triviality, we solve two single-level problems: the high point relaxation problem (Equation (3)) and the bilevel feasibility check problem (Equation (4)).

### Triviality Check process

High point relaxation problem is a single-level optimization problem optimizing the upper-level objective function over the set of all constraints in the bilevel problem, including both the upper and lower-level constraints, as shown in Equation (3). A bilevel problem is considered trivial if its high-point relaxation is bilevel feasible. To verify bilevel feasibility, we solve the bilevel feasibility check problem, where the upper-level variables' solution is fixed (denoted as $\tilde{\boldsymbol{x}}, \tilde{\boldsymbol{y}}$) and the lower-level problem is solved, as shown in Equation (4). If the upper-level objective $F$ calculated by solutions in Equation (4) equals that in Equation (3), the problem is bilevel feasible.

A bilevel optimization problem is termed trivial if its solution can be obtained by solving these two single-level problems: the high-point relaxation (3), and the bilevel feasibility check problem (4). Both single-level problems are solvable using standard optimization solvers. The high-point relaxation provides the lower bound, and the bilevel feasibility check provides the upper bound to the original bilevel problem. When these bounds are equal, the solution corresponds to the original bilevel problem, and the trivial bilevel problem is solved.

$$\min_{\boldsymbol{x},\boldsymbol{y}} F = F_u(\boldsymbol{x_{ud}}, \boldsymbol{y_{ud}}) + F_l(\boldsymbol{x_{ld}}, \boldsymbol{y_{ld}}) + F_c(\boldsymbol{x_{uc}}, \boldsymbol{x_{lc}}, \boldsymbol{y_{uc}}, \boldsymbol{y_{lc}})$$

$$s.t.\, G_{ud}(\boldsymbol{x_{ud}}, \boldsymbol{y_{ud}}) \le 0, G_{uc}(\boldsymbol{x_{ud}}, \boldsymbol{x_{uc}}, \boldsymbol{y_{ud}}, \boldsymbol{y_{uc}}) \le 0,$$
$$g_{ld}(\boldsymbol{x_{ld}}, \boldsymbol{y_{ld}}) \le 0, g_{lc}(\boldsymbol{x_l}, \boldsymbol{y_l}) \le 0,$$
$$g_g(\boldsymbol{x_{uc}}, \boldsymbol{x_{lc}}, \boldsymbol{y_{uc}}, \boldsymbol{y_{lc}}) \le 0\}$$

$$\boldsymbol{x} = \begin{bmatrix} \boldsymbol{x_{ud}} \\ \boldsymbol{x_{uc}} \\ \boldsymbol{x_{ld}} \\ \boldsymbol{x_{lc}} \end{bmatrix}^T, \boldsymbol{y} = \begin{bmatrix} \boldsymbol{y_{ud}} \\ \boldsymbol{y_{uc}} \\ \boldsymbol{y_{ld}} \\ \boldsymbol{y_{lc}} \end{bmatrix}^T,$$

$$\boldsymbol{x} \in R^n, \boldsymbol{y} \in Z^m \tag{3}$$

$$\min_{\boldsymbol{x_{ld}}, \boldsymbol{x_{lc}}, \boldsymbol{y_{ld}}, \boldsymbol{y_{lc}}} f(\boldsymbol{x}, \boldsymbol{y}) = f_l(\boldsymbol{x_{ld}}, \boldsymbol{y_{ld}}) + f_c(\tilde{\boldsymbol{x}}_{\boldsymbol{uc}}, \boldsymbol{x_{lc}}, \tilde{\boldsymbol{y}}_{\boldsymbol{uc}}, \boldsymbol{y_{lc}}):$$
$$st.\, G_{uc}(\boldsymbol{x_{ld}}, \boldsymbol{y_{ld}}) \le 0, g_{lc}(\boldsymbol{x_l}, \boldsymbol{y_l}) \le 0, g_g(\tilde{\boldsymbol{x}}_{\boldsymbol{uc}}, \boldsymbol{x_{lc}}, \tilde{\boldsymbol{y}}_{\boldsymbol{uc}}, \boldsymbol{y_{lc}}) \le 0,$$
$$\boldsymbol{x} = \begin{bmatrix} \tilde{\boldsymbol{x}}_{\boldsymbol{ud}} \\ \tilde{\boldsymbol{x}}_{\boldsymbol{uc}} \\ \boldsymbol{x_{ld}} \\ \boldsymbol{x_{lc}} \end{bmatrix}^T, \boldsymbol{y} = \begin{bmatrix} \tilde{\boldsymbol{y}}_{\boldsymbol{ud}} \\ \tilde{\boldsymbol{y}}_{\boldsymbol{uc}} \\ \boldsymbol{y_{ld}} \\ \boldsymbol{y_{lc}} \end{bmatrix}^T,$$
$$F = F_u(\tilde{\boldsymbol{x}}_{\boldsymbol{ud}}, \boldsymbol{y_{ud}}) + F_l(\boldsymbol{x_{ld}}, \boldsymbol{y_{ld}}) + F_c(\tilde{\boldsymbol{x}}_{\boldsymbol{uc}}, \boldsymbol{x_{lc}}, \tilde{\boldsymbol{y}}_{\boldsymbol{uc}}, \boldsymbol{y_{lc}})$$

$$\boldsymbol{x} \in R^n, \boldsymbol{y} \in Z^m \tag{4}$$

### Exploring Factors Contributing to Triviality

Bilevel optimization problems with different structures have different implication in the real world. Looking into what is causing the bilevel optimization problem triviality can help us identify what is the critical factors that create complex interactions of the problem. We analyzed various problem structures to identify factors contributing to solution triviality. The problems are generated by using naïve random bilevel problem generation process, which we generate the objectives and constraints using random vectors, as detailed in the problem generator and library section.

#### Continuous bilevel optimization problem

In Figure 3, we varied the number of continuous coupled variables $\boldsymbol{x_{uc}}$ and $\boldsymbol{x_{lc}}$ within the range of 2 to 20

while fixing the general constraints $g_g = 10$. The resulting heatmap illustrates the trivial percentage calculated across 30 test instances, where the trivial percentage is defined as the ratio of number of trivial problems to the total number of tests.

Defining the upper-to-lower variable ratio (ULVR) as the number of upper-level variables divided by the number of lower-level variables, we observed the following trends: when $ULVR > 2$, the trivial percentage is high (above 80%); when $2 > ULVR > 0.5$, the trivial percentage is moderate (20–80%); and when $ULVR < 0.5$, the trivial percentage is low (below 20%).

These trends indicate that the lack of lower-level variables in the problem prevents the lower-level objective from competing with the upper-level objective, resulting in triviality. This finding suggests that increasing lower-level competition with the upper-level can help reduce triviality. To test this hypothesis, we modified the lower-level decoupled continuous variable $x_{ld}$, as introducing such variables complicates the lower-level objective but has no direct impact on the upper-level objective. This creates divergences between the two objectives, causing them to compete, resulting in triviality decreases.

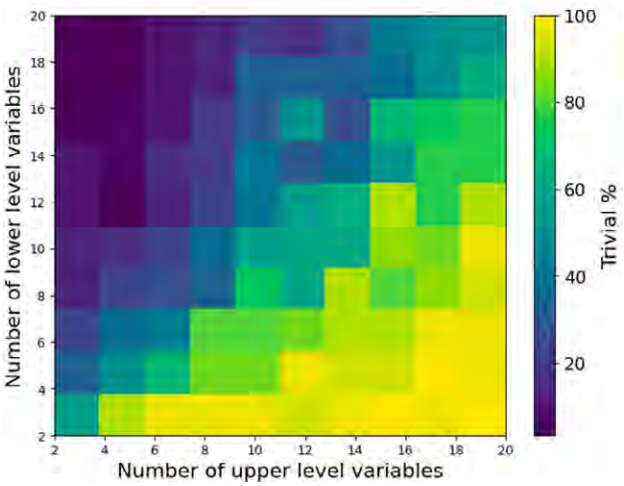

**Figure 3.** Trivial percentage heatmap by varying $\boldsymbol{x_{uc}}$ (2-20) and $\boldsymbol{x_{lc}}$ (2-20) of the continuous bi-level optimization problems. Each structure is tested for 30 times, and the $g_g = 10$ for all instances.

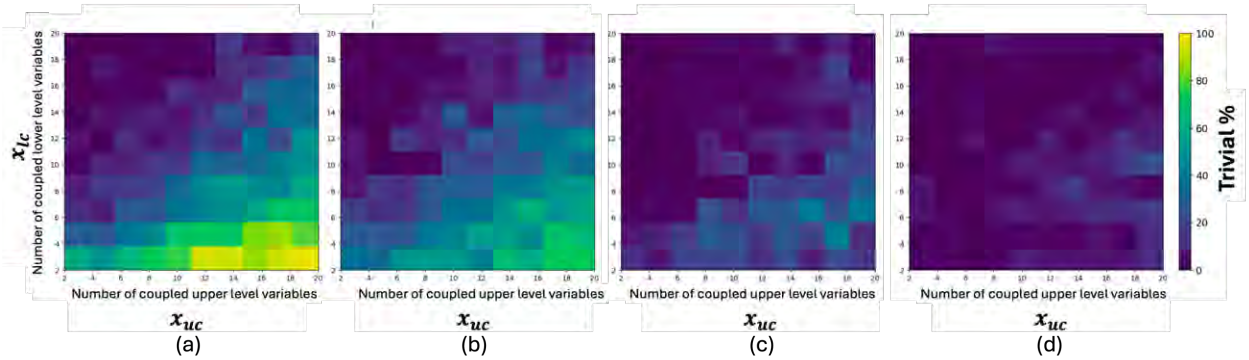

**Figure 1:** Changing $\boldsymbol{x_{uc}}, \boldsymbol{x_{lc}}$ from 2 to 20, fixing Number of decoupled lower level continuous variable $\boldsymbol{x_{ld}}$ at a: 0, b: 1, c: 5, d: 10; $G_{uc} = g_{lc} = g_g = 10$. Each structure is tested for 30 times. As shown by the graph, by changing $\boldsymbol{x_{ld}}$, the triviality decreases. Suggesting Number of decoupled lower level continuous variable is a key factor in triviality.

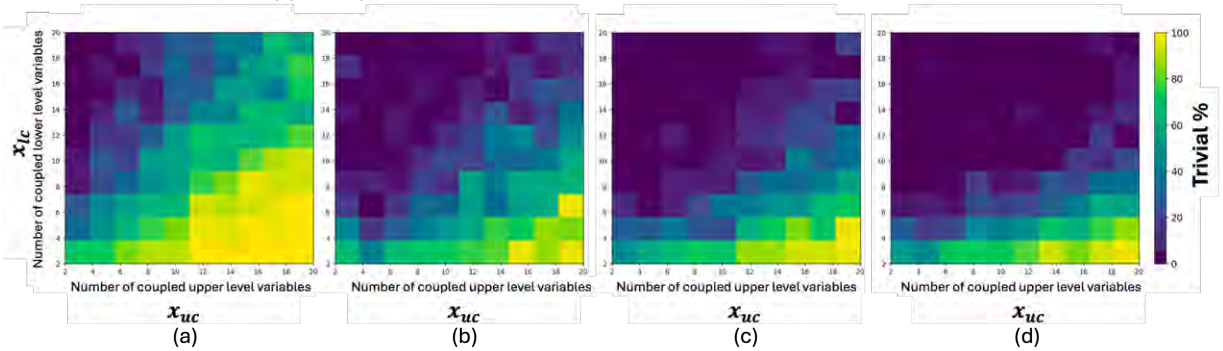

**Figure 2:** Changing $\boldsymbol{x_{uc}}, \boldsymbol{x_{lc}}$ from 2 to 20, fixing Number of binary coupled upper- and binary coupled lower-level variable $(\boldsymbol{y_{uc}}, \boldsymbol{y_{lc}})$ at a: (0,0), b: (2,2), c: (10,10), d: (20,20), $g_g$ is fixed at 20 for each type of constraints. Each structure is tested for 30 times. As shown by the graph, by changing $\boldsymbol{y_{uc}}, \boldsymbol{y_{lc}}$, the triviality decreases. Suggesting

### Continuous bilevel optimization problem with decoupled structure

Figure 2 illustrates the effect of varying the number of pure lower-level decoupled continuous variables ($\boldsymbol{x_{ld}}$) while fixing the values of the coupled variables $\boldsymbol{x_{uc}}$ and $\boldsymbol{x_{lc}}$, and setting the constraints $G_{uc} = g_{lc} = g_g = 10$. Subfigures 2 (a), (b), (c), and (d) represent cases where $\boldsymbol{x_{ld}}$ is set to 0, 1, 5, and 10, respectively. The resulting heatmaps illustrate the trivial percentage across 30 test instances The heatmaps clearly demonstrate that increasing the number of $\boldsymbol{x_{ld}}$ reduces the triviality of the problem. With the addition of just 1 $\boldsymbol{x_{ld}}$, the heatmap results show clear reduction of triviality percentage, as shown in Figure 2 (b). When $x_{ld}$ continuous increases, the percentage of trivial solutions decreases significantly. The triviality percentage goes to near zero in most cases as $x_{ld}$ goes to 10, as shown in Figure 2 (d).

This observation highlights that the number of decoupled lower-level continuous variables plays a crucial role in determining triviality. The results suggest that introducing or increasing $\boldsymbol{x_{ld}}$ enhances the complexity of interactions between levels, reducing the likelihood of trivial solutions.

### Mixed-Integer bilevel optimization problem

Introducing more binary variables also fosters competition between the upper and lower levels. As shown in Figure 3, increasing the number of coupled binary variables reduces triviality; however, the effect is less pronounced compared to the influence of $x_{ld}$ as shown in Figure 2. This effect is less pronounced in the region where the number of continuous coupled lower-level variables $x_{lc}$ is small. We suspect that by only increasing the number of the binary coupled lower-level variables cannot effectively affect the lower-level objective function competence with the upper-level objective function. A minimum amount of the $\boldsymbol{x_{lc}}$ is required to create competence synergetic with the $\boldsymbol{y_{uc}}$, and $\boldsymbol{y_{lc}}$.

Decoupled binary variables also exhibit a similar trend as coupled binary variables, though these results are omitted here for brevity.

In summary, altering the number of variables across different classes significantly impacts the structure of bilevel problems.

## PROBLEM GENERATOR AND LIBRARY

Based on the results in the previous section, we found that naïve implementations of a random bilevel problem generator produce varying levels of triviality depending on the problem's structure. If a problem set with high triviality is used for algorithm testing, it may lead to an overestimation of the solver's capability. To the best of our knowledge, no prior literature has addressed the issue of triviality in generating bilevel optimization problems. Therefore, we developed the random bilevel problem generator, NT-BMIPGen, which can generate non-trivial mixed integer bilevel test problems. The generator cand help the field to generate problems that are non-trivial and truly reflect the ability of the tested algorithm. The generation process is shown in Figure 4.

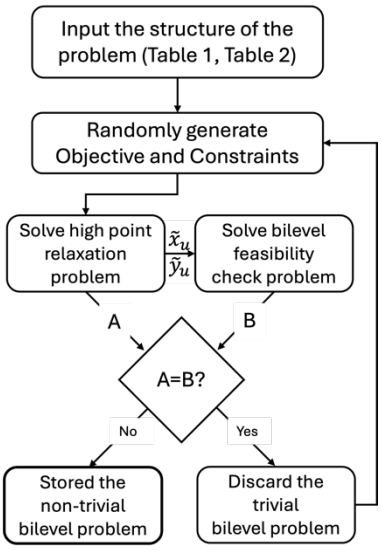

**Figure 4.** Flow diagram showing how random non-trivial bilevel optimization problem generator works.

The user can customize problem structures to explore different forms of two-level interaction by specifying the parameters listed in Table 1 and Table 2. To determine the parameters for the constraints and the objective function, the generator generates a matrix and a vector for each constraint type, along with random vectors for the upper- and lower-level objective subfunctions, based on the number of corresponding variables and constraints number specified.

By default, random parameter values are sampled from a uniform distribution in the range [-10, 10], except for the constraint right hand side vectors, which are restricted to non-negative values in the range [0, 10] to ensure the origin is always feasible. This design ensures the generated problems' feasibility. The continuous variables have a default upper and lower bound of -10 and 10, respectively.

Each problem undergoes a triviality check. The single level subproblems (high point relaxation problem (3) and the bilevel feasibility check problem (4)) are formulated in Pyomo [20] and solved using the Gurobi solver (v11.0.0) [21]. Only non-trivial problems, as verified through this process, are retained and stored with their upper and lower bounds obtained by solving the two subproblems. While the trivial problem is discarded, and the generator will generate another random problem. Each generated problem is stored in a folder, where each matrix and vector are saved in separate CSV files, and

associated parameters and upper and lower bounds solved by the two subproblems are stored in a JSON file. The non-trivial mixed-integer bilevel generator is available at https://test.pypi.org/project/NT-BMIPGen/.

A library with 105 different structure non-trivial B-MIP problems generated from the generator is stored at https://drive.google.com/file/d/185xnM-IG_vziXSDqGIyhSU-HDFgRDr51/view.

## CONCLUSION AND DISCUSSION

This work emphasizes the importance of problem triviality in designing problem generators and using a problem library for bilevel optimization problems, which can lead to the meaningless comparison and evaluation of different solvers, an issue that has been largely overlooked in previous research.

It is worth noting that while the effects of various constraints were also examined, the interaction is more complicated, and no clear trends were observed. A more detailed analysis represents a compelling topic for future research. We acknowledge that our study examines only a limited subset of bilevel problem structures. Future studies will delve into a broader range of bilevel problem structures to gain a deeper understanding of how various parameters influence triviality and its effect on algorithm benchmarking and development.

The proposed bilevel problem generator and library aims to enhance the robustness of continuous and mixed-integer bilevel optimization algorithm testing by ensuring that the generated problems provide a meaningful challenge to the algorithms, and accelerate the development of efficient solvers for complex, real-world bilevel optimization problems.

## ACKNOWLEDGEMENTS

This material is based upon work supported by the Wisconsin Alumni Research Foundation and the Department of Chemical and Biological Engineering at the University of Wisconsin-Madison. Furthermore, we would like to acknowledge the assistance provided by large language models (LLMs), including OpenAI's ChatGPT-4o and Anthropic's Claude 3.5, in the preparation of this manuscript. These tools were used for improving the grammar and fluency of the text, as well as for assistance in coding and commenting.

## ABSTRACT

Process synthesis is a fundamental step in process design. The aim is to determine the optimal configuration of unit operations and stream flows to enhance key performance metrics. Traditional methods provide just one optimal solution and are strongly dependent on user-defined technologies, stream connections, and initial guesses for unknown variables. Usually, a single solution is not sufficient for adequate decision-making, especially, when properties such as flexibility or reliability are considered in addition to the process economics. Wastewater Treatment network synthesis and design is a complex problem that demands innovative approaches in design, retrofits, and maintenance strategies. Considering this, an enhanced framework for improving reliability in wastewater transportation networks based on graph theory and machine learning is presented. Machine learning models were developed to predict failure probability, where the XGBoost model provided the best predictions. To select the appropriate solution, a trade-off between cost and reliability metrics is presented which is implemented by analyzing the results from the non-dominated solutions obtained for the case study demonstrated in this paper.

**Keywords**: Machine Learning, Graph Theory, Wastewater, Reliability, Optimization, Process Synthesis

## INTRODUCTION

The inadvertent consumption of water resources and the discharge of wastewater from domestic, agricultural, and industrial sectors into natural water bodies have intensified issues concerning water availability, quality, and purity. In this regard, Wastewater Treatment (WWT) is critical to prevent environmental problems and ensure that contaminant concentrations are reduced below the limits established by the governmental authorities before being discharged into the ecosystem [1]. Municipal treatment facilities must have a reliable infrastructure to transport the water from different regions to the WWT plant (pipelines, manholes, and pumping stations), and must select the appropriate technologies to accomplish the WWT goals within reasonable costs. Therefore, Wastewater Treatment Network (WWTN) synthesis and design must incorporate reliability estimation, which in turn results in a complex problem that demands innovative approaches in design, retrofits, and maintenance strategies.

Process synthesis (PS) is crucial to finding the best configuration of unit operations/technologies and stream flows that optimize the parameters of interest. The traditional approach is based on superstructure optimization with solvers such as Mixed-Integer Programming (MIP) or Mixed Integer Non-Linear Programming (MINLP) [2]. However, they strongly depend on user-defined technologies, stream connections, and reasonable initial guesses for the unknown variables. As a result, this approach may miss potential structures that might outperform the selected one and can fail when addressing large-scale problems with complex models [3].

In the case of WWTN synthesis and design, some prior studies have identified limitations, including the inability to identify redundancies, the existence of bypass and recycling streams, the dependency on user-selected technologies, and the identification of just one optimal

solution [4,5]. With the increasing complexity of modern industrial processes, there is a growing demand for more advanced design optimization tools.

Considering this, Graph Theory can be applied to PS using the P-graph framework, which can generate the set of n-best feasible solutions as well as rank them from best to worst for the synthesis problem. In this representation, system units are shown as horizontal bars, while their inputs and outputs, which are the material streams, are depicted as circles. These nodes are connected by arcs that illustrate the material flow within the system [6]. However, even the top-ranked n-best solutions may be impractical in real applications due to insufficient information on structural reliability. This is problematic for systems exposed to unpredictable and extreme events, such as floods and thunderstorms, since anticipating potential failures and maintenance needs is challenging.

Machine learning (ML), a subfield of Artificial Intelligence, offers a promising solution to this problem by estimating reliability using existing data from current WWTNs. ML algorithms are well suited for analyzing vast amounts of data and identifying the complex relationships that exist between process parameters [7]. Herein, two ML algorithms are utilized: Neural Networks (NNs) and Extreme Gradient Boosting (XGBoost). NNs are a series of interconnected nodes, or neurons, separated into distinct layers. NNs learn by iteratively adjusting the network's internal parameters, weights, and biases to minimize the difference between the model's prediction and the actual outcome, also known as the loss function. NNs can model highly non-linear relationships, such as those commonly found in PS. XGBoost is an advanced implementation of the gradient boosting algorithm. It utilizes both the gradient and the Hessian (the second-order derivative) to find the minimum of the loss function. It employs regularization techniques to correct for model overfitting and incorporates parallel computing to accelerate data processing times [7]. As a result, it exhibits high computational efficiency and is still able to provide accurate and insightful results, making it a valuable tool for PS.

In this paper, the integration of Graph Theory and ML for the retrofitting of WWTN considering reliability is presented. The case study is focused on the pipeline network and pumping stations, in which the exhaustive enumeration tools of the P-graph framework are used to determine the feasible set of retrofit alternatives. These solutions are evaluated in terms of reliability and cost, evaluating them in terms of reliability and cost. For the reliability estimation, XGBoost and NNs models were utilized to predict the failure probability of the system components using real data from a municipal WWT facility (reliability can be defined as the complement of failure probability). The novelty of this approach lies in using real data from a WWT plant to predict the failure probability of the transportation system and incorporating this information into the P-graph framework rigorous enumeration algorithms for reliability calculation. Finally, a Pareto set is generated with the optimal retrofitting alternatives, which can be evaluated to find the solution that best fits the case study.

## METHODOLOGY

This section discusses the case study, in which the network synthesis and the P-graph representation of the pipeline network and pumping stations are presented. In addition, the ML models used for estimating the network's failure probability are described. Finally, the framework for reliability estimation is explained, where the ML results are integrated with the P-graph framework.

### Case Study and P-graph Representation

The case study focuses on a simplified pipeline

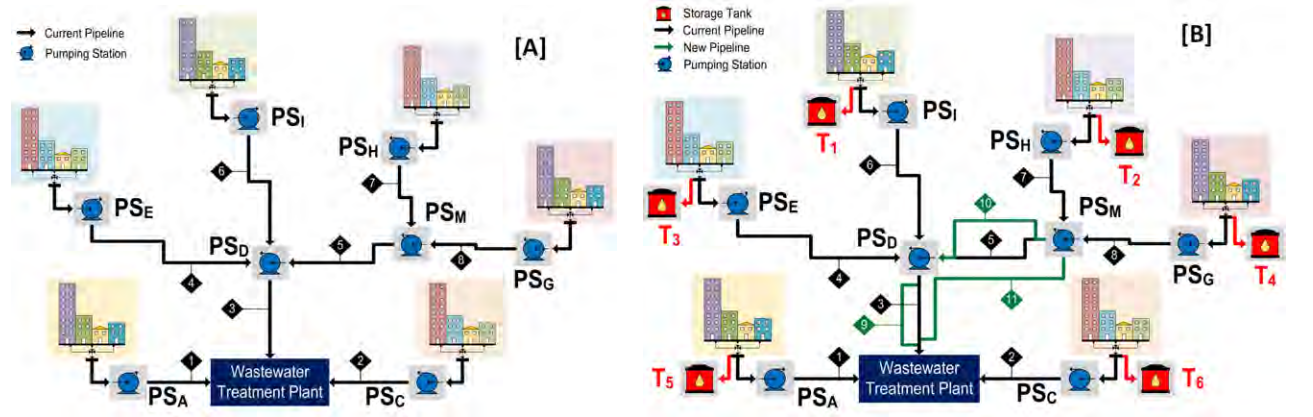

**Figure 1: A.** Base case study for the wastewater treatment pipeline network and pumping stations **B.** Modified pipeline network considering the redundant pipelines (9,10,11) and storage tanks ($T_1$ to $T_6$).

system of a municipal WWT plant with a capacity of approximately 1.6 million gallons per day. The system includes eight pumping stations ($PS_A$, $PS_C$, $PS_D$, $PS_E$, $PS_G$, $PS_H$, $PS_I$, $PS_M$) that collect wastewater from various municipalities through a sewage network. These pumping stations are connected by pipelines that transport the wastewater to the WWT plant as shown in Figure 1A. This system lacks redundancies, meaning there are no alternative routes if a pipeline fails.

Pumping stations $PS_D$ and $PS_M$ are critical as they connect multiple sectors. A pipeline failure between these stations would result in most of the WWTN shutting down. To address this, alternative routes are proposed between pumping stations $PS_D$ and $PS_M$, $PS_D$ and the WWT plant, and $PS_M$ and the WWT plant. Additionally, the installation of tanks ($T_1$, $T_2$, $T_3$, $T_4$, $T_5$, $T_6$) to store wastewater in case of overflow or pipeline failure is evaluated. These tanks are located at pumping stations $PS_A$, $PS_C$, $PS_E$, $PS_G$, $PS_H$, and $PS_I$. Figure 1B illustrates the updated pipeline network, designed to enhance the system's overall reliability.

Figure 2 shows the P-graph structure of the Modified case study, which was adapted from previous work developed by Pimentel et al [8]. The nodes of the main structure are represented in black, additional tanks are shown in red, and additional pipelines are represented in green.

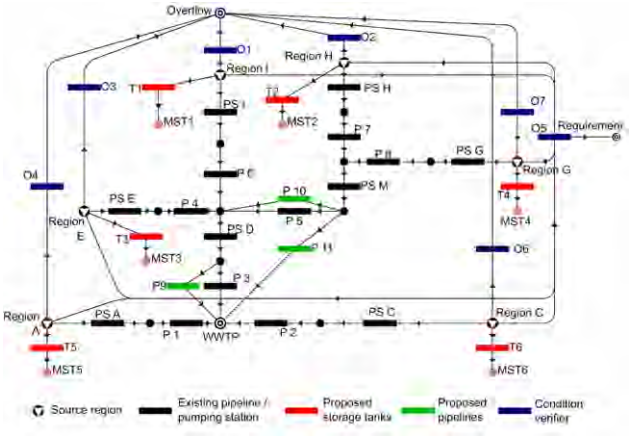

**Figure 2.** P-graph representation of the Modified Case Study.

To assess the feasibility of the system, two additional product nodes are incorporated into the P-graph representation, as shown in Figure 2. The first one, labeled as "Overflow", allows restricting maximum overflow permitted in the system. The second one, labeled as "Requirement", ensures that all water sources are included in the analysis.

## Machine Learning Models

XGBoost and NNs models for regression were developed to predict the failure probability of pipelines. The data provided by the municipal WWT plant includes approximately 250 manholes and 295 pipelines. After data preprocessing, 280 data points were obtained. The features considered for the ML models were pipe size, pipe type (material), segment length, flow rate, flow type (gravity or forced flow), installation date, years since the last inspection, remaining lifespan, population density, and distance from WWT facility. Failure probability values were provided via inspection from experts working at the municipal WWT plant.

For the 'flow type' the values were encoded as follows: gravity flow (0), forced flow (1). Similarly, the 'pipe type' values were encoded in this way: HDPE (1), DIP (2), Steel (3), PVC (4), TCP (5), RCP (6), VCP (7), ACP (8).

For the hyperparameter tuning, the XGBoost model was trained using the following: number of trees = (100, 200, 500, 1000), learning rate= (0.01, 0.05, 0.1, 0.2), maximum depth = (3, 5, 7, 10), subsample = (0.4, 0.6, 0.8, 1.0), colsample by tree = (0.4, 0.6, 0.8, 1.0). In the same way, the regularization for NNs was developed using the following parameters: model neurons = (16, 32, 64, 128), model dropout rate = (0.05, 0.1, 0.2, 0.3), batch size = (10, 20, 30, 40), and epochs = (100, 200, 400, 500). ReLU activation function was used for the NNs model. For both models, cross-validation was implemented.

## Framework for Reliability Estimation

The framework for reliability estimation was developed in a previous work by Pimentel et al [8], in which the objective is to generate a set of retrofitting alternatives for wastewater transportation systems with enhanced reliability. Figure 3 shows the methodology proposed.

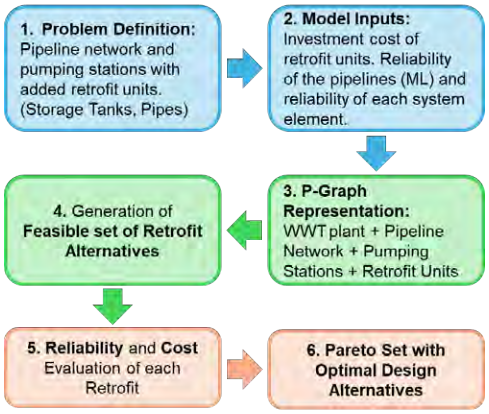

**Figure 3.** Methodology to generate reliable retrofitting alternatives for wastewater transportation systems.

The approach begins with the problem definition by identifying feasible operating units for system expansion. This includes selecting operating units, such as emergency storage tanks, alternative pumping systems, and redundant pipelines that can manage potential failures in

**Table 1:** Pipeline features of the Modified Case Study used for the ML models.

| N | From | To | Remaining Life [years] | Pipe Size [in] | Pipe Type | Segment Length [ft] | Years Since Last Inspection | Original Installation Year | Population Density [pop/mi²] | Flow Type | Flow Rate [Mgal/day] | Distance from WWT plant [km] |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| 1 | $PS_A$ | Plant | 76 | 30 | 3 | 21918 | 24 | 1976 | 3742.25 | 1 | 0.350 | 10.30 |

| 8 | $PS_G$ | $PS_M$ | 52 | 18 | 2 | 26576 | 48 | 1976 | 1929.57 | 1 | 0.250 | 16.90 |
| 9 | $PS_D$ | Plant | 100 | 30 | 6 | 30703.7 | 0 | 2024 | 3541.12 | 1 | 0.990 | 25.40 |
| 10 | $PS_M$ | $PS_D$ | 100 | 24 | 6 | 13698 | 0 | 2024 | 1632.96 | 0 | 0.360 | 5.15 |
| 11 | $PS_M$ | Plant | 100 | 24 | 6 | 13698 | 0 | 2024 | 1632.96 | 1 | 0.360 | 30.55 |

the base structure.

Additionally, the investment cost and reliability of each extension unit must be determined for the model inputs. The reliability values are obtained from the ML model, which is integrated with the P-graph framework to obtain the set of n-best solutions based on reliability and cost.

Afterward, all system elements are represented using the P-graph methodology. Based on this structure, retrofitting alternatives (operational sub-structures) are generated by combining different units and integrating them into the base system.

Then, the total cost and reliability of each alternative can be individually determined. The reliability of the retrofitting alternatives is determined by using the reliability formula shown in equation (1):

$$r = \sum_{(x_1,x_2,\ldots,x_n)\in U}\left(\prod_{i=1}^{n} p_i^{x_i}(1-p_i)^{(1-x_i)}\right) \quad (1)$$

Where $p_i$ is the reliability of the network's elements, $x_i$ represents its operational state (failure or operating), and $U$ is the set of operational structures in the problem [6].

Finally, a Pareto set with the best design alternatives (non-dominated solutions) for the problem is created.

## RESULTS AND DISCUSSION

In this section, the data for the case study as well as the assumptions made to solve the problem are presented. Besides, the results for the XGBoost and NNs are shown, from which the better predictions are chosen as inputs in the Framework for Reliability Estimation. Finally, the Pareto set with the best design alternatives for the problem is presented.

### Case Study and P-graph Representation

The case study data is presented in Table 1, in which the features of each segment are described.

Additionally, in Table 2 the annualized cost of each unit operation in the Modified Case Study required for the P-graph framework is presented. The pipelines are denoted as $P_n$, where n is the pipeline number. The storage tanks (from $T_1$ to $T_6$) are assumed to have an annual investment cost of $62,400, a maximum capacity of 250,000 gallons, and a reliability of 0.95. The reliability values for the pumping stations are assumed to be 0.99. The reliability examination for this case study is carried out considering a time horizon of 1 day, consequently, the wastewater transport system must handle 1.6 million gallons. Also, the operational structure's maximum overflow was set at 83,000 gallons, which means that if this value is exceeded, the structure is not feasible.

**Table 2:** Annualized cost of the unit operations (Cost in thousands of USD per year) with their maximum wastewater flow (Flow in millions of gallons per day).

| Unit | Cost [kUSD/y] | Flow [Mgal/day] |
|---|---|---|
| P1, P2, P4 | 0 | 0.860 |
| P3 | 0 | 1.200 |
| P5 | 0 | 0.700 |
| P6, P8 | 0 | 0.310 |
| P7 | 0 | 0.138 |
| P9 | 123.6 | 0.860 |
| P10 | 34.4 | 0.550 |
| P11 | 108.7 | 0.550 |
| PSA, PSC, PSE, PSG, PSH, PSI, PSM | 0 | 0.500 |
| PSD | 0 | 1.200 |

### Machine Learning Models

The XGBoost and NNs results for the case study are presented in Figures 4 and 5, respectively. The metrics used to validate the models were the mean squared error

(MSE) and the coefficient of determination ($R^2$).

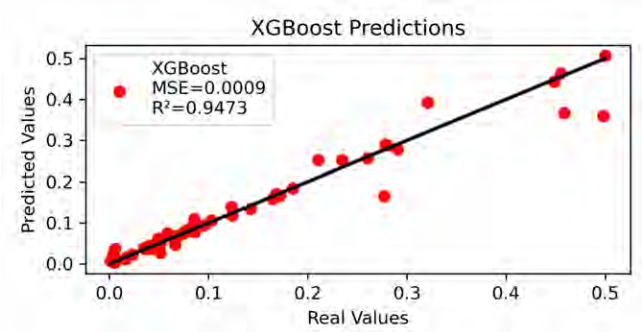

**Figure 4.** XGBoost model for predicting the pipeline failure probability.

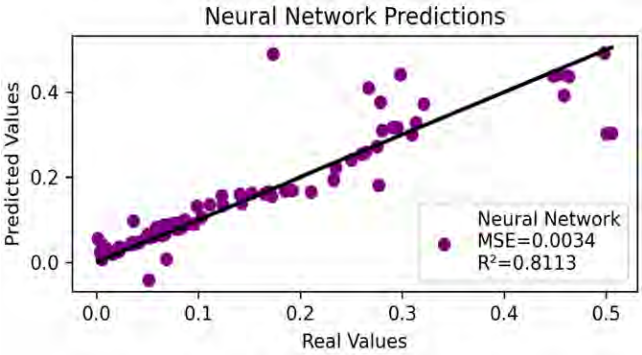

**Figure 5.** NNs model for predicting the pipeline failure probability.

The hyperparameter tuning values for XGBoost provides the following results: Subsample= 0.6, Number of Estimators= 200, Maximum Depth= 5, Learning Rate= 0.1, Colsample by tree= 0.6. For NNs, the following parameter values were obtained after regularization: Model Neurons= 128, Model Dropout Rate= 0.1, Epochs= 400, Batch Size=20

Considering the results for the ML models, XGBoost shows to have better performance than the NNs, which is demonstrated in the $R^2$ value (0.9473 for XGBoost and 0.8113 for NNs) and the lower MSE. The low performance of NNs may be due to the limited amount of data available to train the models. However, we intend to continue training the model with more data obtained from different WWT plants to build a more generalized network.

The predicted values of each model for failure probability and reliability using the features presented in Table 1 are shown in Table 3. To obtain the reliability values for the segments, the failure probability values should be subtracted from 1. From the results obtained for each ML model in Table 3, the failure probability values from the XGBoost model were selected as inputs to the Framework for Reliability Estimation.

Finally, the feature importance results for the XGBoost model are shown in Figure 6. The features with more relevance in the XGBoost model were Years Since Last inspection, Flow Type, and Flow Rate.

**Table 3:** Predicted values of failure probability and reliability for XGBoost and NNs.

| N | XGBoost Failure Probability | NNs Failure Probability |
|---|---|---|
| 1 | 0.2502 | 0.2303 |
| 2 | 0.3223 | 0.6054 |
| 3 | 0.1772 | 0.1993 |
| 4 | 0.2973 | 0.1505 |
| 5 | 0.2940 | 0.7947 |
| 6 | 0.3285 | 0.2375 |
| 7 | 0.2104 | 0.2455 |

| 9 | 0.0999 | -0.0417 |
| 10 | 0.0801 | 0.1843 |
| 11 | 0.0106 | -0.0653 |

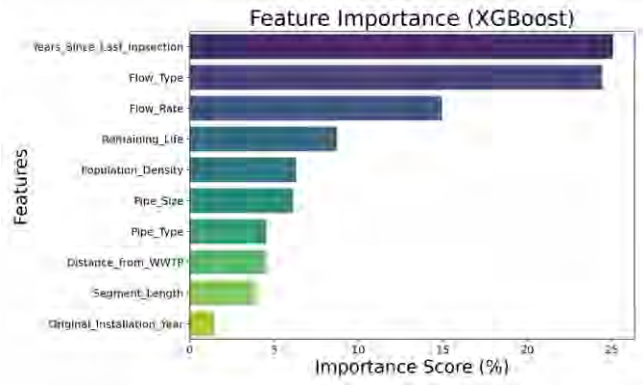

**Figure 6.** Feature importance for the XGBoost model.

## Framework for Reliability Estimation

The results for the non-dominated solution set are obtained from the evaluation of 512 different retrofitting alternatives. The results are shown in Figure 7.

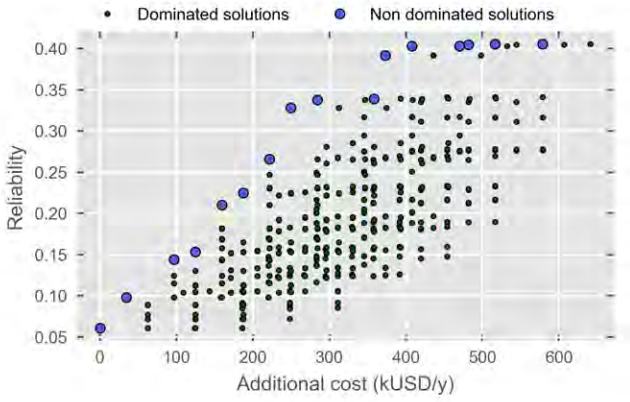

**Figure 7.** Pareto set of solutions for the case study considering Reliability and Annualized cost (USD/y).

In Figure 7 the best solutions regarding cost and reliability are represented by blue circles, while the other solutions are depicted as green circles. Some non-dominated solutions are presented in Table 4.

**Table 4:** Some non-dominated solutions for the case study for reliability and cost metrics. The cost of retrofitting is expressed as kUSD per year.

| Additional Units | Reliability | Cost |
|---|---|---|
| None | 0.061 | 0 |
| $T_2$, $T_4$ | 0.153 | 124.8 |
| $T_2$, $T_4$, $T_6$ | 0.225 | 187.2 |
| $T_1$, $T_6$, $P_{10}$ | 0.210 | 159.2 |
| $T_1$, $T_2$, $T_4$, $T_6$ | 0.328 | 249.6 |
| $T_1$, $T_2$, $T_4$, $T_6$, $P_{10}$ | 0.338 | 284.0 |
| $T_1$, $T_2$, $T_4$, $P_9$, $P_{10}$ | 0.403 | 407.6 |
| $T_1$, $T_2$, $T_3$, $T_4$, $T_6$, $P_9$, $P_{10}$, $P_{11}$ | 0.405 | 578.8 |

In Table 4 it is noted that the most reliable solution is the one with all but one additional unit, but also is the most expensive. On the other hand, the minimum cost is achieved when no additional units are added. In this case, the reliability is low, with a value of 0.061. To select the appropriate solution for the case study, a trade-off between cost and reliability should be considered. By adding four tanks, the reliability value becomes 0.328. This value represents 80% of the maximum reliability value, and the investment cost of 249.6 kUSD/y represents 43.1% of the maximum investment cost, which is 578.8 kUSD/y. For that reason, adding four tanks is one of the best solutions for the case study.

## CONCLUSIONS

In this study, the integration of ML and graph theory in a framework for reliability and cost estimation of WWT networks was presented. The XGBoost model provided better failure probability predictions compared to the NNs model with an $R^2$ value of 0.9473. The low performance of NNs may be due to limited amount of data available to train the models. The features with more relevance in the XGBoost model were Years Since Last inspection, Flow Type, and Flow Rate. The Pareto set showed that to select the appropriate solution, a trade-off between cost and reliability should be considered. Finally, one of the best solutions was adding all the tanks, in which the reliability value was 0.326, which represents 80% of the maximum reliability value, with 43% of the maximum investment cost.

## ABSTRACT

Detailed assessment of fuel production processes at an early stage of a project is crucial to identify potential technical challenges, optimize efficiency and minimize costs and environmental impact. While process simulations often are either very rigid and accurate or very flexible and unprecise, informed decision making can only be maintained by establishing a detailed process model as early as possible within the project lifecycle while keeping relevant aspects of the process flexible enough. In this work, we present the development of a framework based on a dynamic interface between AspenPlus® process simulations and Python, enabling enhanced flexibility and automation for process modeling and optimization. This integration leverages the powerful simulation capabilities of AspenPlus® with the versatility of Python for data analysis and optimization, delivering significant improvements in workflow efficiency and process control. By utilizing the dynamic simulation data exchange with Python, extensive parameter studies can be conducted and post-processed for techno-economic and environmental analyses. Furthermore, the interface allows the implementation of complex kinetic models or optimization routines for single process units. An additional extension for heat integration ensures the technical viability of the process route for reliable comparisons of different routes and process configurations. The functionalities are applied to a biomass- and power-based methanol production process including various process designs and operating conditions. To keep the level of detail at a high level, additional Python scripts are implemented securing a proper scaling of process units such as the methanol synthesis reactor system. The process configurations are assessed technically, economically and environmentally.

**Keywords**: Modelling and Simulations, Aspen Plus, Technoeconomic Analysis, Life Cycle Analysis.

## INTRODUCTION

Aspen Plus is a widely used software tool for process flow sheeting and simulation in chemical engineering. Its robust modeling capabilities enable the design, optimization, and analysis of complex chemical processes across a variety of industries. By providing access to comprehensive thermodynamic models and extensive unit operation libraries, Aspen Plus facilitates efficient process development and performance evaluation.

Despite its strengths, Aspen Plus has limitations that may hinder advanced customization and holistic process analysis. The integration of user-defined scripts, while possible through external tools such as Aspen Custom Modeler or Excel, can be cumbersome and lacks native support, limiting flexibility in certain specialized scenarios. Furthermore, the platform's techno economic analysis (TEA) and life cycle assessment (LCA) features often require external tools or manual data extraction and integration. This lack of transparency and seamless workflow can pose challenges for researchers seeking integrated, transparent assessments that combine process simulation, economic evaluation, and environmental impact analysis.

## METHODOLOGY

A simplified illustration of the cost and environmental impact estimation is depicted in Figure 1. Both estimations are based on a detailed process simulation using the commercial AspenPlus® software and Python. Their base functionality is relying on a direct connection with

the simulation via aspenparserDLR [1] as a python-AspenPlus interface. This requires an active AspenPlus® process and hence longer loading times as well as the requirement of AspenPlus® being available on the machine on which the evaluation is conducted. A description of the functionality of pyteea_tea and pyteea_lca can be found elsewhere [2, 3].

## Parameter variation framework

To split the data generation from the evaluation of different process concepts, the tool pyteea_sc, of which the 'sc' stands for simulation control, is developed to conduct externally-controlled parameter variations and extract the simulation data required for subsequent analyses after each run. The major communication in between the tools is shown in Figure 1.

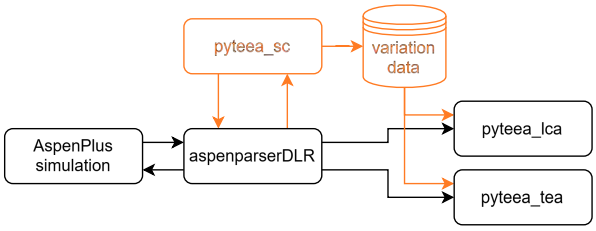

**Figure 1.** Simplified schematic illustration of the utilized tools and their interaction.

Together with the functionality of varying process parameters externally, the tool allows to include and execute user scripts within the parameter runs. This allows to enhance the level of detail and the complexity of certain process steps or to set up own optimization routines which would require a lot of work-arounds in AspenPlus®.

The main program routine of pyteea_sc can be seen in Figure 2. After a main configuration file is read, the major object `SimControl` is initiated. In dependence on the chosen complexity, multiple further configuration files are read to fill the subobjects for the variation run, such as the `linked_objects` which is either an object which communicates with AspenPlus® or a look-up object of a previous variation run. Furthermore, the `process_vars` are initiated, containing a list of process variables and their variation ranges, their paths within the AspenPlus®, as well as their dependencies within each other. The `additional_features` are a list of user defined functions which are being executed with the variation runs. In the `run_options` settings for the data extraction is defined. nformation about the run configuration, as well as information about the variation matrix and the run status:

```
class SimControl:
    linked_objects: list
    process_vars: list
    additional_features: list
    run_options: RunOptions
    var_structure: VarStructure
    var_status: VarStatus

    def run_simulation(self):
       ...
    def export_data(self):
       ...
    def close_simulation(self):
       ...
```

SimControl also allows to define connections between streams from two or more different AspenPlus® files or look-up objects. This functionality comes with a speed advantage since, e.g., a simulation model of an electrolyser requires much less components than a simulation of a hydrocracking process. Hence, the electrolysis can be calculated in a model with limited components and only its resulting hydrogen connected to the hydrocracker model.

Since the communication with AspenPlus® consumes the most time of the whole procedure, as it can be seen in the digital supplementary material, there might be the need to reduce the number of accesses to it. In case of a benchmark run using 'Case1.2_v10.apw' of the Biomass-Gas-and-Nuclear-To-Liquids Simulation Files published by J. Scott and T. A. Adams [4], a short parameter variation took 7:42 min, of which 6:48 min were communicating with AspenPlus® [5]. Therefore, the framework allows to define specific blocks and streams of which all or only limited data is retrieved. In this way the execution time can be significantly be lowered. Yet, this limits the potential of a later setup of the results as a look-up object. In the standard mode, the mass flows for each component is recorded, as well as its molar flow, volume flow, temperature, pressure, vapour fraction, mass density, path, source, and destination. For the different block types, the list differs a lot, since the data from e.g. a Mixer is only its split ratio, and ports, while for a RadFrac unit, also reflux ratio etc. is read.

To ensure a stable execution of the conducted parameter run, the run status after each execution is tracked and the data is only retrieved when it is actually available while a logger records the run status. Nevertheless, in case of unconverged simulation, the data retrieval is skipped the run number is recorded. The list of unconverged simulations can then be executed in a subsequent variation run in order to complete the desired variation matrix. Often, the convergence issues can be overcome in a second run and are originating from an unfavorable order of varied parameters.

After the connection to all simulations or data objects is set up, potential further configuration files for the additional features are read. Eventually, a variation matrix is generated in dependence on potential primary, secondary, etc. parameter relations. The variation matrix is then exported as well as all relevant run settings to ensure the reusability of the run data.

The modular and object-oriented structure of the tool allows to easily include new functionalities and can flexibly work with one or five process parameters, different recorded process units etc. Furthermore, the tools is set up with a clear deviation between input data and functions and allow no hard-coded input.

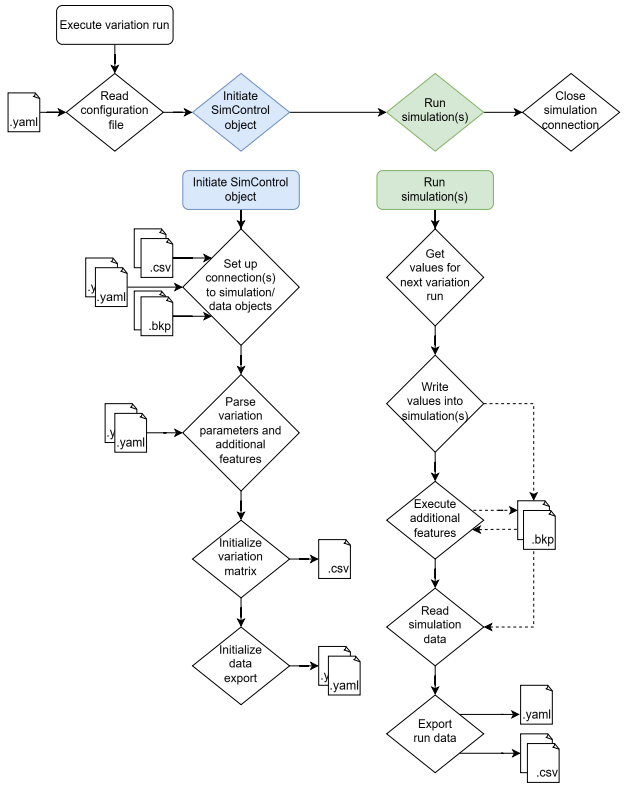

**Figure 2.** Program routine and its major functions and data in- and output.

For the execution of a parameter variation, the values for each single variation parameter are taken from the variation matrix and written into the simulation(s). In case of using look-up objects, the suitable data is prepared in dependence on the given parameters. Then, any additional features are executed. The additional feature which is included in this work is described in the section below. After all simulations converged the simulation data is exported using the aspenparserDLR. To ensure data retrieval for each complete parameter run as well as for each individual simulation run, md5sums are generated based on the run configuration.

## Techno-economic analysis tool

The economic assessment is based on the approach by Peters, Timmerhaus, and West [6] which has been applied in various previous, techno-economic studies [7-9]. A database of reference equipment costs is required to represent any change in the process configurations also in the capital and operational expenditures. Based on the previously described AspenPlus® process model the material and energy flows are used to scale equipment sizes, as well as raw material and by-product streams.

The tool requires a main configuration file which takes plant data input such as lifetime, plant type, operating hours per year, and indirect OPEX cost factors. Together with data coming from various data sources the techno-economic calculations are executed. Currently the tool supports connecting and reading data directly from AspenPlus® simulations, CSV files, YAML files, and JSON files. Once the data is read and parsed from these file input sources, it is further processed in dependence on the reference equipment/raw material/by-products and the costs of the defined product are estimated.

In general, the simulation outputs (material flows, energy flows and equipment dimensions) are employed to calculate capital (CAPEX) and operational expenditures (OPEX) as part of the net production cost (NPC).

## Life cycle assessment tool

The same material and energy flows are also utilized as input for the foreground system of the life cycle inventory (LCI). The background system of the LCI is supplied with data from databases like Ecoinvent or ones created from literature or project partner data. With life cycle impact assessment (LCIA) methods, the environmental impacts are then calculated. Details on the python-based life cycle assessment (pyteea_lca) tool can be found elsewhere [3].

The pyteea_lca tool utilizes the open source LCA framework Brightway2 (Python package) [10]. In order to manage and browse through projects and databases easier and in a more intuitive way the Activity Browser (AB) [11], a graphical user interface (GUI) for Brightway2, can be additionally employed.

To perform the LCA, a configuration file must be set up pointing all additional files which are required for the LCA and defining the general information of the LCA evaluation run. Furthermore, the setup requires a series of YAML files that provide the tool with configurations details, such as linked datasets for Brightway2, functional unit, impact categories from LCIA methods and variation run data.

For conducting the LCA of the generation variation run data batch, a look-up object of that data is initiated reading all the configuration information of the previous parameter run and making it available for the ecological evaluation. Hence, all CSV and YAML files are read, including all stream values (heat-, electricity- and mass flows) for each run, and the variation matrix that describes the varied parameters for each run. These files enable the seamless integration of Aspen Plus® results with pyteea_lca for further analysis. Using the ‘get_current_stream_sizes’ function from pyteea_lca, stream values are extracted from the CSV file and linked to their selected aspen id.

The pyteea_lca tool can either iterate over single runs or run through the whole data batch to perform LCA calculations for each run automatically. After calculating the LCIA results, the tool either generates and stores a single or multiple CSV files. The main result file provides environmental impacts per aspen id.

## Process configurations

The presented tools within this work are applied to the flowsheet model presented by Maier et al. [12]. The study contains the same four process configurations. Two cases which are purely operating with biomass as feedstock, case 1 using bark and case 2 using straw, respectively. Additionally, for both feedstocks a biomass-and-power-based process concept is assessed. In these cases, a PEM electrolyser is integrated providing hydrogen stoichiometrically to the methanol forming reactions. While in previous work the methanol reactor was modelled as an isothermal fixed-bed reactor, in this study a multi-stage quench reactor system is applied.

## Additional feature – Ideal reactor length

As described in section parameter variation framework, another implemented functionality of pyteea_sc is the integration of user scripts which can be included within the parameter variation run.

In this work, an additional feature is implemented that finds the ideal reactor length for each reactor stage in order to prevent over- and underestimation of their size, ensuring that the subsequently calculated costs are properly estimated.

**Table 1.** Reactor dimensioning parameters.

| Parameter | Definition |
|---|---|
| Control parameter | $T_{eq} - T_{out,Ri} = 5 \pm 0.5$ K |
| Control variable | Reactor length |

The routine is using a second RPlug reactor for each reactor stage which is completely oversized to ensure that it reaches equilibrium. A Transfer block ensures that each stage is calculated with the same gas mixture as the regular reactor stage is working with. The methanol formation of each reactor stage over the temperature together with the equilibrium line is given in Figure 3.

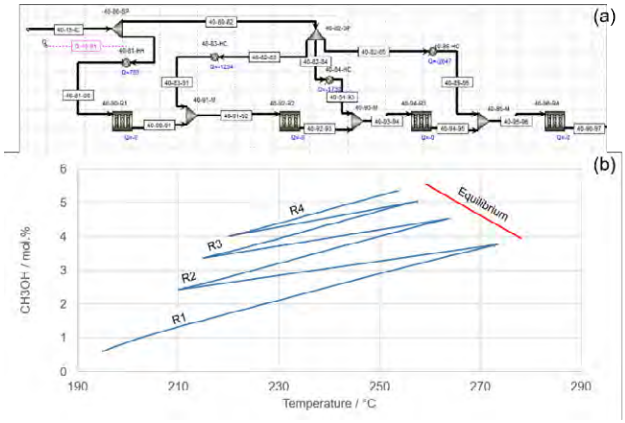

**Figure 3.** Reactor stages in flowsheeting simulation (a); Reaction profiles for all four reactor stages (b)

A Newton algorithm is applied to find the ideal length of reactor including an exiting function when the composition reaches equilibrium in order to prevent the algorithm from running into an asymptotic regime.

# RESULTS & DISCUSSION

## Parameter variation framework

For the conducted parameter variation, the execution time was 36:39 min of which 35:02 min where communication between Python and AspenPlus. If compared to previous approaches for coupling AspenPlus® with a programming software like in the case of Lopez et al. [13], the execution time is much higher which limits the framework's application for operation within larger optimizer routines. For usage in this field, the recording options should be set to a minimum. Especially the implemented additional feature can definitely be improved by that and should be seen as a demonstration of the implementation possibility of user script within the variation loop rather than an ideal solution for reactor design.

Since in the case of this study, the intention of the tool is mainly to make AspenPlus® obsolete for subsequent data analyses such as TEA or LCA, a complete data extraction has been conducted.

## Techno-economic analysis results

Figure 4 shows the techno-economic analysis results for bark and straw and their different process concepts for 100 $MW_{th}$ biomass input.

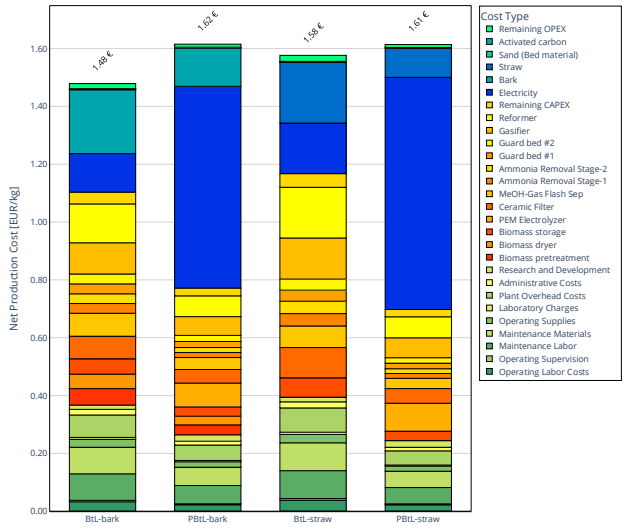

**Figure 4.** Net production costs for the four process concepts.

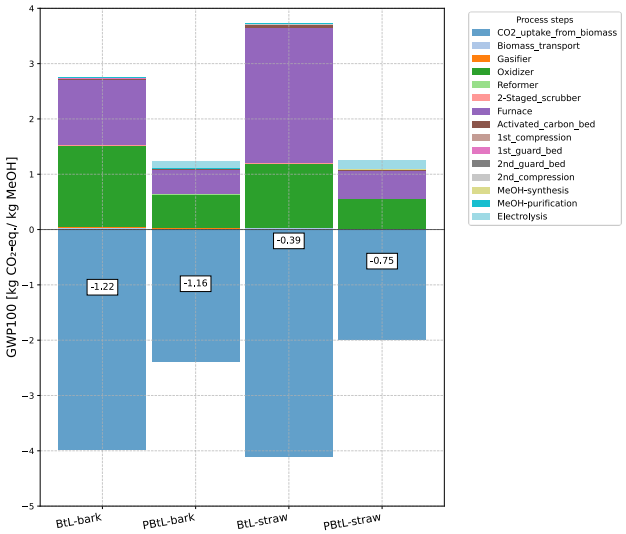

**Figure 5.** LCA results (Cradle-to-Gate) for the four process concepts. Wind energy is assumed as electricity source.

The main aspects which can be identified in Figure 4 are that the net production costs for the power-and-biomass process concepts are higher than their purely biomass-based representative. Main reason is the production of hydrogen at an electricity price of 105 €$_{2023}$/MWh which makes it more expensive than the hydrogen received by biomass gasification. Nevertheless, the implementation of the additional electrolysers nearly doubles the product output of the processes. Hence, even with the very expensive electricity, the PBtL cases are nearly in the same price range as the biomass-based ones.

### Life-cycle analysis results

Using the same simulation data for the ecological analysis of the four process concepts results in the global warming potentials (GWPs) displayed in Figure 5. The figure shows that the processes utilizing bark (BtL-bark & PBtL-bark) have a lower GWP than with straw (BtL-straw & PBtL-straw). Furthermore, when using wind energy as the electricity source, the power-and-biomass based process (PBtL) results in a quite similar GWP in case of bark. In case of straw as a feedstock, the power enhanced process designs results in a 2.2 times higher product yield, which leads to a significant reduction of the process-related emissions since their contribution is divided through a larger amount of product. The gas cleaning steps (reformer, activated carbon bed, 1$^{st}$ guard bed, 2-staged scrubber, 2$^{nd}$ guard bed and 1$^{st}$ compression) and biomass transport (100 km truck transportation) are only contributing 1% for all process concepts and therefore has no significant influence on the GWP. Also, with the MeOH production and purification step (MeOH-synthesis, MeOH-purification and 2$^{nd}$ compression), which are contributing <1%.

The most GWP influencers are the process emissions from the oxidizer flue gas (after biomass gasification) and from furnace (combustion of the purge gas after MeOH-synthesis). These emissions vary depending on the type of biomass. Straw has more emissions from the furnace and bark more from the oxidizer.

## CONCLUSIONS & OUTLOOK

The presented work shows the application of a toolbox which allows extensive process analysis together with the implementation of python-based user scripts. Furthermore, the shown tools allow to divide the process analyses from AspenPlus® simulations, which enables extensive analyses without the need of communicating with AspenPlus® simulations. Hence stability issues of the simulation can be taken care of before the data is further processed. Additionally, the introduction of the parameter run data as an intermediate allows to apply more extensive evaluation features on the data batch opening the whole wide world of python-based data analysis tools for the work with rigorous process simulations in AspenPlus®.

Due to the tool's modular programming approach further objects which allow communication with other simulation or modeling tools could be implemented and included in the list of potential `linked_objects`.

Currently, the tool is completely based on YML files and python scripts and its usability could be improved by including a graphical user interface for the input data definition.

## DIGITAL SUPPLEMENTARY MATERIAL

Digital supplementary material for the mentioned benchmark case is being made public on LAPSE:2025.0042 [5].

## ABSTRACT

Artificial neural networks (ANNs) have gained popularity in the last years as tools to develop data-driven models of chemical process units. However, representing a system only with such artificial intelligence models may lead to a loss in the comprehension of the occurring phenomena. Hybrid models allow combining the predictive capabilities of ANNs with the foundational knowledge of rigorous models. This study explores the impact of hybridization in designing and optimizing shell-and-tube heat exchangers, comparing a full ANN-based model with a hybrid model. The hybrid model incorporates ANN predictions for highly nonlinear components, such as heat transfer coefficients, while other calculations are performed using the rigorous Bell-Delaware model. To generate the necessary data, the rigorous model is solved under randomly selected conditions. Using Python, one ANN predicts the exchanger's cost, while another predicts the heat transfer coefficients. Both models are optimized using the differential evolution algorithm. The results indicate that the hybrid model produces designs with an approximately 67% lower standard deviation compared to the full ANN-based model when compared to the rigorous model's cost predictions. This highlights the hybrid model's ability to balance computational efficiency and accuracy, offering a promising approach for process design applications.

**Keywords**: artificial neural networks, hybrid models, optimal design.

## INTRODUCTION

Heat exchangers are essential components in the chemical industry. Among the various types of exchangers, shell-and-tube heat exchangers stand out for their broad acceptance due to their balance between volume and heat transfer area, as well as their ability to operate over a wide range of pressures and temperatures [1]. The design of these exchangers is typically performed using the Bell-Delaware method, a methodology based on highly nonlinear mathematical relationships that involves managing both discrete and continuous variables [2]. Due to the nature of equations that compose Bell-Delaware method, it represents a non-trivial optimization problem [3].

In recent years, artificial intelligence, particularly artificial neural networks (ANNs), has gained relevance in modeling and analyzing industrial process units. Artificial neural networks are data-driven structures widely used to model chemical process units, such as reactors [4] and separation units [5]. These tools allow the prediction of system behavior from data, analyzing how input variables affect system responses. Nevertheless, developing ANN-based models requires training data, which poses challenges in process design where the equipment does not yet exist and real-world data is unavailable. On the other hand, it is crucial to emphasize the importance of avoiding reliance solely on data-based models, as this might overlook the fundamental principles governing system behavior [6]. Hybrid models address this issue by combining the predictive capabilities of ANNs for complex interactions with the foundational knowledge of mechanistic models.

In this context, this work develops an ANN model to predict the cost of a shell-and-tube heat exchanger. Furthermore, a hybrid ANN model (ANN-H) is implemented, combining predictions of heat transfer coefficient

generated by an artificial neural network with the remaining design calculations, represented with the rigorous Bell-Delaware model.

This work focuses on the development and implementation of ANN and ANN-H models for the design and optimization of shell-and-tube heat exchangers. The goal is to explore methodologies for accurately predicting key parameters such as heat transfer coefficients and equipment costs based on design variables. To achieve this, ANN models are trained to analyze and predict complex relationships within the heat exchanger design, while a ANN-H model is developed to integrates the strengths of ANNs with traditional rigorous calculation techniques, such as the Bell-Delaware method. This hybrid approach leverages the ability of ANNs to predict highly nonlinear behaviors while maintaining the fundamental principles provided by mechanistic models, improving the overall accuracy of predictions.

Moreover, the study employs Bayesian optimization algorithms to determine the optimal architecture of the ANN models, ensuring accurate and reliable predictions. Subsequently, metaheuristic optimization algorithms are applied to identify the optimal values of design variables that minimize the heat exchanger cost, providing a comprehensive approach for cost-efficient design.

The results obtained from the ANN and ANN-H models are compared with the outputs of rigorous models to validate the effectiveness and reliability of the proposed methodologies. By integrating advanced machine learning techniques with traditional engineering approaches, this work seeks to bridge the gap between computational efficiency and the accuracy in heat exchanger design, offering an innovative path for process optimization in the chemical industry.

## METHODOLOGY

The study focuses on a heat exchanger with methanol in the shell and seawater in the tubes [5]. Methanol flows with inlet/outlet temperatures of 95 °C and 40 °C, respectively, and a mass flow rate of 27.8 kg/s. Seawater flows through the tubes with inlet/outlet temperatures of 25 °C and 40 °C, and a mass flow rate of 68.9 kg/s. The shell and tubes are made of carbon steel.

The methodology is developed in three main stages: data generation, model development, and optimization.

### Data Generation

To generate the necessary data for the artificial neural network, a shell-and-tube heat exchanger model was developed with 11 decision variables, each bounded by specific lower and upper limits. Among these, four variables are discrete, with their allowable values listed in Table 1, and seven are continuous, as detailed in Table 2.

**Table 1.** Allowed values for discrete design variables.

| Design variable | | Allowed value |
|---|---|---|
| Tube pitch | $P_t$ | $[1.25d_o, 1.5d_o]$ |
| Tube layout angle | $TL$ | $[30°, 45°, 90°]$ |
| Baffle cut | $B_c$ | $[25\%, 30\%, 40\%, 45\%]$ |
| Number of tube passes | $N_p$ | |

**Table 2.** Upper and lower limits for continuous variables.

| **Design variable** | | **Lower limit** | **Upper limit** |
|---|---|---|---|
| Shell diameter | $D_s$ | 0.3 m | 1.5 m |
| Spacing in central baffle | $L_{b,c}$ | 0.2 $D_s$ | 0.55 $D_s$ |
| Initial and final baffle spacing | $L_{b,i}, L_{b,o}$ | 1 $L_{b,c}$ | 1.6 $L_{b,c}$ |
| Diametrical distance of the hole between the shell and baffles | $\delta_{sb}$ | 0.01 $d_o$ | 0.1 $d_o$ |
| Diametrical distance between tubes and baffles | $\delta_{tb}$ | 0.01 $D_s$ | 0.1 $D_s$ |
| Beam tubes diameter | $D_{otl}$ | 0.8 ($D_s$ - $\delta_{sb}$) | 0.95 ($D_s$ - $\delta_{sb}$) |

The design process incorporated five constraints, including operational limits such as maximum pressure drops on both the tube and shell sides, maximum and minimum fluid velocities on the tube side, and a geometric constraint, as outlined in Table 3.

**Table 3.** Constraints used for the STHE design.

| **Variables** | | **Constraint** |
|---|---|---|
| Pressure drop in tubes | Pa | ≤ 70,000 |
| Pressure drop in shell | Pa | ≤ 70,000 |
| Flow rate in tubes | m/s | ≤ 0.5 |
| | | ≥ 3 |
| L/D Ratio | | ≤ 15 |

A total of 50,000 designs were generated randomly by assigning values to the decision variables within their defined ranges for continuous variables and selecting from the permissible values for discrete variables. Of these, only 11,643 designs satisfied the operational and geometric constraints established for the heat exchanger model. The remaining designs, which failed to meet these constraints, were discarded during the data cleaning to ensure the dataset's reliability.

### ANN Model Development and Implementation

The valid dataset comprising 11,643 designs was utilized to train and validate the ANN. In this context, constraint variables served as input features, while the total equipment cost, calculated based on the methodology outlined in [3], was the output target.

The development of the hybrid model involved

replacing the three traditional equations used to calculate the heat transfer coefficient on the tube side with a neural network model. Specifically:

- Equation 1 applies to the laminar flow regime ($Re_t < 2300$).
- Equation 2 is used for the transitional regime ($2300 \leq Re_t \leq 10{,}000$).
- Equation 3 corresponds to the turbulent regime ($Re_t > 10{,}000$).

$$h_t = \frac{k_t}{d_i}\left[1.86\left(\frac{Re_t Pr_t d_i}{L}\right)^{\frac{1}{3}}\right] \quad (1)$$

$$h_t = \frac{k_t}{d_i}\left[\frac{\frac{f_t}{2} Re_t Pr_t}{1.07 + 12.7\left(\frac{f_t}{2}\right)^{0.5}\left(Pr_t^{\frac{2}{3}} - 1\right)}\right] \quad (2)$$

$$h_t = \frac{k_t}{d_i} Re_t^{0.8} Pr_t^{\frac{1}{3}}\left(\frac{\mu_t}{\mu_w}\right)^{0.14} \quad (3)$$

These traditional equations introduce discontinuities at the transitions between Reynolds number domains. To address this, an ANN was employed to provide a smooth and continuous approximation of the overall heat transfer coefficient on the tube side.

Data for training the ANN were generated by randomly sampling values for tube length and diameter, resulting in 13,127 data points. These variables are fundamental inputs to the traditional correlations, ensuring comprehensive coverage of the Reynolds number ranges and enabling the ANN to capture system behavior across all operational domains.

## ANN Architecture Optimization

The optimal ANN architecture was determined using Bayesian optimization, exploring a predefined search space based on the parameters listed in Table 4. This optimization aimed to identify the configuration that maximizes the ANN's performance in terms of accuracy. The same optimization approach was applied to both the traditional and hybrid models to ensure consistency.

**Table 4.** Selection Parameters for ANN Architecture

| Parameter | Values |
|---|---|
| Number of Layers | 1 to 4 |
| Number of Neurons per Layer | 1 to 16 |
| Activation Function | ReLU, ELU, Leaky ReLU |
| Optimizer | Adam, SGD |

Once the optimal architecture was established, the ANN model was implemented in Python, leveraging machine learning libraries to construct and train the network. The model was designed to process the filtered dataset and predict the total equipment cost based on specific input variables for each design scenario.

## Training and Validation

The dataset was partitioned into training and validation sets, with 80% allocated for training and 20% for validation. This split ensured that the ANN could generalize effectively to unseen data. The training-validation process was conducted independently for each modeling approach, reinforcing robust performance and adequate generalization capability.

In the hybrid model, the ANN replaced the segment of the Bell-Delaware model responsible for calculating convective heat transfer coefficients. The ANN's predictions were seamlessly integrated into the overall cost estimation of the heat exchanger, enhancing the model's continuity and accuracy.

## Metaheuristic Optimization of Design Variables

Metaheuristic algorithms were employed through the MEALPHY library to identify the optimal values of the 11 design variables that minimize the heat exchanger cost. These algorithms iteratively explored the design space to converge on the most cost-effective configurations. The optimized design variable values were subsequently utilized in both the traditional and hybrid models to compute and compare heat exchanger costs, facilitating an evaluation of each methodology's predictive capabilities.

## Analysis and Validation

The performance of the ANN and hybrid ANN-H models was assessed by analyzing the accuracy and standard deviation of their predictions. Additionally, the costs calculated for the optimal design variables were compared between both models and validated against the rigorous Bell-Delaware model. This validation ensured that the proposed methodologies are applicable under real-world conditions, demonstrating their reliability and effectiveness in optimizing heat exchanger design.

# RESULTS

This section presents a comparative analysis of the outcomes derived from the two models developed in this study: the Artificial Neural Network (ANN) model and the Hybrid ANN-H model, which integrates the ANN with the rigorous Bell-Delaware model.

## Performance of the ANN Model

The ANN model was trained using a filtered dataset comprising 11,643 entries. The optimal architecture identified consists of an input layer with 16 neurons, followed by two hidden layers containing 10 and 16 neurons,

respectively, and an output layer.

Table 5 illustrates selected cost predictions from the ANN model alongside the corresponding values obtained from the rigorous Bell-Delaware model.

**Table 5.** Heat Exchanger Cost Comparison: Rigorous Model vs. ANN Predictions.

| Rigorous Model Cost [USD/year] | ANN Predicted Cost [USD/year] |
|---|---|
| 22,973.88 | 24,521.90 |
| 29,617.20 | 33,566.61 |
| 20,656.89 | 18,239.29 |
| 17,710.37 | 17,322.07 |
| 23,430.10 | 24,415.09 |
| 24,726.01 | 23,447.56 |
| 27,128.27 | 26,297.71 |
| 31,251.74 | 31,865.45 |
| 21,422.44 | 23,961.10 |
| 37,979.40 | 38,219.78 |

Figure 1 presents a scatter plot comparing the rigorous model costs against the ANN-predicted costs. The average standard deviation between the ANN predictions and the rigorous model costs is 1,079.591 USD/year, indicating a notable variability in the ANN's cost estimations relative to the rigorous model.

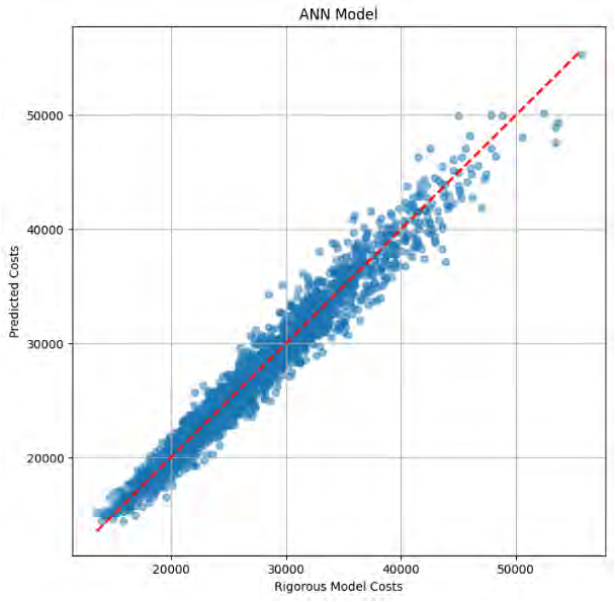

**Figure 1.** Comparison of rigorous model costs and ANN-predicted costs.

## Prediction of Convective Heat Transfer Coefficient

A separate ANN was trained to predict the convective heat transfer coefficient in the tubes using a dataset of 13,125 entries. The optimal architecture for this ANN comprises an input layer with 8 neurons, followed by three hidden layers with 14, 7, and 16 neurons, respectively, and an output layer.

Table 8 provides representative data used for training the ANN predicting the convective heat transfer coefficient.

**Table 6.** Sample Data for ANN Predicting Convective Heat Transfer Coefficient

| $L_t$ [m] | $d_i$ [m] | Flow rate in tubes [m/s] | h [W/m²] |
|---|---|---|---|
| 1.00 | 0.19 | 0.51 | 1662.47 |
| 2.12 | 0.40 | 0.92 | 2304.77 |
| 4.75 | 0.62 | 1.75 | 3519.76 |
| 7.37 | 0.92 | 2.57 | 4430.22 |
| 9.62 | 1.83 | 2.98 | 4346.38 |

Table 7 compares the convective heat transfer coefficients predicted by the ANN-H model with those calculated using the rigorous model. Figure 2 illustrates the relationship between the rigorous model's convective coefficients and those predicted by the ANN-H model. The average standard deviation between the two sets of values is 5.942 W/m²·K, suggesting a closer alignment between the ANN-H predictions and the rigorous model compared to the ANN model's performance in cost predictions.

**Table 7.** Convective Heat Transfer Coefficient Comparison: Rigorous Model vs. ANN-H Predictions

| Rigorous model convective coefficient [W/m²] | Predicted convective coefficient [W/m²] |
|---|---|
| 335.99 | 334.28 |
| 1 662.47 | 1 667.45 |
| 13 044.61 | 13 033.72 |
| 10 297.55 | 10 290.20 |
| 10 726.66 | 10 720.97 |
| 2 652.72 | 2 648.79 |
| 335.99 | 329.62 |
| 10 199.32 | 10 196.65 |
| 8 840.98 | 8 836.88 |
| 9 709.29 | 9 695.50 |

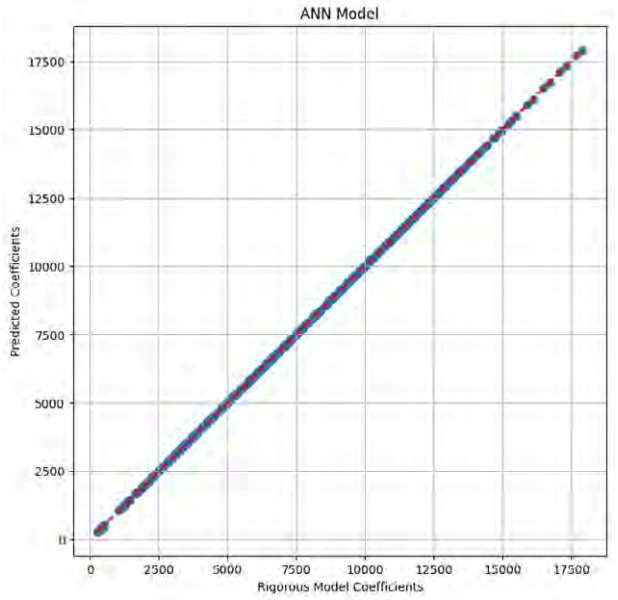

**Figure 2.** Comparison of rigorous model convective coefficients and ANN-H predicted coefficients.

## Performance of the Hybrid ANN-H Model

The Hybrid ANN-H model integrates the ANN to predict the convective heat transfer coefficients, thereby replacing the traditional equations in the rigorous Bell-Delaware model. The cost predictions from the ANN-H model are presented alongside the rigorous model costs in Table 8.

The ANN-H model exhibits an average standard deviation of 348.55 USD/year when compared to the rigorous model, which is significantly lower than the 1,079.59 USD/year observed in the ANN model. This reduction in variability indicates improved consistency and accuracy in cost predictions when utilizing the hybrid approach.

**Table 8.** Heat Exchanger Cost Comparison: Rigorous Model vs. ANN-H Predictions

| Rigorous model cost [USD/year] | ANN- H predicted cost [USD/year] |
|---:|---:|
| 29,617.20 | 30,038.76 |
| 20,656.88 | 21,333.41 |
| 17,710.36 | 18,678.41 |
| 23,430.09 | 23,815.72 |
| 24,726.01 | 25,351.33 |
| 27,128.27 | 27,346.88 |
| 31,251.73 | 31,655.29 |
| 21,422.44 | 21,903.92 |
| 37,979.39 | 38,235.07 |

## Optimization of Design Variables

Table 9 summarizes the optimal values of the design variables obtained through metaheuristic optimization for both the ANN and ANN-H models, along with the corresponding total costs.

**Table 9.** Optimal Design Variables and Costs: ANN vs. ANN-H Models

| Design variable | Optimal value (ANN) | Optimal value (ANN-H) |
|---|---|---|
| Shell diameter | 0.3 m | 0.3 m |
| Tube diameter | $d_o$-0.25in, $d_i$-0.194in | $d_o$-0.25in, $d_i$-0.194in |
| Tube pitch | 1.25 do | 1.25 do |
| Tube arrangement | 45° | 90° |
| Number of passes in the tubes | 1 | 4 |
| Baffle cut percentage | 25% | 45% |
| Spacing in central baffle | 0.2 $D_s$ | 0.2 $D_s$ |
| Initial and final baffle spacing | 1 $L_{b,c}$ | 1.036 $L_{b,c}$ |
| Diametrical distance of the hole between the shell and baffles | 0.01 $d_o$ | 0.1 $d_o$ |
| Diametrical distance between tubes and baffles | 0.01 $D_s$ | 0.09 $D_s$ |
| Beam tubes diameter | 0.948 ($D_s$ - $\delta_{sb}$) | 0.95 ($D_s$ - $\delta_{sb}$) |
| Cost (USD/year) | 13437.20 | 13 404.28 |

Both models suggest similar optimal values for most design variables, with notable differences in the tube arrangement angle and the number of tube passes. Specifically, the ANN model favors a 45° tube arrangement with a single tube pass, whereas the ANN-H model recommends a 90° arrangement with four tube passes. These variations reflect how the ANN-H model's integration of convective coefficient predictions influences the optimization process to achieve lower cost outcomes.

The comparative analysis indicates that the Hybrid ANN-H model consistently demonstrates lower variability in cost predictions compared to the standalone ANN model. The reduced standard deviation in the ANN-H model suggests a closer alignment with the rigorous Bell-Delaware model, thereby enhancing prediction reliability.

Furthermore, the optimization results reveal that while both models converge towards similar solutions for most design variables, the ANN-H model achieves marginally lower total costs. This outcome underscores the potential benefits of integrating ANN with traditional modeling approaches, particularly in achieving more accurate and reliable cost estimations.

## CONCLUSIONS

This study compared an Artificial Neural Network (ANN) model with a Hybrid ANN-H model for the design and cost optimization of shell-and-tube heat exchangers. The results indicate that the Hybrid ANN-H model achieves more accurate cost predictions, evidenced by lower average standard deviations than the standalone ANN model. This improvement is attributed to effectively integrating the rigorous Bell-Delaware model with the ANN, balancing accuracy and computational efficiency.

Despite these advantages, the Hybrid ANN-H model does not consistently match the computational efficiency of the rigorous model across all scenarios. In some cases, it may require additional computational resources, limiting its applicability where rapid calculations are necessary. Nevertheless, the Hybrid ANN-H model remains a viable alternative for scenarios where both predictive accuracy and computational efficiency are critical.

Overall, the findings demonstrate the potential of combining artificial neural networks with traditional engineering methodologies to enhance the design and analysis of industrial process units. This integration offers a balanced approach to managing computational costs while improving prediction accuracy, paving the way for more effective optimization in thermal system design.

## ACKNOWLEDGEMENTS

The authors acknowledge the financial support from Universidad de Guanajuato, Mexico, through project 189/2024. Additionally, CONAHCYT provided financial support through a postdoctoral fellowship granted to Oscar Daniel Lara Montaño (application number 4861420). The resources and academic environment provided by these institutions were fundamental to the successful completion of this research.

## ABSTRACT

Chemical process models often involve high non-linearity due to thermodynamic and kinetic relationships, with non-convex bilinear terms adding complexity to process optimization. Recently, data-driven models, particularly artificial neural networks (ANNs), have gained traction for representing chemical processing units. The predictive accuracy of ANNs depends on data quality, variable interactions, and network architecture, the latter being an optimization challenge itself. This study proposes and evaluates two strategies to optimize ANN architecture for modeling a propylene glycol production process from glycerol. The process includes a reactor and two distillation columns, with training data generated through simulation in Aspen Plus by varying design and operating variables. Two approaches are compared: random ANN structure generation and architecture optimization using the ant colony algorithm, a method suitable for discrete problems. Decision variables include the number of hidden layers and neurons per layer, with the objective of minimizing mean squared error. Both methods yield ANN predictions with high accuracy ($R^2$ > 99.9%), closely matching simulation data. However, the ant colony algorithm achieves a better fit despite slower convergence, demonstrating its effectiveness in fine-tuning ANN architecture for chemical process modeling.

## INTRODUCTION

Rigorous models for process equipment are built upon well-established physical and chemical principles, such as design equations, mass and energy balances, thermodynamic relationships, and, in some cases, cost equations. These models enable the precise representation of system behavior across various operating conditions, offering a robust foundation for process analysis and optimization.

Despite their advantages—such as high accuracy, clear interpretability, and alignment with physical laws, as highlighted in numerous studies—rigorous models have significant limitations. Researchers have pointed out challenges including the high cost of constructing these models, particularly for large and complex systems. Additionally, they require a deep understanding of the system and often involve extensive fine-tuning to achieve accurate predictions [1]. Moreover, the computational demands of rigorous models can be prohibitive, especially when simulating intricate or highly dynamic processes.

These challenges have accelerated interest in data-driven models, which address many of these limitations. Data-driven science, often referred to as the fourth paradigm [2], is transforming how we approach research and problem-solving. Montáns et al. [3] highlight that, unlike rigorous models, data-driven approaches rely on vast amounts of empirical data to uncover patterns, trends, and insights, bypassing the need for exhaustive system-

specific knowledge. These methods enable faster model development and adaptation, particularly for complex, nonlinear systems.

The development of data-driven models is an area of significant interest in Process Systems Engineering. An example of this can be seen in the work by Kwon et al. [4], where data-driven models are applied to the analysis of processing units for controlling distillation columns. Among the various types of data-driven models, machine learning models stand out due to their ability to identify complex patterns without the need for explicit formulation.

Cavalcanti et al. [5] conducted an extensive review compiling a range of successful studies on the application of Artificial Intelligence (AI) in Process Engineering. This comprehensive study covers various fields, particularly showing how ANNs can replace complex phenomenological models, offering the advantage of reduced computational effort.

For an ANN model to perform satisfactorily, both the quantity and quality of the data used for training must be appropriate. Regarding quantity, the performance of ANN models is enhanced as the amount of data available for training increases [6]. Of course, the number of data points required will depend on the complexity of the system being modeled by the neural network. Likewise, the quality of the information used for training the network is crucial. The use of such strategies for process design applications presents a challenge, as the units necessary for generating data to train the network are not available. One strategy that can be employed under such circumstances is the use of rigorous models for data generation [7].

Recent research has focused on optimizing artificial neural network (ANN) architectures to enhance their predictive performance and computational efficiency. Evolutionary algorithms and metaheuristic approaches have been widely explored to automate the design of ANN structures, allowing for improved adaptability to complex systems [8]. In process modeling applications, strategies incorporating statistical criteria for model selection, such as the Akaike Information Criterion (AIC), have been employed to refine ANN architectures and enhance their predictive capabilities [9].

In this work, ANNs are proposed for modeling chemical processing units, employing two different strategies for architecture optimization. The first strategy relies on randomly generated configurations, while the second utilizes the ant colony optimization algorithm [10]. In both approaches, key performance parameters are recorded to enable a subsequent comparison of their effectiveness. The study begins with an overview of the case study, followed by a detailed description of the methodology used to generate the data and evaluate the proposed optimization strategies. Finally, the results are analyzed and discussed, highlighting the advantages of each approach.

## CASE STUDY

Sánchez-Gómez et al. [11] proposed various production schemes for propylene glycol, including conventional and reactive distillation-based configurations. In this study, the focus is on the conventional processing scheme, which is presented in Figure 1.

The feed to the process consists of a crude glycerol stream, represented as a 1:1 mass ratio mixture of glycerol and water, with a total flow rate of 100 kmol/h. This stream enters a reactor where glycerol reacts with hydrogen to produce propylene glycol. However, a secondary reaction also occurs, forming ethylene glycol as a by-product.

The reactor effluent is separated using a direct distillation sequence, where propylene glycol is obtained as the distillate product from the second column, achieving a molar purity of at least 99%. Further details about the process are provided in the work by Sánchez-Gómez et al. [11]. The initial conditions for the process are given in Table 1.

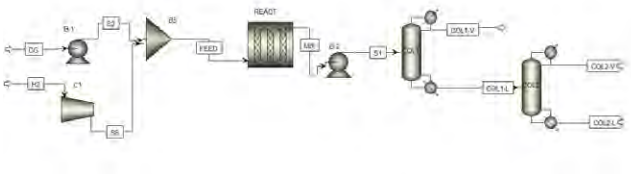

**Figure 1**. Propylene glycol production process from glycerol and hydrogen.

## METHODOLOGY

The analysis has been divided in two stages: (i) data generation, and (ii) development of artificial neural networks. These stages are described below.

### Information Generation

To gather sufficient data for neural network modeling, the analysis begins with an initial simulation in Aspen Plus of the conventional propylene glycol production process (Figure 1), operating under the initial conditions outlined in Table 1. The focus is on modeling the reactor and the two distillation columns using artificial neural networks.

Python programming enables interaction with Aspen Plus simulations [12]. A customized code has been developed to automatically access and modify variables within the simulation, identified as input variables in Table 1. The simulation was executed under various conditions, generating response variable values for 500 random designs.

To define feasible ranges for input variables,

**Table 1:** Manipulated and response variables for sensitivity analysis.

| Reactor | | | |
|---|---|---|---|
| **Manipulated** | **Initial Values** | **Range** | **Response** |
| Diameter | 0.1 m | 1 to 6 m | Heat Load |
| Length | 10 m | 3 to 10 m | Composition |
| Operation temperature | 225 °C | 200 to 250 °C | |
| **Columns 1 and 2** | | | |
| **Manipulated** | **Initial Values** | **Range** | **Response** |
| Number of Stages (NS) | 20 (COL1)<br>40 (COL2) | 10 to 35<br>25 to 50 | Diameter |
| Feed Stage | 5 (COL1)<br>20 (COL2) | From 2 to NS | Composition at bottoms and dome |
| Reboiler Heat Load | 320 kcal/s (COL1)<br>183 kcal/s (COL2) | 157 to 788 kcal/s<br>91 to 457 kcal/s | Condenser heat load |
| Reflux ratio | 0.5 (COL1)<br>2.6 (COL2) | 0.1 to 10 | Temperature at S1, S2, SN and SN-1 |

evaluation intervals were established based on the initial process conditions (Table 1), ensuring the design and operational parameters align with practical standards.

Non-converging or thermodynamically inconsistent simulations were filtered out, leaving a dataset of 351 valid simulations for subsequent economic analysis. For each case, the total annualized cost (TAC) of the process was calculated using Guthrie's method, annualizing equipment costs over 10 years [13].

At the end of this process, the dataset is ready for training and testing the neural networks. An important aspect of the data used to train an artificial neural network is its quality. In this case, the data to be used meets this characteristic, as they come from rigorous simulations conducted in a commercial simulator, Aspen Plus. This simulator is widely recognized in the industry for its ability to accurately and reliably model chemical processes. By using such a simulator, it is ensured that the generated data are representative of actual operational conditions, if adequate datasets and sub-models are employed.

## Development of Artificial Neural Networks (ANNs)

To determine whether the generated data was sufficient, an ANN was developed and trained using Python and the TensorFlow library. For this initial evaluation, a network with two hidden layers, each containing 32 neurons, was employed. The Adam optimization algorithm was used to adjust the weights of the connections between neurons, with the ReLU (Rectified Linear Unit) activation function. In all cases, the output variable was the total annualized cost (TAC) of the equipment being modeled. The dataset was split into training and validation data, using percentages of 80% and 20%, respectively. The results of this preliminary assessment were satisfactory, indicating that the amount of data generated was adequate.

The next step involves identifying the network configuration that minimizes the mean squared error (MSE) of the predictions across the entire dataset. The MSE was quantified using the following objective function:

$$MSE = \frac{1}{n}\sum_{i=1}^{n}(real_i - pred_i)_i^2 \quad (1)$$

Two strategies were evaluated to solve this optimization problem:

(i) Random generation of network architectures.

(ii) A metaheuristic optimization algorithm based on the Ant Colony Optimization (ACO) approach.

### Random Generation

The random generation strategy is widely used as an effective approach for identifying the optimal neural network architecture [14]. This strategy begins by defining the limits for the number of layers and the number of neurons per layer. A code was implemented to randomly generate network architectures within these limits, train them, and evaluate their performance using MSE as the primary metric. Among all evaluated architectures, the one with the lowest MSE was selected. A total of 150 network architectures were tested, with additional performance metrics recorded, such as the coefficient of determination ($R^2$), prediction error percentage, and computation time.

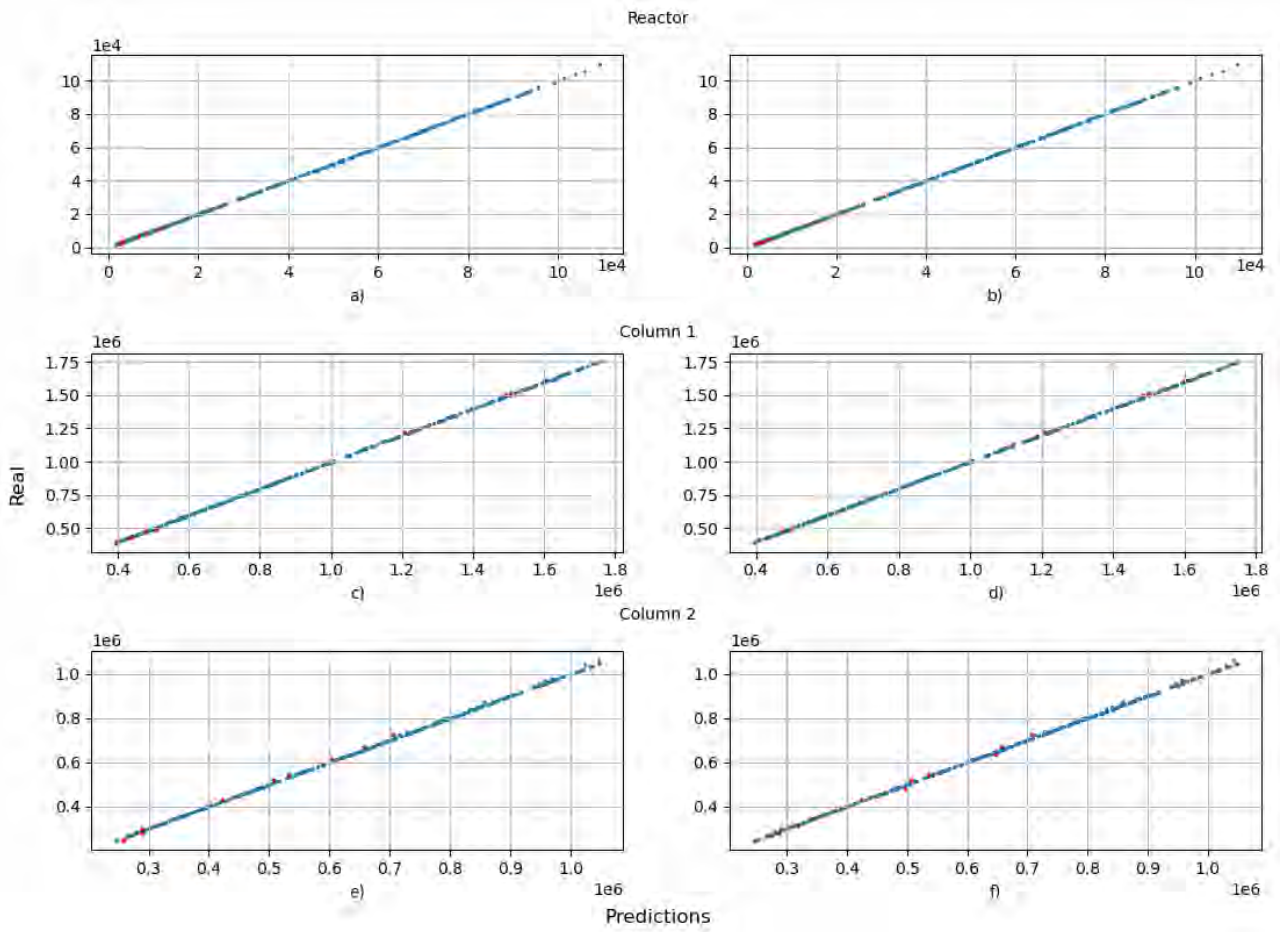

**Figure 2**. Rigorous simulation data (y-axis) vs predictions (x-axis). (a) Reactor with ACO, (b) Reactor with RS, (c) Column 1 with ACO, (d) Column 2 with ACO, (e) Column 2 wirh RS.

### Metaheuristic Optimization Algorithm

Existing ACO algorithm implementations, such as the ACOR algorithm in the *Mealpy* library [15], has been considered. This version of ACOR provides solutions for both integer and continuous variables. However, due to specific needs in this study, the original Ant Colony Optimization algorithm was implemented in Python to address integer-based decisions. The algorithm parameters, along with the ranges for decision variables, are summarized in Tables 2 and 3. These last values were used consistently across both solution strategies.

The number of ants and iterations was set to ensure a total of 150 networks were trained, enabling a fair comparison between the random generation strategy and the metaheuristic approach. Just as in the random generation strategy, metrics such as MSE, $R^2$, prediction error percentage, and computational time were recorded and used to evaluate and compare the performance of both approaches.

## RESULTS

As a result of the analysis conducted six neural network models were obtained, two for each process unit under study, corresponding to each architecture optimization strategy.

Figure 2 shows a comparison of the predictions obtained from both strategies. The data obtained through the Ant Colony Optimization algorithm is presented in the left column, while the corresponding results from Random Search are shown on the right. For each case, the 10 predictions with the highest error percentages can be observed as red points.

**Table 2:** Parameters for the Ant Colony Optimizer.

| Strategy | Iterations | Population | n_best | decay | alpha | beta |
|---|---|---|---|---|---|---|
| ACO | 25 | 6 | 5 | 0.95 | 1 | 1 |
| RG | 150 | - | - | - | - | - |

**Table 3**: Ranges for decision variables.

| Variable | Range |
|---|---|
| Number of layers | [1, 4] |
| Number of neurons | [1, 100] |

Table 4 summarizes the performance measures recorded for each model, as well as the architecture that minimized the MSE. In the last column (Architecture), the first number represents the number of hidden layers, while the information in brackets represents the number of neurons per layer. Among the generated models, only the reactor model obtained through the random search strategy exhibited predictions with an error percentage greater than 5%. In contrast, the remaining models predicted across the entire dataset with an error below 5%. In terms of the values of $R^2$, values higher than 99.9% are obtained for all the cases. However, it is observed that the Ant Colony Optimizer allowed faster convergence, particularly for the model of the second distillation column. It is important to mention that, for both strategies, a high number of neurons per layer are obtained. This is a relevant aspect to be considered for future research, since it is desired to obtain models with a good fitting, but with simpler architectures.

## CONCLUSIONS

In this study, artificial neural networks are used to represent the performance of equipment from a chemical process, particularly the production of propylene glycol from renewable glycerol. Six artificial neural network models were obtained, each achieving accuracy greater than 99%. Several parameters were recorded to analyze their performance and subsequently compare the strategies.

Overall, the random architecture generation strategy yielded slightly better results in terms of MSE and $R^2$. However, the Ant Colony Optimizer required less time than the random search approach to determine the optimal architecture.

## ACKNOWLEDGEMENTS

The authors acknowledge the financial support from Universidad de Guanajuato, Mexico, through project 189/2024. Additionally, CONAHCYT provided financial support through a postdoctoral fellowship granted to Oscar Daniel Lara Montaño (application number 4861420). The resources and academic environment provided by these institutions were fundamental to the successful completion of this research.

## ABSTRACT

As the demand for resources continues to grow, pipelines have become critical for transporting water, fossil fuels, and chemicals. Monitoring pipeline systems is essential, as leaks can lead to severe environmental damage and safety hazards. This study aims to develop a pipeline leakage detection system based on digital twin technology and Physics-Informed Neural Networks (PINNs). By embedding physical principles, such as the continuity and momentum equations derived from the Navier-Stokes equation, into the neural network's loss function, the model can predict pressure and flow dynamics with high accuracy while adhering to physical constraints. PINNs are particularly advantageous as they require minimal data, maintain physical consistency, and provide reliable interpretations, making them well-suited for addressing pipeline safety challenges. The model is designed to simulate fluid dynamics under normal operating conditions, with deviations in prediction errors signaling potential leaks. Statistical analysis of these errors is used to define control limits, establish rejection regions, and create control charts for leak detection. The detection system is further validated using field data to ensure reliability. By combining physical modeling and neural networks, this approach enhances the accuracy and interpretability of leakage detection, laying a solid foundation for an efficient pipeline monitoring solution.

**Keywords**: Pipeline leakage detection, Physics-informed neural networks, Surrogate model, Industrial safety

## INTRODUCTION

As modern society's demand for energy and resources continues to grow, pipeline transportation has become a critical foundation for industrial and domestic supply. However, pipeline leaks not only pose a significant threat to the environment through severe pollution but also endanger the safety of nearby residents and industrial surroundings. Furthermore, such incidents can compromise the quality of transported materials, with ruptured pipelines potentially leading to product contamination. Therefore, the monitoring and control of pipeline systems are of utmost importance.

Current pipeline leakage detection technologies can be broadly classified into two categories: hardware-based methods and software-based methods [1]. Hardware-based methods utilize equipment to detect leaks and their locations. Common techniques include acoustic sensing, fiber optic cables, ground-penetrating radar, gas injection, and infrared thermography. For example, acoustic sensing detects leaks by capturing the vibrations or sound waves generated by high-pressure fluid escaping from the pipeline and converts these signals into electronic data to analyze the leak's size and location [2]. Fiber optic cables, installed along pipeline lengths, change their transmission characteristics when exposed to liquid. Specially designed hydrophones then detect and analyze these signals to pinpoint the leak's location [3]. Infrared thermography identifies abnormal temperature variations in the pipeline environment through real-time thermal detection [4]. While these methods can achieve high accuracy, they often involve high operational costs, complex maintenance, and limited detection ranges, making them less practical for large-scale pipeline systems.

On the other hand, software-based methods rely on models or algorithms to detect and locate leaks using sensor data (e.g., pressure, flow rate, and temperature).

These methods generally require fewer sensors, resulting in lower maintenance costs. Software-based techniques can be divided into two main categories: model-based and data-driven methods. Model-based approaches use theoretical formulas from fluid dynamics to compare computed and measured values, where significant deviations indicate leaks. An example is the Real-Time Transient Model (RTTM) [5, 6]. Data-driven methods include support vector machines [7], convolutional neural networks [8], and wavelet transforms [9], leveraging machine learning, deep learning, anomaly detection, and time series analysis to learn normal system behavior from historical data and detect anomalies indicative of leaks. Meanwhile, purely data-driven (model-based) approaches often require extensive training data or fail to ensure physical consistency in dynamically changing environments. While effective in handling high-dimensional, nonlinear systems, data-driven methods often lack physical interpretability.

This study aims to develop a Physics-Informed Neural Network (PINN) that combines physical knowledge with data-driven approaches for accurate pipeline leakage detection. PINN, introduced by Raissi et al. [10], consists of a neural network for data fitting and a loss function incorporating physical information. By minimizing both prediction and PDE losses, PINN ensures that the model aligns with real-world data and adheres to physical constraints, offering interpretability and reliability. Automatic differentiation (AD) enables efficient computation of partial derivatives during training. In this study, the Navier-Stokes equations, describing fluid pressure and flow variations in the pipeline, are incorporated into the PINN loss function, capturing pipeline dynamics through continuity and momentum equations to enhance leakage detection accuracy. By utilizing only upstream and downstream flow and pressure sensors, our approach reduces operational costs by eliminating the need for expensive hardware, requires minimal maintenance compared to traditional sensor-intensive techniques, enhances long-range leak detection by leveraging both physical knowledge and machine learning capabilities, and ensures physical interpretability, improving reliability in real-world applications.

## METHODOLOGY

The schematic diagram of the pipeline system is illustrated in Figure 1. This underground pipeline, designed to transport liquid fluids, extends over a total length of 39.68 kilometers.

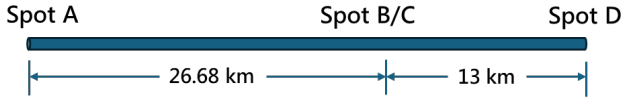

**Figure 1.** Schematic diagram of the pipeline system.

To achieve the goal of leak detection, it is essential to establish an effective leak detection process, with the logic depicted in Figure 2. By training a PINN model using datasets from normal operating conditions, the model is designed to describe the fluid dynamics within a leak-free pipeline. When the input data provided to the model reflects flow rates and pressures under leak conditions, a statistically significant error arises between the model's predictions and the actual values. Therefore, leak occurrence can be detected by applying statistical control to the prediction errors.

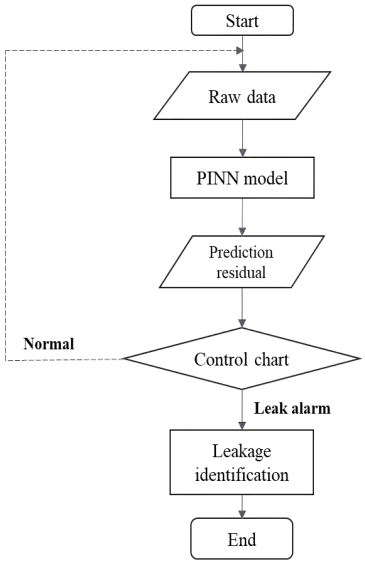

**Figure 2.** Flow chart for leak detection.

### Physics-informed neural networks

To develop a PINN-based surrogate model for predicting pipeline transport variations, it is essential to identify an appropriate physical model and embed it into the loss function to ensure the model adheres to expected physical principles. Considering that the target of this model is to predict the transport behavior of the fluid, the one-dimensional Navier-Stokes equations are employed as the governing equations. These equations describe the motion of fluids (liquids or gases) based on Newton's second law of motion and are derived from the principles of mass conservation and momentum conservation for fluids. The equations are described as follows[11]:

$$\frac{\partial \rho}{\partial t} + \frac{\partial \rho u}{\partial x} = 0 \tag{1}$$

$$\rho \frac{\partial u}{\partial t} + \rho u \frac{\partial u}{\partial x} + \frac{\partial P}{\partial x} + \frac{f \rho u |u|}{2D} = 0 \tag{2}$$

where $u$ is the cross-section averaged velocity (m/s), $\rho$ the density (kg/m$^3$), $p$ pressure (Pa), $f$ (dimensionless) the Darcy friction factor, $D$ (m) pipe diameter.

To establish a PINN model for flow states governed by partial differential equations (PDEs), a deep neural

network (DNN) is first constructed as a surrogate model for solving PDEs. In this study, a feedforward neural network (FFNN) is employed due to its simplicity, which is sufficient for most PDE problems. Considering that the objective at this stage is to identify abnormal transport states, the model must be capable of recognizing the transport state over continuous time under different initial conditions. To enhance the generalization performance of the model, the input layer includes position $x$, time $t$, initial flow velocity condition $u_{IC}$, upstream-downstream pressure difference $\Delta P$, and pressure $P$. The model predicts the output $\hat{u}(x, t, u_{IC}, \Delta P, P, \theta)$, where $\theta$ is a vector containing all weights and biases within the neural network, which are optimized using the gradient descent algorithm during backpropagation. Variables with a hat denote those computed through the neural network. Furthermore, considering that this case involves an inverse problem, the term $f$ in the equations is treated as a model parameter to be estimated.

Ensuring the model's outputs satisfy both real-world data and the physical laws represented by equations (1) and (2) requires minimizing the residuals $g_1$ and $g_2$ as specified in Figure 3. Smaller residual values indicate a high degree of conformity to the underlying physical principles. The time and spatial derivatives are computed using the AD method [12], which eliminates the need for discretizing the computational domain to solve partial differential equations. This approach differs from traditional methods such as the method of characteristics or finite difference methods.

A notable feature of the PINN model is the setup of collocation points, $\{x_f, t_f, u_{ICf}, \Delta P_f, P_f\}$. These points are strategically chosen across different spatial and temporal locations to evaluate the loss based on the problem's requirements. Incorporating these collocation points into the PINN model allows for the calculation of residuals $g_1$ and $g_2$ within the loss function, ensuring that the outputs at these points align with the governing partial differential equations. This enables the neural network to leverage physical knowledge while minimizing the reliance on large datasets of real-world data.

The architecture of the model, as illustrated in Figure 3, consists of an input layer that includes position, time, initial flow velocity condition, upstream-downstream pressure difference, and pressure. The output layer predicts flow velocity. The loss function comprises two components: the error between real-world data and predicted values, and the residual error from the governing partial differential equations. In this study, the weights of these components are set as α = 1 and β = 0.1.

The model configuration includes eight hidden layers, each containing 20 neurons. The activation function tanh introduces nonlinearity. For optimization, a two-stage strategy is applied: initial training is performed using the Adam optimizer, followed by fine-tuning with the L-BFGS-B optimizer to complete the training process.

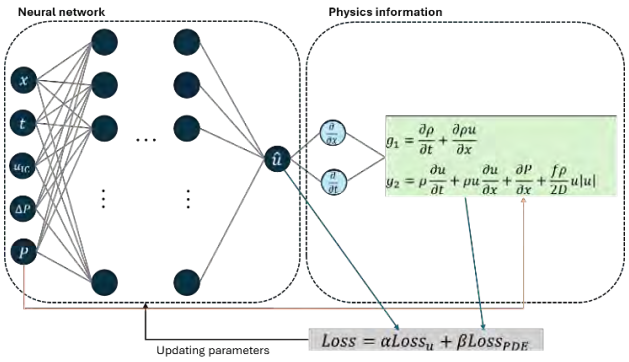

**Figure 3.** Model structure for PINN.

## Dataset splitting and performance evaluation

The dataset used in this study comprises transport data with varying flow rates collected over multiple days of continuous operation. This approach ensures sufficient training of the model and enhances its accuracy and robustness in anomaly detection. The dataset is segmented into fixed windows of 1000 consecutive seconds to create distinct samples, ensuring consistency and precision in the analysis. These samples are further divided into training, validation, and testing sets.

To evaluate the predictive accuracy of the model, the coefficient of determination ($R^2$) and the root mean square error (RMSE) are adopted as evaluation metrics. The $R^2$ measures the model's ability to explain the variance in the data. A value closer to 1 indicates that the model more accurately captures the variability in the data, demonstrating stronger explanatory power. RMSE, on the other hand, quantifies the difference between predicted and actual values in terms of absolute error, providing a direct measurement of the model's accuracy. Lower RMSE values signify that the model's predictions are closer to the actual values, offering a quantitative reflection of the model's predictive performance. By combining these two metrics, the model's performance can be effectively compared, providing a basis for further refinement and improvement.

$$R^2 = 1 - \frac{\sum_{i=1}^{n}(y_i - \hat{y}_i)^2}{\sum_{i=1}^{n}(y_i - \bar{y})^2} \tag{3}$$

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2} \tag{4}$$

# RESULTS AND DISCUSSIONS

For confidentiality purposes, the flow rate data of the fluid has been normalized. After training the PINN model, the prediction results are shown in Figure 4, which displays the diagonal plots of the actual versus predicted values. In this part, the upstream and downstream flow

rate is separately denoted as Q1 and Q4. The model demonstrates excellent prediction performance for both upstream and downstream flow rates across all datasets, with detailed evaluation metrics provided in Table 1.

Since the dataset includes data from multiple days, variations in transportation conditions or operational states across different days result in the diagonal plots being distributed across different ranges, with each cluster representing data from a specific period. It is important to note that, as the dataset was split into six groups, the calculation of the $R^2$ value may be biased. Specifically, the denominator of $R^2$, i.e., the total sum of squares, is relatively large, making the $R^2$ value closer to 1, which could potentially mislead the results. Therefore, relying solely on $R^2$ to evaluate the model's performance is not entirely accurate. Instead, RMSE provides a more realistic measure of the model's effectiveness. The RMSE values for Q1 are 0.0005, 0.0007, and 0.0004 for the training, validation, and testing datasets, respectively. Similarly, the RMSE values for Q4 are 0.0007, 0.0005, and 0.0005 for the same datasets. These results indicate that the model effectively minimizes prediction errors and achieves an exceptional level of performance.

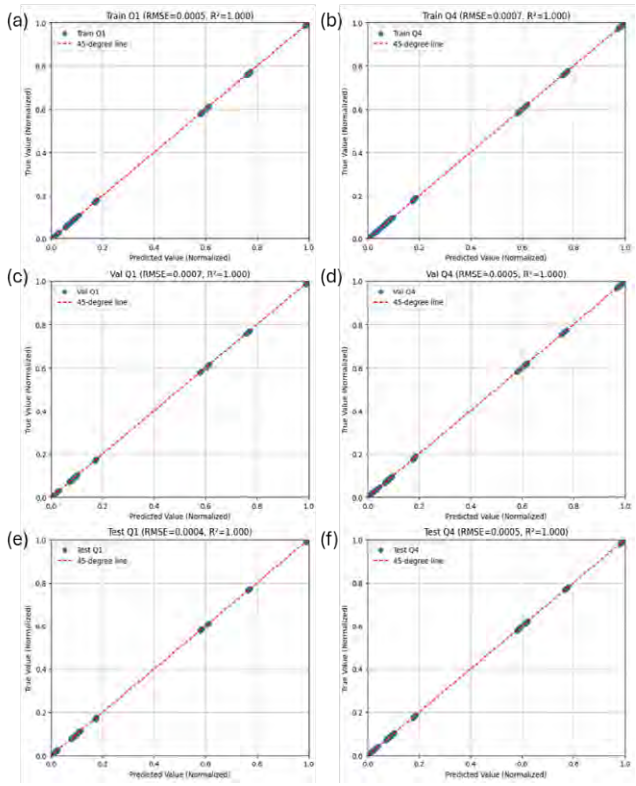

**Figure 4.** Predicted vs. actual values: (a) upstream flow in the train set, (b) downstream flow in the train set, (c) upstream flow in the valid set, (d) downstream flow in the valid set, (e) upstream flow in the test set, and (f) downstream flow in the test set.

**Table 1:** Training, validation, and test performance.

| Dataset | $R^2$(Q1/Q4) | RMSE(Q1/Q4) |
|---|---|---|
| Train | 1.000/1.000 | 0.0005/0.0007 |
| Valid | 1.000/1.000 | 0.0007/0.0005 |
| Test | 1.000/1.000 | 0.0004/0.0005 |

To establish a statistical process control (SPC) chart for anomaly detection, this study selects the validation set for residual sampling. The method involves calculating a range that corresponds to 99.73% of the data distribution, analogous to the 6σ range commonly associated with a normal distribution. This range facilitates subsequent anomaly detection and management. The sampling results are shown in Figures 5 and 6. The residual range of upstream flow lies between -0.0227 and 0.0241, while the residual range of downstream flow is between -0.0272 and 0.0306. These ranges serve as benchmarks for subsequent statistical control, used to detect anomalies based on the model's prediction results. If the residuals of the prediction exceed these ranges, they are considered anomalies, triggering alarms.

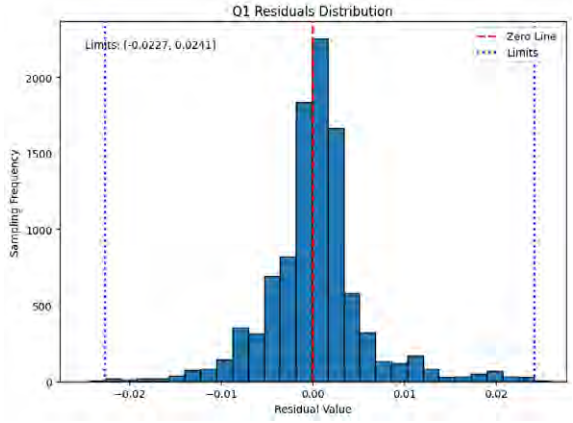

**Figure 5.** Histograms and estmated control limits of the upstream prediction residuals.

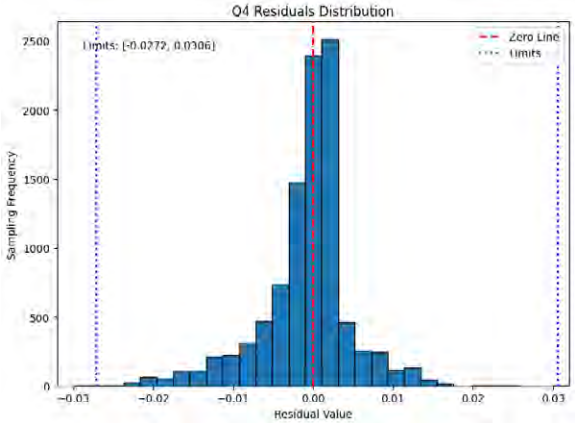

**Figure 6.** Histograms and estmated control limits of the downstream prediction residuals.

Initially, SPC was performed on normal data that the

model had not seen before. Figures 7 and 8 illustrate the monitoring results for upstream and downstream data, respectively. In the control charts, the x-axis represents time, and the y-axis represents the model's prediction residuals. The blue line indicates the actual residual results, while the red dashed lines represent the upper and lower control limits.

From the figures, it is evident that within the selected 1000-second range, the results show that all normal data fall within the in-control range. Additionally, the actual flow rate prediction results over time are shown in Figure 9. For the upstream and downstream flow data, the $R^2$ values reached 1.000 and 0.997, respectively. This demonstrates that the model exhibits high accuracy and reliability in predicting under normal transportation conditions.

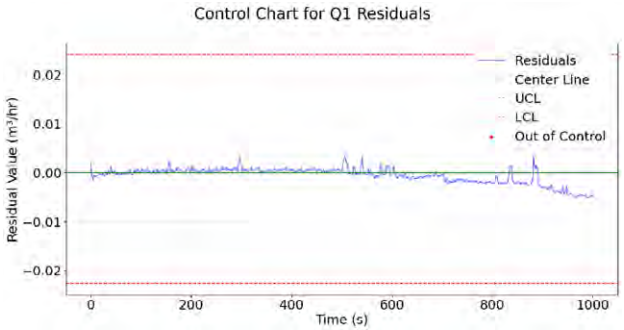

**Figure 7.** Control chart of upstream residuals under normal transportation conditions.

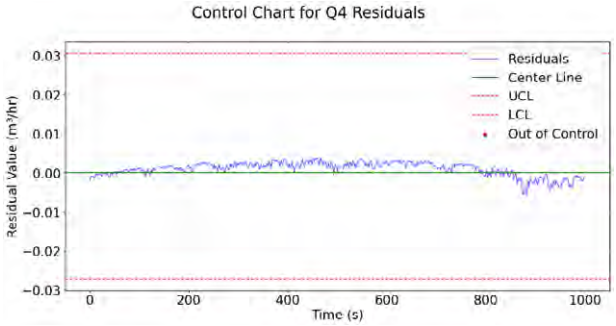

**Figure 8.** Control chart of downstream residuals under normal transportation conditions.

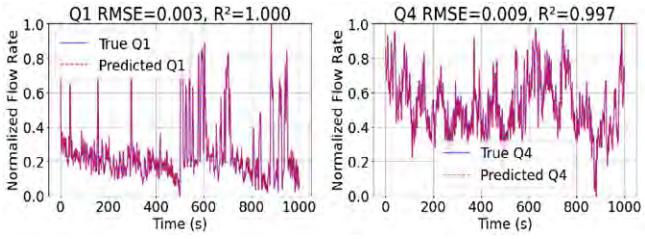

**Figure 9.** Comparison of predicted and true flow rates under normal transportation conditions at different positions in the pipeline system. (a) Flow rate at upstream, and (b) Flow rate at downstream

In the anomaly detection analysis, the statistical control results shown in Figures 10 and 11 clearly reveal abnormal conditions. The upstream data exceed the upper control limit, while the downstream data fall below the lower control limit. A significant number of data points lie outside the control limits, indicating notable differences compared to normal data and suggesting potential anomalies during this time period. Using the control chart, these leakage features can be identified and extracted. Through the above experiments, this study demonstrates the significant impact of leakage events on the distribution of upstream and downstream pressure and flow rate data. The model accurately captures the abnormal behavior during leakage periods.

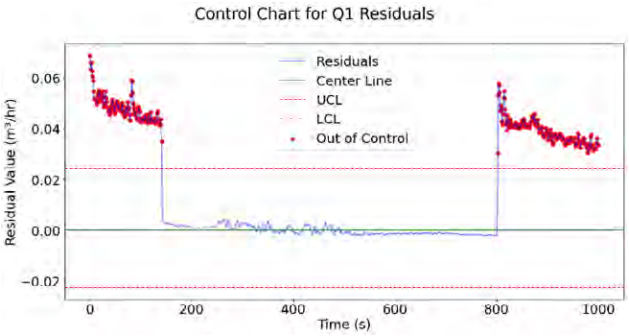

**Figure 10.** Control chart of upstream residuals under leakage conditions.

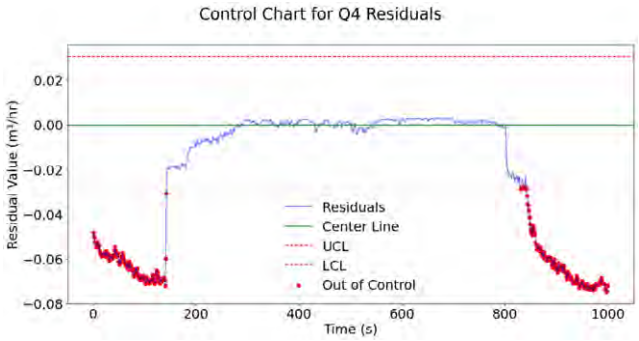

**Figure 11.** Control chart of downstream residuals under leakage conditions.

## CONCLUSIONS

This study developed a pipeline leakage detection system based on Physics-Informed Neural Networks (PINNs), integrating the Navier-Stokes equations of fluid dynamics with deep learning techniques to achieve effective monitoring of pipeline systems. The results demonstrate that the model achieved $R^2$ values close to 1.000. Furthermore, the RMSE values were 0.0005/0.0007 for the training dataset, 0.0007/0.0005 for the validation dataset, and 0.0004/0.0005 for the testing dataset, confirming the high accuracy of its pre-

dictions. Statistical process control chart based on residual analysis, enabling effective differentiation between normal and abnormal states. For normal condition monitoring, the model exhibited strong predictive capability, with residuals from the training, validation, and testing sets remaining within the control limits. For anomaly detection, the model successfully identified the occurrence of leaks, with a significant number of data points exceeding the control limits. By combining the interpretability of physical models with the predictive power of machine learning, this study provides an innovative solution for industrial pipeline safety monitoring, offering a valuable reference for future pipeline system surveillance and diagnosis.

# Rule-Based Autocorrection of Piping and Instrumentation Diagrams (P&IDs) on Graphs

**Lukas Schulze Balhorn[a], Niels Seijsener[b], Kevin Dao[b], Minji Kim[a], Dominik P. Goldstein[a], Ge H. M. Driessen[b], and Artur M. Schweidtmann[a]***

## ABSTRACT

A piping and instrumentation diagram (P&ID) is a central reference document in chemical process engineering. Currently, chemical engineers manually review P&IDs through visual inspection to find and rectify errors. However, engineering projects can involve hundreds to thousands of P&ID pages, creating a significant revision workload. This study proposes a rule-based method to support engineers with error detection and correction in P&IDs. The method is based on a graph representation of P&IDs, enabling automated error detection and correction, i.e., autocorrection, through rule graphs. We use our pyDEXPI Python package to generate P&ID graphs from DEXPI-standard P&IDs. In this study, we developed 33 rules based on chemical engineering knowledge and heuristics, with five selected rules demonstrated as examples. A case study on an illustrative P&ID validates the reliability and effectiveness of the rule-based autocorrection method in revising P&IDs.

**Keywords**: Autocorrection, P&ID graphs, pyDEXPI

## INTRODUCTION

Undetected errors or suboptimal designs in Piping and Instrumentation Diagrams (P&IDs) can cause financial costs, hazardous situations, unnecessary emissions, and inefficient operation. These errors are currently captured in extensive manual revision processes leading to safe, operable, and maintainable facilities. However, engineering projects often involve hundreds to thousands of P&ID pages, leading to a significant revision workload. With the advent of computer vision-based document digitization [1] and data exchange standards such as the Data Exchange in the Process Industry (DEXPI) [2], opportunities arise for algorithmic support of P&ID development and revision [3].

Several studies have been conducted on error detection and correction in engineering diagrams. These studies can be grouped into rule-based approaches [4] and machine learning (ML)-based approaches [5-8]. Specifically, ML-based approaches function as follows: Dzhusupova et al. [5] detect erroneous designs using computer vision in P&IDs. In contrast, Oeing et al. [6] and Rahmen et al. [7] use node classification on P&ID graphs to detect deviations from common P&ID design. In addition, our previous work proposed a generative artificial intelligence approach that generates corrected P&IDs using a string presentation [8]. The ML-based approaches offer the advantage of automatically learning to detect errors from existing P&ID data. However, ML-based approaches require large-scale data for model training, currently lack explainability due to their black-box nature, and pose a risk of hallucination. Furthermore, ML-based methods do not provide a deterministic guarantee that known errors encountered during training will be detected during inference, posing a risk for safety-critical designs. Conversely, rule-based approaches, grounded in chemical engineering knowledge and heuristics, are beneficial for developing highly accurate error detection and correction methods without the need for large-scale P&ID data. Rule-based approaches detect errors using hard-coded rules. These rules can be formulated based on general engineering logic or safety considerations. Moreover, the derived rules can be accompanied by an explanation. Whereas ML-based approaches still lack

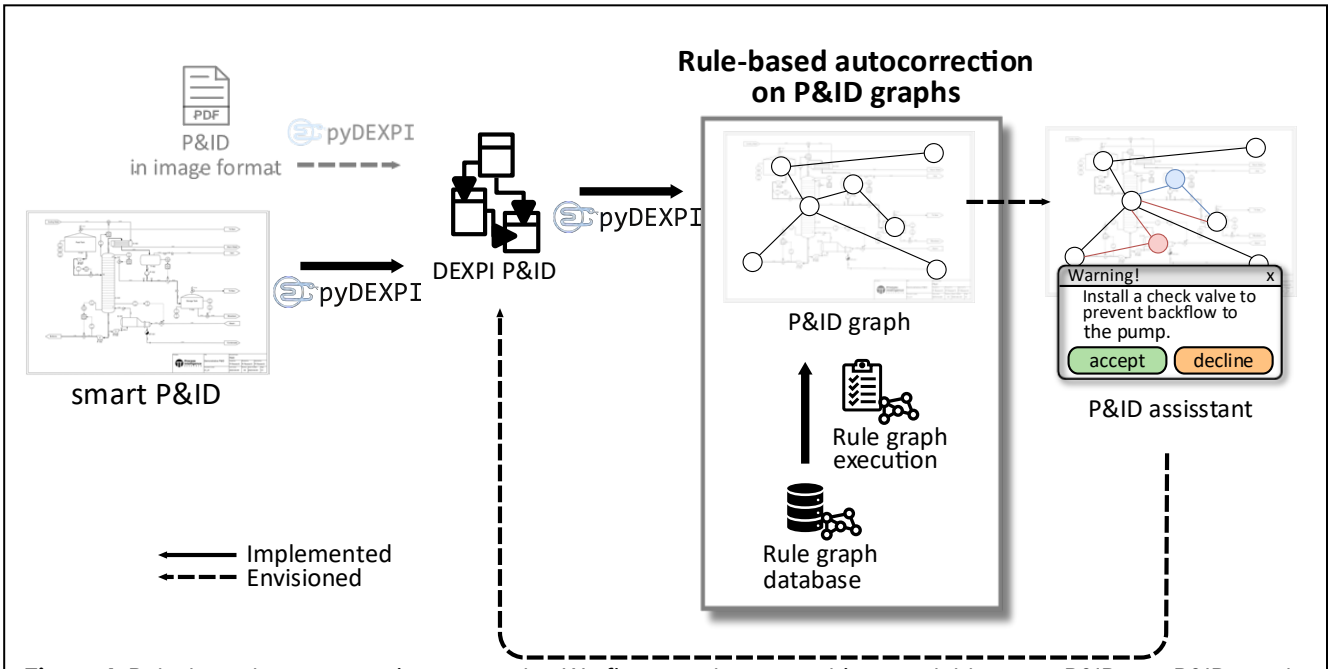

**Figure 1:** Rule-based autocorrection on graphs. We first translate a machine-readable smart P&ID to a P&ID graph. Then, we apply the engineering rules in the form of graph manipulations to the P&ID graph. In future applications, the autocorrection method may be implemented in a P&ID assistant with the human-in-the-loop. Changes can then automatically be updated in the DEXPI P&ID. We envision applying the rule-based autocorrection also on P&IDs in image format via digitization. Steps indicated by solid lines are implemented, steps indicated by dashed lines are envisioned for future projects.

large-scale P&ID data in practice, we expect that a rule-based approach is a good first step for a supporting tool for P&ID revision because it builds trust with the engineer due to the high accuracy and explainability.

Previous rule-based approaches represent P&IDs as graphs and aim to detect errors by identifying abnormal graph patterns [4]. These approaches use graph-based rules to modify P&ID graphs: Once an abnormal graph pattern is identified, specific modifications are applied to correct the P&ID graph. While the previous work is an important contribution toward supporting engineers in P&ID designs, we identify three limitations: (i) Previous methods are not linked to data exchange standards, making their integration into industrial P&ID development difficult, (ii) the literature focuses on digitization errors but neglects engineering errors, and (iii) literature does not account for missing components in P&IDs.

Building on the promising work by [4], we propose a rule-based autocorrection method for DEXPI P&IDs to address the aforementioned limitations. The methodology can be summarized as follows: First, we use our pyDEXPI package [9] to convert a smart P&ID into a graph. Second, rules are formulated based on chemical engineering knowledge and heuristics. These rules are implemented as graphs that describe manipulations to the P&ID graph. Lastly, applying these rule graphs to the P&ID graph completes the autocorrection process.

## RULE-BASED AUTOCORRECTION METHODOLOGY

Figure 1 summarizes our proposed methodology for P&ID autocorrection. First, a smart P&ID is converted into a DEXPI P&ID according to the DEXPI standard. Alternatively, paper-based P&IDs can be digitized. Then, a P&ID graph is generated from the DEXPI P&ID using our pyDEXPI package [9]. We utilize the P&ID graph to facilitate the application of rule graphs which implement various engineering rules for error detection and correction. Next, the rule-based autocorrection yields a corrected P&ID graph. Ultimately, the corrected P&ID graph is presented in a P&ID assistant and transformed back into a DEXPI P&ID. This manuscript focuses on the part from a DEXPI P&ID to a corrected P&ID graph.

### DEXPI P&ID to P&ID graph

The transformation from the DEXPI P&ID to the P&ID graph is achieved through our pyDEXPI package [9]. The pyDEXPI package is a Python implementation of the DEXPI data model, containing data classes that have attribute relationships to encode composition or reference. Furthermore, the pyDEXPI package includes functions for importing and exporting DEXPI data, such as converting a DEXPI P&ID to a P&ID graph. In the P&ID graph, nodes represent P&ID components and directed edges

**Table 1:** List of rules implemented for the case study.

| Rule ID | Rule description | Rule explanation | Implementing the rule is ... |
|---|---|---|---|
| 3 | Do not install a globe valve as a control valve if the pipe diameter is greater or equal to 100 DN (or 4”). | Large globe valves have higher costs compared to other valve types. | suggested. |
| 9 | Install a level instrument on a vessel. | Monitoring the vessel level regularly can prevent accidents caused by overflow. | mandatory. |
| 10 | Install a strainer in the suction line of a pump. | The strainer separates solid matter, which can potentially damage the pump, from the fluid. | suggested. |
| 19 | Install a check valve on a pump's discharge line to avoid backflow. | Backflow is dangerous to the pump because the pump is designed for one-way flow. | suggested. |
| 21 | Install block valves and a drain in the suction and discharge of a pump. | Isolate the pump during maintenance. | mandatory. |

represent pipes and signals. The direction of the edge is determined by the material flow or signal direction. To keep the P&ID graph concise, we only include key P&ID components. Specifically, we include the following components: (i) plant items with a tag, (ii) piping components, such as valves, (iii) actuators, and (iv) process instrumentation. P&ID components not considered mainly store connectivity information which we represent as directed edges.

## Applying rule graphs to a P&ID graph

The rule-based autocorrection method searches for erroneous patterns in P&IDs. If an erroneous pattern is detected, a set of corrections is performed on the pattern. Erroneous patterns and the corresponding set of corrections are collected together in so-called rule graphs. At execution, all rules graphs from a rule graph database are applied sequentially as described in Figure 2.

First, we search for the erroneous graph pattern defined by a rule in the P&ID graph via subgraph isomorphism. The NetworkX package provides a subgraph isomorphism algorithm based on the VF2 algorithm [10]. VF2 is a recursive algorithm that starts by randomly mapping a node from a pattern to a node in the P&ID graph with the same DEXPI class. At each step, the algorithm then tries to include pairs of neighboring nodes in the mapping that also have the same DEXPI class while avoiding previously explored mappings. If the complete pattern is mapped to the P&ID graph, a match is found. There can be multiple matches within a P&ID graph. We extend the work of [4] by incorporating conditions based on conditional statements during the subgraph isomorphism. The conditions allow us to go beyond exact attribute matches and incorporate inequality constraints, ranges, and sets. For example, Rule 3 in Table 1 defines one erroneous P&ID pattern for all line sizes greater or equal to 100 DN (or 4”), instead of defining a separate pattern for every possible line size. Isomorphism conditions are stored as node or edge attributes in the rule graphs.

Second, we correct the P&ID graph according to the rule graph for every match that is found. The graph manipulations include nodes and edges that perform either insertion or deletion. Insertion adds nodes or edges to the P&ID graph, while deletion removes nodes or edges from the P&ID graph. When visualizing a rule graph, insertion is denoted with red and deletion with blue.

A special case involves rules that describe missing components. Here, we search for both the erroneous and the corrected P&ID pattern (i.e., erroneous P&ID pattern with manipulations applied) in the P&ID graph. If a match of an erroneous pattern is included within a match with the corresponding corrected pattern, applying the rule is not necessary because the missing component already exists. However, if a match is found that includes only the erroneous but not the corrected pattern, a component is missing and the graph manipulations should be applied.

Figure 2 (step ④) illustrates an exemplary rule graph to insert a check valve in the pump's discharge line (Rule 19 in Table 1). The rule graph breaks the connection between the pump and the subsequent component “x”. Furthermore, a check valve is added to the graph. Two new connections complete the rule graph: A pipe from the

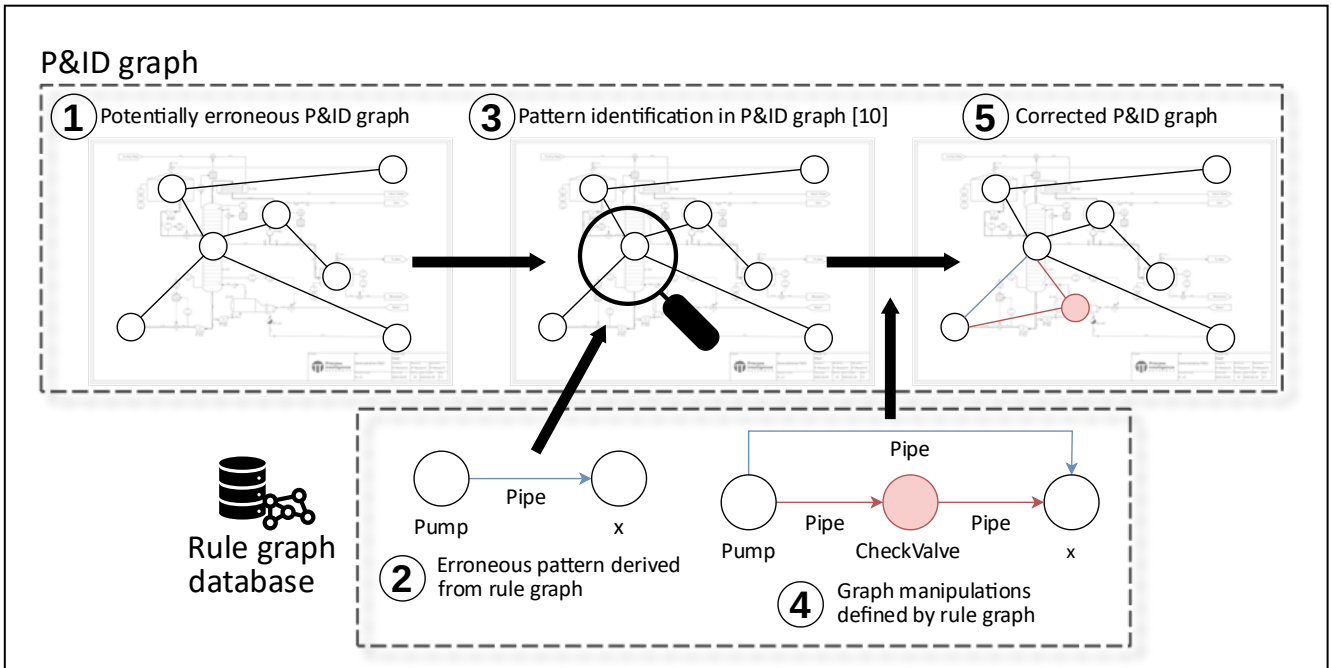

**Figure 2:** Rule graph execution for Rule 19 "Install a check valve in the pump's discharge line". According to P&ID markups, we denote added edges or nodes in red and deletions in blue. Note that for missing components, we search for both the erroneous and the corrected P&ID pattern (i.e., erroneous P&ID pattern with manipulations applied) in the P&ID graph. This is ommitted in the figure for brevity.

pump to the check valve and a pipe from the check valve to the subsequent component. Here, the "x" node can be mapped to any node in the P&ID graph. In addition, a pattern node's DEXPI class can always be mapped to its respective subclasses, i.e., the pump in the rule graph can be mapped to a reciprocating pump in the P&ID graph.

Besides the graph pattern and manipulations, each rule includes further graph attributes: (i) An ID to identify the rule, (ii) the P&ID milestone at which the rule is relevant, for instance, issue for review, issue for design, or issue for construction [11], (iii) a description on how the P&ID should be revised, (iv) an explanation why the P&ID should be revised, (v) the level of recommendation, for instance, the rule is a mandatory revision, a suggestion, or only a consideration, (vi) a boolean stating whether the rule describes a missing component, and (vii) the source of the rule.

In total, we define 33 rules. We define the rules based on engineering heuristics, literature [12], and existing workflows at Flour©. Here, we describe five exemplary rules in Table 1. The output of the methodology developed in this manuscript is a corrected P&ID graph and the meta data of the applied rules as given in Table 1.

## RESULTS AND DISCUSSION

To evaluate the performance of the autocorrection method, we applied the five rules listed in Table 1 in an illustrative case study by the DEXPI initiative (Figure 3). The P&ID includes two pumps, two heat exchangers, and a central vessel, with associated instrumentation for pressure and temperature regulation. The process begins with fluid entering through a pump, passing through a heat exchanger for preconditioning, and then entering a vessel for storage or processing. Post-vessel, the fluid is discharged by another pump and is partly recycled to the vessel. The recycle undergoes additional thermal conditioning for temperature control of the vessel. The resulting P&ID graph consists of 33 nodes and 36 edges. Please note that the case study is not representative for the complexity of a standard P&ID in the process industry.

### Detection and Correction Accuracy

The autocorrection method demonstrates high accuracy in identifying and correcting errors. The method successfully identified all erroneous substructures from the rule graph database, achieving an accuracy of 100%. These substructures were corrected using the corresponding rule graphs. For instance, the vessel is lacking pressure and level control. Rule 9 added a level instrument to the vessel for level control. Additionally, the two pumps are not protected and cannot be isolated for maintenance. Rule 21 facilitates maintenance by isolating the pumps with block valves and drains. To protect the pumps, Rule 10 recommended installing a strainer in the suction line, and Rule 19 suggested placing a check valve in the discharge line. For every applied rule, the method provided an explanation for why the revision was necessary. However, the rule graph database did not address

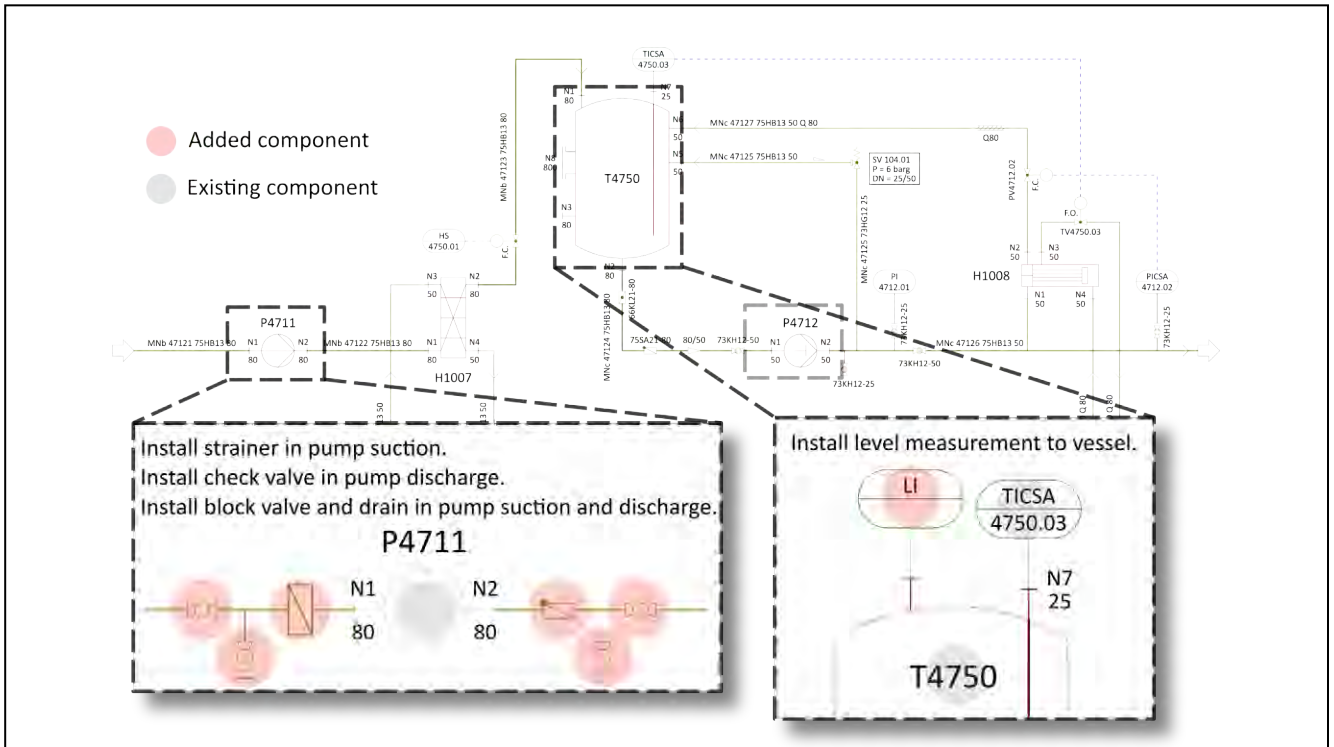

**Figure 3:** Case study for the rule-based autocorrection using the DEXPI v1.3 reference P&ID C01 (https://gitlab.com/dexpi/TrainingTestCases). Note that the P&ID does not reassemble an actual process but acts as a demonstration of the DEXPI data model. The autocorrection method updates pump P4711, pump P4712, and vessel T4750. The same corrections shown for pump P4711 are also applied to pump P4712.

all potential errors; for example, the vessel and heat exchangers were not isolated with block valves and drains, indicating the need for additional rules.

## Computational Performance

The autocorrection method demonstrated computational efficiency. It executed in 0.016 seconds on a laptop equipped with an i7-1185G7 processor (1.8-3.0 GHz) and 16 GB RAM. On average, evaluating a single rule took only 3.2 milliseconds. This performance is significantly faster than manual detection and correction of errors, which can take several minutes to hours, particularly in cluttered P&IDs.

## Discussion

Our findings indicate that the rule-based autocorrection method provides reliable and efficient support for engineers. Its ability to identify and correct errors with deterministic accuracy makes it suitable for safety-critical applications. The rapid execution time also highlights its potential for real-time applications, saving engineers significant time compared to manual reviews. Moreover, the method's integration with smart P&IDs enables it to utilize detailed component attributes, reducing the need for external documentation.

This study emphasizes the importance of applying rules in the correct sequence. For example, applying Rule 21 before Rules 10 and 19 ensures proper placement of strainers and check valves near pumps. Selecting the correct sequence minimizes the risk of overlapping or conflicting corrections.

However, the method's scalability is constrained by the need for manual rule derivation and maintenance. Each rule requires expertise from trained engineers, and as the rule database expands, tracking and managing interactions between rules becomes increasingly complex. In contrast, machine learning-based approaches excel at scaling, offering a promising avenue for future research [3]. Exploring hybrid methods that combine rule-based and ML-based approaches could leverage the strengths of both methodologies [13].

In conclusion, while the rule-based autocorrection method is not a standalone tool, it serves as a valuable support system for engineers, enhancing the accuracy and efficiency of P&ID reviews.

## CONCLUSION

This study presents rule-based autocorrection in DEXPI P&IDs. First, a DEXPI-formatted P&ID is converted into a P&ID graph using pyDEXPI. Subsequently, rule graphs based on chemical engineering knowledge and heuristics are applied to the P&ID graph to detect and rectify errors. The final outcome is a corrected P&ID

graph. We implement five selected rules and test them in a case study. The results show that the autocorrection method has an accuracy of 100% due to the rule-based approach. Therefore, the method is reliable and applicable in safety-critical applications. Besides this, the method detects and corrects errors at a significantly faster rate than humans. This research tackles previous limitations by (i) being compatible with the data exchange standard DEXPI through our pyDEXPI module, (ii) proposing rule graphs embedding engineering experience, and (iii) capturing missing components. However, the rule-based method also comes with limitations. Engineers need to extend and maintain the list of rules. In addition, rules may conflict. Therefore, the order in which we apply the rules and their context is important. Future research should investigate hybrid methods combining rule-based and ML-based for autocorrection. In addition, completing the autocorrection pipeline from Figure 1 by implementing the conversion of P&ID graphs to the DEXPI data model would enable the full integration into existing engineering workflows.

## ABSTRACT

Phase transition enthalpies, such as those for fusion, vaporization, and sublimation, are vital for understanding thermodynamic properties and aiding early-stage process design. However, measuring these properties is often time-consuming and costly, leading to increased interest in computational methods for fast and accurate predictions. Graph neural networks (GNNs), known for their ability to learn complex molecular representations, have emerged as state-of-the-art tools for predicting various thermophysical properties. Despite their success, GNNs do not inherently obey thermodynamic laws. In this study, we present a multitask GNN designed to predict vaporization, fusion, and sublimation enthalpies of organic compounds. We modified the loss function of the GNN, accounting for the thermodynamic cycle of the three phase transition enthalpies. To train the model, we digitized the extensive Chickos and Acree compendium, which encompasses 32,023 experimental measurements. Two approaches were explored: soft constraints, which guide the model toward thermodynamic consistency, and hard constraints, which enforce fully consistent predictions. The GNN achieved root mean squared errors (RMSEs) of 19.9 kJ/mol for sublimation, 11.0 kJ/mol for fusion, and 16.5 kJ/mol for vaporization enthalpies on the test set. Soft constraints were found to provide a good balance between accuracy and thermodynamic consistency, whereas hard constraints prioritized fidelity at the expense of predictive performance. When compared to the conventional Joback group contribution method the GNN demonstrated an improved accuracy and applicability range. This work underscores the potential of thermodynamics-informed GNNs for predicting thermodynamic properties accurately while maintaining consistency, paving the way for more reliable and efficient computational approaches.

**Keywords**: Graph neural networks, Property prediction, Physics informed, Phase transition enthalpies

## INTRODUCTION

Phase transition enthalpies, such as sublimation, melting, and vaporization enthalpies, have numerous applications for designing process unit operations. For example, they are a crucial part of the energy balances of separation units such as distillation towers or crystallization units. Additionally, phase transition enthalpies can be applied within thermodynamic cycles to predict different thermochemical properties[1],[2]. Measuring these properties is time intensive and costly, therefore it is important to develop predictive methods for fast screening of potential materials.

Different approaches have been used to predict these properties. First principal methods are accurate, in particular for vaporization enthalpies[3], but they are computationally expensive and fall short in crystal structure prediction. On the other hand, empirical methods, such as quantitative structure property relationships (QSPR) [4] and the linear solvation energy relationships (LSER) [5], are commonly used. They can be accurate but have a limited applicability range. Especially for novel components, these empirical methods often lack accuracy. Recent improvements in data availability and computational resources drive the use of machine learning to develop robust and fast models to predict phase transition enthalpies. Graph neural networks have become the state-of-the-art method for molecular property prediction because of their flexibility in molecule representation and their ability to learn deep representations [6]. They have consistently surpassed fixed molecular representation methods [7] and are therefore utilized for analyzing

the properties explored in this study.

One limitation of machine learning algorithms is that they do not inherently imply thermodynamic consistency. Recent studies have investigated the inclusion of these thermodynamic laws in the loss function of deep learning property prediction methods [8],[9] to improve the confidence in black-box models. For phase transition enthalpies, we consider thermodynamic consistency in our models by implying the following:

$$\Delta H_{sub,T} = \Delta H_{fus,T} + \Delta H_{vap,T} \quad (1)$$

Two approaches are reported for the inclusion of this law in the loss function. In the first approach, a regularization term is added to the loss function as a soft constraint, where inconsistent predictions are still allowed but penalized. In the second approach, the loss function is reformulated to only allow consistent predictions or also called hard constraint.

To train our models, we digitized the compendium of Chickos and Acree[10],[11],[12], consisting of 32,023 phase transition enthalpy values measured over 135 years. The performance of the machine learning methods is compared to the Joback group contribution method as implemented in the thermo python package[4]. Additionally, the performance is evaluated by comparing single-task and multi-task models, as well as soft and hard constraint loss functions.

# METHODS

## Phase Transition Enthalpy Database

### Database digitization

The data collected from the works of Chickos and Acree's enthalpy compendium[10],[11],[12] is detailed here. In the compendium for each data point the following metrics were reported: the molecular formula, the CAS-number, the measurement temperature, the enthalpy value, the measurement technique, and the original source. From the CAS-numbers, the InChI and SMILES identifiers were retrieved from the PubChem database[13] and Cactus service[14]. Molecules that include metal atoms were excluded, so the dataset is limited to the following atoms list: C, H, B, Br, Cl, F, I, N, O, P, S, and Si.

Additionally, the enthalpies were converted to the standard state (298 K, 1 atm) using the approach proposed by Chickos et al.[15]. This correction was required, since Equation 1 is only applicable when the three phase enthalpies are at the same temperature. For this correction, heat capacity values were required for the solid, liquid and gas phase. The heat capacities of the solid and liquid phase were computed by the group contribution method from Chickos et al.[15], and for the gas phase, temperature dependent heat capacities were calculated using the RMG software[16]. A list of the heat capacities is provided as part of our Research Data Repository.

### Database characteristics

Analyzing the dataset, Figures 1 and 2 show the distributions of the enthalpy values and molecular weights respectively for the three phase transition enthalpies. The reported fusion enthalpy values were smaller in magnitude and distribution width, which is expected as, compared to the vaporization and sublimation enthalpy, they do not depend on the (higher) enthalpy difference with the gas phase.

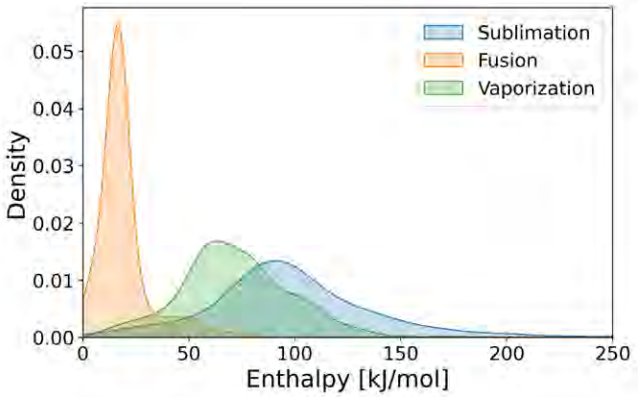

**Figure 1.** Value distribution of the three phase transition enthalpies at 298 K.

The molecular weight distributions for all three enthalpies are showing a widespread, which is critical for training a widely applicable machine learning model. The fusion enthalpy distribution is slightly more shifted to the right, which is inherent for these properties considering organic compounds. For many organic molecules with higher molecular weights, it is not possible to measure vaporization or sublimation enthalpies, since the decomposition temperature will be lower than the boiling point.

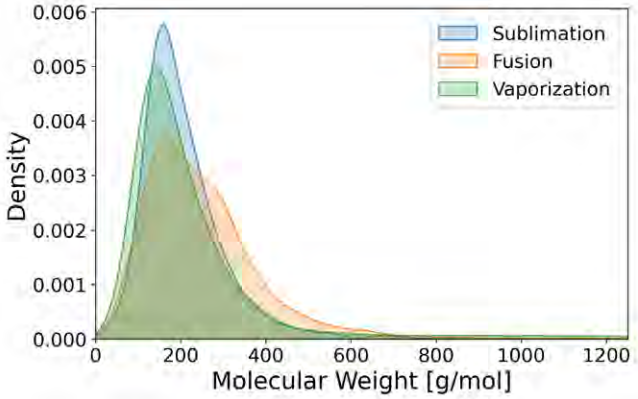

**Figure 2.** Molecular weight distribution of the three phase transition enthalpies.

For data points where all three enthalpies were available, the sum of the fusion and vaporization

enthalpies was compared to the sublimation enthalpy. In Figure 3, a parity plot for this thermodynamic consistency check of the database is shown. It was found that, although the properties are highly correlated, large deviations from the thermodynamic cycle were apparent. It was observed that the experimental sublimation enthalpy is almost consitently higher as compared to the one calculated from the vaporization and fusion enthalpy, with some deviations higher than 50 kJ/mol.

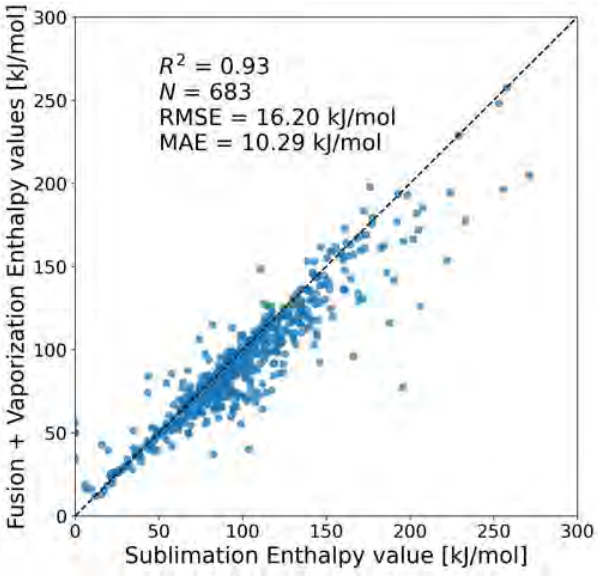

Figure 3. Thermodynamics consistency parity plot for the overlapping values in the phase transition enthalpies at 298 K of the database.

Crystal structures were not reported in the compendium, and different polymorphs could partially account for the observed deviations. Additionally, temperature corrections introduce uncertainty; however, they have been shown to produce acceptable errors and are essential for assessing thermodynamic consistency [11]. The temperature correction for the enthalpy of vaporization introduces an error of 0.016 kJ/(mol K) [11], leading to an uncertainty of 1.6 kJ/mol for a molecule deviating by 100 K from the reference temperature of 298 K. For enthalpies of sublimation and vaporization, an uncertainty of one-third of the total temperature correction can be assumed [11]. As an example, for carbazole, this results in an enthalpy of sublimation of 102.9 ± 1.2 kJ/mol and an enthalpy of fusion of 15.9 ± 3.5 kJ/mol.

The average estimated uncertainties for the temperature correction over the dataset were 0.57, 2.38, and 1.32 kJ/mol for sublimation, fusion, and vaporization enthalpies, respectively. Since sublimation and vaporization enthalpies are commonly reported in the literature at values corrected to 298 K, these uncertainties were averaged only for values that were not reported at 298 K.

Figure 4 shows the distribution of standard deviations for duplicated data points in the dataset before the temperature correction. Duplicates were identified for 1,312 sublimation, 1,143 fusion, and 2,663 vaporization compounds. These standard deviations provide an estimate of experimental uncertainty, specifically aleatoric uncertainty. The average standard deviations are 5.9, 3.3, and 5.4 kJ/mol for sublimation, fusion, and vaporization enthalpies, respectively. This represents the performance limit for a model trained on this data. Notably, the uncertainties introduced by temperature corrections are relatively small compared to experimental uncertainty.

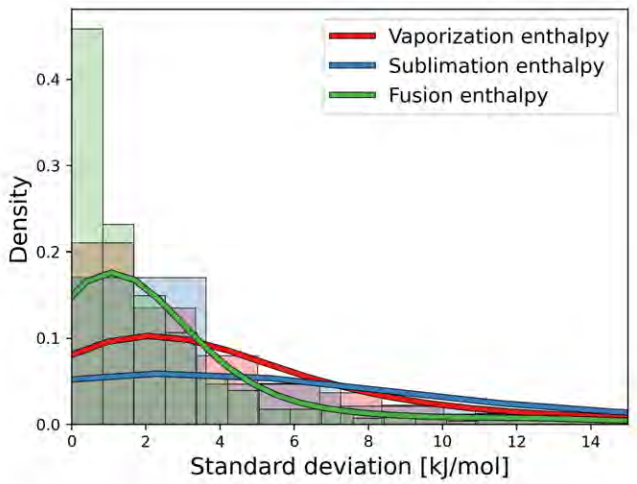

**Figure 4.** A distribution of the standard deviations computed on the duplicated data points in the dataset before the data was adjusted to 298 K.

## Model architecture and training

The graph neural networks (GNNs) were trained using the SolProp repository [2], which focuses on solvation properties and implements directed message passing neural networks (D-MPNN) based on the Chemprop framework [6]. For a detailed explanation, readers are referred to dedicated studies [6],[17]. Figure 5 presents an example model architecture. The model takes a molecular identifier, such as SMILES or InChI, as input and converts it into a featurized molecular graph. This graph representation is then processed by the GNN, which predicts the enthalpy values for phase transitions.

Four different model architectures were trained: single-task, multitask, soft-constraint, and hard-constraint models. The single-task models were trained by initializing three separate neural networks, each focusing on one of the three enthalpy datasets (fusion, vaporization, and sublimation). In contrast, the multitask models used a single GNN with a multi-head output for the multi-layer perceptron (MLP), meaning that a single molecular graph was provided as input, and the network simultaneously predicted all three enthalpies.

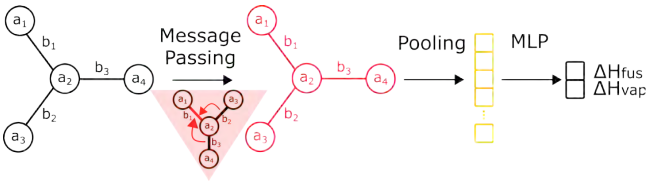

**Figure 5.** Hard-constraint thermodynamics-informed architecture.

The soft-constraint models used a multi-head output for the MLP, but the loss function was modified to include a penalty term that encouraged thermodynamic consistency. This penalty term was scaled by a weight parameter, λ, to balance accuracy in minimizing mean squared error (MSE) while ensuring the enthalpies remained consistent with thermodynamic relationships. After evaluating three values (0.1, 0.01, and 0.001), a λ of 0.01 was found to significantly influence the penalty term without negatively affecting model accuracy. The loss function for soft-constraint models was defined as:

$$\text{Loss} = \sum_{i=1}^{3}\left(y_{i,\text{exp}} - \hat{y}_{i,\text{pred}}\right)^2 + \lambda\left(\Delta\hat{H}_{\text{sub,pred}} - \left(\Delta\hat{H}_{\text{fus,pred}} + \Delta\hat{H}_{\text{vap}}\right)\right)^2 \quad (2)$$

For the hard-constraint models, thermodynamic consistency was strictly enforced within the loss function. Instead of predicting all three enthalpies separately, a single neural network was trained with two outputs: one for fusion enthalpy and one for vaporization enthalpy. The sublimation enthalpy was not directly predicted but was instead computed within the loss function as the sum of the fusion and vaporization enthalpies. The loss function ensured consistency by penalizing deviations from this relationship:

$$\text{Loss} = \left(y_{\text{fus,exp}} - \hat{y}_{\text{fus,pred}}\right)^2 + \left(y_{\text{vap,exp}} - \hat{y}_{\text{vap,pred}}\right)^2 + \left(y_{\text{sub,exp}} - \hat{y}_{\text{fus,pred}} - \hat{y}_{\text{vap,pred}}\right)^2 \quad (3)$$

The dataset was randomly split into a training and validation set (90%) and a test set (10%). Within the training set, a ten-fold cross-validation ensemble was trained to improve model robustness. The standard deviations reported in the results stem from variations between the predictions of the ensemble models. The featurization and hyperparameters remained fixed across all models and were based on prior research in thermodynamic property prediction [17].

### Joback method implementation

The Joback method[4] is a group contribution method that was developed for the prediction of a range of properties among others the vaporization and fusion enthalpy. Here, the implementation from the thermo v0.4.0 python package was used[18]. Predictions were made on the same test set as for the graph neural network. However, the fragmentation algorithm was not able to identify all atoms in the molecules. For the molecules where this was not possible, the predictions were removed from the results, accounting for 16.7% of the compounds in the test set.

Additionally, the Joback method predicts the phase transition enthalpies at the transition temperature, contrary to our method that predicts at the enthalpies at 298 K. Therefore, the fusion and vaporization enthalpies determined with the Joback method, were converted in the same way as the experimental dataset using the approach proposed by Chickos et al.[15]. Since the Joback method was not parametrized for the sublimation enthalpy, this was calculated by the sum of the converted vaporization and fusion enthalpies.

## RESULTS AND DISCUSSION

### Model performance

The model performance is compared for the four different model architectures in Table 1-3 for sublimation, fusion, and vaporization enthalpies respectively. In general, the fusion and vaporization enthalpy were predicted more accurately as compared to the sublimation enthalpy. The best models report an MAE of 13 kJ/mol, 6 kJ/mol, and 8 kJ/mol for the sublimation, fusion, and vaporization enthalpies in the test set respectively.

A similar performance was obtained between the single- and multitask models. A slightly higher RMSE and MAE can be observed for the predictions of the single task models, in particular for sublimation enthalpy. However, these differences are well within the standard deviations between the model ensembles (σ in Table 1-3) which is a measure for the variance contribution to the epistemic uncertainty.

Applying constraints to the multitask model did not lead to a significant improvement in accuracy. Introducing the soft constraint resulted in RMSE and MAE values for all three phase transition enthalpies that remained similar to those of the multitask model. However, when the hard constraint was applied, prediction accuracy declines. Specifically, the RMSE and MAE for the sublimation enthalpy—directly influenced by the hard constraint—increase by more than 10 kJ/mol. This suggests that enforcing thermodynamic consistency through a hard constraint reduces the accuracy of phase transition enthalpy predictions. Moreover, further research is needed to explore the most effective methods for incorporating constraints into neural network training.

Due to the correlation between the three phase transition enthalpies, one would expect a multitask modeling architecture to offer more benefits compared to a single-task model. Additionally, incorporating thermodynamic constraints into the loss function should ideally lead to more accurate predictions. However, as previously discussed, no significant improvements in model accuracy were observed. When comparing model

performance to the average standard deviation from the repeated experiments, the MAE for the fusion and sublimation enthalpies was roughly twice the standard deviation found in the Database Characteristics section. In contrast, the MAE for the vaporization enthalpy was only about 2 kJ/mol from the standard deviation in the dataset, suggesting that the model is close to the aleatoric limit.

A potential explanation for the lower performance of the sublimation and fusion models could be the absence of crystal structure information. The repeated data points in the compendium often came from the same sources or authors, meaning the compounds—and likely their crystal structures—were quite similar. This may have resulted in a low estimate of aleatoric uncertainty. However, further investigation is needed to reach a definitive conclusion.

It is also worth noting that the MAE for the thermodynamic consistency of the experimental data (Figure 3) is 10.3 kJ/mol. While this is not a direct measure of experimental uncertainty, it could offer an indication of its magnitude. Importantly, the MAE for the phase transition enthalpy predictions is lower than 10.3 kJ/mol, except for the sublimation enthalpy.

Lin et al. achieved a RMSE of 4.8 kJ/mol for vaporization enthalpies using first-principles calculations [19], which is notably lower than the standard deviation observed in our data. While our model demonstrates lower accuracy, direct comparison is challenging due to differences in methodologies and test sets. For fusion enthalpies, Chickos et al. reported a prediction error of 6.4 kJ/mol [20], closely matching our model's accuracy. Similarly, Liu et al. used first-principles calculations to estimate sublimation enthalpies, obtaining a mean absolute error (MAE) of 13.5 kJ/mol compared to experimental values [21], which aligns with our model's performance.

**Table 1:** An overview of the model architectures performance for the sublimation enthalpy on the test set.

| Model | RMSE (kJ/mol) | MAE (kJ/mol) | σ (kJ/mol) |
|---|---|---|---|
| Single task | 20.2 | 13.9 | 5.1 |
| Multitask | 19.9 | 13.1 | 3.7 |
| Soft constraint | 19.9 | 13.1 | 1.4 |
| Hard constraint | 30.1 | 24.1 | 2.8 |

**Table 2:** An overview of the model architectures performance for the fusion enthalpy on the test set.

| Model | RMSE (kJ/mol) | MAE (kJ/mol) | σ (kJ/mol) |
|---|---|---|---|
| Single task | 11.0 | 6.3 | 2.1 |
| Multitask | 11.0 | 6.1 | 1.5 |
| Soft constraint | 11.0 | 6.3 | 3.5 |
| Hard constraint | 11.6 | 6.9 | 1.4 |

**Table 3:** An overview of the model architectures performance for the vaporization enthalpy on the test set.

| Model | RMSE (kJ/mol) | MAE (kJ/mol) | σ (kJ/mol) |
|---|---|---|---|
| Single task | 16.2 | 7.3 | 2.8 |
| Multitask | 16.2 | 7.5 | 3.1 |
| Soft constraint | 16.5 | 7.5 | 2.9 |
| Hard constraint | 17.5 | 8.9 | 2.0 |

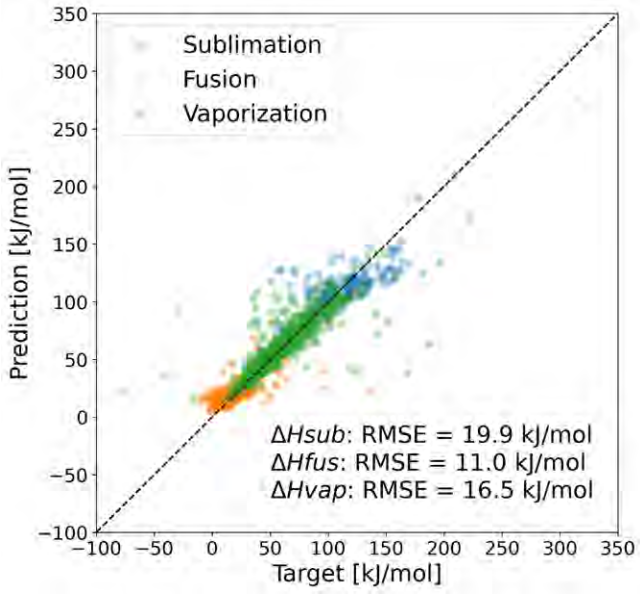

**Figure 6.** Parity plot for the enthalpy predictions made by the SolProp soft-constraint model.

The model predictions for the three phase transition enthalpies are visualized in Figure 6 for the model that includes the soft constraint in the loss function. The majority of the test data is predicted around the parity line, while large deviations are observed for some specific datapoints. The highest deviations for vaporization enthalpy are observed for negative experimental vaporization enthalpies. There were a small group of high molecular weight hydrocarbons for which the temperature correction resulted in a negative value because of the high measurement temperature compared to the reference temperature. Due to the large temperature range the temperature correction is expected to be large too. The low amount of available data for the heavy hydrocarbons and the high uncertainty on the correct can explain the lower performance of the models on this data. We did not find a correlation between the highest errors and the experimental data that showed the highest deviations from thermodynamic consistency in Figure 3, however only 5% of the test set contained experimental measurements for all three phase transition enthalpies. In addition, there was no strong correlation between the epistemic model uncertainties from the model ensemble and the

prediction error.

## Thermodynamic consistency

On top of the model performance, the thermodynamic consistency of the predictions was evaluated. In Figure 7, the predicted sublimation enthalpy is compared to the sublimation enthalpy calculated from the fusion and vaporization enthalpy through Equation 1. The thermodynamic consistency is visualized for the multitask model as well as the model with the soft constraint. The thermodynamic consistency for the model with the hard constraint is omitted from Figure 7 since, as expected from the constraint, the calculated sublimation enthalpy is exactly equal to the predicted sublimation enthalpy.

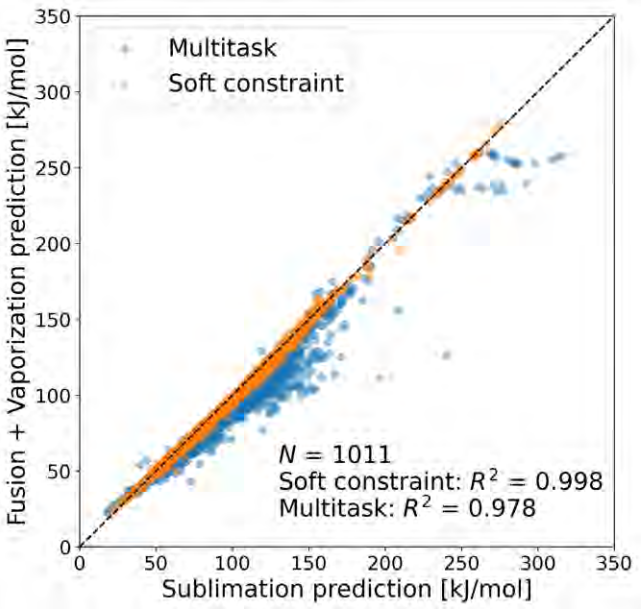

**Figure 7.** Parity plot for the thermodynamic consistency of the multitask and soft constraint model.

The multitask modeling approach already improved the thermodynamic consistency as compared to the experimental measurements with overlapping phase transition enthalpies (**Figure 3**). Yet, the calculated sublimation enthalpy was consistently lower compared to the sublimation enthalpy predicted by the multitask model. The model indeed learned the consistent underestimations that are present in the experimental database. Applying the soft constraint corrects for these discrepancies and a good agreement between calculated and predicted sublimation enthalpy was obtained ($R^2$=0.998). Interestingly, the performance of the model is hardly affected by applying this constraint while the predictions are more consistent. The soft constraint therefore provides a good balance between model performance and consistent predictions. Note that increasing the value of λ in the loss function would result in a higher thermodynamic consistency but at the cost of a lower accuracy of the model.

## Comparison to conventional methods

At last, the performance of our models was compared to the Joback method, which is the conventional way of determining phase transition enthalpies. In Figure 8, a parity plot is given comparing the experimental phase transition enthalpies with the Joback calculations as implemented in the thermo python library. Note that the sublimation enthalpy was determined through the thermodynamic cycle from Equation 1 as it is not directly available from the Joback method.

For fusion and vaporization enthalpies respectively, the RMSEs is the Joback method are 21.8 kJ/mol and 19.4 kJ/mol as compared to 11.0 kJ/mol and 16.5 kJ/mol from our soft constraint model. As such, it is demonstrated that advancements in data availability and computational algorithms can provide a significant improvement in property prediction as compared to conventional methods.

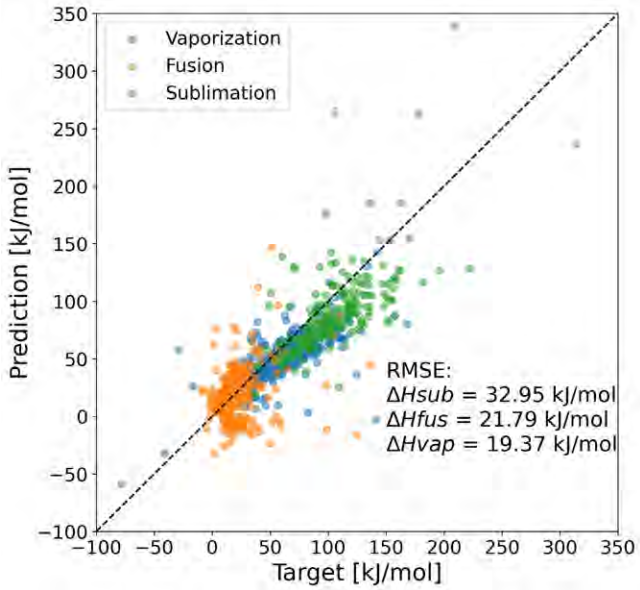

**Figure 8.** Parity plot for the enthalpy predictions made by the Joback method adjusted to standard state[4],[18].

## CONCLUSIONS

In this work, we digitized the compendium of Chickos and Acree for the phase transition enthalpies of sublimation, fusion, and vaporization. The availability of such large and diverse database stimulates the development of deep learning algorithms for the training and prediction of these enthalpies.

Graph neural networks are used to predict these phase transition enthalpies while accounting for thermodynamics. First, no significant improvement in accuracy was found whilst comparing single- and multitask modeling architectures. Additionally, adding a soft-constraint thermodynamics loss function proved to be the best

balance between accuracy and thermodynamic consistency of the predictions. The hard-constraint loss function enforced strict consistency, however at the cost of the accuracy of the model specifically for sublimation enthalpies. A comparison to the Joback method showed an improvement in accuracy and applicability range of the model.

Our graph neural network achieved state-of-the-art performance on sublimation, fusion, and vaporization enthalpies, while adding thermodynamic consistency. This method has the potential to be applied to the screening materials in the early design phase of chemical processes for all three investigated phase transition enthalpies.

## ABSTRACT

This paper presents state-of-the-art object detection and object identification algorithms for digitizing and interpreting chemical engineering diagrams, including, Block Flow Diagrams (BFDs), Process Flow Diagrams (PFDs), and Piping and Instrumentation Diagrams (P&IDs), using computer vision techniques. These diagrams are essential for visualizing plant processes and equipment but are often stored as image-based PDFs, making manual digitization/interpretation labor-intensive and error-prone. The proposed algorithm automates tasks such as detecting unit operations and identifying them using a set of rule-based and predefined approaches including edge and contour-based rules, spatial arrangement rules, and geometric rules. This method avoids data requirements and computational requirements of deep learning approaches, offering a scalable and efficient solution for preliminary extraction of complex process information.

**Keywords**: Chemical Engineering Diagrams, Object Detection, Object Identification, Computer Vision for Chemical Engineering, Optical Character Recognition (OCR), Features Extraction in Diagrams.

## 1. INTRODUCTION

This paper introduces an object detection and identification system designed to interpret chemical engineering diagrams including Block Flow Diagrams (BFDs), Process Flow Diagrams (PFDs), and Piping and Instrumentation Diagrams (P&IDs), which are essential for visualizing material flow, energy transfer, and equipment in chemical processes. The process of manually interpreting these diagrams often requires significant effort, as it is both labor-intensive and susceptible to errors. This not only increases the time and resources needed for analysis but also raises the likelihood of inaccuracies [1]. To address this, the proposed algorithm leverages computer vision techniques to detect key unit operations and identify them based on textual elements. By automating these tasks, the system aims to improve accuracy and speed, reducing reliance on expert analysis and enhancing process design workflows.

A BFD is a simplified representation of a process that outlines the main unit operations and their flow in a highly abstract way. BFDs are often used in the early stages of process design to visualize the overall structure of a process without focusing on details. PFDs, on the other hand, are more complex and detailed than BFDs. They display the relationships between specific unit operations and the flow of materials, PFDs are crucial for understanding the interconnectedness of unit operations and for simulating both individual operations and the entire process. The most detailed level is the P&ID, which reflects the "real" operational state of a process. P&IDs go beyond PFDs to include every piece of equipment, instrument, and control detail, providing a comprehensive view of how the process will operate in practice. The goal is to create a single multipurpose algorithm that can digitize key information by extracting features from these diagrams including automated detection and identification of unit operations, which is the focus of this work.

Predefined computer vision approaches use fixed rules or templates to recognize patterns or symbols in diagrams, offering fast and reliable detection in standardized industries with consistent representation of unit operations, flow paths, and equipment. However, they may struggle with low-quality diagrams, and non-standard, or irregular symbols [2], such as those often present in chemical engineering diagrams. Rule-based approaches, such as edge and contour-based rules, spatial arrangement rules, and geometric rules, leverage domain-

specific knowledge to define tailored rules for detecting and identifying objects, thereby improving detection accuracy. By combining expert insights with predefined, rule-based methods, these approaches ensure flexibility and reliability across diverse scenarios [3]. The proposed algorithms introduce an approach for automating the detection and identification of unit operations in BFDs, PFDs, and P&IDs. Unlike deep learning methods, it does not require manual labeling, making it more easily implementable and adaptable [4][5][6]. The algorithm leverages predefined rules and rule-based approaches to recognize patterns and symbols, enabling consistent performance across diverse and non-standard representations. This approach enhances accuracy and flexibility while streamlining workflows, addressing limitations of past attempts that relied heavily on manual-labor-intensive methods.

## 2. PROJECT METHODOLOGY

This section outlines the workflow for processing chemical process diagrams, from test data acquisition and preprocessing to object detection and identification. Key steps include object detection to isolate elements like unit operations, using OCR to extract labels, and combining these for unit identification.

### 2.1 Data Collection and Preprocessing

The dataset used in this study comprises 100 high-quality diagrams, including PFDs, BFDs, and P&IDs, sourced from various online resources. The primary selection criterion was image clarity and resolution, ensuring minimal noise or distortion. This diverse dataset allowed for comprehensive testing of the model's robustness across diagram types, with a Git repository link provided for access [7].

Performance evaluation focused on object detection and identification efficiency, analyzing metrics such as processing times for the 100 images. To assess the accuracy, a subset of 50 images was manually validated, covering a wide variety of diagrams and characteristics (e.g., different unit operations and types of diagrams). Object detection accuracy was determined by comparing manually counted objects (e.g., unit operations, control loop symbols) with detected ones, while object identification accuracy was validated using domain knowledge of the unit operations and compared to the textual labels assigned by the algorithms.

### 2.2 Algorithm Development

The algorithms presented in this paper aim to process and analyze images by detecting and identifying the main objects within the images. It follows a series of steps designed to identify regions of interest, remove unwanted noise, and highlight the main unit operations in the image. The process includes multiple image processing techniques such as edge detection, contour detection, and the use of OCR for text recognition to effectively detect and identify the different chemical unit operations within the different diagrams.

Object detection and identification focuses on isolating key features and objects within images and labeling them using text in the images, with OpenCV being one of the tools employed for this process [8]. Figure 1 presents pseudo code for the Object Detection algorithm which begins with Canny edge detection to enhance critical boundaries (line 6) [9], followed by contour detection to isolate individual objects based on shape, area thresholds, aspect ratio, and solidity (line 12) [10]. To clean and refine the mask of detected objects, morphological operations like opening and dilation are applied, removing noise, and closing gaps in contours (line 19) [11]. For separating connected components, a distance transform and the watershed algorithm are used, enabling precise segmentation, even in complex scenarios where objects overlap [12].

**Algorithm 1** Image Processing and Contour Detection

```
1  Input: image_dir (directory containing image files)
2  Output: processed images with highlighted contours and separated objects
3  function DETECT_EDGES(image)
4      convert the input image to grayscale
5      smooth the image using Gaussian blur to reduce noise
6      apply Canny edge detection to identify prominent edges
7      return edge-detected image
8  end function
9  function PROCESS_IMAGE(image_path)
10     load the image from the provided file path
11     edges ← DETECT_EDGES(image)          ▷ identify edges in the image
12     contours ← find contours in the edge-detected image
13     for each contour do
14         if the contour meets size and shape criteria then
15             highlight the contour on a separate mask image
16         end if
17     end for
18     use morphological operations to refine the mask and remove noise
19     apply watershed or similar techniques to distinguish overlapping objects
20     return the original image with contours and the refined mask
21 end function
22 function MAIN(image_dir)
23     for each image in image_dir do
24         processed_image, mask ← PROCESS_IMAGE(image)
25     end for
26 end function
```

**Figure 1.** Pseudocode for the object detection algorithm

Figure 2 presents the pseudocode for the Object Identification algorithm. PaddleOCR is employed to extract textual elements from diagrams, while the initial Object Detection algorithm identifies the unit operations [13]. Small objects detected next to one another are merged to account for the possibility that they are different parts of the same object (lines 4-6). The Euclidean distance between the detected text and the detected unit operations is calculated to establish associations, enabling accurate mapping of labels to unit operations. This method allows for localization and detection of components across chemical engineering diagrams.

**Algorithm 2** Object Identification

```
Input: image directory
Output: processed images with identified objects
initialize PaddleOCR model
MERGE_BOUNDING_BOXESbox1, box2
merge boxes by computing min/max coordinates
ARE_BOXES_CLOSEbox1, box2, threshold
return true if distance between centers is below threshold
MERGE_NEARBY_BOUNDING_BOXESword_boxes, threshold
merge nearby boxes based on threshold
DETECT_EDGESimage
apply Canny edge detection after grayscale conversion and blur
PROCESS_IMAGEimage_path, word_boxes
edges ← DETECT_EDGES(image)
contours ← findContours(edges)
word_boxes ← MERGE_NEARBY_BOUNDING_BOXES(word_boxes, threshold)
for each contour in contours do
  if contour area > threshold then
    process contour and match with word boxes
  end if
end for
morph mask, generate main object image
return original_image, main_object, words_cleaned_image
MAINimage_dir
for each filename in image_dir do
  if filename ends with .jpg or .png then
    result ← OCR.OCR(image_path)
    word_boxes ← extract from result
    original_image ← PROCESS_IMAGE(image_path, word_boxes)
    main_object ← PROCESS_IMAGE(image_path, word_boxes)
    words_cleaned_image ← PROCESS_IMAGE(image_path, word_boxes)
  end if
end for
```

**Figure 2.** Pseudocode for the object identification algorithm

## 3. RESULTS AND DISCUSSION

Table 1 shows the computation times for the object detection and object identification algorithms. Overall, the algorithm is fast, offering quick initial results which can speed up digitization workflows.

**Table 1.** Accuracy Distribution for Object Detection and Object Identification.

| Metric | Object Detection | Object Identification |
|---|---|---|
| Average Time per Image (s) | 0.38 | 4.86 |
| Minimum Time (s) | 0.24 | 2.23 |
| Maximum Time (s) | 0.68 | 15.15 |
| Standard Deviation of Time (s) | 0.1 | 2.33 |

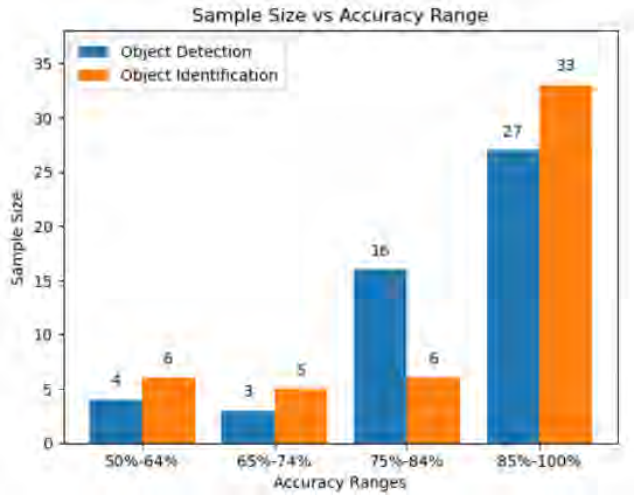

**Figure 3.** Cumulative Time Metrics for Object Detection and Object Identification

Figure 3 summarizes the performance metrics from the manual validation phase of the computer vision models, evaluating accuracy for object detection and identification across the dataset. These results demonstrate the model's effectiveness in detecting and identifying objects within the diagrams. The model achieved strong performance across different accuracy ranges, with the highest sample sizes in the 85%-100% accuracy range. The reason that object identification can have a higher score than object detection is that often multiple objects are mistakenly grouped together (lowering the detection score), however, when analyzing the text of the images multiple labels are assigned to this aggregated space identifying that those operations are all within that space. This evaluation offers insights into the model's consistency for object detection and identification tasks. Specific examples of results are shown below to highlight features of the algorithms' performance as well as situations where the algorithm could be improved.

### 3.1 Object Detection

Figure 4 displays the original and processed images from a BFD. Subfigure 4A shows the original image, while Subfigure 4B presents the results of object detection applied to the same image. The contours and masks are overlaid on the original image, illustrating how the system isolates and identifies key objects. The detected contours are visible, highlighting the effectiveness of the edge detection and contouring methods used. In this example, the accuracy of Object Detection is 100% as it captured all 9 objects within the diagram.

Another example, Figure 5, displays the original and processed images from a PFD. Subfigure 5A shows the original image, while Subfigure 5B highlights the accuracy of the object detection algorithm in handling different object shapes and sizes within the PFD. This visual representation confirms that the system can effectively

manage variations in object appearance and image noise. Some of the drawbacks of the algorithm are visible here as well. The crossing of the streams exiting the central heat exchanger form a closed loop which the algorithm mistakenly identified as belonging to the heat exchanger.

Figure 6 displays the original (A) and processed images (B) from a P&ID. This subfigure demonstrates the algorithm's capability to identify the control aspects of the P&ID and delineate components specific to P&ID diagrams. However, it lacks the ability to capture certain unit operations, such as valves, which will be addressed using template matching techniques in future work. The assigned accuracy of this diagram is 54% as it identifies 19 control icons but misses all 16 valves present in the diagram. P&IDs consistently showed the worst performance in the dataset reflecting their increased complications relative to the other diagrams. Despite some shortcoming, the algorithm shows great flexibility to quickly (<0.5s per image on average) and accurately detect process operations across a wide variety of diagrams with no additional fine tuning required to transition between document types.

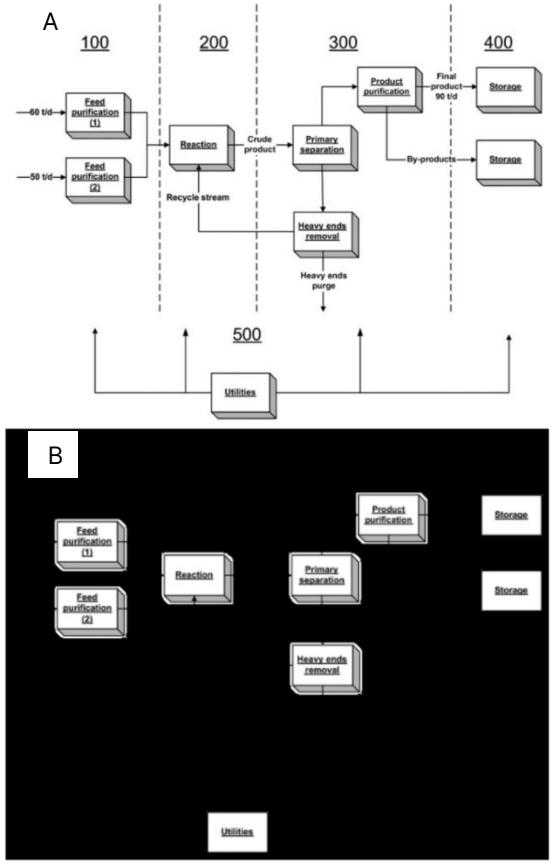

**Figure 4.** (A) Original image of a BFD. (B) Objects detection algorithm output

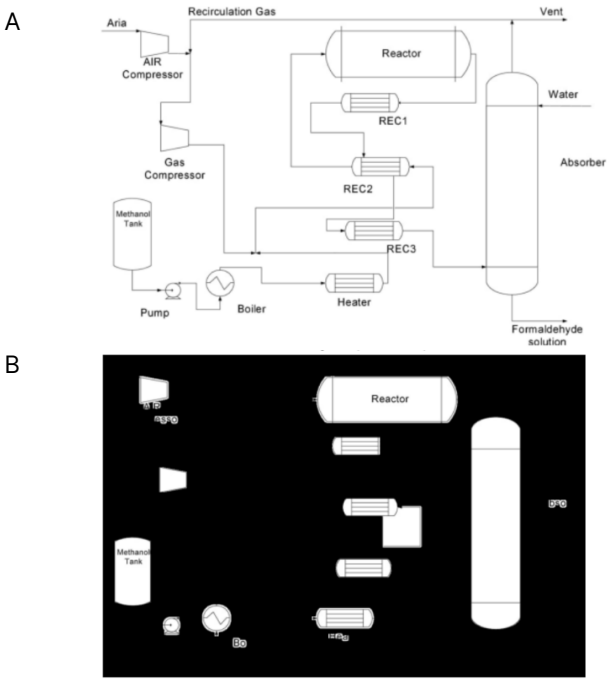
## 3.2 Object Identification

The object identification algorithm is based on spatial proximity, associating each detected object with its nearest detected word by calculating the Euclidean distance between their center points. In the visual representation (Figures 7 & 8), red dots represent detected words, green dots represent detected objects, and the blue lines are drawn between them to show their assignments. These lines visually indicate which word is linked to which object, based on how close their center points are to each other. A simple example result is shown in Figure 7. In this case, the algorithm clearly connects the text inside the boxes with the boxes themselves. An example of the identification algorithm applied to a PFD can be seen in Figure 8. In this case the object identification algorithm can connect text to label adjacent objects. Lines are drawn between the text box and each of the sub objects which are merged within a unit operation (e.g., each of the tubes in a heat exchanger) to determine which object the label is most likely to belong to. The drawback to the algorithm is that if a unit operation label is too far from the object, it is not connected to it (for example the absorber column on the right). Also, textual elements on the diagrams are often encoded with cryptic names (e.g., REC for the heat exchangers). In practice, these names are often encoded in a standard format and could be converted to more meaningful names with a dictionary.



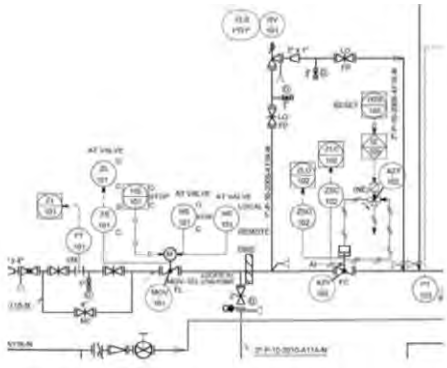


**Figure 5.** (A) Original image of a PFD. (B) Objects detection output from the PFD.

The object identification results demonstrate the algorithm's ability to accurately detect text and associate

it with objects in complex images. High-precision OCR effectively extracts text, with an internal confidence level for reliability of 100%. However, manual validation reveals that in some cases, there may be slight discrepancies between the automated results and the actual text (e.g., chemical formulae containing numbers can get mistaken for text which is “read” incorrectly). One of the major drawbacks to the algorithm is that object identification is based on textual elements in the diagrams, which are often encoded with company- or site-specific naming conventions.

Overall, the system demonstrates fast and accurate detection and text-based identification capabilities, streamlining the preliminary interpretation of chemical engineering diagrams and enhancing workflow efficiency. Compared to deep learning approaches, the proposed algorithm is less computationally intensive, enabling efficient large-scale preliminary data processing. The code processed 100 images with an average of 0.38 seconds for object detection and 4.86 seconds for object identification (on a i7-12700H laptop with 16 GB of RAM and no GPU-based calculations), demonstrating its ability to efficiently handle tasks of varying complexity within a limited timeframe, demonstrating it can help to streamline preliminary digitization workflows at minimal computational expense [14].

## 4. CONCLUSION AND FUTURE WORK

This work presents an object detection and identification system tailored for chemical engineering diagrams, leveraging a combination of rule-based approaches, text extraction, and spatial association. The system quickly and efficiently detects unit operations, establishes connections between text and unit operations to identify objects, and is easily applicable to diverse diagram types, including BFDs, PFDs, and P&IDs. By eliminating the need for manual labeling and relying on predefined rules, the approach is quite flexible streamlining the preliminary interpretation of complex chemical engineering diagrams. Automatically interpreting chemical engineering diagrams reduces the need for manual analysis, significantly saving time and effort. It can improve accuracy by minimizing human errors in identifying process components.

This automation speeds up decision-making,

allowing engineers to focus on optimization rather than diagram interpretation. While the algorithm shows promise, results highlight areas for improvement. Without knowledge of unit operations, it sometimes misidentifies accessory shapes as objects (e.g., recycle loops forming closed shapes). Small objects like valves are often mistaken for noise and filtered out. The object identification relies on linking textual labels to nearby detected objects, but labels often follow site- or application-specific naming conventions.

The next steps involve refining rule-based and predefined approaches, using template matching for smaller objects, and enhancing preprocessing with multi-resolution bounding boxes. Improving OCR with multi-language support, adaptive thresholding, and noise reduction will boost text recognition and object detection. Additionally, the generated data can help integrate deep learning models, further enhancing detection and identification.

## ABSTRACT

We propose a methodology that allows communication with Piping and Instrumentation Diagrams (P&IDs) using natural language. In particular, we represent P&IDs through the DEXPI data model as labeled property graphs and integrate them with Large Language Models (LLMs). The approach consists of three main parts: 1) P&IDs are cast into a graph representation from the DEXPI format using our pyDEXPI Python package. 2) A tool for generating P&ID knowledge graphs from pyDEXPI. 3) Integration of the P&ID knowledge graph to LLMs using graph-based retrieval augmented generation (graph-RAG). This approach allows users to communicate with P&IDs using natural language. It extends LLM's ability to retrieve contextual data from P&IDs and mitigate hallucinations. Leveraging the LLM's large corpus, the model is also able to interpret process information in P&IDs, which could help engineers in their daily tasks. In the future, this work will also open up opportunities in the context of other generative Artificial Intelligence (genAI) solutions on P&IDs, and AI-assisted HAZOP studies.

**Keywords**: Large Language Models, Knowledge Graph, Graph-based Retrieval Augmented Generation

## INTRODUCTION

Piping and Instrumentation Diagrams (P&IDs) are pivotal in process engineering, serving as comprehensive references across multiple disciplines [1]. For process engineers, daily tasks rely on accurate information retrieved from P&IDs. For example, engineers require accurate information and interpretation of P&IDs during design, HAZOP studies, and operation. However, the intricate nature of P&IDs and the system's complexity pose challenges to extracting information accurately and efficiently. The current approach mainly relies on manually tracing processing lines on PDF or Computer Aided Engineering (CAE) documents, which is time-consuming and prone to errors, leading to loss of production time and potentially hazardous situations.

Recent digitalization efforts in process engineering have brought a more data-centric approach to P&ID development. This advancement, often referred to as "smart" or "intelligent" P&ID, overlays a database on top of process diagrams. Also, recent works proposed the digitization of paper-based P&IDs into smart P&IDs [2]. While each CAE software may use distinct formats, initiatives to improve interoperability are underway. For instance, the Data Exchange in the Process Industry (DEXPI) initiative established a unified, machine-readable format for P&IDs [3]. Leveraging this data exchange standard, our group has developed the pyDEXPI Python package, which implements the DEXPI information model for Python [4]. These developments lay essential groundwork; however, a practical, intuitive implementation is still needed to harness this technology fully and enhance the work experience for process engineers.

Large language models (LLMs) have shown exceptional potential in understanding and processing natural language. The release of GPT-4, which was fine-tuned using reinforcement learning from human feedback (RLHF), marked a significant advancement in tasks such as question-answering and general reasoning [5]. Additionally, retrieval-augmented generation (RAG) systems have made notable progress in reducing hallucinations by enabling LLMs to query information from databases [6]. However, applying these techniques to P&IDs presents

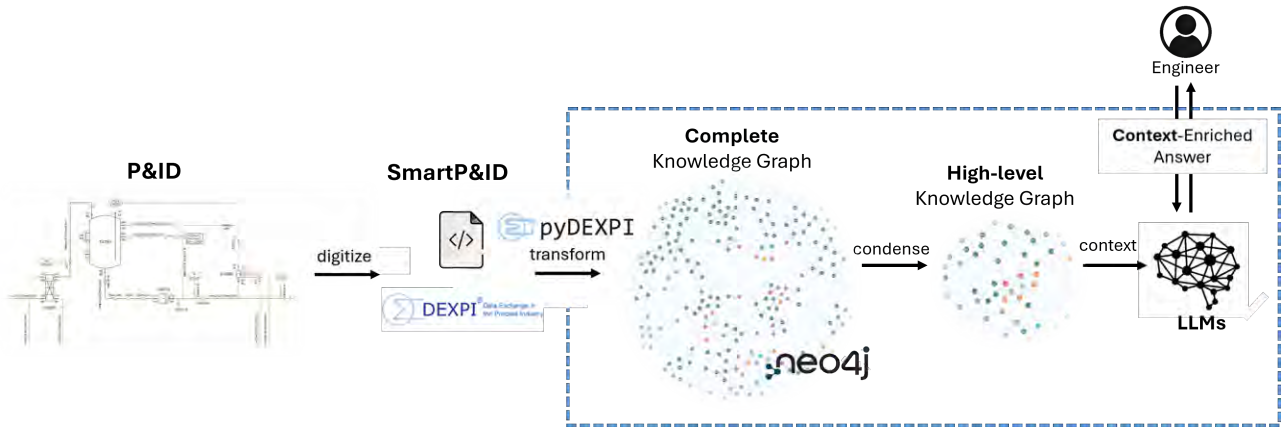

**Figure 1.** This methodology (inside the dashed box) serves as the final element, developed on top and integrated into digitization and contextualization framework. The process begins by digitizing P&ID into smart P&ID using flowsheet digitization tools. The smart P&ID is then transformed into a knowledge graph using the pyDEXPI package. This graph is further condensed into a high-level knowledge graph, which provides contextual input to an LLM for generating context-enriched responses for interaction with the engineer or user.

unique challenges and has not been done yet. As an engineering diagram, P&ID represents the data in both domain and lexical forms. Domain data represents hierarchical information on equipment, piping, and instrumentation, i.e., tubular heat exchangers consisting of a nozzle, shell, and tube bundle. Meanwhile, lexical data captures the interaction relationships between components, i.e., a valve is connected to a tank to regulate inlet flow, while also being connected to an actuator that manipulates the valve opening. This dual nature of P&IDs, involving both structured hierarchy and interlinked relationships, makes effective information retrieval particularly complex.

Building on advancements in process engineering digitalization and LLMs, this work focuses on developing a knowledge graph database derived from P&IDs and its retrieval method. Specifically, DEXPI P&IDs will be transformed into Neo4j labeled property graphs using pyDEXPI. A graph-based RAG technique will then be employed to extract and present relevant information. To ensure LLMs are aware of essential contextual information within P&IDs, high-level representations of P&IDs will be generated and used as context for retrieval. This results in a more intuitive and streamlined approach for process engineers to interact with and retrieve information from P&IDs. Moreover, the integration of P&IDs into foundation models is a key enabler technology for future developments of GenAI applications such as autocorrection of P&D and AI-assisted HAZOPs [7].

## METHOD

This section discusses each of the steps in this methodology, including graph representation, knowledge graph generation, and retrieval method as depicted in **Figure 1**. A DEXPI P&ID sample [3] is used as a case study to demonstrate our approach.

## P&ID GRAPH REPRESENTATION

A graph is an index-free adjacency database consisting of nodes and edges. Nodes represent entities within the dataset, while edges define the relationships between these entities. Due to its flexible structure and intuitive expression, graph databases are widely used in real-world applications, such as social networking, recommendation engines, fraud detection, and knowledge graphs. Graph databases also demonstrated their effectiveness in process engineering to model entire systems like P&IDs [8], [9].

In our data pipeline, smart P&ID in DEXPI format serves as the input, which is parsed using the pyDEXPI package from its XML file into pyDEXPI class instances. The pyDEXPI class framework implements the DEXPI information model in Python; it can be used as a Python package. The graph representation is created by constructing a NetworkX graph from the class instances as pyDEXPI P&ID. The pyDEXPI classes modeled as nodes in this graph representation pertain to the following pyDEXPI packages: 1) equipment, 2) piping, and 3) instrumentation. Meanwhile, edges between these elements are derived from two specific relationships of the pyDEXPI P&ID: domain relationships, which show a child node to the parents, and lexical relationships, which capture the interaction between nodes. The output is a graph showing the network of connection between class instances.

## P&ID KNOWLEDGE GRAPH GENERATION

While the graph captures the structure of the flowsheet, it lacks meaningful semantic context in its raw form. As such, the initial graph representation—comprising Python class instances and their connections—remains abstract and unreadable to LLMs. Semantic information is added to the graph to transform this structure into a readable and functional knowledge graph. This work utilizes a type of knowledge graph called Label Property Graph (LPG) using the Neo4j framework. The LPG graph classifies nodes using the labels and adds key-value pairs as the node properties. This feature is essential to denote different types of components and accommodate the details from the flowsheet.

LPG uses labels as an attribute to distinguish nodes. In our case, multiple labels are employed to classify P&ID components. Node labels are inherited from the pyDEXPI class name and its parent class, which aligns with DEXPI specification. For example, at a higher level, nodes are assigned labels based on their pyDEXPI package, i.e., equipment, piping, or instrumentation. At a more granular level, additional labels are applied according to each component's specific classification, i.e., reciprocatingPump and centrifugalPump. Meanwhile, detailed design information, such as size, operating conditions, tag number, and other specifications, is stored as node properties in key-value pairs. **Figure 2** illustrates an example of a label property graph for a pump, labeled as "equipment" and "reciprocating pump," with its specifications stored as node properties.

The relationship labels in the knowledge graph are also specified following the relationship in pyDEXPI P&ID. Domain relationship labels are remarked as *"has_[componentType]"* or *"is_located_in,"* depending on the direction of the relationship. Meanwhile, the lexical relationship is much more specialized. Material flows were labeled with *"send_to"*; the control structure relationship is represented using words such as *"control," "send_signal_to," "is_logical_end_of,"* and *"measured_by"*.

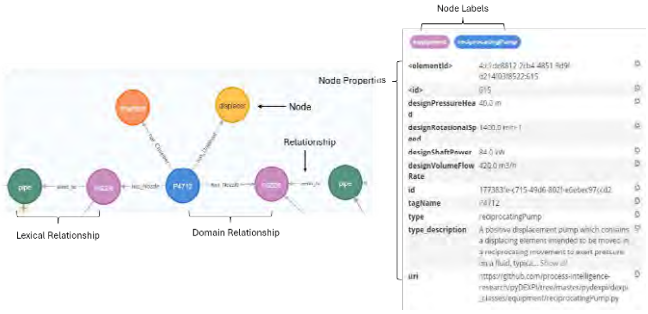

**Figure 2.** LPG structure for a sample of a pump system P&ID. (left) Graph pump node with four child nodes: two nozzles, a displacer, and a pump chamber. The stream enters through the right nozzle and exits at the left. (right) Details of node P4712 with labels of equipment and reciprocatingPump. The node properties contain the pump's specifications.

## GRAPH-BASED RETRIEVAL METHOD

### High-level Graph Context Generation

While the P&ID knowledge graph can be directly used as context for LLMs, extracting information becomes increasingly difficult as the graph's context length and complexity grow. For instance, the illustrative DEXPI flowsheet sample which represents a single page of P&ID with only one tank, two pumps, and two heat exchangers, consists of 212 nodes and 405 relationships. This translates to approximately 67,000 tokens in LLMs, which is inefficient in terms of token usage. The information density in the knowledge graph must be increased to improve efficiency, making the graph more compact and readable for LLMs. The objective is to create high-level graph representations to allow LLMs to focus on the essential structure. This is similar to how engineers read the flowsheet, which develops understanding from a high-level overview of the flowsheet before jumping into details.

Three steps were implemented to create a high-level graph representation:

1. Pruning domain information and connection nodes
2. Condensing low-information nodes
3. Removing non-process-related node properties

These steps reduce the overall complexity while preserving key relationships and concepts. The high-level graph reduces the knowledge graph size from 212 to 53 nodes, 405 to 57 relationships, and tokens usage from approximately 67,000 to 9,000 tokens. The performance of this high-level graph as context will later be compared to the initial complete knowledge graph.

### Chain and Retrieval

The LLM agent was created using the Langchain library. In the chain, the LLM is called using the API key or via a local machine. To enhance the interaction, a memory module is added to allow chat history to become context in LLM's response. As LLM may take time to give a complete response, the stream method is used to show the generated token directly as it is available. For retrieval, the high-level knowledge graph from Neo4j is exported into a graphml file containing information about nodes, relationships, and properties. This file content is then added as context to the engineered system prompt in the chain. In the LLMs, the string from the graphml file is tokenized together with the chat history and user question and passed to the LLM model to generate a history-aware and contextual response.

**Table 1.** Performance comparison of complete and high-level knowledge graph as context across different LLMs. Complete LLMs responses from this study are available in **supporting document**.

| Large Language Models (LLMs) | GPT 4o | | Anthropic Sonnet 3.5 20241022 | | Anthropic Haiku 3 20240307 | | Ollama 3.1: 8B | | Ollama 3.2: 3B | |

## RESULT AND DISCUSSION

In this section, we evaluate our approach's ability to retrieve information from the flowsheet. The model responses are assessed from a series of questions at various configurations of LLM and knowledge graph. The LLMs are varied to determine pipeline performance across different model scales. Additionally, to test our graph condensing method's ability to represent the flowsheet, the model responses from the completed and high-level graphs are also compared.

We designed a series of questions to evaluate distinct aspects, including pattern recognition ability, search completeness, and knowledge inference. The questions are asked sequentially, with each response integrated into the context of the subsequent query to assess how well the model maintains continuity in its analysis. The questions are as follows:

1. *"Describe the process from inlet to outlet."* This question evaluates the model's pattern recognition ability to extract and infer information from the flowsheet.
2. *"List all valves and their specifications."* This question tests the model's capacity for information retrieval and its completeness, specifically its ability to identify and list all valves along with their relevant specifications from the flowsheet.
3. *"Analyze the flowsheet and give recommendations regarding process safety."* This question assesses the model's knowledge inference capability, determining whether it can provide insightful process safety recommendations by leveraging its large corpus of information exposed to LLM during training and information from the flowsheet details.

As provided in **Table 1,** the results showed promising potential for this approach to read, search, and infer information from P&ID. In general, larger LLMs generate more complete and accurate responses. Meanwhile, smaller LLMs have difficulties reading the graph. Besides the current performance, we also see the potential for smaller LLMs, as they are computationally light and relatively affordable to run on local machines and fine-tune for this specific task.

For pattern recognition, as demonstrated in *Question 1*, the model's performance in describing the process is measured by assessing how accurately it follows the flowsheet. A complete score indicates that the model's response correctly traces the process from the inlet to the outlet. A score of 50% signifies that the model only provided a correct description for the first 50% of the process, starting from the inlet. This scoring method is chosen because when large language models (LLMs) make an error early in the response, subsequent parts are likely to be incorrect, as each token is generated based on the preceding tokens. On average, using high-level graph representations improved the model's ability to sequentially describe the process from inlet to outlet by 20% compared to the complete graph. This infers that our condensing methodology to generate high-level graphs better represents the information to improve LLMs' ability to read the P&ID.

The response also reflects the performance of large language models (LLMs) which varies significantly depending on the model size. Larger LLMs generally produce more coherent and accurate responses, whereas smaller LLMs are prone to hallucinations or may refuse to answer altogether. A hallucination occurs when a model generates responses that appear plausible but are factually incorrect, nonsensical, or inconsistent with the given prompt. LLMs are probabilistic models that predict the next word in a sequence, and their accuracy depends heavily on the quality and scope of their training data, as well as the model size. LLMs excel at handling widely popular prompts with established consensus but face challenges on controversial topics or topics with limited data [10]. Additionally, at the cost of computational resources and latency, the model with more parameters tends to have a better performance as it allows for a longer context, which results in better generalization and inferencing [11]. Since all LLMs used in this study are not fine-tuned to read flowsheets in knowledge graph format, the performance represents more of the size of LLMs.

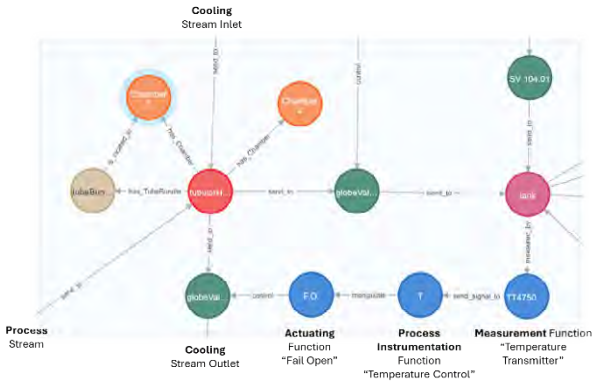

**Figure 3.** Temperature control system in Tank T4750. The tank temperature is measured by the measuring function node TT4750; the measurement signal is then passed to the T process instrumentation function node and actuating function node to the manipulate opening of the globe valve node. The globe valve will control the cooling stream in the tubular heat exchanger to cool the process stream before the tank.

The search completeness results from *Question 2, "List all valves and their specifications,"* demonstrated that both types of knowledge graphs produced the equivalent number of valve retrievals. This indicates that the same amount of information from the flowsheet can be effectively represented using the more compact form of a knowledge graph. Additionally, LLMs with a higher number of parameters showed superior retrieval performance. Notably, all 11 valves were retrieved with detailed information, with Anthropic's Sonnet 3.5 model providing particularly better results. Beyond valve, the LLMs also retrieved the actuators and identified their fail-safe actions. The fail-safe action details were not located directly within the valve node but were instead embedded in the actuating function node, as depicted in **Figure 3**. Despite this, the LLM correctly identified and presented this relevant information. Since all necessary details were included in the system prompt as context, the task essentially information recall.

In the knowledge inference metrics as asked in *Question 3, "Analyze the flowsheet and give recommendations regarding process safety,"* a model that offers more recommendations mentioning specific components of the flowsheet is highly preferred. This indicates that the LLMs are not only able to retrieve information from the flowsheet but also make the inference to the large corpus on which it has been trained. The evaluation shows that using high-level graphs as contexts generally leads to more flowsheet-specific safety recommendations. This aligns with the improvement in pattern recognition observed in the first question; if LLMs can read the pattern, they also generate more relevant recommendations. Below is a sample of Anthropic's Sonnet 3.5 process safety recommendations:

```
1. Pressure Safety:
Current Status:
- One spring-loaded safety valve (SV 104.01) with
set pressure of 6.0 bar
- Design pressures vary from -1 to 60 bar across
equipment
Recommendations:
- Add additional pressure safety valves, espe-
cially around:
  * The centrifugal pump P4711 discharge (60 kW
pump)
  * The reciprocating pump P4712 discharge (84 kW
pump)
- reciprocating pumps are prone to pressure pulsa-
tions
  * Heat exchangers H1007 and H1008 to protect
against thermal expansion
- Install pulsation dampeners around the recipro-
cating pump P4712
- Add pressure indicators and transmitters at more
critical points
```

The results indicate that the Anthropic Sonnet 3.5 is capable of retrieving information on existing safety devices and the design pressure range within the system to formulate relevant recommendations. The recommendations included adding several pressure transmitters at critical locations (though the exact locations were not specified) and installing a pressure safety valve (PSV) on the pump outlet. While the model suggested a PSV, a rupture disc can also be a choice, depending on the fluid, but the recommendation remains relevant as both devices act as pressure protection devices. In addition, the LLMs also highlighted the importance of addressing pressure pulsation in reciprocating pumps, which is

highly pertinent [12]. In the end, the LLMs suggested adding a pressure indicator and transmitter at more critical points. We found this response correct but imprecise; therefore, it's not particularly useful. Other LLMs like GPT-4o and Anthropic Haiku 3 also give process-specific recommendations in their responses but fewer than Anthropic Sonnet 3.5.

Although the results may appear promising, significant challenges remain to be addressed. The field of process engineering demands low tolerance for mistakes due to the risks associated with processing facilities. At the same time, Gen AI models can exhibit hallucinations and can make errors e.g. missing equipment in the response or imprecise response. Therefore, future work will be focused on improving the accuracy and reliability of the tools. This includes experimenting with retrieval methods, refining the knowledge graph schema, integrating a database, and developing more comprehensive evaluation metrics to assess model performance.

## CONCLUSION

We introduced a methodology for intuitive information retrieval and analysis in P&IDs. The methodology encompasses three steps: 1) graph representation of flowsheets using pyDEXPI, 2) knowledge graph generation, and 3) condensing information to a high-level knowledge graph and retrieval using LLMs. We evaluated the model responses across three different metrics: pattern recognition, search completeness, and knowledge inference. The results demonstrated that this approach enables intuitive information retrieval from P&ID using LLMs. The LLMs also showed the potential to read, infer, and generate coherent, contextually accurate information from flowsheets. Additionally, the high-level graph condensing method improved the LLM's ability to retrieve the information from P&ID diagrams. While the current result showed a potential for LLMs to recognize the pattern and infer information from the flowsheet, significant challenges remain to improve the accuracy and reliability in the light of hallucinations of LLMs.

## ABSTRACT

This study focuses on biomanufacturing case study, i.e. Lovastatin production, employing a hybrid modeling framework that combines mechanistic and data-driven approaches. A time-series dataset was generated using the KT-Biologics I (KTB1) plantwide model, a dynamic simulation of continuous biomanufacturing. The dataset captures critical parameters such as nutrient concentrations and API production. The AI-DARWIN framework was used to develop interpretable machine learning models with constrained functional forms, ensuring both accuracy and clarity. The resulting polynomial-based models reveal key relationships between process variables and system performance, bridging mechanistic insights with data-driven predictions. The models demonstrated reasonable accuracy showing minimal difference between the training and testing errors, highlighting their strong generalization. This work advances hybrid modeling in biomanufacturing by integrating plant-wide mechanistic simulations with interpretable machine learning. The approach ensures both accuracy and transparency while enabling robust process monitoring and control at a 'plant-wide' level, contributing to the broader adoption of hybrid modeling in biomanufacturing.

**Keywords**: Hybrid modeling, Biomanufacturing, Plant-wide modeling, Lovastatin production, Interpretable machine learning.

## 1. INTRODUCTION

The biomanufacturing of high-value products, such as Lovastatin, presents unique challenges due to the complex interplay of biological, chemical, and physical processes [1]. Lovastatin, a widely used cholesterol-lowering drug, is produced through microbial fermentation, where variations in nutrient concentrations, reactor conditions, and downstream processing steps significantly influence its yield and quality. Developing accurate and interpretable models to predict and optimize production outcomes is essential for improving efficiency and meeting stringent quality standards.

Traditional modeling approaches in biomanufacturing often rely on mechanistic models, which are grounded in physical and biochemical laws. Developing these mechanistic models can sometimes be challenging, primarily due to the lack of advanced sensing technologies to gather data (for parameter estimation, model validation, etc.) and a limited understanding of multi-scale phenomenological dynamics. However, data-driven modeling has shown great promise in capturing the behavior of complex systems, if and only, there is sufficient amount of data and right measurement of key characteristic phenomena in a process [2]. So, incorporating domain expertise into the modeling framework is crucial.

Bioprocesses, as a prime example of complex systems, are ideal candidates for data-driven modeling, which help bridge gaps in both theoretical knowledge and practical modeling [3]. Although this approach can handle complex, nonlinear relationships in data, It often lacks transparency, making it difficult to trust and interpret its predictions in regulatory and operational contexts. To address this limitation, hybrid modeling approaches that combine mechanistic models with data-

driven techniques have gained significant attention. By combining numeric AI (machine learning) with symbolic AI, a hybrid AI approach can be developed, resulting in robust, interpretable models suitable for complex systems [4].

KT-Biologics I (KTB1) is a dynamic mechanistic simulation model for continuous biomanufacturing, covering the entire Lovastatin production plant [1]. While effective in capturing process mechanisms, KTB1 has long running times and does not fully clarify how process variables influence the final output, limiting its use for real-time monitoring and optimization. To address these limitations, a hybrid modeling approach integrates mechanistic insights with data-driven modeling. The AI-DARWIN framework [5] enables the discovery of interpretable polynomial models by constraining functional forms, ensuring both accuracy and clarity. This approach accelerates computation, enhances understanding of variable relationships, and improves process control efficiency.

This work develops a hybrid model for Lovastatin biomanufacturing, aiming to create an interpretable representation of the process that captures its dynamic behavior, variable interactions, and plant-wide complexities. The approach begins by generating time-series datasets from the KTB1 model under varying nutrient conditions to systematically examine the effects of key variables, such as lactose and adenine, on Lovastatin production. These datasets feed into the AI-DARWIN framework, which builds explainable ML models, laying the foundation for future optimization of nutrient utilization and enabling knowledge transfer to new process scenarios, such as using different microorganisms or producing alternative products.

## 2. SYSTEM DESCRIPTION

### 2.1. KTB1 Model Description

This model presents a comprehensive framework encompassing both the upstream production and downstream purification of Lovastatin, a target compound produced via fermentation. As depicted in Figure 1, the upstream process begins with the introduction of key raw materials—adenine and lactose—into a mixing unit (M-101). The mixed medium is then continuously fed into a Continuous Stirred-Tank Reactor (CSTR, labeled R-101), where the biomass, predominantly *Aspergillus terreus*, facilitates Lovastatin production.

The fermentation broth exiting the CSTR is directed to a hydro-cyclone separator (HC-101), which plays a pivotal role in separating the mixture into two streams. The first stream, rich in biomass, is partially recycled back to the CSTR to sustain fermentation. The second stream, with lower biomass content (stream 5), is transferred to the downstream process.

In the downstream phase, the focus is on a sequence of separation and purification steps. Centrifugation units (C-101 and C-102) initially remove remaining biomass and dense impurities from the solution. Following centrifugation, the process advances to nanofiltration (NF-101), where Lovastatin is concentrated by retaining larger molecules through steric exclusion while smaller impurities pass through. Figure 1 illustrates the complete process flow for the biomanufacturing of Lovastatin, including both the upstream and downstream operations.

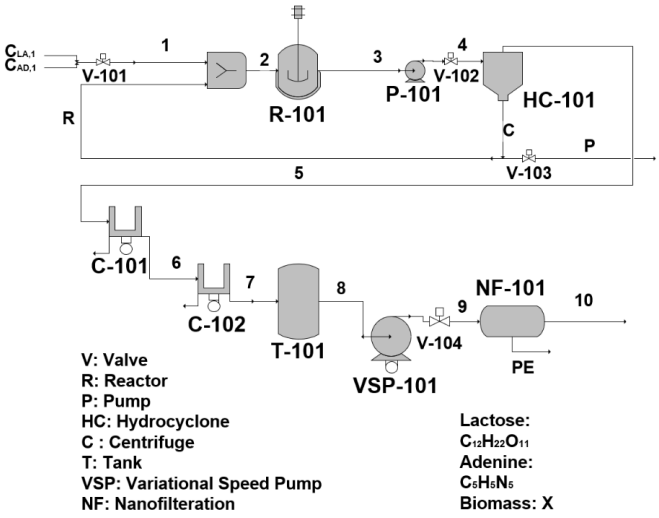

**Figure 1.** Process flow for the biomanufacturing of Lovastatin

#### 2.1.1 Dataset

The datasets used in this study were generated to systematically explore the relationships between nutrient concentrations and Lovastatin API production. Two distinct datasets were created using the KTB1 mechanistic model, each designed to capture specific aspects of the nutrient dynamics in the biomanufacturing process. The datasets include concentrations of various nutrients (such as lactose and adenine), biomass levels in different streams, and the Lovastatin API produced production plant. In these datasets, only one nutrient concentration was varied at a time (by step change) while keeping all other process parameters constant. This method of isolating single variables ensures a controlled environment to study the individual effects of lactose and adenine on Lovastatin production. Each full dataset consists of about 20000 data points. We used 75% for training and 25% for testing, resulting in 15000 training samples and 5000 test samples. Dataset 1 contains information on altering lactose concentration (CLA). And Dataset 2 contains information on altering adenine concentration (CAD). The graphs corresponding to the generated datasets are presented in Figure 2. A step change in lactose at the start of the process, along with a noisy but constant adenine

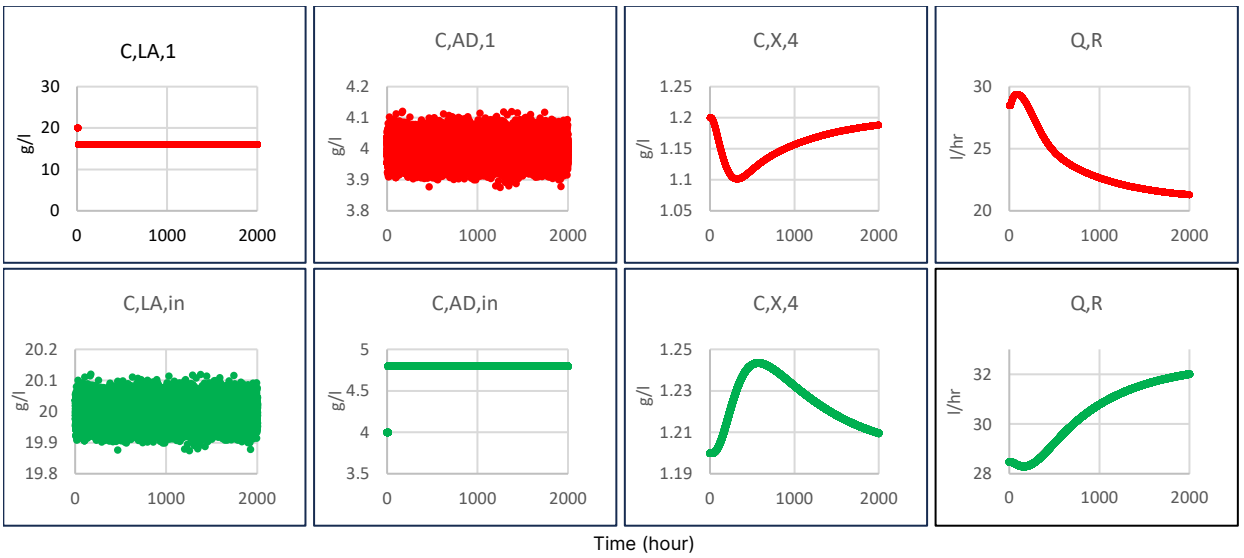

**Figure 2.** Variables in Dataset 1 (in pink) and Dataset 2 (in greens) were varied, with other variables held constant.

input, were introduced to the model. The noise was intentionally added to simulate real-world scenarios, particularly in nutrient supply, where fluctuations are often observed in one of the inputs. Step changes in lactose and adenine, as seen in the first and second datasets, can arise from sensor malfunctions, control system errors, or other process deviations, which are common faults in industrial processes. These variations result in changes to other system variables, such as biomass concentration and flow rates. Figure 2 illustrates how these variations cause dynamic changes in some of the other variables (C,X,4 and Q,R).

## 2.2. AI-DARWIN Framework

The AI-DARWIN framework is a hybrid AI mechanistic model discovery tool designed to uncover interpretable and scientifically valid models from data. Unlike traditional black-box approaches, AI-DARWIN focuses on creating explainable models, ensuring that the resulting mathematical representations are not only accurate but also comprehensible to domain experts. This characteristic makes it particularly suitable for hybrid modeling tasks, such as those encountered in biomanufacturing processes. The framework operates by constraining the model discovery process to specific functional forms, such as polynomials. These constraints allow the generated models to remain aligned with physical laws and domain knowledge, fostering trust and usability in critical applications. By imposing such restrictions, AI-DARWIN ensures that the final models capture essential relationships without unnecessary complexity, making them easier to analyze and validate. For the Lovastatin biomanufacturing process, AI-DARWIN is applied to time-series data generated from the KTB1 mechanistic model. The framework systematically evaluates the dataset to uncover explicit mathematical relationships between input variables, such as nutrient concentrations (e.g., lactose and adenine), and output variables, such as Lovastatin API production. Moreover, normalization using standardization (subtracting the mean of the training data and dividing the difference by the standard deviation of the training data) was used to ensure that all input variables get weighted appropriately

In the context of model optimization and system identification, several frameworks aim to extract meaningful insights from data. One such approach is SINDy [6]. While SINDy is not entirely one-shot (first step of parameter estimation is followed by iteratively sparsifying the coefficients), it comes up with a single best-fit model. AI-DARWIN comes up with multiple options which allow for a broader range of discovery of functional relations between the input variables. This is particularly useful for systems biology models and surrogate models of complex systems. This also can provide a pareto front for further examination of the trade-off between simpler but less accurate models in contrast to complex but more accurate models. Further, AI-DARWIN provides flexibility to incorporate domain-specific constraints, which while limiting in accuracy, reaps rewards in interpretability and eventual robustness over unseen data. The resulting models are expressed in polynomial form, offering a clear interpretation of how each factor influences production outcomes. The generated datasets were used to train the models, with performance assessed using accuracy metrics such as Mean Absolute Error (MAE) and interpretability metrics like $R^2$.

For each dataset, we conducted a series of

modeling steps to predict the concentrations of lactose (C,LA), adenine (C,AD), and lovastatin (C,LOV) in the final stream of the plant (stream #10). Figure 3 shows all the inputs to the model and outputs. However, in AI-DARWIN, we are instructing AI-DARWIN to review all features, select the ones it deems optimal, and potentially arrive at a reduced set of features for the final model.

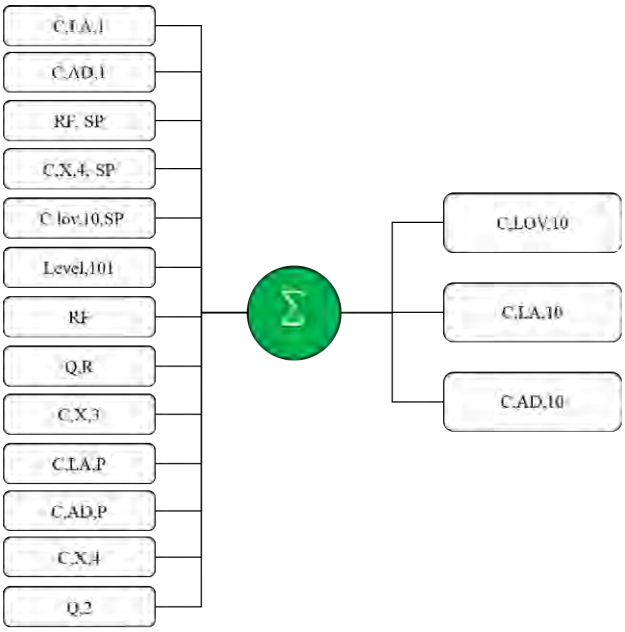

**Figure 3.** All the inputs and outputs of the AI-Darwin framework (C: Concentration, LA: Lactose, AD: Adenine, X: Biomass, LOV: Lovastatin, SP: Setpoint, RF: Recycle factor, Q: flow rate; the numbers represent the streams number at figure 1).

## 3. RESULTS AND DISCUSSION

For each dataset several model architectures were used, and the performance is compared. Table 1 and 2 show selected models developed to predict the concentration of two substrates consumed and the API produced at the outlet of the plant. The results demonstrate that the developed modeling framework effectively captures the complex dynamics of the Lovastatin production plant with low training and testing MAE values, demonstrating high predictive accuracy. Using a combination of mechanistic principles and data-driven modeling, the framework successfully predicts three critical outlet concentrations—C,AD, C,LAC, and C,LOV—at the plant's downstream stage.

For Dataset 1, the models showed strong performance and the minimal error difference between training and testing for all the models suggests strong generalization (Table 1 and Figure 4). The polynomial models, expressed in interpretable forms, highlighted significant contributions from key variables such as 'Q,R' and 'C,LA,1' for predicting adenine concentration, and 'Q,R', 'RF', 'C,X,4', and 'C,AD,P' for predicting lactose and lovastatin concentrations. These terms reflect critical process interactions and nonlinearities inherent in this biomanufacturing system. Adenine concentration in stream 10 (C,AD), being the simplest model, achieves remarkable accuracy ($MAE_{test}$=0.0198), indicating that minimal complexity may suffice for certain targets. In contrast, lactose and lovastatin concentrations (C,LA and C,LOV) include higher-order terms like (C,X,$4^4$) and (C,AD,$P^4$), reflecting more intricate relationships.

These terms suggest significant nonlinearity in the system, consistent with the expected process dynamics. The inclusion of interaction terms, such as (C,X,4)(C,AD,$P^2$), highlights interdependencies between process variables, offering deeper insights into their combined effects on product concentrations. While more complex models (e.g., C,LA and C,LOV) slightly improve accuracy, they may require more computational resources compared to C,AD.

The models developed using Dataset 2 retained this interpretability while incorporating additional interactions and higher-order terms (Table 2 and Figure 5). For example, the C,LA model included interactions like ($RF^2$),(C,X,$4^2$), and (Q,$R^2$), emphasizing the interdependencies between upstream and downstream variables. Similarly, the C,LOV model highlighted the cascading influence of intermediate concentrations, such as C,LA,P on the final product.

The similarity between the MAEs for training and testing sets is due to the relatively large dataset and the low model complexity, which together reduce the risk of overfitting. The large dataset and high sampling

**Table 1.** Model performance on dataset 1 .

| Target | Model | Train MAE | Test MAE |
|---|---|---|---|
| C,AD | $9.72 + 0.25\,(C,LA,1) - 0.56\,(C,LA,1^2)\,(Q,R)$ | 0.0198 | 0.0198 |
| C,LA | $75.4 + 6.45\,(C,X,4^4) - 0.60\,(C,X,4)(C,AD,P^2) + 5.17\,(C,AD,P^3) - 0.94\,(Q,R)\,(RF^2)$ | 0.0785 | 0.0741 |
| C,LOV | $12.04 + 5.17\,(C,X,4^4) - 0.52\,(C,X,4)(C,AD,P^2) + 6.78(C,AD,P^4) - 0.45\,(Q,R)(RF^2)$ | 0.0982 | 0.0971 |

**Table 2.** Model performance on dataset 2 .

| Target | Model | Train MAE | Test MAE |
|---|---|---|---|
| C,AD | $10.18 - 1.75\,(Q,R) \times (RF^2) + 2.06\,(Q,R^4)$ | 0.0158 | 0.0154 |
| C,LA | $77.04 + 3.18\,(C,X,4^4) - 3.21\,(RF^2)(C,X,4^2) + 3.20\,(C,AD,P)\,(Q,R^2) - 2.48\,(C,AD,P^4)$ | 0.0970 | 0.0959 |
| C,LOV | $10.43 - 0.90\,(C,X,4^4) - 0.45\,(RF) + 0.41\,(C,LA,P)(C,X,4) - 0.20\,(C,AD,P^4)$ | 0.0279 | 0.0277 |

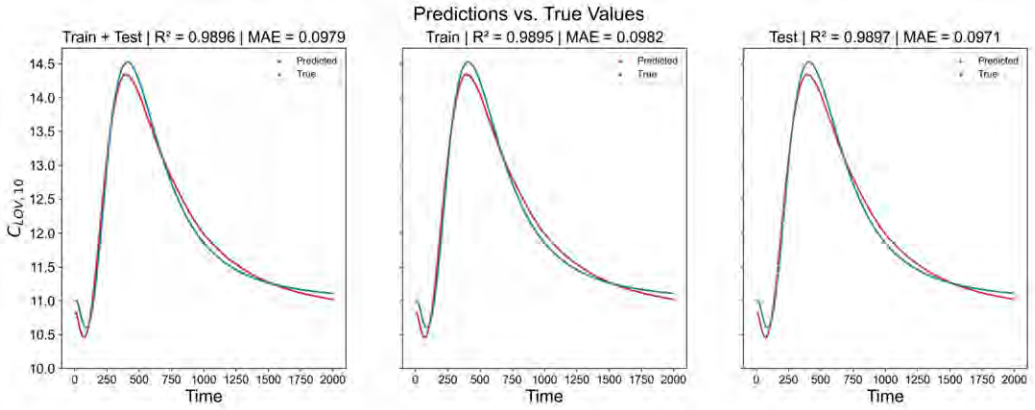

**Figure 4** Model performance on the dataset 1

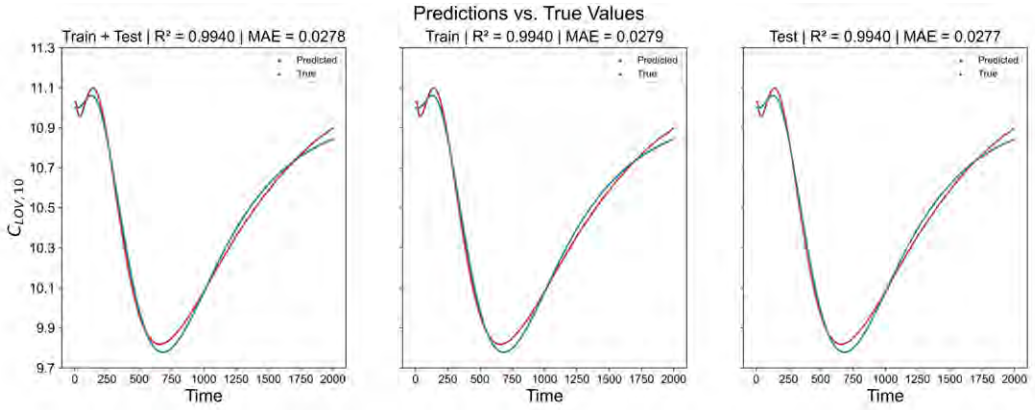

**Figure 5.** Model performance on the dataset 2

frequency could contribute to the observed similarity between training and testing MAEs. However, this sampling strategy reflects realistic process monitoring where frequent measurements are common. The consistent performance across both subsets suggests that the model captures the underlying process behavior without overfitting. Nevertheless, we agree that further validation under different operating conditions would provide a stronger confirmation of generalizability.

Figure 6 presents the sensitivity analysis performed using MAPE. In Dataset 1, the C,AD,P point's distance from the center of the radar chart, represented by the blue line, indicates the highest sensitivity, meaning minor changes in C,AD,P significantly alter the MAPE. Although C,AD,P remain highly influential in Dataset 2 (magenta line), their impact is slightly reduced, which may be attributed to the overall improved fitting performance of the model. Similarly, C,X,4 exhibited significant sensitivity in both datasets, though to a lesser extent than C,AD,P, with Dataset 1 showing a marginally higher sensitivity than Dataset 2. Conversely, RF, Q,R, and C,LA,P demonstrated considerably lower sensitivity in both datasets. Despite slight variations in magnitude, the overall sensitivity patterns regarding biomass concentration were consistent across both datasets, with Dataset 1 showing a slightly higher sensitivity to changes in C,X,4. However, discrepancies in the sensitivities of RF and C,AD,P may arise from the fact that these represent two scenarios modeled for different data conditions (step changes in lactose and adenine, respectively).

This modeling framework demonstrates its capability to model a plantwide biomanufacturing process, laying the groundwork for developing digital twins. The interpretability of the polynomial models facilitates understanding the underlying system dynamics, while the inclusion of complex interactions and nonlinear terms ensures the accuracy needed to capture the intricacies of the process. For models involving biomass concentration at stream 4 (C,X,4 after the fermentation stage) the kinetic models in the KTB1 model can be replaced to calculate biomass concentration in the CSTR for new microorganisms. By transferring the process dynamics knowledge captured in the polynomial models to new scenarios for different products, modeling of new scenarios can also be performed. This idea will be explored in future work, and validation will be required.

Moreover, in the presented study, step changes in lactose and adenine concentrations—representing typical faults encountered in industrial processes—are introduced to the process. Within a broader digital twin framework that includes a fault diagnosis module, once faults are detected and diagnosed, the resulting changes in Lovastatin concentration at the output can be effectively estimated. This estimation can be done using key

process variables, such as flow rates (directly measurable) or biomass concentration (easily calculable), by the models proposed in this study. The biomass concentration can be approximated through a kinetics model within the CSTR. This approach provides an opportunity for the plant to predict the final product concentration—after several units—using operational parameters (recycling factor and flow rate) along with the biomass concentration measured after the fermenter (via the kinetics model) beside nutrient concentrations after the hydro-cyclone.

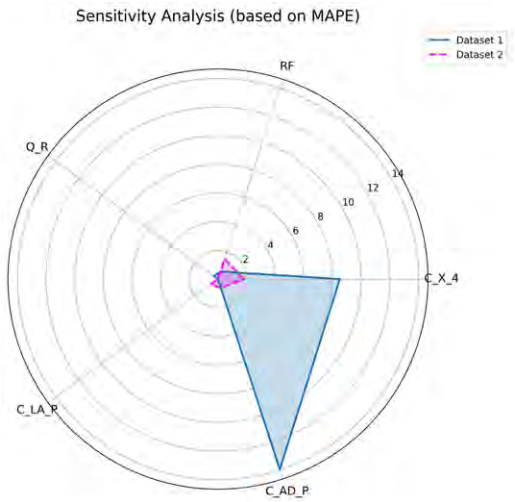

**Figure 6.** Sensitivity analysis of the models developed for lovastatin production using both datasets.

## 4. CONCLUSION

The polynomial models developed in this study accurately capture the complex dynamics of a plantwide bio-manufacturing process, making the framework a valuable tool for advancing digital twins. By incorporating higher-order and interaction terms, the models effectively represent nonlinear relationships and interactions between process variables, enabling predictions under varying operational conditions.

The low MAE values for both training and testing datasets indicate that the models generalize well, balancing accuracy and robustness. Their explicit functional forms provide interpretability, allowing for insight into variable sensitivities and interactions, which is essential for developing digital twins.

Future work will focus on generating more complex datasets by varying multiple variables simultaneously, providing a richer dataset for model development. Additionally, testing more advanced models to ensure the selection of the best, yet simplest, representation would further validate this framework. This approach, coupled with a model selection framework, will optimize the trade-off between accuracy, complexity, and interpretability, expanding the applicability of the models across diverse scenarios. By using polynomial models to determine optimal process setpoints, we can adapt the system for different scenarios, such as changing the microorganism to produce a new product, and transfer insights to new contexts. Additionally, generating natural language explanations from the obtained ML plantwide models by incorporating domain-specific knowledge alongside large language models (LLMs) is part of the vision for future works. This approach could lead to the development of a large knowledge model (LKM) [7] tailored for biomanufacturing. This enhances the interoperability of our obtained models and can be used to generate additional mechanistic insights.

## ABSTRACT

Many small and medium enterprises (SME) often fail to fully utilize the data they collect due to a lack of technical expertise. The ecoKI platform, a low-code solution that simplifies machine learning application for SMEs, showed a promising answer to the challenge. This study explores the application of ecoKI platform to design process monitoring tools for waste sorting plants. NIR separator data were processed through ecoKI's building blocks to train two neural network architectures—MLP and LSTM—for predicting NIR separation efficiency. The results showed that the models accurately predicted NIR output and effectively identified regions where NIR separation performance declined, demonstrating the potential of data-driven approaches for real-time performance monitoring. This work highlights how SMEs can leverage existing data for operational efficiency and decision-making, offering an accessible solution for industries with limited machine learning expertise. The approach is adaptable to various industrial contexts, paving the way for future advancements in automated, data-driven optimization of equipment performance.

**Keywords**: Machine Learning in Waste Management, Waste Sorting Automation, Performance Monitoring

## INTRODUCTION

Data utilization in SMEs, including waste sorting facilities, is often not maximized, preventing them from fully capitalizing on the data they collect. This underutilization stems from several key challenges. First, SMEs typically have limited technical resources and expertise in data analytics and machine learning, which hinders their ability to process and analyze the vast amounts of data generated by their operations [1]. Second, the integration of advanced data-driven technologies requires significant investment in both time and training, which many SMEs find difficult to accommodate within their existing operational structures [2]. As a result, valuable insights that could drive efficiency improvements, cost savings, and enhanced decision-making remain untapped.

Wang et al. demonstrated that the ecoKI platform is a viable solution for those challenges, as it is a low-code platform, requires no prior machine learning knowledge and is simple to use [3]. EcoKI simplifies the transformation of raw measurement data into actionable insights by providing pre-built building blocks and intuitive interfaces, allowing users to implement advanced machine learning solutions without any programming expertise. This feature makes ecoKI particularly well-suited for SMEs, as it lowers the technical barrier, enabling them to harness their data effectively and implement data-driven solutions with ease.

As part of the EnSort project [4], which aims to enhance automation and energy efficiency in waste sorting plants, this study explores the application of the ecoKI platform to process measurement data into actionable insights. Transforming raw data into real-time performance monitoring tools enables operators to track system efficiency more effectively and detects anomalies. Additionally, these performance measurements can be integrated with advanced automation systems, facilitating operations optimization to achieve energy savings and improved overall performance.

## NEAR-INFRARED SEPARATORS

Near-infrared (NIR) spectroscopy can distinguish non-carbon-black plastic with a very high accuracy, as demonstrated in various studies [5-10]. In a waste sorting plant, the final stage of the sorting section typically comprises NIR separators [11, 12, 13]. These separators are arranged in pairs, consisting of a primary separator and a cleaner separator, as illustrated in Figure 1. Kroell et al. showed that this arrangement generates product with higher purity compared to parallel arrangement [14].

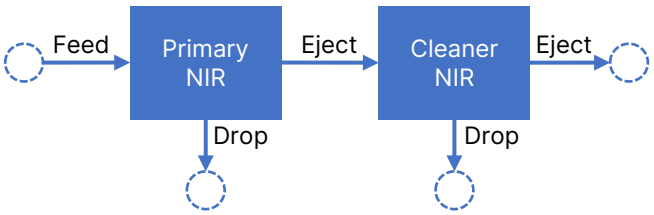

**Figure 1:** NIR Arrangement in Waste Sorting Plant.

The primary NIR separator is designed to maximize the recovery of targeted materials from the waste stream. The cleaner NIR separator, in turn, enhances the purity of the recovered materials by removing unwanted contaminants. Additionally, NIR separators serve a dual function by acting as flow measurement devices, enabling the measurement of the surface flow rate of the material stream.

Multiple datasets (NIR Dataset 1 and 2) were collected from primary-cleaner NIR separator pair in a waste sorting plant located in Northern Europe. The sampling interval of the measurements is 1 minute. Due to the inherent noise in the system, a moving average over the last 5 minutes is applied to smooth the data and improve its reliability.

The system under consideration focuses to separate polypropylene, polyethylene, and their variants, such as polypropylene foil, high-density polyethylene, and polyethylene film. To simplify the analysis and evaluation, the total flow of all targeted materials was calculated from the dataset.

## METHODOLOGY

Machine learning-driven data utilization for performance monitoring has been widely adopted across various fields for maintenance and planning purposes. For instance, Hundi and Shahsavari employed Neural Networks, Random Forests, and Support Vector Machines to estimate power plant performance and identify early-stage equipment malfunctions [15]. In road construction, Cano-Ortiz et al. applied machine learning techniques to assess pavement performance and guide road rehabilitation efforts [16]. Similarly, Gupta et al. used machine learning models to predict the hydrodynamic performance of ships, enabling better estimations of power demand and fuel consumption for planned voyages [17].

The next section will explain how ecoKI platform can be used to develop machine learning models for separation performance prediction.

### Output Prediction

The performance of a primary NIR separator is evaluated based on the amount of targeted material it directs to the cleaner. To predict the outflow, two machine learning model was trained in ecoKI platform and the optimal model was selected based on a balance between complexity and accuracy.

The ecoKI platform offers multiple ready-to-use pipeline templates tailored for different use cases. Each pipeline consists of modular building blocks that represent key steps in the machine learning development process. These blocks provide adjustable options for users with advanced knowledge while also offering default settings for those with limited experience.

In this work, the machine learning models were developed with the Artificial Neural Network (ANN) pipeline. The illustration of the ANN pipeline and its building blocks are presented in Figure 2. The settings for each building blocks are listed in Table 1. The followings sections give a brief explanation on the respective building blocks and their settings.

**Data Reader** first reads the raw dataset. After the user selects the input features and target variable for the machine learning model, the relevant data is extracted from the dataset. Currently, the dataset used for training is the NIR Dataset 1 and the total targeted material flow in the feed stream and eject stream are the input and target variable, respectively.

**Data Sequence Generator** generates input-target sequences based on a defined sequence length to

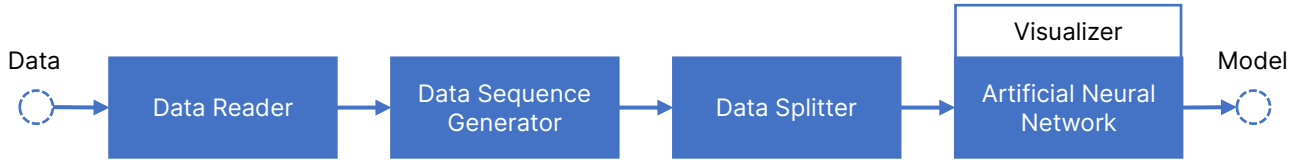

**Figure 2:** Artificial Neural Network Pipeline.

prepare the data for model training. The default value for input step setting is 5 and output step setting is 1, which means the block will pair sequence of five past input data with a one step ahead output.

**Data Splitter** splits the sequence into a training and a test dataset based on the specified fraction. The default setting is 10% of the data is reserved for testing, and the remaining 90% is used for training.

**Artificial Neural Network** block trains an Artificial Neural Network model using the training and test dataset. As of the time of writing, this block supports two ANN models: the Multi-Layer Perceptron (MLP) model and the Long Short-Term Memory (LSTM) model. The neural network structure is fixed with two hidden layers (Layer 1 and 2) positioned between the input and output layers. However, the number of neurons in each hidden layer is adjustable. By default, both hidden layers are set to have two neurons. In this study, both models were used with the default neuron configuration, except for the LSTM model, where Layer 1 was set to four neurons instead of two.

**Visualizer** is connected to the Artificial Neural Network block. It provides graphical representation of the training results, facilitating model evaluation.

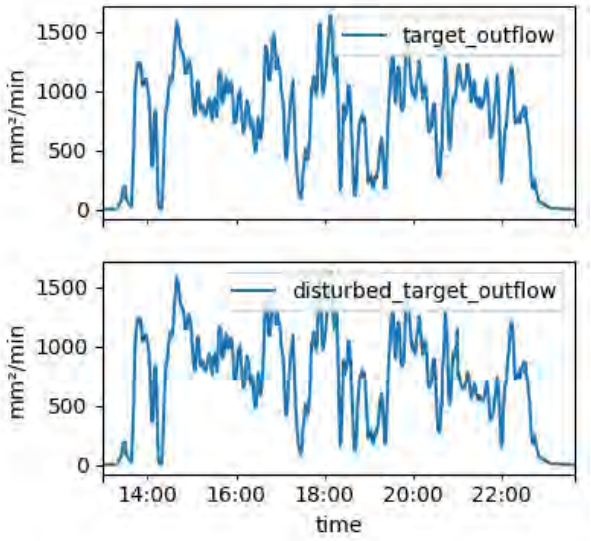
**Table 1:** ecoKI Building Blocks Settings.

| Building Block | Setting | Value |
|---|---|---|
| Data Reader | Inputs columns | Target inflow |
| | Feature column | Target outflow |
| Data Sequence Generator | Input steps | 5 |
| | Output steps | 1 |
| Data Splitter | Test fraction | 0.1 |
| Artificial Neural Network | Model | MLP (LSTM) |
| | Layer 1 nodes | 2 (4) |
| | Layer 2 nodes | 2 |

## Disturbance Detection

To detect disturbances or deterioration in NIR performance, the predicted material flow is compared with the actual flow. Since the predictor was developed using disturbance-free data and solely depend on the input stream, any significant discrepancy between the predicted and actual values indicates potential system disturbances.

To evaluate the effectiveness of this tool, a part of NIR Dataset 2 was artificially modified to simulate reduced NIR performance. The alteration was done by changing the actual outflow value with 50% of the inflow. The targeted material outflow in normal and disturbed conditions is shown in Figure 3. Both flow profiles appear similar, despite modifications applied between 21:00 and 22:00 on September 3. This highlights that relying solely on the flow profile is insufficient for anomaly detection, as the changes would likely go unnoticed by operators under normal monitoring conditions. By overlaying the disturbed outflow profile with the predicted normal outflow profile, the operator will be able to clearly observe the range in which the disturbance occurs, as the two lines will not overlap during the disturbance period.



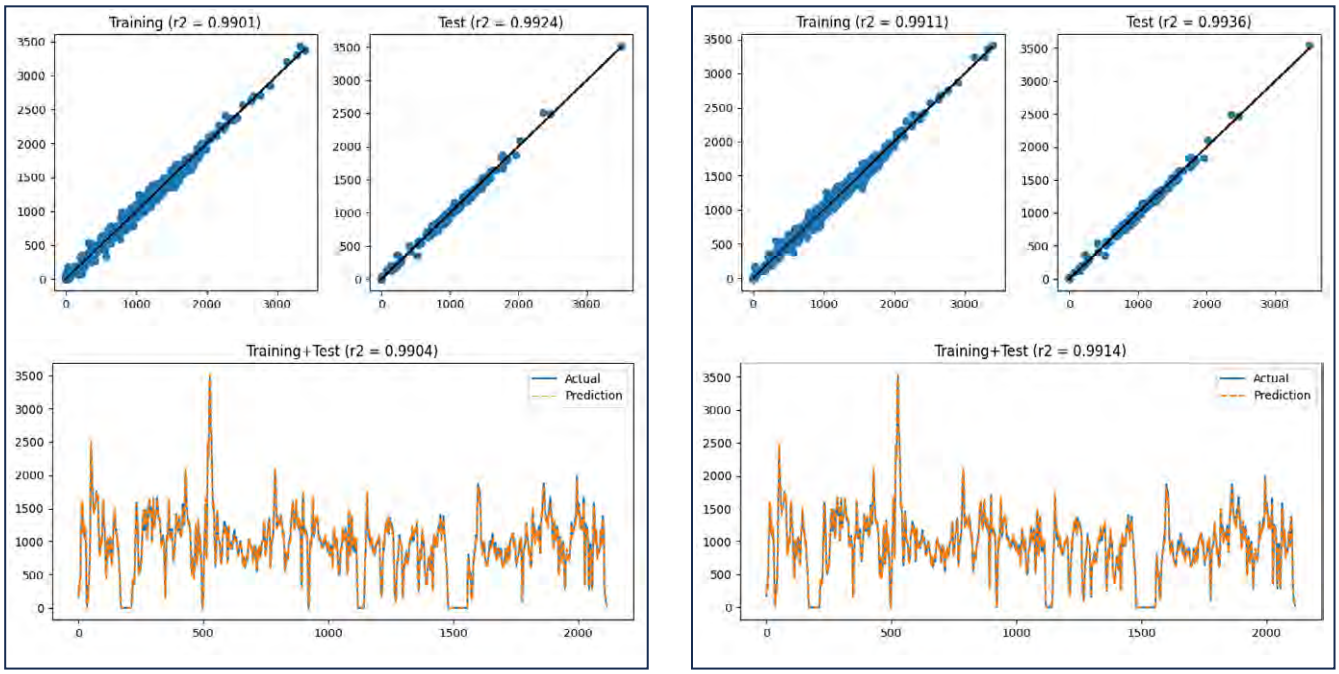


**Figure 3:** Material Outflow Profile on Disturbance Detection (NIR Dataset 2).

# RESULTS AND DISCUSSION

## Output Prediction

The training and testing performance of the MLP and LSTM model are evaluated from ecoKI Visualizer output presented in the left part and right part of Figure 4, respectively. The scatter plot of the training data and the prediction is shown on the top-left and the scatter plot of the test data and the prediction is shown on the top-right. The majority of the data in the training set falls below 2500 mm²/min, while most of the test set data lies below 2000 mm²/min. Despite using the default setting, the generated models demonstrates excellent accuracy as shown by the coefficient of determination. These results imply that ecoKI's automated pipeline effectively optimizes key aspects of model development, enabling users to achieve high-performance predictions without manual fine-tuning. This suggests that even users with minimal expertise in machine learning can leverage ecoKI to develop reliable models, making advanced AI technology more accessible to SMEs. Furthermore, the high accuracy achieved with default settings indicates that ecoKI's pre-configured parameters are well-calibrated for general use cases, reducing the need for extensive trial and error.

The MLP model was ultimately selected as the predictor due to its simplicity, which is evident from the

MLP LSTM

**Figure 4:** LSTM and MLP ecoKI Visualizer. In each model, Top-Right: Training result, Top-Left: Test result, Bottom: Combined result. x and y axis in top plots and y axis in bottom plot are flow in $mm^2/min$, while x axis in bottom plot are the index of the data.

significantly lower number of estimated parameters compared to the LSTM model, as detailed in Table 2. The MLP model, with just 21 parameters, is less complex than the LSTM model, which has 109 parameters. This simplicity not only made the model easier to train but also enhanced its generalization capability. With fewer parameters to optimize, the MLP model was less prone to overfitting, allowing it to generalize more effectively to new, unseen data. This combination of simplicity and robust generalization made the MLP model the preferred choice for the task.

**Table 2:** Machine Learning Model Summary.

| Model | Structure | Trainable Params |
|---|---|---|
| MLP | Dense(2), Dense(2) | 21 |
| LSTM | LSTM(4), Dense(2) | 109 |

## Disturbance Detection

When the actual flow profile is overlaid with the predicted flow profile, as shown in Figure 5 (top), any deterioration in NIR performance becomes immediately apparent. During periods of normal operation, the trained model accurately predicts the outgoing material flow, even when tested on a separate dataset, demonstrating strong generalization capabilities.

The recovery profile, displayed in Figure 5 (bottom), reveals fluctuations, including drops and peaks, corresponding to moments when the machine experienced brief stoppages. These fluctuations are likely due to the cleaner NIR stopping and restarting slightly earlier than the primary NIR. The flat 50% recovery rate near the end of the profile indicates a region where the data has been modified. Approximately 30 minutes before the end, the recovery rate began to decline. However, the flow profile indicates that this behavior is expected as the actual flow match with the predicted flow.

The ability to detect disturbances by comparing actual and predicted flow profiles underscores the practical value of this tool in monitoring and maintaining system performance. By providing real-time insights into deviations from expected behavior, the tool enables early identification of potential issues, allowing operators to take corrective actions before significant disruptions occur. This proactive approach not only enhances process stability but also improves overall efficiency by minimizing unplanned downtime. Furthermore, the tool's strong generalization capability ensures reliable predictions across different datasets, making it a valuable asset for industries seeking to optimize operations with minimal manual intervention.

## How ecoKI Lowers the Barrier for SMEs

As demonstrated in the previous section, ecoKI's default settings achieved a high prediction accuracy, highlighting its ability to generate robust models with minimal input. This is particularly beneficial for SMEs, as ecoKI directly addresses the barriers to adopting machine learning:

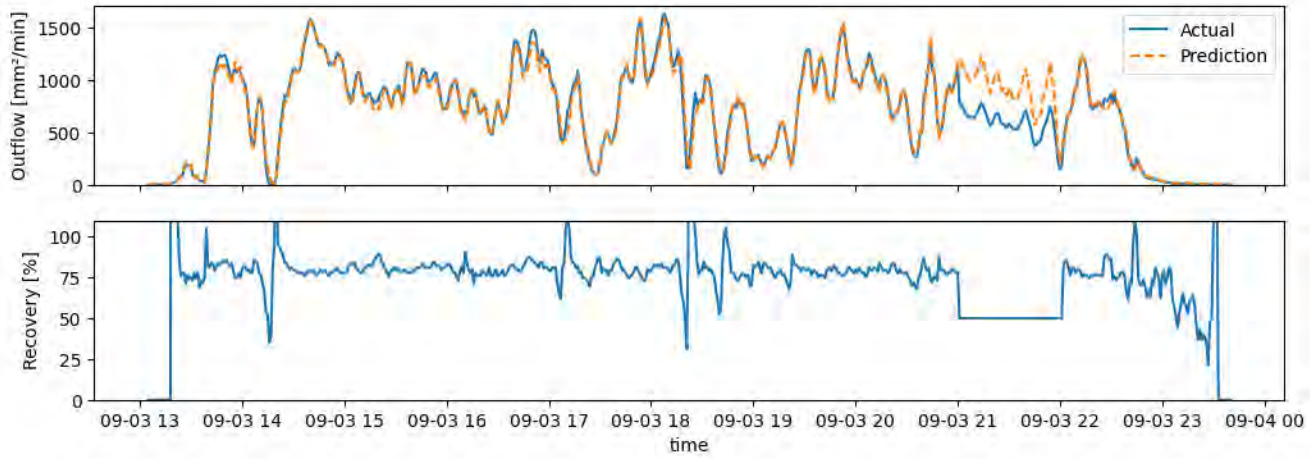

**Figure 5:** Material Outflow Profile on Disturbed System with Prediction Overlay (Top) and Percent Recovery of Targeted Material (Bottom).

- **No-code, automated platform**: Build and deploy accurate models with just a few clicks, as shown by the 99% accuracy.
- **Pre-configured settings**: Default parameters allow users with limited experience to achieve reliable results.
- **Flexibility for advanced users**: Offers customization for experienced users while remaining user-friendly for beginners.
- **Cost-effective, cloud-based solution**: Eliminates the need for expensive infrastructure, making AI accessible to SMEs.
- **Seamless integration**: Easily integrates with existing systems, enabling SMEs to apply AI without disrupting workflows.

By lowering the technical and financial barriers, ecoKI empowers SMEs to utilize their data to develop machine learning models that enhance operational efficiency, reduce downtime, and improve decision-making.

## CONCLUSION

This study successfully demonstrated the application of basic MLP and LSTM models to predict NIR separator output, achieving over 99% accuracy on the training data. The MLP model exhibited strong generalization by accurately predicting outcomes on a separate test dataset. The model's reliance solely on the targeted material feed flow made it effective in detecting instances of performance deterioration in the NIR separator.

The machine learning models were developed using ecoKI's built-in pipeline, building blocks, and default settings for most of the blocks, showcasing the platform's ability to transform raw measurement data into actionable insights without requiring programming expertise. This feature makes ecoKI an ideal solution for small and medium-sized enterprises (SMEs), as it removes the technical barriers to AI adoption and enables businesses to leverage machine learning for operational improvements. The no-code, automated approach, along with pre-configured settings, ensures that even users with limited machine learning experience can develop high-quality models.

While ecoKI proves highly effective for waste sorting applications, it is worth noting its limitations. The platform's model structure offers limited adjustability, which may restrict its use for significantly more complex or customized modeling needs. Nevertheless, ecoKI's approach has significant potential for expansion across various industrial contexts, positioning it as a valuable tool for SMEs seeking to harness machine learning for real-time performance prediction and process optimization.

In conclusion, ecoKI offers a powerful, user-friendly solution for leveraging machine learning to predict the performance of NIR separators in waste sorting plants. By enabling SMEs to tap into AI-driven insights without extensive technical expertise or costly infrastructure, ecoKI paves the way for smarter, more efficient decision-making and process improvement. Future work could explore its scalability and adaptability in diverse industrial settings, cementing ecoKI as a game-changer in the use of machine learning for operational performance prediction.

## ABSTRACT

To address the limitations of traditional sensing instrumentation in industrial processes, this work explores the use of industrial text data. Given that current instrumentation often fails to capture the full scope of process-related information, text data resulting from operation of industrial settings (for example: maintenance, inspection and incident reports) can provide valuable insights. This study focuses on accessing the effectiveness of natural language processing (NLP) techniques in retrieving critical information from industrial text data. To achieve this, the classification of Process Safety and Containment Events (PSCE) was used as case study. Overall, we found NLP methods are effective in information retrieval from industrial text data. However, the integration of the embeddings into machine learning (ML) approaches poses some challenges. The complexity of the information encoded in the embeddings makes them too disparate and unique samples of a larger domain, making challenging the training of a ML model.

**Keywords**: Industrial text data, natural language processing, data mining, chemical manufacturing industry, process safety and containment events.

## INTRODUCTION

In the context of chemical manufacturing industry, a wide range of sensor technologies and data collection methods are available to use. These tools serve to provide valuable insights into an array of critical aspects within the industrial process. They encompass the monitoring of physical and chemical phenomena occurring throughout the process, the status of equipment, prevailing process conditions, attributes related to raw materials and product quality, emissions data, logistic issues, and more [1]. This diversity in sensing instrumentation enables us to capture point measurements of essential parameters such as temperature, pressure, pH, and conductivity. Furthermore, it allows for the acquisition of richer data sources, including spectrum, images, vibrations, and sound profiles. Such comprehensive data gathering empowers us to gain a holistic understanding of the complex processes unfolding within the chemical manufacturing.

Despite the abundance of available instrumentation, this falls short in capturing the entirety of process-related information in industrial settings. Typically, sensors are strategically positioned to provide localized snapshots of a given process state, with the assumption that these snapshots are representative and informative of the operation and phenomena taking place. Furthermore, sensors are inherently designed to provide a single or a set of physical and chemical properties, such as a spectral reading of radiation passing through a sample, temperature measurements at a specific location, or reactor pressure data, among others. Moreover, the compensatory actions executed by control systems often effectively conceal process anomalies from sensor detection. Consequently, crucial details pertaining to process health, including issues such as leaks, corrosion, insulation degradation, and other unforeseen events, may remain concealed within the system, eluding their identification.

To address the limitations of existing instrumentation, it is imperative to explore alternative sources of information. One promising solution utilizes text data from inspection reports, incident/event logs, maintenance

records, work order and more that are typically present in industrial setting. These texts information typically encapsulates insights gained by operators, inspectors, or incident management officers (IMOs) during their responsible activities. For example, observations related to unusual noises or vibrations, signs of corrosion or equipment wear, incidents such as leaks, peculiar odors, ongoing maintenance or repair work orders, and activities undertaken on production lines or equipment, all contain valuable information about the production processes. Therefore, textual data analysis can provide valuable insights about current process health and safety monitoring system.

Existing NLP approaches for processing textual data can be broadly categorized into two main groups: context-free methods and context-based methods [2]. Context-free approaches, exemplified by techniques such as bag-of-words (BoW) and term frequency – inverse document frequency (TF-IDF), or machine learning approaches such Word2Vec, etc., primarily rely on word counting or representation without considering contextual relationships. These methods often result in sparse matrices, which can lead to zero-inflation problems. Additionally, frequency-based approaches are notably sensitive to misspellings. On the other hand, context-based NLP such as bidirectional encoder representations from transformers (BERT), generative pre-trained transformer (GPT) and Flair, employ advanced linguistic techniques to analyze and codify the context and semantics of a given text or document. These methods aim to capture the meaning and relationships between words, making them more robust in handling variations and nuances in language [3].

Context-based approaches are typically based on neural networks (NN) structures, often employing either a recurrent NN (RNN) or transformer architectures specifically trained for various text data processing tasks such as text summarization, text generation, topic identification, named entity recognition (NER), classification, etc. Among these tasks, embedding methods play a pivotal role in encoding text data in a limited set of numerical features. In context-based NLP approaches, embeddings are generated not just through counting frequency of the words; instead, they are calculated by weighting the words, so that the semantic meaning is preserved. This preservation of meaning ensures that the context in which words are used is retained, mitigating the risk of information loss. Furthermore, the context-based NLP models are more robust to misspellings. These factors present a significant advantage over frequency-based text processing methods.

One key drawback of these approaches is their substantial data requirements during the training phase. Typically, industrial datasets consist of only hundreds to thousands of observations per text dataset, spanning a time frame of approximately 4 to 5 years, representing the equipment or process life cycle. This limited data volume can indeed pose challenges in training highly effective NLP models. To address such limitation, pretrained models can be utilized. These models have been trained on extensive and diverse textual data from various sources, enabling them to capture broad language patterns and semantics. This training allows the models to exhibit a form of statistical inferred reasoning, effectively interpreting and processing complex text data [4].

Beyond the inherent methodological limitations observed from an NLP perspective in dealing with industrial data, there is a lack of studies within the existing literature that incorporate industrial text data, particularly in the chemical manufacturing domain. In the present study, the primary objective is to evaluate the effectiveness of NLP approaches for information retrieval from industrial text data. Specifically, our research is conducted in the context of predicting Process Safety and Containment Events (PSCE), a critical topic of concern in industrial operations.

The risk estimation of a PSCE has gained significance within the research community. Recent efforts [5] have aimed to predict unplanned events. Notably, the authors employed process data within a risk assessment and surveillance (RAS) framework to monitor the probability of unplanned shutdown events to take place in the near future, detecting high-risk situations ahead of time when there is still time to act and take countermeasures that may prevent their occurrence. However, it is essential to acknowledge that the information derived from process sensing instrumentation has inherent limitations in providing a comprehensive understanding of the process state and health, as discussed earlier in introduction. Therefore, the exploration of alternative sources of information such as available text data can potentially yield new insights for improving the prediction of PSCE, being that in system coverage, robustness or accuracy.

The remainder of this paper is structured as follows. The Data section offers a detailed information about both the simulated and industrial datasets used in this study. In the Methods section, we provide an overview of the data analysis pipeline, and the methods used. The Results section presents the main findings. The Final Remarks section draws some concluding observations.

## DATA

In this study, two distinct text datasets were used: one is a simulated text data generated from GPT model and the other sourced from an industrial process from one of the manufacturing sites owned by the Dow Chemical Company. Both datasets encompass a collection of incident management reports that document relevant events and their severity level.

## Simulated text data

Incident management reports simulated via the GPT-3.5 model resembles the type of information that can be found in an industrial data. Using carefully designed and crafted prompts, the GPT model was instructed to behave as an IMO who is responsible for writing perfect and complete reports about the incidents that may happen at a designated process. In the simulation, five levels of PSCE events were considered with level 1 being the most severe, such as an unplanned event, and level 5 being the least severe one, where neither the production process is jeopardized, nor any personal safety or environmental hazard is present (this is consistent with actual PSCE level categorization). Given such definitions of PSCE levels, the GPT-based IMO had to attribute a PSCE level to each reported incident. The resulting dataset has a total of 1429 simulated reports covering all kinds of PSCE levels from different units and areas of the process. To generate the simulated reports, ChatGPT was prompted with guidelines to use available data from standardization institutions such as American Petroleum Institute (API) and other relevant sources that might aid in assessing severity level of PSCE events.

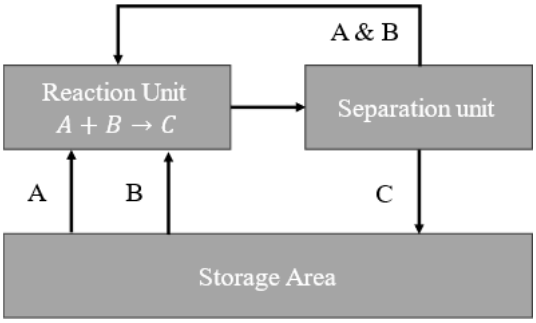

**Figure 1.** Flowchart of the process considered for the simulations of text data.

The process used for simulating the reports was also provided as part of the prompt. It can be described in a simplified version as follows: a system that produces chemical C from chemicals A and B, and consists of a reaction unit, separation unit, and storage areas. In the process, there is a recirculation of chemicals A and B that did not react back to the reactor unit. This process is also summarized in Figure 1. Further considerations are that the chemicals are highly flammable and toxic, Chemical A is in gaseous state, while B and C are liquids.

This dataset is used to establish the benchmark for incident management text data containing reports related to a simplified chemical process, with clear and complete description of the events. Additionally, it served as a proof of concept for the proposed data analysis pipeline.

## Industrial text data

The industrial text data consist of a set of incident management reports with corresponding PSCE levels from a Dow Chemical Company site. These reports contain information introduced by the local IMOs. Overall, these reports present similar characteristics as the simulated data, however, there are also disparities between the reports due to different IMOs, templates or formats used by the local plant. Additionally, these reports contain grammar and spelling errors, abbreviations and site-specific language, involves different writing styles, various functional aggregation levels, and are gathered from multiple processes at a specific site location. Often, incomplete information is available regarding a specific PSCE event. Therefore, it is much more difficult to use for analysis and modeling compared to the simulated reports. For confidentiality reasons no further details can be provided here, and the data were masked before being reported in this paper.

# METHODS

To extract information from textual data, we employed embedding models to convert text into numerical representations first. Then, the numerical embedding vector were used as inputs for a Random Forest (RF) classifier, which predicts the various levels of PSCE events. The following subsections provide an overview of the individual methodologies adopted and data analysis pipeline utilized in this study.

## Embedding Models

Embedding is a process of representing words, phrases, or entire documents as numerical vectors in a high-dimensional feature space. These numerical representations enable the capture of semantic and syntactic relationships between words. The most common embedding techniques are word embedding and document embedding. In this study, document embedding approaches were used. [6]

## Random Forest classifier

The Random Forest classifier is a supervised machine learning method that uses multiple decision trees to predict a class from input features. Each decision tree is constructed by selecting random subsets of the training data, which helps reduce overfitting and increases the model's generalization capabilities. To make a prediction of a class, the random forest algorithm aggregates the results from all the individual trees through majority voting. This ensemble approach improves the model's overall accuracy, stability, and resilience to noise and outliers. [7]

## Data analysis pipeline

One of the premises of the adopted approach is that an efficient information extraction will lead to a

satisfactory performance of the classification pipeline. Thus, the data analysis pipeline consists primarily of two integral stages: (i) information extraction and analysis (ii) classification of PSCE event levels. In the (i) information extraction stage, pretrained NLP models were used to extract pertinent features containing valuable information. Specifically, models from both an open-source python library "Sentence-Transformers" which makes use of BERT architecture [8], and a proprietary model from Azure OpenAI [9] were used. To facilitate effective visualization of the embedding space of the textual data, a dimensionality reduction method named unified manifold approximation and projection (UMAP), was used [10].

After the completion of the information extraction phase, the classification stage (ii) was performed, where the RF model was trained and evaluated, utilizing a total of 100 decision trees. To ensure a rigorous evaluation, our model was trained on 80% of the available data, with the remaining 20% reserved for performance assessment. This data split was executed in a pseudo-random fashion [11], thereby ensuring that both the training and testing subsets maintained a similar representation of the classes. To robustly gauge the model's performance, the model training procedure were repeated 30 times with each iteration having a different 80-20 split of the data set. The evaluation metric employed to assess model performance was the F1-score, as indicated in equation (1). In each iteration, the test and train subsets are the same across different information extraction method.

$$F_1 = 2\frac{precision \times recall}{precision + recall} = \frac{2TP}{2TP + FP + FN} \quad (1)$$

In Equation (1), TP stands for true positives, FP for false positives and FN for false negatives.

## RESULTS

In this section, the main results obtained from the simulated and industrial case studies are presented and discussed.

### Simulated case study

The embeddings for the simulated case study were obtained using the stsb-mpnet-base-v2 model from the Sentence-Transformers python library. UMAP was applied to visualize the simulated dataset, which contains a wide range of events described in the text, as well as different PSCE levels. Figures 2 clearly reflect these distributions. In Figure 2, a gradient of colors indicates that the embeddings effectively encoded relevant information about PSCE levels, although there is some overlap between the levels.

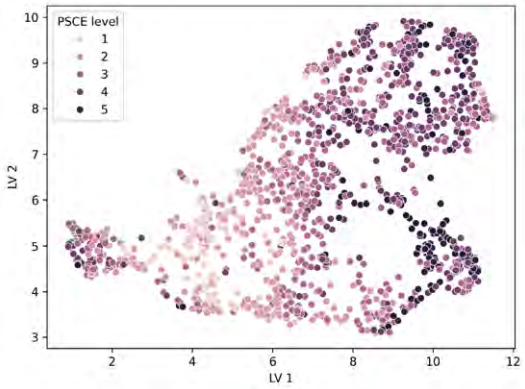

**Figure 2.** UMAP visualization of the Sentence-Transformer embeddings extracted from simulated text data, colored by PSCE Level.

In Table 1, the performance of the Random Forest (RF) model trained on the extracted embeddings is presented in terms of the F1 score. The F1 score is approximately 0.65 for both the training and testing sets. While this performance is not exceptionally high, it is consistent and indicates a low risk of overfitting. This stability suggests that the model is generalizing well to unseen data, even though there is room for improvement in its predictive accuracy.

**Table 1:** Median F1-score of data analysis pipeline applied to simulated case study.

| Training | Test |
|---|---|
| 0.644 | 0.656 |

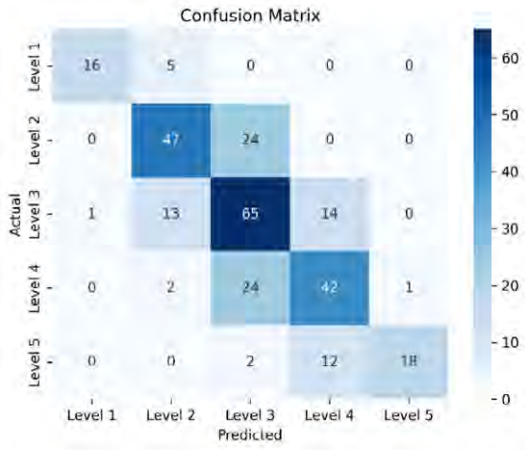

**Figure 3.** Confusion matrix between the actual and predicted PSCE levels, considering one of the testing run from simulated text data.

Upon closer examination of the approach's performance depicted in Figure 3, it becomes evident that the overlap predominantly occurs between adjacent PSCE levels, being consistent with the observations in Figure 2.

For level 1 and 2 PSCEs, the misclassification happens mostly to one level higher (level 2 and 3 respectively) while for level 4 and 5 PSCEs, it is the opposite, misclassification happens mostly to one level lower (level 3 and 4 respectively). For level 3 PSCEs, the misclassification is more balanced between level 2 and 4. Several factors might contribute to this overlap. Firstly, the definitions of the PSCE levels can be somewhat ambiguous near their boundaries. Secondly, the descriptions of events might sometimes be not completely clear or a bit vague. The presence or absence of minor details or the misinterpretation of information can lead to the misclassification of the adjacent PSCE level.

Overall, the results from this case study demonstrate the effectiveness of the proposed processing pipeline. The embeddings successfully encapsulate the relevant information, making them suitable for further data analysis and modeling task. Although the random forest model was not fully optimized, it still managed to classify PSCE levels reasonably well.

## Industrial case study

Applying a similar approach as in the simulated case study to the industrial data, we embedded the text data (using text-embedding-3-large embedding model from OpenAI, this time) and then applied the RF model. Figure 4 shows the UMAP transformation of these embeddings. Unlike the clear separation observed in the simulated case study, the event categories in the industrial data are highly overlapped, making it difficult to distinguish between them.

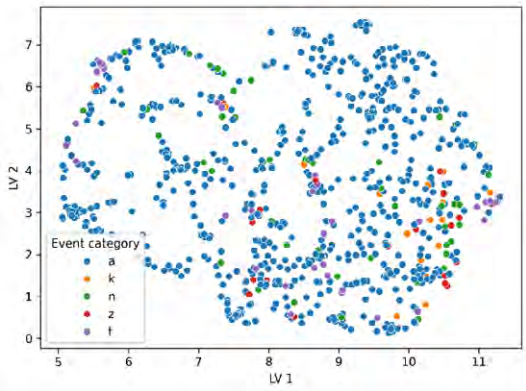

**Figure 4.** UMAP visualization of the Sentence-Transformer embeddings extracted from industrial text data, colored by event category (masked data).

The performance of the RF model is depicted in Table 2. The F1 score for this model stands at approximately 0.18, indicating a very low level of performance. Upon closer examination of Figure 5, it becomes evident that the model predominantly classifies the "a" category as the event category. Additionally, there is a significant imbalance among the classes.

**Table 2:** Median F1-score of data analysis pipeline applied to simulated case study.

| Training | Test |
|---|---|
| 0.182 | 0.179 |

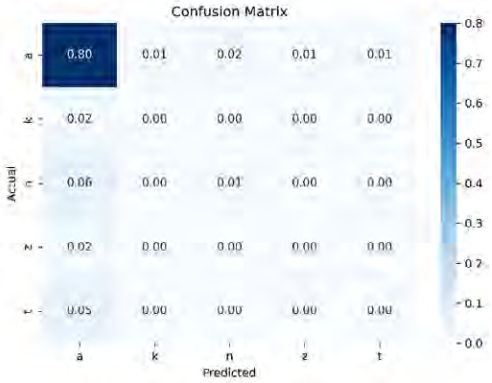

**Figure 5.** Confusion matrix between the actual and predicted event categories, considering one of the testing run of RF model from industrial text data.

**Figure 6.** Confusion matrix between the actual and predicted event categories, considering the LLM based approach and industrial text data.

The approach did not work for the industrial case study due to several contributing factors. Firstly, the complexity of the real-world data far exceeds that of the simulated case study, making it difficult to map the domain accurately (Figure 4). Secondly, the highly unbalanced classes make the classification task nearly impossible, even when we applied resampling. Additionally, the presence of site-specific terminology and potentially incomplete information about the PSCE levels adds additional layer of complexity to the samples.

To address the hypothesis that incomplete information, misspellings, and site-specific language might interfere with performance, a new approach was implemented. This approach involved using a carefully designed prompt in combination with a large language model (LLM), specifically GPT-4 [9], to classify events based on the text data available in the reports. This method proved to be quite effective, achieving an F1

score of approximately 0.78. It performed well across nearly all event categories, except for the "a" and "t" categories, which are closely related and easily confused with each other (see, Figure 6).

The machine learning approach was ineffective due to the complexity of the underlying processes in the generated text data. The considered text data lacked sufficient domain representation to train a high-quality model.

## FINAL REMARKS

In conclusion, we proposed a machine-learning based data analysis pipeline to predict PSCE event level based on text information on 2 different datasets. The proposed workflow works well on the simulated dataset, demonstrating the effectiveness of encoding key information using embedding models. However, the results on the other industrial dataset were not satisfactory. This suggests that the proposed framework was inefficient when the raw text data is originated from a more complex system and wide domain such as chemical manufacturing processes. In this case, the complexity of the underlying phenomena in the real-world case study, combined with low domain representativity and highly imbalanced data, are all possible reasons behind the poor performance. The carefully designed prompts and pre-trained large language models (LLMs) have proven successful on the industrial case study. The extensive training domain of LLMs enhances their capability to extract targeted information, thus retaining key information relevant for classifying PSCE levels. Thus, NLP approaches successfully codified and extracted information from industrial text data. However, integrating these embeddings into ML approaches can be challenging due to limited domain coverage, which is common in industrial text data related to unplanned events. As next steps, a data fusion [11]. approach will be used to integrate text data and process data for the prediction of PSCE.

## ABSTRACT

In an era defined by economic competitiveness and environmental awareness, engineering solutions must maximize profitability, efficiency and sustainability, underscoring the relevance of process optimization and the societal impact any contribution in this research field would bring. In chemical reactor engineering, optimization tasks pose significant challenges due to the highly nonlinear and non-convex nature of reactor models, often involving differential equations. While conventional approaches have proven to be reliable strategies for solving these complex problems, their application becomes impractical as problem size and complexity increase. This work introduces a novel application of Physics-Informed Neural Networks (PINNs) to address constrained optimization problems in reactor engineering and demonstrates the proposed methodology through two illustrative case studies in chemical reactor design and control. In doing so, we highlight the capability of PINNs to efficiently learn optimal reactor patterns and analyse the strengths and limitations of this novel methodology. These findings pave the way for broader adoption of PINN-based techniques in process engineering optimization.

**Keywords**: Constrained Optimization, Reaction Engineering, Machine Learning, Physics-Informed Neural Networks, Differential Equations

## INTRODUCTION

Optimization is crucial in all engineering fields for improving efficiency, reducing costs, and enhancing performance. Focusing on chemical reactor engineering, it helps maximize reaction yields, minimize energy consumption, and ensure safety and environmental compliance, making it essential for both economic and ecological progress.

Optimizing the design and operation of a chemical reactor not only involves achieving specific goals, but also satisfying a set of governing laws and operational constraints. Traditionally, the predominant approach to address these problems relied on mathematical programming, which applies techniques such as gradient descent or branch and bound strategies. Nonetheless, in recent years, genetic algorithms have gained traction as a viable alternative for optimizing complex systems [1]. More recently, reinforcement learning frameworks have emerged as a promising research area [2], particularly in uncertain environments [3]. In this work, we study the application of Physics Informed Neural Networks (PINNs) to solve reactor engineering problems.

PINNs have risen as a promising machine learning approach that integrates domain-specific knowledge, into the network training process [4]. In recent years, the utilization of PINNs has exploded due to its ability to predict complex phenomena when data is scarce or even unavailable, with applications spanning diverse fields, from fluid mechanics to biophysics [5]. Most of its applications involve solving differential equations, where the loss function is constructed from the residual of these equations [6]. Moreover, they have been successfully applied to inverse problems, where unknown parameters of the governing equations are inferred from partial observations [7]. Now the focus points towards extending the application of PINNs beyond simulation and parameter estimation by incorporating optimization objectives into the network training process [8, 9].

In this study, we explore the potential of PINNs in chemical reactor optimization, aiming to provide solutions that satisfy both the governing physical equations

and the desired constraints. This PINN-driven approach poses major challenges, including ensuring feasibility, achieving convergence to optimal solutions, and managing computational resources efficiently. Below, we introduce this novel optimization framework and illustrate its capabilities through two illustrative examples, where we discuss the aforementioned challenges.

## PROBLEM STATEMENT

Chemical reactor optimization aims to design and operate reactors that maximize efficiency, minimize costs or, more broadly, optimize a given objective function $f$, subject to physical laws $h$ and operational constraints $g$. In many cases, these governing equations are represented by ordinary differential equations (ODEs) that describe the evolution of state variables $y$, represented by derivatives $y' = {}^{dy}/_{dx}$. The independent variable $x$ represents a different physical magnitude depending on the case study (e.g., time or reactor length). Only Dirichlet boundary conditions are considered in this work.

A constrained optimization problem can be generally formulated as follows:

$$\begin{array}{lll} min & f(y,x) & \\ s.t., & h(y,y',x)=0 & x \in X \\ & y(x)=bc(x) & x \in \delta X \\ & g(y,x) \le 0 & x \in X \\ & y \in \mathbb{R}^n,\ X \in [x_0, x_F] & \end{array} \quad (1)$$

Solving reactor engineering instances of problem 1 is often challenging, due to the presence of non-linear and non-convex functions, together with stiff ODEs. Furthermore, the optimization problem is typically high-dimensional, characterized by complex interdependencies between decision variables and constraints, especially in large-scale industrial processes. In this context, this work proposes a novel PINN-based framework to assess such challenges.

## METHODOLOGY

The main idea behind using PINNs to solve optimization tasks is to reformulate the original constrained optimization problem into an unconstrained equivalent, whose objective function will ultimately constitute the loss function $\mathcal{L}$ used in the neural network training process to adjust weights $\theta$. Thereby, PINNs integrate physical knowledge by embedding governing equations directly into the neural network's loss function, together with optimization objectives. As derived from Eq. 2, the penalty method is applied to balance individual losses with coefficients $\omega$.

$$\mathcal{L} = \omega_p \mathcal{L}_p + \omega_{bc} \mathcal{L}_{bc} + \omega_{op} \mathcal{L}_{op} + \omega_{ob} \mathcal{L}_{ob} \quad (2)$$

As starting point, a neural network $\hat{y} = \mathcal{N}(x;\theta)$ generates predictions of the state variables $\hat{y}$ taking independent variables $x$ as inputs. Hence, this network works as "ansatz" for solving model equations $h(\hat{y}, \hat{y}', x)$ in problem 1. If needed, derivatives $\hat{y}'$ are computed efficiently and accurately using automatic differentiation.

Then, each term in Eq. 2 is evaluated independently to account for physical and operational constraint satisfaction, as well as for goal minimization.

To ensure network predictions comply with fundamental principles, the physics loss term $\mathcal{L}_p$ in Eq. (3) forces the neural network to satisfy model equations on a set of points $\mathcal{T}_p$ sampled within the domain of the input variables $X$.

$$\mathcal{L}_p(\theta;\mathcal{T}_p) = \frac{1}{|\mathcal{T}_p|} \sum_{x \in \mathcal{T}_p} \| h(\hat{y}, \hat{y}', x) \|_2^2 \quad (3)$$

The integration of the optimization objective in the global loss $\mathcal{L}$ depends on the case study. The definition of $\mathcal{L}_{ob}$ must therefore consider any necessary transformation of function $f(\hat{y}, x)$ to ensure convergence and a smooth training curve (e.g., scaling).

Operational constraints and boundary conditions can be enforced in Eq. 2 expressing the terms $\mathcal{L}_{bc}$ and $\mathcal{L}_{op}$ in the same way as Eq. 3, as shown in Eqs. 4 and 5 respectively. Note that the former guarantees boundary conditions are only satisfied at points $\mathcal{T}_{bc}$ located at the boundary $\delta X$.

$$\mathcal{L}_{bc}(\theta;\mathcal{T}_{bc}) = \frac{1}{|\mathcal{T}_{bc}|} \sum_{x \in \mathcal{T}_{bc}} \| \hat{y} - bc(x) \|_2^2 \quad (4)$$

$$\mathcal{L}_{op}(\theta;\mathcal{T}_p) = \frac{1}{|\mathcal{T}_p|} \sum_{x \in \mathcal{T}_p} \| g(\hat{y}, x) \|_2^2 \quad (5)$$

The preceding approach handles these constraints as "soft constraints" (i.e., the admissible degree of constraint violation is regulated via penalty coefficients $\omega_{bc}$ and $\omega_{op}$). However, they can also be imposed directly or as "hard constraints". In certain cases, operational constraints can be incorporated into the governing equations, as demonstrated in the following section. Alternatively, Dirichlet boundary constraints can be exactly satisfied by modifying the network output, as shown in Eq. 6, following the approach proposed by Lu et al. [10].

$$\hat{y}(x;\theta) = bc(x) + \ell(x)\mathcal{N}(x;\theta) \quad (6)$$

where $\mathcal{N}$ is the network output and $\ell$ is any function satisfying the conditions in Eq. 7.

$$\begin{cases} \ell(x) = 0, & x \in \delta X \\ \ell(x) > 0, & x \in X - \delta X \end{cases} \quad (7)$$

## RESULTS

The proposed methodology is applied to two illustrative examples of reactor engineering by using the library DeepXDE [11]. For comparison purposes, the original optimization models were written in Pyomo and solved applying conventional optimization methods.

## Case Study 1: PFR length optimization

### Problem setup

We first consider the case of cumene production in an isothermal PFR under the elementary reaction $C_3H_6 + C_6H_6 \rightarrow C_9H_{12}$, whose reaction enthalpy is $\Delta H = 9.95 \cdot 10^4\ J/mol$. Arrhenius law is used to calculate reaction rate $r$ as shown in Eq. 8, where $T$ and $n_j$ refer to the temperature and molar flow, respectively, and $\alpha_j$ denotes the stoichiometric coefficient of each species $j$.

$$r_j = \alpha_j r = \alpha_j\, 3500 \exp\left(\frac{-56000}{T}\right) \frac{n_P n_B}{(n_P + n_B + n_c)^2} \tag{8}$$

Aiming to minimize capital and operational costs, the goal is to determine the optimal length $L^*$ required to achieve the desired propene conversion $X_P^* = 0.89$, and the heat flux $Q$ to be removed. The tube cross sectional area is set to $S = \frac{\pi}{4} 1.5^2\ \mathrm{m}^2$ and the feed stream consists of $F^{in} = 324.1\ \mathrm{mol/h}$ at $222°\mathrm{C}$ of a mixture of propene and benzene with mole fractions $x^{in} = [0.659, 0.341, 0]$. The corresponding mass and energy balances are given in Eq. 9. It is worth clarifying that $L^*$ is a trainable variable, while $l$ represents the scaled length $l = L/L^* \in [0,1]$.

$$\frac{dn_j}{dl} = L^* S \alpha_j r \quad \forall\, j \in \{P, B, C\}\ ;\ \frac{dT}{dl} = L^* \frac{dQ/dl - Sr\Delta H}{\sum_j n_j C_{p,j}} \tag{9}$$

### PINN-based optimization

We used a fully connected neural network to predict $\hat{X}_P$ and $\hat{Q}$ taking $l$ as input. The proposed optimization is formulated as a PINN training problem as follows:

$$\mathcal{L} = 10\mathcal{L}_{p1} + \mathcal{L}_{p2} + \mathcal{L}_{bc} + 10\mathcal{L}_{op} + 10^{-4}\mathcal{L}_{ob} \tag{10}$$

$$\mathcal{L}_{ob} = L^* = S n_A^{in} \int_0^1 \frac{1}{r} dl \tag{11}$$

$$\mathcal{L}_{p1} = \sum_{l \in \mathcal{T}_p} \sum_j \left(\frac{d\hat{n}_j}{dl} - \frac{dn_j}{dl}\right)^2 \tag{12}$$

$$\mathcal{L}_{p2} = \sum_{l \in \mathcal{T}_p} \left(\frac{d\hat{Q}_j}{dl} - \frac{dQ}{dl}\right)^2 \tag{13}$$

$$\mathcal{L}_{op} = \hat{X}_P(l=1) - X_P^* \tag{14}$$

$$\mathcal{L}_{bc} = \hat{Q}(l=1) - 0 \tag{15}$$

$$\hat{X}_P = 0 + \mathcal{N}(l;\theta)^T [1 - e^{-l}, 0] \tag{16}$$

While Eqs. 11-15 constitute each one of the terms in Eq. 10, Eq. 16 implies that the initial condition for the first predicted variable (i.e., $\hat{X}_P$) is enforced as a "hard constraint". The coefficients in Eq. 10 were adjusted to achieve a smooth learning curve, which serves as an indicator of a good fit.

### Results

A single-layered neural network with 5 neurons was sufficient to obtain accurate predictions. ODEs were evaluated on a set $\mathcal{T}_p$ containing $100$ samples and Adam optimizer was applied at a learning rate of $10^{-3}$ for $18100$ epochs until the global loss $\mathcal{L}$ dropped below the predefined tolerance of $10^{-5}$. As illustrated in **Figure 1**, the predictive performance stagnates from a certain number of training points. This observation indicates that the selected number of samples is optimal to fully exploit the capacity of the proposed architecture.

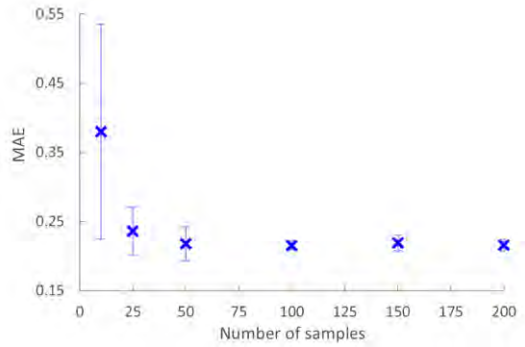

**Figure 1:** Average MAE in prediction of runs with varying number of training points

The output of the PINN was compared to the conventional solution. The latter was obtained by applying orthogonal collocation to discretize the ODEs using the Pyomo DAE extension [12]. The resulting NLP was solved using CONOPT as optimization algorithm.

The results shown in **Figure 2** and **Figure 3** demonstrate that the network accurately replicates reactor dynamics. This observation is further supported by calculating the mean absolute error (MAE) between the network predictions and the Pyomo solution, as reported in **Table 1**, which indicates that the difference is negligible. Both methods also converge to similar reactor length values: $6.34\ \mathrm{m}$ for the PINN solution and $6.38\ \mathrm{m}$ for the Pyomo solution.

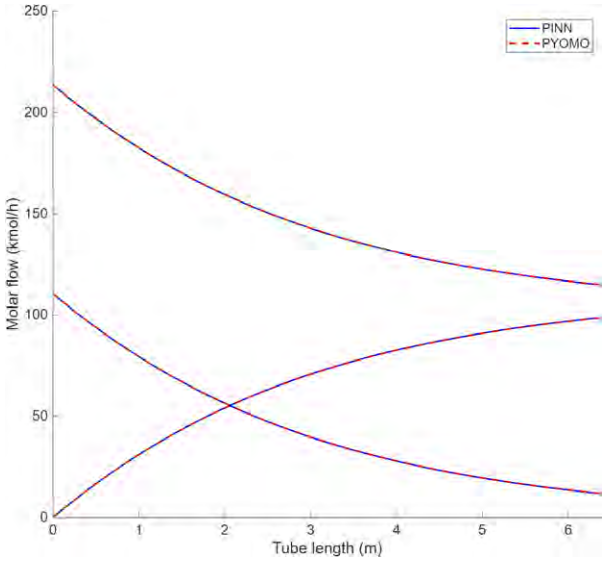

**Figure 2:** Molar profiles in the PFR.

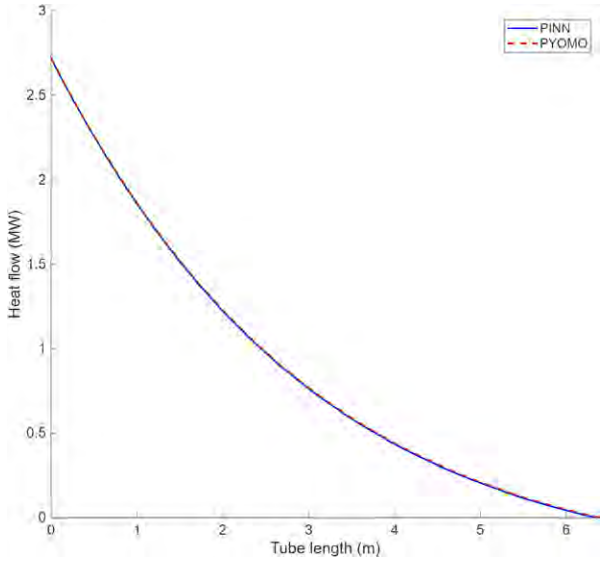

**Figure 3:** Heat flow profile in the PFR.

**Table 1:** Deviation between PINN and Pyomo solutions.

| Compared variable | MAE | Units |
|---|---|---|
| Molar flow | 0,22 | kmol $h^{-1}$ |
| Heat flow | $2{,}24 \cdot 10^{-3}$ | MW |

## Case Study 2: Locus of maximum rates

### Problem setup

Next, the focus is on a batch reactor in which the reversible exothermic reaction $A \leftrightharpoons B$ occurs. For this particular type of reaction, the time required to reach the target conversion $X_A$ can be minimised through precise temperature control ensuring that the reactor consistently operates at the maximum possible reaction rate. This is equivalent to minimising the rate of consumption of species $A$ (i.e., $r_A$), as given by Eq. 17, for each value of $X_A$ through temperature adjustment.

$$r_A = -1{,}79 \cdot 10^5 \, e^{\frac{-1200}{T}} C_A + 1{,}17 \cdot 10^{13} \, e^{\frac{-2400}{T}} \, C_B \qquad (17)$$

The reactor is fed with a solution of pure $A$ in concentration $C_A^0 = 1\ kmol/m^3$ and the temperature cannot exceed $500°C$.

Conventionally, such problems are addressed sequentially: first, by determining the locus of maximum rates $r_A^{max}(X_A)$, and then by numerically solving the integral in Eq. 18. The reader is referred to [13] for further details on the solution procedure.

$$t_{rxn} = C_A^0 \int_0^{X_A^*} \frac{dX_A}{r_A^{max}(X_A)} \qquad (18)$$

### PINN-based optimization

The optimal temperature path following the locus of maximum rates is estimated using a PINN that takes $X_A$ as input and outputs both the temperature $\hat{T}$ that yields the fastest rate of consumption of $A$, and the corresponding value of the latter, $\hat{r}$. A parallel fully connected neural network (PFNN) architecture was preferred to construct an independent network for each output.

The physics-informed loss function used during the PINN training process, as defined in Eq. 19, is composed of the individual loss terms defined in Eqs. 20-22.

$$\mathcal{L} = \omega_{p1}\mathcal{L}_{p1} + \omega_{p2}\mathcal{L}_{p2} + \omega_{ob}\mathcal{L}_{ob} \qquad (19)$$

$$\mathcal{L}_{ob} = \sum_{X_A \in \mathcal{T}_p} \hat{r}_A(X_A) \qquad (20)$$

$$\mathcal{L}_{p1} = \sum_{X_A \in \mathcal{T}_p} \left\| \ln\left(1 - \hat{r}_A(X_A)\right) - \ln\left(1 + r_A(X_A)\right) \right\|_2^2 \qquad (21)$$

$$\mathcal{L}_{p2} = \sum_{X_A \in \mathcal{T}_p} \hat{r}_A(X_A)^2 \cdot 1_{\{\hat{r}_A(X_A) > 0\}} \qquad (22)$$

Unlike the previous example, operational constraints (i.e., temperature bounds) are enforced neither as "soft" nor "hard" constraints, but directly integrating them into Eq. (17) by expressing temperature as:

$$T = T^L + (T^U - T^L)\hat{T} \qquad (23)$$

where $T^L$ and $T^U$ represent feasible temperature bounds and $\hat{T}$ is the scaled temperature, which is the actual prediction of the neural network.

To ensure constraint satisfaction and overcome the risk of ill-conditioned problem when weights in Eq. 19 are large, coefficients $\omega$ were iteratively increased during training following the penalty method [14]. Similarly, residual-based adaptive refinement (RAR) [11] proved an effective technique to improve accuracy by recursively adding sample points in regions where $\mathcal{L}_{p1}$was higher.

### Results

The selected network configuration consists of 3 hidden layers with 10 neurons each for each independent network (i.e., for each output). The penalty method combined with RAR approach was employed during training, using a minimum tolerance of $10^{-5}$ as stopping criterion. At each iteration, Adam optimizer was applied for a maximum of $5000$ epochs at a learning rate of $10^{-3}$, followed by L-BFGS until convergence. The overall training process required $27268$ epochs and $7500$ sample points to evaluate the rate of reaction. The initial training set contained $5000$ samples, and its size was determined following the criteria introduced in the previous case study. The remaining points were subsequently added as a result of RAR algorithm execution.

As in the previous example, the original NLP was solved using the solver CONOPT. Again, the comparison of both solutions shown in **Figure 4** highlights how the PINN-approach effectively reproduces the locus of maximum reaction rates. A quantitative assessment of the error between the conventional and PINN solution is presented in **Table 2**. From this analysis, it is worth noting that the reaction rate computed with Eq. 17 using the optimal temperature predicted by the network, $r(X, \hat{T})$, is

closer to the conventional solution $r(X,T)$ than the actual prediction of the network $\hat{r}$. The presence of large differences of magnitude among the predicted values of the reaction rate might explain the network's difficulties in predicting $\hat{r}$, especially when conversion is close to the target value, since the maximum reaction rate approaches zero in that region. This issue becomes particularly relevant in the evaluation of the reaction time. As **Table 3** illustrates, both methods provide similar estimates for the time required to achieve 50% conversion. However, when considering the entire conversion range, the PINN approach predicts a longer reaction time than the orthogonal collocation-based method. This discrepancy arises because the network slightly underestimates $r_A$ at higher values of $X_A$, and this prediction error is propagated and amplified in the calculation of $t_{rxn}$, as it involves the inverse of the reaction rate.

**Table 2:** Deviation between PINN and conventional solutions for the batch reactor case study.

| Compared variables | MAE | Units |
|---|---|---|
| Temperature | $3{,}46 \cdot 10^{-2}$ | °C |
| $\hat{r}$ and $r(X,T)$ | $5{,}76 \cdot 10^{-4}$ | kmol m$^{-3}$ min$^{-1}$ |
| $r(X,\hat{T})$ and $r(X,T)$ | $1{,}80 \cdot 10^{-7}$ | kmol m$^{-3}$ min$^{-1}$ |

**Table 3:** Comparison of optimal reaction time from PINN and conventional solutions.

| | Pyomo | PINN |
|---|---|---|
| $t_{rxn}$ (h) | 58,6 | 68,4 |
| $t(X_A = 0{,}5 \cdot X_A^*)$ (h) | 3,72 | 3,88 |

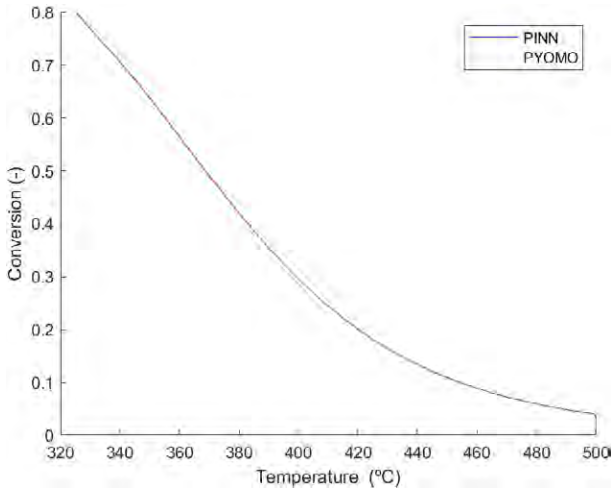

**Figure 4:** Conversion vs. temperature chart following optimal temperature path.

## DISCUSSION

The case studies presented in the previous section proved PINNs are capable of learning the underlying physics of both systems in an unsupervised setting. Moreover, this novel optimization approach provides solutions comparable to those obtained using conventional optimization methods, with the main source of discrepancy arising from the prediction error inherent in neural networks. Given sufficient computational resources, such error can be mitigated by increasing network complexity and decreasing the tolerance threshold.

A key challenge of this methodology lies in the definition of the loss function. Specifically, the individual losses must be carefully formulated to facilitate the learning process and accordingly scaled to prevent significant differences in the order of magnitude among the terms being aggregated. Additionally, the values of the penalty coefficients have a significant impact on the solution, creating a trade-off between the satisfaction of constraints or physical laws and conditioning issues. However, in our numerical examples, we showed how PINN-based optimization can be effectively combined with techniques such as the penalty method and RAR that promote convergence to high-quality solutions.

Due to the non-linear, non-convex nature of this optimization approach, guaranteeing optimality remains challenging when no benchmark solution is available. Nevertheless, the potential of this technique can be significantly enhanced in scenarios where model equations are not perfectly known, but some experimental data is available. This opens promising avenues for future research, where PINNs could be trained to solve optimization problems in a semi-supervised learning setting while also addressing larger-scale problems.

## CONCLUSION

This study delves into the use of physics-informed neural networks (PINNs) for solving chemical reactor optimization problems, demonstrating their potential and underscoring the importance of further research. By integrating governing equations, boundary conditions, and optimization objectives into a single loss function, PINNs provide solutions that are both physically consistent and goal-oriented. The methodology was validated through illustrative case studies, demonstrating its ability to produce results comparable to those of conventional optimization techniques while addressing the inherent challenges posed by non-linearities and non-convexities.

In addition, we employed techniques to enhance training efficiency, including residual-based adaptive refinement (RAR) and the penalty method for enforcing constraint satisfaction. These approaches proved particularly effective for solving more complex instances.

The findings highlight PINNs' flexibility, especially in scenarios where data is scarce or mechanistic models fall short of capturing the system's behavior, paving the way for their application in semi-supervised settings. However, challenges remain in formulating and scaling loss

functions, setting penalty coefficients, and guaranteeing global optimality. Future research should focus on refining these aspects and expanding the framework to tackle larger-scale industrial problems.

PINN-based optimization stands as a promising avenue for advancing chemical reactor engineering, providing a novel approach that bridges data-driven learning and physics-based modeling.

## ABSTRACT

As large language models have shown remarkable capabilities in conversing via natural language, the question arises in which way LLMs could potentially assist chemical engineers in research and industry with domain-specific tasks. We generate dynamic chemical reactor models in Modelica code format from textual descriptions as user input. We fine-tune Llama 3.1 8B Instruct on synthetically generated Modelica code for different reactor scenarios. We compare the performance of our fine-tuned model to the baseline Llama 3.1 8B Instruct model as well as GPT4o. We manually assess the models' predictions regarding the syntactic and semantic accuracy of the generated dynamic models. We find that considerable improvements are achieved by the fine-tuned model with respect to both the semantic and the syntactic accuracy of the Modelica models. However, the fine-tuned model lacks a satisfactory ability to generalize to unseen scenarios compared to GPT4o.

**Keywords**: Text2Model, Large language models, supervised fine-tuning

## 1 INTRODUCTION

Domain-specific languages for interacting with software tools or for data analysis require scientists and engineers to study the conventions and syntax of such languages [1]. While software-user communication may often rely on a graphical user interface, such as AspenPlus or COMSOL, other tools require users to provide specialized code, e.g., MATLAB Simulink or Dymola. In addition to established programming languages for data analysis and visualization, such as Python or R, studying and applying a multitude of different domain-specific languages can be time- and labor-intensive.

Recent developments in using large language models (LLMs), particularly for code completion, code synthesis [2], and code analysis and interpretation [3] make such LLMs promising assistants for using tools such as modeling environments by converting textual information into domain-specific languages [1]. State-of-the-art multilingual open models for code generation or understanding, such as CodeT5+ [3], are literate in a range of programming languages in addition to natural language. Still, there are domain-specific languages in which pre-trained LLMs might not be proficient yet. The ability of state-of-the-art LLMs to converse in a variety of programming languages motivates leveraging LLMs for the synthesis of domain-specific languages analogously.

While there have been propositions that task-specific performance can be increased by few-shot learning [4], fine-tuning is an established approach to tailor LLMs' responses to specific tasks [5], especially for code synthesis [2]. Previous work by Jacobs and Pollice has shown that it is possible to fine-tune GPT 3.5 to generate input files to ORCA, a programming package specific to the quantum chemistry domain [1]. However, there is a lack of literature that investigates the potential of LLMs to generate dynamic models for chemical reaction systems from descriptions in natural language.

We investigate how fine-tuning an open-source pre-trained LLM on dynamic reactor scenarios written in the domain-specific programming language Modelica affects the semantic and syntactic accuracy of such Modelica models generated by the fine-tuned model. We fine-tune Llama 3.1 8B Instruct to synthesize a full, simulatable

Modelica model based on a textual description of a reactor scenario in the user's prompt. The fine-tuning dataset is generated synthetically from a set of templates of dynamic reactor scenarios. The supervised fine-tuning procedure is conducted using low-rank adaptation [6] as a parameter-efficient fine-tuning technique. We evaluate the results manually on samples randomly generated from the templated scenarios and on cases unseen during training. We compare the results of the fine-tuned model against the baseline Llama 3.1 8B Instruct and GPT4o.

## 2 METHODS

We develop (1) a methodology for the synthetic generation of the fine-tuning dataset (Section 2.1), (2) a supervised fine-tuning procedure (Section 2.2), (3) an evaluation procedure (Section 2.3), and (4) a set of evaluation metrics to assess the investigated models (Section 2.4).

### 2.1 Data generation

The synthetic data used for training and evaluation consists of question-and-answer (Q&A) pairs; the user provides a textual description of a dynamic tank reactor scenario in the question and an LLM is trained to provides a corresponding Modelica script as an answer. The training dataset is synthetically generated from templates of Q&A pairs. The question contains a textual description of a reactor scenario in LaTeX syntax and the corresponding reference answer is a model in Modelica code presented as a string object. To provide further explanatory context, each line of Modelica code in the reference answers is appended with a descriptive comment of the defined parameter, the declared variable, or the expressed physics equation.

The reactor scenarios are designed to convey knowledge about modeling heuristics by independently varying the (a) mode of operation, (b) the reaction taking place, and (c) switching between ODE and DAE systems by removing the constant mixture density assumption. The mode of operations (a) are adiabatic isothermal, non-adiabatic isothermal, isothermal non-adiabatic, non-isothermal non-adiabatic. For ODE systems (constant-density assumption), all four modes of operation are considered; for DAE systems, only the non-adiabatic non-isothermal mode is modeled. For the ODE scenarios, six reaction scenarios (b) are considered per mode of operation: Reversible and irreversible reactions between two, three, and four components, e.g., $\nu_A A + \nu_E E \rightarrow \nu_B B + \nu_C C$, or $\nu_A A \leftrightarrow \nu_B B + \nu_C C$. This yields 24 ODE scenarios in total by combining the variations of (a) and (b). For the single mode of operation (a) considered for DAE systems, two reaction scenarios are modeled: reversible and irreversible four-component reactions. This yields two DAE scenarios and thus 26 templated in total. Note that the stoichiometric numbers are assigned randomly for each template.

For each template, we randomly vary the units of measurement of given parameter values in the input question. The objective is to inspect whether it is attainable to perform direct conversions between non-SI and SI units with zero-shot LLM inference. Though Modelica provides conversion commands, such as from degree Celsius to degree Kelvin and vice versa, variables given in caloric energy units, for instance, must be converted to SI units manually.

We generate 988 Q&A data points of which 790 are used for training and 198 are used for evaluation during training. Each of the 26 synthetic data templates is thus repeated 38 times with arbitrary values of given parameters. The parameter values are real numbers sampled from the range $[10^{-4}, 10^{5}]$ except for stoichiometric numbers, which are integer values between 1 and 15.

### 2.2 Fine-tuning procedure

To enhance model performance in Modelica code generation, we fine-tune an existing LLM to adapt its model weights to better capture the nuances of this specific task. We use the model weights of the baseline Llama 3.1 8B Instruct model from Hugging Face [7].

The results presented in this work are obtained from fine-tuning using an NVIDIA A100 80GB GPU with a batch size of one and a maximum sequence length of 2200 tokens. For tokenization, we re-use the same fast byte-pair-encoding tokenizer as the baseline Llama 3.1 8B Instruct model. We train Llama 3.1 8B Instruct for eight epochs but evaluate the model obtained after four training epochs as indications of overfitting are observed after four epochs. We use linear learning rate scheduling with an initial learning rate of 0.0001. We apply a warmup ratio of 0.1, i.e., the initial learning rate of 0.0001 is reached after 632 steps.

We perform parameter-efficient finetuning by using the low-rank adaptation (LoRA) technique introduced by Hu et al. [6]. We use a rank of eight and scale the accumulated gradient updates that are added to the frozen model weights by a factor of two. We thus effectively update 0.26 % of the trainable 8.03 billion parameters. We do not apply quantization as initial studies have indicated shortcomings likely related to using quantization of model weights.

### 2.3 Evaluation procedure

With the evaluation procedure presented hereafter, we aim to evaluate the effect of the fine-tuning. We evaluate the fine-tuned model, the baseline Llama 3.1 8B Instruct, and GPT4o on two evaluation datasets: The first dataset (1) tests whether the cases presented during training can be reproduced (Section 3.1: Examination of

reproducibility of training scenarios); the second dataset (2) checks whether it is possible to extrapolate to reactor scenarios unseen during training (Section 3.2: Examination of generalization ability).

The first test dataset (1) (Section 3.1) contains entries that are randomly generated from each of the templates used for training with different parameter and variable values. This yields 26 samples in total. The second test dataset (2) (Section 3.2) includes four test cases: (a) a consecutive reaction, (b) two parallel reactions, and (c) a non-constant density system with five reaction participants (the reaction scenarios during training contain four components at the most). In the fourth case (d), we deliberately exclude parameter values that are necessary to fully specify the system. This is to investigate whether the missing parameter values are hallucinated in the models' responses or whether such user-generated errors are detected and addressed in the models' responses.

We perform inference on the baseline Llama 3.1 8B Instruct and the fine-tuned model using the same inference settings each. As a decoding strategy, we apply beam search with multinomial sampling using three beams and a temperature of 0.1. The maximum amount of tokens generated is limited to 4000. Inference is performed on the same machine as for fine-tuning, NVIDIA A100 80GB.

## 2.4 Evaluation metrics

We devise a customized set of evaluation metrics to quantify model performance. We manually evaluate each response given by an LLM (fine-tuned, baseline, GPT4o) by counting the number of occurrences of eight pre-defined error cases. These eight error cases are examining general syntax errors, parameter and variable declaration errors, and errors in the system of equations. A detailed description of the eight error cases is provided below. A simplified example of a user prompt and a potential response by an LLM with errors is displayed in Figure 1. The Modelica code given in the response in Figure 1 contains illustrative examples of seven of the eight error cases that are taken into account in this study.

For parameter and variable declaration errors, we distinguish between four subcases: unit conversion errors (1), declaration syntax errors (2), incorrect parameter values (3), and the usage of undefined variables (4). Errors in the equations section of the produced Modelica model are classified into incorrect equations (5), structural errors in the system of equations (6), and unit conflicts (7). General syntax errors (8) capture errors in the syntax of the model that would lead to compilation errors in the Dymola environment.

Unit conversion errors (1) arise from incorrect attempts to convert to SI units of measurement in cases where values given in the user's prompt are provided in non-SI units. Declaration syntax errors (2) are assigned in cases where Modelica syntax is not respected for

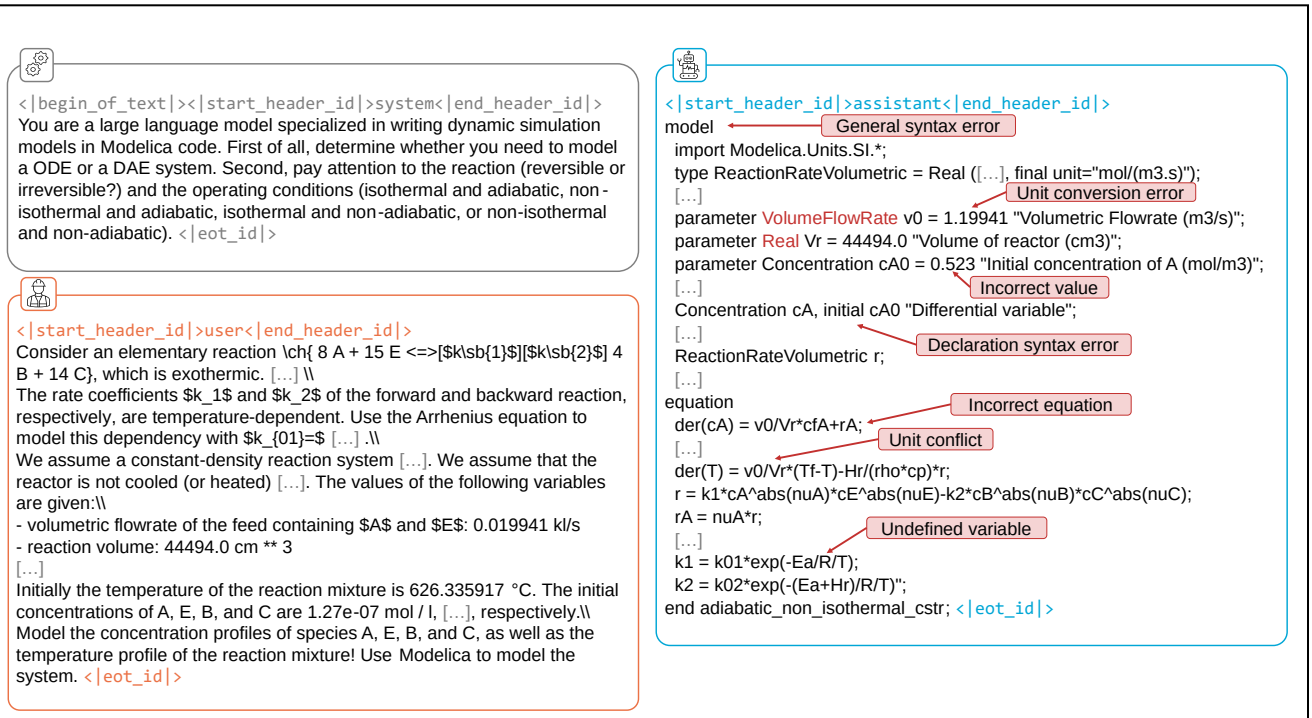

**Figure 1:** System message (top left), example user input (bottom left), and corresponding exemplary response (right). The example input and output are shortened for simplification. The output contains examples of six error cases that are taken into account in this study.

parameter and variable declarations, e.g., in Figure 1, the initial value of cA0 is assigned with the word 'initial', instead of the Modelica convention 'Concentration cA(start=cA0)'. Incorrect parameter values (3) originate from incorrectly transferred values given in the user's question to the output Modelica model. This error category does not punish unit conversion errors, but examines purely fabricated values. Undefined variable errors (4) arise in cases where variables or parameters are used in the equations part of the Modelica model that have not been declared or defined before. Incorrect equations (5) are either physically incorrect or do not respect the constraints given in the users' question, e.g., modeling an adiabatic system although the user requested a non-adiabatic system. Structural errors in the system of equations (6) arise if the defined system of equations is structurally singular, i.e., the defined equations do not allow to determine all of the unknowns. Unit conflicts within the system of equations (7) occur when variables are defined in non-equivalent units of measurement, e.g., using Joules and Calories in the same equation, which do not cancel out. The result is that the lefthand-side value is distorted by an unknown unit conversion factor.

## 3 RESULTS AND DISCUSSION

We examine the results obtained for the two test datasets described in Section 2.3 separately (Section 3.1 and 3.2). In Section 3.1 we present the results for the first test dataset and examine the fine-tuned model's ability to reproduce the reactor scenarios presented during training. In Section 3.2, we asses the second test dataset and inspect the fine-tuned model's ability to extrapolate to reactor scenarios unseen during fine-tuning. We evaluate the fine-tuned Llama 3.1 8B model, the baseline Llama 3.1 8B model before fine-tuning, and GPT4o. For both test datasets, we use the same eight error cases described in Section 2.4 to assess the performance of all three models.

We observe that overall, considerable improvements are achieved by the fine-tuned model compared to the baseline Llama 3.1 8B Instruct for reactor scenarios seen during training (Section 3.1) as well as case studies containing elements unseen during training (Section 3.2). GPT4o shows remarkable performance of Modelica code generation and outperforms the fine-tuned model in cases unseen during training.

### 3.1 Examination of reproducibility of training scenarios

Compared to the baseline Llama 3.1 8B Instruct model, we observe that fine-tuning has a direct influence on both the syntactical correctness of the produced Modelica model and the accuracy of the physics equations. Table 1 presents the absolute number of occurrences per error category (see Section 2.4) for each examined model.

The most prominent error categories of the baseline model are general syntax errors, unit conversion errors in parameter definitions, declaration syntax errors, and incorrect physical equations. On these four error categories, the fine-tuned model yields considerably fewer error cases: General syntax errors are reduced by 73.2 % in the case of the fine-tuned model compared to the baseline model. Unit conversion errors are reduced by 63.4 %, and declaration syntax errors are reduced to zero. In the error category of incorrect equations, the error cases produced by the fine-tuned model are reduced by 65.2 % compared to the baseline model.

The fine-tuned model excels at handling unit conversions from non-SI units in the user's prompt in this first evaluation test set. The responses given by GPT4o contain conversion factors to transparently transform

**Table 1:** Absolute amount of occurrences per error category per model. The test dataset comprises one randomly generated example for each of the 26 reactor scenario templates used for fine-tuning. The baseline model (Llama 3.1 8B Instruct) is fine-tuned and assessed on the same test dataset. GPT4o is assessed on the same test dataset as a benchmark.

| | Parameter and variable declarations | | | | Physics equations | | | General syntax |
|---|---|---|---|---|---|---|---|---|
| | Unit error | Declaration syntax error | Incorrect values | Undefined variables | Incorrect equations | Structural error | Unit conflict | |
| Baseline (Llama 3.1 8B) | 112 | 89 | **0** | 4 | 112 | 6 | 14 | 56 |
| Fine-tuned (Llama 3.1 8B) | **41** | **0** | 17 | 29 | **39** | 14 | **0** | 15 |
| GPT4o | 50 | 27 | 1 | **0** | 42 | **2** | 63 | **4** |

between units while the fine-tuned model is trained towards directly converting between non-SI and SI units if needed. However, the manual unit conversion in GPT4o's responses is not done consistently in 63 cases such that unit conflicts occur in the system of equations. In total, 113 combined error cases are produced by GPT4o in the context of unit conversion for parameter declaration and unit compatibility errors in equations compared to 41 in the case of the fine-tuned model, which is a reduction of 63.7 %. The baseline Llama 3.1 8B Instruct model shows the highest number of error cases in the category unit conversion errors as, in contrast to GPT4o, unit conversions are done less systematically and are thus more error-prone. It should be considered to specifically instruct GPT4o and Llama 3.1 8B Instruct to convert to SI units directly in the system message provided during inference. The decrease of such unit conversion errors in the fine-tuned model gives rise to the assumption that it is reasonable to expect direct unit conversions, however, the fine-tuned model's robustness could benefit from training toward the usage of manual conversion factors instead of direct conversion.

Most notably, the fine-tuned model consistently uses Modelica's built-in variable types, such as Concentration and Density, whereas most of the baseline and GPT4o's responses define parameters and variables as generic Real types. Using generic Real types for parameter definition and variable declarations does not leverage unit checks provided by the Dymola software when attempting to simulate a Modelica model.

Despite the improvements with respect to the physical accuracy of the fine-tuned model, we observe strong shortcomings in the reproducibility of DAE systems. The vast majority of incorrect physics equations produced by the fine-tuned model, 32 out of 39, occur in the two examples requesting DAE systems instead of ODE systems. In the case of the baseline model and GPT4o, physics errors related to DAE systems occur significantly less often with eleven out of 112, and eleven out of 42, respectively. Furthermore, 13 out of 14 structural errors in the system of equations counted in the case of the fine-tuned model occur in the DAE test cases. As merely two of the 26 templated scenarios presented in the training data for fine-tuning contain DAE systems, the decreased performance in the cases of DAE systems during inference could be attributable to this imbalance in the training data. This assumption is supported by the observation that for ODE systems, the fine-tuned model indeed outperforms the baseline model and GPT4o.

A striking difference between the fine-tuned model and both the baseline model and GPT4o is the occurrence of faulty parameter definitions with values that are most likely the result of hallucination. This is observed disproportionately often in the two test cases with DAE systems with eight out of 17 total error cases. We thus hypothesize that hallucinations generally become increasingly frequent the more the test cases deviate from the majority of the training data.

## 3.2 Examination of generalization ability

The fine-tuned Llama 3.1 8B Instruct outperforms its pretrained counterpart on the four test cases that have not been part of the training data. We observe that GPT4o shows a higher physical accuracy of equations than the fine-tuned model. The absolute number of error occurrences per error category is displayed in Table 2.

Most strikingly, the performance of the fine-tuned model is worse than GPT4o in the categories of unit conversion errors in parameter definitions and the accuracy of physics equations. For instance, the reaction rate expressions of parallel and consecutive reactions (cases a and b, see Section 2.3) are not formulated correctly in the responses of both the fine-tuned and the baseline models. In contrast, the responses provided by GPT4o

**Table 2:** Absolute amount of occurrences per error category per model. The test dataset comprises four case studies each containing elements not portrayed in the fine-tuning dataset. The baseline model (Llama 3.1 8B Instruct) is fine-tuned and assessed on the same test dataset. GPT4o is assessed on the same test dataset as a benchmark.

| | Parameter and variable declarations | | | | Physics equations | | | General syntax |
|---|---|---|---|---|---|---|---|---|
| | Unit error | Declaration syntax error | Incorrect values | Undefined variables | Incorrect equations | Structural error | Unit conflict | |
| Baseline (Llama 3.1 8B) | 20 | 39 | 3 | **0** | 25 | 0 | **0** | 9 |
| Fine-tuned (Llama 3.1 8B) | 15 | **0** | **0** | 2 | 14 | 0 | **0** | 1 |
| GPT4o | **5** | 3 | **0** | 1 | **8** | 0 | 1 | **0** |

contain correct rate expressions for both parallel and consecutive reactions. In the case of a requested non-constant density system (case c, see Section 2.3), none of the models examined correctly formulate an algebraic equation for the reaction volume. In the case of left-out parameter values in the user's description (cased d, see Section 2.3), the responses of the fine-tuned model and the baseline model both hallucinate arbitrary values, GPT4o's response defines one parameter arbitrarily and does not define another at all.

We conclude that the fine-tuned model does not show satisfactory ability to extrapolate to scenarios that are not presented during training. Thus, it could be considered to re-train on a wider, more diverse fine-tuning dataset comprising a larger variety of Modelica models with extensive documentation alongside the reference answers. Furthermore, supporting, external knowledge on, e.g., Modelica built-in variable types or textbooks on reactor modelling, could be provided to the LLM via, for instance, retrieval augmented generation (RAG)[8]. Additionally, iterative feedback loops could be implemented by running the produced Modelica script in Dymola and re-routing failed attempts back for improvement.

## 4 CONCLUSIONS

We conclude that it is possible to leverage the potential of LLMs for generating dynamic models of chemical reactor systems from descriptions in natural language. We find that through fine-tuning Llama 3.1 8B Instruct, the syntactic and semantic accuracy of Modelica code generation can be improved compared to the baseline Llama 3.1 8B Instruct model. Compared to GPT4o, the baseline Llama 3.1 8B Instruct model and the fine-tuned counterpart do not show sufficient ability to extrapolate to scenarios unseen during training. We suggest improving model performance through three potential avenues: (1) expanding the fine-tuning dataset, (2) incorporating wider literature and Modelica documentation into the workflow by using RAG, and (3) iterative improvement by leveraging an interface to Dymola. The synthetic generation of a dataset comprising a diverse set of data (1) is labor- and time-intensive, and we also find no evidence of sufficient ability to extrapolate to scenarios not included in the training dataset. We thus suggest providing access to Modelica documentation and literature on reactor modeling (2) as a resource to increase the model's robustness in formulating physically accurate equations and using built-in Modelica variable types. Lastly, simulation of the generated Modelica script could be attempted in Dymola (3) and improved iteratively in case of failure.

## ABSTRACT

Fault diagnosis is critical for ensuring the safety and efficiency of chemical processes, as undetected faults can lead to catastrophic consequences. While deep learning-based methods have shown promise in this field, they often require manual hyperparameter tuning, which is not efficient since they heavily rely on expert knowledge and need iterative trial-and-error. This work introduces a novel approach combining a Multiscale Convolutional Neural Network (MSCNN) with Tree-Structured Parzen Estimator (TPE) for automated hyperparameter optimization to enhance the performance of fault diagnosis for chemical processes. The Multi-Scale Module is to capture complex nonlinear features from the fault data, while the TPE efficiently searches for optimal hyperparameters for MSCNN. An experimental study was carried out on the Tennessee Eastman Process (TE Process) dataset, where the proposed method was benchmarked against state-of-the-art models. The results indicate that the MSCNN-TPE method demonstrated improved performance in terms of precision and recall, achieving 5.26% and 5.63% higher values, respectively, compared to the CNN model. Comparisons of the MSCNN with default hyperparameters further confirmed the effectiveness of these techniques in improving fault diagnosis performance. Additionally, model ensemble technique was explored to further enhance the performance of the model and provide uncertainty estimations. In conclusion, this approach offers a robust and reliable solution for fault diagnosis in the chemical industry, enhancing process safety and efficiency.

**Keywords**: Fault Detection, Machine Learning, Artificial Intelligence

## 1. INTRODUCTION

Fault diagnosis is critical in manufacturing, especially in chemical process, to prevent failures, minimize downtime, and avoid costly repairs and hazardous accidents [1]. With the development of technology, deep learning had been widely used in the field of fault diagnosis for its capability of automatic features extractions and accuracy in diagnosing complex chemical process faults [2].

Bao et al. [3] proposed a fault diagnosis method for chemical processes that combines a deep convolutional neural network (DCNN) with a recurrent neural network (RNN). The application in the Tennessee Eastman (TE) process demonstrated the model's ability to learn dynamic information from raw data in both spatial and temporal domains and achieve high accuracy in identifying abnormal conditions. Lomov et al. [4] proposed to use deep learning architectures, including a novel temporal CNN1D2D model and Generative Adversarial Networks (GANs), for fault detection in the TE process. Souza et al. [5] investigates the development of a fault detection and diagnosis system for TE process using convolutional neural networks (CNNs) and applied transfer learning to address issues of data distribution changes due to alterations in process control strategy. Zhang et al. [6] proposed a fault detection and diagnosis system for complex chemical processes using a bidirectional recurrent neural network (BiRNN) architecture, demonstrating superior performance in fault detection rate (FDR) and fault diagnosis time compared to unidirectional RNNs.

However, the traditional deep learning methods require expert knowledge for hyperparameters tuning to find the optimal hyperparameters for the fault diagnosis

task [7]. This could be time consuming and labour intensive. Liang et al. [8] proposed to use Tree-structured Parzen Estimator (TPE) for hyperparameters optimization in rotating machinery fault diagnosis. Ortiz et al. [9] employed Bayesian optimisation for hyperparameter tuning of machine learning models to achieve high accuracy in fault diagnosis for rotating machinery. Aouichaoui et al. [10] used grid search for hyperparameters tunning for different models and conducted uncertainty estimation methods including bootstrap, ensemble, and dropout to quantify the prediction uncertainty of graph neural networks (GNNs) in chemical property prediction. Nevertheless, research on hyperparameters optimization for fault diagnosis in chemical engineering is limited.

Motivated by the need to overcome the limitations of traditional deep learning-based fault diagnosis approaches which require expert knowledge in tunning hyperparameters, we proposed to utilize MSCNN with Tree-structured Parzen Estimator (TPE) to enhance the performance of fault diagnosis in chemical process. The contributions of this paper are summarized as follows:

1) A novel fault diagnosis framework for chemical process with multi-scale convolutional neural network, leveraging hyperparameters optimization and model ensemble is proposed.

2) Experimental results on TE process indicate the proposed framework outperforms the other comparison methods including PCA, MLP, CNN and MSCNN with default hyperparameters, which highlights the effectiveness of integrating the Multi-Scale module and TPE.

3) Model ensemble technique was conducted to the proposed method, which significantly improved the model performance and provided uncertainty estimations for trustworthy predictions.

The remainder of the paper is organized as follows. Section 2 introduces the methodologies utilized in the proposed method, including the overall proposed workflow, architecture of MSCNN, and introduction of TPE and model ensemble. Section 3 presents the experimental study of the proposed method, using Tennessee Eastman Process (TE process) as case study. Section 4 provides conclusion and future work.

# 2. METHODOLOGIES

## 2.1 Proposed workflow

The proposed workflow mainly consists of 4 steps:

1) Data acquisition and data splitting. The fault data are collected from the simulation and divided into train, validation and test sets.

2) Hyperparameters optimization for MSCNN using TPE. The MSCNN model and training and validation sets are initialized with a specific random seed. The TPE runs 500 trial-and-error iterations automatically to find the optimal hyperparameters set that achieves the highest validation accuracy.

3) Models training. The MSCNN model is trained based on the optimal set of hyperparameters that found by TPE. The trained model is saved for further testing.

4) Model performance testing. The trained MSCNN-TPE model predict the fault type of the given test set samples, and the true positive, false positive and false negative are recorded. Based on this, precision, recall and confusion matrix can be presented to evaluate the performance of the model.

## 2.2 Multi-Scale Convolutional Neural Network

Deep learning has been widely applied in the field of fault diagnosis, with convolutional neural network (CNN) being particularly effective due to their ability to extract hierarchical features. However, traditional CNN often faces challenges in capturing features across multiple scales, which are critical for detecting complex patterns in chemical process data. To address this limitation, a Multi-Scale Convolutional Neural Network (MSCNN) is proposed, as shown in Figure 1.

The key feature of the MSCNN is its ability to extract features at different resolutions through parallel convolutional layers with varying kernel sizes [11]. The one-dimensional fault signal serves as the input to the model, which is processed by a multi-scale convolution module. The module consists of parallel convolutional layer with kernel sizes of 1, 3, and 5. The output of each convolutional layer is computed as follows:

$$z_i^{(j)} = \sum_{k=1}^{K} w_k^{(j)} \cdot x_{i+k-1} + b^{(j)} \quad (1)$$

where $z_i^{(j)}$ is the output of the $j^{th}$ filter at position $i$, $x$ is the input sequence, $w_k^{(j)}$ represents the weights of the $j^{th}$ filter with kernel size $K$, and $b^{(j)}$ is the bias term. The weights and bias are trained with gradient decent.

The outputs of multi-scale convolution module are then concatenated, creating a comprehensive feature representation. A maxpooling operation is applied to the concatenated feature maps to reduce dimensionality while retaining important features. The resulting feature maps are further refined by additional convolutional layers. Finally, the features are flattened and passed through fully connected (FC) layers, followed by a softmax output layer to provide the final diagnostic result, represented as predicted probabilities for each fault class.

The MSCNN is trained using cross-entropy loss function:

$$L(y, \hat{y}) = -\sum_{i=1}^{C} y_i \log(\hat{y}_i) \quad (2)$$

where $C$ is the number of classes (i.e., fault types). $y_i$ is the true label for class $i$, taken from the one-hot encoded target vector (1 for the correct class and 0 for others). $\hat{y}_i$ is the predicted probability output by the softmax layer for class $i$. By minimizing the loss through gradient

decent, the MSCNN achieves optimal fault diagnosis performance.

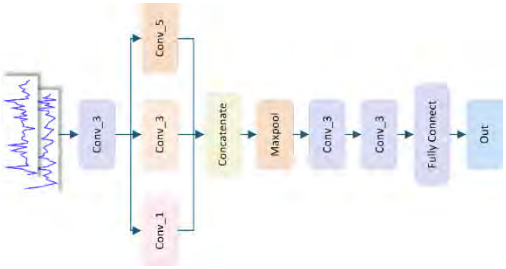

**Figure 1:** Schematic of the MSCNN structure.

## 2.3 Hyperparameters Optimization

To train a model that have the best performance on the validation set, we need to iteratively tune the hyperparameters. Instead of tunning them manually, we proposed to use Tree-structured Parzen Estimator, a Bayesian-based hyperparameters optimization method, to search for optimal hyperparameters automatically, as it has been proven effective in [12].

The search space of the hyperparameters and the default values are shown in Table 1. *Lr* refers to the learning rate of the Adam optimizer in the neural network, whose search space follows a *LogUni* type, which means that the value is uniformly distributed in the logarithmic scale. *Dr* is the drop out rate of the FC layer. *Pre_chan* refers to the channel number of the convolutional layer before the multi-scale module. *Post_chan* represents the channels number of the convolutional layer after maxpool. *Hidden_size* stands for the neurons number in FC layer.

**Table 1:** Hyperparameters Search Space for MSCNN

| Name | Value type | Optional value | Default |
|---|---|---|---|
| Lr | LogUni | [0.0001,0.1] | 0.01 |
| Dr | LogUni | [0.001,0.5] | 0.1 |
| Pre_chan | Choice | 8,16,32,64,128,256,512 | 32 |
| Post_chan | Choice | 8,16,32,64,128,256,512 | 128 |
| Hidden_size | Choice | 25,50,100,200,400 | 100 |

Tree-structured Parzen Estimator (TPE) [13] is utilized to optimize the hyperparameters in this paper. Historical hyperparameters are grouped to “good” set and “bad” set based on their evaluation value, which is the validation accuracy in this paper. The TPE models the likelihood probability of the two groups as follows:

$$p(x|y) = \begin{cases} l(x), & y > y^{\gamma} \\ g(x), & y \le y^{\gamma} \end{cases} \tag{3}$$

where $y$ is the evaluation value of the hyperparameter $x$, $y^{\gamma}$ is the threshold to separate “good” from “bad” observations. By maximizing $l(x)/g(x)$, TPE select the new hyperparameters that have the highest probability to achieve good result relative to a bad one. This strategy allows TPE to search for optimal hyperparameters efficiently compared to manual tunning. In the case study, 500 iterations were conducted, and the searching process took 9 hours and 14 minutes in total.

## 2.4 Model Ensemble

Instead of training a single model for fault diagnosis, we propose to use model ensemble technique to enhance diagnostic results as well as provide uncertainty estimation. For each model in the ensemble, the training and validation dataset are split differently to introduce diversity in the training data, which is different to the bootstrap sampling strategy [10]. In the meantime, each model is initialized with different parameters initialization, which also creates diversity to the models. With different initialization in both data and model, we enable models to learn from different optimization paths. This approach enhances robustness, as a single model may lack the ability to generalize effectively and is more prone to overfitting the data. By aggregating the predictions of multiple models, the ensemble mitigates these limitations and achieves superior overall performance. After training, the predicted probabilities from individual models are averaged to produce the final output, as shown below:

$$p(\hat{y} = c \mid x) = \frac{1}{M}\sum_{m=1}^{M} p(\hat{y} = c \mid x, \theta_m) \tag{4}$$

where $M$ is the number of models, which is set to 100 in this paper, $\theta_m$ is the parameters of the $m^{th}$ model.

# 3. EXPERIMENTAL STUDIES

## 3.1 Dataset Description

The Tennessee Eastman (TE) Process is used as a case study to evaluate the performance of the proposed method. This TE Process dataset, originates from a chemical process simulation by the Eastman Chemical Company, is widely used in the field of fault diagnosis and monitoring in chemical process to serve as a benchmark dataset to test process monitoring and fault diagnosis algorithms.

To be specific, the dataset consists of simulation running with 21 different fault types. For each sample, there are 53 process variables in total, but since the 12$^{th}$ variable remains constant, only 52 variables are considered to serve as input data. Due to the length of the paper, the schematic of the TE Process and the details of the faults can be referred to in [14]. There were 26880 samples in total, training, validation and test sets are separated according to the ratio of 6:2:2. For each fault type, there are 768 samples in the training set, 256 samples in the validation set, and 256 samples in the test set.

## 3.2 Comparison Methods

To highlight the performance of the proposed framework, several comparison methods were carried

**Table 2:** Results of fault diagnosis on the TE Process. P stands for Precision, R stands for Recall, with values expressed as percentages (%). For each fault type, the highest precision and recall are highlighted in bolded.

| | PCA | | MLP | | CNN | | MSCNN | | Proposed | |
|---|---|---|---|---|---|---|---|---|---|---|
| Fault | P | R | P | R | P | R | P | R | P | R |
| 1 | 100 | 98.44 | 87.29 | 99.22 | 100 | 98.83 | 99.61 | **99.22** | **100** | 98.83 |

| Avg | 66.77 | 65.70 | 63.92 | 68.95 | 82.11 | 81.57 | 83.79 | 83.50 | **87.37** | **87.20** |

out for the same diagnosis task. These methods are described as follows:

1) Principal Component Analysis (PCA). A classical dimensionality reduction technique commonly used in machine learning.

2) Multilayer Perceptron (MLP), which is a simple neural network composed of 4 FC layers, with the neurons number of 512, 256, 128, 64 respectively.

3) Convolutional Neural Network (CNN). A deep learning model adapted by replacing the multiscale module in MSCNN with two sequential convolutional layers, each with a kernel size of 3.

4) MSCNN. The MSCNN model trained with the default hyperparameters shown in Table 1. This model utilizes multiscale features to improve diagnostic performance.

5) MSCNN-TPE (Proposed). The MSCNN model trained with the optimal hyperparameters searched by TPE, which is the proposed method.

The experiments were conducted on a cluster server equipped with an AMD EPYC 9354 CPU and an Nvidia Volta 100 GPU. The models are implemented with the python packages scikit-learn and Pytorch 2.5. The optimizer used was Adam, with a learning rate set to 0.01. A learning rate scheduler was applied, reducing the learning rate by 10% every 10 epochs. Early stopping was employed with a patience of 10, meaning the training process would stop if the validation loss did not decrease for 10 consecutive epochs. By using consistent settings across all methods, this setup ensures a fair comparison between the approaches.

## 3.3 Results and Discussion

### 3.3.1 Evaluation Metrics

To evaluate the performance of the fault diagnosis models, we use precision (P) and recall (R) as the key metrics. These are particularly important in scenarios like fault diagnosis, where both false positives and false negatives can have critical consequences. The calculation of precision and recall are calculated as follows:

$$P = \frac{\mathrm{TP}}{\mathrm{TP+FP}} \tag{4}$$

$$R = \frac{\mathrm{TP}}{\mathrm{TP+FN}} \tag{5}$$

True Positive (TP) refers to a positive sample being correctly classified. False Positive (FP) represents a negative sample but misclassified as positive. False Negative (FN) indicates a positive sample that is misclassified as negative. In plain words, precision measures the proportion of correctly identified positive cases among all predicted positive cases, while recall measures the proportion of actual positive cases that the model successfully identified.

### 3.3.2 Results and Discussion

Table 2 shows the overall diagnostic results of the experiment. Some conclusions can be drawn from it:

**Limited competitiveness of PCA, MLP and CNN.** Both PCA, MLP and CNN have poor precision and recall in many of the fault types, especially on fault type 3,9,11 and 15. Among them, PCA performs the worst, followed by MLP, while CNN shows slightly better results. It is also worth noting that MLP fails to detect fault type 8 and 11 entirely, likely due to its architecture limitations in learning distinguishable features in complex high-dimensional feature spaces.

**Effectiveness of the Multi-Scale module in MSCNN.** Compared to CNN, MSCNN demonstrates

improvements in both precision and recall, particularly for some specific fault types. The average precision and recall of MSCNN (83.79%, and 83.50% respectively) are higher than those of CNN (82.11% and 81.57%), indicating the effectiveness of the integration of multi-scale module.

**Effectiveness of TPE.** The proposed method outperformed all comparison methods in terms of both precision and recall in most of the fault types, indicating its superiority. Specifically, the proposed method achieves an average precision and recall improvement of 3.58% and 3.70% respectively, over MSCNN, indicating the effectiveness of TPE in enhancing model performance.

**Comparison of training loss**. The training and validation losses of different approaches are shown as Figure 2. MLP exhibits the highest training and validation losses, and they can't decrease effectively after the longest training epoch, indicating the insufficient capacity of MLP to extract meaningful features from the data. CNN and MSCNN achieve similar losses, while the validation loss of MSCNN is slightly lower. On the other hand, the proposed method achieves the lowest losses, demonstrating its superior performance on both the training and validation sets, which aligns with the results observed on the test set.

**Analyzing of confusion matrix.** Due to the space limitations, only the confusion matrix of the proposed method is shown in Figure 3. By looking into the confusion matrix, we can have an intuitive analysis about the performance of the model and have insights into which fault types are more challenging to classify and how they are confused with one another.

Overall, the proposed method exhibits a higher number of correctly classified samples along the diagonal compared to MSCNN. Specifically, The TP of fault types 9 and 15 are 156 and 169 respectively— significantly higher than those of MSCNN (95 and 126 respectively). This improvement highlights the proposed method's ability to accurately classify faults. This result also indicated that some specific fault types are more difficult to classify and could be easily confused with one another. The reason could be their similar fault patterns, which make their feature representations highly alike. For example, fault 3 (D Feed Temperature (Stream 2) Step) and fault 9 (D Feed Temperature (Stream 2) Random Variation) exhibits similar characteristics, leading to increased misclassification between them.

**Significance of introduction of model ensemble.** As shown in Table 3 are diagnostic results of some difficult faults of the proposed method before and after using model ensemble. The model number is 100 in the ensemble. We can observe a significant improvement in both precision and recall after model ensemble, highlighting its effectiveness. Moreover, the uncertainty estimation of a fault sample can be calculated from the entropy of the probability distribution, and additional analyses can be provided by looking at the standard deviations, mean and other statistics from the 100 models in the ensemble. This approach provides more reliable result compared to using the prediction from a single model, as it captures the diversity in both model initializations and data splits.

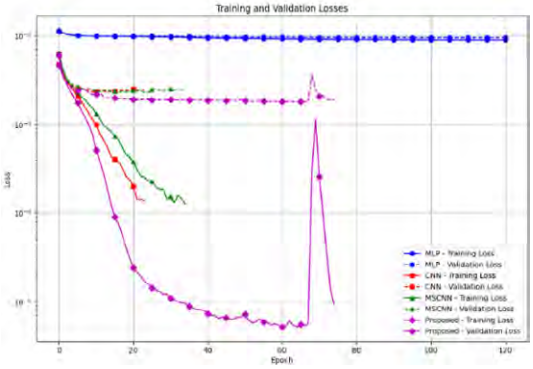

**Figure 2:** Training and validation losses of different approaches.

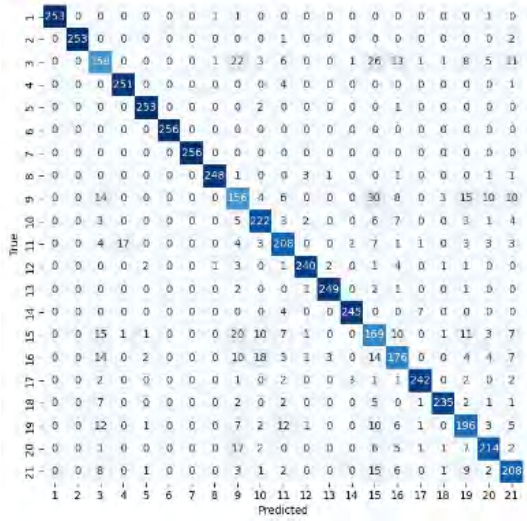

**Figure 3:** Confusion matrix of the proposed method.

**Table 3:** Results before and after model ensemble for difficult faults

| Fault | Proposed-Single | | Proposed-Ensembled | |
|---|---|---|---|---|
| | P | R | P | R |
| 3 | 66.39 | 61.72 | 66.79 | 69.92 |
| 9 | 61.42 | 60.94 | 71.85 | 75.78 |
| 11 | 79.69 | 81.25 | 85.43 | 82.42 |
| 15 | 57.88 | 66.02 | 66.08 | 73.88 |
| 19 | 74.81 | 76.56 | 78.20 | 81.25 |
| Avg | 68.04 | 69.30 | 73.67 | 76.65 |

## 4. CONCLUSION AND FUTURE WORK

To conclude, this paper proposed a fault diagnosis framework that integrates a multi-scale convolutional neural network with hyperparameters optimization and model ensemble to enhance fault diagnosis for complex chemical processes.

Experimental results on TE process indicate the proposed framework outperforms the other comparison methods including PCA, MLP, CNN and MSCNN with default hyperparameters. This shows the effectiveness of the introduction of Multi-Scale module and TPE. Additionally, model ensemble was applied to further improve the fault diagnosis performance and provide uncertainty estimations, enabling more reliable decision-making.

For future study, we aim to further explore model ensemble techniques, compare different models and uncertainty estimation methods, and contribute to trustworthy fault diagnosis that not only focus on the accuracy but also the reliability. Model pruning [15] will also be investigated to reduce model complexity while maintaining a comparable diagnostic performance.

# Picard-KKT-hPINN: Enforcing Nonlinear Enthalpy Balances for Physically Consistent Neural Networks

**Giacomo Lastrucci[a], Tanuj Karia[a], Zoë Gromotka[b], and Artur M. Schweidtmann[a]***

## ABSTRACT

Neural networks (NNs) are widely used as surrogate models but they do not guarantee physically consistent predictions thereby preventing adoption in various applications. We propose a method that can enforce NNs to satisfy physical laws that are nonlinear in nature such as enthalpy balances. Our approach, inspired by Picard's successive approximations method, aims to enforce multiplicatively separable constraints by sequentially *freezing* and projecting a set of the participating variables. We demonstrate our Picard-KKT-hPINN for surrogate modeling of a catalytic packed bed reactor for methanol synthesis. Our results show that the method efficiently enforces nonlinear enthalpy and linear atomic balances at machine-level precision. Additionally, we show that enforcing conservation laws can improve accuracy in data-scarce conditions compared to *vanilla* multilayer perceptron.

**Keywords**: Surrogate modeling, Hard-constrained neural networks, Physics-informed neural networks, Constrained learning

## INTRODUCTION

Surrogate modeling plays a crucial role in simplifying and approximating complex physical models, making them suitable for large-scale simulations and optimization studies of industrial relevance. Machine learning models, such as neural networks (NNs), are particularly well-suited for this purpose due to their simplicity and strong regression capabilities [1]. However, despite exceptional advancements in machine learning, issues and skepticism regarding the black-box nature and physical inconsistency of these models hinder the adoption of machine learning-based tools (and, more broadly, artificial intelligence) in industrial applications [2,3]

To mitigate this limitation, significant research has been carried out to enforce known mechanistic relationships between inputs and predictions in NNs. Soft-constrained neural networks represent an approach in which physical equations are included as penalty terms in the loss function [4,5]. This method does not require any modification of the neural network architecture, but it does not guarantee the exact satisfaction of the constraints. When exact adherence to constraints such as closure of balances is required, hard-constrained neural networks become relevant. Models belonging to this class aim to strictly satisfy given equations or symmetries underlying the original system (constrained learning).

Different methodologies have been proposed for constrained learning. For instance, Beucler et al. (2019) and Donti et al. (2019) apply a method known as prediction and completion, where an NN is trained to predict a subset of variables, while the remaining ones are determined by solving a (non)linear system during training [6,7]. Researchers in optimization proposed to learn solutions to constrained optimization problems leveraging Lagrangian duality [8]; however, aspects of this approach still rely on soft constraints. Chen et al. (2021) introduced a projection step to guide the learning process by enforcing adherence to discretized differential equations [9]. Based on a similar concept, Chen, et al. (2024) presented KKT-hPINN to adjust neural network predictions, ensuring compliance with linear algebraic constraints [10]. Recently, Mukherjee and Bhattacharyya (2024) proposed to train constrained neural network using an NLP solver such as IPOPT [11]. Likewise, Schweidtmann et al. (2019) have used deterministic global optimization to compute guaranteed worst-case accuracies of NNs [12]. However, the use of local or global NLP solvers can be memory and

time-intensive for NNs that have a large number of parameters and training data points. Overall, current approaches (1) rely on external solvers that increase the computational cost to train and evaluate the NN or (2) are limited to enforcing linear equality constraints.

To address these challenges, we introduce a computationally efficient method that enforces relevant physical laws in the form of nonlinear algebraic equations. We extend the KKT-hPINN framework by considering local projections and numerical techniques to ensure exact constraint satisfaction at machine-level precision. Drawing inspiration from Picard's successive approximation method for solving nonlinear PDEs, we name our model Picard-KKT-hPINN.

## METHODS

We introduce Picard-KKT-hPINN, a method to enforce algebraic nonlinear constraints, such as energy balances, in NN predictions. It extends the KKT-hPINN approach with local projections and numerical techniques such as variable-freezing, while maintaining computational efficiency.

### Problem statement

Given a dataset $(\boldsymbol{x}_i, \boldsymbol{y}_i)_{i=1,\dots,N}$, representing the input-output behavior of a physical system (e.g., a unit operation), our goal is to train an NN to approximate the underlying model governing this system. In some cases, algebraic equations describing some relationship between input and output are known beforehand. We aim to develop an NN $f_\theta$ such that the predicted output $\hat{\boldsymbol{y}} = f_\theta(\boldsymbol{x})$ satisfies a set of algebraic constraints $c_k(\boldsymbol{x}, \boldsymbol{y}) = 0, k = 1, \dots, N_C$, which may represent conservation laws or design specifications. The number of constraints $(N_C)$ must not exceed the dimensionality of the neural network's output $(N_O)$. This ensures the system is underdetermined $(N_C < N_O)$, allowing the network to learn from the data while adhering to these constraints.

### Background: KKT-hPINN

Chen et al. (2024) proposed a model denoted as KKT-hPINN to enforce linear relationships in NNs [10]. In KKT-hPINN, the (physically inconsistent) prediction of a generic multilayer perceptron is corrected by an orthogonal projection onto the linear feasible region described by a system of linear equations and geometrically defining a hyperplane.

Specifically, the prediction $\hat{\boldsymbol{y}}$ is corrected so as to respect a linear system by solving the following optimization problem:

$$\tilde{\boldsymbol{y}} = \underset{\boldsymbol{y}}{\operatorname{argmin}} \left|\left|\boldsymbol{y} - \hat{\boldsymbol{y}}\right|\right|^2 \quad \text{s.t.} \quad \boldsymbol{A}\boldsymbol{x} + \boldsymbol{B}\boldsymbol{y} = \boldsymbol{b} \tag{1}$$

The corrected, physically consistent, solution $\tilde{y}$ is achieved by solving the Karush-Kuhn-Tucker (KKT) conditions of this optimization problem (Eq. 1), thus the name KKT-hPINN:

$$\tilde{\boldsymbol{y}} = \boldsymbol{A}^*\boldsymbol{x} + \boldsymbol{B}^*\hat{\boldsymbol{y}} + \boldsymbol{b}^* \tag{2}$$

Considering the identity matrix $\boldsymbol{I}$:

$$\begin{aligned} \boldsymbol{A}^* &= -\boldsymbol{B}(\boldsymbol{B}\boldsymbol{B}^T)^{-1}\boldsymbol{A} \\ \boldsymbol{B}^* &= \boldsymbol{I} - \boldsymbol{B}(\boldsymbol{B}\boldsymbol{B}^T)^{-1}\boldsymbol{B} \\ \boldsymbol{b}^* &= -\boldsymbol{B}^T(\boldsymbol{B}\boldsymbol{B}^T)^{-1}\boldsymbol{b} \end{aligned} \tag{3}$$

The projection matrices $(\boldsymbol{A}^*, \boldsymbol{B}^*, \boldsymbol{b}^*)$ are computed analytically owing to the quadratic objective function and linear constraints. This projection acts as a physics-informed activation layer on the network output, providing a computationally efficient approach to enforce linear constraints. However, its applicability is limited to linear systems, making it unsuitable for scenarios with nonlinearities. For instance, while effective for modeling mass balances in chemical engineering, it struggles with enthalpy balances, which often involve nonlinear relationships.

### Local projection

We generalize the linear constraints formulation in Eq. 1 to any nonlinear function in the input vector $\boldsymbol{x}$:

$$c(\boldsymbol{x}, \boldsymbol{y}) = \boldsymbol{B}\boldsymbol{y} + g(\boldsymbol{x}) - \boldsymbol{b} = \boldsymbol{0} \tag{4}$$

Since the input vector is known for every instance, we can consider it as a constant term and define $v(\boldsymbol{x}) = \boldsymbol{b} - g(\boldsymbol{x})$.Moreover, the input vector does not participate as an optimization variable in the projection process and thus $g(\boldsymbol{x})$ can be any nonlinear. Hence, Eq. 4 can be written as:

$$c(\boldsymbol{x}, \boldsymbol{y}) = \boldsymbol{B}\boldsymbol{y} - v(\boldsymbol{x}) = \boldsymbol{0} \tag{5}$$

where $v(\boldsymbol{x})$ is a vector-valued function $v: \boldsymbol{x} \subseteq \mathbb{R}^{N_I} \to \mathbb{R}^{N_C}$. In particular, $v$ is a nonlinear function of the $N_I$-dimensional input to the NN, meaning that its value is instance-dependent (an *instance* is a given datapoint $(\boldsymbol{x}_i, \boldsymbol{y}_i)$). Thus, the value of the constraint must be updated depending on each datapoint instance and can not be defined offline. Additionally, we consider local (*instance-specific*) constraint definition by allowing the matrix $\boldsymbol{B}$ to depend on the output instance $\boldsymbol{y}_i$. To simplify the notation, we define $\boldsymbol{B}_i = \boldsymbol{B}(\boldsymbol{y}_i)$ and $\boldsymbol{v}_i = \boldsymbol{v}(\boldsymbol{x}_i)$ such that:

$$c(\boldsymbol{x}_i, \boldsymbol{y}_i) = \boldsymbol{B}_i\boldsymbol{y}_i - \boldsymbol{v}_i = \boldsymbol{0} \tag{6}$$

This formulation comprises a wider class of functions in respect to the linear case in Eq. 1 and is foundational to handle local nonlinearities.

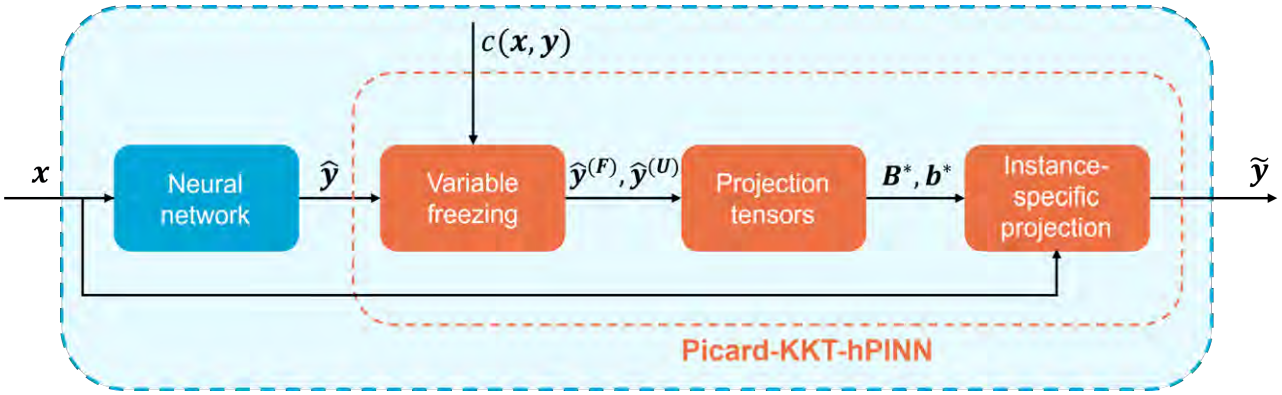

**Figure 1:** Picard-KKT-hPINN consists of a set of non-trainable layers that can be appended on every NN backbone (e.g., multilayer perceptrons, convolutional neural networks, transformers). Multiplicatively separable constraints (Eq. 8) are enforced exactly by partitioning the prediction vector (*variable freezing*). Then, the prediction of the NN is projected onto the feasible space defined by the constraints $c$. The layers composing Picard-KKT-hPINN are differentiable, hence, the NN is trained end-to-end and the architecture is equivalent at training and inference time.

The computational cost to achieve local projection can be reduced by exploiting parallel computing. We perform batch training (with $BS$ being the number of elements in the batch) by building a *rank-3* tensor $\boldsymbol{B} \in \mathbb{R}^{BS \times N_C \times N_O}$ holding a number $BS$ of local $\boldsymbol{B}_i$ matrices. Similarly, we construct a *rank-2* tensor $\boldsymbol{V} \in \mathbb{R}^{BS \times N_C}$ to store the local $\boldsymbol{v}_i$ vectors. The local projection matrices are computed in parallel (Eq. 7), hence reducing the apparent complexity of the most expensive computation, the matrix inversion, from $O(BS \times N^3)$ to $O(N^3)$.

$$\boldsymbol{B}^* = \boldsymbol{I} - \boldsymbol{B}^T(\boldsymbol{B}\boldsymbol{B}^T)^{-1}\boldsymbol{B}$$
$$\boldsymbol{V}^* = \boldsymbol{B}^T(\boldsymbol{B}\boldsymbol{B}^T)^{-1}\boldsymbol{V} \tag{7}$$

More specifically, considering the batch inversion of the tensor $\boldsymbol{B}\boldsymbol{B}^T$, the dimension $N$ is the number of constraints. Assuming to deal with tasks involving $N_C = N < 10^3$, the inversion is performed in a negligible amount of FLOPs in modern hardware. To the best of our knowledge, this dimensionality bound does not limit the applicability of the method for the majority of the surrogate modeling tasks in chemical engineering.

## Picard-KKT-hPINN

Inspired by Picard's successive approximation method for nonlinear partial differential equations (PDEs), we develop a model to exactly enforce nonlinear constraints, including physical balances expressed as algebraic equations (See Figure 1).

### Output partitioning and definition of the constraint class

Given the NN's output vector $\boldsymbol{y} = [y_1, \dots, y_{N_O}] \in \mathbb{R}^{N_O}$, we partition its components as $\boldsymbol{y} = [\boldsymbol{y}^{(F)} \ \ \boldsymbol{y}^{(U)}]$. $\boldsymbol{y}^{(F)}$ is the subvector of *frozen* variables and $\boldsymbol{y}^{(U)}$ is the subvector of *unfrozen* variables, with $\boldsymbol{y}^{(F)} = [y_{j_1}, \dots, y_{j_{N_F}}] \in \mathbb{R}^{N_F}$ and $\boldsymbol{y}^{(U)} = [y_{j_1}, \dots, y_{j_{N_U}}] \in \mathbb{R}^{N_O - N_F}$, with $N_U = N_O - N_F$.

We aim to enforce multiplicatively separable equality constraints of the form:

$$c_k(\boldsymbol{x}, \boldsymbol{y}) = \boldsymbol{B}_k \boldsymbol{y} + F_k\left(\boldsymbol{y}^{(F)}\right) \cdot \boldsymbol{y}^{(U)} - v_k(\boldsymbol{x}) = 0$$
$$k = 1, \dots, N_C \tag{8}$$

The constraint includes some linear function in the output $\boldsymbol{y}$, any nonlinear function $v_k$ in the input $\boldsymbol{x}$, and a scalar multiplication between $F_k$, a nonlinear vector-valued function in the *frozen* variables $\boldsymbol{y}^{(F)}$, and the *unfrozen* variables $\boldsymbol{y}^{(F)}$. Note that $F_k: \mathbb{R}^{N_F} \to \mathbb{R}^{N_U}$.

Steady-state macroscopic conservation principles can be generally formulated as Eq. 8. Thus, the structure of the considered constraint is of interest for engineering and physics-based applications.

More in general, the constraints in Eq. 8 can be formulated in matrix notation as:

$$c(\boldsymbol{x}, \boldsymbol{y}) = \boldsymbol{B}\boldsymbol{y} + F\left(\boldsymbol{y}^{(F)}\right) \cdot \boldsymbol{y}^{(U)} - v(\boldsymbol{x}) = 0 \tag{9}$$

Here, $c(\boldsymbol{x}, \boldsymbol{y})$ is the vector of $N_C$ constraints and $F\left(\boldsymbol{y}^{(F)}\right)$ is an $N_C \times N_U$ matrix. We develop a method to let the NN predictions exactly guarantee constraints belonging to the class in Eq. 9 by *freezing* a partition of the output variables, resembling Picard's iteration method.

### Variables freezing

Given the output $\hat{\boldsymbol{y}}$ of an NN $f_\theta(\boldsymbol{x})$, we aim to guarantee the prediction to satisfy a constraint of the form as in Eq. 9 by projecting the latter onto the feasible space.

The projected prediction $\tilde{\boldsymbol{y}}$ can be computed as the solution of the following nonlinear program (NLP):

$$\tilde{\boldsymbol{y}} = \underset{\boldsymbol{y}}{\operatorname{argmin}} \left|\left|\boldsymbol{y} - \hat{\boldsymbol{y}}\right|\right|^2$$
$$\text{s.t.} \quad c(\boldsymbol{x}, \boldsymbol{y}) = \boldsymbol{B}\boldsymbol{y} + F\left(\boldsymbol{y}^{(F)}\right) \cdot \boldsymbol{y}^{(U)} - v(\boldsymbol{x}) = 0 \tag{10}$$

Instead of relying on an external solver, we reformulate the NLP in Eq. 10 as a quadratic program (QP) solvable analytically. To achieve that, we assume the variables in $\boldsymbol{y}^{(F)}$ as *correct* and thus set them constant. This variable-freezing allows to reformulate Eq. 9 as a linear constraint by defining $\boldsymbol{B}' = \boldsymbol{B}\boldsymbol{y} + F\left(\boldsymbol{y}^{(F)}\right)$:

$$c(\boldsymbol{x}, \boldsymbol{y}) = \boldsymbol{B}'\boldsymbol{y} - v(\boldsymbol{x}) = 0 \tag{11}$$

Since Eq. 11 is the matrix form equivalent of Eq. 6, the local projection is achieved according to Section 2.3 and results in $\tilde{\boldsymbol{y}} = \boldsymbol{B}^*\hat{\boldsymbol{y}} + \boldsymbol{v}^*$,where the projection tensors can be computed exploiting parallel computing during training.

The nonlinear term is handled by projecting only a partition of the output variables. We observe the method to be more efficient when $N_U < N_F$, that is, more variables are projected to guarantee the nonlinear constraints. However, in general, the whole output vector is still potentially projected since linear terms can be present. Such numerical technique resembles Picard's iteration method to solve nonlinear PDEs iteratively (hence, the name Picard-KKT-hPINN), where some variables are kept constant to the previous iteration's value to achieve a linear expression. Similarly, here we exploit the iterative training process to converge towards the ground truth data while guaranteeing the prediction obeys the nonlinear constraint.

## RESULTS AND DISCUSSION

### Case study and constraints

Our proposed method is illustrated on a tubular packed-bed reactor for methanol synthesis, using the same modeling assumptions as in Lastrucci et al. (2024) [13]. The surrogate models involve 10 inputs (inlet temperature, pressure, component flowrates, and coolant flowrate) and 10 outputs (outlet temperature, pressure, component flowrates, and hotspot temperature). The training and test datasets, consisting of 20,000 and 500 data points respectively, are generated by solving the mechanistic model of the reactor implemented in Python under diverse conditions bounded by operational limits derived from flowsheet simulation. Specifically, we simulate the simplified plant for methanol synthesis implemented in the IDEAS library [14] and evaluate extreme recycle conditions to determine those bounds. Hence, each datapoint $(x_i, y_i)$ represents the input-output state variables corresponding to a specific operating scenario. The generated data are intentionally noise-free, as the goal is to develop a surrogate model that faithfully replicates the original mechanistic model. The relevance of this study lies in enabling faster computations, for instance, by eliminating the need for dynamic optimization in flowsheet optimization problems.

We derive algebraic constraints underlying the steady state physical system that we aim to enforce in the surrogate model, such as atomic balance and total enthalpy balance. The system consists of four linear atomic balances (Eq. 12) and one nonlinear equation for the energy balance (Eq. 13):

$$\sum_{i=1}^{N_S} \dot{a}_{ij,in} - \sum_{i=1}^{N_S} \dot{a}_{ij,out} = 0, \qquad j = C, H, O, N \tag{12}$$

$$\sum_{i=1}^{N_S} \dot{n}_{i,in}\tilde{h}_{i,in} - \sum_{i=1}^{N_S} \dot{n}_{i,out}\tilde{h}_{i,out} - \dot{Q} = 0 \tag{13}$$

In Eq. 12, $\dot{a}_{ij,in}$ and $\dot{a}_{ij,out}$ are the molar flowrates of atom $j$ *carried* by species $i$, entering and exiting the reactor, respectively, and $N_S$ is the number of chemical species involved (composed by four atoms, such as carbon, hydrogen, oxygen, and nitrogen). Being the atomic balances linear constraints, they can effectively be enforced using KKT-hPINN [10]. In Eq. 13, $\dot{n}_{i,in}$ and $\dot{n}_{i,out}$ are the molar flowrates of species $i$, $h_{i,in}$ and $h_{i,out}$ are the molar-specific enthalpies and $\dot{Q}$ is the rate of heat transfer out of the system. In general, the specific enthalpy $\tilde{h}_{i,eval} = \tilde{h}_{i,eval}(T_{eval})$ is a nonlinear function of the temperature, depending on the modeling choice for the specific heat at constant pressure $c_P$. Since in the considered case study $\dot{Q} = \dot{n}_c\widetilde{\Delta H}_{ev}(T_c)$ is a function of the input (coolant flowrate, $\dot{n}_c$) [13], the term $\sum_{i=1}^{NS} \dot{n}_{i,in}\tilde{h}_{i,in} - \dot{Q}$ can be regarded as $v_k(\boldsymbol{x})$ in Eq. 8. More importantly, the term $-\sum_{i=1}^{NS} \dot{n}_{i,out}\tilde{h}_{i,out}$ can be seen as the dot-product in Eq. 8, with $F_k\left(\boldsymbol{y}^{(F)}\right) = \tilde{h}_{i,out} = \tilde{h}_i(T_{out})$ and $\boldsymbol{y}^{(U)} = \dot{n}_{i,out}$. Thus, our Picard-KKT-hPINN model can exactly enforce both the atomic (Eq. 12) and the enthalpy balances (Eq. 13).

### Experiments and comparison

We train a shallow Picard-KKT-hPINN consisting of 1 hidden layer with 64 neurons and ReLU activation function, and we compare against a KKT-hPINN and a multilayer perceptron (MLP) with the same backbone architecture. Every model is trained for 50,000 epochs, using the Adam optimizer with a learning rate of $10^{-5}$ and a batch size of 2,000 samples. For reproducibility, the fully connected layers are deterministically optimized from a fixed Glorot initialization [15]. The training time of Picard KKT-hPINN on GPU hardware is comparable to that of MLP and KKT-hPINN, averaging only 15% longer, primarily due to the matrix inversion operation. At inference, the computational time of the three models is equivalent, even on CPU hardware (11th Gen Intel(R) Core(TM) i7-1185G7 @ 3.00GHz, 4 Core(s)).

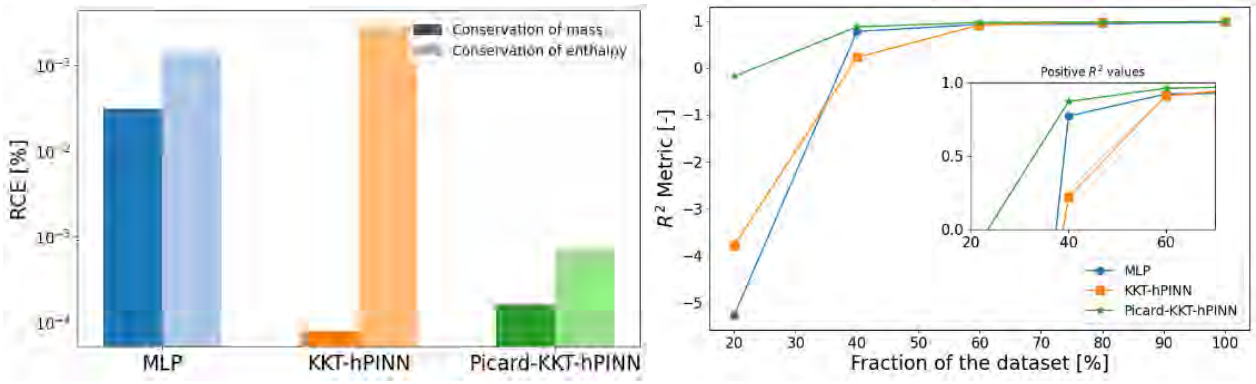

**Figure 2:** Comparison of relative conservation error (RCE) of mass and enthalpy balances (*left*) and model performances in data scarcity conditions (*right*) over the three different models.

**Table 1:** Accuracy comparison over the three different models. We train all the models on a GPU hardware (NVIDIA GeForce RTX 3090).

| | MLP | KKT-hPINN | Picard-KKT-hPINN |
|---|---|---|---|
| $R^2$ [-] | 0.97 | 0.98 | 0.98 |
| MAPE [%] | 0.81 | 0.58 | 0.71 |

The accuracy of the models on the test set is comparable in terms of coefficient of determination ($R^2$) and mean absolute percentage error (MAPE). In Table 1, the metrics are averaged over all the predicted variables in the test set. We do not expect the constraints to increase the accuracy considerably when a traditional MLP is already very accurate.

The focus of the study is to demonstrate the effectiveness of Picard-KKT-hPINN in enforcing both linear and nonlinear constraints. Figure 2 (*left*) shows the relative conservation error of the total mass and enthalpy. The MLP, although very accurate, does not strictly satisfy the balances. As claimed by the authors [10], KKT-hPINN effectively enforces the linear mass balances at machine-level precision (note that the plot is in logarithmic scale), however, the predictions do not strictly satisfy the nonlinear enthalpy balance. Picard-KKT-hPINN, instead, enforces mass and enthalpy balances exactly, reducing the error below 0.001% for both.

In a real-word scenario, the amount of data is often a bottleneck when training *data-hungry* machine learning models such as NNs. We analyze the performance of the models in data scarcity conditions by training on uniformly sampled fractions of the original dataset. We demonstrate that constrained learning can improve model performance in data scarcity conditions (Figure 2, *right*). Specifically, enforcing atomic balance through KKT-hPINN outperforms the MLP when using between 20 and 30% of the original training dataset. When enforcing both atomic and total enthalpy balance with Picard-KKT-hPINN, the model performance shows a positive coefficient of determination ($R^2 \simeq 0.75$) when only 35% of the training dataset is used, while both MLP and KKT-hPINN show a negative $R^2$ in the same data regime.

## CONCLUSION

We propose Picard-KKT-hPINN, a method to ensure that NN predictions adhere strictly to nonlinear algebraic constraints, such as enthalpy balances. Our work extends the recent KKT-hPINN model by Chen, et al. (2024) from linear to nonlinear constraints [10]. Thereby, we address a critical limitation of surrogate models in failing to satisfy fundamental physical principles such as mass and energy conservation.

In our proposed method, we project the NN predictions onto the feasible space defined by mass and enthalpy balances, ensuring the exact satisfaction of these laws. We tested Picard-KKT-hPINN in surrogate modeling tasks, specifically for a methanol synthesis packed bed reactor. The method guarantees atomic and enthalpy balances without adding computational overhead, while also outperforming the accuracy of standard MLPs in data-scarce regimes. These results highlight the potential of Picard-KKT-hPINN to advance the adoption of NNs in relevant chemical engineering applications, including large-scale process optimization and simulation, where developing physically consistent surrogate models is crucial for ensuring both computational efficiency and reliable outcomes.

## ABSTRACT

Accurate mechanistic models provide valuable physical insight and are crucial for efficient process scale-up and optimisation, but their identification requires lengthy experimental data collection, model construction, validation and discrimination. Traditional black-box machine learning transfer methods leverage prior knowledge but lack interpretability and physical insights. To address this, we propose a novel approach using artificial neural network feature attribution to automatically locate corrections and symbolic regression to make structural modifications to an inaccurate or low-fidelity mechanistic model. In a comprehensive in-silico case study, the framework adapted a kinetic model from one biochemical system to a different but related one, enhancing predictive accuracy. Integrated within an iterative model-based design of experiments routine, it minimised the number of new experiments required. The study also discusses the impact of the inductive bias trade-off and alternative ways of incorporating prior knowledge to improve performance, highlighting the framework's flexibility and potential for advancing automated knowledge discovery and high-fidelity predictive digital twin design for novel (bio)chemical processes.

## 1. INTRODUCTION

Developing accurate models to predict bioprocess dynamics is vital for commercial process design, scale-up, and control. Kinetic models, formulated as ordinary differential equations (ODEs), incorporate known reaction mechanisms and parameters with physical significance, thus making them interpretable. However, their construction is difficult due to incomplete and uncertain knowledge of biochemical reaction networks. Data-driven methods such as statistical and machine learning models (e.g., artificial neural networks, Gaussian processes, random forests) can capture complex dynamics without explicit mechanistic knowledge. Still, they lack enough interpretability and demand large, high-quality datasets that are experimentally resource-intensive.

Hybrid modelling has emerged as a pragmatic solution when systems are only partially understood and data is limited. Such models combine mass balances and simplified reaction terms with data-driven components to describe unknown kinetics as time-varying parameters. This corrects for structural mismatch and reflects biochemical systems' inherent transient or hysteretic nature.

Transfer learning accelerates model development by updating pre-trained models from related systems. It has proved effective in fields such as image classification, natural language processing, and, increasingly, chemical processes. In bioprocessing, knowledge of one microalgal strain is leveraged to reduce experimentation for mutant strains or the influence of plant hormones to accelerate screening during early bioprocess development while integrated transfer learning and hybrid modelling carry over mechanistic knowledge [1]. The assumption is that the new system's dynamics are sufficiently similar to the source. However, the degree of similarity is often uncertain, while these approaches remain non-interpretable: by only updating the data-driven and mechanistic parameters of an existing hybrid model, the mechanistic model structure remains unchanged, and updates to the embedded data-driven terms are opaque, providing little physical insight into the new system.

In recent years, the push for interpretable,

parsimonious models has led to algorithms that automatically discover governing equations. Sparse identification techniques have been used to elucidate stoichiometry and kinetics in bioprocesses [2]. However, constructing suitable libraries of candidate functions is not always feasible for complex systems. This has motivated symbolic regression (SR) [3], whereby closed-form expressions built from primitive operators (e.g., addition, multiplication) are generated by genetic programming, transformers, reinforcement learning or recurrent neural networks. SR has succeeded in discovering chemical and approximate biochemical mechanistic equations [4] but risks producing non-interpretable local approximations. SR is NP-hard, and when many features are possible, discovering accurate, parsimonious expressions is intractable.

Existing methodologies also demand sampling frequencies beyond typical experimental capabilities, while biomass, substrate, and product measurements may be noisy. This complicates gradient estimation for ODE discovery unless relatively computationally expensive numerical integration is embedded in the fitness function.

Researchers often utilise prior knowledge when exploring new systems. This work, therefore, proposes a framework integrating SR with artificial neural network (ANN) feature attribution to automatically adapt the structure of an existing mechanistic model from literature or a common concept. This will allow the transfer of physical knowledge between different but related systems to rapidly generate accurate predictive models with limited data – a common scenario in bioprocess development.

In Section 4.1, an in-silico case study will demonstrate the framework when prior knowledge is abundant but partially incorrect for the target domain. Moreover, the framework will be combined with a model-based design of experiments (MbDoE) for model discrimination to iteratively refine the model structure while minimising the number of experiments needed to discover the correct equations for the newly investigated system. Section 4.2 will then discuss how the amount of prior knowledge will impact the flexibility and efficiency of the framework.

## 2. METHODOLOGY

A kinetic model represents the rate of change, $\mathrm{d}\boldsymbol{y}/\mathrm{d}t$, in the concentrations of (bio)chemical species, $\boldsymbol{y}$, with respect to time, $t$, as a system of ODEs, $f(\boldsymbol{y}, \boldsymbol{\theta})$, where $\boldsymbol{\theta}$ are the model parameters. The goal of the framework is to take a mechanistic model for a different but related system or a pre-existing low-fidelity mechanistic model and adapt or improve its structure to more accurately fit and make predictions on a new target system. The initial equations, or source model, are denoted by $f_s(\boldsymbol{y}, \boldsymbol{\theta}_s)$, and the adapted equations, or transfer model for the target domain, are denoted by $f_t(\boldsymbol{y}, \boldsymbol{\theta}_t)$.

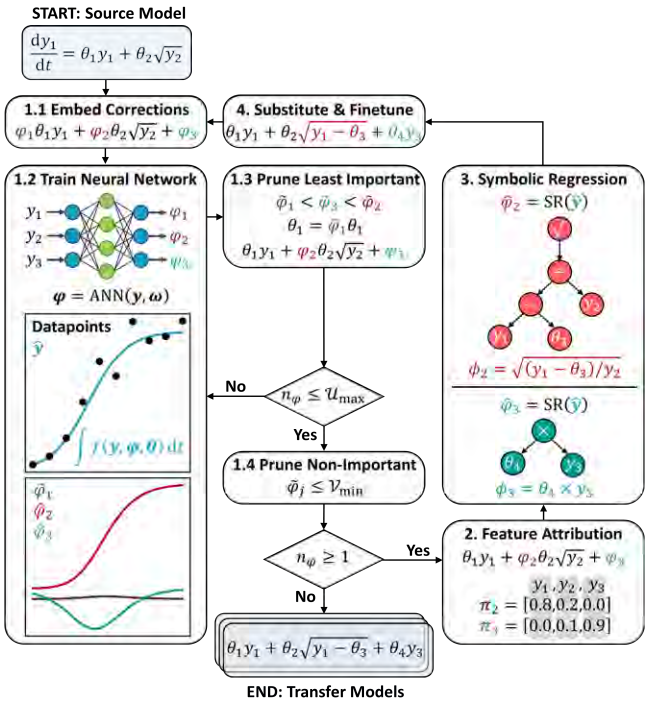

**Figure 1:** ANN attribution guided symbolic regression for dynamic systems. Takes equations for the source model and data for the target domain, and outputs candidate transfer models for model-based design of experiments.

An outline of the framework is depicted in Figure 1. Step 1 identifies which terms need altering by embedding initially unknown correction terms into the kinetic model (Step 1.1). A regularised ANN then learns the relationship between the correction terms and states (Step 1.2), then Steps 1.3-1.4 iteratively prune the corrections with the lowest variance. In Step 2, feature attribution determines which input variables matter most, providing weighting vectors, $\boldsymbol{\pi} = [\pi_1, \pi_2, \pi_3]$, for each feature, $\boldsymbol{y} = [y_1, y_2, y_3]$. Step 3 applies SR to build symbolic corrections guided by $\boldsymbol{\pi}$. Finally, in Step 4, these symbolic corrections are substituted back into the equations and parameters are fine-tuned, yielding $f_t(\boldsymbol{y}, \boldsymbol{\theta}_t)$. Variables $\boldsymbol{y}$ and $t$ are normalised and the source model automatically nondimensionalised; afterwards $f_t(\boldsymbol{y}, \boldsymbol{\theta}_t)$ is automatically re-dimensionalised. Throughout this article, $\hat{\boldsymbol{y}}$ denotes fitted states, $\hat{\boldsymbol{\varphi}}$ fitted corrections, and $\boldsymbol{\phi}$ their symbolic forms or approximations generated by SR. This algorithm's output can be a single model or multiple candidates to be further discriminated by model-based design of experiments (MbDoE).

### 2.1. ANN-Based Algorithm for Locating Structural Corrections

Consider $g_t(\boldsymbol{y}, \boldsymbol{\theta}_t)$ in Eqn. 1a as the target-domain ground-truth equations and $f_s(\boldsymbol{y}, \boldsymbol{\theta}_s)$ in Eqn. 1b as the source equations, where $\boldsymbol{\theta}_t \neq \boldsymbol{\theta}_s$.

$$g_t(\boldsymbol{y}, \boldsymbol{\theta}_t) = \theta_1 \frac{y_1}{y_2 + \theta_2} \frac{y_2}{y_1 + \theta_3} - \theta_4 \frac{y_3}{y_4} \qquad (1a)$$

$$f_s(\boldsymbol{y}, \boldsymbol{\theta}_s) = \theta_1' \frac{y_1 y_2}{y_2 + \theta_2'} - \theta_4' \frac{y_3}{y_1} \tag{1b}$$

$$f_t(\boldsymbol{y}, \boldsymbol{\theta}_t) = \theta_1 \frac{y_1 y_2}{y_2 + \theta_2} \left[\frac{1}{y_1 + \theta_3}\right] - \theta_4 \frac{y_3}{y_1} \left[\frac{y_1}{y_4}\right] \tag{1c}$$

Comparing Eqn. 1a and Eqn. 1b reveals structural errors when using the source model to approximate the ground-truth for the target domain. By inserting $[1/(y_1 + \theta_3)]$ and $[y_1/y_4]$ into Eqn. 1b and re-optimising the parameters, Eqn. 1c and 1a match, illustrating the *simplest* symbolic corrections, $\boldsymbol{\phi}(\boldsymbol{y})$. While these corrections (e.g., $\phi_1(\boldsymbol{y}) = [1/(y_1 + \theta_3)]$, $\phi_2(\boldsymbol{y}) = [y_1/y_4]$) are deduced here by inspection; in practice, they are unknown. Thus, we use an ANN parameterised by a set of weights and biases, $\boldsymbol{\omega}$, as an approximator in Eqn. 2b, to learn $\boldsymbol{\varphi}(\boldsymbol{y})$, embedded into the model as in Eqn. 2c.

$$\min_{\boldsymbol{\theta},\boldsymbol{\omega}} \frac{1}{n_i n_e} \sum_{i=1}^{n_i} \sum_{e=1}^{n_e} \left\| \hat{\boldsymbol{y}}_{i,e}(\boldsymbol{\theta}, \boldsymbol{\omega}) - \boldsymbol{y}_{i,e} \right\|_2 + n_\varphi P(\boldsymbol{y}, \boldsymbol{\omega}) \tag{2a}$$

s. t.

$$\hat{\boldsymbol{\varphi}}(\hat{\boldsymbol{y}}, \boldsymbol{\omega}) = \mathrm{ANN}(\hat{\boldsymbol{y}}, \boldsymbol{\omega}) \tag{2b}$$

$$f_t(\boldsymbol{y}, \boldsymbol{\theta}_t, \boldsymbol{\omega}) = \theta_1 \frac{y_1 y_2}{y_2 + \theta_2} \varphi_1(\boldsymbol{y}, \boldsymbol{\omega}) - \theta_4 \frac{y_3}{y_1} \varphi_2(\boldsymbol{y}, \boldsymbol{\omega}) \tag{2c}$$

$$\hat{\boldsymbol{y}}_{i,e}(\boldsymbol{\theta}, \boldsymbol{\omega}) = \boldsymbol{y}_0^e + \int_0^{t_i} f_t(\boldsymbol{y}, \boldsymbol{\theta}_t, \boldsymbol{\omega})\, \mathrm{d}t \tag{2d}$$

$$P(\boldsymbol{y}, \boldsymbol{\omega}) = \lambda_1 \left\| \frac{\partial \hat{\boldsymbol{\varphi}}}{\partial \hat{\boldsymbol{y}}} \right\|_2 + \lambda_2 \| \hat{\boldsymbol{\varphi}}(\boldsymbol{y}, \boldsymbol{\omega}) - \boldsymbol{b} \|_2 \tag{2e}$$

The transfer model, $f_t(\boldsymbol{y}, \boldsymbol{\theta}_t, \boldsymbol{\omega})$, incorporates ANN-based correction terms, $\boldsymbol{\varphi}(\boldsymbol{y}, \boldsymbol{\omega})$, into the ODEs. The ANN is trained by minimising the mean-square error $\mathcal{L}_{\mathrm{ANN}}(\boldsymbol{\theta}, \boldsymbol{\omega})$ in Eqn. 2a between measured concentrations, $\boldsymbol{y}_{i,e}$, and predictions, $\hat{\boldsymbol{y}}_{i,e}$, obtained by numerically integrating $f_t(\boldsymbol{y}, \boldsymbol{\theta}_t, \boldsymbol{\omega})$ from initial conditions $\boldsymbol{y}_0^e$ to time, $t_i$, where the subscripts $i$ and $e$ are the measurement time interval and experiment number. By automatic differentiation through numerical integration the kinetic parameters $\boldsymbol{\theta}$ and ANN parameters $\boldsymbol{\omega}$ were optimised simultaneously to avoid bias in the estimated corrections. Adaptive Moment Estimation (ADAM) was used to optimise the parameters, as implemented in the *Python* package *PyTorch*.

The $\lambda$-weighted penalty, $P(\boldsymbol{y}, \boldsymbol{\omega})$, in Eqn. 2e is crucial to prevent overfitting. Its first component, the sum of the squares of the elements in the Jacobian, $\partial \hat{\boldsymbol{\varphi}} / \partial \hat{\boldsymbol{y}}$, limits variation in the correction terms, $\hat{\boldsymbol{\varphi}}$, with respect to the fitted states, $\hat{\boldsymbol{y}}$, ensuring only truly influential state variables are retained. Its second component involving a binary vector $\boldsymbol{b}$, pushes additive corrections toward zero and multiplicative ones toward unity, helping to isolate genuine correction locations.

Because correction locations are initially unknown, multiple potential corrections are embedded. Figure 2 illustrates how $\mathcal{D}_{\max}$ sets the initial placement of potential corrections. These, represented by an ANN, are trained together. Unimportant corrections – those with the smallest variance, $\tilde{\varphi}$, over the input domain – are pruned iteratively and the ANN retrained, reducing the number of corrections, $n_\varphi$, until it falls below a pre-defined threshold, $\mathcal{U}_{\max} = 3$. Corrections with variance $\tilde{\varphi} < \mathcal{V}_{\min} = 0.1$ are then also finally removed. On an NVIDIA RTX A1000 GPU, ANN training takes ~20 seconds, so 10 pruning iterations require only a few minutes. Automatic symbolic manipulations using *SymPy* streamline expression modifications throughout.

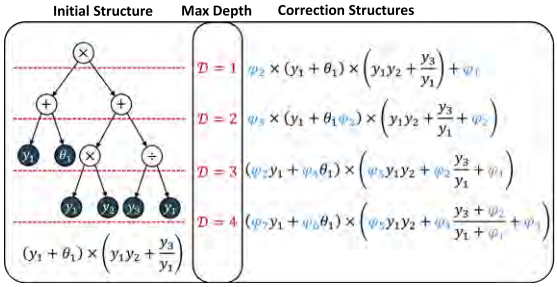

**Figure 2:** Illustration of correction term embedding at various depths ($\mathcal{D}_{\max}$). The initial equation structure (left) transforms into equations with embedded $\varphi_j$ (right). For binary branching trees $n_\varphi = F(\mathcal{D}_{\max}) + \mathcal{D}_{\max}$ where, $F(n)$ is the $n$th entry in the Fibonacci sequence.

## 2.2. Attribution Guided Symbolic Regression to Construct Correction Equations

Not all features are required for every correction term. Integrated Gradients [5] quantifies each feature's, $y_v$, contribution to each fitted correction term, $\hat{\varphi}$. This weights which input features SR should use to construct corrections with the effect of either adding or removing them from the source equations.

$$\mathcal{L}_{\mathrm{SR}}(\phi, \boldsymbol{\theta}) = \frac{1}{n_i n_e} \sum_{i=1}^{n_i} \sum_{e=1}^{n_e} \left( \phi(\hat{\boldsymbol{y}}_{i,e}, \boldsymbol{\theta}) - \hat{\varphi}_{i,e} \right)^2 \tag{3}$$

Once Steps 1 and 2 identify the minimal corrections and key features, in Step 3 SR discovers the symbolic forms, $\phi(\boldsymbol{y}, \boldsymbol{\theta})$, for each correction $\hat{\varphi} = \mathrm{ANN}(\boldsymbol{y}, \boldsymbol{\omega})$. Tournament selection promotes and mutates candidates from a population of expressions using the *Julia* package *SymbolicRegression* [3]. The objective function for fitting corrections is shown in Eqn. 3 as the mean-square-error between the value evaluated by each symbolic expression, $\phi(\hat{\boldsymbol{y}}_{i,e}, \boldsymbol{\theta})$, and the values of the fitted corrections, $\hat{\varphi}_{i,e}$, averaged over each time point, $i$, and experiment, $e$.

After substituting the symbolic corrections into the source equations, yielding the new target equations, the target parameters, $\boldsymbol{\theta}_t$, are then fine-tuned and sparsity in $\boldsymbol{\theta}_t$ promoted by penalising the absolute magnitude, $\|\boldsymbol{\theta}_t\|_2$.

## 2.3. Integrating SR and MbDoE for Model Discrimination

Model-based design of experiments (MbDoE) for model structure discrimination maximises information gain by selecting experimental conditions that maximise differences in predicted responses among model candidates, reducing time and resource expenditure.

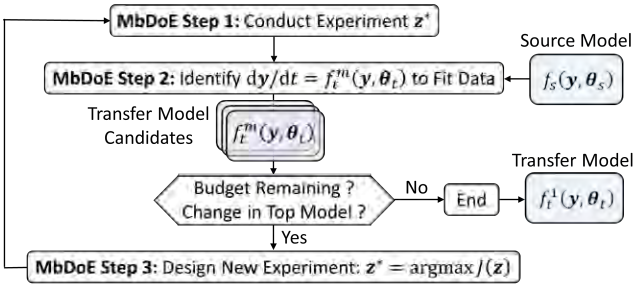

**Figure 3:** Transfer learning integrated with SR-MbDoE.

The SR-MbDoE framework [6] is adapted in Figure 3 to integrate model structure transfer learning. In MbDoE-Step 1, experiments parameterised by $\boldsymbol{z}$ are conducted. MbDoE-Step 2 uses model structure transfer learning to propose different candidate transfer models. In MbDoE-Step 3, so long as the experimental budget has not been exceeded or the equations from one iteration to the next are still being refined, a new experiment is designed by optimising to an objective function, $J(\boldsymbol{z})$.

In model structure transfer learning, SR generates a Pareto set of candidate expressions. These are scored by the derivative in the log-loss with respect to complexity. The top-scoring expressions represent a balance between parsimony and fitting accuracy. By substituting combinations of the top two scoring corrections into the source equations, various candidate transfer models, $f_t^m(\boldsymbol{y}, \boldsymbol{\theta}_t)$, indexed by $m$, are created. In this work, the design variables, $\boldsymbol{z}$, were the initial concentrations of each (bio)chemical species, $\boldsymbol{y}_0$, while the objective function was the Hunter-Reiner criterion.

# 3. BIOPROCESS CASE STUDY

This study considers an in-silico case study representing microalgae cultivation for producing a high-value nutraceutical via carbon substrate consumption. The *source* model, in Eqn. 4, describes the evolution of biomass ($X$), substrate ($S$), and product ($P$) concentration, with the parameters: $\boldsymbol{\theta}_s = (\mu_m, K_S, Y_S, Y_P, \beta)$, where $\mu_m = 0.1\ \mathrm{h}^{-1}$ is the maximum specific growth rate, $K_S = 10\ \mathrm{g\,l}^{-1}$ is the substrate half-saturation constant, $Y_S = 1\ \mathrm{g\,g}^{-1}$ is the growth-dependent substrate yield coefficient, while $Y_P = 0.5\ \mathrm{g\,g}^{-1}$ and $= 0.003\ \mathrm{h}^{-1}$ are the growth-dependent and independent product yield coefficients, respectively.

$$\frac{\mathrm{d}X}{\mathrm{d}t} = \mu_m \frac{S}{S + K_S} X \tag{4a}$$

$$\frac{\mathrm{d}S}{\mathrm{d}t} = -Y_S\, \mu_m \frac{S}{S + K_S} X \tag{4b}$$

$$\frac{\mathrm{d}P}{\mathrm{d}t} = Y_P \mu_m \frac{S}{S + K_S} \cdot X + \beta X \tag{4c}$$

In-silico data for the *target* domain, representing a more productive strain, was generated using the ground-truth model in Eqn. 5. The target model parameters, $\boldsymbol{\theta}_t = (\mu_m, K_S, \mu_d, Y_S, Y_P, \beta, k_d)$, share the same meanings as in the source model but with different values: $K_S = 5\ \mathrm{g\,g}^{-1}$, $\beta = 0.05\ \mathrm{h}^{-1}$. New is a biomass decay constant, $\mu_d = 0.1\ \mathrm{h}^{-1}$, and product reversal rate under substrate-limiting conditions, $k_d = 0.07\ \mathrm{g}^{-1}\,\mathrm{l\,h}^{-1}$, while Eqn. 5 uses Contois, not Monod kinetics, altogether reflecting the physical differences between the source and target systems.

$$\frac{\mathrm{d}X}{\mathrm{d}t} = \mu_m \frac{S}{S + K_S X} \cdot X - \mu_d X \tag{5a}$$

$$\frac{\mathrm{d}S}{\mathrm{d}t} = -Y_S\, \mu_m \frac{S}{S + K_S X} \cdot X \tag{5b}$$

$$\frac{\mathrm{d}P}{\mathrm{d}t} = Y_P \mu_m \frac{S}{S + K_S X} \cdot X + \beta X - k_d X^2 \tag{5c}$$

Batch simulations each run for 144 hours from initial conditions $\boldsymbol{y}_e^0 = (X_{0,e}, S_{0,e}, P_{0,e})$. States $\boldsymbol{y}_{i,e} = (X_{i,e}, S_{i,e}, P_{i,e})$ were recorded every 14 hours with 5% normally distributed noise. This represents practical conditions with measurement uncertainty, and offline data is not frequently collected. Each case study starts with three experiments from different initial conditions. To assess reproducibility and data sensitivity, the framework is re-run ten times, starting from different sets of three experiments generated from different random initial conditions.

# 4. RESULTS AND DISCUSSION

Section 4.1 will demonstrate the robustness of the proposed model structure transfer learning framework, given a detailed but imperfect source model. Section 4.2 will then discuss the impact of the quantity of prior knowledge on the efficiency of the framework.

## 4.1. Scenario with Moderate Inductive Bias

The source model to be modified is given by Eqn. 4. In Section 4.1.1, three initial experiments are used for each of the ten repetitions; Section 4.1.2 extends this with further experiments designed via MbDoE.

### 4.1.1. Single vs Multi-Pass Structure Modification

A single-pass approach first embeds multiple correction terms into the source model, which are then sparingly refined. First, in Step 1 in Figure 1, Eqn. 6 shows where twelve correction terms, $\varphi$, were automatically

embedded into the source model structure. Note that overall specific growth rate, $\mu$, is a shared sub-function. Here $\phi_j^{\mathrm{GT}}$ will denote the *simplest* symbolic corrections when comparing the corrections with the ground truth equations. Comparison with the target ground-truth in Eqn. 5 indicates three key corrections – one for adapting the Monod to the Contois kinetics ($\phi_2^{\mathrm{GT}} = X$), one for biomass decay ($\phi_7^{\mathrm{GT}} = -\mu_d X$) and another for product reversal ($\phi_{12}^{\mathrm{GT}} = -k_d X^2$), while other terms ideally vanish. Note others are possible; should $\phi_7^{\mathrm{GT}} = -\mu_d X$ and $\phi_{12}^{\mathrm{GT}} = -k_d X^2$ then $\phi_3^{\mathrm{GT}} = (S + K_S X - K_S)/S$ or $\phi_4^{\mathrm{GT}} = (S + K_S)/(S + K_S X)$ for example are equally valid, though are not the *simplest*.

$$\frac{\mathrm{d}X}{\mathrm{d}t} = \varphi_6 \mu X + \varphi_7 \tag{6a}$$

$$\frac{\mathrm{d}S}{\mathrm{d}t} = -\varphi_8 Y_S \mu X + \varphi_9 \tag{6b}$$

$$\frac{\mathrm{d}P}{\mathrm{d}t} = \varphi_{11} Y_P \mu X + \varphi_{10} \beta X + \varphi_{12} \tag{6c}$$

$$\mu = \varphi_4 \mu_m \frac{S + \varphi_1}{\varphi_3 S + \varphi_2 K_S} + \varphi_5 \tag{6d}$$

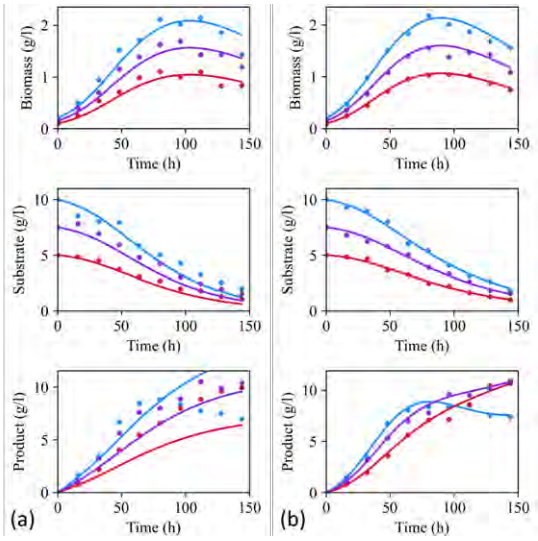

**Figure 4:** Comparison of a model fitting built from one of the random initial experiments after one pass (a) and after three passes (b) of model structure modification.

Across ten repetitions, the source structure was partially corrected in a single pass 10% of the time, where Eqn. 7 illustrates one such partially corrected model; this improves to 50% with sparsity promotion. However, certain terms were often incorrectly inferred: for example, falsely attributing product reversal under substrate-limiting conditions to a product accumulation term that simply diminished towards the end of the batch (i.e., $\phi_{12} = 1.88S$ rather than $\phi_{12}^{\mathrm{GT}} = -k_d X^2$). It could be said that it is prior knowledge that such decay terms should be negligible at the start of the batch; in fact, this information could be incorporated during ANN training but to demonstrate the generality of the method we assume we do not know this.

Now, the equations are returned for further passes to assess whether partially corrected equations can be fully adapted to the target domain. No further passes are required once there are no correction terms with a variance, $\tilde{\varphi}$, greater than the threshold, $\mathcal{V}_{\min}$. Allowing multiple passes of model structure modification raised the success rate from 50% to 80%, illustrating that iteratively refining partially corrected equations is advantageous. For one model, the mean absolute percentage error (MAPE) of fitting improved from 17% to 6.6% as shown in Figure 4a to 4b, once multiple passes discovered the ground truth. Meanwhile, the MAPE of prediction on the unseen experiments dropped from 23% to 10.7%.

### 4.1.2. Model-Based Design of Experiments

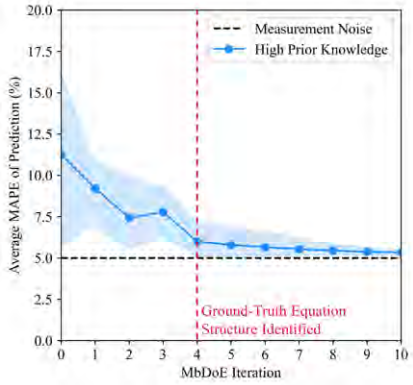

**Figure 5:** The mean absolute percentage error (MAPE) of prediction over each model-based design of experiment (MbDoE) iteration. The shaded region denotes three standard deviations in the MAPEs at each MbDoE iteration over the ten random initialisations, while the markers are the average. Here, multiple passes of structure modification are allowed.

When only a few noisy experiments are available, multiple candidate structures may explain the data equally well. MbDoE identifies experimental conditions for discriminating among those candidates. In Figure 5, given three initial experiments, the average MAPE was 11.2% with a standard deviation of 3.1% across the 10 repetitions. This decreased to 5.3% with a standard deviation of 0.1% after thirteen new MbDoE experiments. Eight out of ten runs achieved a MAPE of 6.0% by the fourth MbDoE iteration, at which point all the runs discovered the ground truth equation structures for the target domain. The product-reversal term ($\phi_{12}^{\mathrm{GT}} = -k_d X^2$) was typically discovered last when it was elucidated that $\phi_{12} = f(X)$ not $\phi_{12} = f(X, S)$ was the simplest correction, highlighting how separating the causal relationship can be difficult when state variables are strongly correlated – such as when one (bio)chemical species reacts to another, and the experiments are poorly designed.

## 4.2. Impact of Prior Knowledge Quantity

The framework's efficiency will be case-dependent. Eqn. 7b replicates the biomass growth model used here, while Eqn. 7a reflects the fundamental assumption that growth is proportional to the current cell population. Starting from a more minimal model will likely require more MbDoE experiments, as more kinetics must be uncovered. However, incorporating more physical knowledge – as in Eqn. 7c with a substrate inhibition term $(K_I/S)$ and a product toxicity term $(P/(P+K_P))$ – increases the risk of introducing incorrect inductive bias, complicating model modification. For a completely new bioprocess, such as a novel strain, it is prudent to start with a simpler source model structure to identify key correction terms, then compare the generated equations with those from higher knowledge source models.

$$\frac{\mathrm{d}X}{\mathrm{d}t} = \mu X \tag{7a}$$

$$\frac{\mathrm{d}X}{\mathrm{d}t} = \mu_m \frac{S}{S+K_S} X \tag{7b}$$

$$\frac{\mathrm{d}X}{\mathrm{d}t} = \mu_m \frac{S}{S+K_S+\frac{K_I}{S}} \cdot X \; - \; \mu_d X \frac{P}{P+K_P} \tag{7c}$$

Prior knowledge can be incorporated beyond the source model structure. Previously, the correction $\phi_{12} = -k_d X^2$ was mistaken as $\phi'_{12} \propto S$ using only the first three experiments. When state variables are strongly correlated – such as when one (bio)chemical species reacts to form another (e.g., $A + 2B \rightarrow C$) – separating the causal relationship becomes more difficult. Fortunately, the framework is highly flexible. In these cases, extra constraints during ANN training are valuable. For example, bioprocess kinetics often follow Eqn. 8, with a growth-dependent term, $\varphi_{GD}(\boldsymbol{y})$, and a growth-independent term, $\varphi_{GI}(\boldsymbol{y})$, (e.g., biomass decay or substrate consumption for maintenance). By providing synthetic data to the ANN that pushes $\varphi_{GI}(\boldsymbol{y})$ to zero when biomass is zero, $\phi_{12} = -k_d X^2$ was reliably identified without MbDoE.

$$\frac{\mathrm{d}\boldsymbol{y}}{\mathrm{d}t} = \mu \cdot \varphi_{GD}(\boldsymbol{y}) + \varphi_{GI}(\boldsymbol{y}) \tag{8}$$

# 4. CONCLUSION

This study introduces a structural transfer learning framework combining symbolic regression (SR) with ANN feature attribution to adapt mechanistic models from literature or common concept for newly investigated systems. Unlike traditional black-box-based transfer learning approaches that only update model parameters, the proposed method modifies the structure of mechanistic models, enabling the discovery of interpretable differential equations. An in-silico bioprocess case study demonstrated the framework's robustness under low-sample frequency, noisy data conditions. Integration with model-based experiment design (MbDoE) minimised experimental effort by efficiently discriminating among candidate transfer models for the new system. Requiring several hyperparameters, the framework offers great flexibility for human-machine interaction, allowing experts to guide model complexity and the interpretability necessary in highly regulated industries. Overall, this general methodology advances automated model discovery for accelerating novel bioprocess development, and within other fast-paced (bio)chemical industries.

## ABSTRACT

This study tackles the challenge of accurate yield prediction in fluid catalytic cracking (FCC) units by comparing conventional supervised regression with time series forecasting methods using industrial data collected from the distributed control system (DCS) of an FCC plant. We introduce a shifted forecast paradigm that preserves temporal relationships between predictors and targets. Our preprocessing pipeline, which employs trimmed mean smoothing, addresses common industrial data challenges. Results demonstrate that the forecasting approach significantly outperforms supervised regression, achieving a mean absolute percentage error (MAPE) of 1.56% for 3-hour shifted predictions compared to 6.20% for supervised regression. The model maintains robust performance even with extended shifts during predictions, showing an MAPE of 3.55% for 14-day forecasts. This research provides valuable insights for implementing predictive analytics in industrial FCC operations, demonstrating the superiority of forecasting methods over traditional supervised regression approaches for process yield prediction.

**Keywords**: Machine Learning, Forecasting, Catalytic Cracking, Predictive Modeling

## INTRODUCTION

Fluid catalytic cracking (FCC) is a cornerstone process in modern refineries, playing a crucial role in meeting global energy demands. It enables the efficient conversion of heavy hydrocarbons into lighter and more valuable products, including gasoline and diesel. As crude oil quality continues to decline while global energy demands increase, refineries must navigate intensifying economic and environmental constraints. Under these challenging conditions, process predictive modeling has emerged as an indispensable tool for understanding, controlling, and optimizing the complex behavior of FCC units [1].

Data-driven modeling approaches have gained significant traction in FCC process modeling. These methods excel at capturing complex nonlinearities and interactions and do not require a detailed understanding of the underlying physicochemical phenomena, making them particularly suitable for FCC process modeling [2]. Researchers can leverage the vast amounts of data generated by FCC units to develop empirical models that capture the complex relationships between process variables. By effectively modeling these relationships, operators can make informed adjustments to operating conditions, thereby optimizing performance and enhancing profitability. Machine learning techniques, such as artificial neural networks (ANNs), support vector machines (SVMs), and Gaussian process regression (GPR), have been successfully applied to model various aspects of FCC operation [2]. However, these models often struggle to extrapolate to future operation conditions. Since the FCC process is inherently dynamic and subject to fluctuations over time, effective data-driven modeling requires incorporating time-related information, namely forecasting.

Given these limitations, time series forecasting approaches offer promising alternatives for FCC process modeling. By analyzing temporal dependencies and trends, this modeling approach captures the dynamic nature of the process and provides insights into potential future states. Traditional supervised learning algorithms typically assume independent, identically distributed (IID) inputs [3], and therefore often fail to capture the dynamic nature of industrial processes. In contrast, forecasting

methods emphasize temporal patterns such as seasonality and trends [4], producing more context-aware predictions.

In FCC data, short-term variable relationships remain stable during steady-state operations despite oscillations. However, long-term operations present challenges as operational contexts and system mechanics evolve, complicating the development of consistent input-output mappings. Integrating forecasting techniques with supervised regression methods enhances prediction robustness while accounting for the inherent variability in industrial time series data. Liu *et al.* [5] proposed a hybrid Gaussian Mixture Model (GMM)-Improved Gaussian Process Regression (IGPR) model for time series prediction in industrial processes with varying operating phases and uncertainties. TC-GATN, a novel multivariate time-series forecast model developed by Li *et al.* [6], uses Granger causality-based graph learning and gated recurrent units with self-attention to capture complex nonlinear dependencies in industrial processes, improving prediction accuracy as demonstrated on methanol and chlorosilane datasets. These advancements in industrial time series analysis reflect a broader trend toward more adaptive and context-aware modeling approaches. Nevertheless, their efficacy is predominantly evaluated using moderate-scale systems and datasets, exhibiting more predictable and stable operational characteristics.

In this paper, we develop a shifted forecast paradigm that directly bridges current operational states with future yield predictions of an FCC process. Our approach differs from conventional time series forecasting by explicitly modeling the temporal gap rather than relying on iterative one-step-ahead predictions. The main contributions of this work include: (1) a robust data preprocessing pipeline that addresses common challenges in industrial time series data, including irregular sampling, outliers, and high-frequency fluctuations; (2) a shifted forecast framework that maintains temporal relationships while avoiding the limitations of traditional supervised regression; and (3) comprehensive evaluation of model performance across different prediction shifts, demonstrating its practical utility for industrial applications.

The remainder of this paper is organized as follows. Section 2 describes the data preparation methodology, including variable selection, preprocessing techniques, and dataset organization. Section 3 presents the theoretical framework of our regression and forecasting approaches, with particular emphasis on the shifted forecast paradigm. Section 4 provides detailed experimental results and a comparative analysis of different modeling approaches across various prediction horizons. Finally, Section 5 concludes the paper with a summary of findings and suggestions for future research directions.

# METHODS

Figure 1 shows the framework for developing the prediction model, which consists of two modules: data preparation and regression forecasting.

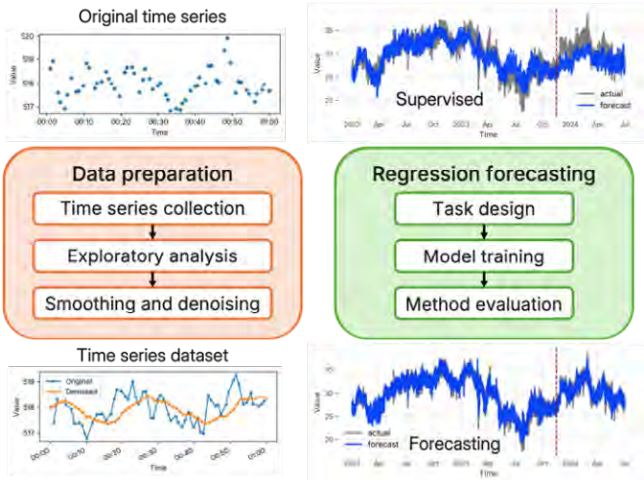

**Figure 1.** Forecast model development framework.

High-quality datasets are generated and then used to build and validate forecast models. The pipelines for data preprocessing and model training are implemented in Python 3.12, using Darts [7], a time series forecasting library.

**Table 1:** Variables in the collected dataset.

| Symbol | Description | Unit |
|---|---|---|
| $T_{\text{feed}}$ | Feed preheat temperature | ℃ |
| $T_{\text{reac}}$ | Reactor temperature | ℃ |
| $T_{\text{regen}}$ | Regenerator riser temperature | ℃ |
| $T_{\text{stripper}}$ | Stripper overhead temperature | ℃ |
| $T_{\text{fractop}}$ | Fractionator overhead temperature | ℃ |
| $T_{\text{naph}}$ | Heavy naphtha extraction temperature | ℃ |
| $T_{\text{LCO}}$ | Light cycle oil (LCO) extraction temperature | ℃ |
| $T_{\text{fracbot}}$ | Fractionator bottoms temperature | ℃ |
| $F_{\text{stripper}}$ | Stripper overhead flow rate | $Nm^3/h$ |
| $F_{\text{feed}}$ | Flow rate of fresh feed | t/h |
| $F_{\text{reflux}}$ | Flow rate of fractionator reflux | t/h |
| $F_{\text{HCO}}$ | Flow rate of heavy cycle oil (HCO) to riser | t/h |
| $F_{\text{recyc_gaso}}$ | Flow rate of recycled stabilized gasoline | t/h |
| COR | Catalyst-to-oil ratio | / |
| $y$ | Diesel yield | wt% |

## Industrial dataset preparation

A typical FCC plant is composed of two core modules: the reactor-regenerator and the downstream

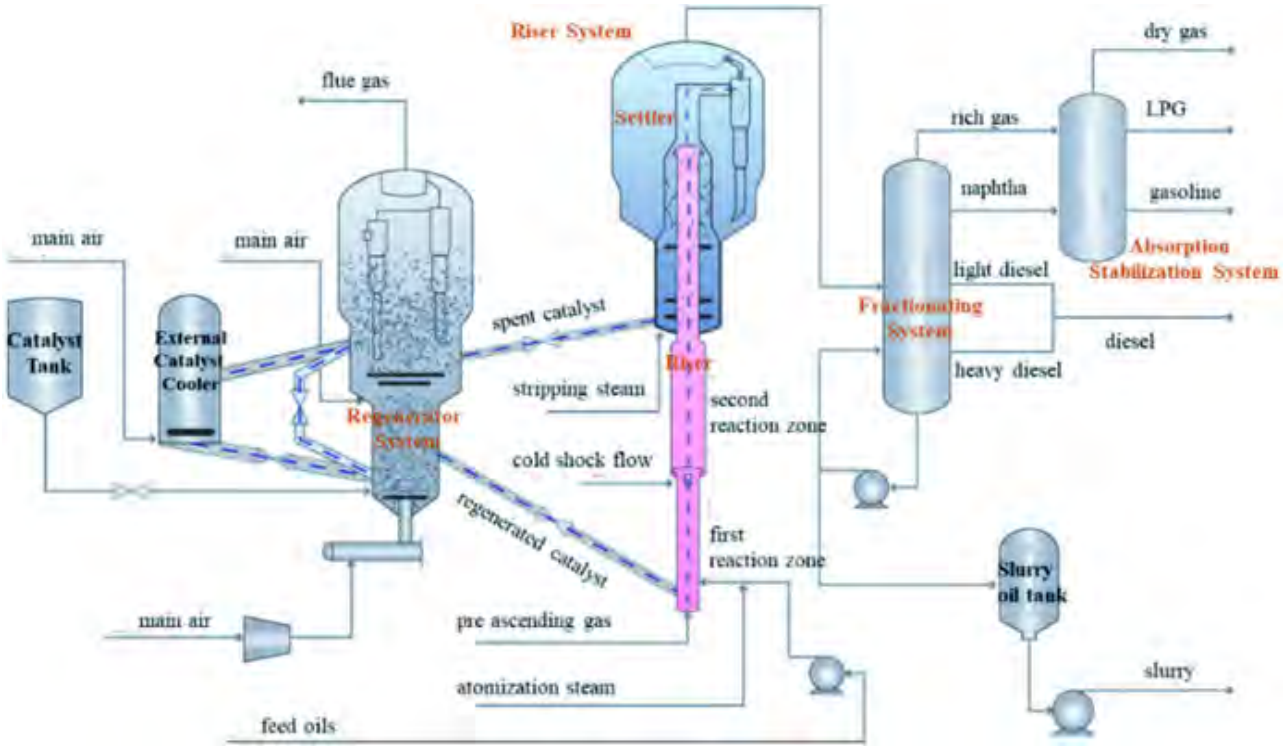

**Figure 2.** A schematic diagram of the FCC unit [8].

product separation system. Raw feedstock is cracked in the riser reactor upon contact with the regenerated catalyst. Subsequently, the cracked mixture is separated into desired products by one or more separation units. In the regenerator, coke is removed by combustion in a controlled process, typically using air. The detailed substance flows are depicted in Figure 2.

We collected time series data from the DCS system in the FCC plant. We preselected variables of interest using domain knowledge, covering the mass flows of feedstocks and products, major operating parameters of the reactor, regenerator, and downstream separation systems like adsorption and distillation columns. A derived variable, catalyst-to-oil ratio (COR), was added to reflect cracking depth, whose values are calculated using an empirical formula. The target variable, diesel yield, is calculated as the mass flow rate ratio of diesel product to fresh feed. Table 1 lists the details of selected variables.

Effective predictive modeling requires robust dataset preparation to ensure data quality and relevance for model training and testing. Data collected from the distributed control system (DCS) may suffer from outliers, irregular sample intervals, and high-frequency fluctuations, hence the need for specific preprocessing methods. These characteristics stem from sensor failures, inconsistent data collection rates, and external measurement influences. Data quality is critical to forecasting performance, and exploratory data analysis (EDA) is necessary for building an effective preprocessing pipeline. Through inspection and visualization, we found the data to be irregularly sampled, with corruptions, outliers, and local oscillations.

To address these challenges, we employed preprocessing techniques to ensure the dataset adhered to the necessary specifications for time series analysis. Irregularly sampled data are aligned to generate a long-form table, facilitating a consistent modeling approach. In time series analysis, rolling window methods—particularly moving averages (or rolling means)—provide an effective approach to smoothing data, helping distinguish signal from noise by minimizing abrupt fluctuations. While simple averaging considers all data points equally, the trimmed mean provides a more robust approach by removing a specified percentage of the most extreme values that could skew the results. The resulting data are aligned and smoothed, and outliers are implicitly removed in this process. This method is called rolling trimmed mean, which can be described as

$$\mathrm{RTM}(p,t,w) = \frac{1}{w-2\lfloor pw \rfloor} \sum_{i=\lfloor pw \rfloor+1}^{w-\lfloor pw \rfloor} x_{(i)} \tag{1}$$

where $t$ represents the current time point, $w$ is the window size, $p$ is the trimming percentage expressed as a decimal, and $x_{(i)}$ represents the $i$-th ordered observations within the window $[t-w+1, t]$ that ends at time $t$.

As a final step, operational parameters are standardized to a similar scale using the z-score method. A temporal split of training and test sets is also carried out,

with the latter taking up 20% of the total data.

## Regression and forecasting

With the dataset prepared, the next phase involves applying time series modeling techniques to forecast future outcomes based on historical data. Among various regression techniques, Bayesian Ridge Regression is selected for its ability to handle multicollinearity and incorporate prior distributions, which helps regularize the model [9]. Bayesian Ridge Regression uses prior distributions for the weights and updates them using observed data. The prior distribution for the weights $w$ is chosen as a normal distribution given by

$$w \sim \mathcal{N}(0, \sigma^2/\lambda) \tag{2}$$

where $\lambda$ is the precision parameter controlling the strength of regularization, and $\sigma^2$ represents the noise variance in the observed data. These hyperparameters are automatically tuned during model training using evidence maximization.

The same regression algorithm is used for different prediction tasks, which can be classified into supervised regression and forecasting. They use the same variable set but with fundamentally different settings in temporal structures and prediction objectives. Supervised regression uses features and lagged versions of them to predict targets, while forecasting methods also use historical values of targets. The forecast model uses two types of input data: the target variable (diesel yield) and covariates (process variables like temperatures and flow rates).

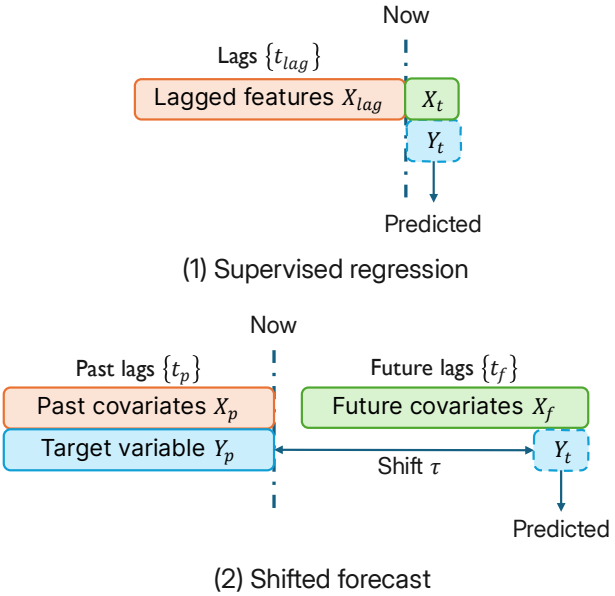

**Figure 3.** Comparison of temporal prediction frameworks illustrating data availability and prediction targets.

Figure 3 illustrates the details of model inputs and outputs, highlighting the difference in the temporal structure. Solid boxes represent available data at prediction time, while dashed boxes indicate predicted values. Vertical dashed lines indicate prediction time points. Past covariates are historical data known up to now, and future covariates are known in the future, at least up to the last forecasted value.

In supervised regression (Figure 3a), the model learns from features $X_t$ and their lagged values to predict a concurrent target variable $Y_t$, where all data is available during training. The model predicts each target independently using lagged features, reflecting a global input-output mapping function.

Conversely, external data are introduced in time series forecasting, which are called covariates. Forecasting makes a distinction between past and future time points relative to the prediction moment. Past covariates are historical data known up to now, and future covariates are known at least up to the last forecasted value (often controlled variables). This approach maintains the temporal ordering essential for time series analysis while avoiding data leakage, as only information available at prediction time is utilized. The lags are chosen to provide local gradients with minimum redundancy:

$$\{t_{lag}\} = \{X_{t-60}, X_{t-30}, X_{t-15}, X_{t-10}, X_{t-5}\} \tag{3}$$

where $t_{lag}$ corresponds to past lags $t_p$ or future lags $t_f$, and $t$ is the timestamp in minutes relative to the end of the corresponding covariate series.

The shifted forecast approach predicts future values by maintaining a fixed time gap between inputs and outputs (Figure 3b). This approach effectively merges lagged inputs (from supervised models) with past covariates (from ordinary forecast models). The temporal difference between past covariates and predicted targets is defined by the prediction shift $\tau$.

A shift of $\tau = 0$ corresponds to one-step-ahead forecasting, where the model leverages data up to the current time point to predict the next value. On industrial datasets with steady states during most periods, the model may degenerate into a naive forecaster that simply repeats the last observation, providing no meaningful information beyond the current state.

Meanwhile, a shifted forecast model with $\tau > 0$ learns to bridge the temporal gap between current information and future outcomes, embedding process information in a way similar to how ordinary supervised regression models learn relationships between input features and output variables. The model implicitly handles slow drifts in process behavior through adaptive corrections of target values with recent historical data.

The models are evaluated with two metrics: mean absolute percentage error (MAPE) and coefficient of variation (CV). In a dataset of n samples, if $y_i$ is the $i$-th target value and $\hat{y}_i$ is the corresponding prediction, MAPE is defined as

$$\text{MAPE}(\mathbf{y}, \hat{\mathbf{y}}) = \frac{1}{n}\sum_{i=0}^{n-1}\left|\frac{y_i - \hat{y}_i}{y_i}\right| \quad (4)$$

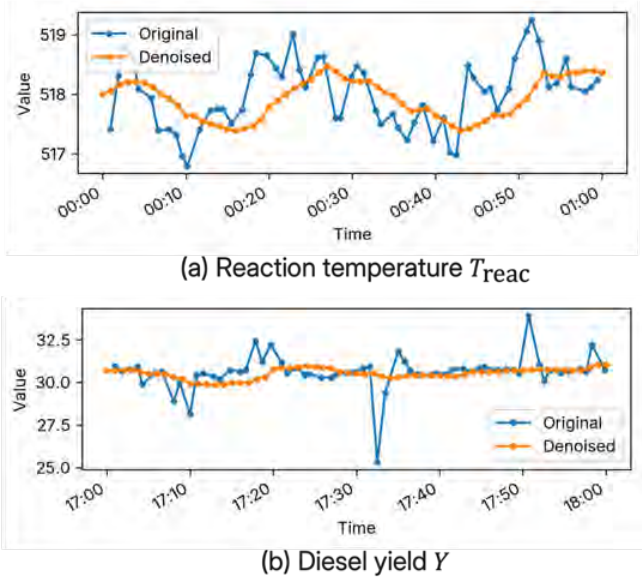
as long as the true values are not close to zero.

The coefficient of variation (CV) is also called normalized root mean squared error (NRMSE), which is defined as

$$\text{CV}(\mathbf{y}, \hat{\mathbf{y}}) = \frac{\text{RMSE}}{\bar{y}} = \frac{\sqrt{\frac{1}{n}\sum_{i=0}^{n-1}(y_i - \hat{y}_i)^2}}{\frac{1}{n}\sum_{i=0}^{n-1} y_i} \quad (5)$$

In brief, our method integrates data preprocessing (alignment, outlier removal, standardization), a supervised regression baseline, and a shifted forecast paradigm that explicitly models time gaps between observations and predictions. These experiments directly compare traditional supervised learning and the proposed forecasting method with various data requirements.

## RESULTS AND DISCUSSION

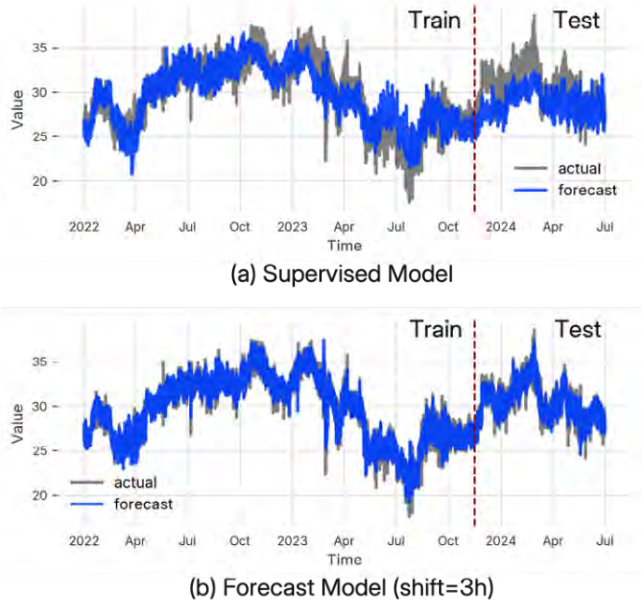


### Data preprocessing

The collected data span two and a half years, from January 2022 to June 2024. Data was sampled approximately once per minute, but the timestamps are not aligned to the minute, and multivariate timestamps are not synchronized. Data points recorded as zero are identified as sensor failures through validation against historical operating ranges. These corrupted readings, comprising approximately 0.12% of the dataset, are removed before further analysis. The dataset undergoes preprocessing using a rolling trimmed mean applied within a 10-minute window. This process involves trimming 5% of extreme values, which effectively smooths the time series and removes outliers, thus preparing it for subsequent modeling. Figure 4 presents examples of original and denoised samples for reaction temperatures and diesel yields.

The denoised temperatures in Figure 4a generally follow the overall trend of the original data but with fewer sporadic deviations. The sharp dip in the original data is significantly reduced in the denoised version, as demonstrated in Figure 4b. The results have smoother and more interpretable trends, providing a good estimate of the system state in the past 10 minutes.

### Model training and validation



The models are trained on data from approximately April 2022 to late 2023, and their predictions are generated on the full dataset without retraining. The results for the supervised and forecast models are depicted in Figure 5.

(a) Reaction temperature $T_{\text{reac}}$

(b) Diesel yield $Y$

**Figure 4.** Comparison of original and denoised data.

(a) Supervised Model

(b) Forecast Model (shift=3h)

**Figure 5.** Performance of supervised and forecast models on the whole dataset.

The supervised model captures the main trends within the training dataset, maintaining an MAPE of 4.42% during this period. However, its performance deteriorates significantly in the test set, where the MAPE increases to 6.20%, indicating potential overfitting. In contrast, the forecast model maintains consistent performance across both sets, with MAPE values of 1.55% and 1.56% for training and test sets, respectively.

Furthermore, three forecast models are trained and tested using 3-hour, 1-day, and 14-day prediction shifts to evaluate the accuracy and robustness across various timescales. These shifts are chosen for operational relevance, representing short-term process control, daily

planning, and long-term strategic forecasting. Figure 6 compares the performance metrics of these three forecast models, revealing the gradual change of their predictive capabilities across different temporal resolutions.

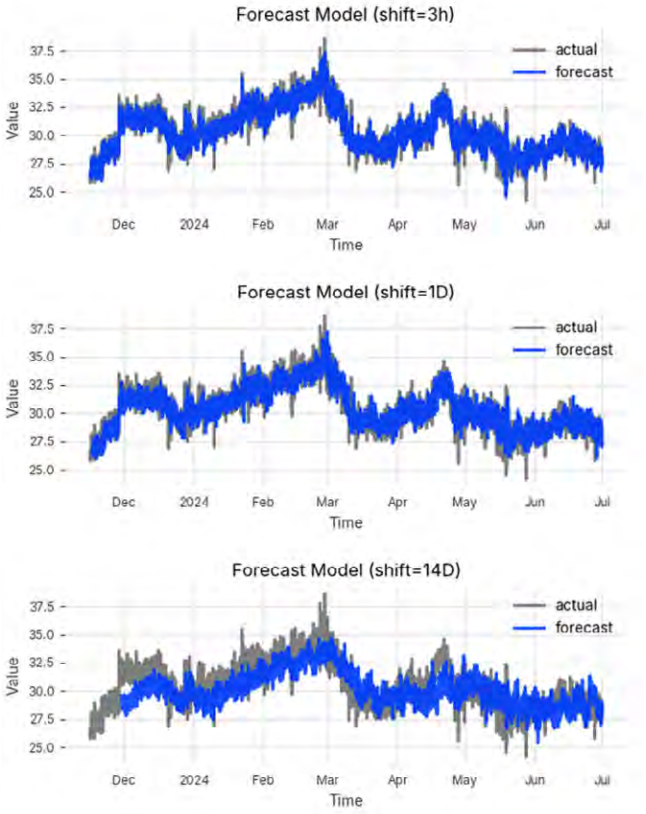


**Figure 6.** Test performance of forecast models using different shifts.

As the shift is prolonged, the model demonstrates reduced accuracy, generally approaching the predictions from the supervised model. However, the forecast model performs much better on the test set, even when predicting the target value 14 days after the known history of diesel yields. This sustained accuracy suggests the successful capture of underlying process relationships rather than simple trend extrapolation.

Table 2 presents the test metrics of different models.

**Table 2:** Test metrics of supervised and forecast models.

| Model | Shift $t_s$ | MAPE (%) | CV |
|---|---|---|---|
| Supervised | / | 6.198 | 7.567 |
| Forecast | 3 hours | 1.564 | 2.120 |
| | 1 day | 2.067 | 2.662 |
| | 14 days | 3.551 | 4.456 |

Forecast models perform better than the supervised one on both metrics, which is reasonable since the inputs to the forecast model are the superset of those available to the supervised one. In real industrial applications, the shift can be selected according to the online data collection mechanism and how often the process states are expected to change.

The forecast model's consistent accuracy validates our approach of explicitly modeling temporal relationships in industrial time series. These results indicate that incorporating historical target values and temporal dependencies is crucial for accurate FCC yield prediction.

## CONCLUSION

This study demonstrates the effectiveness of time series forecasting approaches over supervised regression for predicting FCC diesel yields in industrial settings. The proposed shifted forecast paradigm achieves superior performance across all evaluation metrics, effectively bridging current process states with future operational plans. Experimental results indicate that incorporating historical target values and temporal relationships significantly improves prediction accuracy, with the 3-hour shifted forecast model achieving a 74.8% reduction in MAPE compared to supervised regression (1.56% vs. 6.20%). The model's ability to maintain reasonable accuracy (MAPE of 3.55%) even for 14-day predictions suggests robust learning of process variable correlations. These findings have important implications for industrial applications, enabling more effective process optimization and planning through accurate long-term predictions. The flexibility in selecting prediction horizons makes this approach adaptable to various operational requirements and data collection mechanisms, providing a practical solution for real-world implementation in FCC units.

It is worth noting that feed quality data, such as density and hydrocarbon distribution profiles, were not incorporated in the current model due to the varied and unstable measurement frequency. Future research could incorporate laboratory analysis data, which typically provides more accurate measurements but at much lower sampling frequencies than DCS data. Specifically, integrating laboratory-measured product qualities with high-frequency sensor data could create multi-resolution models that leverage the strengths of both data sources. Further exploration of deep learning methods, particularly transformer architectures that can handle variable-length sequences and capture long-range dependencies, would also be beneficial. Key implementation challenges include handling mixed sampling rates between DCS and laboratory data, managing computational requirements for real-time prediction, and maintaining model interpretability for process engineers. These advancements could potentially extend the application of our forecasting approach to other complex industrial processes facing similar prediction challenges.

## ABSTRACT

Accurate yet interpretable prediction of Global Warming Potential (GWP) is essential for the sustainable design of chemical products and processes. However, existing studies that utilize molecular structure and physicochemical properties for GWP prediction often suffer from low interpretability, relying on black-box models that obscure the underlying relationships between molecular descriptors and environmental impact. To address this limitation, this study employs a Kolmogorov–Arnold Network (KAN) to derive symbolic equations that establish explicit relationships between molecular properties and GWP. By extracting interpretable mathematical expressions, our approach provides a transparent foundation for decision-making in chemical processes and reaction development. Our comparative analysis of machine learning models—including Random Forest, XGBoost, Deep Neural Networks (DNN), and KAN—reveals that Mordred descriptors outperform MACCS keys in GWP prediction, emphasizing the importance of physicochemical properties. The proposed KAN model achieves predictive accuracy comparable to conventional deep learning methods while maintaining interpretability, facilitating data-driven and transparent sustainability assessments in the chemical industry.

**Keywords**: Global Warming Potential (GWP), Life Cycle Assessment (LCA), Explainable Artificial Intelligence (XAI), Kolmogorov–Arnold Network (KAN), Environmental Impact Prediction

## INTRODUCTION

The chemicals industry, as one of the largest global manufacturing sectors, significantly contributes to global greenhouse gas (GHG) emissions.[1] Major research efforts have been made to design new solutions that decarbonize the way chemical products are made.[2] This requires generating reliable yet transparent predictions of the environmental profiles of chemical products. However, a great deal of information is missing – hindering the extent to which fully informed decision-making can be employed in practice.

Life Cycle Assessment (LCA) provides a standardized framework to evaluate environmental impacts, with Global Warming Potential (GWP) being a key metric. While significant efforts have been made to develop LCA databases for retrospective analysis, they remain incomplete in coverage. The diversity of chemical products, the time-intensive nature of LCA model development, and the variability in available data all contribute to this limitation. Consequently, many chemical products and processes are inadequately represented in current databases, limiting the scope of informed decision-making.

To address these challenges, data-driven predictive models have emerged as an efficient alternative to traditional LCA modelling. In particular, GWP prediction based on molecular structure and physicochemical properties has gained significant attention due to the high availability and reliability of such features.[3-5] These models leverage existing LCA data to identify patterns and estimate GWP values for compounds that lack direct assessment. However, most existing predictive models rely on black-box methodologies, such as deep neural network (DNN), which suffer from low interpretability.

Several studies have attempted to predict LCA impact categories using machine learning models. For example, Zhu et al (2020). developed a DNN-based model capable of predicting multiple LCA endpoints, achieving high accuracy for some categories but significantly lower performance for ecosystem-related metrics.[5] Similarly, Song et al. achieved strong predictive accuracy for Eco-

indicator 99 (Coefficient of Determination ($R^2$) up to 0.87) but reported poor GWP prediction accuracy (only 0.48).[3] These results underscore the need for improved modeling approaches specifically designed for GWP prediction.

A critical limitation of existing GWP predictive models is their reliance on increasingly complex machine learning architectures, such as DNN, to enhance predictive performance. While these models improve accuracy, their complexity significantly reduces interpretability, making it difficult to understand the underlying relationships between input features and GWP predictions. Many of these models function as black boxes, limiting their practical applicability in scientific and regulatory contexts. Although explainable AI (XAI) techniques, such as shapley additive explanations (SHAP), have been applied to provide post-hoc explanations, these methods do not fundamentally improve the transparency of the model itself.[6-9] Instead, they serve as an external layer of analysis rather than integrating interpretability into the core predictive framework, highlighting the need for inherently interpretable modeling approaches.

To address the limitations of black-box models, there is a growing need for white-box modeling approaches that provide both accuracy and transparency. Kolmogorov–Arnold Network (KAN) has recently emerged as a promising alternative to DNNs by offering a compact and interpretable model architecture.[10, 11] Unlike traditional neural networks, KAN can extract generalized equations from data, allowing predictions to be directly linked to chemical properties. This feature makes KAN particularly suitable for applications requiring both predictive power and interpretability, such as GWP estimation.

This study evaluates the effectiveness of KAN in developing an interpretable model for GWP prediction. By leveraging molecular descriptors and KAN's symbolic representations, we provide a transparent alternative to existing machine learning models. This approach enhances interpretability in data-driven environmental assessments, supporting informed decision-making and sustainable chemical design.

# METHODS

Our methodology for GWP prediction follows a structured approach focused on feature engineering, model benchmarking, and white-box modelling.

## Data Collection and Preprocessing

The dataset used in this study is sourced from the Ecoinvent v3.8 database, a widely recognized resource for environmental impact assessment. Our dataset consists of 1,689 GWP values spanning 487 different chemicals, ensuring a diverse and representative chemical space for model training. To mitigate data skewness, we applied log transformation, which reduced the effect of extreme GWP values and improved model stability.

## Feature Engineering

To develop a robust predictive framework, we identified and utilized optimal molecular descriptors that capture key structural and physicochemical properties of chemical compounds. Specifically, we employed MACCS keys, a set of 166 binary features representing fundamental molecular functional groups.[12] And Mordred descriptors, which provide a more comprehensive representation of molecular structure and physicochemical properties.[13] These descriptors capture essential structural and chemical characteristics, allowing for accurate GWP predictions based on molecular information.

## Model Development

Our study evaluates multiple machine learning models, including random forest[14] (RF), extreme gradient boosting[15] (XGBoost), DNN[16], and KAN[10, 11], to compare their performance in GWP prediction. Model performance was assessed using $R^2$ to determine the most effective approach for GWP estimation. Among these, KAN was selected as the primary model to investigate its potential to balance predictive accuracy and interpretability by extracting symbolic equations that describe the relationship between molecular descriptors and GWP.

All computational experiments were conducted using Python (version 3.12) in a macOS environment. Random Forest (RF) and XGBoost models were implemented using the scikit-learn library.[17] DNN and KAN models were developed using the PyTorch framework.[18]

## White-Box Modelling

To enhance transparency, we leveraged KAN's unique architecture to derive explicit mathematical expressions that describe the relationship between molecular descriptors and GWP. We also established a comparative baseline by developing interpretable models using linear regression and RF, both of which are commonly employed for their explainability. Unlike traditional black-box models, this approach allows predictions to be traced back to underlying chemical properties, improving interpretability and decision-making.

By focusing on molecular descriptors, our approach aims to establish a transparent, interpretable, and reproducible methodology for GWP estimation. This ensures that predictions are solely driven by intrinsic chemical properties, allowing for a clear understanding of molecular contributions to GWP.

# RESULTS AND DISCUSSION

## Learning Curve Analysis

Learning curve analysis was performed to

determine the optimal data volume for effective training. The dataset was partitioned into subsets based on ascending GWP values, and model performance was evaluated by incrementally increasing the training dataset size. XGBoost was chosen for evaluation due to its strong predictive performance and computational efficiency. As shown in **Fig. 1**, the highest $R^2$ score was achieved using 0.874 of the available data, after which performance declined due to increased data variability. When using only the data from Fold 1 or 2, negative $R^2$ values were observed. Although the $R^2$ score typically ranges from 0 to 1, it can take negative values when the model performs worse than simply predicting the mean, indicating poor generalisation. To ensure optimal predictive performance while maintaining model robustness, only data with GWP values below 5026.3 kg $CO_2$-eq, corresponding to the upper limit of Fold 8, were included in the training dataset. This threshold was chosen based on the observed sharp decline in model accuracy beyond this point, thereby improving generalizability and reducing the risk of overfitting to extreme values

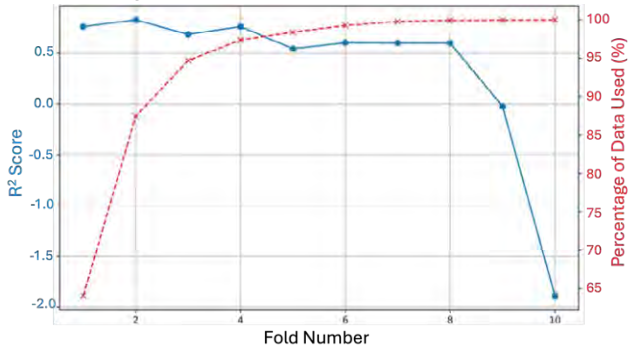

**Fig. 1:** Learning curve analysis through model performance evaluation across different fold numbers.

## Feature Set and Model Performance

We compared the performance of four models—RF, XGBoost, DNN, and KAN—using MACCS keys and Mordred descriptors. **Table 1** shows the $R^2$ prediction results for each model with different features. Mordred descriptors consistently outperformed MACCS keys across all models, with DNN achieving the highest accuracy. This suggests that physicochemical properties captured by Mordred descriptors play a more significant role in GWP prediction than structural fingerprints alone.

**Table 1:** Performance comparison of different models and features for GWP prediction

| | MACCS keys | Mordred |
|---|---|---|
| RF | 0.54 | 0.55 |
| XGBoost | 0.64 | 0.68 |
| DNN | 0.60 | 0.71 |
| KAN | 0.57 | 0.66 |

The results highlight the necessity of incorporating comprehensive physicochemical descriptors for enhanced model performance. The KAN model demonstrated competitive accuracy while maintaining interpretability, making it a viable alternative to DNNs.

## XAI Analysis for Key Feature Identification

To identify the primary factors contributing to GWP prediction, we conducted a post-hoc analysis using the XAI algorithm, SHAP. SHAP quantifies the contribution of each feature to the model's predictions, offering a theoretically grounded approach to explainability in machine learning models.

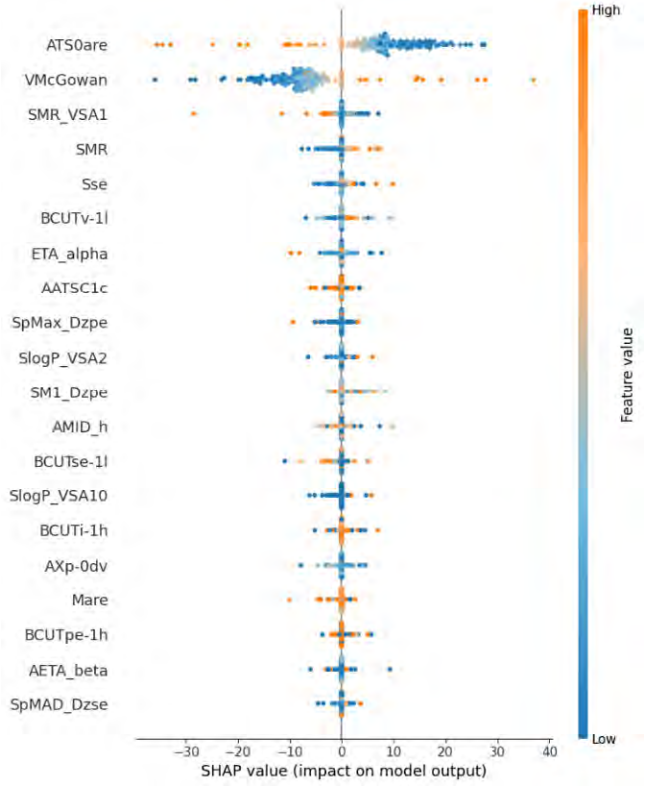

**Fig. 2:** SHAP value distribution for key chemical descriptors, showing their impact on model output.

For this analysis, we examined the DNN model, which achieved the highest predictive accuracy using chemical descriptors, to gain insights into the key molecular properties influencing GWP. As shown in **Fig. 2**, the analysis identified ATS0are and VMcGowan as the most influential descriptors, both exhibiting a strong linear relationship with model outputs. ATS0are, a Mordred descriptor representing the sum of squared atomic electronegativity properties (specifically, Allred-Rochow electronegativity), showed an inverse correlation with GWP. Lower ATS0are values indicate lower molecular electronegativity, which often correlates with increased atmospheric stability, reduced degradation via photolysis, and prolonged greenhouse gas effects. VMcGowan, which quantifies molecular volume based on McGowan's

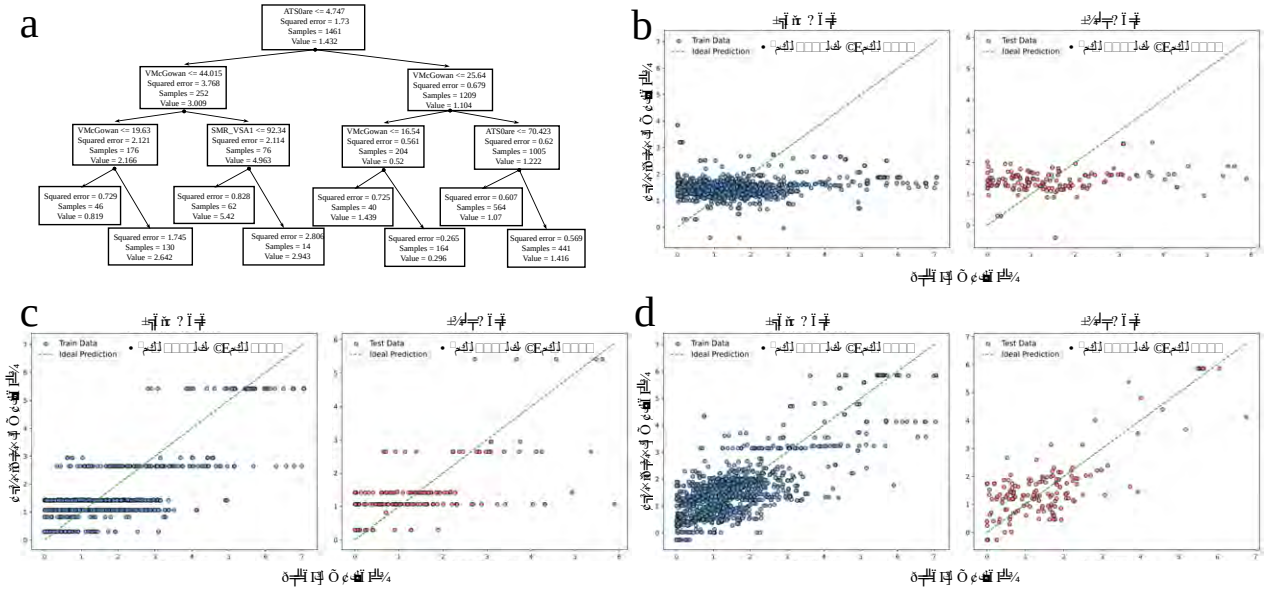

**Fig. 3:** (a) Visualization of the decision tree model trained on key features for GWP prediction. (b) Prediction results for train and test datasets using the linear regression model. (c) Prediction results for train and test datasets using the decision tree model. (d) Prediction results for train and test datasets using the KAN model.

characteristic equation, exhibited a strong positive correlation with GWP. This suggests that larger molecular structures, often associated with higher molecular weights, tend to have prolonged atmospheric lifetimes and greater radiative forcing potential, leading to increased environmental impact. In addition to these primary descriptors, SMR_VSA1, SMR, and SSE ranked as the third, fourth, and fifth most significant features in the model's decision-making process. SMR_VSA1, a van der Waals surface area descriptor weighted by molar refractivity, displayed an inverse relationship with GWP. SMR, representing total molecular refractivity, and SSE, measuring solute excess polarizability, both exhibited positive correlations with GWP, indicating that molecular dispersion forces and polarizability significantly influence environmental impact predictions. These findings highlight the interplay between molecular size, electronic properties, and intermolecular interactions in shaping GWP. Notably, the high correlation between ATS0are and other key descriptors, such as SMR (0.91) and SSE (0.99), suggests that electronegativity-driven features strongly influence GWP predictions. This reinforces the need for white box approaches like KAN to provide explicit, interpretable equations linking molecular descriptors to GWP, ensuring greater transparency in sustainability assessments.

## White-Box Modelling

A white-box modelling approach is proposed to predict GWP scores of chemicals and processes, utilizing the interpretability functions of KAN model.[10, 11] To benchmark the KAN model, we conducted a comparative analysis with two widely used interpretable models: linear regression and decision tree models. To enhance model interpretability, reducing the number of features is as critical as selecting an appropriate model. Therefore, we used the top 20 features identified in **Fig. 2** as inputs for training the white-box models. These features accounted for 87% of the total feature importance, while the remaining features each contributed no more than 1.7%, indicating relatively small influence on model training.

The fundamental benchmark, the linear regression model, produced poor predictive performance, with $R^2$ scores of 0.0598 and 0.0621, and MSE values of 1.6266 and 1.6185 for the training and test datasets, respectively, as shown in **Fig. 3**(b). The mathematical formulation derived from the linear regression model for a given molecule $m$ is provided in Eq. (1):

$$GWP_m = \sum_{i=1}^{20} a_i \cdot x_{m,i} + b \qquad (1)$$

where $x_{m,i}$ represents chemical descriptors, $a_i$ denote regression coefficients, and $b$ is the intercept term representing the baseline GWP. The coefficients derived from the model are summarized in **Table 2**.

Among the descriptors, SpMax_Dzpe has the highest positive coefficient, suggesting that the maximum atomic polarizability along the principal moment of inertia axis is strongly associated with increased GWP. Sse and VMcGowan also exhibit notable positive influences, indicating that solute excess polarizability and molecular volume play key roles in determining GWP. Conversely, SMR_VSA1 has the most significant negative impact, implying that molecular refractivity-weighted van der Waals surface area contributes to lowering GWP.

These observations highlight the limitations of linear

**Table 2:** Coefficients of the linear regression model for GWP prediction.

| Coefficient | Chemical descriptor | Value |
|---|---|---|
| $a_1$ | ATS0are | 0.007946 |
| $a_2$ | VMcGowan | 0.151153 |
| $a_3$ | SMR_VSA1 | -0.800855 |

regression in capturing complex, non-linear relationships between molecular descriptors and GWP. Additionally, the presence of collinear features, such as VMcGowan and Sse, suggests potential redundancies in the feature set, which may further restrict the model's predictive capabilities. While the linear regression model offers simplicity and interpretability, its performance remains inadequate for accurate GWP estimation, underscoring the need for more sophisticated modeling approaches that can effectively capture intricate molecular interactions.

The decision tree model, which allows for more complex yet interpretable modelling, yielded the results visualized in **Fig. 3**(a). The boxed structures in the figure represent the decision criteria at each node of the RF model. The tree comprises 15 nodes, with the root node split on ATS6ave, indicating its dominant influence on GWP prediction. Additional splits based on VMcGowan and SMR_VSA1 further indicate the hierarchical importance of these features. As the depth of the tree increases, prediction error decreases, and terminal nodes provide distinct GWP values. However, as depicted in **Fig. 3**(c), the model's predictive performance remains limited, with $R^2$ scores of 0.5978 and 0.3711, and MSE values of 0.6958 and 1.0852 for the training and test datasets, respectively. While the decision tree model captures non-linear patterns to some extent, its predictive performance still falls short of effectively modelling the complex, non-linear behaviour of chemical properties governing GWP. This demonstrates the inherent trade-off between interpretability and predictive accuracy in traditional white-box models.

To address these limitations, we adopted the KAN framework, widely recognized for its capability to represent symbolic expressions, to develop a GWP prediction model.[19] The KAN model captures non-linear relationships between features and GWP by transforming these relationships into interpretable standard functions such as exponential, polynomial, and trigonometric functions. However, if the fitted model is inherently linear, it can be transformed into a linear model through symbolic transformation, distinguishing KAN from conventional non-linear regression models. The development process of this white-box KAN model, including key steps such as fitting, pruning, fine-tuning, and symbolic simplification. In particular, symbolic simplification is a critical process for ensuring model interpretability. During this process, the model fits various candidate symbolic functions—such as sine, cosine, exponential, logarithmic, and power functions—and systematically selects the form that best represents the underlying non-linear relationship in the data. This automated selection ensures that the chosen functions accurately capture the data's structural patterns while maintaining model interpretability.[10]

As shown in **Fig. 3**(d), the model achieved predictive performance with $R^2$ scores of 0.6287 and 0.6433, and MSE values of 0.6352 and 0.6716 for the training and test datasets, respectively. Remarkably, despite being a fully interpretable white-box model, its performance is comparable to or even exceeds that of black-box models developed in previous studies, which achieved accuracies of 0.63 and 0.48.[3, 5] The mathematical expression for the resulting white-box model is presented in Eq. (2) as follows:

$$\mathrm{GWP_m} = \varepsilon \cdot \cos\left(\sum_{i=1}^{15} g_i(x_{m,i}) + \eta\right) + \iota \qquad (2)$$

where $m$ denotes the molecule, and $x_{m,i}$ represents the input molecular descriptors specific to molecule $m$. the parameters $\varepsilon$, $\eta$, and $\iota$ are set to 5.34842491149902, 8.4815278578314, and 4.47257137298584, respectively. Each function $\mathrm{g_i}(x_{m,j})$ is defined in a general form in Eq. (3) as follows:

$$g_i(x_{m,i}) = \alpha_i \cdot func_i(\beta_i \cdot x_{m,i} + \gamma_i) \qquad (3)$$

where $x_{m,i}$ represents the $i$-th molecular descriptor of molecule m. The parameter $\alpha_i$ is a scaling coefficient that determines the magnitude of the transformation, while $\beta_i$and $\gamma_i$ adjust the input values of the function. The function $func_i$ represents a non-linear transformation applied to the descriptor, which can take forms such as sine, cosine, hyperbolic tangent, absolute value, or power functions. The specific functional forms and parameter values used in this model are summarized in **Table 3**. Among the initial 20 descriptors, five—Sse, AATSC1c, SlogP_VSA10, AETA_beta, and SpMAD_Dzse—were excluded during the pruning process of the KAN model. This process systematically removes features that contribute minimally to

the model's predictive performance or exhibit high redundancy with other descriptors.

The function $g_1(x_{m,1})$ is formulated as a scaled hyperbolic tangent function. This structure suggests that $g_1(x_{m,1})$ primarily captures the non-linear effects of ATS0are on GWP, applying a transformation that emphasizes variations within a specific range, while mitigating extreme values through the saturation properties of the hyperbolic tangent function.

The incorporation of a cosine transformation in Eq. (2) allows the model to capture non-linear saturation effects in GWP contributions. This aligns with chemical intuition, reflecting the stabilising effects of certain structural features as they grow larger or more complex. These transformations enable the KAN model to generalise domain-specific knowledge while maintaining interpretability, bridging the gap between predictive accuracy and interpretability. By integrating these features and their transformations, the KAN model delivers a robust framework for understanding the interplay between molecular descriptors and GWP. The result is a white-box model that combines predictive performance with interpretability, adhering to established chemical principles to provide precise forecasts of environmental impact.

**Table 3**: Functional transformations of molecular descriptors in the KAN model

## CONCLUSIONS

This study highlights the effectiveness of KAN based white-box modeling in GWP prediction. By leveraging the KAN model, we developed a predictive framework that effectively captures complex molecular relationships while maintaining interpretability through symbolic equations. Our findings emphasize the crucial role of physicochemical descriptors, particularly molecular electronegativity and volume, in determining GWP values, reinforcing the feasibility of using purely molecular information for environmental impact assessments.

The developed KAN model offers a structured, explainable approach enhancing transparency in environmental impact modeling. By deriving explicit symbolic equations, the model ensures greater interpretability and supports informed decision-making in the sustainable design and evaluation of chemical processes. This interpretability makes the model highly applicable in industrial and regulatory contexts where transparency is essential. Furthermore, our results demonstrate that KAN achieves predictive accuracy comparable to conventional deep learning models while addressing key interpretability challenges in machine learning-based GWP predictions.

## ABSTRACT

The rapid advancement of computational drug discovery has enabled the generation of vast virtual libraries of promising drug candidates. However, evaluating the synthetic accessibility (SA) of these compounds remains a critical bottleneck. While computer-aided synthesis planning (CASP) tools can provide synthesis routes to the candidate, their computational demands make them impractical for large-scale screening. Existing rapid SA scoring methods, struggle to generalize to out-of-distribution molecules and do not account for economic viability. To address these challenges, we present MolPrice, an accurate and reliable price prediction tool. By introducing a novel self-supervised learning approach, MolPrice achieves robust generalization to diverse molecular structures of various complexities. Our comprehensive analysis of model architectures and molecular representations reveals that substructure-based features strongly correlate with market prices, supporting the relationship between synthetic complexity and economic value. MolPrice performs well on the standard literature SA benchmark, showcasing its ability for SA estimation. MolPrice thus serves as both an accurate molecular price predictor and a rapid synthetic accessibility assessment tool, enhancing the efficiency of modern drug discovery pipelines.

**Keywords**: Molecular Complexity, Machine Learning, Synthetic Accessibility, Virtual Screening, Retrosynthesis

## INTRODUCTION

Generating promising compounds for drug discovery has become increasingly efficient. With the emergence of several open-source tools [1], one can design a whole library of thousands/millions of molecules with desired physical properties in hours.

However, taking these molecules from the virtual library to laboratory testing is a major challenge. This is because the virtual compound needs to be synthesized first, which is costly and time-consuming. Finding synthesis pathways from known building blocks to virtual molecules is a laborious process known as retrosynthesis. Within the past decade, researchers have developed computer-aided synthesis planning tools (CASP) [2] that automate retrosynthetic planning. Whilst these tools are powerful, they are still too slow (~0.5 minutes per molecule). As molecular design routines require a large number of molecular evaluations, CASP tools do not scale [3]. For example, to screen a library of 1 billion molecules within hours, the time scale should be in ms per molecule.

To overcome this issue, researchers have developed efficient scoring systems that can evaluate molecules for *synthetic accessibility* (SA) within milliseconds. The scoring systems classify molecules as either *easy-to-synthesize* (ES) or *hard-to-synthesize* (HS). ES molecules are proceeded for further analysis and HS are usually discarded. Calculated SA scores are based on i) complexity-based indicators [4,5] or ii) retrosynthetic analysis [3,6]. Complexity-based models calculate a score depending on structural indicators such as the presence/absence of functional groups and the number of stereocentres in the molecule [4]. Retrosynthetic-based models predict the output of the slower CASP tool. For example, *Thakkar et al.* [6] attempt to predict whether the CASP tool can successfully find a synthesis route to the molecule. Whilst both methodologies have their merits, they face a significant limitation: the inability to generalize to out-of-distribution molecules. Furthermore, the scoring system is either based on binary classification or

a user-defined scale, lacking physical interpretation.

Inspired by *Sanchez-Garcia et. al.* [7], we propose to assess the synthetic accessibility of a molecule based on its market price. The authors were the first to draw a connection between SA and molecular price. The price prediction model (CoPriNet) presented in [7] accurately recalls the price of purchasable, ES molecules. Similar to other scoring systems, their model fails to generalize to out-of-distribution molecules. In particular, the model is prone to assign a similar price range to both ES and HS molecules. In short, their model cannot distinguish molecular complexity and cannot be used for SA scoring.

This work aims to overcome these challenges by introducing MolPrice, a fast predictive model for molecular price. Using a new self-supervised training methodology, MolPrice learns to distinguish purchasable (ES) molecules from hard-to-synthesize (HS), out-of-distribution molecules. Through systematic analysis of different model architectures and molecular representations, we demonstrate that features capturing substructures strongly correlate with market prices, supporting the fact that synthetic complexity is reflected in economic value. MolPrice can thus be used as an initial starting point for economic analysis (market price of product – reactants).

Finally, MolPrice can be used as an accurate tool for molecular price prediction and as an SA estimation for virtual screening or molecular generation.

# METHODOLOGY

## Model Development

### Data Source

The data was provided by Molport as a snapshot of their purchasable database from March 2024. The database consists of over 5M molecules with their corresponding price in USD per unit weight. Molport provides several prices (by different suppliers) for a range of weights. The first step to obtain a robust dataset is to find a single price value per molecule. We follow the steps below to obtain this database:

1. Molecules that cannot be read by RDKit [8] are filtered out.
2. For each molecule, all corresponding prices are converted from USD per weight to USD per mmol.
3. For each molecule, the lowest price is obtained in USD per mmol.
4. The prices are converted to a logarithmic scale for model training [7].
5. Finally, molecules with a price < 2 USD/mmol on the logarithmic scale are removed (these are mostly stabilizing salts in solution or metals)

The final dataset is plotted in Figure 1.

We acknowledge that over time new molecules may be added to the database. In that case, one can simply retrain the model in a matter of minutes (as outlined in Results and Discussion).

For self-supervised learning, the HS molecules dataset is obtained from *Yu et. al.* [9] consisting of 400K molecules.

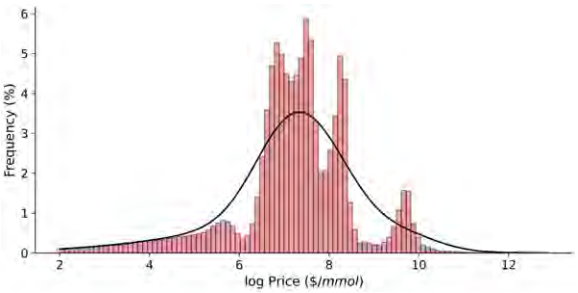

**Figure 1**: Distribution of price dataset

### Model Details

One can use a variety of models for molecular property prediction, the best depending on the specific use case. We screened different molecular featurization schemes and model architectures to select the most accurate and robust model. Particularly, in case of molecular featurization, it is interesting to explore the features that capture the relationship between price and molecule best. This way, we are posing the question whether functional groups or larger molecular moieties determine the economic value of a compound. Below we outline the tested model featurization:

- **Molecular Fingerprints** encode the 2-dimensional molecule in a bit vector. Each bit in the vector indicates the presence or absence of a molecular substructure. Various fingerprint generation algorithms exist. We select four popular algorithms: Morgan (ECFP), Atom-pair, Topological torsion (all three provided by RDKit) and MinHash (Mhfp) [10]. Morgan and Mhfp focus on the circular environment around atoms. Atom-pair considers pairs of atoms and the shortest path between them. Topological torsion considers sequential patterns. One could argue that Morgan/Mhfp best represent functional groups (FGs), atom-pair captures the overall shape of the molecule and topological torsion captures the backbone patterns. The reader is referred to the sources for more detailed information [8,10]. The various fingerprints are then used as input to a multilayer perceptron (MLP).
- **2D Graphs** include the connectivity between atoms in our modelling approach, we explore the direct use of the 2D molecular graph. The graph

features include descriptors for nodes (atom) and edge (bond) features. We use the graph model presented in [6] as the graph neural network (GNN) and as the literature baseline within the results.

- **SMILES** is a text-based representation of a molecule. We explore both the vanilla Transformer and a pre-trained RoBertA model by DeepChem [11]. As a note, the SMILES is tokenized per atom basis.
- **Functional Groups** are features that are constructed through the extended functional groups (EFG) algorithm [12]. Intuitively, EFGs are substructures in the molecule characterizing functionalization such as alcohols, ketones, amides. As molecules have different number of EFGs (different input length), a long-short term memory (LSTM) is a natural modelling choice. As an alternative, one could also construct an EFG fingerprint and use an MLP. This will be investigated in the future.

All models are trained on the MSE loss:

$$L = \frac{1}{M}\sum(y_i - \hat{y}_i)^2, \quad (1)$$

where $y_i$ and $\hat{y}$ are the ground-truth labels and model output, respectively and M is the dataset size. The regression models are compared using mean squared error (MSE), coefficient of determination ($R^2$), Spearman's correlation coefficient ($r_s$) and most importantly, inference time. The selection of time as an evaluation criterion follows naturally from previous arguments; the purpose of *SA* scoring systems is to perform large numbers of evaluations. The Molport dataset is split into 90/5/5 portions for training/validation/testing. This leaves ~500k molecules for validation and testing.

## Self-Supervised Learning

Following model training, the model is still unlikely to generalize to unseen, complex molecules. This is because all molecules in our database are purchasable or in other words, easy to synthesize. Molecules which are not synthesizable (HS) generally will not have a price label since they are not offered by suppliers.

To allow our model to learn price labels for the HS molecules, we use a contrastive learning approach. Particularly, the approach is based on two principles:

First, assuming the model has learnt a good correlation between the *latent* molecule representation and the price, we only need to focus on learning the *latent* representation of the HS molecules. Herein, we define the *latent* representation as the final vector in the model, prior to the readout function. The readout function *f* is defined as $f(\mathcal{R}^N) \rightarrow \mathcal{R}$, that is the function that converts the *latent* representation into the price output. A visual explanation is shown in Figure 2. Following on with this assumption, we freeze the parameters (weights) in the readout function during self-supervised learning. In other words, the only parameters that can be updated during the training, are the parameters that compute the *latent* representation, prior to the readout function.

Second, we assume that each dimension of the *latent* representation follows a Gaussian distribution. The assumption is reasonable as the price distribution of the model output (Figure 3a) is approximate Gaussian (by visual inspection). Using these two principles, we define the loss function for self-supervised learning as:

$$L = \frac{1}{M}\sum_{i\in ES}(y_i - \hat{y}_i)^2 + \lambda \cdot \frac{1}{N}\sum_{j=0}^{N} H_j, \quad (2)$$

$$H_j = \sqrt{\frac{2\sigma_{ES,j}\sigma_{HS,j}}{{\sigma_{ES,j}}^2 + {\sigma_{HS,j}}^2}}\exp\left(-1/4\frac{(\mu_{ES,j}-\mu_{HS,j})^2}{{\sigma_{ES,j}}^2 + {\sigma_{HS,j}}^2}\right), \quad (3)$$

where $H_j$ is the analytical Hellinger distance computed $\forall j \in \{1, \ldots, N\}$ with *N* being the *latent* vector size for Gaussian distributions. In short, the Hellinger distance enforces a separation in the *latent* representation of ES molecules versus HS molecules. The Hellinger distance tends to a minimum of zero when the ES distribution $\mathcal{N}(\mu_{ES,j}, \sigma_{ES,j})$ does not overlap with the HS distribution $\mathcal{N}(\mu_{HS,j}, \sigma_{HS,j})$. Since the parameters of the readout function are not updated during training, a different *latent* vector representation for the HS molecules should lead to a different price. The first term in Eq. 2 is the MSE loss computed over the set of ES molecules and therefore acts as a regularisation term. $\lambda$ is a hyperparameter and was set to a low value of 0.05 by default. By scaling the loss of the Hellinger distance, we do not permit the model to perform poorly on the initial price prediction task. Intuitively, if the two loss terms in Eq. 2 are not conflicting, we should obtain an accurate model for price prediction as well as a model that can distinguish ES from HS molecules.

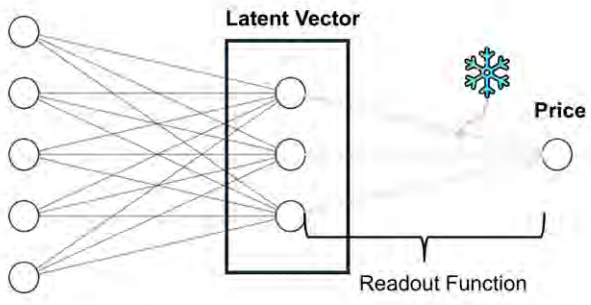

**Figure 2:** Toy example with a latent vector of 3D (N=3). Parameters of the readout functions are frozen.

It is to be noted that there is no theoretical guarantee that the predicted price for the HS molecules will be larger than the predicted price of the ES molecules. This

**Table 1:** Results for different model architectures and molecular featurization schemes on the hold-out test set. The metrics include mean squared error (MSE), coefficient of determination ($R^2$), Spearman's correlation coefficient ($r_s$) and inference time in ms (per single cpu core per molecule)

| Architecture | Feature/Model Type | MSE (↓) | $R^2$ (↑) | $r_s$ (↑) | Inference Time (ms/mol) |
|---|---|---|---|---|---|
| MLP | Atom pair | 0.58 | 0.72 | 0.84 | 1.4 |
| | Topological | 0.61 | 0.71 | 0.84 | 1.4 |
| | Morgan | 0.51 | **0.76** | **0.88** | **1.4** |
| | Mhfp | **0.50** | **0.76** | **0.88** | **1.4** |
| GNN (CoPriNet) | 2D Graph | 0.52 | 0.74 | 0.85 | 21.5 |
| Transformer | SMILES (Vanilla) | 0.88 | 0.58 | 0.72 | 41.1 |
| | SMILES (RoBERTa) | 0.58 | 0.72 | 0.85 | 29.1 |
| LSTM | EFGs | 0.62 | 0.70 | 0.82 | 3.6 |

is because we do not incorporate price labels for the HS molecules and solely rely on the contrastive loss (Eq. 2)

To verify that MolPrice has effectively learnt the difference between ES and HS molecules, we compare its performance to classical SA scoring systems on the test dataset TS1-3 provided in [9], the standard for comparing SA scoring tools.

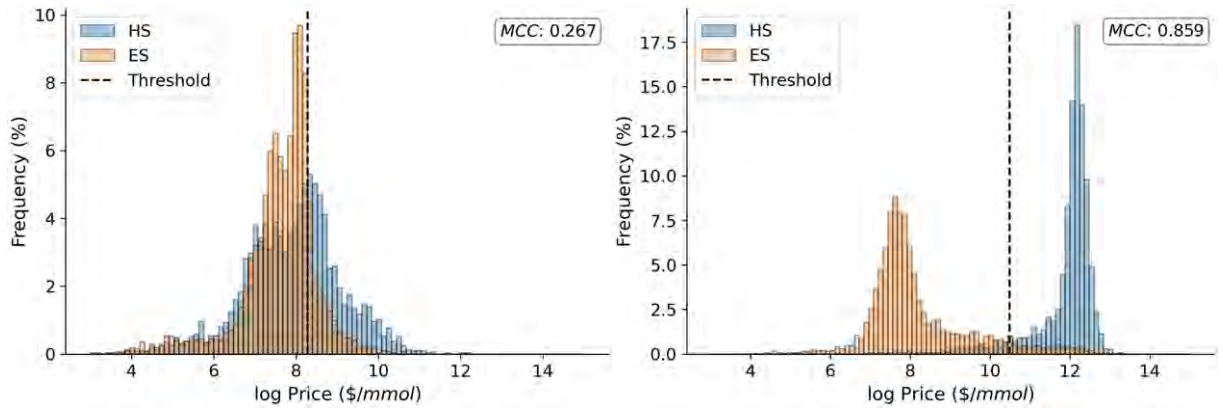
## RESULTS AND DISCUSSION

### Price Prediction

The results for price prediction on the test set are shown in Table 1. Analysing the performance metrics, the neural network (MLP) with Morgan/Mhfp featurization performs best in terms of MSE, $R^2$ and $r_s$. Particularly, the Morgan/Mhfp featurization is preferred over the two other fingerprints tested (Atom pair and Topological). This can be explained by considering the fingerprint construction algorithm: Both Morgan/Mhfp fingerprints are constructed through circular environments around atoms in the molecule. This featurization resembles functional group (substructure) encoding. On the other hand, atom-pair and topological torsion fingerprints consider the sequential order of atoms in a molecule and fail to fully capture fine-grained details such as functional groups.

The GNN model (CoPriNet) is seen to nearly match the fingerprint MLP models. Possibly this can be explained by comparing the internal model workings: Particularly, the message-passing operation commonly used in GNNs is similar to the circular encoding algorithm (for fingerprint construction). Thus, both model architectures share a certain degree of knowledge.

As expected, the pre-trained Transformer (RoBERTa) model performs better than its vanilla counterpart. The pre-training allows the model to learn the SMILES language prior to the downstream prediction task. Nevertheless, both SMILES-based models fail to outperform the GNN or fingerprint MLP. As SMILES are tokenized per atom basis, the model is not aware of molecular substructures, a piece of information available to both the GNN and MLP.



Finally, the extended functional group (EFGs) LSTM is seen to perform acceptably. We believe that the LSTM fails to construct a good latent representation of the molecule due to the sequential input of the EFGs. Instead of using an LSTM, it may be worth constructing a new fingerprint based on EFGs and using an MLP as the model.

Last, a very important factor not yet discussed is the model's inference time. For example, if one wants to screen a database of 1 billion molecules and the scoring takes 1 second per molecule, it would take ~30 years to screen the entire database. From Table 1, we see that the MLP is favourable with a quick inference time of 1.4 ms per molecule (tested on an Intel vPro i9 laptop cpu). The same database could now be screened within 12 days. Both the literature GNN (CoPriNet, literature model) and Transformer models take 20-40x longer for the same task. This is because both models perform a large number of matrix multiplication operations, whereas the MLP only performs 3 overall. The training time of the MLP lies within 30 minutes, whereas both the GNN and Transformer model takes several days, rendering training on a new dataset computationally intensive.

The detailed analysis of different molecular featurization highlights that features capturing substructures correlate well with market prices (Morgan, Mhfp, GNN). This finding underscores the relationship between molecular complexity and market price.

### Learning Synthetic Accessibility

The top two performing models (Mhfp and Morgan) provide the starting point for self-supervised learning. Figure 3 shows the predicted price for both ES and HS molecules before and after self-supervised learning for the Morgan fingerprint. For both Morgan and Mhfp fingerprints, the algorithms learn to assign prices to HS molecules that are different to the ES, purchasable molecule. Empirically, we observe that the model prefers to assign a higher price range to the HS molecules compared to the ES molecules. This is desired, but as outlined previously,

a: Before self-supervised learning b: After self-supervised learning

**Figure 3:** Distributions of ES/HS molecules predicted by MolPrice for Morgan fingerprint. The degree of distribution separation is measured through the Matthews correlation coefficient (MCC).

there is no mathematical guarantee for this observation.

Statistically, the separation between the ES and HS distribution is confirmed in the table below:

**Table 2**: Statistics on HS/ES classification and Price

| **Fingerprint** | **MCC** (↑) | **AUC** (↑) | $\mathbf{R^2}$ (↑) |
|---|---|---|---|
| Morgan | 0.86 | 0.97 | 0.54 |
| Mhfp | 0.89 | 0.98 | 0.73 |

In Table 2, the distribution separation is measured using Matthew's correlation coefficient (MCC) and area under receiver operating characteristic curve (AUC). These two metrics indicate how well MolPrice can distinguish between ES and HS molecules (a binary classification problem). The Mhfp fingerprint slightly outperforms the Morgan fingerprint in both metrics.

More importantly, for the Morgan fingerprint, the MSE loss and Hellinger distance separation were seen to have conflicting objectives. To obtain a higher AUC, the hyperparameter $\lambda$ in Eq. 2 was set to a higher value. This came with a decrease in the accuracy of price prediction for the ES dataset as shown by a lower $R^2$ compared to Table 1. For the Mhfp fingerprint, the $R^2$ only slightly decreased from 0.76 to 0.73. From Table 2, we can deduct that the MLP along with the Mhfp fingerprint results in an accurate price prediction as well as a SA scoring tool.

## Comparison to other SA scoring tools

To confirm that MolPrice is indeed a competitive SA scoring tool, we benchmarked and compared MolPrice to other state-of-the-art SA tools. This analysis is shown in Table 3. From the table, it is seen that MolPrice performs competitively compared to other SA screening tools. Only GASA outperforms MolPrice on the test datasets apart from TS3 – accuracy. While MolPrice is not the top performing model, two things should be kept in mind when analysing the results:

1. GASA and other models were exclusively trained for SA scoring, *i.e.*, the only objective given to the model is the binary classification between ES and HS molecules. MolPrice has to balance between predicting accurate labels for the price as well as learning the difference between the two molecule groups
2. The test sets TS2 and TS3 were curated by using a CASP tool. In short, the HS molecules are labelled as hard-to-synthesize if the CASP tool fails to return a synthesis route for the molecule. It is to note that CASP tools are not perfect and highly depend on the database that it was trained on. Given this, it could be that some molecules that were labelled as ES are

**Table 3:** Comparison of our model MolPrice to other, commonly used SA tools. The test datasets are obtained from [9]. For TS1-3, the area under receiver operating characteristic curve (AUC) is reported as well as the accuracy for TS3. The best performance is highlighted in bold, the second best in italics.

| **Model** | **TS1 (AUC)** | **TS2 (AUC)** | **TS3 (AUC)** | **TS3 (Acc)** |
|---|---|---|---|---|
| *GASA* [9] | **0.999** | *0.881* | **0.850** | *0.759* |
| *SCScore* [5] | 0.881 | 0.487 | 0.575 | 0.511 |
| *SAScore* [4] | 0.989 | **0.919** | 0.772 | 0.664 |
| *RAScore* [6] | 0.919 | 0.865 | 0.790 | 0.701 |
| *MolPrice* (ours) | *0.991* | 0.871 | *0.833* | **0.771** |

actually HS and vice versa.

Given above, it is fair to conclude that MolPrice performs well on these benchmarks. We plan to extend SA testing in future works on case studies as outlined in the next section to solidify the use case of MolPrice of molecular generation and screening.

## CONCLUSION AND OUTLOOK

In this work, we present MolPrice, an accurate tool for both price prediction and synthetic accessibility measurement. MolPrice is based on the Mhfp fingerprint and a fast-to-evaluate MLP, which were carefully selected after exploring a range of model architectures and molecule featurization schemes. Through this exploration, we discovered the importance of molecular substructures for predicting prices, supporting the notion that molecular complexity is reflected in economic value.

By introducing a new contrastive learning approach, we steer MolPrice towards molecules that are out-of-distribution and/or complex.

In the future, we will test MolPrice on different case studies. These case studies will range from multi-objective virtual screening [13] to molecular generation such as in [3]. Furthermore, we want to include MolPrice directly as guidance in retrosynthesis planning. In short, we are interested to see whether MolPrice can steer the synthesis search towards economically viable routes and/or speed up the convergence of the CASP tool.

## DIGITAL SUPPLEMENTARY MATERIAL

MolPrice is hosted on GitHub and usable through https://github.com/fredhastedt/MolPrice

## ACKNOWLEDGEMENTS

This work was supported by the Engineering and Physical Sciences Research Council (EPSRC) funding grant EP/S023232/1.

We thank Molport (https://www.molport.com/) for sharing their private data used for model training.

## ABSTRACT

The increasing complexity of industrial biotechnology demands advanced modeling techniques capable of capturing the intricate dynamics of bioreactors. Traditional regression-based and empirical methods often fall short when confronted with the highly nonlinear behavior and limited experimental data characteristic of bioprocesses. Addressing these challenges requires a more intelligent approach—one that leverages domain knowledge to model complex bioprocess dynamics effectively, even with sparse data, while maintaining interpretability and robustness. In this study, we introduce a process-informed, data-driven methodology for modeling the dynamics of industrial bioreactors, leveraging the capabilities of the rising field of Scientific Machine Learning (SciML). Our approach leverages Physics-Informed Neural Networks (PINNs) to seamlessly integrate domain knowledge encoded in physical laws with sparse experimental data and deep learning techniques, enabling precise simulation and modeling of bioreactor operations. The framework is validated using real-world experimental data, demonstrating its capability for state and space estimation, essential for optimizing biomanufacturing processes. Our findings underscore the potential of Physics Informed Neural Networks to address the challenges of dynamic modeling in bioprocesses, paving the way for the development of intelligent, autonomous, and data-driven solutions in industrial biotechnology. This fusion of data-driven and mechanistic modeling represents a transformative step toward enhancing the efficiency, scalability, and sustainability of modern biomanufacturing practices.

**Keywords**: Machine Learning, Simulation, Dynamic Modelling, Industry 4.0, Intelligent Systems

## INTRODUCTION

The increasing complexity of modern industrial biotechnology underscores the urgent need for advanced modeling and simulation techniques. Many biomanufacturing processes still rely heavily on empirical knowledge and operator expertise, which limits their ability to effectively handle the increasing intricacies and dynamic nature of contemporary bioprocesses. This dependency on traditional methods constrains the scalability, efficiency, and optimization of biomanufacturing, highlighting the need for more data-driven and adaptive approaches. As bioprocess systems become more sophisticated, traditional control strategies struggle to address emerging challenges, including raw material variability, unpredictable biological dynamics, and the imperative for real-time, data-driven decision-making. The advent of Industry 4.0—characterized by digitalization, automation, and intelligent data integration—has initiated a transformative shift towards smarter, more efficient, sustainable, and adaptive bioprocessing systems [4]. Digital transformation in bioprocesses involves integrating multiple technologies, yet the inherent complexity, high dimensionality, and dynamic nature of these systems, driven by numerous interacting parameters, pose significant challenges in optimizing process efficiency, maintaining stability, and maximizing product yields [6].

Artificial Intelligence (AI) is gaining increasing recognition for its potential to revolutionize bioprocesses modeling by effectively leveraging real-world experimental data. Recently, a growing number of AI technologies have been applied in bioprocess optimization and control to enhance the performance of bioprocess. These advancements demonstrate that AI holds great promise

for enhancing bioprocess efficiency, scalability and adaptability, making it a valuable tool for addressing the challenges faced in modern biomanufacturing [6]. However, conventional machine learning approaches, such as neural networks, face significant limitations in this domain due to their reliance on large datasets to achieve optimal performance. In bioreactor applications, the availability of data is often sparse and limited, posing a critical challenge for purely data-driven methodologies. Moreover, traditional neural networks operate as black-box models, lacking the ability to incorporate physical knowledge of the underlying bioprocess, which is essential for ensuring reliability and interpretability in complex biomanufacturing systems.

To address these challenges, in this study, we introduce a novel approach that leverages the principles of Scientific Machine Learning (SciML) to overcome the challenges of bioreactor modeling. Specifically, we employ Physics-Informed Neural Networks (PINNs), a cutting-edge framework that integrates physical knowledge directly into the machine learning process. Unlike traditional neural networks, PINNs embed governing equations, such as mass balance, energy balance, and reaction kinetics, as constraints within the learning architecture. This enables the model to respect the underlying physics of the bioprocess while learning from limited experimental data. In addition to enabling accurate dynamic modeling with limited data, the Physics-Informed Neural Network framework offers the capability to perform parameter estimation directly within its architecture. Traditional methods for parameter estimation in bioprocesses often require extensive experimental data or rely on iterative optimization techniques that can be computationally expensive and time-consuming. In contrast, PINNs naturally incorporate parameter estimation by treating unknown process parameters as trainable variables within the network. We validate our approach using a dynamic model of a batch bioreactor and real-life experimental data. Our demonstration highlights the effectiveness of PINNs in achieving accurate dynamic modeling and parameter estimation, even with very limited experimental data.

# METHODS AND MATERIALS

## Dynamic Model

As a pilot study, we expanded upon the work of [1], which successfully demonstrated the production of recombinant nanobodies with scorpion antivenom activity in Escherichia coli. Nanobodies (VHH), derived from camelid antibodies, were produced intracellularly in E. coli WK6 through fed-batch cultivation, with production yields significantly improved using dynamic modeling techniques [2]. In our study, experimental data from the batch phase of the bioreactor were utilized to develop a predictive model using Physics-Informed Neural Networks (PINNs). The bioreactor is assumed to be an infinitely mixed culture without any transfer limitation. The mass balances for biomass and glucose are given by Eq. (1) and (2):

$$\frac{\mathrm{dX}}{\mathrm{dt}} = \frac{\mu_{max} \cdot S}{K_S + S} \cdot X \quad (1)$$

$$\frac{dS}{dt} = -\frac{1}{Y_{XS}} \cdot \frac{\mu_{max} \cdot S}{K_S + S} \cdot X \quad (2)$$

where X and S are the concentrations of biomass and glucose (in $g/L$), $\mu_{max}$ is the maximum specific growth rate (in $h^{-1}$), $K_S$ is the substrate saturation coefficient (in $g/L$) and $Y_{XS}$ is the yield coefficient of substrate (in $g \cdot cdw/gS$).

## Scientific Machine Learning

Scientific Machine Learning (SciML) is an innovative and rapidly evolving field that merges principles from machine learning (ML) with scientific computing to tackle complex challenges across various domains, including physics, biology, and engineering [5]. This interdisciplinary approach leverages the strengths of both data-driven methods and traditional physics-based models, aiming to enhance predictive capabilities and facilitate data-driven discoveries. This integration enables more accurate simulations and predictions, particularly when the under-lying physics of a system is only partially known or too complex to model explicitly.

By incorporating scientific knowledge, SciML techniques require less data to achieve accurate and robust predictions, which is especially beneficial when collecting large amounts of data is expensive or impractical. Furthermore, these methods maintain interpretability by embedding physical principles and domain knowledge into the models, allowing for better understanding of the underlying processes and greater trust in the predictions they provide.

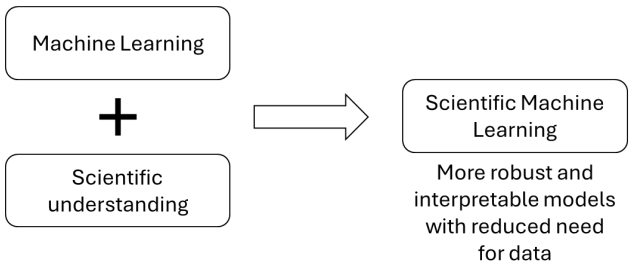

**Figure 1:** Scientific Machine Learning

## Physics-Informed Neural Network

Physics-Informed Neural Networks (PINNs) represent a significant advancement in the intersection of machine learning and computational physics, providing a framework for solving complex mathematical models governed by partial differential equations (PDE).

Introduced in [3], PINNs leverage the capabilities of deep learning to incorporate physical laws directly into the learning process, enabling the networks to approximate solutions to both forward and inverse problems effectively. This approach allows one to automatically find data-driven solutions for PDEs or ODEs. In this paper, we consider parametrized nonlinear system of ODEs given by:

$$\mathcal{F}\left(t, \boldsymbol{y}(t), \frac{d\boldsymbol{y}(t)}{dt}; \boldsymbol{\lambda}\right) = 0 \tag{3}$$

where $\boldsymbol{y}$ represents the state of the dynamic system (i.e., the latent ODE solution) and $\boldsymbol{\lambda} = [\lambda_1, \ldots, \lambda_2]$ are the ODE parameters. In the context of PINNs, a fully connected feed-forward neural network with multiple hidden layers is employed to approximate the solution of the differential equations. The network takes time $t$ as input and outputs:

$$\boldsymbol{y} = f_{\boldsymbol{w}}(t) \tag{4}$$

where $f_{\boldsymbol{w}}$ represents the mapping function learned by the neural network, parametrized by adaptive weights $\boldsymbol{w}$. This setup requires the network to learn to compute the solution of the given ODEs. The neural network in a PINN framework is trained by minimizing a mean squared error (MSE) cost function, typically defined as:

$$MSE = \mathcal{L}_{data} + \mathcal{L}_{physics} \tag{5}$$

where $\mathcal{L}_{data}$ represents the data-based loss term, and $\mathcal{L}_{physics}$ enforces the physical consistency of the solution. These loss terms are formulated as follows:

$$\mathcal{L}_{data} = \frac{1}{N_y}\sum_{i=1}^{N_y}\frac{1}{N_t}\sum_{j=1}^{N_t}\left\|y_i(t_j) - y_i^*\right\|_2^2 \tag{6}$$

$$\mathcal{L}_{physics} = \frac{1}{N_y}\sum_{i=1}^{N_y}\frac{1}{N_{\mathcal{F}}}\sum_{j=1}^{N_{\mathcal{F}}}\left\|\mathcal{F}(y_i(t_j))\right\|_2^2 \tag{7}$$

where, $N_t$,$N_{\mathcal{F}}$ and $N_y$ correspond to the number of training data points, the number of collocation points and the number of outputs of the neural network respectively; $y_i$ is the $i$-th output of the neural network; $y_i^*$ represents the desired $i$-th output, considering the $j$-th data pair $(t_j, y_i^*(t_j))$. The data-based loss term penalizes discrepancies between the network's predictions and the desired outputs from the training data. The physics-based loss term enforces the alignment of the network's outputs with the governing differential equations of the physical system by minimizing the residuals of these equations at a finite set of randomly sampled collocation points. Together, these terms allow the network to approximate the solution of the system's dynamics while adhering to physical laws. By incorporating prior knowledge through the governing equations, the PINN framework reduces the reliance on large datasets, enabling it to perform accurate dynamic modeling and parameter estimation even with sparse data. This integration of theoretical models with experimental data enhances the efficiency and robustness of process modeling, making PINNs particularly suitable for complex, data-limited systems. PINNs can also be employed in a inverse setup to perform parameter estimation of the governing ODEs. In this configuration, unknown parameters within the ODEs are treated as additional trainable variables within the neural network. By incorporating these parameters into the optimization process, the network learns not only the dynamic behavior of the system but also estimates the values of the unknown parameters. This process enables PINNs to infer parameters even in cases where traditional methods struggle due to sparse or noisy data.

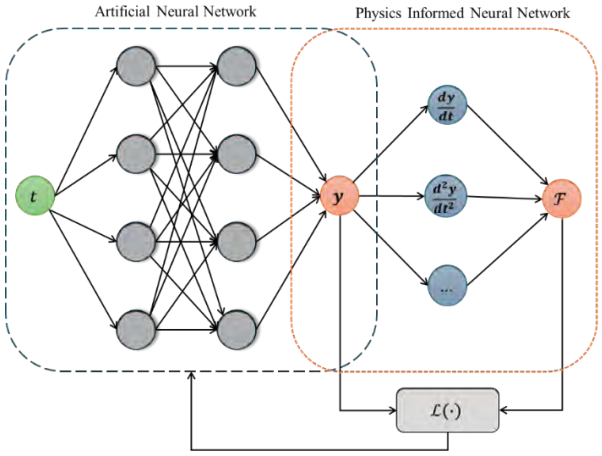

**Figure 2:** Physics Informed Neural Network

## RESULTS

Leveraging experimental data from [1] and the dynamic model described previously, we applied our approach to a batch bioreactor, showcasing the ability of Physics-Informed Neural Networks (PINNs) to accurately capture the system's state-space dynamics and unlock predictive insights, thereby advancing data-driven intelligence in bioprocess modeling. The dataset consists of measurements of biomass and glucose concentrations over time in a batch bioreactor (**Figure 3**).

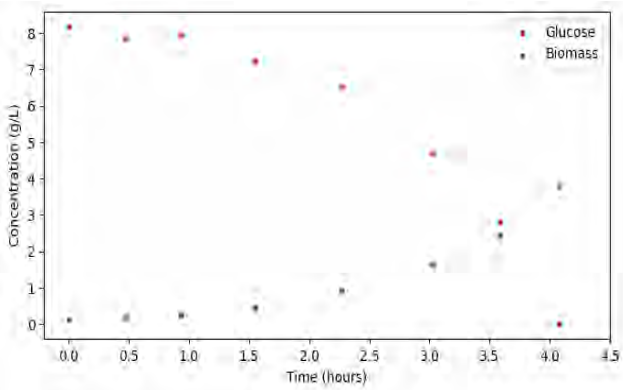

**Figure 3:** Experimental data for batch phase

The results demonstrate that this physics-informed framework effectively overcomes the key challenges of conventional dynamic modeling methods, particularly those arising from sparse and limited experimental datasets. The PINN architecture utilized in this study is a fully connected feed-forward neural network comprising one input layer, three hidden layers (with 64, 1024 and 1024 neurons) and one output layer. The $ReLU$ activation function was applied to the input and final hidden layers, while the $Tanh$ activation function was used for the intermediate layers, a combination that enhanced the network's accuracy and overall performance. The network was trained using the $Adam$ optimizer with a learning rate of $0.0001$ over $30{,}000$ epochs, with early stopping implemented to prevent overfitting.

The network's single input was the time ($t$) variable, and its output layer provided predictions for Biomass ($X$) and Glucose ($S$). To capture the system's underlying dynamics, 50 collocation points were used during training. These points enforced the governing ODEs, ensuring that the PINN not only fit the available data but also adhered to the physical laws governing the system. The PINN was trained by solving the optimization problem:

$$\underset{\boldsymbol{w},\boldsymbol{p}}{minimize}\ \mathcal{L} \tag{8}$$

$$\mathcal{L} = \mathcal{L}_{data} + \mathcal{L}_{physics} \tag{9}$$

where

$$\mathcal{L}_{data} = \frac{1}{2}\cdot\frac{1}{N_y}\left(\sum_{j=1}^{N_y}\left\|X(t_j) - X^*\right\|_2^2 + \sum_{j=1}^{N_y}\left\|S(t_j) - S^*\right\|_2^2\right) \tag{10}$$

and

$$\mathcal{L}_{physics} = \frac{1}{2}\cdot\frac{1}{N_{\mathcal{F}}}\left(\sum_{j=1}^{N_{\mathcal{F}}}\left\|\frac{dX(t_j)}{dt} - \frac{\mu_{max}\cdot S(t_j)}{K_S + S(t_j)}\cdot X(t_j)\right\|_2^2 + \right.$$
$$\left. + \sum_{j=1}^{N_{\mathcal{F}}}\left\|\frac{dS(t_j)}{dt} + \frac{1}{Y_{XS}}\cdot\frac{\mu_{max}\cdot S(t_j)}{K_S + S(t_j)}\cdot X(t_j)\right\|_2^2\right) \tag{11}$$

In the equations (8)-(11), $\boldsymbol{w}$ are the neural network's trainable weights and $\boldsymbol{p}$ are the unknown kinetic parameters of the dynamic model. $\mathcal{L}_{data}$ represents the data-driven loss function, measuring how well the predictions of the model match the experimental data at specific time points. Finally, $\mathcal{L}_{physics}$ represents the physics-driven loss function, which ensures that the model adheres to the physical laws governing the bioprocess system. By minimizing the loss function ($\mathcal{L}$) with respect to both the network weights ($\boldsymbol{w}$) and the unknown kinetic parameters ($\boldsymbol{p}$) of the dynamic model, we simultaneously train the neural network and perform parameter estimation for the dynamic system. Addressing collinearity between network weights and kinetic parameters is essential to ensure that the estimated parameters accurately represent the underlying system dynamics, rather than being influenced by artifacts of the optimization process. Techniques such as regularization, orthogonalization, or introducing additional constraints can help mitigate this issue and improve the robustness of the parameter estimation process.

## Parameter Estimation

We first demonstrate the capability of the PINN to accurately estimate the unknown kinetic parameters of the dynamic model using only a sparse set of measurements. Estimating these parameters is a critical step in effectively modeling and understanding the complex dynamics of bioprocesses, as they govern key aspects such as microbial growth rates and substrate consumption.

By employing the PINN in an inverse configuration, we successfully performed parameter estimation, with the resulting kinetic parameter estimates summarized in next table (**Table 1**).

**Table 1**: Estimated kinetic parameters

| Kinetic parameter | Value |
|---|---|
| $\mu_{max}$ | 0.7267 |
| $K_S$ | 0.1634 |
| $Y_{XS}$ | 0.3983 |

As a reference, the dynamic model calibrated parameters reported in [1] are presented in **Table 2**.

**Table 2**: Model parameters reported in literature

| Kinetic parameter | Min. value | Max. value |
|---|---|---|
| $\mu_{max}$ | 0.67 | 0.87 |
| $Y_{XS}$ | 0.29 | 0.47 |

These findings highlight the ability of PINNs to accurately estimate unknown kinetic parameters, even when experimental data is sparse, showcasing their potential for applications in bioprocess modeling and control. In contrast to traditional parameter estimation approaches, which often require the full trajectory of data—available only at the end of the process—PINNs can achieve accurate parameter estimation using only the available data points at any time during the process. This allows for a more adaptive modeling approach, particularly in bioprocesses where real-time data collection is limited or costly. As a result, kinetic parameters can now be described as dynamic functions of time rather than fixed constants, providing a more realistic and accurate representation of the evolving nature of complex bioprocesses.

## Simulation

In this paragraph, we demonstrate the ability of PINNs to perform accurate simulations of the bioprocess. By leveraging both sparse experimental data and the governing equations of the system, the PINN effectively captures the complex dynamics of the process. Accurate simulation is vital for understanding the system's behavior, predicting outcomes under various operating conditions, and optimizing bioprocess performance. This

capability is particularly important in biomanufacturing, where precise control of dynamic variables such as biomass and substrate concentrations are crucial for achieving consistent product quality and yield. Unlike conventional regression approaches, which rely solely on fitting data and often require large datasets to achieve acceptable accuracy, PINNs integrate prior physical knowledge into the learning process. This integration significantly reduces the dependency on extensive datasets, making PINNs especially well-suited for applications where experimental data is limited or costly to obtain. Furthermore, the physics-based loss function in PINNs ensures that the model predictions adhere to the underlying laws of the system, improving the interpretability and robustness of the simulation results.

The simulation performance of the PINN is evaluated leveraging the mean squared error (MSE) between the predicted state variables and the experimentally measured values for both biomass and glucose. This performance metric provided a quantitative assessment of the model's ability to replicate the observed dynamics of the bioreactor (**Table 3**).

**Table 3**: PINN simulation performance

| Number of data points | Biomass (MSE) | Glucose (MSE) |
|---|---|---|
| 8 | 0.012 | 0.018 |

The low MSE values indicate that the PINN is capable of accurately modeling the dynamics of the batch bioprocess. A key advantage of the PINN also lies in its interpretability, as it incorporates prior process knowledge in the form of governing ODEs directly into the modeling framework.

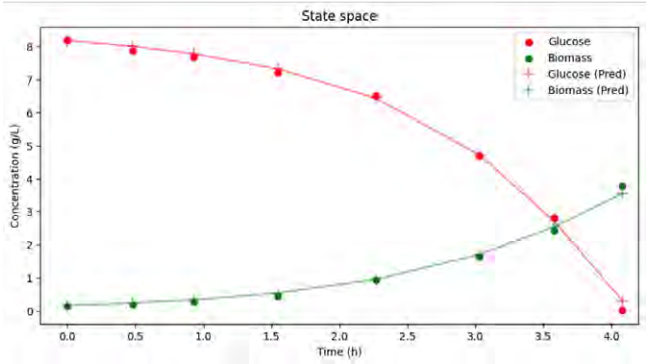

**Figure 4:** PINN simulation results

**Figure 5** presents a comparison of the simulation results obtained by solving the system of ODEs using kinetic parameter values estimated through a traditional regression approach [1] versus the simulation results obtained through PINN. The values of kinetic parameters estimated using standard regression techniques and used for simulating the system dynamics are $\mu_{max} = 0.77$, $K_s = 0.214$ and $Y_{xs} = 0.40$. The results clearly demonstrate that the PINN provides a better fit to the experimental data points compared to the traditional regression-based approach. This improved accuracy in state estimation is achieved because PINNs integrate both sparse experimental data and fundamental process knowledge encoded in the system's governing equations. Unlike pure data-driven methods, which may struggle with limited or noisy datasets, PINNs leverage physical constrants to guyide learning, ensuring consisntesy with known bioprocess dynamics. The superiority of PINNs becomes even more evident in scenarios where fewer experimental data points are available or when modeling occurs in real-time rather than at the end of the process. Traditional regression-based methods typically require a complete dataset spanning the entire process to provide reliable parameter estimates. In contrast, PINNs can extract meaningful insights even from sparse or incomplete data by leveraging the underlying physics of the system.

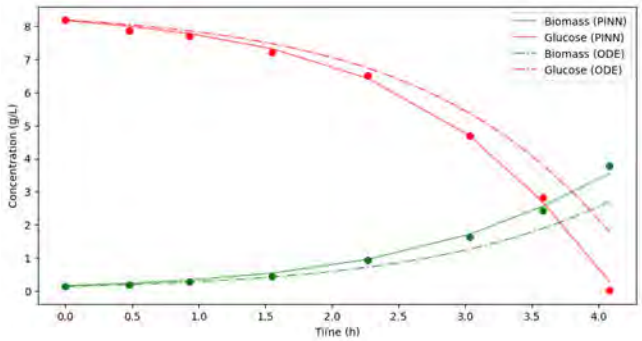

**Figure 5:** Simulation results of PINN and traditional regression approaches

## CONCLUSIONS

Accurate modeling of complex bioprocess systems is hindered by several key challenges. One of the primary issues is the sparse availability of experimental data, as generating comprehensive datasets can be costly and time. Additionally, traditional black-box data-driven methods often lack interpretability, making it difficult to understand and the underlying predictions or to derive actionable insights. "Furthermore, the inherently complex and highly non-linear nature of bioprocesses presents additional challenges, making it difficult to develop robust and accurate models that can effectively capture the intricate and dynamic behaviors involved. n this study, we aim to address these challenges by leveraging Physics-Informed Neural Networks (PINNs), a powerful tool for modeling and simulating the dynamics of complex bioprocesses. By integrating prior knowledge in the form of governing ODEs with sparse experimental data, PINNs offer a robust framework for accurate dynamic modeling and parameter estimation.

The results obtained from a batch bioreactor system highlight the ability of PINNs to capture intricate state-space dynamics, even when data is limited, and to provide interpretable, physics-consistent predictions. Furthermore, the application of PINNs in an inverse setup for estimating kinetic parameters underscores their versatility and effectiveness in addressing one of the key challenges in bioprocess modeling. Compared to conventional regression approaches, PINNs not only reduce the dependency on extensive datasets but also ensure adherence to the physical principles of the system, enhancing both reliability and interpretability.

This integration of machine learning and scientific principles represents a significant step toward more intelligent, data-driven solutions for industrial biotechnology. Future work will focus on extending this approach to more complex bioprocess systems, incorporating real-time data, and exploring adaptive learning strategies to further enhance the scalability and applicability of PINNs in dynamic modeling and control.

## ABSTRACT

The industrialization of catalytic processes requires reliable kinetic models for design, optimization, and control. While white box models are preferred for their interpretability, they demand considerable time and expertise for their construction. This research enhances the ADoK-S framework by embedding prior expert knowledge using mathematical constraints and integrating uncertainty quantification. The improved methodology consists of: (I) a genetic programming algorithm with constraints to produce physically coherent candidate models, (II) a sequential optimization algorithm for parameter estimation, (III) model selection based on the Akaike information criterion (AIC), and (IV) uncertainty quantification of the chosen model's predictions. The refined approach not only requires less data for discovering kinetic models but also ensures physically sound proposals. With the inclusion of uncertainty quantification, the method bolsters prediction reliability, and aids in safer system developments – crucial for decision-making and risk management. These improvements enhance data efficiency, model reliability, and position automated knowledge discovery as a real alternative to traditional kinetic modeling techniques.

**Keywords**: chemical reaction engineering, kinetic model generation, automated knowledge discovery, expert knowledge, uncertainty quantification.

## INTRODUCTION

Catalytic processes stand at the forefront of industrial advancement, and their significance is amplified in the face of climate change and the pressing need to reduce waste and enhance efficiency. In the journey from design to industrialization of catalytic processes, the role of reliable kinetic models is paramount, particularly in the development, optimization, and control of chemical reactors. These models act as the centerpiece of process understanding, enabling the refinement, and scaling of catalytic operations to meet environmental and economic goals.

Yet, the task of developing reliable kinetic models is fraught with challenges. The traditional approach has seen experts making closed-form, interpretable models, known as white box models, from the ground up, guided by physical principles and their domain-specific expertise. Despite their obvious appeal, these models are notoriously cumbersome and time-consuming to develop. As an alternative, the rise of black box models – such as neural networks and Gaussian processes – and hybrid models, which aim to integrate the interpretability of white box models with the flexibility of black box models, has been observed. Nevertheless, these models come with their own caveats, most notably the high volume of data needed for training, which is typically not available in kinetic studies. Moreover, their lack of interpretability raises safety and reliability concerns for deployment in safety-critical processes.

In response to these challenges, a new paradigm has been embraced within the community: automated knowledge discovery or symbolic regression. Symbolic regression, an emerging tool in the field of machine learning and data analysis, offers a novel approach to model discovery. Unlike traditional regression methods that fit predetermined models to data, symbolic regression autonomously searches for mathematical expressions that best describe observed datasets. This method utilizes evolutionary algorithms or other heuristic techniques to explore an extensive space of mathematical constructs, ranging from simple algebraic equations to complex

interactions embodying non-linear behaviors. Its ability to uncover underlying patterns and relationships without pre-specified model structures makes it particularly valuable in scientific research, where it can reveal previously unrecognized phenomena or propose novel theoretical models. As a result, symbolic regression is gaining traction across diverse scientific domains including kinetic modeling, providing a powerful tool for exploratory analysis and advancing our understanding of complex systems.

Techniques such as SINDy (Sparse Identification of Nonlinear Dynamics) and ALAMO (Automated Learning of Algebraic Models for Optimization) have emerged to solve symbolic regression, yet not without limitations. They often depend on significant, accurate prior assumptions about the model structure, are vulnerable to noisy data, and lack a justified model selection routine. These gaps in methodology led the way for the development of ADoK-S and ADoK-W (Automated Discovery of Kinetics using a Strong/Weak formulation of symbolic regression) frameworks, as introduced in the work of de Carvalho Servia et al. [1]. Despite the benefits of this approach, these frameworks were recognized to require enhancements, specifically an uncertainty quantification mechanism for model's predictions and the integration of expert knowledge via mathematical constraints to enrich and ease the model discovery process.

This paper introduces these novel enhancements to the ADoK-S framework, incorporating a sampling-based uncertainty quantification algorithm to evaluate the reliability of a chosen model's predictions – a critical component for the safe design, optimization, and control of processes. Additionally, by assimilating expert knowledge through mathematical constraints, the data requirements for the model discovery phase are reduced. The subsequent sections of this paper are organized as follows: Section 2 revisits the ADoK-S framework, and presents the new methods for uncertainty quantification and constraint handling; Section 3 discusses the case study employed to evaluate the enhanced algorithm, now termed physics-informed ADoK-S (PI-ADoK-S); Section 4 presents the results where PI-ADoK-S improves upon the performance of the unconstrained algorithm; and Section 5 concludes with the study's main contributions.

## METHODOLOGY

In prior works, ADoK-S was presented as a solution to the challenges of conventional modeling paradigms and positioned itself as an alternative to other automated knowledge discovery methodologies such as SINDy and ALAMO [1]. The ADoK-S framework is structured around three main components: (I) a genetic programming (GP) algorithm, which generates candidate models; (II) a sequential optimization algorithm designed for the estimation of parameters in promising models; and (III) a transparent and reasoned model selection routine that utilizes the Akaike Information Criterion (AIC) for determining the best-suited model (for a detailed discussion on the choice of AIC as the criterion of choice, readers are referred to de Carvalho Servia and del Rio Chanona [2]).

ADoK-S implements symbolic regression in its traditional form, often referred to as the strong formulation. This method necessitates the development of rate models to stem from rate measurements, which, being experimentally inaccessible, must be estimated. Following the outlined three-step process, ADoK-S first uncovers the optimal concentration profiles (i.e., a time dependent function), describing the dynamic evolution of species' concentrations in the system. These profiles are then differentiated to approximate the rate measurements of the reaction system. Subsequently, utilizing the same three steps, ADoK-S aims to discover kinetic rate models that best fit these estimated rates. The selected rate model is integrated and compared against the original concentration data. Should the model output prove unsatisfactory – owing to either contradictions of prior knowledge or poor model fitting – ADoK-S offers a closed-loop approach. The modeler can run an optimal experiment, as determined by a Model-Based Design of Experiments (MBDoE) scheme, which is then concatenated with the initial dataset. The Hunter-Reiner criterion is used to find the optimal experiment that maximizes the error between the prediction of two competing models (in this study, the competing models are the best two models found using our methodology) [3]. With the new experimental data, ADoK-S can be iterated, and the subsequent model output examined. This iterative process can continue as required by the modeler or until the experimental budget is exhausted. For a detailed explanation of the ADoK-S algorithm, readers are referred to de Carvalho Servia et al. [1].

Despite favorable results, ADoK-S had its own limitations. Particularly, its lack of a direct and flexible mechanism for injecting prior knowledge through mathematical constraints during the model generation phase, and an absence of a quantifiable measure of the uncertainty in the predictions of the selected rate model. The following subsections delve into these newly incorporated features that have led to the development of PI-ADoK, an improved version of the ADoK-S framework. Figure 1 provides a detailed and visual representation of the workflow of PI-ADoK.

### Inclusion of Mathematical Constraints

The effectiveness of integrating mathematical constraints within a symbolic regression framework has been a subject of debate in the literature. On one hand, studies such as Kronberger et al. [4] indicate that constraints

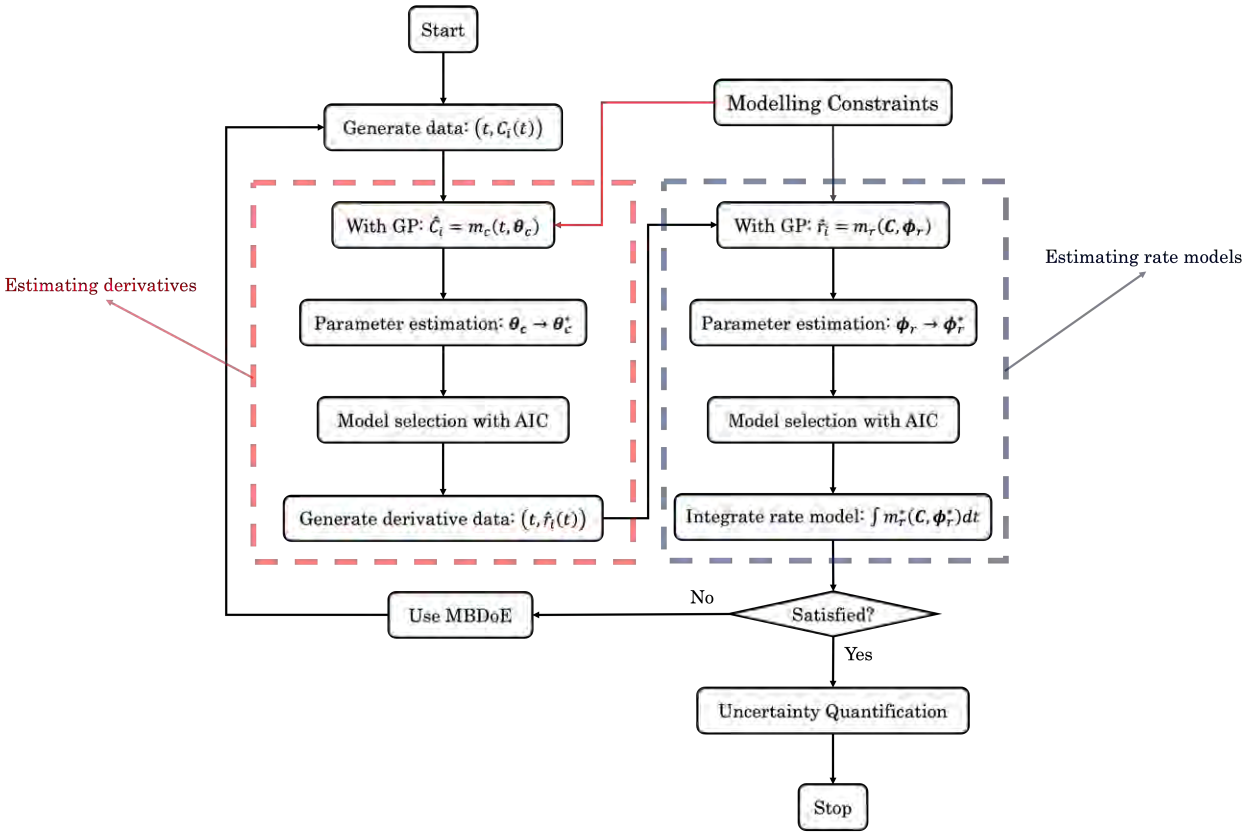

**Figure 1:** Illustration of the PI-ADoK framework, emphasizing its two main tasks: derivative estimation (red box) and rate model generation (blue box). The derivative estimation phase begins with genetic programming to generate candidate concentration models, followed by parameter estimation and model selection based on AIC. These selected models are then numerically differentiated to approximate reaction rates. In the rate-modeling phase, the estimated rates are used to construct kinetic expressions, which are further refined through parameter estimation and model selection. If the current model is insufficient, Model-Based Design of Experiments (MBDoE) suggests new experiments to improve data quality, iterating until a reliable model is obtained. Finally, uncertainty quantification is performed to assess predictive reliability of the best model. Constraints are applied at each step to guide the genetic programming algorithm toward physically meaningful models.

may lead to higher prediction errors on both training and testing datasets. The authors suggest that this could be attributed to slower convergence or a more rapid loss of diversity. However, they also note that the benefits of including constraints may become more relevant in scenarios with higher noise levels. Following up on this, the same authors published Haider et al. [5], investigating case studies with higher noise. Their findings concluded that constraints could aid in identifying better models, characterized by lower prediction errors, though the differences were not statistically significant compared to cases without constraints. On the other hand, other studies like Błądek and Krawiec [6] have demonstrated that in smaller datasets, the inclusion of mathematical constraints can lead to statistically significant improvements compared to a GP algorithm without constraints.

Given the ambiguity in the literature, the necessity for a flexible method to incorporate prior knowledge (which can be extensive in some kinetic studies), and the intuition that including constraints should improve the physical soundness of proposed models, PI-ADoK was developed and benchmarked against the original ADoK-S framework. The integration of mathematical constraints within the GP algorithm is nuanced by a delicate balance of exploration versus exploitation, and the preservation of diversity. GP typically operates in vast search spaces, and constraints can reduce this space and facilitate the exploitation aspect of the argument. However, overly stringent constraints risk premature convergence to suboptimal solutions. Furthermore, maintaining diversity in the population while respecting constraints is a challenging task, that often also leads to early convergence to suboptimal solutions.

With these considerations in mind, our approach to integrating constraints is intentionally straightforward. In PI-ADoK, constraint violation is treated as a penalty in the

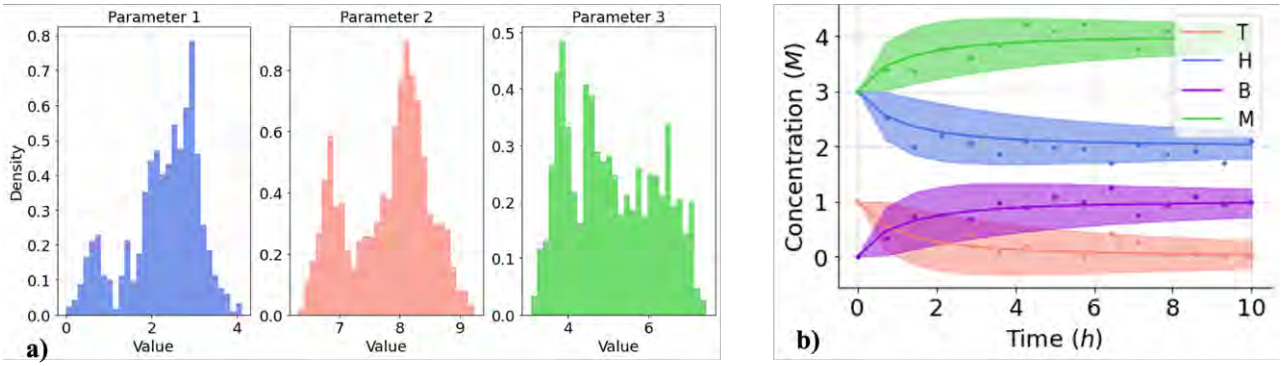

**Figure 2: a)** Histogram of the posterior distribution of the kinetic parameters of the discovered model; **b)** Plot of the in-silico data generated from the seventh experiment along with the average prediction and prediction intervals calculated from 5000 samples, where *T*, *H*, *B* and *M* represent toluene, hydrogen, benzene and methane, respectively.

calculation of a model's performance metric. Specifically, the GP algorithm operates similarly to a standard GP algorithm, with a crucial modification: each constraint acts as a test for candidate models. If a model satisfies the constraints, its performance metric is simply its prediction error. In contrast, if a model fails to meet a constraint, its performance metric is penalized based on the degree of constraint violation and a predefined hyperparameter. This inclusion of hyperparameters allows the modeler to fine-tune the algorithm, ensuring the search space is neither overly constrained, which could yield poor models, nor under-constrained, which could yield physically implausible models.

### Uncertainty Quantification

In uncertainty quantification, various methods range from simpler approximations like Laplace approximations and sigma points to more complex sampling algorithms like Metropolis-Hastings (MH) and Hamiltonian Monte Carlo (HMC). The choice depends on balancing computational efficiency with accuracy. For our purposes, where accuracy is prioritized, we have chosen the MH algorithm for its suitability in propagating uncertainty in kinetic models. MH handles complex, non-linear distributions well, does not require gradient information, and offers flexibility in proposal distributions, making it adaptable for complex models and high-dimensional spaces. While computationally intensive and requiring careful tuning, MH's adaptability and convergence make it a robust choice for uncertainty quantification in complex systems.

The MH algorithm is a Markov Chain Monte Carlo method designed to sample from a complex target distribution, such as a posterior distribution in Bayesian inference. Starting from an initial state, the algorithm iteratively generates a candidate sample from a proposal distribution. It then computes an acceptance probability based on the ratio of the target densities (adjusted by the proposal densities) to ensure detailed balance. If a random draw from a uniform distribution is less than this acceptance probability, the candidate becomes the new state; otherwise, the current state is retained. Over many iterations, this process produces a chain of samples that, after discarding a burn-in period, approximates the target distribution accurately. For more details on MH, see Chib and Greenberg [7].

## CASE STUDY

The case study used for the performance analysis of PI-ADoK is the catalytic toluene hydrodealkylation to benzene, where toluene ($C_6H_5CH_3$) and hydrogen gas ($H_2$) is transformed to benzene ($C_6H_6$) and methane ($CH_4$). The reaction is shown below:

$$C_6H_5CH_3 + H_2 \rightleftharpoons C_6H_6 + CH_4. \quad (1)$$

The kinetic rate model that describes the evolution of the concentrations of $C_6H_5CH_3$, $H_2$, $C_6H_6$ and $CH_4$ through time is shown below. This expression has been directly borrowed from Fogler [8].

$$r = -\frac{dC_T}{dt} = -\frac{dC_H}{dt} = \frac{dC_B}{dt} = \frac{dC_M}{dt} = \frac{K_A C_T C_H}{1+K_B C_B + K_C C_T}. \quad (2)$$

In Equation (2), $C_T$, $C_H$, $C_B$ and $C_M$ represent the concentration of reactants toluene and hydrogen, and of products benzene and methane, respectively. The kinetic parameters of the kinetic rate model are represented by $K_i$ where $i \in [A, B, C]$.

The computational experiments, chosen randomly from a $2^k$ factorial design, are run with the following initial conditions (in molar units): ($C_T(t=0)$, $C_H(t=0)$, $C_B(t=0)$, $C_M(t=0)$) $\in$ {(1, 8, 2, 3), (5, 8, 0, 0.5), (5, 3, 0, 0.5), (1, 3, 0, 3), (1, 8, 2, 0.5)}. For each experiment, the concentration of the reactant and products are recorded 15 times, at evenly spaced intervals between time $t_0$=0 h and $t_f$=10 h. The kinetic parameters were defined as: $K_A$=2 $M^{-1}$ $h^{-1}$,

$K_B$=9 $M^{-1}$ and $K_C$=5 $M^{-1}$.

Gaussian noise is added to the in-silico measurements to simulate a realistic chemical system. The added noise had zero mean and a standard deviation of 0.2 for $C_T$, $C_H$, $C_B$ and $C_M$. This noise addition allows the approximation of the response of a real system.

## RESULTS AND DISCUSSION

Our primary objective was to evaluate if the implementation of constraints could enhance the performance of our discovery algorithm, PI-ADoK-S. For this purpose, we introduced specific constraints at two different stages: the estimation of derivatives and the estimation of rate models. During the derivative estimation phase, the constraints included are: (I) ensuring that the proposed concentration models align with the accurately measured initial conditions of the system, (II) requiring concentration models to converge to a concentration value to simulate equilibrium, (III) ensuring that concentration models do not predict negative concentrations to maintain physical plausibility, and (IV) specific to our case study, ensuring reactant concentrations always decrease while product concentrations always increase. In the rate model estimation stage, we applied the following constraints: (I) ensuring the rate of consumption (or production) of reactants (or products) is consistently negative (or positive), and (II) that these rates should always be decreasing (or increasing) as per the specifics of our case study.

To assess the efficacy of these constraints, we conducted a benchmarking study between the unconstrained ADoK-S and the constrained PI-ADoK-S. Assuming an unlimited experimental budget, we ran as many extra experiments as required to uncover the data-generating rate model presented in Eq. (2) (the extra experiments are determined by solving the Hunter-Reiner criterion – a MBDoE technique for optimal model discrimination [1]). Due to the inherent stochasticity of genetic programming and its sensitivity to initial seeding, we conducted three independent runs. From these, we observed that ADoK-S required 16 experiments to identify the ground-truth model, whereas PI-ADoK-S needed only 10 – representing a 37.5% reduction in experimental effort. However, further investigations – such as ablation studies and exploring the impact of hyperparameters in the constraint penalty – would provide a more in-depth understanding of the methodology itself.

## CONCLUSIONS

This paper introduces PI-ADoK-S, an advancement of the ADoK-S algorithm, featuring the integration of mathematical constraints for prior knowledge injection and an uncertainty quantification method using the Metropolis-Hastings algorithm. The inclusion of constraints streamlines the genetic programming algorithm, significantly reducing the experimental burden by 37.5% on average, though further testing is beneficial for deeper understanding of these results. For instance, additional testing could examine the impact of hyperparameters, individual constraints, and initial DoE strategies on the performance of PI-ADoK. The uncertainty quantification aspect enhances the understanding of the reliability of a certain model's predictions, which can be used to guide future investigative efforts. These improvements underscore PI-ADoK-S as a significant upgrade over ADoK-S, both in terms of efficiency and depth of analysis, marking it as a valuable tool for experts in kinetic modeling and chemical process research.

## ABSTRACT

Understanding data with complex patterns is a significant part of the journey toward accurate data prediction and interpretation. The relationships between input and output variables can unlock diverse advancement opportunities across various processes. However, most AI models attempting to uncover these patterns are not explainable or remain opaque, offering little interpretation. This paper explores an approach in explainable AI by introducing a multi-agent system (MaSR) for extracting equations between features using data. We developed a novel approach to perform symbolic regression by discovering mathematical functions using a multi-agent system of LLMs. This system addresses the traditional challenges of genetic optimization, such as random seed generation, complexity, and the explainability of the final equation. We utilize the in-context learning capabilities of LLMs trained on vast amounts of data to generate accurate equations more quickly. This study presents research on expanding the reasoning capacities of large language models alongside their mathematical understanding. The paper serves as a benchmark in understanding the capabilities of LLMs in mathematical reasoning and can be a starting point for solving numerous complex tasks using LLMs. The MaSR framework can be applied in various areas where the reasoning capabilities of LLMs are tested for complex and sequential tasks. MaSR can explain the predictions of black-box models, develop data-driven models, identify complex relationships within the data, assist in feature engineering and feature selection, and generate synthetic data equations to address data scarcity, which are explored as further directions for future research in this paper.

**Keywords**: Symbolic regression, Large Language Models, Multi-Agent Systems

## INTRODUCTION

The foundation of any machine learning algorithm lies in understanding the mathematics behind it. The entire field of artificial intelligence is built upon mathematical principles, using data as its starting point. Accurately uncovering and interpreting relationships within data is a critical step for advancing tasks in data science and its applications. These relationships often take the form of equations that serve as governing rules, applicable across a wide range of domains, including simulations and industrial processes. To address this critical challenge, we developed a multi-agent system using large language models (LLMs) to effectively uncover these mathematical relationships, enabling advancements across various domains such as simulations and industrial processes.

## SYMBOLIC REGRESSION: AN OVERVIEW

One powerful technique for discovering such relationships is Symbolic Regression[1,2], which identifies mathematical expressions that best describe the relationships between variables in a dataset. This technique can be implemented through various approaches, including genetic optimization[1,2], reinforcement learning[5], recurrent neural networks (RNNs)[5], generative adversarial networks (GANs)[6], and emerging methods. Despite differences in implementation, these methods follow a common set of steps that define symbolic regression as a process: finding, evaluating, and refining relationships to generate interpretable equations.

Symbolic Regression (SR) plays a crucial role in Process Engineering by enabling the discovery of mathematical models that accurately represent complex chemical processes. In process systems, understanding the underlying relationships between variables is essential for optimization, control, and design. SR offers a powerful tool for automatically deriving these models from experimental or simulated data without requiring prior knowledge of the system's functional form. This capability is particularly beneficial in fields like chemical engineering, where processes can be highly nonlinear, dynamic, and data-intensive. By using SR, engineers can gain insights into the fundamental behavior of a process, leading to improved efficiency, better decision-making, and enhanced predictive capabilities for process design and operation.

## FRAMING SYMBOLIC REGRESSION AS A SEARCH PROBLEM

Symbolic regression can be framed either as a learning task[4] or a search problem, where the objective is to identify the optimal equation or parameters within the domain of possibilities. By leveraging **large language models (LLMs)**, the symbolic regression process can be significantly enhanced. LLMs, with their extensive domain knowledge and in-context learning capabilities, have the potential to act as the "brain" of the process, streamlining and optimizing the discovery of symbolic equations. This approach shifts reliance from purely data-driven metrics to a more knowledge-driven framework. The domain of equations can be constrained by the context of the problem statement and the space within which the equation is being searched.

## INTRODUCTION TO MASR FRAMEWORK

To explore this potential, we introduce **MaSR: Multi-Agent Symbolic** Regression, a novel framework that employs LLMs to execute and coordinate the various steps of symbolic regression. In this system, multiple agents, each powered by an LLM, collaborate to handle tasks such as searching for relationships, optimizing equations, and explaining results. By integrating LLMs as the core of the process, MaSR not only automates symbolic regression but also provides interpretable and robust equations for practical applications.

## PROBLEM AND EXISTING SOLUTIONS

Discovering relationships and hidden patterns within datasets is essential for optimization, prediction, forecasting, and other applications.

### Challenges with Existing Models

- The models commonly used for these purposes are often black-box models.
- They are not always well-suited to the specific data being used, as they rely on a limited set of predefined models.
- There is often no mathematical relationship available to effectively link features for tasks like feature selection, synthetic data generation, or feature engineering.
- A lack of physics-based or domain-specific equations ensures constraints are not always adhered to in applications.
- Many transparent models available today are nonlinear and difficult to interpret.
- Traditional models require large amounts of data to perform predictions and learn from the data effectively.

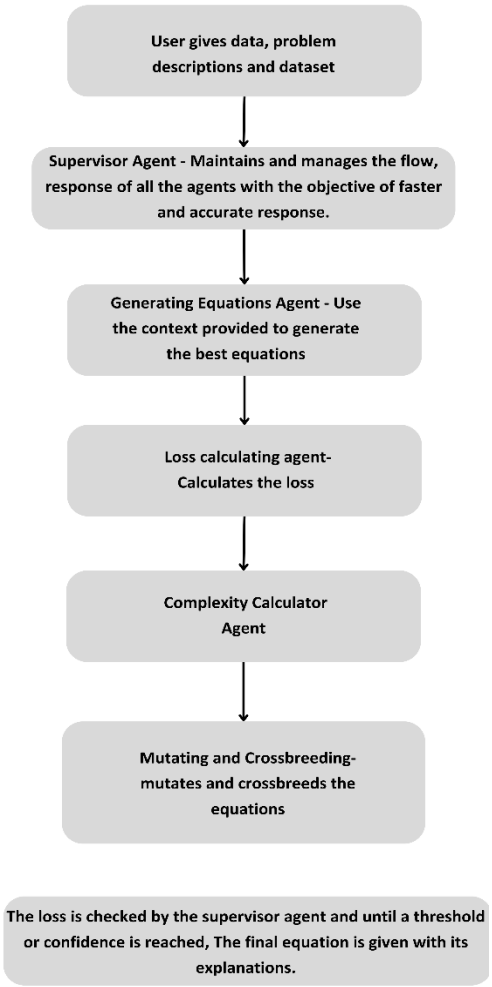

**Figure 1.** Step-wise process of MaSR framework.

Our goal is to derive mathematical equations and

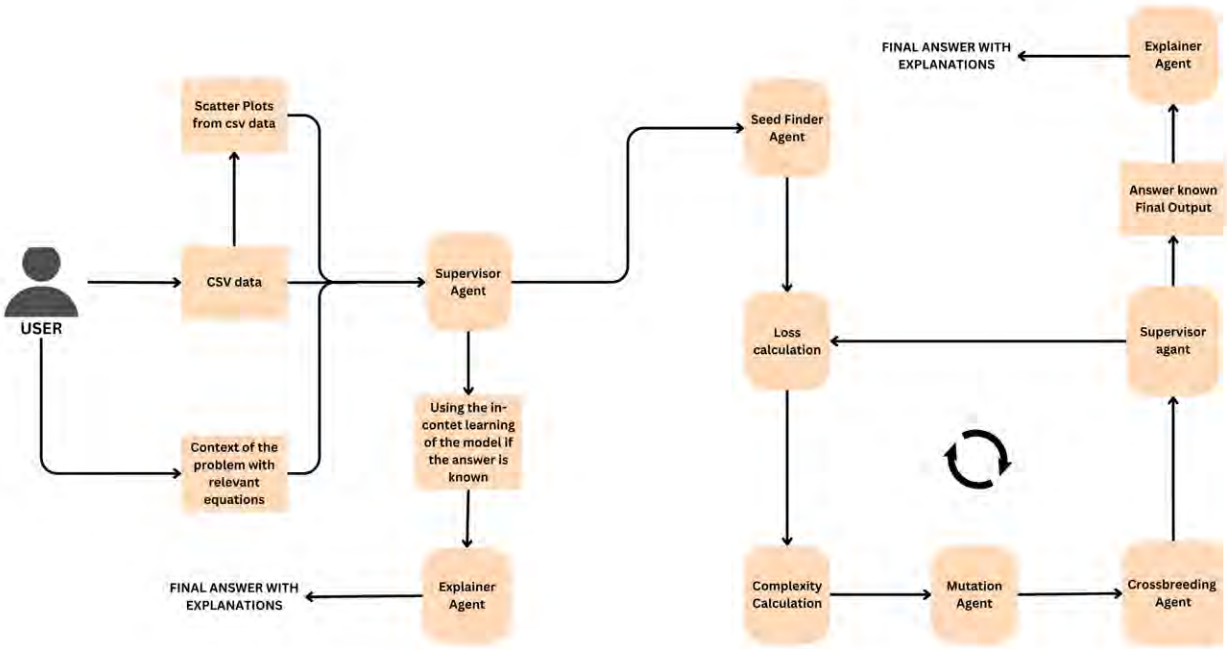

**Figure 2**: This image illustrates the complete workflow of a multi-agent symbolic system. The process begins with the user providing context and a CSV file to the system. The CSV data is transformed into scatter plots, which are then passed to the supervisor agent along with the original CSV data and user-provided context. If the supervisor agent already has knowledge of a relevant equation within its in-context learning capabilities, it directly returns the equation. Otherwise, the data and context are forwarded to the seed finder agent, followed by the loss finder agent, the complexity calculator agent, and finally the mutation and cross-breeding agent. Throughout the process, the supervisor agent continuously evaluates the equation against a loss threshold. Once an equation meets the specified conditions, it is passed to the explanation module, which provides detailed explanations for the equation. The final output includes both the optimal equation and its corresponding explanations.

relationships from data, creating an explainable white-box model for various applications.

## Existing Solutions and Their Limitations

The problem has been addressed using genetic optimization, with several variations and libraries available, including PySR[1], gplearn[2], and SINDy[9]. However, these libraries have the following limitations[8]:

- Random generation of seed functions.
- Managing equation complexity.
- Ensuring the explainability of the final equation.
- Lack of domain-specific knowledge integration.

These limitations are being tackled separately by different methods, such as Pareto-Symbolic Regression[10] and Symbolic GPT[4].

However, no single method currently solves all these problems simultaneously, particularly the challenge of making the equations explainable

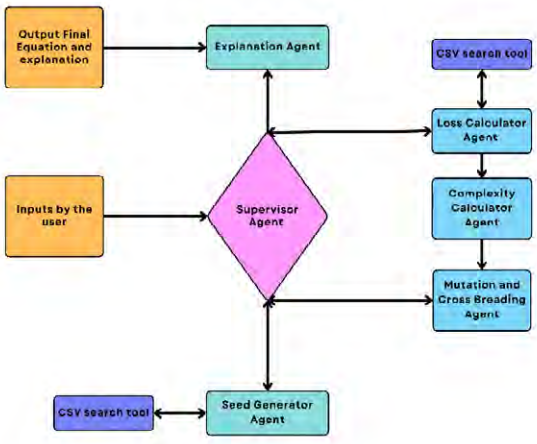

**Figure 3.** Interaction between different agents of MaSR Framework.

## MASR FRAMEWORK

The MaSR framework divides the task into multiple steps, with each step performed by a dedicated agent equipped with specific tools and knowledge bases. These agents collaborate by discarding less accurate or less insightful equations based on metrics such as mean squared error and equation complexity.

The process mimics genetic optimisation and is designed entirely using LLMs to derive relationships from the data.

### Foundation of the MaSR Framework

The framework is built upon the reasoning capabilities of large language models (LLMs), leveraging their in-context learning. Its architecture relies on the in-context learning of LLMs and their ability to effectively identify the seed generation agent. The prompts used in each agent provide the necessary context and instructions. A **sample prompt** from one of the agents (seed finder) is provided below:

"""

### Task:

You are a mathematical equation generator. Your goal is to derive the accurate and complex equations that describe the relationship between the target variable ['target_variable'] and the independent variables ['independent_variables'], based on the provided scatter plot,csv file data and domain knowledge.

### Context:

You have knowledge of ['domain'], including relevant physical and mathematical principles such as dimensional analysis and proportionality. You also have access to:

Data points from a **CSV file** that illustrate the values of all the variables.

**scatter plots** representing the relationship between the independent variables and the target variable.

Equations: ['Equations'].

Available operators: ['Operators'].

Dimensional information: ['Dimensions'].

### Instructions:

1. **Analyze the Data**: Start by analyzing the scatter plot and the data points from the CSV file to understand the relationships between the target variable and the independent variables.

2. **Use Domain Knowledge**: Leverage your understanding of ['domain']}, including fundamental physical and mathematical concepts like distance calculation, to guide your equation formulation.

3. **Generate Equations**: If no existing equation is found, generate up to ['number_of_functions'] possible equations using the operators provided. Start with basic forms and build progressively more complex equations. Incorporate the general proportional relations and dimensional constraints provided.

### Output:

Provide the final ['number_of_functions'] functions as mathematical equations that best describe the relationship between ['target_variable'] and ['independent_variables'].

If an existing equation from the domain of ['domain'] is found, present it as the final solution.

### Output Format:

Return the entire mathematical equations as strings, formatted like this: `"f1(x) = ..."`, `"f2(x) = ..."`, etc as complex and creative as possible.

You must not output python code and must not use mnemonics in the equation it must be from ['target_variable']

and ['independent_variables'].

"""

### Agents and Their Roles

- Seed Function Generator Agent: Generates candidate equations based on the relationships between target and independent variables using the provided data and context.
- Loss Calculator Agent: Evaluates each eqution by calculating the loss to determine its fit to the data.
- Complexity Calculator Agent: Assesses and scores

the complexity of each equation, prioritising simpler models.

- Equation Mutating Agent: Modifies equations to reduce loss and complexity, aiming to improve accuracy.
- Supervisor Manager Agent: Manages the entire process, ensuring effective collaboration among agents to identify the best equation.
- Explainer Agent: Provides detailed insights into the final equation's behaviour and the relationships between the target and independent variables across the domain.

### Framework Overview

The MaSR framework employs a systematic multiagent system of LLMs to discover accurate mathematical relationships from data. These relationships can be utilised for modelling, feature engineering, and feature selection. The framework addresses limitations in existing methods and includes the following key components:

- Hierarchical Structure: A supervisor agent oversees the process, ensuring proper flow of outputs between agents and delivering the final equation with its explanation.
- Agent Responsibilities: Agents handle specific tasks such as seed function generation, loss calculation, complexity evaluation, mutation, and explanation.

### Explainability from MaSR?

The framework explains the final equation by breaking down its terms and coefficients. A simplified example is provided below to demonstrate the output of the MaSR framework:

'''

*To understand this equation, let's define its components first.*
*MD_power: This term represents some measure that depends only on MD, whose value ranges from 3 to 95.*
*SG130: This term stands for another measure depending solely on SG130, ranging from 10 to 570.*
*TemperatureMD: This variable is equal to the expression* (3 * MD_power + 0.845 * SG130) x 0.118 + 36.375), *where MD_power and SG130 take on any values within their respective ranges.*
*Now, let's analyze the equation based on the above definitions.*

*Firstly, observe the multiplicative factor (3) associated with MD_power; since it has a positive sign, increasing MD_power results in higher values assigned to TemperatureMD. Consequently, when working within the context of this problem, larger MD_power values lead to greater temperatures.*
*Next, see the additive component (0.845) linked to SG130; because this term also carries a positive sign, raising SG130 leads to increased values attributed to TemperatureMD. Therefore, more significant values of SG130 imply hotter conditions according to the problem definition.*

*Note the coefficient (0.118) applied directly onto the sum of the previous two terms. Since this constant is positive too, enlarging the outcome originating from the sum generates amplified values of TemperatureMD. Hence, augmenting the total output by a substantial quantity raises the observed temperature.*
*Lastly, consider the additive term (+36.375). Regardless of changes in either MD_power or SG130, this constant consistently contributes a minimum of 36.375 toward the calculation of TemperatureMD.*
*In conclusion, the given equation defines the interplay among factors affecting certain environments' temperatures, namely MD_power and SG130. By raising both MD_power and SG130, the resulting temperature increases proportionally due to the additive properties present in the equation.*
'''

## RESULTS

The paper primarily aims to introduce a novel approach to performing a traditional method. The framework can be adapted with new agents, data sources, and methods to address specific problems. The current architecture was tested against various applications and compared with traditional genetic optimization methods.

1. We evaluated the performance of genetic optimization methods such as gplearn and MaSR to derive the equations governing the physics of industrial chillers. These equations were used as a loss function of ANNs to create a Physics Informed Neural Network (PINNs). Our key observations were as follows:

- The framework's performance, in terms of metrics like the $R^2$ score, was 2% better than the traditional methods.
- The initial equation selected by the seed generation agent adhered to the physics of cooling in chillers.
- The MaSR framework converged to the final equation more quickly and was effective even with a limited or scarce dataset.
- Combining MaSR with traditional genetic

optimization algorithms can enhance the overall performance of Symbolic Regression.

- The final equation derived by MaSR provided an interpretable explanation and aligned with known proportionalities.

2. We validated the framework using 20 Feynman equations, successfully identifying all of them based on the in-context learning capabilities of the underlying models. This method can accurately determine the governing physical equation when it is uncertain. In contrast, other genetic optimization methods without an embedded learning mechanism fail in this regard.

## KEY ADVANTAGES OF MASR

The main differences between our framework and existing solutions are as follows:

Utilizing LLMs: Utilises the in-context knowledge base and domain-specific expertise of LLMs to generate accurate equations quickly, even with sparse data.

- Explainability: Provides detailed explanations and insights from the final equations, fostering transparency and interpretability.
- Guided Seed Generation: Addresses the issue of random seed generation in current methods by guiding the process toward more accurate equations swiftly and efficiently.
- Simplified Complexity: Ensures the final equations are concise and easy to understand, enhancing their explainability and usability.

## CHALLENGES AND LIMITATIONS

The major challenge we faced during the implementation process was accurately enabling the agents to collaborate efficiently while adhering to the workflow. We were able to partially address this by using well-crafted prompts and improving the conditions under which an agent reaches out to another. However, the issue of agents fully understanding and consistently maintaining the workflow for complex tasks remains unresolved and requires further attention.

Another significant issue we encountered was stopping the process when agents reached optimal conditions. To address this, a clear stopping criterion must be defined and strictly enforced through implementation.

In this study, the large language models (LLMs) we explored ranged from multimodal models like Gemini to GPT-based models such as GPT-3.5-Turbo and open-source models like LLaMA 3. We chose to focus on Gemini due to its ability to effectively interpret and process data. To support this, we utilized a combination of Retrieval-Augmented Generation (RAG), structured data in prompts, and scatter plots as data sources. However, passing numerical data to LLMs remains an area that requires significant attention. Ensuring that LLMs can effectively use numerical data in reasoning tasks was a primary objective of this study.

The CrewAI framework we tested for open-source models did not yield the desired results, leading us to switch to LangGraph. We also implemented the system using a structured workflow and conditions crafted for LLMs. Limitations we faced during the implementation included the token size restrictions of both open-source and GPT models, as well as subscription-related challenges with GPT.

## CONCLUSION

This framework explores the combination of logical reasoning with data-driven processes, testing the capabilities of LLMs in reasoning tasks and creating explainable, insightful procedures. The complex tasks performed by the LLMs demonstrate that the system can serve as a starting point for executing intricate

reasoning and tasks requiring coordination. Notably, the multi-agent symbolic regression represents a significant step towards understanding LLM behaviour in such processes.

The method shows promising performance in scenarios where the physics of the system is unknown or when the governing equations are dictated by physical laws embedded in the data. It also examines the reasoning and data interpretation capabilities of LLMs, revealing a key limitation: the inability to fully integrate numerical data into their reasoning and responses. Enhancing the suitability for these tasks involves presenting data in various forms, such as CSV files stored as vector databases, screenshots of data included in prompts, or scatter and insight plots.

The architecture of the supervisor agent has proven to be valuable in aiding complex reasoning, as evidenced by our experiments. Frameworks like CrewAI and LangGraph assist in creating multiagent systems, but the use of a set of LLMs as agents—designed to conditionally exchange responses with other agents and collectively decide on final outputs—has shown promising results. With minor adjustments to prompts and structure, this framework can be adapted to other complex tasks involving data analysis. It holds significant potential across the diverse applications of symbolic regression in today's world.

## ABSTRACT

Process engineers in the Chemical and Oil & Gas industries extensively use process simulation for the design, development, analysis, and optimization of complex systems. This study investigates the integration of Artificial Intelligence (AI) with AVEVA™ Process Simulation (APS), a next-generation commercial simulation tool. We propose a framework for a custom chatbot application designed to assist engineers in developing and troubleshooting simulations. This chatbot application utilizes a custom-trained model to transform engineer prompts into standardized queries, facilitating access to essential information from APS. The chatbot extracts critical data regarding solvers and thermodynamic models directly from APS to help engineers develop and troubleshoot process simulations. Furthermore, we compare the performance of our custom model against OpenAI technology. Our findings indicate that this integration significantly enhances the usability of process simulation tools, promoting more innovative and cost-effective engineering solutions.

**Keywords**: Artificial Intelligence, Process Design, Machine Learning, Chatbot

## INTRODUCTION

Process simulation is a model-based representation of chemical, physical, and biological processes to analyze, optimize, and design. Process simulation tools are widely used in Chemical, and Oil & Gas industries in various phases of a project. Process simulation can enable the transformation of process engineering as part of the digital twin, an important building block of digital transformation [1]. Simulation and modeling can help accelerate the design cycle of chemical processes. The rapid evolution of Artificial intelligence (AI) and Machine Learning (ML) technologies has significant implications across various domains including engineering. AI and ML technologies have been widely used in various applications of chemical engineering such as process modeling, simulation, control, classification, fault detection and diagnosis [2]. Recent research has focused on integrating AI with process simulation tools to enhance design efficiency [3]. Stergiou et al discuss combining ML algorithms with process simulation tool to optimize plant design parameters, resulting in more efficient and cost-effective chemical production [4]. The application of AI techniques such as Artificial Neural Networks (ANN) is used to model the operation of hydrogen production system [5].

A chatbot is a computer-based program that simulates human conversation with an end user, and they are usually built using AI and Natural Language Processing (NLP) with the goal of interpreting human questions and automating customized responses [6]. ChatGPT (Chat Generative Pre-Trained Transformer) is a recently developed conversational chatbot created by OpenAI [7], and it uses Natural Language Processing (NLP) to generate human-like responses to user input.

This research paper discusses applications of AI in a next-generation process simulation tool using both custom trained model and OpenAI model to answer questions based on the process simulation. The performance of these models is quantified and compared using different types of similarity scores. This innovative approach of integrating AI technology with a next generation process simulation tool is expected to transform AVEVA™ Process Simulation (APS) by making it more user-friendly and efficient, leading to novel and cost-effective solutions in process engineering.

## METHODOLOGY

The architecture of a chatbot encompasses its foundational structure and design principles. It outlines how the chatbot interprets and processes text, influenced by various factors including the domain, use case, type of chatbot, and prompts used [8]. Models in ChatBot utilize NLP engines to process user input and transform it into machine-readable formats; however, traditional NLP engines struggle to fully comprehend human language. To address this limitation, large language models (LLM) were developed to enhance AI's understanding of natural language, enabling the generation of more realistic and coherent human-like text.

### Chatbot architecture

The architecture for implementing the chatbot is illustrated in Figure 1. User input is processed by either a LLM or NLP, which may be a custom-trained model or a pre-trained one, such as OpenAI's Generative Pre-Trained Transformer (GPT) or Google's BERT, LaMDA, and PaLM [9]. The chatbot leverages the LLM to extract relevant information from unstructured textual data through techniques like text classification and entity recognition.

Text classification is essential for identifying user intents by categorizing messages into classes such as inquiries or requests, which guides the chatbot's response strategy. Entity recognition enhances this process by extracting specific information, such as names or dates, from user inputs. Together, these features enable the chatbot to engage in more meaningful, context-aware interactions, significantly improving user satisfaction and overall effectiveness. The unstructured text is then converted into a structured XML format based on user input, which is utilized to build simulations or troubleshoot existing ones. The Next generation process simulation software, AVEVA™ Process Simulation (APS) developed by AVEVA, is used in this work. APS is designed for modeling, simulating, studying thermodynamic behavior and optimizing process operations in industries such as oil and gas, chemicals, and manufacturing.

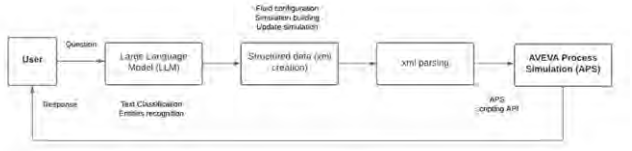

**Figure 1.** Architecture for ChatBot implementation.

The chatbot framework interfaces with the APS through the scripting interface of the process simulator tool, enabling bidirectional communication between the process simulation and the chatbot application using Application Programming Interface (API's) in Python. These API's facilitates tasks such as creating a component slate with thermodynamic models, building simulations, and extracting essential solver and thermodynamic information from the simulation results to help process engineers design, analyze and optimize chemical processes.

### Custom trained model

SpaCy is a Python-based open-source NLP library used to develop custom models. It features built-in pre-trained pipelines and supports tokenization, as well as neural network models for tagging, parsing, named entity recognition (NER), and text classification. In our custom model, text classification and NER are integrated within the pipeline, sharing a token-to-vector layer between the two components. The text classification component categorizes user input into specific types, such as "sim building," "model query," or "fluid building," based on labeled training text. Meanwhile, the NER component identifies and classifies named entities in the text into predefined categories, including models, component names, and thermodynamic methods.

To generate training data for the spaCy model, we utilize Faker, a Python package that creates fake data. The training data patterns are designed to mimic various likely user inputs, and entities are annotated using spaCy's rule-based matching as shown in Figure 2.

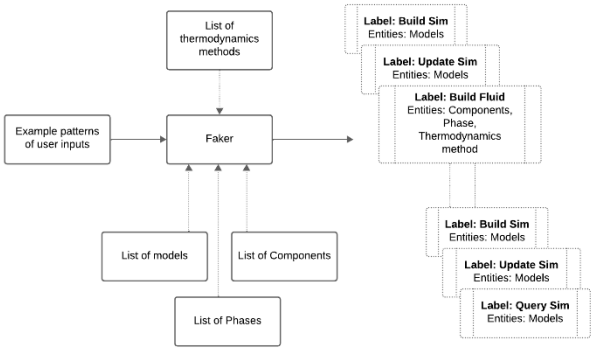

**Figure 2.** Preparation of training data.

The custom training of the spaCy pipeline components is saved as the best model on disk. A simple scoring system, applying equal weights (50-50) to text classification and NER, determines the best model. Once constructed, the NLP pipeline utilizes the pretrained components, allowing user input to be fed into the spaCy pipeline for classification and custom entity identification. Based on this classification, the appropriate XML generation occurs, with named entities represented as XML tags and attributes. From this stage of XML generation onward, the code is consistent between the OpenAI-based model and the custom model. The XML data is then parsed, and the information is sent to the APS through a scripting interface for feedback. Standard

XML template used are presented in the supplementary material.

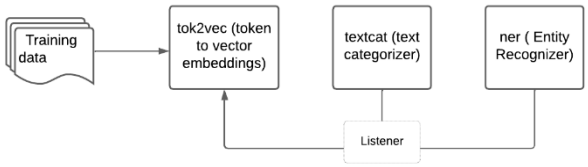

**Figure 3.** SpaCy training pipeline components.

## Pre-trained model

The pretrained GPT-3.5-turbo model is utilized as the base model through the Python API endpoint. Communication with the OpenAI model is facilitated by sending HTTP requests to the API endpoints and receiving corresponding responses.

# RESULTS AND DISCUSSION

To compare the XML results generated by OpenAI and the custom model, it is essential to assess both the structural and content-based similarities. The most effective approach to evaluating the response is by examining both the structural and contextual aspects of the returned XML, such as the similarity of tags and the accuracy of the extracted data. This can be accomplished by establishing a "golden file," which represents the desired XML response, and then comparing the generated XML against this reference. Four metrics have been utilized to assess these differences, each focusing on a distinct aspect of the generated XML file.

## Jaccard similarity

Jaccard similarity quantifies the overlap between two sets. When applied to XML, focusing solely on tags, it evaluates the similarity of the structures between two XML documents. This metric is useful for assessing how closely the structure of a generated XML document aligns with the desired structure. The process involves extracting the unique tags from both XML documents, converting them into sets, and computing the Jaccard similarity, as defined by [10]:

$$J(A,B) = \frac{|A \cap B|}{|A \cup B|} = \frac{|A \cap B|}{|A|+|B|-|A \cap B|} \quad (1)$$

By evaluating both the structural elements of the XML and the data they contain, it enables the assessment of the correctness of the XML structure as well as the accuracy of the data.

## Cosine Similarity

Cosine similarity is employed to assess the similarity between two documents by calculating the cosine value between the term vectors of the documents [11]. This method transforms documents into vectors within a multi-dimensional space, enabling effective comparison of textual data extracted from XML elements. Consequently, cosine similarity is particularly well-suited for evaluating the semantic similarity of text within tags.

## Levenshtein Distance

Levenshtein Distance measures the differences between two sequences, accounting for variations in both equal-length and unequal-length sequences [12]. It determines the minimum number of single-character edits necessary to transform one string into another to identify even the smallest textual differences between two files.

## Case studies

The ChatBot framework is evaluated through a series of case studies designed to simulate real-time user prompts typically posed by process engineers in an industrial setting as presented in supplemented material. The intent, along with the user prompts and associated metrics, is presented in the following section.

## Case study 1

Intent Build a simulation in APS using user prompts in a sentence structure with intentional grammatical errors and typos.

### User Prompts

Prompt 1: Add a source, compressor, valve, pump, valve and sink and connect them. Now update temperature and pressure conditions of source model to 450 K and 250 psi

Prompt 2: Try connecting source, compressor, valve, pump, valve and sink. Also update temperature and pressure of source model to 450 K and 250 psi

Prompt 3: Try connecting source, compressor, valve, pump, valve and sink. Also update T and P of source model to 450 K and 250 psi

Prompt 4: Try connecting source, compressor, valve, pump, valve and sink. Also update temperature and pressure of source model to 100 C and 250 psi1

Prompt 5: Build a simulation with source, valve and sink. Also update temperature and pressure of source model to 100 C and 250 psi

**Table 1:** Metrics for xml generation from user prompts using pre-trained ChatGPT model

| Prompt# | Jaccard Similarity | | Cosine Similarity | Levenshtein Distance |
|---|---|---|---|---|
| | Tags | Data | | |
| 1 | 1 | 0.65 | 0.99 | 6 |
| 2 | 0.63 | 0.51 | 0.99 | 336 |
| 3 | 0.63 | 0.51 | 0.99 | 336 |
| 4 | 1 | 0.65 | 0.99 | 6 |
| 5 | 0.34 | 0.31 | 0.99 | 1246 |

**Table 2:** Metrics for xml generation from user prompts using custom trained model

| Prompt # | Jaccard Similarity | | Cosine Similarity | Levenshtein Distance |
|---|---|---|---|---|
| | Tags | Data | | |
| 1 | 1 | 1 | 1 | 0 |
| 2 | 1 | 1 | 1 | 0 |
| 3 | 0.66 | 0.81 | 0.99 | 38 |
| 4 | 1 | 1 | 1 | 3 |
| 5 | 1 | 1 | 1 | 0 |

## Observation

In the analysis of Prompt #1, both OpenAI and the custom model effectively handled the intentional typographical error. However, with Prompts #2, #3, and #4, OpenAI introduced extraneous and irrelevant sections from the template XML, which negatively impacted both the Jaccard similarity and Levenshtein distance metrics as shown in Table 1 & 2. Despite this, the key information necessary for constructing the simulation in APS was successfully extracted. In contrast, the SpaCy model, which was trained on specific data, did not exhibit this issue and generated a more accurate XML output. For Prompt #5, OpenAI unexpectedly converted units of measure, while the SpaCy model did not. These findings highlight the significant role of sentence structure in the conversion of prompts into structured XML.

## Case study 2

Intent Troubleshoot a built simulation in APS shown in Figure 4, using user prompts in a sentence structure with intentional grammatical errors and typos.

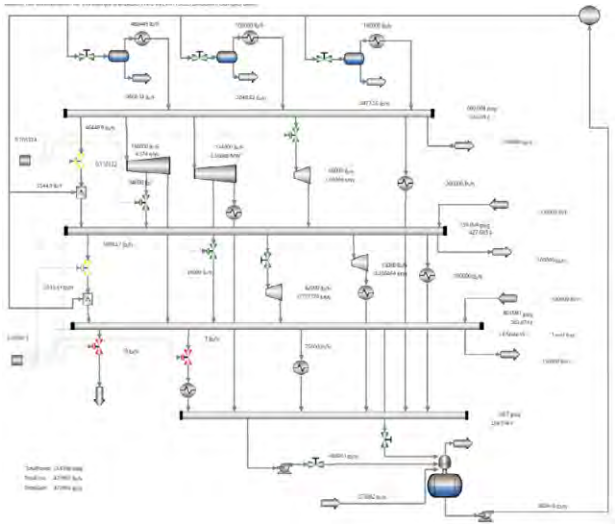

**Figure 4.** Refinery Steam Balance simulation built in APS.

## User Prompts

Prompt 1: Find how many sources, sinks, and valves are present in the simulation

Prompt 2: Find the count the number of sinks, valves and sources1 in the simulation

Prompt 3: Find all Source where temperature is greater than 200 K

Prompt 4: Find all Valves with DP more than 25 kPa

Prompt 5: Can you tell which valves have a DP is greater than 33 kPa

**Table 3:** Metrics for xml generation from user prompts using pre-trained ChatGPT model

| Prompt # | Jaccard Similarity | | Cosine Similarity | Levenshtein Distance |
|---|---|---|---|---|
| | Tags | Data | | |
| 1 | 1 | 1 | 1 | 1 |
| 2 | 1 | 1 | 0.95 | 48 |
| 3 | 1 | 1 | 1 | 1 |
| 4 | 1 | 1 | 1 | 1 |
| 5 | 1 | 0.7 | 0.99 | 236 |

**Table 4:** Metrics for xml generation from user prompts using custom trained model

| Prompt # | Jaccard Similarity | | Cosine Similarity | Levenshtein Distance |
|---|---|---|---|---|
| | Tags | Data | | |
| 1 | 1 | 1 | 1 | 0 |
| 2 | 1 | 1 | 1 | 0 |
| 3 | 0.05 | 0.05 | 0.89 | 283 |
| 4 | 0.5 | 0.5 | 0.92 | 172 |
| 5 | 0.5 | 0.5 | 0.87 | 282 |

## Observation

The OpenAI model successfully extracts the correct information from the APS simulation for prompts #1, #3, and #4, as indicated by the metrics in Table 3. However, for prompt #2, the XML output contains irrelevant information, which negatively impacts the cosine similarity and Levenshtein distance scores as shown in Table 3 & 4. In the case of prompt #5, the OpenAI model generated incorrect tags, specifically "valve1" and "valve2," along with duplicate information in an improper XML format. This error adversely affected the cosine similarity and Levenshtein distance values, ultimately leading to a failure to return a valid response to the user prompt.

The SpaCy model successfully parsed and generated XML for Prompts #1 and #2 when no conditions were included. However, when conditions were introduced, the model failed to generate the relevant sections and was unable to identify the items for Prompts #3 and #5. While the item for Prompt 4 was correctly identified, the associated condition was not parsed accurately. Overall, the SpaCy model performed better with smaller templates but struggled to handle the added complexity introduced by diverse section types.

## Case Study 3

Intent Create a fluid in APS to calculate mixture properties and predict vapor liquid equilibrium using descriptive user prompts

## User Prompts

Prompt 1: Get Vapor fraction for a fluid containing Water, Ethanol, Acetone, and molar composition of 0.5, 0.4, 0.1 using system method NRTL and phase vapor and single liquid equilibrium. Show the fluid details along with mixture liquid density property data at 400k and 200 psi and binary interaction data. Also perform flash calculations at 400 K and 200 psi with the given molar composition.

Prompt 2: Get VF for a fluid with Water, Methanol, Ethanol, Acetone, and molar composition of 0.5, 0.2, 0.2, 0.1 using system method NRTL and one phase vapor liquid equilibrium. Show the fluid details along with mixture density property data at 500 K and 1000 kPa and binary interaction data. Also perform flash calculation at 500 K and 1000 kPa with the same defined composition.

Prompt 3: Get VF for a fluid with Water and Acetone, and molar composition 0.6, 0.4 using method NRTL and phase vapoingle and single liquid. Show the fluid details along with mixture liquid density and binary interaction data. Perform flash at 450 K and 1000 kPa

Prompt 4: Get VF for a fluid with components Methane, Ethane, Water, Butane, and molar composition 0.2, 0.2, 0.4, 0.2 using method SRK and system phase vapor liquid equilibrium.

Prompt 5: Get VF for a fluid with components Methane, Ethane, Water, Butane, and molar composition 0.2, 0.4, 0.2, 0.2 using system method SRK and phase vapor single liquid equilibrium

The information extracted from the prompts are categorized as follows,

1. Component Names
2. System method and Phase
3. Fluid properties – details, mixture properties, interaction parameters
4. Flash conditions – Temperature and pressure (along with unit of measure)

Table 5 presents the information extracted by both the OpenAI and custom models, with "Y" indicating correctly extracted information and "N" representing either incorrect or missing information in the XML format.

**Table 5:** Status of information extracted from user prompts using Custom and OpenAI model

| Category | | 1 | 2 | 3 | 4 |
|---|---|---|---|---|---|
| Prompt 1 | OpenAI | Y | Y | Y | Y |
| | Custom | Y | Y | Y | Y |
| Prompt 2 | OpenAI | Y | N | Y | Y |
| | Custom | Y | Y | Y | Y |
| Prompt 3 | OpenAI | Y | Y | Y | Y |
| | Custom | Y | N | Y | Y |
| Prompt 4 | OpenAI | Y | Y | Y | Y |
| | Custom | Y | Y | N | Y |
| Prompt 5 | OpenAI | Y | Y | N | Y |
| | Custom | N | N | N | N |

**Table 6:** Metrics for xml generation from user prompts using pre-trained ChatGPT model

| Prompt# | Jaccard Similarity | | Cosine Similarity | Levenshtein Distance |
|---|---|---|---|---|
| | Tags | Data | | |
| 1 | 1 | 0.89 | 0.99 | 17 |
| 2 | 1 | 0.89 | 1 | 1 |
| 3 | 1 | 0.85 | 0.99 | 27 |
| 4 | 1 | 0.7 | 1 | 7 |
| 5 | 1 | 0.79 | 1 | 6 |

**Table 7:** Metrics for xml generation from user prompts using custom trained model

| Prompt# | Jaccard Similarity | | Cosine Similarity | Levenshtein Distance |
|---|---|---|---|---|
| | Tags | Data | | |
| 1 | 1 | 1 | 0.99 | 28 |
| 2 | 1 | 1 | 1 | 2 |
| 3 | 1 | 1 | 0.99 | 269 |
| 4 | 1 | 1 | 0.99 | 21 |
| 5 | 0.05 | 0.05 | 0.78 | 948 |

## Observation

OpenAI successfully extracted the information from prompt #1 and generated the XML with the expected unit of measure conversion, matching the XML template. However, for prompts #2, #3, and #4, the phase was extracted as VLLE instead of VLE, which could lead to incorrect results in APS depending on the fluid behavior. Additionally, for prompts #4 and #5, fluid properties were included in the XML and APS results, despite not being requested by the user. It is important to note that while the component names, system method, and flash conditions are correctly extracted from the user prompt, the

phase is inaccurately determined due to the sentence structuring of the prompt.

The custom model successfully predicted the outputs for Prompts #1, #2, and #3. However, Prompt #4 yielded an incorrect result due to an error in parsing the MixturePropertyData tag, which led to a failure during XML parsing. In contrast, Prompt #5 resulted in a complete failure in XML creation, with entities being misclassified as shown in Table 5. Notably, the prompts in question are largely like Prompt #4, differing primarily in sentence structuring and a typo error.

## CONCLUSION

The conversion of user prompts into a standardized XML format provides significant flexibility for modifying underlying APIs, facilitating easier updates to the simulator. This process enables the rapid development of new XML-to-API generators compatible with various simulation tools. Both the custom and pre-trained models can address a variety of challenges when extracting information from prompts, including grammatical errors, typos, repetitive unit operations, abbreviations, and unit of measure conversions. These models successfully convert the extracted data into a structured XML format, which can subsequently be used to generate simulations in APS. However, the quality of the XML output is influenced by factors such as the sentence structure of the prompt, the specificity of model variables, and the units of measure employed. Based on the case studies, it can be observed that the custom model excelled at standard queries, while the OpenAI model handled complex prompts with intricate sentence structures more effectively, despite occasionally introducing unexpected XML changes.

The pretrained GPT-3.5-turbo OpenAI model is readily accessible and easy to use, whereas the SpaCy model, being custom-trained, requires significant investment in terms of labor, cost, and ongoing maintenance as the model needs to be retrained with new datasets.

## ABSTRACT

Hybrid modelling is widely employed in chemical engineering to generate highly accurate predictions. Such an approach merges first-principle modelling with machine learning techniques to identify and model the epistemic uncertainty from experimental data. Despite its advantages, this still requires cross-domain competencies that are difficult to find in the chemical industry and high human involvement. The possibility of automating the identification and training model would be significantly beneficial for the widespread adoption of hybrid modelling methodology within the chemical industry. This work presents a novel algorithm for the automatic identification of hybrid models (HMs) starting from the first-principle representation of the system, described by differential equation sets. The methodology formulates the problem as mixed-integer programming, identifying the equation running under uncertainty, identifying the machine learning model hyperparameters, and training the latter. The Differential Evolution algorithm drives the identification and training tasks. The methodology is validated in three cases, namely a dynamic reaction system, a dynamic bioreactor and a Lotka-Volterra oscillator deviated with polynomial or MRF equation on different levels, generating 14 validation cases. On all of them, the model correctly identifies the position of the uncertainty and the functional form to approximate it. The methodology returns automatically trained HMs with a mean absolute percentage error in the range of 10%, which is in line with the experimental error of the data. The methodology presented in this work presents a step toward the automatic generation of HMs for dynamic systems and the widespread of this technology in the chemical industry.

**Keywords**: hybrid modelling, automatic identification, epistemic uncertainty, differential evolution, machine learning

## INTRODUCTION

Model accuracy is crucial for effective process design and optimization in the chemical industry. However, model performance often suffers from epistemic uncertainty due to unknown phenomena that current knowledge or analytical techniques cannot fully capture. This uncertainty biases predictions and compromises design quality. Hybrid modelling (HM) has emerged as a promising approach to mitigate these issues by integrating first-principle models (FPMs) with machine learning (ML) methods [1]. Here, experimental data are used to capture unmodeled phenomena in a functional form, thereby enhancing accuracy and providing insights into system behaviour.

In chemical process system engineering, FPMs are typically formulated as differential-algebraic equations that include conservation laws, thermodynamic relations, and other fundamental principles. Each of these equations may run under epistemic uncertainty, making them candidates for correction through a data-driven model (DDM). Constructing an HM requires three steps: (1) identifying the equation affected by epistemic uncertainty, (2) selecting an appropriate DDM structure to capture the unmodeled effects, and (3) training the DDM using available experimental data. The DDM must be sufficiently complex to represent the system accurately while maintaining a number of parameters that align with data availability.

Despite the benefits of HM techniques, their

widespread adoption in the chemical industry is hindered by the need for interdisciplinary expertise in chemical engineering, modelling, and ML. Other fields have benefited from automated ML frameworks that streamline model training and simplify the adoption process. An analogous automated framework for HM could facilitate its broader use, enhancing the interpretability of models and providing new insights into the system dynamics.

Currently, the identification of the epistemic uncertainty location relies heavily on domain expertise and physical insight. While some progress has been made in automating other aspects of HM, the literature lacks a comprehensive methodology for automatically locating epistemic uncertainty. Several studies have explored the selection of DDM structures and hyperparameters using approaches such as integer programming and genetic programming. For example, the ALAMO approach employs quadratic integer programming to approximate unknown physical functions by selecting suitable elementary function candidates and fitting parameters to experimental data [2]. Similarly, Narayanan et al. used genetic programming to approximate the right-hand side of differential equations, aiming to capture the entire physical relationship without additional physical constraints [3]. Furthermore, Willis and von Stosch introduced a mixed-integer linear programming framework that utilizes multivariate rational functions as approximators, validating their method on biochemical reactions and adjusting model complexity based on data availability [4].

In addition to the aforementioned techniques for generating hybrid models (HMs), recent studies have employed symbolic regression (SR) and sparse identification of dynamic systems (SINDy) for data-driven equation discovery [5, 6]. Both methodologies utilize a library of candidate functions to identify underlying equations, producing highly interpretable symbolic representations that approximate the unknown aspects of a system. However, they adopt distinct strategies tailored to different applications. Symbolic regression is typically applied to tabular data, using evolutionary algorithms to construct expression trees of elementary operations. This process identifies the optimal equation configuration that minimizes the discrepancy with experimental data. A notable advantage of SR is its ability to incorporate constraints during optimization, ensuring that the derived models are physically consistent and capable of integrating qualitative information. On the other hand, SINDy is designed for dynamic systems and focuses on uncovering the functional forms governing the temporal evolution of state variables. It employs sparse regression techniques, particularly quadratic optimization, to directly tune model parameters based on state derivative expressions without requiring the explicit solution of differential equations. While both approaches have demonstrated high performance in their respective fields, neither has been systematically evaluated for generating hybrid models in chemical processes.

To our knowledge, no framework exists that can automatically generate a hybrid model solely from an FPM representation and experimental data by simultaneously executing all three HM design steps. Addressing this gap involves solving a mixed-integer programming (MIP) problem that integrates categorical variables (e.g., the location of epistemic uncertainty), discrete variables (e.g., ML hyperparameters), and continuous variables (e.g., DDM fitting parameters). In this paper, we propose an algorithm that automatically identifies the equation affected by epistemic uncertainty, selects the most appropriate DDM hyperparameters, and trains the model using a heuristic global optimization strategy. This approach aims to enhance data efficiency while remaining compatible with the constraints of industrial data availability.

## METHODOLOGY

### The algorithm

The MIP problem to identify and train the HM was solved using the Differential Evolution (DE) algorithm (Scipy v.1.11.3) [7], compatible with integer variables and constraints. For the constraints, the library implements the algorithm proposed by Lampinen [8]. The MIP problem is divided into 3 subproblems, namely 1) the identification of the equation running under epistemic uncertainty, 2) the identification of the most suitable data-driven function structure to capture the said uncertainty from the training data, and 3) training the DDM identifying its continuous parameter values; these three problems are solved simultaneously by the DE. The algorithm employs polynomial equations as the data-driven function. The algorithm can activate each of the monomial terms contained in the polynomial.

The first problem is treated as a discrete optimisation problem, where the discrete variable $P$ sets which equation in the system runs with epistemic uncertainty and should be corrected by the DDM. The discrete variable P varies between 0 and ($N_s$-1), where $N_s$ is the number of equations in the system.

The second solved problem is the structure identification of the data-driven function. The algorithm implements a polynomial function as an approximator by deriving monomial terms from the states of the differential equation, constructing a K-order polynomial, and scaling the exponents of each term within the predefined range *EX_MIN* and *EX_MAX*. This ensures a balanced representation of the system dynamics, enabling accurate approximations while maintaining numerical stability and computational efficiency. This work employed K=4, EX_MIN=0.5 and EX_MAX=2. The structure of the polynomial function to train is selected, activating only certain monomial terms. In the polynomial data-driven function,

each of the monomial terms is multiplied by a continuous and a binary variable

$$M_i = \delta_i w_i \cdot f_i(x_1, x_2, \dots) \quad (1)$$

where $\delta_i \in \{0,1\}$ is the binary variable, $w_i$ is the continuous variable, $x_i$ is the i-th state of the differential equation system and $f_i$ is the polynomial form related to $M_i$. Both $\delta_i$ and $w_i$ of (1) are identified by the DE algorithm; the first is treated as a bounded discrete variable, while the second one is encoded as a bounded continuous variable. This work employed $w_i \in [-5,5]$. The configuration reported in (1) allows for reducing the number of parameters used in the DDM, reducing the overfitting risk in the model training phase. The number of active parameters $\delta_i w_i$ is reduced by limiting the amount of $\delta_i$ values being non-zero. Such a condition is given as a constraint to the DE

$$\sum_i \delta_i < N_{MAX}$$

where $N_{MAX}$ is the maximum cardinality allowed by the optimisation. This work employed $N_{MAX} = 5$.

The Bayesian Information Criterion (BIC) was used as the training loss function to balance the performance of the HM with the structural complexity of the DDM and avoid overfitting the training set. The formulation by Willis and von Stosch was employed in this work [4]. The BIC was computed for each experiment, and the loss function value was calculated as their sum.

The DE algorithm was executed with 300 generations using the default settings of the SciPy implementation. Afterwards, the continuous parameters of the most performant individual were refined using the L-BFGS-B.

The computational complexity of the proposed approach is linear in the number of experiments included in the training set because the most time-consuming part is the resolution of the ODE through numerical solvers.

## The test cases

Three FPMs were employed as test cases to evaluate the performance of the algorithm. These were selected to represent typical dynamic systems in the chemical engineering domain. The first test case, *the reaction system*, is a set of chemical reversible reactions described by the chemical system $A \leftrightharpoons R \leftrightharpoons S$, each running on first-order kinetic in batch conditions assumed isothermal; therefore, described through the set

$$\begin{cases} dC_A/dt = -k_{1,d} \cdot C_A + k_{1,i} \cdot C_R \\ dC_R/dt = k_{1,d} \cdot C_A - k_{1,i} \cdot C_R - k_{2,d} \cdot C_R + k_{2,i} \cdot C_S \\ dC_S/dt = k_{2,d} \cdot C_R - k_{2,i} \cdot C_S \end{cases}$$

with $k_{1,d} = 0.3\ min^{-1}$, $k_{1,i} = 0.1\ min^{-1}$, $k_{2,d} = 0.02\ min^{-1}$, $k_{2,i} = 0.01\ min^{-1}$. The equations were solved with initial conditions in the range [0, 10], with 10 points obtained using the Latin hypercube sampling (LHS).

The second test case is *the Lotka-Volterra oscillator*, described by the system

$$\begin{cases} dx/dt = (1-y) \cdot x \\ dy/dt = (x-1) \cdot y \end{cases}$$

The equations were solved with initial conditions in the range [0, 1], with 10 points obtained using the LHS.

The third evaluation case is *the bioreactor system*, describing the growth of biomass, X, in a continuous bioreactor fed with the nutrient S, influenced by Monod kinetics. The system is described by the equation set

$$\begin{cases} \dfrac{dX}{dt} = \dfrac{\mu_{max} \cdot S}{K_S + S} \cdot X - D \cdot X \\ \dfrac{dS}{dt} = D \cdot (S_{in} - S) - \dfrac{\mu_{max} \cdot S}{K_S + S} \cdot \dfrac{X}{Y_{xs}} \end{cases}$$

with $\mu_{max} = 0.4\ min^{-1}$, $K_S = 0.5\ mol/L$, $S_{in} = 1\ mol/L$, $Y_{xs} = 0.6\ g/mol$ and $D = 0.1\ min^{-1}$. The equations were solved with initial conditions in the range [0.2, 1], with 10 points obtained using the LHS.

Each of the equations in the FPMs was deviated using 2nd-order polynomial or 1st-order MRF functions to mimic the epistemic uncertainty source. The employed parameters were sampled in the range [-1,1]; following that, the output was multiplied by a constant value to enhance the effect of the deviation.

For each validation case, one of the abovementioned deviations was applied to one of the set equations individually. Therefore, the algorithm was validated using 14 cases combining the FPMs and the deviation position. These served as experimental data for the algorithm to identify the position of the epistemic uncertainty and the most suitable data-driven function structure for the HM generation.

Each of the deviated equations was solved using LSODA solver (SciPy v1.11.3). Each of the experiments contained 14 points uniformly sampled in the time range [0,20] min; noise of ±10% was added to the output, mimicking the measurement noise. The test set for the reaction system comprises 5 train points and 5 test points randomly selected. The test set for the Lotka-Volterra oscillator and the bioreactor system comprises 4 points selected to be within the initial conditions convex-hull.

The trained models were evaluated on a test set. The quantitative comparison of the trained HM performance was executed using 1) the coefficient of determination ($R^2$), to evaluate the explained variance of the model, 2) the mean absolute percentage error (MAPE) to have a quantitative deviation of the model from the point weighted on their experimental value, and 3) the mean absolute percentage error (MAE) to have a quantitative deviation of the model prediction from the experiments.

# RESULTS

The results of the identification algorithm are reported differentiated by the test case on which they have

been validated. Tables 1, 2 and 3 report the accuracy of the identified HM on the overall test set, the actual level of the epistemic uncertainty within the equations and the one identified by the algorithm for the reaction system, the Lotka-Volterra oscillator and the bioreactor system, respectively. Figures 1, 2, and 3 report the graphical representation of the model performance on selected experiments contained in the test set, respectively, for the reaction system, the Lotka-Volterra oscillator, and the bioreactor system.

## The reaction system

In the reaction system, the developed algorithm correctly identifies the epistemic uncertainty location within the equations set for all the proposed test conditions (Table 1). Moreover, HMs identified from the algorithm return low prediction errors on the test set.

**Table 1.** Quantitative performance of the identified HM from the algorithm on the test set. The table reports the equation on which the deviation was applied, the one identified by the algorithm, and the obtained metrics.

| *Actual* | | *Identified* | | | |
|---|---|---|---|---|---|
| Level | Deviation | Level | MAPE | MAE | $R^2$ |
| 1 | Poly | 1 | 10.8% | 0.48 | 0.11 |
| | MRF | 1 | 18.4% | 10.53 | 0.59 |
| 2 | Poly | 2 | 15.7% | 7.32 | 0.82 |
| | MRF | 2 | 7.55% | 0.43 | 0.24 |
| 3 | Poly | 3 | 6.07% | 0.27 | 0.29 |
| | MRF | 3 | 6.3% | 0.56 | 0.77 |

Excluding the system deviated on the 1st equation with MRF and the system deviated on the 2nd equation with polynomial, the trained HM predicted the system behaviour with a MAPE error in line with the given experimental error (i.e., ± 10%). The quality of the model is also confirmed by the MAE value, returning low metrics; this highlights how the error is evenly distributed within the entire range without any significant bias toward any area of the output range. On the other hand, in the two cases with high MAPE and MAE, the model cannot accurately predict the output in some experiments contained in the training set. The low amount of data mainly drives this behaviour for a system having 3 states. Performing the convex-hull selection also in this case, the train set comprises 8 points and improved performances; however, this was not included because of poor reliability on the test set.

Despite the low MAPE and MAE values, the $R^2$ obtained on the test set is quite low for some of the cases (e.g., the one with polynomial deviation on the 1st equation or the MRF deviation on the 2nd equation), showing that the trained model has limited capabilities in explaining the variance of the experimental set. We hypothesise that this is driven by the poor ability to identify continuous parameters. The algorithm uses a heuristic approach to identify all the system parameters, but it is quite inefficient for continuous parameters since heuristics do not guarantee the minimisation of the loss function for a given configuration. On the other hand, the continuous parameters can be identified by gradient-based optimisation approaches, improving the quality of the training.

From Figure 1, it is possible to observe how the employed FPM has significant deviations compared to the experimental data, especially for the profile of the reactant S, where it predicts a completely different behaviour. On the other hand, this effect is mitigated by including DDM, which corrects the model prediction and correctly identifies the deviation source. This results in improved model metrics, such as the MAPE decrease of 5 folds. The case reported in Figure 1 runs with epistemic uncertainty on S concentration. S is being generated from something else that is not included in the mathematical system. The mechanistic model of the system closes the mass balance, but in reality, the system description violates this hypothesis. To ensure mass balance, a further investigation of what is causing the S growth is required.

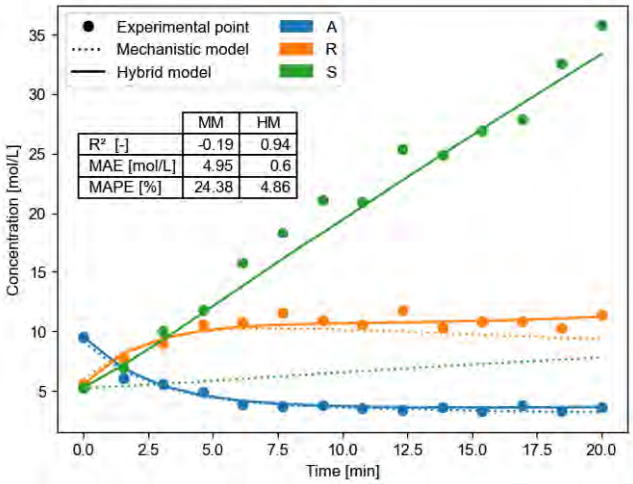

**Figure 1.** First-principles model and hybrid model performance on one of the test examples on the reaction system. The reported experiment is obtained with MRF deviation on the 3rd equation.

## The Lotka-Volterra oscillator

Like the reaction system, also for the Lotka-Volterra case, the developed algorithm performs correct identification of the epistemic uncertainty location both for polynomial and MRF deviation (Table 2). The metrics reported in Table 2 show the enhanced prediction accuracy of the identified HM. For all the validation cases, the HM has low MAPE and MAE with $R^2$ very close to 1, showing how the HM was able to explain the variance of the experimental system completely.

Figure 2 depicts the performance of the mechanistic and HM on one of the test set experiments, having deviation on the 2nd equation with a polynomial function. Here, it is possible to observe how the FPM shows high

deviation on both the variables with error accumulating with time, resulting in a significant shift of the actual and modelled peaks for $t > 7.5\ min$. Additionally, the FPM returns a wrong prediction of peaks amplitude, with a systematic overestimation for both the system states. This behaviour is not observed with the identified HM, returning accurate predictions within the entire simulation time. The HM has effects not only on the peak position but also on their magnitude, which are now correctly predicted. In summary, the HM correctly identifies the behaviour of the test system returning MAPE around 5% and an $R^2$ = 0.98, where the FPM has worse prediction accuracy with an $R^2$=-0.05, indicating that the model returning the average of the points return better prediction than the FPM, and a MAPE around 38%, with a value 7 times higher than the value obtained with the HM predictions.

**Table 2.** Quantitative performance of the identified HM from the algorithm on the test set. The table reports the equation on which the deviation was applied, the one identified by the algorithm, and the obtained metrics.

| *Actual* | | *Identified* | | | |
|---|---|---|---|---|---|
| Level | Deviation | Level | MAPE | MAE | $R^2$ |
| 1 | Poly | 1 | 5.29% | 0.066 | 0.96 |
| | MRF | 1 | 5.51% | 0.068 | 0.95 |
| 2 | Poly | 2 | 5.68% | 0.051 | 0.96 |
| | MRF | 2 | 8.95% | 0.084 | 0.92 |

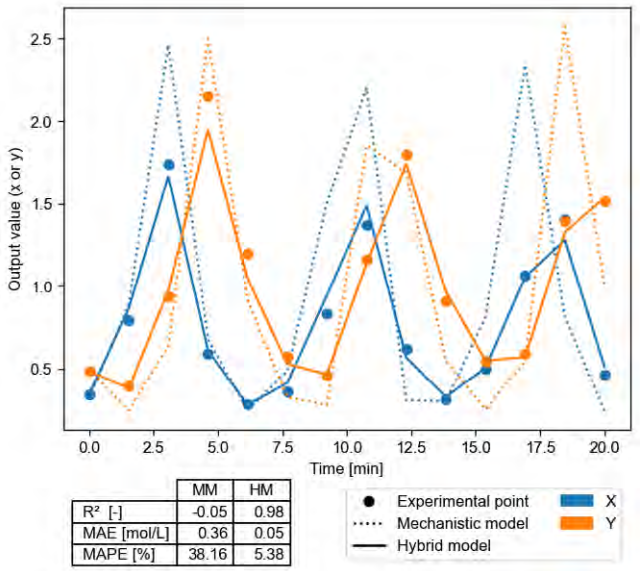

**Figure 2.** First-principles model and hybrid model performance on one of the test examples on the Lotka-Volterra oscillator. The reported experiment is obtained with polynomial deviation on the 2nd equation.

## The bioreactor system

When describing the bioreactor system, the model correctly identifies all the validation cases, with deviations both on biomass growth and substrate profile (Table 3). The source of the epistemic uncertainty has been correctly identified by the algorithm, as well as the approximation for the deviation function. The algorithm did not show any identification bias (i.e., model accuracy or level identification) among the various cases, returning for each of the test case metrics with the same order of magnitude.

**Table 3.** Quantitative performance of the identified HM from the algorithm on the test set. The table reports the equation on which the deviation was applied, the one identified by the algorithm, and the obtained metrics.

| *Actual* | | *Identified* | | | |
|---|---|---|---|---|---|
| Level | Deviation | Level | MAPE | MAE | $R^2$ |
| 1 | Poly | 1 | 6.02% | 0.027 | 0.77 |
| | MRF | 1 | 5.4% | 0.033 | 0.88 |
| 2 | Poly | 2 | 6.87% | 0.042 | 0.8 |
| | MRF | 2 | 6.00% | 0.035 | 0.83 |

Figure 3 depicts one of the test experiments for the case having deviation on the 1st equation described by a polynomial function. Here, the FPM shows significant deviation that is cumulating over time; such behaviour is related to the fact that the numerical resolution of differential equations relies on predicted system state values to run the prediction at the current state, letting the error accumulate over time.

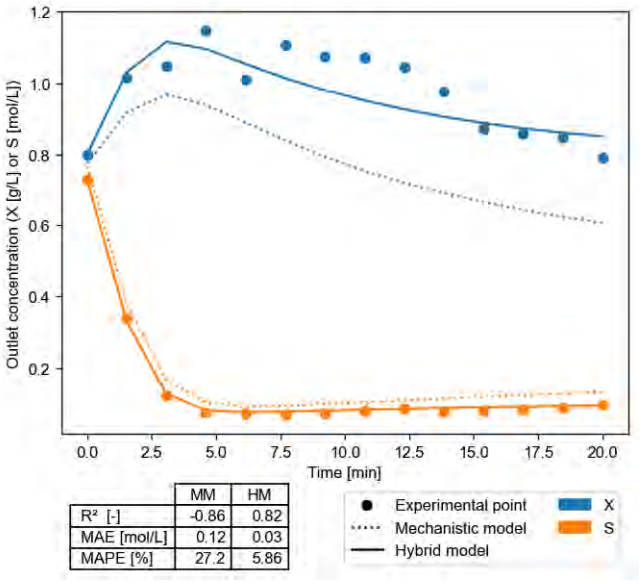

**Figure 3.** First-principles model and hybrid model performance on one of the test examples on the biochemical system. The reported experiment is obtained with polynomial deviation on the 1st equation.

On the other hand, the HM prediction correctly overlaps the experimental points within the entire time range without any significant deviation happening over time, demonstrating the robustness and reliability of the HM obtained with the proposed methodology. It is important to note that both the FPM and the HM identify the same

overall trend, but the HM better identify the change in system behaviour (e.g., the location of the maxima for the X profile), the magnitude of the first derivate of the profile and the plateau location for both the curves. Such an improvement in behaviour prediction resulted in better metrics for the HM over the FPM; the FPM returned a MAPE=27.2% while the $R^2$=-0.86, quantitively proving the poor prediction capabilities of the FPM. On the other hand, the HM results in a MAPE=5.86%, a value around 4.6 times lower than the one obtained for the FPM, and an $R^2$=0.82.

## ALTERNATIVE APPROACHES

A primary limitation of the proposed approach is the need for iterative ODE resolution during parameter identification. This process significantly prolongs identification time and is susceptible to mathematical instabilities, thereby reducing compatibility with derivative-based optimizers. A potential solution to mitigate these issues is the application of SINDy-like techniques [6]. This alternative framework would allow the reformulation of the identification problem using quadratic integer programming to locate epistemic uncertainty while also accommodating multiple model deviations.

## CONCLUSIONS

This work presents an automatic algorithm that identifies and trains hybrid models for dynamic chemical processes. Starting from a first-principle model under epistemic uncertainty, the method integrates missing information from experimental data into a data-driven component. It locates the epistemic uncertainty within the system equations and selects the most suitable data-driven model (DDM) for its mitigation. A constrained mixed-integer Differential Evolution algorithm is used to determine the uncertainty's position along with the hyperparameters and parameters of the DDM.

To work with limited data and minimal experimentation, the method employs a sum of monomial terms as the data-driven function and uses the Bayesian information criterion as the loss function, thereby reducing model complexity and overfitting risk. The approach was validated on a reactive chemical system, a bioreactor with biomass growth, and the Lotka-Volterra oscillator, accurately identifying uncertainty and achieving prediction errors (MAPE) below 10% on unseen cases.

This methodology marks a significant step toward automating hybrid model creation in the chemical industry. Future improvements include integrating deterministic algorithms for continuous parameter identification, testing additional chemical cases, and extending uncertainty identification to model parameters beyond differential equations.

## ABSTRACT

Modeling process systems by use of partial differential equations is often complex and computationally expensive, especially for inverse problems such as optimization, state identification, or parameter estimation. Data-driven methods typically provide efficient alternatives with lower computational cost. One such method is Graph Neural Networks (GNNs), which can be used to model dynamical systems as graphs. However, dynamic GNNs often face challenges with extrapolation and representability. Integrating mechanistic insights in surrogate models can improve both prediction accuracy and interpretability. This study compares different strategies for embedding physics-based insights into GNNs to model the dynamic behavior of a catalytic $CO_2$ methanation reactor. The hybrid integration of physics-informed GNNs aims to improve the predictive ability and interpretability while reducing the model development time, thereby facilitating faster deployment. Results show that penalizing the predicted change in reactor states from one time step to the next during training reduces the Frobenius error norm of GNN predictions from about 2.2 % to 1.4 %. In contrast, using a traditional physics-based loss function during training results in a Frobenius norm as high as 8.7 %. This highlights the importance of comparing different strategies for embedding physical laws into data-driven models.

## INTRODUCTION

Process systems are often spatially distributed, dynamic, and exhibit highly nonlinear behavior. Modeling these systems requires the abstraction of process knowledge into a mathematical representation.

Accurate mechanistic models, often represented by mass and energy balances, combined with thermodynamic and kinetic laws, and abstracted as a system of partial differential equations (PDEs), require significant effort in terms of development time. The expertise and deep understanding required for this type of modeling adds to its complexity. Due to the intricate nature of process systems, analytical solutions are rarely achievable, necessitating the use of numerical methods. These methods rely on discretization schemes, in terms of temporal and spatial coordinates of the system. Furthermore, the complexity of problems arising from the numerical treatment increases with finer discretization, especially in inverse applications such as optimization, state identification, or parameter estimation. Despite these challenges, mechanistic models offer significant advantages. Their parametric nature allows sensitivity and scenario analysis, as well as critical flexibility analysis for dynamically operated process systems.

Recent developments in machine learning (ML), especially deep learning (DL) methods, have facilitated surrogate modeling of complex systems. Data-driven models are relatively easy to develop and take less time to build, provided sufficient data is available in both quantity and quality. However, they do require tuning of hyperparameters, which, while not trivial, is generally less time consuming than building mechanistic models from scratch. However, data-driven surrogate models face challenges related to interpretability and the ability to make meaningful extrapolative predictions.

Hybrid methods that integrate ML with knowledge-based models are often referred to as scientific machine

learning (SciML). SciML models leverage the strengths of both mechanistic and data-driven approaches, integrating domain expertise with data-driven insights. They contain embedded physical laws, can be used for extrapolative predictions, and generally provide better interpretability [1, 2].

The principles of modeling of spatially distributed dynamical systems have practical applications in the design and optimization of energy conversion technologies capable of storing renewable energy. Renewable energy plays a critical role in addressing climate change and increasing energy independence, but its intermittent nature presents significant challenges. To overcome these challenges, renewable energy can be converted into other forms, such as chemical energy, to facilitate its long-term storage, transportation, and distribution. One such conversion process is methanation, in which carbon dioxide and hydrogen are converted to methane, with water as a byproduct. The hydrogen, often referred to as green hydrogen, is typically produced by electrolysis of water using renewable energy [3]. This process allows methane to be used as an efficient chemical energy carrier that can be easily stored and transported within the existing infrastructure. The methanation reaction is as follows:

$$\mathrm{CO_2} + 4\,\mathrm{H_2} \rightleftharpoons \mathrm{CH_4} + 2\,\mathrm{H_2O} \tag{1}$$

$CO_2$ methanation is assumed to take place in a one-dimensional polytropic reactor which can be mechanistically described by the mass and energy balances [4]:

$$\frac{\partial X}{\partial t} = -\frac{\mathrm{u}}{\epsilon_\mathrm{R}}\frac{\partial X}{\partial z} + \frac{M_{\mathrm{CO_2}}}{\epsilon_\mathrm{R}\,\rho\,y_{\mathrm{CO_2,in}}}(1-\epsilon_\mathrm{R})\sigma_\mathrm{eff}, \tag{2}$$

$$\frac{\partial T}{\partial t} = -\frac{u_\mathrm{in}\rho_\mathrm{in}C_p}{(\rho C_p)_\mathrm{eff}}\frac{\partial T}{\partial z} + \frac{1}{(\rho C_p)_\mathrm{eff}}\frac{\partial}{\partial z}\left[\Lambda_\mathrm{ax}\frac{\partial T}{\partial z}\right] + \frac{4U}{D\,(\rho C_\mathrm{p})_\mathrm{eff}}(T-T_\mathrm{cool}) - \frac{\Delta H_r}{(\rho C_p)_\mathrm{eff}}(1-\epsilon_\mathrm{R})\sigma_\mathrm{eff}, \tag{3}$$

with the initial and boundary conditions:

$$X|_{z=0} = 0, \quad X|_{t=0} = X_0, \quad T|_{t=0} = T_0, \quad \Lambda_\mathrm{ax}\frac{\partial T}{\partial z} = u_\mathrm{in}\rho_\mathrm{in}C_\mathrm{p}(T-T_\mathrm{cool}), \quad \left.\frac{\partial^2 T}{\partial z^2}\right|_{z=L} = 0. \tag{4}$$

Hereby, $X$ and $T$ denote carbon dioxide conversion and reactor temperature, respectively. $z$ stands for the spatial (axial) and $t$ for the time coordinate. The constants $\epsilon_\mathrm{R}$, $M_{\mathrm{CO_2}}$, $y_{\mathrm{CO_2,in}}$, $u_\mathrm{in}$, $\rho_\mathrm{in}$, $D$ and $L$ describe the specific reactor dimensions and settings. The variables $u$, $\rho$, $\sigma_\mathrm{eff}$, $C_\mathrm{p}$, $\Lambda_\mathrm{ax}$, $U$, $T_\mathrm{cool}$ and $\Delta H_r$ are modeled by algebraic equations.

The initial conditions $X_0$ and $T_0$ are set for a load change scenario where the hydrogen depends on the time-varying renewable energy generation. The synthetic data used in this work, visualized in Figure 1, is generated using the mechanistic model reported above, with the parameter tuned as reported in [5].

This work extends the graph neural network (GNN) study presented in [5] by optimizing the hyperparameters, modifying the network architecture, and exploring different strategies for embedding physical information into the loss function. Three different models are investigated: (i) a baseline GNN, (ii) a GNN incorporating the time derivatives of the data into the loss function, and (iii) a GNN incorporating the underlying physics described by Equations 2 and 3 into the loss function.

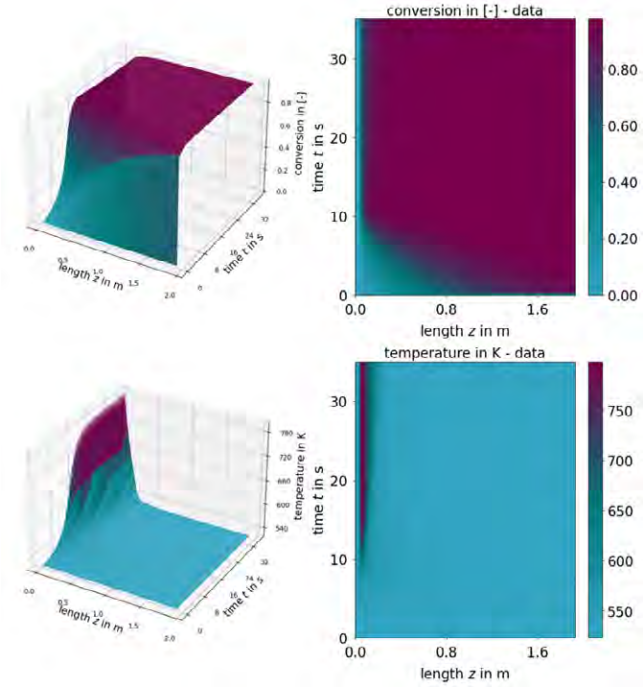

**Figure 1.** Conversion and temperature profiles generated from the mechanistic model and used to train and test GNNs.

## METHODS

### Graph Neural Networks

GNNs, introduced in [6], are a class of DL methods that operate on graphs. GNNs require the system to be represented as a graph '$\mathcal{G}$' with a set of nodes '$V$' and their inter-connectivities as edges '$E$'. A graph is then defined as the tuple of its node attributes and edge attributes along with the information of connectivity $\mathcal{G} = (V, E)$. The individual nodes and edges are denoted as $\mathrm{v}_i \in V$ for the $i^{th}$ node and $\mathrm{e}_{ij} \in E$ for the edge connecting the $i^{th}$ and $j^{th}$ node. The learning in GNNs is based on a message passing strategy where each target node receives the embeddings of all the neighbouring nodes and edges. These embeddings are then aggregated using a permutation invariant operator. Afterwards, this aggregated message is combined with the target node's own embedding using an update function, usually non-linear. This

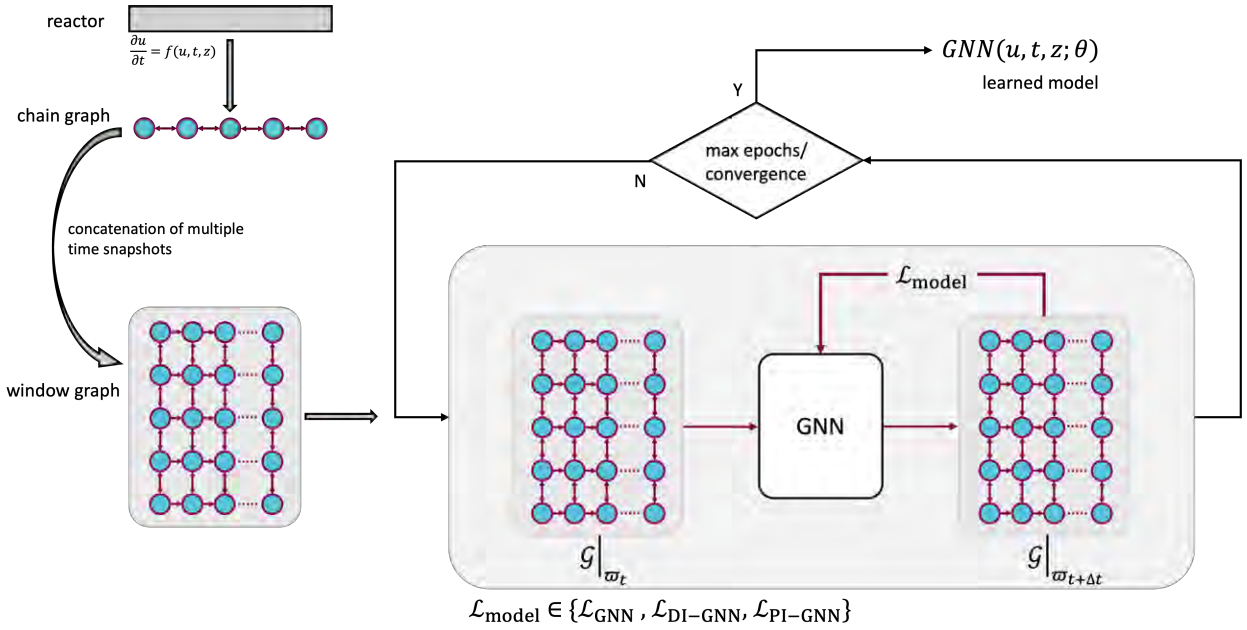

**Figure 2:** Generic schematic diagram of hybrid Graph Neural Networks.

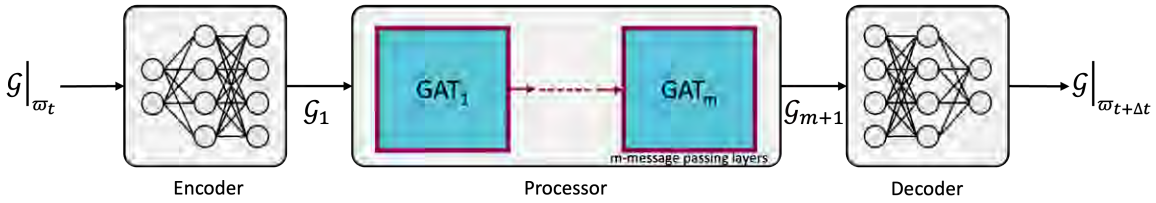

**Figure 3:** Network architecture of Graph Neural Networks.

mechanism, mathematically represented in Equation 5, makes GNNs spatially aware models

$$h_i^{k+1} = \phi\left(h_i^k, \zeta^k(\{h_j^k, \forall j \in \mathcal{N}(i)\})\right). \quad (5)$$

Here, $h$ represents the node embeddings, $\phi$ is the update function, $\zeta$ is the aggregate function, $i$ and $j$ denote the target node $i$ with nodes $j$ in its neighborhood $\mathcal{N}$, $k$ denotes the $k^{th}$ message passing layer.

For spatio-temporal systems, GNNs require the integration of a temporal model to effectively capture their dynamic behavior, leading to the development of spatio-temporal GNNs. Graph attention networks (GATs) [7] are one of these methods, where the message passing equation is modified using an attention coefficient resembling cognitive attention. The mathematical form is given in Equation 6

$$h_i^{k+1} = \phi\left(\sum_{j\in\mathcal{N}(i)} \alpha_{ij}\, \mathcal{W}^k\, h_i^k\right). \quad (6)$$

Here, $\mathcal{W}^k$ stands for the weights matrix at layer $k$ and $\alpha_{ij}$ is the attention coefficient for the connection between node $i$ with its neighboring nodes $j$. The integration of other temporal models, like recurrent neural networks, with GNNs has also been explored in the context of dynamical systems modeling [8].

## Graph representation of dynamical systems

Spatial dependence in systems can be represented structurally using grids for evenly spaced data or meshes for more general arrangements. Graph based models for learning complex physics simulations have been reported in [9-11]. In this work, we represent the dynamical system as a graph, where grid or mesh points are translated into nodes, and their connections are represented by edges. In the case of a methanation reactor, since the system is assumed to be one-dimensional in space, it is represented as a one-dimensional grid or a chain graph, as reported in [5]. Each graph corresponds to a snapshot of the domain at a specific time point. For improved learning, multiple time snapshots or chain graphs are concatenated to form a window graph, as shown in Figure 2. Adjacent nodes at each time point are connected by bi-directional edges, while corresponding nodes in two chain graphs are connected by unidirectional edges from the past to the future. The outputs of the mechanistic model, namely conversion and temperature, are used as node features, while the distances between two

neighboring spatial points are used as edge embeddings. The data is pre-processed using min-max scaling and split sequentially before embedding.

As shown in Figure 3, an encoder-processor-decoder architecture is used for GNN processing. The window graph is passed to an encoder, essentially a multilayer perceptron (MLP), which encodes the node features to the hidden dimension of the architecture. The encoded information is then processed using multiple GAT message passing layers. Finally, a decoder model of structure akin to the encoder is used to get the learned node features back to the original dimensions. The optimized hyperparameters are the hidden dimension of the architecture (228) and the window size (number of chain graphs processed at a time) of 20.

The output from the GNN block is used to calculate the loss function,

$$\mathcal{L}_{\mathrm{GNN}}(\theta) = \sum_{m=1}^{N_t}\sum_{n=1}^{N_z} \| \overline{u}(\varpi_m, z_n) - u(\varpi_m, V_n;\ \theta) \|_2^2. \quad (7)$$

In Equation 7, $\theta$ are the learned parameters of the GNN, $\varpi_m$ is the $m^{th}$ window graph, $V_n$ is the $n^{th}$ node, $N_t$ and $N_z$ denote the total number of window graphs and nodes in each graph, respectively. A stochastic optimization method from [12] with a learning rate of $5 \times 10^{-5}$ is used for GNN-training. This workflow is used in an iterative roll-out manner to predict multiple future time levels.

## Derivative-Informed Graph Neural Networks

The framework of a simple GNN implementation is modified by incorporating the time derivatives of the node features as additional information for the GNN. The architecture is also updated by replacing the MLPs in the encoder and decoder with deep neural networks (DNNs) and including more message-passing steps to enhance the system's awareness of neighboring nodes. Simply using the time derivative information as additional node features does not improve predictions, likely because the model perceives it as additional noise. Therefore, a more robust implementation of the derivative-informed GNN (DI-GNN) was developed by modifying the loss function to incorporate the derivative loss. This approach is based on the hypothesis that, at each time step or for each window graph, although the GNN is informed of the neighboring node embeddings, it remains unaware of how the node embeddings have changed from one time step or window graph to another.

The modified loss function reads:

$$\mathcal{L}_{\mathrm{DI-GNN}}(\theta) = (\gamma_{\mathrm{d}}) \sum_{m=1}^{N_t}\sum_{n=1}^{N_z} \|\overline{u}(\varpi_m, z_n) - u(\varpi_m, V_n;\ \theta)\|_2^2 + (1-\gamma_{\mathrm{d}}) \sum_{m=1}^{N_t}\sum_{n=1}^{N_z} \left\| \frac{d\overline{u}(\varpi_m, z_n)}{dt} - \frac{du(\varpi_m, V_n;\ \theta)}{dt} \right\|_2^2, \quad (8)$$

where $\gamma_{\mathrm{d}}$ denotes the data to derivatives weight.

## Physics-Informed Graph Neural Networks

To make the model truly semi-parametric in nature, the mechanistic model was integrated with the GNN implementation, into a physics-informed GNN (PI-GNN) framework. The modified GNN architecture in DI-GNN was used and the loss function was modified to resemble a physics-informed neural network (PINN) [13]. Ideally in a PINN loss function, the total sum is built of the data loss and physics loss which includes initial conditions loss and boundary conditions loss. In our case, the initial conditions are already satisfied with the first window graph in the train split, while boundary conditions are met within the equation system itself as equations are declared in their discretized form, i.e., as sets of ordinary differential equations (ODEs).

The modified loss function reads:

$$\mathcal{L}_{\mathrm{PI-GNN}}(\theta) = (\gamma_{\mathrm{p}}) \sum_{m=1}^{N_t}\sum_{n=1}^{N_z} \|\overline{u}(\varpi_m, z_n) - u(\varpi_m, V_n;\ \theta)\|_2^2 + (1-\gamma_{\mathrm{p}}) \sum_{m=1}^{N_t}\sum_{n=1}^{N_z} \left\| \frac{d\overline{u}(\varpi_m, z_n)}{dt} - PDE_{\mathrm{sys}(u(\varpi_m, V_n;\ \theta))} \right\|_2^2, \quad (9)$$

where $\gamma_{\mathrm{p}}$ denotes the data to physics weight. $PDE_{\mathrm{sys}}$ denotes the right-hand side of the mechanistic model given by Equations 2 and 3.

## COMPARATIVE ANALYSIS

The comparison between the predictions of the three models is based on the relative Frobenius error between the synthetic data and the model predictions. The Frobenius norm is defined as the square root of the sum of the absolute squares of all matrix elements:

$$\|E\| := \sqrt{\sum_{i=1}^{m}\sum_{j=1}^{n} |E_{ij}|^2}. \quad (10)$$

Each model uses a different GNN architecture and loss function. To reduce computation time and avoid overfitting, we used early stopping, which stops training when validation performance stops improving. This resulted in different training epochs for each model.

Both DI-GNN and PI-GNN are evaluated for two weight factors of 0.5 and 0.7 to evaluate the effect of individual loss terms on the predictions. Table 1 lists the relative Frobenius norms for GNN, DI-GNN ($\gamma_d = \{0.5, 0.7\}$), and PI-GNN ($\gamma_{\mathrm{p}} = \{0.5, 0.7\}$). The profiles predicted by these models have been graphically visualized in Figures 5-7. Out of the simulated time of 35 seconds, the first 20 seconds were used for model training while the remaining 15 seconds were reserved for model testing/performance evaluation. This split has been marked with a horizontal black line on all the figures.

GNNs are able to capture the overall dynamics of the data, but we observe an error propagation with time. This error propagation is reduced in case of DI-GNN, which performs best amongst the three models.

The predictive capability of DI-GNN is influenced by

the data to derivative weight ($\gamma_d$). On increasing the influence of data over derivatives, the DI-GNN theoretically approaches a simple GNN implementation, but because of the presence of an additional derivative loss term, its loss value increases, resulting in poorer predictions than possible with a simple GNN.

PI-GNN performs poorly as compared to simple GNN or DI-GNN, and it is also not trivial to tune. The discretized equations contain non-linear polynomial expressions which are dependent on the discretization of the system, the node distribution in a graph, as well as the number of graphs in the complete domain. The effect of data to physics weight ($\gamma_p$) is opposite to that observed in the case of DI-GNN. One possible cause is that once the model is physics-informed, prioritizing data over physics would make the predictions worse.

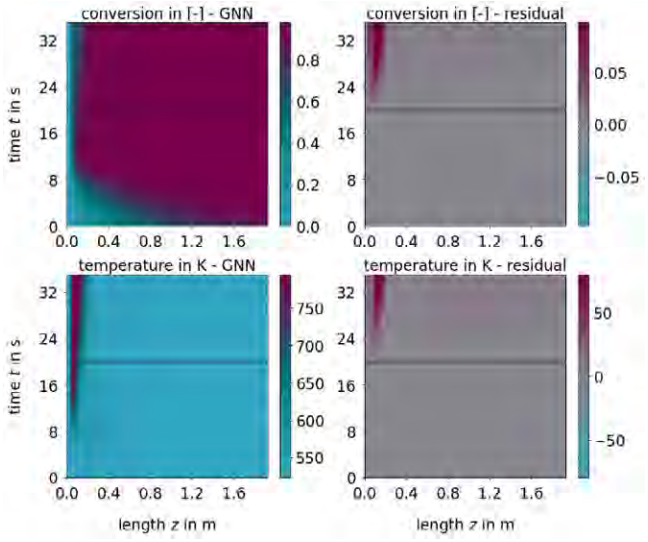

**Figure 5.** Conversion and temperature profiles predicted by the GNN and their comparison to the original data.

**Table 1:** Relative Frobenius Norms

| Method | Weight ($\gamma_-$) | $\|E\|$ for T | $\|E\|$ for X |
|---|---|---|---|
| GNN | - | 2.199 % | 2.165 % |
| DI-GNN | $\gamma_d$ = 0.5 | 1.389 % | 1.077 % |
| | $\gamma_d$ = 0.7 | 2.933 % | 3.845 % |
| PI-GNN | $\gamma_p$ = 0.5 | 8.715 % | 7.015 % |
| | $\gamma_p$ = 0.7 | 4.612 % | 6.755 % |

PI-GNN shows promising results in scenarios where we have sparse experimental data or certain boundary conditions must be explicitly enforced. They also ensure that the physical/scientific limitations are not violated (reactor temperature is below the maximum design temperature, conversion is not above 100%, etc.). But, as shown here, for the construction of surrogate models from mechanistic ones, their development can be cumbersome. The computation time/ epoch required for training of these models also varies with changing complexity ($t_{\mathrm{PI-GNN}} > t_{\mathrm{DI-GNN}} > t_{\mathrm{GNN}}$).

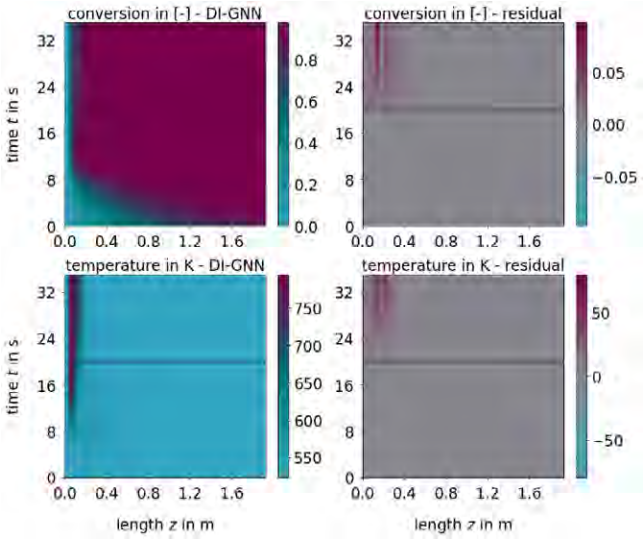

**Figure 6.** Conversion and temperature profiles predicted by the DI-GNN ($\gamma_d$ = 0.5) and their comparison to the original data.

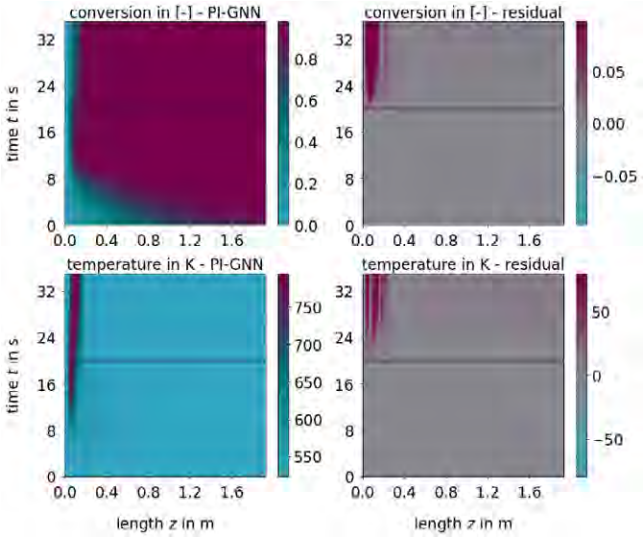

**Figure 7.** Conversion and temperature profiles predicted by the PI-GNN ($\gamma_p$ = 0.5) and their comparison to the original data.

## CONCLUSIONS

Efficient modeling of dynamical systems is critical for insightful predictions and effective decision making. To explore broader process alternatives, a faster model development and deployment pipeline is needed, which can be achieved through surrogate modeling techniques. However, the quality of a surrogate model is highly dependent on the representativeness of the available data. In our case, the training data may not fully capture the dynamics of the system, which could limit the accuracy

and generalizability of the model.

Present implementation of physics-informed models shows comparatively poor predictive capabilities but might outperform other purely data-driven models in scenarios where we have sparse experimental data and in inverse problem constructs for optimization or parametric adaptation of the model. These physically-informed models require more computing resources than a purely data-driven surrogate model. This computational burden can be alleviated by replacing the full mechanistic model with a reduced-order model, an approach particularly relevant for higher-order and multi-dimensional spatial domains.

To maximize the potential of current implementation, further work should ensure thorough hyperparameter optimization for GNN architecture as well as the loss function. The framework can also be extended and evaluated on different dynamical spatio-temporal systems, e.g. fluid mechanics, distribution networks, etc. A well-tuned, parametrized framework should be able to precisely capture the underlying dynamics and be well suited for use in optimization, uncertainty quantification and control.

## ABSTRACT

The analysis of large chemical reaction space sheds light on reaction patterns between molecules and can inform subsequent reaction pathway planning. With the aim to discover more sustainable production systems, it became worthwhile to explicitly model the reaction space reachable from biobased feedstocks. In particular, the space that reactions in integrated biorefineries span for optimised biorefinery planning is of interest. In this work we show a network-theoretical analysis of biorefinery reaction data. We utilise the directed all-to-all mapping between reactants and products to compare the reaction space obtained from biorefineries with the entire network of organic chemistry (NOC). In our results, we find that despite having 1000 times fewer molecules, the constructed network resembles the NOC in terms of its scale-free nature and shares similarities regarding its small-world property. Additionally, we analyse the coverage rate of the biorefinery reaction data and find that many common second and third-level intermediates are present, while the querying strategy leads to a lack of data on value-added refinery end-products and on feedstock molecules, requiring more advanced and combined data querying strategies in the future.

**Keywords**: Biosystems, Refining, Reaction, Algorithms, Planning, Network Science, Reaction Space

## INTRODUCTION

Biorefineries are facilities converting a feedstock-mix of biomass into multiple products through selected processing steps [1], in other words, they produce value-added (bio-)chemicals out of biomass. They comprise a range of (bio-)chemical reactions to cater for the desired refinery product portfolio.

The reaction space that is covered in biorefineries can be complex combining chemical and biological transformations. It is known that a wide range of biomass sources is suitable for the conversion into valuable products through many different routes, which makes the design of optimal biomass conversion pathways a challenging problem [2]. With the aim to design both economical and sustainable refineries, several works focus on biorefinery optimisation approaches where optimal reaction pathways and processes are selected [3-5]. While such works perform a manual preselection of reactions and process units to be considered, the automatization of this task has received notable attention, so that in the future larger (bio-)chemical reaction spaces mined from electronic databases can be evaluated quickly [6-8].

To this end, i.e., reaction pathway planning, but also for automated retrosynthesis planning [9], it became generally necessary to understand the large reaction spaces covered in electronic chemical databases better. Such large chemical reaction space covering millions of molecules are thus analysed intensively.

The reaction space is commonly represented as a graph, where depending on the chosen graph model, molecules are represented by nodes and reactions by edges [10], hyperedges [11], or a second node type [12]. For instance, the work of Jacob & Lapkin performed a holistic statistical analysis on the network of organic chemistry (NOC) to inform on subsequent planning and prediction tasks. In particular, they focused on network characterisation through graph theoretical properties such as degree distributions, pathlengths, wiring pattern and others [10]. They found that the known chemical space organises into a scale-free network, which allowed them to draw conclusions on the likely evolution of the reaction space and molecular participation in synthesis routes across the data space.

Here, we perform a similar network theoretical analysis of the reaction space found in biorefineries and compare it to the chemical reaction space, i.e. the NOC. Insights gained during the analysis of the biorefinery space can improve and speed up the search for promising pathways and identify bottlenecks. In particular, we investigate the following aspects: (i) how is the biorefinery reaction network characterised by network theoretical metrics, (ii) does the biorefinery reaction space exhibit selected similarities to the NOC, and (iii) how (bio-)chemically complete is the biorefinery reaction space investigated in this work with regard to molecules present in the data?

# METHODS

## Data extraction and preprocessing

With more than 46 million recorded reactions and more than 119 million recorded molecules REAXYS is one of the largest databases to investigate reaction spaces [13]. To extract relevant reactions from REAXYS using their web-interface and the Query builder tool, we utilise the "title, abstract and keywords" search with the "contains" parameter set, for the word "biorefiner". The word is not finished on purpose to give the results for both singular and plural forms. Such query provides almost 1300 reactions from the papers that contained the sub-word "biorefiner" in their title, abstract or set of keywords and included information on reactants, products and the number of reaction steps.

During the preprocessing steps, reactions that contain empty reactants or empty product fields are removed. Some of the reactions are recorded as having multiple steps. From this data, we do not know which intermediate molecules are omitted, yet we opt to keep the data due to the relatively small size of the entire biorefinery reaction space.

## Graph model and implementation

The constructed model is a weighted, directed graph connecting reactants and products with directed edges, using an "all to all" wiring scheme, as illustrated for one reaction in **Figure 1**. Each node represents one chemical compound while the edges leaving it represent the reaction that is utilising this molecule as reactant and producing a product at the end of the edge. To distinguish multi-step from single-step reactions for network analysis, we represented the number of reaction steps with the weight of the edge. This way certain properties can still be computed despite the missing intermediates. Duplicate edges are removed, keeping the one with minimal distance in the data. While this representation is a severe simplification as it disregards the polyadic relationships in the data (e.g. multiple reactants are needed to create multiple product(s)), it makes it comparable to other network theoretical studies. We follow these simplification to compare our analysis with the analysis of the NOC [10].

The acquired reaction data is used in the graph model and implemented with Python 3.11. We made use of the NetworkX and powerlaw packages to work with and analyse the graph data [14,15].

**Figure 1.** Illustration of the directed graph model. Nodes represent molecules, edges represent reactant-product relationships. Note that this neglects polyadic and stoichiometric relationships.

## Network analysis metrics

Network metrics are measured to assess the structure of the reaction space and how it compares to the NOC. Here, we focus our analysis on the following network properties.

Firstly, we analyse if the biorefinery network can be classified as scale-free network with similarity to the NOC. We do so by performing statistical testing of the degree distributions. The in-degree is the number of edges incoming to a node and the out-degree is the number of edges outgoing from a specific node. For instance, in **Figure 1**, node B has an in-degree of 0 and an out-degree of two. We first test against an exponential fit and then investigate differences between four heavy-tailed distributions: power law, truncated power law, lognormal and stretched exponential [15]. For the statistical tests the `distribution_compare` method from the powerlaw package is used. We further compare the exponents of the power law fits with those of the NOC.

Secondly, we are interested in understanding if we can expect a "small-world" behaviour in the biorefinery reaction space. This is characterised by the average shortest path scaling proportionally with the logarithm of the number of nodes [10], while also exhibiting high clustering. On average a relatively small number of steps (network edges) connects any two entities (network nodes) in "small-world" networks. We calculate the average shortest path length ($\bar{L}$) in Eq. 2. and the global clustering coefficient ($\bar{C}$) in Eq. 1, which measures the average probability that two vertices connected to a third vertex are also directly connected to each other [10]. We then compare the values with those of the NOC. The metrics are calculated on the weighted, undirected, largest connected component of the network (clustering coefficient) and weighted, directed graph (average path length) respectively.

$$\bar{C} = \frac{3 \times number\ of\ triangles}{number\ of\ triads} \quad (1)$$

$$\bar{L} = \sum_{\substack{u,v \in F \\ u \neq v}} \frac{d(u,v)}{|F|} \quad (2)$$

where a triad consists of two edges that share a vertex , $|F|$ is the set of nodes $u, v$ where the distance $d(u,v)$ between $u$ and $v$ is finite, [18] and $d(u,v)$ is the shortest path from node $u$ to node $v$.

Thirdly, to describe the network topology we consider metrics based on betweenness centrality. We calculate the global central point dominance ($\overline{C_B}$) in Eq. 3 and perform clustering (on the largest connected component of the graph) based on the Girvan-Newman algorithm using betweenness centrality ($c_B$) as edge weights. We choose a suitable number of clusters using a simplified cluster evaluation score ($score_{Cl}$) comparing edges within and between clusters, see Eq. 5.

$$\overline{C_B} = \frac{1}{n-1} \sum_{i \in V} c_B(i^*) - c_B(i) \quad (3)$$

$$c_B(i) = \frac{1}{((n-1)(n-2))} \sum_{s,t \in V} \frac{\sigma(s,t|i)}{\sigma(s,t)} \quad (4)$$

$$score_{Cl} = \frac{1}{g} \sum_{j}^{g} \frac{2\ e_{intra,j}}{e_{inter,j}} \quad (5)$$

where $c_B(i)$ is the normalised betweenness centrality of node $i$, $c_B(i^*)$ is the largest betweenness centrality in the graph, $\sigma(s,t)$ is the number of shortest pathways from node $s$ to node $t$ and $\sigma(s,t|i)$ is the number of shortest pathways from node $s$ to node $t$ that go through node $i$. Further, $g$ is the number of clusters (node groups) and $e_{intra,j}$ and $e_{inter,j}$ are the numbers of intra- (within) and inter- (between) cluster edges given a clustering $j$.

While all metrics are compared to the NOC, the clustering is qualitatively investigated and mapped against referenced molecules of lignocellulosic biorefinery from selected literature [16].

## Coverage analysis

To analyse the coverage of the biorefinery space, we investigate the following aspects: the split of molecules into clusters based on Eq. 5 and the Girvan-Newman algorithm, a quantitative comparison of our detected molecules with platform molecules named in selected literature [16], and the impact of the querying strategy on the completeness of the biobased molecular space.

For the impact of the querying strategy, we compare our naïve query strategy using a REAXYS keyword search with one that targets common feedstock molecules of biorefineries and the reactions that they are listed in. The targeted feedstock molecule search for the lignocellulosic case includes lignin, cellulose and hemicellulose as feedstock molecules, and for the blue biorefinery chitin, chitosan, laminarin, fucoidan and alginic acid as feedstock molecules. The Jaccard similarity coefficient is calculated between molecules found in the different networks. Additionally, we calculate the percentage of how many of the specialised molecules from the targeted search are also picked up by the naïve keyword search.

# RESULTS AND DISCUSSION

Firstly, we present the network-theoretical analysis of the biorefinery reaction space and compare this with the NOC to draw conclusions about the similarities of both data spaces. Secondly, we qualitatively discuss the coverage of the reaction space in the biorefinery network.

## Reaction space

The constructed network consists of 1273 vertices and 2009 edges. It is a disconnected graph separated into 78 components where the largest connected component contains 79.5% of all the nodes. At the same time, the second largest connected component contains less than 1.5 % of all the nodes. This indicates that most of the reaction space is connected and concentrated within a single cluster, suggesting high interconnectivity between those molecules. The remaining molecules form small and unconnected islands of molecular species, connected by one or few reactions.

**Table 1.** Summary of compared metrics between the biorefinery network and the NOC.

| | Global clustering coefficient | Average shortest path length | Central point dominance | In-degree exponent | Out-degree exponent |
|---|---|---|---|---|---|
| NOC | 0.00058 | 6.02 | 0.003719 | 3.0436 | 2.0935 |
| Biorefinery | 0.09001 | 4.77 | 0.009864 | 3.1755 | 2.1651 |

## Network analysis and comparison with NOC

Despite having three orders of magnitude fewer molecules, the constructed network resembles the NOC's topology. The biorefinery network exhibits similarities in scale-free and small-world properties. This could indicate that the sampling strategy (biorefinery reactions are also captured in the NOC) does not destroy the topology and also, that there are intrinsic properties of (bio-)chemical networks that remain unchanged. These could be for instance common numbers of reacting molecular species, common reaction patterns, common reaction

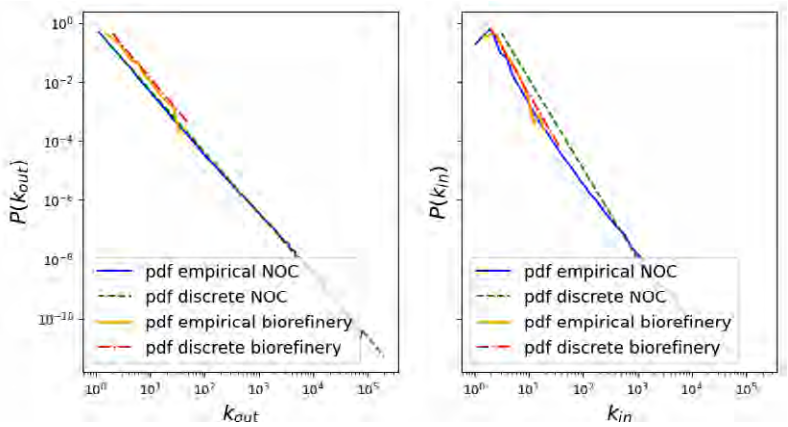

**Figure 2.** Degree distributions of the NOC and biorefinery network as the probability of observing a degree of $k$, using the Python package *powerlaw*. The term pdf empirical denotes the plotted distribution from the observed data, while pdf discrete represents the predicted distribution from power-law model based on the fitted exponent.

publishing practices. The scale-free and small-world properties are discussed in the following sections, while all metrics are provided in **Table 1**.

## Scale-free property

A power law distribution fits the biorefinery network data, which approves the hypothesis that both in- and out-degree are heavy-tailed distributions and to an extend similar to the NOC. Yet, we also identify that other distributions fit our data well.

Both in- and out- degree distribution show a high loglikelihood ratio with a significant p-value of 0.04 (in-degree) and 0.03 (out-degree) for the data to be described by a power law distribution rather than an exponential distribution. This minimum alternative is checked to classify the distribution as heavy-tailed. We illustrate the degree distributions of the biorefinery network as power law fit in **Figure 2**. For the in-degree, further comparisons of the power law distribution against truncated power law, lognormal, or stretched exponential distributions do not lead to statistically significant results. For the out-degree, we see that the lognormal, stretched exponential, and truncated power law distributions are slightly preferred over a power law.

To compare the exponents with those of the NOC, we opt to make use of the power law fit. We find exponents of 3.17 and 2.16 for the in-degree and out-degree respectively. Thus, the respective power law exponents indicate that the network topology can be described as scale-free. Jacob and Lapkin reported an exponent of 3.04 for the in-degree and 2.09 for the out-degree of the NOC [10]. Our findings closely resemble the topology of the NOC. Note that the in-degree distribution deviates from the power law distribution for the in-degree of one, meaning that for those nodes, the power law predicts a higher frequency, which was also seen in the NOC and in further literature [17]. For the in-degree, a $k_{min}$ of three was used for the NOC, while for biorefinery network $k_{min}$ was set to two. For the out-degree, a $k_{min}$ of one was used for fitting the NOC, while for the biorefinery network a $k_{min}$ of two was set.

## Small-world property

We discuss the small-world property based on the global clustering coefficient and the average shortest path length. Connected to these, we also discuss the central point dominance.

The clustering coefficient found in the biorefinery network is 0.09, which is significantly higher than the clustering coefficient of 0.00058 in the NOC. A high clustering coefficient is indicative of the small-world property of a network. In the original work the NOC was described to exhibit the small-world property [10]. We expect that the difference in coefficient is mainly due to our more specialised smaller network, which as a subset of the full NOC is composed of very well-connected molecules and reactions.

The average shortest path length of the biorefinery network is 4.77, while in the NOC an average shortest path length of 6.02 was measured. Besides the average, we illustrate both probability distributions of observing a path with a certain length in **Figure 3**. Commonly, in small-world networks the average shortest path should be approximately the logarithm of the number of nodes, which in the case of the biorefinery network would be $\log_{10} 1273 = 3.10$. Thus, here our network shows longer average path length than normally found in small-world networks.

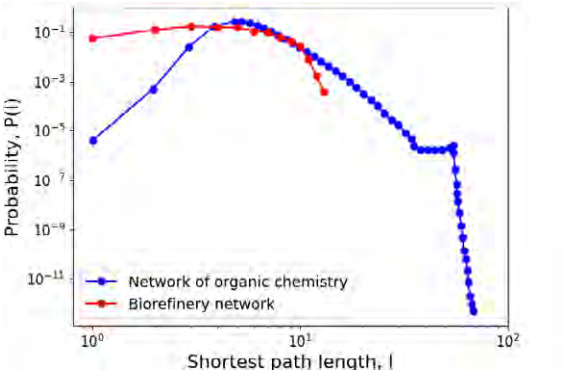

**Figure 3**. Comparison of the probability $P(l)$ of observing the shortest path with length $l$, between the NOC [10] and the network of biorefineries. NOC plot recreated using WebPlotDigitizer.

Lastly, we consider the central point dominance. The central point dominance in the biorefinery network is 0.0099, which is moderately higher than the central point dominance of 0.0037 of the NOC. This suggests that the biorefinery network has a slightly higher centralisation, meaning that a bigger proportion of reactions and pathways in the network go through a central node than in the NOC.

## Coverage of the biobased space

We note that our biobased data space is not significantly fragmented yet lacks some important biorefinery platform molecules as well as feedstocks and end products. This indicates that while our naïve query strategy is successful in mapping general reaction pathways throughout a refinery, to retrieve a holistic picture of all possible molecules and reactions, more advanced query strategies are needed.

### Cluster analysis

We utilise the scoring function described in Eq. 5 to identify the best number of clusters for the biorefinery network. The highest score of 42.92 was achieved with three clusters. We tested values between two and 100 clusters. The clustering based on the Girvan-Newman algorithm is displayed as a schematic overview in **Figure 4**.

Cluster one contains molecular derivatives and pathways mainly from lignin-based feedstock (orange cluster in **Figure 4**). This is not surprising as lignocellulosic biorefineries are one of the major biorefinery classes studied and we can therewith expect them to be highly present and well annotated in REAXYS.

Cluster two contains mostly pathways that produce and utilize 2-methoxy-phenol (yellow cluster in **Figure 4**). 2-methoxy-phenol is also derived from lignin and an important model compound towards the production of green chemicals, flavour molecules such as vanillin, and in the medical sector. We assume that it is very prominent in the network due to its role as important and versatile intermediate.

Cluster three contains a limited number of reactions, all involving 3-methylpyridine as a reactant (green cluster in **Figure 4**). 3-methylpyridine is a precursor for agrochemicals. This cluster is only loosely connected to the remaining space and does not contribute much to the main network characteristics.

We cannot visually detect any fragmentation of the network that clearly separates biorefinery processing steps or types of biorefineries. We note that while we used generic search terms, lignin processing and its associated pathways and derivatives are prominently represented, while other types of biorefineries (e.g. blue biorefinery) do not appear notably in the clusters.

**Figure 4.** Clustering of the biorefinery network using the Girvan-Newman algorithm and three clusters.

### Molecular species coverage

Common biobased feedstock molecules such as hemicellulose or chitosan are lacking in our biorefinery

**Table 2.** Presentation of the network coverage for the lignocellulosic biorefinery molecules from Tey et. al. [16]. It shows how many molecules from the paper are present in the constructed biorefinery network.

| | 1st intermediate | 2nd intermediate | 3rd intermediate | 4th intermediate | Final product |
|---|---|---|---|---|---|
| # species | 3 | 11 | 41 | 33 | 10 |
| # species in data | 2 | 9 | 25 | 11 | 3 |

network. Yet we find that their first, second, and third order derivatives along reaction pathways are present in the biorefinery network. We show in our quantitative analysis based on the platform molecules summarised by Tey et. al. [16] in **Table 2** that 66% of the 1st order intermediates, 82% of the 2nd order intermediate, and 61% of the 3rd order intermediates of lignocellulosic biorefineries are present. This indicates that the naïve query strategy is a sufficient proxy to assemble the data space spanning from 1st to 3rd order intermediates. We find significant less 4th order intermediates and final products in our network. Some products like ethanol and methanol are recorded, yet many more specialised possible biorefinery end products are not present. This, in combination with our cluster analysis, indicates that for fully automated pathway planning, additional effort is needed to query or manually add feedstock and product molecules.

### Database querying strategy

As comparison to our naïve keyword search strategy, we perform targeted molecular search strategies (see the method section coverage analysis) to gain insights on the impact of data acquisition. Both feedstock targeted searches bring networks of about 750 molecules (775 for the lignocellulosic search and 707 for the blue biorefinery search). The Jaccard similarity of the lignocellulosic network and the general biorefinery network in this work is only 8.20% and the Jaccard similarity between the blue biorefinery network and the general biorefinery network in this work is only 2.70%. We find that 20.00% of the molecules in the specialised lignocellulosic network are also part of the general biorefinery network and only 7.36% of the molecules from the specialised blue biorefinery network are present in the general biorefinery network. This indicates that despite the high coverage of common biorefinery 1st to 3rd order intermediates, currently a relatively large space of specialised molecular species at early processing stages of biorefineries remains unexplored by the keyword search strategy. We conclude that a more advanced strategy querying for targeted molecular species and their connecting reactions is needed to obtain a complete picture of possible design options for biorefineries.

## CONCLUSIONS

This paper investigates the reaction space in biorefineries. We present two main contributions. Firstly, this paper characterises the network space through network theoretical metrics and illustrates the topological similarities between the biorefinery reaction space and the NOC. For instance, the analysis of degree distributions shows that the network is scale-free with $\gamma_{in} \approx 3.2$ and $\gamma_{out} \approx 2.2$ resembling the NOC while containing 1000 times less vertices. Secondly, this paper presents evidence that the naïve keyword querying strategy contains many of the important first, second, and third intermediates of lignocellulosic biorefineries. Yet, it also shows that the current network is preliminary, lacking both some specialised products and feedstock molecules, as well as molecules and reactions from different biorefinery types. Our finding that about 80% of the data space is a closely connected network structure, makes this approach very useful for integrated biorefinery planning with the potential of automated reaction pathway optimisation. Our recommendations for future work are to work with a less severe abstraction in the graph data model and to focus on the addition of, in this work identified, bottleneck areas in the data.

## DIGITAL SUPPLEMENTARY MATERIAL

Our code for this work is available at GitHub (https://github.com/Intelligent-molecular-systems/network-analysis-of-biorefineries).

## ACKNOWLEDGEMENTS

## ABSTRACT

Photochemical monolith reactors offer advantages over microreactors by providing high mixing efficiency and surface area to volume ratio while being scalable. However, optimizing monolith design parameters like channel number, shape, and stacking is critical to maximizing light usage and reactor efficiency. This work proposes using Bayesian optimization and COMSOL Multiphysics simulations to automatically design translucent monoliths for photochemical reactions. The goal is to maximize both photochemical space-time yield and space-time yield. Ray tracing simulations were performed while evaluating five different channel geometries (circular, elliptical, triangular, square, and pentagonal) and optimizing parameters, including channel diameter, vertical stacking, shape rotation, and ellipse axis ratio. Results showed a clear trade-off between Space-Time Yield (STY) and Photochemical Space-Time Yield (PSTY), with optimized elliptical channels achieving up to 15.3% improvement in STY with minimal PSTY increase and 9.0% enhancement in PSTY with negligible STY decrease.

**Keywords**: Photochemistry, Photoreactors, Ray tracing, Bayesian Optimization, Monoliths

## INTRODUCTION

Photochemical reactors harness light energy to drive chemical transformation under mild conditions with high energy efficiency [1]. Despite their numerous advantages, including enhanced selectivity and control, reduced organic solvent requirements, renewable energy utilization, and access to novel reaction pathways, industrial adoption remains limited due to several key challenges [2]. The primary obstacles include suboptimal apparent reaction rates, insufficient energy efficiency, and reactor design limitations that impede effective scale-up largely arising from limited light penetration into the reaction environment, leading to low light utilization [3]. While microreactors can partially address these limitations through high surface area-to-volume ratios and improved illumination uniformity [4], their restricted throughput capacity and spatial mismatch between the light source and the reactor channels present significant barriers to industrial implementation. Consequently, there is a pressing need for innovative reactor designs that can effectively balance photon distribution, mass transfer, and scalability considerations.

Monolith reactors offer a scalable approach combining microreactor advantages with industrial throughput. While microreactors excel in mass and photon transfer due to high surface area-to-volume ratios, their scalability limits industrial use. Translucent monolithic structures overcome these limitations, enabling efficient light penetration across reaction channels and achieving substantially higher energy efficiency than conventional designs [6]. However, optimal geometry and opacity are crucial to prevent non-uniform light distribution between surface and reaction regions.

Light scattering in photochemical reactors significantly influences reactor performance through complex light-matter interactions [7]. The geometry of reactor channels, particularly their diameter and spatial arrangement, plays a crucial role in determining photon distribution and utilization efficiency [8].

Ray-tracing simulations can accurately predict photon distribution patterns within a reactor volume. Several studies in the literature have employed ray tracing to optimize the geometrical configurations of photoreactor

systems. Singh et al. conducted a parametric study to optimize the geometry of a photocatalytic monolith reactor, focusing on the optimal aspect ratio of channels and the lamp-to-monolith distance, achieving a maximum photon efficiency of 50% [9]. Athanasiou et al. optimized a photocatalytic reactor design integrating membranes and optical fibers for water purification [10]. Their study identified an optimal intermediate channel thickness of 2 mm, enabling the treatment of 50 $m^3$/day of water with a pressure drop of 1.5 bar. In another study, Martín-Somer et al. investigated reflector geometries for a tubular UV reactor [11]. They demonstrated that parabolic reflectors achieved the highest optical efficiency (65.9%). Jacobs et al. developed translucent monoliths for the degradation of pharmaceutical micropollutants during wastewater treatment. Using COMSOL ray tracing, they optimized the design with 2 mm channel diameter, 2 mm spacing, and 3 vertically stacked rows of channels. The optimized reactor showed significantly improved energy efficiency compared to conventional internally illuminated monoliths [6].

Coupling ray tracing simulations with a gradient-free optimization algorithm, such as Bayesian optimization (BO), can enable the automated design of photochemical reactors. BO can systematically navigate multiple design variables simultaneously - including channel geometry, dimensions, and orientation - while minimizing the number of required simulations. This combined approach offers several advantages over classical optimization approaches where parameter sweep analysis is employed for addressing complex geometrical configurations. These advantages include a continuous design space, rapid identification of optimal design parameters, efficient exploration in high dimensional spaces, and a significant reduction in the experimental effort required for reactor design [12]. Moreover, the flexibility and extensibility of the coupled approach make the optimization process adaptable to various photocatalytic reactor design problems, allowing for the incorporation of additional physical models and design variables.

In this study, the multi-objective optimization of translucent monolithic structures is investigated using ray tracing simulation and Bayesian optimization to maximize the efficiency of the reactor previously studied by Jacobs et al. [6]. To the best of our knowledge, this is the first study to couple ray tracing simulations with Bayesian optimization. The objective function is linearized through space-time yield (STY) and photochemical space-time yield (PSTY) to balance reactor efficiency and energy efficiency, respectively. The effect of weights assigned to STY and PSTY on the optimal configuration is also examined through varying weights. Six channel geometries (circular, elliptic, triangular, square, and pentagonal) are examined along with channel rotation, number of vertically stacked rows, channel diameter, and aspect ratio.

# METHODOLOGY

## Ray Tracing Simulation

COMSOL Multiphysics 6.2 employs nonsequential ray tracing to model complex light-matter interactions in photochemical reactors. The algorithm solves coupled first-order ordinary differential equations for ray position (q) and wave vector (z) components:

$$\frac{dz}{dt} = -\frac{\partial w}{\partial q} \quad (1)$$

$$\frac{dq}{dt} = -\frac{\partial w}{\partial z} \quad (2)$$

The simulation begins by discretizing the geometry and establishing initial ray positions and directions. Primary rays are generated from a source, and when these rays encounter interfaces with different refractive indices, the algorithm computes new directions based on Snell's law and Fresnel's equations: Snell's law describes how light bends when passing between two mediums defined by $n_1$ and $n_2$, and the refractive indices of the two mediums, $\theta_1$and $\theta_2$, the angles of incidence and refraction. Fresnel's equations quantify how much light is reflected and how much is transmitted (refracted) at an interface between two media defined by reflection and transmission coefficients.

Figure 1 shows the 2D geometry of a monolith design example used in this study, implemented in COMSOL, including elliptic channel geometries. The refractive index of the reaction medium is determined by the concentration of photocatalyst, which is 0.0125 mol $TiO_2/m^3$ Water. The wall condition at the outer border of the reactor is set to deactivate any rays that exit the reactor. Number of rays per release is set to 100, and rays are realesed with a canonical ray direction vector with a cone angle of π/6 from the boundary release as it is depicted in Figure 1. The total source power per unit thickness is 50 W/m. Lastly, a deposited ray power is located on channel surfaces to capture the amount of absorbed light by the reaction medium.

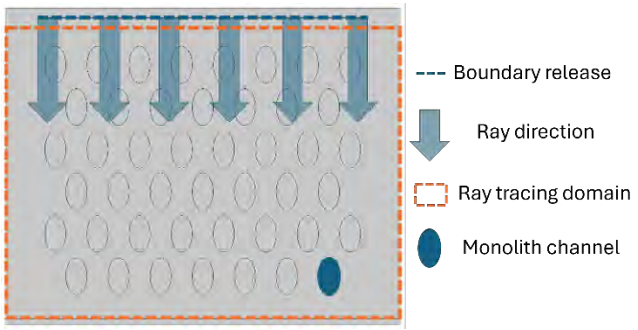

**Figure 1.** 2D geometry of the monolith reactor.

The maximum number of secondary rays was limited to 500,000 to prevent memory overflow. Optimal number

of mesh density is chosen to be the same with Jacobs et al. [6]. A lower limit threshold is also employed to discard secondary rays fall below a certain amount of energy. Table 1 shows the parameters set in the simulation:

**Table 1:** Parameters of ray tracing simulation employed in this work

| Ray tracing parameters | Value |
|---|---|
| Mesh density | 70 elements per $mm^3$ |
| Number of primary rays | 10,000 |
| Limit for secondary rays | 500,000 |
| Refractive index of the 3D-printed material | 1.5403 |
| Refractive index of air | 1 |
| Refractive index of $TiO_2$-Water suspension | 1.335 |
| Wavelength of the Light | 550 nm |
| Source power per unit thickness | 50 W/m |
| Ray release cone angle | π /6 |

## Theoretical Framework

The evaluation of different reactor designs requires a comprehensive thinking on both energy efficiency and reactor performance, as indicated by PSTY and STY, respectively. The energy of a single photon, $E_{photon}$ [J], can be expressed as where $v$ is the speed of light, $h$ is Planck's constant, and $\lambda$ is the wavelength of the absorbed light

$$E_{photon} = \frac{v \cdot h}{\lambda} \quad (3)$$

then, the total amount of absorbed photonic energy divided by the energy of a single photon gives the number of photons absorbed, $\vartheta$, which can be expressed as:

$$\vartheta = \frac{P_{abs}}{E_{photon}} \quad (4)$$

where $P_{abs}$ is the absorbed power by the reaction medium, which is obtained from simulation by integrating deposited power over channel surfaces. Further, dividing $\vartheta$ to Avogadro's number, $N_A$, gives the moles of absorbed photons in $mol \cdot s^{-1}$:

$$\vartheta = \frac{P_{abs} \cdot \lambda}{v \cdot h \cdot N_A} \quad (5)$$

$STY$ is defined as the amount of treated wastewater per unit volume of the reactor. In this study, the quantum yield is assumed to be 2.35%, representing the fraction of absorbed photons that actively contribute to the photodegradation process. To calculate the actual rate of pollutant degradation, the quantum yield is multiplied by the number of absorbed photons (in $mol \cdot s^{-1}$). Once the pollutant degradation rate is obtained, the volume of treated water, expressed in $m^3$ $water.s^{-1}$, can be calculated by dividing the pollutant degradation rate by the pollutant concentration, $C_{pollutant}$ (in $m^3$ $water.s^{-1}$). The value of $C_{pollutant}$ is taken as 0.1 $mol.m^3$ $water^{-1}$. Then, $STY$ (in $m^3$ water. $m^3$ $reactor^{-1}.s^{-1}$), is determined by normalizing this treated water volume by the reactor volume, $V_{reactor}$:

$$STY = \frac{\vartheta \cdot \Phi}{C_{pollutant} \cdot V_{reactor}} \quad (6)$$

Consequently, $PSTY$ is calculated by dividing $STY$ to normalized lamp power, $P_{norm}$ (W). $PSTY$ considers how much energy spent for a unit volume of reactor, and normalized lamp power is calculated by dividing lamp power, $P_{lamp}$, to the reactor volume, $V_{reactor}$. $1\ m^3$ of reactor is taken as reference volume:

$$P_{norm} = \frac{P_{lamp}}{V_{reactor}} \times 1\ m^3 \quad (7)$$

$$PSTY = \frac{STY}{P_{norm}} \quad (8)$$

$STY$ and $PSTY$ provide a robust framework to evaluate reactor designs, enabling a balanced assessment of energy efficiency and performance for optimized photoreactor operation.

## Bayesian Optimization

Bayesian optimization is an efficient method for finding the global optimum of black-box functions that are expensive to evaluate. It combines a probabilistic surrogate model that approximates the objective function and provides uncertainty estimates with an acquisition function that determines the most promising points to evaluate next. The surrogate model is updated as new observations are made, continuously improving its predictions of the underlying function. The algorithm works iteratively by initializing with a few random samples and then fitting the surrogate model to the observed data. At each iteration, it selects the next evaluation point by maximizing an acquisition function that balances exploration (sampling uncertain regions) and exploitation (sampling regions likely to have good values). The acquisition function is a mathematical function used in BO, and it assigns a value to each potential point, indicating how valuable it would be to evaluate that point next.

Expected Improvement (EI) was chosen to guide the optimization process for the remainder of the study due to its adaptive behavior between exploration and exploitation. The loss function is defined as a linear combination of the normalized STY ($STY_{norm}$) and normalized PSTY ($PSTY_{norm}$), as shown in Equation 9. For the normalization process, initial estimates of the minimum and maximum values are based on prior knowledge.

$$Loss = w_{STY} \times STY_{norm} + w_{PSTY} \times PSTY_{norm} \quad (9)$$

$$STY_{norm} = \frac{STY - STY_{min}}{STY_{max} - STY_{min}} \quad (10)$$

$$PSTY_{norm} = \frac{PSTY - PSTY_{min}}{PSTY_{max} - PSTY_{min}} \quad (11)$$

To determine an appropriate weight set ($w_{STY}$, $w_{PSTY}$) for the objective function, the optimization algorithm is executed for varying weight values. The assigned weights range from 0.1 to 0.9, discretized in increments of 0.1, resulting in 9 different weight sets. Each run is initialized with 25 random configurations and iterated for an additional 75 simulations.

**Table 2:** Variables defining the geometry in the ray tracing simulation.

| Variable | Domain | Range |
|---|---|---|
| Characteristic diameter | Real | 1-6.5 |
| Aspect ratio | Real | 0.25-1.75 |
| Number of vertically stacked rows | Integer | 1,2,3 |
| Channel Shape | Categorical | Elliptic, circular, square, triangular, pentagonal, plus-signed |
| Rotation | Real | 0-90 degree |

Variable space is defined as shown in Table 2. Six channel geometries (i.e., circular, elliptic, triangular, square, and pentagonal) are examined along with channel rotation, number of vertically stacked cell rows, characteristic channel diameter, and aspect ratio of ellipses. The characteristic diameter is defined as the diameter for circles, the minor axis length for ellipses, the side length for triangles and squares, and the side length of the cross frame for plus-shaped channels. Analyzed channel shapes are depicted in Figure 2. Python library *scikit-optimize* is utilized for the optimization study. After the simulation is loaded onto a Python interface using MPh v1.2.4, the optimization study is initialized with 25 random points and run for an additional 75 iterations. During each iteration, a COMSOL ray tracing simulation is executed for a new geometrical configuration. The resulting absorbed power is retrieved from the simulation, and the surrogate model is updated before the next evaluation point.

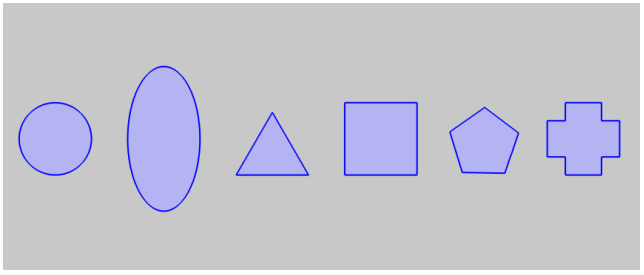

**Figure 2.** Candidate channel shapes

## RESULTS AND DISCUSSION

The geometric configuration of each iteration is recorded, as each represents a valid reactor design. Figure 3 presents the best three solutions for each weight set, distinguished by unique color and marker combinations. As expected, when the weight of STY increases, the best solutions tend to cluster around the bottom-right corner of the figure, where STY is maximized. Conversely, assigning larger weights to PSTY causes the solutions to shift toward the upper-left corner of the figure, resulting in higher PSTY values and lower STY yields. This competing relationship between STY and PSTY is also evident in the figure. Consequently, more balanced solutions are obtained for weights $w_{STY}$=0.5 and $w_{PSTY}$=0.5. These weights are utilized for the remainder of the study. It should be noted that each run may yield different solutions due to the probabilistic nature of the optimization process. Nevertheless, the general trend is consistent across varying weights, and the selected weights are deemed reliable.

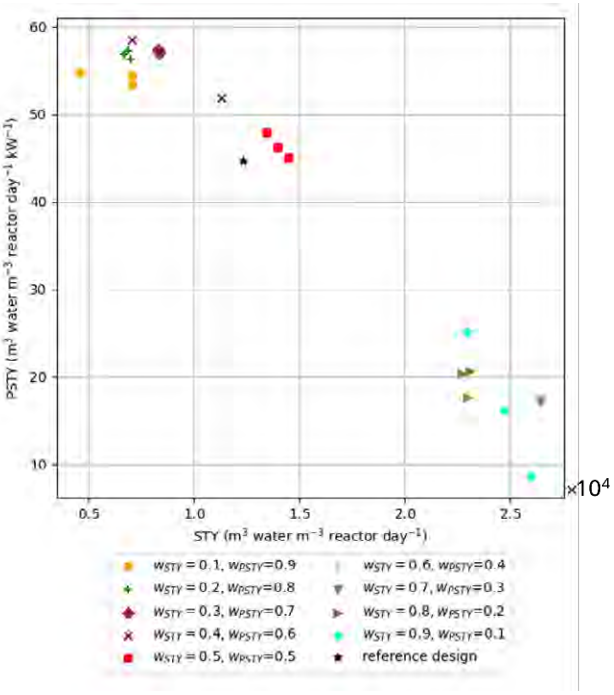

**Figure 3.** effect of weights on STY and PSTY

Following the investigation on the weight effect, a BO optimization with 50 random points and 150 additional simulations was conducted. All candidate points are shown in Figure 4. The STY ranges from approximately 5,000 to 22,500 m³ water/m³ reactor/day, while the PSTY ranges from about 15 to 60 m³ water/m³ reactor/day/kW. As expected, a negative correlation between STY and PSTY is observed, indicating a trade-off between these two parameter. The results are compared to the reference design, shown with a black marker: three unit cells

with 2 mm diameter circular channels, as described by Jacobs et al. [6]. A general trend is observed where larger PSTY values correspond to increased channel volumes. This is attributed to a greater amount of photocatalyst, which can absorb more light energy. However, designs with similar volumes may vary in the amount of absorbed light, demonstrating the impact of geometrical configuration.

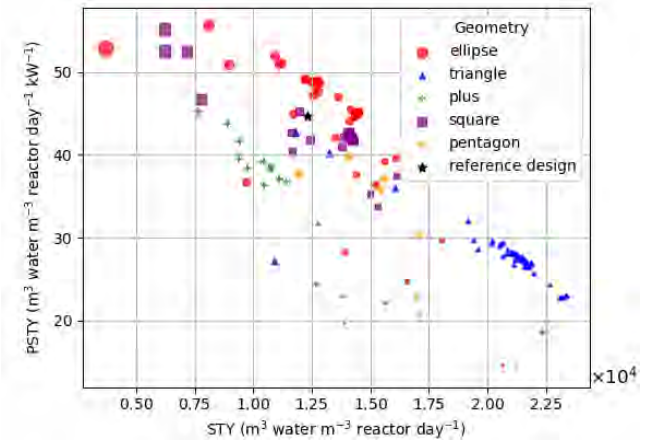

**Figure 4.** Bayesian optimization results (marker sizes proportional to channel volumes.)

Triangular channels are predominantly located in the bottom-right corner of Figure 4, where the STY is maximized. For pentagonal and plus-shaped channel geometries, the results are relatively suboptimal compared to the other geometries. Square channels are positioned in the middle and upper-left regions of the figure, showing some of the highest PSTY values. Elliptic channels dominate the balanced region and are clustered around the reference design, indicating promising solutions.

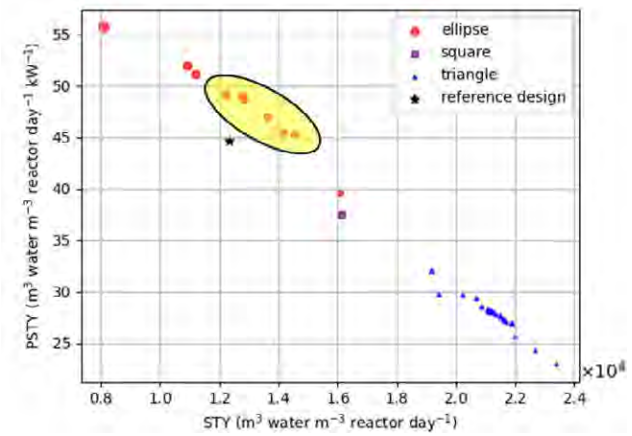

**Figure 5.** Pareto optimal solutions with dominating solutions indicated by the yellow area.

The Pareto front, which represents the non-dominating designs, is plotted separately in Figure 5. Dominating solutions, highlighted in yellow, include points that outperform the reference design in both objectives, as well as those that are slightly worse in one objective. The exact geometrical configurations of the dominating solutions are detailed in Table 3. Each solution is defined by its characteristic diameter (a), aspect ratio for ellipses only (b/a), rotation angle (r), number of vertically stacked rows (N), and total channel volume (V). All dominating solutions feature an elliptic channel shape, with a consistent aspect ratio (b/a) of 1.75 across all configurations, indicating highly elongated ellipses. The rotation angle (r) ranges from 56.4° to 90.0°, reflecting variations in the orientation of the elliptical geometry within the design. The characteristic diameters fall between 1.00 mm and 1.95 mm despite being examined over a broader range of 1.00 mm to 6.50 mm, suggesting that smaller geometries are more favorable. Table 3 also indicates that an optimal design can be achieved with two vertically stacked rows. At one extreme, the optimization study enables a 15.3% increase in STY with only a 1.2% increase in PSTY. Additionally, a roughly 9.0% increase in PSTY can be achieved with a minor reduction in STY at the other extreme. These findings demonstrate the influence of geometrical configuration on the performance of a photo-reactor, and the results emphasize the importance of considering both reaction efficiency and energy efficiency together in reactor design.

**Table 3:** Geometrical configurations of the dominating solutions. (**a**: Characteristic diameter/minor axis length for ellipses, **b/a**: Aspect ratio of the ellipse, **r**: Rotation, **N**: Number of vertically stacked rows, **V**: Total volume of channels, **ΔSTY**: Percent change in STY compared to the reference design, **ΔPSTY**: Percent change PSTY compared to the reference design )

| a (mm) | b/a | r (°) | N | Shape | ΔSTY (%) | ΔPSTY (%) |
|---|---|---|---|---|---|---|
| 1.95 | 1.75 | 90.0 | 2 | Ellipse | -0.6 | 9.1 |
| 1.21 | 1.75 | 57.1 | 3 | Ellipse | 3.6 | 8.7 |
| 1.21 | 1.75 | 56.5 | 3 | Ellipse | 4.1 | 8.1 |
| 1.10 | 1.75 | 56.4 | 3 | Ellipse | 9.6 | 4.8 |
| 1.01 | 1.75 | 56.5 | 3 | Ellipse | 13.0 | 1.7 |
| 1.00 | 1.75 | 81.6 | 3 | Ellipse | 15.3 | 1.2 |

BO is particularly effective for optimizing functions with up to 20 variables. Although this study includes categorical and discrete variables, which make the optimization problem more complex, the total number of variables is much lower than 20. Hence, computational efficiency is not a limiting factor for either BO or the ray tracing simulation, considering that it is a 2D simulation. The proposed methodology can be extended to alternative channel shapes and various types of photoreactors. However, if a more free-form surface controlled by multiple parameters is used, computational

complexity must be considered for 3D simulations, as well as geometrical complexity and reactor dimensions.

## CONCLUSION

This study demonstrates the successful application of Bayesian optimization for designing translucent monolithic photochemical reactors. Through a systematic multi-objective optimization approach considering both STY and PSTY, we identified optimal channel geometries that outperform circular designs. The results revealed important trade-offs between STY and PSTY, with elliptical channels showing the best performances. Two optimized elliptical configurations achieved up to 15.3% improvement in STY with minimal PSTY increase and 9.0% enhancement in PSTY with negligible STY decrease. The methodology established here provides a framework for optimizing photochemical reactor designs using ray tracing-coupled Bayesian optimization. The findings demonstrate that geometric optimization can significantly enhance throughput and energy efficiency in translucent monolithic reactors.

## ABSTRACT

Piping and Instrumentation Diagrams (P&IDs) play a crucial role in the chemical industry, yet they are often stored as scanned images or computer-aided design (CAD) drawings, limiting their seamless integration into modern digital workflows. Consequently, the task of automating P&ID digitization has attracted significant attention from the computer-aided design (CAD) research community. Traditional approaches, which typically rely on conventional object detection techniques, often demand extensive manual annotations to accurately identify and classify the various symbols in P&IDs. In this paper, we proposed a novel framework for automating the recognition of P&IDs. Our method first extracts key features of geometric primitives in CAD drawings through an automated process. Subsequently, a Transformer-based model is employed to predict the layer assignment of these primitives. Following this, an unsupervised clustering method, guided by predefined rules and geometric distances, is applied within each layer type to facilitate the automatic identification of devices, pipes, instrumentation, valves, insulation, and utilities in P&IDs. Extensive evaluation on an annotated dataset comprising 336 authentic P&IDs demonstrates that the proposed semantic annotation method achieves an overall accuracy exceeding 92%. The results of the unsupervised clustering are visualized, demonstrating promising performance and supporting the effectiveness of the proposed method. This study provides valuable insights into the intelligent digitization of P&IDs and lays the groundwork for further advancements in intelligent chemical process design.

**Keywords**: Intelligent Systems, Piping and Instrumentation Diagram, Computer Aided Design

## 1 INTRODUCTION

Piping and Instrumentation Diagrams (P&IDs) play a central role at every stage of chemical engineering design. They serve as an essential tool for communication among engineers, operators, and maintenance personnel by depicting how piping systems connect with industrial processing equipment and how processes are controlled through automated systems. By indicating critical information such as isolation valves and emergency shutdown devices, P&IDs aid operators in executing safe operations and responding effectively in emergencies.

Over the years, millions of P&IDs have been manually generated, scanned, and stored in image formats, encapsulating a wealth of valuable engineering design knowledge [1]. However, analyzing the complex information within these diagrams—due to the intricacy of devices, text, and pipelines—has traditionally required extensive manual effort by engineers. This manual analysis is not only time-consuming but also prone to errors. Therefore, the ability to automatically extract information from P&IDs would significantly enhance productivity and minimize human error. Moreover, since P&IDs are a primary source of design and safety information in chemical engineering, the extracted data can be integrated with intelligent algorithms for process simulation, optimization, and safety analysis, promoting more effective chemical process management and design.

To support digital storage and interoperability, the Digital Exchange of Process and Instrumentation Diagrams (DEXPI) standard [2] was introduced. By defining a comprehensive set of structured data formats based on

eXtensible Markup Language (XML), DEXPI enhances the efficiency and accuracy of engineering processes. In recent years, numerous deep learning-based image recognition algorithms have been developed to convert image-format P&IDs into drawings that comply with the DEXPI standard. For example, Kim et al. proposed a P&ID digitization system that employs two independent Generative Flow Networks (GFL) for recognizing equipment symbols of varying sizes [3]. Despite advances in deep learning-based image recognition, digitization of P&IDs remains challenging due to the high irregularity of ordering and uncertain orientations [4].

Transitioning from these challenges, most traditional P&ID files are created using computer-aided design (CAD) tools, which means that beyond the visible image data, these drawings inherently contain detailed information about the shapes, positions, and layer properties of various geometric primitives (such as lines, arcs, polygons). This fine-grained semantic data can greatly enhance the effectiveness of P&ID recognition by addressing the limitations of traditional methods that rely solely on images. Building on this insight, in this paper we propose a novel intelligent symbol recognition framework that tokenizes various geometric primitives found in CAD drawings, then a Transformer-based model is employed to automatically annotate the layer assignment of these primitives. After that, we apply unsupervised clustering to group the isolated primitives into meaningful symbols (including devices, valves, etc.). Validation on 336 authentic P&IDs demonstrates that our framework achieves an overall accuracy of 0.927 in annotating geometric primitives. The visualization of the clustering results further demonstrates the effectiveness of our approach.

# 2 METHODOLOGY

## 2.1 Data Preprocessing

This paper primarily uses two data sources: CAD drawings and rasterized images. The CAD drawings are in Drawing Exchange Format (DXF), exported from AutoCAD. DXF files employ a vector-based data format, providing detailed attribute information for various geometric primitives and defining the blocks and layers within the drawing. The rasterized images are in Portable Network Graphics (PNG) format, converted from the DXF files. Thus, there is a one-to-one correspondence between the CAD drawings and the rasterized images.

We use the Python library ezdxf to extract the types and layer information of geometric primitives from CAD drawings. The layer information for these geometric primitives is manually created by the designer and typically conveys the specific meaning of the primitives in the P&ID. Therefore, we use the layer information as the semantic label for the primitives. In P&ID drawings, the layers are primarily categorized into 11 distinct categories, the details of which are shown in Table 1.

Next, we utilize the Shapely Python library to convert various types of geometric primitives from the DXF file into Shapely geometric objects. Specifically, straight lines and open polylines are directly converted into LineString objects, while closed polylines are transformed into Polygon objects. For curves in the DXF file, we approximate them with a polyline consisting of 72 endpoints, converting them into either LineString or Polygon objects based on whether they are closed. Subsequently, we employ functions from Shapely to calculate the centroids of the geometric primitives and the minimum distances between each pair of primitives. For each primitive, we identify the 128 nearest geometric primitives as its neighboring nodes and construct the adjacency matrix.

**Table 1.** Common layer definitions in P&IDs.

| Layer name | Definition |
|---|---|
| **Device** | Contour of Physical devices used in the system, such as pumps |
| **Instrument** | Symbol of measuring and controlling instruments |
| **Valve** | Symbol of valves in the system |
| **In-out Signal** | Communication signals for system input and output |
| **Pipeline** | Symbol of the pipework that are used to transport process materials |
| **Control Line** | Symbol of the control lines that are used to carry signals |
| **Insulation** | Symbol of the insulation around piping or equipment |
| **Hot Utility** | Symbol of systems that provide heat |
| **Cold Utility** | Symbol of systems that provide cooling |
| **Arrow** | Symbol of the flow of materials |

## 2.2 Model for Layer Assignment Prediction

### 2.2.1 Backbone Architecture

The backbone architecture of the predictive model is illustrated in Figure 1. PNG images derived from CAD drawings are processed using the pre-trained HRNetV2-W48 model [5] to automatically extract features. Additionally, the previously discussed feature extraction method is used to extract the normalized center coordinates of geometric primitives from the CAD drawings and to construct an adjacency matrix.

Using these normalized coordinates, we project each geometric primitive from the CAD drawing to its corresponding position in the PNG image. We then apply bilinear interpolation-based upsampling to align the feature maps with the positions of the geometric primitives, calculating the feature vectors at each primitive's location. These interpolated feature vectors undergo further linear transformations and ReLU operations to generate the

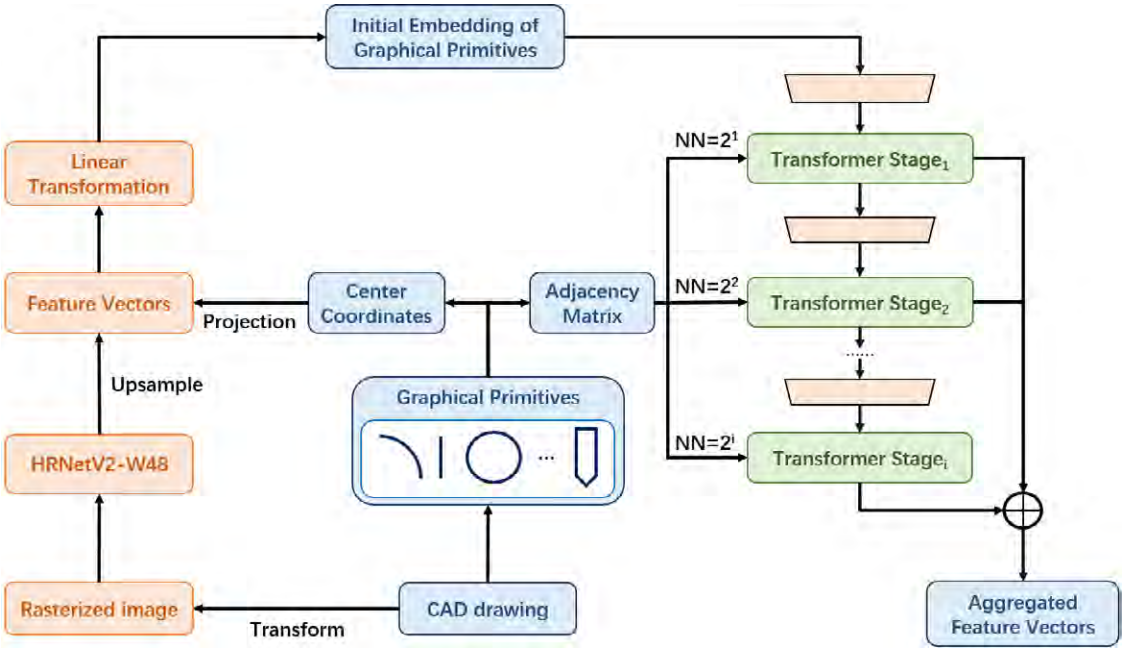

**Figure 1.** Backbone architecture for predicting layer assignment of the geometry primitives.

initial embedding for each geometric primitive. The updated vectors are subsequently processed using a Transformer model that consists of various stages, each stage applies self-attention with spatially localized k-nearest neighbors, enabling the refinement of each primitive's representation using its local features. The features across different stages are then fused by calculating the mean of the output of the Transformer stages.

### 2.2.2 Layer Assignment Prediction Task

The updated vector representations of geometric primitives are then processed using a multi-layer perceptron (MLP) to predict the layer to which each primitive belongs. The MLP model outputs a predicted score for each geometric primitive corresponding to each layer, which is then compared to the actual layer properties of the primitives. The loss function employed is based on the cross-entropy loss function:

$$L_{sem} = -\frac{1}{M}\sum_{m=1}^{M}\sum_{i=1}^{N} y_{i,m} log(p_{i,m}) \quad (1)$$

where $M$ is the total number of geometric primitives, and $N$ is the number of layer categories, $y_{i,m}$ represents whether the $m$-th geometric primitive actually belongs to the $i$-th layer; it is equal to 1 if it does, and 0 if it does not. Additionally, $p_i$ represents the predicted score for the model's prediction of the geometric primitive belonging to the $i$-th layer. In order to overcome the impact of class imbalance, we choose AM-Softmax loss function [6], which introduces an additive margin to the target class's logit. During the inference process, the predicted semantic label is the layer with the highest predicted probability.

## 2.3 Clustering for Symbol Recognition

After assigning layer for the geometric primitives, in order to extract higher-level features, such as the contours of devices, and to better understand the physical process layout, we perform unsupervised clustering for each layer to automatically group isolated geometric primitives into meaningful symbols.

For instances with closed contours, such as equipment, instruments, valves, insulation, and inlet/outlet labels, we apply a Depth First Search (DFS) algorithm to cluster all geometric primitives within the same layer. We assume that if the distance between two geometric primitives is less than the specified threshold, they are considered to intersect. By utilizing a stack to simulate the recursive depth-first search, we group all intersecting geometric primitives into the same cluster, while non-intersecting ones are assigned to separate clusters.

For instances without closed contours, such as pipelines, control lines, cold utilities, and hot utilities, we distinguish instances based on predefined rules. For example, when two perpendicular pipelines intersect, it typically signifies that a main pipeline is branching into two directions. In such cases, the algorithm generates three clusters: one for the main pipeline and two for the branch pipelines. Conversely, if two perpendicular pipelines cross without an intersection point, it suggests that the two pipelines are physically offset. In this scenario, one pipeline may be represented as two straight lines in the drawing. The algorithm identifies collinear segments with distances that are consistent with common knowledge

and merges them into a single cluster.

# 3 EXPERIMENTS

## 3.1 Datasets and Evaluation Metrics

The dataset utilized in this study consists of 336 real P&ID drawings stored in DXF format, each labeled with its corresponding layer assignment. These drawings represent 17 process flows designed for the deep desulfurization of industrial flue gas, providing detailed information about the piping systems, instruments, valves, process topology, and utilities. Although the original versions of these drawings include layer annotations, the naming conventions for the layers are inconsistent. Consequently, we standardized the layer names across the drawings into 11 categories, as detailed in Table 1. Additionally, we converted the drawings from DXF format to PNG format. Prior to being input into the model, each PNG image was cropped into square blocks, each measuring 14m × 14m. The training, validation, and test sets were divided in an 8:1:1 ratio, resulting in 268, 33, and 35 P&ID drawings, respectively.

The Transformer-based layer prediction model we employed has an input dimension of 384 and consists of four layers of self-attention. The number of neighboring nodes utilized by each self-attention layer increases from 2 in the first layer to 4 in the second, 8 in the third, and 16 in the fourth layer. The output dimension is 11, corresponding to the 11 layer categories. During training, the initial learning rate is set to 0.00025, and the Adam optimizer is used with $\beta_1 = 0.9$ and $\beta_2 = 0.999$. Every 20 epochs, the learning rate is reduced to 50% of its previous value. The original momentum is set to 0.1, with momentum decay set to 0.5. The model is trained for 300 epochs. The batch size is fixed to 6, and we trained our model with 6 NVIDIA RTX 4090 GPUs with 1 training sample on each GPU.

We evaluated the effectiveness of the proposed model using the following classic classification metrics:

- Precision: The proportion of correctly predicted instances of a specific layer among all instances predicted as that layer.
- Recall: The proportion of correctly predicted instances of a specific layer among all instances that actually belong to that layer.
- F1 Score: The harmonic mean of precision and recall, considering the balance between these two metrics.
- Accuracy: The proportion of correctly predicted samples out of the total number of samples.

Additionally, we employed a confusion matrix to analyze which geometric elements of the layers are more likely to be mistaken for one another.

## 3.2 Results on Layer Assignment Prediction

The quantitative evaluation results on the test set are presented in Table 2. Figure 2 shows the detailed prediction results for each class in the form of a confusion matrix. The diagonal elements of the matrix represent the number of correctly classified samples, while the off-diagonal elements indicate misclassifications, reflecting the model's ability to distinguish between different categories. It can be seen that our model performs well in overall layer classification for all geometric primitives, achieving an $F_1$ score of 0.9224, with precision of 0.925, recall of 0.9224, and accuracy of 92.7%.

**Table 2.** Evaluation results of the layer prediction model.

| Layer name | $F_1$ | Precision | Recall |
|---|---|---|---|
| **Device** | 0.9249 | 0.9051 | 0.9457 |
| **Instrument** | 0.9643 | 0.9611 | 0.9676 |
| **Valve** | 0.9608 | 0.9606 | 0.9611 |
| **In-out Signal** | 0.9845 | 0.9772 | 0.9919 |
| **Pipeline** | 0.8693 | 0.8487 | 0.8910 |
| **Control Line** | 0.7844 | 0.7977 | 0.7716 |
| **Insulation** | 0.9349 | 0.9496 | 0.9207 |
| **Arrow** | 0.9290 | 0.9290 | 0.9290 |
| **Hot Utility** | 0.3042 | 0.5192 | 0.2151 |
| **Cold Utility** | 0.6973 | 0.7765 | 0.6328 |
| **Total** | 0.9244 | 0.9250 | 0.9224 |

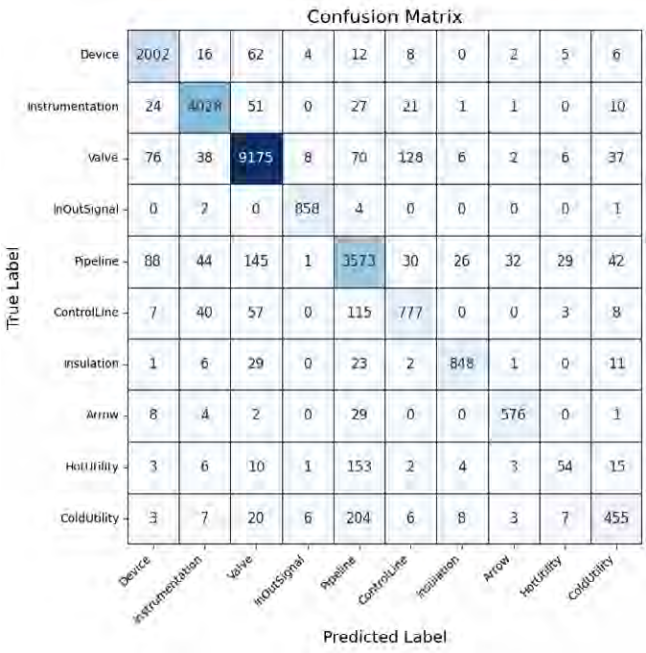

**Figure 2.** Confusion Matrix of Classification Results.

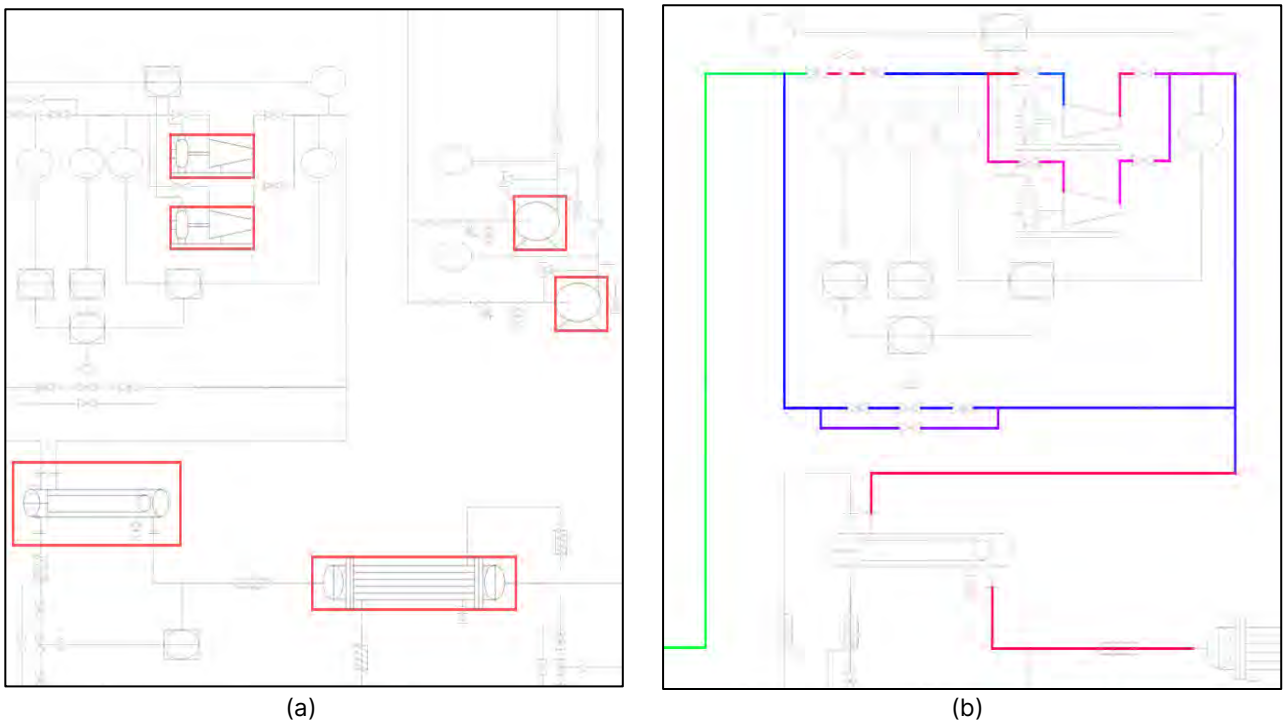
Among the geometric primitives in each layer, the model demonstrates high accuracy in recognizing devices, instruments, valves, inlet/outlet markers, insulation



layers, and arrows, with F1 scores exceeding 0.9. We hypothesize that this is due to the relatively standardized shapes of the symbols in these layers and the large number of training samples available.

In contrast, there is room for improvement in the recognition of pipes, control lines, and utilities. This is likely because these layers consist mainly of multiple line segments, which can form highly variable combinations. As indicated by the confusion matrix, some pipelines are misclassified as equipment outlines or valves. Furthermore, the geometric primitives in the control lines, cold utilities, and hot utilities layers are difficult to distinguish from those in the pipeline layer. We believe this is not only because these layers contain fewer geometric primitives than the pipeline layer, but also because they cannot be easily differentiated based solely on the positional information of the geometric primitives. Specifically, the key distinction between control lines and pipes is whether both endpoints of the line segments (or polylines) are connected to control instruments. Similarly, the fundamental criterion for distinguishing between utilities and process material pipelines is whether the transported substance is process material, which requires additional textual information, such as piping codes, from the P&IDs.

## 3.3 Visualization of Clustering Results

The clustering results of the equipment, and pipelines layers are shown in Figure 3, which not only allows us to observe the performance of target recognition for each layer, but also helps assess the clustering precision of different layers. The clustering outcomes for the equipment layers are illustrated in Figures 3(a), respectively. Due to variations in size and distribution density between the equipment and other identified objects, we applied distinct distance thresholds for each layer. For the equipment layer, a larger threshold of 6 units effectively groups adjacent primitives together. While for all other layers, a smaller threshold of 0.001 units ensures more precise clustering by grouping close geometric primitives together, minimizing redundancy and incorrect clustering. From the clustering visualization, we can see that the contours of most equipment and instruments, including instrument interface pipes, are accurately recognized and clearly distinguishable. This demonstrates the strong potential of using a DFS algorithm for closed-contour target recognition.

The clustering results for the pipelines layers are presented in Figures 3(b), respectively. It can be observed that the various pipelines were effectively distinguished according to the established rules. However, some pipelines were not successfully recognized by the layer assignment predictive model, and as a result, their clustering results were not reflected in the drawing. What's more, since the current rule definitions are relatively simplistic, certain specific scenarios, such as the presence of bypass valves on pipelines have not been adequately addressed. In these cases, the bypass pipe should merge with the main pipeline. Consequently, the

(a) (b)

**Figure 3.** (a) Clustering visualization for the equipment layers; (b) Clustering visualization for the pipelines layers.

redundancy in the pipeline clustering results can be reduced by refining the rules.

## 4 CONCLUSION

In this study, we propose a novel intelligent symbol recognition framework for P&ID based on CAD drawings. During the data preprocessing stage, CAD drawings are divided into fine-grained geometric primitives, and an adjacency matrix is constructed based on the distances between these primitives. The symbol recognition framework consists of two stages: layer assignment prediction and symbol recognition. In the layer assignment prediction stage, the classic image recognition framework HRNetV2-W48 is employed to generate feature vectors from the converted PNG images of the CAD drawings, enabling the positional encoding of each geometric primitive. Then, a Transformer-based architecture is utilized to update the encoding of each geometric primitive by leveraging information from the nearest neighbors in the spatial domain. Finally, the membership probability of each geometric primitive to different layers is determined through a linear transformation. In the symbol recognition stage, the symbols with closed contours and open contours are recognized by unsupervised clustering using depth-first search and predefined rule, respectively.

Experimental results showed that the model for layer assignment prediction achieved a multi-class accuracy of 92.7% and an $F_1$ score of 0.9224 on the test set. This indicates the potential of using the Transformer architecture for layer assignment prediction tasks. Unlike traditional object detection frameworks, which perform regression to detect bounding boxes and classify targets within the boxes, this study directly utilizes fine-grained geometric primitive from CAD drawings. It extracts essential geometric features and spatial topology, further refining the embedding representation of geometric primitives using the self-attention mechanism. This approach allows for improved handling of diverse combinations and randomly orientation of the symbols. The effectiveness of unsupervised clustering is demonstrated through visualization, where symbols are accurately clustered according to predefined rules and geometric distances.

Although the experimental results are generally satisfactory, several areas require further improvement. Firstly, the current classification model tends to confuse geometric primitives of pipes, control lines, and utilities across different layers, and some pipes are misidentified as equipment contours or valve components. Secondly, the clustering of pipes, control lines, and utilities may result in redundancy. Finally, the extraction of grounding lines and textual information, and their interrelationships were not addressed in this study. In future work, we plan to develop a model to establish the matching relationships among equipment, instruments, and textual descriptions, thereby automatically forming a process topology network with node descriptions. We believe this study will provide a novel approach to the digitalization of P&ID and contribute to the advancement of intelligent process design, risk analysis, and large language models in the field of chemical engineering.

# Enhancing Predictive Maintenance in Used Oil Re-Refining: a Hybrid Machine Learning Approach

**Francesco Negri[a,b], Andrea Galeazzi[c,d], Francesco Gallo[a], Flavio Manenti[b*]**

## ABSTRACT

Maintenance is critical for industrial plants to ensure operational reliability and worker safety. In process industries, fouling, the accumulation of solid residues in equipment, poses a significant challenge, causing inefficiencies and productivity losses. Effective modeling of fouling evolution over time is essential for maintenance planning to prevent equipment from operating under suboptimal conditions. Traditional approaches to fouling prediction include equation-based models, which offer high precision but may struggle with continuously changing process boundaries, and machine learning techniques, which are more adaptable but less effective at capturing rapidly evolving trends driven by complex underlying physics. This study introduces an innovative hybrid machine learning approach for predictive maintenance, combining the strengths of both methods. Pressure differential is modeled using an equation-based approach that links pressure data with fouling thickness, while the fouling growth rate is estimated through Gaussian Process Regression (GPR). This hybrid model generates pressure drop profiles with vertical asymptotes that closely mimic real-world behavior. Applied to a vacuum distillation column processing fouling-prone used oil, the proposed predictive method achieves a significant reduction of over 60% in suboptimal operating time compared to the current maintenance strategy, based on a fixed threshold.

## INTRODUCTION

Maintenance plays a crucial role in industrial plants, directly impacting operations reliability and worker safety. One of the most common and tough challenges tackled with periodic maintenance in process plants is fouling, which is the accumulation of solid deposits in piping, machines, and process equipment, leading to energetic inefficiencies, higher operating costs, and lower productivity [1–3].

Modeling accurately fouling evolution over time is crucial to proper maintenance planning. For this purpose, equation-based models using phenomenological approaches offer precision but may give less satisfactory performances under continuously changing process boundary conditions. Alternatively, machine learning methods, like Gaussian Process Regression, predict fouling trends using process data alone, automatically adapting to evolving conditions. However, these may offer less accurate results with fast-changing profiles following complex underlying physics.

Hybrid machine learning models combine both methods by leveraging the predictive power of machine learning while incorporating physical models to improve accuracy, interpretability, and robustness, especially in complex systems [4].

The aim of this work is to introduce a hybrid machine learning model and use it to enhance the reliability of predictive maintenance techniques applied to vacuum distillation. Complex industrial vacuum distillation equipment working with used oil, a fouling-prone waste feedstock, is considered as a case study.

# METHODS

## Process Operations and Maintenance

Industrial equipment analyzed in this work is part of a used oil regeneration process, currently operational in the Itelyum SpA production plant located in Pieve Fissiraga, Lodi, Italy. The used oil regeneration process is composed of three consecutive steps: *preflash* (PF), *thermodeasphalting* (TDA), and *hydrofinishing* (HDF), with a maximum used oil processing capacity of 130 kt/y.

In the PF section, water and solvents are removed from waste oil under mild vacuum at 120–140°C. The preflashed oil enters the TDA section, where it is heated above 360°C and distilled under strong vacuum using structured packing. This process deasphalts the feedstock, producing bitumen (VISCOFLEX) and fractionating it into gasoil (VGO) and three lubricant base oils: heavy (HLF), light (LLF), and spindle (SLF). All cuts, except bitumen, are then hydrogenated in the HDF section at over 300°C and 100 bar, yielding regenerated products.

The TDA column analyzed in this work suffers from fouling phenomena due to the severe operating conditions and the intrinsic propensity to fouling shown by used oil waste feedstock. The main key performance indicator showcasing this phenomenon is the pressure differential between top and bottom of the column (ΔP), which is carefully monitored during operations to understand when it is more appropriate to perform maintenance of the unit. A typical evolution in time of the ΔP profile specific to the unit of mass is shown in Figure 1 as an example, as a function of dimensionless time τ.

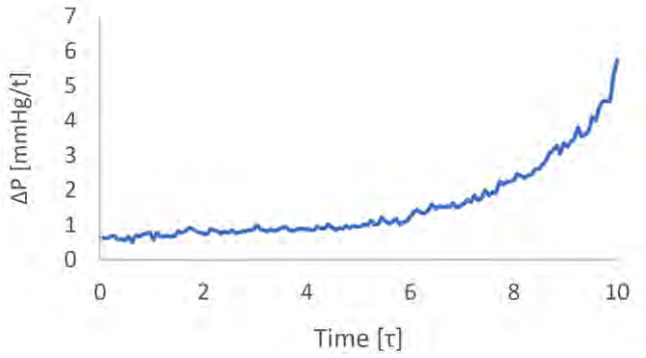

**Figure 1.** Typical TDA column ΔP profile during operations

Currently, maintenance scheduling relies on a condition-based approach, where a shutdown is planned when the pressure drop (ΔP) exceeds a semi-empirical warning threshold [2,3]. This paper introduces an advanced predictive maintenance strategy, leveraging a hybrid machine learning algorithm coupled with an equation-based model, to enhance the reliability and efficiency of maintenance planning.

## GPR Algorithm

Gaussian Process Regression (GPR) is a non-parametric Bayesian approach to regression, widely used in machine learning for its ability to model complex relationships with uncertainty quantification. GPR defines a Gaussian distribution over functions, where predictions are derived as probabilities rather than fixed values, offering flexibility and interpretability. Its key strengths include providing confidence intervals, and capturing nonlinear patterns efficiently [5].

This paper exploits a GPR-based algorithm developed in the work by Galeazzi et al. [1], already tested and validated on complex industrial equipment.The algorithm uses *Linear* (LIN), *Radial Basis Function* (RBF), and *Rational Quadratic* (RQ) kernels. These covariance functions have the following mathematical expressions:

$$k_{LIN}(t,t') = \sigma^2 + t \cdot t' \quad (1)$$

$$k_{RBF}(t,t') = \sigma^2 exp\left(-\frac{(t-t')^2}{2\lambda^2}\right) \quad (2)$$

$$k_{RQ}(t,t') = \sigma^2\left(1+\frac{(t-t')^2}{2\alpha\lambda^2}\right)^{-\alpha} \quad (3)$$

where *k* is the covariance function (or kernel), *t* and *t'* are two points of the input space (time, in this work), $\sigma^2$ is the variance, λ is the length scale parameter, and α is the power of the RQ kernel.

These kernels where chosen since they provided a good balance between prediction reliability when applied to complex industrial datasets, and computational efficiency. Regression models in the algorithm are Gaussian Processes obtained by the combination of these kernels through suitable operators such as *addition (+)* and *multiplication* (·).

The algorithm developed by Galeazzi et al. [1] finds the optimal kernel combination to describe the investigated dataset by applying the following recursive strategy, based on a *greedy search* approach:

- *LIN*, *RBF*, and *RQ* kernels are combined by applying operators (+, ·), obtaining several regression models.
- GPR models are evaluated through an 80/20 train/test split, where 80% of data is used to train the model, and 20% for cross-validation.
- The optimal model is chosen according to the *Mean Absolute Error* (MAE) metric, the best one showing the lowest error.
- Starting from the best kernel combination, the algorithm re-applies the same operators (+, ·), creating new kernel combinations to be tested.

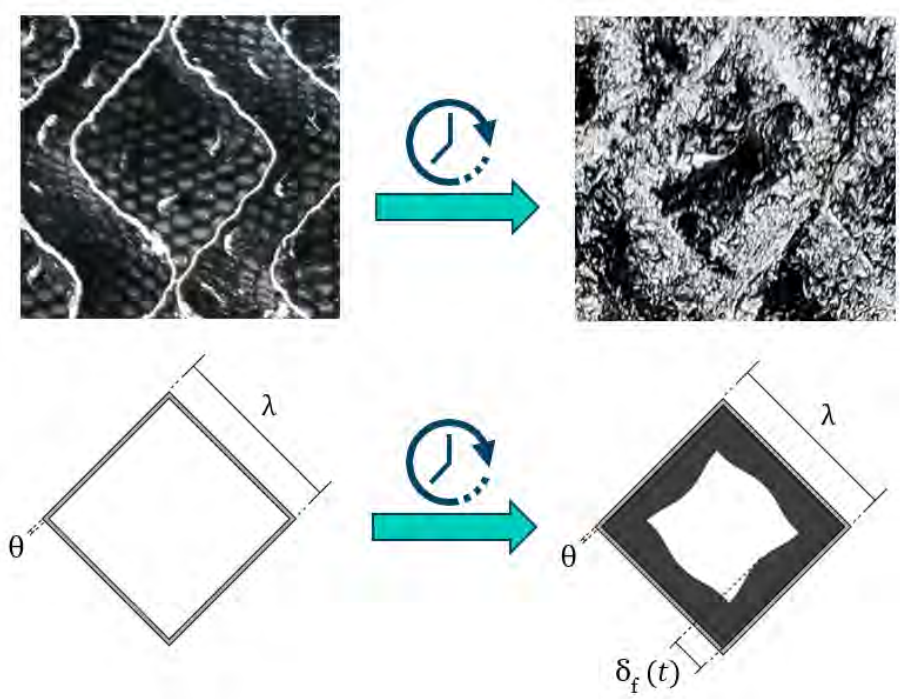

**Figure 2:** Details of the actual structured packing used in the distillation column investigated in this work, and corresponding schematic modeling approach. On the left, packing is represented at the start of run, with characteristic length λ, and thickness θ. On the right, the same equipment is reported during the run, with the addition of the time-dependent fouling thickness $\delta_f(t)$. Geometric parameters are dimensionless.

Regression models created with the kernel combination strategy described here follow a *greedy search* approach, meaning that the search tree is descended by taking the best model at each iteration. This is a compromise between modeling accuracy and computational effort. The algorithm is set to reach a maximum tree depth of five layers, to avoid long computational time and possible overfitting problems, while also ensuring good prediction capabilities. For more details regarding the algorithm, please refer to the work by Galeazzi et al. [1].

## Pressure Drop Model

The algorithm from Galeazzi et al. [1] was effectively applied by Negri et al. [2,3] for predictive maintenance of the same TDA column analyzed in this work. Specifically, they used a GPR algorithm on ΔP datasets to improve maintenance scheduling. While GPR adapted well to the varying used oil composition, providing a robust and reliable maintenance strategy, it gave less accurate results when predicting the steep ΔP increase near end-of-run conditions.

To address this limitation, this paper proposes a hybrid machine learning approach that combines GPR with a tailored ΔP model for the TDA column. This method enhances predictive reliability across the entire time domain, albeit at the cost of reduced generality, as it requires a unit-specific model rather than being universally applicable.

The pressure drop model considered in this work is the one reported for structured packing in the work by Bravo et al. [6], shown in eq. 4.

$$\Delta P = \Delta Z \frac{f \rho_g U_{gs}^2}{S \sin^2(\beta) \varepsilon^2 g_c} \quad (4)$$

where $\Delta P$ is the pressure drop, $\Delta Z$ is the packing height, $f$ is the friction factor, $\rho_g$ is the gas density, $U_{gs}$ is the superficial gas velocity, $S$ is the side dimension of packing corrugation (its characteristic length), $\beta$ is the angle with horizontal for corrugation channel, $\varepsilon$ is the void fraction of the packing, and $g_c$ is the gravity conversion factor (=1.0).

This model is significantly affected by the geometry of the packing. Thus, before applying it to the case of the TDA column, it is necessary to understand how fouling affects geometrical quantities during operations. The effect of fouling in a structured packing can be observed in Figure 2, which shows the packing used in the TDA column and a corresponding schematic modeling view, before the start of run, and after experiencing operations. The scheme shows the characteristic length and thickness of packing, represented by letters λ and θ, respectively. The geometrical quantities shown in the picture, indicated by Greek letters, are made dimensionless by dividing them by a standard side dimension of packing corrugation, $S^0$, to protect Itelyum's industrial secret.

It is possible to see that the main effect of fouling is

the restriction in the cross-sectional area of the packing caused by a growing film, represented by the time-dependent fouling thickness, indicated by the dimensionless parameter $\delta_f(t)$.

The growth in time of this fouling thickness will impact packing void fraction ε, which is a key parameter for pressure drop, as indicated by the formula presented previously in eq. 4. The mathematical relationship showing ε as a function of $\delta_f(t)$ is reported in eq. 5.

$$\varepsilon = \frac{V_{void}}{V_{total}} = \frac{A_{void}\Delta Z}{A_{total}\Delta Z} = \frac{\left(\lambda - 2(\theta+\delta_f)\right)^2}{\lambda^2} = \left[1 - \frac{2}{\lambda}\left(\theta + \delta_f\right)\right]^2 \quad (5)$$

where $V_{void}$, $V_{total}$, $A_{void}$ and $A_{total}$ refer to void and total volume and cross-sectional area, respectively. The proposed expression for ε can be plugged into the model previously shown in eq. 4, obtaining the relationship between ΔP and fouling thickness $\delta_f(t)$.

To simplify the modified ΔP model for the TDA column, the authors assume that the reduction in cross-sectional area due to fouling quickly becomes the dominant factor, a phenomenon which is primarily determined by packing geometry and fouling growth. Thus, all parameters are grouped into a constant, α, except those related to packing geometry (λ, θ, $\delta_f$). This constant also includes the feedstock flowrate, making ΔP specific to the unit mass while protecting Itelyum's industrial confidentiality. The final expressions are shown in Eq. 6 and 7.

$$\Delta P = \frac{\alpha}{\lambda} \cdot \left[1 - \frac{2}{\lambda}\left(\theta + \delta_f(t)\right)\right]^{-4} \quad (6)$$

$$\delta_f(t) = \frac{\lambda}{2} \cdot \left[1 - \left(\frac{\alpha}{\lambda \cdot \Delta P}\right)^{0.25}\right] - \theta \quad (7)$$

The expression in eq. 6 has a vertical asymptote when $\delta_f \rightarrow (\lambda/2 - \theta)$, meaning that pressure drop gradually increases as fouling thickness grows, then it rapidly degenerates to extremely high values when $\delta_f$ approaches the asymptotic limit. Interestingly, this is coherent with the behavior of ΔP in the real industrial system, as shown previously in Figure 1.

This model can be used for predictive maintenance by coupling it with the GPR-based algorithm, by leveraging it to obtain the expected fouling growth rate in the future, something that would hardly be possible to estimate otherwise.

## RESULTS AND DISCUSSION

Maintenance for the TDA column is centered around a key concept: there is a *Normal Operations Limit* (NOL) for the column fixed at 2.5 mmHg/$t_{oil}$ that should not be overcome. Operating the column over this limit should be avoided because the additional stress caused by the high pressure drop makes it less economically advantageous to run the regeneration process. Thus, a proper maintenance strategy should aim at scheduling activities so that the column can be stopped just before this limit, to maximize the acceptable operating range and the economical advantages associated with it. In case the limit is overcome, and the column enters the *Suboptimal Operating Region* (SOR), the timeframe within it should be as low as possible.

### Condition-based Maintenance Strategy

Currently, Itelyum applies a condition-based strategy to schedule maintenance in its plant. This method can be summarized in the following steps:

- TDA column specific ΔP is checked with regular frequency.
- When the pressure drop overcomes a semi-empirical warning threshold of 2 mmHg/$t_{oil}$, maintenance starts being scheduled.
- Typically, there is a time delay of 1 τ (±30%) between scheduling and real maintenance.
- Maintenance should take place before the column overcomes the NOL fixed at 2.5 mmHg/$t_{oil}$.

The biggest limit in this strategy is the aprioristic definition of the warning threshold, which is statically fixed at 2 mmHg/$t_{oil}$ and has no link to the actual operating conditions. While it represents a good rule of thumb to have an approximate idea of the column's behavior, it cannot adapt to the continuously changing composition of used oil waste feedstock, which is something inherently intertwined with fouling behavior. Results from the application of this strategy are shown in Table 1 as an example, where two different runs of the TDA columns are reported and referred to as cases A and B.

Here, $\tau_M$ is the time at which the warning threshold is overcome, and scheduling starts. $\Delta\tau_M$ is the time delay between scheduling and actual maintenance, a period which normally lasts around 1τ, even though unusually long delays do happen, as shown in case B. Finally, $\Delta\tau_{SOR}$ is the timeframe during which the column operates within the Suboptimal Operating Region, a value that should be as low as possible.

It is possible to see that the condition-based strategy is not reliable in consistently providing low permanence within the SOR, with case B showing a residence time within it more than three times higher compared with case A.

**Table 1:** Characteristic times for condition-based maintenance strategy.

| Case | $\tau_M$ | $\Delta\tau_M$ | $\Delta\tau_{SOR}$ |
|---|---|---|---|
| A | 6.48 | 0.69 | 0.48 |
| B | 7.79 | 2.21 | 1.52 |

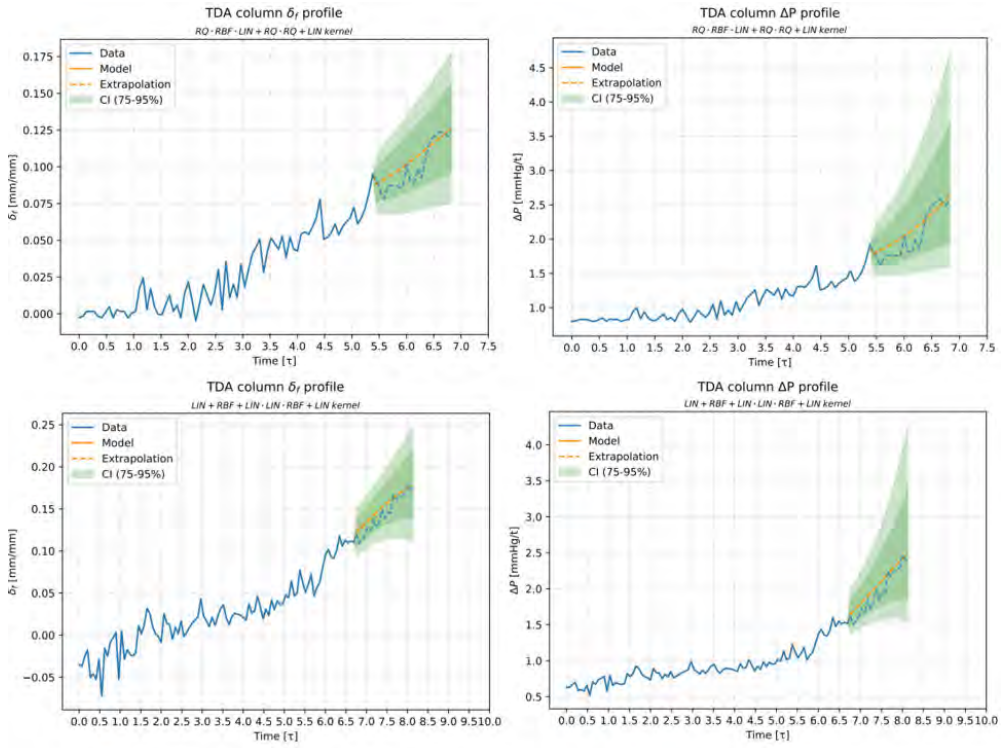

**Figure 3:** Predictions from the forecasting algorithm when NOL overcoming is forecasted ($\tau = \tau_M$). On the left, fouling thickness ($\delta_f$), on the right, pressure drop ($\Delta P$), on the top, case A, and on the bottom, case B.

## Predictive Maintenance Strategy

The authors of this work propose an alternative predictive maintenance strategy to increase the reliability of maintenance scheduling in Itelyum plant, composed of the following steps:

- $\Delta P$ datasets are transformed into equivalent fouling thickness ($\delta_f$) datasets, by applying the formula in eq. 7.
- The GPR-based algorithm is applied to $\delta_f$ datasets following a rolling forecasting approach.
- Algorithm training always starts at $\tau = 0$ and increases at fixed intervals, with a new prediction being performed at every step.
- Prediction horizon has a fixed value of 1.5 $\tau$, which is 50% higher than the average time lag between scheduling and maintenance.
- Forecasting results on $\delta_f$ are transformed back into $\Delta P$ values by applying eq. 6 pointwise to several points of the forecasted probability distributions.
- Maintenance is scheduled for the day in which the algorithm predicts that the most probable value for $\Delta P$ will overcome the NOL.

Graphical outputs from the algorithm at the moment in which overcoming is forecasted ($\tau = \tau_M$) are shown in Figure 3. Here, the best kernel combinations chosen by the algorithm is shown at the top of each graph, the continuous blue line represents the training and cross-validation dataset analyzed by the algorithm, the orange dashed line is the most probable prediction, the dashed blue line represents the validation dataset, the dark and light green shaded areas represent 75% and 95% confidence intervals, respectively.

It is possible to observe both the prediction of $\delta_f$ with its uncertainty, and the corresponding values of $\Delta P$ resulting from the transformation of each forecasted value. Predictions show good accordance between the most probable evolution in time for the investigated variables (orange dashed lines) and real data (blue dashed lines). Moreover, the natural variability of real data is contained within the 95% confidence interval calculated by the regression procedure, confirming the reliability of the model.

Results from the application of this predictive strategy are shown in Table 2, where the same two runs of the TDA column are shown as a comparison with the condition-based strategy. To ensure that the comparison is meaningful, the largest interval between the prediction horizon and the real-life time lag between scheduling and maintenance is taken as value for $\Delta\tau_M$ in each case.

**Table 2:** Characteristic times for condition-based maintenance strategy.

| Case | $\tau_M$ | $\Delta\tau_M$ | $\Delta\tau_{SOR}$ |
|---|---|---|---|
| A | 5.38 | 1.34 | 0.19 |
| B | 6.69 | 2.21 | 0.49 |

When comparing results between Tables 1 and 2, it is clear that the adoption of the predictive maintenance strategy increases significantly the reliability of maintenance scheduling, as highlighted by the systematic and remarkable reduction in the runtime within the SOR for both cases.

This fact is further highlighted in Figure 4, showing the percentage reduction in $\Delta\tau_{SOR}$ parameter for both cases by means of the parameter $R_{SOR}$, defined as follows in eq. 8.

$$R_{SOR} = \frac{\Delta\tau^{P}_{SOR} - \Delta\tau^{CB}_{SOR}}{\Delta\tau^{CB}_{SOR}} \cdot 100 \qquad (8)$$

Where $\Delta\tau^{P}_{SOR}$ and $\Delta\tau^{CB}_{SOR}$ are the timeframe within the SOR for predictive and condition-based strategy, respectively. Reductions of more than 60% for suboptimal operating time are achieved for both cases.

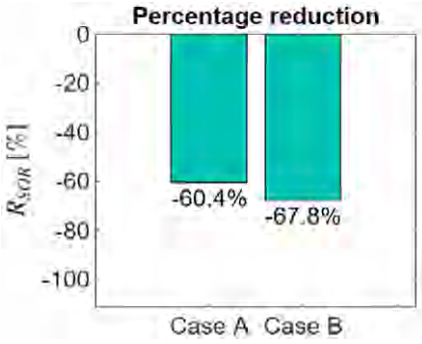

**Figure 4.** Percentage reduction in SOR runtime when shifting from condition-based to predictive maintenance

The significant reduction in suboptimal operating time demonstrates the increased reliability of maintenance planning with the proposed strategy, and robustness across different operating conditions. Additionally, considering the results for the predictions shown previously in Figure 3, it is interesting to notice that the algorithm would have actually avoided the column to enter the SOR altogether in case B, if it wasn't for the exceptionally long time delay between scheduling and maintenance. In case this time lag would have been within the usual value of 1 $\tau$ (±30%), the SOR would have been completely avoided thanks to the algorithm prediction.

## CONCLUSIONS

This study focused on a vacuum distillation system processing used oil, proposing a predictive maintenance strategy. A physics-based model was developed, and a Gaussian Process Regression algorithm was leveraged to forecast fouling thickness ($\delta_f$) evolution.

The hybrid model demonstrated strong alignment with plant data, particularly in the end-of-run region, where ΔP increased rapidly due to packing occlusion. Applying this approach to a predictive maintenance strategy reduced suboptimal operating time by over 60% compared to the current condition-based method in two different cases, offering a more reliable and effective solution for maintenance scheduling.

## ABSTRACT

The accumulation of heavy polynuclear aromatics (HPNAs) in hydrocracking units (HCUs) poses significant challenges to catalyst performance and process efficiency. This study proposes an integrated machine learning framework that combines ridge regression, K-means, and long short-term memory (LSTM) neural networks to predict HPNA formation, enabling proactive process management. For the training phase, weighted average bed temperature (WABT), catalyst deactivation phase—clustered using unsupervised K-means clustering—and hydrocracker feed (HCU feed) parameters obtained from laboratory analyses are utilized to capture the complex nonlinear relationships influencing HPNA formation. In the simulation phase, forecasted WABT values are generated using a ridge regression model, and future HCU feed changes are derived from planned crude oil blend data provided by the planning department. These forecasted WABT values, predicted catalyst deactivation phases, and anticipated HCU feed parameters serve as inputs to the LSTM model for predicting future HPNA levels. This approach allows us to simulate various operational scenarios and assess their impact on HPNA accumulation before they manifest in the actual process. By identifying critical process parameters and their influence on HPNA formation, the model enhances process engineers' understanding of the hydrocracking operation. The ability to predict HPNA levels in advance empowers engineers to implement corrective actions proactively, such as adjusting feed compositions or operating conditions, thereby mitigating HPNA formation and extending catalyst life. The integrated framework demonstrates high predictive accuracy and robustness, underscoring its potential as a valuable tool for optimizing HCU operations through advanced predictive analytics and informed decision-making.

## 1. INTRODUCTION

Hydrocracking is a pivotal unit operation in modern petroleum refining, offering flexibility and high yields of valuable middle distillates and lighter products. By coupling hydrogenation and catalytic cracking, HCUs can process a wide range of feedstocks—from vacuum gas oils to heavier coker feed streams—under severe operating conditions to maximize conversion [1]. However, these severe conditions facilitate the formation of HPNAs as byproducts, which typically contain 11 or more fused aromatic rings. HPNAs present a unique challenge, especially in the latter stages of a catalyst's life cycle, as they can cause critical fouling issues, accelerate catalyst deactivation, and reduce overall process efficiency. The rate of HPNA formation intensifies with increasing conversion levels and the use of heavier feedstocks [2]. Especially as the catalyst approaches the time for regeneration, HPNA accumulation increases very rapidly, making it challenging to manage and optimize unit conditions. Proactively managing HPNA accumulation is thus central to prolonging catalyst life, maintaining product quality, and sustaining high plant profitability.

Recent advances in data analytics and machine

learning have opened up new avenues for tackling this problem. Traditional physics-based or semi-empirical models, while useful, often struggle to capture the highly nonlinear relationships between feed characteristics, operating conditions, and HPNA formation. Machine learning methods—such as artificial neural networks [3], K-means [4], and ensemble techniques—can learn these complex interactions from historical data, yielding more accurate predictions of HPNA buildup under varying future scenarios. Moreover, the integration of multiple models, each specialized in a different task (e.g., forecasting Weighted Average Bed Temperature, clustering catalyst deactivation phases, and predicting HPNA levels), creates a robust predictive framework. The ability to forecast HPNA accumulation before it reaches operationally critical levels enables data-driven decision-making, reducing unplanned shutdowns, streamlining catalyst regeneration cycles, and minimizing downstream fouling costs.

Against this backdrop, the present work introduces an integrated machine learning framework that combines ridge regression, K-means, and LSTM neural networks to model and predict HPNA formation in HCUs. By incorporating both laboratory-based and real-time operational parameters, the framework offers a holistic solution. It not only forecasts HPNA levels but also provides case-study simulations illustrating how variations in operational parameters can drastically alter HPNA accumulation. The study aims to demonstrate how predictive analytics can add tangible value, offering refiners a proactive toolkit for making informed adjustments in feed composition and reactor severity, ultimately balancing higher conversion rates with catalyst longevity and fouling minimization.

## 2. MATERIALS AND METHODS

### 2.1. HPNA Formation Mechanisms

In the hydrocracking process of Heavy Vacuum Gas Oil (HVGO) feedstocks, HPNAs are generated as byproducts. These compounds pose significant challenges by fouling process equipment and shortening the lifespan of catalysts. The rate of HPNA formation intensifies with increasing conversion levels and the use of heavier feedstocks [2]. This issue becomes particularly critical as the catalyst nears the end of its cycle, where HPNA accumulation accelerates rapidly, making it difficult to manage and optimize unit conditions. To maintain the catalyst regeneration process and costs at an optimal level, it is essential to monitor and effectively control HPNA accumulation.

### 2.2. Data Collection and Preprocessing

There are two data frequency types of features: laboratory samples and process values. While process values are continuous, laboratory sample data are collected at irregular intervals; they are collected at different frequencies, such as twice a day or three times a week. Continuous process values are collected as hourly averages and then merged with laboratory sample data. Since this merging is done based on datetime, missing values (NaNs) occur in the laboratory sample data when no sample analysis is available. When NaN values appear due to the nature of laboratory sampling, the corresponding dates are removed from each model's input dataset. Additionally, data from periods when the unit was in shutdown conditions were excluded to ensure consistency in the analysis. All tasks were performed using Python 3.8, and approximately three years of data were used for model training, validation, and testing.

For simulation part, some input parameters for the models which are affected from crude oil change, is calculated from planning department's future crude oil blending plans. Parameters that cannot be derived from these plans are assumed to remain constant, with their last observed values carried forward into the future. A ridge regression model is employed to forecast WABT values, while a K-means clustering model is used for catalyst deactivation modeling. The predicted WABT values, along with the estimated catalyst deactivation phases and the calculated future HCU feed parameters, are then used as inputs for an LSTM model to estimate future HPNA levels.

### 2.3. Catalyst Deactivation Clustering via K-Means

The catalyst in the HCU reactor deactivates over time, undergoing distinct phases that can be clustered using the K-means method. The plant dataset is divided into $k$ categories, with data points in these categories chosen as initial cluster centers. The algorithm assigns each data point to the nearest center, forming clusters, and iteratively updates the centers until convergence is achieved [4]. Six clusters have been identified as the most effective way to categorize the catalyst's deactivation phases from the start of operation to the present, covering approximately three years. Reactor WABT and the cumulative processed feed amount, measured from the catalyst's first day of operation to now, are used to create the clusters for the deactivation phases. The processed feed amount reflects the catalyst's HPNA accumulation, while WABT varies significantly with the HPNA levels. Therefore, these two features are the best inputs for clustering the catalyst deactivation phases due to their strong correlation with HPNA accumulation. Based on these cluster labels, the HPNA sample data is fitted to quadratic functions for each cluster, effectively representing HPNA accumulation while reflecting the key features of catalyst deactivation. This approach captures the deactivation pattern despite some inconsistencies in

laboratory sample points (Figure 1).

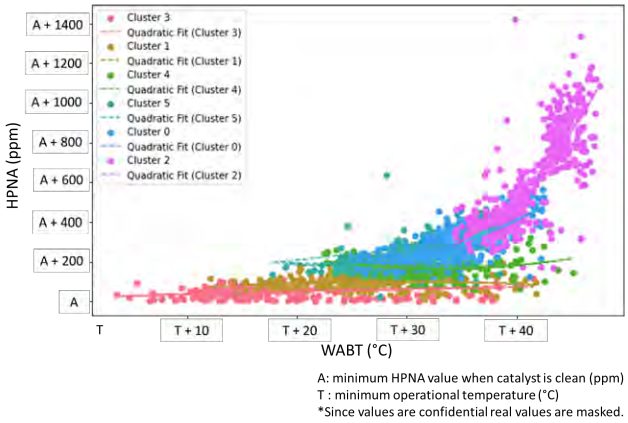

**Figure 1.** K-means clustering model.

## 2.4. WABT Forecasting with Ridge Regression

The WABT in HCU's reactors is a key operational parameter that directly influences conversion rates and catalyst deactivation. Since HPNA formation—and consequently catalyst deactivation—is inevitable over time, engineers increase reactor temperatures to maintain a consistent conversion rate. However, this increased severity also accelerates HPNA formation. Therefore, for simulating future plant operations and predicting HPNA formation, it is essential to accurately forecast the WABT profile in the reactors.

Ridge regression, a popular method for estimating parameters in multivariate regression, is applied to model the relationship between WABT, HPNA accumulation, and other influencing factors, particularly in the presence of collinearity. By adding a regularization term to prevent overfitting, ridge regression can enhance prediction accuracy despite its limitations, such as reduced interpretability and lack of variable selection [5]. The WABT prediction model uses the following inputs: ten-day moving average of HCU feed sulfur content, cumulative processed feed amount, one-day average flow of HVGO from the crude oil unit to the HCU, four-day moving average of HCU feed nitrogen content, and denoised heavy coker gas oil (HCGO) flow from the delayed coker unit to the HCU, lagged six hours. These features were selected based on their established influence on reactor temperature dynamics and catalyst aging. Smoothing the input data is necessary because WABT is highly sensitive to these variables, and smoothing makes the model more robust.

The model is trained on historical plant data spanning three years, with the test set comprising 20% of the dataset. The model's test set performance metrics are $R^2$ = 0.57 and Mean Absolute Percentage Error (MAPE) = 0.46%. Figure 2 shows the model's predictive performance by comparing actual and predicted values for both the training and test datasets over time. The close alignment of the predicted (blue and red) and actual (green and purple) values suggests that the model captures overall trends effectively, though some deviations remain, particularly in regions of high variability. The general upward trend in later timestamps indicates that the model adapts well to changes over time. However, minor fluctuations between actual and predicted values may point to areas where the model struggles with short-term variability. Despite these imperfections, the relatively low MAPE suggests the model maintains strong predictive accuracy. The model successfully captures WABT trends, which are crucial for estimating future HPNA accumulation and enabling proactive process adjustments, and it serves as an input for the simulation to forecast HPNA accumulation under varying future process conditions.

## 2.5. LSTM Model for HPNA Prediction

As the catalyst approaches the end of its cycle, the HPNA amount in the output feed of HCU reactors increases due to the cumulative effect of catalyst deactivators. Therefore, the HPNA profile—comprising previous HPNA samples—serves as an indicator for the current HPNA amount. Given the dynamic behavior of this process, time series modeling is crucial, as the problem is inherently time-dependent. Furthermore, the absence of data from previous catalyst life cycles makes it even more challenging to learn from and accurately model this behavior.

LSTM networks, a type of recurrent neural network,

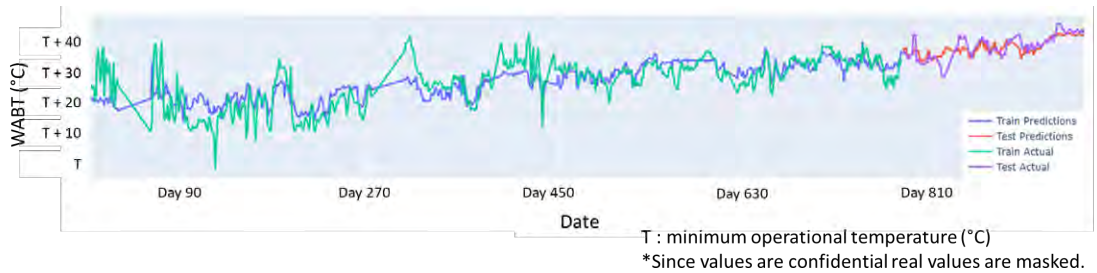

**Figure 2.** WABT prediction model.

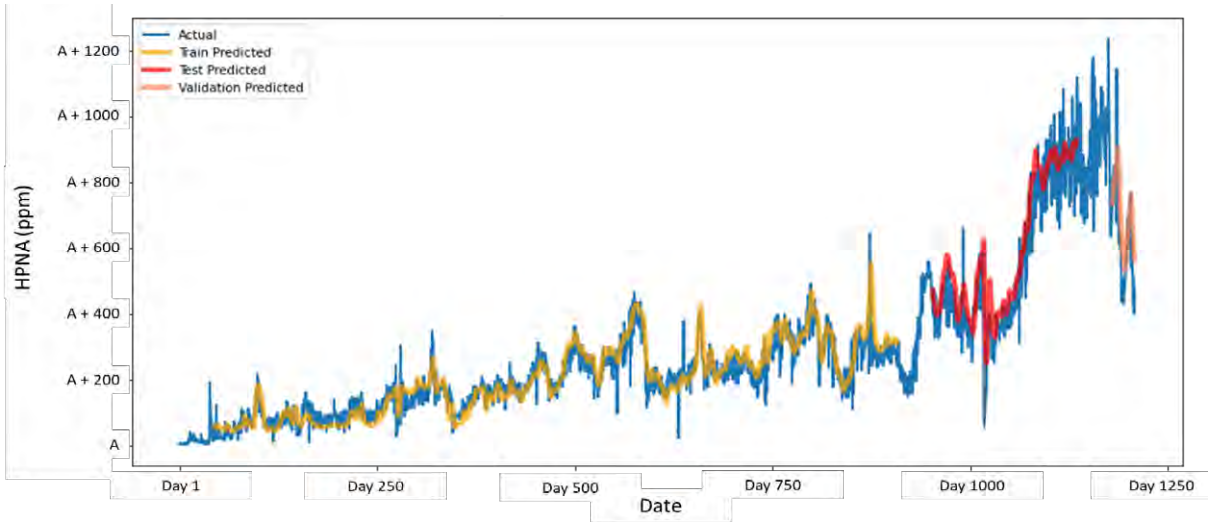

**Figure 3.** LSTM model performance.

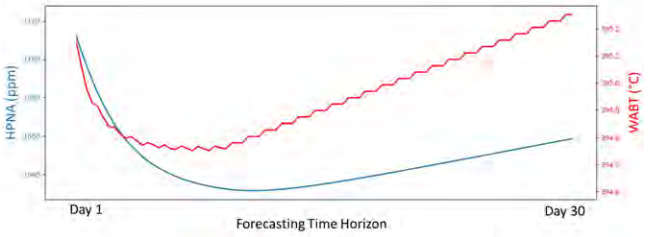
are particularly well-suited for such time series problems. LSTMs introduce gating mechanisms to effectively learn dependencies in sequential data, making them ideal for modeling the nonlinear dynamics of chemical processes and catalyst behavior [3]. Studies have demonstrated the effectiveness of LSTM models in handling complex dynamics in chemical processes, further validating their potential for modeling processes like HPNA accumulation.

After conducting correlation analysis, the best parameters for the prediction of HPNA amount in the output flow of HCU's reactors were identified as the 98% distillation temperature of HCGO, reactor's WABT, sulfur and nitrogen content in the HCU feed. However, the initial results were unsatisfactory, as real historical outputs were not directly incorporated into the predictions. This limitation arose because the LSTM model relied only on an abstract representation of past states. To address this, the HPNA refitted feature—reflecting catalyst deactivation and detailed in Section 2.3—was also included as an input.

The model was trained using these five inputs, with the target being the HPNA amount in the HCU output flow. To predict the target variable, the LSTM neural network architecture was implemented using the Keras/TensorFlow framework. Before model development, the dataset, spanning approximately three years, was scaled using the MinMaxScaler to normalize all features. The data was then split chronologically into training (80%) and testing (20%) subsets without shuffling, preserving the time dependency. A sliding window approach was adopted to capture temporal dependencies. Specifically, a window length of 90 time steps (corresponding to one and a half months of data, with two samples per day) was used to create training sequences. Each sequence of 90 time steps was used to predict the target value at the subsequent time step. A batch size of 8 was chosen to balance memory constraints and training stability. The LSTM architecture consisted of two stacked LSTM layers, each with 64 units and a dropout of 0.2, followed by a dense layer of 32 neurons (ReLU activation) and a final output neuron. The model was trained with a mean squared error loss function and the Adam optimizer. Early stopping (with a patience of 2) and an exponential decay learning rate scheduler (triggered after 10 epochs) were employed, using a portion of the data to monitor validation loss during each epoch. To ensure no data leakage between validation and testing steps, an additional one-month validation set was used as unseen data to evaluate model performance with 80 mean absolute error. Figure 3 displays the LSTM model's performance in predicting HPNA accumulation trends. Gaps appear in each prediction set because the initial data from the sliding window is used to predict the last value. The model demonstrates a strong ability to track HPNA trends, with predictions aligning closely to actual values. This enables process engineers to anticipate HPNA formation and take preventive measures proactively.

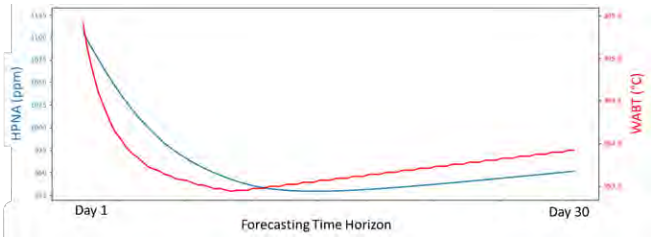
## 3. SIMULATION RESULTS OF CASE STUDIES

Beyond merely predicting current HPNA levels, a key advantage of this integrated approach lies in its capacity to forecast the future performance of the HCU. By incorporating the planning department's projections for crude oil blends, models' some of parameters influenced by changing feedstocks can be accurately estimated.



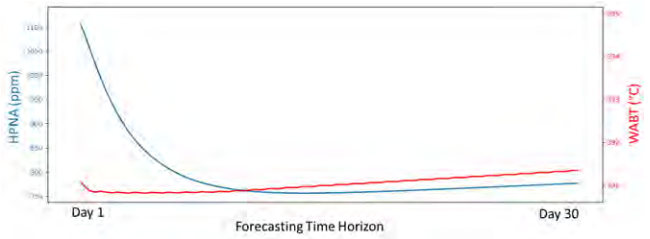
These forecasts serve as critical inputs to the three-model framework—the ridge regression model for WABT prediction, the K-means clustering method for catalyst deactivation phases, and the LSTM network for future HPNA estimation—thereby enabling process engineers to proactively adjust feed compositions or operating conditions. Such targeted interventions not only help mitigate HPNA formation but also extend catalyst life. In addition, the models provide insights into how various parameters affect both HPNA levels and WABT, empowering users to make informed decisions and fine-tune process settings. In Figure 4, the influence of adjusting these parameters on each model's output is illustrated as case studies.

The base case (Figure 4.a) represents the standard operational scenario, with no adjustments to input parameters within one month. At the initial point, there is a decrease due to the residual effects of the moving window size (one and a half months) still influencing the LSTM model, which forecasts one month. Once a steady-state condition is reached, HPNA accumulation increases, and WABT rises over time, reflecting the natural progression of catalyst deactivation in the HCU under current operating conditions.

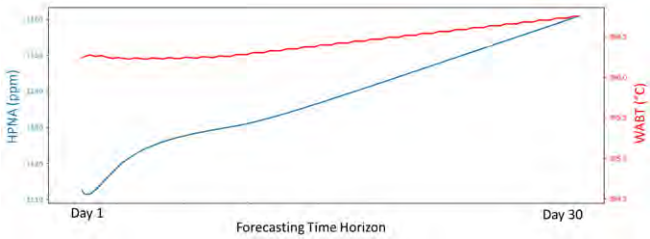


In the case of Figure 4.b, the sulfur content in the HCU feed is increased by 0.46 %wt. This leads to a reduction in cracking reactions due to the presence of sulfur-containing compounds, resulting in a lower temperature. Consequently, both HPNA accumulation and WABT decrease more rapidly, leading to lower final levels of HPNA and WABT compared to the base case. These findings suggest that the observed reduction in HPNA accumulation and WABT is not directly caused by the sulfur increase itself, but rather by the decreased cracking conversion due to sulfur retention in the diesel fraction, which helps maintain overall conversion levels. This mechanism ultimately mitigates fouling and improves operating conditions.

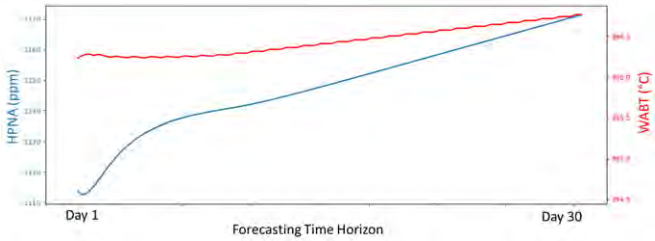
Reducing the flow of HCGO by 47.5 $m^3$ results (Figure 4.c) in a notable slowdown in HPNA accumulation. Correspondingly, WABT remains lower and more stable over time. This indicates that reducing HCGO flow mitigates fouling and slows catalyst deactivation, providing a potential strategy for process optimization.



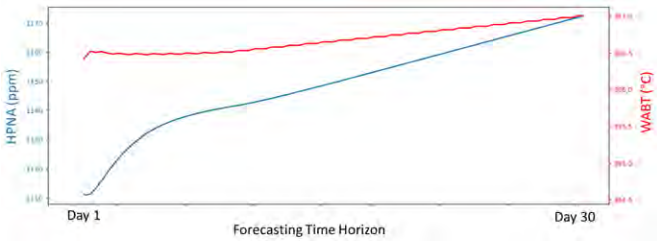
An increase in nitrogen content in the HCU feed by 55 ppm (Figure 4.d) leads to a significant acceleration in HPNA formation, as indicated by the steep rise. However, WABT remains relatively unchanged, suggesting that while nitrogen compounds strongly influence HPNA buildup, they do not significantly impact WABT in the short term. This highlights the critical importance of controlling feed nitrogen content to manage catalyst performance and minimize long-term fouling effects.



**a)** base case.



**b)** sulfur amount in the HCU feed increases by 0.46 %wt.



**c)** HCGO flow decreases by 47.5 $m^3$.

**d)** nitrogen amount in the HCU feed increases by 55 ppm.

**e)** 98% distillation temperature of HCGO decreases by 15 °C.

**f)** HVGO flow increases by 42.5 $m^3$.

**Figure 4.** Simulation results for each case studies.

When the 98% distillation temperature of HCGO is reduced by 15°C (Figure 4.e), HPNA accumulation continues significantly, while WABT remains relatively stable. This case highlights the effectiveness of reducing heavier components in the feed to mitigate fouling and improve catalyst performance, as the lower temperature likely decreases the presence of high-molecular-weight components that contribute to HPNA formation.

Lastly, increasing the HVGO flow rate by 42.5 $m^3$ (Figure 4.f) results in an increase in HPNA accumulation, implying that heavier feed fractions contribute more significantly to HPNA precursor formation. These findings highlight the critical role of feed composition and process conditions in controlling HPNA buildup within the HCU, providing valuable insights for optimizing unit operation and extending catalyst life.

## 4. CONCLUSIONS

This study demonstrates the effectiveness of a multi-model, machine learning-based approach for predicting HPNA accumulation in hydrocracking units, providing refineries with a proactive strategy for managing catalyst health. By integrating ridge regression for WABT forecasting, K-means clustering for catalyst deactivation phases, and a LSTM model for HPNA projection, the framework captures the complex, time-dependent interactions that drive HPNA formation. The case studies highlight how variations in feed properties, process parameters, and operating conditions influence HPNA accumulation trends, offering insights that can inform operational adjustments to mitigate fouling and extend catalyst life.

While the model was trained using three years of historical data from a specific hydrocracking unit, its underlying methodology is not confined to a single facility. The approach—integrating machine learning framework for temperature forecasting, catalyst deactivation clustering, and HPNA prediction—can be generalized to other HCUs with appropriate modifications. However, challenges such as differences in feedstock composition, process severity, and catalyst formulations may necessitate model retraining or recalibration. Despite these variations, the overall framework offers a transferable, data-driven strategy that can be adapted for predictive maintenance and process optimization across multiple refining operations.

Future research could focus on incorporating advanced optimization algorithms to provide real-time control recommendations, further bridging the gap between predictive analytics and operational decision-making. Additionally, expanding the dataset to include multiple catalyst cycles or integrating kinetic models could enhance the robustness and generalizability of the predictions. Overall, the results underscore the potential of an integrated data-driven strategy to enhance catalyst performance, improve process economics, and maintain the reliability of hydrocracking operations in a rapidly evolving refining landscape.

## ABSTRACT

This work presents a model for optimizing shell-and-tube heat exchanger design using Q-learning, a reinforcement learning technique. An agent is trained to interact with a simulated environment of a heat exchange model, iteratively refining design configurations to maximize a reward function. This reward function balances heat exchanger effectiveness and pressure drop, emphasizing designs that minimize pressure drop. Results showed that simpler configurations consistently achieved higher rewards, despite complex designs offering better heat transfer efficiency.

**Keywords**: heat exchanger, reinforcement learning, design optimization, machine learning

## INTRODUCTION

Heat exchangers are essential components across industries, facilitating heat transfer between fluids of differing temperatures [1]. Since their development in the early 20th century for industrial steam generators and power plant condensers, their applications have expanded into refrigeration, automotive cooling, waste heat recovery, and petrochemical processes [2]. The optimization of heat exchangers is directly connected to the energy and operational costs [3]. Thus, linking this equipment to important performance parameters. However, traditional design methods often rely on iterative manual processes that fail to guarantee optimal solutions due to the complexity of influencing parameters [4].

Recent advancements in Scientific Machine Learning (SciML) offer promising avenues for addressing these challenges. By integrating scientific principles with machine learning, SciML has shown potential in optimizing intricate systems like heat exchangers [5]. For instance, reinforcement learning (RL), a branch of SciML, can be utilized to identify optimal designs by exploring vast solution spaces without manual intervention. For example, a Scopus search using "heat exchanger" and "machine learning" revealed 259 studies, the narrower term "q-learning," an RL technique, yielded just five results. Research highlights, such as Wang et al. (2023) [6], demonstrate the potential of machine learning and computational fluid dynamics to enhance heat transfer in finned heat pipe radiators by optimizing parameters like fluid flow and thermal efficiency. By leveraging machine learning models trained on CFD simulation data, the authors identified design configurations that significantly enhanced thermal performance while maintaining manufacturability. This approach highlights the value of integrating machine learning with traditional physics-based methods to tackle the complexities of heat exchanger optimization.

Studies leveraging machine learning for heat exchanger optimization have explored diverse methods. For instance, Nevin et al. (2023) [7] employed Gaussian Process Regression and Random Forest models to enhance performance with turbulator inserts. In contrast, Keramati et al. (2022) [8] applied Deep Reinforcement Learning to optimize heat exchanger geometry, balancing heat transfer efficiency with reduced pressure drop. While these techniques have made notable advances, commercial optimization tools like Aspen EDR and HTRI Heat Exchanger Suite are still widely used in industry. These tools typically rely on meta-heuristics to solve

design problems, which, while effective, are often computationally intensive and require significant time for design iteration [9, 10]. This work differentiates itself by applying Q-learning, a simpler yet efficient reinforcement learning method, to optimize shell and tube heat exchangers, offering a potential for faster design evaluation and reduced computational time compared to traditional methods. The study focuses on maximizing a reward function defined by heat exchanger effectiveness and pressure drop. Despite limited precedent in applying Q-learning to this field, the findings from this exploratory work provide a foundation for further development.

# BACKGROUND

## Shell and Tube Heat Exchangers

Shell and tube heat exchangers are versatile and widely used in industrial applications due to their scalability, durability, and flexibility. In these exchangers, one fluid flows through a bundle of tubes, while another fluid circulates around the tubes within a shell. This arrangement enables heat transfer, where the hotter fluid warms the cooler one or vice versa. The efficiency of this process depends on factors like the overall heat transfer coefficient, heat transfer surface area, and the temperature gradient between fluids [1].

To optimize heat transfer, shell and tube exchangers incorporate numerous small tubes within a single shell. Baffles inside the shell direct the fluid in a serpentine path, creating turbulence that enhances heat transfer by breaking up thermal boundary layers on the tube surfaces [1]. Figure 1 illustrates a typical shell and tube heat exchanger with a one-shell pass and one-tube pass configuration, showing the internal structure and flow arrangement.

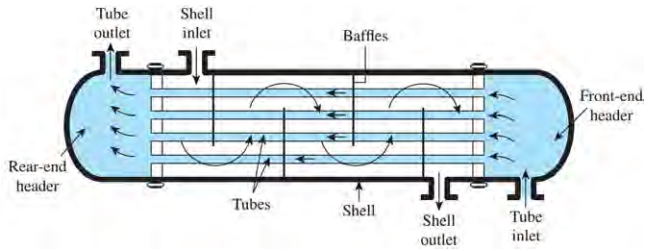

**Figure 1.** Shell and tube heat exchanger with one-shell pass and one-tube pass scheme.[1]

The flexibility of shell and tube heat exchangers allows for various configurations tailored to specific operational needs. These designs, combined with their ability to withstand high pressure and temperature, make them ideal for chemical processing, power generation, and petrochemical production [1]. This work employs the effectiveness-NTU (ε-NTU) method to evaluate the performance and design of such heat exchangers.

## Performance-indicating Parameters

The heat transfer rate (q) in a shell and tube exchanger is often calculated using the rate equation:

$$q = UA_s\Delta T_{lm} \quad (1)$$

where *U* is the overall heat transfer coefficient, $A_s$ is the total surface area for heat transfer, and $\Delta T_{lm}$ is the log mean temperature difference (LMTD). However, when only inlet temperatures are available, the effectiveness-NTU method simplifies the process by introducing dimensionless parameters like NTU (number of transfer units) and heat capacity ratios to directly estimate the exchanger's effectiveness (ε) [10].

The relationship for effectiveness in a single-shell pass shell and tube exchanger is:

$$\varepsilon_1 = \frac{2}{1 + C_r + \sqrt{1 + C_r^2}\,\frac{1 + exp\,(-\Gamma)}{1 - exp\,(-\Gamma)}} \quad (2)$$

where $C_r$ is the heat capacity ratio $C_r = C_{min}/C_{max}$, and $\Gamma = NTU\sqrt{1 + C_r^2}$. For exchangers with multiple shell passes, the generalized effectiveness equation is:

$$\varepsilon = \frac{\left(\frac{1-\varepsilon_1 C_r}{1-\varepsilon_1}\right)^n - 1}{\left(\frac{1-\varepsilon_1 C_r}{1-\varepsilon_1}\right)^n - C_r} \quad (3)$$

High effectiveness values indicate efficient heat transfer, making these parameters crucial for assessing exchanger performance. Additional considerations, such as temperature profiles and pressure drop, provide a comprehensive evaluation.

The pressure drop (ΔP) is critical for evaluating performance, calculated using the *Darcy-Weisbach* equation [12]:

$$\Delta P = f\frac{v^2}{2}\frac{L}{d_i} \quad (4)$$

Here, $\Delta P$ is the pressure drop across the tubes; f is the friction factor; and L is the total length of the pipes, calculated as the length of each pipe (l) multiplied by the number of shell passes (n): L = l · n. The friction factor is determined using the *Colebrook* equation [12]:

$$\frac{1}{\sqrt{f}} = -2\log\left(\frac{\frac{e}{d_i}}{3.7} + \frac{2.51}{Re\sqrt{f}}\right) \quad (5)$$

where *e* is the absolute roughness of the pipes, and *Re* is the Reynolds number. The Reynolds number describes the flow patterns of a fluid, indicating whether the flow is laminar or turbulent. For fluid flow within a pipe, it is defined as [13]:

$$Re = \frac{v d_i \rho}{\mu} \quad (6)$$

where $\mu$ is the fluid viscosity.

These equations provide the foundation for evaluating heat exchanger performance by calculating key metrics such as effectiveness, temperature profiles, and pressure drop. In this work, these parameters play a central role in assessing and optimizing heat exchanger designs through the application of Q-learning.

## Reinforcement Learning

Reinforcement learning (RL) is a machine learning technique where an agent interacts with an artificial environment to maximize cumulative rewards, based on the Markov Decision Process (MDP) [14]. The MDP provides a mathematical framework for decision-making, particularly suited to dynamic programming and optimization challenges [15].

In an MDP, the agent observes the current state $S_t$ , selects an action $A_t$, and receives a reward $R_t$+1 alongside a new state at each time step [16]. Transitions between states follow the Markov Property, where the next state depends only on the current state and action. A visual representation of this process is illustrated in Figure 2.

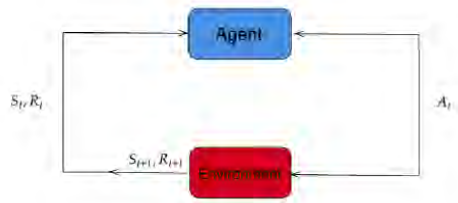

**Figure 2.** A simplified representation of MDP.

The agent's goal is to maximize total return over time by optimizing its policy $\pi$ (a|s), which determines the probability of taking action a in state s. Value functions are key to RL, estimating the expected return for a policy π. Iterative evaluation and policy improvement enable the agent to identify the optimal policy $\pi *$, maximizing returns.

While models of the environment can simplify this process, RL often relies on experience, where episodes of states, actions, and rewards guide learning [16].

## Q-Learning

Q-learning, introduced by Watkins (1989), is a reinforcement learning algorithm based on Temporal Difference (TD) learning. It estimates an optimal decision strategy for infinite-horizon problems without requiring an environmental model [17, 18]. Q-learning adopts an off-policy approach within TD learning, meaning that the optimal value function derives from actions chosen independently of the current policy $\pi$ (a|s) [16]. The updating rule proposed by *Watkins* (1989) is [17]:

$$Q\ (S_t, A_t) \leftarrow\ Q\ (S_t, A_t) + \alpha[T_{t+1} + \gamma\ max_a Q(S_{t+1}, A_{t+1}) - Q(S_t, A_t)] \quad (7)$$

Here, α is the learning rate, γ is the discount factor, and $max_a Q(S_{t+1}, A_{t+1})$ represents the estimated optimal future reward. A Q-table, as shown in Table 1, stores these values to guide the agent's decisions.

**Table 1:** A simple schematic of a Q-table.

| | $A_1$ | $A_2$ | ... | $A_n$ |
|---|---|---|---|---|
| $S_1$ | $Q\ (S_1, A_1)$ | $Q\ (S_1, A_2)$ | ... | $Q\ (S_1, A_n)$ |
| $S_2$ | $Q\ (S_1, A_1)$ | $Q\ (S_1, A_2)$ | ... | $Q\ (S_1, A_n)$ |
| ... | ... | ... | .... | ... |
| $S_m$ | $Q\ (S_m, A_1)$ | $Q\ (S_m, A_2)$ | .... | $Q\ (S_m, A_n)$ |

The agent balances exploration (trying new actions) and exploitation (choosing the best-known actions) using the ϵ-greedy method. Exploration probability ϵ decreases over time, transitioning from exploration to exploitation.

Q-learning's adaptability and effectiveness make it a powerful tool for solving dynamic decision-making problems, enabling agents to learn optimal strategies through continuous experience.

# METHODOLOGY

The development and execution of the Python program for this work were conducted on the following computer setup:

- Hardware:
  - Processor: 1.4 GHz quad-core Intel Core i5
  - Memory (RAM): 8 GB 2133 MHz LPDDR3
  - Storage: 256 GB
- Operating System: macOS Sonoma V. 14.4.1
- Development Environment:
  - IDE/Editor: Virtual Studio Code V. 1.88.0
  - Python Version: Python 3.9.18
  - Key Libraries and Frameworks: NumPy, Matplotlib, SciPy, Gym, Pandas, Os

## Database

To enable Q-learning and train the model, a database containing the necessary input parameters for the heat exchanger had to be provided. Since experimental data was not available, this database was artificially created using randomly selected values with reasonable intervals. For simplicity, all fluids were assumed to be water. The required input data included inlet mass flow ($\dot{m}$), overall heat transfer coefficient (U), heat capacities (Cp), and inlet temperatures (T) for both the hot and cold fluids. The intervals set for each parameter were chosen based on plausible values, as shown in Table 2.

**Table 2:** Model input parameters with corresponding intervals.

| Parameter | Interval |
|---|---|
| U [W/$m^2$K] | [400, 1500] |
| $\dot{m}_{hot}$ [kg/s] | [0.2, 1.5] |
| $\dot{m}_{cold}$ [kg/s] | [0.2, 1.5] |
| $C_{p.hot}$ [kJ/kgK] | [3.8, 4.5] |
| $C_{p.cold}$ [kJ/kgK] | [3.8, 4.5] |
| $T_{hot}$ [°C] | [70, 200] |
| $T_{cold}$ [°C] | [10, 30] |

The database was created using a for-loop that generated 100 examples, which were stored in a DataFrame1. These data points were then randomly selected by the program during each training step.

## Heat Exchanger Calculations

A core component of the program calculates key performance parameters:

**Effectiveness (ε):** Calculated using the ε-NTU method, considering the number of shell and tube passes. The program implements the necessary equations for single and multiple shell passes.

**Pressure Drop (ΔP):** Calculated using the Darcy-Weisbach equation, with the friction factor determined using the Colebrook equation and the Reynolds number.

**Temperature Profiles:** Calculated by solving discretized versions of the energy balance PDEs for the tube and shell sides, including a stabilizing thermal diffusion term.

The calculate_performance() function takes input parameters (from the database and chosen action) and predefined fluid/tube properties (Table 3) to compute these performance metrics. The hot fluid was consistently assigned to the tube side and the cold fluid to the shell side.

**Table 3:** Predefined parameters for the shell and tube side.

| Parameter | Tube side | Shell side |
|---|---|---|
| Type of fluid | Water | Water |
| Density, $\rho$ $[kg/m^3]$ | 997 | 997 |
| Dynamic viscosity, $\mu$ $[Pa \cdot s]$ | $10.52 \cdot 10^{-3}$ | $10.52 \cdot 10^{-3}$ |
| Thermal conductivity, $\kappa$ $[W/m \cdot K]$ | 0.61 | 0.61 |
| Internal diameter of tubes, $d_i$ $[m]$ | $20 \cdot 10^{-3}$ | |
| Outer diameter of tubes, $d_o$ $[m]$ | $22 \cdot 10^{-3}$ | |
| Tube length, $l$ $[m]$ | 1 | |

## Q-Learning Implementation

The Q-learning algorithm was implemented through a structured framework consisting of an environment, an agent class, and a systematic training process:

Environment Class The reward function combines the effectiveness factor (ε) and pressure drop (ΔP) to evaluate the performance of the heat exchanger. By adjusting the pressure drop to a scale of [0, 22] psi, the model is incentivized to maximize ε and minimize ΔP, promoting optimal design outcomes with high efficiency and low energy loss. The step() function calculates the next state, reward, and a stop criterion based on maximum steps per episode and steps since reward increase. The reset() function initializes the environment for each new data point.

$$reward = \varepsilon + \frac{1}{\Delta P_{psi}} \quad (8)$$

**Table 4:** Total number of configurations based on the action space.

| Tube passes / Shell passes (n) | 2n | 4n | 6n |
|---|---|---|---|
| 1 | (1,2) | (1,4) | (1,6) |
| 2 | (2,4) | (2,8) | (2,12) |
| 3 | (3,6) | (3,12) | (3,18) |

**Agent** Class Implements the Q-learning agent. It initializes with a learning rate (0.1), discount factor (0.9), and epsilon value (0.1). The choose_action() function uses the ε-greedy policy for action selection. The update() function updates the Q-table based on the Q-learning update rule.

**Training Process (training.py):** The training process follows these steps:

1. Read heat exchanger parameters from the database.
2. Initialize the agent and environment.
3. Iterate through episodes (50) and data points (10 per episode).
4. For each data point:
   - Randomly select heat exchanger parameters.
   - Reset the environment.
   - While the stop criterion is not met:
     - Agent chooses an action using ε-greedy.
     - Environment performs the action and returns the next state, reward, etc.
     - Agent updates the Q-table.
5. Store best-performing data points, cumulative rewards, and trained agents.

## RESULTS

The implementation of the program required approximately 48 hours on the specified computer, averaging under one hour per episode. The average reward per episode is shown in Figure 3.

Performance varied significantly across episodes due to the reset of training for each new episode, which provided insight into diverse configurations. The training aimed to optimize performance for specific parameters, achieving near-optimal designs through 5000 simulation steps per episode.

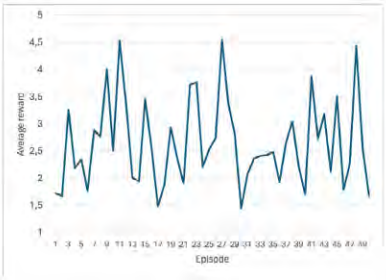

**Figure 3.** Average reward for each episode of the training procedure.

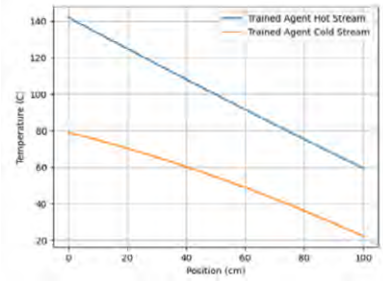

**Figure 4.** Temperature profile for the best performing epoch within data point 10, episode 27.

## Best and Worst Performing Episodes

Episode 27 achieved the highest reward, with an average score of 4.549. Within this episode, data point 10 reached a peak reward of 10.450. The details are presented in Table 5, and the corresponding temperature profile is illustrated in Figure 4.

**Table 5:** Properties of the best performing epoch within data point 10, episode 27.

| Properties | Hot fluid | Cold fluid |
|---|---|---|
| Reward | 10.450 | |
| Effectiveness factor, $\varepsilon$ [-] | 0.687 | |
| Pressure drop, $\Delta P$ [psi] | 0.706 | |
| Overall heat transfer coefficient, U [W/$m^2$K] | 683 | |
| Inlet mass flow, $\dot{m}$ [kg/s] | 0.218 | 0.358 |
| Heat capacity, $C_p$ [kJ/kgK] | 4.392 | 3.891 |
| Inlet temperature, $T_{in}$ [ºC] | 142 | 22 |
| Action, (nº shell passes, nº tube passes) | (1,2) | |

The heat exchanger achieved 69% effectiveness with minimal pressure drop (0.7 psi), using a configuration of one shell pass and two tube passes. Although higher effectiveness might be expected for better performance, the reward function heavily penalizes high-pressure drops, making this configuration optimal. The temperature profiles indicate consistent energy conservation principles, with the hot stream cooling from 142°C to 59°C and the cold stream heating from 22°C to 79°C.

In contrast, episode 30 recorded the lowest reward, averaging 1.450. Data point 2, with a reward of 0.780, stands out as the poorest performer due to a high-pressure drop of 190 psi despite achieving 75% effectiveness. This pressure drop renders the configuration impractical for real-world applications. The suboptimal results highlight the importance of balancing effectiveness and pressure drop for optimal design.

## Optimal Design Insights

Analysis of the top-performing epochs identified the (1, 2) configuration as the most effective design. This configuration consistently achieved superior rewards due to a favorable balance between moderate effectiveness (~69%) and minimal pressure drop (~0.7 psi). Although designs with additional shell or tube passes offered higher effectiveness, they incurred significantly higher pressure drops, reducing their overall performance scores.

## Comparative Analysis

Simpler configurations like (1, 2) outperformed more complex designs, demonstrating the trade-off between heat transfer efficiency and system practicality. The reward system penalized configurations with excessive pressure drops, reinforcing the preference for designs that optimize both criteria.

# CONCLUSION

This work proposed a novel framework for optimizing heat exchanger design using Q-learning, showcasing the integration of Scientific Machine Learning (SciML) with heat exchanger optimization. The model was built upon fundamental heat transfer principles and the ε-NTU method, enabling a thorough performance evaluation based on effectiveness and pressure drop across the heat exchanger.

Q-learning was chosen for its capability to operate without a precise system model, relying instead on trial-and-error exploration to navigate the design space. The model's training process incorporated an environment, an agent, and a structured training sequence, with the agent iteratively maximizing the reward function by exploring various design configurations.

The findings revealed that the simplest design was identified as optimal within the model's constraints, primarily due to the reward function's emphasis on minimizing pressure drop over maximizing heat transfer effectiveness. This outcome underscores the critical role of reward function design in guiding optimization priorities. A comparative analysis demonstrated that while more intricate designs improved heat transfer efficiency, they yielded lower reward scores due to higher pressure drops.

Future improvements to the framework should focus on enhancing its versatility and realism. These enhancements include incorporating a broader range of fluid types, integrating more detailed and accurate heat transfer equations, expanding the diversity of design configurations, and refining the reward function to balance multiple performance parameters more effectively. Additionally, leveraging real-world datasets for training and validation will increase the model's reliability and applicability, paving the way for more robust and practical optimization outcomes.

## ABSTRACT

Operational decision-making in Process Systems Engineering (PSE) has achieved high proficiency at specific levels, such as supply chain optimization and unit-operation optimization. However, a critical challenge remains: integrating these layers of optimization into a cohesive, hierarchical decision-making framework that enables sustainable and automated operations. Addressing this challenge requires systems capable of coordinating multi-level decisions while maintaining interpretability and adaptability. Multi-agent frameworks based on Large Language Models (LLMs) have demonstrated significant promise in other domains, successfully simulating traditional human decision-making tasks and tackling complex, multi-stage problems. This paper explores their potential application within operational decision-making for PSE, focusing on sustainability-driven objectives. A realistic Gas-Oil Separation Plant (GOSP) network is used as a case study, mimicking a hierarchical workflow that spans from initial back-of-the-envelope multi-objective optimization for cost-emissions trade-offs to a negotiation phase reflecting upper management decision-making, and culminating in high-fidelity simulations to validate operational setpoints at the plant level. This workflow serves as a canvas to assess the benefits of multi-agent LLMs, including their ability to integrate multi-layered decisions, enhance the explainability of strategies, and streamline automation in PSE workflows. The results demonstrate the potential of multi-agent LLMs to address the integration challenge in PSE, supporting sustainable and efficient operational decisions. Beyond GOSPs, this research highlights promising applications of multi-agent LLMs across process engineering, contributing to the vision of hierarchical, automated decision-making for the 'plant of the future,' where diverse models and tools operate within an intelligent, unified framework.

**Keywords**: operational decision-making, large language models (LLMs), sustainability, optimization.

## INTRODUCTION

Operational decision-making (ODM) is pivotal in Process Systems Engineering (PSE), serving as the foundation for optimizing the performance, efficiency, and sustainability of industrial processes. In an era where industries face mounting pressure to achieve net zero emissions while maintaining cost-effectiveness, the necessity for robust ODM frameworks has become increasingly critical. Optimization in PSE is conducted at multiple hierarchical levels: system-wide optimization enhances supply chain efficiency by managing the flow of materials, information, and funds; plant-wide optimization focuses on improving operational efficiency within individual plants, such as utility management; and unit operation optimization targets specific processes like reactor performance. Despite these layered approaches, a significant challenge remains—the automation and seamless integration of multi-layered decision-making processes. As industrial systems grow in complexity, there is a need for automated tools that can unify these layers, providing operators with rapid access to comprehensive insights or suggestions. Such automation not only promises substantial cost savings but also facilitates significant reductions in emissions, thereby driving industries toward more sustainable and economically viable operations.

An increasing number of studies are emerging that focus on leveraging Generative Artificial Intelligence (GenAI) within PSE [1]]. GenAI encompasses a range of technologies, including Large Language Models (LLMs),

which are advanced AI systems trained on vast amounts of text data to understand and generate human language. LLMs have found applications in PSE such as supporting the automatic generation of P&IDs [2], and fault detection and diagnosis in chemical processes [3].

## Multi-Agent LLMs

Multi-agent LLMs are a development in GenAI that extends the capabilities of individual language models by orchestrating multiple specialized LLMs, known as agents, to collaborate on complex tasks [4]. Studies indicate that multi-agent LLM systems have the potential to surpass single-agent approaches in both accuracy and complex problem-solving capabilities [5]. In tasks replicating human behavior, multi-agent architectures have demonstrated substantial accuracy gains, with some findings suggesting a direct correlation between the number of agents and overall performance [5]. The "More Agents Is All You Need" approach (Agent Forest) further shows that increasing the number of instantiated LLM agents through sampling and voting can boost accuracy, particularly on difficult tasks [6]. Meanwhile, the Mixture-of-Agents (MoA) approach leverages iterative collaboration among multiple models to address more intricate problems, outperforming single agents on benchmarks such as AlpacaEval 2.0, MT-Bench, and FLASK [7].

Building on these performance advantages, multi-agent LLMs excel in advanced multi-step problems through agent specialization: specialized agents can be developed and dedicated to distinct subtasks or areas of expertise, avoiding reliance on a single model for all problem aspects. Hence, multi-agent systems are inherently modular and thus flexible, making them easier to reconfigure as operational needs evolve. Adding or updating agents—each responsible for a particular function—can often be done with minimal disruption to the broader system. This adaptability ensures that multi-agent LLM frameworks remain robust and scalable, even in rapidly changing industrial or research environments.

Multi-agent LLMs have already seen application across a wide range of industries [8]. For example, ChatDev integrates different phases of the software development lifecycle into a unified communication system using LLM agents. It enhances collaboration through multi-turn dialogues, chat chain organization, and dehallucination, improving software design, coding, and debugging [9]. Compared to its single-LLM counterpart, GPT-Engineer, ChatDev achieves higher Quality (0.3953 vs. 0.1419) and Consistency (0.8021 vs. 0.7887). These results demonstrate that multi-agent systems can outperform single-agent systems, particularly in managing complex, multi-stage tasks [9].

More recent works have demonstrated the implementation of multi-agent systems in process engineering contexts. For example, industrial automation of control systems has been explored using multi-agent frameworks with LLM-based agents, incorporating validation and reprompting architectures to improve accuracy, adapt to dynamic disturbances, and enhance reliability in complex operational environments [10].

## Study Aim

Although multi-agent LLMs have demonstrated success across various industries and are beginning to gain traction in PSE, there remains a substantial opportunity to harness their capabilities specifically for ODM. By leveraging their capacity for complex problem-solving and coordination of multi-step tasks through specialized agents, these systems could serve as a decision-support tool that fully automates and integrates ODM. This, in turn, unlocks significant cost savings and emission reductions, supporting PSE operations in meeting global sustainability targets. This work investigates the application of multi-agent LLM systems for ODM in PSE. This study explores how these systems can represent multiple stakeholders across the decision-making landscape to address the complexities of hierarchical workflows, and focuses on the following key areas:

- **Integration:** Assessing how multi-agent LLMs can integrate the different layers of decision-making, from management to operator level.
- **Negotiation:** Investigating the potential of agents to simulate realistic stakeholder negotiations, addressing trade-offs between competing business units and goals such as economic performance and sustainability.
- **Automation:** Exploring how multi-agent LLMs can reduce human intervention while maintaining transparency and explainability, ensuring that the system's decisions are interpretable and actionable.

Together, these focal points aim to assess the feasibility and transformative potential of multi-agent LLMs in enabling sustainable, efficient, and intelligent decision-making within PSE.

# METHODOLOGY

To explore the potential of multi-agent LLM systems for operational decision-making, it is essential to select a case study that is both realistic and representative of industrial challenges. This curated case study draws inspiration from production planning in the oil and gas industry, a sector characterised by extensive, interconnected supply chains and complex, interdependent decision-making processes that are needed of sustainable operations. The detailed case study, optimization formulation, and HYSYS flowsheet can be found in the work by Bahamdan et al. [11]. This example not only captures multi-layered workflows typical of PSE but also integrates simulation and optimisation components, making it an ideal

testbed for assessing LLMs' tool usage. Furthermore, the cost-emissions trade-off provides a compelling scenario to explore LLM agent negotiation, mirroring real-world industrial decision-making dynamics.

## Gas-Oil Separation Plant (GOSP) Case Study

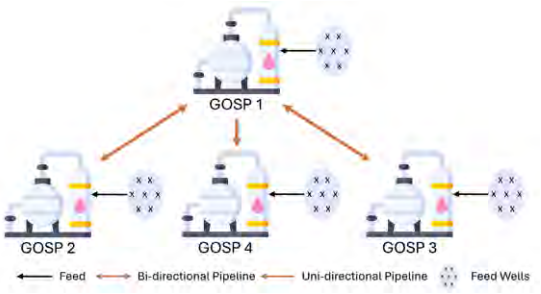

**Figure 1.** Schematic of four interconnected GOSPs connected by uni- and bi-directional pipelines.

This study focuses on the midstream sector of the oil and gas supply chain, which forms the logistical backbone, facilitating the production, processing, and transfer of products. This sector comprises a network of Gas-Oil Separation Plants (GOSPs) that separate oil, gas, and water phases, remove impurities, and ensure products meet customer specifications. These facilities are interconnected via swing pipelines to optimize operations and handle disturbances effectively. A simplified network of four GOSPs, as illustrated in Figure 1, is considered for this study. Each GOSP processes feedstock from a dedicated cluster of production wells. Although all wells within a cluster produce oil of the same grade, feed quality varies slightly but remains within acceptable limits.

Typical GOSPs consist of three main sections: crude oil, associated gas, and oily water. Each incorporates a series of separation vessels and energy-intensive rotating equipment, which contribute significantly to emissions in fossil-based fuel production. This case study builds on recent work that employs state-of-the-art, data-driven methods to decarbonize and optimize GOSP networks by utilizing swing pipelines.

## Hierarchical Decision-Making Workflow

Building on the previously defined 4 GOSP system, this case study examines the production planning process of a typical oil and gas company involving multiple stakeholders from different organizations. Within industry, the production planning process typically follows the following structure. A month in advance, a central planning group receives government-issued monthly production targets. An upstream team uses advanced reservoir simulations to determine optimal production capacities for each well, coordinating with midstream planners to ensure processing systems are ready. Once all parties agree on production targets and midstream capacities, the decision is finalized. Afterwards, separate organizations for production and environmental compliance monitor real-time data to make necessary adjustments for the remainder of the planning period.

Closely mirroring the status quo of industry, this study's production planning process takes the following structure. The objective of the ODM workflow is to determine an operational setpoint for a given schedule, defining the system's cost and emissions through a three-stage decision-making process. The '**Initial Analysis**' stage employs Multi-Objective Optimization (MOO) to balance cost and emissions, generating a Pareto front of operational set points. As Operating Expenses (OPEX) are primarily driven by the power consumption of major equipment, a low-fidelity surrogate was trained on plant operation data to avoid expensive, iterative runs of a process simulation. The surrogate outputs the power consumption of the four major rotating equipment that represent 90% of the total power consumption, which is used as a proxy for cost. Emissions, including scope 1 (flaring and venting) and scope 2 (indirect emissions from power generation) are calculated by using mass balances to determine surplus gas. Model constraints include design capacities for the GOSPs and swing pipelines, material balances, and flow direction of swing pipelines. This problem is formulated as a Mixed-Integer Linear Program (MILP), determining the optimal feed rate for each facility, as well as the swing pipe configuration. The **'Strategic Selection**' involves choosing an operational setpoint from the Pareto front by evaluating trade-offs between cost and emissions, aligning with the management's strategic priorities and considering market and regulatory factors. Finally, the '**Operational Realization**' stage implements the chosen setpoint in system operations, transitioning from theoretical optimization to practical application while accounting for operational uncertainties such as equipment performance variations and external disruptions.

## Multi-Agent LLM Framework

### LLMs and Architecture

The workflow employs two LLM models, both deployed locally using Ollama on an RTX 3060 GPU. Llama-3.1 8B is used for reasoning and decision-making tasks, such as debate evaluation and argument generation. For tasks requiring tool integration, the Llama-3-Groq-8B-Tool-Use model is used, which is fine-tuned for structured tool use and function calling. This model scores 89% overall accuracy on the Berkeley Function Calling Leaderboard used for benchmarking LLM tool usage [12]. The agentic system was implemented using LangGraph, selected for its ability to build workflows around a graph structure. In this framework, agents are represented as nodes, and edges define the routing logic, making the workflow intuitive and easy to visualise. Multi-agent LLM

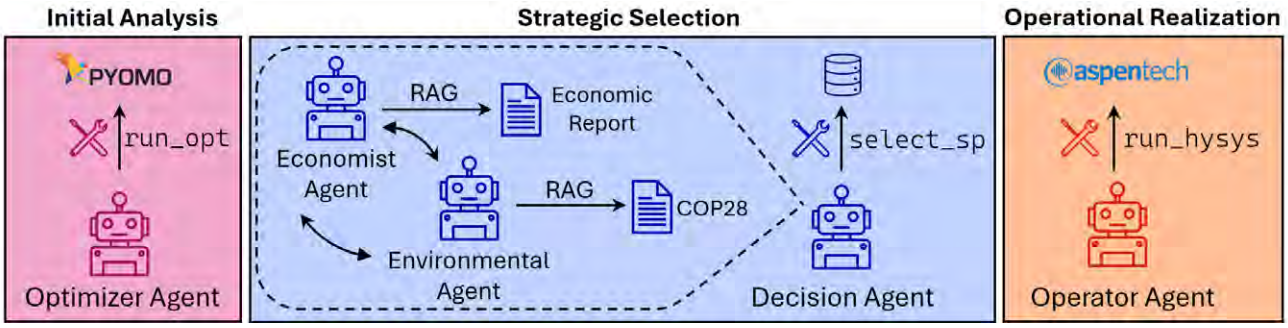

**Figure 2:** Multi-agent LLM workflow: Initial Analysis - The Optimizer Agent utilizes `run_opt` to calculate the Pareto front for a user-given schedule; Strategic Selection - Decision Agent reviews a debate between RAG-enhanced Economist and Environmental Agent and uses `select_sp` to choose the set point; Operational Realization - Operator Agent takes operational parameters at selected setpoint and runs GOSP system using `run_hysys`.

architectures refer to the connections, or edges, that direct workflows between agents [13]. Different architectures are suited to different tasks. For example, sequential architectures are simple and efficient, making them ideal for workflows with clearly defined stages. This workflow employs an architecture that combines the sequential structure to address each decision-making layer systematically and incorporates a cycle for the setpoint debate between Environmental and Economist agents. This design enables focused negotiation, improving decision quality through iterative exchanges without unnecessary complexity.

## Agents and Tools

The workflow relies on three specialized tools to facilitate decision-making and system simulation, as summarised in Table 1.

**Table 1:** Workflow tools and their functionalities.

| Tool | Description |
|---|---|
| `run_opt` | Takes the initial feed, executes Pyomo-based MOO, and returns Pareto front. |
| `choose_sp` | Takes setpoint identifier, retrieves the Pareto front, and returns the selected operational parameters. |
| `run_hysys` | Takes finalized operating schedule, runs a HYSYS simulation, returns key unit operations power consumption and OPEX. |

The framework also integrates Retrieval-Augmented Generation (RAG), which enhances LLM responses by incorporating external documents or knowledge bases, enabling a more informed and contextually relevant output [14]. Both the Environmental and Economic agents employed RAG to strengthen their arguments. The Environmental agent referenced sustainability-focused documents, such as the COP28 report [15]. Meanwhile, the Economic agent had access to economic and corporate documents to support its arguments.

**Table 2:** Overview of agent roles in the workflow.

| Agent | Role Description |
|---|---|
| Optimisation Agent | Extracts the ICF from user input and runs the `run_opt` tool to compute the Pareto front, balancing cost and emissions. |
| Economic Agent | Advocates for cost minimisation in the debate phase. |
| Environmental Agent | Advocates for emissions reduction, using RAG on documents such as COP28 in the debate phase. |
| Decision Agent | Evaluates arguments, selects the setpoint, and retrieves operational parameters with `choose_sp` tool. |
| Operator Agent | Uses `run_hysys` to run operations and validate cost and emissions. |

## Agentic Workflow Description

Figure 2 illustrates the agentic workflow aligned with the three-stage decision-making process. It begins with the Optimisation Agent, which extracts the Initial Condition Factors (ICF) from the user prompt and uses its `run_opt` tool to execute a Pyomo-based MOO. This generates a set of feasible operational configurations for the GOSP which forms a Pareto front representing the trade-off between cost and emissions.

The Economic and Environmental Agents then engage in a structured debate to select the operating setpoint. The Economic Agent advocates for cost minimization, while the Environmental Agent prioritises emissions reduction, using RAG with sources like COP28 to support its arguments. Each agent presents two arguments in turn, advocating for their preferred setpoint.

Next, the Decision Agent evaluates the debate transcript to select the winning setpoint based on argument quality. Using the `choose_sp` tool, it retrieves the corresponding operational parameters from the Pareto front. The Operator Agent uses these parameters with the `run_hysys` tool to interact with the HYSYS simulation,

set stream values, and retrieve power consumption data to calculate the actual OPEX for the chosen configuration.

## RESULTS

The multi-agent LLM framework successfully executed the entire operational workflow in all trials. Upon receiving a user prompt with the latest ICF schedule, the Optimizer Agent generated the Pareto front using the `run_opt` tool. Subsequently, the Decision Agent evaluated the arguments presented by the Economist and Environmentalist agents to select the optimal operational setpoint. Finally, the Operator Agent applied the parameters from the chosen configuration to operate the GOSP network. Across ten runs, the agentic workflow had an average runtime of 79.2 seconds on an RTX 3060 GPU.

### Agent Debate and Decision-Making Process

To evaluate the multi-agent LLM framework's responsiveness to evolving information, two distinct runs were conducted under identical ICF schedules with differing informational inputs. From the back-and-forth exchange between the agents, two quotes are presented to highlight some of the more significant arguments.

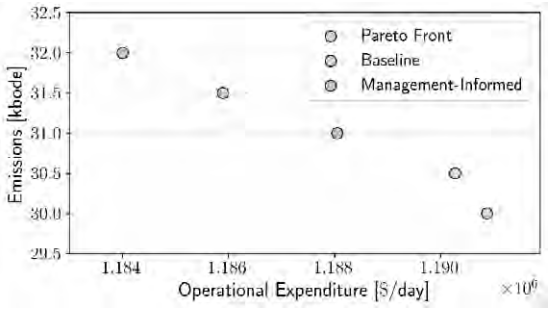

**Figure 3.** Pareto front illustrating the trade-off between operational costs and emissions. Each point represents a feasible operational configuration for the GOSP network.

### Baseline Run

In the initial run, no additional economic directives were provided. The agents engaged in a debate focused solely on balancing emissions and operational costs. The Environmentalist Agent cited global sustainability commitments, emphasizing recent international agreements:

> `At COP28, Parties emphasized the importance of accelerating emissions reductions and promoting a just transition for energy systems worldwide. If we fail to make ambitious choices now, we risk undermining these global commitments.` **`-Environmental Agent`**

Influenced by these arguments, the Decision Agent opted for a setpoint that minimised emissions, resulting in the highest operational cost among available options.

### Second Run (With Economic Directive)

In the next run, an "Economic Directive" document was introduced to the Economist Agent via RAG. This directive stipulated a soft constraint on operational costs of 1,188,500 [$/day], from upper management. Equipped with this information, the Economist Agent adjusted its arguments to align with the new budgetary constraint:

> `Given upper management's directive to keep costs below $1,188,500 per day, we must explore a more balanced trade-off. Setpoint 3 adheres to the strict budget while mitigating emissions.` **`-Economist Agent`**

Consequently, the Decision Agent adopted a setpoint that achieved a balanced compromise between emissions and costs, ensuring compliance with the managerial cost threshold while still addressing environmental concerns. This outcome marked a clear departure from the earlier sustainability-focused solution, illustrating how new information can prompt a recalibration of priorities in the workflow, resulting in a shift in outcome.

Overall, these findings highlight the adaptability of the multi-agent LLM framework. When presented with evolving objectives—be it a sustainability pledge linked to COP28 or a budgetary mandate from upper management—the agents' internal debate naturally reorients toward fulfilling the most pressing constraint. In doing so, the system demonstrates how LLMs, when integrated into an orchestrated multi-agent workflow, can reconcile environmental imperatives with operational costs, integrating new information into decision-making processes. A workflow like the one presented in this work could integrate into the production planning cycle, enabling real-time adjustments to operational parameters to optimize the alignment between planned and actual performance.

## CONCLUSION

In line with this study's aim to explore the potential of multi-agent LLMs for ODM in PSE, our findings demonstrate the efficacy of these frameworks within the midstream sector of the oil and gas supply chain. By leveraging multi-agent LLMs, the framework effectively integrates complex, multi-level decision-making processes in an automated and highly interpretable manner, dynamically adapting to evolving operational constraints and directives. This highlights the ability of multi-agent LLMs to navigate trade-offs, balancing sustainability and economic objectives.

Presented as a decision-support tool to complement human expertise, the multi-agent LLM framework accelerates stakeholder alignment by providing a structured and interpretable approach to complex decision-making. In real deployments, domain experts will remain vital to validating final setpoints, and ensuring adherence to plant safety protocols, corporate objectives, and

operational constraints. Although multi-agent LLMs are rapidly advancing, they still face challenges, such as scalability, model alignment, and governance.

### Future Work

One key direction is expanding argument quality and industrial relevance through RAG by integrating dynamically updated reference documents (e.g., industry standards, real-time news) and proprietary materials (e.g., sustainability reports, financial data). Incorporating live economic or environmental metrics would enhance both precision and relevance. Another focus is generalization and scalability: by adjusting the `run_opt` tool and the MILP, the workflow could handle different numbers of GOSPs of varying capacities. To further validate the benefits of multi-agent LLMs for ODM in PSE, work should explore their use in other sectors, e.g., chemical manufacturing.

Introducing additional agent roles (e.g., Regulatory Agent, Safety Manager) and enabling agents to learn from prior runs or user feedback would enrich the decision-making process. User interaction and overrides also warrant attention, allowing domain experts to review and override decisions, supported by access to Pareto fronts, and debate transcripts. Finally, assessing the framework's robustness under incomplete or conflicting information is critical to ensure feasible outcomes. Addressing ethical and interpretability concerns is equally important for building trust, requiring alignment with ethical standards and clear explanations of agent reasoning.

## ABSTRACT

Balancing economic and environmental goals in industrial applications is critical amid challenges like climate change. Multi-objective optimization (MOO) and multi-criteria decision analysis (MCDA) are key tools for addressing conflicting objectives. MOO generates viable solutions, while MCDA selects the optimal option based on key performance indicators such as profitability, environmental impact, safety, and efficiency. However, large datasets pose a challenge in selecting the preferred solution during the MCDA process This study introduces a novel machine learning-enhanced MCDA framework and applies the method to analyze decarbonization solutions for a European refinery. A stage-wise dimensionality reduction method, combining AutoEncoders and Principal Component Analysis (PCA), is applied to simplify high-dimensional datasets while preserving key spatial features. Geometric analysis techniques, including Intrinsic Shape Signatures (ISS), are employed to refine the identification of typical configurations for baseline evaluations. Once typical configurations are identified, Large Language Models (LLMs) are utilized to enhance decision-making by providing contextual problem explanations and generating weight proposals for the weighted sum method, ensuring alignment with decision criteria. This framework is designed to support stakeholders in making informed, transparent decisions in complex, uncertain environments.

**Keywords**: Artificial Intelligence, Key performance indicator, Machine Learning, Multi-Criteria Decision Analysis

## INTRODUCTION

In chemical engineering, balancing economic and environmental goals is crucial amidst challenges like climate change. To address conflicting objectives, tools like multi-objective optimization (MOO) [1] and multi-criteria decision analysis (MCDA) [2] are utilized. MOO generates a range of viable solutions on Pareto fronts, while MCDA helps select the most suitable option considering key performance indicators (KPIs) like profitability, environmental impact, safety, and efficiency. These tools aid in making informed decisions amidst complex trade-offs and uncertainties. However, the vast number of solutions generated by MOO presents a significant challenge, as it is impractical for human decision-makers to compare and analyze all configurations manually. This raises a critical question: how can preferred solutions be effectively selected from such a large solution database?

The selection process is generally divided into two steps: first, identifying typical configurations from the database, and second, selecting preferred configurations from this identified set based on MCDA.

To identify typical configurations, data-driven approaches have garnered significant attention, particularly those utilizing clustering methods [3]. These methods analyze the solution space by dividing it into several clusters instead of examining the entire dataset. This approach effectively captures the global distribution of the data by segmenting it into distinct groups. However, existing clustering techniques are generally based on selected KPIs of each configuration, like operating costs, which are typically calculated under uncertain market conditions. Configurations should instead be analyzed based on their inherent features, where each feature represents an independent dimension such as the material and energy flows describing the configuration. Notably,

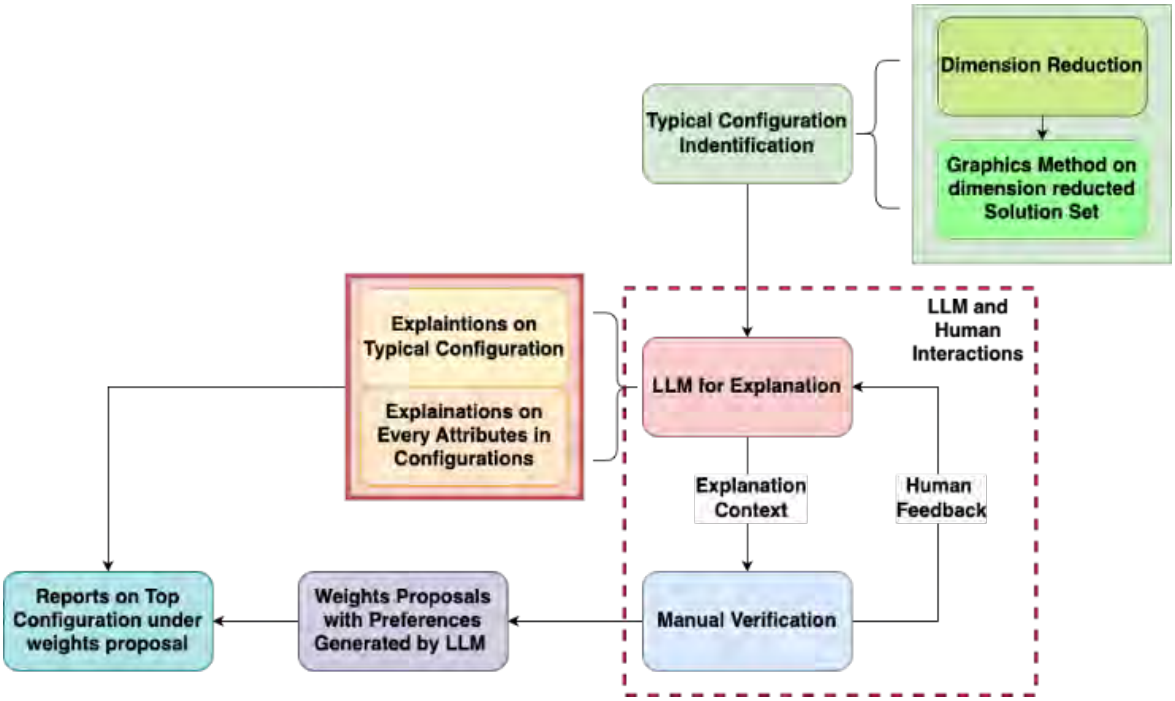

**Figure 1.** Method of feature-oriented MCDA processes

two different configurations may share the same KPIs despite being fundamentally distinct. Consequently, KPI-based clustering may fail to accurately represent the underlying differences among configurations. In addition, a notable drawback of the traditional clustering method is the neglect of intra-cluster distributions. The loss of local features within clusters can significantly impact the depth and accuracy of the analysis.

For preferred solution selection, the weighted sum method [4] remains the most popular approach in both research and industry. This method involves assigning a weight to each KPI, computing the score of each solution, ranking the scores, and selecting the top configurations as optimal solutions. Despite its widespread use, this approach suffers from several limitations:

**Lack of Diversity:** Due to the inherent properties of Multi-Objective Optimization (MOO), solution datasets often contain repeated configurations. As a result, the top-ranked solutions derived from the weighted sum method frequently share the same configuration, leading to a lack of diversity in the selected solutions.

**Limited Individual-Oriented Decision Making:** The subjective nature of weight assignments also poses challenges for accommodating diverse perspectives, which can hinder personalized or individual-oriented decision-making. The core of the weighted sum method lies in the assignment of weights to each KPI, which translates user preferences into quantifiable metrics. This process often requires domain expertise, making it challenging to generalize. Furthermore, the assigned weights are highly influenced by the individual expert's subjective preferences, introducing bias into the decision-making process.

**Difficulty in weight collection:** Gathering accurate and reliable weights for KPIs is a significant challenge. The process requires domain expertise and often lacks sufficient data support, making it difficult to establish objective and robust weight assignments.

To address these issues, a novel method is proposed that utilizes machine learning techniques, specifically Large Language Models (LLMs), to enhance the MCDA process under uncertain market conditions. The weight proposals for the weighted sum method are generated using the LLM model by incorporating specific preferences, eliminating the need for random identification or sole reliance on expert judgment. The primary contribution of this work lies in applying advanced machine learning methods to capture both global and local features in the solution space while leveraging LLMs for weight generation and MCDA.

## METHODS AND MATERIALS

The method is outlined in Figure 1, beginning with the identification of typical configurations, followed by the application of an LLM model to generate weight proposals for different KPIs to support the selection of preferred configurations.

### Typical Solution Identification

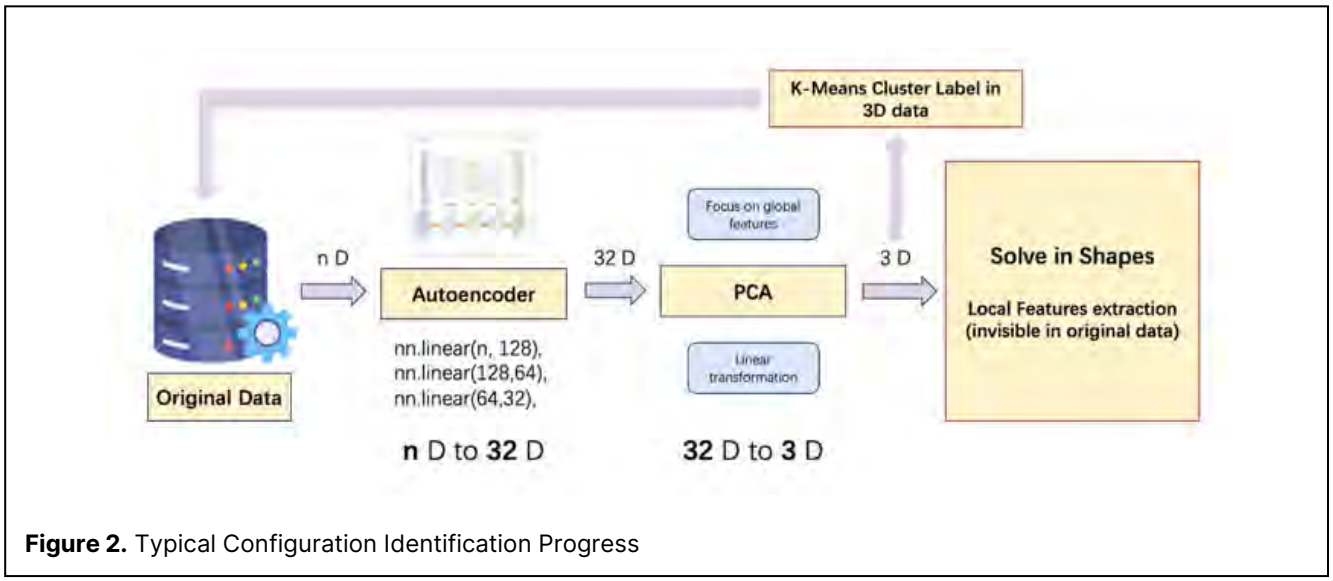

**Figure 2.** Typical Configuration Identification Progress

In complex energy systems, configurations often involve a vast number of features, making them a high dimension space impractical for manual analysis. Dimension reduction serves as an effective strategy to address this issue by simplifying the scale of the data while retaining its essential features. Clustering methods are then applied in dimension reduction datasets to identify the representative configurations, as shown in Figure 2.

## Dimension Reduction

In this study, the Linear Combiner (LC) is proposed, a two-stage dimensionality reduction approach combining AutoEncoder [5] and Principal components analysis (PCA) [6] to enhance clustering performance on high-dimensional datasets. The PCA can identify the linear connections in the resulting dataset in linear space. However, the feature space exhibits non-linear relationships due to interdependencies. The Autoencoder captures the complex, nonlinear structures of the data by reducing the input dimensionality to an intermediate dimensional latent space. Subsequently, PCA is applied to further reduce this latent representation to 3 dimensions, effectively preserving the most significant linear features while eliminating redundant information.

To validate the effectiveness of the approach, its ability to preserve the essential spatial distribution characteristics of the data after dimensionality reduction is evaluated. Clustering is performed in a three-dimensional space, and the resulting cluster labels are projected back to the original high-dimensional space, which is assessed using two metrics: the Davies-Bouldin Score (DB Score) [7] and the Calinski-Harabasz Index (CH Index) [8].

## Clustering based on the graphical method

In the pursuit of identifying the most representative solutions within the dataset, cluster centroids obtained through the K-Medoids method are selected as the reference case. However, empirical observations revealed critical limitations in this approach. The derived cluster centers proved overly dependent on intra-cluster density distributions, occasionally failing to encapsulate the essential characteristics that define typical configurations across the entire solution space. This realization motivated the development of a more robust identification strategy.

Building on the prior dimensionality reduction of the dataset into three-dimensional embeddings, graphical are used to extract latent spatial patterns that reveal structural relationships and density variations hidden in high-dimensional data. This 3D projection creates a visually interpretable landscape, where topological properties and neighborhood continuity can be algorithmically quantified, offering a more robust criterion for identifying typical configurations beyond centroid proximity. To achieve this, an advanced technique from graphics and computer vision—Intrinsic Shape Signatures (ISS) [9], is employed, providing a unique perspective to better understand the dataset's structure and identify typical configurations.

## LLM for MCDA

To effectively integrate Large Language Models (LLMs) into Multi-Criteria Decision Analysis (MCDA), the first step is to enable the LLM (e.g., ChatGPT series [10]) to comprehend the dataset. This involves providing the model with a curated subset of typical configurations rather than the entire dataset, as processing large datasets directly is impractical. The LLM is tasked with generating explanations for each attribute in the dataset, enhancing its reasoning ability through structured prompts and human verification. By manually verifying the explanations provided by the LLM, one can assess whether the LLM has properly understood the dataset. This allows the LLM to interpret the data contextually and provide meaningful

insights, paving the way for subsequent weight generation and decision-making processes.

## Data set interpretation

The reasoning ability of LLMs is crucial for accurate dataset interpretation. To enhance this capability, hierarchical explanation mechanisms and structured prompting are implemented to improve depth, accuracy, and reliability. Additionally, a human verification mechanism is introduced, enabling experts to review and validate AI-generated outputs at key stages. This interactive process identifies and corrects potential errors or biases while refining the model's reasoning through iterative feedback. By integrating human oversight, the framework ensures reliable, domain-aligned outputs, significantly enhancing the system's robustness and credibility.

**Hierarchical Explanation**:

A hierarchical explanation approach is applied, instructing the large language model (LLM) to first categorize attributes into their respective subcategories, and then provide detailed explanations for each attribute based on its assigned category. This method is beneficial because it enforces a structured organization of data, increasing the inductive bias, reducing hallucination, and enabling clear verification of each reasoning step. The overall workflow (Figure 3) proceeds as follows: (1) Identify attributes that require explanation. (2) Classify attributes into relevant subcategories. (3) Provide detailed explanations for each attribute under its subcategory. (4) Present the final output by listing each attribute's classification alongside its detailed explanation.

Meanwhile, a verified explanation ensures the stakeholders without mathematical expertise can interpret and validate decisions, which is particularly useful in a diverse disciplinary team.

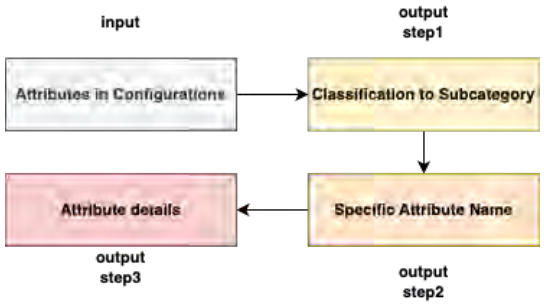

**Figure 3.** Hierarchical Explanation for increasing the reasoning ability of the LLM agent

**Prompts Structure**: To further enhance the reasoning process, a structured prompting framework is designed inspired by the Chain of Thought (CoT) and its related research [11], which has demonstrated significant improvements in reasoning tasks. This framework involves 3 independent LLM agents proposing distinct strategies, each addressing specific aspects of the problem. These strategies are then evaluated through a voting mechanism by a panel of 5 additional LLM agents, ensuring an unbiased assessment. The most effective strategy is subsequently selected and refined into an optimal solution, integrating the strengths of individual proposals while minimizing potential biases and limitations. Notably, all 8 experts involved in this process are distinct LLM agents.

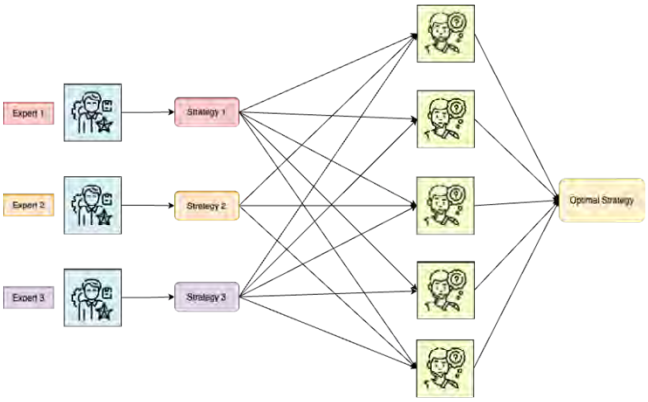

**Figure 4.** Prompts Structure with 3 experts for strategy generating and 5 experts for voting

## Weights Proposals Generation

For weight generation, three key inputs are utilized, including user-defined preference settings, typical configurations identified in previous sections, and explanations generated by LLMs. This process leverages the structured prompting framework introduced earlier, which guides the weight assignment in a manner analogous to group-based decision-making mechanisms. Specifically, the framework facilitates the aggregation of preferences and the systematic integration of insights from the three inputs, ensuring a balanced and well-informed weight assignment process.

Traditional weight generation in MCDA often relies on expert input, which presents several challenges, including the need for domain expertise, difficulty in collecting reliable weight proposals, and potential bias from individual preferences. Moreover, integrating multiple expert opinions into a coherent weighting scheme remains a complex task. In contrast, LLMs offer a more flexible and scalable alternative. With their extensive training in diverse knowledge sources, LLMs can generate weight proposals more efficiently, accommodate various preference settings, and reduce dependence on subjective expert judgment. This approach enhances efficiency and consistency in decision-making while allowing for greater adaptability across different application scenarios.

# CASE STUDY

The method is applied to rank solutions for decarbonizing petroleum refining processes. The case study is

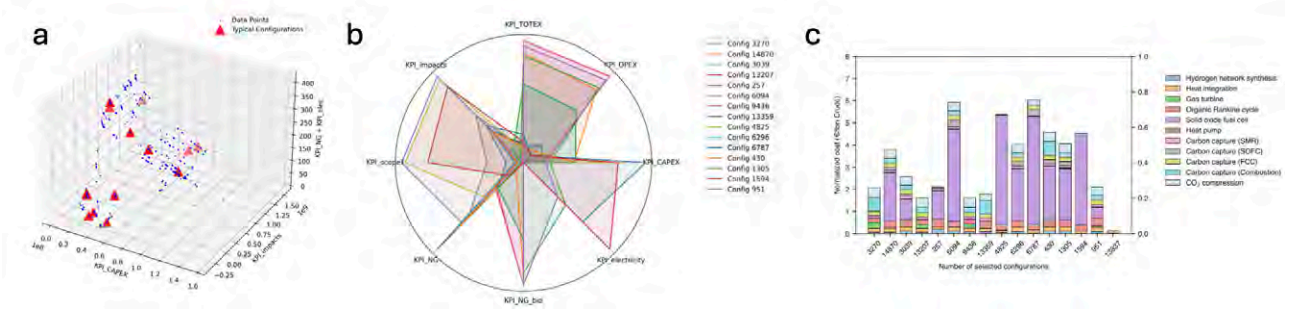

**Figure 5:** (a) Clustering results visualized in a 3D solution space using KPI_CAPEX, KPI_impacts, and the sum of KPI_NG, and KPI_elec. **(b)** Selected configurations displayed in a radar graph with key KPIs. **(c)** Selected configurations represented by features, indicating the size of different decarbonization technologies implemented in the refinery.

based on a superstructure of refining processes integrating various decarbonization technologies, including energy efficiency measures, carbon capture and storage, low-carbon hydrogen, and renewable energy resources. A total of 16,000 decarbonization configurations are generated using a MILP formula to balance the trade-offs between investment, electricity and natural gas consumption, and $CO_2$ emissions (Scope 1 and Scope 2). Solutions are derived under a wide range of market and other conditions, considering factors such as natural gas and electricity prices, carbon pricing policies, and electricity carbon footprint. Each of the 16,000 configurations represents an optimal solution for a specific set of input conditions.

Each configuration is represented by two data sets: KPIs and features. The KPI set includes total cost (KPI_TOTEX), operating costs (KPI_OPEX), annualized investment (KPI_CAPEX), and resource consumption metrics such as natural gas, biogas, and electricity usage (KPI_NG, KPI_NG_bio, and KPI_electricity), along with scope 1 and scope 2 emissions (KPI_scope1 and KPI_scope2). These KPIs are derived from the material and energy flows as well as the installed units, which constitute the configuration's features. Unlike KPIs, which vary based on different conditions, features remain constant for a given configuration.

# RESULTS

## Typical configuration identification

Figure 5(a) visualizes the dimension-reduced dataset, with 16 clustering centers highlighted by red triangles, identified using the graphical methods described in the method section. Clustering performance is quantified using established metrics. The selected configurations are further presented by their KPIs (Figure 5(b)) and features, such as the installed capacity of decarbonization technologies (Figure 5(c)). This provides a clearer representation, demonstrating that the selected configurations are distinct in both KPIs and features.

## Preferred configuration selection

Dataset interpretations were first generated independently by LLM, incorporating hierarchical explanation and structured prompting to enhance its reasoning ability. However, as shown in Figure 6, three key misinterpretations were identified in the initial LLM explanation: (1) *KPI_impacts* should only include scope 1 and 2 emissions, (2) *KPI_CAPEX* should be annualized, and (3) Heat Exchange Variables should be treated solely as intermediate computational values. Notably, despite lacking predefined conditions, the LLM correctly avoided assigning weights to Heat Exchange Variables. After manual feedback alignment, the second iteration showed a significantly improved understanding of the dataset and problem, leading to a more accurate interpretation.

Following the correct understanding achieved through human alignment with the LLM-generated context, Figure 7 presents an example of the complete weights-generation process. From the outset, the priority was set to "Focusing on the Environmental Impact." The deduction progress in weights generation follows the structure of the prompts we designed in the previous section, prompting experts to vote on various KPIs. After consolidating the voting results, higher weights were allocated to KPIs most strongly tied to environmental impact, while moderate values were assigned to other attributes like CAPEX and OPEX. This iterative, feedback-driven approach demonstrates how the LLM can integrate expert judgment and maintain alignment with an overarching priority—namely, reducing environmental impact—within its weights-generation process.

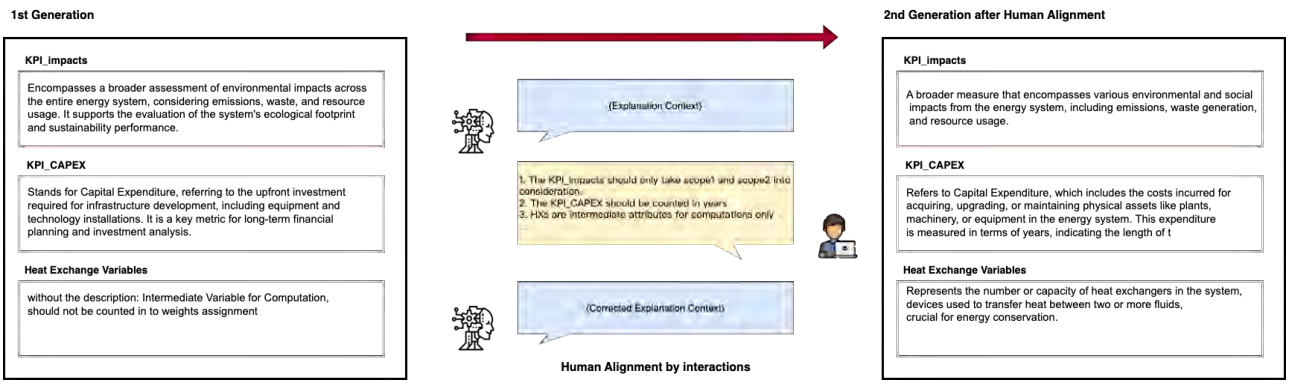

**Figure 6:** The Human Alignment progress in case study to ensure the AI-generated context trustworthy

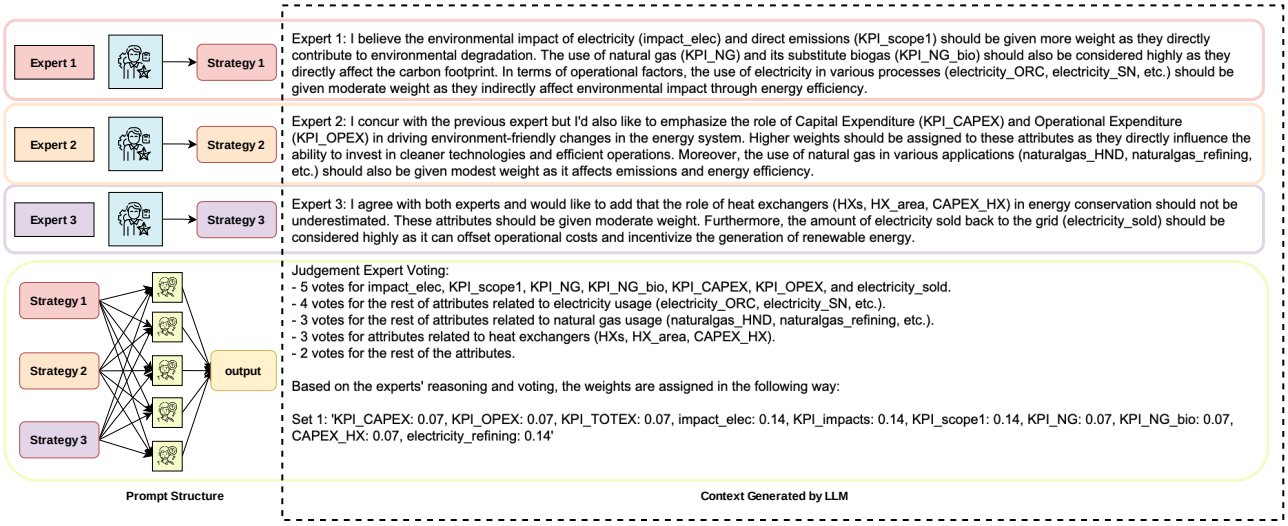

**Figure 7:** The Deduction Progress of generating the weights proposals withthe preferrence is setted as the "focus on Environmental Impact" and the weights proposal is listed in Set 1.

Figure 8 presents the ranking results obtained from the weighted sum method, with weights generated by the LLM agent as illustrated in Figure 8. The top-ranked configurations (e.g., Configurations 257, 4825, and 1594) exhibit varying ranking weighted sum scores under the focus on "Environmental Impact," as they are identified as typical configurations. Figure 5(b-c) highlights the corresponding KPIs and features of these configurations, revealing distinct characteristics and orientations that contribute to their differentiation within the solution space.

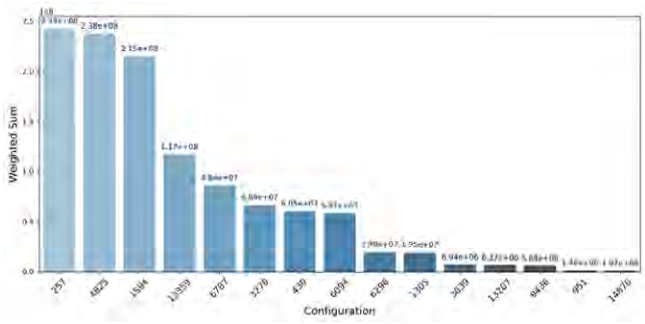

**Figure 8.** Typical Configuration weighted sum scores are computed with weights generated by LLM.

## DISCUSSION

This study presents a feature-oriented MCDA framework with machine learning method that addresses key challenges in selecting preferred solutions from large industrial datasets. First, by integrating dimensionality reduction and geometric analysis, our approach effectively captures both global and local structural features, enhancing decision-making transparency and robustness. Second, through hierarchical explanation, prompt engineering, and human verification, the LLM-assisted explanation and weight generation process reduce reliance on subjective expert input, ensuring consistency, efficiency, and adaptability in preference-based decision-making across diverse industrial applications.

Applied to refinery decarbonization, our framework successfully identifies representative solutions while ensuring diversity and interpretability in high-dimensional solution spaces. Additionally, the AI-driven methodology leverages Large Language Models (LLMs) with enhanced

reasoning ability to provide context-aware explanations for decision attributes and generate weight proposals aligned with user preferences. This approach reduces reliance on subjective expert input and improves decision-making efficiency. This scalable, interpretable, and adaptable solution demonstrates its applicability to complex multi-criteria decision-making problems.

## ABSTRACT

Physics-Informed Symbolic Regression (PISR) offers a pathway to discover human-interpretable solutions to partial differential equations (PDEs). This work investigates three fitness metrics within a PISR framework: PDE fitness, Bayesian Information Criterion (BIC), and a fitness metric proportional to the probability of a model given the data. Through experiments with Laplace's equation, Burgers' equation, and a nonlinear wave equation, we demonstrate that incorporating information theoretic criteria like BIC can yield higher fidelity models while maintaining interpretability. Our results show that BIC-based PISR achieved the best performance, identifying an exact solution to Laplace's equation and finding solutions with $R^2$-values of 0.998 for Burgers' equation and 0.957 for the nonlinear wave equation. The inclusion of the Bayes D-optimality criterion in estimating model probability strongly constrained solution complexity, limiting models to 3-4 parameters and reducing accuracy. These findings suggest that a two-stage approach-using simpler complexity metrics during initial solution discovery followed by a post-hoc identifiability analysis may be optimal for discovering interpretable and mathematically identifiable PDE solutions.

## INTRODUCTION

Understanding dynamical system models, their solutions, and potential failures is critical, especially in safety, health, and security. Traditionally, symbolic models with identifiable parameters, input-output relationships that provide tractable logic, and physically meaningful terms have established trust in deployed models [1]. However, these techniques to establish trust are ineffective for machine-learned models. Consequently, while machine learning has motivated advancements in understanding black-box model decisions [2], the simplicity and clarity of concise symbolic expressions make them inherently more straightforward to understand than their deep learning counterparts.

Dynamical system models often take the form of differential equations (DEs). When properly built and used, DEs enable engineers and scientists to predict future or hidden states while also explaining the underlying phenomena which drive system dynamics. Thus, DE-based system models are crucial for making informed decisions in process design and control.

Because of their importance, significant effort has been dedicated to simplifying and solving systems of PDEs [3,4]. Various methods for DEs include identifying coordinate transformations to simplify dynamics [5], linearizing models for rapid prediction and control, and finding analytical solutions to replace differential equations with algebraic relationships where possible. Depending on the DE and its application, different methods may be preferred. However, among the most challenging DEs to manage are those that include partial differential equations (PDEs).

Prominent in fluid flow, chemical reactions, and biological systems [6], PDEs can exhibit complex dynamics that make identifying solutions difficult. Common approaches for discovering PDE solutions are challenging to implement and require highly specialized skills and knowledge. Often PDE models can be linearized to leverage linear PDE theory, and Taylor series expansions can be used to find solutions via perturbation theory or finite differences among other methods. However, these

solution paths are subject to strict convergence and stability conditions that are difficult to meet.

Alternatives to traditional methods are emerging from the field of machine learning [7]. Large foundation models for physics can help predict dynamics across various domains. Focusing on smaller problems, tools like DeepONets can learn neural operators that map inputs to outputs [8], while physics-informed machine learning methods can learn solutions to PDEs with known initial/boundary conditions [9, 10]. Although many of these tools are changing the way PDEs are solved, they often fall into the same pitfalls as other use cases of machine learning: the solutions they produce lack interpretability.

One exception to the lack of interpretability in machine learning for PDEs is physics-informed symbolic regression (PISR) [11, 12]. PISR leverages symbolic regression (SR) to produce solutions to PDEs in symbolic form. Previous works have shown that PISR can learn exact analytical solutions to PDEs when they exist and provide good approximations with physically meaningful terms when analytical solutions do not exist [11, 12]. Therefore, as an approach to simplify PDEs into explicit algebraic relationships, PISR is particularly attractive when model trust is important.

An important aspect of building model trust is to ensure that all model parameters are mathematically identifiable [1]. In this work, we explore various information-theoretic criteria as fitness metrics within PISR, beyond the metrics used in [11, 12], to learn interpretable solutions to PDEs that are simple, and concise. We examine the effect of the fitness criterion (loss function) within PISR on the discovered solutions through three examples: Laplace's equation, Burgers' equation, and a nonlinear wave equation.

The remainder of this paper is structured as follows: First, the PISR method and motivating examples will be introduced along with three fitness criteria. Following the methods, the results of our experiments are presented and briefly discussed. Finally, the paper concludes with a summary of the results and findings.

## Methods

The goal of PISR is to discover an explicit mathematical relationship that provides tractable logic from coordinate inputs to state outputs, ensuring consistency with a known PDE. This is achieved using symbolic regression. As the symbolic regressor generates different expressions, their derivatives are determined using automatic differentiation and evaluated against the known PDE. A solution with good fitness will have derivatives that satisfy the PDE, while those of an unfit solution are unlike to agree with that PDE. The symbolic regressor can take advantage of different fitness metrics to search for an optimal solution to a known PDE.

## Symbolic Regression

In this work, genetic programming (GP) is used to perform the symbolic regression. GP is an evolutionary algorithm that operates on a population of mathematical expressions, represented as binary expression trees, to explore the space of feasible expressions. Each individual in the population is constructed using an argument set and a primitive set. The argument set includes all arguments for the final model, while the primitive set is comprised of all mathematical operations that can appear in the model.

Genetic operators, along with evolutionary pressure from the selected fitness criterion and a tournament selection, iteratively evolve a population of expressions towards optimal fitness. Tournament selection is implemented using the selTournament method from the open-source evolutionary algorithm framework DEAP [13]. The genetic operators used can be categorized into crossover and mutation. In each generation, the population selected for offspring generation through tournament selection is subjected to these operators.

Crossover, an exploitative process, shuffles subexpressions from two individuals to create two offspring. The crossover operator used here is DEAP's cxOnePoint [13]. Complementary to crossover, mutation is an exploratory process that makes random changes to a single individual to generate one offspring. Each expression used to generate offspring is operated on by one of four operators each generation: mutShrink, mutInsert, mutNodeReplacement, and mutUniform from DEAP's library [13]. This combination of mutation operators helps explore the symbol space while reducing bloat, or the tendency of symbolic regression to evolve overly complicated expressions.

Once the population of offspring is generated using genetic operations, they are added to the total population along with a hall of fame that is made of the fittest individuals ever evolved. To promote diversity, some individuals are randomly removed. Before the next tournament selection can begin, fitness values must be calculated for any new individuals.

## Fitness Metrics

Fitness metrics are crucial in ensuring that the evolutionary pressure from the tournament selection process eliminates unfit individuals. However, different fitness measures may yield different solutions for the same PDE. Therefore, it is important to investigate the effect of different fitness criteria on the solutions learned for PDEs using PISR. Here, we introduce three fitness criteria used in the discovery of solutions to PDEs in this work.

### PDE Fitness

The first fitness criterion is the simplest PISR fitness metric, $\mathcal{L}_{PDE}$, which is defined in Equation 1. $N_C$ represents the number of collocation points at which the nonlinear

PDE $F\left(x, u(x), D^{\alpha^1}u(x), D^{\alpha^2}u(x), \ldots, D^{\alpha^m}u(x)\right) = 0$, written using multi-index notation, is evaluated in the $n$-dimensional domain $X \subseteq \mathbb{R}^n$. The variables $\lambda_0$, $\lambda_j$, $N_{BCs}$, $N_{BC_j}$, and $\Gamma_j$ respectively represent hyperparameters for the PDE, hyperparameters for each boundary condition, the number of boundary conditions, the number of collocation points on the $j^{\text{th}}$ boundary condition, and the $j^{\text{th}}$ boundary condition. The goal of $\mathcal{L}_{PDE}$ is to capture how well an expression represents a PDE and its initial and boundary conditions.

$$\mathcal{L}_{PDE} = \lambda_0 \sum_{i=1}^{N_C} F(\mathbf{x}_i, u(\mathbf{x}_i), \ldots)^2 + \sum_{j=1}^{N_{BCs}} \lambda_j \sum_{k=1}^{N_{BC_j}} \Gamma_j(\mathbf{x}_k, u(\mathbf{x}_k), \ldots)^2 \quad (1)$$

To calculate $\mathcal{L}_{PDE}$, the derivatives of the expression being evaluated must be determined. In this work, we used the automatic differentiation tool CasADi [14] to obtain exact derivatives quickly and efficiently. Next, those derivatives must be used to evaluate $F$ at the $N_C$ collocation points and each $\Gamma_j$ at the $N_{BC_j}$ collocation points. **Table 1** shows a symbolic evaluation of $F = u_t - \alpha u_{xx} = 0$ with constant $\alpha$ for two different expressions, demonstrating how $\mathcal{L}_{PDE}$ can be determined.

**Table 1:** Example of symbolic evaluation of $F = u_t - \alpha u_{xx}$ for different expressions when $\alpha$ is a constant.

| $u$ | $u_t$ | $u_{xx}$ | $F$ |
|---|---|---|---|
| $t - \alpha x^3$ | $1$ | $-6\alpha x$ | $1 + 6\alpha^2 x$ |
| $\exp(-\alpha\omega^2 t)\sin(\omega x)$ | $-\alpha\omega^2 u$ | $-\omega^2 u$ | $0$ |

## Bayesian Information Criterion

A limitation of $\mathcal{L}_{PDE}$ is that it only evaluates how well the proposed expressions satisfy the PDE and boundary conditions at the collocation points. While this is crucial for obtaining accurate solutions to PDEs, it is also important to consider the complexity of the relationships between the input coordinates and the state output. $\mathcal{L}_{PDE}$ does not provide safeguards against excessing model complexity, meaning the symbolic regressor can quickly suffer from expression bloat and learn overly complicated expressions that are difficult to interpret and understand.

One potential remedy to this limitation is to use the Bayesian Information Criterion (BIC) [15]. The BIC is an information-theoretic criterion that helps mitigate model complexity by balancing the fitness of the expression in terms of both its agreement with the PDE and its complexity. Equation 2 calculates the BIC, where $N_{points}$ represents the weighted number of collocation points used (given by $\lambda_0 N_C + \sum_{j=1}^{N_{BCs}} \lambda_j N_{BC_j}$), and $k$ denotes the model node complexity, which is determined by counting the number of nodes in the expression tree.

$$\mathcal{L}_{\text{BIC}} = N_{points} \log \mathcal{L}_{PDE} + k \log N_{points} \quad (2)$$

## Probability of Solution

The BIC is often a powerful criterion for identifying concise and descriptive expressions in symbolic regression. However, in many cases, simply balancing model complexity and fit does not guarantee that the model is identifiable. To ensure that each model parameter is mathematically identifiable based on the information provided, an additional term must be used.

A strong candidate for this additional term is the Bayes D-optimal criterion, $\Psi_D$ [16]. $\Psi_D$ is an information-theoretic criterion that uses the determinant, denoted as $|\cdot|$, of the Fisher Information Matrix (FIM) to give insight into the precision of parameter estimates. It can help determine if a model is identifiable, meaning that there exits a unique parameter set defining the optimal solution [16]. $\Psi_D$ also appears in the derivation of the BIC but is omitted in its final form due to asymptotic assumptions.

The FIM can be calculated using the sensitivity matrix $\mathbf{Q} = \nabla_{\boldsymbol{\theta}} \mathcal{L}_{PDE}$, where $\boldsymbol{\theta}$ is the vector of parameters proposed by the symbolic regressor. Typically, the sensitivity matrix is calculated with a variance term to account for noise in the data. However, in PISR, since there is no data, this variance term is omitted, implicitly assuming a variance of $1$. With $\mathbf{Q}$ defined, we can now introduce the third fitness criterion, $\mathcal{L}_{BIC,\Psi_D}$, as shown in Equation 3. This criterion is proportional to approximate probability of the PDE given the model $m$ at the maximum likelihood estimator $\widehat{\boldsymbol{\theta}}$, $p(F|m)$, which is derived using the same process as the derivation of the BIC.

$$\mathcal{L}_{BIC,\Psi_D} = \mathcal{L}_{BIC} - \log\left|\mathbf{Q}^{\mathrm{T}}\mathbf{Q}\right| \quad (3)$$

## Test Cases

With the fitness criteria established, the performance of PISR using each criterion must be assessed. This evaluation was conducted using three two-dimensional second-order PDEs. For each criterion and PDE pair, PISR was run 50 times, with support from a $30 \times 30$ grid of collocation points. The PDEs and boundary conditions were evaluated on this grid, and each run produced a hall of fame containing the 10 most fit evolved solutions. The experiments were executed on an Intel® Xeon® W7-2495X processor across 10 threads.

Solution evaluation was carried out on a $50 \times 50$ gird of points, where the true solution at each point was computed either using an exact analytical solution or a numerical method. The symbolically regressed models were compared using three metrics: mean-squared error (MSE) against the ground truth, the $R^2$-value against the ground truth, and model parameter complexity, $N_p$, defined as the number of parameters in the model.

## Laplace's Equation

The first PDE investigated was Laplace's equation, a second-order linear PDE with an exact analytical solution for the boundary conditions specified in Equation 4. Laplace's equation is a fundamental PDE in process

systems engineering, as it models many steady-state phenomena such as heat transfer and diffusion. The domain for this PDE, as explored in this study, was $(x, y) \in [0,1] \times [0,1]$. The primitives used to discover solutions to Laplace's equation were $\{+, -, \exp, \sin, \sinh\}$, with arguments $\{x, y\}$. The tuning parameters for $\mathcal{L}_{PDE}$ were selected as $\boldsymbol{\lambda} = [0.001, 0.8, 0.8, 80, 0.8]$.

$$\begin{aligned} u_{xx} + u_{yy} &= 0 \\ u(x,y) &= 0 \quad \text{when } x = 0 \\ u(x,y) &= 0 \quad \text{when } x = 1 \\ u(x,y) &= \sin(2\pi x) \quad \text{when y} = 0 \\ u(x,y) &= 0 \quad \text{when y} = 1 \end{aligned} \tag{4}$$

### Burgers' Equation

The second PDE explored in this work was Burgers' equation, which is often used to describe one-dimensional viscous fluid flow. It is a quasi-linear second-order PDE in two dimensions and does not have an exact strong form analytical solution. The domain considered in this work was $(x, t) \in [0,10] \times [0,10]$. The primitives used to discover solutions to Burgers' equation were $\{+, \times, \exp, \sin, \sinh, u_{diff}\}$, where $u_{diff}$ is the solution to the diffusion equation with the same initial and boundary conditions in Equation 5, solved using eigenfunction expansion. For more details on the method of the primitive set selection see [12]. The arguments used were $\{x, t\}$, and the tuning parameters for $\mathcal{L}_{PDE}$ were $\boldsymbol{\lambda} = [1, 0.8, 0.8, 0.8]$.

$$\begin{aligned} u_t - 0.1u_{xx} - 0.2uu_x &= 0 \\ u(x,0) = \exp -0.2(x-5)^2 \quad &\text{when } t = 0 \\ u_x(0,t) &= 0 \quad \text{when } x = 0 \\ u_x(10,t) &= 0 \quad \text{when } x = 10 \end{aligned} \tag{5}$$

### Nonlinear Wave Equation

The third and final PDE explored in this work was the nonlinear wave equation, which is commonly used to model waves in shallow water. It is a nonlinear second-order PDE in two dimensions and, like Burgers' equation, does not have an exact analytical solution. The domain considered in this work was $(x, t) \in [0,1] \times [0,1]$. The primitives used to discover solutions to the nonlinear wave equation were $\{+, \times, \exp, \sin, \sinh, \mathrm{u_{linwave}}\}$, where $u_{linwave}$ is the analytical solution to the linear wave equation with the same initial and boundary conditions in Equation 6. The arguments used were $\{x, t\}$, and the tuning parameters for $\mathcal{L}_{PDE}$ were $\boldsymbol{\lambda} = [0.1, 0.8, 0.8, 80]$.

$$\begin{aligned} u_{tt} - u^2 u_{xx} &= 0 \\ u(x,0) = \frac{1}{2}\sin(3\pi x) \quad &\text{when } t = 0 \\ u(0,t) &= 0 \quad \text{when x} = 0 \\ u(1,t) &= 0 \quad \text{when } x = 1 \end{aligned} \tag{6}$$

## RESULTS AND DISCUSSION

The results of our experiments demonstrate that the selection of fitness criterion can significantly influence the solutions discovered using PISR. When model complexity is considered during exploration, PISR tends to return models with fewer parameters. Moreover, when PISR produces models with more parameters, those trained with complexity considerations align better with the solution to the PDE compared to those trained without considering complexity. When a metric of identifiability, or the ability for all parameter values in a model to be uniquely identified given the available information, is incorporated into the fitness criterion, PISR is more likely to return models with only a few parameters and those models tend to perform as well or worse than models learned using other fitness metrics.

### Results: Laplace's Equation

These relationships between fitness metrics and the discovered solutions are particularly clear for Laplace's equation. Laplace's equation, with the boundary conditions shown in Equation 4, has an exact analytical solution, allowing the learned solutions to be compared symbolically with the exact solution. PISR successfully learned the exact solution to Laplace's equation using $\mathcal{L}_{PDE}$ and $\mathcal{L}_{PBIC}$ as fitness metrics, but not when using $\mathcal{L}_{BIC,\Psi_D}$.

Although PISR did learn exact analytical solutions to Laplace's equation, on average, the models discovered across the 50 runs for each fitness criteria did not perfectly match an analytical solution. **Figure 1** illustrates the average MSE values at different model parameter complexities. This figure also shows the number of models returned at each parameter complexity for the different fitness metrics.

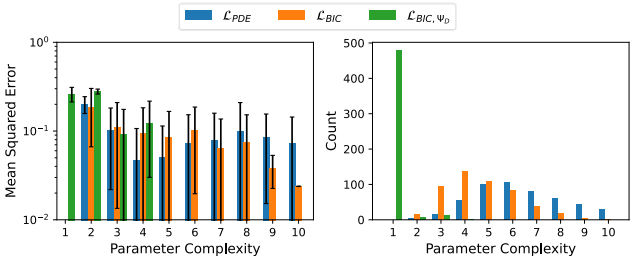

**Figure 1:** Left: Average MSE values per model parameter complexity for Laplace's equation solution discovery. Right: Count of learned models with different parameter complexities.

The results show that the selection of fitness criteria has little impact on the quality of the solutions when models have only a few parameters. However, the fitness criteria did affect the likelihood of a learned model have a small number of parameters, with stricter definitions of complexity leading to more models with fewer parameters. As the number of parameters in a model increases, $\mathcal{L}_{BIC}$ tends to yield the best solutions on average. Notably, no model learned using $\mathcal{L}_{BIC,\Psi_D}$ had more than 4 parameters.

While limiting model complexity may be advantageous for building models that are easy to interpret, it can also impede the discovery of better models. By including the $\Psi_D$ term in the fitness, the symbol space is constrained to consider only expressions that are mathematically identifiable. This constraint may make it more difficult to discover models that fit the underlying PDE well, as it restricts access to certain regions of the symbol space in which useful intermediate expressions may lie.

## Results: Burgers' Equation

The results from the Burgers' equation experiments tell a similar story to those from Laplace's equation. The best-learned models using each of the three fitness criteria are shown in **Table 2**. Since Burgers' equation does not have an exact analytical solution, all metrics of agreement with the ground truth were compared to the solution computed using the method of lines.

**Table 2:** Best models learned for Burgers' equation using different fitness criteria. The MSE and $R^2$-values are calculated using the solution calculated using the method of lines as the ground truth.

| Fitness | Model | MSE $\times 10^4$ | $R^2$ |
|---|---|---|---|
| $\mathcal{L}_{PDE}$ | $u_{diff}[x - 0.189t \cdot u_{diff}(x, 17.317), t]$ | 3.850 | 0.996 |
| $\mathcal{L}_{BIC}$ | $u_{diff}[x - 0.167t \cdot u_{diff}(x - 0.066x, t), t]$ | 1.796 | 0.998 |
| $\mathcal{L}_{BIC,\Psi_D}$ | $u_{diff}[x - 0.174t \cdot u_{diff}(x, x + t), t]$ | 4.466 | 0.995 |

As in the previous experiment, $\mathcal{L}_{PDE}$ and $\mathcal{L}_{BIC}$ produced better solutions than $\mathcal{L}_{BIC,\Psi_D}$. The best model was discovered using $\mathcal{L}_{BIC}$. Furthermore, the best solutions learned using all three fitness criteria have similar structures shown in **Table 2**.

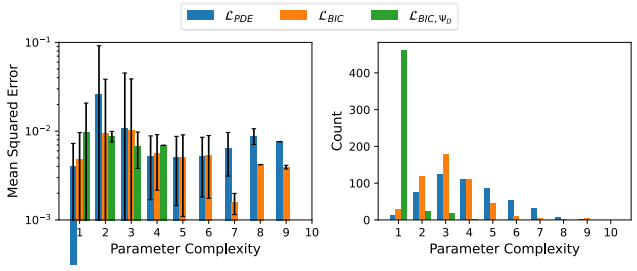

**Figure 2:** Left: Average MSE values per parameter complexity Burgers' equation solution discovery. Right: Count of learned models with different parameter complexities.

To better understand the average performance of the discovered solutions for Burgers' equation, **Figure 2** displays the average MSE values at different model parameter complexities, along with the number of models returned at each parameter complexity for the different fitness metrics. Analysis of these plot reveal the same trends as those discussed for **Figure 1**.

## Results: Nonlinear Wave Equation

The third PDE explored was the nonlinear wave equation, which proved more challenging to solve using PISR than the other two PDEs. This increased difficulty in solution discovery is reflected in the learned models, which . **Table 3** presents the model parameter complexities, $N_p$, node complexities, $k$, as well as the MSE and $R^2$-values of the best solutions discovered using the three fitness metrics. These complexity measures were chosen because the learned solutions are long and difficult to interpret, although still have fewer parameters than solutions learned using neural networks.

**Table 3:** Characteristics of best models learned for Burgers' equation using different fitness criteria. The MSE and R2-values are calculated using the solution calculated using the method of lines as the ground truth.

| Fitness | $N_p$ | $k$ | $MSE$ | $R^2$ |
|---|---|---|---|---|
| $\mathcal{L}_{PDE}$ | 5 | 40 | 0.020 | 0.941 |
| $\mathcal{L}_{BIC}$ | 5 | 27 | 0.015 | 0.957 |
| $\mathcal{L}_{BIC,\Psi_D}$ | 3 | 19 | 0.125 | 0.633 |

These solutions are significantly more (node) complex than those learned for the previous two PDEs. Nevertheless, all three best solutions use fewer than 10 parameters, and PISR with $\mathcal{L}_{PDE}$ and $\mathcal{L}_{BIC}$ returned models with $R^2$-values greater than 0.9. With more time, effort, and hyperparameter optimization, it is possible even better symbolic solutions exist within the explored symbol space. Once again, PISR using $\mathcal{L}_{BIC}$ yielded the best model among the fitness metrics considered.

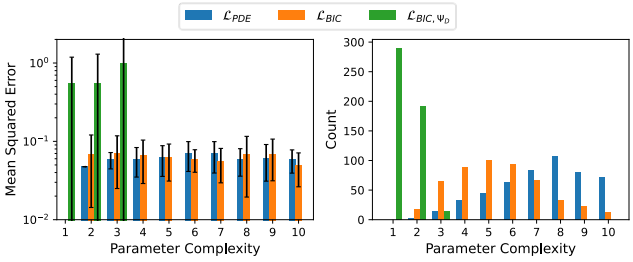

**Figure 3:** Left: Average MSE values per parameter complexity of Wave equation solution discovery. Right: Count of learned models with different parameter complexities.

**Figure 3** shows the average MSE values at different model parameter complexities and the number of models returned at each model parameter complexity for the

three fitness criteria. Consistent with the results from the other two cases, the results shown in the right-side plot of **Figure 3** follow a similar pattern with respect to the number of models learned at each parameter complexity. However, unlike the other two cases, solutions learned using $\mathcal{L}_{BIC}$ do not, on average, perform better than those learned using $\mathcal{L}_{PDE}$ as the parameter complexity increases. At low parameter complexity, solutions learned using $\mathcal{L}_{BIC,\Psi_D}$ perform worse than those discovered using other fitness metrics.

## CONCLUSIONS

PISR is an approach for learning symbolic, interpretable solutions to PDEs. Its efficacy varies depending on the type of PDE and it can struggle to find a balance between interpretability and accuracy in representations to solutions of complex PDEs. Its performance can be influenced by the selection of a fitness criterion. In this work, we demonstrate that using an information-theoretic fitness criterion can help learn higher-fidelity solutions to PDEs. Penalizing model complexity can promote simpler, more easily interpreted solutions. However, using metrics that incorporate model identifiability can constrain the symbol space, potentially hindering solution discovery.

This tension between model fit and simplicity is difficult to balance. While mathematically identifiable solutions are often desired, our findings suggest it may be more effective to use symbolic regression with less stringent metrics, such as parameter or node complexity, and to access mathematical identifiability post hoc, only after candidate solutions have been discovered.

# Towards Self-Tuning PID Controllers: A Data-Driven, Reinforcement Learning Approach for Industrial Automation

**Kyle Territo[a], Peter Vallet[a], and Jose Romagnoli[a*]**

[a] Louisiana State University, Department of Chemical Engineering, Baton Rouge, Louisiana, United States

## ABSTRACT

As industries embrace the digitalization of Industry 4.0, the abundance of process data creates new opportunities to optimize industrial control systems. Traditional Proportional-Integral-Derivative (PID) controllers often require manual tuning to address changing conditions. This paper introduces an automated, adaptive PID tuning method using historical data and machine learning for a continuously evolving, data-driven approach. The method centers on training a surrogate model using historical process data to replicate real system behavior under various conditions. This enables safe exploration of control strategies without disrupting live operations. An RL (Reinforcement Learning) agent interacts with the surrogate model to learn optimal control policies, dynamically responding to the plant's state, defined by variables like operational conditions and measured disturbances. The agent adjusts PID parameters in real-time, optimizing metrics such as stability, response time, and energy efficiency. After training, the RL agent is deployed online to monitor and adjust PID controllers in response to real-time deviations. The system continuously integrates new data to refine the surrogate model and RL agent, ensuring adaptability to long-term process changes. This continuous learning enhances resilience and scalability, maintaining optimal performance in dynamic environments. By combining data-driven modeling with RL, this method automates PID tuning, maximizing process data utility and aligning with Industry 4.0 principles. It reduces manual oversight while improving efficiency, reliability, and sustainability, addressing the challenges of increasingly complex and data-rich industrial systems.

**Keywords**: Surrogate Model, Industry 4.0, Intelligent Systems, Process Control, Machine Learning

## 1. INTRODUCTION

In recent years, advancements in machine learning and artificial intelligence have transformed industries by enabling systems that can learn, adapt, and operate autonomously. Technologies like self-driving cars and autonomous drones exemplify the potential of data-driven decision-making to improve efficiency, safety, and performance in complex environments. Yet, while such innovations have gained traction in consumer and transportation sectors, their application to industrial operations remains mostly underexplored. Industrial facilities, particularly in manufacturing and process industries, face similar challenges of dynamic conditions, complex systems, and a demand for optimal performance. Current control systems often rely heavily on manual oversight and static configurations, leaving them ill-equipped to handle evolving demands. This raises a provocative question: If a car can navigate city streets autonomously, why can't a plant adapt and optimize itself in real time? The answer lies in the integration of adaptive control systems with the wealth of process data available in modern industrial environments. By leveraging machine learning and reinforcement learning, it becomes possible to create "self-driving" plants that monitor their own states, respond dynamically to disturbances, and continuously improve over time.

Proportional-Integral-Derivative (PID) controllers are fundamental to industrial automation, providing a straightforward yet effective method to maintain desired

process variables (PVs) through proportional, integral, and derivative adjustments. However, traditional tuning methods, such as Ziegler-Nichols, are often inadequate for dynamic or nonlinear environments [1]. In addition, this method pushes the plant to its stability limits in order to find the ultimate gain—a necessary component for its controller parameter calculations. Model Predictive Control (MPC) represents a significant step forward, using mathematical models to predict system behavior and optimize control actions, excelling in multivariable and constrained systems. Despite these advantages, MPC relies on accurate models and high computational resources, making it less adaptable to rapidly evolving industrial conditions [5]. Emerging techniques in machine learning (ML) and reinforcement learning (RL) offer dynamic adaptability by leveraging data-driven models to learn and optimize control strategies, reducing reliance on explicitly defined physical or mathematical models [3][6]. Contrary to traditional optimization techniques, RL learns optimal policies through direct interaction with the environment—guided by a custom reward function—making it well suited for complex, high dimensional, and uncertain systems. By integrating these approaches, adaptive PID tuning leverages surrogate models for safe strategy exploration and RL agents for real-time parameter optimization, enabling continuous learning and improved resilience under varying conditions [2]. This method aligns with Industry 4.0 principles, utilizing IoT and big data to enhance control systems for modern industrial processes [4].

This paper presents a step toward such a vision by introducing an automated and adaptive method for PID controller tuning, combining historical process data and artificial intelligence to drive optimal performance across diverse operating conditions. The format of this paper will consist of an overview of the process pipeline for this implementation followed by a case study of a demethanizer unit.

## 2. PROPOSED ADAPTIVE CONTROL PIPELINE

### 2.1 Data Collection/ Data Preprocessing

The data collection process is a critical step in developing a robust surrogate model, particularly because the quality and diversity of the data significantly influence the model's ability to generalize. Diverse data is essential to ensure the model can accurately capture the wide range of behaviors and dynamics in the system it is designed to emulate. Inadequate data diversity can lead to overfitting, where the model performs well on the training data but poorly on unseen scenarios. To mitigate this, it is crucial to collect data representing various operating conditions, disturbances, and system responses. This diversity allows the model to learn from a broader spectrum

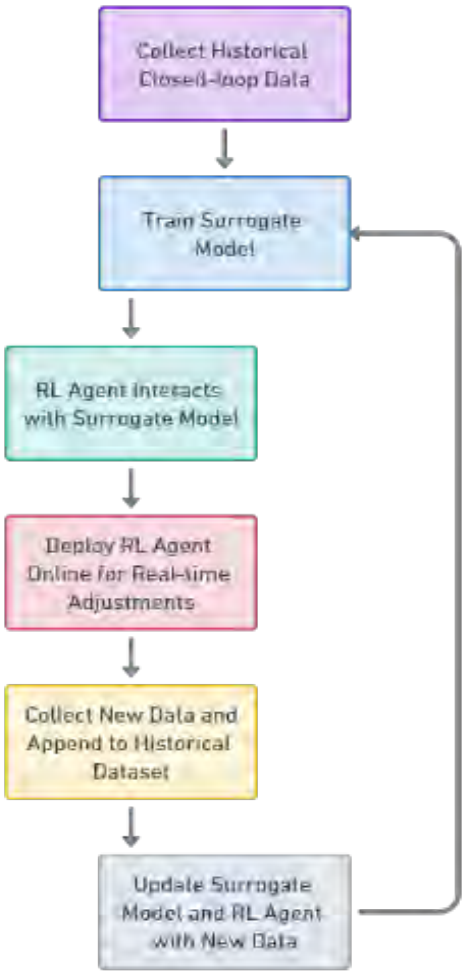

***Figure 1:*** Pipeline for Adaptive Control

of scenarios, enhancing its predictive accuracy and reliability when deployed in real-world applications. For this surrogate model, the data requirements are specific and targeted. The model relies on frames of data associated with setpoint (SP) changes, as these transitions encapsulate critical information about system behavior. *Each frame must include detailed operating conditions, measured disturbances, and, most importantly, labeled controller parameters such as the proportional gain ($Kc$) and integral time ($Ti$).* If PID controllers were too be tuned as well, $T_D$ values will have to be collected as well. These labeled parameters are vital for the model to associate the controller's configuration with the resulting system dynamics. The data collection process begins with a thorough analysis of historical data. The first step is to filter out frames of data corresponding to instances where SP changes occurred. This filtering is crucial as it isolates the dynamic segments most relevant for training the surrogate model. However, historical data may not always be sufficient in terms of volume or diversity. If gaps exist, manual experimentation will be necessary. This involves intentionally perturbing the system to induce SP

changes under a controlled range of operating conditions. Such self-perturbation ensures the acquisition of an adequate variety of frames to capture the full scope of system behavior. By combining historical data and carefully designed manual experiments, the data collection process can yield a comprehensive and diverse dataset for training the surrogate model effectively. After compiling the dataset, preprocessing begins with cleaning to remove missing values and outliers, ensuring data integrity. Next, features are individually normalized to a uniform range, preventing scale imbalances and enhancing model accuracy and training efficiency.

## 2.2 Building Surrogate Model

After collecting and preprocessing the historical data, the development of the initial surrogate model for the plant can commence. A feedforward neural network will be constructed using PyTorch. PyTorch was selected as the deep learning framework due to its flexibility, automatic differentiation capabilities, and extensive support for optimization techniques. The neural network will have three sections: the input layer, hidden layers and output layers. The input layer will take a combination of relevant features, including static characteristics of the step response, such as operating conditions, measured disturbances, and controller parameters, all of which influence the system's transient and steady-state behavior. To enhance the model's capacity for learning intricate patterns in the data, multiple hidden layers will be incorporated, each utilizing non-linear activation functions. Each hidden layer contained 64 neurons as a result of our hyperparameter optimization of the model. This design choice allows the network to generalize well across different operating conditions and adapt to variations in system dynamics. The output layer will generate the predicted PV response, providing an efficient approximation of the plant's behavior.

## 2.3 Training a RL Agent

The reinforcement learning (RL) framework consists of an agent and an environment. The **agent**, implemented using the Proximal Policy Optimization (PPO) algorithm from Stable Baselines3, interacts with the environment to learn optimal control strategies. PPO was chosen for its stability and efficiency in handling continuous control tasks and high-dimensional state spaces. The agent iteratively adjusts controller parameters based on reward signals that assess system performance. The **environment** provides the agent with observations reflecting the system's state and allows it to modify controller parameters. A pretrained surrogate model of the plant is integrated into the environment, enabling rapid testing and refinement of strategies without relying on computationally expensive simulations or real-world interactions. The **state** represents the system's current condition and includes the same input features as the surrogate model, excluding controller parameters, which are adjusted by the agent. The action is the update to the controller parameters, carefully constrained—perhaps within historical controller settings of the plant. The **reward function** drives the learning process by evaluating the PV response after an action. It assigns a numerical score based on key performance metrics, including the Integral of Squared Error (ISE), rise time ($T_R$), settling time ($T_S$), overshoot (OS), and control effort (CE):

$$R = -ISE[\alpha + (\beta * T_R) + (\gamma * T_S) + (\delta * OS) + (\varepsilon * \mathrm{CE})] \quad \boldsymbol{Eqn.1}$$

To prioritize specific objectives, weight factors ($\alpha, \beta, \gamma, \delta, \varepsilon$) adjust the relative importance of each metric. For instance, if minimizing settling time or overshoot is critical, their corresponding weights can be increased. ISE was chosen as the basis as it effectively quantifies overall control performance.

## 2.4 Online Implementation and Updating

Once the agent is trained on the surrogate model, it can be deployed online to monitor and interact with the system in real time. The agent continuously observes the process for significant changes in the state of the selected controller. When such a change is detected, the agent is tasked with recommending a new set of controller parameters, which can then be applied to the controller in real time. During its online operation, the agent also collects new data whenever a SP change occurs, storing these frames for future use. Once a sufficient amount of data has been accumulated, the surrogate model can be updated, and the agent can update its policy accordingly. This iterative approach ensures the pipeline remains adaptive, enabling the system to evolve and improve over time as new behaviors and conditions are encountered. An overview of the process pipeline is shown in ***Figure 1***.

# Case Study: Demethanizer HYSYS Simulation

In this case study, transient plant data was gathered from a HYSYS simulation of a demethanizer unit within an LNG production system (***Figure 2***). The demethanizer column (T-100) is the central unit in this separation process, consisting of a 30-stage multicomponent distillation column with a reboiler (E-103). This unit is designed to separate the methane, the lightest component, from the heavier portion of the gas. For this reason, the CRR plant has to operate under cryogenic conditions with a nominal temperature in the top tray of approximately -116°C. Among the different control loops in the process, the temperature controllers have a key role in ensuring

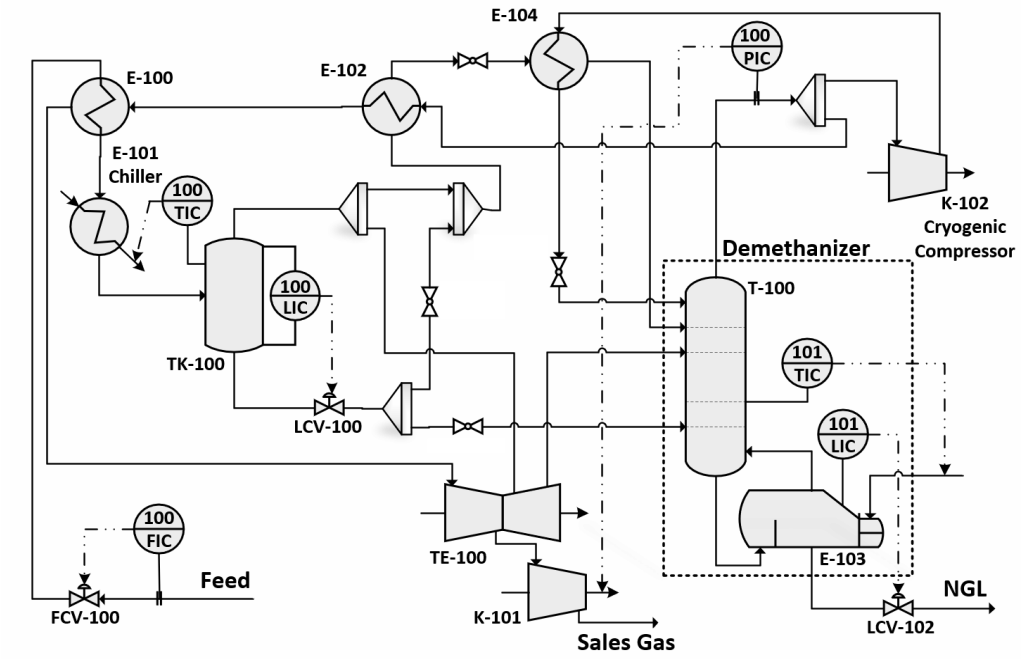

**Figure 2:** Schematic of the demethanizer unit

the product specifications in terms of ethane recovery and methane impurity in the bottom product of the demethanizer. The indirect control of ethane recovery is achieved by regulating the temperature in the separator upstream of the demethanizer and manipulating the cooling fluid flowrate of the chiller (E-101). The control of methane composition in the column bottom product is attained by manipulating the rebuilder's duty. The tuning of these valves are critical. However, different load changes and disturbances can affect the quality of the control—often leading to manual tuning efforts. The proposed strategy was implemented to automatically update all main controllers of the unit. Only results involving the composition controller (XIC-100) and ethane recovery control (ERIC-100) are shown here (controllers not depicted in ***Figure 2***).

The data collected was for different measured disturbances: change in feed temperature, change in feed pressure, and change in feed primary mole fraction (D1, D2, D3 respectfully) as well as a variety of tuning constants. These values can be seen in ***Tables A.1 and A.2*** of the *Appendix*. Again, this data is PV response data to a SP change under the specific combination of the state {KC, TI, D1, D2, D3}. The surrogate model was then trained in this simulation in order to have an initial model to represent the plant. It is important to note that the model will only be as good as the data that it is trained on—the more extensive data collected the more robust the predictions will be. From this initial model, a PPO agent will interact with it by subjecting random bounded state values (D1, D2, D3) and taking a control action. Each time an action is taken, one episode is completed, and

the reward is collected based on the step response metrics and ***Eqn. 1***. For example, fast control has lower weights on overshoot compared to tight control. In this case, four controller policies were inquired: fast, slow, tight, and ISE. These four policies were learned and tested for composition control (XIC-100), and the results are shown in ***Figure 3.*** The initial settings are shown in the blue series to have a baseline for comparison. Then each agent was subjected to the same state change and called upon to make a control adjustment. The green, yellow, purple, and red series show the PV responses for the control adjustments for the respective control policies. In addition, the models are validated by showing the neural network predictions in the colored dashed lines in each subplot. Each agent successfully learns the appropriate control actions required to meet the specified control objectives while subjected to a constant operational state for each case. The recommendations vary based on the selected policy: the *Fast Policy* suggests a gain of 2.51 and an integral time of 1; the *Slow Policy* advises a gain of 1 and an integral time of 17; the *Tight Policy* recommends both a gain and integral time of 1; and the *ISE Policy* prescribes a gain of 1.96 and an integral time of 4.37.

The next test was to see how a controller behaves within a chosen control objective to different states. In the first case, tight control was chosen for the composition controller (XIC-100). The controller was then tested with different states as shown in ***Table 1***. Here,

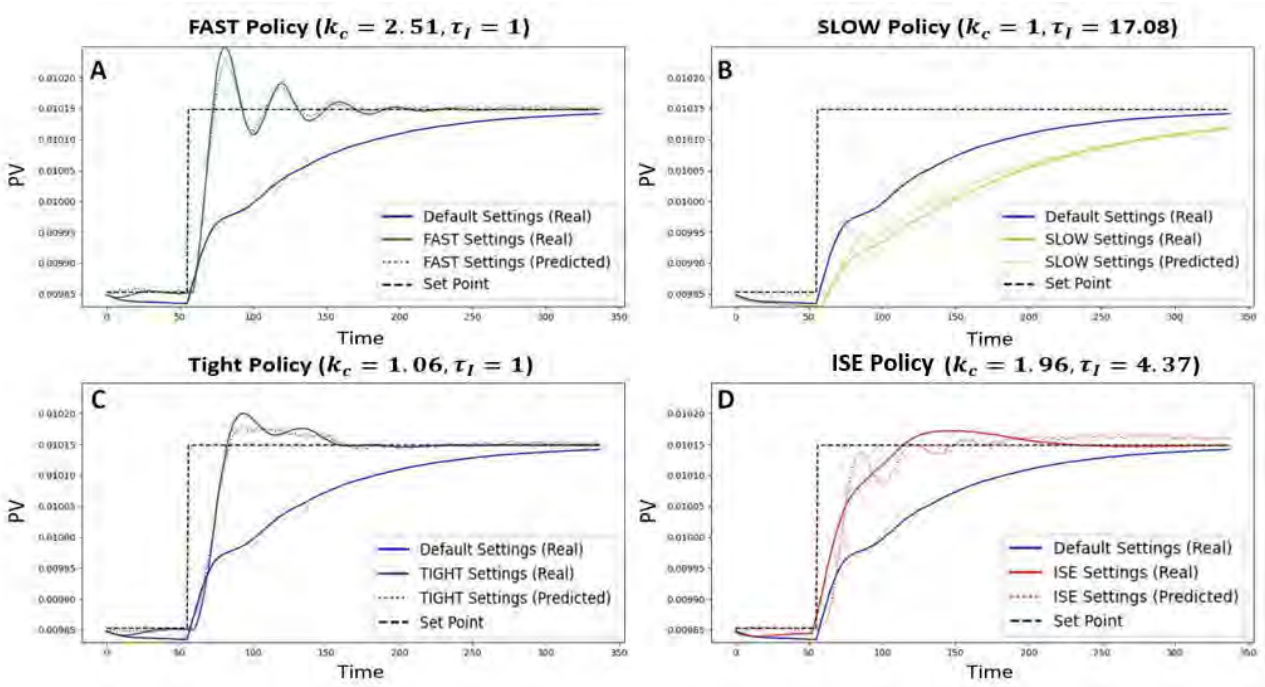

***Figure 3***: Different control policies learned via the reinforcement learning agent subjected to different reward function weights. **A.** *Fast control policy*. **B.** *Slow control policy*. **C.** *Tight control policy*. **D.** *ISE based control policy*.

***Table 1:*** Tight Control Agent for Composition (XIC-100) Results

| Trial | Description | State | Kc | Ti (min.) |

***Table 2:*** ISE Control Agent for Ethane Recycle Control (ERIC-100) Results

| Trial | Description | State | Kc | Ti (min.) |
|---|---|---|---|---|
| 1 | Min | {31.5, 6004, 0.842658} | 0.004 | 0.04051 |
| 2 | Max | {35, 6320, 0.842686} | 0.004 | 0.04270 |
| 3 | Avg | {33.25, 6162, 0.842672} | 0.004 | 0.04173 |
| 4 | Min -1% | {31.185, 5943.96, 0.834231} | 0.004016 | 0.04 |
| 5 | Max +1% | {35.35, 6383.2, 0.851113} | 0.004 | 0.04319 |

different state configurations were chosen in order to test the robustness of the predictions. The configurations are as follows: the minimum bounds of the state, the maximum bounds, the average of the bounds, +1% of the maximum bounds, and -1% of the minimum bounds—with the bounds being the limits of the training data. By doing so, the interpolative and slight extrapolative abilities of the proposed agent can be studied. From these results, the controller was able to fine tune its gain and integral time in order to best stay on track with the learned policy. In most cases, the policy learned to just slightly adjust the gain value with the exception of the minimum -1% entry where the integral time was slightly adjusted. It makes sense here knowing that the minimum kc value that the model was trained on was 1, so the agent learned that it had to start adjusting the ti value. For the second example, a general ISE policy was learned for the ethane recovery control. The adaptive controller was subjected to the same changes in state as previously mentioned. The agent updates are shown in ***Table 2***. As observed, the

agent learned to fine tune the integral time in this case in order to best maintain the optimal policy for the changes in state with the exception of the -1% of the minimum bound again. Where—in this case—the ti value hit the minimum value of 0.04 and the kc value had to take more of the responsibility of the control action.

## CONCLUSION

This research presents a robust framework for adaptive PID controller tuning, combining data-driven surrogate models and reinforcement learning to address the challenges of dynamic industrial environments. By utilizing historical process data, the surrogate model accurately mimics system behavior, enabling safe and efficient exploration of control strategies. The reinforcement learning agent, trained with a customizable reward function, optimizes controller performance in real-time, adapting to varying operating conditions and process demands.

The application to a demethanizer unit demonstrates the method's flexibility and effectiveness, showcasing its ability to align with specific control objectives, whether fast, slow, or precise responses are required. More results and use cases will be sought after, but the preliminary results affirm the framework's capacity to adapt to evolving plant conditions, ensuring reliability and efficiency through continuous learning and optimization.

Looking forward, the approach has potential for broader application across complex industrial processes, where enhanced robustness of surrogate models and advanced reward functions can unlock even greater adaptability. This research represents a step toward fully autonomous control systems, laying the groundwork for the realization of "self-driving" industrial plants that continuously monitor, optimize, and improve themselves in real time.

## ACKNOWLEDGEMENTS

We extend out gratitude to ExxonMobil for their research collaboration and support. We also wish to acknowledge the Process Systems Engineering group at LSU, led by Dr. Romagnoli, for guidance and expertise. Additionally, we would like to thank the LSU Chemical Engineering Department for the facilities and resources to complete this research.

## ABSTRACT

Compartmental models are widely used to simplify the analysis of complex fluid dynamics systems, yet subjective compartment definitions and computational constraints often limit their applicability. The CompArt algorithm introduces an AI-driven framework that automates compartmentalization in Computational Fluid Dynamics (CFD) simulations, optimizing both accuracy and efficiency. By leveraging unsupervised clustering techniques such as Agglomerative Clustering, CompArt identifies coherent flow regions based on velocity and turbulent kinetic energy dissipation rate, ensuring a data-driven, physically consistent segmentation. The methodology integrates a connectivity-based clustering strategy, where compartments are dynamically optimized using the Silhouette score and adjacency matrix. This approach enables the reduction of high-resolution 3D CFD simulations into a network of interconnected sub-systems, significantly lowering computational costs while preserving system heterogeneity. The framework was tested on turbulent stirred tank simulations at 200 and 400 RPM, demonstrating its ability to capture both large-scale flow structures and fine-scale turbulence features. At higher RPM, increased mixing leads to a more fragmented dissipation pattern, which the model successfully adapts to. With scalability up to industrial scale meshes (~1M cells) and full automation of hyperparameter selection, CompArt enhances the applicability of CFD compartmental models in crystallization, multiphase flow, and process optimization. By bridging AI-driven clustering with physical modelling, this novel framework streamlines CFD simulations, making real-time industrial applications feasible without sacrificing predictive accuracy.

**Keywords**: Artificial Intelligence, Computational Fluid Dynamics, Mixing, Industry 4.0, Process Design

## INTRODUCTION

Compartmental models have long been a cornerstone, offering a simplified yet effective framework for analyzing and simulating complex processes [1]. These models divide a system into interconnected compartments, each representing a sub-region with uniform properties, such as temperature, concentration, or velocity. By reducing a continuous system into discrete, manageable units, compartmental models facilitate the study of phenomena such as mass transfer, reaction kinetics, mixing dynamics and their interplay.

The strength of compartmental models lies in their ability to provide insightful approximations while significantly reducing computational demands compared to full-scale three-dimensional (3D) simulations. They are widely applied in fields such as reactive crystallization, multiphase flow, and pharmaceutical manufacturing, where understanding process heterogeneity and scaling effects is critical [2–4]. However, despite their utility, compartmental models face significant limitations that constrain their broader applicability and accuracy.

One major challenge is the reliance on expert judgment to define the number, size, and connectivity of compartments [5]. This process is often subjective, time-intensive, and prone to inconsistencies, particularly for systems with high spatial complexity. Additionally, traditional compartmental models struggle to preserve fine-scale heterogeneity, leading to oversimplified representations that may overlook critical interactions within the system.

Another limitation lies in their adaptability. Classical approaches are often tailored to specific scenarios,

requiring extensive reconfiguration when applied to new processes or scales. This lack of flexibility reduces their utility in dynamic, industrial contexts where process conditions and requirements frequently change.

Finally, the integration of multiple governing variables, such as velocity, turbulent energy dissipation rate, and temperature, remains a challenge. While these factors are crucial for accurately describing complex systems, incorporating them into compartmental models without introducing prohibitive computational costs is a significant hurdle [6].

Addressing these limitations is crucial to enhance the predictive power, scalability, and versatility of compartmental models, ensuring they remain a relevant and powerful tool in modern chemical engineering applications.

## CompArt algorithm

CompArt is an innovative approach to modelling complex systems, based on Computational Fluid Dynamics (CFD) simulations. CFD plays a crucial role in various industries such as chemical engineering, pharmaceuticals, and energy, where understanding fluid flow, heat transfer, and mass transport is vital for optimizing process performance. However, simulating large-scale 3D systems is computationally expensive, which limits their real-time applicability in industrial applications. The CompArt project addresses this challenge by exploiting artificial intelligence (AI) to reduce computational costs without compromising the fidelity of the simulation results.

## Objectives

The primary goal of the CompArt project is to innovate the way complex systems are modelled. A central ambition of the project is the integration of unsupervised AI-driven clustering techniques to automate the compartmentalization process. Traditionally, determining the optimal number of compartments for a CFD simulation has relied heavily on expert knowledge, requiring iterative manual adjustments to balance computational cost and simulation accuracy [7]. By using AI, CompArt automates this process, enabling the system to autonomously define the most suitable number of compartments based on input parameters. This not only reduces the dependence on domain-specific expertise but also enhances the consistency and efficiency of the modelling process.

Scalability is another cornerstone of the project. By representing the 3D system as a network of interconnected sub-systems, CompArt provides a structured way to reduce the computational burden associated with CFD simulations. Each compartment is characterized by uniform properties, such as velocity or turbulence dissipation rates, which significantly simplifies the mathematical complexity of the problem. This reduction allows for real-time simulations, even in industrial contexts where rapid decision-making is essential.

Finally, CompArt places a strong focus on preserving the heterogeneity and spatial characteristics of the system. While simplifying the model, the framework ensures that the inherent complexity of the system, such as variations in flow dynamics or reactive processes, is not lost. This attention to detail is particularly critical in applications like crystallization, where system heterogeneity plays a vital role in determining the outcome of processes. By maintaining these features, CompArt strikes a balance between computational efficiency and the fidelity required for accurate simulations.

# METHODOLOGY

## Simulation Setup and Governing Equations

To test the proposed methodology, simulations are performed on 3D stirred tanks. The simulations use the Reynolds-Averaged Navier-Stokes (RAS) approach with the $k-\varepsilon$ turbulence model. The governing equations include the incompressible Navier-Stokes equations, along with transport equations for turbulent kinetic energy ($k$) and its dissipation rate ($\varepsilon$)

$$\frac{\partial \boldsymbol{u}}{\partial t} + \boldsymbol{u}\cdot\nabla\boldsymbol{u} = \nu_t\nabla^2\boldsymbol{u} - \frac{1}{\rho}\nabla p + \boldsymbol{g} \quad (1)$$

$$\frac{\partial k}{\partial t} + \boldsymbol{u}\cdot\nabla k = \Gamma_{t,k}\nabla^2 k + \frac{P}{\rho} - \varepsilon \quad (2)$$

$$\frac{\partial \varepsilon}{\partial t} + \boldsymbol{u}\cdot\nabla\varepsilon = \Gamma_{t,\varepsilon}\nabla^2\varepsilon + \frac{C_{\varepsilon 1}\varepsilon}{k}\frac{P}{\rho} - \frac{C_{\varepsilon 2}\varepsilon^2}{k} \quad (3)$$

$$\nu_t = \frac{C_\mu k^2}{\varepsilon} \quad (4)$$

The Navier-Stokes equations describe the motion of an incompressible, Newtonian fluid, where turbulence effects are modeled through the turbulent viscosity ($\nu_t$). This additional viscosity accounts for the enhanced momentum diffusion due to turbulent eddies, which cannot be directly resolved in a Reynolds-Averaged Navier-Stokes (RAS) framework.

The turbulent kinetic energy equation ($k$) quantifies the energy associated with turbulent velocity fluctuations. It includes terms for production ($P$), which arises from the mean velocity gradients, dissipation ($\varepsilon$), which represents the conversion of turbulent energy into thermal energy, and diffusion ($\Gamma_t$) to account for spatial transport of turbulence.

The turbulent dissipation rate equation ($\varepsilon$) governs the rate at which turbulent kinetic energy is dissipated into smaller scales.

## AI-driven Clustering for Compartmentalization

Clustering plays a pivotal role in compartmentalization by grouping cells in the mesh based on similar characteristics. Several clustering methods were considered,

including k-means and DBSCAN. However, we focused on using Agglomerative Clustering, which is an unsupervised neural network that maps high-dimensional data onto a lower-dimensional (embedded) space, preserving the topological relationships in the input data. This algorithm is well-suited for clustering spatial data in CFD simulations, as it can efficiently handle the inherent complexity of fluid dynamics and capture system heterogeneity.

The AI-driven model autonomously determines the optimal number of clusters based on the user-defined input parameters, such as velocity and turbulent kinetic energy dissipation rate, using the Silhouette score as a quantitative metric. The Silhouette score evaluates the quality of clustering by measuring how similar a data point is to its cluster compared to other clusters, indicating the cohesion and separation of the clusters.

### Feature Processing and Connectivity

In CFD simulations, the fluid domain is represented as a mesh of interconnected cells, and dividing this mesh into meaningful compartments requires a robust understanding of cell connectivity. To achieve this, a connectivity matrix is constructed to capture the relationships between neighboring cells efficiently. Leveraging parallel computation, the matrix is built using a sparse format, significantly reducing the computational time and making the process suitable for large-scale meshes. Once the connectivity is established, the input features, such as velocity and turbulent dissipation rate, are normalized. This normalization, performed using standard scaling techniques, prepares the data for effective clustering. To enhance the accuracy of the Agglomerative Clustering algorithm, key hyperparameters are optimized using the Silhouette score, automating the process and eliminating the need for expert-driven adjustments. This streamlined approach ensures efficient and reliable compartmentalization of complex systems, paving the way for broader application in industrial simulations.

## RESULTS

The results underscore the effectiveness of unsupervised algorithms in clustering CFD data, accurately identifying zones with differing velocities, as shown in Figure 1. However, velocity alone is insufficient to capture the complexity of processes like reactive crystallization [8], where the turbulent kinetic energy dissipation rate plays a crucial role in flow dynamics and system behavior. By incorporating both velocity and turbulence dissipation as input features, the clustering algorithm produces a more refined segmentation, effectively capturing system heterogeneity.

The velocity and turbulence dissipation rate fields at 200 and 400 RPM, shown in Figure 1, were processed using the CompArt algorithm to generate dynamically optimized compartments. The compartmentalization strategy was guided by two key criteria: the silhouette metric, ensuring well-defined clusters, and cell connectivity, preserving the physical consistency of adjacent regions. The resulting segmentation effectively captures both large-scale flow structures and fine-scale turbulence features. At 200 RPM, turbulence dissipation is more localized near the bottom and walls, whereas at 400 RPM, the enhanced mixing leads to a greater number of high-dissipation regions.

A crucial observation is the ability of the algorithm to adapt to changes in the flow and turbulence fields as the RPM increases. At 200 RPM, the region with the highest variation in velocity and turbulence is concentrated near the impeller. However, as the rotational speed increases, the system becomes globally more turbulent, leading to the formation of strong gradients, particularly in stagnant zones (below the impeller) and at the interface between the bulk fluid and the wall (wall effect). Even for an expert, it would be challenging to manually delineate these zones accurately, whereas CompArt successfully identifies them. A particularly evident example is the stagnant fluid region below the impeller. In crystallization processes, this reactor zone can lead to Critical Quality Attributes (CQA) of the product that do not meet specifications, as particles in this region can grow or agglomerate due to prolonged residence times.

Another notable feature of CompArt is its ability to define clusters composed of just a few layers of cells. In both cases, a distinct compartment is observed wrapping around the impeller shaft. It is important to note that, although at lower magnitudes, the shaft also rotates at a certain velocity, thereby exchanging momentum with the surrounding fluid. This characteristic is captured by the algorithm, enabling the monitoring of processes such as secondary nucleation or agglomeration, which are directly linked to turbulent kinetic energy dissipation near moving walls.

These findings highlight the robustness of the CompArt framework in systematically identifying meaningful compartments while preserving spatial heterogeneity and flow physics. By integrating data-driven clustering with physical constraints, this methodology provides an efficient and adaptive approach for reducing CFD complexity while maintaining predictive accuracy.

## CONCLUSIONS

The CompArt framework demonstrates a significant advancement in the compartmental modelling of fluid dynamics systems by integrating AI-driven clustering techniques with CFD simulations. Through the application of Agglomerative Clustering, the methodology effectively partitions the computational domain into meaningful

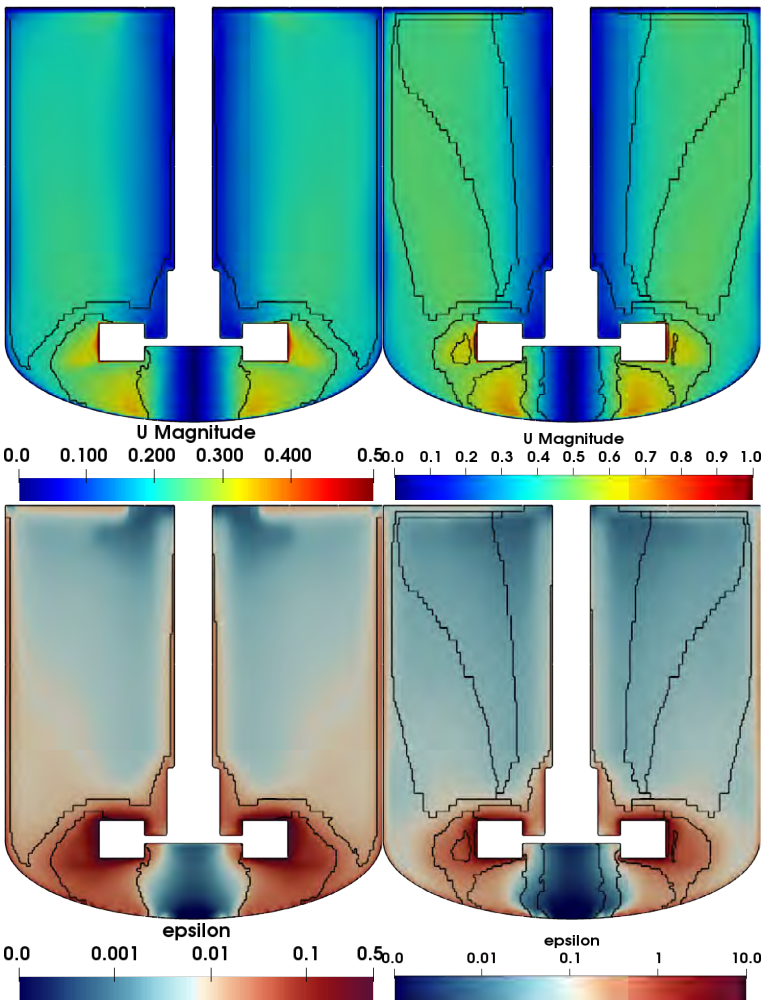

**Figure 1:** Velocity (*top row*) and turbulence dissipation rate (*bottom row*) compartmentalized fields at 200 RPM (*left*) and 400 RPM (*right*). The compartmentalization was performed using the CompArt algorithm.

compartments, preserving the spatial heterogeneity and critical flow structures. This novel approach addresses the key limitations of traditional compartmental models by eliminating the reliance on expert-driven segmentation and enhancing the adaptability of the model across different process conditions.

One of the primary strengths of CompArt is its ability to autonomously determine the optimal number of compartments based on quantitative metrics such as the Silhouette score, ensuring well-defined and physically relevant clusters. Additionally, the framework's capacity to incorporate multiple variables, such as velocity fields and turbulent kinetic energy dissipation rates, allows for a more accurate representation of flow dynamics, which is crucial in applications like crystallization and multiphase flow systems.

The studies at different rotational speeds (200 and 400 RPM) illustrate the robustness of the approach. The model successfully captures key flow features, such as the formation of strong turbulence gradients near stagnation zones and wall regions, which are critical in industrial applications. The ability of the algorithm to detect small-scale but significant structures, such as the interaction of the impeller shaft with the surrounding fluid, further underscores its capability to enhance predictive accuracy.

By reducing computational complexity while maintaining fidelity, the CompArt framework provides a scalable and efficient tool for industrial CFD simulations. Its automation, adaptability, and accuracy make it a promising solution for optimizing process performance in various engineering domains, facilitating real-time decision-making and improved process control.

## ABSTRACT

The efficient separation of carbon dioxide ($CO_2$) and methane ($CH_4$) is crucial for chemical processes, including biogas upgrading and natural gas purification. Metal-organic frameworks (MOFs) have gained significant attention as promising adsorbents for these processes due to their high porosity and tunable structures. Estimating the adsorption capacity of MOFs is essential for screening high performing adsorbents. While molecular simulations are commonly used to estimate the adsorption capacities, their computational intensity acts as a bottleneck in screening MOF adsorbents. In this study, we propose a machine learning (ML)-based framework for the high-throughput prediction of adsorption isotherms for $CO_2$ and $CH_4$ in MOFs. A graph neural network (GNN) model was developed to predict adsorption capacities, effectively replacing the time-consuming molecular simulations. The GNN model processes the structural graphs of MOFs, capturing their spatial configurations, such as surface structure and pore characteristics, which are closely related to adsorption performance. Based on the adsorption capacities predicted by the GNN model, an isotherm model was derived to characterize the adsorption behavior of the MOFs. This framework enables the rapid and reliable screening of MOFs with superior adsorption performance for $CO_2/CH_4$ separation, offering a computationally efficient approach that paves the way for broader applications of MOFs in carbon dioxide separation technologies.

**Keywords**: Adsorption, Machine Learning, Carbon Dioxide Capture

## 1. INTRODUCTION

The separation of carbon dioxide ($CO_2$) and methane ($CH_4$) from gas mixtures is a critical process in chemical processes such as biogas upgrading [1]. Efficient separation of these gases is essential for enhancing biomethane purity, reducing greenhouse gas emissions, and improving the sustainability of energy production. Pressure swing adsorption (PSA) is one of the most widely used techniques for gas separation, relying on porous solid adsorbents to selectively capture $CO_2$ from gas mixtures. The performance of PSA largely depends on the properties of the adsorbent, including its adsorption capacity and selectivity. Therefore, the development of high-performance adsorbents is crucial for improving the efficiency of $CO_2/CH_4$ separation. Metal-organic frameworks (MOFs), characterized by high porosity and structural tunability, have emerged as promising candidates for PSA adsorbents owing to their outstanding adsorption capacities and selectivity [2]. The modular nature of MOFs, which allows flexible design of their chemical composition and physical structure, enables tailored designs for specific gas separation applications. However, this tunability poses a challenge in efficiently identifying materials optimized for specific separation processes.

Traditional methods for determining MOF adsorption properties, such as molecular simulations and experimental measurements, are both time-intensive and computationally expensive, especially when screening large datasets [4]. Machine learning (ML) has recently emerged as a powerful alternative, enabling rapid and accurate predictions of MOF adsorption properties. By reducing computational costs and accelerating analysis,

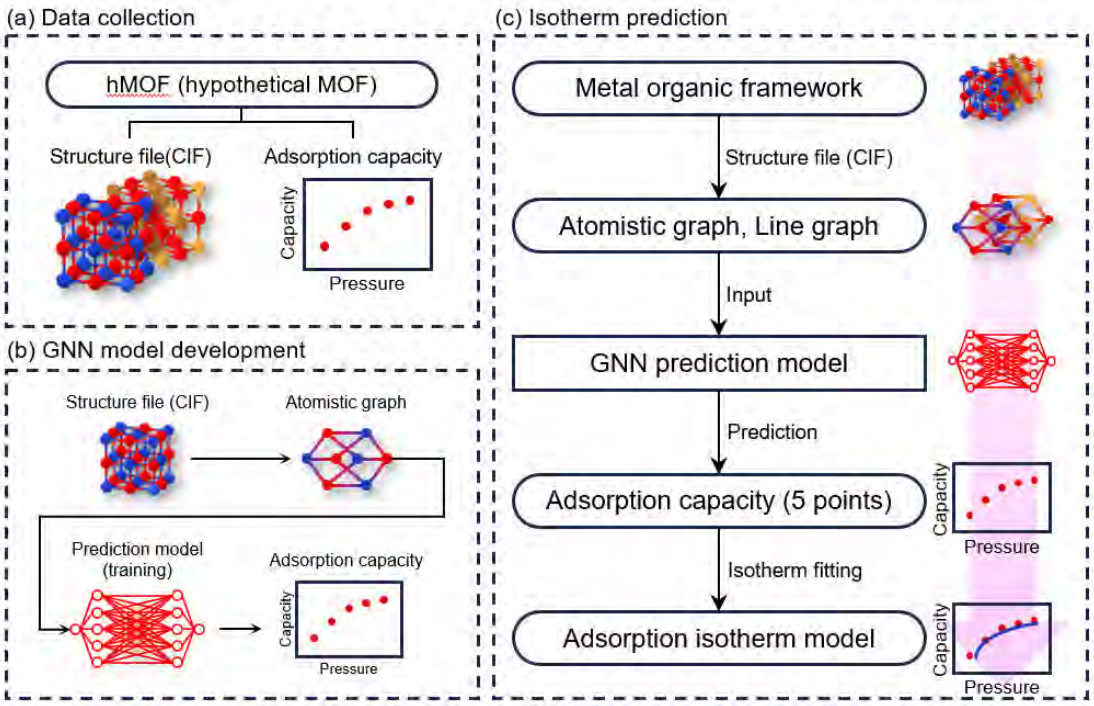

**Figure 1:** Research overview

ML provides a transformative approach for efficiently screening MOFs across diverse applications. Among ML approaches, graph neural network (GNN) stand out as a highly effective and specialized method for predicting MOF properties. Unlike conventional ML models, which rely on predefined descriptors or simple structural representations, GNN directly process chemical structures as graphs, where atoms are represented as nodes and bonds as edges [5]. This unique capability allows GNN to inherently capture both atomic- and bond-level features while preserving the spatial and topological complexity of MOFs. As a result, GNN excel in modeling the intricate relationships between structural characteristics and adsorption behavior, making them exceptionally suited for analyzing the complex and diverse architectures of MOFs.

This study introduces a framework for predicting the adsorption isotherms of $CO_2$ and $CH_4$ in MOFs. Using graph representations of MOFs, the GNN model predicts adsorption capacities. These predictions are subsequently processed by the pyAPEP software, which fits adsorption isotherms using established models such as the Langmuir or Dual-Site Langmuir equations [6].

By leveraging advanced GNN model and large-scale MOF datasets, this study provides a scalable framework for predicting $CO_2$ and $CH_4$ adsorption isotherms with reduced computational costs.

## 2. METHOD

### Data collection

In this study, we used the hypothetical MOFs (hMOF) dataset from the MOFX database to train the model. The MOFX database is a comprehensive repository that consolidates diverse datasets of MOFs, including both hypothetical and experimentally synthesized structures [7]. It provides Crystallographic Information Files (CIFs) containing atomic coordinates and structural properties, along with adsorption and textural property data. Such detailed information is instrumental in facilitating the screening of MOFs for adsorption-based applications.

The hMOF dataset, comprising 137,953 hypothetical MOF structures, was selected from the MOFX database for the present study [8]. These structures were computationally generated by systematically combining a diverse set of 102 building blocks, including metal nodes and organic linkers, to explore a wide range of potential MOF configurations. The resulting hypothetical structures represent the diverse structural and chemical properties of MOFs.

In this study, preprocessing was applied to filter out structures unsuitable for adsorption studies. MOFs lacking methane adsorption data were removed, and those with a pore limiting diameter (PLD) smaller than 3.3 Å were excluded. The PLD represents the smallest pore diameter of an adsorbent, and if it is smaller than the gas molecules, adsorption cannot occur as the molecules cannot enter the pores. Since this dataset is used to

train a model for predicting $CO_2$ adsorption capacity, information on MOFs that are physically incapable of adsorbing $CO_2$ must be excluded. Therefore, a 3.3 Å constraint, corresponding to the molecular diameter of $CO_2$, was applied to filter out such structures. After preprocessing, 112,351 MOFs remained as training data. The dataset was then split into training, validation, and test sets with a ratio of 0.8:0.1:0.1. CIFs of the hMOF structures were utilized to construct graph-based representations, where atoms and bonds correspond to nodes and edges, respectively. These graph representations served as input data for training the GNN model.

The adsorption data of $CO_2$ and $CH_4$ from the hMOF dataset were used as target values for model training, which were computed using Grand Canonical Monte Carlo (GCMC) simulations at 298 K across multiple pressure conditions [9]. We obtained five adsorption data points for each gas, with $CO_2$ adsorption data including simulation results at pressures of 0.01, 0.05, 0.1, 0.5, and 2.5 bar, and $CH_4$ adsorption data including simulation results at pressures of 0.05, 0.5, 0.9, 2.5, and 4.5 bar. The TraPPE (Transferable Potentials for Phase Equilibria) force field was employed to model molecular interactions for the adsorption gases, and the UFF (Universal Force Field) was used for the MOF structures. Each simulation included 1,000 initialization cycles for system equilibration, followed by 1,000 production cycles to gather adsorption data.

## GNN model development

We developed a GNN model to predict the adsorption capacities of $CO_2$ and $CH_4$ for MOFs, based on the Atomistic Line Graph Neural Network (ALIGNN) architecture. ALIGNN combines atomistic and line graph representations to effectively capture structural and bond-level interactions within MOFs, enabling accurate predictions of material properties [10].

In the atomistic graph representation, atoms are represented as nodes and bonds as edges. For this study, 8 atomic features were used: column number, atomic radius, ionization energy, electronegativity, electron affinity, valence electrons, atomic volume, and block (outermost shell). Edge features, representing bond distances, were encoded using a radial basis function (RBF) expansion with a cutoff of 8 Å. To ensure structural completeness, a periodic 12-nearest-neighbor configuration was applied during graph construction.

The line graph representation complements the atomistic graph by treating interatomic bonds as nodes and bond angles as edges. Bond angles were encoded using RBF features and propagated with bond distance features through Edge-gated Graph Convolutions. Alternating convolutions between atomistic and line graphs allowed ALIGNN to efficiently update atom, bond, and bond-angle features, capturing both local and higher-order structural relationships in MOFs.

The ALIGNN architecture consisted of 4 ALIGNN layers and 4 graph convolution (GCN) layers, each with 256 hidden nodes. Initial bond and bond angle features were embedded into a 64-dimensional space using 80 RBF features for bond distances and 40 RBF features for bond angles. Final atom-wise representations were averaged and passed through a linear layer to generate regression outputs. This robust architecture enabled ALIGNN to capture both local and higher-order structural relationships in MOFs, allowing accurate prediction of adsorption capacities across various pressure conditions.

## Adsorption isotherm fitting

To construct adsorption isotherms for each MOF, the predicted adsorption capacities at five pressure points were fitted using the pyAPEP software package. pyAPEP is a comprehensive software designed for adsorption process simulations, automating data processing and fitting adsorption isotherms to enable accurate modeling of gas adsorption behavior [6].

pyAPEP employs a well-designed algorithm to automatically determine the most suitable isotherm model for a given pressure-uptake dataset. This is achieved by optimizing parameters, minimizing errors, and selecting the best-fitting model from five established options: Langmuir, Freundlich, Sips, Quadratic, and Dual-Site Langmuir. Each model is described by the following equations:

Langmuir model: $q(P) = \frac{K_1 K_2 P}{1+K_2 P}$ (1)

Freundlich model: $q(P) = K_1 P^{K_2}$ (2)

Sips model: $q(P) = \frac{K_1 K_2 P^{K_3}}{1+K_2 P^{K_3}}$ (3)

Quadratic model: $q(P) = K_1 \frac{(K_2+2K_3 P)P}{1+K_2 P+K_3 P^2}$ (4)

Dual-site Langmuir model: $q(P) = K_1 \frac{K_2 P}{1+K_2 P} + K_3 \frac{K_4 P}{1+K_4 P}$ (5)

This approach efficiently generates adsorption isotherms from limited data, providing a robust basis for analyzing and screening MOFs based on their adsorption performance.

## Model validation

To validate the generalizability of the model, the CRAFTED dataset, which provides adsorption data for 690 experimentally synthesized MOFs extracted from the CoREMOF2014 database, was utilized [11]. This dataset includes simulated adsorption data performed for the adsorption of $CO_2$ with two fields (i.e., UFF and DREIDING), six partial charge schemes (i.e., no charge, Qeq, EQeq, PACMOF, MPNN, and DDEC), at three temperatures (i.e., 273, 298, 323 K).

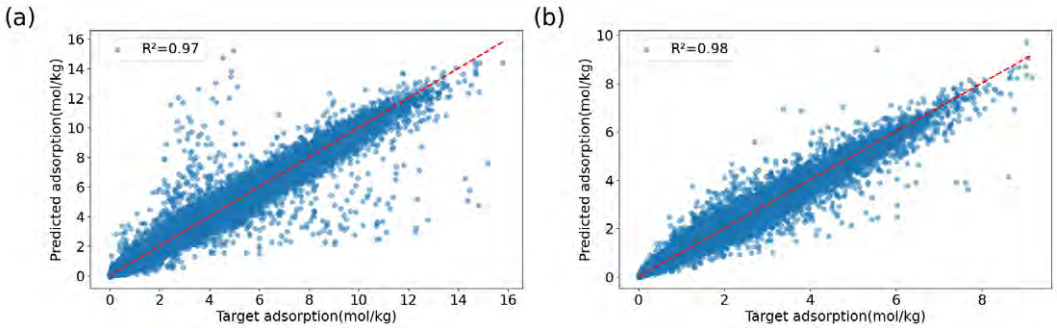

**Figure 2:** Comparison of target vs predicted adsorption capacities for (a) carbon dioxide adsorption with model accuracy ($R^2$ = 0.97), (b) methane adsorption with model accuracy ($R^2$ = 0.98)

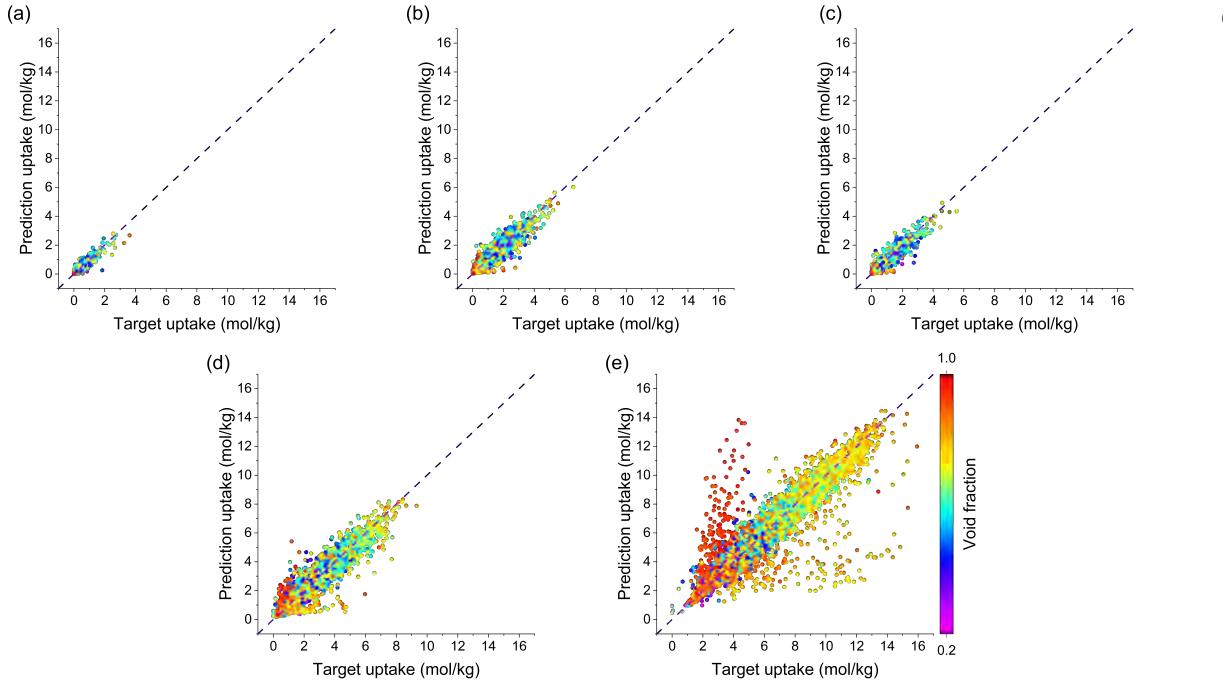

**Figure 3:** The plots of target vs predicted $CO_2$ adsorption capacity colored by void fraction at five pressure points
(a) 0.01 bar, (b) 0.05 bar, (c) 0.1 bar, (d) 0.5 bar, (e) 2.5 bar

To ensure compatibility with the GNN model's training conditions, adsorption data simulated with the UFF force field, EQeq partial charge calculation method, and a temperature of 298 K were selected. Based on this simulated data, simulated adsorption isotherms were fitted and compared with the isotherms predicted by the GNN framework.

## 3. RESULT ANALYSIS

### Model accuracy

We evaluated the accuracy of the adsorption prediction models for $CO_2$ and $CH_4$ using the coefficient of determination ($R^2$), which measures the proportion of variance in the target values explained by the predictions. $R^2$ scores range from 0 to 1, with higher values indicating greater predictive accuracy. The evaluation results showed $R^2$ scores of 0.97 for $CO_2$ and 0.98 for $CH_4$, demonstrating the explanatory power of the prediction models in estimating adsorption capacities for both gases. Additionally, Figure 2 illustrates the alignment between the target and predicted adsorption capacities, highlighting the high accuracy of the models.

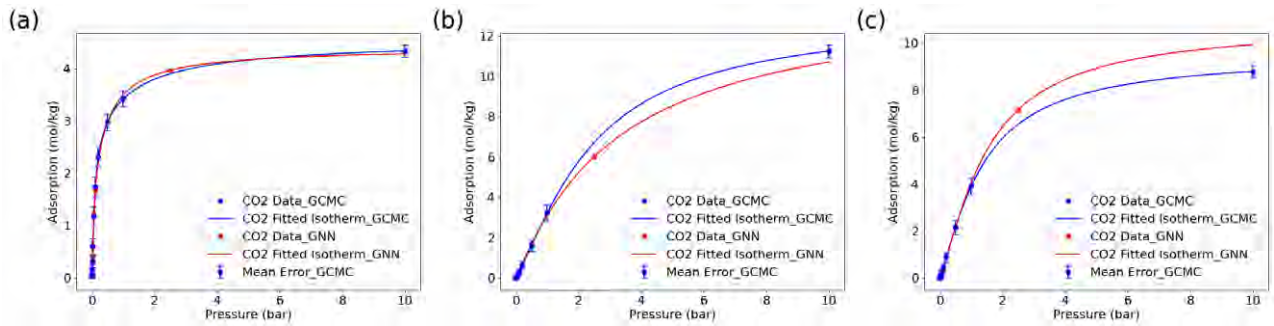

**Figure 4:** Three examples of CRAFTED dataset validation results: GCMC vs. GNN $CO_2$ isotherm

**Table 1.** $R^2$ scores for each pressure point for $CO_2$ adsorption model

| Pressure (bar) | $CO_2$ model ($R^2$ score) |
|---|---|
| 0.01 | 0.88 |
| 0.05 | 0.92 |
| 0.1 | 0.93 |
| 0.5 | 0.94 |
| 2.5 | 0.88 |

**Table 2.** $R^2$ scores for each pressure point for $CH_4$ adsorption model

| Pressure (bar) | $CH_4$ model ($R^2$ score) |
|---|---|
| 0.05 | 0.92 |
| 0.5 | 0.95 |
| 0.9 | 0.95 |
| 2.5 | 0.94 |
| 4.5 | 0.94 |

In addition to overall accuracy, Table 1 and 2 provides $R^2$ scores for each pressure point across the two gases, offering a detailed assessment of model performance. While the $CH_4$ model maintained consistently high $R^2$ scores across all pressure points, the $CO_2$ model exhibited lower accuracy at some pressure points. For example, at 0.01 bar and 2.5 bar, the model exhibited $R^2$ score of 0.88

To investigate the factors responsible for the lower accuracy of the $CO_2$ model at specific pressure points, we analyzed the textural properties of MOFs with significant prediction errors. Among the textural properties, void fraction, which is known to have a significant association with adsorption, was identified as the property most strongly influencing the model's predictive performance. The analysis revealed that MOFs with large prediction errors were predominantly those with high void fractions. The relationship between target and predicted $CO_2$ adsorption capacities at five pressure points is visualized in Figure 3, with void fraction represented as a color gradient. At 2.5 bar, the structures with the most significant prediction errors were mostly MOFs with void fractions greater than 0.8. This pattern suggests that the unique structural characteristics of MOFs with high void fractions are not fully captured by the current GNN model. This limitation is interpreted as resulting from the graph representation of MOFs, where a cutoff distance of 8 Å is used to define connections between atoms, assuming bonds exist between the 12 nearest neighbors within this range. For MOFs with high void fractions, the relative distances between atoms are often larger, making the graph representation less effective at capturing their structural features. These findings highlight the need to refine the model into a more robust framework that ensures high accuracy across diverse MOF characteristics.

## Computational efficiency

To demonstrate the computational efficiency of our model, we compared its performance with molecular simulations by analyzing the time required for adsorption data generation. In GCMC simulations, generating adsorption data for a single pressure point requires approximately 8.6 hours [12].

While the initial training process for the GNN model requires 31.5 hours for $CO_2$ and 16.5 hours for $CH_4$, this is a one-time computational cost. Once trained, the model is capable of rapidly predicting adsorption data for any given MOF. This makes the proposed framework advantageous for handling large-scale datasets compared to GCMC simulations. This advantage is particularly significant in high-throughput screening processes, where predicting adsorption properties for a vast number of MOFs is required.

## CRAFTED dataset validation

Figure 4 presents the validation results comparing the GNN-predicted and GCMC-simulated isotherms for MOFs included in the CRAFTED dataset. The results indicate a strong alignment between the two isotherms. However, minor discrepancies are observed at comparatively high-pressure ranges. For example, Figure 4 (b) and (c) show noticeable deviations at pressures above 2 bar. The reason for this discrepancy is attributed to the absence of high-pressure adsorption data in the training

set.

These results demonstrate the generalizability of the proposed framework in accurately predicting the adsorption behavior of diverse MOFs.

## 4. CONCLUSION

This study proposed a GNN-based framework utilizing the ALIGNN to predict adsorption isotherms for $CO_2$ and $CH_4$ in MOFs. We developed a GNN model to predict adsorption capacities using a large-scale dataset of hypothetical MOFs and applied an isotherm fitting algorithm to rapidly and accurately fit adsorption isotherms based on the predicted capacities. The developed model demonstrated high predictive accuracy. The computational efficiency of the framework was validated by comparing its calculation time with that of molecular simulations, highlighting its comparative advantage. Furthermore, the framework's generalizability to experimentally synthesized MOF datasets was confirmed through validation.

Consequently, the proposed framework is expected to be utilized for rapid high-throughput screening of MOF adsorbents. Future research should be directed toward developing a model capable of capturing complex MOF structures and establishing a framework that demonstrates high generalizability to diverse MOFs.

## ABSTRACT

This research addresses the challenges associated with data-driven soft sensors in industrial applications, where successful implementations remain limited. The scarcity of practical applications can be attributed to variable operating conditions and frequent disturbances in real-time processes. Industrial data are often nonlinear, dynamic, and highly unbalanced, complicating efforts to capture the essential characteristics of underlying processes. To tackle these issues, we propose a comprehensive solution for industrial application, that encompasses feature selection, feature extraction, and model updating. Feature selection aims to pinpoint the independent variables that have a substantial impact on key performance indicators, including quality, safety, efficiency, reliability, and sustainability. By doing so, it simplifies the model and boosts its predictive accuracy. The process begins with screening variables based on process knowledge, followed by a thorough analysis of correlation and redundancy to eliminate redundant information, which can burden computational resources and degrade prediction accuracy. We propose a mutual information-based algorithm for feature selection that assesses the relevance and redundancy among process variables through a comprehensive correlation function. This algorithm ranks variables by their importance using a Greedy search method to identify the optimal set of variables. After selecting the optimal variables, feature extraction is carried out to derive internal features from this set and establish a relationship between these latent features and the output variables. Given the intricate nature of industrial processes, we employ deep learning techniques, specifically Long Short-Term Memory (LSTM) networks, which are a type of Recurrent Neural Network (RNN) well-suited for capturing long-term dependencies in sequential data. LSTMs excel at modeling temporal correlations due to their ability to maintain memory states that allow for learning from sequential data over extended periods. To address short-term nonstationary features resulting from process disturbances, we incorporate a differential unit into the latent layer of the LSTM network. Once trained, the model is updated during online applications to incorporate gradual changes in equipment and reaction agents. Quality-related data, although typically available only post-measurement, can be leveraged to fine-tune model parameters, ensuring sustained predictive accuracy over time. To validate our approach, we present a case study on a delayed coker unit, yielding promising long-term predictions for tube metal temperature and showcasing the potential of our methodology for industrial applications.

**Keywords**: quality prediction, feature selection, feature extraction

## 1.INTRODUCTION

In chemical production, quality variables serve as indicators of plant operating status and are directly linked to product quality and production efficiency. However, the online acquisition of these quality variables isn often challenging due to limitations in measurement methods and the high cost of instrumentation. To address this challenge, soft sensor technology has been developed to

indirectly estimate quality variables through easily measurable secondary variables such as temperature, pressure, and flow rate [1-2].

Effective selection of secondary variables is a crucial prerequisite for ensuring the performance of soft-sensing models. Distributed control systems can be used to collect a large number of variables, while inputting all of them into the model to establish a correlation with quality variables would increase computational complexity, and the introduction of irrelevant variables would also affect the model prediction performance [3]. Operators can initially determine the range of relevant variables based on their process knowledge, but in front of complex actual chemical processes and control networks, their understanding of the relationships between variables is still insufficient [4]. Therefore, a series of correlation analysis methods have been introduced to assess the degree of correlation between each pair of secondary variables and the quality variable. The Pearson correlation coefficient, a classic correlation analysis tool in machine learning, can effectively measure the linear relationship between candidate features and the target variable [5]. However, chemical processes are typically nonlinear, and some key variables are difficult to identify effectively through linear analysis methods [6]. For the nonlinear relationships between variables, information theory methods, represented by Mutual Information (MI), show significant advantages [7]. One limitation of MI is that its value is unbounded, making it difficult to determine an objective threshold to judge whether the correlation between variables is significant. To address this issue, Ji et al. proposed estimating the MI threshold through random sequences generated by the Monte Carlo method [8]. Estevez et al. introduced a variable selection method based on normalized MI to standardize MI to a range of 0 to 1 [9]. To improve the accuracy of MI estimation, Reshef et al. proposed the Maximal Information Coefficient (MIC) based on MI [10]. MI can be seen as a quantification of the degree of information overlap between secondary variables and quality variables. However, at the same time, variables with high MI values may also have information overlap, i.e., redundancy. The above methods can screen out a series of variables with the strongest correlation with quality variables, but they neglect the information redundancy between variables. Information theory also provides a theoretical basis for the calculation of redundancy between variables. The Maximum Relevance Minimum Redundancy (mRMR) algorithm was proposed from an information-theoretic perspective to measure the correlation and redundancy between variables [11]. Based on this, Xiao et al. proposed an mRMR method based on neighborhood MI [12]. Yin et al. proposed a feature selection method based on Maximum Dynamic Relevance and Minimum Redundancy [13]. Bennasar et al. proposed a joint MI maximization method to measure the importance of candidate features based on conditional MI [14]. However, these methods only consider the information redundancy between secondary variables and ignore their common redundancy with quality variables. Ji et al. considered common information redundancy and proposed a variable selection method based on conditional information entropy, which was validated in the soft-sensing of ethylene components [15]. However, it has limitations in ranking the importance of secondary variables and still does not obtain the optimal set of secondary variables. Che et al. proposed a feature selection method based on Maximum Relevance and Minimum Common Redundancy, which comprehensively considers the correlation and redundancy information between variables to rank the importance of candidate features [16]. Although this method can objectively calculate the ranking of the importance of candidate features, it does not provide a method for determining the optimal feature subset in different machine learning tasks.

To more comprehensively consider the importance and information redundancy of secondary variables in the selection of secondary variables for soft-sensing tasks, this paper introduces the Maximum Relevance and Minimum Common Redundancy feature extraction algorithm based on MI in the variable selection for soft sensor modeling. It establishes an objective evaluation function that comprehensively considers variable correlation and redundancy, updates the set of secondary variables through the Greedy search algorithm to determine the ranking of their importance, and ultimately obtains the optimal set of secondary variables by evaluating the information gain of the secondary variables for predicting the target variable. Then the optimal variable set is input into Long Short-Term Memory (LSTM) networks to extract the nonlinear and temporal features from sequential data and establish mapping relationship with the target variable. To validate the effectiveness of the proposed method, a case study was conducted on a delayed Coker unit at an actual chemical enterprise. The results demonstrate a promising potential for real-time estimation of quality variables in chemical production.

## 2. BACKGROUND

### 2.1 Information theory

Information theory is a mathematical theory proposed by American scholar Shannon, which provides an explanation for the information content of signals and their transmission based on probability theory and mathematical statistics. Due to its clear statistical significance, it is widely used in measuring the correlation and redundancy of variables in industrial processes [17]. The information content of a signal can be measured by the information entropy in Equation (1),

$$\mathrm{H}(X) = \sum_{x \in X} -p(x)\log\left(p(x)\right) \quad (1)$$

where $p(x)$ is the marginal distribution of variable $x$. When extending information entropy to two-dimensional variables, the shared information between them can represent their degree of correlation, which can be calculated using Mutual Information (MI) [18], as shown in Equation (2),

$$\mathrm{I}(X,Y) = \sum_{x \in X}\sum_{y \in Y} p(x,y) log \frac{p(x,y)}{p(x)p(y)} \quad (2)$$

where $p(x,y)$ represents the joint probability distribution of $x$ and $y$, and $p(x)$ and $p(y)$ represent the marginal distributions of $x$ and $y$, respectively, which can usually be approximated using kernel density estimation [19]. According to Equation (2), if the variables are independent, the MI value is 0; the stronger the correlation between the variables, the larger the MI value. In research, the MI values between each variable and the target variable are often used as the basis for ranking variable importance. However, when measuring the correlation between multidimensional variables using information content, redundant information must be considered, as variables with high correlation may not cover more information about the target variable. Taking a ternary variable as an example, when variables $X_1, X_2$ are known, the information content of the target variable $Y$ is,

$$\mathrm{H}(Y|(X_1,X_2)) = H(Y) - I(X_1,Y) - I(X_2,Y) + I(X_1,X_2,Y) \quad (3)$$

where $I(X_1,X_2,Y)$ is the common mutual information among the three variables, also representing the common redundancy among them. From Equation (3), even if variable $X_2$has a strong correlation with the target variable, if its redundancy with variable $X_1$ and target variable $Y$ is also high, it does not necessarily mean that it is highly important for predicting the target variable. Therefore, in variable selection for soft sensors, both correlation and redundancy need to be considered comprehensively to rank the importance of predictor variables and select the optimal set of auxiliary variables. To this end, the MI-based correlation-redundancy feature selection algorithm adopted in this paper is based on the above information theory knowledge, which constructs a correlation evaluation function to measure the importance of each auxiliary variable and determine the optimal variable set. The specific calculation and implementation steps are introduced in Sections 3.

### 2.2 Long short-term memory neural networks

The dynamics of industrial processes are abundant in process data and must be explicitly taken into account to enhance the effectiveness of process monitoring. To this end, recurrent neural networks (RNNs) are frequently utilized to capture these dynamics by transitioning through hidden states. However, as the time-step accumulates, conventional RNNs may fail to maintain the long-term temporal dependencies of the process. A well-recognized variant of RNNs that can address this issue is the LSTM unit, which excels at extracting long-term temporal dependencies. Its advantage lies in the gate-controlled memory transitions, which can be formulated as follows,

$$i_t = \sigma(W_i \cdot [h_{t-1}, x_t] + b_i) \quad (4)$$

$$f_t = \sigma\left(W_f \cdot [h_{t-1}, x_t] + b_f\right) \quad (5)$$

$$g_t = tanh\left(W_g \cdot [h_{t-1}, x_t] + b_g\right) \quad (6)$$

$$o_t = \sigma(W_o \cdot [h_{t-1}, x_t] + b_o) \quad (7)$$

$$C_t = f_t \odot C_{t-1} + i_t \odot g_t \quad (8)$$

$$h_t = o_t \odot tanh(C_t) \quad (9)$$

where $i_t, f_t, o_t$ stand for the input gate, forget gate, and output gate, respectively, $x_t$ is the input at the current time step, $g_t$ is the current candidate state, $C_t, C_{t-1}$ are the memory cells of the current and last time step, $h_t, h_{t-1}$ are the hidden states of the current and last time step, $W., b.$ are the weight and bias, and $\sigma, tanh$ are sigmoid and tanh activation functions. With the gate structure, irrelevant information of hidden states from the previous time step can be forgotten and useful information from the current time step can be retained by the memory cell, making the LSTM unit more effective in extracting long-term time dependency.

## 3.THE PROPOSED MI-BASED FEATURE SELECTION ALGORITHM FOR DATA-DRIVEN QUALITY PREDICTION

The correlation-redundancy feature selection algorithm based on mutual information adopted in this paper takes into account both the correlation among variables and information redundancy to determine the optimal set of auxiliary variables. For the initial set of auxiliary variables $W$ and the quality variable $Y$, this method aims to obtain the optimal variable set $S$ through a correlation evaluation function. The calculation formula is as follows,

$$f(x_i) = \frac{I(x_i,Y)}{I(Y,Y)} - \frac{CI(x_i,S,Y)}{I(Y,Y)} \quad (10)$$

This function consists of two parts. The first part is the ratio of the mutual information between the candidate variable $x_i$ and the target variable $Y$ to the information entropy of the target variable $Y$. It reflects the degree of correlation between the candidate variable $x_i$ and the target variable $Y$. The second part is the proportion of the redundant information $CI(x_i,S,Y)$ among the candidate variable $x_i$, the already selected set of auxiliary

variables $S$, and the target variable $Y$, relative to the information contained in the target variable $Y$. This part reflects the degree of redundancy of the candidate variable $x_i$. The calculation of redundant information is as follows,

$$CI(x_i,S,Y)=\frac{I(x_i,S)}{Max\{I(x_i,\mathrm{S}),\mathrm{I}(x_i,Y),I(S,Y)\}}\times Min\{I(x_i,Y),I(S,Y)\}(11)$$

In summary, this evaluation function comprehensively considers the correlation between each variable $x_i$ and the target variable $Y$, the maximum redundancy between $x_i$ and $S$, as well as the minimum common redundancy among $x_i$, $S$, and $Y$. A higher value of this function indicates a greater importance of the candidate variable $x_i$ for predicting the target variable $Y$. Additionally, the value of this correlation evaluation function is related to the order of variable input. Therefore, this paper adopts a greedy search algorithm to ensure that the variable selected in each round maximizes the value of the correlation evaluation function, thereby more comprehensively and objectively ranking the importance of each auxiliary variable. Meanwhile, after selecting a sufficient number of auxiliary variables, the coverage of information for the target variable $Y$ reaches saturation, and adding more auxiliary variables will not introduce new information, i.e., the correlation evaluation function decreases near zero, thereby finally determining the optimal set of auxiliary variables.

The modeling and implementation steps of the proposed method are shown in Figure 1. The training data is normalized, and the Mutual Information (MI) values between each variable and the quality variable are calculated using Equation (2). The variable with the maximum MI is taken as the initial value of the undefined set $S$, while the remaining variables, excluding this one, are taken as the initial value of $W$. Then, based on the correlation evaluation function in Equation (10), a greedy search approach is used to iteratively calculate the importance of each auxiliary variable in $W$, and $S$ and $W$ are updated accordingly, until the value of the correlation evaluation function decreases to 0. This determines the final set of auxiliary variable features, $S$. Subsequently, a soft sensor model is established based on the ranked auxiliary variables. During online testing, the optimal auxiliary variables determined during the training phase are selected, standardized based on the mean and variance of the training data, and input into the offline-trained soft sensor model to obtain real-time predictions of the target variable. The Mean Absolute Error (MAE), Root Mean Square Error (RMSE), R2, and mean absolute percentage error (MAPE) metrics are calculated to evaluate the prediction performance of the soft sensor model.

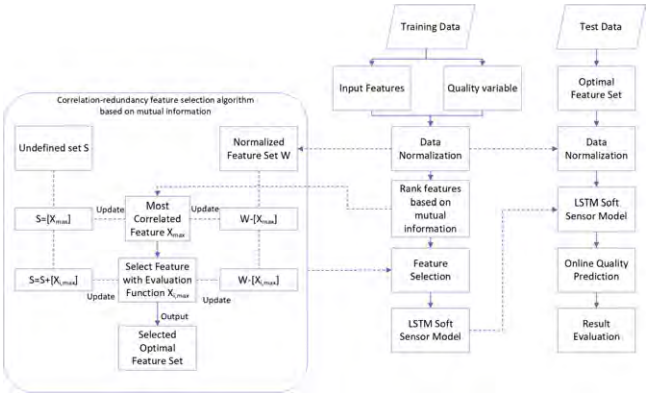

**Figure 1.** Flowchart of the proposed MI-based correlation-redundancy feature selection and soft sensor method.

## 4.CASE STUDY

In this section, data from a delayed Coker unit of an operating factory is investigated to evaluate the proposed method. The delayed Coker unit is a critical component in the refining industry to convert heavy residual oils into lighter, more valuable products. One of the key parameters that significantly influences the performance and reliability of these units is the Tube Metal Temperature (TMT). This temperature represents the heat level within the tubes of the Coker, where the cracking process takes place. An accurate and online estimation on TMT is necessary to enable insights like determination of coking in tubes and drive correct actions, for optimal operating conditions, preventing tube damage, and maintaining high product quality while minimizing costs.

In this case study, 438,049 data points from January 1, 2020 to March 1, 2024 are collected, in which data from ten complete production cycles before 2023 are applied to build the proposed feature selection and soft sensor model and data from the latest one year are employed as test set.

While the range of relevant variables can be identified using the expertise and experience of operators, the significance of these variables for prediction and the redundancy among them may not be fully addressed. To address this problem, the proposed correlation-redundancy feature extraction algorithm based on MI is first applied to all available variables to select an optimal subset of auxiliary variables. Then, a soft sensor model is established using the selected variables.

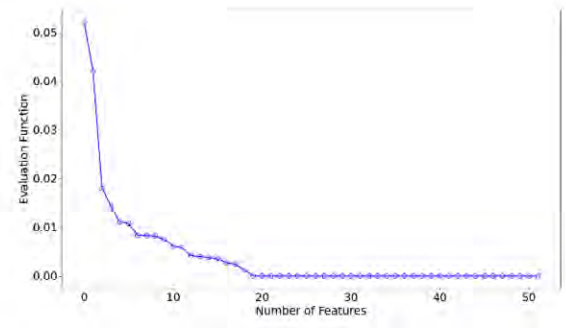

**Figure 2.** Variation of the evaluation function with the number of features.

Using all available variables as inputs, a Greedy search algorithm is employed to iteratively calculate a correlation evaluation function to obtain the importance ranking of each variable. The variation of the evaluation function with the number of features after sorting is shown in Figure 2. It can be observed that as the number of auxiliary variables increases, the amount of information conducive to predicting the target variable continuously grows, and the evaluation function gradually decreases. When the number of auxiliary variables reaches 20, the evaluation function drops to 0, reaching an inflection point, indicating that adding more variables will not introduce new information. Thus, the optimal set of auxiliary variables is finally determined.

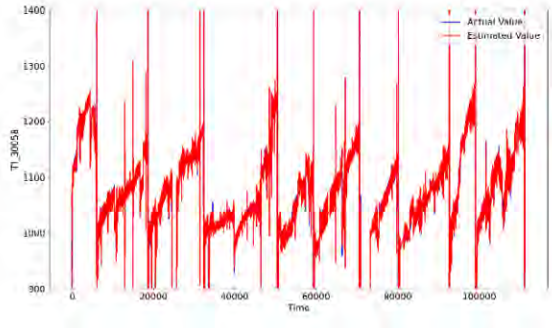

**Figure 3.** The prediction result for TMT.

Using the auxiliary variables determined based on the results in Figure 2, an LSTM-based soft-sensing model is established for online testing using the whole year data in 2023. The online prediction results for TMT are shown in Figure 3. It can be observed that the auxiliary variables selected using the method proposed in this paper can fit the true trend of the quality variable, providing reliable process information to operators and valuable guidance for their online operational decisions. The prediction evaluation metrics for each model are presented in Table 1. It can be seen that the R2 values obtained using our method are all above 0.98, and various error metrics are below 3%. This is attributed to the method's ability to effectively reduce information redundancy among variables while maximizing the coverage of quality variable information.

**Table 1:** The evaluation for prediction results dated from January 9, 2023 to January 30, 2024 except the period from March 15 to May 2, 2023.

## 5.CONCLUSIONS

In conclusion, this study tackles the auxiliary variable selection challenge in soft sensor modeling for chemical processes by introducing a mutual information-based relevance-redundancy feature selection algorithm. This algorithm thoroughly evaluates the correlations and redundancies among variables to obtain an optimal feature set for prediction. By leveraging LSTM networks, the study effectively captures the complex patterns and temporal dependencies present in industrial data, thereby enhancing the predictive accuracy of the soft sensor models. Furthermore, a model update mechanism is integrated to maintain the accuracy and reliability of the models over time. The effectiveness of this comprehensive approach is illustrated through a case study on a delayed Coker unit. Overall, this study offers a robust and objective strategy for auxiliary variable selection in soft

sensor modeling, significantly improving model predictive performance and laying the groundwork for optimizing and controlling chemical processes.

## ABSTRACT

Catalysis design and reaction condition optimization are considered the heart of many chemical and petrochemical processes and industries; however, there are still significant challenges in these fields. Advances in machine learning (ML) have provided researchers with new tools to address some of these obstacles, offering the ability to predict catalyst behaviour, optimal reaction conditions, and product distributions without the need for extensive laboratory experimentation. In this contribution, the potential applications of ML in heterogeneous catalysis and photocatalysis are explored by analysing datasets from different reactions, including Fischer-Tropsch synthesis and photocatalytic pollutant degradation. First, datasets were collected from literature. After cleaning and preparing the datasets, they were employed to train and test several models. The best model for each dataset was selected and applied for optimization.

**Keywords**: Catalysis, Machine Learning, Modelling, Optimization, Alternative Fuels, Environment, Fischer-Tropsch Synthesis, Photocatalysis

## INTRODUCTION

Developing catalysts (heterogeneous and photocatalysts) and selecting the optimum reaction conditions are considerable challenges. In this process, complex variables need to be addressed, including active material selection, catalyst structure design, or operating parameter optimization [1]. All these tasks require considerable effort in lab and numerous reaction tests, which are not only energy- and time-intensive but also costly. Recent advances in Machine Learning (ML) provide scientists with powerful tools to model and predict the behavior of catalysts, optimize reaction conditions, and forecast product distributions [2]. These methods leverage large datasets and employ sophisticated algorithms, significantly reducing the energy, time, and money spent in laboratory research. By using ML to model and optimize the processes, researchers can now identify patterns, simulate complex reactions, and generate previously unattainable insights. ML enables correlation analysis to uncover relationships between various parameters and catalyst performance. Predictive models, trained on existing data, can forecast the effectiveness of new materials. Additionally, ML provides data-driven insights that offer valuable guidance for catalyst design and optimization [3].

This work introduces a comprehensive framework unifying various aspects of catalyst development and optimization, addressing a significant gap in existing research. The framework's novelty lies in its holistic approach, integrating multiple aspects of catalytic processes, including catalyst formulation, structure, preparation, activation, and operating conditions. Unlike previous studies focusing on individual aspects, this integrated approach provides a more complete understanding of catalyst behavior across diverse catalytic processes: environmental pollutant degradation using photocatalysts, and Fischer-Tropsch Synthesis (FTS) for liquid fuel and jet fuel production, respectively, using heterogeneous catalysts.

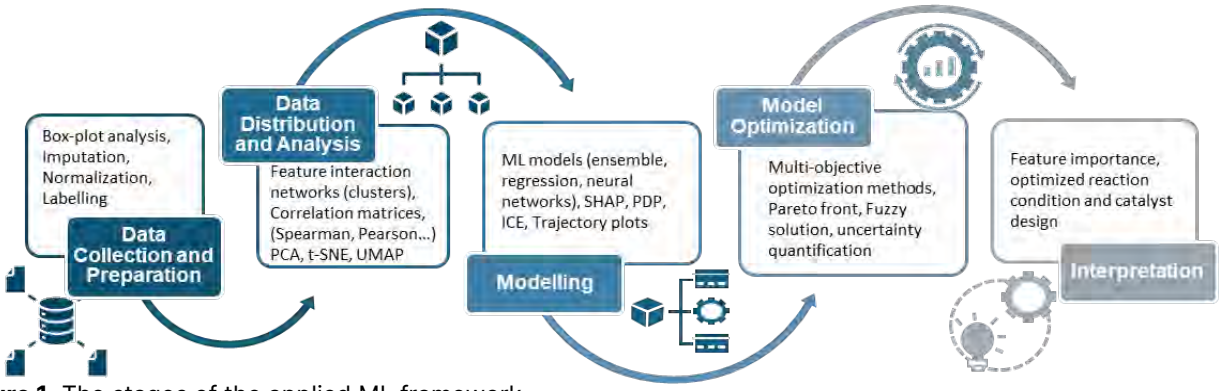

**Figure 1.** The stages of the applied ML framework.

## METHODOLOGY

First the data is collected from literature. The datasets are categorized based on different features like catalyst formulation, catalyst characterization, activation, and reaction conditions with the goal of predicting catalyst performance. To prepare the datasets, the data is cleaned, labelled, imputed and normalized. Techniques such as Spearman correlation matrices, dendrograms, pair plots, and dimensionality reduction methods are applied to uncover relationships between descriptors and catalyst performance. The data is then employed to train and test several models. Performance metrics such as root mean square error (RMSE), mean absolute percentage error (MAPE), Akaike Information Criterion (AIC), and coefficient of determination ($R^2$) are used to assess model accuracy. Given the non-linear nature of the models, RMSE was selected as the primary evaluation metric for model selection, while R2 is reported as a complementary measure to provide additional context. After selecting the best model, it is used for optimization to find the optimum point with the highest catalysis performance. Figure 1 illustrates this framework, and the subsequent subsections provide a more detailed description of each step in the process.

### Data Collection and Preparation

The three datasets used in this work are for perfluorooctanoic acid (PFOA) degradation with photocatalysis, FTS for liquid fuel production, and FTS for jet fuel production.

**Table 1.** Number of descriptors and target responses in the different datasets of three case studies.

| Reaction | Descriptors | Target Responses |
|---|---|---|
| PFOA photocatalysis | 9 | 2 |
| FTS for liquid fuel | 26 | 2 |
| FTS for jet fuel | 21 | 2 |

The data is manually extracted from literature. The derived data is classified as descriptors and target responses as mentioned in Table 1. These descriptors are different parameters describing the catalyst formulation, catalyst characterization, catalyst activation, and reaction conditions.

The data is prepared using standard methods. These steps include removing outliers with box-plot analysis, labeling through label encoding or one hot labeling, imputing missing data using methods such as Soft Impute, k-nearest neighbours (KNN), etc., and normalizing to improve data quality.

### Data Distribution and Analysis

Cluster analysis and Spearman correlation analysis were also used to examine the relationship between features.

In the datasets with a large number of datapoints, principal component analysis (PCA) was used to reduce the dimension of the experimental datasets. PCA transforms high-dimensional data into a lower-dimensional space, preserving key patterns and relationships by identifying directions (principal components) that capture maximum variance in the data.

### Modelling

Several ML algorithms (models) including Random Forest, CatBoost, Boosted Gradient, Artificial Neural Networks (ANN) etc. are used to predict the target responses. The performance of the models is evaluated and compared using the performance metrics mentioned above. Important features were identified using Shapley Additive Explanations (SHAP) and Partial Dependency Diagram (PDP) techniques.

### Optimization

The Non-dominated Sorting Genetic Algorithm II (NSGA-II) was used for multi-objective optimization to find the optimum conversion and selectivity as target responses [4]. This method helps to identify the optimum points on the Pareto front. Subsequently, a Fuzzy-based

method selected a balanced solution using membership functions with parameters [0.2, 0.5, 0.8] from normalized data. Here, 0.2 sets the minimum acceptable value, 0.5 the ideal target, and 0.8 the upper limit. The solution maximizing the minimum satisfaction score ensured both objectives remained strong without trade-offs, aligning with multi-criteria decision-making [5]. The most important descriptors for the best solution are determined and compared with the experimental data.

## RESULTS AND DISCUSSION

### Photocatalysis of PFOA

The database for the case study of photocatalytical PFOA degradation consists of 127 datapoints, with two target responses and nine descriptors. One-hot labeling is used to convert categorical data to numerical data. For dealing with missing data, five different imputation methods were tested like Stochastic Within-Zone (SWZ), Robust Principal Component Analysis (RPCA), smallest squares, Automatic JMP imputing and mean Python imputing, as well as the removal of these points. Before running the model, the data is also normalized.

The data distribution shows mostly similar patterns, yet some unique distributions result from the different imputation methods. A prominent example (pH) is shown in Figure 2. Further differences include: The smallest squares method leads to additional peaks in higher regions for pH and degradation in comparison to SWZ and RPCA. Automatic JMP and mean Python distributions are highly similar, with a prominent brooding of pH- and defluorination-distributions. The mean Python method shows a distribution for light type and degradation as similar to the method, where all missing values were removed. Yet, this last method shows the broadest distribution for all descriptors and target responses. Thus, it can be concluded that the data distribution is biased.

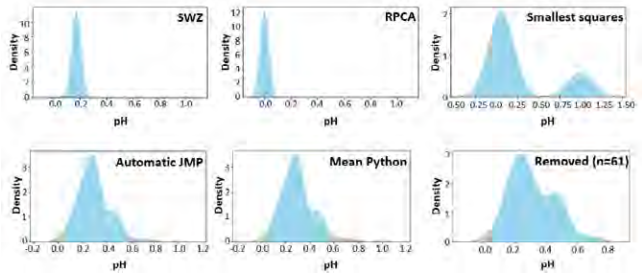

**Figure 2.** Data distribution with different imputation methods.

Pearson correlation analysis reveals that the imputation method plays an important role in the linearity, as this correlation specifically measures linear relationships between two variables. It can be noticed that there is very little linear correlation in this photocatalytic dataset. In general, the correlation is more positively linear for the defluorination (here correlation to treatment time and pH), which might be attributed to a higher number of missing values. For degradation, the correlation is mostly negatively linear, especially for the variables such as catalyst amount, initial PFOA concentration and in some cases pH.

Spearman correlation analysis is conducted as well. Compared to Pearson, Spearman reveals fewer negative correlations overall, indicating that the data has significant non-linear relationships not captured by the linear correlation. Furthermore, for all imputation methods (beside of missing value removal) a much stronger negative correlation between degradation and initial PFOA concentration is depicted. This is found for the defluorination response as well in Automatic JMP, mean Python and removal methods. For SWZ, RPCA and smallest square imputations no positive correlations, as in the case with Pearson, can be found and treatment time shows a highly negative correlation with defluorination.

The model screening runs 5 times and model optimization is conducted using 10 loops of hyperparameter optimization (GridSearch). Based on high $R^2$ and low RMSE values. the best result for predicting the degradation response is achieved with the KNN model (SWZ-imputation) and partly with the Neuronal Boosted model (removal of missing data). The defluorination response is captured well with the Neuronal Boosted model (SWZ, RPCA and Automatic JMP imputations).

Best results for the response degradation are obtained with SWZ imputation and the KNN model ($R^2$=0.843, RMSE=0.004), while the defluorination response is captured well by the SWZ imputation and Neuronal Boosted model ($R^2$=0.987, RMSE=0.021), as well as by Automatic JMP imputation with the Neuronal Boosted model ($R^2$=0.998, RMSE=0.009). For comparison, with a simple linear regression model, an average $R^2$ of 0.8 for the defluorination response can be reached (RMSE and MAE<1, AIC=-2 to 45).

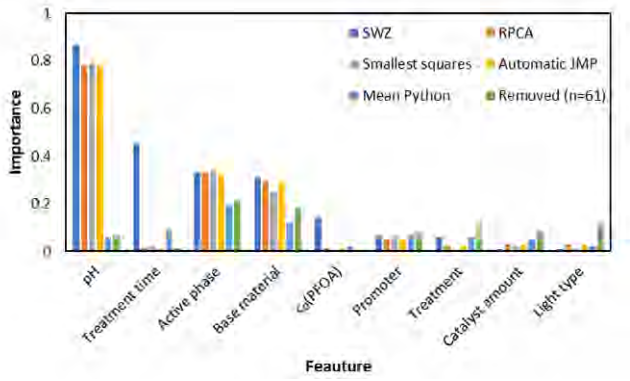

**Figure 3.** Feature importance with linear regression model for defluorination response with different imputation methods.

The importance of each feature on the defluorination response for the linear regression model is shown in Figure 3, where slight changes can be seen with each imputation method. Main features that influence PFOA defluorination are the pH and the nature of the catalyst (active phase, base material). Linked to the latter is the light type. Interestingly, treatment time plays a minor role in most imputation methods, which highlights the biased data (only small treatment times reported). Beside of the latter (due to bias), the results match other publications on this topic regarding photocatalysis of PFOA [6]. A more theoretical and compound-based approach for the defluorination of Per- and Polyfluoroalkyl Substances (PFAS) has been reported by Raza et al. [7].

## FTS for Liquid Fuel Production

A dataset of 96 datapoints is used to model and optimize liquid fuel production using FTS. This dataset includes 26 features consisting of catalyst formulation, characteristics, and operational conditions. As for the targets, CO conversion and $C_{5+}$ selectivity are chosen to represent the liquid fuel production.

To prepare the dataset, after removing the outliers, label encoding is used to change the categorical data to numerical data. Similarly to the previous case study, different methods are used for imputation of the missing data; among them, automated imputation in JMP has shown the best performance and is selected for this dataset. Then data is normalized for the effect of features to be comparable.

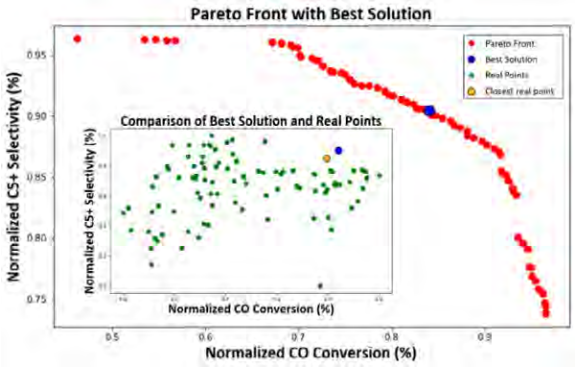

**Figure 4.** Pareto front with Fuzzy-based solution for normalized CO conversion and $C_{5+}$ selectivity.

To find the best model for describing the behaviour of the dataset, 5 different models are tested and compared, including: XGBoost, LightGBM, Gradient Boosting, CatBoost, and Random Forest. To compare the performance of these models, different criteria, described in the previous sections are used. Among the models, CatBoost had the best performance with $R^2$, MSE, RMSE, and MAE equal to 0.95, 0.003, 0.057, 0.041, respectively for CO conversion and 0.88, 0.004, 0.063, 0.035 for $C_{5+}$ selectivity.

The CatBoost model is then used for optimization. The aim was to optimize the CO conversion and $C_{5+}$ selectivity. The Pareto front with the optimal Fuzzy solution, as well as the comparison of the best solution and the real data, are depicted in Figure 4.

Since the data was normalized in the preparation step, to recover the real data, de-normalization is carried out. The best Fuzzy solutions for CO conversion and $C_{5+}$ selectivity are 76.24 % and 81.89 %, respectively. The best Fuzzy solution is also compared with the experimental values and the closest point is also detected [8]. The values for these two points are summarised in Table 2.

**Table 2.** Descriptor values for the best optimum point and closest real point.

| Descriptor | Best Solution | Closest Real Point |
|---|---|---|
| Support | ZSM-5 | ZSM-5 |
| Active metal | Cobalt | Iron |
| Active metal loading (%) | 16.66 | 18.00 |
| $H_2$/CO ratio | 2 | 2 |
| Zeolite $SiO_2/Al_2O_3$ ratio | 19.31 | 280.00 |
| Calcination temperature (°C) | 371.55 | 450.00 |
| Calcination time (h) | 3.10 | 8.00 |
| Pore volume ($cm^3/g$) | 0.58 | 0.17 |
| Meso-pore volume ($cm^3/g$) | 0.16 | 0.13 |
| Reduction temperature (°C) | 402.66 | 420.00 |
| Reduction time (h) | 1.84 | 10.00 |
| Reaction temperature (°C) | 241.38 | 280.00 |
| Reaction pressure (bar) | 19.91 | 19.00 |
| Time on stream (h) | 67.78 | 34.46 |
| Loading of catalyst (g) | 1.34 | 0.50 |
| $C_{5+}$ selectivity (%) | 81.89 | 78.20 |
| CO conversion (%) | 76.24 | 72.40 |

## FTS for Jet Fuel Production

To develop a ML method for modelling and optimizing jet fuel production through FTS, a dataset of 41 datapoints from 10 recent research papers was collected. The data was manually extracted and included 21 features related to catalyst formulation and operating conditions. The model targets included $C_8$-$C_{16}$ selectivity and CO conversion rate.

The data was prepared by removing outliers using box-plot analysis, imputing missing data with methods such as Soft Impute and KNN, and normalization to improve data quality. Cluster analysis and correlation matrix methods were also used to examine the relationship between features.

Several ML algorithms including Random Forest, CatBoost, Boosted Gradient, and ANN were evaluated to predict $C_8$-$C_{16}$ selectivity and CO conversion. The CatBoost model showed the best performance using metrics such as $R^2$, RMSE, and MAPE. Important features were

identified using SHAP and PDP techniques.

These analyses showed that the $H_2$/CO ratio, the reaction temperature, and the catalyst specific surface area had a significant impact on the selectivity and conversion rate. For example, higher reduction temperature and moderate active metal loading led to improved catalyst performance.

The NSGA-II algorithm was used to simultaneously optimize selectivity and conversion. This method helped to identify the optimal points on the Pareto front. Then, the optimal parameters including active metal loading, reduction temperature, reaction temperature, and $H_2$/CO ratio were determined. The results were evaluated using statistical indices and comparison with experimental data.

**Table 3.** Value of the features for best solution point

| Parameter | Best solution | Closest Real Point |
|---|---|---|
| Active metal | Iron | Iron |
| Promoter | Yes | Yes |
| Active metal loading (%) | 50.5 | 100.0 |
| Promoter loading (%) | 5 | 6 |
| Average pore size of catalyst (nm) | 4.25 | 4.24 |
| Specific surface area of catalyst ($m^2$/g) | 283.8 | 14.6 |
| Specific surface area of support ($m^2$/g) | 504.0 | 458.4 |
| Acidity of support (μmol/g) | 1040 | 465.8 |
| Active metal particle size (nm) | 12.30 | 11.44 |
| Calcination time (h) | 4 | 4 |
| Calcination temperature (°C) | 450 | 450 |
| Reduction atmosphere | $H_2$/CO | $H_2$/CO |
| Reduction time (h) | 6.5 | 10.0 |
| Reduction temperature (°C) | 407.5 | 350.0 |
| Reaction temperature (°C) | 265 | 250 |
| Reaction pressure (bar) | 39.45 | 20.00 |
| Loading of catalyst (g) | 1.6 | 0.5 |
| $H_2$/CO ratio | 1.25 | 2.00 |
| Time on stream (h) | 99 | 60 |
| $C_8$-$C_{16}$ selectivity (%) | 36.86 | 30.00 |
| CO conversion (%) | 49.32 | 50.00 |

Statistical analyses showed that properties such as active metal loading and specific surface area of the catalyst had a significant effect on catalyst performance. For example, increasing the metal loading by about 15 % increased the selectivity, but loading beyond this value led to a decrease in performance. In addition, properties such as support acidity and surface area played a key role in improving the $C_8$-$C_{16}$ selectivity.

The CatBoost model showed the best performance with an accuracy of $R^2$=0.82 for CO conversion and $R^2$=0.84 for $C_8$-$C_{16}$ selectivity. This model had higher accuracy than other methods such as Neural Networks and Random Forests and was able to better analyze the complex relationships between properties and responses. Also, the use of model interpretability techniques such as SHAP helped to better understand the effect of the properties.

The $H_2$/CO ratio had a nonlinear effect on selectivity. Increasing this ratio to 2 improved the $C_8$-$C_{16}$ selectivity, but higher values produced lighter products. Also, the reaction temperature between 245 °C and 260 °C provided the optimal conditions for jet fuel production.

It was found that the specific surface area of the catalyst and the support acidity played an important role in increasing the selectivity. Catalysts with mesoporous structure and moderate acidity performed best. These features helped to improve the chain reactions and reduce light by-products.

Additionally, the Fuzzy satisfaction levels for solutions obtained using a multi-objective genetic algorithm were evaluated. The optimized parameters achieved a MSE of 0.015 and an $R^2$ of 0.70, indicating high accuracy. The best compromise solution offered 36.48 % $C_8$-$C_{16}$ selectivity, 48.95 % CO conversion, and a Fuzzy satisfaction level of 0.99, suggesting a well-balanced trade-off. Further refinement used the minimize function from the SciPy optimization library to match target values of 36.48 % $C_8$-$C_{16}$ selectivity and 48.95 % CO conversion. The optimized input features, shown in Table 3, closely matched these targets with predicted values of 36.86 % and 49.32 %, respectively. This accuracy validates the robustness of the models and the optimization process. The optimal parameters were identified as a reduction temperature of 407.5 °C, a reaction temperature of 265 °C, a reaction pressure of 39.45 bar, and a $H_2$/CO ratio of 1.25. These values provided a balance between selectivity and conversion. The results obtained were in good agreement with the experimental data and confirmed the effectiveness of the applied framework.

## CONCLUSIONS

In this work, an applied ML framework is used for modeling and optimizing different datasets on photo-catalysis and heterogeneous catalysis.

For the photocatalytic degradation of PFOA the importance of data quality is highlighted, as biased data influenced the efficiency of the modelling procedure. Reliable (in-house generated) experimental data for photocatalysis is recommended for ML processes. Regardless of this, the influence of different imputation methods is presented, which can be considered in future applications. Additionally, the resulting feature importance for defluorination is in accordance with recent literature.

Moreover, the applied ML framework provides a

powerful tool for the rational design of FTS catalysts and operating conditions to maximize liquid and jet fuel production, respectively. For liquid fuels, zeolite $SiO_2/Al_2O_3$ ratio, pore volume, and reaction temperature and pressure are identified as key parameters. In the case of jet fuel production, $H_2/CO$ ratio, temperature, and surface area are key to jet fuel selectivity. Multi-objective optimization was used to identify optimal catalysts and FTS operating conditions.

In the case of liquid fuel production, the CatBoost model is the best model and can predict the dataset satisfactorily. After using this model for optimization, the best solution for maximizing the CO conversion and $C_{5+}$ selectivity are also obtained.

The ML framework not only predicts outcomes but also guides experimental efforts by identifying key parameters for catalyst optimization. It reconciles conflicting trends in literature and contributes to the FTS mechanism debate. Moreover, for experimentalists, it offers a practical tool for understanding performance limits, focusing on achievable improvements, and predicting optimal parameters without extensive trial-and-error.

For the next step, the identified optimal catalysts with the best optimized solutions will be tested experimentally to check their performance. This can be used both for model verification/validation and for actual catalysis optimization. For further work, the suggested framework will also be used for datasets of other catalytic reactions, expanding its applicability and ensuring robustness in diverse reaction conditions.

## ABSTRACT

Deep learning faces significant challenges in efficiently training large-scale models. These issues are closely linked, as efficient training often depends on precise and computationally feasible gradient calculations. This work introduces innovative methodologies to improve deep learning network (DLN) training in complex systems. A novel approach to DLN training is proposed by adapting the block coordinate descent (BCD) method, which optimizes individual layers sequentially. This is combined with traditional batch-based training to create a hybrid method that harnesses the strengths of both techniques. Additionally, the study explores Iterated Control Random Search (ICRS) for initializing parameters and applies quasi-Newton methods like L-BFGS with restricted iterations to enhance optimization. By tackling DLN training efficiency, this contribution offers a comprehensive framework to address key challenges in modern machine learning. The proposed methods improve scalability and effectiveness, especially for handling complex real-world problems. Examples from Process Systems Engineering illustrate how these advancements can directly enhance the training of large-scale systems.

**Keywords**: Artificial Intelligence, Machine Learning, Numerical Methods.

## INTRODUCTION

Deep learning, a specialized subset of machine learning, utilizes artificial neural networks with multiple layers to model and learn intricate patterns from large datasets. Unlike traditional machine learning, which often relies on manually engineered features, deep learning autonomously extracts hierarchical representations of data through its layered architecture. This capability enables it to address highly complex problems in domains such as image and speech recognition, natural language processing, drug discovery, and genomics [1]. By learning directly from raw data, deep learning reduces the need for domain-specific feature engineering, offering remarkable flexibility and scalability.

Despite this transformative potential, deep learning faces several challenges. One of the primary obstacles is computational complexity. Training deep neural networks (DNNs) requires substantial resources, including high-performance GPUs and significant memory capacity for data storage. These requirements make deep learning both resource- and cost-intensive. Additionally, deep models demand large amounts of data to achieve high accuracy, posing a limitation in fields where data collection is sparse or expensive.

Optimization of deep learning models presents another significant challenge. Training involves tuning numerous hyperparameters (i.e., learning rates, layer configurations), which is both time-consuming and computationally demanding. Various optimization techniques, including stochastic gradient descent (SGD) or ADAM have been developed, to improve training efficiency and convergence. However, the process remains difficult due to the complexity of deep architectures.

Despite these challenges, significant advancements continue to improve the robustness and efficiency of deep learning systems. The training of deep learning networks (DLNs) involves optimizing a loss function to minimize the difference between model prediction and actual targets. Backpropagation, introduced by Rumelhart et al. [2], remains the foundational algorithm for training DLNs, efficiently calculating gradients using the chain rule. However, backpropagation faces challenges such as vanishing gradients in deep networks, which slow or halt

learning [3]. Techniques like batch training and optimization methods such as stochastic gradient descent (SGD) or ADAM have been developed to address these issues, improving convergence and computational efficiency. Recent advances include block coordinate descent (BCD) [4], which updates parameters layer by layer to reduce computational overhead, and its application in binary neural networks for resource-constrained devices.

While the algorithmic logic of such methods is implementation-agnostic, the practical deployment of deep learning frameworks can benefit significantly from modern software engineering practices. Object-oriented programming (OOP) facilitates modular and reusable code structures, which are particularly valuable for building and scaling complex deep learning systems. Frameworks like TensorFlow or PyTorch adopt OOP principles to encapsulate components such as layers, optimizers, and loss functions, facilitating scalability and distributed training [5]. These innovations collectively address the growing complexity of DLNs while improving training efficiency and adaptability across diverse hardware environments. The proposed framework, while using algorithmic innovations of BCD and ICRS, leverages the advantages of OOP to create a flexible and extensible platform. The following sections will detail the algorithmic aspects of the approach, and where relevant, highlight how OOP principles contribute to its practical implementation.

## METHODOLOGY

This contribution introduces a novel approach to deep learning optimization by addressing key limitations in traditional methods, particularly in computational efficiency, scalability, and flexibility. Unlike conventional techniques such as SGD and ADAM, which optimize all parameters simultaneously and often struggle with the complexity of deep networks, the proposed framework illustrated in Figure 1 leverages a Block Coordinate Descent (BCD)-based strategy.

This method dynamically identifies and optimizes the most influential layers using sensitivity measures [3], ensuring computational resources are allocated effectively. The modularity enabled by the proposed OOP design allows to easily swap and configure different BCD variants, such as those using different sensitivity measures or layer selection strategies.

To further enhance global exploration and avoid local minima, the framework integrates Iterated Control Random Search (ICRS) [6], a global optimization technique that efficiently explores non-convex parameter spaces. By combining ICRS for initial exploration with BCD for layer-specific refinement, the framework achieves more robust convergence and improved training stability for complex neural architectures. Additionally, the framework incorporates object-oriented design to overcome the modularity and adaptability of existing deep learning tools. The ICRS optimizer is implemented as a separate class that can be easily integrated with other components of the framework due to the well-defined interfaces of the OOP design. Similarly, different optimization algorithms (Table 1) are encapsulated within dedicated classes, adhering to a common interface, facilitating easy swapping and comparison of optimization strategies. The framework is implemented in Python 3.11 on an AMD Ryzen 9 7950X 16-core processor with 56GB RAM.

It is important to clarify that the algorithm depicted in Figure 1 represents the computational flow of the proposed hybrid training approach and is, in principle, independent of any specific programming paradigm. The core logic of BCD and ICRS could be implemented in various ways. However, an OOP approach is chosen to enhance code organisation, reusability and maintainability. Specifically, the framework is structured around classes representing different layers, optimizers and training strategies. This facilitates easy swapping and modification of individual components without affecting the rest of the system.

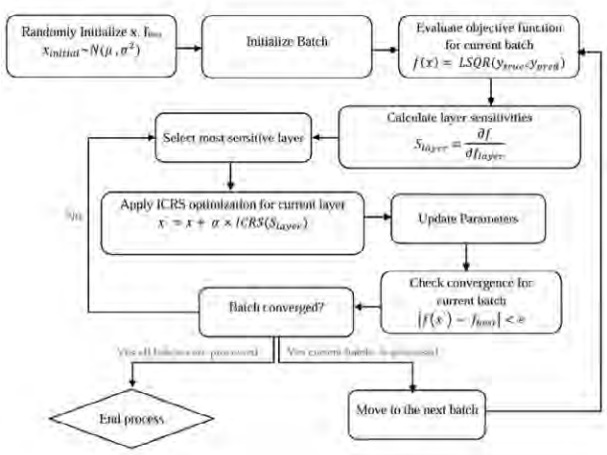

**Figure 1.** OOP deep learning network training algorithm

**Table 1:** Optimization methods

| Optimizer | Type |
|---|---|
| ADAM | Stochastic gradient-based |
| L-BFGS | Quasi-Newton gradient-based |
| Barzilai-Borwein | Gradient-based |
| ICRS | Derivative free |

## CASE STUDIES

To evaluate the performance of the proposed deep learning framework, two datasets from the UCI Machine Learning Repository [7] are utilized: the combined cycle power plant (CCPP) dataset, and the steel industry energy consumption (SIEC). The CCPP dataset consists of

9,568 samples with four features and one target variable. This dataset captures data from a CCPP where electricity is generated through gas and steam turbines working in tandem, making it a well-suited benchmark for regression tasks in industrial energy systems.

The SIEC dataset contains 35,040 samples with fifteen features and one target variable. The data is collected from a smart small-scale steel industry in South Korea at 15-minute intervals over a year, providing a high-resolution temporal dataset suitable for time-series forecasting and energy efficiency analysis.

For the CCPP dataset, a fully connected deep learning network was implemented, with an input layer of four neurons (one per feature), followed by hidden layers with varying configurations (i.e., 5,5,5; 10,10,10, etc.) and an output layer consisting of a single neuron for predicting power output. Each layer type (input, hidden, output) is implemented as a separate class, allowing for easy modification of layer parameters and the addition of new layer types without affecting other parts of the network.

To further enhance performance, four distinct block-selection strategies were explored: most sensitive layer selection, random layer selection, forward sequential selection, and ping-pong directional updates. The model's accuracy was assessed using the coefficient of determination ($R^2$), mean squared error (MSE), and mean absolute error (MAE).

For the SIEC dataset, a similar architecture is adopted with fifteen input neurons in the input layer and sensitivity-based block selection is employed to adaptively refine layer-wise updates. Various activation functions, including sigmoid, Tanh, ReLU and Leaky ReLU activation functions, are tested in the hidden layers for both datasets, to evaluate their impact on learning dynamics. Each activation function is implemented as a distinct class. This allows for easy experimentation with new activation functions by simply creating a new class that implements the required interface, without modifying the core network architecture.

Hyperparameters for both datasets were tuned to ensure effective and stable learning and included parameters such as batch subset size set to 1.1 times the number of network parameters and sensitivity tolerance adjusted to 10 times the projected gradient tolerance. The tuning process involved systematically exploring different combinations of learning rates, batch sizes, etc. to optimize model performance.

## RESULTS AND DISCUSSION

### The CCPP dataset

The first stage of evaluating the performance of the proposed DLN training framework looked into the different types of activation functions, while keeping the network architecture and hyperparameters constant.

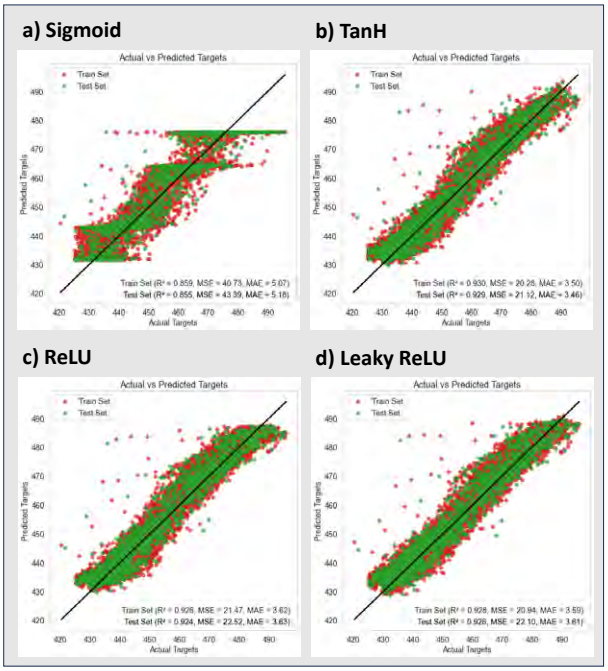

**Figure 2.** Performance comparison for various activation functions

As illustrated in Figure 2, Tanh emerges as the most reliable activation function, achieving high $R^2$ values (0.929 for the test set) and low MSE/MAE across multiple runs. LeakyReLU performs comparably but exhibits slightly higher variability in predictions. ReLU shows good performance but has more scattered test points compared to Tanh and LeakyReLU. Sigmoid performs the worst due to higher residual variance and non-uniform distributions. Visualizations of actual versus predicted values confirm that Tanh and LeakyReLU produce predictions closer to the diagonal line, indicating more accurate fits. Residual plots further demonstrate that Tanh has more uniform residuals with fewer outliers compared to other activation functions.

To ensure robustness, multiple runs are conducted with randomized test sets for Tanh and LeakyReLU. This approach assesses whether these activation functions maintain consistent performance across different data splits. Results confirm that Tanh consistently outperforms LeakyReLU in terms of stability and accuracy, with slightly higher $R^2$ values and lower MSE/MAE on average. For example, in one run, Tanh achieves an $R^2$ of 0.930 on the test set compared to 0.926 for LeakyReLU. Additionally, Tanh exhibits tighter clustering of residuals around zero across runs, suggesting better generalizability. Further, the impact of different block selection strategies on deep learning model performance strategies have been examined.

Figure 3 illustrates the different layers selected by each of the four approaches considered. The findings revealed that the most sensitive layer method consistently

outperformed the other strategies across the performance metrics. This method demonstrated the highest and most consistent $R^2$ values for both training and test sets, while also exhibiting lower and more uniform MSE and MAE values across multiple runs. Notably, the Most Sensitive Layer approach showed the lowest standard deviation in $R^2$, MSE, and MAE, indicating superior robustness and stability compared to the other methods.

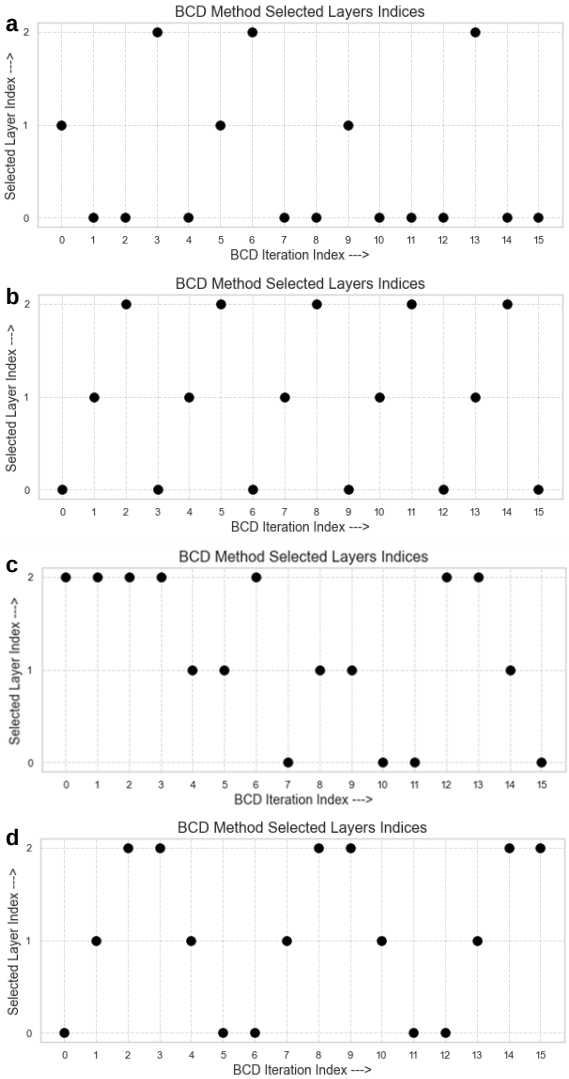

**Figure 3.** Selection of layers for the BCD using: a) most sensitive layers; b) random layer; c) forward sequentially; and d) ping-pong directionality approach.

The results suggest that the most sensitive layer method is better suited for handling variations in handling input data compared to the other methods, making it the most robust and reliable strategy for optimizing the performance of the deep learning model. To investigate the influence of the four optimization algorithms, and their integration with the BCD, a batch shell method is employed to improve model performance. BCD divides the dataset into mini-batches, optimizing each batch separately, while the Batch Shell Method focuses on layer-by-layer optimization, prioritizing the Most Sensitive Layer in the network.

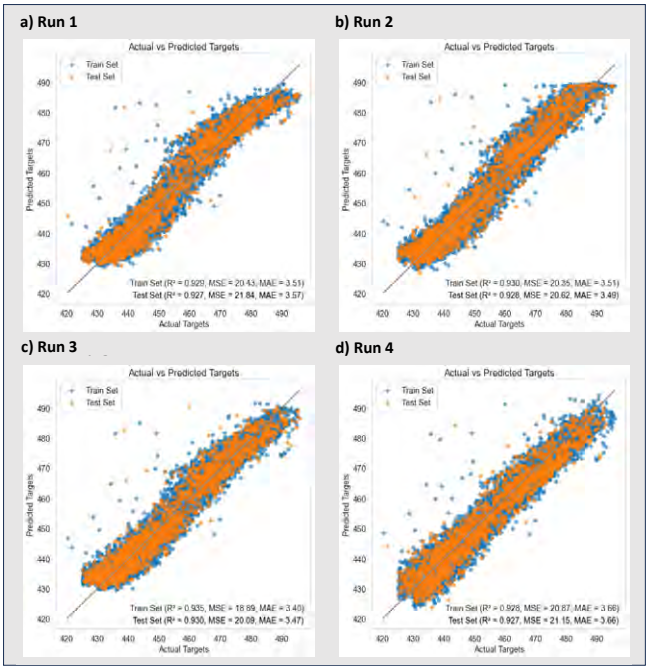

**Figure 4.** Performance comparison for four runs with ICRS for the CCPP dataset

A randomized test set approach is employed to compare ICRS and L-BFGS across five runs, revealing comparable performance but slight differences in consistency (Figure 4). ICRS achieves test $R^2$ values ranging from 0.921 to 0.931, with MSE between 19.79 and 23.27 and MAE between 3.46 and 3.60, while L-BFGS shows test $R^2$ values from 0.914 to 0.931, MSE between 20.01 and 25.53, and MAE between 3.44 and 3.80. Although both optimizers perform well, ICRS demonstrates slightly better stability across runs, particularly in residual distributions.

When combining these optimization methods with BCD and Batch Shell, ADAM provides faster convergence due to its adaptive learning rates but is more sensitive to noisy gradients in smaller datasets or complex models. In contrast, L-BFGS achieves slightly higher accuracy but requires longer training times due to its computational intensity in approximating curvature information. The Batch Shell Method emerges as a promising approach for improving layer-specific optimization by targeting the Most Sensitive Layer, especially when combined with robust optimizers like ICRS or L-BFGS. This integration ensures that the model benefits from both global optimization strategies (e.g., ADAM) and targeted improvements in layer-specific sensitivity (via Batch Shell).

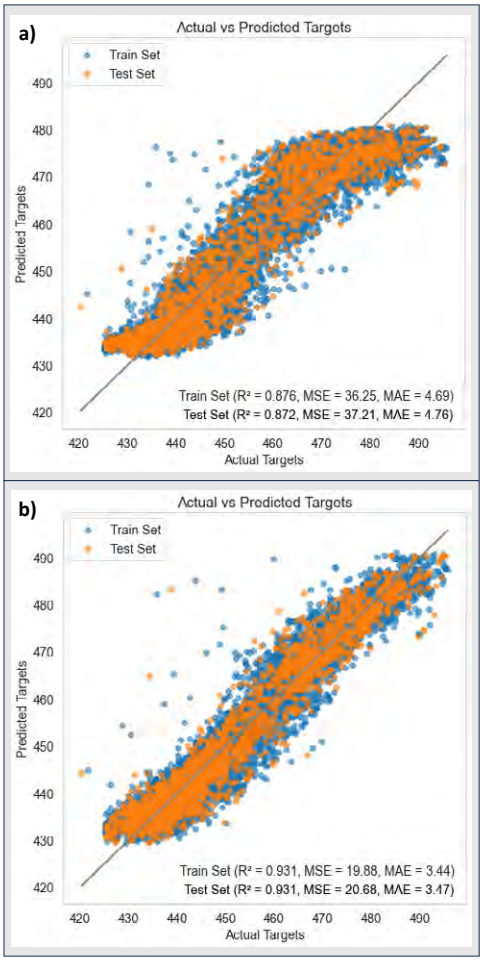

**Figure 5.** Performance comparison for model training using the CCPP dataset: a) without integration of ICRS with BCD; and b) with integration of ICRS with BCD.

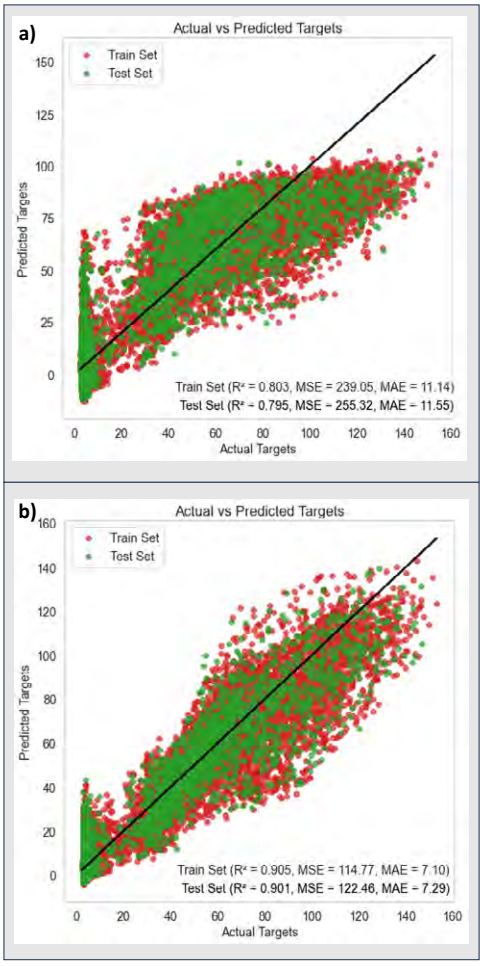

**Figure 6.** Performance comparison for model training using the SIEC dataset: a) without integration of ICRS with BCD; and b) with integration of ICRS with BCD.

Overall, the study highlights that combining advanced optimization techniques with structured learning strategies can significantly enhance deep learning performance for predictive tasks.

To assess the implementation of the BCD as a key optimization strategy, this sequential procedure to optimize model parameters layer by layer has been integrated with the ICRS to enhance the initialization of parameters and improve convergence in high-dimensional spaces. Using the CCPP dataset, the model trained with BCD and ICRS achieved $R^2$ values of 0.931 on both training and test sets, demonstrating superior accuracy compared to the model trained without BCD, which yielded $R^2$ values of 0.876 and 0.872 for training and test sets, respectively.

As shown in Figure 5, the BCD-ICRS combination significantly enhances model convergence and improves training efficiency.

BCD's layer-specific optimization, coupled with the robust parameter initialization provided by ICRS, allows the model to converge to a higher accuracy faster than training without BCD, reducing the computational cost of achieving optimal performance.

## The SIEC dataset

The procedure was subsequently applied to the SIEC dataset. Similarly to the results for the CCPP case study, the most sensitive layer approach showed a more uniform distribution of performance metrics compared to the other methods, both in training and testing phases.

Furthermore, the integration of the ICRS optimizer with the BCD method demonstrated strong performance across various block selection strategies, as illustrated in Figure 6. These results demonstrate that the targeted layer optimization provided by the BCD improves the accuracy and robustness of the SIEC model, showcasing the adaptability of this method to the specific characteristics of this dataset. The performance improvement, while specific to the SIEC data, suggests the potential of

BCD for generalizable application in complex system modelling, as also evidenced by the similar benefits observed with the CCPP dataset (Figure 5), albeit with different data characteristics.

Overall, the object-oriented framework proved effective for both datasets by leveraging modularity and advanced optimization techniques. A core contribution of this work is demonstrating the algorithmic advantages of the proposed hybrid approach. In this prototype implementation, training the SIEC dataset with L-BFGS took ~220 minutes, while BCD-ICRS achieved comparable results in just 35 minutes (6x speedup). For the CCPP dataset, L-BFGS required ~35 minutes, whereas ICRS converged in 7 minutes (5x acceleration). These results validate the method's efficiency gains with substantial empirical improvements. While GPU-accelerated frameworks can train similar models in seconds, the focus is on advancing algorithmic efficiency, which remains critical for large, high-dimensional problems, where solver performance is a key bottleneck [8].

## CONCLUSIONS

This work introduces a novel hybrid deep learning training framework that addresses key challenges in optimizing complex neural networks. While object-oriented programming is prevalent in modern deep learning solutions, our approach distinguishes itself through the novel integration of BCD and ICRS, allowing for modular experimentation with layer-specific optimization strategies. BCD enables sequential, resource-efficient layer optimization, while ICRS provides robust initial parameters, enhancing convergence in high-dimensional spaces. This combination improves scalability and computational efficiency while offering a customizable environment adaptable to diverse architectures and datasets.

The framework's ability to integrate batch-based processing with adaptive optimization methods underscores its ability to handle large-scale DLNNs. Empirical validation on CCPP and SIEC datasets from the UCI Machine Learning Repository demonstrates significant improvements in training efficiency, accuracy, and robustness over conventional methods, setting a new benchmark for industrial applications. Its modularity allows users to easily adjust network configuration and integrate additional layers without extensive programming, making it highly adaptable for various datasets or applications.

Current work focuses on extending this framework to additional datasets and domains to further validate its scalability and generalizability. Future efforts will implement the hybrid approach in CUDA to fully quantify its practical impact on deep learning workloads, particularly for complex models where second-order optimization remains computationally challenging. Additionally, integrating automated hyperparameter tuning and exploring real-time applications in industrial settings will provide valuable insights into optimizing deep learning models for practical use cases.

Moreover, automatic network architecture configuration will enable the framework to dynamically adjust its architecture, such as the number of layers, neurons per layer, and activation functions, based on the characteristics of the dataset and the optimization goals. Exploring real-time architecture reconfiguration during training could provide valuable insights into dynamic optimization strategies, allowing models to adapt to changing data distributions or computational constraints in industrial applications. While this presents significant implementation challenges, advancements in adaptive learning algorithms and hardware acceleration may make such dynamic reconfiguration feasible in future research.

## ABSTRACT

This paper introduces a prototype for constructing an edge AI system utilizing the contemporary Machine Learning Operations (MLOps) concept. By employing microcontrollers such as the Raspberry Pi as hardware, our methodology includes data scrubbing and machine learning model deployment on edge devices. Crucially, the MLOps pipeline is fully developed within the ecoKI platform, a research platform for ML/AI applications. In this study, we thoroughly investigate the performance of our ecoKI platform by comparing it with the established Edge Impulse platform. We deployed the ML model with different weight quantization methods, such as FP32 and INT8, to compare accuracy variations and inference speed between these two platforms and quantization strategies on edge devices. In our experiments, we identified that the average accuracy performance of the ecoKI platform is 3.61% better than the edge impulse. Moreover, real-time AI processing on edge devices enables microcontrollers, even those with limited resources, to effectively handle tasks in areas such as predictive maintenance, process optimization, quality assurance, and supply chain management.

**Keywords**: Artificial Intelligence, Industry 4.0, Energy Efficiency, Machine Learning, Big Data, Edge Intelligence.

## INTRODUCTION

Presently, Edge AI is a rapidly growing field combining edge computing principles with artificial intelligence (AI) to enable the execution of AI algorithms directly on edge devices. This eliminates the need to transmit and process data on remote servers. Thereby This significantly reduces latency and improves the efficiency of AI-driven applications. By processing data closer to its source, Edge AI supports faster decision-making and enhances real-time functionality. According to recent market analysis [1], the global Edge AI hardware market, estimated at $24.2 billion in 2024, is projected to reach approximately $55 billion by 2029. This growth is driven by the increasing adoption of Internet of Things (IoT) devices across various industries, including smart homes, industrial automation, healthcare, agriculture, and transportation.

While edge computing has existed for years, the integration of AI has recently fueled the development of Edge AI [2]. Many IoT devices lack the computational power to handle complex processing tasks and, therefore, often rely on cloud-based solutions that can be costly and time-intensive. Edge AI addresses this limitation by enabling on-device data processing and reducing dependence on external data centers. Additionally, industries increasingly focus on lightweight vision inspection systems designed for specific tasks, moving away from bulkier automated optical inspection (AOI) machines. These streamlined edge device-based solutions offer advantages such as real-time insights, reduced physical space requirements, and simplified setups. However, several challenges remain in fully realizing the potential of Edge AI. One major issue is the limited availability of detailed performance benchmarks, particularly for processing large datasets or high-resolution images.

## RELATED WORK

Recent studies have evaluated the performance of various Edge AI devices for deep learning applications, particularly object detection, highlighting how different

accelerators like GPUs and TPUs provide viable alternatives to traditional cloud-based processing [3]. Evaluations focused on throughput, power consumption, cost-effectiveness, accuracy, and latency [4,5]. Edge devices with AI chips demonstrated significant performance improvements compared to traditional edge devices. However, the choice of device depends on specific application requirements, as performance varies across different architectures and precision levels [6]. While some devices, like the Jetson AGX Orin and Intel NUC, showed promising results, others, like the Raspberry Pi, exhibited limitations in processing speed [7]. These comparative analyses provide valuable insights for selecting appropriate edge AI devices based on specific use cases and performance needs.

## .METHODOLOGY & DATASET

### A) Methodology

To derive our main insights, we perform a comparative analysis of industrial Edge MLOps platforms, specifically Edge Impulse and the ecoKI Platform. We follow contemporary MLOps practices [8,9], including model optimization and deployment on edge devices. "Lastly, we compare performance characteristics using an evaluation matrix consisting of the ROC curve, precision, recall, and F1 score. Based on this methodology, we elaborate on our findings about the pros and cons of both platforms in the next sections.

### B) Dataset

In line with the objectives of evaluation studies, aligning the experiment's goals with a suitable dataset is crucial. In this work, our initial task involved selecting an appropriate dataset and preparing a trained model. Given our primary focus on wearable devices, we selected a dataset tailored to this domain. To further enhance the analysis, we incorporated a dataset capable of detecting 12 distinct sleep positions with finer granularity under energy-efficient constraints [10]. Leveraging accelerometer data from wearable devices across various timeframes, this dataset supports detailed position inference, offering insights valuable for both sleep quality analysis and energy-efficient wearable solutions.

## EVALUATION

### A) Edge Impulse

Edge Impulse [11], a leading AI development platform, enables intelligence on any edge device. There are several steps to perform a complete inference in the Edge impulse platform and for the deployment.

#### i. Data acquisition

For the sleep dataset, a CSV wizard was used to load the data from a .csv file into the Edge Impulse platform

#### ii. Create Impulse

Creating an impulse is central to Edge Impulse, combining features, data pre-processors, neural network architectures, and desired outputs. Raw data undergoes signal processing to extract features, which are subsequently used by learning blocks for tasks such as classification or regression. Signal processing includes DSPs and FFTs to reduce noise and generate intermediate inputs for learning. Then, spectral analysis and classification were selected for accelerometer data, and raw data was converted into processed features using FFT to enhance model complexity and learning capability.

#### iii. Signal Processing Block

In Edge Impulse, spectral features processing is used to extract frequency, power, and signal characteristics from accelerometer data, leveraging FFT to decompose signals into frequency components.

This approach filters unwanted frequencies, analyzes patterns, and reduces model size for efficient and reliable machine learning. Here, the pre-processing block has been used spectral features for the sleep classification data. This SP block extracts a signal's frequency, power, and other characteristics.

#### iv. Learning Block

The learning block defines the neural network architecture, comprising a fully connected model with a 63-neuron input layer, two hidden layers (80 and 40 neurons), and a 12-class output layer as depicted in the Figure 1.

The result of the classifier for training data set for model FP32 is shown in Figure 2 and corresponding metric in table 1. The on-device performance can be seen in Figure 3 with accuracy and its loss.

Similarly, the result of the classifier for training data set for model int8 is depicted in Figure 4 and corresponding metric in table 2. The on-device performance can be seen in Figure 5 with accuracy and its loss.

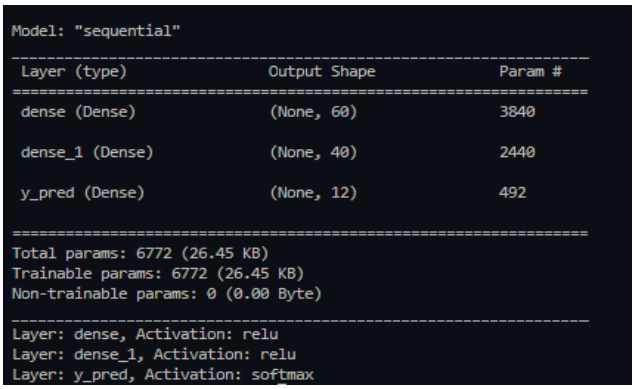

**Figure 1.** Deep Neural Network architecture used in Edge Impulse platform.

**Figure 2.** Validations result of DNN unoptimised (float32) model in Edge Impulse platform.

**Table 1:** Metrics **(validation set of unoptimized (float32) model).**

| METRIC | Value |
|---|---|
| Area under ROC Curve | 1.00 |
| Weighted avg. Precision | 0.98 |
| Weighted avg. Recall | 0.97 |
| Weighted avg. F1 score | 0.97 |

**Figure 3.** On-device performance of unoptimised (float32) model.

**Figure 4.** Validation result of DNN Quantized(int 8) model in Edge Impulse platform.

**Table 2:** Metrics **(validation set of quantised (int8) model).**

| METRIC | Value |
|---|---|
| Area under ROC Curve | 1.00 |
| Weighted avg. Precision | 0.96 |
| Weighted avg. Recall | 0.94 |
| Weighted avg. F1 score | 0.93 |

**Figure 5.** On device performance of Quantized(int 8) model.

## v. Model Test Result

Generally, quantization reduces model weight precision, potentially impacting performance, with options like quantized (INT8) and unoptimized (Float32) models offering varying accuracy.

In Edge impulse, model testing involves selecting the different versions, either unoptimized (float32) or quantized (int8) via the platform; the result of each has been presented in Tables 3 and 4 correspondingly.

**Table 3:** FP_32 accuracy, Metrics for Classifier test results.

| Accuracy: 90.39% | |
|---|---|
| **METRIC** | **Value** |
| Area under ROC Curve | 1.00 |
| Weighted avg. Precision | 0.98 |
| Weighted avg. Recall | 0.97 |
| Weighted avg. F1 score | 0.97 |

**Table 4:** int_8 accuracy, Metrics for Classifier test results.

| Accuracy: 88.21% | |
|---|---|
| **METRIC** | **Value** |
| Area under ROC Curve | 1.00 |
| Weighted avg. Precision | 0.96 |
| Weighted avg. Recall | 0.94 |
| Weighted avg. F1 score | 0.93 |

## vi. Model Deployment

The model offers versatile deployment options, including a standalone C++ application, board-specific binaries for devices like Nordic Thingy:91, or downloadable Keras (.h5) and TFLite formats. Testing confirms successful performance even on resource-constrained hardware such as the Raspberry Pi 2 (ARM V7).

**Table 5:** Metrics comparison for FP32 and Int8 quantization of ML model deployment result at Edge Impulse.

| Model quantization | File size | Ram usage | Inference time | Accuracy |
|---|---|---|---|---|
| FP 32 | 11MB* | 128KB | 0ms | 90.39 |
| INT_8 | 11MB* | 128KB | 0ms | 88.21 |

*11 MB is the file size of the build not the whole zip.

# B) ecoKI Platform

The ecoKI platform follows a streamlined workflow from data preparation to deployment: data loading, selection, train-test splitting, hyperparameter tuning, neural network training, and time series visualization. This systematic process ensures efficient and effective implementation of the ecoKI-Platform.

## i. ecoKI Data Reader

The ecoKI data reader building block enables seamless data integration through multiple input methods: local CSV files, MongoDB databases, or Dataverse integration [12]. This versatile approach ensures compatibility with diverse data sources, streamlining the entire workflow while maintaining optimal efficiency.

## ii. Data Selection

In ecoKI platform, the front end provides the functionality of data selection. This process not only enhances data quality by removing noise and redundancies

but also reduces computational overhead, enabling more efficient processing and analysis.

### iii. Split train and test data

In ecoKI, the front end provides the functionality of splitting data into training and testing because selecting input and output features is essential. This selection ensures ecoKI preprocesses the data into the required format for seamless analysis.

### iv. Train and predict NN multi-class

Then, ecoKI performs training and testing via the dashboard using a fully connected neural network with customizable activation functions, epochs, and neuron counts. Upon completion, it generates the model (.h5), weights, parameters, and a TFLite model for inference, as can be seen in Figure 6.

```

```

**Figure 6.** Deep Neural Network architecture (classification) used in ecoKI platform.

### v. Time series visualizer

The final step involves generating data for analysis supported by visualization capabilities integrated into this module, as illustrated in Figure 7 (a). This feature allows for exploring key insights by presenting critical data points in an accessible and interpretable format. Through comprehensive visualization tools, users can effectively analyze trends, patterns, and relationships within the data, enabling more informed decision-making and a deeper understanding of the results.

### vi. Model Test Result

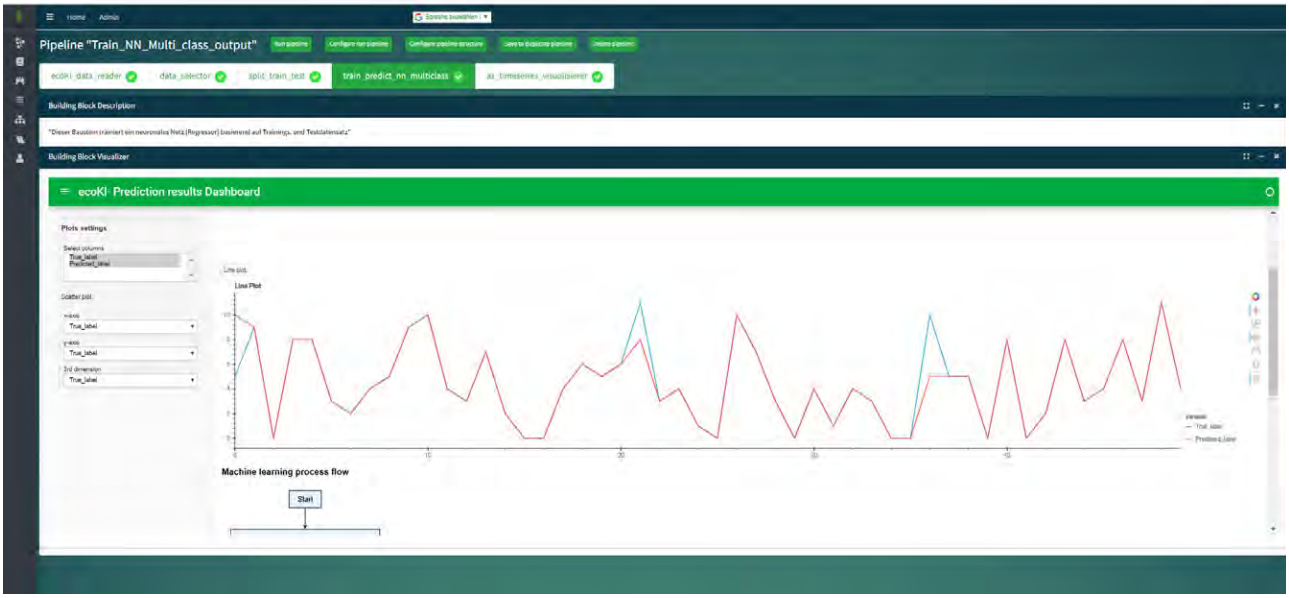
Model evaluation in ecoKI is conducted using comprehensive testing metrics, including a confusion matrix to assess classification accuracy and detailed performance measures such as Mean Squared Error (MSE), accuracy, precision, recall, and F1 score. The results can be seen in Figure 7. b and c. These metrics provide a holistic understanding of the model's performance, capturing its predictive accuracy and ability to balance false positives and negatives. This rigorous evaluation ensures the reliability and effectiveness of the trained model in real-world applications.

### vii. Model Deployment

The ecoKI platform provides a TFLite model in FP32 format, designed for seamless integration and deployment. The model can be wrapped using C++ or Python wrappers to enable inference, which serve as interfaces to invoke the TFLite interpreter; the model result is shown in Table 6.

**Table 6:** Model deployment result on ecoKI platform.

| Model quantization | File size | Ram usage | Inference time | Accuracy |
|---|---|---|---|---|
| FP 32 | 9.53KB | 128KB | 0.1ms | 94% |



## DISCUSSION AND CONCLUSION

In the rapidly evolving field of machine learning at the edge, platforms like ecoKI and Edge Impulse provide powerful tools for efficient model development and deployment. Both platforms offer robust features tailored to specific needs, but they differ in their approaches, strengths, and limitations.

On the one hand, ecoKI excels in comprehensive data preprocessing, handling various data formats seamlessly, and offering advanced features such as ModelCheckpoint and dynamic learning rate adjustments.

*ModelCheckpoint* ensures the model or its weights are saved at specific intervals in checkpoint files, enabling training to resume from a saved state if needed. It offers flexibility by allowing users to save only the best-performing model based on a monitored metric or to save the model at the end of every epoch, regardless of performance. Users can define 'best performance' by selecting the metric to monitor and determining whether it should be maximized or minimized. In contrast, the dynamic learning rate adjustments allow for a dynamic reduction of the learning rate when the monitored metrics show no improvement for a specified number of epochs. This adaptive learning rate reduction, typically by a factor of 2–10, helps models to overcome stagnation and enhances convergence, ultimately improving training efficiency and model performance by 3.61% for the FP32 model compared to Edge impulse. ecoKI's flexible workflow also supports detailed hyperparameter tuning and real-time data processing. However, larger datasets may require more setup and computational resources.

On the other hand, Edge Impulse provides a user-

**(c)**

**Figure 2:** a) The front-end dashboard of the EcoKI platform provides an intuitive interface for visualizing test data and b) test predictions, enabling comprehensive validation of model performance. It includes a confusion matrix offering insights into classification accuracy. c) Additionally, model metrics such as Mean Squared Error (MSE), accuracy, precision, recall, and F1 score are evaluated and displayed to ensure thorough performance assessment.

friendly interface for rapid model development and de ployment, which is especially suited for edge devices. Its support for lightweight quantized models and pre-built learning blocks enhances efficiency as it provides the standalone C++ model and TFlite interpreter. That is the reason it supports many hardware configurations. However, it has limitations in handling complex data pipelines and high-performance inference tasks. In summary, ecoKI offers flexibility and deep data integration, while Edge Impulse excels in ease of use and edge deployment efficiency. The ultimate choice depends on specific research needs and deployment requirements. The results of this study could be extended in future research by expanding the number of compared MLOps platforms and the number and variety of the used metrics. Furthermore, these platforms' scaling and reliability characteristics

require further investigation to make decisive statements about their capabilities.

## ABSTRACT

Developing ultra- or high-performance liquid chromatography (HPLC) methods for analysis or purification requires significant amounts of material and manpower, and typically involves time-consuming iterative lab-based workflows. This work demonstrates in two case studies that an autonomous HPLC platform coupled with a mechanistic model that self-corrects itself by performing parameter estimation can efficiently develop an optimized HPLC method with minimal experiments (i.e., reduced experimental costs and burden) and manual intervention (i.e., reduced manpower). At the same time, this HPLC platform, referred to as Smart HPLC Robot, can deliver a calibrated mechanistic model that provides valuable insights into method robustness.

**Keywords**: Industry 4.0, Modelling and Simulations, Optimization, Genetic Algorithm, Batch Process, Self-driving, Autonomous, Digital Twin, Mechanistic Model, Chromatography

## INTRODUCTION

One of the most important analysis and purification methods in the fine chemical and pharmaceutical industry is liquid chromatography [1]. The degree of separation necessary for success is dictated by the affinity of the solutes (i.e., the dissolved molecules) towards the solid phase (i.e., the adsorbent). The greater the affinity of the solute for the solid phase, the slower its movement through the chromatography column, resulting in a later elution. Considering a column with a fixed solid phase, one of the most significant factors affecting the affinity of the solute is solvent composition, where the solvent in HPLC processes is typically a mixture of organic and inorganic solvents. The simplest way to operate an HPLC process is through isocratic elution, where the solvent composition remains constant throughout the operation. However, isocratic elution often has limitations, such as long process time (the time taken for the last component to elute) or the inability to satisfactorily resolve a complex mixture. An alternative mode of operation is gradient elution, where the solvent composition varies over time. This approach introduces additional degrees of freedom, such as the initial and final solvent composition, the duration of the composition change, and the number of gradient steps, adding complexity to the process. Even so, gradient elution is generally preferred for complex mixtures due to its enhanced ability to resolve components more efficiently and quickly [2].

Developing gradient based HPLC methods usually requires significant material and manpower, and typically involves time-consuming and iterative laboratory-based workflows. Recent technological advancements now enable fully computer-controlled workflows; these allow not only automated but also streamlined autonomous (that is, self-driven) HPLC method development, with minimal to no human intervention (employing robotic solutions for iterative workflows [3]). In this article, we summarize two recent applications of autonomous processes; readers are referred to Tom et al. [3] for a comprehensive review of the concepts of autonomous processes in laboratories (coined as self-driving laboratories in the review article). Boelrijk et al. [2] and Dixon et al. [4] demonstrated the potential of autonomy for developing HPLC methods. Both authors achieved autonomy of gradient method development via the following steps:

1. **Initial Small Experimental Campaign,** e.g. as in Boelrijk et al. via random input parameter selection [2] or Dixon et al. via Latin Hypercube Sampling (LHS)[4].
2. **Fit the data-based surrogate model** using experiments performed in step 1.

3. **Optimize the HPLC process** using the surrogate model, where the optimizer **suggests the next experiment(s)** to perform. Both authors used Bayesian optimization aimed to optimize gradient methods regarding time, and number of resolved peaks.
4. **Run model-guided additional real experiments** and **analyze key indicators in-silico** (=computationally), e.g., peak height, peak width, retention time. The key indicators are analyzed by a surrogate model and are automatically sent to the optimizer (used in the next step); no manual interpretation is required.
5. **Repeat steps 2 and 3** until reaching stopping criteria.

Both groups demonstrated that satisfactory optimal results could be achieved autonomously with the help of in-silico surrogate models. However, surrogate models rely on data to be informative and effective, making them less efficient in the early stages. Due to their data-driven nature, they may not accurately reflect known physical phenomena, limiting their ability to provide reliable guidance, especially when only a few experiments are available for model training and development.

To address the above-mentioned issue, **this work proposes an autonomous process guided by a mechanistic model** for knowledge-driven (instead of purely data-driven) decision-making. One of the challenges when using a mechanistic model is to find a set of good parameters (e.g., isotherm parameters) that can represent the real experimental results (e.g., chromatogram) sufficiently well. Therefore, a parameter estimation step is added to the previously mentioned automation step (see discussion for Figure 2 in the methodology section). This framework, here called "Smart HPLC Robot", is an intelligent platform enabling the development of an optimized HPLC method with minimal experiments while simultaneously delivering a calibrated mechanistic model that provides valuable insights into method robustness. Importantly, since mechanistic models are physics-based and not tied to a specific objective function, they can be applied to optimization tasks with different objectives and provide reliable predictions beyond the range of experimental settings used for training (i.e., extrapolation). Once model parameters are properly determined and experimental conditions remain consistent (e.g., using the same mixture), mechanistic models offer better adaptability, require fewer calibration experiments, and do not need retraining, unlike the data based surrogate models used in previous works.

**Figure 1**. Communication protocol of Smart HPLC Robot.

## METHODOLOGY

The Smart HPLC Robot features mechanistic simulations and an autonomous process; thus, it requires efficient communication between laboratory equipment and chromatography simulators. The developed autonomous workflow, including the communication between model and HPLC system, is illustrated in Figure 1 and discussed in this section. In addition, the working principles (shown in Figure 2) will also be discussed.

### Communication Protocol

The user interface is developed in Python, which also bridges the communication between equipment and simulators. As shown in Figure 1, the current project is developed with Agilent equipment and simulators such as gPROMS and CADET (https://cadet-web.de/), but it is not limited to those and can be integrated with other systems, provided that users adhere to a standard communication framework. To integrate equipment from different manufacturers, users can leverage, for example, Application Programming Interfaces (APIs) to efficiently establish communication and exchange key values.

In this project, the communication protocol for Agilent OpenLab is written in C# (left part in Figure 1). Therefore the equipment control sequences (e.g., modifying experimental input sequence and executing sequence) are all implemented in C# for better compatibility and operation efficiency. A C# web API facilitates seamless data exchange by providing a standardized communication interface while isolating equipment control sequences. The right part of Figure 1 illustrates the communication between the Python framework and simulators. Currently, gPROMS and CADET are supported, and the communications with Python are via gO:Python and CADET-Python, respectively.

### Working Principle

The working principle of the Smart HPLC Robot can be divided into two main steps as shown in Figure 2: (1) the preparation step (a one-time execution) and (2) the mechanistic loop (i.e., mechanistic model-guided autonomous method development). The former requires configuring the Smart HPLC Robot and performing initial experiments, and the latter involves parameter estimation for model calibration and optimization for the generation of new experiments. This section will detail each step together with associated challenges and solutions.

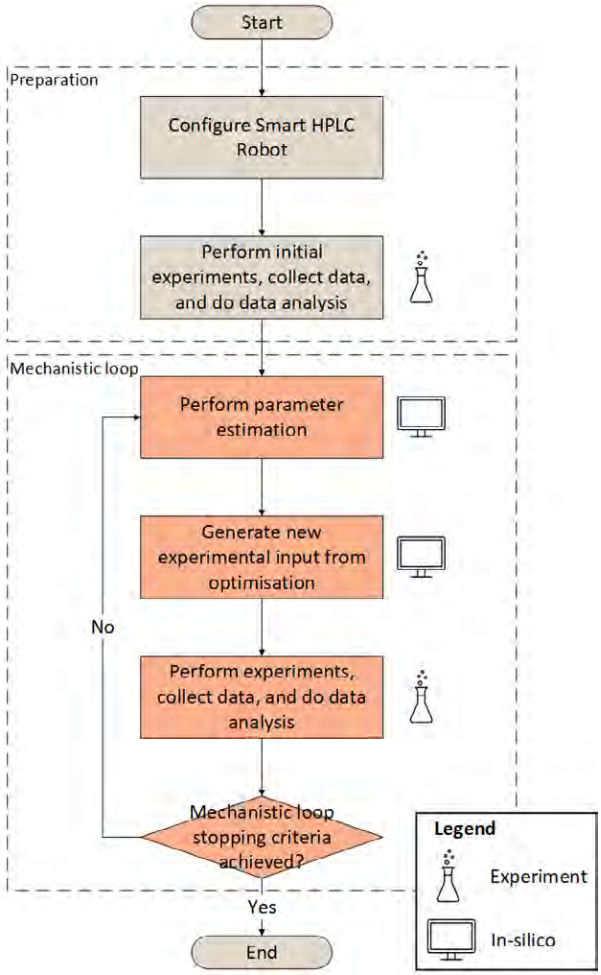

**Figure 2.** Smart HPLC Robot working principle. All steps are performed autonomously after the initial manual configuration of the robot (e.g., input column dimension, model selection, optimization settings).

## Preparation

In contrast to using machine learning [2,4], the mechanistic model framework used in this work requires prior knowledge of the number of components in the system for model development. This step is more straightforward with a mass spectrometer than an ultraviolet (UV) detector, as a UV detector cannot distinguish overlapping components, leading to inaccurate method development. When using a UV detector (as done here), it is recommended to perform preliminary experiments at low flow rates and a low initial organic solvent fraction and low gradients. This approach can, theoretically, maximize the separation of components with the current system, providing an initial understanding of the number of components that can be resolved from the (potentially) unknown mixture.

Besides the number of components, other information, e.g., column dimensions, selection of isotherms and mass transport model, and parameter estimation/optimization settings, including boundaries of parameter estimation/optimization variables and objective functions, is also required for configuring the mechanistic model of the Smart HPLC Robot. Most information can be obtained from equipment manufacturers or is based on the aim of the task. The boundaries of variables are crucial to the success of the HPLC method development, but they are often tricky to determine. For design variables, such as flow rates, percentage of organic solvent, and column temperature, the boundaries are often defined as the equipment physical limitations. Isotherm parameters, on the other hand, lack clear boundaries. The Smart HPLC Robot conducts a basic boundary analysis using Sobol sampling across an initial input search space (HPLC settings), typically with broad boundaries. This process helps identify regions with a higher likelihood of yielding optimal results, as indicated by the objective function's quantification of the HPLC method quality. Hence, shrinking the search space for the subsequent parameter estimation step, leading to an improved efficiency.

Once all necessary information is provided, users can execute the program and the robot will do all other steps without further human interference. The first automated step is to generate and perform a user-defined number of initial experiments generated from sampling methods (e.g., LHS or factorial design). The number of initial experiments is a trade-off between accuracy of prediction and experimental burden. For the low-parameter mechanistic models used thus far, four experiments provided a good foundation

## Model Calibration and Validation Loop

The mechanistic model's initial training (parameter estimation) will begin once the Smart HPLC Robot completes the initial experiments and sends the results to Python. The first step in the loop is to estimate the parameters for the selected isotherm(s) (e.g., linear isotherm or Langmuir isotherm) based on the user-defined objective functions (e.g., maximum likelihood method or least square method). In this step, all experiments, including initial experiments and those generated in the mechanistic loop, will be taken into account.

Once calibrated with the best available parameter estimates, the mechanistic model computationally optimizes the HPLC method settings (i.e., the inputs such as flow rate, initial and final mobile phase composition, and gradient time) based on the selected method objectives (such as achieving sufficient resolution for all or selected components in the shortest possible time). Therefore, selecting an appropriate objective function is crucial to yield the desired HPLC method.

Once computational optimization is complete, the HPLC system will automatically execute the updated

method (using the optimum inputs) and return key data (including UV absorbance, retention time, and peak width, i.e., the method results) to Python. The latter aims to validate whether the computed optimum has been achieved and to determine if a sufficiently robust HPLC method now meets the stopping criteria. If not, it serves as a new experiment to refine the mechanistic model parameters and rerun the computational optimization. The stopping criteria may include factors like reaching the maximum iterations or no further method improvement. Once met, the Smart HPLC Robot reports the validated model and optimal HPLC method settings. In most cases, the mechanistic loop requires multiple iterations. During the parameter estimation step, both stochastic and deterministic optimizers carry the risk of yielding worse isotherm parameters than the previous iteration (stochastic optimizers due to inherent randomness and deterministic ones due to sensitivity to initial values).Therefore, the newly estimated model parameters will be compared with the previous best values, and only those yielding an improved estimation of parameters (reduced error between experiment and model calculation) will be used to update the model.

## RESULTS AND DISCUSSIONS

Two case studies were performed in this work: (1) an in-silico system case study to quantify the performance of the Smart HPLC Robot, and (2) a real world case study for initial showcase. The simulations for both case studies were performed using the CADET-Core simulator. The mass transfer model used is the native Equilibrium Dispersive Model, and the isotherm model is a non-native linear isotherm coupled with the Linear Solvent Strength (LSS) theory:

$$\text{Linear isotherm: } q_i = a_i\, C_i \qquad \forall i = 1, \dots, n \qquad (1)$$

$$\text{LSS theory: } a_i = a_{0.i} \exp\left(-S_{s,i}\, \phi\right) \quad \forall i = 1, \dots, n \qquad (2)$$

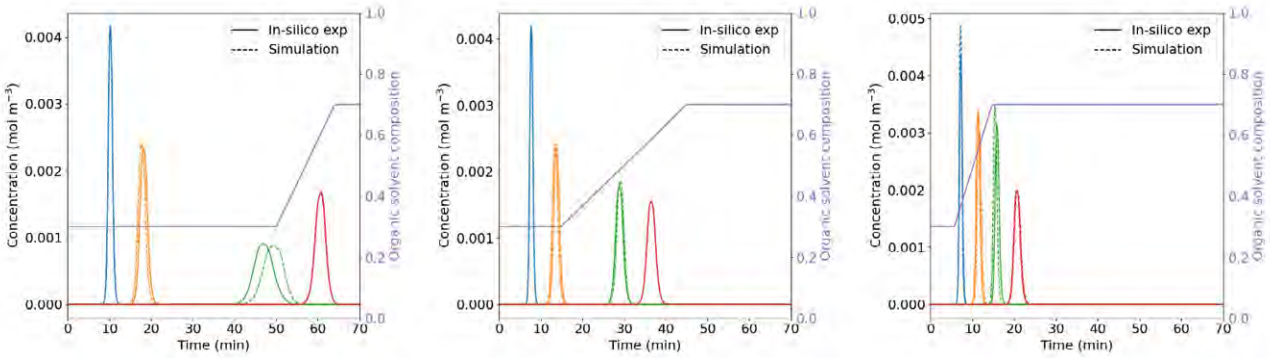
where $n$ is the number of components in the mixture, $q$ is the equilibrium concentration in the stationary phase, $C$ is the concentration in the liquid phase, $a$ is the Henry coefficient, $a_0$ and $S_s$ are the numerical constants in LSS theory, and $\phi$ is the organic solvent composition (i.e., volumetric fraction of the organic modifier in the solvent).

In both case studies, initial experimental conditions are generated via LHS, which are then performed either in-silico using the aforementioned model or sent to the instruments (see setup in later section) to perform real experiments. A virtual column is used in the in-silico system case study, while the Agilent Poroshell 120 EC-C18 column (G7104C096) is used in the real world case study. The column information is summarized in Table 1.

Parameter estimation is then performed in-silico by minimizing the mean of the relative errors ($EE_{PE}$) [5] via genetic algorithm (using Python package "geneticalgorithm2"):

**Table 1**. Information of the columns in the case studies.

| Parameters | In-silico | Real |
|---|---|---|
| Col. length (mm) | 150 | 100 |
| Col. radius (mm) | 5 | 3 |
| Total porosity (-) | 0.645 | 0.840 |
| Internal porosity (-) | 0.189 | 0.160 |
| Particle radius (μm) | 2.50 | 1.35 |



$$EE_{PE} = \frac{1}{n}\sum_{i=1}^{n}\left(\frac{\left|t_{R,i}^{\text{sim}} - t_{R,i}^{\text{exp}}\right|}{t_{R,i}^{\text{sim}}} \times 100\right) \quad \forall i = 1, \dots, n \qquad (3)$$

where $t_R^{\text{sim/exp}}$ are the simulation (using the mechanistic model)/experimental retention times. The parameters that are varied to minimize the model error $EE_{PE}$ are $a_{0,i}$ and $S_{s,i}$.

Next, the isotherm parameters in the simulation model are updated with those obtained from the parameter estimation step before performing optimization. The optimizer used is also a genetic algorithm. During optimization, the objective function (note that this is not the same as the objective function in parameter estimation) is to minimize the method time (i.e., the retention time of the last eluting component) subject to a critical resolution constraint (i.e., the smallest resolution of all component pairs) of at least 1.5. The critical resolution is calculated considering the peak asymmetry and peak width at 0.135 peak height as suggested by Boelrijk et al. [2]. The optimization variables (and model inputs) are the flow rate, gradient start time, and gradient change duration. The gradient starting and ending volume fractions are fixed at 0.3 and 0.7 for the in-silico system case study, and 0.5 and 1.0 for the real world case study (but could also be optimized). The "optimal" experimental conditions are then performed in the HPLC platform considered, and the model parameter estimation and HPLC method optimization steps are repeated until the stopping criteria are satisfied. Here, a simple stopping criterion of a maximum of four mechanistic loops was used in both case studies.

### (1) In-silico System Case Study

An in-silico system is used as a case study so that the performance of the Smart HPLC Robot can be analyzed quantitatively as the true values of the parameters involved are all known. A four-component mixture is considered. In this case study, simulations and in-silico (i.e., virtual) experiments are carried out using the simulation model described above without considering any uncertainties in the model parameters. Note that for the in-silico experiments, the isotherm parameters are pre-defined and fixed. Therefore, theoretically, the parameter

*(a) Worst parameter estimation case* *(b) Best parameter estimation case* *(c) Final optimized condition*

**Figure 3.** Chromatograms of simulation and in-silico experiments obtained from (a,b) parameter estimation and (c) optimization. All chromatograms are obtained at the last mechanistic loop (loop 4).

estimation should be capable of yielding the true isotherm values, but the optimizer cannot guarantee global optimality, so there is still a small deviation of about 4% absolute average difference in this case study. The parameter estimation (see Equation 3 for the objective function) is performed on all previously executed experiments, and Figures 3a and 3b show the bad and good cases, respectively. It is clearly seen that the simulation and in-silico experiment chromatograms for "fast" (i.e., short method time) cases have greater similarities (i.e., indicating better predictions of the isotherm parameters), which benefits the objective function as this is to minimize the method time.

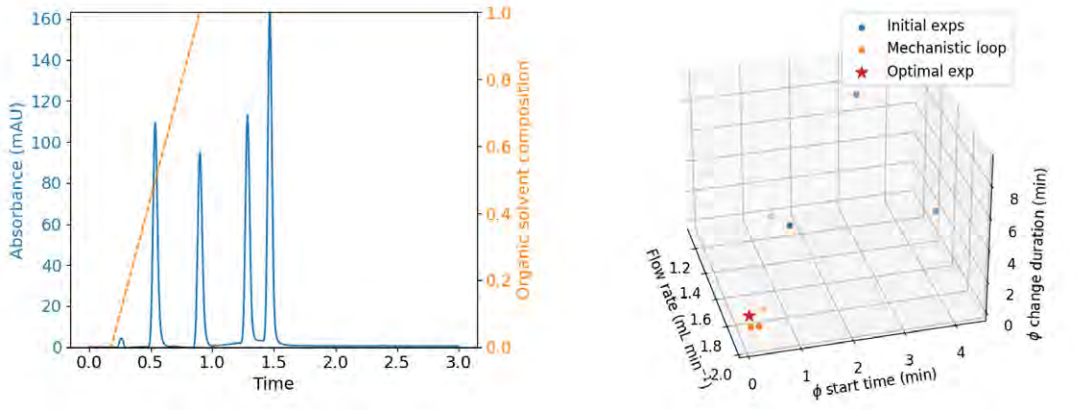


Figure 3c shows the optimized chromatogram for the in-silico experiment and the associated simulation. The results deliver two main takeaways: (1) the chromatograms nearly overlapped, indicating a fairly accurate prediction of isotherm values; (2) all components are completely resolved with a short/minimum gap between adjacent components, illustrating a good quality of the optimized experiment condition.

## (2) Real World Case Study

Having validated the performance of the Smart HPLC Robot, a real world case study is carried out to demonstrate its applicability to laboratory-based experiments. The simulations are performed using the same mechanistic model as for the in-silico system case study, and the real experiments are carried out with an Agilent 1260 Infinity II system. The system is equipped with a quaternary pump (G7104C), an online sample manager set (G3167AA) that consists of an auto-sampler and an online valve configured for off-line sampling, a multicolumn compartment with thermostat (G7116A), and a variable wavelength detector (G7114A). The UV absorbance is recorded at a wavelength of 254 nm and a frequency of 5 Hz. The needle is set to draw the sample at 100 µL $min^{-1}$, eject at 400 µL $min^{-1}$, and an equilibration time of 1.2 s. A four-component sample is used as model sample, with an injection volume of 1 µL.

Compared to the in-silico case study, two new challenges arise for real system. Firstly, the raw experimental data from Agilent provides UV absorbance, and calibration is required to convert absorbance to concentration, but this requires prior knowledge of each component which is sometimes unavailable. Therefore, as done in Case Study 1, component retention times are used as the sole performance indicator for parameter estimation (see Equation 3). The second challenge is that numerical diffusion may contribute significantly to the band broadening in the simulation if the discretization grid of the column is not fine enough. Conversely, a fine discretization may increase the computational burden, leading to a long simulation time. To obtain accurate retention times and peak widths within a short time, this work uses a loose discretization grid to estimate only the retention time, and the peak widths are extracted directly from the experiments. In the first iteration, the peak width of each component is based on the average from initial experiments, and the chromatogram is approximated by a Gaussian curve centered on the retention time. In subsequent iterations, the previous iteration's peak width is used, enabling progressive self-correction and refinement of the method.

As the simulation and experiment generate different profiles (concentration vs absorbance), only the final optimal experimental results are shown in Figure 4a. It is noted that the first small peak is the solvent front, which is not considered a component during parameter estimation and optimization. After four iterations of the mechanistic loop, the method time is minimized to about 1.49 min while achieving complete separation (critical resolution $\geq 1.5$) of all components, which is 49% to 78% faster compared to the initial experiments. In Figure 4b, the distribution of all experiments performed is plotted together. It shows that the initial experiments are spread across the search space and are away from the final optimal experiment, showing how simulations helped eliminate the real

*(a) Optimal chromatogram* *(b) Experiment propagation*

**Figure 4.** Key indicators of the real system case study: (a) The optimal chromatogram obtained from real experiment; (b)The propagation of the experiments throughout the whole automation process.

experiments that are otherwise needed to finally arrive at the optimal point. Also, note that the optimized experiments are close to each other, indicating that they have similar performances. Therefore, the goal is not necessarily to develop a perfect model, but rather a robust method that achieves reliable results. Ideally, this would be complemented by a well-calibrated mechanistic model, which can provide added value, such as enabling sensitivity studies and further refining the process.

## CONCLUSIONS

This work has presented an autonomous HPLC method development program coupled with a mechanistic model, here termed the Smart HPLC Robot. Unlike literature methods, which rely solely on a data-driven approach, incorporating a mechanistic model retains the physics of the system, providing valuable insights and enabling easy model reuse. Throughout the process, the model automatically calibrates itself using real-time data feedback, making it a digital HPLC twin.

The Smart HPLC Robot's performance was validated through an in-silico case study, demonstrating its ability to accurately predict isotherm model parameters and optimize HPLC methods. In a real-world case study, it efficiently explored the search space, improving the HPLC method (e.g., minimizing method time). Notably, the goal of the Smart HPLC Robot is to deliver an optimal method, not a perfect model.

To conclude, the Smart HPLC Robot has two main benefits: (1) reduction in experimental costs and burden through efficient search space exploration, and (2) reduced manpower by enabling self-driven method development until “satisfaction” compared to traditional iterative experimental workflow through automation.

## ACKNOWLEDGEMENTS

We gratefully acknowledge funding from UCL's Impact Acceleration Account, which supported this project, as well as Eli Lilly for their specific support and Agilent for their valuable contributions, all of which were vital to the success of this work

## ABSTRACT

Surface tension is a fundamental property at the liquid/gas interface, influencing phenomena such as capillary action, droplet formation, and interfacial behavior in chemical engineering processes. Despite its significance, experimental determination of surface tension is time-intensive and impractical for in silico-designed compounds. Predictive models are essential for bridging this gap. This study expands on Gaudin's COSMO-RS-based model, which assumes uniform molecular orientation at the surface, by testing its predictive capability across broader temperatures (5–50°C) and developing a hybrid model combining first-principle and machine learning insights to improve Gaudin's model predictions. The HM employs a serial configuration where COSMO-RS predictions serve as inputs alongside molecular descriptors, derived using the Mordred library. SHAP analysis guides feature selection, enhancing model interpretability. An artificial neural network refines predictions, optimized via Bayesian optimization for architecture and hyperparameters. Using a diverse dataset of 85 organic molecules, the HM demonstrates improved accuracy, reducing various metrics compared to standalone first-principle predictions.

**Keywords**: COSMO-RS, Machine Learning, Hybrid Modeling, Surface tension, First-Principle modeling.

## INTRODUCTION

Surface tension is a key property at the liquid/gas interface and plays an important role in various chemical engineering processes, including liquid flow and transport through porous media. This property is responsible for various phenomena, such as capillary action, droplet formation, and the behavior of liquid interfaces. Surface tension has practical applications in various fields, e.g., thin layer technologies, sol–gel technologies, phase separation techniques, drug carriers and treatment of raw materials [1]. Experimental measurement results for this property require specialized equipment and are time-consuming, therefore predictive models for surface tension are essential. Moreover, significantly different surface tension values for a given compound can arise from the method used (e.g., Wilhelmy plate, Du Noüy ring, maximum bubble pressure, dropweight, or hanging-drop) and the liquid purity [2]. Additionally, a transition to a greener chemical industry requires the development of innovative and sustainable solvents. Utilizing an in-silico model enables the pre-screening of these materials without the need for experimental procedures, thereby accelerating process development. Therefore, reliably predicting surface tension values for candidate compounds is essential. Numerous predictive models have been proposed in the literature for surface tension, e.g. neural network regression and graph machine regression [2], Quantitative Structure-Property Relationship (QSPR) models [3], combination of group-contribution and machine learning (ML) models [4]. These rely on large datasets and maintain reliability only within the boundaries of their training data. Moreover, they do not incorporate any underlying physical principles of the system. Quantum chemistry-based models are highly effective in predicting a wide range of physicochemical properties of organic compounds. The Conductor-like Screening Model for Real Solvents (COSMO-RS) method,

introduced by Andreas Klamt in 1995, integrates unimolecular quantum chemical calculations with exact statistical thermodynamics [5]. This approach enables the prediction of chemical potentials in liquids, which can be used to derive various thermodynamic equilibrium properties, without relying on experimental data. For example, COSMO-RS can be used to compute interfacial tension, which represents the free energy per unit surface area required to maintain an interface between two condensed phases. However, accurately predicting surface tension remains a significant challenge for COSMO-RS [6]. Recently, Gaudin proposed a COSMO-RS based model to predict surface tension ($\sigma$) of pure liquids [7]. Gaudin's approach is employed in this work and explained in the Methodology paragraph of this manuscript. Briefly, this method assumes uniform molecular orientation, meaning that every surface segment has an equal probability of being exposed. While originally tested on a limited set of molecules at 20°C, this study aims to (1) evaluate its predictive performance across a broader temperature range and (2) develop a Hybrid Model (HM) that combines COSMO-RS predictions with molecular descriptors to estimate experimental surface tension for more robust predictions. By integrating domain knowledge, HMs improve system understanding while requiring less data than purely ML models. This approach enhances reliability and offers a high benefit-to-cost ratio for complex systems [8]. In this work, a serial HM is employed, where the first-principle model (FPM) predictions are used as an input for the ML model together with molecular descriptors. The ML model then predicts the experimental surface tension value.

# METHODOLOGY

## First Principle predictions

Gaudin proposed a COSMO-RS based model to predict surface tension ($\sigma_{sim}$) of pure liquids [7]. The model is described by

$$\sigma_{sim} = -\frac{\Delta G_{sim}}{S_{sim}}, \quad (1)$$

where $\sigma_{sim}$ (mN/m) is the simulated surface tension, $\Delta G_{sim}$ (kcal/mol) is the COSMO-RS simulated Gibbs free energy of self-solvation and $S_{sim}$ (Å$^2$) is the molecular flat surface. The implicit assumption of this model is that the molecular orientation at the surface is neglected: any surface segment has the same probability to be exposed at the surface. However, this assumption may not be true for compounds where specific molecular orientations are energetically favored. In such cases, surface segments with lower desolvation energy are more likely to be exposed. Both the authors of this work and Gaudin suggest that deviations in surface tension predictions stem from this simplified hypothesis.

## Data gathering

The experimental surface tension data, used for model training, has been retrieved online (surface-tension.de website). The dataset contains values for 85 organic molecules. These molecules vary from small, simple compounds to larger, complex structures, with molecular weights ranging from 18.02 g/mol (water) to 260.8 g/mol (hexachlorobutadiene). The dataset includes hydrocarbons, halogenated compounds, alcohols, and nitrogen-containing molecules. Additionally, there are compounds with oxygen-containing functional groups, such as ethers, esters and ketones. The molecules exhibit a broad range of polarities, with polar compounds contrasting nonpolar hydrocarbons. Structural complexity also varies, including linear alkanes, aromatic rings, and cyclic compounds. This chemical diversity makes the dataset suitable for exploring a wide range of physical and chemical properties. The Gibbs self-solvation free energy ($\Delta G_{sim}$) and molecular surfaces ($S_{sim}$) were caulcated from COSMOTherm software (version 24.0.0) using the BP-TVZP parameterisation, as suggested by Gaudin. Simulations were conducted over a temperature range of 5 to 50 °C, with increments of 5 °C for $\Delta G_{sim}$ predictions. Molecular flat surface data were extracted from the COSMO file of each molecule. A comparison between the simulated surface tensions in this study and those from Gaudin's work revealed strong agreement. Error metrics have been calculated point by point for $\Delta G_{sim}$, $S_{sim}$ and $\sigma_{sim}$, at T = 20 C, at which Gaudin results are available. The maximum absolute error observed was 0.66 kcal/mol for $\Delta G_{sim}$, 8.41 Å$^2$ for $S_{sim}$ , and 6.74 mN/m for the $\sigma_{sim}$. The maximum absolute percentage error observed was 8% for $\Delta G_{sim}$, 5% on the $S_{sim}$ and 11% for $\sigma_{sim}$. The coefficient of determination ($R^2$) for $\sigma_{sim}$, $S_{sim}$ and $\Delta G_{sim}$ is 0.989, 0.999 and 0.991 respectively. The small deviations observed could be due to slightly different parametrization in older versions of COSMOTherm or to the chosen molecules conformer.

## Features selection and data preprocessing

The developed model is a HM where the FPM is the one reported in Eq 1 and the ML part is composed by an Artificial Neural Network (ANN). The starting point of the ML part is the Simplified Molecular Input Line Entry System (SMILES) of the molecules. SMILES strings were stored from COSMOTherm along with simulation results, but can be easily retrieved from RDKit library as well. The SMILES strings are processed using the RDKit library (version 2024.9.4) in Python to generate chemical structures, substructures, and conformations, represented as text-based connection tables (MOL files). The resulting MOL files are subsequently analyzed with the Mordred library (version 1.2.0) in Python to compute molecular descriptors [9]. 37 2D descriptors are calculated, among which four are selected as inputs for the model. The

calculated descriptors concern the molecule aromaticity, structure, geometry, polarity. They were chosen for their potential influence on surface tension. Deviations in flat surface measurements are already expected due to polarity and may also result from molecular geometry, weight, hydrophobicity, and aromaticity. Feature selection is conducted iteratively using SHAP analysis, a game-theoretic approach that explains machine learning model predictions by assigning contribution values (SHAP values) to each feature [10]. This method helps identify which features drive the predictions and whether their influence positively or negatively affects the predicted surface tension. The SHAP (version 0.46.0.) library in Python has been used for the analysis. The selection process begins with training a neural network with a randomly chosen structure (e.g., three hidden layers with 30 nodes per layer) and evaluating its performance on test set metrics. In each iteration, the least important feature identified through SHAP analysis is removed, and the model is retrained. This process continues until the model achieves satisfactory performance, i.e. a MSE lower than that of a standalone FPM. This procedure is shown in Figure 1. The final selected features are the atom and bond polarizability, the average molecular weight, and the number of double bonds in Kekulized structure. In addition to these features, the COSMO-RS simulated surface tensions and the corresponding temperature are also used as model input. The dataset is therefore composed of molecular descriptors, temperatures, and surface tension calculations at every temperature. Given 85 molecules and temperatures ranging from 5 to 50°C with a step of 5°C, the dataset is composed of 850 examples and 6 features: simulated surface tension, temperature, atom and bond polarizability, average molecular weight and the number of double bonds in kekulized structure. The molecules have been organised by CAS Number and the test set has been randomly selected, while making sure that the molecules appearing in the test set are not included in the training set. For simplicity, the first 680 rows, e.g. the first 68 molecules of the dataset are used as training set and the remaining 170 rows, e.g. 17 molecules are used as test set. The data is then standardized prior to model training using a standard scaler in scikit learn (version 1.6.1) library.

## Model development

The workflow of the HM is given in Figure 2. Once the FPM calculations are completed, literature data gathered and features selected, the ANN can be trained for predicting experimental values of surface tensions from 5 to 50°C. The trained neural network is built and optimized in Keras library (version 3.5.0) in Python. The loss function is represented by the mean squared error (MSE). Activation function is Leaky Rectified Linear Unit (Leaky ReLU) with $\alpha$ = 0.01 for all layers, except the output one which has a linear activation function. The number of layers, neurons per layers and learning rate of the ANN are optimized through a Bayesian optimization (BO). The number of hidden layers to be chosen by the optimizer ranges from 2 to 5, while the number of nodes per layer ranges from 5 to 100 with a step of 3. The learning rate minimum and maximum boundaries were $10^{-4}$ and $10^{-2}$ respectively. During BO, the dataset is divided into training, validation, and test subsets. The test set comprises the last 17 molecules in the dataset, while the validation set is formed by randomly selecting 7 molecules (corresponding to 70 rows) from the training set across temperatures ranging from 5 to 50 °C. The loss function is the MSE on the validation set. After identifying the optimal network structure, the molecules initially used for validation are reintegrated into the training set, ensuring that the test set remains entirely unseen by both the model and the optimizer throughout the process. The proposed structure is formed by three hidden layers. The number of nodes per layer is 17,65,59 respectively and the learning rate is 0.00184. The model prediction accuracy is evaluated on various metrics both on training and test set e.g. the Mean Absolute Error (MAE), Mean Absolute Percentage Error (MAPE), MSE, the Root Mean Squared Error (RMSE), and the $R^2$. The same evaluation metrics are also used to compare the FPM standalone prediction accuracy.

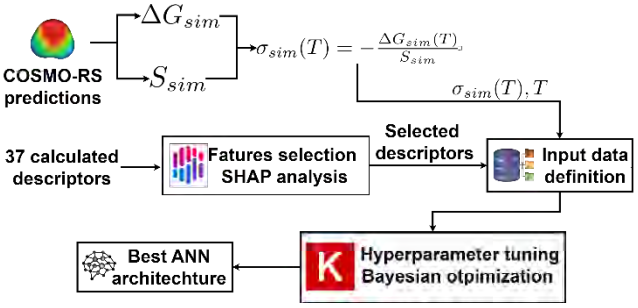

**Figure 1:** Training workflow. Self-solvation energies and molecular flat surfaces are obtained from COSMO-RS predictions, and surface tension is subsequently calculated. A total of 37 molecular descriptors are computed. Feature selection is carried out using SHAP analysis through an iterative process. Upon completion, the selected descriptors, simulated surface tension, and corresponding temperature constitute the input dataset. Hyperparameter tuning is then conducted to identify the optimal model architecture.

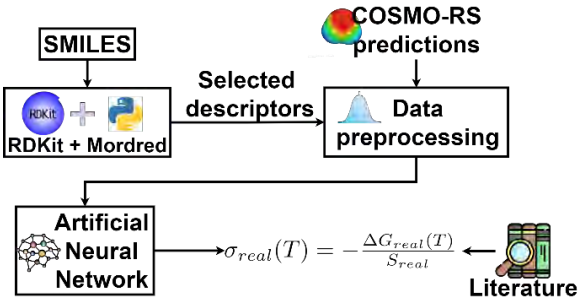

**Figure 2:** HM model workflow. Mol files are retrieved from SMILES in RDKit library. Molecular descriptors are calculated from Mordred library. Surface tensions, temperatures and descriptors are provided to an ANN which can predict temperature-dependent surface tensions experimental data.

## RESULTS

### Model prediction accuracy

Figure 3 shows a comparison of the predicted surface tension using Gaudin standalone model, the developed HM and experimental values. The left plot shows the parity plot for a range of temperatures from 5 to 50°C, while the right one shows predictions for a temperature of 25°C for the HM only, middle point of the selected temperatures. Looking at the standalone FPM, for some, less polar molecules, e.g. cyclohexane, 1-chlorobutane, dodecane, carbon tetrachloride, 1-nitropropane, Gaudin approximation seems to hold. Nevertheless, some molecules that show strong hydrogen-bonding association may orient in a specific way at the interface, with consequent deviations from experimental measurements. Overestimated surface tension is indeed evident for molecules above the 20% error line. These are methanol, ethanol, water, formamide, glycol, propanol and 2-propanol. 5 of these are also cited as overestimated outliers in Gaudin's paper. Overall, apart from the molecules mentioned above, the standalone FPM slightly underestimates surface tension. This trend is visible in the clustering of green data points below the parity line. Focusing on the HM model predictions, instead, all the points, for both training and test sets, fall within the 20% error region, showing the improved accuracy of the HM compared to the FPM. The plots demonstrate that the ANN effectively corrects the deviations of the FPM, even for the aforementioned polar molecules that exhibit significant discrepancies from the experimental values. Table 1 presents Gaudin's standalone model metrics for predicting surface tension, along with the percentage improvement in these metrics when the FPM is compared to the HM test set performance. The decrease of all the error metrics and the outstanding increase of the $R^2$ confirm that the HM offers a significant improvement in predictive performance.

**Table 1:** FPM metrics and corresponding percentage improvement achieved when compared to the HM test set metrics.

| Metric | FPM | Improvement (%) |
|---|---|---|
| MAE | 5.99 mN/m | -75.6% |
| MAPE | 17.95 % | -78.9% |
| MSE | 70.25 $mN^2/m^2$ | -95.0% |
| RMSE | 8.3816 mN/m | -77.8% |
| $R^2$ | 0.4281 | +111.0% |

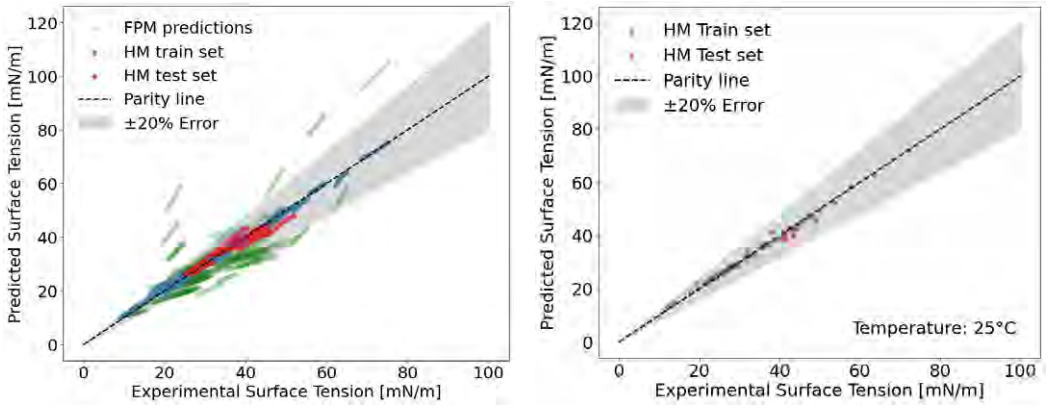

**Figure 3**: Comparison between the FPM, the HM developed in this work and experimental data. The left plot shows results of surface tension calculations from 5 to 50 °C. The green points represent the FPM model predictions. Blue and red points represent the HM train and test dataset, respectively. The black dashed line represents the ideal scenario where predicted values perfectly match experimental values, indicating a model with no error. The gray shaded region shows a ±20% error margin, providing a visual reference for acceptable prediction deviations. The right plot shows a parity plot of the simulated vs experimental surface tension at 25 °C for the HM only.

Table 2 shows the HM metrics, both for training and test set. The training set metrics highlight the model accuracy on known data, indicating excellent fit. For the test set, the metrics remain robust, also demonstrating good agreement with experimental data.

**Table 2:** HM metrics on training and test sets.

| Metric | Train | Test |
|---|---|---|
| MAE | 0.60 mN/m | 1.4619 mN/m |
| MAPE | 2.27% | 3.77% |
| MSE | 0.6281 $mN^2/m^2$ | 3.4852 $mN^2/m^2$ |
| RMSE | 0.7925 mN/m | 1.8669 mN/m |
| $R^2$ | 0.99 | 0.90 |

## SHAP analysis

Figure 4 shows a SHAP violin plot for the presented model. In the violin plot shown, SHAP values are plotted for the features evaluated on the test set, with the horizontal axis representing the SHAP value (i.e., the impact on the model's output) and the vertical axis listing the features. The shape of each violin represents the distribution of SHAP values for a feature across the dataset, highlighting variability in its impact.

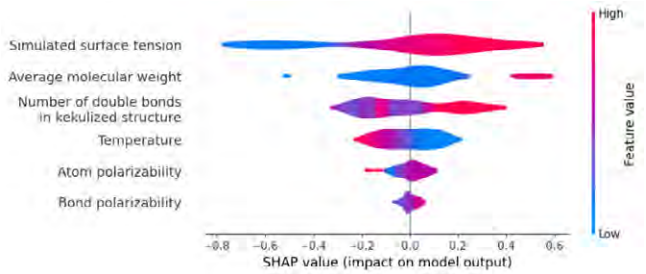

**Figure 4:** SHAP analysis violin plot. Simulated surface tension is the most relevant feature, bond polarizability the least relevant one.

Additionally, the color gradient within each violin indicates the corresponding feature value, with red denoting high feature values and blue denoting low feature values. This dual representation allows for an intuitive understanding of both the direction and magnitude of feature contributions to the model predictions. For the developed HM, the simulated surface tension is the most influential feature, with higher simulated surface tension (red) generally increasing the model's predictions and lower values (blue) reducing them. The widespread indicates a substantial variability in its impact. The average molecular weight of a molecule is nothing else than the sum of molecular weights of its elements divided by the number of elements. It is strictly correlated with the molecular weight, which can affect the hydrophobicity of a molecule, thus affecting how it behaves at a liquid interface. However, the effect can vary depending on the compound's structure and functional groups. For example, if the molecule is large but contains hydrophobic regions, it may reduce surface tension by disrupting water's hydrogen bonding network. Conversely, molecules with hydrophilic groups and higher molecular weights may increase surface tension by reinforcing interfacial interactions. The average molecular weight feature shows a less pronounced but consistent positive influence on predictions when its values are high, while lower values have little to no effect. Aromaticity can be defined in a multitude of ways. Moreover, 'aromatic' moieties in structures can be represented in Kekulé form using alternating single and double bonds [11]. Double bonds introduce rigidity and delocalized π-electron systems, which can affect molecular interactions. Molecules with a higher number of double bonds in the Kekulized structure could exhibit increased molecular polarizability, which can contribute to higher surface tension. Additionally, these aromatic systems may alter the hydrophobicity or hydrophilicity of a molecule, further affecting how it behaves at liquid interfaces. The number of double bonds in kekulized structure feature has a balanced influence, with higher values slightly increasing the predictions and lower values reducing them. The spread of SHAP values suggests moderate variability in its impact. High temperatures tend to lower the prediction values, while lower temperatures slightly increase them. This behavior aligns with expectations. As temperature rises, the self-solvation energy slightly increases (e.g. becomes less negative). Since surface tension is calculated as the negative ratio of the self-solvation energy to the molar surface (which is temperature-independent), an increase in temperature results in a decrease in surface tension. Polarizability measures how easily the electron cloud around an atom can be distorted by external electric fields. It affects the strength of van der Waals forces, which play a significant role in determining surface tension. Atomic polarizability is a parameter depending on the ease of deforming the valence electron clouds of a chemical species. Mordred iterates over all atoms and bonds of a molecule and then return the sum of all atomic and bond polarizabilities as a total value. Molecules with higher atom polarizability often exhibit stronger intermolecular attractions, potentially increasing surface tension. Similar to atom polarizability, bond polarizability refers to the distortion of electron density within bonds. It influences the molecule's ability to interact with neighboring molecules. While its direct impact on surface tension may be weaker compared to atom polarizability, it can contribute to intermolecular forces. The variability indicates a modest but significant influence. Atom and bond polarizability exhibit a narrower range of SHAP values, indicating a limited impact overall.

## CONCLUSIONS

A HM to accurately predict surface tension of organic molecules from 5 to 50°C has been presented. This study highlights the value of integrating first-principle and data-driven methods to enhance prediction. Nevertheless, the developed HM was trained on a relatively small dataset consisting of 68 molecules. The authors of this work have parallelly revisited a comprehensive but largely inaccessible, due to its outdated digital format, dataset of over 2000 surface tension measurements, transforming it into a machine-readable format to eliminate manual transcription errors. The experimental data utilized in this work originates from Jasper's compilation [12]. The dataset will be used for model training in future work. Moreover, the authors are currently working at an improved, physics-informed, version of the current model. In order to prove previous assumption on deviation source, 53 pseudo-experimental self-solvation free energies have been found from dGsolvDB1 dataset [13]. Through the FPM, calculations of the real molecular surface can be performed. The ANN can be therefore trained to also predict the deviation between the flat surface and the real one, in order to show how restrictive this hypothesis can be. Additionally, developing a model capable of pointing the sources of FPM deviations and addressing them could be highly beneficial. Such a model could then be adapted and extended to a wider range of applications.

## ABSTRACT

Sustainable development goals have spurred advancements in bioprocess design, driven by improved process monitoring, data storage, and computational power. High-fidelity models are essential for advanced process system engineering, yet accurate parametric models for bioprocessing remain challenging due to overparameterization, often resulting in poor predictive accuracy. Hybrid modeling, combining parametric and non-parametric methods, offers a promising solution by enhancing accuracy while maintaining interpretability. This study explores hybrid models for succinic acid fermentation by *Escherichia coli*, a critical process for sustainable bio-based chemical production. The research presents a structured exploration of hybrid model architectures and their robustness under varying conditions. Experimental data were preprocessed to remove noise and outliers, and hybrid model structures were developed with differing levels of hybridization (from one to all reaction rates). Kinetic parameters were recalibrated and compared against original values. Machine learning algorithms, including Artificial Neural Networks, Support Vector Machines, and Gaussian Processes, were tested, with tuning strategies applied to original or recalibrated parameters. Due to a considerable variability in individual model performance for validation, an ensemble learning approach was proposed to enhance robustness. Results demonstrate that despite not solving the overparametrization issues, all hybrid models outperform the original parametric model, with the best-performing hybrid model achieving a 52.3% lower RMSE of validation, avoiding overfitting. Ensemble approaches further improved predictions, reducing RMSE by up to 62.3% compared to individual parametric models. This highlights hybrid modeling's potential to enhance bioprocess prediction accuracy, even with limited data, supporting future advancements in bioprocess scale-up, digitalization, and sustainable biorefinery implementations.

## 1. INTRODUCTION

Succinic Acid is considered as one of the key molecules to pave the way for sustainable bio-based production of chemicals. Succinic acid is used to produce over 30 commercially available products, including food ingredients and additives, commodity chemicals like polymers (PBS), solvents and other organic acids and even pharmaceutical intermediates [1].

The increasing focus on sustainable development goals has spurred significant research into bioprocesses optimization, particularly through technological advancements in process monitoring, data storage, and computational capabilities. These developments, combined with modelling techniques and simulation tools, are driving substantial advances on digitalization of biomanufacturing. In this context, hybrid modelling has emerged as a powerful approach, combining parametric and non-parametric methods to mitigate their individual drawbacks. Parametric kinetic models for succinic acid fermentation tend to be overparameterized and uncertain, leading to poor predictive performance [2,3], presenting prediction

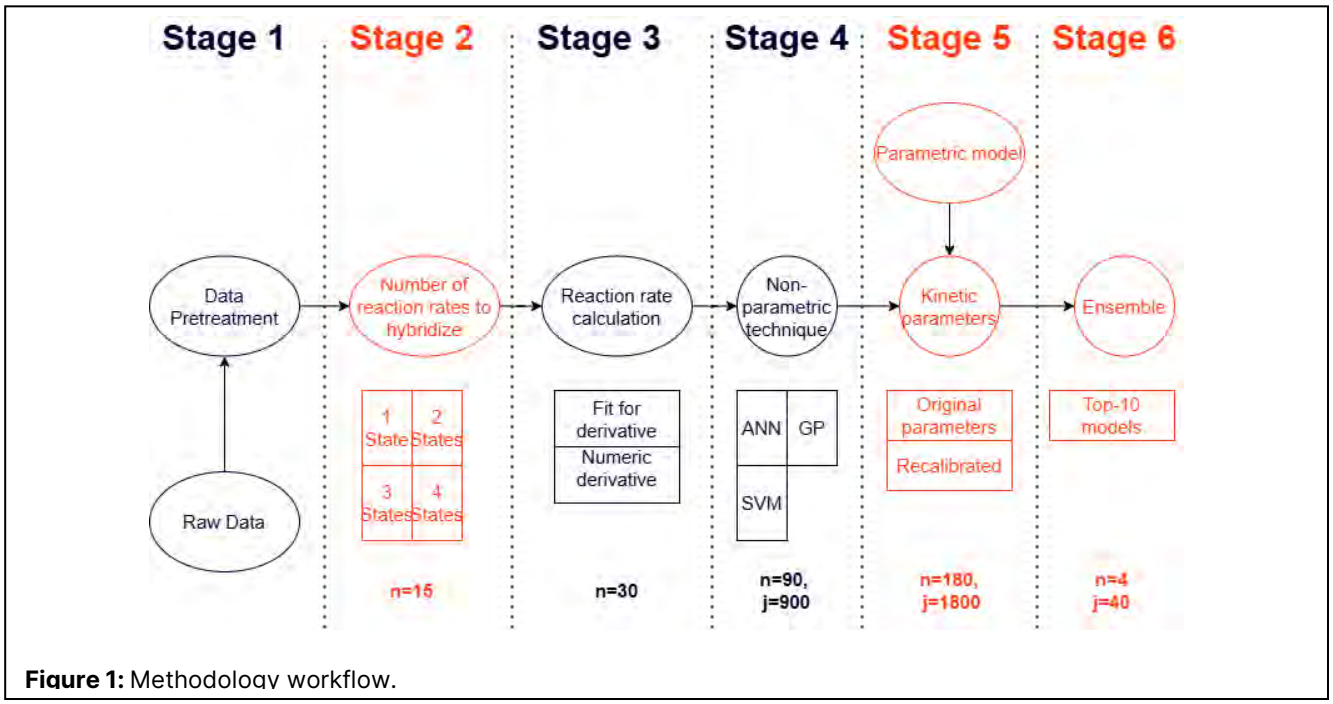

**Figure 1:** Methodology workflow.

errors up to 30% in key variables such as biomass and product concentrations [4]. Hybrid modelling has been successfully applied to describe fermentations, reducing errors in industrial settings up to 50% when compared against parametric models [5]. Therefore, hybrid modelling rises as an alternative to increase accuracy and precision for describing succinic acid fermentations.

This study focuses on developing a hybrid model to harness limited experimental data and improve states' predictions of succinic acid fermentation by *Escherichia coli* [6]. To achieve this objective, model structures and nonparametric techniques were systematically constructed and investigated. Different levels of hybridization were tested, ranging from 1 to 4 reaction rates replaced by either Artificial Neural Networks (ANNs), Support Vector Machines (SVMs), and Gaussian Processes (GPs). Ensemble learning was proposed to enhance predictive capabilities, due to high variability between predictions of individual models and poor performance. This paper is structured as follows: section 2 presents the methodology for constructing the hybrid models, detailing data pretreatment and model structure choices. In section 3 results are shown, comparing different model structures and their combinations. Finally, section 4 provides the conclusions of this investigation.

## 2. METHODOLOGY

Figure 1 presents the workflow proposed in the present work. Stages colored in orange represent structural decisions made to develop the model and stages presented in dark blue represent numeric decisions. Mass balances constitute the parametric knowledge incorporated to the hybrid model whereas reaction rates are replaced by nonparametric techniques. In the lower part of Figure 1, *n* refers to the number of model structures involved in the stage, while j refers to the total number of possible trained models. Notice that the sequential stages from 2 to 5 correspond to model structures building and do not mean those models were trained in each stage. The total number of models trained were 1800 in Stage 5.

### 2.1 Data Pretreatment

The experimental data was taken from the original paper [6]. First, outliers were detected and removed following established methodologies [7]: i) Outliers were identified using a moving median window of three datapoints and ii) if an outlier was identified, this was replaced using the Savitsky-Golay polynomial approach. Then, data augmentation was performed to enhance the predictive capabilities of the ML algorithms. Originally, experiments ranged from 21 to 37 experimental datapoints and the data augmentation procedure was done, so each experiment had 50 datapoints for each variable. Experiments were separated in training and validation in the same partitions as the original authors [6].

### 2.2 Reaction rate hybridization

In Stage 2, a decision is made to quantify how many and which reaction rates will be replaced by non-parametric model. There are a total of 15 possible combinations of reaction rates replaced by non-parametric techniques.

As such, the reaction rate of a state is replaced by a

non-parametric technique, as exemplified in eq. 1 for Succinic Acid ($SA$):

$$\frac{dSA}{dt} = f(t, S_{in}) \quad (1)$$

where $f(t, S_{in})$ represents the output of a non-parametric technique that receives time ($t$) and initial substrate concentration $S_{in}$ as inputs.

## 2.3 Reaction rate calculation

Reaction rates are used to train the non-parametric techniques chosen in Stage 4. To approximate these rates two different approaches were tested: i) a sigmoidal fit for substrate, succinic and acetic acid, and a polynomial fit for biomass were implemented, and then derived to obtain the reaction rate, and ii) the numeric derivative was calculated using the smoothed experimental data. This procedure yields 30 different model combinations to evaluate.

## 2.4 Non-parametric technique

In Stage 4, the non-parametric technique used to describe the reactions rates replaced in Stage 2 and calculated in Stage 3 is chosen. In this work, Artificial Neural Networks (ANN), Support Vector Machines (SVM), and Gaussian Processes (GP) were tested for each hybrid model. Notice that the same non-parametric technique was used for all the reaction rates, not considering mixtures such as one reaction rate modeled using GPs and other using ANNs. Therefore, there are 90 model combinations to evaluate. Each combination was trained 100 times, yielding 900 different trained models. Hyper-parameters were optimized using MATLAB 2024b® built-in functionalities.

### Hybrid Model structure

#### 2.1.1. Parametric model

For the succinic acid fermentation, the original researchers proposed a model to describe biomass growth, succinic and acetic acid production, and substrate consumption composed by 4 ODE's and 16 parameters. The biomass growth is expressed using a modified Monod expression (eq. 2) incorporating the product and substrate inhibition terms proposed by Levenspiel [8]. Cell lysis was considered, and it's expressed in eq. 3:

$$\mu = \mu_{max} \cdot \left(\frac{S}{S+k_S}\right) \cdot \left(1 - \frac{SA}{SA_{crit}}\right)^p \cdot \left(1 - \frac{S}{S_{crit}}\right)^n \quad (2)$$

$$k_L = k_{l,max} \cdot \left(\frac{k_l}{S+k_l}\right) \quad (3)$$

$$\frac{dX}{dt} = (\mu - k_L) \cdot X \quad (4)$$

where, $S$ the substrate concentration, $SA$ the succinic acid concentration, $X$ represents the biomass concentration, $\mu$ is the specific growth rate, $\mu_{max}$ the maximum specific growth rate, $SA_{crit}$ the critical succinic acid concentration for inhibition, $p$ the power constant of succinic acid inhibition, $S_{crit}$ the critical substrate concentration for inhibition, $n$ the power constant of substrate inhibition..

Product formation of Succinic Acid and Acetic Acid was described using Luedeking-Pirett expressions, shown in eqs 5 and 6, where $AA$ represents the acetic acid concentration, $\alpha_{SA}$ and $\alpha_{SA}$ represent the growth associated constants for $AA$ and $SA$ respectively, whereas $\beta_{AA}$ and $\beta_{SA}$ represent the non-growth associated constants for $AA$ and $SA$, respectively.

$$\frac{dSA}{dt} = \alpha_{SA} \cdot \frac{dX}{dt} + \beta_{SA} \cdot X \quad (5)$$

$$\frac{dAA}{dt} = \alpha_{AA} \cdot \frac{dX}{dt} + \beta_{AA} \cdot X \quad (6)$$

Substrate consumption depends on two terms: one associated with biomass growth (eq. 7) and a term associated with biomass maintenance (eq 8). The substrate consumption rate is shown in eq. 9:

$$w = \frac{1}{Y_{X/S}} + \frac{\alpha_{SA}}{Y_{SA/S}} + \frac{\alpha_{AA}}{Y_{AA/S}} \quad (7)$$

$$z = \frac{\beta_{SA}}{Y_{SA/S}} + \frac{\beta_{AA}}{Y_{AA/S}} + m_{e,X} \quad (8)$$

$$\frac{dS}{dt} = -(w \cdot dX + z \cdot X) \quad (9)$$

where $Y_{X/S}$,$Y_{SA/S}$,$Y_{AA/S}$ represent the yields for biomass, succinic acid and acetic acid respectively. $m_{e,X}$ represents the cell maintenance coefficient of substrate consumption.

#### 2.1.2. Remaining Kinetic Parameters values

For the hybrid model consolidation, the kinetic parameters that remain in the mass balances, after replacing the reaction rates predicted by the ML technique in Stage 4, are evaluated in two different schemes:

- Keeping the original values proposed by the authors.
- Recalibrating the kinetic parameters.

This final procedure yields 180 model combinations, and 1800 models trained.

#### 2.1.3 Ensemble learning approach

In preliminary simulations, high variability in predicted outputs and poor performance of individual models were observed. To address this issue and improve model performance, an ensemble approach was implemented by algebraically averaging predictions. Specifically, 100 models were trained for each model structure, and the top 10 models were selected and evaluated based on their performance. From these, the best combinations were identified for cases involving the replacement of 1, 2, 3, and 4 reaction rates. This process resulted in the selection of 4 model structures and a total of 40 trained models, which were ultimately used for

predictions.

### 2.1.4 Computational Aspects

Simulations were conducted on a commercial laptop with an Intel(R) Core (TM) i7-10510U CPU 1.80GHz, 2304 Mhz with 4 cores, 8 GB of RAM and no dedicated GPU. Calculations were performed in Matlab 2024a®. Models were trained in parallel with training times ranging from 9 up to 49 hours.

To compare the results of the different models, the RMSE reduction was calculated, as seen in eq 10:

$$RMSE_{reduction} = \frac{RMSE_{Parametric\ Model} - RMSE_{Hybrid\ Model}}{RMSE_{Parametric\ Model}} \quad (10)$$

## 3. RESULTS

Figure 2 shows the SA concentration in a validation experiment for the parametric model, when only the SA reaction rate is replaced using GPs.

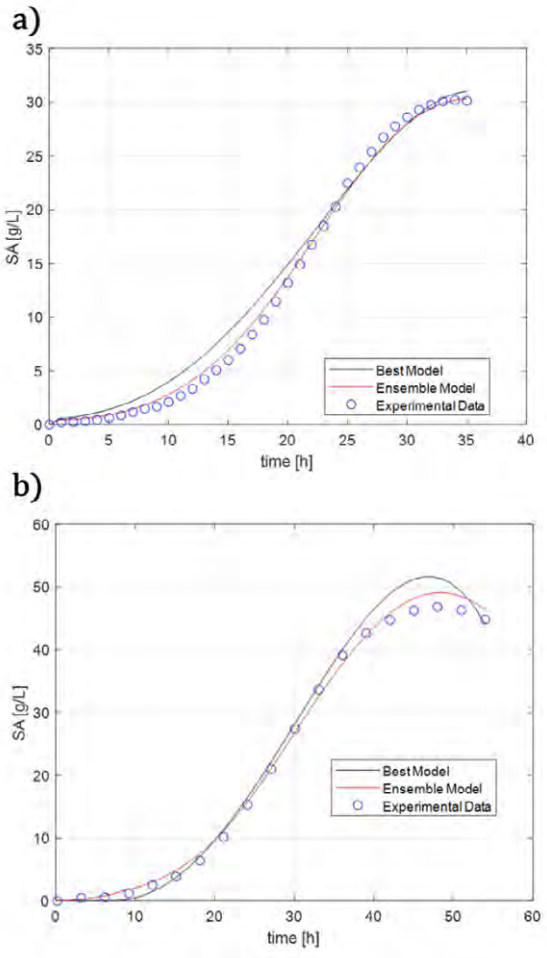

**Figure 2.** Best individual model fit and ensemble predictor when replacing only the SA reaction rate . a) initial concentration of 40g/l of Xylose. b) concentration of 60g/l of Xylose.

As seen in Figure 2, the best individual model (GPs, numeric derivatives for reaction rates and no kinetic parameter recalibration) correctly predicts the general trends and values of experimental data, but the ensemble model (GPs, numeric derivatives for reaction rates and no kinetic parameter recalibration) is closer to them. Consequently, the parametric model has an RMSE of 7.03, while the best individual fit has an RMSE of 6.68 and the ensemble prediction presents an RMSE of 6.37. Although both the best individual model and the ensemble model perform better than the parametric one, the ensemble approach yields a significantly better RMSE, with an RMSE reduction of 9.9% against the 4.9% yielded by the best individual fit. Overall, ensemble approaches show prediction errors in the validation set ranging from 5% to 14% lower when compared to the best individual models, with the greatest gains observed when replacing all four reaction rates.

Figure 3 shows the ensemble model and its confidence intervals when using GPs and replacing only the SA reaction rate. Confidence intervals are built using the lowest and highest prediction of SA within the ensembled models for each sample time. The median confidence interval presents a 10% deviation from the ensemble model's prediction. Higher deviations are seen for lower times, whereas the model's confidence intervals become narrower as the time advances, becoming as narrow as 2.3%. As a result, 94% of the experimental datapoints lie inside the confidence interval with all the points outside of it being in fermentation times less than 4 hours, signaling that the ensemble model is robust enough to average the weaknesses and strengths of individual models while accurately describing the dataset.

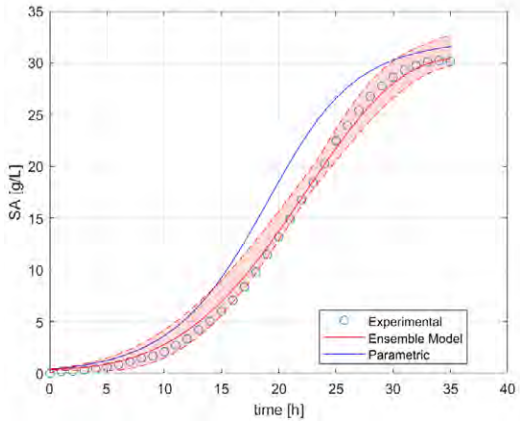

**Figure 3.** Ensemble predictor uncertainty when replacing only the SA reaction rate

Figure 4 presents the profiles obtained for the ensemble models when replacing SA, and X for ANNs and using numeric derivatives in validation experiments. It is noteworthy that despite the similarities in the profiles, the Hybrid Models have different performances, with an

RMSE of 5.68 (RMSE reduction of 27.1%) for the hybrid model with the original parameters and 5.22 (RMSE reduction of 34.8%) for the hybrid model recalibrating the other initial parameters.

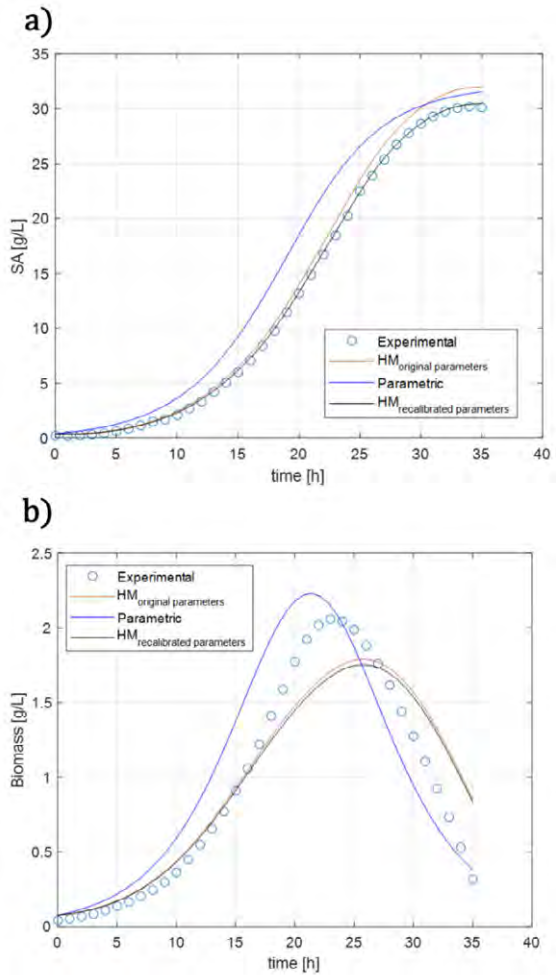

**Figure 4.** Performance of the ensemble models when replacing SA, and X for ANNs and using numeric derivatives. a) Succinic Acid for an initial concentration of 40 g/L of Xylose. b) Biomass for an initial concentration of 60 g/L of Xylose. HM stands for "Hybrid Model".

As seen in Figure 4, the Hybrid models represent more accurately the behavior of SA, whereas the parametric model tends to overpredict concentrations. Nonetheless, the Hybrid Model that uses the original kinetic parameters results in higher final SA concentrations than both the parametric model and the experimental data. For biomass, the parametric model tends to overestimate concentrations and predicts the biomass peak earlier than the experimental data shows, with a steep descent that results in an underestimation of the biomass concentrations. Hybrid Models perform better up until the 20h mark, where the Hybrid Models deviate, predicting lower concentrations and a lower peak displaced around 5h. After the predicted peak, the Hybrid Models tend to predict higher concentrations than both the parametric model and experimental data.

When recalibrating the kinetic parameters, their values differed on average 14.9% when compared against the original ones. The mass balances show high dependency between one another, therefore replacing reaction rates could provide better description for a specific variable while worsening other predictions.

Table 1 shows the RMSE reduction in validation classified by number of reaction rates and machine learning technique for the best ensemble models. The best ensemble models for the three machine learning techniques are as follows, with all of them using numeric derivatives and recalibrating kinetic parameters:

- Replacing only one reaction rate (SA).
- Replacing two reaction rates (SA and AA)
- Replacing three reaction rates (SA, AA and X)

**Table 1**: Percentage of RMSE reduction in validation experiments classified by number of reaction rates replaced and nonparametric technique used.

| Black Box Technique | 1 rate | 2 rates | 3 rates | 4 rates |
|---|---|---|---|---|
| ANN | 20.9% | 34.8% | 61.4% | 62.3% |
| GP | 15.6% | 29.8% | 50.9% | 57.0% |
| SVM | 13.3% | 27.1% | 40.5% | 47.3% |

As expected, for all machine learning techniques, the model predictions improve by increasing the number of reaction rates replaced. However, there are diminishing returns each time, since the biggest performance gains are seen when jumping from 2 to 3 reaction rates, reducing RMSE around 50% for all cases. This is due to the states interact between each other in the model, therefore, a better description of one state does not necessarily translate into better description of the other states. This occurs despite recalibrating the remaining model parameters, as can be seen in Figure 3 for biomass.

Generally, ANNs perform better than SVMs and GPs for all cases. However, the performance of ANNs and GPs is comparable, with latter needing fewer intensive calculations. When replacing the four reaction rates, GPs reduce the RMSE 57%, with ANNs presenting a 62.8% reduction despite taking almost 5 times larger training time (9 hours versus 45 hours). SVMs have comparable performance to the other two machine learning techniques up to replacing two states, however the performance gains when using three or more are less than what GPs and ANNs present.

Despite gaining better performance when replacing more reaction rates, the structure of the model becomes

less parametric and approaches more to a full non-parametric technique. This means that the model loses interpretability and explainability in exchange for more numeric precision. Moreover, the performance gains seen from three to four reaction rates replaced are small, signalling diminishing returns.

## 4. CONCLUSIONS

The results of this study underscore the transformative potential of hybrid modeling in succinic acid fermentation by *Escherichia coli*. The hybrid models demonstrated superior predictive accuracy, achieving RMSE reductions of up to 62.3% when replacing four reaction rates, significantly outperforming traditional parametric models. Also, the individual hybrid models suffer from low robustness during validation, making necessary the use of ensemble learning, which is not commonly use in ML applications. Ensemble approaches provided higher accuracy, by leveraging the strengths of the individual models while minimizing their weaknesses. Ensemble approaches could be very useful for developing bioprocesses because they are usually less sensitive to noisy data, making them more robust than traditional models. Among the non-parametric techniques tested, Artificial Neural Networks (ANNs) delivered the highest accuracy but at a greater computational cost, whereas Gaussian Processes (GPs) provided comparable performance with reduced complexity, making them an efficient alternative. The recalibration of kinetic parameters emerged as a critical factor for optimizing model performance, particularly when paired with numeric derivatives for reaction rate calculation. While increasing the number of replaced reaction rates improved numerical precision, this came at the expense of model interpretability, with diminishing returns observed beyond three reaction rates. Besides using black box techniques to replace reaction rates does not solve the issue of overparametrization of kinetic models in bioprocesses which might lead to overfitting and poor prediction capabilities in the validation sets. However, it has been shown that using ensemble approaches helps to reduce models' individual weaknesses and enhance their strengths, therefore increasing and enhancing prediction capabilities, as seen by better predictions in the validation set with reduced predictor uncertainty.

## ABSTRACT

A reinforcement learning framework is developed for the synthesis of distillation trains. The rigorous Naphtali-Sandholm algorithm for equilibrium separation modeling was implemented in JAX and coupled with the benchmarking Jumanji RL library. The vanilla actor-critic agent was successfully trained to build distillation trains for a seven-component hydrocarbon mixture. A transformer encoder structure was used to apply self-attention over the agent's observation. The agent was trained on minimal data representation containing quantitative component flows and relative volatility parameters between present components. Training sessions involving $5{\cdot}10^4$ episodes ($3{\cdot}10^5$ column designs) were typically run in under 60 minutes. While training was fast and reliable with appropriate tuning of the hyperparameters, further improvements are needed in the generalizability performance for similar separation problems.

**Keywords**: Artificial Intelligence, Machine Learning, Process Synthesis, Distillation, Optimization, Reinforcement learning, Transformer Blocks

## INTRODUCTION

The field of process systems engineering (PSE) has witnessed significant advancements through the combination of machine learning (ML) techniques with traditional PSE methods. Among these, reinforcement learning (RL) has emerged as a promising approach [1], due to its capacity to tackle sequential decision-making problems inherent to process synthesis. Notably, Midgley (2020) [2] pioneered RL in PSE for process synthesis with the introduction of the Distillation Gym, an open-source platform designed for optimizing distillation train configurations simulated in ChemSep/COCO for user-defined multicomponent feeds. This foundational work was further developed by van Kalmthout et al. (2022) [3], who integrated Aspen Plus for rigorous process modeling within the RL framework. However, major improvements were not achieved due to the insufficient data transfer speed and (un)reliability of the RL/Aspen Plus interface.

Considering flowsheet synthesis involving multiple unit operations and recycles, Göttl et al. (2021) [4] proposed a two-player game framework in which an RL agent competes against itself to generate profitable flowsheets involving multiple unit operations simulated using short-cut models. Building on this, Göttl et al. (2023) [5] explored the generalizability of RL methods by applying them to azeotropic distillation case studies. Using similar process simulation models, Khan et al. (2022) [6] integrated RL with mathematical programming (MP) to allow RL agents to design unit operation sequences while optimizing these sequences via MP.

Recent efforts have addressed challenges related to simulation accuracy and computational efficiency. For instance, Wang et al. (2023) [7] proposed an RL framework coupled with IDEAS as a process simulator. Gao et al. (2023) [8] addressed the issues of slow and inaccurate process simulators by introducing transfer learning. In their approach, the RL agent is pretrained on short-cut process models to facilitate rapid learning, followed by fine-tuning training on rigorous simulations using DWSIM for improved accuracy. Reynose-Donzelli et al. (2024) [9] applied policy masking techniques to simplify the RL agent's learning process while leveraging Aspen Plus for simulations.

The need for process flowsheet data embedding to create meaningful data representations for the RL agent has been widely acknowledged. Stops et al. (2022) [10] emphasized the creation of meaningful flowsheet data

embeddings using graph neural networks (GNNs). Göttl et al. (2023) [5] used MLP-mixer methods. Seidenberg et al. (2023) [11] introduced knowledge graphs to represent flowsheet object-relation dynamics more concretely. Wang et al. (2023) [7] exploited the well-established convolutional neural network (CNN) agent architecture.

These studies collectively underscore the versatility and potential of RL in PSE, from distillation train optimization to generalized flowsheet synthesis and novel approaches to data representation and simulation efficiency. This growing body of work highlights RL's promise in addressing complex, real-world challenges in process synthesis engineering. Yet, challenges remain both in developing a thorough understanding of the RL agent's performance and integration of fast, reliable, and accurate process simulators in the proposed RL applications.

This work continues the search for optimal RL performance through combining rigorous process modeling with the existing open-source benchmarking Jumanji [12] platform for RL applications, leveraging the use of state-of-the-art RL agent features combined with effective data embedding through transformer blocks. Jumanji is developed in JAX, which is a layer on top of Python and developed for machine learning purposes by Google DeepMind. JAX provides explicit features including parallel computing on GPU backends, Just-In-Time (JIT) compilation, and automatic differentiation. These features are used in this work to simulate equilibrium-based separation processes in JAX, seamlessly integrating with Jumanji.

The choice for transformer data embedding as an alternative to the aforementioned embedding techniques has been made to explore its capacity for the given purpose and optimally exploit parallel computing in JAX. It is explored how the transformer architecture operates on a variety of information representation in terms of quality and quantity.

# METHODOLOGY

The work involved the implementation of the rigorous Naphtali and Sandholm (N&S) algorithm into JAX for simulating multi-component equilibrium separation and coupling this algorithm with the RL framework for distillation train sequencing. The N&S algorithm is an equation-grouping-by-stages procedure and exploits the NR iteration for finding the non-linear solution vectors. Finding the Jacobian for the NR iterations either numerically or analytically is traditionally a tedious process involving significant computational effort. In the current work, the JAX library has been leveraged to use automatic differentiation (AD) for finding the Jacobian in a highly efficient and accurate way.

**Table 1:** Data representation in the initial observation by the RL agent.

| **Component** | **C3** | **I-C4** | **C4** | **C5** |
|---|---|---|---|---|
| Fraction | 0.143 | 0.143 | 0.143 | 0.143 |
| **Component** | **C-C5** | **C6** | **T-C4** | **$R_{tot}$*** |
| Fraction | 0.143 | 0.143 | 0.143 | 1 |

*$R_{tot}$ gives the ratio of the current total stream quantity over the initial feed to the train instead of the current stream absolute flow value to minimize steep gradients during training.

## RL framework

The RL problem is formally defined by the Markov decision process (MDP). The MDP can be described by the tuple M ={S,A,P,R} where S is the collection of states describing the environment, A contains the possible actions for the agent to take in the environment, P is the transition function describing the system dynamics via the probability of space action trajectories, and R is the reward function. The agent runs an episode which is a series of time steps. In each time step, the agent observes the current state upon which it selects an action to let the environment transition to a new state and receive a reward for the chosen action from the environment. The episode is finalized once the terminal state is reached. The agent learns to maximize the reward.

In this framework, the state observation is an available component stream to be separated. The agent decides on the column design parameters for the observed stream, after which it receive a financially based reward for the generated separation. The episode is terminated once the minimum number of columns has been completed to recover all components in the initial feed as pure products based on binary separation. This termination condition is chosen as it is deemed not reasonable to built additional columns for the presented easy-to-separate mixture.

### State space

The state space contains all possibly flowsheet configurations of the multi-component separation train. State representations are stored in a stream table structure wherein the connectivity of separation units and stream information is represented. This potentially includes component flow quantities, column design parameters, column installed and operating costs, and stream revenues if a product purity criteria is met.

### Observation space

Given the Markov property, the observation of a current state should provide all information relevant to the RL agent to inform its decision upon action taking. It is considered that all information to build a distillation column is contained in the quantity and quality of the feed stream. The origin of such a feed stream in terms of preceding column passes is therefore irrelevant in this approach and information about existing flowsheet top-

ology is not contained in the observation. Table 1 gives the data presented with only the stream composition in the initial observation (see Figure 1).

**Table 2:** Design parameter windows and discretization for the multi-variable discrete action space

| | Lower | Upper | Steps |
|---|---|---|---|
| Stage number | 5 | 85 | 81 |
| Reflux ratio | 0.1 | 10 | 30 |
| Distillate ratio | 0.01 | 0.99 | 150 |
| Feed location* | 0.2 | 0.85 | 30 |

* The feed location is defined as the column fraction above the feed

### Action space

While several literature studies focused on hierarchical action space structures, a simplified approach is used in this work. Each time step will generate at least one non-pure outflow stream as long as there are still more than two feed components present. These outflows are systematically acted upon by the agent, either until the product purity constraint is met for all streams or if the maximum number of columns allowed has been built.

For a given observed single stream, the agent must decide on the column design parameters including number of trays, distillate rate, reflux ratio, and feed location. A multi-discrete action space has been exploited where each action involves adapting the four design parameters. The chosen feasible parameter bounds and the number of discretization steps are summarized in Table 2. The given discretization gives roughly 11M possible action values combinations for a single column design. Action masking is used to control the different number of discretization steps for each design parameter. The small discretization step size for the distillate ratio was chosen to potentially allow the agent to achieve optimal purity close to the minimum requirement (95%).

### Reward definition

The RL agent aims to maximize a cumulative award. It is essential to effective learning that the reward definition accurately captures the environment dynamics. For a flowsheet configuration, reward can be expressed in financial terms through the potential revenues of product streams minus the installed and operating costs.

$$Reward = Revenue - (C_{installed} + C_{operating}) \quad (4)$$

The installed costs were estimated using the Marshall & Swift index correlations and operating costs are considered for heating and cooling in the reboiler and condenser, respectively. The cost correlations for both contributions are detailed in the supplementary material.

The same revenue value is chosen for all components, regardless of possible deviations in market values to prevent introducing bias during learning. A hypothetic constant product revenue of 20$/kmol has been selected.

### RL agent architecture

The agent architecture has been adopted from the Jumanji library [12] and features state-of-the-art functionalities. The actor-critic baseline agent uses bootstrapping for the objective function, preventing it from collapsing. The advantage is used for update estimates, and an entropy term is introduced to favor exploration.

### Data embedding

The transformer architecture is implemented as an encoder structure with self-attention to the input sequences. The structure allows for addressing the relative importance of input parameters with respect to the overall input for the system dynamics. The transformer encoder takes in a query (Q), key (K), and value (V). Scaled dot self-attention is applied over Q and K and a SoftMax function is used to create the attention weights. The weights are multiplied with V to obtain a weighed value representation indicating the relative importance of the vector entries in Q to focus on the most relevant information from the sequence to take its next action.

Q, K, and V are all the same for the encoder transformer and contain the observation of the environment. Learnable weight matrices are introduced for Q, K, and V to transform the observation into a higher dimensional representation before entering the self-attention mechanism. Trainable parameters are the Q, K, and V weight matrices, the feedforward NN layers, and the linear transformation layers. The agent learns by calculating the update for each of the parameters via the gradient of the loss function with respect to the parameters. The parameter updates are applied for the critic and actor network.

## SCOPE

A case study is selected where a multi-component hydrocarbon mixture needs to be separated into >95% pure product streams. The components are listed in Table 3 and have been chosen for their reasonable relative volatilities, rather than representing a potential real system. Non-ideality is not considered in the algorithm. Feed streams are always considered to be liquid at boiling point. Heating and cooling duty costs are based on standard cooling water, even though this may not be realistic for the light boiling components present in the initial feed.

The rigorous algorithm takes in the number of stages, feed location, distillate rate, reflux ratio, feed rate, operating pressure, and feed composition. The algorithm has been tested for its reliability and speed as function of number of components in multi-component systems. It was chosen to initiate random feeds with and

find reasonable column designs for these feeds using the Fenske-Underwood-Gilliland shortcut method. These column design were then evaluated using the rigorous algorithm. For batches containing 1000 random initiated feeds for a given number of components, it was found that full convergence for all columns in a batch could no longer be guaranteed with more than nine components present. It was deemed reasonable to verify the RL framework performance using a seven-component mixture to introduce separation complexity while guaranteeing reliable and stable performance of the separation algorithm.

**Table 3:** Components considered in the multi-component separation train.

| Component | BP@1 atm | CAS | Not. |
|---|---|---|---|
| propane | $-42\ ^oC$ | 74-94-6 | C3 |
| isobutane | $-12\ ^oC$ | 72-28-5 | I-C4 |
| n-butane | $-1\ ^oC$ | 106-97-8 | C4 |
| n-pentane | $36\ ^oC$ | 109-66-0 | C5 |
| cyclopentane | $49\ ^oC$ | 287-92-3 | C-C5 |
| n-hexane | $69\ ^oC$ | 110-54-3 | C6 |
| 2,2,3-trimethyl butane | $81\ ^oC$ | 464-06-2 | T-C4 |

**Table 4:** Hyperparameter settings used for the RL framework.

| Agent | | Transformer network | |
|---|---|---|---|
| Learning rate | 0.4e-3 | Blocks | 1 |
| Bootstrap factor | 0.95 | Heads | 1/2/4 |

| **Training** | | | |
| Batch size | 32 | | |
| Episode steps | 6 | | |

## RESULTS

The goal for the agent was to construct a flowsheet in which all seven components are recovered as purified product streams using six separation units producing 2000 kmol/hr total pure product. When trained on a fixed feed composition, the agent was well capable of doing so, given that the framework hyperparameters were appropriately chosen. While the hyperparameter settings can be tuned over a wide range, findings for fixed sets of the hyperparameter as given in Table 4 are presented. The choice for these fixed parameter values is informed by the settings for different games with similar RL networks as provided within the Jumanji library.

Figure 1 shows the episode return as function of episode number or time. In the base case, training is done on basis of quantitative component flow observation ($\phi$)

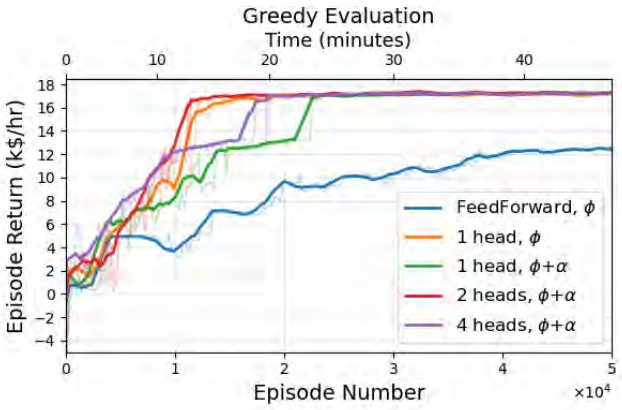

**Figure 1:** Episode return using argmax over the policy parameters as function of episode number (lower axis) or time (upper axis). $\phi$ for training on quantitative component flows observation. $\phi + \alpha$ for training on additional relative volatility data.

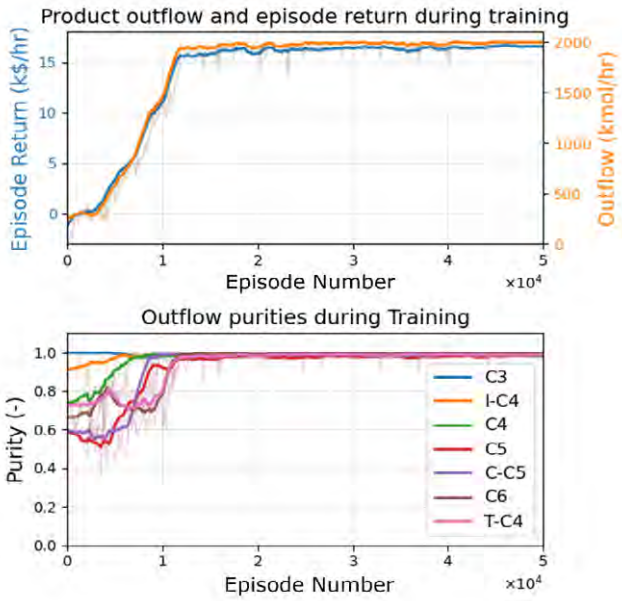

**Figure 2:** Training progression profiles in terms of cumulative episode return (Fig 2A), total product recovery during training (Fig 2A), and outflow purity development during training (Fig 2B) for 2 heads $\phi + \alpha$ (Figure 1).

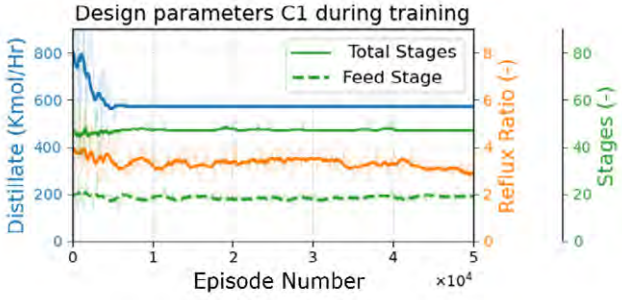

**Figure 3:** Separation column design parameter of the first column in the sequence profiles during training.

using single head attention. In the absence of a transformer encoder (feedforward network), the agent was not able to learn how to produce all outflows as products with six columns. The impact of adding the relative volatilities to the observation space is illustrated ($\phi + \alpha$) in combination with the number of attention heads. It is observed that the fastest learning was achieved for the observation space of form $\phi + \alpha$ in combination with two heads. The effectiveness of multi-head attention is however not easily quantified as also the training parameter set size changes upon adding additional attention heads in the current setup. Having four attention heads shows decreased learning performance indicated by the slowdown in convergence towards full product recovery.

Figure 2A shows the total molar outflow of streams being product streams and the episode return. The episode return corresponds to the cumulative reward received by the agent for completing one flowchart of 6 columns. The product outflow strongly correlates with the episode return as the agent receives high reward for producing product streams. It can be expected that the reward increases if the agent would more closely approach the purity constraint by tuning the design parameters for a converged flowsheet. However, such reward optimization is hardly observed for the current training (flat purity profiles once seven components are recovered as product streams), indicating the potential need for reward shaping to achieve better static optimization. Figure 2B showcases, however, that the agent was able to learn the purity constraint of >95 mol% on product flows, based on the reward definition.

Figure 3 provides an exemplary plot based on the first column in the flowchart for the learned design parameter tuning by the agent. The variation remains larger for the reflux ratio, and feed location which is due to the larger discretization steps for both parameters (see Table 1).

## Flowchart benchmarking

The performance of the RL agent was validated through the generation of benchmark flowcharts in Aspen Plus. The comparison of episode return is done for the flowchart generated by the agent and two flowcharts where either all distillate or bottom streams are >95% pure products. The comparison is summarized in Table 3. The column number of stages, feed locations, and distillate rates are determined using the DWSTU model in Aspen Plus. The reflux is determined using a purity design spec after converting the DWSTU models into RADFRAC models. The comparison shows that the episode return obtained by the agent is competitive with the values found for the benchmark flowcharts. It must be noted that the DWSTU involves a shortcut method for which the dynamics might be different compared to the reward function on which the agent was trained.

**Table 5:** Flowchart episode return comparison between RL-generated and Aspen Plus optimized designs and learned flowsheet column design parameters. $RR$ is reflux ratio, $D$ is distillate rate (kmol/hr), $N_{tot}$ and $N_f$ is total and feed stage number, respectively.

| RL | Distillates | Bottoms |
|---|---|---|
|  |  |  |
| 17.3 k$/hr | 17.2 k$/hr | 15.8 k$/hr |

**Column design parameters RL flowchart**

| | $RR$ | $D$ | $N_{tot}$ | $N_f$ |
|---|---|---|---|---|
| **C1** | 2.8 | 572 | 47 | 19 |
| **C2** | 1.6 | 296 | 82 | 51 |
| **C3** | 1.7 | 296 | 35 | 20 |
| **C4** | 3.2 | 287 | 42 | 13 |
| **C5** | 2.3 | 570 | 55 | 24 |
| **C6** | 2.3 | 283 | 79 | 35 |

* Using argmax over the policy params

## Inference

RL is believed to be capable of outperforming other optimization approaches for its inference properties. Where traditional approaches optimize problem-specific, the RL approach involves the optimization of its policy to make the right decisions under the given circumstances. As such, new problems following a similar problem definition as the problem trained for may be solvable by the RL agent using its trained policy. This inference property has been tested in the current work to provide some insight into how well the agent is capable of generalizing between similar problems. Since the agent was trained on a fixed initial feed composition, inference can be tested by introducing random distributions for the feed composition and see how well the agent is capable of obtaining an optimal reward for these distributions.

**Table 6:** Inference capacity of the trained networks in Figure 1.

| **Policy** | **Mean reward** (k$/h) | **Mean product outflow** (kmol/h) |
|---|---|---|
| $\boldsymbol{random}$ | -1.9 | 470 |
| $\boldsymbol{1\ head, \phi}$ | 3.3 | 504 |
| $\boldsymbol{1\ head, \phi + \alpha}$ | 3.8 | 562 |
| $\boldsymbol{2\ head, \phi + \alpha}$ | 2.6 | 463 |
| $\boldsymbol{4\ head, \phi + \alpha}$ | 3.8 | 532 |

The episode return for 100 randomly sampled feed distributions with a minimum fraction of 0.05 for each component was evaluated for the trained policies in Figure 1. The results are in Table 6. The trained policy outperforms the random policy in terms of episode return

but there is hardly a gain in product recovery and also no strong correlation between number of heads vs performance is found.

## CONCLUSIONS

With the implementation of rigorous modeling into JAX, seamlessly integrated with the Jumanji framework, this work demonstrates the potential of combining RL with rigorous simulation methods for process synthesis. The RL agent successfully handles the complexity of the optimization problem, managing an extensive action space containing 11 million possible action values for a single state. Flowsheet convergence toward full product recovery was typically achieved after evaluating fewer than 20,000 episodes (or six-column flowcharts). The simplified approach of using a non-hierarchical action space and single-stream observations highlights that RL does not necessarily require massive data input for optimal learning. However, the need for meaningful data representation was indicated, as flowchart convergence was not achieved without a transformer encoder. While transformer structures are renowned for their parallel multi-head attention, adding more attention heads did not necessarily improve learning performance.

Further improvements are needed to enhance the inference performance of the trained policy. While there was a slight improvement in reward gain between the trained and random policies, the overall performance remains unsatisfactory. One possible way to improve generalizability could be to train the agent on random feed distributions for given multi-component mixtures, rather than relying on fixed compositions as is currently done.

The major limitation from a process synthesis perspective lies in the feedforward structure of the generated flowchart. Process synthesis relevance could be enhanced by incorporating a variety of unit operations along with the presence of recycle streams. Additionally, challenges are likely to arise in achieving convergence of the rigorous model when non-idealities are introduced.

## ABSTRACT

Optimizing the operational conditions of electrochemical separation systems to achieve higher separation efficiency remains a complex challenge due to their nonlinear and dynamic nature. In this work, we proposed a Reinforcement Learning (RL)-based control framework to address this challenge. By applying various RL algorithms, we trained an RL-based controller that adapts to different system configurations and conditions. Also, the trained model learns the optimality between the removal efficiency and energy consumption. Overall, this approach autonomously learns the optimal operational parameters, significantly improving ion removal efficiency. The proposed RL-based control system enhances the performance of electrochemical system, providing a versatile and adaptive solution for optimizing separation across multiple electrochemical technologies. This work demonstrates the potential of RL in advancing the design and control of sustainable water purification systems.

**Keywords**: Reinforcement Learning , Separation, Intelligent Systems, Process Control, Machine Learning

## 1. INTRODUCTION

Water is one of the most essential and valuable natural resources, critical to sustaining all forms of life [1]. However, water scarcity remains a critical global challenge, with projections indicating that the average per capita supply of clean water will decline by one-third within the next 20 years [2,3]. Efforts from governments, industries, and academia have increasingly focused on developing advanced separation processes to address this issue. Desalination has emerged as a viable solution for converting brackish and seawater into potable water, but many desalination technologies are energy-intensive and capital-demanding [4,5]. Broadly, these technologies include pressure-driven, electrically driven, and thermal-driven processes [5]. Examples include reverse osmosis (RO) and ultrafiltration for pressure-driven processes, electrodialysis and capacitive deionization for electrically driven processes, and distillation for thermal-driven processes [5,6]. Although significant advancements in desalination technologies over the past decade have enhanced their reliability and reduced capital costs, high energy consumption remains a major concern, especially in regions with limited energy resources.[7] While RO dominates other desalination technologies, electrically driven processes like electrodialysis (ED) are particularly advantageous for low salinity/brackish water desalination, low pressure requirements and decentralized water treatment due to their modular design [6,8].

Electrochemical processes, such as ED, are well-positioned to play a critical role in addressing water scarcity in specific scenarios, such as brackish water treatment, and in supporting sustainable mineral supply chains and nutrient cycle management [9]. The design of ED systems involves numerous factors, including applied voltage, current density, feed ion concentration, ion type, and ion-exchange membrane (IEM) properties, as well as trade-offs in unit size (e.g., number of stacks) [10]. These parameters collectively influence separation efficiency, energy consumption, and overall costs. However, optimizing ED is challenging due to the intricate interactions among these parameters and their effects on system performance. Addressing these complexities requires precise, adaptable, and rapid control tools capable of real-time optimization to ensure high water quality and energy efficiency.

To achieve real-time control of chemical processes, researchers have increasingly turned to advanced

algorithms such as Reinforcement Learning (RL). Unlike traditional control methods, RL algorithms are robust to nonlinearities arising from operational irregularities and complex process dynamics [11]. RL eliminates the need for complete prior understanding of these intricate processes by learning optimal control strategies through trial-and-error interactions between the agent and its environment. This adaptability has led to RL's widespread application in engineering fields, including reactor design [12], distillation [13], and separation [14]. However, despite its potential, RL has been underutilized in electrochemical separation processes. Notably, recent studies by Moon et al. [14,15] have focused primarily on membrane capacitive deionization, which has been shown to consume more energy (i.e., have lower energy efficiency) compared to electrodialysis (ED).

The present study examines the implications of incorporating RL-based control strategies in ED operations. Specifically, we evaluate the performance of different RL algorithms in maintaining high separation efficiency at low energy consumption under dynamic operating conditions (Figure 1). We explore reward functions designed for both single-objective and multi-objective optimization. The goal is to develop a controller capable of achieving performance metrics close to 99% separation efficiency and 0.3 kWh/m³ specific energy consumption. The RL control framework employs a numerical model to predict system states—such as separation efficiency and energy consumption—based on dynamic actions like applied voltage and operational time. By leveraging these advanced AI controllers, this work aims to enhance water quality, improve process efficiency, and reduce operational costs, thereby addressing the complexities inherent in electrochemical separation systems.

## 2. METHODOLOGY

The implemented framework "OptiDial" in this study is elucidated in Figure 1. Initially, a numerical modeling technique that approximate the working principle of the electrodialysis (ED) process is proposed. Afterwards, the set up and training of the AI-based controller is outlined.

### 2.1 Physics-based modeling

To model the physical processes happening in the electrochemical system, we adopted the physics model from our previous work [10]. This complex and non-linear dynamical system is modeled as a tank with inflow and outflow into main compartment and selectively through the membrane into the adjacent compartment. Thus, for an electrochemical device system as shown in Figure 2 with diluate ($dc$) and concentrate ($cc$) compartments component mass balance with concentration $C_i$ in the cell compartment with volume $V_i^k$ at a volumetric flowrate $Q_i$ and reservoir tank with volume $V_i^T$ is given as follows in equation (1) – (3). Herein, there is a flow across the membrane (anion exchange membrane, a; cation exchange membrane, c) with diffusion coefficient Da/c and thickness $l_{a/c}$ upon application of voltage E which resulted into ohmic drop across the two fluid compartment ($E_{ohm}^{cc}$, $E_{ohm}^{dc}$), ohmic drop across the membrane ($E_{mem}$) and electrodes ($E_{anode}$, $E_{cathode}$). Upon solving the coupled ordinary differential equations presented in equations (1) – (3), the desalination metrics such as ion removal efficiency (SR) and specific energy consumed (EC) are computed as in equations (4) – (5).

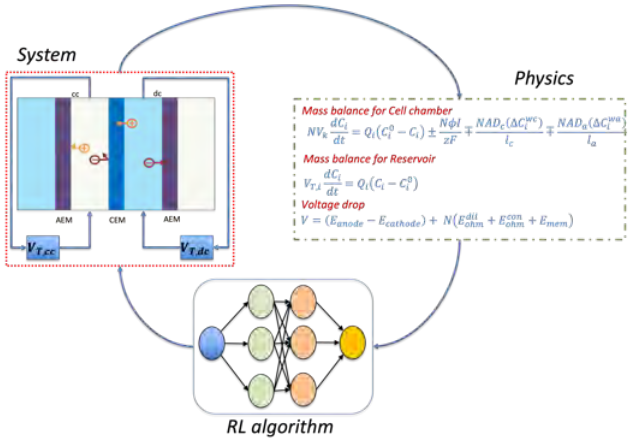

**Figure 1:** The architecture of "OptiDial", a reinforcement learning-based real-time control of electrodialysis.

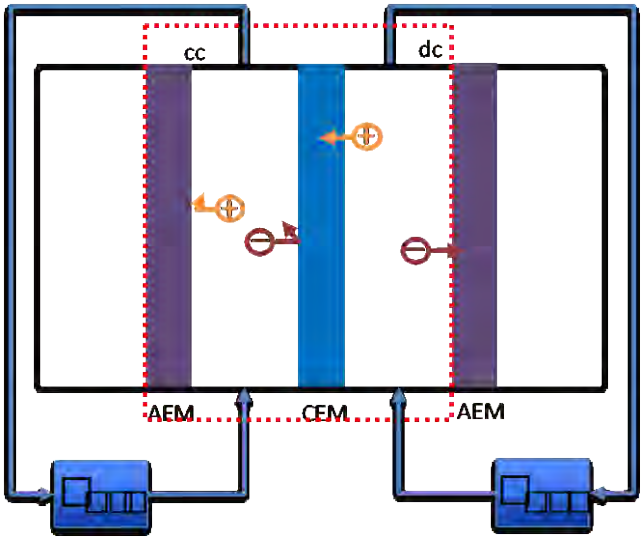

**Figure 2.** Schematic representation of the electrodialysis device. The red outline highlights a stack composed of a concentrate compartment, a diluate compartment, and alternating anion exchange membranes and cation exchange membranes.

$$NV_i^k \frac{dC_i}{dt} = Q_i(C_i^{in} - C_i) \pm \frac{N\phi I}{zF} \mp \frac{NAD_a}{l_a}(C_{cc}^{wa} - C_{dc}^{wa}) \mp \frac{NAD_c}{l_c}(C_{cc}^{wc} - C_{dc}^{wc}) \quad (1)$$

$$V_i^T \frac{dC_i^{in}}{dt} = Q_i\left(C_i - C_i^{in}\right) \quad (2)$$

$$E = (E_{anode} - E_{cathode}) + N \cdot \left(E_{ohm}^{cc} + E_{ohm}^{dc} + E_{mem}\right) \quad (3)$$

$$SR = 1 - \frac{C_{dc}^f}{C_{dc}^{in}} \quad (4)$$

$$EC = \frac{E \cdot \int I dt}{V_{dc}^T} \quad (5)$$

## 2.2 Reinforcement Learning Framework

### Theory

Reinforcement Learning (RL) is a branch of machine learning where an agent learns to make decisions by interacting with an environment to maximize a cumulative reward [16]. Unlike supervised learning, RL does not rely on labeled data but instead uses trial-and-error to discover an optimal policy [17]. The agent's actions influence future states and rewards, making RL particularly suited for sequential decision-making tasks. Generally, the core components of RL (as shown in Figure 3) include the agent, environment, state, action, reward, and policy [16,17].

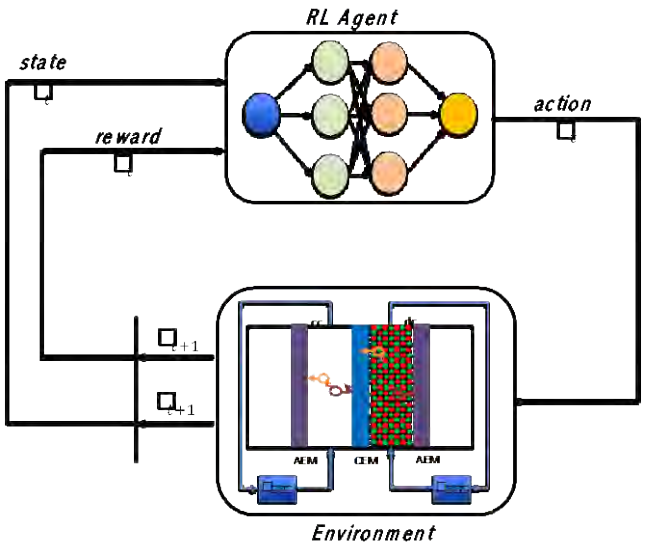

**Figure 3:** Schematic workflow of the RL-coupled electrochemical desalination process.

### Problem set up

In this work, we will focus mostly on the proximal policy optimization (PPO), Soft Actor Critic (SAC), and Advantage Actor Critic (A2C) algorithms. Though the RL models have a similar framework and are data-driven models but differs in their training algorithm. For example, the PPO algorithm maximizes the gradient of an expected reward function while the A2C containing two components an actor (policy, which selects actions to maximize cumulative rewards) and critic (a value function, which evaluates the quality of the chosen actions) maximizes the expected cumulative reward by combining two components. Lastly, the SAC maximizes the expected cumulative reward while incorporating an additional term for entropy to encourage exploration.

During the learning process, the RL agent interacts with the environment (approximated by the numerical model) and explores different action values based on the observations from the numerical model to maximize the reward function. See Table 2 for the range of action and state parameters. The action in this work considers key operational parameters such as the number of stacks ($N$), applied voltage ($E$) operational time ($T_{tot}$), volume of the diluate reservoir tank ($V_{dc}^T$) and volume of the concentrate reservoir tank ($V_{cc}^T$). Meanwhile, we adopted the salt removal efficiency ($SR$), specific energy consumed ($EC$), final effluent concentration from diluate tank ($C_{dc}^f$), and final effluent concentration from concentrate tank ($C_{cc}^f$). As the RL agent requires a reward function to direct the training process, we created a reward function (F1, F2, F3) that attempts to enhance the desalination metrics such as SR and EC as defined in eq 6 – 8. In this work, the RL environment is inherited the gym environment provided in the OpenAI Gym python library.

$$\text{F1: } R(t) = \alpha \cdot SR \quad (6)$$

$$\text{F2: } R(t) = \alpha \cdot SR + \beta \cdot {}^{EC}/_{10} \quad (7)$$

$$\text{F3: } R(t) =\cdot SR + \beta \cdot \left(1 - {}^{EC}/_{10}\right) \quad (8)$$

### Training and Testing

Once the RL environment and variables are defined, model training is the next. In this work, we trained the RL model with the three RL algorithms (PPO, SAC, A2C) and three reward functions under the same condition (30,000 epochs and $10^{-3}$ learning rate). Herein, we used the RL algorithms implementation in stable-basline3 for easy reproducibility [18]. Throughout training, the RL algorithm iteratively refines its policies to achieve improved SR and/or EC while considering the complex interplay of these variables. Afterward, the trained RL agent recommends optimized action values ($N$, $E$, $T_{tot}$, $V_{dc}^T$, $V_{cc}^T$) during the testing step.

**Table 1:** Parameters of the RL environment employed in training the agent.

| Parameters | Variable | Range |
|---|---|---|
| Action | N | 20 – 80 |
| | E | 0.1 – 2.0 V |
| | $V_{conc}^T$ | 0.1 – 2.0 m$^3$ |
| | $V_{dil}^T$ | 0.01 – 0.5 m$^3$ |
| States | SR | 0 – 1 |
| | EC | 0 – 10 KWh/ m$^3$ |
| | $C_{conc}^f$ | 0 – 1000 mol/m$^3$ |
| | $C_{dil}^f$ | 0 – 1000 mol/m$^3$ |

**Table 2:** Range employed in the sensitivity study.

| Variable | Range |
|---|---|
| N | 5 – 100 |
| E | 0.1 – 2.0 V |
| $V_{conc}^{T}$ | 0.2 – 2.0 m$^3$ |
| $V_{dil}^{T}$ | 0.01 – 0.6 m$^3$ |
| $C_{conc}^{f} = C_{dil}^{f}$ | 500 – 1000 mol/m$^3$ |

**Algorithm 1:** Training algorithm for the RL model.

**Parameters:**

- Action: $N$, $E$, $T_{tot}$, $V_{dc}^{T}$ , $V_{cc}^{T}$.
- State: $SR$, $SEC$, $C_{dc}^{f}$, $C_{cc}^{f}$.
- Reward: as defined in eq. 6 – 8.
- Termination: $SR \geq 0.99$ or $EC \leq 0\ KWh/m^3$.

**Algorithm:**

*Step 1: Initialize Agent*
Set up RL agent with an initial policy & parameters.

*Step 2: Observe Current State*
Agent observes the state of the system

*Step 3: Choose Action*
Select an action from the action space

*Step 4: Simulate Environment*
Apply action to the numerical model to predict the next state.

*Step 5: Compute Reward*
Calculate the reward using one of the 3 functions.

*Step 6: Update Policy*
Update the agent's policy using the reward & state feedback.

*Step 7: Convergence Check*
If the policy has converged, terminate the process. If not, repeat from Step 2.

## 3. RESULTS AND DISCUSSION

### 3.1 Physics-based modeling

Before applying the numerical model for real-time control, it is crucial to evaluate whether the model aligns with experimentally observed trends. A sensitivity analysis was conducted to validate model accuracy and reliability, ensuring an accurate representation of electrodialysis (ED) system behavior. The analysis identified key factors affecting predictions and explored variable ranges and magnitudes within the system. Systematic variations in the number of stacks, applied voltage, concentrate reservoir volume, and diluate reservoir volume were analyzed to assess their impact on critical ED performance metrics, such as salt removal (SR) and specific energy consumption (SEC). The parameter ranges for this study are outlined in Table 2, and the sensitivity results are shown in Figure 4.

The results confirmed consistency with theoretical trends within the specified boundary conditions. For example, SR and SEC increased with the number of ED stacks, as predicted by theoretical equations and prior studies. Adding more unit cells improves ion removal capacity but demands higher energy. Similarly, increasing applied voltage showed a comparable trend, with higher energy enabling more efficient ion removal in agreement with experimental data from Karimi et al. [19]. In contrast, increasing the diluate reservoir size reduced SR and SEC, likely due to a larger volume being retained rather than processed. The concentrate reservoir size had a minimal effect on these metrics. Additionally, higher feed concentrations led to lower separation efficiency owing to reduced diffusion of ions through the IEMs and increased energy demands [20,21]. These observations align closely with experimental findings, demonstrating the robustness and reliability of the numerical model in capturing the complex dynamics of the ED system.

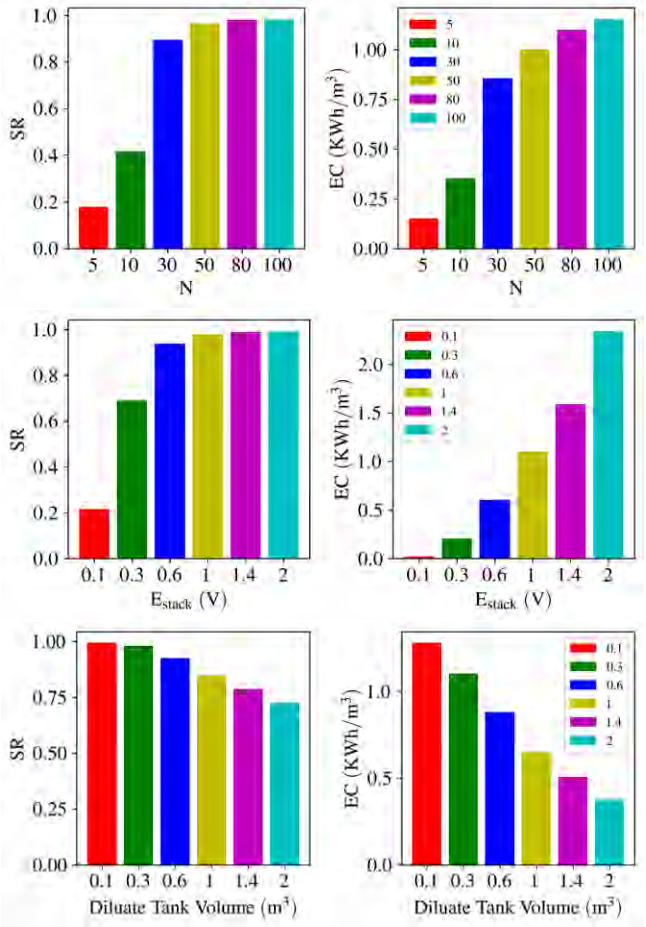

**Figure 4:** Sensitivity analysis of the mathematical model subject to the number of ED stacks, applied voltage, and volume of diluate tank volume.

In summary, a further correlation analysis using the Pearson coefficient as shown in Figure 5 revealed a positive correlation between SR and parameters such as

the number of stacks (N), stack energy ($E_{stack}$), and treatment time ($T_{tot}$), while a negative correlation was observed between SR and feed concentration, as well as diluate and concentrate reservoir sizes. For SEC, a similar relationship was identified, except that feed concentration exhibited a positive correlation with energy consumption.

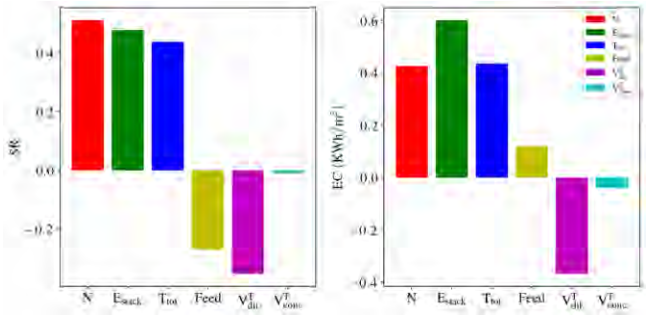

**Figure 5.** Correlation analysis of the ED parameters and the performance metrics.

## 3.2 Reinforcement Learning
